The second setup is essentially the same as the first but uses the blue filter. The purpose is to identify any areas of fluorescein staining. After fluorescein is applied, the blue filter is "clicked" into position, and the beam is widened to 3 or 4 mm. A patient can tolerate a wider beam without photophobia if it is blue. Corneal defects (as discussed earlier in the section on the fluorescein examination) are sought with this setup. The blue filter is also used with applanation tonometry, as discussed earlier in the section on tonometry.

The purpose of the third setup is to search for cells in the anterior chamber—either the white cells of iritis or the red cells of a microscopic hyphema. The height of the beam should be shortened to 3 or 4 mm and should be as narrow as possible. The microscope should be switched to high power. The beam is first focused on the center of the cornea and is then pushed forward slightly so that it is focused on the anterior surface of the lens. When the joystick is again pulled back to a focus point midway between the cornea and the lens, it will be focused on the anterior chamber (Fig. 64-46). One should keep the beam centered over the pupil so that there is a black background. Normally, the aqueous humor of the anterior chamber is totally clear. If small particles are visible floating up or down through the beam, these are usually circulating cells. If the beam lights up the aqueous like a searchlight in the fog, then the examiner has found the protein flare that accompanies iritis. Note should be made of the fact that

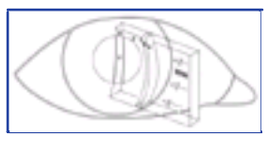

Figure 64-46 Appearance of the left eye during anterior chamber examination under low power: *a,* corneal epithelium; *b,* corneal stroma; *c,* corneal endothelium; *d,* anterior chamber (potential location of cells or flare); *e,* iris; *f,* lens reflection. The slit of light shines in the temporal to nasal direction at 45° to the anterior surface of the cornea. The depth of the cornea and anterior chamber examination are best done under high power in a dark room.

fluorescein can penetrate an abraded cornea, producing a fluorescein flare on slit-lamp evaluation. To avoid confusion, some clinicians prefer to examine for anterior chamber flare before the stain is used.

Summary

In practice, the 3 setups described here take only 1 minute per eye. Experience with the instrument enhances the ability of the user. The device is helpful for the evaluation of ocular infections and corneal lesions, the removal of corneal FBs, the measurement of IOP by applanation tonometry, and the diagnosis of iritis.

UNILATERAL LOSS OF VISION

There are a variety of reasons that an individual may sustain a complete loss of vision in one eye, but most commonly such loss may be related to occlusion of the central retinal vein or the central retinal artery or to optic nerve damage. Less commonly, pressure in the orbit from a retro-orbital hemorrhage may compromise the ophthalmic artery.

Although discussion of all the potential causes of unilateral loss of vision is beyond the scope of this text, amaurosis fugax deserves special mention. Amaurosis fugax is a transient loss of vision that is most commonly due to cholesterol or platelet emboli from atherosclerotic carotid occlusive disease. When plaques are visualized in the retinal vasculature, it is prudent to auscultate for carotid bruits and to refer the patient for ultrasound examination of the carotid artery. [111] [112]

Central Retinal Artery Occlusion

The patient with central retinal artery occlusion generally presents with a recent sudden (complete or nearly complete) unilateral vision loss. On examination there is an afferent pupillary defect (i.e., sluggish or nonreactive pupil in the affected eye with direct illumination with a normal consensual response) and reduced visual acuity. Immediately after the event, the fundus may appear nearly normal; however, it soon becomes pale and a classic "cherry-red spot" in the macula may be evident as a result of patent choroidal vessels showing through the transparent fovea.

Therapy

Visual recovery has been noted to occur up to 3 days after central retinal arterial obstruction. It has been recommended that treatment be started if the patient is seen within 24 hours after onset of symptoms.[113] Ophthalmologic consultation should be made while initiating therapy.

Most of the emergency techniques suggested to treat vascular insults to the eye in the ED are theoretically sound but are not supported or refuted by rigorous scientific data. No specific standard of care has been promulgated for these interventions by emergency clinicians. Techniques discussed below are likely safe and possibly useful, and may be attempted in an emergency situation. It is unknown whether or not these interventions will be vision saving.

Although of unknown value, slow *rebreathing* into a paper bag is believed to increase the arterial CO_2 level, thus aiding vasodilation and permitting the occlusion to move more peripherally, possibly reducing the ischemic area. The clinician should concurrently initiate *digital globe*

Figure 64-47 Digital globe massage is performed by applying firm steady pressure on the globe with the examiner's thumb for approximately 5 seconds, followed by abruptly releasing the pressure for 5 to 10 seconds. The process is repeated for up to 20 minutes or until improvement of vision is observed.

massage. With the patient lying supine, firm steady pressure is applied to the affected globe through the patient's closed lids using the clinician's thumb. The pressure is applied for 5 seconds and then abruptly released (Fig. 64-47). The procedure is immediately repeated several more times for up to 20 minutes. The technique is intended to help break up the occlusion and to encourage its movement more peripherally.

A more aggressive therapy, generally performed only by ophthalmologists, is *anterior chamber paracentesis*. In the absence of available consultation, this technique may be considered when central retinal occlusion is recent and unresponsive to the previously described therapeutic approaches. For this procedure, the patient is kept supine with the head and eyelids secured. The cornea is anesthetized with topical anesthetic drops (e.g., 0.5% proparacaine drops) and the conjunctiva is anesthetized. The conjunctiva is injected adjacent to the limbus using a 27- or 30-ga needle until the entire perilimbal area is infiltrated, giving the appearance of chemosis in all quadrants. During the remainder of the procedure, an assistant must firmly grasp the conjunctiva with toothless forceps at the 3 and 9 o'clock positions to stabilize the eye. A 30-ga needle on a tuberculin syringe is then inserted obliquely just adjacent to the limbus, at either the 4:30 or 7:30 o'clock position and directed toward the 6 o'clock position to avoid the lens (Fig. 64-48). After 1 to 2 drops of aqueous are expressed with gentle pressure on the globe, the needle is withdrawn.[114] [115]

One study describes a systematic approach in which ocular massage, sublingual isosorbide dinitrate 10 mg, acetazolamide 500 mg intravenously (IV), mannitol 20% (1 mg/kg) or oral glycerol 50% (1 mg/kg), anterior chamber paracentesis, methylprednisolone 500 mg IV, streptokinase 750 kIU, and retrobulbar tolazoline 50 mg were given until visual symptoms improved or until all steps were complete.[116] Of the 11 patients in this arm of the study, 8 had improved visual acuity. In those who improved, all had symptoms =12 hours. The presumed cause was either platelet-derived or cholesterol embolus from atheroma, or glaucoma. [115] Although this study is small, it supports emergent ophthalmology consultation and aggressive treatment of patients who present within 12 to 24 hours of symptom onset.

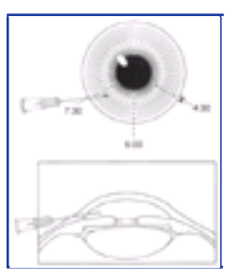

Figure 64-48 Anterior chamber paracentesis. After topical and subconjunctival anesthesia (see text), a 30-ga needle is directed obliquely from the 4:30 or 7:30 o'clock position toward the 6 o'clock position to avoid the lens. An assistant stabilizes the globe with forceps, grasping the conjunctiva (see text). *Top*, Anteroposterior projection. *Bottom*, Tangential projection. *(From Knoop K, Trott A: Ophthalmologic procedures in the emergency department: I. Immediate sight-saving procedures. Acad Emerg Med 1:408, 1994.)*

Complications

Overzealous globe massage has the potential to produce intraocular trauma including retinal detachment and intraocular hemorrhage. Anterior chamber paracentesis may produce hemorrhage, infection, or mechanical injury to the cornea, iris, or lens. [117] Although these complications are rare, ophthalmologic consultation for assistance with the underlying central retinal artery occlusion and surveillance for these potential complications should be initiated on an emergent basis.

Orbital Compartment Syndrome

Acute facial trauma or recent retrobulbar anesthesia may produce retrobulbar hemorrhage with sufficient pressure to compromise the ophthalmic artery, resulting in an orbital compartment syndrome. A form of post-traumatic glaucoma may also occur when the retrobulbar hematoma forces the globe against the eyelids. In this case IOP rises precipitously because the globe is in a relatively closed space due to the firm attachment of the eyelids to the orbital rim by the medial and lateral canthal ligaments. The optic nerve and its vascular supply, and the central retinal artery are compressed, resulting in ischemia and subsequent visual loss. In this situation an emergency canthotomy may be considered for relief of the pressure on the eye. It would not be considered a standard of care for most emergency

clinicians to possess the skills for this procedure, but under the proper scenario, it may be a prudent intervention.

Ophthalmoscopic evaluation reveals a blanched ophthalmic artery in the presence of obvious retrobulbar pressure and ecchymosis around the eye. The patient exhibits *decreased visual acuity,* and an afferent pupil defect is often seen. The IOP is markedly elevated but may be relieved by an emergency lateral canthotomy and cantholysis. Such a procedure needs to be performed quickly because the ischemic retina will not retain function if it is deprived of blood for a long period of time.

Technique: Lateral Canthotomy and Cantholysis

The goals of the procedure are to release pressure on the globe and to decrease IOP enough to reinstitute retinal artery blood flow. Because retinal recovery is unlikely to occur if rapid relief of ischemia is not accomplished, taking time to clean the eye beyond simple saline cleansing of the lids and lateral canthus is ill-advised. While the patient's head and lids are stabilized, the lateral canthus is first anesthetized with injectable 1% to 2% lidocaine with epinephrine. A small hemostat is used to crush the lateral canthus for 1 to 2 minutes to minimize bleeding before incising the lateral canthus. The canthus is incised using iris or Steven's scissors, with precautions taken to avoid injury to the protruding globe (Fig. 64-49). The incision begins at the lateral canthus and extends toward the orbital rim. The superior and inferior crus of the lateral canthal tendon are found and released from the orbital rim. Some operators prefer to release the inferior crus and reassess the IOP before considering release of the superior crus. An instructional video of the procedure can be found on the World Wide Web at *www.brown.edu/Administration/Emergency_Medicine/eye.htm*. [118]

Complications

Although hemorrhage, infection, and mechanical injury may result from the procedure, these complications generally respond to therapy better than retinal injury from prolonged ischemia. Emergent ophthalmologic consultation should be obtained, although when the procedure is indicated, it may be considered by the emergency clinician. Lateral canthotomy incisions generally heal without suturing or significant scarring.

REDUCTION OF GLOBE LUXATION

Although luxation of the globe is uncommon, the emergency clinician should be aware of the condition and its mechanisms, know how to reduce the globe, and know when to prioritize ophthalmologic consultation. With luxation of the globe there is extreme proptosis, which permits the lids to slip behind the globe equator (Fig. 64-50). Subsequent spasm of the *orbicularis oculi* muscles sustains the luxation and limits extraocular movements. Traction on the optic nerve and retinal vessels may produce direct or indirect injury to the optic nerve and retina.

Luxation may be spontaneous, voluntary, or traumatic. A variety of conditions (e.g., orbital neoplasms, Graves disease, histiocytosis X, cerebral gumma, and craniofacial dysostoses) may predispose the patient to luxation. Triggering events include maneuvers increasing intraorbital pressure (e.g., the Valsalva maneuver), trauma to the orbit or forehead, or eyelid manipulation.

Indications and Contraindications

Early globe reduction is indicated to relieve symptoms and to minimize visual impairment. Attempts at reduction in the ED

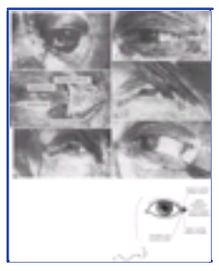

Figure 64-49 *A,* Severe proptosis secondary to acute traumatic retrobulbar hemorrhage. *B,* Anatomy of orbital structures demonstrating the inferior and superior crura of the lateral canthal tendon beneath the lateral canthus. The crura join and as a common tendon are attached to the inner aspect of the lateral orbital wall, forming Whitnall's tubercle. The lateral canthus, formed by the upper and lower eyelid, has been removed. *C, D,* A clamp crushes the lateral canthus to reduce bleeding when it is incised. The canthotomy allows the inferior crus to be exposed and cut to decompress the eyeball. *E,* A 1 centimeter horizontal incision is made in the lateral canthus, through the tissue that was compressed. *F,* The lower lid is pulled down and away from the lateral orbital rim, separating the skin and conjunctiva. If bleeding hinders identification of the inferior crus, it may be palpated. *G,* Only the inferior crus need be lysed initially. If intraocular pressure is not reduced, the superior crus is lysed. *(From S. Vassallo et al: Traumatic retrotubular hemorrhage: Emergent decompression by lateral canthotomy and cantholysis. J Emerg Med 22:21, 2002.)*

Figure 64-50 Appearance of bilateral luxated globe; superior (*top)* and lateral (*bottom*) projections. *(From Love JN, Bertram-Love JE: Luxation of the globe. Am J Emerg Med 11:61, 1993; original photographs courtesy of WR Green, MD, Wilmer Eye Institute, Baltimore.)*

are relatively contraindicated when there is obvious rupture of the globe.

Technique

Before globe reduction, it is valuable to perform a rapid eye examination to document visual acuity, range of eye motion, pupillary reactivity, and any evidence of globe rupture (see earlier discussion). [119] The patient is made comfortable in a recumbent position, and a topical ocular anesthetic agent (e.g., 0.5% proparacaine) is administered. When the lashes are visible, an assistant should apply steady outward and upward traction while the globe is gently pushed behind the lids. The globe is manipulated back into the orbit using gloved fingers to apply steady scleral pressure. When the lashes cannot be grasped, a lid retractor may be introduced behind the lid to provide countertraction. Others recommend placement of a suture through the anesthetized skin of each lid to provide countertraction.

After the procedure, a repeat eye examination documenting visual acuity and extraocular movement is warranted. It is not uncommon for return of full visual function to be delayed for several days, occasionally longer.

Complications

It is common with this procedure for lashes to be retained in the conjunctival fornices. It is important to evaluate for and remove any free lashes to prevent corneal injury. Edema, retrobulbar hemorrhage, or orbital deformity may prevent outpatient reduction. When reduction is not possible in the ED, saline drops should be applied to the globe and a noncontact eye shield applied.

Aftercare

Patients with spontaneous luxation and no visual impairment in whom the globe is easily reduced warrant follow-up within 24 to 48 hours. Instructions to avoid potential triggering maneuvers should be given. Recurrent luxation may warrant lateral tarsorrhaphy. Further evaluation of potential precipitating illness can be pursued on an outpatient basis.

Patients with traumatic luxation are at greater risk for underlying ophthalmic injury and warrant emergent consultation. A computed tomographic scan of the orbit is helpful for

evaluating both the soft tissue and bony structures about the globe.

Chapter 65 - Otolaryngologic Procedures

Ralph J. Riviello

Examination of the oropharynx, larynx, ear canals, and nasal passages and the management of related acute disorders are most effectively performed using special equipment and techniques. This chapter addresses these techniques from the perspective of the emergency clinician, who often must assess injuries or illnesses of potential compromise to the airway and to auditory function. Decisions related to definitive treatment in the emergency department (ED) vs timely referral are addressed. Related topics, including airway management, esophageal and laryngeal foreign bodies (FBs), and assessment of caloric testing, are discussed elsewhere in the book.

PHARYNX/LARYNX

Examination of the Larynx

Several techniques to visualize the larynx are discussed. The clinician should become adept at examining the hypopharynx and larynx with more than one method (Fig. 65-1). Laryngoscopy is indicated for the evaluation of unexplained hoarseness, dysphagia, odynophagia, or FB sensation. The majority of patients will require a repeat examination by an otolaryngologist for verification, but laryngoscopy in the ED may identify pathologic conditions requiring more urgent consultation. Clinicians should follow guidelines for "universal precautions" (as described in Chapter 71) to protect themselves and their patients from infection transmitted by blood and body fluids.

Laryngoscopy has traditionally been discouraged in the patient with a high potential for epiglottitis, as oropharyngeal manipulation may in rare cases precipitate laryngospasm and acute respiratory arrest. However, some authors report that careful laryngoscopy may be performed in stridulous patients with the presumed diagnosis of croup to rule out epiglottitis when the suspicion for the latter condition is low. [1]

When impending airway obstruction from epiglottitis is suspected, the first priority is to quickly assemble a predesignated team (usually consisting of an anesthesiologist and an otolaryngologist) in the operating room. Any attempt at laryngoscopy should follow full preparation for rigid bronchoscopy or a surgical airway. Patients with severe laryngeal trauma or partially obstructing hypopharyngeal FBs should be approached in a similar manner.

Illumination

The reflected light from a head mirror or direct illumination from a head lamp can be used not only for indirect laryngoscopy, but also for inspection of, and procedures in, the oropharynx, nares, and auditory canal. For example, a peritonsillar abscess is afforded excellent illumination for drainage with such devices. The advantages of a head mirror are the high degree of brightness it provides into deep recesses and its simplicity of design. Generally, the beam of light from an electric head lamp is easier to focus than is the head mirror.

Procedure

Head mirror/Light source.

The head mirror is convex with a central hole that allows the examiner to see directly along the reflected light beam. Begin by swinging the mirror down over the dominant eye just touching the skin or glasses. Position the light source (a 150-watt bulb works well) over the patient's shoulder on the same side as the head mirror. Keeping your eyes open, adjust the focus of light by adjusting your distance from the patient. Change the direction of the beam by tilting the mirror or turning your head slightly.

Head lamp.

The electric head lamp also attaches by a forehead strap, and the light should be placed nearly between the examiner's eyes to be maximally effective. The intensity of light in this position is nearly as bright as the head mirror. After securing the head lamp, hold your hands in front of you at a distance that is comfortable for working. Focus the beam of light at this point by adjusting the head lamp into position without moving your head or eyes. This allows for the beam to shine on and follow the area on which your eyes are focused.

Indirect Laryngoscopy

This traditional method is most commonly used by the otolaryngologist, but it has some application in the emergency setting if the necessary equipment is readily available.

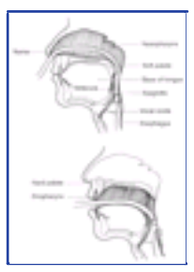

Figure 65-1 Anatomy of the oropharynx. Sagittal section of the neck. Also depicted is the use of the nasopharyngeal scope through the nasopharynx and the oropharynx.

The clinician who is unfamiliar with this method should practice frequently, as it requires significant eye-to-hand coordination to reflect the light beam off the angulated mirror onto the larynx. When this procedure is properly performed, most patients are able to tolerate it without anesthesia of the oropharynx. Fiberoptic nasopharyngoscopy has largely replaced indirect laryngoscopy in the ED when the equipment is available.

Begin by establishing rapport with the patient by explaining how the examination will be performed. Have the patient sit erect in the "sniffing position," with the feet flat on the floor and leaning slightly forward. Warm the mirror with warm water or in a flame to prevent fogging, but check the temperature of the mirror with your hand before placing it into the oropharynx so as not to burn the patient. Alternatively, anti-fogging solutions can be applied to the mirrored side. Wrap the patient's tongue with gauze to prevent it from slipping or being injured by the lower incisors and then grasp it with the nondominant hand (Fig. 65-2). Apply gentle traction to the tongue with your thumb and index finger while lifting the patient's upper lip with your middle finger. Slide the mirror into the oropharynx with the glass surface parallel to the tongue but not touching it. Place the back of the mirror against the uvula and soft palate, smoothly lifting until the larynx is visualized. While this should not induce gagging, try to make only slight changes in mirror position to inspect the appropriate structures.

In patients who cannot tolerate this procedure without gagging, apply topical anesthetic to aid in the examination. Benzocaine (Hurricaine spray or Cetacaine gargle) or aerosolized tetracaine or lidocaine may be used. One or two quick sprays of benzocaine into the posterior oropharynx are sufficient. Prolonged or repeated spraying may rarely result in methemoglobinemia. Reassure the patient beforehand that although this may make the throat feel as if it is swelling or paralyzed, in actuality it is just the numbness that accounts for

Figure 65-2 Indirect mirror evaluation of oropharynx. Grasp the patient's tongue between the thumb and first finger, using a gauze pad to provide traction. Elevate the upper lip with the middle finger. Advance the warmed laryngeal mirror into the posterior oropharynx, taking care not to stimulate the posterior tongue or pharynx. Remember that the structures in the mirror will

be reversed. Always use universal precautions.

the sensation. The tendency to gag also can be minimized by having the patient concentrate on his or her breathing efforts and keep the eyes open, with vision fixed on an object in the distance.

Once the patient is anesthetized, repeat the steps described earlier and position the mirror against the soft palate. Rotate the angle of the mirror and systematically inspect the base of the tongue, valleculae, epiglottis, pyriform recess, arytenoids, false and true vocal cords, and, if possible, the superior aspect of the trachea (Fig. 65-3). Observe for masses, evidence of infection, asymmetry, or FBs. Further evaluate the anterior structure of the larynx and function of the vocal cords by having the patient say "eeee" in a high-pitched voice. This should move the epiglottis away from blocking the view of the larynx and bring the true cords together at the midline.

Laryngoscopy by Angled Telescopes

A less frequently used method of examining the larynx in the emergency setting is by rigid angled laryngoscopy (e.g., LarynxVue II, Astralite Corp., Anaheim, CA). This provides a clear and more continuous view of the larynx during respiration, but its use is limited in patients whose epiglottis blocks the view. The light source is powered by batteries or a wall outlet. The degree of mirror angulation is fixed, but it may vary between instruments (usually 70° to 90°). At 70° of mirror angulation, the scope does not need to be placed as far posteriorly into the oropharynx to visualize the structures.

Position the patient as for indirect laryngoscopy and anesthetize the soft palate if necessary, as previously described. Gently grasp the tongue and slide the scope into the oropharynx. Stabilize the scope on the fingers that are holding the tongue, taking care not to touch the sensitive base of the tongue. Once the scope is touching the soft palate and is near proper position, look into the eyepiece and make final adjustments to bring the laryngeal structures into focus. Observe the anatomy and function as previously described in a systematic fashion.

Flexible Fiberoptic Laryngoscopy

Fiberoptic examination of the nasopharynx and larynx can be accomplished with either a flexible nasopharyngoscope or a bronchoscope. The nasopharyngoscope is thinner, shorter, and easier to manipulate (Fig. 65-4). Fiberoptic visualization is especially useful in patients who are difficult to examine because of persistent gagging or unusual anatomy.

Figure 65-3 View of the larynx from above. The true and false vocal cords are sketched, with the arytenoid eminences behind them on each side. The epiglottis, piriform fossae, and valleculae are also labeled.

Figure 65-4 Fiberoptic scope with light source.

Attach the endoscope to its light source, attach the suction to its port (if available), and ensure that both are functioning properly before beginning. Before inserting the scope, adjust the eyepiece to the operator's visual acuity; it is helpful to check the scope focus on newsprint or a small object at this time. Review of the scope's directional controls is also recommended. Examine the nares and choose the more patent one to enter. Anesthetize and vasoconstrict the naris with lidocaine and epinephrine (as described in Epistaxis, later in the chapter). Some clinicians also anesthetize the pharynx to minimize gagging. Warm the end of the scope in warm water to help prevent fogging. The patient should be seated, with the head placed against a headrest, in the "sniffing" position. Insert the tip of the lubricated scope just inside the naris. A series of soft nasal trumpets may be used to dilate the nasal cavity, allowing easier passage of the scope. The movement of the scope against the inside of the nasal passage may be irritating; this discomfort can be minimized by resting the fourth and fifth fingers on the bridge of the patient's nose while stabilizing and guiding the passage of the scope between the thumb and index finger (Fig. 65-5).

While looking through the eyepiece, slowly advance the endoscope past the inferior turbinate into the nasopharynx or through the lumen of the trumpet. To clear fogging or mucus off the lens, have the patient swallow, wipe the lens against the pharyngeal mucosa, or use the suction. Once it is in the nasopharynx, direct the tip inferiorly, using the thumb control near the eyepiece. *Up-and-down movements of the scope may be accomplished with the thumb control, whereas rotating the scope about its axis and then applying the thumb control provides for lateral movement and visualization.* At this point, the base of the tongue and tonsils will come into view. Slide the scope further caudad to bring the larynx into focus. Once again, systematically view the anatomy and function during both respiration and phonation.

If the nasopharyngeal scope will not pass through either naris, pass it through the oropharynx. Properly anesthetize the oropharynx and avoid the posterior tongue to prevent gagging. Cut a 10-mL syringe (without the plunger) in half. Have the patient hold this in the mouth between the incisors. Pass the fragile endoscope through this tube to prevent accidental biting of the scope.

Complications include traumatic abrasions and bleeding anywhere along the path of the laryngoscope. In patients with

Figure 65-5 Fiberoptic nasopharyngoscope in use. Prepare the patient's throat and nares with topical anesthetic. Topical vasoconstrictors may also be used in the nares. The use of a nasal trumpet is optional. Advance the scope slowly into the naris with the hand stabilized on the patient's nose; guide the scope using the thumb and index finger. Visualize the passage of the scope through the naris into the posterior nasopharynx. Always use universal precautions.

head injury, there is always the slight risk of passing the scope intracranially if a basilar skull fracture exists, but use of a soft nasal trumpet significantly reduces this risk. The induction of laryngospasm and acute airway compromise is possible in patients with paraglottic infections.

Peritonsillar Abscess

Anatomy

Peritonsillar abscess (PTA), also known as *quinsy*, is most common during the second and third decades. It is rarely seen in children younger than 6 years of age, making it diagnostically challenging in younger children and infants. It remains the most common head and neck abscess in children and adults. The incidence for PTA is about 45,000 cases annually in the United States. The relative anatomy must be understood to treat peritonsillar abscesses (Fig. 65-6). The palatine tonsils are located between the anterior and posterior pillars of the throat, bound in a capsule and covered by mucosa. The lateral wall of the tonsil is defined by the superior pharyngeal constrictor muscle. Of great importance is the *internal carotid artery,* which lies approximately 2.5 cm posterolateral to the tonsil.

Pathophysiology and Presentation

Peritonsillar abscesses occur in patients with inadequately treated tonsillitis and in recurrent tonsillitis. The abscess is usually unilateral and is defined as a collection of pus between the tonsillar capsule, the superior constrictor muscle, and the palatopharyngeus muscle. It is believed to arise from the spread of infection from the tonsil or from the mucous glands of Weber, located in the superior tonsillar pole. [2] The abscess is most commonly initiated from the upper pole of the tonsil. However, it can also spread from the middle or inferior poles. Complications may include pharyngeal obstruction or extension into the closely approximated neurovascular bundles and parapharyngeal space.

Figure 65-6 Anatomy of a peritonsillar abscess. The palatine tonsil and peritonsillar space are identified on the patient's right. A peritonsillar abscess is shown on the patient's left. Note that the abscess can extend medially, displacing the uvula. The carotid artery and jugular vein are posterior and lateral to the abscess. Avoid lateral angulation of the aspirating needle and use a needle guard to prevent injury.

Most patients present primarily with a peritonsillar abscess, but some have been previously treated for tonsillitis. There are no data proving that antibiotics, even the correct ones in proper doses, invariably prevent the progression of tonsillitis to abscess formation. Inadequately treated tonsillitis can progress to abscess when a patient fails to follow the prescribed regimen or when the regimen is inadequate. The latter may occur as the result of an improperly chosen antibiotic or because of increasing antibiotic resistance. Although penicillin still remains the best initial treatment for tonsillitis, anecdotal cases of failure after intramuscular long-acting penicillin have also been noted. Although Group A *Streptococcus* remains the leading cause of peritonsillar abscess, *Staphylococcus aureus*, *Haemophilus influenzae*, *Bacteroides, Peptostreptococcus,* and mixed anaerobic infections are common. ß-lactamase-producing organisms are present in about 50% of cases. [3] Fine-needle aspiration of peritonsillar abscesses may allow identification of organisms and appropriate modification in antibiotic therapy, thus avoiding the need for tonsillectomy.

Patients with peritonsillar abscesses present with sore throat, odynophagia, low-grade fever, and a variable degree of trismus. The trismus develops secondary to pterygoid muscle irritation. The patient may also complain of ipsilateral otalgia. As the abscess expands, the patient may experience dysphagia with drooling. Patients are often dehydrated secondary to poor oral intake. Voice changes are common (hot potato voice) and are caused by transient velopharyngeal insufficiency and muffled oral resonance. Rancid breath is also common. Tender ipsilateral anterior cervical lymphadenopathy is frequently present. Fever >39.4°C has been associated with parapharyngeal extension and sepsis. [4]

Examination of the oropharynx may be difficult because of associated trismus. Have the patient sit with the head in the "sniffing" position. Encourage the patient to open the mouth as wide as possible, and depress the tongue to obtain a better view of the oropharynx. Use a head lamp or head mirror/light source to ensure adequate illumination. Digital palpation for a fluctuant site can be useful, and may be the best way to differential abscess from cellulitis. The clinician places the gloved index finger into the mouth and feels for hardness or fluctuance in the peritonsillar region (Fig. 65-7). If no abscess can be appreciated, the diagnosis is unlikely. This technique is usually well tolerated but the patient may gag or bite the examiner by reflex. Physical findings are often diagnostic of a peritonsillar abscess, but in about 20% of cases the diagnosis is in doubt until needle aspiration is performed. Inferior and medial displacement of the tonsil and uvula are noted along with a fluctuant mass involving the tonsillar pillar. Swelling obliterates the normally sharply delineated pillar-like

Figure 65-7 Clinical symptoms and visual inspection may not be sufficient to differentiate peritonsillar abscess from cellulitis. The clinician's gloved index finger is used to palpate the peritonsillar area to search for fluctuance and localized swelling.

structure. The tonsil looks edematous and erythematous, and may be covered with a whitish exudate.

The differential diagnosis for this acute process includes unilateral tonsillitis, peritonsillar cellulitis, retropharyngeal abscess, infectious mononucleosis, *Herpes simplex* tonsillitis, retromolar abscess, neoplasm, FB, and, possibly, internal carotid artery aneurysm. Chronic conditions include leukemia, carcinoma, and parapharyngeal space tumor.

Differentiation of a peritonsillar abscess from peritonsillar cellulitis may be difficult, especially in the early stages of an abscess. The history and time course for the two disease processes are quite similar. Trismus and uvular deviation are uncommon in peritonsillar cellulitis. [5] Needle aspiration will be diagnostic if purulent material is removed. However, a negative test does not rule out an abscess. The abscess may be located posteriorly, and not accessible by the aspiration needle. Intraoral sonography has a sensitivity and specificity of 91% and 80%, respectively, in detecting peritonsillar abscesses [6] and may therefore augment diagnostic accuracy. Also, if there is any question as to the diagnosis or actual location of the abscess, CT scanning may be utilized.

General Treatment

The treatment of peritonsillar abscess has undergone significant change in the past 100 years and continues to do so at this writing. A myriad of opinions exists on the appropriate treatment method, although most agree that some form of drainage procedure should be performed in conjunction with antibiotics and pain control. Three options for surgical drainage include: needle aspiration, incision and drainage, and immediate (quinsy) tonsillectomy. Each method will be discussed.

Needle aspiration is relatively simple, can be performed by clinicians who are not head and neck specialists, does not require special equipment, and is relatively inexpensive. Other benefits of needle aspiration over incision and drainage include decreased pain and trauma. Many feel that this should be the initial surgical drainage procedure for adults and children. The recurrence rate following needle aspiration is 10% [7] and its cure rate is about 94%. [2] About 4% to 10% of patients require repeat aspiration. [2] [7] One drawback is that needle aspiration may miss the peritonsillar abscess and therefore allow misdiagnosis as peritonsillar cellulitis. Up to 12% to 24% of abscesses have been missed on initial aspiration. [8] [9] Therefore, some authors propose admission of patients with negative aspirations with the presumed diagnosis of peritonsillar cellulitis for intravenous (IV) antibiotics and observation to prevent further morbidity. [10] Although most studies were performed with hospitalization and IV antibiotics, selected outpatient treatment with oral antibiotics has been successful. [10] [11] Most patients with a successfully drained peritonsillar abscess can be safely and effectively managed with needle aspiration and outpatient antibiotics. [12]

Incision and drainage is commonly done as an outpatient procedure under local anesthesia. This procedure is usually performed after pus is obtained by needle aspiration, but occasionally it is the primary procedure. It seems most logical to first attempt aspiration and only follow with incision and drainage if additional pus is suspected or there are other extenuating circumstances. The recurrence rate following incision and drainage is 5.9% to 22.7%. [13] Despite these shortcomings, incision and drainage is the initial surgical treatment used by an estimated 54% of U.S. otolaryngologists. [2]

Immediate (quinsy) tonsillectomy is thought by some to be the only way to completely drain the abscess and completely eliminate the risk of recurrence. They also feel that hospital time and the patient's disability are shortened. Arguments against this rationale include:

1. An initial PTA is no longer an indication for tonsillectomy.
2. Needle aspiration/incision and drainage have high success rates.

3. Studies have shown longer recovery times for patients following immediate tonsillectomy compared to the other drainage procedures.
4. There is a time delay (6 to 70 hours) in assembling equipment and personnel for the tonsillectomy. Patients successfully treated with needle aspiration are often well on the way to recovery in that amount of time. [7]

Treatment guidelines based on a review of the literature [2] [7] suggest that pediatric patients with peritonsillar abscess and adults without history of recurrent tonsillitis be initially treated with needle aspiration. Incision and drainage and immediate tonsillectomy should be reserved for treatment failures or recurrences. Adult patients with *recurrent* tonsillitis/peritonsillar abscess should be treated with either needle aspiration followed by delayed tonsillectomy or with abscess tonsillectomy alone. These procedures can be done in combination with hospital admission and administration of IV antibiotics or as an outpatient with oral antibiotics. The approach depends on the patient's clinical status and medical history. Decisions about the treatment of a peritonsillar abscess in the ED are often made by the emergency clinician, but as local protocols dictate, consultation with an otolaryngologist is often appropriate.

Needle Aspiration/Incision and Drainage

The two procedures described here include needle aspiration and incision and drainage. They should only be performed in the cooperative patient without severe trismus. With the carotid artery located 2.5 cm behind and lateral to the tonsil, there is minimal room for error, patient movement, or poor anesthesia.

Have the patient sit upright, with a support behind the head. This is best done as a two-person procedure. An assistant can retract the cheek laterally to maximize visibility. A head lamp provides optimal lighting; a double tongue-blade setup aids visualization of the operative area (Fig. 65-8). It is

Figure 65-8 Needle aspiration of a peritonsillar abscess. The patient sits upright with the head supported by the back of the stretcher (or a dental chair head rest). A head lamp provides light and an assistant retracts the cheek laterally to maximize visibility.

Figure 65-9 *A*, As a safeguard to prevent deep penetration of a needle used to drain a peritonsillar abscess, select a long 18- to 20-gauge needle. Remove the plastic needle guard and cut off the distal 1 cm. *B*, Replace the guard on the needle and tape it to the hub.

suggested that parenteral narcotic analgesia or mild sedation, or both, be administered before attempts at aspiration. Fentanly, 2 to 3 mcg/kg IV a few minutes before the procedure, is often ideal. Midazolam may be judiciously used, but the patient should not be overly sedated. The combination of midazolam, ketamine, and glycopyrrolate has been reported as being safe and effective for the outpatient peritonsillar drainage in children. [14]

Anesthetize the area topically with Cetacaine spray, or 4% to 10% lidocaine. Determine the fluctuant area of the abscess by manual palpation. Additionally anesthetize this area with local infiltration of 1 to 2 mL of 1% lidocaine with 1:100,000 epinephrine via a 27-gauge (ga) needle. Using a 5-mL syringe with a long needle allows visualization of the area to be injected, while a small syringe often causes the clinician's hand to block the view. Infiltrate the lidocaine intramucosally for the best results, and *seek a blanching area*

Figure 65-10 *A*, Needle aspiration of a peritonsillar abscess. Anesthetize the posterior pharynx with topical lidocaine spray. Blanch the mucosa with lidocaine/epinephrine with a 27-gauge (ga) needle on a long syringe (to allow visualization of the site) in the area to be aspirated. Advance an 18- or 20-ga needle with needle guard into the area of greatest fluctuance, usually the superior pole. Aspirate as you advance the needle. Advance the needle in the sagittal plane. Do *not* direct the needle laterally toward the carotid artery or jugular vein. *B,* The superior pole is aspirated first, but the middle and inferior poles should be aspirated if pus is not obtained initially. Note that the tonsil itself is not aspirated. The *peritonsillar space* contains the abscess.

on the mucosal surface. During the injection, be careful not to increase the abscess size by direct injection into the abscess cavity. With proper local infiltration the patient will not feel the penetration of the aspirating needle. If the trismus is so pronounced as to prevent adequate anesthesia administration, it will probably be too difficult to aspirate or incise the abscess properly.

For *aspiration*, prepare a long 18- to 20-ga needle on a 10- to 20-mL syringe. Fashion a needle guard by cutting off the distal 1 cm of the plastic needle cover, replace the cover on the needle, and securely attach this guard to the needle and syringe with tape to prevent inadvertent displacement (Figs. 65-9 A & B). Ensure that the needle protrudes only 1 cm beyond the cover. This procedure will limit the depth of needle penetration and lessen the risk of entering any major vascular structure. If pus is not obtained at a 1-cm depth, deeper penetration is discouraged. Insert the needle into the

most fluctuant (or prominent) area as previously determined, which is most commonly the superior pole of the tonsil. Note that the tonsil itself is not aspirated because the abscess develops in the peritonsillar space surrounding the tonsil. *The needle is advanced only in the sagittal plane and is not directed laterally, where it may injure the carotid artery.* If the aspirate is positive, remove as much purulent material as possible. If the aspirate is negative, attempt aspiration again in the middle pole of the tonsil approximately 1 cm caudal to the first aspiration. A third and final attempt should be performed at the inferior pole. Up to 30% of abscesses will be missed if only the superior pole is aspirated. It must be stressed that a negative aspirate does *NOT* rule out a peritonsillar abscess.

Usually 2 to 6 mL of pus is obtained. It is unusual to recover more than 8 to 10 mL (Fig. 65-11). There is no specific advantage of sending the aspirate to the laboratory for culture. Many clinicians forgo culturing since it has not been demonstrated that culture results influence treatment. [10] When significant amounts of pus are aspirated, the patient usually feels immediate improvement in pain and dysphagia. After the needle is removed, some bleeding will be noted. A slight ooze may be noted for a few hours, especially if warm water rinses are used. There may be continued drainage of pus, often sensed as a foul taste by the patient. If significant additional pus drains, this may be an indication for a repeat aspiration, incision and drainage or hospital admission.

Some clinicians advise a formal incision and drainage (see later) if frank pus is obtained, whereas others now accept needle aspiration (with close follow-up) as the definitive *initial* treatment. Theoretical reasons to combine aspiration and formal drainage in the same visit are if large amounts of pus are obtained (>5 to 6 mL) or if pus continues to drain from the aspiration site. There are no agreed-upon standards regarding best practice for this issue.

To *incise* a peritonsillar abscess, anesthetize the area as described earlier. Prepare a No. 11 or 15 scalpel blade by taping over all but the distal 0.5 cm of the blade to prevent deeper penetration (Fig. 65-12). Incise the area of maximal fluctuance or where a preceding aspiration, if one was performed, located pus. Incise the mucosa in an area 0.5 cm long in a posterior to anterior direction. A stab incision with

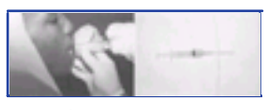

Figure 65-11 Needle aspiration usually yields 2 to 6 mL of thick pus. Greater volumes are unusual. Removing only a small amount will produce a marked reduction in symptoms.

a No. 11 blade usually suffices. Warn the patient that the pus will flow posteriorly and he or she must expectorate this fluid. Expect bleeding, as this is a vascular

area. Suction the incised area with a No. 9 or 10 Frazier suction tip or a tonsil suction tip to aid in removal of the purulent material. Place a closed Kelly clamp into the opening and gently open it to break up the loculations. Allow the patient to rinse and gargle with a saline or dilute peroxide/saline solution. Packing is *not* used in the drainage of this abscess. *Following aspiration or incision, it is prudent to observe the patient for about an hour to watch for complications (e.g., bleeding) and to ensure the ability to tolerate oral fluids.* Most patients can be discharged with 24 hour follow-up. Toxic patients, those with excessive volumes of aspirate, those with persistent bleeding, or those unable to take oral antibiotics are candidates for admission or more prolonged observation. Frequent rinses with warm saline are quite helpful in relieving postaspiration symptoms.

Following either needle aspiration or incision and drainage, antibiotics are recommended to eradicate the offending organisms. Penicillin, clindamycin, or cephalosporins are a reasonable first choice. Resistance rates to penicillin range from 0 to 56% but laboratory sensitivity testing is not always reflective of a clinical response.[7] Alternatives include ampicillin/sulbactam and amoxicillin/clavulanate. Reasonable cure rates have been obtained with oral penicillin in modest doses (500 mg per os [PO] four times a day [QID]). Many clinicians prefer to administer an IV loading dose of penicillin (5 million units) or cefazolin (1 g) before releasing the patient. While the benefit is not well established, many clinicians empirically also administer a single parenteral dose of dexamethasone (10 mg) and this may further ameliorate symptoms. Any patient who appears to have a toxic response, whose immune system is compromised, is unable to take oral antibiotics, or is dehydrated should be admitted for IV fluid hydration and antibiotic administration. Reevaluation of all patients treated with needle aspiration should be performed in 24 hours to assess the need for repeat aspirations or formal incision and drainage. At 24 hours most patients are markedly improved, and failure to see this response requires further evaluation. Warm saline gargles and mild opioid analgesics also are recommended with outpatient care. All patients should

Figure 65-12 Aspiration is often the only procedure required to successfully treat a peritonsillar abscess, but it has a 10% failure rate. In some instances the clinician will opt for incision and drainage of a peritonsillar abscess. This procedure may used initially, or after aspiration if copious pus is aspirated, or if pus continues to drain or reaccumulates. *A,* Normal-appearing oropharynx. *B,* Peritonsillar abscess on the right side of the throat. *C,* Incision of the abscess at the area of greatest fluctuance. Notice that the scalpel is taped to prevent deep penetration. *D,* Loculations are removed by gentle probing with hemostats.

immediately return for recurrence of symptoms, fevers, or continued bleeding from the incision.

Complications

Needle aspiration is an accepted, safe, and effective technique for the ED treatment of peritonsillar abscess. There is an approximate 10% failure rate or need for subsequent drainage. Aspiration or incision of the carotid artery or a misdiagnosed carotid artery aneurysm may have devastating results. The potential for penetrating a deep vascular structure is largely theoretical if proper technique is followed—there are no documented cases in recent literature. If the patient has cellulitis, the aspiration will be of no help, but it will not worsen morbidity. Failure to obtain pus should prompt highdose antibiotics and a recheck in 24 hours. Many clinicians will opt for admission in such instances. A too-large or too-small incision may lead to poor healing or inability to completely evacuate the abscess, respectively.

EAR

Anatomy of the External Auditory Canal

The external auditory canal (EAC) extends from the tympanic membrane to the concha and measures approximately 2.5 cm in the adult. It is relatively short and straight in early infancy but begins to take on its adult S-shape and overall anterocaudal orientation beginning at age 2 years. Initially, the EAC is almost entirely cartilaginous, but by adulthood its medial two-thirds is comprised of bony support with an overlying thin, stratified, squamous epithelium. The lateral third has a less sensitive, thicker, hairy epithelium that produces cerumen and retains its cartilage as support. The arterial supply to the EAC originates from the external carotid artery via the posterior auricular, maxillary, and superficial temporal branches. The mandibular branch of the fifth cranial nerve (V_3) and the vagus nerve innervate the ear.

Other important anatomic considerations include the following: (1) Two natural narrowings of the EAC exist, which are important when considering FBs. One is located at the junction of bone and cartilage and the other lies just lateral to the tympanic membrane. (2) A blind spot may occur in the tympanic sulcus (inferior and anterior to the tympanic membrane) due to the oblique orientation of the tympanic membrane. An examiner using a simple otoscope may not visualize an FB in this sulcus.

Anesthesia of the Ear

External Ear/Auricle

Indications for local anesthesia of the auricle include closure of extensive lacerations or other painful procedures, such as

Figure 65-13 *A* and *B,* External anatomy of the ear and innervation of the auricle.

hematoma incision and drainage. Four nerve branches supply the external ear, and knowledge of their anatomy is required to understand the location for anesthesia injection (Fig. 65-13*A* and *B*). The *greater auricular nerve* (branch of the cervical plexus) innervates most of the posteromedial, posterolateral, and inferior auricle. A few branches of the *lesser occipital nerve* may contribute to this area. The *auricular branch of the vagus* supplies the concha and most of the area around the auditory meatus. The *auriculotemporal nerve* (from the mandibular branch of the trigeminal nerve) supplies the anterosuperior and anteromedial aspect of the auricle.

Procedure

Fill a 10-mL syringe with either 1% lidocaine or 0.25% bupivacaine (both with epinephrine if a regional block is planned in an area *without* evidence of traumatized vascularity) and attach the syringe to a 25- or 27-ga needle (5 to 7 cm in length). One of several methods may be used to accomplish partial or complete anesthesia, depending on the area of concern. The greater auricular and lesser occipital nerve branches may be anesthetized by injecting between 3 and 4 mL of anesthetic in the posterior sulcus (Fig. 65-14*A*). Insert the needle behind the inferior pole of the auricle and gradually aspirate and inject toward the superior pole, following the crescent-shaped contour of the posterior auricle. Anteriorly, the auriculotemporal nerve may be anesthetized by placing 3 to 4 mL of anesthetic just superior and anterior to the cartilaginous tragus. Use the technique shown in Figure 65-15 and Figure 65-16 to provide anesthesia of the auricular branch of the vagus to include more central areas of the auricle.

Another and possibly more effective option is the regional block shown in Figure 65-14*B* . Insert the needle subcutaneously (SQ) at a point approximately 1 cm above the superior pole of the auricle and direct it to a point just anterior to the tragus. Be sure to inject the skin of the scalp while avoiding the auricular cartilage. Aspirate, then slowly withdraw the needle, injecting anesthetic until the needle is almost to the puncture site. Redirect the needle posteriorly and repeat the process while aiming at the skin just behind the mid-auricle. Remove the needle and perform the same procedure, but

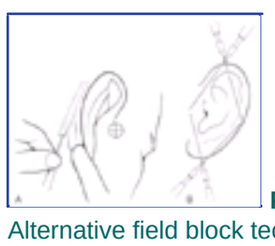

Figure 65-14 Field blocks of the auricle. *A,* One method uses approximately 3 to 4 mL of anesthetic, both in the posterior sulcus and at a point just anterior to the tragus. *B,* Alternative field block technique that deposits 2 to 3 mL of anesthetic for each needle pass. See text for more details.

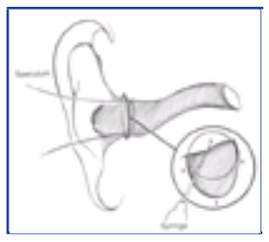

Figure 65-15 Four-quadrant field block anesthesia of the external auditory canal. Local anesthetic is injected subcutaneously in the four quadrants of the lateral portion of the ear canal. The largest speculum that will fit is used to guide the injections. The speculum is withdrawn slightly, tilted toward each of the four quadrants, and the needle is inserted subcutaneously *(x)*. A very small amount of anesthetic (0.25 to 0.50 mL) is injected to produce a slight bulge in the soft tissue. A total of 1.5 to 2.0 mL of anesthetic is usually sufficient to anesthetize the ear canal and permit painless removal of a foreign body.

insert the needle just inferior to the insertion of the ear lobule and anesthetize in a superior direction. Again, block the auricular branch of the vagus as described in Figure 65-17 if additional anesthesia of the concha is required.

Use caution if adding epinephrine to the anesthetic solution when placing regional blocks of the ear, especially if

Figure 65-16 Diagram of injection sites for an alternative technique to anesthetize the ear canal and central concha. Each site should be injected with approximately 0.5 mL of 1% lidocaine. Do not inject if external signs of infection are present.

Figure 65-17 Examination of ear canal. The pinna is retracted in a superior and posterior direction to straighten out the ear canal. The scope is held in the other hand and stabilized against the patient's head. This prevents inadvertent injury if the patient moves unexpectedly.

the blood supply has already been traumatically reduced. Do not include epinephrine when directly infiltrating wounds of the auricle, as restriction of blood flow through end arteries here may result in tissue necrosis. Other complications related to local anesthetics and regional blocks of the head and neck may be reviewed in Chapter 30 and Chapter 31 .

External Auditory Canal and Tympanic Membrane

The EAC is innervated by the auricular branch of the vagus (inferiorly and posteriorly) and by the auriculotemporal nerve (superiorly, anteriorly, and inferiorly). The primary indication for local anesthesia of the auditory canal is for FB removal, including debridement of otitis externa or removal of significant cerumen impaction. It is very difficult to obtain adequate anesthesia of the inner ear and tympanic membrane for painful procedures. Simply stated, no easy and completely effective procedure consistently works well. If total anesthesia is required, general anesthesia, especially in children, is often the only alternative. Topical anesthetics are inadequate due to their poor absorption through the rather impermeable and keratinized epithelial surface of the EAC. Although effective for some procedures, injecting local anesthetics in and around the auditory meatus is quite painful and is often difficult to perform in a struggling and uncooperative patient. Certain instances warrant adjunctive use of conscious sedation (see later discussion under Foreign Body Removal).

It is quite difficult to obtain anesthesia of the tympanic membrane. The membrane is sensitive and can be stimulated during attempts at removing a FB from the ear canal. Topical anesthetics have limited value, but Moller and Grontved demonstrated that 10% aerosolized lidocaine (first sprayed into a syringe and shaken to evaporate the propellant) and 4% lidocaine suspension, when dripped into the ear canal, provided good anesthesia of the membrane. [15] However, it required 30 minutes for this anesthesia to take effect. Both solutions were alkaline and it was noted that lidocaine

hydrochloride, the form usually used for wound infiltration, is acidic and provided no anesthesia when applied topically. Auralgan, a combination of benzocaine and other ingredients, may provide analgesia for painful earaches due to otitis, but it has little benefit for painful procedures.

Procedure

Local anesthesia is performed with a 25- or 27-ga needle (3 to 5 cm in length) attached to a syringe of 1% lidocaine with epinephrine (1:100,000). A 1:10 mixture of 8.4% sodium bicarbonate to lidocaine helps to reduce pain with injection in this sensitive area. Place a speculum just inside the auditory meatus and inject 0.3 to 0.5 mL of the anesthetic into the SQ tissue, stopping after a small bulge in the skin is raised. Inject in this manner in all four quadrants by moving the speculum after each injection (see Fig. 65-15). If additional anesthesia is necessary, give two more small injections. Inject the same amount slightly farther into the canal, once along the anterior wall and again at the posterior wall at the bone-cartilage junction.

Another similar technique involves depositing the anesthetic just lateral or exterior to the external auditory meatus. Using the same size needle and type of anesthetic solution as just described, inject approximately 0.5 to 1.0 mL into each of 5 points around the auditory meatus and tragus (see Fig. 65-16).

Examination

Several methods are available to examine the EAC and tympanic membrane. In all methods, the superior pinna should be grasped and pulled cephalad and posterior to straighten the slightly tortuous EAC. The most common manner of examination is with a *fiberoptic otoscope* (see Fig. 65-17). The clinician may insufflate the tympanic membrane as well as examine the EAC with the diagnostic head, while the operating head allows for instruments to be passed into the EAC and maneuvered more easily. A plastic or metal speculum may be placed in the auditory meatus for examination, using a head lamp or head mirror/light bulb as a light source. Although this provides excellent illumination, magnifying loupes are generally needed for adequate visualization during procedures. The ideal setup for cerumen or FB removal consists of an operating microscope and a speculum. This provides binocular vision and frees the examiner's hands for instrumentation (unfortunately this equipment is seldom found outside of the otolaryngology clinic setting). The hand holding the otoscope is stabilized against the patient's temporal skull to prevent inadvertent canal injury due to unexpected patient movement.

Cerumen Impaction

The excretion of the ceruminous or apocrine and sebaceous glands together with cells exfoliated from the external auditory canal combine to form cerumen. One study[16] found that cerumen is composed of lipids, complex proteins, and simple sugars. Cerumen repels water, has documented antimicrobial activity, and forms a protective barrier against infection. Cerumen often becomes impacted, causing complaints of a "blocked" ear, hearing impairment, or dizziness. Symptomatic impaction is an indication for removal, although symptoms are rare until complete obstruction is present. The sudden loss of hearing is a common complaint in patients with totally occluding impacted cerumen. Cerumen obstructs visualization of the tympanic membrane and can be evacuated as a part of the evaluation of a febrile child or the patient complaining of ear pain. However, cerumen removal in a child is rarely indicated in the ED simply to visualize the tympanic membrane.

Cerumen impacted for prolonged periods, and vigorous attempts to remove it, may precipitate otitis externa. It is reasonable to instill antiseptics (Vol Sol and others) or antibiotics for a few days post cerumen removal to prevent this. No standard exists and practices vary widely.

Cerumen Removal

Irrigation is an effective approach for cerumen removal and has the advantage of being painless and simple to perform. The patient does not have to remain completely still; thus, it is ideal for the pediatric population. It is estimated that 150,000 ears are irrigated in the United States each week. [17] Although usually more time-consuming than manual extraction, irrigation is an appropriate initial method to attempt and can be performed by technicians with guidance from the clinician. One contraindication is known or suspected tympanic membrane perforation. Use irrigation judiciously in elderly and immunocompromised patients, as malignant otitis externa is frequently preceded by irrigation of the EAC. [18] Generally, the procedures used to remove cerumen are safe; however, otologic injury has resulted from this "minor" procedure and has even resulted in litigation. [17] Whichever of the following techniques are used, some tips for successful cerumen removal include: use proper lighting, pay attention to patient comfort, and never continue beyond the patient's comfort level.

Ceruminolytics

These products may soften obviously hardened or impacted cerumen. They are used as adjuncts to other procedures—simply instilling ceruminolytics into the canal will not remove enough cerumen to aid the emergency clinician. If irrigation fails, the continued outpatient use of ceruminolytics is often prescribed, often combined

with home irrigation using a bulb syringe. Although many products are available as ceruminolytics, a 5% or 10% solution of sodium bicarbonate disintegrates cerumen much more quickly and efficiently compared with commercially prepared ceruminolytics and other products. Cerumenex, Cerumol, Auralgan, Buro-Sol, alcohol, and oils were all tested and took more than 18 hours to disintegrate cerumen vs ~90 minutes for the sodium bicarbonate solutions. [19] Hydrogen peroxide is another commonly used ceruminolytic, but its use has not been systemically studied. One study [20] found the liquid preparation of the stool softener docusate sodium (Colace) was much more effective as a ceruminolytic than Cerumenex. Place the patient in the supine position with the affected ear up and instill the solution at least 15 minutes before attempts at removal. Instillation can be repeated between attempts at manual extraction or irrigation.

Irrigation (Ear Syringing)

This procedure is best achieved by having the patient sit upright and holding an emesis or ear irrigation basin flush against the skin just below the ear lobule (Fig. 65-18). Insert the irrigation tip into the EAC only as far as the cartilage-bone junction, and direct the stream of water superiorly to wash the impacted cerumen away from the tympanic membrane. Water should be near body temperature to prevent caloric

Figure 65-18 Irrigation is a simple, painless, and usually successful way to remove cerumen. After a wax-softening agent has been instilled for 15 to 20 minutes, an assistant applies traction on the ear to straighten the canal, and the plastic tubing of a 19-ga butterfly device (needle and wings removed) is inserted 1 cm into the canal. A basin is held by the patient, and warm water is introduced with a 20-mL syringe. A number of irrigations may be required, and the procedure may be supplemented with careful removal of large cerumen pieces with a curette.

stimulation. Multiple attempts may be necessary, and intermittent attempts at manual removal of loosened cerumen may help hasten the process. During the irrigation, the operator or an assistant should apply traction to the pinna to straighten the canal for more efficient irrigation.

Irrigation techniques using manual pressure to discharge the water include metal ear syringes and bulb syringes. The metal ear syringe (*Reiner-Alexander Ear Syringe*) is inexpensive and readily available. Some disadvantages include: slow operation, it is poorly balanced, the tip tends to wobble, and minor canal trauma is common.[17] [21] Improvisational irrigation systems can be assembled with equipment found in the ED. Attach a 20- or 30-mL syringe to a 19-ga or larger butterfly device, cutting off the needle and wings and leaving the resultant tubing for irrigation. A plastic or Teflon IV catheter (16- or 18-ga with the needle removed) can similarly be affixed to a syringe. Contraindications to ear syringing include [22] :

Patient aversion to or history of injury from syringing

History of middle ear disease

History of ear surgery

Perforated tympanic membrane

Severe otitis externa

Narrow ear canals

FBs, especially sharp objects and vegetable matter

Uncooperative patient

Occluding aural exostoses

Known inner ear disturbance, especially if patient has severe vertigo

History of radiation therapy to the external or middle ear, skull base, or mastoid

The most common way to irrigate an ear is with a syringe and catheter (Fig. 65-19). Although most commonly found in an otolaryngologic clinic, automated pressure devices may also be available. The *DeVilbiss irrigator* (Fig. 65-20) uses a pressurized air source to propel the irrigating solution into the ear. It allows the clinician to control the water pressure and direction, making it pleasant for the patient. Unfortunately, it is rarely available in hospitals, requires a pressure source, and clinician training is needed. Use of *oral jet irrigators* (Water Pik) is another accepted method. They are fast, portable, and inexpensive. Disadvantages to the oral jet irrigator include: trauma to the stapes and cochlea, off-label use may expose the clinician to litigation, there is splash back, and many patients find it uncomfortable. The Hydro Med Ear Irrigator Tip (Hydro Med, Sherman Oaks, CA) can be combined with the Water Pik to improve safety and comfort. The tip keeps the stream of water from hitting the eardrum. The tip is smooth and convex, reducing the potential for injury. [17] Although the instances have been rare, tympanic membrane rupture has

Figure 65-19 The most readily available device for ear irrigation is an 18-gauge flexible catheter attached to a 60-mL syringe. Since multiple irrigation may be required, small syringes are counterproductive.

Figure 65-20 This DeVilbiss irrigator uses compressed air to eject the irrigating solution, which should be near body temperature to avoid caloric stimulation of the inner ear. The more conventional metal ear syringe can be equally effective and does not require a source of compressed air to function.

been documented with these apparatuses.[23] Therefore, use the lowest-power setting and guide the stream of the water against the EAC wall, not directly toward the tympanic membrane.

After irrigation of the EAC, application of several drops of isopropanol in the EAC will facilitate evaporation of residual moisture. The tympanic membrane must be intact if isopropanol is to be used. Further, topical Cortisporin Otic suspension drops may be soothing after prolonged irrigation. Since diabetics can develop severe otitis external following irrigation, some clinicians routinely prescribe antibiotic ear drops (fluoroquinolones and others) for a few days post irrigation in high-risk patients.

Although more common with jet irrigators, complications may occur with any method of ear irrigation. These include otitis externa, tympanic membrane perforation, or

middle ear injury from a preexisting defect in the tympanic membrane. Irrigation should be stopped and the tympanic membrane examined in any patient experiencing sudden pain, tinnitus, hearing loss, nausea, or vertigo. If the membrane is ruptured, prophylactic antibiotics for otitis media should be given along with a referral to an otolaryngologist.

Manual Instrumentation

This procedure is more advantageous as it is usually quicker, and the examiner may more easily remove hardened or larger concretions of cerumen under direct visualization. However, it is difficult to manually remove cerumen without causing significant pain. Either the diagnostic or operating head of the fiberoptic otoscope or a speculum may be placed in the auditory meatus to serve as a protective port through which instruments are passed and manipulated (Fig. 65-21). An operating microscope works best in this situation, but, again, is usually not available. To prevent startling or agitating an already anxious patient, allow the patient to experience the sensation of an instrument in the canal by first placing the instrument softly against the ear canal wall.

Instruments used for cerumen removal include *flexible plastic or wire loops, right-angle hooks, suction-tip catheters, or plastic scoops* (Fig. 65-22). The spoonlike instruments and irrigation are both more effective in removing softer cerumen. Firm cerumen ordinarily is more easily withdrawn with loops or right-angle hooks. Gently tease the cerumen off of the

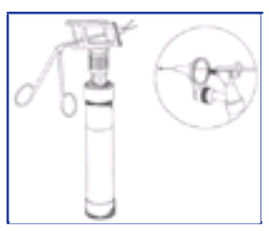

Figure 65-21 Technique for direct visualization and mechanical removal. Use of alligator forceps through a diagnostic otoscope. Note that the magnification device has been slid laterally and that no ear speculum has been attached. *Inset,* Use of ear curettage through operating otoscope. *(From Fritz S, Kelen GD, Sivertson KT: Foreign bodies of the external auditory canal. Emerg Med Clin North Am 5:184, 1987.)*

canal wall using loops and then pass hooks or loops around the cerumen and withdraw the cerumen slowly (Fig. 65-23). Care should be taken to keep both hands in contact with the patient's head, as any sudden movement may cause trauma to the canal or the tympanic membrane. Complications most commonly occur when inadvertent contact is made with the thin, friable skin of the bony canal. Trauma may cause EAC laceration, hematomas, otitis externa, or tympanic membrane perforations.

Otitis Externa

Otitis externa, or "swimmer's ear," is an inflammation of the skin of the external auditory canal. This is essentially a cellulitis of the ear canal. Otitis externa can be disabling enough to cause 36% of patients to interrupt their daily activities for a median duration of 4 days. [24] Precipitants of otitis externa include water exposure and trauma. Excessive moisture in the canal raises the pH and removes the cerumen. Keratin can now absorb water, creating a medium for bacterial growth. Trauma, especially self-manipulation with FBs (cotton swabs, fingernails, etc.), causes abrasions to the ear canal and introduces infection. Removal of cerumen by water irrigation is a well-recognized risk factor for the development of otitis externa. [24] [25]

The disease process involves a continuum of gradually worsening inflammatory changes. The patient may present with symptoms ranging from slight itching and discomfort to severe pain, purulent discharge, or systemic toxicity. Pain with manipulation of the pinna is the hallmark for otitis externa. Otoscopy of the external auditory canal may initially reveal minimal debris and erythema, but as the infection progresses, more edema, exudate, erythema, and possibly even a surrounding cellulitis may become apparent. In severe stages the edema may obstruct the canal, preventing instillation of eardrops.

Figure 65-22 Instruments used for foreign body extraction. From left to right: alligator forceps, bayonet forceps, right-angle hook, wire loop, soft-tipped suction, Frazier suction.

Common bacteria cultured from patients with otitis externa include *Pseudomonas aeruginosa* and *Staphylococcus aureus*. Other bacteria include *Acinetobacter*, *Proteus*, *Enterococcus*, and *Bacteroides*. Approximately 50% of patients have polymicrobial infection and 8% have anaerobic isolates. [26] Of concern, one study[27] found that 6% of staphylococcus isolates were methicillin resistant. Fungi are identified in about 10% of otitis externa cases and are often coexistent with bacterial infections. Aspergillus is responsible for 80% to 90% of cases followed by Candida. It characteristically presents as a furry lining of the ear canal with a fluffy white discharge. Herpes zoster affecting the geniculate ganglion may appear as grouped vesicles on an erythematous base within the canal. This condition, known as Ramsay Hunt syndrome, is associated with facial nerve palsies, hearing loss, and other cranial nerve impairment.

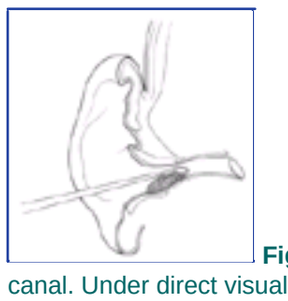

Figure 65-23 Removal of impacted cerumen. Pass the tip of the wire loop beyond the wax and gently tease the wax off the ear canal wall. Extract the wax slowly from the canal. Under direct visualization, avoid contact with the skin of the ear canal to prevent pain and excoriation.

Diabetics and other immunocompromised patients, especially HIV-positive patients, are susceptible to *malignant (necrotizing) otitis externa*, a life-threatening form of otitis externa caused by *Pseudomonas*. Deep tissue necrosis, osteomyelitis, intracranial extension, and systemic toxicity are hallmark features. Malignant otitis externa is difficult to treat and mortality rate can be as high as 53%. [24] The diagnosis of malignant otitis externa should be considered in the diabetic or immunocompromised patient with significant symptoms who fails to respond to initial outpatient treatment.

Canal Debridement/Wick Placement

It has been touted that key to successful treatment is adequate removal of canal debris. However, vigorous attempts to remove debris on the first visit are very painful, of unproven value, and often eschewed. Gentle attempts to remove debris with small swabs (e.g., urethral swab) (Fig. 65-24) are reasonable, but reserving this procedure for treatment failure or at a follow-up visit is also practiced. Gentle irrigation is one initial approach, but many patients will be cured without extensive debridement. Because the inflamed canal is susceptible to trauma, debris removal may also be accomplished by suctioning under direct visualization using the open or operating otoscope head and a 5 or 7 French (Fr) Frazier tip suction. Irrigation of the canal can be performed only if the clinician is assured there is no tympanic membrane perforation, which may be difficult to confirm due to edema and patient discomfort. [24] [25] [26] For more advanced cases presenting with significant exudate and edema, debris removal remains necessary but is intensely painful. The author recommends using a local block of the auditory canal (see Fig. 65-16) as long as the cellulitis has not extended out to the tragus or concha. Administer parenteral analgesics if additional pain control is required.

Ear wicks may be used when edema, debris, and exudate are marked enough to impede antibiotic drops from contacting the canal skin. The wick is used as a conduit to deliver the antibiotic solutions to the ear canal. After debridement, use one of several methods to accomplish this. The true benefit of wick implantation is unknown. One approach is to place a 0.25-in. strip of Nu-Gauze dressing covered with an antibiotic and steroid cream (Cortisporin Otic cream) into the external acoustic canal

in a fashion

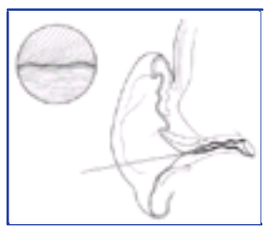

Figure 65-24 Debridement of external otitis. A cotton-tipped applicator is inserted into the canal and debris is gently removed from the canal. Irrigation of the ear may also be helpful if the tympanic membrane is not perforated. *Inset,* the edema has almost closed the canal and will not allow medication to be instilled into the inner canal. An ear wick will prove useful in this situation.

similar to the technique used for anterior nasal packing. Using an otoscope and alligator forceps, place the leading edge of the gauze deeply in the canal until it is fully packed. Withdraw the otoscope and finish by packing the lateral aspect of the canal as well.

Another choice is to place commercially available ear wicks, such as the Pope Merocel ear wick. Place this wick into an edematous canal and apply antibiotic/hydrocortisone drops onto it. The wick swells and helps to reduce edema by the antimicrobial and anti-inflammatory effects of the solution and through pressure exerted against the walls as it expands. Leave wicks in place until the patient is followed up in 24 to 48 hours for removal and further debridement. Although relatively safe to use, the ear wick is designed for short-term use. Generally these wicks will fall out of the canal as edema subsides. However, the unusual retention of these wicks can harbor bacteria and cause tissue ingrowth, resulting in long-term problems for the patient. [28]

Antibiotic Therapy and Follow-up

Most cases of otitis externa can be effectively treated with debridement and topical antibiotic drops. A study by Halpern [29] showed that <20% of patients have a concomitant diagnosis treatable by oral medications, yet 40% of patients receive topical and oral medications and many of the oral antibiotics prescribed are not active against Pseudomonas and Staphylococcus. They also found that only 7% of adult doctor visits and 2% of pediatric clinician visits reported ear irrigation. Antibiotic eardrops most frequently consist of some combination of neomycin and polymyxin, but an acetic acid solution is another acceptable first-line therapy. Eardrops are instilled as 2 to 4 drops QID for 7 to 10 days. Hydrocortisone may be added to either the antibiotics (Cortisporin suspension or solution) or the acetic acid (VoSol HC). Cortisporin Otic *solution* (clear appearing) is harmful to the middle ear if it passes through the tympanic membrane. At times it is difficult to distinguish between a ruptured tympanic membrane secondary to otitis media and severe otitis externa in a child. Therefore, the cloudy-appearing Cortisporin *suspension* is recommended in any case of suspected or known tympanic membrane perforation. Topical antibiotic preparations have been recommended for chronic suppurative otitis media, tympanostomy tube otorrhea, and acute otitis media. [30] Antibiotic preparations entering the middle ear are rarely problematic. There is no compelling reason to withhold drops if the tympanic membrane has been ruptured, although in that circumstance, gentamycin preparation and corticosporin solution (not suspension) are discouraged.

Fluoroquinolones have good activity against Pseudomonas and Staphylococcus. Two topical fluoroquinolone preparations are available, ofloxacin 0.3% (Floxin Otic) and Ciprofloxacin 0.2% with hydrocortisone 1% (Cipro HC Otic). Ofloxacin solution is approved for treatment of otitis externa and otitis media with perforated or ventilated tympanic membrane. Ciprofloxacin suspension is approved for the treatment of otitis externa only. Both may be used in patients one year and older. The topical fluoroquinolones show equal efficacy when compared to polymyxin B-neomycin-hydrocortisone suspension. Side effects are minimal and there is no reported ototoxicity.[31] Some practitioners consider these agents first-line therapy.

Holten and Gick[32] provide an evidence-based review of otitis externa treatment. The best evidence demonstrated equivalent results with ear cleaning, ear wick, and topical agents. Treatment with 1 of 3 regimens for 4 days was recommended. The regimens are: (1) ear cleaning + ear wick + acidifying agent dosed QID, or (2) ear cleaning + ear wick + topical antibiotic dosed QID (twice daily if fluoroquinolone), or (3) ear cleaning + ear wick + topical antibiotic/steroid combination dosed QID (twice if fluoroquinolone). There was less evidence for the use of single topical treatment or oral antibiotics. This paper also provides evidence-based treatment options for malignant otitis externa as well.

Inform patients to avoid getting water in the ear for the full course of treatment and to apply their eardrops immediately if water does contact the ear canal. Follow up severe cases in 24 to 36 hours and repeat debridement if needed. Generously administer oral opioids for the first 24 to 48 hours, as this condition can be quite painful. Nonsteroidal anti-inflammatory drugs are also effective for pain control. To prevent the recurrence of otitis externa, patients should avoid its many precipitants. This is especially true for patients who perspire excessively, regularly participate in water sports, have unusually viscous cerumen, have a narrowed external auditory canal, or systemic allergies. Measures include: drying the external auditory canal with a hair dryer on the lowest heat setting after bathing or swimming, using prophylactic acidifying drops with alcohol (Swim Ear) or without (Burow's solution, Star-Otic), avoiding scratching or overzealous cleaning, and using protective barriers while swimming (tight-fitting bathing cap or well-fitting ear plugs).

Broad-spectrum oral antibiotics should be used in cases of persistent otitis externa, concomitant otitis externa, systemic symptoms, and local cellulitis. A cautious approach to treating the mild to moderate case of otitis externa in the immunocompromised patient without toxic reaction is to add oral ciprofloxacin for greater coverage of *Pseudomonas*. Promptly admit suspected cases of malignant otitis externa and begin an IV anti-pseudomonal antibiotic. In addition, immediately consult an otolaryngologist for possible surgical debridement.

Patients with Ramsay Hunt syndrome should be treated with antivirals. Some clinicians suggest admission for administration of IV acyclovir. Treat otomycosis by swabbing the canal with a cotton-tipped applicator saturated with an antifungal solution (such as clotrimazole or boric acid/alcohol) in an effort to remove debris. Repeat this if necessary on follow-up in 3 to 7 days. If the infection is not responding, over-the-counter clotrimazole 1% solution (Lotrimin) can be used. If the tympanic membrane is perforated, then use tolnaftate 1% solution (Tinactin). Topical solutions of thimerosol and M-cresyl acetate are also effective. All of these topical agents are prescribed as 3 or 4 drops twice daily for 7 days. Because Aspergillus may be resistant to clotrimazole, oral itraconazole (Sporanox) can be used. [24] Do *not* administer corticosteroids in cases of known fungal otitis externa.

Foreign Bodies of the Ear Canal

Despite its small size, the EAC may play host to numerous types of FBs.[33] [34] Living insects account for most FBs found in adults. Children frequently place food (e.g., peas, beans), organic matter (e.g., grass, leaves, flowers), and inorganic objects (e.g., beads, rocks, dirt) into the ear canals during play, and they often fail to admit this to parents. Button batteries may cause significant tissue destruction in a matter of hours, and it is vital to immediately obtain otolaryngologic consultation for removal if the button battery is not easily extracted. Symptoms of FB retention are usually ear pain, fullness, or impaired hearing in the adult, whereas the pediatric patient may not present until an associated otitis externa with a purulent discharge has developed. Tinnitus, vertigo, significant hearing loss, or bleeding from behind the object should raise a high suspicion for an associated tympanic membrane rupture.

As previously described, the anatomy of the external auditory canal predisposes to the entrapment of FBs in either a lateral or deeper position. Removal of more medial objects can be much more painful and anesthesia is usually required. Even the most cooperative patient may become difficult after feeling pain during manipulation of the ear canal. It is probably impossible to adequately immobilize the head of an uncooperative awake child to delicately extract a FB. Some authorities claim local anesthesia makes extracting FBs even more difficult because of soft tissue distortion, although swelling should be minimal if proper amounts of anesthetic are used. Anesthesia of the auditory canal may be difficult to achieve. Topical anesthetics have a partial effect and a four-quadrant technique may not produce complete anesthesia, especially of the tympanic membrane.[35] A more realistic concern is that if the FB is deeply or firmly embedded, the patient should be referred early for removal under an operating microscope, before canal trauma and swelling mandate admission for removal under general anesthesia. Conscious sedation (preferably an analgesic-sedative combination or dissociative anesthetic) can aid in the removal of FBs in the distraught child by preventing further struggling and potential canal trauma. Ketamine is an excellent anesthetic for simple FB removal in the outpatient setting. The care provider must weigh the inherent risks of

conscious sedation against those of general anesthesia and the cost of hospital admission.

Before initiating removal, the clinician should set realistic limits on the number of attempts to be made. Even the best clinician can become too aggressive as frustration builds with failed attempts to extract the object. Early consultation with an otolaryngologist should not be considered a failure in cases of difficult FBs. Indeed, with the proper equipment and experience, most objects can be atraumatically removed.

Adequate visualization of the object is needed for successful removal. One study showed that canal lacerations occurred in 48% of patients where removal was attempted without a microscope and 4% when it was used.[35] The otoscope is the traditional ED instrument for viewing FBs of the ear canal. The otoscope is less likely to be useful in retrieval because it is difficult to instrument through or around the small speculum end. A specialized ear, nose, and throat (ENT) speculum allows more space for instrumentation. A head lamp provides a good light source and leaves both hands free. Magnifying loupes also provide hands-free magnification. Table 65-1 lists the equipment helpful for FB removal in the ED. [35]

Procedures

It is reasonable to make a judicious attempt to remove ear FBs in the ED setting. Prolonged traumatic attempts should be avoided since this often terrifies the patient, further complicates subsequent attempts, and can cause bleeding and swelling. These factors make subsequent efforts difficult. Most approaches to FB removal are anecdotal and are found in the literature as case reports or case series rather than as prospective clinical trials. The clinician should be familiar with several techniques, as the most appropriate choice can vary depending on depth of impaction or the size, shape, and consistency of the object. A summary of these techniques is provided in Table 65-2 . [35]

Irrigation is the least invasive option and the techniques and related complications are explained in detail earlier in this chapter (see Cerumen Removal). Deeply embedded vegetable matter (such as beans, peas, or seeds) should not be irrigated, however, as swelling may occur and make extraction more difficult. Irrigation works particularly well with small rocks, dirt, or sand that lie deep in the canal next to the tympanic membrane.

Suction-tip catheters.

This technique works well with objects that are round and difficult to grasp. Suction is readily available in the ED and needs to provide 100 to 140 mm Hg of negative pressure to be useful. To prevent iatrogenic injury, the patient must be informed of the impending noise to prevent sudden movements from a startle reflex. Place either the blunt or soft plastic tip against the object and slowly withdraw. If using a suction instrument with a thumb-controlled release valve (as with the Frazier suction) (see Fig. 65-22), remember to cover the port to activate the suction.

The Hognose (IQDr, Inc.), a commercially available device designed by an emergency clinician, aids in the removal of auditory canal FBs. It is used in combination with an otoscope and suction setup. It is essentially an otoscope speculum with suction attachment and a soft self-molding tip that can attach to objects. The flange comes in three color-coded sizes: 4mm, 5mm, and 6mm. To use, first attach the Hognose to the otoscope and standard wall suction set at low to medium vacuum setting (Fig. 65-25*A*). Next, under direct visualization, approach the FB with the otoscope. Finally, engage suction by applying finger pressure to the open insufflation port and withdraw (Fig. 65-25*B*).

Manual instrumentation.

This approach may be attempted with various instruments (Fig. 65-26). Illumination

TABLE 65-1 -- Removal Techniques for Aural and Nasal Foreign Bodies

Technique	Orifice	Advantages	Disadvantages
Irrigation	Ear	Ease of use	Contraindicated in TM perforation and vegetable matter
	Nose (possibly)		
Positive pressure	Nose	Nontraumatic	Risk of barotrauma
		Parent participation	
Negative pressure	Both	Easy to use	Need solid seal
		Good for round, small objects	Posterior FBs difficult
		Anterior FBs	Noise may frighten children
Glue	Both	Easy to use	Adhesion of glue to patient
		Nontraumatic	Must visualize FB
		Good for round, smooth objects	
Catheter techniques	Both	Good for awkward and posterior FBs	Cost and catheter availability
			Possible trauma
			Needs good anesthesia
Surgical instruments	Both	Availability	Trauma
			Posterior displacement of FBs
Manufactured instruments	Both	Instrument can be designed to fit the FB shape	Trauma
			Posterior displacement of FBs

FBs, foreign bodies; TM, tympanic membrane.

and magnification are accomplished by either the diagnostic or operating head of a fiberoptic otoscope. An assistant should hold the pinna back and out so that the examiner may hold the otoscope with one hand and manipulate the instrument with the other. A speculum and either a head lamp or head mirror/light source can also provide illumination, but magnifying loupes are usually required for adequate visualization. Use small alligator forceps to remove objects with edges that can be grasped, but avoid trying to encircle an impacted round FB, as this may cause trauma to the canal wall. A small right-angle hook is another choice. Place the tip past the object, rotate it 90°, and then pull the object from the canal. Fine-tissue or Adson forceps, curettes, and skin hooks are other instruments

Irrigation equipment
Hartman's forceps
Foley and Fogarty catheters

that are used occasionally. Use of these instruments is commonly associated with abrasions and bleeding of the ear canal. [35] They should be used only on compliant, cooperative patients and direct visualization of the object is essential.

Small fogarty catheters.

Small Fogarty catheters (biliary or vascular) may be used in a manner similar to that described later in the chapter for nasal FB removal. [36] Attach the catheter tip to a 2-mL syringe and gradually inflate the balloon once the tip is past the object; then drag the FB out along with the balloon. Immediately deflate the balloon if sudden pain occurs because tympanic membrane rupture is a potential complication.

Cyanoacrylate (Superglue).

The use of glue in FB removal was first reported in India in 1977. [35] [37] Glue is most effective in removing smooth, round objects that are difficult to grasp. The FB should be dry and easily visualized. Apply a small amount of glue to the tip of a thin paintbrush, a straightened paper clip, or the blunt end of a wooden cotton-tipped applicator.[36] Allow the glue to become tacky. Place the tip against the object, allow it to dry, then carefully withdraw the FB. Minor complications are possible if the tip dries against the canal wall (abrasion, excoriation) or if the glue spills or drips onto the wall (creating a new FB). This technique may be more useful in adults as cooperation is required. [37]

Dissolution of styrofoam.

Styrofoam impaction in the ear canal can be problematic. Application of acetone in a very small amount (0.1 mL) was reported to effectively dissolve deep-seated Styrofoam in a child's ear canal.[39] The ear was irrigated immediately after carefully dripping the acetone directly onto the Styrofoam, and no significant complications of the canal or tympanic membrane were noted. The potential ototoxic effects of acetone in the middle ear have not been studied; therefore, this technique should not be performed if there is any suggestion or history of tympanic membrane perforation. Ethyl chloride has also been effective in dissolving Styrofoam beads. [35] Once again, this technique should not be performed if there is any suggestion or history of tympanic membrane perforation.

Removal of Insects.

Cockroaches are the most commonly found live insect as an intra-aural FB; treatment consists of instillation of various substances into the ear canal to first immobilize or kill the bug before removing it. This helps retrieval by allowing for a stationary target and also halts the disturbing and painful movement of the insect. Controversy exists about which agent most effectively accomplishes this. Mineral oil has traditionally been used, although lidocaine has been reported to paralyze roaches and to allow for easier extraction than the more viscous mineral oil. An in vitro comparative study showed that immersion in mineral oil and 2% or

Figure 65-26 Application of various methods of foreign body removal from the ear canal. *A*, Right-angle hook. *B*, Irrigation. *C*, Alligator forceps. *D*, Soft-tipped suction.

4% lidocaine solution killed roaches in <60 seconds (~27 and 41 seconds, respectively). [40] The roaches struggled less in the viscous oil than in the lidocaine, which did not appear to cause paralysis. Other substances (Auralgan, isopropanol, water, succinylcholine, hydrogen peroxide) were shown to be ineffective in killing the roaches in a reasonable amount of time. Once disabled, insects may be removed with mechanical extraction as previously described, and pieces can be suctioned out if fragmentation occurs. Mineral oil is safe, but lidocaine has been reported to cause vertigo and middle ear symptoms in patients with tympanic membrane perforations.[41]

Figure 65-27 *A,* Subperichondrial hematoma within the concha of the ear. *B,* Needle aspiration of an auricular hematoma. A topical antiseptic is used to clean the ear, but local anesthesia is seldom required. While stabilizing the pinna with the thumb and fingers, the most fluctuant part of the hematoma is punctured with a 20-ga needle. The thumb "milks" the hematoma into the syringe until the entire hematoma has been evacuated. The thumb maintains continued pressure on the ear for 3 minutes after the needle has been withdrawn. A pressure dressing is then applied, and the ear is checked for reaccumulation of blood in 24 hours. Reaspiration may be required, and persistent accumulations require incision and drainage. *(B redrawn with permission from Fleisher GR, Ludwig S, Henretig FM, et al: Textbook of Pediatric Emergency Medicine. Baltimore, Williams & Wilkins, 1983.)*

Follow-up/Complications

Hearing should be evaluated before and after FB removal, especially in patients with suspected tympanic membrane or middle ear injuries. Examine both the opposite ear and nose of children to search for the rare but possible second FB. Minor lacerations or excoriations of the canal usually heal quickly with or without antibiotic eardrops, so long as the canal is kept clean and dry. Document preexisting canal trauma or suspected tympanic membrane rupture before attempts at removal; otherwise, this may falsely be attributed

Figure 65-28 Auricular hematoma. *A*, Hematoma separating the perichondrium from the cartilage. *B*, Incision *(arrows)* made along the skin curvature at the posterior edge of the hematoma. Hematoma is evacuated and area irrigated. *C*, Two anterior dental rolls are secured with sutures to a posterior dental roll to maintain normal anatomy of the pinna. *D*, Side view illustrates position of sutures and dental rolls in relation to incision site. Note that the perichondrium is apposed to the cartilage. *(From Clemons JE, Seveneid LR: Otohematoma. In Cummings CW (ed): Otolaryngology—Head and Neck Surgery, 2nd ed. St Louis, Mosby-Year Book, 1993, p 2866.)*

to iatrogenic causes at a later date. Most patients with FBs that cannot be removed in the emergency setting can be safely referred to an otolaryngologist the next day. Exceptions that require immediate consultation include severe pain, suspected tympanic membrane rupture, embedded button batteries, or a concomitant canal infection. Generally, no routine follow-up is necessary except in cases of infection, severe trauma, or tympanic membrane perforation. Parents should be educated to reduce the exposure of children to potential FBs.

Auricular Hematoma

Auricular hematomas occur after a shearing force to the ear, most commonly in wrestlers. A subperichondrial hematoma forms, separating the perichondrium from the cartilage. Recurrent or untreated injuries allow the development of new cartilage, which subsequently deforms the auricle (cauliflower ear).

Procedure

The treatment of an auricular hematoma involves complete evacuation of the subperichondrial hematoma and reapproximation of the perichondrium to the cartilage.

Needle aspiration.

Aspiration of an auricular hematoma is performed by perforating the hematoma with a 20-ga needle (Fig. 65-27). The hematoma is "milked" between the thumb and forefinger until the entire hematoma is evacuated. A pressure dressing is subsequently applied. Frequently reexamine

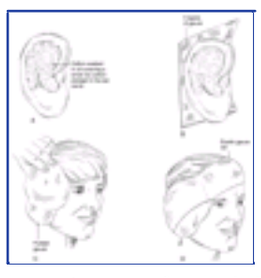

Figure 65-29 Compression dressing of the ear. Following successful aspiration of an auricular hematoma, a compression dressing is used to prevent reaccumulation of the hematoma or fluid. *A,* Dry cotton is first placed into the ear canal. A conforming material is then carefully molded into all the convolutions of the auricle. One may use Vaseline gauze or cotton soaked in mineral oil or saline. *B,* When the convolutions are fully packed, a posterior gauze pack is placed behind the ear. A V-shaped section has been cut from the gauze to allow it to fit easily behind the ear. *C,* Multiple layers of fluffed gauze are placed over the packed ear, and the entire dressing is held in place with Kling gauze or an elastic gauze roll. *D,* The ear is thus compressed between two layers of gauze, and the packing ensures even distribution of pressure to all parts of the auricle.

the ear for reaccumulation of the hematoma. Reaccumulation of blood requires reaspiration. Because of the possibility of inadequate evacuation and recurrent hematomas, the author does not recommend needle aspiration.

Incision.

The auricular hematoma, if <7 to 10 days old, may be incised along the natural skin folds. Anesthetize the pinna using local infiltration of 1% lidocaine (without epinephrine) or by an auricular block (described earlier). Incise the skin with a No. 15 blade at the edge of the hematoma, following the curvature of the pinna (Fig. 65-28). Gently peel the skin and perichondrium off the hematoma and underlying cartilage. Completely evacuate the hematoma and irrigate the remaining pocket with normal saline.

Aftercare.

After removal of the hematoma, apply antibiotic ointment and reapproximate the perichondrium to the cartilage via a pressure dressing. A compression dressing may be applied to the ear as shown in Figure 65-29 . An alternative

technique is to suture dental rolls over the area (see Fig. 65-28).[42] To accomplish this, pass a 4-0 nylon suture through the entire thickness of the ear over the hematoma. Wrap the suture around a dental roll on the posterior aspect of the ear and then pass the needle back through the pinna. Wrap and tie the suture around a second dental roll on the anterior aspect of the pinna. A second suture may be placed to secure a third dental roll. The dressing should firmly re-approximate the perichondrium to the cartilage without vasculature compromise. Remove the dressing in 1 week.

Prescribe anti-staphylococcal antibiotics and instruct the patient to inspect the wound frequently for evidence of vascular compromise or infection, or both. Reevaluate the wound in 24 hours for recurrence of the hematoma. Infection is treated with bandage removal, surgical drainage, and IV antibiotics. Refer patients with auricular hematomas of >7 days' duration to a surgeon, as the new perichondrial growth must be debrided to prevent auricular deformation.

NOSE

Anatomy

The nose consists of the vestibule, nasal septum, lateral wall, and the nasopharynx. The vestibule is the anterior most portion of the nares, which is composed of skin and contains the hair follicles. The nasal septum is the midline structure, which is composed of cartilage anteriorly and of bone posteriorly. The lateral wall of the nose contains the superior, middle, and inferior turbinates as well as the auditory tube opening.

Three major arteries supply the nose and conjoin via anastomoses. The sphenopalatine artery emerges from the sphenopalatine foramen, which is located at the posterior aspect of the middle turbinate (Fig. 65-30). This is the most common source of posterior epistaxis. This artery supplies the turbinates laterally and the posterior septum. The anterior and posterior ethmoidal arteries branch off the ophthalmic artery and penetrate the cribriform plate to supply the superior nasal mucosa. The superior labial branch of the facial artery completes the triad, supplying the nasal septum and vestibule. The

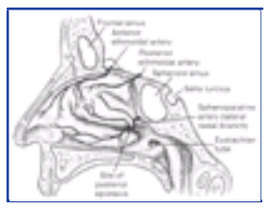

Figure 65-30 Vascular supply to the lateral wall. The most common site of posterior epistaxis is the sphenopalatine artery as it emerges posterior to the middle turbinate. *(From Maceri DR: Epistaxis and nasal trauma. In Cummings CW (ed): Otolaryngology—Head and Neck Surgery, 2nd ed. St Louis, Mosby-Year Book, 1993, p 728.)*

watershed area on the anterior septum, also known as Kiesselbach plexus, is the most common source of anterior epistaxis (Fig. 65-31).

Anesthesia

Apply local anesthetic and vasoconstrictors on cotton swabs. Placement of these swabs is illustrated in Figure 65-32 . If a larger area of anesthetic is required, use cotton pledgets. Figure 65-33 describes the procedure of making pledgets. Soak each pledget in anesthetic or a vasoconstricting substance and then squeeze the excess fluid out of the pledget. Be aware of the total amount of drug being administered and stay within recommendations for the maximum safe dosage. Place each pledget horizontally on the floor of the nasal cavity,

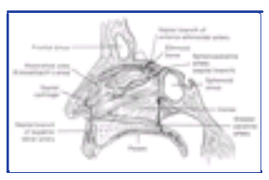

Figure 65-31 Vascular supply to the septum. The most common site of anterior epistaxis is within the area labeled Kiesselbach's plexus. *(From Maceri DR: Epistaxis and nasal trauma. In Cummings CW (ed): Otolaryngology—Head and Neck Surgery, 2nd ed. St Louis, Mosby-Year Book, 1993, p 728.)*

Figure 65-32 Placement of local anesthetic in the nose for anesthesia before reduction of nasal fracture by blockage of the anterior ethmoidal nerve superiorly and the sphenopalatine ganglion at the posterior end of the middle turbinate. *(From DeWeese DD, Saunders WH, Schuller DE, Schleuning AJ II (eds): Otolaryngology—Head and Neck Surgery, 7th ed. St Louis, CV Mosby, 1988.)*

stacking the next pledget on top. Three pledgets are usually required to pack the nasal cavity. These can be replaced with new pledgets in 5 minutes if the desired anesthetic effect is not achieved. Hurricaine spray may also be used as a topical

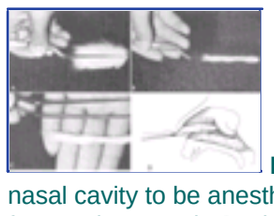

Figure 65-33 Topical anesthetic and vasoconstrictors are applied on individually made cotton pledgets. The size of the pledget may be changed according to the extent of the nasal cavity to be anesthetized and the size of the patient. *A,* An appropriately sized cotton pledget is grasped in a bayonet forceps. *B,* The cotton is then grasped with the opposite hand, and the forceps is rotated. *C,* The pledget is removed and is ready for insertion. *D,* To completely anesthetize the nasal cavity, three pledgets are necessary. The first is placed on the floor of the nose, the second in the middle meatus between the inferior and middle turbinates, and the third in the roof of the nasal cavity and the anterior nasal vestibule. *Note:* This pledget technique can be used to make a cotton wick for the treatment of otitis externa.

anesthetic. Remind the patient that excess anesthetic may numb the throat but will not inhibit swallowing.

As with all drugs, review the maximum dose allowed before administering the anesthetic (see Chapter 30). Always use the smallest amount of anesthetic required to obtain adequate analgesia. The maximum dose of lidocaine without epinephrine is 5 mg/kg, up to 300 mg. The maximum dose of lidocaine with epinephrine is 7 mg/kg, up to 400 mg. The maximum dose for cocaine is 3 mg/kg for mucosal application, up to 200 mg. Remember that these are guidelines and that any patient can have a severe reaction with less than the total dose. For a 60-kg person, the maximum total dose of lidocaine would equal 300 mg (60 kg × 5 mg/kg = 300 mg). A 1% solution (10 mg/mL) would allow for a total of 30 mL to be administered (30 mL × 10 mg/mL = 300 mg). A 2% solution (20 mg/mL) would allow for only 15 mL to be administered (15 mL × 20 mg/mL = 300 mg). Cocaine is packaged in a 4% solution (40 mg/mL), allowing only 5 mL for a mucosal application to a 70-kg patient (3 mg/kg × 70 kg = 210 mg; 5 mL × 40 mg/mL = 200 mg, which is the maximum total dose). Clinicians should be familiar with the side effects and potential complications of the drugs being administered. Cocaine can induce tachycardia, hypertension, irregular respirations, seizures, and hyperpyrexia (especially in children). Lidocaine will manifest its antiarrhythmic and membrane stabilization effects.

Examination

Examination of the nares is relatively straightforward. When using a nasal speculum, insert it into the naris with the handle parallel to the floor and slowly open the blades in the superior-to-inferior direction. Stabilize your hand on the patient's nose to prevent damage to the mucosa due to unexpected movement (Fig. 65-34).

When attempting to visualize the nasal passageway, remember to have the patient keep the floor of the nose parallel to the ground. Tilting of the head only allows for a view of the anterosuperior area (Fig. 65-35). A nasopharyngoscope may be used to view the nasal passageway as well, and its use is described in the previous section on examination of the pharynx.

Epistaxis

Nasal hemorrhage commonly presents to the ED. Identification of the source of bleeding and subsequent control are paramount to the treatment of epistaxis. Although this can be frightening to both clinician and patient, a systematic approach with the proper equipment will lessen the anxiety of the situation. The purpose of the procedure is to tamponade the bleeding. If the source is anterior, this may be the final treatment. For posterior bleeds, these are generally temporizing maneuvers until a consultant can complete a definitive hemostatic procedure. The procedures can be performed in the ED with proper lighting and the equipment listed later in this section. Controlling epistaxis may be a time-consuming process without proper equipment or patient cooperation.

In preparation for any procedure to treat epistaxis, evaluate the patient's hemodynamic status by assessing vital signs and orthostatic symptoms and quantifying blood loss. Also determine if the patient has any underlying medical problem, such as angina or chronic obstructive lung disease, which may be exacerbated due to hypovolemia or anemia. If the patient is symptomatic in any of these areas, or if the blood loss is deemed significant, start a large-bore IV line and administer fluid boluses. Hematologic testing is rarely useful and not required for most patients, but if there are extenuating circumstances, obtain a complete blood count

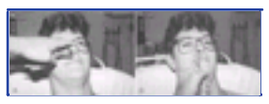

Figure 65-34 To examine a nose properly, a nasal speculum must be used. *A,* The clinician's index finger rests on the bridge of the nose, and the speculum is spread in an inferior-to-superior direction. *B,* It is *incorrect* to spread the speculum laterally or to use the instrument in an unsupported manner.

and consider a type and screen. Coagulation studies are not routinely indicated but should be undertaken in patients taking anticoagulant therapy, those with underlying hematologic abnormalities, or those with recurrent or prolonged epistaxis. [43]

Many patients with epistaxis are hypertensive as well. No direct correlation has been proven between hypertension and epistaxis. Most authors now consider hypertension to be a stress response instead of an inciting event. [44] Therefore, hypertension does not require treatment until the bleeding is controlled and the anxiety of the situation has resolved. However, any patient exhibiting other signs of a hypertensive emergency needs immediate treatment in addition to control of the epistaxis.

Indications/Contraindications

Any continuing episode of epistaxis can be treated with the following techniques. Massive facial trauma with the possibility of a basilar skull fracture would preclude the use of an intranasal balloon, as it may travel into the skull cavity.

Equipment

The key to successful management of a patient with epistaxis is preparedness. The following list of equipment should be readily available to the emergency clinician.

- Chair with headrest or gurney with inclinable back
- Headlight with light source, head mirror
- Wall suction with multiple suction catheters
- Gloves, mask, and gown for clinician
- Gown or drapes for patient
- Topical anesthetic
- Topical vasoconstrictor
- Nasal speculum
- Tongue depressors
- Small red rubber catheters
- Bayonet forceps
- Scissors
- Kidney basin
- Gauze (4 × 4 in., 2 × 2 in.)
- Dental rolls or cotton
- No. 2 surgical silk ties

- 1.2-cm wide Vaseline gauze or 0.5-in. wide Nu-Gauze packing
- Antibiotic ointment
- Silver nitrate sticks or electrocautery
- Pediatric Foley catheters (12 Fr)
- Nasal tampons
- Dual balloon pack

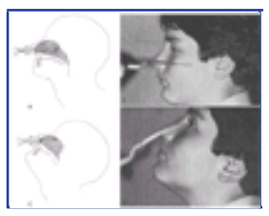

Figure 65-35 *A* and *B,* Correct position for examining and treating diseases of the nasal cavity. The patient is in the "sniffing" position, sitting upright or leaning slightly forward with the head only slightly extended. When the nasal tip is raised with the nasal speculum, the view is parallel to the floor of the nose and allows visualization of the entire nasal cavity. *C* and *D,* When told that their nose will be examined, most patients extend the neck and look toward the ceiling. In this position, only the most anterior portions of the nasal cavity are visible.

Epistaxis Examination

As most patients are frightened by continued epistaxis, reassure the patient that you will control the bleeding. Drape the patient with a gown to protect his or her clothing from the bleeding. Have the patient hold an emesis basin to collect any continued bleeding and as a precaution to emesis of swallowed blood. Minor anterior bleeds are usually easily controlled with minimal techniques, patients with significant epistaxis can be quite anxious, and manipulation of the nose can be quite painful. Therefore, parenteral sedation/analgesia with appropriate physiologic monitoring should be considered when extensive manipulation is anticipated.

Have the patient sit upright in the "sniffing" position with the neck flexed and head extended. The base of the nose should remain parallel with the floor. Position yourself in front of the patient, level with the patient's nose after putting on a face shield, gown, and protective gloves. Allow the patient to clear the nose of any blood clots by forceful blowing or, alternatively, you may suction the passageway until it is free of clots. Suctioning should be done from front to back along the nasal septum, then laterally. If the bleeding is minimal, attempt to identify the bleeding source. If the bleeding is too profuse for visualization, administer a topical anesthetic and vasoconstrictor. The easiest way to apply the preparations is to simply soak a cotton pledget in the solution and place it in the nose for 4 to 5 minutes. The patient can clamp the nostrils to limit bleeding and promote contact with the mucosa. Numerous preparations are available. A 4% cocaine solution would be ideal, but it is not commonly stocked. The 1% to 2% lidocaine used for laceration repair does little to provide topical anesthesia or vasoconstriction. A solution of 1% tetracaine and 0.05% oxymetazoline (Afrin) is an effective

Figure 65-36 If an arterial bleeding site is found in the nasal septum, both hemostasis and anesthesia for cautery can be accomplished by injecting the mucosa at the base of the bleeder with a small amount of lidocaine with epinephrine via a tuberculin or insulin syringe. This procedure best follows an initial application of topical anesthesia.

topical anesthetic and vasoconstrictor.[45] If a discrete bleeding site is initially identified, an effective way to provide hemostasis and anesthesia before cautery is to inject the mucosa at the base of the bleeder with 2% lidocaine with 1:100,000 epinephrine via a tuberculin syringe (Fig. 65-36).

Insert the nasal speculum into the naris and use the suction catheter to evacuate any blood. Do not hesitate to reapply anesthetic or vasoconstrictor if the desired results have not been achieved. As most cases of anterior epistaxis occur in Kiesselbach plexus, inspect this area closely for areas of bleeding, ulceration, or erosion. If the patient presents with a history of epistaxis but is no longer bleeding, gentle stroking of the anterior nasal mucosa with a cotton swab or having the patient forcefully blow the nose may reveal the bleeding source. If no source is found and the bleeding has ceased, pack the nose only if the epistaxis is recurrent. If no anterior source is found and bleeding continues down the posterior pharynx, assume a posterior source and pack the nose with an anterior and posterior pack.

Figure 65-37 Equipment used for treatment of epistaxis. *Top:* Electrocautery device and silver nitrate sticks. Left to right, bottom row: Merocel nasal tampon, posterior packing ball, Merocel nasal tampon with catheter included (Doyle Pack), anterior packing gauze with bayonet forceps, Foley catheter, Epistat dual balloon catheter.

Cautery

After identifying an anterior source of bleeding, there are several options to obtain hemostasis (Fig. 65-37). *Silver nitrate sticks* may be used to cauterize the area. Remember that silver nitrate sticks will not cauterize an actively bleeding source; therefore, hemostasis must be achieved first. If a bleeding site is seen, hold the silver nitrate stick tip gently against the site for 4 to 5 seconds. If needed, a second application can be applied. If the bleeding site is not seen, but a blood vessel is identified, the lightly moistened cautery stick can be gently stroked along the vessel until the desired burn depth is achieved. Wipe away any excess silver nitrate to prevent inadvertent cautery of other areas of the nose. If this restarts the bleeding, the initial cautery was insufficient. *Electrocautery* will work in the same manner, but the cauterization will penetrate more quickly than the silver nitrate sticks. In either cautery technique, care must be taken to prevent inadvertent septal perforation due to overaggressive or repeated cautery. If cautery has not been successful after two attempts (either twice at the first visit or on the second visit), another technique is indicated. *Multiple cautery attempts can significantly injure the nasal septum, and bilateral cautery should not be performed.* Cautery works well for a small, circumscribed area of bleeding.

If this is the initial bleed and hemostasis is achieved, no packing is necessary. If this is a recurrent bleed within 72 hours of another, or if cautery does not provide hemostasis, the anterior cavity should be packed. If hemostasis is accomplished, apply Vaseline or antibiotic ointment to the area to prevent desiccation. Do not administer aspirin or nonsteroidal anti-inflammatory drugs for 4 days after epistaxis. If bleeding recurs at home, instruct the patient to pinch the nostrils closed for 20 minutes. Instruct the patient to return to the ED if this maneuver is unsuccessful or the bleeding is profuse.

Anterior Nasal Packing

Anterior gauze packing is placed to complete hemostasis, prevent desiccation, and protect the area from trauma. However, improperly placed packing may further abrade the area, dislodge prematurely, or migrate into the posterior pharynx. Anterior packing must be placed with adequate analgesia,

proper visualization, and deliberate movements. Traditional petrolatum gauze packing is applied in an "accordion" fashion so that each layer extends the entire length of the nasal cavity. However, this type of packing has been almost entirely replaced with specialized compression devices that are easier to place, better tolerated, and very successful.

Coating any packing material with antibiotic ointment aids in its placement and theoretically prevents infection and toxic shock syndrome secondary to nasal packing. Proper placement of the speculum allows visualization of the floor of the nasal cavity. Lay a strip of 1.2-cm (0.25- or 0.5-in. Nu-Gauze) gauze across the nasal floor, with the starting end of the gauze at the naris (Fig. 65-38). Replace the speculum over the layer of gauze, gently packing it to the floor of the nose. Measure the gauze to twice the length of the nasal cavity. Grasp the gauze at the midpoint and insert this point to the posterior aspect of the nasal cavity. This allows placement of the gauze without movement of the underlying layer. Continue this pattern, replacing the speculum after each layer until the cavity is filled.

Preformed nasal packing products are convenient alternatives to anterior nasal packing (e.g., Merocel *nasal tampon*

Figure 65-38 The key to placement of an anterior nasal pack that will control epistaxis adequately and stay in place is to lay the packing into the nasal cavity in an "accordion" manner, so that part of each layer of packing lies anteriorly, preventing the gauze from falling posteriorly into the nasopharynx. *A,* The first layer of 0.25-in. Vaseline gauze strip is grasped approximately 2 to 3 cm from its end. *B,* The first layer is then placed on the floor of the nose through the nasal speculum (not pictured here). The bayonet forceps and nasal speculum are then withdrawn. *C,* The nasal speculum is reintroduced on top of the first layer of packing, and a second layer is placed in an identical manner. After several layers have been placed, it is often useful to reintroduce the bayonet forceps to push the previously placed packing down onto the floor of the nose, making it tighter and more secure. *D,* A complete anterior nasal pack can tamponade a bleeding point anywhere in the anterior nasal cavity and will stay in place until removed by the clinician or patient.

or Epistat II nasal catheter [Xomed Surgical Products, Jacksonville, FL]) (Fig. 65-39*A* and *B*). The Merocel packing consists of compressed polyvinyl acetate with or without a drawstring that expands on contact with fluid. The pack can be trimmed with scissors or a scalpel before insertion. The Merocel Doyle nasal pack (see Fig. 65-37) has an airway tube in the center of the compressed material and is a more anatomic shape. Each are available in various sizes, but usually an 8 × 1.5 × 2-cm standard Merocel or 8 × 1.5 × 3-cm Doyle will suffice. The Rapid Rhino Stat Pac (Applied Therapeutics, Tampa, FL, rapidrhino.com) is a high-volume, low-pressure balloon device with an open lumen air passage, a pilot cuff to check pressure, and a gel knit covering designed to promote platelet aggregation. Numerous variations for anterior, posterior, and combination packs are available (Fig. 65-40).

The easily applied nasal tampon is a reasonable first choice for most anterior bleeds. The tampon is lubricated with antibiotic ointment and inserted into the nasal cavity with a bayonet forceps. The insertion may be painful so a rapid single motion is suggested. Generous ointment and careful trimming can minimize the trauma of insertion. The packing is

Figure 65-39 Nasal packing alternatives. *A,* Merocel nasal pack. (1) Merocel sponge compressed and expanded. To insert the sponge packing, lubricate the device with an antibiotic ointment and place it in the nasal cavity. (2) Some trimming of the product may be needed and prior use of topical anesthesia is advised. When the sponge is in place, hydrate it with saline. Expansion of the moist sponge will compress the bleeding site. (3) It may remain in place for up to 3 days. Rehydrate the sponge before removal. *B,* Epistat II nasal catheter. The catheter is usually left in place up to 3 days and can be used in outpatients. A hollow inner airway tube allows the patient to breathe.

advanced along the floor of the nose. Once the packing is in the nasal cavity, it is expanded with 5 to 10 mL of saline, although, oftentimes, contact with moisture will cause it to swell (Fig. 65-41). It is sometimes necessary to place two tampons side by side before inserting them, to fill the nasal cavity. [44] [46] Advantages to the Merocel tampon include rapid insertion, little discomfort, ease of use even in inexperienced hands, and possible inhibition of bacterial growth. [47] Corbridge[48] found that there was no significant difference in efficacy, patient tolerance, or complications when compared to gauze packing.

Anterior packs are usually left in for 2 to 5 days. Premature removal may result in rebleeding. During use and before removal, the commercial nasal tampon should be hydrated with saline. If it contains an airway tube, first remove the tube, then irrigate the space once occupied by the tube.

Complications

Any packing in the anterior nasal cavity may obstruct drainage of the paranasal sinuses or block the nasolacrimal ducts. In addition, because it is a FB, it will stimulate mucus production and act as an impetus for infection. Antibiotics (amoxicillin, trimethoprim/sulfamethoxazole, and others) are often prescribed with any packing left in the nose after emergency treatment because of the risk of sinusitis and toxic shock syndrome. The necessity of antibiotics for short-term anterior packing is unproven. Decongestants are also often concomitantly prescribed to decrease secretions. Practices vary and no common standard exists. Hollis [47] reported massive pneumocephalus following Merocel nasal tampon insertion in an elderly woman, presumably from fracture of the ethmoid plate. There have been case reports of ethmoid

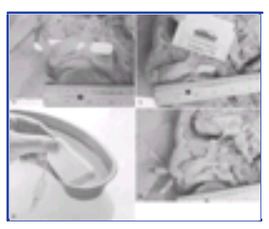

Figure 65-40 Examples of various packs for epistaxis in a cadaver model. *A*, The posterior Merocel sponge, not inflated, will stop most nosebleeds and is more comfortable than some balloon devices. *B*, Wetting the Rapid Rhino before placement activates the slippery covering for easier insertion. *C*, Anterior/posterior Rapid Rhino in place. *D*, Posterior pack with balloon inflated.

fracture following anterior nasal gauze packing and with the use of an intranasal balloon.

Posterior Nasal Gauze Packing

The patient has posterior epistaxis if no source of bleeding is found anteriorly and the patient continues to hemorrhage down the posterior pharynx. Posterior epistaxis may respond to topical vasoconstrictors. However, anterior nasal packing will not provide hemostasis for a posterior bleed, as it will not cover the source of bleeding. A posterior pack directly compresses the sphenopalatine artery and prevents the passage of blood or anterior packing into the nasopharynx.

The *posterior nasal gauze pack* is the classic method of treating posterior epistaxis. However, because balloon devices are easier to use and are less distressing to the patient, posterior nasal packing is less commonly used. To place a posterior nasal gauze pack, anesthetize the patient's nares and posterior pharynx with topical anesthetic. Prepare a roll of gauze with two No. 2 silk ties secured around the middle and extending in opposite directions. One set of ends will be used to place the posterior pack and the second will remain extruding from the oral cavity to remove the pack. Place a No. 10 red rubber catheter through the bleeding nostril (Fig. 65-42 Fig. 65-42). When it is seen in the posterior pharynx, grasp it with forceps, and guide it out of the mouth. Attach it to one set of ends of the silk ties secured to the gauze pack. Retract the red rubber catheter, thus carrying the No. 2 silk tie through the nasopharynx and out of the nose. Grasp the suture and pull the pack into the nasopharynx. Guide the pack swiftly into the oral cavity and nasopharynx with the other hand. Attach the silk tie that remains in the oropharynx to the patient's cheek to aid in removal or rescue of the posterior pack. Use the silk ties exiting the nostril to maintain the position of the posterior pack. Pack the anterior passage as described for anterior epistaxis. Secure the silk ties over a gauze pad or dental roll. Patients with this type of posterior pack are admitted to the hospital.

Inflatable Balloon Packs

Inflatable balloons come in two varieties. The *Foley catheter* is often used as a posterior pack because of its availability,

Figure 65-41 An expanding Merocel tampon is ideal for minor anterior bleeds. The dehydrated pack is trimmed to fit the nose and generously lubricated with antibiotic ointment. A swift single motion is used to insert the pack to its full length. The pack expands when hydrated with saline. The patient continues to keep the pack moist at home and it is again well hydrated just before removal.

ease of use, and successful tamponading effect.[49] Insert a 12 Fr Foley catheter through the bleeding naris into the posterior pharynx (Fig. 65-43). Inflate the balloon halfway with about 5 to 7 mL of normal saline or water. Slowly pull the Foley into the posterior nasopharynx and secure it against the posterior aspect of the middle turbinate. Finish inflating the balloon with another 5 to 7 mL of normal saline or water. If there is pain or inferior displacement of the soft palate, deflate the balloon until the pain resolves. Complete inflation of the balloon before proper placement causes the balloon to remain too posterior in the nasopharynx, thus failing to achieve hemostasis.[50] While maintaining constant gentle anterior tension on the Foley catheter, an anterior nasal packing is placed using layered petroleum-impregnated gauze. The opposite nasal cavity is packed to counteract septal deviation. Then, place a short section of plastic tubing over the catheter and secure it with a nasogastric tube clamp or umbilical clamp. Be careful not to exert undue pressure on the nasal alar, as this may cause necrosis.

The second type of inflatable balloon pack is the premade *dual balloon tamponading system*. Goitschach Nasostat (Sparta Surgical Corp, Hayward, CA) and Xomed Epistat (Xomed Inc, Jacksonville, FL) are examples of available devices. The *dual balloon pack* has a posterior balloon that inflates with about 10 mL of air and an anterior balloon that inflates with about 30 mL of air (Fig. 65-44). Each device may vary slightly (Fig. 65-45). After appropriately anesthetizing the naris, place the lubricated pack along the floor of the affected naris as far back as possible. Inflate the posterior balloon about halfway with air and then pull the balloon into place up against the posterior aspect of the middle turbinate. Complete the inflation of the posterior balloon with air. Some clinicians prefer to inflate all balloons with saline instead of air since air may deflate slowly. If the patient complains of pain or if the posterior soft palate deviates downward, deflate the balloon until the symptoms are relieved. Maintain the position of the balloon and inflate the anterior balloon with up to 30 mL of air. Again, halt the inflation if the patient experiences increasing pain or deviation of the nasal septum. Some authors suggest packing the opposite naris to prevent this lateral deviation. A small piece of gauze is placed between the nose and external catheter hub to decrease skin irritation.

Other Techniques

ENT consultation may be required for posterior nosebleeds that do not respond to the previously described posterior packing techniques. Other treatment options include ligation or embolization of the internal maxillary artery and posterior endoscopic cautery.

Complications

Care of the posterior nasal packing is of some concern. Posterior nasal packing is uncomfortable and often painful. These bleeds are more complicated than simple anterior septal bleeds. Complications associated with posterior packing include infection, dysphagia, eustachian tube dysfunction, tissue necrosis, and dislodgment. Other serious complications associated with posterior packing are hypoxia, hypercarbia, aspiration, hypertension, bradycardia, arrhythmias, myocardial infarction, and death. [51] Therefore, most patients, with a posterior pack, especially the elderly and those with pulmonary and cardiovascular diseases, should be admitted to the hospital for sedation and monitoring. This recommendation was common for formal posterior packs, but the ease and safety of the balloon devices now allow select patients to be treated as outpatients despite the presence of posterior packing. Rebleeding may also be seen with early pack removal; one series found pack removal within 48 hours to increase the risk of rebleeding. [52] Most posterior packs are left in place 72 to 96 hours.

Infection risk with posterior packing includes toxic shock syndrome, nasopharyngitis, and sinusitis. The packing blocks the sinus ostia, preventing proper drainage of the sinuses. In addition to coating the packing with antibiotic ointment, broad-spectrum antibiotics should be administered. *Dysphagia* due to the packing can lead to poor oral intake, and IV fluid hydration may be required.

A significant decrease in PaO_2 (7.5 to 11 torr) and increase in $PaCO_2$ (7 to 13 torr) is seen in patients with nasal packing who are treated with sedation. [53] A posterior pack will cause vagal stimulation, resulting in varying degrees of bradycardia and bronchoconstriction. This physiologic adaptation is even more worrisome in patients with underlying lung or heart disease. With the risk of *hypercarbia* and *hypoxia*, patients with lung disease with posterior nasal packs should be closely monitored in an intensive care setting.

Tissue necrosis of the nasal ala, nasal mucosa, and soft palate has been described secondary to improper placement or padding. Protecting the skin with gauze placed under the device will reduce skin maceration. The risk of necrosis increases with the duration of the packing, so all packing should be removed in 3 to 5 days. Bleeding from the nasolacrimal duct is a common benign problem with nasal packing (Fig. 65-44*D*)

If the *posterior pack becomes dislodged*, it will fall into the oropharynx with the risk of asphyxiation, vomiting, and aspiration. The patient and nursing personnel need to be familiar with the technique for removing the pack. To accomplish this, cut the anterior sutures that exit the naris from the gauze roll if they have not already broken. Grasp the sutures exiting the mouth and guide the packing out of the nasopharynx. It may be necessary to manually extract the packing with forceps or digits.

Figure 65-42a Posterior nasal pack. *A,* Following topical anesthesia, a red rubber catheter is passed through the nose and carefully grasped in the oropharynx with ringed forceps and brought out through the mouth. *B (upper right),* A posterior nasal pack made by wrapping a cotton ball in a 4 × 4-in. gauze pad and tying 2 long silk sutures or umbilical tapes around the neck of the pack. One tie must be left long so that it can be taped to the cheek until needed for removal of the pack. *C (*center), Alternatively, a gauze pad can be folded and rolled into a cylinder and tied with two strings. Two of the long strings are used to tie the pack to the tip of the catheter and the other two will be used to remove the pack. *D,* As an option, a second catheter, which has been passed through the nonbleeding side and brought out the mouth, can be used to retract the palate forward to aid in the placement of the pack (not shown). The optional "retraction" catheter is removed after the pack is in the proper position.

Figure 65-42b *E,* The pack is digitally guided into the nasopharynx. *F,* A gauze roll secures the pack to the nose and the rescue ties are taped to the cheek.

Toxic shock syndrome has been rarely described with nasal packing. [46] [54] The syndrome is caused by a toxin released by *Staphylococcus aureus* infection of the packing. Sudden onset of vomiting and diarrhea with high fever, as well as development of an erythrodermic rash, heralds the onset of the disease. Untreated, the disease can advance into shock and multi-system organ dysfunction. Therefore, in addition to coating the gauze with antibiotics to decrease the local bacterial concentration, broad-spectrum antibiotics should be given to any patient with nasal packing. No single antibiotic has been traditionally recommended, but a cephalosporin (such as cephalothin), ampicillin/sulbactrim (Unasyn), or ampicillin/clavulanate (Augmentin) appear reasonable. Any symptoms of toxic shock syndrome

should prompt the removal of the packing and admission to the hospital for fluid hydration and IV nafcillin or vancomycin therapy.

Figure 65-43 Foley catheter placed into the nasopharynx, inflated with water, and retracted into position. The distal tip of the catheter has been cut off. An anterior pack (not shown) is then placed around the catheter. The ala and columella are protected with gauze padding, and a plastic umbilical clamp or nasogastric clamp is applied to the catheter to maintain slight tension on the balloon.

Septal Hematoma

Trauma to the anterior portion of the nasal septum may cause a hematoma to form. A buckling stress tears the submucosal blood vessels. If the mucosa remains intact, the blood will accumulate between the mucoperichondrium and the septal cartilage. Stagnant blood is an excellent medium for growing bacteria and forming an abscess. Common bacteria include Staphylococcus aureus, Streptococcus pneumoniae, and Group A ß-hemoltyic streptococcus. Other complications of an untreated hematoma include septal perforation and cartilage destruction, with resultant saddle-nose deformity. Septal hematomas may present immediately following the trauma or, more commonly, may occur in the first 24 to 72 hours following the injury.[55] Septal abscess formation may occur in a matter of days and significant destruction of the nasal cartilage and a cosmetic deformity may be seen.

It is usually possible to diagnose a septal hematoma by inspecting the nasal septum *with a speculum* for swelling, pain, and a fluctuant area. The presence of septal asymmetry with a bluish or reddish hue of the mucosa is suggestive of a septal hematoma. Direct palpation may be necessary, as newly formed hematomas may not yet be ecchymotic. Inspect both sides, as bilateral hematomas are possible. The best way to palpate for a septal hematoma is to insert the gloved small fingers in each side of the nose and palpate the entire septum, feeling for swelling, fluctuance, or widening of the septal space (Fig. 65-46). Most common symptoms of a septal hematoma are nasal obstruction, pain, rhinorrhea, and fever. Most patients will complain of inability to breathe through the affected side, but the absence of nasal obstruction does not rule out a septal hematoma.

Drainage

Treatment of a septal hematoma consists of evacuation of the clot with subsequent reapproximation of the perichondrium to the cartilage. To drain the hematoma, *incise* the mucosa horizontally over the hematoma after adequate anesthesia is achieved (Fig. 65-47). Suction out all of the clot and then irrigate with normal saline. Excise a small amount of mucosa to prevent premature closure of the incision and place a section

Figure 65-44 *A* and *B,* The balloon tamponade device serves as both an anterior and a posterior pack. It is easily inserted and is often successful for the temporary control of posterior epistaxis in the emergency department. *C,* Although often effective for hemorrhage control, balloon inflation within the nasal cavity can be quite painful and prolonged pressure on the nasal alae can produce tissue injury. Gauze should be placed between the external balloon and the skin of the nose. *(Courtesy of Xomed Inc, Jacksonville, FL) D*, Although alarming to the patient, blood in the eye from back bleeding via the nasolacrimal duct from a balloon pack is benign.

of a sterile rubber band to act as a drain. The nostril should then be packed, as in anterior epistaxis, to reapproximate the perichondrium to the cartilage.

Give the patient broad-spectrum antibiotic therapy. Inspect the septum daily for signs of infection, recurrent hematoma, or necrosis. Recurrent hematomas should be evacuated. When there is no further hematoma for a 24-hour period, remove the drain. Pack the affected naris for 1 more day to complete the apposition of the perichondrium to cartilage where the drain has been. Any evidence of infection should prompt admission for IV antibiotics and surgical debridement.

Nasal Fracture

Nasal fracture is the most common facial fracture. Nasal fractures present with symptoms ranging from mild swelling to epistaxis to periorbital ecchymosis with obvious deformity. As with any trauma to the head, the patient must be evaluated for coexistent intracranial injury or neck injury. In the evaluation of nasal trauma, rule out the existence of a septal hematoma or cerebrospinal fluid rhinorrhea. In most cases, swelling and soft tissue deformity prevent adequate evaluation or treatment, or both. Evaluation of the patient with a suspected nasal fracture should include a thorough history, external nasal examination, and internal nasal examination using a nasal speculum with or without the use of a rigid nasal endoscope. Nasal radiographs are not routinely recommended, as they will not alter the course of treatment or injury.[56] [57] [58] Have the patient apply ice to the area and keep the head elevated to treat the soft tissue swelling. Refer the patient to an otolaryngologist or plastic surgeon for reexamination and definitive treatment in 3 to 5 days. Stress to the patient the importance of being evaluated again within 10 days so that the bones do not set in a malaligned state.

Nasal Fracture Reduction

Simple fractures with minimal local swelling can be treated with closed reduction. To minimize potential litigation, obtain written consent and take prereduction and postreduction photographs. Inform the patient that the outcome is not guaranteed, as impacted fractures may not reduce and greenstick fractures may deform again after reduction. Any swelling may obscure the extent of the deformity or the degree of reduction.

Anesthetize the mucosa as described earlier (see Fig. 65-32 and Fig. 65-33). Topical anesthetic (cocaine 4% to 10%) is usually adequate; however, infiltration with 1% lidocaine without epinephrine may be used adjunctively. For infiltrative anesthesia, inject the lidocaine either deep to the nasal fracture by entering intranasally or externally into the fracture site for a hematoma block. The latter approach may be quite uncomfortable for the patient. In the external technique, the needle enters bilaterally at the caudal edge of the nasal bone, midway between the nasal bridge and the maxilla. Bilateral infraorbital blocks may also be used. Intravenous sedation may be required. There is debate in the literature as to which method provides adequate anesthesia with minimal patient discomfort. [58] [59]

Use Asch forceps, Walsham forceps, or a scalpel handle to advance into the naris with the dominant hand (Fig. 65-48). Apply pressure in an anterosuperior direction at a right angle to the ridge of the nasal bone. The other hand manipulates the nasal fracture in an anteroinferior direction. Firm, constant

Figure 65-45 Xomed Rhinology Products. *A,* Xomed Epistat nasal catheter. *B,* Pope Flex-Pak nasal packing (shown expanded and compressed). *C,* Xomed Epistat II nasal catheter. *D,* Staxi-Stat pack without drawstring. *E,* Large Fast-Pak nasal pack with applicator. *F,* Weimert epistaxis packing. *G,* Small Fast-Pak nasal pack with applicator.

pressure is maintained until the bone shifts back into its original position. Alternatively, a Boies elevator may be used to lessen the risk of nasal mucosa damage.

Care must be taken not to perforate the cribiform plate when using these surgical instruments. Assess the reduction for malalignment or subsequent displacement secondary to a greenstick fracture. If either occurs, refer the patient to an otolaryngologist for the possibility of open reduction.

Exterior splint dressings can be applied to maintain reduction. Some authors believe this will mask an incomplete reduction or adversely manipulate the reduction during placement. Remove the splint in 7 to 14 days.[60] As in most closed fractures, antibiotics are not indicated. Epistaxis or direct evidence of an open fracture should prompt referral to an otolaryngologist and initiation of broad-spectrum antibiotics.

Figure 65-46 If visual inspection of the nose with a speculum does not rule out a septal hematoma, the clinician's gloved fingers, passed posteriorly along both sides of the septum, may reveal bulging or fluctuance.

Nasal Foreign Bodies

Nasal FBs frequently present in the pediatric patient, but it is not uncommon to find them in psychiatric or mentally retarded populations as well. Usually a family member has witnessed the event or the patient actually complains of

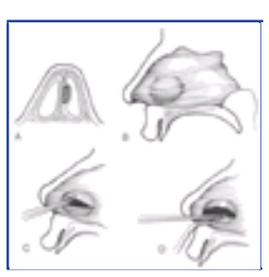

Figure 65-47 *A*, A small left-sided septal hematoma. *B*, After applying appropriate topical anesthesia, supplemented with local infiltration, if necessary, a *horizontal* incision is made through the mucosa and the perichondrium covering the hematoma. *C,* A small cup forceps or scissors is used to remove enough mucosa to prevent premature closure of the wound and reaccumulation of hematoma. *D,* A sterile rubber band is then placed as a drain, and the naris is packed.

Figure 65-48 Reduction of a depressed and dislocated nasal bone fracture. This reduction is accomplished in two steps following anesthesia by first elevating the depressed nasal bone as illustrated and then manually displacing the pyramid to the midline. The handle of a scalpel may be used if an elevator is unavailable. *(From Adams GL, Boies LR Jr, Hilger PA (eds): Boies Fundamentals of Otolaryngology, 6th ed. Philadelphia, WB Saunders, 1989.)*

discomfort from the FB. However, the lack of a history of FB insertion is of little value as most children will not admit to doing it. Therefore, emergency clinicians need to maintain a high level of suspicion for nasal FB, especially in patients who present with unilateral purulent nasal discharge (which may be bloody), unilateral sinusitis, or recurrent unilateral epistaxis. Retained FBs, especially plastic ones, can often initially fail to cause pain or other symptoms. [61] [62]

Types of nasal FBs vary widely and often include food (e.g., meat, nuts, beans), rubber erasers, paper wads, pebbles, marbles, sponges, beads, jewelry, hardware (e.g., nuts, screws), and even certain living larvae or worms.[62] Alkaline button batteries pose a unique problem because they may cause significant nasal injury within hours to days. They are composed of heavy metals like mercury, zinc, silver, nickel, cadmium, and lithium. Injuries reported include mucosal burns, ulcerations, liquefaction necrosis, and even septal perforation, synechiae, and stenosis of the nasal cavity. [62] [63] [64] It is imperative to remove these batteries promptly before tissue damage occurs from leakage of battery contents, electrical currents, or direct pressure. A relatively new and interesting nasal FB is the magnetic nose ring. These are small, commercially available earth magnets usually worn on either side of the alar cartilage, giving the appearance of a pierced nasal stud. The magnets can displace and become polarized across the nasal septum. The magnetic attraction can be quite strong and can lead to pressure necrosis of the nasal mucosa and possible septal perforation. This attraction can also make removal difficult as well as painful for the patient. [65] [66]

Nasal FBs often come to rest on the floor of the anterior or middle third of the nose. Metallic or calcified objects may show up on x-ray, but physical examination remains the most reliable means for diagnosis. Maxillary, ethmoid, or sphenoid sinusitis may also accompany FB retention. Plain radiographs or facial computed tomographic scanning may be of value in detecting sinusitis, although these studies are usually not necessary in the acutely retained object.

Failure to remove nasal FBs results in admission for removal under anesthesia; therefore, it behooves emergency medicine clinicians to be skilled in this procedure. Admission incurs increased cost, inherent procedural risks, and psychological stressors for parents and patients. Like the removal of auricular FBs, the removal of nasal FBs can be both frustrating and time consuming.

Nasal Foreign Body Removal

A cooperative patient is essential; therefore, young children often require general anesthesia for more posterior FBs. While conscious sedation may aid in removal and preclude the need for admission and general anesthesia, the possible increase in aspiration risk must be considered with use of agents that blunt protective airway reflexes. Before attempting removal, anesthetize and vasoconstrict the affected naris, as previously described in the chapter. Obtain assistance to stabilize the patient's head, and immobilize younger patients as required. The more cooperative patients should be placed in the "sniffing" position, and a head lamp should be used for proper illumination. Several of the techniques previously mentioned for EAC FB removal, including the use of cyanoacrylate glue, can be used in the management of a nasal FB.

Use *alligator forceps* or *bayonet forceps* to retrieve more anteriorly lodged FBs with edges that are amenable to grasping. For hard, larger objects, *wire loops, right-angle hooks,* or even a properly bent *paper clip* may be carefully passed beyond the object and rotated, allowing it to be pulled from the naris (see Fig. 65-22). Direct mucosal trauma and epistaxis may occur with any of these methods. FBs with smooth, rounded edges that are difficult to grasp or to pass instruments around may be extracted with a *suction-tip catheter* in a similar manner as that described earlier for EAC FBs. The Hognose catheter described earlier also works well for nasal FBs.

Objects that cannot be removed with anterior instrumentation may be removed with *balloon catheters*. Several case series[67] [68] have depicted Fogarty catheters as being highly effective in removing nasal FBs (Fig. 65-49). A No. 4 or 5 vascular Fogarty catheter, a 12 Fr Foley catheter, and a No. 6 biliary Fogarty catheter have all been described in the literature for this use. The biliary catheter reportedly is less apt to rupture. The patient lies supine after proper vasoconstriction and anesthesia of the affected naris. With a 5-mL syringe attached, and the catheter lubricated with lidocaine gel, the tip is passed above the object and into the nasopharynx. The balloon is then inflated with air or water (approximately 2 mL in small children and 3 mL in older children) with the thumb controlling the syringe plunger and, thus, balloon size. The catheter is slowly withdrawn until resistance is felt, and then the object is removed. The Katz Extractor oto-rhino FB remover (InHealth Technologies, CA) (Fig. 65-50) is a disposable, single unit, composed of a syringe with attached flexible catheter with balloon tip. The procedure for its use is similar to that of a Fogarty catheter. Complications mentioned in the literature are limited to occasional mild posttraumatic bleeding only, but the theoretical risk of airway obstruction by the balloon or aspiration from further displacement of the object should be considered.

A newly reported yet controversial method is the nasal wash technique. [69] [70] In this method, a bulb syringe filled with approximately 7 mL of sterile normal saline is

placed in the opposite nostril from the one that contains the FB. The bulb is forcibly squeezed and the object is expelled through the

Figure 65-49 *A* and *B,* Fogarty balloon extraction of nasal foreign body. Insert the lubricated catheter tip above the foreign body, then gradually inflate the balloon. Slowly withdraw until resistance is met, then pull the object out of the naris.

nostril containing the object by the flow of saline. This technique may be difficult in uncooperative, younger patients. There is risk of injury to the nasal mucosa from the syringe tip and the flow of saline into the nasopharynx may cause coughing, choking, and discomfort. Other complications include reflux of saline and nasal contents into the eustachian tubes and FB aspiration. Because this technique has not been extensively studied, manual removal of the FB under direct visualization is still the preferred method.

Figure 65-50 The Katz Extractor (InHealth Technologies, Carpinteria, CA) for oto-rhino foreign body removal shown with balloon inflated.

Another approach to the posteriorly placed nasal FB is blowing the object out with *positive air pressure*. The simplest way is to ask the child to blow his or her nose while occluding the unaffected nostril. This is really only effective in the older child. Alternatively, a bag-valve mask [71] can be placed over the child's *mouth* to provide the positive pressure. The opposite nostril should be occluded and the Sellick maneuver applied to prevent air passage into the esophagus. This technique often requires restraint and can also be threatening to a young child. Another technique [72] [73] requiring no instrumentation is performed by having the child lie supine and occluding the unaffected nostril (Fig. 65-51). The patient then exhales air until resistance (from the patient's epiglottis shutting) is felt. Next, as in mouth-to-mouth resuscitation, air is briskly blown into the mouth which produces an outward pressure behind the object. This either moves it within grasping reach or pops it completely out of the naris, usually onto the clinician's cheek. Once again, this can be a frightening experience for the child, it requires restraint, and there is a theoretical risk of disease transmission. An effective compromise is using "a parent's kiss." In this technique, the child is allowed to sit or stand and no restraint is required. The parent is asked to make a firm seal with his or her mouth over the child's open mouth and then to give a short, sharp puff of air into the child's mouth. The opposite nostril is occluded throughout the procedure. To gain the child's cooperation, tell them that the parent is going to "give them a big kiss." If it fails, the technique can be repeated. A study of the "parent's kiss" by Botma et al. [74] found a success rate of 79%, and all parents thought the technique was acceptable and preferable

Figure 65-51 Bag-valve-mask technique to blow foreign body out of the naris. Ensure that the face mask forms a tight seal around the patient's mouth and that the unaffected nostril is completely occluded. Attempt to firmly compress the bag as the patient exhales (an assistant is helpful to hold the mask snugly and to occlude the other nostril). This technique works best with objects that completely occlude the nostril.

to instrumentation or restraint. Although theoretical complications include possible barotrauma to the tympanic membrane or other complications seen with positive-pressure ventilation (pneumothorax, mediastinal emphysema), no reported complications have been published in regard to these three positive-pressure techniques.

CONCLUSION

A number of procedures are relevant to the examination of the ears, nose, and throat. These procedures generally require a calm and cooperative patient for success and minimization of complication risk. When patients are uncooperative or their anxiety cannot be addressed by mild sedation, specialist referral and examination under general anesthesia should be considered.

Chapter 66 - Emergency Dental Procedures

Kip Benko

Complaints pertaining to the teeth and supporting maxillofacial structures are common, and patients frequently present to the emergency department (ED) for initial evaluation. Complaints may range in scope from a simple chipped tooth to a severe odontogenic deep space infection or maxillofacial injury. Treating these patients can be challenging and frustrating for the busy emergency clinician. Many emergency clinicians do not receive specific training in dental emergencies during their residencies, yet it is important for them to be able to recognize and treat a wide range of dental problems. Some dental emergencies can lead to life-threatening airway compromise while others lead to morbidities such as tooth loss, pain, infection, and craniofacial abnormality.

Management of specific dental emergencies requires a thorough understanding of adult and pediatric dentition. The relevant anatomy of both populations will be outlined. The techniques described for management of the various traumatic and infectious problems will, in most cases, be temporizing until definitive dental or oral/maxillofacial surgery referral can be obtained. Those conditions requiring emergent consultation will be discussed. Topical, local, and regional anesthesia are of particular importance and utility in the management of odontogenic emergencies and the clinician should be very familiar with these techniques (see Chapter 30 and Chapter 31). Trauma to the facial bones and other facial structures is covered in another chapter.

Although this chapter describes the diagnosis and treatment of dental injuries that may confront the emergency clinician, there is no standard of care mandating that dental problems be definitively handled in the ED setting. It is appropriate to refer all significant dental pathology to a dentist or oral surgeon, and failure to stabilize teeth or provide invasive drainage procedures in the ED should not be considered substandard care.

ANATOMICAL REVIEW

Stomatognathic System

The muscles of mastication are responsible for opening and closing the mouth and are those most frequently associated with temporomandibular disorders (TMDs). The clinician must be knowledgeable about the position of the muscles in order to perform an examination properly and to recognize the origin of certain painful conditions. The muscles that close the mouth are those most often associated with TMDs and include the masseters, the temporalis, and the medial pterygoids (Fig. 66-1). The contraction of this group of muscles bilaterally serves to move the condyle superiorly and posteriorly, causing the mouth to close. The opening muscles include the anterior digastric, posterior digastric, mylohyoid, geniohyoid, and infrahyoid muscles (Fig. 66-2). They are not often affected in TMDs. The lateral pterygoids are responsible for anterior translation and lateral movement of the mandible (Fig. 66-3). Unilateral contraction causes lateral movement away from the side of the muscle contraction while bilateral contraction causes protrusion of the mandible.

The mandible consists bilaterally of the horizontal body and the ascending ramus, which are connected by the angle. The bodies of the mandible are connected by the symphysis in the midline. The ascending ramus gives rise superiorly to two processes, the condylar process and the coronoid process (Fig. 66-4). The mandibular condyle, along with the mandibular fossa and the articular eminence of the temporal bone, make up the temporomandibular joint (TMJ). The TMJ provides for both hinge and gliding actions. Between the mandibular condyle and the articular eminence is a fibrous collagen disk, also known as the meniscus. A ligamentous joint capsule surrounds the TMJ and serves to limit condylar movement. TMJ pain may be caused by a number of conditions, both traumatic and nontraumatic. The main distinction to be made is whether the pathology is intracapsular or extracapsular. This is often difficult to determine and the focus in the emergent setting is to rule out fracture as a cause of pain.

Teeth

The adult dentition normally consists of 32 teeth, which comprise four types: 8 incisors, 4 canines, 8 premolars, and 12 molars. From the midline to the back of the mouth there is a central incisor, a lateral incisor, a canine, two premolars (bicuspids), and three molars, the last of which is the wisdom

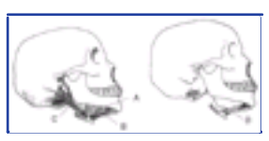

Figure 66-2 Muscles responsible for mandibular opening. Oblique skull views illustrating the anatomical positions of the following muscles: *A,* Mylohyoid. *B,* Anterior belly of the digastric. *C,* Posterior belly of the digastric. *D,* Geniohyoid. *(From King R: Oral-Facial Emergencies-Diagnosis and Management, 1st ed, Porland, Or: JBK Publishing, 1994.)*

tooth (Fig. 66-5). The 20 primary or deciduous (baby) teeth consist of eight incisors, four canines, and eight molars. From the midline to the back of the mouth there is a central incisor, a lateral incisor, a canine, and two molars (Fig. 66-6 (Figure Not Available)). Agenesis, or the lack of proper formation of a tooth or teeth, is not uncommon, especially in the maxilla. Likewise, supernumerary, or extra, teeth also occur. The adult teeth are numbered from 1 to 32, with the first tooth being the right upper third molar and the 16th tooth being the left upper third molar. The left lower third molar is 17th, and the 32nd tooth is the right lower third molar (see Fig. 66-6 (Figure Not Available)). There are numerous classification and numbering systems of the teeth; however, it is probably best for clinicians to simply describe the location and type of tooth in question (e.g., upper left second premolar, lower right canine). This removes any question when you are discussing a case with a consultant.

A tooth consists of the central pulp, the dentin, and the enamel (Fig. 66-7). The pulp contains the neurovascular supply of the tooth, which is responsible for carrying nutrients to the dentin, a microporous substance that consists of a system of microtubules. The dentin makes up the majority of the tooth and cushions the tooth during mastication. The enamel is the white, visible portion of the tooth and is the hardest part of the body. The tooth may also be described in

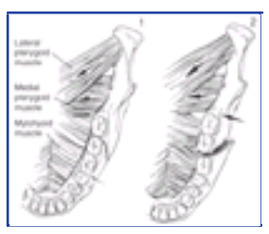

Figure 66-3 Axial view of the floor of the mandible. The arrows indicate the direction of pull of the lateral pterygoid, medial pterygoid, and mylohyoid muscles. *(From Eisele D and McQuone S: Emergencies of the Head and Neck, 1st ed. St. Louis, MO, Mosby, 2000.)*

terms of the crown (coronal portion) or the root. The crown is that portion covered in enamel, and the root is the part which serves to anchor the tooth in the alveolar bone.

The following descriptive terminology is used for the different anatomic surfaces of the tooth. These terms are useful when describing the specific tooth injury to a consultant or colleague:

- *Facial:* that part of the tooth that faces the mouth. This is the part that you see when somebody smiles. This is a general term applicable to all teeth.
- *Labial:* refers to the facial surface of the incisors and canines.
- *Buccal:* refers to the facial surface of the premolars and molars.
- *Oral:* that part of the tooth that faces the tongue or the palate. This is a general term applicable to all teeth.
- *Lingual:* toward the tongue, the oral surface of the mandibular teeth.
- *Palatal:* toward the palate, the oral surface of the maxillary teeth.
- *Approximal/Interproximal:* the contacting surfaces between two adjacent teeth.
- *Mesial:* the interproximal surface facing anteriorly or closest to the midline.
- *Distal:* the interproximal surface facing posteriorly or away from the midline.
- *Occlusal:* biting or chewing surface of the premolars and molars.
- *Incisal:* biting or chewing surface of the incisors and canines.
- *Apical:* toward the tip of the root of the tooth.
- *Coronal:* toward the crown or the biting surface of the tooth.

The Periodontium

The periodontium, also known as the attachment apparatus, consists of two major subunits and is necessary for maintaining the integrity of the normal dentoalveolar unit.

The *gingival* subunit consists of the junctional epithelium and the gingival tissue. The gingival tissue is keratinized, stratified, squamous epithelium and it can be divided into the *free gingival margin* and the *attached gingiva*. The free gingiva is the cuff of tissue that is formed around the neck of the tooth. The gingival sulcus is that space between the free gingiva and the tooth. It is rarely greater than 2 to 3 mm in depth in normal healthy dentition. The attached gingiva is the portion of gingiva that is attached to the alveolar bone and extends apically (away from the tooth) to the mucogingival junction (or the mucobuccal fold). At this point the tissue, loose

and nonkeratinized, is called the alveolar mucosa (or buccal mucosa).

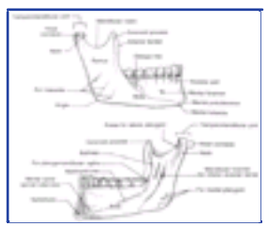

Figure 66-4 Anatomy of the mandible. *Top,* View from lateral (buccal) perspective. *Bottom,* View from medial (lingual) perspective. *(Redrawn from Grant JC: Grant's Atlas of Anatomy, 5th ed. Baltimore, Williams & Wilkins, 1962.)*

The *periodontal subunit* includes the periodontal ligament, alveolar bone, and the cementum of the root of the tooth. The periodontal ligament consists of collagen that extends from the alveolar bone to the root of the tooth. One end of the periodontal ligament inserts into the alveolar bone, the other end into the cementum (see Fig. 66-7).

The gingival subunit is primarily responsible for maintaining the integrity of the periodontal subunit. Certain disease states such as gingivitis weaken the attachment apparatus and can result in tooth loss.

DENTOALVEOLAR TRAUMA

Dental Fractures

Dentoalveolar trauma is a common reason for ED visits. Injury to the maxillary central incisors accounts for between 70–80% of all fractured teeth. [5] [6] [16] Trauma to the teeth is usually not life-threatening; however, the morbidity associated with dental fractures can be significant and includes the following: failure to complete eruption, color change of the tooth, abscess, loss of space in the dental arch, ankylosis, abnormal exfoliation, and root resorption. Dental injuries are often associated with intraoral lacerations. When a tooth is chipped or missing, and there is a concomitant intraoral laceration, it should be noted that the missing portion of the tooth may be imbedded in the depths of the laceration.

Some general principles apply to the evaluation and management of dental trauma. First, identify all fracture fragments and mobile teeth. Each tooth surface should be percussed for mobility and sensitivity. If a tooth is missing, it cannot always be assumed that it has been avulsed. Teeth are aspirated into the respiratory tract, or they can be fully intruded into the maxillary sinus, alveolar bone, or nasal cavity. Radiographs should be taken if there is any suspicion of aspiration of tooth fragments or intrusion of fragments into the gingiva or alveolar bone. Second, the dentition is much more easily manipulated if the patient is not in significant discomfort. Tooth infiltration and common dental blocks should be part of the emergency clinician's armamentarium. Third, topical tooth remedies and analgesics, both over-the-counter and prescribed, should be discouraged as their use can lead to the development of sterile abscesses and soft tissue irritation. Fourth, tetanus vaccination should be administered if needed.

The management of fractured teeth depends upon the extent of fracture with regard to the pulp, the degree of development of the apex of the tooth, and the age of the patient. There are many ways to classify dentoalveolar injuries and, in particular, tooth fractures. [7] The Ellis classification is one system that is often cited in the emergency medicine literature; however, many dentists and maxillofacial surgeons do not use this nomenclature, making it less than ideal when discussing these types of injuries (Fig. 66-8).[6] The most easily understood method of classification is, perhaps, one based on injury description.

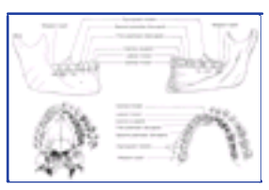

Figure 66-5 Classification of teeth. *Top left,* Lateral view. *Top right,* Medial view. *(Redrawn from Grant J, Basmajian J: Grant's Method of Anatomy, 7th ed. Baltimore, Williams & Wilkins, 1965.)*

Crown fractures may be divided into uncomplicated and complicated categories. Uncomplicated crown fractures result from injuries to the enamel alone or to a combination of the enamel and the dentin.

Ellis class I fractures.

Uncomplicated crown fractures through the enamel only are called Ellis class I fractures. They are usually not sensitive to either temperature or forced air. These fractures usually pose no threat to the health of the dental pulp. They may feel sharp to the patient's tongue, lips, or buccal mucosa. Immediate treatment is not necessary but may consist of smoothing the sharp edge of the tooth with an emery board or rotary disk sander. The patient should be reassured that the tooth can be restored by a dentist to its normal appearance with composite resins and bonding materials. Follow-up is important with these injuries as pulp necrosis and color change can rarely occur (in less than 1%) (Fig. 66-9*A, B*). [2] [6]

Ellis class II fractures.

Uncomplicated fractures through the enamel and dentin are called Ellis class II fractures. Fractures that extend into the dentin are at higher risk of pulp necrosis and, therefore, need more aggressive treatment by the emergency clinician (Fig. 66-10). The risk of pulp necrosis in these patients is 1–7%, but this increases as treatment time extends beyond 24 hours.[6] These patients often complain of sensitivity to heat, cold, or forced air. The physical exam reveals the yellow tint of the dentin in contrast to the white hue of the enamel. Fractures that are closer to the pulp cavity will reveal a pink tinge to the dentin. The tooth is usually sensitive to percussion with a tongue blade. The porous nature of the dentin allows passage of bacteria from the oral cavity to the pulp that may result in inflammation and infection of the pulp chamber. This is more likely to occur after 24 hours of dentin exposure but occurs sooner if the fracture site is closer to the pulp. Likewise, patients younger than 12 years have a pulp/dentin ratio larger than in the mature adult and are at increased risk for pulp contamination. For this reason, younger patients should be treated aggressively and should be seen by their dentist within 24 hours. [1] [11]

The goal of treating dentin fractures is twofold: to cover the exposed dentin, thus preventing secondary contamination or infection, and to provide pain relief. After the tooth is covered, the dentist can rebuild it with modern composites in many cases. A supraperiosteal infiltration or a regional tooth block performed prior to any tooth manipulation allows for easier application of the dressing since the procedure then becomes relatively painless.

Dressings that may be applied to the surface of the tooth include calcium hydroxide, zinc oxide, and glass ionomer composites. Recent literature suggests that glass ionomers may be superior to other coverings; however, the difference is probably slight and the increased cost of the glass ionomers is not justified for routine ED use at this time.[4] [5] Certain composites may be cured with a bonding light. This is routinely done in the dentist's office but is beyond the scope of most emergency practice. Bone wax and skin glues such as the cyanoacrylates are not recommended as dressings. Most dressings come as a base and a catalyst, which require mixing. This is easily accomplished with a dental spatula and a mixing pad, which are obtainable from any dental supply house. A commonly used ED dressing is Dycal (calcium

Figure 66-6 (Figure Not Available) Identification of teeth. *(From Beaudreau R: Oral and Dental Emergencies. In Tintinalli J, Kelen G, Stapczynki S: Emergency Medicine-A Comprehensive Study Guide, 5th ed. New York, McGraw-Hill, 2000.)*

hydroxide). The catalyst and the base are mixed in equal portions, and a small amount is placed on the exposed area with an applicator such as a dental spatula or another appropriate instrument (Fig. 66-11).

The tooth surface should be dry prior to application to assure adherence of the CaOH. This can be accomplished by having the patient bite into gauze pads. Dycal will dry within minutes after being exposed to the moist environment of the mouth. Although placing dental foil over the CaOH dressing is recommended, it is not usually necessary if the patient plans to follow up with a dentist within 24 to 36 hours. To prevent dislodging the dressing, the patient should be

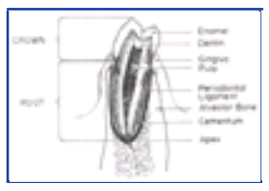

Figure 66-7 The dental anatomic unit.

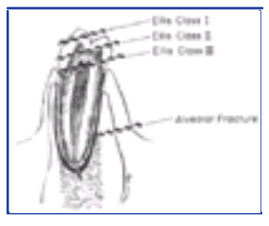

Figure 66-8 The Ellis classification for fractured alveolar teeth. The easiest method to classify fractured teeth is by description (e.g., fracture through the dentin of the first upper right molar).

instructed to eat soft foods only until seen by the dentist. Although unproven, it is reasonable to begin antibiotic treatment with penicillin or clindamycin until definitive dental treatment can be obtained.[10] [11]

Many patients who sustain a fracture through the dentin will require a root canal or other definitive endodontic treatment. The timely application of an appropriate dressing in the ED, however, may prevent contamination of the pulp and make root canal therapy unnecessary. As with any trauma to the anterior teeth, it is advisable to explain to the patient that disruption of the neurovascular supply is possible and that long-term complications such as pulp necrosis, color change, and resorption of the root may occur.

Ellis class III fractures.

Complicated fractures of the crown involving the pulp are called Ellis class III fractures. Complicated fractures of the crown that extend into the pulp of the tooth are true dental emergencies. These fractures result in pulp necrosis in 10% to 30% of cases even with appropriate treatment.[6] They may be distinguished from fractures of the dentin by the pink color of the pulp. The fractured surface of the tooth should be wiped off with gauze and observed for frank bleeding or a pink blush, which indicates exposure of the pulp. Fractures through the pulp are often excruciatingly painful but occasionally there is a lack of sensitivity secondary to a disruption of the neurovascular supply of the tooth.

Immediate management includes referral to a dentist, oral surgeon, or endodontist. The patient often requires a pulpectomy (complete removal of the pulp) or, in the case of primary teeth, a pulpotomy (partial removal of the pulp) as definitive treatment.[2] [5] The longer the pulp is exposed, the greater the likelihood of contamination and abscess formation. If a dentist cannot see the patient immediately, the emergency clinician should attempt to relieve the pain and cover the exposed pulp. If significant pain is present a dental block should be performed. Subsequently, the tooth should be covered with one of the dressings described earlier (Fig. 66-12). Sometimes bleeding is brisk and needs to be controlled before applying a dressing. This can usually be accomplished by having the patient bite into a gauze pad that has been soaked with a topical anesthetic containing a vasoconstrictor such as epinephrine. Alternatively, a small amount of the anesthetic/vasoconstrictor may be injected into the pulp to control bleeding. After the covering is applied, the patient is instructed to follow up as soon as possible with a dentist. Antibiotics with coverage directed at oral flora

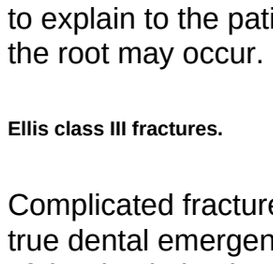

Figure 66-9 *A,* A common injury from a fist to the mouth results in a chipped tooth (here, fractured through the enamel only) and a laceration of the lip. One should always explore the mucosal laceration, looking for the missing piece of tooth. *B,* When this lip laceration was explored, a piece of tooth was found embedded within the laceration. If this foreign body is not removed, an infection is certain a few days later. *C,* Smoothing the enamel with a disc sander or an emory board will ameliorate the cosmetic deformity of a chipped tooth.

(e.g., penicillin, clindamycin) should be prescribed and only soft foods should be eaten. Removal of the pulp with specialized instruments by the emergency clinician is not recommended, although some authors have advocated this in

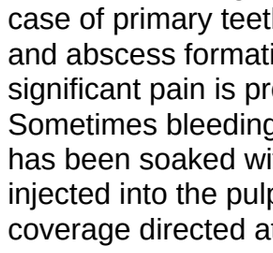

Figure 66-10 A fracture through the dentin.

the past. This procedure is the realm of the dental professional and is likely to result in complications if not done properly.

Luxation, Subluxation, Intrusion, and Avulsion

Luxation and subluxation.

Subluxation refers to teeth that are mobile but not displaced. Luxation refers to teeth that are displaced, either partially or completely, from their sockets. Luxation injuries are divided into four types:

1. Extrusive luxation is an injury in which the tooth is forced partially out of the socket in an axial direction (Fig. 66-13).
2. Intrusive luxation, or intrusion, occurs when the tooth is forced apically and may be accompanied by crushing or fracture of the tooth apex (Fig. 66-14 and Fig. 66-15).
3. Lateral luxation occurs when the tooth is displaced either facially, lingually, mesially, or distally (Fig. 66-16). This injury is often associated with injuries to the alveolar wall.
4. Complete luxation, also known as complete avulsion, results in loss of the entire tooth from the socket.

Even minor trauma to the oral cavity requires meticulous examination for loose or missing teeth. Each tooth surface should be examined for mobility by using a

Figure 66-11 *A,* Calcium hydroxide paste is one acceptable material to cover dentin or pulp fractures. *B,* Mixing the calcium hydroxide paste with a spatula on a mixing pad. *C,* Application of the periodontal paste to the fractured surface of the tooth.

back and forth motion on each side of the tooth surface with the fingertips or two tongue blades. Any blood in the gingival crevice (area where the gingiva touches the tooth) is suggestive of a traumatized tooth.

Teeth that are minimally mobile and are not displaced do very well with conservative treatment only. The tooth will tighten up in the socket if not retraumatized. Patients should be instructed to eat only a soft diet for 1 to 2 weeks and follow up with their dentist as soon as possible.

Grossly mobile teeth require some form of stabilization as soon as possible. It is important to note that in certain patients with poor gingival health, luxated teeth may not be

Figure 66-12 *A,* Covering the pulp fracture with calcium hydroxide paste. *B,* The calcium hydroxide paste hardens quickly in the moist environment of the mouth.

salvageable due to disease of the attachment apparatus. Fixation is best performed by the dental specialist with enamel bonding materials or wire ligation (Fig. 66-17). Although many different "home remedies" exist for splinting loosened teeth in the ED, one must be aware of the concern for aspiration of teeth if the splint fails. The clinician should also avoid the use of nonapproved medications in the mouth. An example is the use of skin adhesives, which, to date, have not been approved for intraoral use.

Splinting techniques are suitable for the emergency clinician to perform as temporizing measures until definitive care can be arranged. One simple technique for emergency

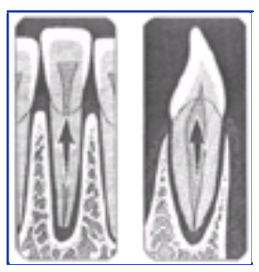

Figure 66-13 Extrusive luxation occurs when the tooth is forced partially out of the socket in an axial direction. *(From King R: Oral-Facial Emergencies-Diagnosis and Management, 1st ed. Portland, OR, JBK Publishing, 1994.)*

use is to apply periodontal paste commercially available as Coe-pak. Coe-pak consists of a base and a catalyst that, when mixed, form a moderately sticky claylike dressing. This dressing becomes firm after application. It is applied over the enamel and gingival, as well as the adjacent teeth, to splint the subluxated tooth into place. Although the splint performs best if placed on the facial and buccal surfaces of the teeth, it is usually sufficient to apply the paste only to the front (facial) surface of the teeth (Fig. 66-18 and Fig. 66-19). The dressing is most easily applied when the clinician's gloves are lubricated with water or lubricating jelly and the gingiva and enamel are completely dry. It is important to apply the dressing into the grooves between the teeth as well as to the adjacent teeth. The

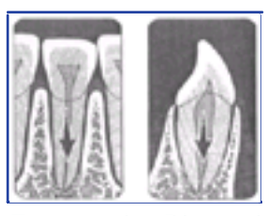

Figure 66-14 Intrusive luxation of a tooth compresses the periodontal ligament and vascular supply of the pulp. It may even crush the apical bone. *(From King R: Oral-Facial Emergencies-Diagnosis and Management, 1st ed. Portland, OR, JBK Publishing, 1994.)*

patient is reminded to eat a soft diet until seen in follow up within 24 hours.

Self-cure composite is another splinting option in the ED. Self-cure composite is a compound that does not need a curing light to harden. It is formed by mixing a base and a catalyst, which harden when combined. This product is only applied to the enamel of the involved tooth, not the gingiva, and to the nonmobile adjacent teeth (Fig. 66-20). Both Coe-pak and self-cure composite are fairly simple for the dentist to remove during formal restoration.

Teeth that are luxated in either the horizontal or axial plane or are slightly extruded can also be splinted with the techniques described earlier. It is important that the loosened tooth be in perfect alignment when the final adjustments are made at the dentist's office; however, the alignment does not need to be precise when the tooth is splinted in the ED. The important point is that the tooth is splinted adequately and follow up is ensured.

Intrusion and avulsion.

Intruded teeth are those that have been forced apically into the alveolar bone. This often results in disruption of the attachment apparatus or fracture of the supporting alveolar bone, especially in permanent teeth with mature roots. [1] [3] These teeth are usually immobile and do not require stabilization in the ED. Intruded teeth often require endodontic treatment because of pulp necrosis. It is important to consider the possibility of an intruded tooth anytime there is a space in the dentition. Undiagnosed intrusion of the teeth can lead to infection and craniofacial abnormalities. X-rays should be obtained anytime there is uncertainty as to whether a tooth is intruded or simply avulsed. Intruded teeth are best managed by the dentist or dental specialist and referral should take place within 24 hours. Permanent teeth often require repositioning and immobilization, but primary teeth are usually given a trial period to erupt on their own before any intervention is taken.

Avulsed teeth are those that have been completely removed from their ligamentous attachments and are true dental emergencies. The first consideration in treating dental avulsions is to ask, "Where is the tooth?" Missing teeth may have been intruded, fractured, aspirated, swallowed, or embedded into the soft tissues of the oral mucosa; therefore, x-rays should be considered anytime an avulsed tooth cannot be located. Management of the avulsed tooth in the ED is dependent upon a number of factors. These include the age of the patient, the amount of time that has elapsed since the tooth was avulsed, associated trauma to the oral cavity such as alveolar ridge fractures and the overall health of the periodontium. [3] Primary teeth are not replaced after avulsion because they can fuse to the alveolar bone and potentially cause craniofacial abnormalities or infection. Reimplanted primary teeth may also interfere with the eruption of the secondary teeth. The parents of these patients need to be reassured that a prosthetic replacement for the avulsed teeth can easily be made and worn until the permanent teeth erupt.

Time is the other important consideration when deciding whether to replace an avulsed tooth. In general, the longer the tooth is out of the socket, the higher the incidence of periodontal ligament necrosis and subsequent failure of reimplantation. The periodontal ligament cells generally die within 60 minutes outside of the oral cavity if they are not placed in appropriate transport media. [13] A significant amount of research has been conducted on different media used to keep the cells of the periodontal ligament alive.

Figure 66-15 Intruded tooth secondary to trauma. On superficial examination it appears that the tooth was simply knocked out. A dental radiograph or CT scan is necessary to determine intrusion or avulsion. Intruded teeth create the potential for infection or cosmetic deformities. Intrusion of an upper tooth into the maxillary sinus can cause recurrent sinusitis. Teeth can also intrude into the nasal cavity and cause infection or bleeding, or they can be aspirated into the airway. The incisors are the most commonly intruded teeth. *(From Johnson R: The treatment of the traumatized incisor in the child patient. In University of Pennsylvania School of Dental Medicine: Continuing Dental Education, vol 2. Philadelphia, University of Pennsylvania, 1978.)*

Various transport media that have been studied include milk, Hank's Balanced Salt Solution, Save-A-Tooth, saliva, cell culture media, and water. Although certain cell culture media have been developed to stimulate the periodontal ligament cells to proliferate and remain viable, milk and the commercially available Save-A-Tooth are best for both prehospital care and ED storage (Fig. 66-21).[13] [15] Both will preserve the periodontal ligament for up to 8 to 12 hours; however, reimplantation should take place at the earliest possible opportunity. The key is to get the tooth into the transport media immediately because even 10 minutes outside of some type of storage media can cause desiccation and death of the periodontal ligament cells. Saliva should be used at the scene if milk or Save-A-Tooth is not available. The tooth should be reimplanted by the patient in the prehospital setting, if possible. The following principles should be

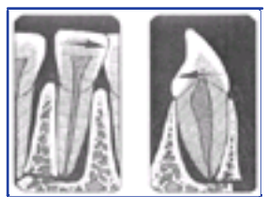

Figure 66-16 Lateral luxation occurs when the tooth is displaced in either a lingual, mesial, distal, or facial direction. Fractures of the alveolus frequently accompany lateral luxation injuries. *(From King R: Oral-Facial Emergencies-Diagnosis and Management, 1st ed. Portland, OR, JBK Publishing, 1994.)*

followed when providing instructions to prehospital providers or to a patient who calls for advice:

- The tooth should be handled by the crown only. Handling the tooth by the root can damage the alveolar ligament.
- The tooth should not be replaced if it is fractured or if there is significant maxillofacial trauma such as an alveolar ridge fracture.
- If the tooth can be replaced in the prehospital setting, the root should be gently rinsed off first to remove any debris. The root should not be wiped off as this removes the periodontal ligament.
- If the tooth cannot be reimplanted successfully in the field, it should be placed in a transport media as described earlier. Transporting the tooth in the oral cavity such as a cheek is risking aspiration. This location is also not ideal for keeping the periodontal ligament alive because of the bacterial flora and low osmolality of the saliva.
- Once the patient arrives in the ED, the treating clinician should confirm proper placement and alignment. It is not important that the tooth is in perfect position, as final adjustments can be made by the dentist. Splinting of the repositioned tooth with periodontal paste or composite as outlined above may be necessary if mobility is present.

Should reimplantation not be successful in the prehospital setting, it must be done in the ED using the following guidelines:

- The tooth should be stored in appropriate media if reimplantation is delayed for any reason.
- It is extremely helpful to perform a supraperiosteal dental infiltration before the manipulation or replacement of teeth. This makes the procedure more comfortable for the patient and easier for the clinician to perform.
- The oral cavity should be checked for trauma. If an alveolar ridge fracture is present or the socket is significantly damaged, the tooth should not be reimplanted.
- The socket first must be suctioned with a Frasier suction tip to remove the accumulated clot. Be careful not to damage the walls of the socket as this can further damage periodontal ligament fibers. Gentle irrigation should follow suctioning. If the clot is not removed, reimplantation and

realignment will be difficult. Any debris on the tooth should be rinsed, not scrubbed, with saline. The tooth is then implanted into the socket using firm, but gentle, pressure. Remember to handle the tooth only by the crown.
- Having the patient gently bite down on gauze may help to align the tooth. The tooth may require splinting after replacement. If significant mobility is present such that temporizing splints are not adequate, wiring or arch bars may need to be placed by the dental consultant.
- Tetanus should be updated as necessary. A liquid diet should be prescribed until seen in follow up.

Antibiotics are controversial in the treatment of fractured and avulsed teeth. Although the American Association of Endodontics does not recommend the routine use of antibiotics for fractures or avulsions, other authors recommend the use of antibiotics that cover mouth flora (e.g., penicillin, clindamycin) to decrease the inflammatory resorption of the root.[6] [18] It is probably prudent to use antibiotics if the root or socket are heavily soiled; otherwise, treatment should be tailored to the individual patient and discussed with the consultant.

Prognosis.

The prognosis of a reimplanted tooth depends on many things. As discussed earlier, the time to

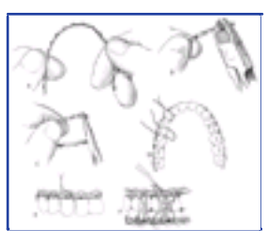

Figure 66-17 Application of Erich arch bars. *A through C,* A commercially available arch bar is shaped to fit the maxillary and mandibular arches. *D and E,* Stainless steel wire secures the bar to the necks of the teeth. *F,* The maxilla and the mandible are brought into occlusion and held in place with rubber bands. This technique is generally not used by the emergency clinician, but this equipment should be available for the oral or maxillofacial surgeon. *(From Converse JM: Reconstructive Plastic Surgery, 2nd ed, vol 2. Philadelphia, WB Saunders, 1977.)*

reimplantation is critical. Likewise, the age of the patient, the stage of development of the root (younger is better), and the overall health of the gingiva are also very important. An individual with gingival disease is more likely to have an unsuccessful reimplantation.

The goal in any tooth avulsion or fracture is to keep the native tooth if at all possible. A tooth that has been avulsed and reimplanted usually loses the majority of its neurovascular supply and undergoes pulp necrosis. However, if the periodontal ligament remains intact, there is a greater chance of a functional tooth. It is important that the patient be aware that some root resorption is always going to occur after reimplantation, and loss of the tooth may occur.

Alveolar Bone Fractures

Trauma involving the anterior teeth may be associated with fractures of the alveolus, which is the tooth-bearing portion of the maxilla or mandible. Alveolus or alveolar ridge fractures often occur in multi-tooth segments and will vary in the number of teeth involved, the amount of displacement, and the mobility of the affected segment. The patient usually complains of pain as well as malocclusion. The diagnosis is usually clinically

Figure 66-18 *A,* Squeeze out equal-sized ribbons of the periodontal paste. *B,* Mix the base and catalyst together with a tongue blade. *C,* Using moistened gloves, apply the paste to the dry enamel and gingiva.

apparent and is notable for a section of teeth that are misaligned and variable in mobility. Avulsed teeth, fractured teeth or displaced teeth may be present within the alveolar segment itself. Dental bite wing x-rays confirm the diagnosis. In the ED, Panorex or facial films may show the fracture line just apical to the root of the involved teeth; however, these films are often inconclusive or normal.

Treatment of alveolar ridge fractures involves rigid splinting after repositioning of the involved segment. This is usually beyond the scope of the emergency clinician, and urgent consultation with an oral surgeon or dentist is necessary. The role of the emergency clinician is to identify the injury as well as any avulsed or fractured teeth and preserve as much of the alveolar bone and surrounding mucosa as possible. Alveolar bone that is lost, debrided, or missing is difficult for the specialist to restore properly.[4]

Lacerations and Dentoalveolar Soft Tissue Trauma

Trauma to the face and perioral region is often associated with soft tissue injuries such as abrasions or lacerations. Before any repair can take place, it is imperative to do a thorough inspection of all wounds and abrasions to determine the extent of the wound and whether or not foreign bodies are present. Through-and-through lacerations are easily overlooked as are small foreign bodies and debris such as tooth fragments. Radiographs may be helpful if there is any question of tooth fragments. Potential airway compromise should also be identified at this time.

As a general rule, injured teeth should be repaired before any soft tissue management is undertaken because manipulation of the soft tissue, as would occur when repairing teeth, will likely cause further damage to sutures already placed in the soft mucosa. The repair of lacerations in the perioral region begins with standard wound care. After appropriate local or regional anesthesia, devitalized, crushed, or macerated tissue should be debrided. Profuse irrigation should follow. The role of antibiotics in mucosal trauma has not been definitively established, and there is no definitive standard of care promulgated. Several studies suggest a minimal benefit; however, this remains to be completely proven.[17] A reasonable guideline to follow is to use antibiotics if a significant amount of devitalized or crushed tissue is present or if the wound is through-and-through. Coverage of oral flora (e.g., penicillin, clindamycin) is fine for mouth lacerations and additional skin coverage should be considered for through-and-through lacerations (clindamycin, dicloxacillin). Dentoalveolar trauma may present the emergency clinician with several different situations that should generally be approached as follows.

Buccal mucosa.

Most lacerations and abrasions of the buccal mucosa heal quickly and rapidly without repair. If only the mucosa is lacerated, even seemingly large lacerations heal well and quickly. However, large lacerations (>1–2 cm) should generally be repaired. Many clinicians still prefer using chromic gut in the mouth, but any absorbable suture, such as vicryl in the 4-0 to 5-0 size, may be used. Absorbable sutures are preferred and they should be placed so that the knots are buried. Silk can be used as an alternative, but it has

Figure 66-19 Application of periodontal paste. *A,* Equal-length ribbons of base and catalyst are squeezed onto the mixing pad. *B,* The base and catalyst are mixed together using a moistened spatula or tongue blade. *C and D,* Using moistened gloves, roll the mixture into a ribbon. *E through H,* Apply to the enamel and gingiva, extending the paste two teeth on each side of the loosened tooth. The paste adheres best when the surface of the enamel and gingiva are as dry as possible.

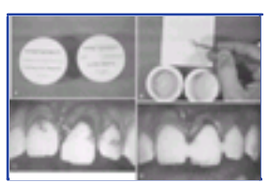

Figure 66-20 *A and B,* Equal amounts of the self-cure composite are placed on the mixing pad and mixed together. *C,* Subluxed teeth should be repositioned prior to application of the composite. *D,* The mixture is applied only to the dry enamel of the teeth. The composite should extend to one tooth on each side of the loosened tooth.

higher reactivity and is nonabsorbable. Nylon should be avoided because it is sharp and irritating to the tissues.

Through-and-through lacerations of the oral cavity present a special situation. The integrity of the salivary ducts (Wharton's duct and Stensen's duct) and the facial nerve needs to be established. If intact, repair can proceed. Guidelines

Figure 66-21 Using the "Save A Tooth" system, a tooth is placed into the container and closed. The preservative will increase the life span of traumatized periodontal ligament cells.

for closure are controversial, but generally, larger lacerations (>1–2 cm) should be closed. The mucosa should be closed as noted earlier and the skin closed aesthetically with 6-0 nylon, prolene, or a rapidly absorbable suture. The mucosa should be closed first so as not to disturb the skin repair. If the mucosal wound is small or is a puncture wound, it is reasonable to close only the skin layer. Very large, gaping, or complicated lacerations should be referred to an oral surgeon.

Large lacerations or through-and-through lacerations of the oral cavity should be rechecked in 2 to 3 days. Sutures should be removed (if nonabsorbable) in 7 to 10 days. Saline rinses 4 to 6 times a day and a soft diet may be prescribed. A topical skin antibiotic may be applied for 24 to 48 hours and intraoral antibiotic ointment (Ora-5) (Fig. 66-22) can be considered, as well, for the first several days.

Gingiva.

Small lacerations of the hard gingiva overlying the maxillary or mandibular alveolus usually heal uneventfully without repair. If the laceration is large, if there is a flap present, or bone is exposed, the gingiva should be approximated with a 4-0 or 5-0 vicryl or dexon suture. As earlier, silk is an option. Difficulty sometimes arises when suturing gingiva as there is little supporting soft tissue underneath. A helpful technique is to circumferentially wrap the suture around the teeth and use the teeth as anchors (Fig. 66-23 and Fig. 66-24). Suture and wound care is as described earlier.

Frenulum.

The maxillary frenulum rarely requires sutures for simple lacerations. If the laceration is extensive

Figure 66-22 The Ora 5 Topical Bactericidal Agent can be applied to intraoral lacerations or injuries to help prevent infection.

or extends significantly into the surrounding mucosa or gingiva, it should be approximated with a chromic vicryl or dexon suture. These wounds are often significantly painful and analgesia should be prescribed, even if the wound does not require suturing. The lingual frenulum is very vascular in nature and often will need a suture or two to control hemostasis. A local anesthetic with a vasoconstrictor aids in hemostasis while the wound is repaired.

The tongue.

Tongue lacerations are challenging (see Chapter 36). Although they may be tempting to suture, any

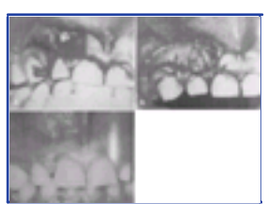

Figure 66-23 *A,* Gingival lacerations sometimes leave little tissue for approximation. *B,* The teeth can be used as anchors for sutures and help approximate the lacerated tissue. *C,* Gingival lacerations usually heal rapidly. (See also Fig. 66-24 .)

large lacerations of the body of the tongue, such as those that occur from a seizure, will heal well without suturing. Tongue lacerations that have the wound edges approximated do not need to be sutured, but larger lacerations that gape need repair because the cleft left by the wound will epithelialize leaving a grooved or bifid appearance. Likewise, wounds that are bleeding profusely, are flap-shaped, involve muscle, or are on the edge of the tongue should be approximated. Small avulsions or those in the center of the tongue usually heal without intervention.

Explaining the procedure in detail to the patient goes a long way in the repair of these wounds. The tongue usually can be secured by an assistant holding it with gauze. If the tongue cannot be secured in this manner, a towel clip applied to the end of the anesthetized tongue can be used. Children with tongue lacerations that need repair usually require sedation or repair by a specialist in the surgical suite, but many of these lacerations are small and heal uneventfully on their own.

Repair should be initiated with either a local infiltration of anesthetic or a lingual block. Lidocaine with epinephrine may be infiltrated locally to promote hemostasis. Repair should take place using absorbable sutures such as 4-0 chromic, vicryl or dexon. Silk can be used, but it must be removed in 7 to 10 days. Nylon is not used because it is very irritating to the surrounding tissues. Lacerations extending through muscle should be closed with one deep stitch penetrating both the mucosa and muscle. When possible, bury the knots of absorbable sutures as they often work their way loose. Full thickness lacerations can be closed in a number of ways. A suture that is placed through all three layers is acceptable as is the technique of closing the top mucosa and muscle together and, subsequently, doing the same thing on the underside of the tongue. Bleeding from large lacerations is almost always controlled with primary repair.

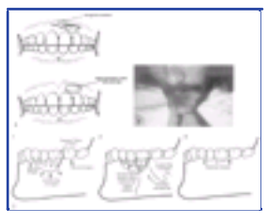

Figure 66-24 Repair of avulsed or lacerated gingiva. *A,* simple flap lap lacerations are approximated and closed with interrupted soft sutures, such as dexon or vicryl. *B,* Large gingival avulsions should be approximated to an anatomical position with interrupted sutures. *C1,* The exposed roots of the teeth should be covered. The thin and friable avulsed gingiva can not be sutured to the remaining gingiva or submucosal tissue. *C2,* The suture begins on the outer surface of the avulsed flap and is passed behind an anchoring tooth, like dental floss. The underside of the avulsed segment is then entered by the suture needle so the needle exits on the gingival surface. *C3,* Sutures pull the gingival to an anatomical position to cover the roots of the teeth and are tied on the outer surface. Sutures are removed in 5–7 days. See also Figure 66-23 .

In some instances hemostasis can be achieved without the use of sutures with the use of Gelfoam impregnated with topical thrombin (Fig. 66-29).

ORAL HEMORRHAGE

Bleeding from the oral cavity is not unusual and is most commonly associated with dental procedures. It is important to ascertain whether any recent dental work has been performed and of what nature it was. Spontaneous bleeding of the gingiva or oral cavity not associated with dental manipulation or trauma is suggestive of advanced periodontal disease or an underlying systemic process. It is also important to ask about other medical conditions that predispose to bleeding (liver disease, platelet abnormalities, etc.) as well historical factors, which may suggest a bleeding abnormality or clotting factor deficiency. It should be determined whether the patient is taking aspirin or other anticoagulants. Laboratory testing should be considered if there is significant suspicion for a pathologic coagulopathy, but not routinely in the patient presenting after dental manipulation.

Gingival bleeding after scaling or minor dental procedures is usually controllable with direct pressure and saline/hydrogen peroxide rinses. Bleeding that persists from the gingival areas despite pressure and rinses should raise suspicion for a bleeding abnormality. A much more common cause of oral hemorrhage that presents to the ED is postextraction bleeding. Minor oozing from dental extractions, such as wisdom teeth extraction, is normal for 2 to 4 days post surgery, but many patients get concerned when bleeding persists, despite warning from the oral surgeon. These patients usually present when their dentist cannot be contacted and after many hours of futile attempts at home to stop the bleeding. There are a number of options that the emergency

clinician can use to obtain hemostasis from postextraction bleeding.

Direct pressure.

Although the patient may have been using this technique at home, a few simple procedures may make it more effective. Any excessive clot that has built up around the oozing site should be removed with a suction catheter and the area gently irrigated. The clot that is in the socket (if any is present) should be left intact. Often, this clot is missing or partially missing. Once the clot is removed, gauze should be inserted as firmly as possible directly onto the bleeding site. This is best accomplished by using dental roll gauze (see section on dental materials later in this chapter) inserted directly over the bleeding site and then covered with 2 × 2 gauze. Dental roll gauze has the advantage of fitting more precisely between the teeth and, therefore, affords more pressure; however, 2 × 2s can be substituted. Most EDs have a topical vasoconstrictor such as epinephrine on the ENT cart for nosebleeds. It helps to moisten the roll gauze with topical vasoconstrictor before placement over the bleeding site. The patient should then be instructed to bite down and hold pressure for 15 minutes or so.

If active bleeding persists after 15 minutes, infiltration with a vasoconstrictor should be performed. Infiltrate the bleeding area and the gingiva surrounding the socket with lidocaine and epinephrine (1:100,000) until blanching occurs. Reapply the gauze over the site and instruct the patient to bite down for 15 more minutes. The injection serves two purposes: It causes vasoconstriction, and it anesthetizes the area so that adequate pressure can be generated during biting.

If bleeding persists, insert coagulating agents (Gelfoam, Surgicel, Avitene, Instat) into the socket and then loosely close the gingiva surrounding the socket with silk suture. Instruct the patient to bite down on gauze placed over the sutures. Soaking Gelfoam with topical thrombin is a good way to halt minor persistent bleeding (see Fig. 66-29).

If these measures fail to control the bleeding, consult a specialist. It is also reasonable to check blood counts and coagulation profiles at this time.

Patients whose bleeding is controlled can be discharged and instructed not to take anything by mouth for four hours and then only liquids and soft foods. Silk sutures require removal in seven days.

ALVEOLAR OSTEITIS (DRY SOCKET)

The pain associated with an extracted tooth is significant but usually manageable with current pharmacologic modalities. The pain associated with dry socket, however, can be very severe and often requires more definitive treatment. Alveolar osteitis, or dry socket, is a localized osteomyelitis that occurs when the alveolar bone becomes inflamed. This condition usually occurs when the clot that is normally present in the socket after a tooth extraction becomes dislodged or dissolves and is most common in the 2- to 4-day period after a tooth extraction. The exam is essentially unremarkable with the exception of a missing clot where the tooth was extracted. Anything that increases negative intraoral pressure in the mouth (e.g., smoking, excessive rinsing, spitting, drinking from a straw), as well as hormone replacement and periodontal disease, will predispose a patient to a dry socket. Only a small percentage of patients will develop a dry socket (2%–5%); however, this number increases with traumatic extractions or impacted third molars. [10] [14]

Figure 66-25 Dry Socket Paste. Apply alone or as a slurry mixed with Gelfoam into the socket to relieve alveolar osteitis pain.

The pain associated with a dry socket is extremely severe and if a patient presents several days after an extraction with a relatively normal exam and severe pain, it is likely a dry socket. The pain will not be relieved with traditional pain medications, but a dental block usually provides instant relief. Once the block is performed, the alveolar osteitis can be treated. The socket should be irrigated and gently suctioned to remove any accumulated debris. Next, the socket may be filled using a variety of techniques, which will prevent recurrence of pain and allow healing to begin.

The socket may be packed with ¼ in. gauze that is impregnated with eugenol (oil of cloves) or a local anesthetic. These can be obtained from the hospital pharmacy. The gauze tends to dry out and loosen and, therefore, should be replaced in 24 to 36 hours. Patients should be seen by a dentist the next day if at all possible. The socket may also be packed with a slurry of Gelfoam and eugenol. The Gelfoam acts as a matrix to hold the eugenol in the socket. A commercial product known as Dry Socket Paste (Fig. 66-25) can be applied by itself into the socket or it can be mixed with Gelfoam and placed into the socket. Dry Socket Paste is a very sticky thick paste containing eugenol. It often stays in place longer than gauze and does not dry out. (See section on dental materials later in this chapter.)

Although antibiotics may be given to prevent alveolar osteitis, they are not usually necessary once the socket has been packed and should be prescribed at the discretion of the patient's oral surgeon or dentist. [1] [4] [10]

DENTOALVEOLAR INFECTIONS

Infections of the oral cavity run the spectrum from minor, easily managed abscesses to severe, life-threatening, deep-space infections that require airway management and operative drainage. Although dental infections of all severity present to the ED, the most common are those related to pulp disease. Others are associated with the attachment structures of the teeth such as the gingiva, periodontal ligament, and the alveolar bone. These infections are often chronic conditions, but they can progress to the point where periodontal abscesses form and emergency treatment is required.

Emergency clinicians will be called on to drain abscesses of dental origin that do not extend into the deep spaces and that have well-defined boundaries that are easily accessible by intraoral or external drainage.

Disease of the pulp.

Disease of the pulp can occur from trauma, operations, or other unknown causes, but the most frequent cause is invasion of microorganisms after carious destruction of the enamel. As the enamel is destroyed, caries development progresses more rapidly through the dentin and into the pulp chamber causing an inflammatory response, referred to as pulpitis. If the path of carious destruction through the tooth is adequate for drainage of the developing inflammation, the patient may be asymptomatic for a long time. If drainage is blocked, however, the process progresses forward to rapidly involve the entire pulp cavity and the periapical space. The tooth is usually exquisitely tender at this point. Abscesses in the periapical region are usually picked up on dental x-rays and less commonly on a Panorex; however, unless extension through the cortex exists, it is not important for the emergency clinician to make the distinction between pulpitis and a periapical abscess. Examination often reveals gross decay of one or many teeth and percussion tenderness of the abscessed tooth. A periapical abscess will follow the path of least tissue resistance if not treated. This may be through the alveolar bone and gingiva and into the mouth or into the deep structures of the neck. If the infection has progressed apically through the alveolar bone and localized swelling and tenderness exists, incision and drainage should be performed (discussed subsequently).

In the ED setting, it is uncertain as to whether a periapical abscess or simple pulpitis exists. Dental x-rays are usually not available. In the absence of trauma or recent instrumentation, it is prudent to begin antibiotic coverage for the typical oral flora. Penicillin and clindamycin are good choices. Analgesia should be provided as well. A supraperiosteal infiltration (tooth block) using a long-acting anesthetic should be performed in most cases as this not only provides immediate and long lasting relief, but it also decreases the requirement for narcotic analgesics once the anesthetic effect has dissipated. A supraperiosteal injection should not be performed if the abscess has extended through the gingival tissue and is present near the injection site.

DISEASE OF THE PERIODONTIUM

Periodontal disease is also a very common disease and affects practically all adults to some degree. Periodontal disease refers to infection of the attachment apparatus of the teeth: the gingiva, the periodontal ligament, and the alveolar bone. Unlike pulpal disease, periodontal disease is not usually symptomatic and, therefore, rarely is a primary reason to come to the ED. *Gingivitis* is an inflammation of the gingiva caused by bacterial plaque. In advanced disease the gingiva becomes red and inflamed and tends to bleed easily. With chronic periodontal disease, an abscess can form when organisms become trapped in the periodontal pocket. The purulent material usually escapes through the gingival sulcus; however, occasionally it invades the supporting tissues, the alveolar bone, and the periodontal ligament (periodontitis). Periodontal abscesses that are not draining spontaneously through the sulcus can be drained in the ED. Saline rinses are encouraged to promote drainage. Antibiotics should be reserved for severe cases or for abscesses that cannot be drained. If it is uncertain whether the abscess is from the pulp or the periodontium, antibiotics should be prescribed even if the abscess is drained. [10] [14]

Pericoronitis is a localized inflammation that occurs when gingiva overlying erupting teeth becomes traumatized and inflamed. Third molars are especially susceptible; however, any tooth can be affected. The gingiva overlying the crown may entrap bacteria and debris. Subsequent infection may develop. Typical signs of inflammation and infection may develop including erythema, edema, pus, and foul breath. Examination of the overlying gingiva with a tongue blade or finger will elicit tenderness and may produce drainage from the infection underlying the tissue flap. Pain may be moderate to severe and referral to the ear region is common. The localized infection occasionally spreads to deeper spaces such as the pterygomandibular or submasseteric spaces. Clinically, patients with significant spread of their pericoronal infection will present with trismus secondary to irritation of the masseter and pterygoid muscles.

ED treatment of pericoronitis is directed at detecting regional spread to the deeper spaces. Trismus or other systemic signs of advanced infection require IV antibiotics and urgent consultation for drainage procedures that usually require extraction of the offending tooth. If pericoronal infection is localized, local or nerve block anesthesia is followed by removal of submucosal debris. Saline rinses and oral antibiotics are prescribed with dental follow-up in 24 to 48 hours.

DRAINAGE OF DENTOALVEOLAR INFECTIONS

The important determination for the emergency clinician to make is whether or not the odontogenic infection is localized, confined, and easily accessible or whether it is complex and involves several potential spaces. Likewise, the patient must not appear toxic or exhibit any signs of airway compromise or trismus. Patients not meeting these criteria require specialist referral.

Several anesthetic techniques can make the drainage process more comfortable. Topical anesthetics work well, but the best performing of these agents are often not present in the ED. Benzocaine 20% gel or lidocaine 5% gel generally provide good topical anesthesia. Application of these to the mucosa before injection of the local anesthetic decreases the pain of injection. After application of the topical anesthetic, local anesthetic with a vasoconstrictor should be infiltrated slowly until the tissue blanches. Either a short-acting anesthetic (2% lidocaine) or a longer-acting anesthetic (0.5% bupivacaine) may be used depending upon the clinical circumstances. Regional or dental blocks may be performed instead of local infiltration if needle placement will not track already infected tissues into healthy areas. Otherwise, local infiltration over the site of the abscess should be considered. Instruments necessary for drainage of dentoalveolar abscesses are those usually found on a standard incision and drainage tray and include hemostats, scalpel (#15 or #11), packing material (¼ in. gauze), and a fenestrated penrose drain (Fig. 66-26).

Intraoral Technique

Intraoral abscesses don't routinely require any antiseptic mucosa preparation prior to drainage. After anesthetizing the

Figure 66-26 Equipment for incision and drainage of dental infection. From left to right on lower row. Cotton-tipped applicators, dental (aspirating) syringe with local anesthesia, topical anesthetic and 2 × 2 gauze, scalpel with No. 11 blade, hemostat, iris scissors, gauze (Nu-gauze) packing, and needle holder.

region, a small incision (0.5–1.0 cm) is made over the area of fluctuance, keeping the point of the blade toward the alveolar bone. The hemostat is then used to bluntly dissect the abscess and break up any loculations. Cultures are not necessary unless the patient is immunocompromised, etc. The wound should then be irrigated profusely with normal saline. If the wound is large enough to place a drain or gauze, one end should be tacked to the mucosa with a silk suture to prevent aspiration. Discharge instructions include hourly salt water rinses and follow-up in 24 to 48 hours by the dentist or oral surgeon to remove the drain and provide continued management. The source of the abscess is not always known to the emergency clinician and, therefore, antibiotics are usually prescribed (Fig. 66-27).

Extraoral Technique

Most simple dental infections can be drained intraorally, but occasionally, an abscess may spread to the face and require drainage through the skin. It is important to realize that most dental infections should be drained through the mouth, if possible, as any extraoral drainage will cause some scarring. Abscesses on the face, which should be drained in the ED, are usually very localized and fluctuant and have not spread to any of the deep spaces of the head or neck. It is also important that any incisions made on the face are not in direct proximity to important structures such as the facial nerve or the parotid gland and duct.

The patient is prepared in the usual manner for incision and drainage with a skin scrub and povidone-iodine (Betadine) preparation. The face is draped and the skin is infiltrated with local anesthetic containing a vasoconstrictor (1% or 2% lidocaine with epinephrine). Any incision should be made in the healthy skin slightly below the area of fluctuance and should follow the dynamic skin tension lines. After the incision is made, blunt dissection is made in a direction toward the most fluctuant area until adequate drainage is achieved. The abscess cavity is then profusely irrigated and a drain or packing is placed. The abscess cavity should not be packed tightly, but just enough to keep the incision open and draining. Unlike intraoral drainage, suturing the drain in place is not necessary (Fig. 66-28). The patient should be instructed to take antibiotics and follow up with the oral surgeon in 24 to 48 hours for packing change and definitive management.

Not all infections about the mouth are the result of a simple dental infection. Osteomyelitis of the mandible, various tumors, and other exotic diseases can present as a dental infection.

DEEP-SPACE INFECTIONS OF THE HEAD AND NECK

It is not unusual for odontogenic infections to spread into the various potential spaces of the face and neck. Presenting signs and symptoms consist of fever, chills, pain, difficulty with speech or swallowing and trismus. Although infections of certain teeth usually spread to particular contiguous spaces, the rapid spread of these infections often makes localizing the exact space involved difficult. Any space including the buccal, temporal, submasseteric, sublingual, submandibular, parapharyngeal, and others, may be involved (Fig. 66-30 and Fig. 66-31).

Maxillary extension of periapical abscesses can spread into the infraorbital space and, subsequently, to the cavernous sinus through the ophthalmic veins, resulting in cavernous sinus thrombosis. Cavernous sinus involvement is associated with periorbital cellulitis as well as meningeal signs or a decreased level of consciousness. Periapical infections of the anterior mandibular teeth often spread to the buccinator space or the sublingual space, while those of the mandibular molars spread into the submandibular space. The submandibular space connects with the sublingual space. Infection involving both of these spaces is known as Ludwig's angina, which can be life-threatening (Fig. 66-32). As infection progresses, the submandibular, submental, and sublingual spaces all become edematous and there may be elevation of the tongue and the soft tissues of the mouth. The soft tissues of the posterior

Figure 66-27 *A,* This patient presented with facial swelling up to the right eye. She had minor tooth pain but mostly complained of an ache in the face. X-rays revealed maxillary sinusitis with an air-fluid level. *B,* Intraoral examination revealed a pea-sized pointing abscess at the base of an upper tooth, the cause of sinusitis. *C,* Following local anesthesia, a blade incised the abscess, with drainage of copious pus. *D,* A hemostat was inserted into the abscess cavity to assure drainage, and a small piece of gauze was placed into the cavity. IV antibiotics (clindamycin) followed by oral antibiotics were given, the patient saw her dentist the next day, and plans to extract the tooth were made. She recovered fully.

pharynx can also become involved. Securing the airway becomes of paramount importance. The suprahyoid region of the neck appears tense and indurated, and landmarks may be obscured.

The management of complicated odontogenic head and neck infections centers on airway management, surgical drainage, and antibiotics. If there is uncertainty as to whether the deep spaces are involved, CT scanning can delineate the extension of the infectious process. Airway intervention should be performed early if there is any question of compromise, and tracheostomy may need to be considered. Surgical consultation with an oral maxillofacial surgeon is mandatory as drainage and removal of necrotic tissue may be necessary. Antibiotics should be administered to slow down the spread of the infection and decrease hematogenous dissemination. The bacteria involved are typically a streptococcus/staphylococcus combination but a mixed aerobic/anaerobic infection is also possible. There has recently been an emergence of ß-lactamase-producing organisms in upwards of 40% of isolates from odontogenic neck abscesses. [14] Antimicrobials of choice in complicated odontogenic infections are usually the penicillins. The expanded spectrum penicillins (Amp/Sulb, Tic/Clav, Pip/Tazo) are effective against ß-lactamase-producing bacteria and also cover the anaerobe B. fragilis. Clindamycin is an effective choice when patients are allergic to penicillin. It should be used in combination with a cephalosporin, such as cefotetan, or cefoxitin, in order to cover recently emerging resistant organisms. It is important to realize that in many of these infections, antibiotics are adjunctive therapy and not a substitute for surgical intervention.

DENTAL MATERIALS

As a general rule, EDs should have a well-stocked supply of basic dental materials. Many commercially available products can be used interchangeably with many of the items listed below. These can often be kept with the ENT cart or in another appropriate location. The following is a basic list to consider:

1. Packing gauze
2. Dental roll gauze
3. Calcium hydroxide paste, glass ionomer cement, or zinc oxide cement
4. Dry Socket Paste or eugenol
5. Topical anesthetic gel (20% benzocaine or 5% lidocaine)

6. Topical bactericidal intraoral solution (Ora-5)
7. Periodontal paste (Coe-pak) or self-cure composite
8. Bupivacaine cartridges with epinephrine
9. Save-A-Tooth Tooth Preservation System or fresh milk
10. Zinc oxide/eugenol temporary cement (Temrex)
11. Ringed injection syringe
12. Stainless steel spatula and mixing pads
13. Oral surgery tray with arch bars and ligature wires
14. Tongue blades and cotton-tipped applicators

Figure 66-28 *A,* Most dental infections associated with facial swelling should be drained intraorally. Illustration of a facial abscess that points extraorally. *B through F,* Technique of cutaneous drainage in a second patient. *B,* Anesthetic infiltrated below abscessed area. *C,* Incision. *D,* Drainage with blunt dissection. *E,* Gauze packing. *F,* Gauze sutured in place. This step may be omitted if desired. *G and H,* Osteomyelitis of the jaw presenting as a dental problem. This patient had a toothache for weeks that had turned into an abscess pointing on the side of the face. She had been to several emergency departments and was given prescriptions for antibiotics. No history of trauma was forthcoming. *G,* An obvious pointing abscess over the mandible. *H,* A panorex x-ray revealed an old fractured mandible with osteomyelitis draining into the soft tissues.

Figure 66-29 *A*, For persistent bleeding of a tongue, mucosa, or dental extraction site, topical thrombin can be sprayed onto gelfoam. *B*, A tongue laceration like this will heal well without sutures once bleeding is controlled. Topical thrombin may be an option if hemostasis is problematic.

MANDIBULAR DISLOCATION

In acute dislocation of the mandible, the condyle moves too far anteriorly in relation to the eminence and becomes locked. Subsequent muscular trismus prevents the condyle from moving back into the temporal fossa. Spasm of the external pterygoid, masseter, and internal pterygoid muscles, as well as the associated edema, results in extreme discomfort and anxiety for the patient. It is difficult for the patient to verbalize a complaint because he or she cannot close the mouth. Predisposing factors include anatomic disharmonies between the fossa and the interior articular eminence, weakness of the capsule forming the temporomandibular ligaments, and torn ligaments. Dislocation is likely to occur during maximum opening, such as during yawning, laughing, or "popping" of the mandible in an open position. Although the TMJ is a double joint, dislocation may occur bilaterally or unilaterally. The jaw may be locked open symmetrically or may deviate to the side opposite the side of dislocation. Palpation of the TMJs may reveal them to be anterior to the articular eminence. In the face of trauma, radiographs should be taken to rule out

Figure 66-32 *A,* Ludwig angina may initially appear benign. *B,* In Ludwig angina, rapid progression may compromise the airway in a few hours.

fracture, since the clinical picture of both of these conditions is similar and similar occlusal disturbances are produced. Radiographs may not be necessary on an emergency basis if there is no history of trauma or if the condition is recurrent. [14]

Technique for Reduction

If one appreciates the anatomy of the TMJ, the proper sequence for manual manipulation to reduce the dislocation is clear. Following dislocation, the powerful masseter muscles may be in tremendous spasm. For a smooth reduction, it is mandatory to relieve the patient's pain and muscle spasm with slow IV injection of a benzodiazepine, with or without an opioid (see Chapter 35). Some clinicians advocate direct injection of the condylar area with a local anesthetic. When the patient is sufficiently relaxed and analgesia is obtained, the physician faces the patient and grasps the mandible with both hands—one on each side—with the thumbs (which have been wrapped with gauze alone or tongue blades wrapped in gauze) facing the occlusal surfaces of the posterior teeth. The fingertips are placed around the interior border of the mandible in the region of the angles. Some prefer to have the patient seated in a chair or on the floor with the patient's back against the wall. Alternatively, the patient may be in a recumbent position. Downward pressure is slowly and steadily applied to free the condyles from their anterior position to the eminence. The chin is then pressed backward after the jaw has been forced downward, and the mouth is closed while the condyle returns to its position in the fossa. In cases of severe muscle spasm, the jaw may snap back quickly. Therefore, protection of the thumbs is essential.

Following the procedure, the patient should be instructed to stay on a soft diet for 1 week, to avoid wide opening of the mandible, and to take analgesics and muscle relaxants. Local heat may also provide relief. Chronic dislocations or patients who suffer acute recurrences may be helped by a bandage applied around the head holding the mandible to the maxilla for 2 weeks to prevent maximum opening, but this is rarely used. Very severe cases may require intermaxillary wiring and fixation for complete control with the use of Erich arch bars (described in Dental Alveolar Trauma). Patients who have suffered dislocation of the TMJ should be referred to an oral or maxillofacial surgeon for follow-up, since chronic dislocation may require a surgical alteration of the eminence for relief.

CONCLUSION

Dental emergencies presenting to the ED are rarely life-threatening; however, they are often very painful and of great cosmetic concern to patients. They are also common. Many emergencies covered in this chapter are definitively best handled by specialists in the dental or maxillofacial field, but often these patients present to the ED first. The emergency clinician must have a basic working knowledge of the stomatognathic anatomy and be prepared to intervene in order to save a tooth, repair soft tissue, treat severe infection, and relieve pain. The procedures discussed in this chapter will avail themselves to every emergency clinician who practices clinical medicine. The medications, medicaments, glues, and pastes will improve over time and ED personnel should feel free to discuss these advances with their dental colleagues. Likewise, the treatment of any dental or maxillofacial emergency should involve specialty consultation when the emergency is beyond the scope of the emergency provider's practice. Despite the fact that many patients present to the ED with dental problems or postsurgical complications, it is not standard for emergency clinicians to be familiar with complex dental problems.

Acknowledgments

The contributions of Robert H. Benko, DDS, to this material are greatly appreciated. The editors and author also wish to acknowledge the contributions of James T. Amsterdam to this chapter in previous editions.

Section XIII - Special Procedures

Chapter 67 - Procedures Pertaining to Hypothermia

Timothy Erickson
Heather Prendergast

With an increase in outdoor activities, changing weather patterns, and the growing epidemic of homelessness in our country, issues pertaining to hypothermia remain in the forefront. Hypothermia not only is a common diagnosis in rural areas, but also has become even more commonplace in urban centers across the nation secondary to inadequate housing or lack of preparation for cold weather changes. [1] Every year many recreational and elite athletes participate in outdoor sporting events. The higher the environmental stress, the greater the potential for performance failure and development of hypothermia. [2] Optimal treatment for hypothermia remains controversial. It is, however, a well-accepted practice that resuscitation of these individuals is carried out for extended periods of time. The medical literature contains numerous anecdotal reports of profoundly hypothermic individuals who are successfully resuscitated and are neurologically intact at the time of discharge. [3] [4] [5] Despite these spectacular reports of survival, there continues to be both morbidity and mortality from hypothermia. The annual mortality rate is estimated at 757 lives.[6]

This chapter critically reviews approaches and procedures appropriate to the management of several categories of hypothermic patients. The recommendations combine treatment efficacy with safety. Before describing procedures and making recommendations, essential terms are defined and the pathophysiology of hypothermia is briefly reviewed.

DEFINITIONS

Accidental hypothermia (AH) has been defined as an unintentionally induced decrease in the core (vital organ) temperature below 35°C (95°F). [3] [6] Victims of hypothermia can be separated into the following categories: *mild hypothermia*, 35° to 32°C (95.0°–90.0°F); *moderate hypothermia*, <32° to 30°C (<90.0°–86.0°F); and *severe hypothermia*, <30°C (<86.0°F). Other factors that may be useful in separating groups of patients with AH include the presence of underlying illness, [7] [8] [9] [10] altered neurologic state on arrival, hypotension, and the need for prehospital cardiopulmonary resuscitation (CPR). A hypothermia outcome score that incorporates some of these factors and may permit comparison of outcomes for patient groups treated with different modalities has been developed. [11]

Risk factors for the development of AH include: burn injuries, extremes of age, ethanol intoxication, dehydration, major psychiatric illness, trauma, use of intoxicants, significant blood loss, sleep deprivation, malnutrition, and concomitant medical illnesses. [12] [13] Risk factors for development of indoor hypothermia include: advanced age, coexisting medical conditions, being alone at time of illness, being found on the floor, and abnormal temperature perception or regulation. [9] [14]

Because signs and symptoms may be vague and nonspecific, mild to moderate hypothermia may easily be overlooked in the emergency department (ED). A common error is failure to routinely obtain an accurate core temperature on all patients at risk. Often the diagnosis is delayed because of false reliance on standard oral temperatures. Presenting symptoms such as confusion in the elderly and combativeness in the intoxicated patient may not initially be recognized as symptoms of hypothermia. *Hypothermic patients frequently will not feel cold or shiver.* This is particular true in the elderly populations who have impaired thermoregulatory responses because of their advanced age. [15] [16] Paradoxical undressing, a cold-induced psychiatric dysfunction, has been described in confused patients who develop the sensation of heat at lowered body temperatures as a result of constricted blood vessels near the body surface, which suddenly dilate. In many cases, these patients are mislabeled as psychotic, leading to further delays in appropriate treatment. [17]

CORE TEMPERATURE MEASUREMENT

Because of the nonspecific nature of symptoms of hypothermia, an accurate temperature assessment is a necessity in any clinical setting where the diagnosis may be suspected. It is of paramount importance not only for confirmation of the diagnosis but also for guidance in further diagnostic and therapeutic decisions. Any thermometer that does not record temperatures in the hypothermic range is *inappropriate* for evaluating significant hypothermia. Standard glass/mercury thermometers generally cannot record temperatures of <34°C (<93.2°F), although some models are available to record temperatures as low as 24°C (75.2°F) (Dynamed, Inc, Carlsbad, CA). An electronic probe and accompanying calibrated thermometer (Fig. 67-1) is recommended when monitoring this vital sign.

Figure 67-1 Electric thermometer (without probe). This is model 43TA with Fahrenheit and Celsius scales. Infrared tympanic membrane thermometers are acceptable alternatives, but the rectal probe has the advantage of providing a continuous readout. *(Image courtesy of Yellow Springs Instrument Company, Yellow Springs, OH.)*

Core temperature is traditionally estimated with a rectal probe. The rectal temperature, however, often lags behind the core temperature because of large gradients within the body.[18] Esophageal probes may be used, although they may be affected by warm humidified air therapy, which is commonly used in severe hypothermia. Other possible sites for temperature measurement include the tympanic membrane, nasopharyngeal passage, and the urinary bladder. [18] [19] [20] Fresh urine temperature can closely approximate core temperature.[21] "Deep forehead" temperatures measured with a Coretemp thermometer (Teramo, Tokyo, Japan) have also demonstrated excellent accuracy and approximation of core temperatures.[22] For continuous monitoring purposes, rectal or bladder probes are preferred. Infrared tympanic temperatures have demonstrated excellent correlation with core temperatures. Studies show that although easier to use and faster, infrared tympanic temperatures can be inaccurate with extremes of temperature by underestimating higher temperatures and overestimating lower temperatures.[23] When a rectal probe is used, it should be inserted at least 10 cm beyond the anal sphincter and its position frequently verified. One should remember that temperature gradients exist in the human body and consistency of monitoring at one or more sites is mandatory. A chart and formula that convert centigrade to Fahrenheit temperatures will assist the clinician in assessing the severity of hypothermia (Fig. 67-2).

PATHOPHYSIOLOGY

AH results from the failure of the body's thermoregulatory responses to generate enough heat to compensate for heat losses. These thermoregulatory responses include shivering, tachycardia, tachypnea, increased gluconeogenesis, peripheral vasoconstriction, and shunting of blood to central organs. [24] As

Figure 67-2 Temperature conversion scale. To change Celsius (centigrade) to Fahrenheit, multiply the Celsius temperature by 9/5 and add 32. To change Fahrenheit to Celsius, subtract 32 from the Fahrenheit number and multiply by 5/9.

the core temperature drops despite these compensatory mechanisms, the patient becomes poikilothermic and cools to the ambient temperature.

Four methods of heat loss affect the body: radiation, conduction, convection, and evaporation. Radiation involves the transfer of heat from a warmer body to a cooler environment and accounts for approximately 60% of heat loss in a normothermic individual. Conduction refers to heat loss from direct contact with a cooler surface. These losses are most profound with immersion hypothermia. Convection occurs when cool air currents pass by the body and accounts for 15% of heat loss, especially with a wind chill factor. Evaporation refers to significant heat loss through sweating and insensible water losses. [16] [24] In hypothermia, the enzymatic rate of metabolism itself decreases two to three times with each 10°C (18°F) drop and cerebral blood flow decreases 6 to 7% per 1°C (1.8°F) drop.

Signs and symptoms of hypothermia vary according to the core temperature. The overall functioning of all organ systems are impaired by the cold. [25] The greatest effects, however, are seen with the cardiovascular, neurologic, and respiratory systems (Table 67-1). As the core body temperature drops below 33°C (91.4°F), the patient becomes confused and ataxic.[26] The initiation of involuntary motor activity (shivering) prevents the reduction in core temperature. [27] Shivering thermogenesis in skeletal muscle operates on acute cold stress. In the malnourished patient, the mechanism may be rendered ineffective secondary to reduced muscle mass. [28] Shivering stops at about 32°C (89.6°F); however, shivering artifact on an electrocardiogram has been associated with increased survival in severe hypothermia. [29] Atrial fibrillation occurs frequently as the temperature continues to drop and the patient loses consciousness. A J wave in the electrocardiogram often appears before ventricular fibrillation (Fig. 67-3). Although classically considered pathognomonic for hypothermia, the J or "Osborne" wave has no prognostic or predictive value in cases of hypothermia. A recent study found that Osborne waves occurred in 36% of AH survivors and in 38% of nonsurvivors. [29] [30] Ventricular fibrillation may occur below 29°C (84.2°F) and becomes common as the core drops to 25°C (77°F).[31] The electroencephalogram flattens at 19° to 20°C (66.2°F–68°F), [32] and asystole commonly occurs at 18°C (64.4°F) but has been seen at higher temperatures. Initial core temperature does not necessarily correlate with vital outcome. [33] The lowest recorded temperature for a survivor of AH is 9.0°C (43.7°F). [24]

INITIAL EVALUATION AND STABILIZATION OF THE HYPOTHERMIC PATIENT

The treatment of hypothermia can be divided into prehospital care and ED management.

Prehospital Care

In the prehospital setting, the primary focus is removal of the individual from the current environment to prevent further decreases in core temperature. Studies have shown that oral temperatures are sufficiently accurate for field use. [34] In addition, infrared tympanic thermometers may not be reliable in the prehospital setting. [35] Special care must be taken in handling these patients, as aggressive measures can inadvertently trigger

TABLE 67-1 -- Signs and Symptoms of Hypothermia

Core Temperature	Cardiovascular System	Respiratory System	Central Nervous System
34–35°C	Tachycardia	Tachypnea	Lethargy
	Increased afterload	Increased minute ventilation	Mild confusion
	Increased systemic blood pressure		Loss of fine motor coordination
30–34°C	Progressive bradycardia	Increased bronchial secretions	Delirium
	Decreased cardiac output	Diminished gag reflex	Slowed reflexes
	Hypotension	Depressed cough response	Muscle rigidity
	Lengthening of cardiac conduction		Abnormal EEG
	Atrial/ventricular dysrhythmias		
<30°C	Spontaneous ventricular fibrillation	Respiratory rate decreased to 5 breaths/minute	Aflexia
	Osborne waves at 25°C		Coma
			Fixed pupils
			Rigidity
			EEG silent at 19°C

cardiac dysrhythmias. Prolonged transport times should be avoided. [36] [37] Patients should be wrapped in dry blankets after removal of wet clothing. Studies have shown that for mild hypothermia, resistive heating (e.g., warming blankets) can be safely used in the prehospital setting. Resistive heating augments thermal comfort, increases core temperature by approximately 0.8°C/hr, and reduces patient pain and anxiety during transport. [34] In one study, resistive heating more than doubled the rewarming rate compared to passive insulation without producing an afterdrop. [38]

Potential traumatic injuries to the spine or extremities should be immobilized before transport. Continuous attention to airway maintenance should be a priority. Fluid resuscitation can be initiated with intravenous crystalloid, preferably with D5NS.

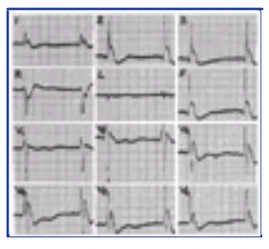

Figure 67-3 In severe hypothermia, the electrocardiogram (ECG) exhibits marked elevation of the J deflection, so-called Osborne waves. The height of the J wave is proportionate to the degree of hypothermia, and this finding is usually most marked in the midprecordial leads. The ECG is of a patient with sinus bradycardia, but approximately half of patients with a temperature below 32°C (89.6°F) develop slow atrial fibrillation, a rhythm that usually converts spontaneously with rewarming. *(From Marriott HJ: Practical Electrocardiology, 8th ed. Baltimore, Williams & Wilkins, 1988.)*

Most hypothermic patients are *dehydrated* because fluid intake is reduced and cold causes a diuresis. Theoretically, it is best to avoid using lactated Ringer's solution because of the decreased metabolism of lactate by cold-induced hepatic dysfunction. If possible, warmed intravenous fluids can be administered to patients and are generally well tolerated. [39] [40] Flameless heaters currently used by military medical units provide easy field-expedient means of warming fluids in the prehospital setting.[41] Unresponsive patients should be intubated, although there is no universal agreement on when to intubate a hypothermic patient who has detectable vital signs. Pulse oximetry is usually not helpful since vasoconstriction limits blood flow to the periphery and readings may be inaccurate or not possible.

Some authors suggest that pulseless victims with core temperatures below 32°C should be transported with continuous CPR. [39] Other authors believe that it is unnecessary to perform CPR on a patient who has any perfusing cardiac rhythm since it may precipitate ventricular fibrillation. [5] At this juncture there is no universally accepted standard for intubation or CPR in hypothermic patients with detectable vital signs.

Emergency Department Management

Treatment priorities in the ED setting are preventing further decreases in core body temperature; establishing a steady, safe rewarming rate while maintaining the stability of the cardiopulmonary system; and providing sufficient physiologic support. The rate of rewarming and the techniques used depend upon the degree of hypothermia and the severity of the patient's clinical condition (Table 67-2). Inherent in the goals of management of these patients is the anticipation and prevention of complications.

In the pulseless, apneic patient, CPR should be initiated and continued until the core temperature is above 34°C. Profound hypothermia results in coma, hyporeflexia, fixed and dilated pupils, severe bradycardia, and often unobtainable blood pressure. In severe hypothermia, a pulse may not be palpable and blood pressure measurement may require the use of a Doppler device. Electrocardiographic monitoring provides rate and rhythm status. All patients who have more than minimal impairment require frequent determination of their oxygenation, ventilation, and acid-base status by means of arterial blood analysis. All patients should have large-bore IV lines established, if feasible. Maintenance IV fluids should be given routinely. Warming of all IV fluids to 40° to 42°C (104°–107.6°F) is reasonable, but the usual volumes administered will not contribute significant calories of heat. In addition with long standard IV tubing, the heated IV fluids may actually cool to room temperature before entering the patient's IV site.

TABLE 67-2 -- Rewarming Techniques

Core Temperature	Method and Techniques
>32°C	Passive external rewarming (PER)
	• Dry blankets, clothing
	• Heated IV solutions (43°C) D5NS
	• Warm fluids if fully alert
=32°C	Active external rewarming (AER)
	• Heated blankets, heating pads, warm air convection
	• Radiant heat sources
	• Alcohol-circulating blankets
	Active core rewarming (ACR)
	• Peritoneal dialysis
	• Bladder, gastric or colonic lavage with warm fluids (43°C)
	• Heated IV fluids
	• Heated humidified oxygen
	• Thoracic cavity lavage (43°C)
	• Extracorporeal blood rewarming
	• Hemodialysis
	• Ultrasonic and low frequency microwave diathermy
	• Arteriovenous anastomoses rewarming

With a mild to moderate reduction in core temperature, the level of mentation correlates with the severity of the AH, associated illness, or both. Noteworthy exceptions are alcoholics and diabetics who can present in comas at higher core temperatures because of concomitant hypoglycemia. These patients should routinely have bedside glucose measurements performed upon arrival to the ED. There is a high correlation between alcohol consumption and development of hypothermia especially in colder climates. [1] A review of 68 cases of hypothermic deaths in Jefferson County, AL found that a significant number of cases involved middle-aged males who had consumed alcohol. [42] In the 22 cases of AH reviewed by Fitzgerald, [43] all except two patients were alcoholics. The serum glucose level was <50 mg/dL in 41% (nine patients). This study noted glycosuria in two patients, even when low serum glucose values were evident, and described a renal tubular glycosuria in AH. Such glycosuria may worsen or cause hypoglycemia; *hence, glycosuria in AH is no guarantee of an adequate serum glucose concentration*. This supports the routine use of supplemental IV glucose unless a normal serum glucose value can be quickly ensured. Also, IV thiamine (100 mg) and a trial dose of 0.4 to 2 mg IV naloxone (Narcan) may be considered. Although failure to rewarm spontaneously has been noted in victims with hypothyroidism and other endocrine deficiencies, the use of thyroid hormones and corticosteroids is reserved for those patients with suspected thyroid and adrenal insufficiency, respectively.

The thermoregulatory vasoconstriction caused by hypothermia significantly decreases the subcutaneous oxygen tension. [16] A good correlation between the incidence of wound infections and the subcutaneous oxygen tension exists. As core temperatures decrease from 41°C to 26°C, neutrophil function is significantly impaired. [16] Conversely, in animal models, hypothermia appears to decrease leukocyte sequestration within brain parenchyma, offering some resistance to meningitis. [44] Although antibiotics are not routinely indicated in uncomplicated mild hypothermia, some authors advocate the routine empirical initiation of broad-spectrum antibiotic therapy on admission of severely hypothermic patients. No specific standard exists.

MANAGEMENT GUIDELINES

Hypothermia affects virtually every organ system owing to the generalized slowing of the body. Management goals depend upon the severity of hypothermia, but in all cases the primary goal is to increase the core temperature and prevent further losses. In the patient with mild hypothermia, a conservative approach to rewarming is generally advocated. Overly aggressive methods may be more harmful to the patient by causing a worsening hypotension, a paradoxical decrease in core temperature, and cardiac dysrhythmias. Other complications may include bleeding [16] and infection of surgical incisions. The optimal rewarming rate remains unclear and varies with each case. Standard rewarming rates are a 0.5°C/hr to 2.0°C/hr (0.9°F/hr–3.6°F/hr) rise in temperature *in the otherwise stable patient* (Table 67-3). Invasive therapy should be carefully considered and individualized to the severity of the hypothermia and the condition of the patient, and one should avoid the temptation to *overtreat and overmonitor with invasive techniques the otherwise stable hypothermic patient*.

TABLE 67-3 -- Warming Rates (°C/hr)

	Passive External	Active External	Inhalation of Warm Air	Peritoneal Lavage	Colon/Gastric/Bladder Lavage
1st hr	1.4	1.5	1.5	1.5	1.3
2nd hr	1.4	2.4	2.0	2.5	1.7
3rd hr	1.8	2.0	1.9	3.2	1.8

From Danzl D, Pozos RS: Multicenter hypothermia study. Ann Emerg Med 16:1042, 1987.

The patient with severe underlying problems such as hypoglycemia, hyperglycemia, sepsis, adrenal crisis, drug overdose, or hypothyroidism should be treated appropriately for those conditions as well as aggressively for hypothermia because long-term outcome may depend more on treatment of the underlying illness than the hypothermia.[45]

Passive External Rewarming

The cornerstone of effectiveness for this method relies on the body's ability to restore normal body temperature through its own mechanisms for heat production. Initial management begins with the removal of wet clothing followed by placement of blankets. Warm fluids containing glucose may be given orally to the patient who is fully alert. For patients with mild AH, removal of wet clothing followed by *passive external rewarming* with blankets generally suffices (Fig. 67-4). The technique is simple; however, the patient must be capable of generating enough body heat for this method to be successful. Patients who cannot shiver, patients who are hypotensive, or patients who are intoxicated or malnourished may not have this capability. Survival rates using passive external rewarming have ranged from 55–100%.[46] [47] [48]

Figure 67-4 Passive external rewarming features. Further heat loss must be stopped through insulation and environmental manipulation. Damp clothing is removed. Dry, warmed blankets are applied. Warmed intravenous fluids are given to counteract the cold-induced diuresis. Internal heat generation is required for rewarming. Rewarming rates are relatively slow. Aggressive intervention with drugs and invasive monitoring may be more harmful than helpful in the otherwise stable hypothermic patient. Note the absence of tracheal intubation, central lines, and Foley catheter in the mild to moderately hypothermic patient.

For patients in the moderate or severe category of hypothermia, a more aggressive approach may be warranted. The options available are active external rewarming and active core rewarming. Active core rewarming techniques can be further divided into less invasive and more invasive techniques. Generally, the aggressiveness of therapy depends more on the patient's underlying health, hemodynamic status, and response to initial therapy than the initial temperature.

Active External Rewarming

The application of heat to the skin of the hypothermic patient has been termed *active external rewarming*.

Indications

Although there is some suggestion that active external rewarming of profoundly hypothermic patients by immersion may be associated with an increase in mortality over other treatments,[11] [49] more recent studies have suggested that this technique is highly effective for mild hypothermia. [26] [50] It should be used selectively and limited to the trunk. Other forms of active external rewarming are increasingly used in the ED as adjunctive care of moderately hypothermic, otherwise healthy individuals. Vasoconstriction limits the ability to increase core temperature using techniques that primarily warm the skin. [51]

Active external rewarming is most beneficial in cases where heat supplied by the external source is greater than the loss of rewarming heat incurred by the cessation of shivering. Finally, in settings where more aggressive warming techniques are precluded owing to lack of equipment or personnel, active external rewarming with body-to-body contact may be the only option available to the rescuer. However, the rewarming contribution of body-to-body contact appears limited. [52]

Equipment

Traditionally, immersion therapy has used a heated (40° to 42°C) water tank of the type present in most burn units. Generally, the hypothermic patient is immersed entirely except for the extremities and head (Fig. 67-5), although immersion of the extremities may hasten rewarming.[18] [53] [54] Alternatively, conduction warming is performed using warm water-filled heat exchange blankets (e.g., Blanketrol; Cincinnati Sub-Zero Products, Cincinnati, OH). Intraoperative studies have demonstrated excellent results.[53] A forced warm air convection system (Bair Hugger; Augustine Medical, Eden Prairie, MN; Snuggle Warm Convective Warming System; Sins Level 1, Inc., Rockland, MA) has been used for postsurgical rewarming.[53] [55] This approach also has been used successfully for ED-based AH therapy. Warm air convection rewarming permits continued monitoring in the ED and is better tolerated than immersion due to the less rapid development of vasodilation in peripheral tissues.

Technique

Because profound fluid shifts can occur with conduction warming, the patient should receive supplemental IV fluid that has been warmed to 40°C (Hotline Fluid Warmer; Sims Level 1, Inc., Rockland, MA), given at a rate sufficient to generate a urinary output of 0.5 to 1.0 mL/kg per hour. An initial fluid bolus of 500 mL of 5% dextrose and normal saline may be beneficial. Note that blood pressure is not an accurate way to gauge fluid resuscitation because serious hypothermia is always accompanied by "physiologic" hypotension. Because

Figure 67-5 Active external rewarming features. A heat source warms the skin. Traditionally, warm water immersion has been used (as shown). Rates of rewarming are very rapid in some series. There have been suggestions of increased mortality with this method when used for patients with moderate to severe hypothermia, but certain conditions may warrant its use. A major drawback is the inability to closely monitor the patient undergoing immersion. Use of warm air convection (e.g., use of Bair-Hugger device, Eden Prairie, MN), however, allows rewarming in the ED with full patient monitoring and less rapid vasodilation during rewarming.

patients requiring mechanical ventilation have rarely been subjected to tank immersion, it cannot be recommended for hypothermic patients who require intubation. Rewarming rates ranging from 0.9° to 8.8°C (1.6° to 15.8°F) per hour have been reported with immersion therapy. [4] [56]

A heat exchange blanket allows the patient to receive other treatments that may be difficult or impossible to carry out in a tub, such as defibrillation, CPR, or more invasive warming techniques. With this latter form of conduction heating, the heating blanket and overlying cloth sheet is placed under the patient. The blanket temperature is set at 40° to 42°C, and the measures described under passive rewarming techniques (see Fig. 67-4) are initiated.

Forced-air rewarming (convection) uses a blanket cradle to create an environment through which heated air is blown. Access to the patient is quite good with this system in that the overlying blankets can be raised temporarily to evaluate the patient or perform procedures. One study found this approach superior to a heating blanket.[57] Experience with mild immersion-induced hypothermia in volunteers suggests that the forced-air technique warms at a rate comparable to vigorous shivering, but with less metabolic stress and less afterdrop. [58]

Arteriovenous Anastomoses Rewarming

Ateriovenous ananstomoses (AVA) rewarming involves the immersion of the distal extremities (hand, forearms, feet, and lower legs). Advantages include rapid rewarming rates. A study in healthy volunteers using AVR immersion in temperatures of 45°C and 42°C, respectively, demonstrated rewarming rates of 9.9°C/hr (±3.2°C/hr) for the former and rewarming rates of 6.1°C/hr (±1.2° C/hr) for the latter. There was also a decrease in postcooling afterdrop. AVR is well tolerated by patients because of the rapid rise in core temperature and the shortened period of shivering. [18]

Complications

There is concern that surface warming with accompanying vasodilation may produce a relative hypovolemia in the hypothermic patient. Other complications described with the active external rewarming method include core temperature afterdrop and rewarming acidosis. In core temperature afterdrop, colder peripheral blood is transported to the warmer core organs, further reducing the core temperature. In rewarming acidosis, there is a return of colder blood and lactic acid to the core organs, worsening the acidosis. To limit these complications in moderate hypothermia, some authors advocate using active external warming only after active internal techniques have been initiated. [24]

Importantly, CPR and other advanced cardiac therapy and monitoring are impossible with immersion rewarming. Until studied further, active external rewarming should only be considered in a clinically monitored setting for mildly hypothermic patients who can protect their airways. When using a heating device, the potential for burns to the areas in greatest contact with the heating source should also be monitored.

Active Core Rewarming

There is evidence that active core rewarming may decrease mortality from *severe* hypothermia exposure compared with other techniques. In the face of circulatory failure, often the best chance of survival is treatment with extracorpeal circulation (ECC) and warming of the blood. [59] Several methods have been described, including the use of warm humidified air through an endotracheal tube or mask (Fig. 67-6), peritoneal lavage, gastric or bladder lavage with warm fluid, thoracic tube lavage, cardiopulmonary bypass (Fig. 67-7), arteriovenous anastomoses, peripheral vascular extracorporeal warming, hemodialysis, and thoracotomy with mediastinal lavage (Fig. 67-8). These techniques transfer heat actively to the body core, achieving varying rewarming rates. The specific techniques as well as some of the advantages and disadvantages for each procedure follow.

Figure 67-6 Active core rewarming methods. Inhalation of warm, humidified air or oxygen causes gradual core rewarming and should be a *mainstay of rewarming therapy*. This method can be combined with other methods such as heated intravenous fluids. Peritoneal lavage is a more rapid method of core rewarming that requires placement of one or more intraperitoneal catheters. Other techniques are described in the text.

Figure 67-7 Active core rewarming cardiac bypass features. Bypass technology and a surgical team are needed. The rewarming rates are rapid. This method is useful in a patient with cardiac arrest; the technique is invasive, expensive, and technically difficult.

Emergency Warming of Saline in a Microwave

Under ideal circumstances saline is kept warm in a standard warming device. When large amounts of saline are required for such procedures as peritoneal lavage, saline bags may be rapidly warmed in a standard microwave oven.[59A] Although devices will vary, a 650-watt microwave has been demonstrated to warm a liter of room temperature nondextrose containing saline from 21.1°C to 38.3°C (70°F to 101°F) in 120 seconds on the high setting. A suggested protocol is midcycle (i.e., after 60 seconds) interruption with agitation, and end-cycle agitation before infusion.

Inhalation of Heated Humidified O_2 or Air

The use of warm humidified oxygen to treat hypothermia was described by Lloyd in 1972. [60] Average rates of rewarming of 1°C/hr via mask and 1.5°C to 2.0°C/hr via endotracheal tube with heated aerosol at 40°C can be obtained. [4] [26] Faster rewarming rates may be accomplished using a maximum safe aerosol temperature of 45°C (113°F).

Figure 67-8 Active core rewarming open thoracic lavage features. The heart is warmed directly. This method requires surgical backup and is relatively invasive. The rewarming rates are rapid. An alternative that is more practical for the ED is pleural rewarming repeatedly using 200 to 300 mL warmed saline intermittently placed, then withdrawn through a chest tube (see text).

Core rewarming with the technique occurs through the following mechanisms. The warmed alveolar blood returns to the heart, thereby warming the myocardium. The warmed humidified air delivered to the alveoli also warms contiguous structures in the mediastinum by conduction. Finally, warming the inhaled air or oxygen eliminates a major source of heat loss.

Indications and contraindications.

The use of heated humidified air or oxygen is a simple technique that *should be used routinely*, either by itself or in combination with other methods, in all patients with hypothermia, regardless of severity. If the correct equipment is available, it can be used in the field as well as the hospital. [36] [37] However, one must address the risk of burns during inhalation of warm air in the field environment. [61] Mouth-to-tube ventilation in the intubated hypothermic prehospital patient has the theoretical advantage of providing warm humidified air without special equipment. The ventilating rescuer can inhale oxygen before expiring into the patient's endotracheal tube to provide air with increased oxygen content. There are no contraindications for or reported complications from the use of warm humidified air for hypothermia, and there is no afterdrop. [62]

Technique.

A heated cascade nebulizer can be used with a mask for patients with spontaneous respirations or with a volume ventilator for intubated patients. It is important to monitor the inspired air to maintain a temperature of approximately 45°C. [63] Temperatures higher than 50°C (122°F) may burn the mucosa, and temperatures lower than 45°C (113°F) do not deliver maximum heat. The air or oxygen must be humidified, and the heater module may need modification because many units have feedback mechanisms that shut off at a given temperature. As a practical issue, it may be difficult to deliver oxygen at the recommended temperature because of equipment limitations. In many cases the air temperature is only 30°C (86°F).

Summary.

Studies have suggested that the rewarming rate of inhalation therapy is inferior to that of peritoneal lavage, thoracic lavage, and bath rewarming. [4] However, because inhalation therapy can be combined with any and all other methods of rewarming and because it is relatively noninvasive and inexpensive, it should be considered as the initial treatment of choice for hypothermic patients.

Peritoneal Dialysis (Lavage)

Peritoneal dialysis (lavage) is an attractive treatment for severe hypothermia because it is available in most hospitals and does not require any unusual equipment or training. Rewarming rates of 2°C to 3°C (3.6° to 5.4°F)/hr, depending on the dialysis rate, can be achieved without sophisticated equipment that may delay therapy or require transfer of the patient to a tertiary care facility. [64] This technique can also be used to help correct electrolyte imbalances.

Peritoneal dialysis rewarming was first used successfully in a patient in ventricular fibrillation with a temperature of 21°C (69.8°F). [65] Since that time, there have been reports of successful rewarming with peritoneal lavage in stable, severely hypothermic patients and unstable hypothermic patients in cardiac arrest. [66] [67] Peritoneal lavage works through heat transfer from lavage fluid to the peritoneal cavity. The peritoneal great vessels and abdominal organs provide a large surface area for heat exchange. The use of warmed peritoneal lavage fluid is an effective approach to rewarming. [68] There have been reports of success in the literature

using rapid high-volume peritoneal lavage (RHVP) in pediatric patients. The technique involves use of an infra-umbilical "mini-laparotomy" incision followed by placement of a large silicone peritoneal dialysis catheter. The catheter is connected to a rapid infusion device with the delivery of 1 liter of warmed normal saline every 90 seconds. [68]

Indications and contraindications.

Peritoneal dialysis is appropriate therapy in any severely hypothermic patient. In practice, however, it is often omitted if other measures appear to be successful. There are no universally agreed upon criteria for performing peritoneal lavage in hypothermic patients who have detectable vital signs. Although theoretically less effective than other techniques that directly warm the thorax in the setting of cardiac arrest, it has been used successfully in that situation. It is theoretically useful in hypothermic patients who have overdosed with a dialyzable toxin. Other less invasive methods, such as gastric or bladder lavage, or warm nebulized air or oxygen inhalation, may be preferred in stable patients with temperatures higher than 26°C to 28°C (78.7°F to 82.4°F). Peritoneal dialysis should not be performed on patients with previous abdominal surgery. It should be used with extreme caution in patients with a coagulopathy after the risks and benefits have been considered.

Equipment.

The equipment described in Chapter 44 is needed. We recommend using the Seldinger technique with a commercially available disposable kit (e.g., Arrow Peritoneal Lavage Kit, product no. AK-09000, Arrow International, Inc., Reading, PA) because of the ease of performance and minimal morbidity associated with this procedure.

Technique.

In the noncritical patient, a coagulation profile should be obtained before the procedure, but in life-threatening situations immediate initiation of the procedure is warranted before laboratory studies. The patient should be supine with a Foley catheter and nasogastric tube in place. After infiltration with lidocaine, an infraumbilical stab incision is made with a No. 11 blade, and an 18-ga needle is placed into the peritoneal cavity directed toward the pelvis at a 45° angle. A standard flexible J-wire is inserted through the needle, and the needle is removed. The 8-Fr dialysis catheter is passed over the wire with a twisting motion, and the wire is removed.

Lavage rates of 4 to 12 L/hr can be achieved with two catheters. Fluid is warmed with a standard blood warmer to 40°C to 45°C. A standard 1.5% dextrose dialysate solution is used; adding potassium (4 mmol/L) is recommended if the patient becomes hypokalemic. Ringer's solution and normal saline have also been used successfully. The rate should be at least 6 L/hr and preferably 10 L/hr. [67]

Complications.

The Seldinger method has a complication rate of <1%. [69] [70] A "mini-lap" using direct dissection may also be used but may have a higher complication rate. [69] Further discussion of potential complications is provided in Chapter 44 .

Summary.

Peritoneal dialysis is a useful method because it uses readily available fluid and can be done with a self-contained disposable kit. [71] If a hospital also treats trauma victims, the same lavage kit can be used for evaluation of abdominal trauma. If this technique is combined with warm nebulized inhalation, warming rates of 4°C

(7.2°F) per hour can be achieved.[72]

Gastrointestinal and Bladder Rewarming

Gastric or bladder irrigation offers some of the same advantages as peritoneal dialysis without invading the peritoneal cavity. Heat is delivered to structures in close proximity to the core. In the Multicenter Hypothermia Study, gastric/bladder/colon lavage had a first hour rewarming rate of 1.0° to 1.5°C/hr and a second hour rewarming rate of 1.5° to 2.0°C/hr for severe hypothermia. [71] In a multifactorial analysis of the Multicenter Hypothermia Study, there was a trend toward improved survival in patients on whom this method was used.[11]

Although the amount of heat delivered with gastric lavage appears less than that delivered with peritoneal dialysis, it is somewhat easier to use and less invasive. When combined with other methods, gastric or bladder lavage provides significant warming. [71] [72] Serum electrolyte levels should be monitored if large volumes of tap water are used, because dilutional electrolyte disturbances may occur. Children and geriatric patients may be more susceptible to electrolyte changes with tap water irrigation.[73]

Indications and contraindications.

Warmed gastric or bladder lavage may be used as adjunctive therapy in moderate or severe hypothermia. It can be combined with other warming techniques when rapid rewarming is needed. Patients who are obtunded and lack protective airway reflexes should have endotracheal intubation before gastric lavage to prevent aspiration of gastric contents. Refer to the appropriate chapters concerning nasogastric tube placement (see Chapter 41), gastric lavage (see Chapter 43), and urethral catheterization (see Chapter 56) for specific contraindications to these procedures.

Equipment.

Use a large-diameter 32- to 40-Fr lavage tube with normal saline or lactated Ringer's solution warmed to 40° to 45°C (in a microwave or blood warmer with verification of temperature before use) and a Y connector and clamp as described in Chapter 43 . Although smaller tubes are easily passed nasally, oral placement of the large lavage tubes is recommended. A modified Sengstaken tube with gastric and esophageal balloons may also be used.

Technique.

Generally, 200- to 300-mL aliquots of fluid are instilled into the stomach before removal by gravity drainage. For bladder irrigation, the optimal volume is not known but bladder distension should be avoided (100- to 200-mL aliquots should be sufficient). The amount of time that the irrigant should be left before removal is not known, but rapid exchanges with a dwell time of 1 to 2 minutes is suggested.

Complications.

Lavage complications include trauma to the nasal turbinates (especially if a large tube is passed nasally), gastric and esophageal perforation, dilutional hyponatremia, inadvertent placement of the tube in the lungs, and pulmonary aspiration. All of these can be minimized by careful, proper technique. Fluid overload or electrolyte disturbances when using tap water are potential complications in pediatric and geriatric patients.

Summary.

Gastrointestinal and bladder lavage with heated fluids is easily performed using equipment and solutions available in any hospital. Because of its ease and availability, it can be started early in the resuscitation and combined with any other rewarming method to significantly add heat, [58] although the specific effect on morbidity and mortality is not known.

Thoracic Cavity Lavage

Thoracic cavity lavage can be performed either *closed*, through chest tubes placed in the one hemithorax,[74] [75] or *open*, after resuscitative thoracotomy.[76] The former approach offers the advantages of being less invasive and an effective form of treatment in hospitals not equipped for cardiopulmonary

---

bypass.[75] Furthermore, closed-chest CPR can be continued while this technique is used. The open thorax approach offers the theoretical advantage of direct heart warming and the option of open-chest cardiac massage. Rapid warming rates of 6° to 7°C in 20 minutes have been described. [74] [75]

Indications and contraindications.

Thoracic cavity lavage should be considered for patients requiring rapid core rewarming in the setting of cardiac arrest or inadequate perfusion (e.g., shock, during CPR) when cardiac bypass is not available. Open thoracic lavage should be considered in those patients who will receive open chest massage or thoracotomy for other reasons (e.g., hypothermic arrest with penetrating trauma). Thoracic lavage is not necessary for patients with mild or moderate hypothermia who can be rewarmed by other, less invasive methods. The technique should be avoided in the patient with a coagulopathy unless needed as a life-saving measure.

Closed thoracic lavage.

Two large-bore thoracostomy tubes (e.g., 36- to 38-Fr in 70-kg adults) are placed in one hemithorax (see Chapter 10). One chest tube is infused with 3-L bags of heated normal saline (40° to 41°C [104° to 105.8°F]) using a high-flow fluid infuser (e.g., Level-1 Fluid Warmer, Technologies, Inc, Marshfield, MA). The effluent is collected with an autotransfusion thoracostomy drainage set (e.g., Pleur-evac, Deknatel A-5000-ATS, Fall River, MA), and the removable reservoir is repeatedly emptied as needed. The use of a single chest tube system using a Y-connector arrangement similar to gastric lavage is also effective. Aliquots of 200 to 300 mL with a 2-minute dwell time followed by suction drainage (at 20 cm H_2O) are recommended.

Closed-chest massage is used until adequate spontaneous perfusion occurs. Closed-chest defibrillation may be required in the patient warmed to 30°C (86°F) with persistent ventricular fibrillation. Thoracic lavage is generally continued until the patient's temperature approaches 35°C (95°F).

Open thoracic lavage.

A left thoracotomy is performed as described in Chapter 18 . Saline warmed to 40° to 41°C can then be continuously poured into the thoracic cavity, bathing the heart while an assistant suctions the excess fluid from the lateral edge of the thoracotomy. Alternatively, fluid may be added to the thorax and mediastinum intermittently and suctioned after several minutes, and more warm saline may be added (see Fig. 67-8). This technique also allows for direct myocardial temperature monitoring. Direct cardiac massage is used until adequate spontaneous perfusion occurs. Direct cardiac defibrillation may be required in the patient warmed to 30°C with persistent ventricular fibrillation. When defibrillation is successful, direct myocardial warming should continue until the patient's temperature approaches 35°C. If defibrillation is unsuccessful at a core temperature of 30°C, further warming is warranted while oxygenation, perfusion, and other physiologic parameters are optimized before further defibrillation attempts.

Summary.

Thoracic lavage is an effective form of active core rewarming that is usually reserved for hypothermic arrest patients. [74] [75] Thoracic lavage may be considered when

vital signs are inadequate or unstable enough to severely limit perfusion. However, precise indications are not clarified beyond the patient in cardiac arrest.

Cardiac Bypass

The use of cardiac bypass or an extracorporeal shunt through either the femoral artery-femoral vein or aorta-caval procedure can result in rapid rewarming but requires surgical expertise, availability of appropriate equipment, and technical support. [3] [5] [7] This procedure has not been compared with other rewarming methods in a controlled fashion and few centers have this modality available in a time frame that would impact survival rates. Its main advantages appear to be the rapid rate of warming it produces and optimal patient oxygenation and perfusion. Femoral flow rates of 2 to 3 L/min with the warmer set at 38° to 40°C (100.4° to 104°F) will raise the core temperature 1 to 2°C every 3 to 5 minutes. [4] Drawbacks include potential delays in assembling the appropriate team and equipment, delays owing to the time necessary to complete the operation, complications from the operation, the expense of the procedure and bypass equipment, and the potential for infection. Its use in extreme situations that may include cardiac arrest should be based on individual characteristics of the patient, physician team, and hospital resources. If rapidly available, it should be strongly considered in hypothermic patients with asystole or ventricular fibrillation. [33] If oxygenation is not a consideration, venovenous rewarming with an extracorporeal venovenous rewarmer can achieve rapid rewarming rates (2 to 3°C [3.6 to 5.4°F]/hr), although they are slower than cardiopulmonary bypass.[77] Such a device is relatively easy to use, uses readily available technology, and probably does not require heparin. However, it needs to be assembled before patients present with hypothermia.

Hemodialysis

Hemodialysis was first described in the management of AH in 1965. [6] It is a rapid and efficient modality of rapid internal rewarming for moderate-to-severe AH, but it is rarely used in clinical practice. Core rewarming by hemodialysis has been achieved after placement of a dialysis catheter or with use of an existing shunt. Some of the potential advantages and drawbacks of cardiac bypass also apply to this procedure, although slower warming rates have been reported. A range from 0.6°C/hr to rates as high as 4.5°C/hr have been achieved with fluid warmed to 40°C. [6] For patients who have ingested a dialyzable toxin (such as barbiturates and toxic alcohols), hemodialysis can be used to both remove the toxin and rewarm the blood. In such cases its use may be appropriate.

Experimental Techniques

Ultrasonic, radiowave, and low-frequency microwave diathermy rewarming appears to be a rapid, safe, noninvasive technique with promise in animal studies. [56] [78] Frequencies of 13.6 to 40.7 MHz are typically used. However, the technique seems less effective than immersion therapy and equivalent to passive rewarming techniques in a volunteer study.[78]

Total liquid ventilation is currently being studied in animals as a method to rapidly rewarm the core using warmed oxygenated perflurocarbon. Benefits include shorter rewarming times when compared with warm humidified oxygen (1.98 ± 0.5 versus 8.61 ± 1.6 hours; $p < 0.0001$), no afterdrop phenomenon, and no increase in lactate dehydrogenase and aspartate aminotransferase.[62]

Very hot intravenous fluids (65°C [149°F]) have been used in animals with little vascular damage or hemolysis. Trials in humans undergoing burn debridement have been very successful in preventing hypothermia during operative procedures. Patients had saline heated to 60°C using modified fluid warmers infused through central venous access. Patients had no evidence of intravascular hemolysis or coagulopathy

following infusions.[79] The role of hot intravenous fluids in the management of accidental hypothermia is currently undefined.

SPECIAL SITUATIONS

Cardiac Arrest

Cardiac arrest from AH requires immediate treatment for the best chance of a successful outcome. Rapid rewarming and restoration of cardiac rhythm is essential for patients in cardiopulmonary arrest and can best be achieved by a combination of passive and multiple active core rewarming techniques. Because numerous cases of survival from hypothermic cardiac arrest with prolonged external cardiac compression exist, [3] [33] [80] thoracotomy is not mandatory but does offer some theoretical advantages, such as increased cardiac output with open-chest massage, [76] direct observation of cardiac activity, and direct warming of cardiac tissue with thoracic cavity lavage of warm fluid. Cardiopulmonary bypass is an effective technique for rapid rewarming. Blunt trauma and head trauma victims were previously not ideal candidates for cardiac bypass because of the anticoagulation requirement. However, some authors have advocated this technique using heparin-bonded tubing even in the setting of known traumatic injury.[3] A review of outcome from hypothermic cardiac arrest from one institution found that the average time from thoractomy to development of a perfusing rhythm was 38 minutes (range, 10 to 90 minutes).[3] The optimal rate of cardiac compression in hypothermia is not known, but because of decreased oxygen consumption of vital organs, the rate required in hypothermic cardiac arrest is less than that recommended in normothermic cardiac arrest. Cardiac compressions should be initiated at half the normal rate in profoundly hypothermic patients. Guidelines developed by the American Heart Association and the Wilderness Medical Society recommend that CPR should be initiated in accidental hypothermia unless any of the following conditions exist: a "do not resuscitate" (DNR) status is documented and verified, obvious lethal injuries are present, chest wall depression is impossible, any signs of life are present, or rescuers are endangered by evacuation delays and altered triage conditions. [4] [81]

The duration of CPR depends on the time required to raise the core temperature to a level at which defibrillation should be successful (i.e., >30°C [86°F]). Previously, it was recommended that patients should not receive a set of three countershocks until a core temperature above 30°C can be reached. However, there have been reports of successful defibrillation in patients with profound hypothermia with core temperatures of 25.6°C. [82] The decision to terminate resuscitative efforts remains a clinical decision. However, there are certain poor prognostic factors. Certainly, survival is unlikely in patients who persist in asystole or go from ventricular fibrillation to asystole as they are warmed past 32°C (89.6°F). Prognostic markers for patients with severe hypothermia and cardiac arrest have been proposed as contraindications to ED thoractomy and/or cardiac bypass by some authors. [3] These include elevated potassium levels above 10 mmol/L (meq/L) and pH levels below 6.5. Nonetheless, there are survival reports for patients with higher potassium levels and a pH as low as 6.51. [3] Therefore, the decision to continue resuscitative efforts should not be based solely on specific laboratory values or presenting core temperature.

Isolated reports of survival with prolonged CPR in hypothermic patients make extended efforts to resuscitate such patients reasonable. Children may be the best candidates for heroic measures.[5] Under ideal conditions, hypothermic cardiac arrest patients may reasonably be admitted to an intensive care unit for a 4- to 5-hour trial of rewarming with CPR in progress. Manual CPR should be replaced by mechanical methods if equipment is available (see Chapter 17). The oxygen-powered "thumper" has been successful during prolonged hypothermic resuscitations. Absence of responsiveness to treatment in conjunction with a highly elevated potassium level is an indication for termination of resuscitative efforts.

Airway Management

A secure functioning airway must be maintained for the hypothermic patient, just as in any critically ill patient. In mild hypothermia, heated humidified oxygen can be delivered effectively by a face mask. The hypothermic patient can be combative and uncooperative and may require arm restraints if a mask is used. For the patient with decreased sensorium who cannot reliably maintain his or her airway or the hypothermic patient who may be hypoxic, endotracheal intubation may be performed safely without the added risk of ventricular dysrhythmias.[10] The technique for endotracheal intubation depends on the specific presenting circumstances and the expertise of the operator. Once an endotracheal tube has been placed and secured, it may be used for treatment of the patient with warm humidified oxygen. There is no evidence that tracheal intubation is detrimental in the severely hypothermic patient, and should be considered if indicated for ventilation, oxygenation, or airway protection.

Acid-Base Disturbances

Acid -base disturbances are variable and can lead to metabolic acidosis from carbon dioxide retention and lactic acidosis or metabolic alkalosis resulting from decreased carbon dioxide production or hyperventilation. The interpretation of arterial blood gases in the hypothermic patient has been the cause of some confusion. Previously it was suggested that all blood gases be corrected for temperature with correlation factors. With a decrease in temperature of 1°C, the pH rises 0.015, the PCO_2 drops by 4.4%, and the PO_2 drops 7.2% compared to values that would be obtained on blood analyzed under normal conditions. Despite the conversion guide, optimal or normal values in hypothermia have not been well documented. [26] The most recent literature supports the use of uncorrected arterial blood gases to guide therapy with bicarbonate or hyperventilation. [24] [26] This approach appears appropriate to support optimal enzymatic function. A gradual correction of acid-base imbalance will allow for the increased efficiency of the bicarbonate buffering system as the body warms. Arterial pH did not correlate with patient death in the Multicenter Hypothermia Study[72] and should not be used as a prognostic guide to resuscitation.

Coagulopathies

Abnormal clotting frequently occurs in hypothermia, probably because cold inhibits the enzymatic coagulation cascade. [83] Hypothermia-induced coagulopathy does not result from

excessive clot lysis, but rather from impaired clot formation.[16] Platelet function is also impaired during hypothermia because the production of thromboxane B_2 is inhibited. Hypothermia-induced platelet aggregation (HIPA) with or without neutrophil involvement has been associated with neurological dysfunction in patients undergoing surgical procedures.[12] Hypercoagulability with risks of thromboembolism may also occur, but the main importance of cold-induced coagulopathy is in patients with coincidental trauma. Such victims often have bleeding that is difficult to control. Replacement of appropriate clotting factors and use of warm blood may limit further blood loss and worsening of hypothermia.

Trauma and Hypothermia

Clearly, there is an increased mortality in trauma patients with temperatures below 32°C (89.6°F). It is not clear if this increased mortality is actually a result of hypothermia or whether hypothermia is merely an indicator of severe injury and response to a massive transfusion of cold fluid. [16] [84] [85] Patients with severe trauma are prone to hypothermia because their injuries often expose them to environmental heat loss. Concurrent alcohol intoxication may add to the heat loss owing to the vasodilatory effects on cutaneous vasculature and prolonged cold exposure secondary to altered mental status. Severe injury victims also lose heat because of exposure during resuscitation and rapid administration of cold fluids.

The degree to which correcting the hypothermia improves outcome is unknown. Nevertheless, devices to rapidly infuse warm fluids such as the Level 1 fluid warmer (Level 1 Technologies, Rockland, MA) and the Thermostat 900 (Arrow International, Reading, PA) are frequently used to warm large volume fluid transfusions. These devices seem reasonable to prevent the hypothermia associated with massive transfusions (see Chapter 24). Their use in hypothermia not associated with severe trauma is limited by the relatively low fluid requirements of environmental exposure hypothermia.

PHARMACOTHERAPY AND MONITORING

Hypothermia alters the pharmacodynamics of various drugs. It markedly alters drug kinetics, but not enough is known about this phenomenon to define specific therapeutic guidelines. Drug administration in the hypothermic patient must be done with caution (Table 67-4). Because of the negative effects of hypothermia on both hepatic and renal metabolism, toxic levels of medications can accumulate rapidly after repeated use. Certain drugs, such as digitalis, should be avoided entirely. Sinus bradycardia and most atrial arrhythmias do not require pharmacological treatment as most resolve with rewarming. Transient ventricular dysrhythmias also do not require treatment. For those patients requiring medication for ventricular dysrhythmias, bretylium is the preferred agent, although lidocaine, magnesium, and propranolol have been used safely.[24] For severe acidosis (pH < 7.1), IV sodium bicarbonate can be used with extreme caution. Vasopressors should be used with caution, perhaps in much smaller doses than usual, because of the arrhythmogenic potential and the delayed metabolism. A review of ICU admissions for hypothermic patients found that treatment with vasoactive drugs was an independent risk factor for mortality, but this phenomenon remains poorly understood. [33] In

TABLE 67-4 -- Commonly Used Medications in Hypothermia

Clinical Situation	Medication	Dosage
Hypoglycemia	D50 W	1 mg/kg IV
Alcoholic/Malnourished	Thiamine	100 mg IV
Altered mental status	Naloxone	0.4 to 2 mg IV
Ventricular fibrillation	Bretylium*	5 mg/kg IV
	Magnesium sulfate	100 mg/kg IV

*The role of more available antidysrhythmics such as amiodarone in hypothermia remains to be determined.

animal studies, use of epinephrine impaired myocardial efficiency in cases of moderate hypothermia. [86] There also was no advantage to repeated doses of epinephrine or high-dose epinephrine in the hypothermic cardiac arrest animal models. [87] The use of inamrinone (formerly known as amrinone) has been investigated in cases of deliberate mild hypothermia. Initial results indicate that amrinone accelerates the cooling rate of core temperature potentially limiting the usefulness in management of accidental hypothermia.[88] Intravenous fluids should be slowly administered to prevent fluid overload as a result of the decreased cardiac output. In addition, fluids should be started early because most hypothermic patients have intravascular volume depletion. Dextrose 5% with normal saline has been advocated as the ideal initial resuscitation fluid. [50] [56] Potassium should be avoided until electrolytes are measured and normal renal function is confirmed.

Placement of a Swan-Ganz catheter and close monitoring of urinary output may assist in the fluid management of severely hypothermic patients. The risks of precipitating ventricular fibrillation should be weighed against the potential benefits of the Swan-Ganz catheter.

Elevation of creatine phosphokinase in hypothermic patients may indicate rhabdomyolysis, and careful monitoring of renal function is essential. Aggressive fluid replacement may prevent the development of renal failure.

Finally it should be emphasized that hypothermic patients exhibit a "physiologic" (and probably somewhat protective) hypotension, hypoventilation, depressed mental status, and bradycardia, the extent of which depends on the core temperature. This observation prohibits precise recommendation on the indications and use of medications, intubation, CPR, and other resuscitative interventions that are better defined in the normothermic patient. Hypothermic patients who present with a blood pressure, respiratory rate, or mental status that would prognosticate certain morbidity in normothermic patients may recover with minimal intervention to their normal pre-hypothermic state. *The clinician should avoid aggressive therapies or medications that are aimed at providing the hypothermic patient with vital signs that would be desirable in the normothermic patient but which may be supraphysiologic in the hypothermic patient.*

FROSTBITE

Hypothermic patients frequently suffer other forms of cold-related injuries in addition to their systemic hypothermia. The mildest form of frostbite is termed *frostnip*, a condition that involves only the skin, sparing the subcutaneous tissues. The skin is blanched and numb, but the injury is immediately reversible with no permanent sequelae if the area is quickly

rewarmed. Rapid rewarming should be done in a water bath at 40° to 42°C. Frostnip occurs most frequently on the distal extremities, the nose and ears. Nonfreezing temperatures also produce *trenchfoot*, an intermediate step in the progression to true frostbite. Trenchfoot is the result of prolonged immersion. Treatment involves rewarming followed by dry dressings.[89] [90]

In frostbite, the body parts most susceptible are those farthest away from the body's core: the hands, feet, earlobes, and nose. Exposure of the fingers to severe cold leads to cold-induced vasodilation (CIVD). [91] [92] Apical structures rich with AVAs can shunt blood flow away from tissues.

The pathophysiology of frostbite includes three pathways of tissue freezing: (1) through the extracellular formation of ice crystals, (2) hypoxia as a result of cold-induced local vasoconstriction, and (3) the release of inflammatory mediators. These pathways can and often do occur simultaneously, intensifying tissue damage. At the early stages of frostbite, the "hunting reaction" is observed whereby the body alternates between periods of vasoconstriction and vasodilation. As the temperature continues to decrease the reaction stops and vasoconstriction persists. [31] [90] Cold also increases blood viscosity, promotes vasospasm, and precipitates microthrombus formation. The release of inflammatory mediators prostaglandins PGF2 and thromboxane A2 that are found in blister fluid cause further vasoconstriction leading to cell death. The release of these mediators peaks during rewarming, and cycles of recurrent freezing and rewarming only increase their tissue levels. *Rewarming must be avoided until refreezing can be prevented.*

The clinical signs and symptoms of frostbite vary according to the degree of injury. Although useful clinically, the degree classification does not predict the extent of further tissue damage.[31] [83] The appearance of the affected extremity will depend on the extent of the frostbite. In superficial frostbite, the affected extremity appears pale, waxy, and numb; has poor capillary refill; and is very painful on rewarming. In deeper frostbite, the affected extremity is hard, solid, and blanched. Hemorrhagic blisters may be present. Initially there is no pain or feeling in the frostbitten extremity. After rewarming, the affected area develops severe edema and blistering, eventually exhibiting dry gangrene and mummification, leading to tissue sloughing.

Favorable prognostic signs for frostbite include intact sensation, normal color, warm tissues, early appearance of clear blisters, and edema. Unfavorable prognostic signs include no sensation, cold, cyanotic appearance, white "frozen" appearance, late appearance of hemorrhagic or dark blisters, and absence of edema. [93] Based on early bone scans and retrospective studies, researchers from France have proposed a new classification for predicting frostbite outcomes on day 0. [94] Four degrees of severity are defined. With first degree, there is complete recovery. Second degree often leads to soft tissue amputation. With third degree there is the need for bone amputation, and with fourth degree, there are systemic effects.[94]

Rapid rewarming is the treatment of choice for frostbite.[89] [90] The aim is to limit the length of time the tissue remains in the frozen state. The most practical way to rewarm an extremity is to totally immerse the area in warm water at 40° to 42°C for 15 to 30 minutes. The affected area should be carefully protected to ensure that the tissue is not additionally injured through contact with the sides or rim of the container. After thawing, the area should be meticulously protected from injury. An extremity should be elevated and cotton or gauze placed between the toes/fingers to limit maceration. White or clear blisters should be debrided. Hemorrhagic or dark blisters should be left intact as disruption may cause damage to the vascular supply and viable tissue.

The use of topical aloe vera (a thromboxane inhibitor) and systemic antiprostaglandins (such as ibuprofen) may be helpful. The use of semiocclusive dressings has shown promising results for management of deep frostbite injuries of the fingertips.[95] Tetanus prophylaxis should be provided. Adjuvant therapies involving the use of heparin or low-molecular-weight heparin, warfarin, vasodilators, corticosteroids, or immediate surgical sympathectomy have failed to improve outcomes. There has been mixed success with the use of hyperbaric oxygen and thrombolytics.[96]

Agents that can inhibit the formation of free radicals are promising. These agents include superoxide dismutase, PGE1 analogues, and drugs containing antiplatelet activity such as pentoxifylline.[31] [90] The use of antibiotics is controversial, although some authors advocate agents with staphylococcus/streptococcus coverage (e.g., cephalosporins, pencillins). Debridement of tissue should be avoided in the ED. Patients should be given analgesics (IV opioids) as needed.

COLD WATER IMMERSION/SUBMERSION

One of the leading causes of hypothermia remains cold water immersion/submersion. [97] In one retrospective review of accidental hypothermia cases in a three-year period, submersion hypothermia accounted for the greatest number of cases. [98] Unlike in cases of AH secondary to cold exposure, risk factors (both internal and external) are harder to identify secondary to the high mortality from drowning. [83] Studies have shown that at cold water temperatures (8°C), core cooling occurs at slower rates in persons with increased body mass and subcutaneous fat, and at faster rates when there is increased voluntary activity (e.g., treading water). Risk factors for submersion hypothermia include impaired performance and initial cardiorespiratory response to immersion. A study in healthy volunteers found that swimming efficiency and length of stroke decreases while rate of stroke and swim angle increases as the water temperature drops. [99]

The body's response to cold-water immersion (head-out) has been previously described as occurring in three phases. [55] The initial phase involves the "cold-shock response," which typically occurs within the first 4 to 6 minutes. Signs include peripheral vasoconstriction, gasp reflex, hyperventilation, and tachycardia. At this stage, there is a higher incidence of sudden death resulting from hypocapnia, inability to breathhold, and increased cardiac output. [55] Following the initial cold shock response, the body undergoes profound cooling of the peripheral tissues. The peripheral cooling tends to be the greatest in the hands leading to incoordination and grasping difficulties. [55] In prolonged immersion in cold water, heat is lost from the body quicker than it is produced, thus predisposing to hypothermia. [100]

In cases of cold-water submersion, researchers have found that rapid cooling is protective against neurological impairment and increases chances of survival. There are numerous reports in the literature of survival following cold-water submersion in children, but very few reports in adults. There are reports of survival following up to 66 minutes

of cold water submersion. [101] Recently, there was a case report of survival in an elderly male following 22 minutes of submersion. [102] Overall, children tend to have a better prognosis because of the presence of the mammalian dive reflex, and a greater body surface area to mass ratio that allows for more rapid cooling. Orlowski identified five poor prognostic factors for near drowning in pediatric patients: (1) maximum submersion time >5 minutes, (2) comatose upon arrival to ED, (3) arterial blood gas pH <7.10, (4) age younger than 3 years, and (5) resuscitation not attempted for at least 10 minutes following rescue. [103] [104] Adults tend to have higher mortality rates because of the following: (1) the lack of the mammalian dive reflex and (2) slower rates of temperature cooling secondary to lower body surface area to mass ratios in adults as compared to children.

Various mechanisms for brain and body cooling during submersion hypothermia have been described including the mammalian dive reflex, cold-induced changes in neurotransmitter release, and water ventilation. [103] The mammalian dive reflex prevents or delays aspiration or ventilation until the body has cooled to a point where hypothermia protection occurs. Much attention has focused on the theory of water ventilation as a key component of accelerated brain cooling. Animal studies comparing immersed (head-out) and submersed dogs found that cooling rates were faster in the submersed dogs than in the immersed dogs. The submersed dogs cooled by convective heat exchange in the lungs whereas the immersed dogs cooled by surface conduction only. Laboratory data obtained following the submersion indicated that there was indeed ventilation exchange in the water. [101] The body also undergoes a relative bradycardia as another protective measure. Bradycardia is inversely proportional to the water temperature with heart rates reaching 18 bpm in 10°C water. [103]

Many authors advocate therapies aimed at symptoms resulting from near drowning rather than severe hypothermia because in fatal cases of submersion, death occurs too rapidly for hypothermia to be a significant contributor. Complications of near drowning include pneumonia, lung edema, hemorrhagic pancreatitis, and skin edema. [83]

CONCLUSION

Mortality rates from AH are decreasing due to increased recognition and advanced therapy. Caution should be used when extrapolating published data obtained in adults to children.[46] With the exception of severe hypothermia, the prognosis mostly correlates with the presence or absence of underlying disease states. Studies have shown that the prognosis is excellent in patients in whom no hypoxic event precedes hypothermia and no serious underlying disease states exist. [105] Previously healthy individuals usually have a full recovery with mortality rates <5%, whereas patients with coexisting medical illnesses have reported mortality rates of >50%. [45]

As a general guideline, one should take a conservative approach to rewarming the stable hypothermic patient, with avoidance of overtreatment and the selective and careful use of invasive monitoring. The patient's "physiologic" hypotension, hypoventilation, and bradycardia should be evaluated with regard to that which is expected for the core temperature.

In moderate hypothermia, underlying problems should be sought, passive rewarming and basic support started, and less invasive core rewarming begun. This approach should include mask ventilation with warm humidified air or oxygen in the conscious patient and intubation and ventilation in the unconscious patient. In selected patients, gastric or peritoneal lavage with warm fluid may be considered.

For severely hypothermic, *unstable* patients, cardiac bypass and thoracic lavage may offer additional benefits, including rapid warming rates and direct heart warming. The benefits should be weighed against the institutional capabilities, time, expense, and the danger of complications that these procedures entail.

Acknowledgments

The authors wish to thank David Doezema and David P. Sklar for their invaluable contributions and authorship of previous chapter editions.

Chapter 68 - Procedures Pertaining to Hyperthermia

Timothy B. Erickson
Heather M. Prendergast

Human epidemics of heat-related illness have been well documented historically. [1] [2] A Roman army was decimated by heat in 24 BC, and King Edward's heavily armored crusaders were defeated by "heat and fever" during the final battle of the Holy Land. In Peking, 11,000 residents died during a heat wave in 1743. More than 1000 heat-related deaths occurred during a pilgrimage to Mecca in the early 1960s. In the United States in 1980, 1983, and 1988 (years with prolonged heat waves), 1700, 556, and 454 deaths, respectively, were attributed to heat exposure. [3] In the 1990s, there were a significant number of hyperthermia-related fatalities in major metropolitan cities across the country, including Chicago and Los Angeles. [1] [4] [5] [6] [7]

In contrast, malignant hyperthermia and neuroleptic malignant syndrome (NMS) have been recognized and described only since the 1960s. [8] [9] [10] These conditions are largely iatrogenic and are most commonly triggered by modern pharmacologic therapy. In addition, the incidence of severe hyperthermic conditions induced by psychostimulant drugs of abuse, such as cocaine and amphetamine derivatives, is on the rise. [11]

Heatstroke remains a common clinical problem with significant morbidity and mortality. Each year, 175 to 200 people on average die from heat-related illnesses. [12] As the weather patterns continue to change with a trend toward hot and humid summers, the number of individuals adversely affected by the heat continues to rise. A variety of cooling techniques have been advocated since World War II. Although some cooling techniques have been compared in controlled human and animal models of heatstroke, practice decisions are not solely based on the theoretical rate of cooling. Other important factors include the ease of use, rapidity of initiation, and safety.

Before considering the various cooling techniques, it is essential that the underlying disorder of hyperthermia be clearly understood. Heat illness presents a spectrum of disease ranging from mild heat exhaustion (primarily a volume loss disorder) to severe heatstroke (with the thermal-related multiorgan-dysfunction syndrome). The latter includes disorders such as malignant hyperthermia and NMS. Treatment of this spectrum of disease requires a discriminating approach, including supportive care only for heat exhaustion and rapid cooling for heatstroke. Malignant hyperthermia requires specific pharmacologic therapy (e.g., dantrolene) in addition to cooling measures. A brief discussion of hyperthermic disorders is therefore necessary before describing cooling techniques.

NORMAL THERMOREGULATION

Body temperature typically follows a diurnal pattern, increasing from about 36°C in the early morning to 37.5°C in the late afternoon, and reflects the balance between heat production and heat dissipation. [13] [14] Heat is produced as a by product of all metabolic processes and when ambient temperatures exceed the body temperature. The body temperature increases when the rate of heat production exceeds the rate of heat dissipation. In response to rising core temperature, the thermal center (located in the preoptic nucleus of the anterior hypothalamus) activates efferent fibers of the autonomic nervous system to produce vasodilation and increase the rate of sweating. Vasodilation dissipates heat by convection, and sweat dissipates heat by evaporation.

Hyperthermia occurs when thermoregulatory mechanisms are overwhelmed by excessive metabolic production of heat, excessive environmental heat, or impaired heat dissipation. In contrast, fever occurs when the hypothalamic setpoint is increased by the action of circulating pyrogenic cytokines, causing peripheral mechanisms to conserve and generate heat until the body temperature rises to the elevated setpoint. Hyperthermia and fever cannot be differentiated clinically on the basis of the magnitude of temperature or on the pattern of its changes. [14] [15] [16]

In the ensuing discussion, temperatures are given in degrees Celsius (centigrade). A temperature conversion scale is provided in the previous chapter (see Fig. 67-2).

TYPES OF HYPERTHERMIA

Mild Heat Illness

Heat cramps and heat exhaustion are induced by a hot environment. [17] [18] [19] In general, the body's heat dissipation mechanisms are able to keep up with heat production and absorption in these disorders. Symptoms are largely due to the mechanisms used by the body to dissipate heat, and body temperatures remain at or near normal. Rapid cooling techniques are *not* required, and supportive care and hydration in a cool environment are usually adequate therapy.

Heat cramps are intensely painful but generally benign, involuntary skeletal muscle spasms (most often in the calves, hamstring, or quadriceps muscles). The pain may also be in the arms and back. The cramps may be severe and prolonged and rarely may lead to rhabdomyolysis. Heat cramps occur after strenuous exercise or heavy labor in a hot environment. Previously heat cramps were considered the result of dehydration associated with significant sodium chloride losses; however, recent clinical observations have not proven this to be accurate. In fact, cramps can occur at rest or during exercise under any environmental conditions. Cramps appear to be specific neither to exercise nor to exercise in heat. [20] The most recent theory suggests that cramps may be the result of alterations in the spinal neural reflex activity triggered by fatigue in susceptible individuals, underscoring the importance of adequate stretching before and after exercise. There are no controlled clinical trials evaluating the efficacy of electrolyte replacement, quinine, or other medications. [20] Nonetheless, commonly followed practices of rest in a cool environment and vigorous oral fluid replacement with isotonic solutions are usually adequate therapy, but in some cases IV saline is required. A common mistake is to rely on thirst to indicate dehydration. Severe cramping may be surprisingly resistant to narcotics in the absence of adequate fluid replacement.

Heat exhaustion, commonly referred to as heat syncope, is a poorly defined syndrome with a spectrum of nonspecific symptoms that *occur after heat exposure*. Malaise, influenza-like symptoms, orthostasis, dehydration, nausea, headache,

and collapse may all occur. Heat exhaustion is considered the result of dehydration-induced heat retention that is not severe enough to cause heatstroke. [21] As distinct from the more severe heat disorders, mental status is normal and body temperature is normal or mildly elevated. There does not appear to be any thermoregulatory failure in heat exhaustion. Rehydration (usually IV), rest, and supportive care in a cool environment are adequate therapy for heat exhaustion. [22] Theories as to the etiology of heat exhaustion include sudden onset of postural hypotension after cessation of exercise (owing to a precipitous fall in central rather than circulating blood volume). Some authors advocate cooling and elevation of the patients' legs or by placing them in the head-down position between the knees in order to decrease skin blood flow and increase venous blood flow to the heart. [20] [21] Recovery is usually evident within a few minutes to hours. Occasionally heat exhaustion is accompanied by heat cramps, presenting a confusing scenario if the diagnosis is not suspected. Rapid cooling techniques are not usually required, but patients should be observed for progression to heatstroke as heat exhaustion and heatstroke are a continuum of one disease process. [23]

Heatstroke

When the body's normal heat dissipation mechanisms are overwhelmed, core temperature elevation and heatstroke rapidly ensue. Heatstroke represents a true state of thermoregulatory failure. [12] [16] [24] [25] Two forms of heatstroke are described in the literature. *Classic (nonexertional) heatstroke* usually occurs during summer heat waves. Poor people, urban elderly people, infants, and people with impaired mobility are at greatest risk. [18] [21] [26] [27] Dehydration, lack of air conditioning, obesity, neurologic disorders, hyperthyroidism, marginal cardiovascular status, impaired mentation, and medications that interfere with heat dissipation (e.g., phenothiazines, diuretics, anticholinergics) predispose this population to heatstroke. *Exertional heatstroke,* a consequence of strenuous physical activity, usually afflicts a younger segment of the population. Highly motivated, poorly acclimatized, or unconditioned athletes and military recruits are common victims, as are individuals who perform heavy physical labor in hot, humid conditions. [28] [29] In exertional heatstroke, the risk appears to be greatest in those individuals performing high-intensity exercise for relatively short durations. [20] A retrospective review of long-distance cyclists participating in the California AIDS Ride found that as the number of chronic medical illnesses increased so did the risk of developing an exertional heat-related illness. Human immunodeficiency virus seropositivity alone was not associated with an increased risk of exertional heat-related illness. [30]

The degree of hyperthermia necessary to produce heatstroke in humans is unknown. In tissue culture cells, thermal injury is observed in the range of 40 to 45°C. Studies of hyperthermia in cancer therapy reveal that tissue sensitivity to heat is increased by relative hypoxia, ischemia, and acidosis. [31] [32] [33] Studies suggest that the critical thermal maximum in humans is a temperature of 41.6°C to 42°C for 45 minutes to 8 hours. Cellular necrosis and the destruction of all cellular structures occurs in <5 minutes with body temperatures >49°C. [25]

The specific tissue pathophysiology of heat stroke is complex and multifactorial. One current theory is that thermoregulatory failure is coupled with an exaggerated acute phase response that involves direct cytotoxity of heat, and inflammatory and coagulation responses of the host. This process involves the interplay and modulation of inflammatory cytokines, such as tumor necrosis factor, numerous interleukins, and interferons. The initiating event may be splanchnic hypoperfusion resulting in alterations in immunologic and barrier functions of the intestines. The end result is multiorgan dysfunction, including disseminated intravascular coagulation. [25]

The key clinical findings in the diagnosis of heatstroke are (1) a history of heat stress or exposure, (2) a rectal temperature higher than 40°C, and (3) central nervous system (CNS) dysfunction (e.g., altered mental status, disorientation, stupor, seizures, coma). The cerebellum is most sensitive to heat, and ataxia may be an early clue. Although anhidrosis is traditionally described as a classic sign of heatstroke, investigations have demonstrated that cessation of sweating is only a latent sign. Failure to consider the diagnosis of heatstroke in a diaphoretic patient with mental status changes could prove disastrous. [21] [34] All patients with heatstroke exhibit hyperventilation and tachycardia. Hypotension is common. In *nonexertional* heatstroke, common laboratory abnormalities include hypophosphatemia, hypercalcemia, hypokalemia, and a respiratory alkalosis. *Exertional* heatstroke manifests hyperphosphatemia, hypocalcemia, and hypokalemia, usually seen after cooling. The acid-base disturbance is both a respiratory alkalosis and lactic acidosis.

The sequelae of heatstroke are caused by thermal damage to multiple organ systems. [12] After a hyperthermic event, tissue injury continues. [35] Delirium, seizures, and coma can result from direct effects of heat on the CNS. Cardiovascular collapse results from dehydration, maximal cutaneous vasodilation, and direct heat-induced myocardial depression. Coagulopathies and liver dysfunction (elevated levels of bilirubin and transaminases) occur as consequences of thermal breakdown and consumption of serum proteins, as well as direct heat damage to hepatic cells. Children often demonstrate diarrhea. Renal failure can result from myoglobinuria (related to rhabdomyolysis) and acute tubular necrosis. [24] [27] In addition to encephalopathy, rhabdomyolysis, acute renal failure, and DIC, other manifestations of multi-organ dysfunction include acute respiratory distress syndrome, intestinal ischemia or infarction, and pancreatic injury.

Rodent studies of hyperthermic events demonstrated significant gastrointestinal changes. In rats successfully cooled to normothermia, delayed secondary deterioration occurred with massive GI bleeding. [35] Metabolic acidosis is the primary acid-base alteration observed in heatstroke with the prevalence increasing with the degree of hyperthermia. [36]

The treatment of these sequelae in acute heatstroke does not differ from that in other disorders, with the sole exception that rapid cooling is necessary to prevent further damage and reverse heat stress. The more rapidly the rectal temperature is reduced to 38°C, the better the prognosis. [16] [18] [24] Importantly, the human body tolerates hyperthermia poorly. Unlike patients with hypothermia, in whom slow, gentle rewarming and supportive care often result in a favorable outcome, victims of severe heatstroke must be aggressively treated with measures designed to rapidly lower the core temperature. Studies investigating precooling techniques before exertion to avoid heatstroke have been relatively unsuccessful in attenuating increases in core body temperature and are not recommended. [37] In contrast, whole body precooling is shown to increase overall exercise endurance. [38]

Malignant Hyperthermia

Malignant hyperthermia (MH) is a pharmacogenetic disease, which predisposes the patient to the triggering of a life-threatening, hypermetabolic syndrome. [39] MH results from a rare inherited autosomal dominant abnormality of the skeletal muscle membrane with an incidence of 1:50,000 in adults. [8] [10] [40] In response to certain stresses or drugs (Table 68-1), patients with this disorder sustain a massive efflux of calcium from skeletal muscle sarcoplasmic reticulum, resulting in contraction of the sarcomeres; skeletal muscle rigidity; increased skeletal muscle metabolism, elevated serum creatine kinase levels, and heat production; and, finally, systemic hyperthermia.[41] [42] Hyperthermia is a late development occurring after rigidity has been present for some time and the body's normal heat dissipation mechanisms have been overwhelmed. The earliest signs of malignant hyperthermia are increased CO_2 production, muscle rigidity, and tachycardia. [42] [43] Cardiac output and cutaneous blood flow also increase to maximize heat loss. Malignant hyperthermia is diagnosed based on the clinical triad of (1) exposure to an agent or stress known to trigger the condition, (2) skeletal muscle rigidity, and (3) hyperthermia.

Malignant hyperthermia is usually encountered in the operating room while patients are undergoing general anesthesia, particularly with halogenated inhalation agents and depolarizing muscle relaxants. Heat production in the anesthetized patient can be profound with as much as a fivefold increase in oxygen consumption. [39] However, cases of malignant hyperthermia may be encountered anywhere general anesthetics or neuromuscular blocking agents are used. [44]

As with heatstroke, treatment of malignant hyperthermia requires rapid cooling and supportive care for the sequelae described previously. Unlike heatstroke, which does not respond to pharmacologic agents, malignant hyperthermia requires specific pharmacologic therapy to stop excess heat production by skeletal muscle. Dantrolene sodium induces muscle relaxation in malignant hyperthermia by blocking calcium release from muscle cell sarcoplasmic reticulum. [42] [43] In all cases of malignant hyperthermia, the inciting stimulus (see Table 68-1) should be discontinued immediately and dantrolene therapy administered. Although different treatment regimens exist, the editors recommend an aggressive dosing (3 mg/kg IV every 10 minutes for three doses) until the episode resolves. Procainamide has been used successfully when dantrolene is unavailable. [45]

TABLE 68-1 -- Triggers for Malignant Hyperthermia

Drugs	Conditions
Halothane	Heat stress
Methoxyflurane	Vigorous exercise
Enflurane	(?)Emotional stress
Diethyl ether	
Cyclopropane	
Succinylcholine	
Tubocurarine	
Lidocaine	
Mepivacaine	
Isoflurane	
Ketamine	
Trichloroethylene	
Chloroform	
(?)Gallamine	
(?)Nitrous oxide	

It has been suggested that dantrolene administration speeds cooling of heatstroke victims by reducing skeletal muscle heat production. [46] However, in a porcine model of heatstroke, dantrolene administration resulted in faster cooling rates than those seen with conventional cooling methods but did not appear to be superior. [47] Although one small study of exercise-induced heatstroke in humans during a religious pilgrimage suggested that dantrolene may speed cooling rates in exertional heatstroke,[48] a larger controlled trial in a similar setting found no benefit. [49] Dantrolene administration is best reserved for patients with clinical muscle rigidity or suspected malignant hyperthermia. Routine use of this drug in heatstroke patients is not recommended. [50]

New and promising treatments for malignant hyperthermia are being investigated. Researchers have discovered mutations in the gene coding for the ryanodine receptor calcium release channel (RyRI) in families with MH, which may be the functional basis for MH. Recent studies have examined the effects of MH mutations on the sensitivity of the RyRI to drugs and endogenous channel effectors including Ca^{2+} and calmodulin.[39] [51]

Neuroleptic Malignant Syndrome

First described in the late 1960s, NMS is characterized by fever, muscle rigidity, altered level of consciousness, and autonomic instability. [9] Mortality from NMS is estimated at 20% of patients who develop the condition.[52] This idiosyncratic disorder follows the therapeutic use of neuroleptic drugs, including phenothiazines, butyrophenones, thioxanthenes, lithium, and tricyclic antidepressants. The reaction is triggered by blockade of dopaminergic receptors, resulting in spasticity of skeletal muscle, which generates excessive heat and impairs hypothalamic thermoregulation and heat dissipation. [53] Muscle rigidity, described as "lead-pipe" rigidity in its most severe form,[54] can manifest as oculogyric crisis, dyskinesia, akinesia, dysphagia, dysarthria, or opisthotonos. NMS occurs in 0.2% of patients who receive neuroleptic agents either chronically or acutely. Haloperidol appears to be the most common offending agent. Temperatures can exceed 42°C. Initial agitation often progresses to stupor and coma. Catatonia and mutism may also be present. Autonomic instability manifests as tachycardia, labile blood pressures, sweating, and incontinence. Ventilations are impaired by chest wall rigidity.

This syndrome is not secondary to a drug overdose per se, but more likely to occur at the initiation of or after an increase in neuroleptic dosage. It may also occur if antiparkinsonian drugs are suddenly discontinued. [52] NMS resembles malignant hyperthermia but usually takes considerably longer to develop (2 to 3 days) and lasts longer (5 to 10 days) after the inciting drug is discontinued. The syndrome may be misinterpreted as a worsening of the underlying psychiatric disorder, drug intoxication (e.g., cocaine, amphetamines), a severe dystonic reaction, tetanus, or a variety of CNS infections. In addition to agents with increased dopaminergic blocking activity, other risk factors for NMS include: dehydration, prior history of dystonia, catatonia, or agitation, and iron deficiency. [45] The mortality rate is high, and respiratory failure, renal failure, cardiovascular collapse, or thromboembolic disease usually cause death. Unlike malignant hyperthermia, NMS is thought to be caused by a central disorder of thermoregulation.

Treatment of severe NMS (i.e., hypotension, hyperthermia, marked rigidity) closely follows that of malignant hyperthermia, except that therapy must be maintained for several days until symptoms resolve. Discontinuation of the triggering agent, rapid cooling, benzodiazepines, and supportive treatment for ensuing organ failure remain the cornerstone of therapy.[53] Although the effects are not immediate, pharmaceutical therapy is directed at overriding the dopaminergic blockade caused by offending neuroleptic agents or dopamine depletion resulting from the cessation of antiparkinsonian medications. There are reports of successful treatment of NMS using subcutaneous apomorphine monotherapy.[55] As with malignant hyperthermia, dantrolene (2 to 3 mg/kg IV every 10 minutes for 3 doses) can be given to treat NMS-induced muscle rigidity. The beneficial response stems not only from the effects at the sarcoplasmic reticulum of skeletal muscles, but also from central dopamine metabolism of calcium in the CNS. In addition, bromocriptine, a central dopamine agonist, is reported to be efficacious in NMS therapy at doses of 2.5 to 10

mg 3 times a day.[53] Although both agents have been noted to reduce the duration of hyperthermia, there have been mixed results of success using bromocriptine and dantrolene.[53] [58] [59]

A more recently described disorder that is often confused with NMS is the *serotonin syndrome*.[60] This syndrome involves the newer antidepressants (fluoxetine, paroxetine, citalopram, fluvoxamine, venlafaxine, and sertraline), [45] [58] [59] [60] [61] [62] which are selective serotonin reuptake inhibitors (SSRIs). These drugs can adversely react with other stronger serotonin receptor agents such as monoamine oxidase inhibitors (MAOIs) and non-selective serotonin reuptake inhibitors (clomipramine and tricyclic antidepressants) to induce a clinical presentation similar to that of NMS, only milder. Serotonin syndrome classically occurs when two or more drugs that interfere with serotonin metabolism act synergistically on the 5-HT $_{1A}$ receptor leading to overstimulation.[45] [60] Drugs that act at any of the other serotonin receptors are not likely to produce the syndrome.[45] The range of symptoms varies from mild gastrointestinal upset, insomnia, and agitation to the most severe symptoms including: muscle spasms, seizures, ataxia, rhabdomyolysis, and autonomic instability. In a review, Mills [62] found that muscle rigidity, more commonly involving the lower extremities, was present in 50% of cases. Treatment is primarily supportive in milder cases and consists of prompt recognition and withdrawal of the offending agent. Most cases resolve spontaneously within 24 hours. For the more severe cases, aggressive ICU management is warranted to prevent renal failure and death. The drug cyproheptadine (Periactin) in doses of 4 to 8 mg PO has shown promise in managing the agitation often seen with severe cases.[45] Cyproheptadine is an antihistamine with antiserotonergic properties. There has been limited success using benzodiazepines and ß-blockers in these patients, but various benzodiazepines are commonly given for agitation.[45]

Hyperthermia and Psychostimulant Overdose

As mentioned earlier, the recognized incidence of hyperthermia induced by sympathomimetic psychostimulant drugs of abuse is on the rise. The offending agents most commonly described are cocaine, phencyclidine, amphetamine, and the amphetamine derivatives such as 3,4-methylenedioxymethamphetamine (MDMA; "Ecstasy") and 3,4-methylenedioxyethamphetamine (MDEA; "Eve").[63] [64] A number of studies have looked specifically at the club drug MDMA and its impairment of heat dissipation.[11] Animal studies in rats have suggested that MDMA-induced hyperthermia results not from MDMA-induced 5-HT release, but from an increased release of dopamine acting at D1 receptors suggesting a future role for use of dopamine antagonists in clinical treatment.[65]

Hyperthermia is a common feature of these potentially severe to lethal poisonings with sympathomimetic psychostimulant drugs and may be the primary cause of fatality in many cases.[63] Because of the nonlinear pharmokinetics of MDMA and GHB, it is difficult to estimate a dose-response relationship.[63] Some have applied a pathophysiologic model of exertional heatstroke or NMS to profound cocaine intoxication.[66] [67] In addition to profound hyperthermia (>42°C), acute rhabdomyolysis, severe metabolic acidosis, disseminated intravascular coagulation, psychiatric and cognitive sequelae, renal failure, coma, seizures, and death have been described in these patients.[63] [64] [65] [66] [67] As demonstrated by Roberts and colleagues, even a patient with a core temperature of 114°F owing to acute cocaine intoxication may survive with aggressive cooling methods.[68] Treatment requires prompt recognition, maintenance of adequate hydration, rapid cooling (as outlined later), correction of metabolic acidosis, and the *aggressive use of sedative or paralyzing agents, or both, to control agitation*. Importantly, the longer that psychostimulant-overdosed patients remain hyperthermic, the higher their morbidity and mortality rates. Sudden unexpected death in a previously healthy individual is not uncommon if this syndrome is not aggressively treated. Agitation and seizures must be chemically controlled, as they lead to continued generation of heat and muscle injury. Physical restraint, without the use of chemical restraint, has been associated with increased mortality. Therefore, very liberal doses of benzodiazepines are recommended.[69] [70] [71] There is no maximum dose of benzodiazepines. Standard doses are generally ineffective and as much as 500 to 2000 mg of diazepam may be required to gain control of the patient. By the time such doses are required, however, muscular paralysis should have been instituted. Some have advocated the use of bromocriptine[71] and dantrolene[72] as for malignant hyperthermia and NMS, but their efficacy in the setting of drug-associated hyperthermia remains controversial.

Hemorrhagic Shock and Encephalopathy Syndrome

The condition of hemorrhagic shock and encephalopathy (HSE) in children (mainly infants, but some older children) resembles heatstroke in adults. The full-blown syndrome includes hyperthermia, coagulopathy, encephalopathy, and renal and hepatic dysfunction.[73] [74] [75] Although there may be an association with concurrent viral illness, the condition generally follows a temperature elevation, which may be triggered by the "bundling" of a child with a low-grade fever. Therapy is largely supportive and includes volume replacement and rapid cooling of the hyperthermic child while sources of bacterial infection are sought and treated.

COOLING TECHNIQUES

The treatment of heat cramps, heat exhaustion, and other forms of hyperthermia are discussed earlier. The therapeutic

objectives in patients with heatstroke are immediate cooling, the maintenance of adequate cardiorespiratory function, and support of all organ system functions. The basic function of all cooling measures is to transfer heat from the core, to the skin, to the environment, without compromising other physiologic functions. Cooling occurs via internal and external conduction techniques, and by convection and evaporation techniques. There have been no controlled studies comparing the effects of various commonly used techniques on cooling times or outcome in humans with heatstroke. Therefore, there are no totally agreed upon standards of care for empiric therapies that intuitively seem reasonable. Various techniques are discussed later, but the clinician should use the easiest and most logical technique as dictated by the specific clinical scenario and available logistical support.

General Considerations

Heatstroke mortality is proportional to the magnitude and duration of thermal stress measured in degree-minutes. [76] *Delay in cooling may represent the single most important factor leading to death or residual disability in those who survive.*[24] In addition, advanced age and underlying disease states are significant contributing factors.[12] [18] [19] Residual brain damage may occur in as many as 20% of survivors despite optimal treatment. The overall mortality rate may approach 50%.

Many exertional heatstroke victims are volume-depleted and may present with hypotension. As a result, initial stabilization with cooled (room temperature) IV fluids and correction of electrolyte abnormalities are valuable in the hypotensive patient. Traditional sources recommend a rate of 1200 mL over the first 4 hours, [77] [78] whereas others advise a 2 L bolus over the first hour, with an additional 1 L/hour for the following 3 hours. [78] Seraj and colleagues[79] have challenged this more aggressive recommendation. In their study of pilgrims who suffered heatstroke, 65% had a normal or above normal central venous pressure (CVP) measurement on arrival. They found that an average of 1 L of saline was sufficient to normalize the CVP during the cooling period in their patients, who had a mean age of 55 years (range, 31 to 80 years). Hence, fluid resuscitation should be monitored carefully in older patients to avoid pulmonary edema.

For heatstroke, there are no pharmacologic agents to accelerate cooling that are effective or that are associated with decreased morbidity or mortality. Specifically, dantrolene sodium is ineffective for heatstroke unassociated with malignant hyperthermia. Even in the latter setting, dantrolene sodium is an *adjunct* to direct cooling techniques.

Regarding antipyretics, *there is no known benefit for either salicylates or acetaminophen in the setting of heatstroke,* as their efficacy depends on a normally functioning hypothalamus. In addition, overzealous use of acetaminophen could theoretically potentiate hepatic damage, and salicylates may promote bleeding tendencies.[15] [80] A study comparing acetaminophen and physical cooling methods found that in patients treated with antipyretics only, the mean body temperature increased by 0.2°C on average.[81] The role of immunomodulators, such as interleukin receptor antagonists, antibodies to endotoxin, or corticosteroids is unproven.

Given that rapid cooling is accepted as the cornerstone of effective heatstroke therapy, the clinician must choose which cooling technique to use. Studies in animal models are based on the assumption that the fastest cooling technique is the best. In clinical patient care, other factors will also influence the choice of technique. Patient access, monitoring, safety, ease of use, and availability are all considerations, in addition to speed of cooling. A technique that may not be the most rapid but allows easy patient access and is readily available may be preferable to more cumbersome (albeit more rapid, once established) cooling techniques in some clinical settings.

The cooling rates achieved in various human and animal studies of heatstroke are summarized in Table 68-2 . As experimental subjects and techniques vary, it is not surprising that reported cooling rates show considerable variation. The relative advantages and disadvantages of various cooling techniques are outlined in Table 68-3 .

In addition to the cooling procedures outlined later, it is imperative that the clinician use judicious sedation and/or muscle paralysis to control agitation, suppress shivering, reduce energy expenditures, and to make the patient receptive to sometimes unpleasant therapies. [15] [21] [24] In general, IV benzodiazepines are the easiest and safest first-line drugs used for sedation.

Indications for Rapid Cooling

Rapid cooling should be instituted as soon as the diagnosis of heatstroke (rectal temperature >40°C, altered mental status, history of heat stress or exposure) is made. Rapid cooling is also indicated for the treatment of malignant hyperthermia and NMS but should be instituted concurrently with discontinuation of the triggering agent or drug and administration of dantrolene. Because studies show that the degree of organ damage correlates with the degree and duration of temperature elevation above 40°C, a reasonable clinical goal is to reduce the temperature to below 40°C within 30 minutes to an hour of the start of therapy. [12] [16] [24] There is no evidence to support a specific temperature end point at which cooling should be halted, but most series have halted aggressive cooling when the rectal temperature has dropped below 39.5°C.[25]

Contraindications for Rapid Cooling

Rapid cooling, per se, is never contraindicated in the presence of heatstroke. Immersion cooling is relatively contraindicated when cardiac monitoring of an unstable patient is required or when limited personnel make constant patient supervision impossible. Iced gastric lavage is contraindicated in patients with depressed airway reflexes unless the airway is protected by endotracheal intubation. Gastric lavage is also contraindicated by conditions that preclude placement of an orogastric or nasogastric tube. Cold peritoneal lavage is relatively contraindicated when multiple previous abdominal surgeries make placement of a lavage catheter risky owing to potential bowel perforation (see Chapter 44).

Evaporative Cooling

Evaporating water is thermodynamically a much more effective cooling medium than melting ice. Evaporating 1 g of water requires 540 kcal. Melting 1 g of ice requires only 80 kcal. In theory, therefore, evaporative cooling should be approximately seven times more efficient than ice packing. In practice, evaporative cooling is more efficient.[15] [82] In separate human studies, Wyndham et al.[83] and Weiner and Khogali[84]

TABLE 68-2 -- Cooling Rates Achieved with Various Cooling Techniques

Technique	Author(s), Year	Model	Rate (°C/min)
Evaporative	Weiner & Khogali, 1980	Human	0.31

	White, 1993	Dog	0.14
Cyclic lung lavage	Harris et al, 2001	Dog	0.5

found evaporative cooling to be 1.5 to 2.2 times faster than ice water immersion. Studies in primate models demonstrated faster cooling rates using evaporative cooling as an adjunct to ice bag placement.[85] Methods using convection and evaporation were more effective than those involving conduction for the treatment of hyperthermia.[15] In clinical practice, ice water immersion or ice packing are commonly undertaken because it causes heat loss by conduction, as well as by heat consumption by the phase change of melting ice. In healthy volunteers, evaporative cooling techniques (e.g., facial fanning) were associated with decreased thermal sensation and improved thermal comfort.[86]

Despite the continued enthusiasm of some clinicians for ice water immersion, *evaporative cooling is the fastest noninvasive cooling technique in human studies.*[13] [82] [86] To maximize evaporative cooling rates, several factors must be optimized. Air

TABLE 68-3 -- Advantages and Disadvantages of Various Cooling Techniques

Technique	Advantages	Disadvantages
Evaporative	Simple, readily available	Constant moistening of skin required
	Noninvasive	
	Easy monitoring and patient access	
	Relatively fast	
Immersion	Noninvasive	Cumbersome
	Relatively fast	Patient access and monitoring difficult
	Low mortality rates reported	Shivering
		Poorly tolerated by conscious patients
Ice packing	Noninvasive	Shivering
	Readily available	Poorly tolerated by conscious patients
Strategic ice packs	Noninvasive	Relatively slower cooling
	Readily available	Shivering
	Can be combined with other techniques	Poorly tolerated by conscious patients
Cold gastric lavage	Can be combined with other techniques	Relatively slower cooling
		Invasive
		Requires airway protection
		Human experience limited
Cold peritoneal lavage	Rapid cooling	Invasive
		Human experience limited

flow rates must be high (large fans are required). The air must be warm (but *not* humid), as evaporation is decreased at lower temperatures. The entire body surface must be exposed to airflow and continuously moistened with water (ideally the patient is suspended in a mesh sling to expose the back to airflow and moisture). Finally, the temperature of the water used to moisten the skin must be tepid (15°C). If the water is ice cold, evaporation will be slowed. Conversely, if it is hot, conductive heat gain may occur. Studies conducted in heat-stressed laying hens demonstrated superior cooling rates with ventral cooling regimes as compared to dorsal cooling. [87]

Weiner and Khogali[84] have constructed a sophisticated "body cooling unit" (BCU) to maximize evaporative cooling. Patients in the BCU are suspended in a mesh net. High airflow rates (30 m/min) at temperatures of 45°C are maintained both anterior and posterior to the mesh net. Atomized water at

15°C is continuously sprayed on all body surfaces. For emergency departments (EDs) without access to a BCU, temporary units can be set up using shower sprays and fans, providing the ambient temperature in the ED is relatively cool. [88] Dematte and colleagues recommend use of a body-cooling unit as a preferred technique for rapid cooling.[89]

The realities of clinical practice make these conditions impossible to fully replicate. Half the body surface (the back) will usually be unavailable for evaporative cooling. Airflow rates and temperatures are usually limited by the ambient temperature in the treatment facility and by the size and power of the fan available. These realities are reflected in the slower cooling rates achieved with evaporative cooling in a clinical setting.

Procedure

Evaporative cooling is accomplished by undressing the patient completely, positioning a fan or fans (usually at the foot of the bed or stretcher) as close to the patient as possible, and then sponging or misting the skin continuously with tepid 15°C water. A single care provider can continue the technique and monitor the patient once cooling has been initiated. It is important to keep as much body surface as possible moist and exposed to airflow. Covering sheets or clothing will impede skin evaporation and cooling.

Complications

Complications of evaporative cooling are rare and more often attributed to the underlying disorder than to the cooling technique. Wet skin may interfere with electrocardiogram (ECG) monitoring, but this can usually be avoided by using electrodes on the patient's back. Shivering occurs infrequently with this technique when compared with other cooling techniques, because the water is relatively lukewarm. [88] [90] Because the rectal temperature lags behind the core (esophageal) temperature, evaporative cooling should be discontinued when the rectal temperature reaches 39°C. In cases of mild hyperthermia, tympanic temperatures also accurately reflect core temperatures and can be useful in this setting. [91] Continued cooling beyond this temperature may lead to subsequent "overshoot hypothermia" due to continued core temperature drop after active evaporative cooling is discontinued. Shivering indicates that the core temperature has decreased to 37°C or below. [20]

Immersion Cooling

In one of the first studies of heatstroke cooling techniques, Daily and Harrison demonstrated that rats with hyperthermia cooled faster with ice water immersion than with evaporative cooling. [92] Some contemporary sources continue to recommend ice water immersion as the cooling technique of choice for heatstroke. [89] [93] Plattner and colleagues [93] demonstrated cooling rates with ice-water immersion that were six times faster than rates seen with forced air or circulating water.

Costrini and colleagues [95] reported no fatalities in 252 consecutive young marine recruits who were treated for exertional heatstroke over a 15-year period with ice water immersion within 20 minutes of diagnosis. They regard ice water immersion as superior in reducing mortality rates when compared to other conventional methods described in the literature.

Overall, in clinical trials, cold water immersion remains the second fastest noninvasive cooling technique available (see Table 68-2). In situations where an adequate evaporative cooling system is not available, immersion may be the cooling technique of choice. Several factors are important in maximizing the rate of immersion cooling. Conductive heat loss is dependent on cutaneous blood flow to maintain a heat gradient from skin to water. Theoretically, contact with ice water causes skin and subcutaneous (SQ) vasoconstriction, blocking heat exchange and turning these structures into insulators. [96] Intense cutaneous vasoconstriction will impede conductive heat loss. Mekjavic et al. [97] reported that motion sickness actually potentiates core cooling during immersion by attenuating the vasoconstrictor response to skin and core cooling, thereby augmenting heat loss and the magnitude of the decrease in deep body temperature. Careful monitoring is required because this may predispose patients to hypothermia. Magazanik et al. [98] in a canine study, suggested that warmer water (15°C) may actually cool faster than ice water (0°C). The optimal water temperature for cooling human heatstroke patients has not been defined.

Regardless of the water temperature, it is clear that increasing surface area increases conductive heat loss. Maximizing the body surface area in contact with the water will increase cooling rates with immersion cooling. In clinical practice, this means that complete immersion of the trunk and extremities will cool the patient faster than partial immersion of the trunk (back only) with the extremities extended out of the bath.

Procedure

Immersion cooling is accomplished by undressing the patient completely before transfer to a tub of water of a depth sufficient to cover the torso and extremities. Various water containers have been used. A regular bathtub, if available, can be used. Most clinical reports describe tubs that can be moved to the emergency treatment area when needed. A child's plastic wading pool and a decontamination tub or stretcher with waterproof sides and drainage capability are examples of the latter approach. The patient's head must be continuously supported out of the bath. In cases where tubs are unavailable, patients can be placed on water impermeable sheets and placed in a sling apparatus while ice and water are poured into the sling. [89] Temperature and ECG leads must be securely attached to the patient if monitoring is to be continued during immersion. The patient is removed from the bath when the rectal temperature reaches 39°C, because core temperature will continue to drop for a short period, even after the patient is removed. An electronic temperature monitor with a long flexible rectal probe is useful for continuous temperature monitoring during immersion. Studies show that rates of cooling close to 1°C per minute can be achieved. [23]

Complications

The common complications of immersion cooling are patient shivering, cutaneous vasoconstriction, patient discomfort, and the loss of monitoring capability. Shivering generates considerable heat through muscle metabolism. Cutaneous vasoconstriction impedes conductive heat loss. If significant shivering does occur, it can be reduced with benzodiazepine agents such as diazepam. Although the use of phenothiazines such as chlorpromazine has been advocated for shivering in the past, their use is currently discouraged because they also may impair heat loss by their anticholinergic effects on sweat glands, contribute to hypotension via a-adrenergic blockade, lower the seizure threshold, and cause dystonic reactions. In addition, they possess central dopamine-blocking effects

---

that may exacerbate symptoms of NMS. [53] Benzodiazepines are also valuable if the patient is hyperthermic secondary to sympathomimetic agents such as cocaine. Magazanik et al. [98] also suggested that warmer water temperatures (15°C) minimize shivering and increase cutaneous blood flow, thereby increasing cooling rates. DeWitte and Sessler [99] reported that shivering occurs only as the body's final defense after maximal arteriovenous shunt vasoconstriction and behavior modifications have proved to be insufficient in maintaining core temperature. Shivering typically occurs after temperatures fall below 37°C. [20]

Patient monitoring is a problem under water. Electrodes can be used on the nonimmersed upper shoulders. ECG artifact often becomes a major problem during vigorous shivering. Immersion cooling is not recommended for patients with unstable cardiac rhythms or patients who are at risk for developing these rhythms. A significant change in cardiac rhythm might go undetected during the labor-intensive process of immersion cooling.

Patient access for resuscitative procedures is also a major problem with this technique. Should the patient develop ventricular fibrillation, he or she must be removed from the bath and dried prior to defibrillation. Invasive and diagnostic procedures (e.g., IV access, radiography) cannot be performed during the cooling period. Care must be taken to avoid displacement of IV lines during placement in and removal from the bath.

As body temperature drops, mental status will improve in many heatstroke victims. When awake, most people find ice water immersion difficult to tolerate. IV sedation may be required.

Finally, this technique is labor-intensive. Several caregivers must be present throughout the process. The patient's head must be maintained out of the bath. If massage is used, one or more individuals will need to immerse their own hands in water to continuously massage the patient. Medications should be given IV, and constant attention to temperature and ECG monitors is also necessary. This cooling technique should be used only if adequate personnel are available.

Whole-Body Ice Packing

Packing the heatstroke victim in ice may enhance conductive heat loss without the attendant logistical problems caused by water immersion (Fig. 68-1). Constant attendance, as required for skin moistening with evaporative cooling and as described for immersion cooling, may not be necessary with ice packing. Kielblock et al. [100] demonstrated in a human study of mild, exercise-induced hyperthermia that whole-body ice packing cooled just as fast as evaporative cooling (see Table 68-2).

Procedure

Whole-body ice packing is accomplished by undressing the patient completely and then covering the extremities and torso with crushed ice. As with any cooling technique, constant temperature monitoring using an electric thermometer and a long, flexible rectal probe is recommended. A large supply of crushed ice will be needed whenever this technique is used. Logistically, ice packing may be problematic. Whole-body ice packing can usually be performed on the ED stretcher without additional equipment. Ideally the patient is placed in a container that facilitates ice contact with the skin and

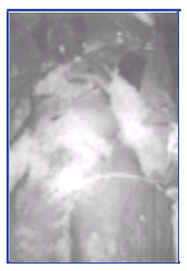

Figure 68-1 It is absolutely essential to rapidly lower the core temperature of a severely hyperthermic patient by instituting cooling techniques as soon as possible. Evaporative cooling (see text) is usually quite effective and technically easy. An alternative approach, albeit poorly studied, is to literally pack the patient in ice. In this case, plastic trash bags were used to hold the ice and to prevent water from dripping on the floor. A child's plastic wading pool is another option for this ice packing technique.

prevents water from dripping onto the floor. This is best accomplished by placing the patient in a child's lightweight plastic pool, which is available in toy stores. Lacking this equipment, plastic cloths or trash bags may be placed under the patient with the edges curled up to form a slinglike apparatus. As with immersion cooling, ECG monitoring can be potentially difficult owing to shivering artifact and displacement of electrodes. Alert patients usually do not tolerate ice packing well, and IV sedation or restraint is usually required. Excessive shivering can be treated with benzodiazepines if the rate of cooling is decreased. The ice is removed, and the patient dried off, when the rectal temperature reaches 39°C.

Strategic Ice Packs

Noakes has suggested that selective placement of ice packs over areas of the body where large blood vessels run close to the skin may be an effective cooling technique.[101] Cooling in these areas occurs despite cutaneous vasoconstriction, owing to direct conductive heat loss from the blood within the vessel, across the vessel wall, subcutaneous tissue, and skin to

the ice. The most common areas used for strategic ice packing are the anterior neck (carotid and jugular vessels), the axilla (axillary artery and vein), and the groin (femoral vessels). There have been numerous reports of successful cooling using ice packs as primary or adjunctive therapy (see Table 68-2).[88] [89] [101] In addition, application of ice packs, although easier to perform than immersion or total-body ice packing, limits the conductive cooling offered by the latter two procedures. [102] However, a study in pigtail monkeys demonstrated that a combination of strategic ice packs with evaporative cooling resulted in faster cooling than either technique alone, although the relative increase achieved by adding ice packs to evaporative cooling was small. [103]

In unconscious patients or in awake patients who can tolerate ice packs without excessive shivering, this technique could be added to evaporative cooling. However, the clinical value of strategic ice packs alone or in combination with other techniques remains to be determined. Anecdotally, during the Chicago heat wave of 1995, the majority of heatstroke patients who presented to EDs survived after being effectively cooled using the evaporation method accompanied by strategic placement of ice packs.

Procedure

This technique is best accomplished by placing large plastic bags filled with crushed ice or an ice water mixture in both axillae and over both femoral triangles. Do not diminish the effectiveness of the ice packs by wrapping them in towels—apply them directly to the patient. If the neck is used, the packs must be placed laterally, with care taken not to compress the trachea or apply excessive weight over the carotid arteries. The neck area should probably not be packed in the presence of carotid bruits or a history of cerebrovascular disease. Some sources advocate rubbing the body surface briskly with plastic bags containing ice after the body has been wet down with water. This is effective, provided it is combined with evaporation therapy. [21]

Complications

Complications of strategic ice packing are limited to shivering and patient discomfort as described previously for whole-body ice packing. The ice packs are removed when the rectal temperature reaches 39°C to avoid excessive core temperature drop. Prolonged direct contact with ice can produce cold injury. However, if the temperature is monitored and the ice packs are removed as soon as the target temperature is reached, such injury is unlikely.

External vs Core Cooling

All of the external cooling techniques described previously are noninvasive and use heat loss by evaporation or conduction across the skin as the primary cooling mechanism. With each of these techniques, dropping of the central temperature will continue even after the technique is discontinued and the skin is dried. This is due to a delay in the establishment of an equilibrium between the cold skin and the core. The amount of "core after-drop" can exceed 2°C. [93] For this reason, cooling is discontinued when the core temperature reaches 39°C.

Because the sites of significant cell damage with heatstroke are centrally located (e.g., liver, kidney, heart), central cooling techniques theoretically are preferable to external techniques. Core cooling techniques studied in both animal and human models include iced gastric lavage, intravascular cooling, bladder lavage, and peritoneal lavage.[93] [104] [105] [106] [107] Central venous cooling is effective in rapidly decreasing core temperatures. [108] Studies conducted in healthy volunteers demonstrated reductions of core temperatures varied according to the temperature of the infused fluid. Subjects receiving 30-minute infusions of fluid at 4°C experienced decreases in core temperatures of 2.5° ± 0.4°C. Subjects receiving 30-minute infusions of fluid at 20°C experienced decreases of 1.4°C (±0.2°C). [108] Clinical trials investigating cooling via the respiratory tract had no significant impact on temperature changes when used exclusively, yet demonstrated effectiveness as an adjunctive measure to other external cooling techniques. [91] Cool air (10°C) was administered via a hood or mask. Cooling via the respiratory tract has been studied in animals but not investigated clinically. [91] Central cooling techniques are necessarily more invasive than external techniques and therefore have the potential for more significant complications.

Cold Gastric Lavage

The stomach lies in close proximity to the liver, great vessels, kidneys, and heart. The gastric mucosa is not subject to the intense vasoconstriction observed on skin exposure to ice water.[109] For these reasons, lavage of the stomach might be expected to be an effective central cooling method. In one human trial, lavage with ice water at a rate of 500 mL/10 minutes was associated with increased abdominal cramping and diarrhea. [93] Human heatstroke victims have been successfully cooled with gastric lavage, but only in combination with external techniques. In practice, this technique is rarely used. Cold gastric lavage seems best suited for use in patients with severe hyperthermia who are cooling at a slow rate with external techniques alone. The presence of an endotracheal tube and the passage of a large-bore gastric tube make rapid lavage without aspiration possible. This technique should be reserved for patients whose airways are protected by endotracheal intubation and who do not have contraindications to gastric tube placement (see Chapter 41 Chapter 42 Chapter 43).

Procedure

Cold gastric lavage is best accomplished by instilling 10 mL/kg of iced tap water into the stomach as rapidly as possible (usually over 30 to 60 seconds). After a 30- to 60-second dwell time, the water is removed by suction or gravity. [107] Cooling will theoretically be faster if a high temperature gradient is maintained in the stomach. To this end, the lavage should proceed quickly. A faster lavage rate is usually maintained if suction is used to withdraw instilled fluid. A large container of ice-temperature water maintained 1 to 1.5 m above the patient's body will facilitate instillation of fluid. This container should be directly connected to the lavage tubing and should ideally allow passage of water but not ice, which may occlude the tube. Since large volumes of water are needed, it is helpful if ice can be added to the container without interrupting the lavage. A large syringe can be used as an alternative to gravity instillation, but this is usually slower.

A simple system that accomplishes this procedure can be devised from readily available equipment in most EDs. A standard lavage setup (for use in drug overdoses) and a large-bore gastric tube are used. The lavage bag is cut open at

the top to allow water and ice to be added. It is then suspended above the patient's body and connected to the orogastric tube by Y tubing with clamps. The other arm of the Y tubing is connected to suction. Using the clamps, ice water can intermittently be instilled by gravity and withdrawn by suction.

Complications

A major potential complication of cold gastric lavage is pulmonary aspiration. The use of a cuffed endotracheal tube minimizes the incidence of this complication. Owing to the large volume of water used and the frequent depression of airway reflexes seen with severe heatstroke, this technique should rarely be used in a patient who is not endotracheally intubated.

If tap water is used, water intoxication, hyponatremia, and other electrolyte disturbances are *potential* complications particularly in pediatric or geriatric patients. Water is absorbed from the stomach and, with large-volume lavage, may pass the pylorus into the small intestine. In canine studies, large-volume gastric lavage with tap water did not cause electrolyte abnormalities.[110] The actual incidence of these potential complications in human heatstroke has not been determined. The use of normal saline instead of tap water would eliminate this potential problem.

Theoretically, the passage of cold water through the esophagus, located directly behind the heart, has the potential to induce cardiac dysrhythmias. Dysrhythmias have not been observed in canine studies or in case reports of human heatstroke victims cooled with this technique.[109] [110]

Cold Peritoneal Lavage

The surface area and blood flow of the peritoneum greatly exceed those of the stomach. Peritoneal lavage is therefore expected to exchange heat much faster than gastric lavage. Peritoneal lavage demonstrates some of the fastest cooling rates ever reported in large animal or human studies (see Table 68-2). A case report of cold peritoneal lavage cooling for hyperthermia following ecstasy ingestion demonstrated rapid cooling.[111] As with gastric lavage, this central cooling technique offers the advantage of directly cooling the core organs that are most susceptible to thermal damage. Unlike with gastric lavage, endotracheal intubation is not required. Peritoneal lavage is used extensively to treat hyperthermia under various conditions and typically decreases core temperatures 5°–10°C/hour.[93] [104] [111]

Peritoneal lavage is a more invasive cooling technique. Surgical placement of the lavage catheter is necessary. Since heat exchange is more efficient across the peritoneum, smaller volumes of fluid can be used. This cooling technique is relatively contraindicated by conditions that preclude placement of a lavage catheter (e.g., multiple abdominal surgical scars) (see Chapter 44).

Peritoneal lavage is the most rapid central cooling technique. It can theoretically be combined with other techniques to speed cooling of the heatstroke patient with refractory hyperthermia. Being the most invasive cooling technique, it requires time, proper equipment, and surgical expertise to institute. Although effective, it is seldom used in clinical practice. Its use is probably best suited to situations in which heatstroke patients are not responding to external cooling and adequate equipment and personnel are readily available.

Procedure

To institute peritoneal lavage cooling, 2 to 8 L of sterile saline is immersed in an ice water bath to cool while the catheter is being placed. A standard peritoneal lavage catheter (as for diagnostic use in trauma patients) is placed using any of the techniques described in Chapter 44 . Standard contraindications apply. Use of a larger peritoneal dialysis catheter may speed fluid instillation and withdrawal. Actual lavage volumes and rates have not been established. One approach is to instill and withdraw 500 to 1000 mL every 10 minutes until adequate cooling is achieved. Rectal temperature may be falsely low during the lavage owing to the presence of cold water about the rectum at the level of the rectal temperature probe.[107] [112] It may be preferable to monitor tympanic membrane or esophageal temperature when using this technique. The lavage is discontinued when core temperature reaches 39°C to avoid excessive core temperature after-drop.

Complications

The potential complications of peritoneal lavage cooling are primarily related to placement of the catheter and include bowel or bladder perforation and placement into the rectus sheath rather than the peritoneum. These potential problems are discussed further in Chapter 44 .

Other Cooling Techniques

Although high-frequency jet ventilation (HFJV) causes core cooling in critically ill patients,[114] efforts to use the respiratory tract to cool heatstroke victims have been unsuccessful. In a canine model of heatstroke, the use of HFJV is shown to be a relatively ineffective cooling technique.[115] Heat loss by convection (air transfer) is relatively inefficient compared with the conductive heat loss mechanism used by other cooling techniques. The use of dry, hot air to maximize evaporative heat loss from the lungs might cause respiratory complications.[114]

In human trials, ice water lavage of the bladder (300 mL iced Ringer's solution/10 min) provided only minimal cooling with rates of 0.8°C (±0.3°C) per hour.[93] Iced water lavage of the rectum would theoretically provide faster cooling rates secondary to the increased surface area and better perfusion; however, it has not been investigated in human trials.[94]

Hemodialysis or partial cardiopulmonary bypass could theoretically be used to cool heatstroke patients. Before the availability of dantrolene in 1979, partial cardiopulmonary bypass was one treatment for malignant hyperthermia.[105] Its specific use in management of heatstroke has not been studied. Drawbacks could potentially include lack of technical expertise as well as preparation time for the procedure.

Cyclic lung lavage using cold perflurochemical lung lavage in animal models is currently under investigation. Benefits include rapid cooling rates of 0.5°C per minute and are minimally invasive in the already mechanically ventilated subject.[116] [117] [118]

In addition to physical cooling techniques, pharmacological agents have demonstrated merit as adjunctive agents in the management of hyperthermia. There are anecdotal reports of enhanced temperature reduction using intravenous ketoralac. In a recent study, Cienki and colleagues[119] demonstrated enhanced temperature decreases using ketorolac, 30 mg IV. All patients received standard treatment for

hyperthermia (e.g., ice packs, iced lavage, circulating air). Patients were randomized to receive ketorolac versus saline. In the group receiving ketorolac, the average rectal temperature after 90 minutes was two times lower than that of those receiving placebo saline (3.7°F vs 1.6°F).

SUMMARY

Rapid cooling is the key step in the emergency management of heatstroke patients. Survival approaches 90% when elevated temperatures are lowered in a timely fashion.[19] [27] The highest documented temperature in the medical literature with survival is 48.8°C (115°F). In this case, the patient was rapidly cooled and recovered without neurologic sequelae.[34] Evaporative cooling appears to be the technique of choice. It combines the advantages of simplicity and noninvasiveness with the most rapid cooling rates achieved with any external technique. It is also logistically easier to institute, maintain, and monitor evaporative cooling than any other cooling technique. If a patient is not cooling rapidly with evaporative cooling, other techniques can be added. Ice packing or strategic ice packing is a common alternative technique that can be rapidly instituted in any ED. If the patient is endotracheally intubated, gastric lavage can be instituted. If facilities and personnel are available, peritoneal lavage cooling can be used as a rapid central cooling technique.

If muscle rigidity is present or malignant hyperthermia is suspected, dantrolene sodium should be administered. In addition, the clinician should have a heightened index of suspicion for NMS and sympathomimetic drug toxicity. Regardless of the cause, a reasonable clinical goal is to reduce the rectal temperature to 40°C or below within 30 minutes of instituting therapy.[89]

Immersion cooling is best limited to centers with the proper equipment and skilled medical personnel experienced in managing hyperthermic patients. This method may also be effective in conditions in which electric power for evaporative cooling is unavailable (e.g., in wilderness settings where bodies of cool water are available nearby and the victim is far from more sophisticated medical care). Central venous cooling with iced saline is a promising cooling technique for rapid cooling for severe hyperthermia. Other cooling techniques require further study before a clear recommendation as to their efficacy can be made.

Acknowledgments

The authors wish to acknowledge and thank Dwight E. Helmrich and Scott A. Syverud for their valuable contributions and authorship in previous editions.

Chapter 69 - Ultrasound-Guided Procedures

Sarah A. Stahmer
Lisa Mackowiak Filippone

Sonographic guidance for invasive procedures is a logical addition to the practice of emergency medicine. As of this writing, however, it is not considered standard of care that the emergency clinician is skilled in, or has access to, bedside ultrasonography. Bedside sonography images deep tissue anatomy, thus increasing the chance of successful performance of a wide range of invasive procedures and minimizing associated complications. Consensus guidelines developed by the American College of Emergency Physicians for use of ultrasound (US) by emergency clinicians include sonographic guidance for procedures as being within the scope of practice for emergency clinicians.[1] This chapter is not meant to be a comprehensive description of the US examination, nor should it be viewed as a tutorial for emergency clinicians unskilled in the use of US. It is assumed that the emergency medicine clinician using US has had some formal training in the performance and interpretation of directed bedside US as outlined in the ACEP 2001 guidelines. The following chapter will describe those procedures within the scope of practice of emergency clinicians for which there is a role for bedside US. The procedures described here are covered in detail elsewhere in the text, and this section will focus primarily on the role of US.

PHYSICS

US images are created by high-frequency sound waves, which are generated and interpreted by a transducer and then converted electronically to form an image on a screen. The transducer is a probe that contains crystals, which change shape and vibrate when an electrical current is applied, creating sound waves. This is referred to as the *piezoelectric* effect. The crystals emit sound for a brief moment, and then wait for the returning echo reflected from the structures in the plane of the sound beam. When the echo is received the crystals vibrate, generating an electrical voltage proportional to the strength of the returning echo. This is then converted electronically into an image on the viewing screen.

Sound waves are reflected back to the transducer from tissue interfaces that have different acoustic impedances (the density of the tissue times the speed of sound in tissue). Tissues of higher density such as bone that interface with lower density substances such as muscle or fluid will reflect nearly all the sound waves, and will appear on the monitor as brightly echogenic (white) structures. Fluid transmits nearly all the sound waves, and will appear black or anechoic. Tissues will vary in their echogenicity or brightness based on their density, compliance, and adjacent structures (Fig. 69-1).

The purpose of using US during a procedure is to allow the clinician to "see" the area of interest below the skin surface. The area on the body surface that will provide the best images is referred to as the *acoustic window*. There are some general principles that help determine the suitability of an area as an acoustic window. Sound waves travel best through structures that are composed of closely packed molecules. Air, because the molecules are widely spaced, is a very poor conductor of sound. Therefore, structures that contain air, such as the lungs and bowel, cannot be imaged with US. In addition, structures that lie beneath an air-filled structure (such as the aorta, which lies beneath loops of small bowel) may not be clearly visualized. In contrast, fluids have tightly packed molecules and conduct sound well. Fluid-filled structures are readily visualized with US because the fluid/tissue interface is highly reflective, creating a clear image. Fluid-filled structures also serve as excellent acoustic windows to structures that lie beneath them. Therefore, procedures involving entry into a fluid-filled space are best suited to sonographic guidance. For each of the procedures listed in this chapter, the optimal acoustic window is described.

INDICATIONS AND CONTRAINDICATIONS

US may be used to guide cannulation of vessels, aspirate fluid collections within cavities (e.g., pericardium, pleurae, bladder, or joints), and locate soft tissue foreign bodies. US may be used to mark the site for skin puncture or provide continuous real-time visualization throughout the procedure. The real and potential applications for bedside sonography continue to expand as technology improves and clinical expertise in the hands of emergency clinicians grows. It is truly an extension of the examining clinician's eyes and hands and may be used to visualize any portion of the anatomy that is amenable to sonographic imaging. US is especially helpful in answering clinical questions regarding depth, size, and nature of subcutaneous masses or collections and determination of the presence of fluid within body cavities.

Figure 69-1 Longitudinal image of the gallbladder, demonstrating variability in tissue echogenicity. *A,* The anechoic appearance of fluid. Water, plasma, non-clotted blood, and urine will have the same appearance. *B,* The highly reflective appearance of a calcified stone in the gallbladder. Foreign bodies, needles, and bone will have a similar brightly echogenic appearance. *C,* The relatively hypoechoic appearance of tissue. Clotted blood, particulate material within fluid (lipid or purulent material) will appear the same, with echogenicity intermediate to bone and fluid.

The clinician choosing to use sonography must have training and experience in the use of US technology and image interpretation. Clinical errors directly related to the use of bedside US usually result from incorrect use of the technology or misinterpretation of sonographic images. Technological errors may occur when the wrong probe is used. For example, procedures requiring high resolution (central vein cannulation or foreign body detection) should be guided with a high-frequency probe. Lower frequency probes may not adequately delineate structures and hence lead to error. Imaging of the heart often requires a probe with a small "footprint" that will allow for imaging between the ribs; a larger footprint probe will include rib shadows that may affect the quality of the examination. Inadequate amounts of gel and air bubbles in the probe cover can create artifacts that adversely affect the technical quality of the images. Finally, the sonographer must be familiar with the various settings on the machine that will determine image quality. For example, inappropriate gain settings are common sources of error and image misinterpretation; too much gain may give the appearance of echogenic shadows within spaces. These shadows may then be interpreted as tissue or clot.

Problems with interpretation usually arise when the clinician is attempting to interpret an image that is suboptimal, due to poor patient preparation or positioning, the presence of air-filled structures between the probe and structure of interest, or lack of appreciation of sonographic artifacts. Emergency clinicians are often required to perform procedures under suboptimal conditions, and the same is true for sonography. Bedside sonography is often performed simultaneously with other procedures on a patient who may be unable or unwilling to fully cooperate. The patient may be receiving active chest compressions or be profoundly hypotensive, leaving vessels flaccid with poor flow. There may be subcutaneous air or significant soft tissue swelling between the probe and object of interest, and veins may be filled with clot or scar from previous central lines. For these reasons, the clinician using sonography must adhere to a few important principles. First, do not attempt to interpret a sonographic image that does not clearly depict the structure or organ of interest. Second, interpret the sonographic image in the context of the clinical picture—what you see must make sense to what is happening clinically. Finally, if you are not sure of what you are seeing—obtain an alternative imaging study or expert assistance.

For the remainder of this chapter, it is assumed that the clinician performing a US-guided procedure has appropriate training and experience. To avoid redundancy, this point will not be restated. That is, lack of sonographic training and experience is a contraindication for incorporating bedside sonography with any procedure.

EQUIPMENT

The crystals determine transducer frequencies. Those used most commonly for medical diagnostic imaging range from 2 MHz to 10 MHz. Lower frequency probes are used for viewing deeper structures, such as the heart or the aorta, and larger patients, but produce images that are of lower resolution. Higher frequency probes provide high-resolution images of fairly superficial structures, such as veins and subcutaneous tissues, and are recommended for use in children and very

Figure 69-2 The curvilinear array probe is used for lower frequency (2.0 to 5.0 MHz) scanning of the abdomen and chest. It is best used for cardiac and abdominal imaging. The linear array probe is used for high frequency (6 to 10 MHz) scanning of superficial tissues, vessels, subcutaneous masses, and foreign bodies.

thin adults. The highest possible frequency probe should be used because it will provide superior resolution.

Transducers vary also in the array of their piezoelectric elements, or crystals. The nature of the array will affect the overall field of imaging. The transducer array with the widest range of applications for emergency sonography is the curvilinear array, which has a narrow near field and pie-shaped window, allowing for a small acoustic window and large imaging area. This is ideal for imaging between ribs and curved surfaces. The linear array is used for high-frequency scanning of superficial tissues and is ideal for imaging vessels, subcutaneous masses, and fluid collections (Fig. 69-2).

There are several needle guidance systems available. Attached to the probe of such a system is a metal or plastic device through which the needle passes (Fig. 69-3). While these systems are designed to improve the accuracy of needle insertion, the path of the needle is determined by the probe angle, which can be altered by even subtle hand movements. Needle guidance systems are most useful when the target

Figure 69-3 An ultrasound needle guide is ideally used to guide needle placement into deep or small structures. *(Courtesy of Dymax Corp, a subsidiary of Bard Access Systems.)*

organ is deep or small in size, and are usually not necessary for the majority of emergency department (ED) procedures.

GENERAL APPROACH

Most procedures facilitated by the use of bedside US require the use of two hands. Therefore, the clinician must make a decision whether to have an assistant hold the probe, perform the procedure with one hand while holding the probe in the other (freehand), or use the US probe to simply mark the point of entry prior to the procedure (blind approach). When the procedure requires two hands, it is best to have an assistant hold the probe. This is particularly important when one needs to visualize needle entry into the space or vessel. The freehand approach requires the operator to hold the probe in one hand while performing the procedure with the other. This is best suited for procedures that require only one hand, such as needle aspiration of large joint spaces or abscesses.

The blind approach is best used for large collections of fluid, such as ascites or large pleural effusions. The optimal site is identified prior to the start of the procedure and the area marked with a sterile pen. The depth of the collection is noted by referring to the depth markers to the right of the imaging screen, which indicate the distance from the skin surface to the most anterior margin of the collection or vessel. Depending on the area of interest, it may be necessary to note the patient's position and phase of respiration when identifying the point of entry. This is particularly important when attempting thoracentesis (phase of respiration) or paracentesis (patient positioning).

Catheters, wires, and needles appear as brightly reflective structures within the fluid-filled anechoic space. Keeping the needle perpendicular to the plane of the US beam will maximize the chance of visualizing the needle. Other methods that have been reported to improve visualization include placing the focal zone in the near field and bobbing the needle. The latter requires an in-and-out jiggling type of movement that moves the needle within the sonographic window. [2]

When the probe is left in place during the procedure, it needs to be covered with a sterile rubber sheath (a sterile glove is usually adequate). When available, a transparent sterile drape can also be used. In either case, a layer of acoustic gel should be placed between the probe and sterile cover or drape. Another layer of sterile acoustic gel should be placed between the skin surface and the probe cover or drape.

Central Venous Line Placement

Obtaining vascular access is central to the care of many patients in the ED, particularly those who are critically ill or injured. Peripheral access is often difficult in these patients and central venous catheter placement is necessary. Bedside US has been shown to improve the chance of successful central vein cannulation and to reduce the number of complications. While internal jugular and femoral vein access are amenable to sonographic guidance, the subclavian vein is difficult to visualize sonographically secondary to the presence of the clavicle and will not be described here.

Background

Sonographic guidance (using two-demensional echo) of central vein access was first described in 1986. [3] In 1990, Mallory et al. compared the standard landmark-guided technique to the US-guided technique for cannulation of the internal jugular vein in intensive care unit patients. They demonstrated a 100% success rate in the US-guided group versus a 65% success rate in the landmark group. [4] Another prospective study in 1991 evaluated 160 cardio-thoracic surgical patients requiring right internal jugular vein cannulation. The US group had a greater overall success rate (100% vs. 95%), a higher percentage of first-attempt cannulations (73% vs. 54%), fewer attempts per cannulation (1.4 vs. 2.8), shorter time per cannulation (61 vs. 117 seconds), and fewer carotid punctures (1 vs. 7) compared with a control group using the standard landmark technique. [5] In 1993, Denys et al. conducted the largest prospective trial to date, comparing the results of 302 US-assisted internal jugular vein cannulations with 302 cannulation attempts using the standard external landmark-guided technique. The US group had a higher success rate with fewer attempts, a decrease in the mean time to cannulation, and a reduction in complications including carotid puncture, brachial plexus injury, and hematoma. [6] Another study performed on ED patients by emergency clinicians again demonstrated more successful single-needle-pass punctures of the internal jugular vein using US guidance, particularly in patients with no visual or palpable landmarks. [7]

The benefits of using US for central venous access have also been demonstrated in children. [8] [9] This is no surprise since children's vessels are smaller, cooperation is unpredictable, and tensions are often high when performed under emergent conditions. In addition, compared with older children and adults, studies have demonstrated that younger children have more failed attempts and more complications. [8] [10] [11] [12] In a study of infants under 12 months of age undergoing preoperative central line placement, one study found that cannulation of the internal jugular vein was 100% successful using US guidance (n = 43) vs 77% in infants using the standard landmark-guided technique (n = 52). [8] The time for cannulation was also significantly reduced (3.3 minutes vs 10 minutes) and the incidence of carotid punctures was lower (0% vs 25%) in the US group. [8]

There have been few studies evaluating the use of US for femoral vein access, but the evidence to date is encouraging. In 1997, Kwon et al. demonstrated greater success (100%) in cannulating the femoral vein using US guidance compared with the standard landmark-guided technique (89%) in patients requiring central venous access for hemodialysis. [13] Complication rates were also lower in the US-guided group. [13] Hilty et al. compared success and complication rates of US-guided femoral line placement with that of the standard landmark-guided approach in ED patients during cardiopulmonary resuscitation. The success rate using US was 90% vs 65% in the control group. There were no arterial punctures in the US group; however, the femoral artery was punctured in 20% of blind attempts. [14]

Other vessels besides the internal jugular and femoral veins can be cannulated safely using US guidance. Of particular interest is the brachial vein, which is usually not attempted due to absence of reliable landmarks, deep location, and proximity to important structures (e.g., nerves, brachial artery). A study by Keyes et al. showed that the brachial vein can be safely cannulated using sonographic guidance in patients with limited access (50 intravenous drug users and 21 obese patients). The brachial vein was successfully cannulated in 91% of patients within a mean time of

77 seconds. Reported complications were pain, line failure due to falling out or infiltration (8%), and brachial artery cannulation (2%). [15]

Indications and Contraindications

If sonographic equipment is readily available, the emergency clinician should have a very low threshold for using it to guide central venous cannulation. It is especially helpful when access is required on a patient with distorted anatomy, obesity, history of multiple prior central lines, and hypotension, and when blind attempts have been unsuccessful. The benefits include localization of the vein and artery and demonstration of venous patency through ease of compression and free flow (if Doppler is available). There are no reported contraindications specific to sonographic guidance of venous cannulation.

Equipment

A high-frequency (7.5 MHz to 10 MHz) linear probe is highly recommended for imaging the relatively superficial internal jugular and femoral veins. A needle guide may be helpful for deep or small veins, but may make coordinating imaging and access more difficult for less experienced sonographers (see Fig. 69-3). If a linear probe is not available, any high-frequency probe, such as the endovaginal probe, can be used. A sterile sleeve (or glove) and sterile conductive medium are required. A sterile marking pen can be used to mark the location of the vein if the US probe is removed before puncture (see later in this section). Two persons are usually required—one to perform the US while the other obtains vascular access.

Image Interpretation

The internal jugular vein and carotid artery will appear as relatively superficial structures on the monitor. When viewed in the transverse plane, the internal jugular vein is a thin-walled, circular, anechoic structure anterior and lateral to the carotid artery. However, there is some variability in the relationship between the two

vessels.[16] [17] Denys et al. studied the location of the internal jugular vein relative to the carotid artery in 200 patients. They found that 2% of patients had an internal jugular vein that was positioned medially, overlying the carotid artery. The internal jugular vein was found more laterally than expected in 1% of patients. [16] Turning the patient's head will also alter the relationship between the vein and artery, usually moving the vein medially over the artery. When patent, the internal jugular vein will increase in size with inspiration and Valsalva maneuvers. Light pressure applied with the probe directly over the vessels will easily compress the internal jugular vein and only one anechoic circular structure, the carotid artery, will be seen on the monitor. Once pressure is released, the lumen of the internal jugular vein will reappear. The external jugular vein is not usually seen on the monitor. Because of its superficial location and compressibility, it is usually flattened just by placement of the probe on the neck.

The femoral artery and vein also appear as superficial anechoic circular structures when viewed in the transverse plane. The vein is located medially and the artery is located laterally. As the probe is moved toward the patient's head, this relationship changes, with the vein eventually lying behind the artery. Other sonographic findings helpful in distinguishing the femoral vein are that it is easily compressed and will increase in size by squeezing the thigh. The artery is not readily compressed and can be seen to pulsate. One exception to this may be in patients who are undergoing cardiopulmonary resuscitation, where pulsations will be seen primarily in the femoral vein and not the artery. Coletti et al. described the presence of femoral pulses in canines when cardiopulmonary resuscitation was in progress and the proximal femoral artery was clamped. These pulses disappeared when the proximal femoral vein was clamped and the artery unclamped. [18]

Procedure and Technique

Internal jugular vein

To access the internal jugular vein, the patient is placed in the supine position with the head turned slightly to the opposite side of the vein being cannulated. The lateral aspect of the neck is prepped and draped in the usual fashion (see Chapter 22). A small amount of US medium is placed on the probe. A sterile sleeve or glove is placed over the probe. It is important to remove any air bubbles between the gel on the probe and the sterile cover, as this will create artifacts. Sterile gel is then placed over the cover. A sterile towel or drape can be wrapped around the rest of the probe and cord to help maintain sterility.

The US probe is placed parallel and superior to the clavicle over the groove made by the two heads of the sternocleidomastoid muscle (Fig. 69-4). The beam of the US probe should intersect the carotid artery and the internal jugular vein in a transverse or cross-sectional plane. At this level, the internal jugular vein is usually anterior and lateral to the carotid artery (Fig. 69-5*A* and *B*). Additional maneuvers can help in differentiating the internal jugular vein from the carotid artery (e.g., the vein will markedly increase in diameter with Valsalva maneuvers). Asking the patient to blow on his or her

Figure 69-4 Imaging window for the internal jugular vein and carotid artery. The ultrasound probe should be covered with acoustic gel and then a sterile cover or glove. An additional layer of sterile gel should be placed over the cover. The probe is then placed parallel and superior to the clavicle over the groove made by the two heads of the sternocleidomastoid muscle. The probe should be pointed toward the patient's right. Care should be taken not to apply undue pressure on the probe to avoid compression of the easily collapsible internal jugular vein. Asking the patient to blow on his or her thumb or performing a Valsalva maneuver will increase the luminal diameter of the vein. *(Lydia F. Roberts, Photographer)*

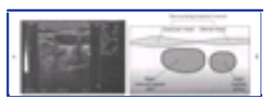

Figure 69-5 The internal jugular vein and carotid artery. *A,* Sonographic image; *B,* Schematic representation. The beam of the ultrasound should intersect the carotid artery and the internal jugular vein in a transverse or cross-sectional plane. The internal jugular vein is easily identified by its compressibility and response to Valsalva maneuvers (i.e., it increases in diameter).

thumb is often helpful in creating a sustained Valsalva maneuver that will readily identify a patent internal jugular vein. If one applies gentle pressure to the vein, it will collapse. On the screen, only the carotid artery lumen will remain. Either color or power Doppler can also readily distinguish a vein from an artery. Pulsatile flow within the carotid artery appears quite different from lower amplitude, phasic venous flow that augments with Valsalva maneuvers. Once visualized, the internal jugular vein should be centered on the monitor screen, allowing the center of the probe to be used as a guide for needle puncture. The needle will first indent the vein. Then the vein will appear to collapse on the monitor as it is entered (Fig. 69-6*A* and *B*). The needle is advanced slightly farther and the vein will re-expand once it has been entered. The needle may seen on the monitor, particularly if the US beam is perpendicular to needle (Fig. 69-7*A* and *B*). Once venous blood is aspirated, the US probe may be removed. A guidewire is then threaded through the needle and the catheter is placed as described in Chapter 22 .

An alternative method, requiring only one operator, is to use the US to locate the underlying vein and then mark its location with a sterile pen. The internal jugular vein is usually a very superficial structure between the two heads of the

Figure 69-6 *A* and *B,* Once the vein is positioned directly under the probe, needle aspiration can be attempted. If the site of skin puncture is correct, the needle will indent the vein and the vein will appear to collapse as it is entered.

sternocleidomastoid muscle, and easily accessed once its location and patency is confirmed with US. Care must be taken not to readjust the position of the patient's head at this time. Rotating the head farther away from the vessel being cannulated will usually cause the vein to move medially over the carotid artery, and increase the risk of inadvertently puncturing it. The probe is removed after the vein has been located and needle puncture is performed.

Femoral vein

The patient is placed supine with the leg extended and slightly rotated externally. The patient is prepped and draped as usual (see Chapter 22), and the US probe is prepared as described earlier. If the patient has a palpable pulse, the US probe is placed over the pulse in a transverse orientation inferior to the inguinal ligament. If the patient does not have a palpable pulse, the probe should be placed approximately midway between an imaginary line drawn from the anterior superior iliac spine to the ipsilateral pubic tubercle just inferior to the inguinal ligament. The vein will be the vessel located medially. Similar maneuvers as described earlier can be done to help distinguish the femoral vein from the artery. These include compression with the probe and squeezing the thigh, which is the "Valsalva equivalent" for the femoral vein and

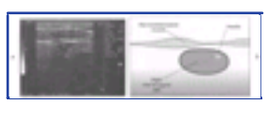

Figure 69-7 *A* and *B,* The needle may be visualized within the vessel lumen, and will appear as a brightly echogenic structure.

will increase the vessel caliber in a patent vein. Once located, the vein should be centered on the screen so that the middle of the probe can be used as a guide for the needle stick. Once the vein is entered the probe can be removed and a guidewire advanced through the needle. Subsequent cannulation of the vein is described in Chapter 22 .

Complications

Complication rates for the standard landmark-guided approach of internal jugular vein cannulation are between 4% and 10%. [19] [20] [21] Reported complications include vascular perforation and laceration, pneumothorax or hemothorax, tracheal perforation, brachial plexus and phrenic nerve injury, hematoma formation, thoracic duct injury, and catheter malposition. Several trials have shown that using US guidance to cannulate the internal jugular vein decreases complication rates, particularly carotid artery puncture.[5] [6] [8] [22] Troianos et al. reported a decrease in the carotid artery puncture rate from 8.43% to 1.39% using standard vs US-guided cannulation of the internal jugular vein.[5] Likewise, Denys et al. demonstrated a similar decrease in carotid artery punctures using US guidance, as well as decreases in brachial plexus irritation and hematoma formation.[6]

Potential complications unique to femoral vein cannulation include retroperitoneal hematoma, bowel perforation, and bladder perforation. Two studies comparing the complication rates of US-guided vs standard femoral vein cannulation have demonstrated reduced complications using US. [13] [14]

Complications unique to using US are rare and usually due to poor technique or attempts to use a low-resolution probe to image the vessels. One commonly encountered problem is in patients with proximate clot or stricture in the vein from prior central lines. In these patients, the vein will be seen and readily accessed, yet there will be little to no flow. A clue to this possibility is a vein that does not easily compress. When in doubt, comparison with the opposite side may also be helpful. In addition, Doppler can identify those vessels with proximate obstruction, but is not essential. Finally, remember that the anatomical relationships between the internal jugular vein and artery will change with head turning, and may place the artery beneath the vein. If the blind approach (i.e., marking the skin and removing the US probe prior to insertion) is used, the vessels should be imaged after final head positioning and the patient kept immobile until the line is secured.

Pericardiocentesis

The role of bedside sonography in the management of patients with suspected pericardial effusion is to establish the diagnosis and to visualize placement of a drainage catheter within the pericardial sac. The diagnosis of a clinically significant pericardial effusion is readily determined by bedside sonography, and is far superior to physical examination alone. Sonography is the study of choice for identification of pericardial effusions, and the availability of bedside US has the potential to shorten time to diagnosis of patients with clinically significant effusions. [23] [24] [25] [26] [27] For the subset of patients who are hemodynamically compromised by their effusion, pericardiocentesis performed under sonographic guidance is a safe and effective alternative to blind aspiration.

Background

Aspiration of the pericardial sac by emergency clinicians is usually a last-ditch effort to resuscitate patients with pulseless electrical activity (PEA) and is often unsuccessful. This is because the diagnosis is usually considered only after the patient has become unstable and pericardiocentesis is performed late in the resuscitation effort. Recent studies have shown that while large pericardial effusions are a rare cause of hemodynamic instability in the ED, a low threshold for performing bedside US may increase detection of effusions before they become hemodynamically significant. [25] [28] [29]

The traditional approach to the patient with a suspected clinically significant effusion has been to blindly access the pericardial sac using the subxiphoid approach. This technique is associated with a variety of complications, including puncture of the liver, lungs, myocardium, and epicardial vessels [30] [31] (see Chapter 16). In hemodynamically stable patients, a surgical window is usually performed in order to avoid the complications of blind aspiration. Over the past decade there has been increased enthusiasm for echocardiographically guided pericardiocentesis. The techniques first described in 1998 [30] are applicable to the ED setting and can be used for management of patients with hemodynamically significant pericardial effusions.

Indications and Contraindications

Patients presenting with acute and subacute cardiac tamponade usually do not display the classic triad of hypotension, neck vein distention, and muffled heart tones. Waiting for their appearance to order a confirmatory test will often delay diagnosis and possibly jeopardize the safety of the patient. The heart should be imaged whenever a clinically significant pericardial effusion is suspected. Scenarios warranting consideration of a pericardial effusion include a patient with hypotension of unclear etiology, particularly those patients with known malignancies, recent myocardial infarction, and end-stage renal disease, and victims of trauma, both blunt and penetrating.[25] [26] [27] [28] [29] Early demonstration of a large pericardial effusion will guide further work-up, support early consultation from either cardiology or cardiothoracic surgery, and facilitate therapeutic drainage for those patients who remain hypotensive in spite of fluid resuscitation. For patients in extremis, the clinician most clinically experienced in both sonography and aspiration of the pericardial sac should perform pericardiocentesis without delay. For patients with large effusions who are relatively stable, management options are greater and may include a pericardial window. Consultation with either cardiology or cardiothoracic surgery is advised prior to performing aspiration on stable patients.

Equipment

The optimal probe frequency is 2 to 4 MHz. It should have a small enough footprint to allow for imaging between the rib spaces, particularly if the parasternal windows are used. For the subxiphoid view, the standard 2 to 3.5 MHz curvilinear probe will provide excellent images.

Acoustic Windows

The cardiac examination is dynamic. The sonographer must identify the imaging window that provides images which best demonstrate the effusion or cardiac chamber of interest. Most frequently used are the subxiphoid and parasternal windows. It is important for the sonographer to develop expertise in using a variety of imaging windows to obtain the necessary clinical information.

Figure 69-8 To obtain a subxiphoid view of the heart and pericardium, the probe should be placed beneath the xiphoid process with the probe marker pointing to the patient's right. The probe should be angled upward and slightly to the left. *(Lydia F. Roberts, Photographer)*

Subxiphoid view

This view provides the most comprehensive information for a single view, and is therefore the most important acoustic window for the less experienced sonographer to learn. It will readily identify a circumferential pericardial effusion and allow assessment of overall cardiac wall motion. The subxiphoid view can usually be obtained within 1 minute, and may be the only view required. To obtain the subxiphoid view, the probe is placed transversely at the left costal margin at the level of the xiphoid process with the beam aimed at the left shoulder (Fig. 69-8). The angle and rotation of the probe should be adjusted to obtain the appropriate views. The structures closest to the probe will appear at the top of the display and include the liver, diaphragm, pericardial space, and right ventricle (Fig. 69-9*A* and *B*).

Figure 69-9 *A,* Sonographic appearance of a normal heart and pericardium obtained through the subxiphoid window. The right ventricle will be the most anterior cardiac structure, bordered superiorly by the pericardium and diaphragm. *B,* Schematic representation.

Figure 69-10 To obtain a parasternal view of the heart, the probe should be placed adjacent to the left sternal border in the left second or third intercostal space. The patient's head is at the lower edge of the photograph. *(Lydia F. Roberts, Photographer)*

Parasternal view

The next most useful view is the parasternal long axis view. To obtain this view, the transducer is placed in the left parasternal area between the second and fourth intercostal spaces. The plane of the beam should be parallel to a line drawn from the right shoulder to the left hip with the marker pointing to the right shoulder (reverse if the image is not set for cardiac views) (Fig. 69-10). The parasternal view provides excellent images of the left atrium, mitral valve, left ventricle, aortic valve, and the proximal ascending aorta. It is also the best view to identify small dependent collections within the pericardial sac (Fig. 69-11*A* and *B*).

Image Interpretation

The normal pericardium will appear as a single, brightly echogenic stripe adjacent to the myocardium. Fluid within the pericardial space will collect between the visceral and parietal pericardium and will appear as a large, non-beating, anechoic area adjacent to the ventricular myocardium (Fig. 69-12*A* and *B*). A small amount of fluid in the dependent portion of the pericardial space is normal. The sonographic appearance of the clinically significant effusion is distinct. The sonogram will reveal a hyperkinetic heart within a circumferential pericardial effusion, with diastolic collapse of the right-sided chambers. This reflects pressures within the pericardial space that are greater than the right ventricular filling pressure during diastole. The inferior vena cava will be dilated and not show respiratory variation or collapse when the patient is asked to "sniff."

Procedure and Technique

Tsang et al. described the technique for US-guided pericardiocentesis in 1998. [30] The ideal site of skin puncture is where the largest area of fluid accumulation is closest to the skin surface. On US, this is demonstrated by visualizing a large anechoic area at the top of the screen (which is the body area

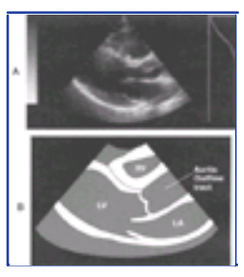

Figure 69-11 *A,* Sonographic appearance of a normal heart and pericardium obtained through the parasternal long axis window. This view is an excellent imaging window for posterior effusions. *B,* Schematic representation.

Roberts, Photographer)*

closest to the probe) and usually corresponds to the left anterior chest wall (rather than the subcostal region) (Fig. 69-13*A*,*B* , and *C*). In addition to being closer to the skin surface, this approach avoids injury to the liver. Inadvertent puncture of the lung is also prevented using this approach, because air in the lung will not conduct sound waves and will prevent visualization of the heart when located immediately beneath the probe. The clinician should avoid choosing a site that might puncture either the internal mammary artery, which lies 3 to 5 cm from the parasternal border, or the neurovascular bundle located at the inferior rib border. The best site should be marked with a sterile pen.

The needle trajectory and depth should be confirmed prior to skin puncture. Repositioning the patient will alter the position of the heart and pericardial sac within the chest and requires reassessment. The skin should be prepared antiseptically and a sterile cover placed over the probe. If time permits, the selected area should be anesthetized with 1% to 2% lidocaine, using the superior border of the adjacent rib as a landmark. The needle should ideally have an "over-the-needle" sheath that allows the needle to be withdrawn after the pericardial space is entered. This helps avoid injury to the heart and other vital structures. A 16- to 18-ga needle that is 5 to 8 cm in length is ideal. A saline-filled syringe should be attached to the needle, and gentle aspiration applied while the needle is advanced. The US probe can remain on the chest wall immediately adjacent to the aspiration site or removed after the fluid is localized.

Once the pericardial space is entered, agitated saline can be injected to confirm needle placement, particularly if the pericardial fluid is grossly bloody or there is any question concerning needle position. A saline echo contrast medium is prepared by using two 5 mL syringes, one with saline and the other air, connected via a three-way stopcock to the needle catheter sheath. Saline in one syringe is rapidly injected between the syringes and then injected into the sheath. Entrance of the agitated saline into the pericardial space can be monitored sonographically, appearing as a brightly echogenic stream.

After confirmation of needle placement, a wire can be passed through the sheath and a dilator (6 to 8 Fr Cordis) placed over the wire. The dilator is removed and an introducer sheath-dilator (6 to 8 Fr Cordis) placed over the wire. Both the wire and the sheath can then be removed and the introducer sheath left in place. The pigtail angiocatheter is inserted through the introducer sheath, and fluid aspirated to confirm placement [30] (see Chapter 16).

Complications

The potential complications associated with US-guided pericardiocentesis are the same as those with blind aspiration and are discussed in detail in Chapter 16 . The use of US will significantly minimize the risk of many of these complications, especially inadvertent puncture of the myocardium, epicardial vessels, and liver. [24] [30] Additional complications uniquely associated with US are due to misinterpretation of the sonographic image. For example, epicardial fat pads are common in obese patients and can be misinterpreted as clot or fluid within the pericardial space. [24] Although they have a similar echogenicity, there are a number of important findings that can aide in differentiating an epicardial fat pad from clot or fluid in the pericardial space.

First, the epicardial fat pad is an anterior structure. Clot in the anterior pericardial space suggests that the effusion is circumferential, and therefore should also be seen in the dependent portion of the pericardial space. This is best

demonstrated using the parasternal long axis view. Alternatively, the probe can be aligned longitudinally so that the inferior vena cava is visualized as it enters the right atrium. The right side of the heart can be seen adjacent to the diaphragm, and blood or fluid within the pericardial sac can be readily identified (as long as it is not loculated).[24]

Second, the inferior vena cava should collapse when the patient sniffs; collapse of less than 50% indicates increased intrathoracic pressure and possibly tamponade. Third, blood clotting is a dynamic process, with clots continuously forming and being broken down. If blood is present within the pericardial sac, careful examination should reveal fronds of clot waving within an anechoic (black) pericardial space. Finally, and most importantly, an anterior fat pad should not cause collapse of the right ventricular free wall. If after careful examination doubt still exists as to the presence of an effusion, hemodynamically stable patients should have a formal echocardiogram or computed tomography scan performed.

Also remember that fluid within the pericardial space is not always pathologic. A small (<0.5 to 0.9 cm) effusion may not be clinically significant, and the sonographer should exercise caution in over reading an effusion, particularly when the patient is hemodynamically stable. The patient who is hemodynamically compromised by a pericardial effusion should have a sizable effusion (the size can vary) with diastolic collapse of the right ventricular free wall, septal bulging, and dilation of the hepatic veins and inferior vena cava. The heart is usually beating rapidly with hyperkinetic wall motion, and may appear to swing to and fro within the pericardial sac.

Transvenous Pacemaker Insertion (TVPM)

Transvenous cardiac pacing can be life-saving in patients with symptomatic bradycardia or heart block. Optimal conditions for placement of a TVPM are the presence of forward flow to float the catheter into the right ventricle and fluoroscopy to guide placement. Unfortunately, ED patients who require emergent pacing are usually hemodynamically compromised by their rhythm and have poor forward flow. In the absence of flow, pacing wires may fail to pass through the tricuspid valve, coil in the right atrium, or fail to make contact with the right ventricular wall. Bedside sonography can readily demonstrate the passage of the pacing wire into the right ventricle, confirm contact with the right ventricular myocardium, and verify successful capture of the ventricle.

Background

Success rates for blind TVPM insertion with capture of the heart are highly variable, ranging from 10% to 90%. [32] [33] [34] Reasons for failure are often difficult to determine without adjunctive imaging, but malposition of the pacemaker wire is likely to play a role. US can readily demonstrate not only the passage of the pacing wire into the right ventricle, but also confirm contact with the myocardium. In two case series, bedside sonography was extremely helpful in guiding pacemaker wire placement and demonstrating capture in patients with hemodynamically significant bradyarrhythmias. [32] [33] Additionally, US can detect complications of blind pacemaker placement, including malpositioning of pacemaker wires and intraventricular septal perforation. [32]

Indications and Contraindications

Patients with symptomatic bradycardia or heart block for whom the placement of a TVPM is clinically indicated are excellent candidates for US-guided pacemaker wire placement. While there are no absolute contraindications, the presence of obesity or hyperinflated lungs (e.g., patients with chronic obstructive pulmonary disease) may interfere with visualization of the heart and pacing wire.

Equipment

A 2 to 3.5 MHz probe should be used to optimally visualize the right ventricle.

Procedure and Technique

The techniques for placing a TVPM are described in Chapter 15 . When using US guidance, the subxiphoid view is the best imaging window because it provides excellent views of the four cardiac chambers, pericardial space, and overall cardiac wall motion. In order to minimize interference with the procedure, it is best performed with the patient supine and with the probe placed distant from the Cordis introducer. Pacing catheter wires are highly reflective of sound waves and appear as bright linear echoes within the heart (Fig. 69-14*A* and *B*). The pacing wire can be tracked as it passes into the right ventricle and placed in the right ventricular apex. Myocardial capture is readily demonstrated sonographically as rhythmic contractions of the heart.

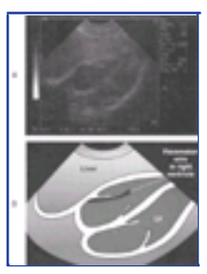

Figure 69-14 Pacing wire within the right ventricle. *A,* Songraphic image. *B,* Schematic representation. The right ventricle is seen through the subxiphoid window, which provides excellent views of the heart without interfering with pacemaker line placement. The pacemaker wire is seen as a brightly echogenic structure within the right ventricle.

Complications

Complications of TVPM insertion are discussed in Chapter 15 . There have been no reported complications specific to the use of US, although experience to date is limited.

Thoracentesis

Clinicians typically have localized fluid within the pleural space by percussion of the patient's chest and listening for dullness. This can be unreliable and inexact, particularly in obese or very muscular patients. US is an excellent tool for identification and aspiration of a pleural effusion, and can detect even small amounts of fluid within the pleural space. It has been shown to be at least comparable, and in some studies superior, to chest radiographs in the detection of pleural fluid. [35] [36] [37] [38] [39] US offers several advantages to the ED management of pleural effusions. The examination is rapid, can be performed at the bedside with suboptimal patient positioning, and percutaneous insertion of the needle is not blind. This reduces the risk of inadvertent puncture of a vessel, lung, or subdiaphragmatic organs.

Background

The use of US to identify the presence of pleural fluid and to guide aspiration is not new, and has become routine for pulmonary and critical care practitioners managing pleural effusions. Prior to the use of US, complications associated with blind thoracentesis included pneumothorax, dry aspiration, inadvertent liver or splenic lacerations, and subcutaneous hematoma. These complications are significantly reduced when performed under sonographic guidance. [40] [41] In addition, US can readily distinguish between tissue masses and fluid in patients with chest radiographs that show a "white lung" or opacifications that do not layer freely.

Indications and Contraindications

Any patient with a suspected pleural effusion is a potential candidate for sonographic imaging. Patients who are at greater risk for complications, such as those with small effusions, underlying malignancies, or for whom there are concerns regarding whether the fluid is free flowing, are ideal candidates. There are no absolute contraindications to the use of US. However, the study may be limited when there is subcutaneous emphysema or massive obesity.

Equipment

A 3.5 to 5.0 MHz probe can readily identify most pleural effusions.

Image Interpretation

In the normal chest, the interface between the air-filled lung and the visceral pleura is highly reflective, and blocks further transmission of sound waves into the chest. The image on the screen will appear as a pattern of bright echoes, which are due to reverberation artifacts. If pleural fluid is present, there will be an anechoic area indicating fluid above the diaphragm, which appears as a brightly echogenic curved line above the liver and spleen (Fig. 69-15*A and B*). Dynamic signs of pleural fluid include flapping movement of the atelectatic lung within the fluid, anechoic appearance of the fluid, and visualization of internal septa or intrapleural debris. [40] [42]

Procedure and Technique

Patient preparation, needle insertion, and fluid removal are discussed in Chapter 9 . All patients should have a chest

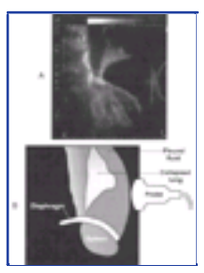

Figure 69-15 Sonographic appearance (*A*) and schematic representation (*B*) of a pleural effusion. Fluid will appear as an anechoic area over the brightly echogenic diaphragm. The collapsed lung can usually be seen as a wedge-shaped echogenic structure moving with respirations within the fluid. Note that the sonographic image has been rotated 90° clockwise to match the schematic drawing.

radiograph prior to starting the procedure. This will demonstrate the presence and general location (e.g., left or right pleural space) of the fluid. The optimal position for thoracentesis is to have the patient sitting with arms resting on a bedside table. Fluid will then collect in a dependent position. The probe should be positioned on the chest wall at the midaxillary line, above either the spleen or the liver (Fig. 69-16). The lung should be seen moving freely within the fluid as the patient breathes. The diaphragm must be visualized to avoid puncture of the liver or spleen; this may be especially difficult on the left side where there is no optimal acoustic window. The kidneys can usually be easily seen and then the probe moved superiorly to identify the diaphragm. The pleural fluid will be seen adjacent to the diaphragm. For large effusions, the thoracentesis needle can be advanced over the rib that is immediately adjacent to the fluid. If the fluid pocket is small, then the aspiration can be performed under directed sonographic guidance by covering the transducer with a sterile glove/cover and puncturing the chest wall directly alongside the transducer.

Complications

Complications of thoracentesis are discussed in Chapter 9 . While rare, complications directly related to use of US may occur in complicated effusions secondary to image misinterpretation. Echogenic material within the fluid can suggest the

Figure 69-16 Probe positioning for identification of a pleural effusion. The probe should be placed longitudinally over the lateral or posterior chest wall on the side of the suspected effusion. The probe should be moved inferiorly to identify the kidney, liver or spleen, and diaphragm. *(Lydia F. Roberts, Photographer)*

presence of clot, pus, and even bowel depending on the sonographic appearance. Solid masses with few internal echoes may appear as a loculated effusion and care should be taken to identify free fluid. Fortunately, most masses adjacent to the pleura do contain echoes that readily distinguish them from free fluid.

Paracentesis

US is a fairly sensitive tool for identification of fluid within the peritoneal cavity and has virtually replaced diagnostic peritoneal lavage (DPL) in patients with traumatic injuries and suspected hemoperitoneum.[43] In such patients, demonstration of free fluid is presumed to be blood. Most patients will subsequently undergo exploratory laparotomy or computed tomography scanning. Patients requiring paracentesis in the ED usually have atraumatic peritoneal fluid collections. The benefits of paracentesis for these individuals include diagnosis of spontaneous bacterial peritonitis, differentiating transudative from exudative effusions, and therapeutic aspirations for patients with large amounts of ascitic fluid (see Chapter 44).

Background

US is the diagnostic study of choice for demonstration of intraperitoneal fluid. The primary use in the ED is for identification of patients with intraperitoneal blood secondary to both blunt and penetrating trauma. [43] [44] [45] [46] [47] Demonstration of free fluid in these patients usually leads to exploratory laparotomy or computed tomography scanning to further delineate the extent of intra-abdominal injury and rarely results in paracentesis. Patients requiring paracentesis in the ED are generally those with nontraumatic fluid collections requiring either a diagnostic or therapeutic tap. Many of these patients have end-stage liver disease or underlying malignancy. Although relatively rare, intraperitoneal hemorrhage, abdominal wall hematomas, and bowel perforation are reported complications of blind paracentesis (see Chapter 44). Risk factors for complications include coagulopathic states, obesity, small amounts of fluid, and prior surgery. US can minimize these risks by identifying the largest pocket of readily accessible fluid. [48] [49]

Indications and Contraindications

The indications for therapeutic and diagnostic paracentesis are discussed in detail elsewhere (see Chapter 44). Specific indications for sonographic imaging are patients without a known diagnosis of ascites, obesity, patients with prior abdominal surgeries, or failed blind aspirations. US is the study of choice for identification of

ascites, and can readily establish the presence of intraperitoneal fluid. It can also show the size of the collection and identify the best site for aspiration. Ascitic fluid in patients with prior abdominal surgeries may be loculated, and US can identify areas of free-flowing fluid.

Equipment

A 3.5 to 5.0 MHz probe can readily identify free fluid within the peritoneal cavity.

Image Interpretation

Free fluid will appear as an anechoic, black, sharp-edged collection in the most dependent area of the peritoneal cavity. In contrast to the usual "snowstorm" appearance created by the air-filled loops of bowel, large amounts of fluid will appear to fill the peritoneal cavity and floating loops of bowel will be distinct (Fig. 69-17). Blood or pus within the fluid will create echogenic shadows. In addition, pus will usually layer out, creating an echogenic stripe in the dependent portion of the fluid. Blood clots will also layer or appear as fronds floating within the fluid. Structures within the peritoneal cavity, particularly bowel and bladder, can be easily identified and avoided during needle aspiration.

Procedure and Technique

The patient can be imaged in the supine or reverse Trendelenburg position to allow flow of smaller amounts of fluid into the pelvis. A full bladder can be confused with an intraperitoneal fluid collection and should be emptied prior to

Figure 69-17 Sonographic appearance of peritoneal free fluid. Fluid will appear as a large anechoic area with loops of bowel floating freely. The optimal area for needle insertion is where there is a large pocket of fluid just under the skin surface, closest to the probe.

the procedure. The liver, spleen, bladder, and loops of bowel should be identified to avoid inadvertent puncture. For the best result, the largest pocket of free fluid should be located. This is usually found in the lower quadrant of the abdomen and will appear as a black, anechoic area. Once this area is identified, paracentesis is performed as described in Chapter 44 , with the needle placed directly over the area adjacent to the fluid and carefully avoiding the bladder and inferior epigastric arteries.

Complications

Complications directly related to the use of US are rare, and likely to be due to misinterpretation of the images. A full bladder or large cystic masses within the abdomen (e.g., ovarian) may be confused with intraperitoneal fluid. A clue to differentiation of fluid contained in either the bladder or a cyst is that ascitic fluid will have an irregular appearance due to bowel indentation, whereas the bladder or cyst will have a smooth curved surface outline. In addition, free intraperitoneal fluid will collect dependently, and will have a sharp-edged appearance when bounded by peritoneal reflections. In contrast, fluid contained in the bladder or cyst will have rounded edges.

Joint Aspiration

Joint pain is a common complaint in the ED. Identification of fluid within the joint space has important implications for both diagnosis and treatment. For the patient presenting with a warm, swollen joint, it is often difficult to differentiate cellulitis, soft tissue abscess, or septic/inflammatory arthritis by physical examination alone. US has been widely used by rheumatologists as an adjunct to their clinical examination to define joint and synovial pathology and monitor response to treatment. [50] [51] In the hands of the ED clinician, it can aid in identification of clinically significant fluid within the joint, identify extra-articular sources of pain, and guide aspiration of joint spaces.

Background

US can demonstrate the presence of as little as 1 mL of intra-articular fluid in any joint space that has a sonographic "window," in particular the hip, shoulder, knee, ankle, and wrist.[52] [53] [54] [55] [56] Although some joints, such as the knee, are readily aspirated using the blind approach, other joints are often difficult to aspirate successfully and may require multiple attempts. US will not only confirm the presence of fluid, which in itself is of clinical value, but can also identify the optimal site for joint aspiration.

Additional benefits to sonographic imaging of the joints include characterization of the joint fluid (see later in this section) and identification of extra-articular sources of pain. When no fluid is seen within the joint space, and the patient has pain, swelling, or both, it can be assumed that the source of discomfort is outside the joint space (e.g., involving skin, tendon, bone, ligament, or extra-articular bursa). In experienced hands, US can also diagnose disease of the periarticular tissues. [52]

Indications and Contraindications

Sonographic examination of the joint is indicated whenever identification of fluid within the joint space is clinically relevant. This includes patients presenting with acute joint pain due to trauma, patients with suspected inflammatory or infectious arthritis, and nontraumatic hemarthrosis, particularly those associated with coagulopathic states. There are no reported contraindications to the use of US.

Equipment

The most commonly used probe for assessment of the joint space is a high-frequency linear array probe (7.5 to 10 MHz).

Acoustic Windows

A detailed discussion of the sonoanatomy of all joints is beyond the scope of this section. The knee, shoulder, and ankle are most often involved in traumatic and inflammatory conditions, and the sonographic windows for these joints are described as follows.

The knee

Knee effusions are often difficult to reliably identify on physical examination alone, particularly when the patient is obese or when severe pain limits the examination. The knee should be flexed (approximately 20°) and a roll placed behind the popliteal fossa. The anterior views of the knee begin with a longitudinal scan above the patella, which is the bony landmark for imaging the suprapatellar bursa. [52] [53] The suprapatellar bursa communicates with the knee joint, extending approximately 6 cm above the patella just deep to the quadriceps tendon (Fig. 69-18). The medial and lateral recesses of the knee (extensions of the suprapatellar bursa) should then be viewed in longitudinal and transverse orientation. In a normal joint, the bursa is a thin hypoechoic line no more than 2 mm thick. Fluid within the bursa will appear as an anechoic stripe beneath the quadriceps tendon (Fig. 69-19A).[52] [55] Extra-articular fluid commonly located in the prepatellar bursa can also be readily identified as a fluid collection anterior to the patella.

The shoulder

The shoulder joint can be imaged using anterior or posterior windows. The anterior window, easiest to acquire, consists of longitudinal and transverse scans of the long head of the biceps tendon (Fig. 69-20). The biceps tendon has a synovial sheath, which is an extracapsular extension of the joint synovium. Consequently, fluid within the joint is often demonstrated within the synovial sheath (Fig. 69-21*A* and *B*). For the anterior window, the patient is placed in the sitting position with the elbow adducted and the hand palm-up. Alternatively, the patient can lie prone on a gurney with the arm hanging down. [52] The posterior window is performed with the patient prone or seated leaning forward with the hand on the affected side placed on the opposite shoulder to open up the joint space (Fig. 69-22).

Fluid will preferably accumulate in the posterior recess due to capsular thinning and minimal adjacent structures to prohibit distention (Fig. 69-23*A*, *B*, and *C*). This fluid is usually seen first in the anterior window, but the posterior aspect of the shoulder can be imaged to guide aspiration if that is the preferred approach.

The ankle

The foot should be positioned in plantar flexion, and the transducer oriented longitudinally over the anterior surface of the tibia (Fig. 69-24). Moving the transducer toward the foot and seeing the curved dome of the talus will identify the joint space. An effusion will appear as an increased anechoic space at the anterior aspect of the tibio-talar joint (Fig. 69-25*A*, *B*, and *C*). [52] [54] [56] [57]

Image Interpretation

Three basic types of effusions will be encountered when performing bedside sonography: noninflammatory, post-traumatic,

Figure 69-18 *A,* Probe positioning for sonographic imaging of the suprapatellar bursa. The probe should be placed in the longitudinal position superior to the patella. Following identification of fluid within the bursa, the probe can be rotated transversely to identify the medial and lateral extent of the fluid. *B,* Schematic representation. *(Lydia F. Roberts, Photographer)*

and inflammatory. Simple, noninflammatory joint effusions will appear as an anechoic or hypoechoic area within the joint space. Traumatic effusions are typically complicated by the presence of either free-floating clot or fat lobules. These effusions will have a heterogeneous appearance with echogenic particles or fronds (clot) floating within the hypoechoic joint

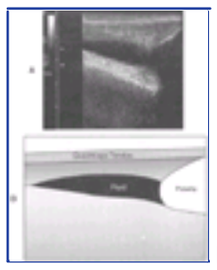

Figure 69-19 *A,* Sonographic appearance of a suprapatellar effusion. Fluid will appear as an anechoic area superior to the patella and beneath the quadriceps tendon. *B,* Schematic representation.

space. In both septic and inflammatory arthritis, the fluid often appears hypoechoic with internal echoes, giving it a particulate appearance. [51] [52] Layering may be seen whenever there is pus, blood, or excess lipid within the effusion.

Procedure and Technique

Arthrocentesis is described in Chapter 54 ; US can be used to locate the effusion and confirm optimal needle placement. Joints should be imaged using a variety of sonographic windows. It is helpful to move the joint under direct sonographic guidance to aid in identification of intra-articular and periarticular structures. Compression of the joint is extremely

Figure 69-20 Probe positioning for the anterior view of the shoulder joint. The patient's arm should be placed palm up and the elbow flexed and supported. The arm should be rotated externally. The probe should be placed in the transverse position over the anterior aspect of the shoulder and the biceps groove visualized. *(Lydia F. Roberts, Photographer)*

useful in differentiating fluid (or clot) from tissue or cartilage. The affected joint should always be compared to the contralateral (normal) side by use of the multi-image function on the US machine. Once the effusion is identified, the needle should be placed over the area adjacent to the fluid collection. For small effusions, continuous imaging during the procedure can confirm needle entry into the joint. Alternatively, the location of the effusion can be marked with a sterile marking pen.

Complications

The most common pitfall associated with joint imaging is failure to recognize artifacts common to musculoskeletal US. Knowledge of these artifacts can aid in identification of important pathology (such as reverberation artifact for foreign bodies), but may be problematic if confused with actual structures. Although many important artifacts have already been discussed, one that is most common to musculoskeletal imaging is due to anisotropy of joints and ligaments. This refers to the fact that linear structures (such as tendons and ligaments) must be imaged perpendicular to the plane of the US beam to demonstrate their true echogenicity. [52] [58] [59] Failure to do so will give them a falsely hypoechoic appearance, which may be misleading. The relatively hypoechoic appearance of muscle or tendon surrounding most joints can also be confused with fluid. Fortunately, when an effusion is adjacent to bone, the difference in sonographic appearance of fluid and bone will usually minimize the risk of errors. In addition, movement of associated structures by the patient can be helpful in identifying anatomic structures, and comparison to the unaffected (normal) side can improve the accuracy of image interpretation. [52]

Foreign Body Localization

Detection of foreign bodies retained in soft tissues is often difficult, and missed or delayed identification may lead to infection, inflammation, or both. Of the available imaging modalities, plain radiography is the most widely used to screen for foreign bodies, but will only detect radiopaque objects. Computed tomography and magnetic resonance imaging are alternative imaging modalities that reliably detect most foreign bodies, but are costly, time-consuming, and often unavailable. US has been shown to be a potentially useful adjunct in detection of both radiopaque and radiolucent foreign bodies.

Background

Studies to date vary considerably in their conclusions regarding the utility of US in identification of subcutaneous foreign bodies. Accuracy of the sonographic examination is highly dependent on the composition of the foreign body, how long it has been embedded, composition of adjacent structures, and sonographer skill. For radiopaque substances (e.g., glass, metal), plain radiographs consistently identify a greater proportion of foreign bodies. [60] [61] Manthey et al. had two independent radiologists image 120 chicken thighs embedded

Figure 69-22 Probe positioning for the posterior view of the shoulder joint. The probe should be placed in the transverse position over the posterior aspect of the shoulder. The glenoid rim can be readily identified in this position. *(Lydia F. Roberts, Photographer)*

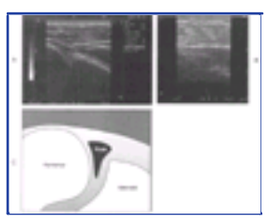

Figure 69-23 Sonographic appearance of the posterior shoulder. *A,* Normal; *B,* Effusion present; *C,* Schematic representation. with either gravel, metal, glass, cactus spine, wood, or plastic. The overall sensitivity and specificity for US in detecting the foreign substances was 43% and 70%, respectively. No individual foreign body reached a US detection rate of 50%. Plain radiography demonstrated radiopaque substances (gravel, glass, metal) 98% of the time, but was unable to reveal any of the radiolucent substances (wood, plastic, cactus spines). [61]

US is superior to plain radiographs in identification of radiolucent objects, specifically wood, plastic, and cactus spines. [62] [63] [64] [65] [66] [67] [68] [69] One large study of high-frequency sonography demonstrated an overall accuracy of 82% (sensitivity 79%, specificity 86%, positive predictive value 85%, and negative predictive value 80%) when US was used to identify wooden foreign bodies embedded in chicken thighs. [70] Another experimental study compared sonography with magnetic resonance imaging in the evaluation of embedded wooden foreign bodies in cadavaric specimens. While the two imaging modalities were comparable in detection of foreign bodies, magnetic resonance imaging was superior to US when the substance was embedded near bone. [68] Other studies using various models (beef cubes, chicken thighs, cadaver hands and legs) and embedded foreign bodies (wood, glass, metal) have shown that while imperfect, sonography can identify radiolucent substances that may be missed on plain radiographs. [64] [66] [67] [68] [69] US appears to have a unique role in identifying foreign bodies that are radiolucent, and is most helpful when a foreign body is positively identified. When exclusion of a retained foreign body is critical and none is seen on US, it may be advisable to obtain an alternative imaging study.

Figure 69-24 Probe positioning for assessment of ankle effusion. The foot should be positioned in plantar flexion, and the transducer oriented longitudinally over the anterior surface of the tibia. Moving the transducer toward the foot and seeing the curved dome of the talus will identify the joint space. *(Lydia F. Roberts, Photographer)*

Figure 69-25 Sonographic appearance of the ankle. *A,* Normal; *B,* Effusion present; *C,* Schematic representation. An effusion will appear as an increased anechoic space at the anterior aspect of the tibio-talar joint. The optimal site for needle placement is where there is an anechoic space immediately under the probe.

Indications and Contraindications

All patients with a suspected foreign body should have a plain radiograph performed initially. If the foreign body is readily visualized, then it is unlikely that sonography will provide any further useful information about the foreign body itself. However, it will demonstrate the presence of fluid around the foreign body and adjacent fluid-filled structures, such as vessels, that may be injured during the extraction process. If there is no clear evidence of a foreign body on plain radiographs, and there is clinical suspicion of a subcutaneous foreign body, then US imaging is indicated.

Equipment

A high-frequency (7 to 10 MHz) linear probe is best for localization of subcutaneous foreign bodies.

Image Interpretation

The appearance of a foreign body will depend on the orientation of the foreign body to the US beam, adjacent tissues, surrounding edema or abscess, and the density of the foreign body itself. In general, all foreign bodies are hyperechoic and will appear as brightly echogenic structures, distinct from surrounding bone or calcifications. Additional clues to the location of a foreign body include acoustic shadowing (for stone, wood, and plastic) and reverberation or comet-tail artifacts (for glass and metal objects) (Fig. 69-26*A* and *B*). Secondary signs associated with some soft tissue foreign bodies may also help in their identification. For example,

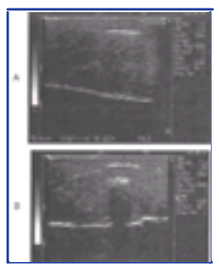

Figure 69-26 Sonographic appearance of a retained metallic foreign body (*A*) and a retained glass foreign body (*B*). Foreign bodies are usually hyperechoic, and will appear as brightly echogenic structures, distinct from surrounding bone or calcifications. Clues to the location of a foreign body will be acoustic shadowing and reverberation artifact.

in the acute setting, air may be trapped within the tract and appears as a brightly reflective trail to the foreign body. Hematomas will have a characteristic hypoechoic appearance. Substances that have been in place for longer than 24 hours may have surrounding edema, which will appear as a sonolucent area surrounding the hyperechoic foreign body. Wooden objects will initially appear as hyperechoic objects with acoustic shadowing, but if left in place will decompose and eventually lose their echogenicity. They are often best recognized by a localized area of inflammation that appears as a heterogeneous fluid collection.

Procedure and Technique

The probe is placed on the skin with a layer of acoustic gel, or for very superficial foreign bodies, a stand-off pad can be used. This is either a gel pad or a 100 to 250 mL bag of saline with the air removed that is placed between the probe and the skin. The use of a stand-off pad will eliminate near-field artifacts and bring the object into the transducer focal zone. The US beam should be angled perpendicular to the area of interest. A particular advantage of US is the fact that the examination can be focused over the entrance of the foreign body or area of maximal tenderness or erythema. The area should be scanned from a variety of angles because a foreign body can be easily missed if the lie is not perpendicular to the beam. Once the foreign body is identified, its relationship to surrounding structures such as bone and vessels should be documented. The exploring hemostat or forceps should be angled parallel to the US beam. [67] It is helpful to have an assistant hold the probe during the extraction procedure. See Chapter 37 , Chapter 38 , and Chapter 52 for specific foreign body removal details.

Complications

Complications directly related to the use of US are usually due to an over-reliance on US as a screening tool for detection of a foreign body. There are many reports of false-positive and false-negative scans, largely due to the presence of artifacts that can mimic a foreign body and failure to detect a foreign body, respectively. The brightly echogenic interfaces between bone and tissue, and vessels imaged "end-on" may be mistaken for a foreign body, and lead to unnecessary wound exploration.[68] Conversely, a foreign body that is isodense with the surrounding tissue, such as a retained wooden splinter, may not be seen. [64] [66] [67] [68] [69] The clinician must rely on clinical judgment and knowledge of potential artifacts when performing musculoskeletal US. In addition, appropriate discharge instructions and close follow-up are imperative.

Bladder Aspiration

Needle aspiration of the bladder may be required when a patient, usually an infant, is unable to provide a sterile urine specimen. The bladder is a superficial structure that is readily identified with US. The role of US is to localize the bladder, demonstrate that the bladder is full, and guide needle aspiration. [71] A secondary role of bladder sonography is to assess bladder volume, which may be particularly helpful when the patient is unable to provide a spontaneous urine sample and the differential diagnosis includes dehydration vs bladder outlet obstruction.

Background

The approach to blind suprapubic bladder aspiration requires localization of the bladder by percussion and palpitation. While relatively straightforward for most children and adults, it may be difficult in infants in whom the bladder is an intra-abdominal organ and in children who are agitated, volume depleted, or have abdominal distention. US has been identified as an extremely useful tool to locate the bladder, estimate bladder volumes, and guide suprapubic aspiration. [72] [73] [74] Recent studies have shown that US guidance increases the likelihood of successful bladder aspiration. In a study of 140 male infants less than 2 years of age, Ozkan et al. demonstrated a 90% success rate in the US-guided group compared with 64% ($p < 0.05$) in the blind aspiration group. [73] There were also fewer passes made in those patients who had the procedure done under ultrasonographic guidance. [73] Another study of similar design looked at the impact of bedside US on aspiration attempts in 59 infants. Aspiration was successful on the first attempt in 26 of 28 patients (93%) with US guidance, but in only 13 of 21 patients (62%) undergoing blind aspiration.[74] In these studies, complications in both the experimental and control groups were rare.

Indications and Contraindications

US-guided aspiration is indicated in the infant, child, or adult for whom blind aspiration is unsuccessful or where localization of the bladder may be difficult due to dehydration or abdominal distention. In the child who is agitated, clear localization of the bladder may facilitate the speed and success of the procedure. Adult patients with prior abdominal surgery or irradiation may have adhesions of the bowel to the bladder, and will also benefit from sonographic guidance. US can also

Figure 69-27 Sonographic appearance of the bladder in transverse view. The bladder will appear as an anechoic structure immediately beneath the skin surface, with a characteristic rhomboid appearance on transverse view.

be used to guide placement of cystostomy tubes in adults. There are no contraindications specific to the use of US.

Equipment

A 5 MHz curvilinear probe is usually adequate for pediatric patients. A lower frequency probe (3.5 MHz) should be used for adults.

Procedure and Technique

The bladder should be full for best results. The probe should be placed just above the pubic symphysis and the bladder imaged in both the longitudinal and transverse planes. The bladder will appear as an anechoic structure immediately beneath the skin surface, with a characteristic rhomboid appearance on transverse view (Fig. 69-27). A layer of acoustic gel and a sterile cover should be placed over the probe. A second layer of sterile gel should be placed between the probe cover and the skin surface. The skin should be punctured immediately above the portion of the bladder closest to the skin surface (at the top of the imaging screen). The site can either be marked with a sterile pen prior to skin puncture, or the probe left in place to guide aspiration. For a complete discussion of suprapubic aspiration, see Chapter 56 .

Complications

General complications of bladder aspiration are discussed in Chapter 56 and include viscus perforation, microhematuria, and unsuccessful aspiration. Complications directly related to the use of US are rare, but may occur if aspiration is attempted and the bladder is not full or if there is free fluid in the peritoneal cavity that is mistaken for urine in the bladder. In addition, the outlines of the bladder wall may be difficult to identify when there is peritoneal fluid, particularly if the fluid is loculated. In general, bladder fluid has a curved outline, whereas fluid within the peritoneal cavity will be indented by loops of free-floating bowel.

Fluid Collections and Abscesses

US is a very useful adjunct for identification of subcutaneous masses. It can readily differentiate between solid and fluid-filled masses, estimate the size and depth of the fluid collection and demonstrate the presence of septations or foreign bodies. [51] [65] This is often of clinical value, particularly when the examination suggests a large mass and aspiration is unsuccessful or limited. [75] US can also provide critical information regarding the extent of the collection and proximity to important structures such as blood vessels and vital organs.

Background

US is widely used by both radiologists and rheumatologists to characterize soft tissue collections, which include subcutaneous abscesses and hematomas. It has proven value in differentiating subcutaneous fluid collections from solid masses and identifying the presence of foreign bodies (particularly wood) that may serve as a nidus for infection. [51] [56] [65] It is a logical adjunct to the assessment of subcutaneous masses in the ED, especially when percutanous aspiration or incision and drainage is planned.

Indications and Contraindications

Any subcutaneous mass should be imaged when demonstration of a fluid collection is of clinical significance. It is particularly important when the collection is near vital structures, the extent of the collection is difficult to assess due to location or body habitus, and when prior attempts at aspiration have been unsuccessful. There are no contraindications to the use of US for this purpose.

Equipment

The depth and size of the collection will determine optimal probed selection. Large or deep collections should be imaged with a 3.5 to 5.0 MHz probe. Small or superficial collections will be best seen with higher frequency probes.

Image Interpretation

In the early stages of abscess formation, the affected tissue will contain an increased amount of fluid, which will appear as horizontal bands of hypoechoic or anechoic areas. As the abscess forms, the central area liquefies and the surrounding tissue forms a wall of scar tissue. Sonographically, an abscess appears as a discrete anechoic area often surrounded by a brightly reflective wall (Fig. 69-28). The fluid will usually be black, but will often contain scattered echoes representing purulent material or necrotic debris. The fluid may contain septations, which appear as echogenic walls that traverse the fluid cavity.

Procedure and Technique

Imaging should be performed in both the longitudinal and transverse planes to demonstrate the full depth and extent of the fluid collection or mass. Surrounding structures, particularly blood vessels, should be identified prior to aspiration or incision and drainage. The use of Doppler (either color or power) to demonstrate absence of flow within the collection can add a measure of safety (but is not required). The depth of the collection can be determined by using the depth markers on the right side of the monitor screen. Specific procedural details for drainage of fluid collections are provided in Chapter 38 .

Complications

While image interpretation is usually straightforward, complications may occur due to misinterpretation of like images. Cellulitic areas will have a heterogeneous, layered appearance (alternating bands of anechoic and echogenic layers) that may be mistaken for a discrete fluid collection. Blood vessels, when imaged in the transverse plane, can appear as a cystic fluid collection, undermining the importance of imaging the collection in both the longitudinal and transverse planes. It must also be remembered that fluid collections do not

Figure 69-28 Sonographic appearance of a subcutaneous fluid collection. An abscess appears as a discrete anechoic area that may be surrounded by a brightly reflective wall. The fluid will be anechoic, but will often contain scattered echoes representing purulent material or necrotic debris. The fluid may also contain septations, which appear as echogenic walls traversing the fluid cavity.

always indicate abscess, and may be Baker cysts, bursae, or hematomas. Clinical judgment must be exercised during image interpretation.

SUMMARY

US has become a valuable adjunct to the practice of emergency medicine and the spectrum of procedures amenable to sonographic guidance is rapidly expanding. The procedures described in this chapter reflect proven efficacy to the role of emergency US. The principles and approaches described can also be broadly applied to any procedure involving percutaneous cannulation or aspiration of a fluid-filled body cavity. It is likely that future texts will describe an expanded role for sonography in the ED.

Although sonography is now within the scope of practice of many emergency clinicians, care must be taken by the individual to understand the limitations of the sonographic examination and obtain appropriate training before using it to guide clinical practice. Additionally, nonemergency clinician sonographers can and should be used to provide sonographic guidance for procedures when there is no skilled sonographer in the ED, or when there are concerns with the examination performance or interpretation.

David C. Lee

ASSESSMENT OF URINE

Obtaining a Urine Specimen

Several methods are available for obtaining a urine specimen. These can be listed in order of increasingly precise collection techniques, which tend to come at the cost of increasing difficulty and/or patient discomfort:

1. *Random voided:* Any specimen provided by the patient.
2. *Midstream voided:* No skin preparation, container placed in urinary stream 2 to 3 seconds after the initiation of micturition.
3. *Clean catch:* Same as item 1, with antiseptic cleansing of the urethral area. In males this is performed by retraction of the prepuce (the labia in females) and cleansing of the meatus in an anterior to posterior direction using three swabs soaked in Betadine (or some other antiseptic solution). For female patients who are physically capable, the ideal position is sitting astride a toilet, facing backward. This helps to separate the labia and position the cup for specimen collection.
4. *Midstream clean-catch* specimen (MSCC): Cleansing as in item 3, with midstream collection as in item 2.
5. *Catheterized:* Obtained from a newly placed catheter.
6. *Suprapubic aspiration* (SPA) (see Chapter 56).

The low levels of bacteriuria induced in 2% to 8% of patients after straight catheterization [262] are generally clinically insignificant. Catheterization does cause minor local injury, as reflected by bacteriuria and low-level hematuria (1 to 3 red blood cells [RBCs]/high-power field [hpf]) in =15% of patients. [103] [262] SPA continues to be advocated by some for neonates in cases in which accurate diagnosis is essential and the risk of infection must be minimized. SPA (see Chapter 56) has a 10% "failure rate" (i.e., no urine obtained after three attempts) in most series and may actually take longer than most methods, especially when multiple attempts are considered. SPA can also cause spuriously lowered leukocyte or bacterial colony counts due to the necessity of maximally filling the bladder before performing the procedure.[215] Surprisingly, older men who underwent both catheterization and SPA strongly preferred the latter procedure because it caused less discomfort. [164]

Recommendations for Urine Collection

Since the mid-1950s there have been proponents and opponents for each technique. In choosing a method for obtaining a urine specimen, the disease under consideration affects both the interpretation of the results and the quality of the specimen required. For the purposes of this discussion, the diagnostic categories can broadly be divided into infectious and non-infectious. With the exception of testing for blood, most of the non-infectious tests (e.g., ketones, glucose, bilirubin, protein) are not affected by collection method. Since the detection of infection is the most common purpose of urine testing in emergency practice, this will be considered first.

Urinary tract infections (UTI) are either symptomatic or asymptomatic. The group to which a patient belongs is the first step in determining which collection method is required (Fig. 70-1). The typical emergency department (ED) patient is in some way "symptomatic." This includes patients with classic signs and symptoms of UTI (e.g., urgency, frequency, dysuria) as well as those with systemic signs of infection (e.g., fever and chills) who are unable to accurately report on symptoms. [263] In addition, ED clinicians cannot afford to miss detecting asymptomatic bacteriuria in high-risk patients (e.g., the immunocompromised, neonates and infants, pregnant patients, diabetics), or in those who require urine cultures because of a history of relapsing, recurrent, complicated, or childhood UTIs. [141]

Whether the nonspecific findings of undifferentiated abdominal pain or fever constitute "symptoms" of UTI has never been studied, although they are frequent indications for urine testing in the ED.[263] However, to interpret tests for UTI it is necessary to estimate the extent to which the patient's symptoms are urinary in origin (making it a test of the "symptomatic" patient), versus non-urinary (making it a screening test). This is because in symptomatic UTI, extremely low levels of bacteriuria (10^2 CFU/mL) and pyuria are of clinical significance.[149] [154] [255] [257] This fact has been obscured by studies on *asymptomatic* patients showing that the threshold for "significant bacteriuria" is =10^5 CFU/mL.[124] [125] [199] Furthermore, specimens are not necessarily contaminated if multiple pathogens are isolated. Up to 50% of symptomatic women may have polymicrobial infections.[255] [257]

It behooves the clinician to obtain specimens as carefully as possible, because contamination is most likely to produce the finding of low-level or polymicrobial bacteriuria, which may be clinically significant in symptomatic patients. Although several studies have failed to demonstrate a statistical difference in contamination rates with various urine collection techniques, most studies show trends in favor of more meticulous and/or invasive collection methods. [110] [163] [164] [166] [226] [275] In cooperative, motivated males and females with symptoms of uncomplicated lower UTI or pyelonephritis who are capable of diligently performing the necessary maneuvers, an MSCC specimen is as accurate as a catheterized specimen, especially when the possibility of urethral and/or prostatic trauma and patient discomfort are considered.[164] In females in whom symptoms are equivocal, and in all patients unable to provide an MSCC specimen, a catheterized specimen is usually warranted.

If no symptoms of UTI are present, the urine examination can be considered as a "screening" test. In the asymptomatic patient, routine screening for bacteriuria is unwarranted in all but two clinical situations: pregnant women and all patients for whom urologic surgery has been scheduled. [209] [256] If only a urine culture is to be performed, some would argue that any spontaneously voided specimen would suffice, since the diagnosis of asymptomatic bacteriuria depends on =10^5 CFU of a single pathogen per milliliter of urine, and with such criteria, contaminants are usually easily identified. [110] However, performing cultures in all such patients is prohibitively costly, so that dipstick and/or urinalysis (UA) is commonly used for screening. [169] [178] With these tests, contamination by bacteria, leukocytes, or erythrocytes can still cause diagnostic

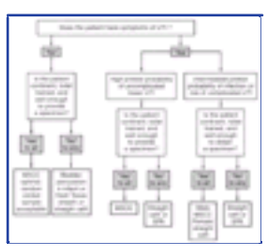

Figure 70-1 Algorithm for deciding method of obtaining urine specimen for evaluation of possible urinary tract infection. MSCC, midstream clean catch; SPA, suprapubic aspiration; UTI, urinary tract infection.

confusion. Thus, the advantages of a less contaminated specimen are worth the minimal extra effort of asking the patient to provide an MSCC sample.

The approach described in Figure 70-1 covers the vast majority of situations. A few circumstances and techniques deserve special mention.

Bladder Percussion and the Midstream Specimen in Infant Males

The emergency clinician is familiar with how frequently a urine stream is generated in infants who are confronted by the alarming ED environment and a cold stethoscope. Rather than wasting a potentially perfect MSCC specimen on a laboratory coat, with an ensuing delay in obtaining urine, the emergency clinician can exploit this response by approaching the patient with an open sterile urine container in hand in case of a spontaneous micturition. The process is facilitated with the application of cold povidone-iodine to the genitalia. Such an approach has been shown to generate a urine sample in a median time of 10 minutes. [5] This is much less than the typical time needed for straight catheterization or suprapubic aspiration, especially since it can be performed concomitant with the history and physical examination. It also circumvents an invasive procedure, with its associated complications, resource expenditures, and stress to both patient and staff. If the urine specimen is not immediately forthcoming, a parent can be instructed to catch the specimen in the sterile container, freeing up ED staff for other tasks.

Two techniques to actively induce voiding in infants have been described. The first, which is useful in newborns, exploits the Perez reflex. [24] After cleansing of the genitalia (with povidone-iodine or some equivalent non-irritative antibacterial agent), the infant is held in one hand while the paraspinal muscles are stroked, cephalad to caudad. This causes extension of the back, and flexion of the hips and induces micturition in less than 5 minutes in the majority of cases. [24]

The second technique is known as "bladder tapping." After urethral cleansing, if there is still no urine, two fingers may be tapped on the suprapubic area at a rate of approximately once per second for a full minute, followed by a minute's rest. The cycle is then repeated until urine is produced. The mean time prior to the production of urine is about 5 minutes. This technique, while not practicable for the staff in a busy ED, can provide an infant's parents with a task that invests them in the clinical process.[266]

Bag Collection in Non-Toilet-Trained Children

The incidence of unsuspected UTI in the febrile neonate or infant is about 3% to 5%. Because a true UTI in an infant or child requires a subsequent evaluation for urinary tract pathology, and the disease may produce significant morbidity (e.g., hypertension, renal disease), one must be certain of the presence or absence of infection in this subgroup. Numerous studies demonstrate the disutility of urine specimens obtained for culture from a collection bag stuck to an infant's perineum. [7] [24] [26] [58] [95] [266] Bag specimens obtained for a routine UA in suspected UTI are equally unreliable, with white blood cell (WBC) concentrations routinely 25-fold higher and bacterial counts 1000-fold higher than in a catheterized specimen. [7] In the occasional situation in which urine is needed exclusively for chemical analysis (e.g., glucose, ketones, urobilinogen, pH, specific gravity), a bag specimen will suffice. The utility of obtaining a bag specimen to "screen" the UA before deciding on antibiotic treatment or whether to send a formal culture is only defensible if the suspicion of UTI is low, as the sensitivity for markers of a UTI (discussed later), is only 50% to 85%.[58] [102] In summary, an

---

MSCC, catheter, or SPA specimen is required for an accurate UA or urine culture in neonates and infants.

Urine Specimens from Patients with Chronic Urinary Drainage Systems

Urine obtained from any part of a chronic urinary drainage system is highly inaccurate for bacteriologic purposes. If UTI is suspected, a new catheter should be inserted and fresh bladder urine specimens subsequently obtained. [90] A small study advocating replacement of a chronically applied "Texas sheath" catheter with a fresh one was performed on subjects who did not have symptoms of UTI.[206] Such a method might be sufficiently accurate for screening of asymptomatic patients, but a Foley catheter should be used to obtain urine from patients with sheath catheters who have signs or symptoms of acute UTI.

Urine Dipstick

Urine dipstick tests are available to test for 10 separate parameters. The unassuming appearance and commonplace use of the urine dipstick might lead one to mistakenly underestimate its technical sophistication. Because each colored square on

TABLE 70-1 -- Overview of Urine Dipstick Tests

Test	Sources of Error and Artifact	Comments
Glucose	False-negative with ascorbate, ketones, and increased SG	Hypothermia may cause glycosuria despite hypoglycemia
	False-positive with peroxide and hypochlorite	
Ketones	False-positive with ascorbate, levodopa, valproate, pyridium, *N*-acetyl cysteine, high-protein diet, phenylketones, phthalein compounds	Very susceptible to deterioration with humidity, causing false-negative
Nitrites	False-positive with contamination, pyridium	75% false-negative rate when dipsticks exposed to air for 15 days
	False-negative with high SG, ascorbate, high urine pH, and urine standing in specimen cup >2 hr	
Protein	False-positive with pH>7, and chlorhexidine	Only reliable for albumin (glomerular proteinuria)
	False-negative with low pH, very dilute urine	
Blood	False-positive with povidone-iodine, certain (peroxidase-producing) bacteria, hypochlorite (bleach)	Positive test with speckles or dots implies non-hemolyzed blood
	False-negative with high SG, and high concentrations of urinary nitrites, ascorbate, or captopril.	Positive test with diffuse pattern implies hemolyzed RBC or myoglobin
Bilirubin	False-positive with iodine, stool contamination, chlorpromazine, mefenamic acid	Hard to read with agents causing marked urine discoloration
	False-negative after prolonged standing	
Urobilinogen	False-positive with pyridium, gantrisin, sulfonamides, porphyrin, methyldopa, procaine, aminosalicylic acid, 5-hydroxyindolacetic acid	Use fresh specimen; rapidly broken down by light and in acid urine
	False-negative with gantrisin and pyridium	
Leukocyte esterase	False-positive with vaginal contamination (commonest cause), oxidizing agents, eosinophils in the urine, *Trichomonas*	
	False-negative with high glucose, ketones, protein (especially albumin), pH, or SG and male sex, cephalexin, tetracycline, pyridium, oxalates, ascorbic acid, neutropenia	
pH	Urea splitting bacteria elevate pH	Use fresh specimen: standing raises pH by loss of CO_2
	Run off from protein strip can falsely lower pH	
Specific gravity	Overestimates SG with low pH, ketoacidosis, and protein	Not reliable at SG >1.025

	Underestimates SG due to glucose, urea, or with pH >7	

a urine dipstick involves a complex assay, it is essential to *meticulously follow the manufacturer's instructions for storage and use*.[81] Even with optimal storage and testing conditions, the false-negative and false-positive rates of these tests are problematic. In addition, most of the tests are susceptible to interference from a variety of substances (Table 70-1).

Method

Urine specimens should be tested as soon as possible after they are collected. If urine has been standing, it should be stirred or shaken well, because cells rapidly sink in a container. The test strip should be completely immersed for 1 second or less. The edge of the strip is drawn along the rim of the specimen container and can also be lightly tapped to remove excess urine, thus avoiding mixing of the reagents between different test patches. Hold the strip horizontally or place it on a clean gauze pad until the recommended time has elapsed. Most strips are designed so that all of the tests can be read together after 1 to 2 minutes.

Interpretation

Glucose.

The urine glucose test is normally negative. Urine glucose testing has limited usefulness in quantitative

testing because the serum glucose level at which spillage occurs varies (although in most patients it starts at between 180 and 200 mg/dL). [99] Changes in urine glucose lag behind changes in blood glucose by approximately half the interval between voids. [114] Glycosuria in the absence of hyperglycemia suggests renal tubular dysfunction. Glycosuria may occur in hypothermic patients in the absence of hyperglycemia, and indeed may mask true hypoglycemia in alcoholic patients who are hypothermic.[76]

Ketones.

Ketones are found in the urine during starvation, inadequate carbohydrate intake, diabetic and alcoholic ketoacidosis, isopropyl alcohol poisoning, or glycogen storage disease. Urine testing for ketones is not sensitive to all forms of ketonemia or ketonuria, and the absence of a positive ketone test by dipstick should not categorically dismiss a significant ketotic state. Tests for urine ketones are 5 to 10 times as sensitive to acetoacetate as to acetone. Similar to the serum "acetone test," dipsticks do not detect 5-hydroxybutyrate, which comprises 80 to 95% of the 3 "ketone bodies," and is the predominant form in the setting of ketoacidosis. However, urine ketone testing is significantly *more* sensitive than serum ketone testing.[79] Indeed, there is generally no need to obtain "serum acetones" to diagnose or manage diabetic ketoacidosis (DKA) when urine ketone monitoring is coupled with blood gas and anion gap analyses.

Nitrites.

Normally, urine does not contain nitrites. Nitrites are specific (approximately 95%), but not sensitive (approximately 45%) indicators of UTI. [119] [209] [213] Urinary nitrates are converted to nitrites most strongly by enteric coliform bacteria, explaining the nitrite test's 90% sensitivity in detecting UTI caused by *Escherichia coli*.[148] *Enterococcus*, a moderately frequent urinary pathogen, and *Pseudomonas* species and *Acinetobacter* do not convert nitrates to nitrites and therefore are not detected by the nitrite test. False-negative results also occur because of lack of dietary nitrate, frequent voiding, and/or diuresis. [215] Early morning-voided specimens are ideal (allowing time for conversion of nitrate to nitrite), but they are rarely available in the ED; if possible, a specimen obtained =4 hours after the last voiding is preferred.

Protein.

Proteins with molecular weight below 50,000 to 60,000 daltons can pass through the glomerulus to be reabsorbed in the proximal tubule. Normal protein passage in the urine is less than 150 mg/24 hours, or approximately 10 mg/dL of urine. About 10% to 33% of urinary protein is albumin, 33% is Tamm-Horsfall glycoprotein (secreted by renal tubular cells), and the balance is made up of a variety of immunoglobulins and other proteins. Proteinuria is a finding noted in about 5% of routine urine screens in men.[45] Whether this represents a normal variant is unclear, as 3% to 5% of young healthy adults have postural proteinuria (proteinuria when standing, but not when recumbent).[95] The urine dip-stick detects negatively charged proteins much more strongly than positively charged ones; it is therefore most sensitive to albumin.

In assessing a patient with proteinuria, it is helpful to divide the list of causes into those associated with hematuria and those not so associated. These are listed in Table 70-2 . Proteinuria can be due to either systemic or renal causes. Systemic causes can be physiological after strenuous exercise and in "postural" proteinuria; or pathological due to severe dehydration; hypovolemia; hypotension; hemorrhage; fever; congestive heart failure; severe infection; or hyperproteinemic states, which cause overflow proteinuria. Hyperproteinemic states include multiple myeloma, leukemia, massive intravascular hemolysis, and rhabdomyolysis. Elevated urinary protein due to renal causes, in the absence of any of the systemic conditions listed in Table 70-2 , is much more common. The source is either glomerular, with passage of normally unfiltered proteins; or tubular, with failure to reabsorb physiologically filtered, low molecular weight globulins. The former condition causes albuminuria. Renal tubular proteinuria is characterized by low levels of urinary albumin, and therefore more likely to be missed.

The likelihood that a positive urine protein dipstick reflects renal disease (as opposed to a systemic) etiology heightens with an increasingly positive result, as it does in patients with conditions such as hypertension, diabetes, connective tissue diseases, peripheral edema, gout, or elevated serum creatinine. A study of ED patients with severe acute hypertension identified renal dysfunction (as evidenced by an elevated serum creatinine) with 100% sensitivity using urine dipstick detection of 1+ proteinuria or hematuria.[123] As noted, proteinuria is an incidental finding in 5% of the normal population, so mildly elevated proteinuria in asymptomatic patients without systemic disease or renal insufficiency with otherwise normal urine sediment is likely of no clinical significance. [293]

The urine dipstick test is positive for protein with pyuria of more than 6 WBCs/hpf. [288] This is technically a false-positive finding but is useful when the urine dipstick is being used to screen for a UTI, since the threshold for leukocyte esterase is often much higher. Hematuria only slightly elevates urine protein levels.

"Blood."

The blood section of the urine dipstick shows a positive result in the presence of RBCs, hemoglobin, or myoglobin. Guidelines for distinguishing these are outlined in Table 70-3 . Moderate intravascular hemolysis does not cause hemoglobinuria, as the hemoglobin is tightly bound to haptoglobin and is therefore not filtered. Massive intravascular hemolysis gives rise to free plasma hemoglobin with a molecular weight of 32,000 daltons, which can pass through the glomerulus. Myoglobin has a molecular weight of 17,000 daltons, permitting easy passage through the glomerulus.

Urine in young, healthy volunteers contains <7 RBCs/µL (RBCs/µL).[274] Studies have shown that although the urine dipstick is only 93% sensitive compared to microscopy of unspun urine at the very low level of 1 RBC/hpf, it generally is very sensitive to 10 RBCs/µL. [274] Hence, false-negative results are confined to clinically insignificant hematuria.[133] [188] In asymptomatic men older than 50 years, significant disease can be signaled by intermittent positive dipstick hematuria, mandating careful follow-up of patients with this incidental finding. [184]

Dipsticks are vitiated by humidity and air and give false-negative results after improper storage. [54] Because RBCs lyse rapidly in urine with high pH or low specific gravity, delays in performing a microscopic UA may suggest myoglobinuria or hemoglobinuria. Microscopy or dipstick testing of a *freshly* obtained specimen can clarify this issue. The dipstick pad should be inspected for discrete positive "dots," indicative of nonhemolyzed RBCs. Conversely, urine with high specific gravity or low pH can inhibit the lysis of erythrocytes, which is necessary for the dipstick chemical reaction to occur, thus causing a false-negative result. [160] Povidone-iodine was reported to cause false-positive results in vitro, but a study reproducing typical clinical conditions demonstrated that this does not happen in vivo. [200] Iatrogenically caused trace positive results may occur after straight catheterization in 15%

TABLE 70-2 -- Causes of Proteinuria with and without Hematuria

Proteinuria usually with hematuria
(Generally indicative of glomerular disease; most etiologies in early stages can present without hematuria)
Infectious diseases
Post-streptococcal GN, pneumococcal pneumonia, ABE, meningococcemia, secondary syphilis, hepatitis B, severe viral infections, malaria, toxoplasmosis, Guillaín-Barré, etc.
Multisystem diseases
Vasculitides: Henoch-Schönlein purpura, PAN, Wegener's granulomatosis, Kawasaki disease, etc.
Connective tissue diseases (SLE, RA, scleroderma), neoplasms, etc.
Rhabdomyolysis (usually causes artifactual hematuria)
Goodpasture's syndrome
Cryoglobulinemias
Toxemia of pregnancy
Serum sickness
Proteinuria usually without hematuria
(Generally indicative of tubular/interstitial disease, or of overflow proteinuria. In advanced disease, can develop hematuria.)
Systemic conditions
Fever, post exercise, orthostatic
Diabetes
Amyloidosis
Sarcoidosis
"Overflow states": multiple myeloma, lymphoma, leukemia, rhabdomyolysis, etc.
Renovascular hypertension
Medications, drugs, and toxins
NSAIDs, gold, penicillamine, probenicid, captopril, lithium, cyclosporine, etc.
Heroin
Heavy metal nephropathy: lead, mercury, or cadmium
Renal diseases
Chronic pyelonephritis
Interstitial nephritis
Fanconi's syndrome

of cases, but at such low levels that they should not be a source of confusion with emergency urologic conditions. [103] [262]

Urine bilirubin.

Urine bilirubin represents the filtered, soluble, conjugated form of bilirubin. Unconjugated bilirubin is protein-bound, and does not pass through the glomerulus. Bilirubinuria is therefore due to intrahepatic or extrahepatic cholestasis. Bilirubinuria will be detected significantly earlier than clinical jaundice. Urinary bilirubin excretion is enhanced by alkalosis. A fresh sample of urine should be tested, because bilirubin glucuronide is hydrolyzed when exposed to light. Ascorbic acid and high levels of urinary nitrites decrease the sensitivity of the test to bilirubin.

Urobilinogen.

In a healthy person, conjugated bilirubin is excreted in bile. In the colon it is broken down into a number of compounds, which includes urobilinogen. Most of these compounds are excreted in the stool, giving the characteristic color. A small amount of urobilinogen is absorbed

TABLE 70-3 -- Aids in Distinguishing Hematuria, Intravascular Hemolysis, and Myoglobinuria

	Hematuria	**Myoglobinuria**	**Intravascular Hemolysis**
Serum findings	Color: clear	Color: clear	Color: pink
		Haptoglobin: normal	Haptoglobin: low
Urine appearance	Color: Clear to brown, clears with centrifugation	Color: Clear to red/brown; no clearing with centrifugation	Color: Clear to brown; no clearing with centrifugation
Urine microscopy	RBC, RBC casts, and protein implies glomerular source	Possible occasional RBC and tubular cells secondary to rhabdomyolysis-induced renal damage	Usually unremarkable
	No RBC casts, tubular cells, small protein: nephron source		
	Just RBC: source distal to nephron (e.g., ureterolithiasis)		

from the colon, and if it is not taken up on the first pass through the liver, it enters the circulation. Ultimately, some of this urobilinogen is filtered by the glomerulus to enter the urine, so that it is normal to have zero to moderate levels of urinary urobilinogen on dipstick testing. Most diseases causing hepatocyte dysfunction (viral or drug-induced hepatitis, cirrhosis, congestive heart failure with passive liver congestion, or cholangitis) also cause increased urinary urobilinogen excretion. This is because there is greater impairment of hepatic uptake of urobilinogen than there is of hepatic excretion of conjugated bilirubin. As a qualitative test with a wide range of normal values, it is rarely helpful, but in evaluating a patient with jaundice, it can have diagnostic significance (Table 70-4).

Leukocyte esterase.

This portion of the dipstick test is designed to detect enzymes from the azurophilic granules in neutrophils. Normally the test is negative. Studies report a

TABLE 70-4 -- Relationship between Urinary Bilirubin, Urobilinogen, and Stool Color in the Jaundiced Patient

	Healthy, Normal	Complete Biliary Obstruction	Intravascular Hemolysis	Hepatocellular Disease
Urinary bilirubin	None	Elevated	None	Elevated
Urinary urobilinogen	None or present	None	Present, sometimes large	Normal early, Increased late
Stool color	Normal	Acholic	Normal	Normal

wide and clinically important range of thresholds for dipstick testing sensitivity, from 10 to 100 WBCs/µL urine. [169] [178] [230] Studies suggest that the test is between 50 and 96% sensitive in detecting infection. [83] [85] [149] [151] [211] [217] [230] The specificity for presence of WBCs is between 91 and 99%. [52] [83] [151] [209] [211] The most common cause of a false-positive leukocyte esterase test is vaginal contamination.

pH.

Average daily excretion of 50 to 100 mmol of H^+ in the urine gives rise to a typical urine pH of approximately 6. Dietary protein lowers the urinary pH, whereas fruit and vegetables, especially citrus fruits, tend to increase it. The normal urinary pH ranges from 4.5 to 8. The significance of pH testing is in the assessment of normal renal function. In most states of alkalosis and acidosis, the healthy kidneys maintain homeostasis by conserving or excreting H^+. Failure to do so suggests renal disease, especially renal tubular acidoses. An exception is the "paradoxical aciduria" of hypokalemic alkalosis secondary to volume contraction, hypercorticism, or diuretics, where the highest priority of the renal tubule is to conserve sodium. Note that pH is falsely elevated by the action of urea-splitting bacteria, especially *Proteus* species. This can occur with "stasis" of urine, either in the bladder or in specimen cups awaiting processing in the laboratory. A persistently alkaline urine is seen in patients with struvite (triple phosphate) urolithiasis.

Specific gravity.

The dipstick test for urine-specific gravity assays for the primary urinary cations, sodium and potassium. True specific gravity, which is also dependent on anions, albumin, proteins, urea, and glucose, is therefore not measured. Artifactually low specific gravity readings are obtained in alkaline urine. Acid urine and albumin falsely elevate the specific gravity reading. [1] Some investigators believe that these strips on the dipstick test are of marginal clinical utility at best. [10] Other clinical indicators of a patient's hydration status are probably more reliable. If necessary, a refractive-specific gravitometer or a hygrometer should be used.

Microscopic Urinalysis

Microscopic UA is performed to identify cells, bacteria, and other microbes as well as formed elements such as casts and crystals (Fig. 70-2 (Figure Not Available)). The following discussion will focus on the findings of significance in diagnosing UTI: WBCs, bacteria, and WBC casts. The presence of WBCs with bacteria distinguishes infection from colonization (bacteriuria without pyuria). Some authorities state that significant infection without pyuria occurs in less than 5% of cases, making pyuria a sensitive marker of infection. [172] [195] [253] [254] Other studies do not support reliance on pyuria as an indicator of infection. [102] [125] [146] [149] [154] [164] [224] The presence of WBC casts distinguishes pyelonephritis ("upper UTI") from cystitis ("lower UTI").

Microscopic UA is performed using one of five methods, listed subsequently. Traditionally, the most common technique has been the examination of unstained centrifuged urine (technique 3). It has the advantage of concentrating formed elements that might otherwise be missed. The disadvantage is that the presence and quantity of elements in a specimen will vary depending on many uncontrolled factors: the volume of the specimen, the time and speed of centrifugation, the fragility of the formed elements, the volume of the "drop" in which the pellet is resuspended after removal of the supernatant, and the size of the microscope's "high-power field" (hpf). [36] [125] [256] [277]

1. *Examination of unspun urine in a hemocytometer counting chamber.* The hemocytometer is a precisely milled slide etched with measured squares, allowing for the exact enumeration of cells in each square. Because the distance between the etched surface and the coverslip is exactly known, it is possible to determine the number of cells per unit volume of specimen. Enough fresh unspun urine is placed on the slide to fully cover the counting area, and the cells are counted. There should usually be less than 1 WBC/µL, [80] [195] although more than 10 WBCs/µL and more than 5 RBCs/µL are unequivocally abnormal. The threshold for diagnosing UTI is usually set at = 8 WBCs/µL. [36] [80] [95] [252] [257] Bacteria do not sink to the surface of the hemocytometer, so that counting them through the many focal planes of the chamber is not possible, although methods to estimate the bacterial count per unit volume have been described. [224] [277] Casts should be approximately 125-fold less numerous than WBC, so they should not be found in the hemocytometer unless by chance. [134]
   The hemocytometer is accurate, fast (time need not be spent in staining or centrifugation), and easy to master. Its two major drawbacks are cost (around $150 for the slide and cover slip) and fragility (these are both easily destroyed if dropped). These problems may be insurmountable given the equally cramped budgets and laboratory facilities of many EDs. In the identification of formed elements other than WBC and RBC, the hemocytometer is less accurate than spun urine microscopy since these elements appear in very low concentrations.
2. *Examination of unspun, unstained urine placed on a regular microscope slide* is a qualitative method sometimes used in the diagnosis of UTI. Using 1 organism/hpf as a positive result, the sensitivity and specificity in detecting 10^5 CFU/mL are between 60% and 90%.[118] This method only identifies 1 WBC/hpf with the highly pyuric state of 250 WBCs/µL, [252] leading some to advocate the use of more than 1 WBC/*low-power* field as a criterion for infection. [195]

3. *Examination of unstained, centrifuged urine* is performed by centrifuging 10 mL of urine at approximately 450 g (1000 to 4000 rpm) for 3 to 5 minutes. Roughly 9 mL of supernatant is poured off, and the pellet is resuspended in the remaining fluid. This suspension is placed on a slide with a coverslip and examined. The larger formed elements, especially casts, tend to migrate to the edge of the coverslip, and they can be seen with low magnification. One or two casts, depending on the clinical context, may be normal; more are not. The morphology of the more commonly encountered formed elements of urine sediment is shown in Figure 70-2 (Figure Not Available) . The significance of each is beyond the scope of this text, but this information can be found in a standard textbook of clinical laboratory procedures and diagnostic testing. [99] [114] When examining centrifuged urine, more than 5 WBCs/hpf seen in the middle of the coverslip has traditionally been taken as indicative of abnormal pyuria. Most authors have estimated that 10 WBCs/µL are equivalent to approximately 1 WBC/hpf; thus, this oft-cited threshold for diagnosing UTI is actually equivalent to 50 WBCs/µL. [36] [80] [195] [252] [257] Since the gold standard for diagnosis of UTI is =8 WBCs/µL, many infections will escape detection using this method.
   Various numbers of bacteria per high-powered field have been used as criteria for the diagnosis of UTI. A threshold of 10 to 20 organisms/hpf has been recommended to rule out bacteriuria at the 10^5 CFU/mL level.[118] This threshold does not exclude infection in symptomatic patients.

4. *Examination of Gram-stained, uncentrifuged urine* is also a semiquantitative measurement. It is estimated that 1 bacterium/hpf is equivalent to 10^5 CFU/mL in bacterial culture. [99] [118] [125] [147] [236]
5. *Gram stain of centrifuged urine* is probably the optimal technique, short of culture, in the assessment of bacteriuria. It is more than 95% sensitive and more than 60% specific to 10^4 CFU/mL—an order of magnitude lower concentration of bacteriuria than the previously described methods. [118] [167] Detection of 1 organism/oil-immersion field constitutes a positive result. [118] [228] Specificity is increased to 95% if 5 organisms/hpf are seen. [118]

Figure 70-2 (Figure Not Available) *1,* Red and white blood cells (RBCs and WBCs); *2,* WBCs with bacteria in an infected urine specimen; *3,* fine granular cast; *4,* WBC cast (seen in intrinsic renal diseases such as pyelonephritis and glomerulonephritis: note the discernible nuclei and cell boundaries); *5,* RBC cast (the distinct and uniformly spherical shape of the erythrocyte is visible); *6,* epithelial cast (present in tubular disease); *7, Trichomonas vaginalis; 8,* budding yeast forms; *9,* calcium oxalate crystals; *10,* phosphate crystals; *11,* urate crystals; *12,* cystine crystal (indicative of cystinuria). *(1, 3–9, and 12 from Urine under the Microscope. Summary of Tests Used in the Diagnosis of UTI

The three tests commonly used to evaluate a patient for the presence or absence of UTI are urine dipstick, microscopic UA, and urine culture. Each represents an increasing degree of expense, delay, and resources. A brief discussion of their relative strengths and weaknesses ensues.

Urine Dipstick

Dipstick testing of urine is faster than microscopic UA; is less labor-intensive, thus cheaper; and circumvents multiple sources of potential and proven error. [135] Is it sufficiently accurate to replace it? Using *either* leukocyte esterase (LE) *or* nitrites to indicate infection, the dipstick is still only 50 to 90% sensitive to culture-proven infection.[6] [167] [169] [212] [213] [217] This is clearly not adequate to rule out infection in symptomatic patients, but may be acceptable in screening populations of asymptomatic patients, because such a group is likely to have a low prevalence of disease so that the test will have a serviceably high negative predictive value of 95 to 99%.[135] [169] [213] [214] In symptomatic patients, sensitivity should be enhanced by taking a positive result in *any one* (or more) of *either* LE *or* nitrites *or* protein *or* blood as indication of a UTI.[91] [174] [192] [236] [240] Sensitivity can also be augmented by allowing more time before reading the strip.[169] [240] An approach that maximizes sensitivity is indicated in symptomatic females for whom empiric treatment is recommended and the prevalence of disease high. In such patients a completely negative dipstick should prompt a careful search for another source of infection, but not deter from empiric treatment, since it is still inadequately sensitive to rule out infection.[174] [236] Clearly, maneuvers to enhance sensitivity will diminish specificity, which may be as low as 26%, [263] leading some to advocate microscopic UA for all urines abnormal by dipstick.[25] However, as discussed later, this probably adds little to a carefully performed dipstick test.

Microscopic Urinalysis

If the urine dipstick has such poor specificity when it is used as a test with adequate sensitivity, should it be discarded altogether, and microscopic UA relied upon in its stead? Apart from the hemocytometer, the most reliable method for identifying significant bacteriuria is oil-immersion microscopy of Gram-stained, centrifuged urine.[118] Despite this, the practice in most hospital laboratories is to examine the resuspended pellet of unstained, centrifuged urine. The problems with this method have been discussed. In various studies a range between 1 and 10 organisms/hpf or 5 WBCs/hpf has been considered a "positive" test (as the threshold number rises, so does specificity, at the price of sensitivity).[118] [219] In aggregate, the accuracy of microscopy in the diagnosis of UTI is similar to that of the dipstick alone, with 22% false-positive, and 23% false-negative rates when compared to culture.[53] [89] [277] Thus microscopic UA cannot rule out infection in symptomatic patients. The specificity of pyuria will be improved when viewed as a marker of all genitourinary infections including urethritis, prostatitis, epididymitis, vaginitis, and cervicitis. These diagnoses must always be entertained in patients with urinary symptoms, especially if the urine is sterile with pyuria.

Urine Culture

Cultures are indicated for any potentially complicated UTI. This includes those in children; men; women with recurrences or relapses; the immunocompromised; patients with urinary tract pathology, including stones and possible pyelonephritis; and pregnant patients. They are usually recommended around the 16th week of gestation. As previously discussed, every effort should be made to obtain a high-quality specimen owing to the difficulty of distinguishing contamination from significant low-count bacteriuria in symptomatic patients, and in view of the expense of cultures and treatment, if the culture is positive.

Conclusion

It is well established that female patients with symptoms of uncomplicated lower UTI can be treated without culture.[39] [46] [119] [129] [140] [208] [256] Treatment is generally benign, and 95% of urine cultures that are positive will grow out a limited number of organisms with predictable antibiotic susceptibilities. [46] [231] [256] Many authors recommend dipstick and/or microscopic UA in this group.[119] [208] [256] While these tests cannot rule out disease in symptomatic patients, if they are negative, alternative diagnoses should be considered more carefully. Symptomatic patients with negative dipstick and/or UA can be treated empirically, with cultures sent and instructions for follow-up.[119] Urine testing is more likely to alter management as well as increase clinical accuracy in patients whose symptoms are equivocal (intermediate pretest probability).[263] The UA will also help in equivocal situations where it can help in distinguishing pyelonephritis (WBC casts), vaginitis (rarely pyuria or hematuria on careful MSCC or catheterized specimen), and urethritis (usually pyuria, rarely hematuria), from cystitis (pyuria and often hematuria). [140] [256] In the ED, the ease of obtaining a dipstick argues for its use without UA since it is equally sensitive, unless formed elements such as cells, casts, crystals, trichomonas, or other parasites are suspected.[151] [169] In patients with pyelonephritis, urine cultures are probably warranted because they will alter therapy in about 5% of cases. [270] In most asymptomatic patients, a negative dipstick or UA has sufficient negative predictive value to rule out disease unless the patient is pregnant or getting urologic surgery. Special clinical considerations in some patients (e.g., the immunocompromised, diabetic females at high risk for UTI) may mandate adjustments of this approach.[169] In febrile infants and children, pyuria less consistently accompanies infection, rendering the dipstick and UA less sensitive than in adults. [7] [95] [102] Cultures are recommended for febrile infants younger than 2 months.[58]

TESTING FOR PREGNANCY

Pregnancy tests are based on the detection of ß-human chorionic gonadotropin (ß-hCG) in serum or urine. ß-hCG is secreted by trophoblastic cells of the placenta starting from the time of implantation of the blastocyst. Qualitative serum tests and the urine test detect ß-hCG levels of between 15 and 25 mIU/mL. [187] The concentration of hCG is usually lower in urine than in serum, which accounts for the slight advantage of serum tests in detection of early pregnancy. Optimal urine pregnancy tests are obtained on first-voided concentrated morning specimens. Home urine pregnancy test kits detect levels of ß-hCG of about 50 mIU/mL in the urine.

ß-hCG levels of 5 to 8 mIU/mL correspond to the 9th to 11th day after ovulation (23 to 25 days after the first day of the last normal menstrual period). In a viable intrauterine pregnancy, the ß-hCG level doubles approximately every 2 days during the first 4 weeks of gestation, reaching a serum level of 25 to 300 mIU/mL, detectable by virtually all ß-hCG-based pregnancy tests in urine or blood, on or around the first day of the missed menstrual period. The doubling rate declines to every third day thereafter, [179] [246] with the quantitative ß-hCG reaching a peak of around 100,000 to 200,000 mIU/mL between the 10th to 14th gestational weeks and declining to around 10,000 to 20,000 mIU/mL for the rest of the pregnancy (Table 70-5). There is a wide range of ß-hCG levels among different women at the same stage of gestation, making definite clinical determinations on the basis of a single quantitative test impossible. [59] Furthermore, since antigens in each patient vary, there is up to a full two-fold range of discordance in simultaneously measured ß-hCG levels. [55] [56] This is likely to be of clinical significance only when hCG levels are extremely low. False-positive tests have been described in association with molar pregnancy, choriocarcinoma, teratoma, occasional malignancies outside the genitourinary tract, and very high levels of proteinuria. There is one report of a positive urine hCG (but normal serum hCG) associated with tubo-ovarian abscess. [161]

The rate of decline of quantitative ß-hCG after gestation varies depending on the reason for the conclusion of the pregnancy. After a term delivery, ß-hCG falls to zero in

2 weeks. After surgery for an ectopic pregnancy the range is 1 to 31 days, with a median of 8.5 days; after a first-trimester spontaneous abortion, the range is 9 to 35 days (median, 19 days); and after first-trimester elective abortion the range is 16 to 60 days (median, 30 days). [99]

Although a previous quantitative ß-hCG level is rarely available to the emergency clinician, doubling rates are an important part of the assessment of a healthy first-trimester pregnancy. Fetal nonviability, ectopic pregnancy, and intrauterine demise are signaled by abnormalities in the predicted rise in quantitative ß-hCG. [28] [62] [120] A serum quantitative ß-hCG level that does not increase by 66% every 48 hours has a 75% chance of being due to a nonviable pregnancy. [120] [121] The ß-hCG levels in a healthy intrauterine pregnancy (IUP) and associated sonographic findings are listed in Table 70-6 .

The association between ß-hCG levels and gestational dates has led to the concept of the "discriminatory zone." In a normal pregnancy with a quantitative ß-hCG level of >1000 to 1500 mIU/mL, a double decidual sac should, at the very least, be sonographically identifiable by transvaginal ultrasound. [27] The discriminatory threshold for identifying early IUP by transabdominal ultrasound is considered to be =6500 mIU/mL. If these ultrasound findings are absent at these thresholds, the pregnancy is almost certainly abnormal, with a significant possibility of ectopic. However, the converse—that ectopic pregnancy will always be accompanied by a

TABLE 70-6 -- Relationship between Gestational Age, Quantitative ß-hCG Levels, and Ultrasound Findings

IUP: intrauterine pregnancy

ß-hCG level =1000 mIU/mL—is *not* true. Only 15% of ectopic gestational sacs examined pathologically have evidence of an embryo. This observation, combined with

a variety of pathologic characteristics and sites of implantation, leads to highly variable quantitative ß-hCG levels in ectopic pregnancies. [65] In general, an ectopic pregnancy elaborates quantitatively small amounts of ß-hCG, with 1% of ectopic pregnancies having a quantitative ß-hCG of <10 mIU/mL and up to 8% having ß-hCG levels of <25 mIU/mL.[225] About 10% of ruptured ectopic pregnancies are associated with a ß-hCG level less than or equal to 100 mIU/mL. [65] Overall, about 25% of ectopics will be diagnosed with a ß-hCG of <1000 mIU/mL,[57] although in one series, at the time of operation, 50% of women with unruptured ectopic and 40% with ruptured ectopic pregnancies had serum ß-hCG levels of <1000 mIU/mL.[65] Patients with abdominal and/or pelvic pain or vaginal bleeding and a ß-hCG level =1000 mIU/mL have a fourfold increased risk of ectopic pregnancy compared with those with the same symptoms and a ß-hCG level =1000 mIU/mL.[122]

Thus, it can be seen that the "discriminatory zone" can only be used to identify patients in whom ultrasound should definitely demonstrate signs of healthy IUP: a transvaginal ultrasound that fails to show an IUP with a ß-hCG level =1000 is >86% specific for ectopic pregnancy. [28] While there will be an increased rate of non-diagnostic ultrasounds below this level, a sonographic diagnosis will still be possible in a third or more of patients. [12] [61] Thus, the ß-hCG titers provide a basis for interpreting ultrasounds, *but not a basis for deciding whether or not to get them*.[57] [122] [177]

BLOOD CULTURES IN THE EMERGENCY DEPARTMENT

Indications

Blood cultures are indicated when there are clinical findings suggestive of an otherwise unidentifiable bacteremic state (Table 70-7). Traditional use of blood cultures in patients with pneumonia and pyelonephritis is of increasingly questionable utility. [100] [270] [283] [290] It should be noted that 25% of patients with documented bacteremia have periods without fever.[196] In the elderly the proportion is even higher, with 50% of bacteremic patients over 65 having a temperature between 97.1°F (36.2°C) and 100.9°F (38.3°C); and at least

TABLE 70-7 -- Summary of Indications for Obtaining Blood Cultures

Patients with fever and any of the following:
Unexplained alterations in mental status, functional status, or autonomic status in previously healthy patient between the ages of 5 and 65 years, or
No source, if <2 years, >65 years, or immunocompromised, or
Age <2 months
Patients with or without fever and any of the following:
Rigors, or
toxic or "septic" appearance: (i.e., unexplained hypotension, altered mental status, shock), or
suspicion of infectious endocarditis, or
serious focal infections (e.g., meningitis, septic arthritis, osteomyelitis)

13% with no documented temperature greater than 99.1°F (37.3°C) at any time. [47] [77] [86] [243] In the elderly, increasing age, vomiting, altered mental status, presence of a Foley catheter or urinary incontinence, and greater than 6% band forms are predictive of positive blood culture results. [77] [222] The subjective impression of "having fever" in adults is not a reliable indicator of the presence of fever, although the subjective impression of "no fever" is much more likely to be accurate. [38] Prediction models to improve the use of this costly laboratory procedure have been developed, [14] but lack widespread validation or acceptance. [193] [296]

In children, the indications for blood cultures are under active investigation. Traditional teaching that blood cultures are indicated for all patients younger than 2 years with fever >38.6°C (>101.5°F) and without obvious source is being modified by the effectiveness of *Haemophilus influenzae* type b (HIB) vaccination. In the post-HIB era, the commonest etiology of "occult bacteremia" is the pneumococcus, accounting for >75% of cases, the majority of which resolve spontaneously. [3] [157] Bacteremia is more likely the higher the temperature and WBC count, the lower the patient's age, and the more rapid the onset of illness. [35] [93] [113] [150] In infants younger than 2 months with temperatures higher than 38°C (>100.5°F), some authorities would recommend blood cultures regardless of the presence or absence of a source, although this approach is subject to modification by experienced clinicians based on the patient's age and clinical setting. A child with a normal temperature in the ED and a history from the parents of tactile fever needs to be approached in the same way as a patient with fever documented on physical exam for several reasons. First, bacteremic children, like adults, have intermittent fever, with up to 50% afebrile rates in children with demonstrated bacteremia. [138] Second, parents' tactile impression of fever has been shown to be highly reliable. [11]

The Controversy Regarding "Outpatient Blood Cultures"

There is a long-standing debate regarding the utility of outpatient blood cultures (i.e., blood cultures on patients who are discharged from the ED pending results). Arguments for and against outpatient blood cultures are summarized in Table 70-8 .

TABLE 70-8 -- Summary of Arguments for and Against the Performance of Outpatient Blood Cultures

Arguments against outpatient blood cultures:
1. Low true-positive rates.
2. True positives are rarely clinically significant.
3. High false-positive rates are expensive and time-consuming for both patient and health care system.
4. Difficulty of ED follow-up makes positive blood culture results a medicolegal liability.
Arguments for outpatient blood cultures:
1. Permits outpatient management in certain groups with low prevalence of disease with financial, psychological, and nosocomial cost savings for patients and society.
2. Allows initiation of antibiotics without fear of a potentially irrevocably lost opportunity for blood cultures (especially with infectious endocarditis).
3. May give useful etiologic information and antibiotic susceptibility profiles about diseases under outpatient treatment.

The data on the subject is still inconclusive. Opponents cite medicolegal issues, problems with follow-up, high contamination rates, low rates of positive cultures, and even lower rates of frequency of patients in whom therapy is changed because of culture results. [72] [250] [261] Proponents also cite medicolegal concerns, positive rates similar to those seen with inpatient blood cultures, cost savings, and the benefit of diagnosing significant, yet subtle, bacteremic states (such as endocarditis). [73] [244] They also point out that the high false-positive rates seen in many ED series should be an indictment of poor technique, not of the test itself.

On the basis of current data, it would seem to be fiscally extravagant to admit all patients in whom a bacteremic state is possible, and injudicious to deny blood cultures solely on the basis of a patient not appearing "toxic enough" to warrant admission. Outpatient blood cultures, with due attention to collection technique, patient selection, and diligent follow-up, would therefore seem to be an appropriate component of emergency medicine practice.

Technique of Obtaining Blood Cultures

Studies have demonstrated sources of contamination at every stage of the process of obtaining and processing blood cultures. In addition to obvious sources of contamination from the patient's and the phlebotomist's skin, antiseptic agents [21] [201] and gloves[297] have been implicated. Some authorities have argued that the primary source of contamination is in the laboratory processing of specimens. [237] However, the consensus is that the most common source of contamination is the process of phlebotomy and inoculation of blood culture bottles. [112] [281] Obviously this is the single step over which emergency clinicians have control, either directly, or via protocols of technique for blood culture phlebotomy. Contamination rates are typically between 1.5 and 3%, [3] [74] [186] although many ED series show much higher rates than this, reflecting the difficulty of obtaining effective blood cultures in the ED setting. [251] [261] [271]

A high degree of sensitivity is required of blood cultures. Many significant bacteremic illnesses have been documented with as little as one colony-forming unit (CFU) per 10 mL of blood.[98] [132] Human skin has a bacterial concentration between 10^3 and 10^6 CFU/mL, on the forearm and groin, respectively. [235] Designed to detect vanishingly low concentrations of bacteria, the test is clearly susceptible to false-positive results (impaired specificity) when blood must necessarily be obtained by

passing a needle through the skin. Eighty percent of the skin flora are transient, superficial, and removable; 20% inhabit the sebaceous ducts and hair follicles, and are not removable without destroying the skin.[170] [235] The former group are predominantly gram-positive and gram-negative aerobes and are the target of skin disinfectants.

The primary agents for skin disinfection are iodine compounds, alcohols, chlorhexidine, and hexachlorophene. Iodine solution remains a gold standard, killing bacteria, fungi, protozoa, and viruses, but has been replaced in many institutions due to concerns about skin burns and allergic reactions. Reports of the former were probably due to the use of 7% solution: The risk of a burn or an allergic reaction is thought to be negligible with the currently available 2% preparation. [96] [281] The most effective cleansing agent is tincture of iodine, which is a mixture of 2% iodine solution and 70% alcohol. [137] [165] [259] [260] Povidone-iodine 10% solution (Betadine) has a much lower free iodine concentration than iodine solution and is therefore less potent. Iodine is superior to hexachlorophene and chlorhexidine in killing gram-negative bacteria. Iodine, like other antiseptic agents, is inhibited by the presence of organic matter, emphasizing the need for thorough skin cleansing before the application of any skin disinfectant.

Ethyl or isopropyl alcohol should be used in 60 to 80% solution. Alcohol prep pads, which generally contain 70% isopropanol, have solved traditional concerns regarding evaporation of alcohol from cotton balls stored in jars. Alcohol is a less powerful germicide than iodine in vitro, and kills only 90% of surface bacteria after a full 2 minutes with reapplication to prevent drying.[96] Alcohol foam applicators can avoid premature drying. Alcohol is inactive against fungi, spores, and viruses; however, in vivo studies of blood culture contamination rates have shown it to compare favorably with iodine. [157] [259] Because iodine solution is often not available, and iodophor solutions are less potent, alcohol still has an important place in skin antisepsis. In addition, alcohol is an excellent solvent, so that alcohol pads are a good tool for skin preparation prior to the application of iodine compounds.

Chlorhexidine (Hibiclens) and hexachlorophene (pHisoHex) are antiseptics that are more effective against gram-positive than gram-negative bacteria. Both agents have intradermal absorption, which causes prolonged antimicrobial activity and is the basis of their popularity as surgical scrub and operative site preparations. This also makes them preferable agents where indwelling lines, especially central lines, are being placed. [173] For routine blood culture phlebotomy, they are not as effective as alcohol and iodine combinations, although they are superior to povidone-iodine solution. [186] Most studies show chlorhexidine to be more potent than hexachlorophene, and it has not been associated with induction of seizures in infants.

The results of studies of contamination rates with various skin preparation agents are not unanimous. Table 70-9 presents a consensus skin preparation protocol. Optimal results seem to be obtained by alcohol-iodine mixtures.[165] [232] [235] [260] The most important concept in skin disinfection is that bacteria do not die at the instant of contact with disinfectant agents. Iodine (2%), which is twice as potent as 10% povidone-iodine, requires at least 90 seconds in contact with the skin to

TABLE 70-9 -- Skin Preparation and Technique for Drawing Blood Cultures

1. Cleanse the skin with alcohol swabs three times, or until the swabs appear entirely free of surface dirt after application.
2. Allow to dry.
3. Apply 10% povidone iodine or (preferably) 2% iodine solution or (ideally) 2% tincture of iodine in 70% alcohol, three times, in centrifugal circles from the anticipated site of venipuncture.
4. After third swab, allow to dry at least 60 seconds.
5. During this period, prepare lids of blood culture bottles with iodine and/or alcohol; lay out sterile gloves, and use paper wrapper as a sterile field for the needle and syringe (not necessary if using a vacutainer system).
6. Wipe off dry iodine at venipuncture site with alcohol. Substitute chlorhexidine if placing an indwelling catheter.
7. Obtain at least 20 mL of blood to place in 2 bottles. (This is one blood culture set.)
8. Inoculate bottles without changing needles.

kill 90% of surface bacteria.[96] In many ED patients it will be necessary to use alcohol prep pads to remove gross dirt and debris from phlebotomy sites before initiating the steps of the formal skin preparation.

Special Considerations in Obtaining Blood Cultures

"Changing the Needle" After Phlebotomy

In considering this issue, it is important to emphasize the distinction between *needle changing* and *needle recapping*.[284] The latter is a well-established risk to health care workers; it contravenes standard recommendations for universal precautions, *and should not be performed*. Needle replacement using the standard needle removal device on "sharps" containers is an unquantified risk, but clearly much less dangerous than recapping.

Based on very little scientific data,[233] it was long considered essential to change the phlebotomy needle before inoculating blood culture bottles. With increasing awareness of the risk of bloodborne infections associated with needle-stick injuries, this practice has come under scrutiny. One large, well-controlled study showed no difference in contamination rates with or without needle changing.[144] Other studies show a clear trend *toward* a lower contamination rate with needle change, without reaching statistical significance.[51] [112] [158] [245] In conclusion, not changing needles before blood culture bottle inoculation is acceptable practice for obtaining routine blood cultures. However, in those situations in which the results of the blood culture are of paramount importance (e.g., suspected infectious endocarditis, for which empiric antibiotic coverage will be started immediately), it is suggested that needles be changed prior to inoculation of culture bottles, but not recapped.

Special Access Sites

Some studies show that newly placed intravenous catheters are an acceptable source of blood culture specimens, providing that the usual measures are taken in skin preparation,[111] [245] although other series have less favorable results.[74] Previously placed IV catheters (central and peripheral) and arterial lines have been compared with fresh percutaneous phlebotomy for blood cultures in several studies. Chronically placed lines either trend toward, or show, statistically significant increased contamination rates,[37] [75] [265] [272] [273] [294] with the exception of carefully tended central venous access ports in cancer patients, which may have increased sensitivity in identifying bacteremia (possibly due to the fact that the catheters themselves are often a source of bacteremia in those patients).[63] Thus, with the possible exception of chronic venous access ports in cancer patients, chronically indwelling vascular lines should, in most situations, be avoided as a source of blood cultures.

Heel Stick in Neonates

This technique resulted in recovery rates of bacteria equivalent to phlebotomy in two studies.[139] [176] Since approximately 25% of bacteremic infants have less than 25 CFU/mL of blood, this proportion (25%) will be missed if = 0.2 mL is obtained for culture. For this reason, heel stick should be considered as a source of last resort for blood culture.

Intraosseous Specimens

This technique may also be used when phlebotomy is impossible.[205]

Timing of Blood Cultures

In most circumstances, the timing of blood cultures is moot in the ED. Most patients are sick enough to warrant the initiation of empiric antibiotics, or are well enough for discharge, so that two or more sets need to be drawn immediately. The situation in which the timing of blood cultures might become a consideration is in a patient

requiring admission but in whom the diagnosis of bacteremia is sufficiently in doubt that antibiotic therapy is not to be initiated empirically.

Contrary to the time-honored tradition of obtaining blood cultures during a fever spike, the data show a trend toward a higher proportion of true positive cultures in patients whose blood is drawn in the 12 hours *before* a fever spike.[20] [281] Furthermore, excepting infectious endocarditis, most clinically significant bacteremia is thought to be intermittent, so that multiple sets of cultures obtained at one time would heighten the risk of missing the period of bacteremia. [197] [280] Therefore, for patients admitted to the hospital with the tentative diagnosis of sepsis, it is theoretically advantageous not to draw all three sets of blood cultures in the ED, but to space them over the following 12 to 24 hours.[49] However, if administration of antibiotics is clinically indicated, two or three sets of cultures separated by 20 to 30 minutes are obtained in the ED before initiation of antibiotic therapy.

Blood Culture Volumes

Volumes in Adults

A large number of studies almost uniformly demonstrate that the sensitivity of blood cultures is directly related to the volume of blood cultured. [9] [34] [94] [109] [183] [227] [238] [269] In a representative study, Ilstrup and Washington showed that 20 mL and 30 mL of blood yielded, respectively, 38% and 62% more true-positive results than 10 mL.[109] Mermel and Maki showed that each additional mL of blood yields an average of 3% more true-positive results. [183] This finding is also consistent with the fact that 40% of adults with bacteremia have less than 1 CFU/mL of blood, and that 20% have less than 1 CFU/10 mL. [98] [132] Alternatively expressed, if 10 mL of blood is obtained for culture, 20% of patients with continuous bacteremia will be missed. Since most bacteremia is intermittent, and since endogenous factors in blood will cause some inhibition of bacterial growth even with modern lysis- and filtration-centrifugation techniques, the false-negative rate in clinical practice will always be significantly higher. On purely mathematical grounds, 10 mL per set of blood cultures is an absolute bare minimum for culture. In adults, most authorities recommend at least 30 mL of blood per culture site/set. [131] [282] [287]

To ensure dilution of the blood's antibacterial properties (e.g., immunoglobulins, complement, WBCs), blood should be placed in a concentration less than 10% (i.e., not > 1 part of blood to 10 parts of medium).[282] Thus, if 30 mL of blood is obtained from one site, it should be equally divided into three of the usual 100-mL broth bottles.

Volumes in Children

A blood volume of 30 mL from a 70 kg adult is equivalent to 0.5 mL of blood in a 3.5 kg neonate. Fortunately (for the validity of the blood culture), it has been shown that levels of bacteremia are typically 10-fold higher in infants than adults [64] [176] [258] ; and that the sicker the child, the greater the likelihood of a high level of bacteremia.[64] Although one study[198]

failed to show any effect on the rate of detection of bacteremia with increasing volumes of blood specimens, many studies have suggested that small culture volumes are at increased risk of false-negative results, just as in adults. [70] [111] [264] [292] Furthermore, the studies showing high CFU/mL rates were performed on neonates. As the immune system matures during infancy, levels of bacteremia might be expected to fall toward those seen in adults. In two reviews, it was recommended to obtain a similar volume of blood with respect to body mass as would be drawn in adults: approximately 1 mL/2.5 kg, or 4 mL per 10 kg body mass. [44] [207] These recommendations are summarized in Table 70-10 .

How Many Sets of Blood Cultures Should Be Tested?

A *set* of blood cultures is the sample obtained from a single site. A one mL specimen from a neonate placed in an aerobic bottle, and a 30 mL specimen from an adult divided between fungal, aerobic, and anaerobic bottles, are both a *single set* of blood cultures. Two or more sets of blood cultures make up a *series*. [8] [49] The information derived from the blood culture sets is pooled in such a way as to make both the sensitivity and specificity of the series greater than that of the component sets. Sensitivity is enhanced because even with continuous bacteremia, an individual set is usually only 80% sensitive. [8] Specificity is improved by determining whether pathogens that are also frequently contaminants are found in more than one set of the series.

While this conceptual process is applied to all blood culture series, the focus of inquiry varies depending on the infectious process being ruled in or out. For example, in an elderly patient with fever and purulent urine, it is extremely unlikely that the causative organism is a typical skin contaminant. The usual causes of "false-positive" blood cultures will therefore be easily recognized, thus lowering the false-positive rate for the series, and making for a test with intrinsically higher specificity. At the same time, with typical pathogens in this clinical context being nonfastidious organisms, sensitivity is typically around 99% with two sets of 20 mL blood per set.[287] Conversely, in a patient with a prosthetic heart valve, fever, and signs of septic emboli, many likely pathogens are also skin contaminants (this phenomenon lowers the specificity of each individual blood culture set), so at least two sets of cultures must be *positive* with such organisms before the overall test (i.e., of the *series*) is considered positive. At the same time, this clinical picture makes the pretest probability of disease very high (diminishing the negative predictive value of a negative set), so that an extremely sensitive overall test (i.e., series) will be needed to adequately rule out disease. Thus, in

TABLE 70-10 -- Optimal Specimen Volumes to Be Drawn per Blood Culture Set in Children *

Age Group/Weight (kg)	Ideal Volume of Specimen per Set (mL)
Neonates	1–2
Infants (5–10)	2–4
Children (7–20)	3–8
Children > 20	10
Children > 40	20
Adults and children > 60	30

*Rule of thumb: 4 mL of blood per 10 kg weight.

TABLE 70-11 -- Numbers of Blood Culture *Sets* to Be Obtained for an Adequate *Series* in Various Clinical Situations in Adults

No. of Sets (Minimum)	Clinical Context
2 sets	Etiology is likely to be easily distinguished from contaminants and pre-test probability of bacteremia is low to moderate
3 sets	Skin contaminants are possible causes of infectious process, *or* pre-test probability of bacteremia is high, *or* infectious endocarditis is a consideration, but with low to moderate pre-test probability
4 sets	Infectious endocarditis AND either moderate to high pre-test probability or the patient has recently been on antibiotics

this clinical context, most authorities would recommend four sets of blood cultures, with good volumes in each. [8] [280] Except in infants, single sets of blood cultures are of insufficient sensitivity or specificity to be of any utility, and should not be drawn. [8] [130] [202] [223] [280] [281] Recommended numbers of sets of blood cultures as they relate to the pre-test probability of disease, as well as causative organism are summarized in Table 70-11 .

Aerobic versus Anaerobic (vs Other) Bottles

Anaerobic infections, by nature, tend to occur in poorly perfused tissues or locations, frequently evolving into abscesses, which further isolate them from the bloodstream, decreasing the likelihood of bacteremia, and making them intrinsically elusive to blood cultures. In addition to these pathophysiological considerations, a significant decrease in the proportion of positive blood cultures owing to anaerobic organisms has been widely reported over the past 15 years. [67] [82] [168] [194] [239] The vast majority of anaerobic bacteremias occur in clinically identifiable situations listed in Table 70-12 .

In recent series, anaerobic pathogens account for only 1 to 5% of positive blood cultures. [67] [194] [239] [271] [280] Clinically significant isolates—those that could not have been predicted on the basis of the clinical picture, or that alter management—are much rarer. [168] Thus, with a typical true-positive blood culture rate of 3 to 7% and with only 3% of positive blood cultures being anaerobic, approximately 500 to 1000 series of blood cultures need to be drawn for every positive anaerobic blood culture. This is borne out by empiric observations showing positive anaerobic blood cultures in 1.4 per 1000 patients receiving blood cultures. [50] Of these, more than 90% had clinical indications of anaerobic infection, so that 10,000 blood culture series would be needed to generate a single anaerobic result to alter clinical management.[50] In addition to

TABLE 70-12 -- Infectious Processes Which can Cause Anaerobic Bacteremia

Odontogenic head and neck infections
Aspiration pneumonia
Abdominal/pelvic infections
Deep soft tissue infections (e.g., myofascitis)
Sepsis with decubitus ulcers or necrotic tissue

TABLE 70-13 -- Blood Culture Bottle Types to Be Used in Various Clinical Settings

Clinical Situation	Bottles to Be Obtained
Children <12 yr	Aerobic bottles only unless patient has peritonitis or fasciitis (in which case draw standard aerobic and anaerobic cultures)
Adults and children >12 yr	If anaerobic infection is unlikely, use aerobic bottles only unless the patient is immunocompromised
	In the immunocompromised, consider a bottle for fungal culture (usually effective in aerobic bottles, but consult the laboratory)
	If anaerobic infection is possible, each set consists of 1 aerobic and 1 anaerobic bottle per set

the very limited clinical utility of anaerobic cultures, they are likely to actually diminish the sensitivity of the test to aerobic bacteremia (>95% of cultured pathogens), which increases by about 3% per additional milliliter of blood. [183] [239] The use of blood culture specimens in anaerobic bottles will also diminish the likelihood of identifying fungal infections, which are increasingly common, especially in immunocompromised patients. [197]

The arguments for a selective use of anaerobic blood cultures are compelling. Based on these considerations, and analysis of a number of review articles, [49] [190] [197] [207] [239] [271] [280] Table 70-13 suggests guidelines for inoculation of blood obtained for culture.

Identifying Contaminants

The emergency clinician must be prepared for telephone calls from the laboratory with positive results of cultures obtained on previous shifts. "False-positive" blood cultures can be due to true contamination, but also may be caused by the intermittent bacteremia that occurs in normal, healthy people. This situation has been complicated by increasingly common identification of *Staphylococcus epidermidis* and *Streptococcus viridans* and fungi as pathogens in blood culture series. [63] [117] [242] [298] The expense of false-positive blood cultures has been estimated at $900 per episode for discharged patients, and more than $5,000 per episode for in-patients. These costs emphasize the importance of good technique in obtaining blood cultures. [15] [234]

Distinguishing contaminants from clinically significant bacteremia is based both on microbiologic information and the patient's clinical condition. Features of false-positive blood culture results are listed in Table 70-14 .[8] [40] [287] Notwithstanding these guidelines, it would probably be prudent to contact discharged patients with positive blood cultures even when contamination is suspected on a microbiological basis, to ensure that their condition is improving.

Fungal Cultures

Generally, fungi are difficult to isolate in blood cultures, and it may take 4 to 6 weeks to obtain a positive yield. If a fungemia is suspected, it is best to discuss culture media and technique with the laboratory before cultures are taken. Cultures

TABLE 70-14 -- Features Suggestive of Contaminant ("False Positive") Blood Culture Results

1. Coagulase-negative staphylococci (*S. epidermidis*) or *S. viridans* in a single bottle in patients not suspected of infectious endocarditis, and without chronic indwelling intravenous access catheters, are usually contaminants.
2. Corynebacteria (previously known as "diphtheroids"), propionibacterium acne, and bacillus species are usually contaminants, but can be pathogenic in the immunocompromised.
3. Multiple organisms in a series suggests contamination.
4. Species that grow out after prolonged culture have a higher likelihood of being contaminants. Conversely, early-growing bacteria have a much higher likelihood of being pathogens.[3] [145]
5. The patient's symptoms have resolved or are inconsistent with sepsis (beware with infectious endocarditis, which can have an indolent course).
6. A primary source (e.g., sputum, urine) has a different pathogen isolated.

of bone marrow are occasionally positive in deep mycoses when blood cultures are negative.

BEDSIDE TESTS FOR GASTROINTESTINAL HEMORRHAGE

Detection of Blood in the Stool

Bedside fecal blood tests make use of the peroxidase-like activity of hemoglobin. The test card is impregnated with a compound that exhibits a blue color reaction when oxidized. The original test used guaiac, but current tests use more sensitive and more reliable dyes. The addition of hydrogen peroxide developer solution will oxidize the dye in the presence of a peroxidase (e.g., hemoglobin).

Testing for occult blood in the stool is associated with false-positive and false-negative results, but in its primary role in emergency medical practice the test is usually reliable in detecting significant acute gastrointestinal (GI) hemorrhage. [114] Low pH, heat, dry stools, reducing substances (e.g., ascorbate), and antacids can cause false-negative findings. [116] [175] [220] Slow bleeding in the upper GI tract in which heme can be converted (denatured) to porphyrin during transit through the gut may not be identified by stool testing. False-positive results have been attributed to the ingestion of partly cooked or large quantities of meat (dietary sources of myoglobin and hemoglobin), and peroxidase-rich food. [87] [220] Most vegetables contain peroxidase, including (in decreasing order) broccoli, turnips, cantaloupe, red radishes, horseradish, cauliflower, parsnips, Jerusalem artichokes, bean sprouts, beans, lemon rind, mushrooms, parsley, and zucchini. [87] However, a simple in vivo study convincingly calls into question the possibility of peroxidase's passing through the stomach without being denatured. [185] False-positive tests can also be caused by the presence of povidone-iodine solution in concentrations less than 0.1% (a 1% dilution of the 10% solutions commonly available at the bedside). False-positive fecal occult blood tests are uncommon, and a positive test should be considered evidence of the presence of blood until proven otherwise. Routine iron supplementation should *not* be considered as a cause for a false-positive Hemoccult test, [6] [180]

although iron does (like bismuth preparations) cause the stools to appear black on gross examination. Despite this, early in vitro studies demonstrating an artifactual false-positive effect of iron are still frequently cited.

Normal GI blood loss is limited to less than 2.5 mL/day, which translates to less than 2 mg of hemoglobin per gram of stool (0.2% by weight). [2] The sensitivity of the Hemoccult test varies both with the concentration of hemoglobin present in the stool, and the extent to which hemoglobin is exposed to the proteolytic effects of the digestive tract. The Hemoccult test is 37% sensitive to stool containing 2.5 mg hemoglobin per gram of stool, but 95% sensitive when the concentration is 20 mg Hb/g of stool, indicating that low to moderate levels of blood may be missed. [99] The test is much more likely to detect lower GI hemorrhage than an identical rate of upper GI bleeding due to the 100-fold diminution of peroxidase activity of blood during transition through the GI tract. [71] Impaired detection of hemoglobin may also occur as a result of dilution due to diarrheal illness. [99] [114] [191]

Method

The stool specimen is smeared onto the reagent area on the card and a drop of developer is added. Because the reaction must occur in an aqueous medium, a drop of water should be added to very dry specimens and allowed to moisten them before addition of developer. Adding water will increase the false-positive rate, however. [175] [220] Formation of a blue color on the paper anywhere around or under the specimen within 60 seconds should be considered a positive result.

Testing for Gastric Blood

Heme tests designed for use on stool specimens can be unreliable when applied to gastric juices, with an increasingly high false-negative rate (low sensitivity) as pH decreases. [155] Thus, while a positive test of gastric contents using a fecal Hemoccult card is likely to be accurate, a negative test with the fecal Hemoccult card does not rule out the presence of blood. The Gastroccult card uses a modified guaiac developer containing buffers to neutralize gastric acid, thereby facilitating accurate hemoglobin detection. The test works on the same basis as the fecal guaiac test using the properties of hemoglobin as a peroxidase. In product testing, the Gastroccult card was 100% sensitive in detecting specimens of =500 parts per million of blood by volume, equivalent to 0.05%, or 0.25 mL of blood in 500 mL of gastric contents. Polyethylene glycol and high concentrations of iron (in an in vitro study simulating iron overdose) prevent both fecal occult blood tests from detecting blood. [106]

Method

Apply a drop of gastric aspirate to the test area. Apply two drops of developer to the sample. Look for formation of a blue dye within 1 minute. Do *not* use fecal blood test developer. In a specimen that is already a bilious green, the test is only considered positive if new *blue* color is formed. The Gastroccult card also contains a pH testing strip located close to the occult blood testing area, which might be useful in testing emesis after an acid or alkali ingestion. False-positive results might be expected to occur (although studies to investigate this have not been performed) with meats and peroxidase-rich foods. False-negative reactions are likely in the presence of reducing substances, such as ascorbic acid. The accuracy of Gastroccult should not be affected by the presence of cimetidine or sucralfate. [106]

DIAGNOSTIC AND THERAPEUTIC TOXICOLOGIC BEDSIDE PROCEDURES

The management of patients who present with an altered mental status can be challenging, especially if the clinician suspects drug overdose or poisoning. These patients often present with no available history or an inaccurate history. [295] Therefore, clinicians must rely heavily on physical examination findings and other sources of information to diagnose or confirm their clinical suspicions of poisoning or overdose. [48]

The hospital toxicology laboratory can be valuable in select cases. Limited screening tests for commonly ingested drugs are available, and ascertaining levels of specific drugs (e.g., acetaminophen, lithium, digoxin, phenytoin) can be helpful. However, most hospital laboratories are not equipped to perform timely analytic procedures for the thousands of possible drugs or toxins. In fact, the results obtained from the drug screening panels that most hospitals use have been shown to rarely influence medical management of adult ED patients. [127] [128] In select pediatric patients, on the other hand, the use of drug screens may have more of an impact on medical management.[18]

Diagnostic bedside testing for specific poisons or toxins has the advantage of being cost-effective and timely. When applied appropriately, certain bedside tests provide immediate information to the clinician and can have a significant and timely influence on medical management. This section discusses bedside diagnostic and therapeutic toxicologic procedures.

Noninvasive Diagnostic Procedures

Amatoxin: Meixner Test

The ingestion of several types of mushrooms (e.g., *Amanita phalloides*) can be fatal. The most poisonous of these are the mushrooms containing amatoxins. Patients who have ingested these mushrooms often complain of gastrointestinal symptoms consisting of nausea, vomiting, diarrhea, and abdominal cramping beginning 6 to 8 hours after ingestion. They often bring in specimens of the mushrooms chopped, crushed, cooked, or mixed with stool or gastric contents. Standard hospital laboratories cannot confirm or exclude the diagnosis of amatoxin poisoning; therefore, treatment decisions must be made on clinical grounds. [204] [276]

Meixner reported a simple colorimetric test for detecting amatoxins that can be used on gastric contents, stool, or actual mushroom samples. The basis of this test is the acid-catalyzed color reaction of amatoxins with lignin, a complex organic compound found in wood pulp. Cheaper grades of paper (e.g., newsprint or the white pages of a telephone book) contain high amounts of lignin. Although there have been no extensive reports of in vivo studies, in vitro tests have shown this method to be highly sensitive and relatively specific for amatoxins. [23] [156] Psilocybin-containing mushrooms can cause false-positive results for amatoxin. [22]

The procedure for a qualitative detection of amatoxin consists of squeezing a drop of liquid from a fresh mushroom sample or squashing a piece of fresh mushroom onto a piece of newspaper. If a stool or a gastric sample is the only

available specimen, the sample is mixed with reagent grade methanol (99.8%). The methanol will extract the amatoxin. If the samples are mixed with methanol, they should then be centrifuged and filtered. Place a drop of the liquid extract on the newspaper. Gently air dry all specimens at room temperature and avoid direct sunlight. Add two to three drops of concentrated hydrochloric acid (37%) to the dried specimen. Use an adjacent area for a control. High amounts of amatoxin in the dried samples exhibit a blue color in 1 to 2 minutes. Small amounts of amatoxin show a blue color in the sampled area in 10 to 20 minutes. Note that this procedure has *not* been proven effective using other bodily secretions, such as blood or urine. [23]

Mothball Identification

Present day commercial mothballs are composed of either paradichlorobenzene or naphthalene. Paradichlorobenzene is nontoxic whereas naphthalene can cause a significant hemolytic reaction in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency and in neonates. [229] In the past, mothballs were also produced from camphor, which can cause central nervous system (CNS) depression and seizures in overdoses. Fortunately, these mothballs are no longer commercially available, although they may still exist in some households. A rapid differentiation between these groups of mothballs can expedite patient management and disposition. Several bedside tests that take advantage of the physical and chemical properties of these agents have been used to differentiate between them.

TABLE 70-15 -- Diagnostic Odors

Characteristic Odor	Responsible Drug or Toxin
Acetone (sweet, fruity; pear-like)	Lacquer, ethanol, isopropyl alcohol, chloroform, diabetic ketoacidosis, alcoholic ketoacidosis, trichloroethane, paraldehyde, chloral hydrate, methylbromide, *Pseudomonas* infections
Alcohols	Ethanol, (congeners) isopropyl alcohol
Ammonia-like	Uremia
Automobile exhaust	Carbon monoxide (odorless, but associated with exhaust)
Beer (stale)	Scrofula
Bitter almond	Cyanide
Carrots	Cicutoxin (or water hemlock)
Coal gas (stove gas)	Carbon monoxide (odorless, but associated with coal gas)
Disinfectants	Phenol, creosote
Eggs (rotten)	Hydrogen sulfide, carbon disulfide, mercaptans, disulfiram, *N*-acetylcysteine
Feculent	Intestinal obstruction
Fish or raw liver (musty)	Hepatic failure, zinc phosphide, hypermethioninemia, trimethylaminuria
Fruit-like	Nitrites (e.g., amyl, butyl), ethanol (congeners), isopropyl alcohol
Garlic	Phosphorus, tellurium, arsenic, parathion, malathion, selenium, dimethyl sulfoxide (DMSO), thallium
Halitosis	Acute illness, poor oral hygiene
Hay	Phosgene
Mothballs	Naphthalene, *p*-dichlorobenzene, camphor
Peanuts	*N*-3-pyridyl-methyl-*N*-*p*-nitrophenyl urea (Vacor)
Pepper-like	*O*-chlorobenzylidene malonitrile
Putrid	Anaerobic infections, esophageal diverticulum, lung abscess, scurvy

Rope (burned)	Marijuana, opium
Shoe polish	Nitrobenzene
Sweating feet	Isovaleric acid acidemia
Tobacco	Nicotine
Vinegar	Acetic acid
Vinyl-like	Ethchlorvynol (Placidyl)
Violets	Turpentine (metabolites excreted in urine)
Wintergreen	Methyl salicylate

From Chiang WK: Otolaryngologic principles. In Goldfrank LR, Flomenbaum NE, Lewin NA, et al (eds): Goldfrank's Toxicologic Emergencies. 5th ed. East Norwalk, Conn, Appleton & Lange 1994, p 374.

From 3rd edition Roberts and Hedges, p 1232, Figure 74-13.

1. Paradichlorobenzene is heavier than naphthalene, which is heavier than camphor. In lukewarm tap water, camphor will float while naphthalene and paradichlorobenzene will sink. In a solution of 3 tbsp of table salt thoroughly dissolved in 4 oz of lukewarm water, camphor and naphthalene will float and paradichlorobenzene will sink. [143]
2. Paradichlorobenzene has a lower melting point than naphthalene. Paradichlorobenzene mothballs will melt in a water bath at 53°C whereas naphthalene requires a water bath >80°C. [221]
3. Paradichlorobenzene is described as "wet and oily," whereas naphthalene is described as having a "dry" appearance. Paradichlorobenzene is familiar to many people as a cake of disinfectant used in urinals and diaper pails.

Body Secretion Analysis

Careful analysis of patients' bodily secretions, odor, and urine color can help identify certain toxins. Some characteristic smells and urine colors are noted in Table 70-15 and Table 70-16 .

Bedside Toxicologic Tests on Urine

Ethylene glycol.

Evaluation of the urine of patients who may have been exposed to ethylene glycol can be helpful. Microscopic inspection of urine for *calcium oxalate crystals* (a metabolic by-product of ethylene glycol metabolism) may be helpful in the diagnosis of ethylene glycol exposure. The presence of either envelope-shaped calcium dihydrate crystals or needle-shaped calcium monohydrate indicates high oxalate

*Drug imparts more than one color to urine and is listed under each color it adds.

levels in the serum (Fig. 70-3). Calcium monohydrate crystals can be easily confused with sodium urate crystals; therefore, the presence of the dihydrate crystal tends to be more specific for ethylene glycol ingestion. The absence of these crystals does not rule out significant ethylene glycol ingestion, because the excretion of these may occur late in the ingestion (more than 6 hours) and occasionally does not occur at all. [107] [108] [115]

Visual inspection of urine under a Wood's lamp or ultraviolet light to ascertain *fluorescence* may also be helpful in the diagnosis of ethylene glycol exposure. Antifreeze is the most common source of ingested ethylene glycol. Fluorescein, a fluorescing material, is often placed in commercially available antifreeze to enable mechanics to detect radiator leaks with a Wood's lamp or other ultraviolet light source. Fluorescein is a nontoxic inert vegetable dye that is eliminated unchanged in the urine. Therefore, high levels of fluorescein in urine suggest significant ethylene glycol ingestion. However, a lack of fluorescein does not rule out a significant exposure, because not all antifreezes contain fluorescein or high concentrations of fluorescein in relation to ethylene glycol. False-positive findings can occur if certain plastic urine containers are used. [291]

To perform the test, fill glass test tubes with (1) the test urine sample, (2) a positive control urine sample (containing fluorescein) and (3) a negative control urine sample (not containing fluorescein). Inspect all three samples for fluorescence under a Wood's lamp in a dark room. The use of positive and negative controls may increase sensitivity and specificity from 49 and 75% to a sensitivity and specificity of 100%. [278] [291] Fluorescein is readily available in most EDs since fluorescein-containing strips are commonly used in ophthalmologic procedures (see Chapter 64).

Salicylates.

Several qualitative bedside tests have been developed to detect salicylates in urine. These include 10%

Figure 70-3 "Prism-shaped" calcium monohydrate crystals *(right)* resembling hippurate or urate crystals, and octagonal calcium dihydrate crystals *(left)*. *(Illustration by NJ Miller.)*

ferric chloride solution, Trinder solution, and Phenistix reagent strips. All tests are rapid, inexpensive, and sensitive.

Ferric chloride and Trinder solution both have sensitivities of 100% with serum salicylate levels of 5 mg/dL. False positives can occur with both tests in the presence of acetoacetic acid, acetone, and phenylpyruvic acid. Thus they may be falsely positive in patients with diabetic, alcoholic, or starvation ketoacidosis. Phenol-containing drugs such as diflunisal, sulfasalazine, and salicylamide may also produce false positives. A positive result, therefore, requires a confirmatory quantitative serum salicylate assay. [286]

The *ferric chloride test* is a commonly used rapid, qualitative, urinary screening procedure. To perform this test, several drops of 10% ferric chloride are added to 1 or 2 mL of urine that has been collected in a test tube. The immediate appearance of a bluish purple color signifies that salicylates are present in urine. This test is very sensitive, and as few as two aspirin taken within 24 hours will give a positive result. It requires 90 to 120 minutes from time of ingestion for this reaction to become positive in the urine of patients with normal renal function, so when tested before this time, the results may be misleading. [33]

The *Trinder test* uses a mixture of mercuric chloride and ferric nitrate in deionized water. To perform this test, 1 mL of urine is mixed with 1 mL of Trinder solution. A violet or purple color signifies the presence of salicylates. Acetoacetic acid and high levels of phenothiazines may give false-positive results. [136]

Phenistix reagent strips were originally developed to detect phenylketonuria. However, Phenistix strips also turn brown in the presence of salicylates. False-positive findings for salicylates can occur if phenothiazines are present. [29]

Bedside Toxicologic Tests on Oral Secretions and Breath

Ethyl alcohol.

There are several bedside devices to measure alcohol concentrations in bodily fluids. Measurements of alcohol concentration in expired air or saliva have been shown to correlate well with blood alcohol concentrations in the appropriate settings.

Breath alcohol analyzers were developed in the 1950s and are presently used in law enforcement. These devices typically use an infrared spectral analysis to determine the concentration of alcohol in expired air. Almost all the alcohol found in expired air at the level of the mouth is secondary to alcohol diffused from the bronchial system rather than the alveolar system. [101] Minor alterations in breathing patterns can cause large variations in readings. Thus, uncooperative patients who do not exhale properly may give an inaccurate reading. Other causes of inaccurate readings include the use of alcohol-containing products including ingesting them, belching or vomiting, use of inhalers, poor technique, or restrictive pulmonary pathology. [69] [152] [159]

A more recent technology for bedside measurement of alcohol concentration has been the use of a dipstick-like device to measure alcohol concentrations in saliva. These devices use an enzymatic reaction involving alcohol dehydrogenase to measure alcohol concentrations. [16] Patients who are dehydrated (a common occurrence in alcohol-intoxicated patients) are frequently unable to provide adequate saliva samples and inaccurate readings have occurred in patients with high blood alcohol concentrations. [19] [126]

Bedside Toxicologic Tests on Blood

Methemoglobinemia.

Patients with methemoglobinemia will often have a normal partial pressure of oxygen (pO_2) on routine arterial blood gas analysis, a normal *calculated* hemoglobin saturation, a nondiagnostic pulse oximeter reading, and cyanosis that does not clear with O_2 administration. Bedside visual inspection of venous or arterial blood may be helpful in the diagnosis of methemoglobinemia. Methemoglobinemia occurs when normal hemoglobin is exposed to an oxidant stress (Fe^{2+} converted to Fe^{3+}). If the erythrocytes cannot handle this stress, such as in the presence of G6PD deficiency, hemoglobin remains in an oxidized state (methemoglobin), causing a color change in the molecule. Methemoglobin levels higher than 15% are reported to cause a cyanotic appearance in a patient. [60]

The evaluation procedure for methemoglobinemia is to place a drop of sample blood on a white background (a white coffee filter is appropriate) in a well-lit environment. Next to this, place a drop of normal blood as a comparison control sample. Blood with methemoglobinemia appears "darker" or "chocolate-brown." [97]

This method relies on the ability of the examiner to distinguish color changes and therefore may have a degree of interobserver variance. Methemoglobin levels of less than 10% may only slightly alter the color of blood and thereby cause a false-negative finding. Methemoglobin levels of between 12% and 14% may cause a false-negative reading 50% of the time. However, at methemoglobin levels of 35% or higher, the identification of methemoglobinemia by visual inspection is quite accurate. [97] At this level, most patients are obviously cyanotic and significantly symptomatic.

Invasive Diagnostic Procedures

Several invasive diagnostic bedside procedures can be useful in the assessment of possible drug overdoses. The basic premise of these procedures is that patients who have been exposed to a certain drug or poison will respond in a particular fashion if given a diagnostic challenge dose of another particular drug or true antidote.

Naloxone

Naloxone hydrochloride (Narcan) is an opioid receptor antagonist that has the ability to reverse the effects of chemical agents affecting all opioid receptor sites, particularly respiratory and CNS depression. Because of this, a trial of naloxone has been recommended for all patients with CNS depression. [68] Certain clinical findings such as miosis, decreased respiratory rate, and evidence of illicit drug use can predict many patients who will respond to a diagnostic challenge dose of naloxone. [104]

If a patient's mental status improves significantly after a dose of naloxone, the patient should be considered to have been exposed to an opioid substance. This is true even if a laboratory drug screen is negative for opioids. One English study of laboratory drugs of abuse screens had false-positive rates of 4% and false-negative rates of 8%. [42] Furthermore, many of the synthetic opioid agents, such as fentanyl, propoxyphene, meperidine, methadone, and pentazocine may not be detected by the routinely used immunoassay drug screen. [78] Although cases have been reported of patients with other nonopioid overdoses (such as alcohol or phencyclidine) responding to

naloxone, those single observations have not been confirmed in controlled animal or human studies.

The traditional challenge dose of naloxone in an adult or child is 2 mg every 2 minutes IV until a response is achieved or 10 mg is given. [105] Some clinicians prefer to use much smaller doses (0.1 to 0.2 mg) and titrate to effect. This may partially reverse opioid overdose-related symptoms and confirm the diagnosis without precipitating the opioid withdrawal syndrome seen in patients with opioid dependency. Most patients with an opioid overdose will exhibit some response to 1 to 4 mg of naloxone, but some massive overdoses may require larger amounts. A patient who does not respond at all to 10 mg of naloxone probably does not have a pure opioid overdose.

The high doses of naloxone presently recommended are needed to reverse many synthetic narcotic agents, such as propoxyphene and methadone. Lower doses can be given (0.4 to 0.8 mg in adults or 0.01 mg/kg in children) to reverse known opioid-induced respiratory depression without reversing analgesia. Because naloxone has a half-life between 30 and 60 minutes, a continuous drip of naloxone can be used to avoid resedation. A reasonable choice is to set the hourly IV dose at two-thirds of the initial bolus dose that achieved the desired reversal effect. For example, a patient who satisfactorily responded to 1.5 mg of naloxone might receive a naloxone solution of 10 mg of naloxone in 500 mL of normal saline at a rate of 1 mg (50 mL)/hour IV. [88] Nalmefene, a long-acting opioid receptor antagonist that has a terminal half-life of roughly 11 hours, can also be given to patients with suspected overdoses. Theoretically, a single dose of nalmefene will be effective longer than the effects of heroin or most abused opiate substances. The initial recommended dose is 1.0 to 1.5 mg IV.

Naloxone and nalmefene have minimal significant side effects, other than precipitating withdrawal from patients addicted to opioids. Unlike alcohol withdrawal, naloxone-induced opioid withdrawal in the adult is short-lived and is usually not life-threatening. Withdrawal can be avoided if lower initial doses of naloxone or nalmefene are given and then are slowly titrated upward to the desired effect.

Flumazenil

Flumazenil is a competitive benzodiazepine receptor antagonist that has the ability to reverse the CNS and respiratory depression caused by all currently commercially available benzodiazepines. The use of flumazenil as a *routine diagnostic bedside challenge in all obtunded patients is discouraged,* and its use in the setting of possible benzodiazepine overdose is controversial. Unlike naloxone, flumazenil can have significant side effects in certain subsets of patients. [104] These include precipitating seizures or a withdrawal syndrome in benzodiazepine-dependent patients. To minimize the chance of seizures, flumazenil should be avoided in patients who may have ingested epileptogenic drugs (e.g., cyclic antidepressants, cocaine, theophylline, lithium, carbamazepine, isoniazid). [248]

In suspected benzodiazepine overdoses where patients present with obtundation and have no history of seizures or suspicion of involvement of epileptogenic agents, flumazenil can be administered IV at a dose of 0.2 to 0.5 mg/min. Most benzodiazepine-overdosed patients show mental status improvement with 1 mg of flumazenil and almost all respond to 3 to 5 mg. It is prudent to use small, escalating doses given very slowly (maximally, 0.5 mg/min). Larger doses can be given at one time as a bolus, although this increases side effects such as anxiety, agitation, and emotional lability; it also increases the chances of precipitating withdrawal in benzodiazepine-dependent patients.[247] Fortunately, seizures that occur after flumazenil use are usually transient and can frequently be controlled with additional benzodiazepines. In rare cases, higher doses of benzodiazepines, barbiturates, and phenytoin may be required. [248]

If a patient responds to flumazenil with an improvement in depressed mental status, this only suggests that the patient is under the influence of a benzodiazepine. Flumazenil can partially reverse the effects of many other agents or conditions that affect the ?-aminobutyric acid (GABA) pathway, such as zolpidem and hepatic encephalopathy[13] [92] [153] [275] ; however, it does not have any significant effect on alcohol, barbiturates, and other non-benzodiazepine sedative-hypnotics.

Physostigmine

Physostigmine is an acetylcholinesterase inhibitor that can penetrate into the CNS and thus reverse both the central and peripheral effects of anticholinergic agents. In the majority of patients with anticholinergic toxicity, no laboratory tests are available to rapidly confirm the diagnosis, and testing for specific drugs is limited. A clinical picture that may consist of mydriasis, dry and flushed skin, dry mucous membranes, urinary incontinence, absent bowel sounds, tachycardia, hyperthermia, hallucinations, agitation, and seizures suggests an anticholinergic toxicologic syndrome. A rapid and dramatic response to physostigmine often confirms a diagnosis of anticholinergic toxicity. In these patients, physostigmine reduces much of the CNS toxicity of the agents and decreases the degree of agitation and confusion. [17] [43] [201] The use of physostigmine as a diagnostic challenge can be helpful in select situations, but similar to flumazenil, the *routine use of physostigmine as a diagnostic bedside challenge in all obtunded patients should be discouraged*.

As a diagnostic challenge or therapeutic intervention, physostigmine can be administered IV under constant cardiac monitoring at a dose of 1 to 2 mg in adults and 0.02 mg/kg in children, over 5 minutes. Some clinicians empirically pretreat with a benzodiazepine to prevent seizures, but this practice has not been proven effective or necessary. Because the half-life of physostigmine is 30 to 60 minutes, a repeat dose of 2 mg can be given as clinically indicated.

Similar to flumazenil, physostigmine has been reported to interact detrimentally with cyclic antidepressants, often causing life-threatening dysrhythmias. Physostigmine also can cause an excess of acetylcholine and a resultant cholinergic crisis. This syndrome includes salivation, lacrimation, urination, defecation, bradycardia, bronchorrhea, and seizures. Dysrhythmias, including asystole, have also been reported. [210] For this reason, 1 mg of atropine IV should be readily available to reverse potential cholinergic excess when using physostigmine.

Deferoxamine

Deferoxamine is an organic compound derived from the bacterium *Streptomyces pilosus*. Deferoxamine can chelate iron and can be used as therapy or as a diagnostic challenge in patients with iron overdoses. Patients who have unstable vital signs or significant GI or CNS symptoms usually require therapeutic doses of deferoxamine. *Asymptomatic* patients with a

history of iron overdose usually require supportive care only. Patients with persistent but mild symptoms, such as vomiting and diarrhea, may be given a diagnostic challenge dose of deferoxamine. A diagnostic challenge is preferential over ancillary laboratory testing because tests such as iron levels and total iron binding capacity in the setting of iron overdose can be inaccurate, misleading, and time-consuming. [162] [241] [268]

A diagnostic challenge dose of deferoxamine is administered IM or IV over 45 minutes at doses of 40 to 90 mg/kg up to a maximum of 1 g in children and 2 g in adults. Deferoxamine can also be administered IV as a constant drip of 15 mg/kg/hour. A positive result occurs when chelated iron in the form of ferrioxamine appears in the urine. This usually causes the urine to turn a reddish orange or "vin rosé" color in 2 to 3 hours after initiation of treatment. The color change is qualitative only and has no prognostic significance. Color change caused by ferrioxamine is pH and concentration dependent, and false-negative test results occur. [181] [218]

Chronically administered deferoxamine has been reported to have multiple adverse effects, such as adult respiratory distress syndrome (ARDS), visual defects, and enhancement of *Yersinia enterocolitica* infections. In the setting of the single challenge dose, flushing, erythema, tachycardia, urticaria, and hypotension caused by rapid administration of deferoxamine are the most serious side effects.[289]

Invasive Therapeutic Procedures

The indications and rationale for use of certain therapeutic procedures in toxicology are often misunderstood.

Alkalinization of Urine and Blood

Alkalinization of urine consists of manipulating the pH of urine to enhance excretion of certain drugs (Table 70-17). Weak acids remain in ionic form in a basic milieu. The ionic form often prevents reabsorption of that drug in the proximal tubule, and urinary alkalinization can therefore promote elimination in the urine. For certain drugs, this can play a significant role in their elimination. For example, salicylate elimination increases proportionately to the urinary flow rate, but it increases *exponentially* with increases in the urinary pH.[189] [216]

Recommendations differ on the actual method or formula to achieve urinary alkalinization. No body of literature exists that supports one method of urinary alkalinization over another.[285] In general, this procedure should be titrated to the patient's fluid and acid-base status to achieve a urinary pH of 7.5 to 8.0. Many authors recommend the use of a constant infusion of a relatively isotonic solution consisting of 3 ampules of sodium bicarbonate (44 mmol/ ampule) added to 1 L of 5% dextrose in water (D_5 W). Another reasonable formula is to begin with a bolus of two ampules of IV sodium bicarbonate, or 1 to 2 mmol/kg of body weight. The bolus is

TABLE 70-17 -- Drugs That Have Increased Elimination with Urinary Alkalinization

Chlorpropamide
2,4-Dichlorophenoxyacetic acid
Formate
Methotrexate
Phenobarbital
Salicylates

followed with a constant infusion of three ampules of sodium bicarbonate in 1 L of D_5 W solution with 20 to 40 mmol of potassium (if the patient has normal renal function) infused at 100 to 300 mL/hour. Although repetitive boluses of sodium bicarbonate ampules also can be used, this may increase the chances of hypernatremia, hypokalemia, relative hypocalcemia, fluid overload, and alkalemia. All of these are potential adverse effects of aggressive urinary alkalinization. The actual amount of fluids and bicarbonate administered requires titration to the patient's clinical condition. Therefore careful monitoring of electrolyte, pH, and fluid status is encouraged.[267]

Urinary alkalinization can sometimes be difficult to achieve or maintain. Hypovolemia is probably the leading cause of an inability to achieve alkaline urine. Other theoretical causes are hypokalemia and hypochloremia. Several authors have suggested that in patients with severe salicylate poisoning, urinary alkalinization may

be difficult if not impossible to achieve with reasonable doses of bicarbonate. [285]

Ethanol Infusion

Recently, fomepizole (4-methylpyrazole) has been approved by the FDA for the treatment of ethylene glycol poisonings. It has also been used successfully in treating methanol poisonings.[31] [182] Compared to the traditional treatment of toxic alcohol poisoning, namely ethanol, fomepizole has the advantages of ease of use, fewer side effects (specifically hypoglycemia), and ability to maintain therapeutic levels. [30] [32] However, owing to the cost and the logistics of stocking this antidote, many hospitals may not have this drug readily available.

Ethanol can be used as a therapeutic intervention in patients with methanol or ethylene glycol poisoning due to ethanol's much greater affinity for alcohol dehydrogenases. These enzymes metabolize methanol and ethylene glycol to even more toxic by-products. However, with serum ethanol levels of 100 mg/dL, minimal amounts of ethylene glycol or methanol are metabolized by alcohol dehydrogenases. [31] [32] [41] Ethanol infusions are not useful in the treatment of isopropyl alcohol poisoning.

Ethanol can be administered orally or IV (Table 70-18). Intravenous ethanol has the advantages of obtaining therapeutic levels rapidly, ensuring complete absorption, limiting chances of aspiration, and avoiding gastritis. A 5% concentration of ethanol, which can be given in a peripheral vein, requires the use of large fluid volumes. In a 70-kg patient, a loading dose requires 1.4 L of 5% solution, with a maintenance dose of 700 mL/hr. In contrast, oral loading can be achieved using much lower volumes. However, oral loading can be difficult in the uncooperative or unconscious patient or if vomiting or GI hemorrhage is present. A therapeutic level is reached slower with oral loading.

Ethanol metabolism can vary widely, and ethanol is dialyzable. Therefore, it may be difficult to maintain appropriate ethanol levels during dialysis therapy of ethylene glycol or methanol. Frequent measurements of ethanol should be obtained and the infusion adjusted accordingly. [84] When patients are given ethanol infusions, CNS depression and hypoglycemia are common adverse effects (the latter is particularly true in diabetics and children). Serial levels of ethanol and glucose should be obtained. If IV ethanol is given, careful attention to cardiopulmonary status should be maintained. [142] [249]

300 mg/kg/hr[‡]	30	45	90	150	210	300
350 mg/kg/hr[‡]	35	53	105	175	245	350
Oral Ethanol: Maintenance Dose (A 20% volume/volume concentration yields approximately 200 mg/mL; infusion to be given each hour immediately following a loading dose; aim is to maintain serum ethanol level of 100–150 mg/dL; [†] each dose may be diluted in juice and given orally or via nasogastric tube)						
	Infusion rate (mL/hr [§] ***for various weights***[¶])					
Normal maintenance range	*10 kg*	*15 kg*	*30 kg*	*50 kg*	*70 kg*	*100 kg*
80 mg/kg/hr	4	6	12	20	28	40
110 mg/kg/hr	6	8	17	27	39	55
130 mg/kg/hr	7	10	20	33	46	66
Approximate range for chronic alcoholic or for patient receiving continuous oral activated charcoal						
150 mg/kg/hr	8	11	22	38	53	75
Range required during hemodialysis						
250 mg/kg/hr	13	19	38	63	88	125
300 mg/kg/hr	15	23	46	75	105	150
350 mg/kg/hr	18	26	52	88	123	175

*Note: *Concentrations higher than 10% are not recommended for IV administration. Concentrations higher than 30% are not recommended for oral administration.* The dose schedule is based on the premise that the patient initially has a *zero* ethanol level. The aim of therapy is to maintain a serum ethanol level of 100 to 150 mg/dL, but constant monitoring of the ethanol level is required because of wide variations in endogenous metabolic capacity. Ethanol is removed by dialysis, and the infusion rate of ethanol must be increased during dialysis. Prolonged ethanol administration may lead to *hypoglycemia*. Note: 10% ethanol for infusion may be difficult to find in the hospital pharmacy. To formulate 10% ethanol for infusion (1) remove 50 mL from a 1-L bottle of 5% ethanol/D_5W and replace it with 50 ml of 100% ethanol, or (2) remove 100 mL from a 1-L bottle of D_5W and replace it with 100 ml of 100% ethanol.

[a] If a 5% ethanol solution is used, *double* the volume of the loading dose.

[b] Equivalent to a 40 proof solution.

[c] If a 5% ethanol solution is used, *double* the volume rate; monitor closely for potential volume overload.
†Serum ethanol levels should be monitored closely.
‡At higher infusion rates, it may be necessary to administer by volume rather than by mL/hr.
§For a 30% concentration, divide the amount by 1.5.
¶Rounded off to nearest milliliter.

Chapter 71 - Standard Precautions and Infectious Exposure Management

Peter E. Sokolove
Aaron E. Bair

Body fluid contamination of health care workers is a frequent occurrence in the emergency department (ED). In a prospective study of ED health care workers, skin and clothing contamination with body fluids occurred in 1 of 35 patient visits. [30] These fluids may contain various transmissible infectious diseases, as the prevalence of HIV infection, hepatitis, and other communicable diseases can be high in certain ED patient populations. [5] [24] [27] [43] For example, investigators from an inner city ED reported a patient seroprevalence of 6% for HIV infection, 18% for hepatitis C, and 5% for hepatitis B surface antigen. [26] One in four patients tested positive for at least one of these diseases. Patient characteristics were found to be poor predictors for hepatitis positivity, making it more difficult to identify which patients pose a risk to health care workers.

Unfortunately, compliance with standard precautions, formerly known as universal precautions, is far from universal. [3] [20] [25] Baraff and Talan[3] reported poor compliance, even in the setting of treating critical trauma patients. Compliance rates were 75% for gloves, 27% for gowns, 19% for eyewear, and only 2% for masks. Despite having recently received education about standard precautions, Hammond et al [20] also reported low compliance rates during invasive procedures and with high-risk patients. Compliance improved when equipment was organized and placed in trauma resuscitation rooms. In 1985, this combination of high-risk illness with low compliance barrier use prompted the Centers for Disease Control and Prevention (CDC) to recommend guidelines for the protection of health care workers. [7] In 1991, these recommendations were enacted into law by mandate of the Occupational Safety and Health Administration (OSHA).

Figure 71-1 *A,* Recapping a needle by holding the cap in the hand is the most common way to sustain a needle puncture. *B,* It is best to discard the needle/syringe without recapping, but an alternative is to partially recap *without* holding the guard (needle cap), so that at least 80% of the needle is covered before completing the recapping with the second hand.

The primary focus of the CDC guidelines is to reduce mucocutaneous body fluid exposures by encouraging hand washing and barrier protection. However, these measures do little to protect from percutaneous exposures, which are the most efficient exposures in the transmission of hepatitis and HIV. [31] [32] The current strategy for risk reduction in the ED includes immunization against hepatitis B virus, use of standard precautions (including re-engineered safety products), and prompt initiation of post-exposure prophylaxis (PEP) when appropriate.

STANDARD PRECAUTIONS GUIDELINES

Appropriate precautions for all patient contact must be viewed as a consistent practice or "way of life" in the ED. The following guidelines, based upon the CDC recommendations, should be used when there is any possibility of body fluid contact:

Barrier Precautions

1. *Gloves* should be used for any patient contact with the risk of body fluid exposure. Both cutaneous and percutaneous exposures can be reduced by the use of gloves. In an animal model, Mast et al.[33] reported a 46 to 86% reduction in the volume of blood transferred via needlestick injury when the needle first punctured a glove. Fisher et al[17] compared the biomechanical performance of powder-free, latex, and nitrile examination gloves. The nitrile examination gloves exhibited greater puncture resistance, despite being thinner than the latex examination gloves.
2. *Mask and protective eyewear* should be used when exposure to body fluid aerosols is possible (e.g., wound irrigation, traumatic chest wound).
3. *Gown and shoe covers* should be worn when there is the risk of large splash volumes of body fluids (e.g., chest tube, thoracotomy).

Sharps Precautions

Most importantly, this means no recapping, bending, or breaking of needles. If needle recapping is deemed necessary, a single-handed technique should be used (Fig. 71-1). A safer alternative is immediate disposal of the needle into an approved sharps container without recapping. In an observational study

of ED employees, the rate of needle recapping was 34%, and most practitioners used a two-handed technique. [22] There are various re-engineered products for use in the ED, including retracting scalpels, auto-capping needles, and needle-less intravenous systems. A survey of infection control professionals at Iowa and Virginia hospitals found that implementation of such devices was the most common action taken to decrease percutaneous injuries. [4]

Respiratory Precautions

During contact with patients with suspected or confirmed pulmonary tuberculosis, providers should wear a National Institute of Safety and Health (NIOSH)-approved N-95 particulate respirator. These masks are designed to efficiently filter 1- to 5-µm particles. A more costly and less comfortable alternative is the use of a HEPA-filtered mask. In addition, such patients should be placed into respiratory isolation in a room with negative pressure, high circulation (optimally at least 12 air changes per hour), and external exhaust. Procedures resulting in increased release of infectious droplets, such as sputum induction, should be avoided in the ED. Potentially infectious patients should wear a surgical-type mask themselves, especially during transportation outside of the respiratory isolation room (e.g., to radiology). [9]

Hand washing.

Any skin surface coming into contact with body fluids should be washed immediately with soap and water.

Annual education.

All workers should receive a mandatory annual review of infection control and safe practices.

OCCUPATIONAL DISEASE EXPOSURE

Occupationally acquired infections cause considerable morbidity and mortality among health care workers despite OSHA requirements for precautions. Given the often occult presentation of disease in the ED patient population, emergency health care workers are at high risk for significant exposure from many pathogens. Owing to the high prevalence of particular diseases among ED patients and specific concerns for pathogens associated with high morbidity and mortality, this chapter focuses on HIV, hepatitis B and C viruses (HBV, HCV), and tuberculosis.

TABLE 71-1 -- Recommendations for Hepatitis B Prophylaxis Following Percutaneous or Permucosal Exposure

	Source		
Exposed person	***HBsAg-positive***	***HBsAg-negative***	***Source unknown or not available***
Unvaccinated	HBIG × 1[*] and HB vaccine series	Initiate HB vaccine series	Initiate HB vaccine series
Vaccinated			
Known responder	No treatment	No treatment	No treatment
Known nonresponder	HBIG × 2 or	No treatment	If known high-risk source, treat as if source were HBsAg-positive
	HBIG × 1 and initiate revaccination[§]		
Response unknown	Test exposed person for anti-HBs	No treatment	Test exposed person for Anti-HBs
	1. If adequate,[†] no treatment		1. If adequate, no treatment
	2. If inadequate, HBIG × 1 plus vaccine booster		2. If inadequate, HB vaccine booster and recheck titer in 1 to 2 months

*HBIG dose 0.06 mL/kg IM.
§§The option of giving one dose of HBIG and reinitiating the vaccine series is preferred for nonresponders who have not completed a second three-dose vaccine series. For persons who previously completed a second vaccine series but failed to respond, two doses of HBIG are preferred.
†Adequate anti-HBs is = 10 mIU/mL.

Hepatitis B Virus

HBV Transmission

HBV is a well-recognized occupational risk for health care providers, and multiple studies have documented the high prevalence of hepatitis among ED patients. [16] [26] [28] Despite the attention focused on transmission of HIV, the infectivity of HBV is significantly higher because of the virulence of the organism and relatively small inoculum required for disease transmission.[18] Percutaneous injuries are among the most efficient modes of HBV transmission, but many infected health care workers do not recall a specific injury. [19] [39] Many body fluids other than blood contain hepatitis B surface antigen, but the levels of infectious HBV particles in blood-free body fluids are 100 to 1000 times lower than blood itself. Because implementation of the CDC's standard precautions, along with the OSHA regulations for barrier protection and pre-exposure vaccination, the incidence of HBV transmission has sharply declined. [14]

To understand the risk of HBV transmission resulting from occupational exposure, one must be familiar with a few key serologic markers for HBV. Hepatitis B surface antigen (HBsAg) is a marker of active infection in the source patient. From a practical standpoint, HBV can be transmitted when HBsAg is present, and is generally not transmissible when this marker is absent. Hepatitis B surface antibody (HBsAb) is a protective antibody against HBV. In vaccinating health care workers, the goal is to stimulate the immune system to produce a sufficient quantity of this antibody. Hepatitis Be antigen (HBeAg) can be found in the bloodstream of HBV-infected individuals during times of peak virus replication. When a source is positive for HBeAg, their bloodstream contains a much larger number of infectious HBV particles. If a non-immune individual sustains a needle stick from an HbsAg-positive patient, the risk of HBV transmission is dependent upon the HBeAg status of the source. [50] The risk of clinical hepatitis is approximately 2% (range, 1% to 6%) if HBeAg is absent, compared with a risk of 22% to 31% if HBeAg is present. [14]

HBV Post-exposure Management

Post-exposure prophylaxis following exposure to an HBsAg positive source may require hepatitis B vaccine, HBIG, both, or neither (Table 71-1). This is dependent upon the vaccination and antibody response status of the exposed health care worker. HBIG is derived from pooled human plasma and

provides passive immunization for non-immune exposed individuals. This preparation is very safe and is not known to transmit disease. [14] When HBIG is used for PEP, ideally it should be given within 24 hours following exposure and it is of questionable value beyond 7 days. [8] In some cases, hepatitis B vaccine is also used for post-exposure prophylaxis. Health care workers who have any chance of exposure to infectious body fluids should be routinely vaccinated against hepatitis B. Adverse reactions to the hepatitis B vaccine are generally quite mild, and it is even safe to give during pregnancy. Primary immunization consists of an initial intramuscular (IM) injection, with subsequent IM vaccinations at 1 and 6 months. Antibody levels (HBsAb) should be checked at 4 to 6 weeks after the series is completed, and the desired titer is at least 10 mIU/mL. Vaccinated individuals who achieve this antibody level are referred to as "responders" and may be immune for life. While about 25% to 50% of vaccine responders demonstrate a decline in HBsAb antibody levels to below 10 mIU/mL within 5 to 7 years, these individuals are still protected against clinical disease. This results from a robust immune system memory or anamnestic response. [23] Post-exposure prophylaxis with these agents is not contra-indicated during pregnancy or lactation. Health care workers who have previously been infected with HBV are immune to re-infection, so PEP is not indicated in such individuals.

Hepatitis C Virus

HCV Transmission

Approximately 1.8% of Americans (3.9 million) are infected with hepatitis C virus, and many of these individuals are unaware they are infected. HCV is often acquired from injection drug use, and was once commonly transmitted by blood transfusion (now rare with modern screening). While HCV can be transmitted sexually, this a minor route. Percutaneous transmission is most efficient. The incidence of seroconversion following an HCV-positive needle stick is about 1.8% (estimates range from 0 to 7%).[14] Mucous membrane transmission of HCV is possible but much less common. It is useful to remember that the risk of HCV transmission following a needle stick is similar to that of HBV transmission when the source is HBeAg negative. When seroconversion does occur, 80% of patients will demonstrate antibodies at 15 weeks and 97% at 6 months following exposure. While the clinical course of hepatitis C virus is often asymptomatic or mild, approximately 85% of patients will

develop chronic hepatitis, 10% to 20% cirrhosis, and 1% to 5% hepatocellular carcinoma. [10] [11] [12]

HCV Post-exposure Management

Unfortunately, post-exposure prophylaxis for HCV exposure is currently not available. HCV exhibits a high degree of genetic heterogeneity and a very rapid mutation rate, making the development of vaccine extremely difficult. The use of post-exposure immune globulin is probably not helpful, and there are currently no clinical trials of agents such as interferon or ribavirin for HCV post-exposure prophylaxis. [14]

Human Immunodeficiency Virus

HIV Transmission

According to the CDC, through June 2000, there were 56 cases of occupational HIV transmission to health care workers in the United States. Additionally, another 138 health care workers demonstrated HIV seroconversion, which may have been occupationally related. [13] The risk of contracting HIV from working in the ED depends upon the prevalence of HIV in the local patient population. One study reported an annual HIV seroconversion risk of 1/3800 for high-prevalence EDs and 1/55,000 for low-prevalence EDs.[32] Wears et al.[49] estimated the cumulative career risk of contracting HIV from occupational exposure in a high-prevalence ED to be as high as 1.4%. The author suggests, however, that this risk can be reduced with adequate precautionary measures. When seroconversion occurs, HIV antibodies can be detected as early as 3 weeks after exposure, and are almost always present by 6 months. Seroconversion at 6 to 12 months is rare, but has been reported with HIV and HCV virus co-infection. Acute retroviral syndrome is a clinical manifestation of HIV seroconversion that occurs in approximately 80% of newly infected individuals at a median of 25 days after exposure. The presentation of acute retroviral syndrome is similar to mononucleosis, with fever, lymphadenopathy, and rash.

The overall risk of HIV seroconversion is about 1/300 (0.3%) following needlestick and less than 1/1000 for mucous membrane exposures. Cardo et al. [6] demonstrated that the risk for HIV seroconversion following needlestick injuries is not uniform. Seroconversion was found to be more likely for deep injuries (odds ratio [OR] = 15), if blood was visible on the device (OR = 6.2), if the needle had been used in a source patient's artery or vein (OR = 4.3), or if the source patient suffered from terminal AIDS (OR = 5.6). It is essential to gather information regarding the nature of the injury to "risk stratify" the exposure.

HIV Post-exposure Management (CDC, 2001)

Evidence supporting post-exposure prophylaxis.

In 1998, the U.S. Public Health Service recommended the use of post-exposure prophylaxis (PEP) for selected HIV exposures. [11] [12]

These recommendations were based upon a number of animal and human studies suggesting that post-exposure prophylaxis may be effective. While animal studies are mixed in both methodology and outcomes, PEP with various agents has successfully prevented HIV infection. In human studies, the use of anti-retroviral agents during pregnancy decreased perinatal HIV transmission by 67%. [15] In addition, when children born to HIV-positive mothers were given HIV PEP within 48 hours of birth, HIV transmission was also decreased.[47] While perinatal exposures are different than occupational needle sticks, this evidence supports the concept of a "window of opportunity" during which PEP may prevent HIV transmission to an exposed individual. The most important human study of the efficacy of PEP is a CDC-sponsored case-control study undertaken in the United States, France, the United Kingdom, and Italy. [6] This investigation compared 33 health care workers who seroconverted following HIV exposure with 665 control health care workers who did not seroconvert following HIV exposure. About 90% of patients in this study were exposed via hollow bore needles. When post-exposure zidovudine (AZT) was used, the risk for HIV infection was reduced by 81% (95% confidence interval, 48% to 94%). While the study methodology is limited by its retrospective design and the potential for recall bias, these results strongly support the efficacy of AZT for PEP. Currently there are no published randomized controlled human trials of agents for

HIV PEP. Given the results of the CDC case-control study, it is highly unlikely that such trials will ever be published, as the use of a control group is now considered unethical.

Selecting patients for PEP.

In June 2001, the U.S. Public Health Service published updated recommendations regarding the use of HIV PEP. [14] In general, the decision to use PEP depends on the type of exposure and the source HIV status. The first step in determining if PEP is indicated is to assess the exposure severity. Percutaneous exposures can be categorized as less severe or more severe. A less severe exposure involves a solid needle, a superficial injury, and without blood visible on the device. All other percutaneous injuries are categorized as more severe. Exposure to mucus membrane and non-intact skin are categorized as either small volume (few drops of blood) or large volume (a major blood splash). There are no reported cases of HIV seroconversion following blood exposure to intact skin.

Following assessment of the exposure severity, one must next determine the potential infectivity of the source. PEP should only be considered for blood and body fluid exposures from a source who is known to be or likely to be HIV-positive. Exposures from an HIV-negative source do not require PEP. Testing of sharp instruments for HIV is not recommended or reliable. HIV-positive source patients are categorized as either lower risk (class 1) or higher risk (class 2). Class 1 patients have asymptomatic HIV infection and a low viral load (less than 1500 RNA copies/mL). Higher risk patients include those with symptomatic HIV, AIDS, acute seroconversion, or a high viral load. Once exposure severity and source HIV status are determined, Table 71-2 and Table 71-3 can be used to guide the proper PEP regimen. For skin and mucous membrane exposures, the PEP regimen chosen falls into three general categories. For small volume exposures from an HIV class 1 source, the basic regimen (two drugs) should be *considered*. If either the exposure is of large volume or the source is HIV class 2, then the basic regimen should be *recommended*. In cases where there is both a large volume exposure and an HIV class 2 source, the expanded regimen (three drugs) should be recommended. For most percutaneous exposures, the expanded regimen should be recommended. However, for less severe percutaneous exposures from an HIV class 1 source, the basic regimen should be recommended.

A number of special circumstances may arise when determining the need for HIV PEP. When a source is known, but his or her HIV status is pending, the use of PEP should be decided on a case-by-case basis. When the source is high-risk, PEP can be initiated and then stopped or modified once the HIV status is determined. When a source can be identified, but his or her HIV status is unknown and will not become available, PEP is generally not recommended. However, use of the basic two-drug regimen should be considered if the source has HIV risk factors. Sometimes an exposure will occur where the source is completely unknown. While PEP is generally not recommended for such exposures, the basic regimen should be considered if the exposure occurred in an HIV-likely setting (e.g., exposure to a discarded needle on an AIDS ward).

Choice of PEP medications.

When HIV PEP is administered, a minimum of two drugs is recommended. While there is no direct evidence that combination PEP regimens are beneficial, concerns about antiretroviral resistance and the synergistic effects of antiviral medications when treating patients with AIDS supports such an approach. As discussed earlier, the U.S. Public Health Service recommends using a basic (two-drug) PEP regimen for lower risk HIV exposures and an expanded (three-drug) PEP regimen for higher risk exposures. The basic PEP regimen consists of two nucleoside reverse transcriptase inhibitors, usually zidovudine (AZT) plus lamivudine (3TC). Alternative basic regimens include 3TC plus d4T (stavudine) or d4T plus ddI (didanosine). When using the expanded PEP regimen, either a protease inhibitor or a non-nucleoside reverse transcriptase inhibitor is added to the basic regimen. Most commonly either nelfinavir or indinavir is preferred as the third drug. A number of second-line and alternative agents may be chosen for HIV PEP. Expert consultation is recommended if antiretroviral resistance is suspected. An important resource for emergency clinicians is the national clinicians' postexposure prophylaxis hotline at UCSF/San Francisco General Hospital. Expert consultation can be obtained by calling 888-448-4911.

PEP timing, duration, and side effects.

HIV exposure should be considered a true emergency, and PEP should be initiated as soon as possible after exposure, ideally within 1 hour. Animal studies indicate

that the efficacy of PEP diminishes with delayed initiation.[42] HIV PEP regimens consist of a 4-week course of therapy. In the ED, patients can be prescribed the first 3 days of medications, as long as outpatient follow-up is arranged. Side effects are experienced by about 50% of health care workers taking PEP, causing approximately 33% of health care workers to discontinue therapy prematurely.[43] Table 71-4 lists some of the major side effects experienced when taking PEP agents. Depending upon the choice of PEP medications, patients should also be prescribed antiemetics and antidiarrheal agents when PEP is initiated. A very useful and practical resource that can be used in the ED is the UCLA needle-stick Web site, www.needlestick.mednet.ucla.edu. This Web site allows one to enter information about a specific patient exposure. It then advises the clinician of the appropriate tests to obtain, recommends a PEP regimen, and provides printable discharge instructions and prescriptions.

Tuberculosis

Tuberculosis Transmission

During the mid-1980s the United States experienced a resurgence in tuberculosis (TB), especially among HIV-positive patients. This disease poses a serious risk to both public health and health care workers. Tuberculosis is transmitted by infectious droplets 1 to 5 µm in size. Primary infection occurs when one to three organisms are inhaled into the alveoli, where they begin to replicate. Host defenses usually stop infection within 2 to 10 weeks, and the patient enters the latent period. During this time, patients are not contagious and are asymptomatic. Reactivation occurs when cell-mediated immunity wanes, and patients are again contagious. This can be due to advancing age, HIV infection, steroid use, malignancy, malnutrition, or other causes of immune suppression. The lifetime risk of reactivation is 10%, with about half of this risk occurring in the first 2 years after primary infection. Patients with increased infectivity include those with pulmonary or laryngeal TB, an active cough, positive sputum smears for acid-fast bacilli, cavitation on chest radiographs, and those on inadequate therapy. Children are overall less contagious than adults, but can still transmit

TABLE 71-2 -- Recommended HIV Postexposure Prophylaxis for Percutaneous Injuries

Infection Status of Source

¢If PEP is offered and taken and the source is later determined to be HIV-negative, PEP should be discontinued.

TABLE 71-4 -- Primary Side Effects Associated with Antiretroviral Agents

Antiretroviral Class/Agent	**Primary Side Effects and Toxicities**
Nucleoside reverse Transcriptase Inhibitors (NRTIs)	
Zidovudine (Retrovir; ZDV; AZT)	Anemia, neutropenia, nausea, headache, insomnia, muscle pain, and weakness
Lamivudine (Epivir; 3TC)	Abdominal pain, nausea, diarrhea, rash, and pancreatitis
Stavudine (Zerit; d4T)	Peripheral neuropathy, headache, diarrhea, nausea, insomnia, anorexia, pancreatitis, increased liver function tests (LFTs), anemia, neutropenia, and ascending neuromuscular weakness

Didanosine (Videx; ddI)	Pancreatitis, lactic acidosis, neuropathy, diarrhea, abdominal pain, and nausea
Abacavir (Ziagen; ABC)	Nausea, diarrhea, anorexia, abdominal pain, fatigue, headache, insomnia, and hypersensitivity reactions
Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)	
Nevirapine (Viramune; NVP)	Rash (including cases of Stevens-Johnson syndrome), fever, nausea, headache, hepatitis, and increased LFTs
Delavirdine (Rescriptor; DLV)	Rash (including cases of Stevens-Johnson syndrome), nausea, diarrhea, headache, fatigue, and increased LFTs
Efavirenz (Sustiva; EFV)	Rash (including cases of Stevens-Johnson syndrome), insomnia, somnolence, dizziness, trouble concentrating, and abnormal dreaming
Protease Inhibitors (PIs)	
Indinavir (Crixivan; IDV)	Nausea, abdominal pain, nephrolithiasis, and indirect hyperbilirubinemia
Nelfinavir (Viracept™; NFV)	Diarrhea, nausea, abdominal pain, weakness, and rash
Ritonavir (Norvir™; RTV)	Weakness, diarrhea, nausea, circumoral paresthesia, taste alteration, and increased cholesterol and triglycerides
Saquinavir (Fortovase; SQV)	Diarrhea, abdominal pain, nausea, hyperglycemia, and increased LFTs
Amprenavir (Agenerase; AMP)	Nausea, diarrhea, rash, circumoral paresthesia, taste alteration, and depression
Lopinavir/Ritonavir (Kaletra)	Diarrhea, fatigue, headache, nausea, and increased cholesterol and triglycerides

the disease. Extrapulmonary TB is only contagious in the cases of an open skin lesion or oral cavity involvement. [9]

Depending upon the patient population and geographic location, ED personnel can be at high risk for occupational TB infection. In a 1993 study at a county hospital in Los Angeles, it was reported that 31% of ED workers became PPD-positive during employment, including 20% of attendings, 32% of nurses, and 33% of residents.[44] PPD conversion risk was found to be 6% after 1 year of ED employment, 14% after 2 years, and 27% after 4 years. EDs typically care for higher risk patients—those who are homeless, foreign-born, recently incarcerated, or chronically debilitated. Overcrowding can lead to extended waiting periods and delays in admissions. The clinical presentation of TB in ED patients is often atypical, and this can lead to delayed diagnosis. [45] [46] This is especially true for HIV-infected patients, where symptoms may mimic *Pneumocystis carinii* pneumonia (PCP), skin tests are often negative, chest radiographs are commonly atypical, and sputum tests may be less sensitive.[2] [21] [25] [36] [37] [38] [41] In one ED study of patients with TB, the mean time from ED registration to respiratory isolation was 6.5 hours, and 46% of patients were first isolated on the hospital ward.[34]

Preventing TB exposure requires a multifaceted approach.[9] Proper ED ventilation plays a key role, and inadequate ventilation has been a contributing factor in many nosocomial outbreaks. Ideally, there is single-pass airflow from waiting rooms to the outside. Within the ED, air should flow from clean areas to less clean areas, not vice versa. If patients with TB are seen frequently, there should be at least one true respiratory isolation room available. Such rooms are recommended to have at least 12 air changes per hour and should be "negative pressure" (air flows *into* the room from other ED areas). Other engineering approaches to TB infection control include the use of HEPA filters and upper room ultraviolet light irradiation.

ED personnel should be familiar with the appropriate use of respiratory protection against TB. Surgical masks (e.g., string-tie masks) are indicated for source control. These should be placed on potentially contagious patients to decrease the production of infectious droplets into the air. Because air can leak around such masks, they are not optimal for health care worker protection. In late 1995, NIOSH certified a new class of masks known as N-95 particulate respirators. [40] These filter 1-µm-size particles with at least 95% efficiency, and are the preferred mask for health care workers. They are available in a variety of shapes, sizes, and manufacturers. Before these masks were available, HEPA-filtered masks were used for respiratory protection. While these are very effective, they are more costly and can make breathing uncomfortable.

Attempts should be made to initiate respiratory isolation of patients with suspected pulmonary tuberculosis as soon as possible in the ED, ideally at triage. Screening protocols at triage can detect patients with more classic presentations of TB, but unfortunately, reported protocols are only moderately sensitive and somewhat cumbersome.[45] [46] Immediate respiratory isolation should be considered for patients with high-risk chief complaints, such as HIV-positive patients with cough, those with hemoptysis, or patients with a history of TB presenting with cough or fever. The best guideline is to initiate respiratory isolation as soon as TB is considered as a possible diagnosis. Masks should be placed on such patients *prior* to obtaining chest radiographs.

Tuberculosis Post-exposure Management

Health care workers who are exposed to patients with active pulmonary TB should be referred to either employee health care or their primary care clinician for follow-up testing and treatment. To establish the health care worker's baseline PPD status, skin testing is usually performed within days following exposure. If the baseline test is negative, a follow-up skin test is then performed 3 months later to determine if PPD-conversion has occurred. A positive baseline test indicates previous exposure or infection. Health care workers who convert their PPD to positive (5-mm induration) after an exposure should undergo chest radiography to screen for active pulmonary TB. If active disease is present, treatment should be initiated with at least four anti-tuberculous medications. PPD-converters who do not have active disease should be considered for chemoprophylaxis. When deciding whether or not to initiate chemoprophylaxis, one must balance the potential benefit of TB prevention with the risk of medication-associated hepatitis. In general, chemoprophylaxis should be given in the case of a recent PPD-conversion (within 2 years), a known TB contact, a patient who is medically predisposed to TB, HIV-infected or using intravenous drugs, or younger than 35 years. This means that occupationally exposed health care workers who are PPD-converters should usually receive chemoprophylaxis, regardless of age. The preferred regimen for HIV-negative persons is daily isoniazid (INH) for 9 months, although acceptable alternative regimens can be considered. [1] For exposures to multi-drug resistant TB (MDR-TB), expert consultation is advised for selecting an individualized regimen. Baseline and serial liver function testing is not necessary in most cases, but close monitoring for clinical symptoms suggestive of hepatotoxicity is very important.

Chapter 72 - Educational Aspects of Emergency Department Procedures

Catherine B. Custalow
Dane M. Chapman

The psychomotor skills required to perform many emergency department (ED) procedures are complex and the acquisition of these motor skills is a highly individualized educational process. Although many of these skills are difficult to learn, emergency clinicians can become extremely competent in their performance when provided with adequate training and sufficient practice.

EDUCATIONAL THEORY AND PROCEDURAL SKILL TRAINING

According to the behaviorist theory, the learning of a motor skill can be divided into three phases: a cognitive phase, when the student learns the individual procedural steps; an associative phase, when these specific steps are mastered and integrated together; and an autonomous phase, when the entire skill can be executed smoothly and without any cognitive input.[19]

Elsewhere in the literature, four types of learning have been described as essential for acquiring competence in performing emergency surgical procedures.[11] All four types of learning are essential to mastering a procedural skill. They include:

Memorization of facts.

The clinician must memorize the critical steps of the procedure and their sequence.

Application of rules.

The clinician must be able to apply rules in novel situations, such as the indications and contraindications of performing the procedure.

Visual cue recognition.

The clinician must be able to recognize visual cues, primarily the critical structures of human anatomy.

Psychomotor coordination.

The clinician must be able to coordinate the mind and the body when performing the procedure.

Procedures can be taught to trainees in a consistent and organized manner by observing a set of eight steps for procedural learning as described by Chapman[11] and shown in Box 72-1 . These steps incorporate the four types of learning that are important to understand when teaching a procedural skill or when testing for procedural competency.

Long-Term Procedural Skill Retention

Long-term retention of procedural competency is also an important aim of training because some decay of procedural skills is naturally observed in complicated psychomotor tasks. Educators would like to know how long the effect of procedural training will last and how often clinicians need to practice in order to retain speed and accuracy for resuscitative procedures. Information may be lost from short-term memory (memory that is held for less than 30 seconds) through decay and interference, but once committed to long-term memory, it is assumed to be virtually permanent.[2] [58] This is analogous to certain learned skills that are retained indefinitely, such as riding a bicycle. These skills are never forgotten most likely owing to a process called *overlearning*. Retention of skills depends, in part, on the adequacy of the initial educational experience.[64] Research studies of motor learning and control have shown that execution of active movements is best recalled when the movements are practiced actively rather than following a passive demonstration.[39] [57] For most ED procedures, which are rarely overlearned, practice may be required in order to retain those skills.[11] One study demonstrated that airway management skills decline early after initial training but performance may be maintained effectively with independent practice and periodic feedback.[37]

Box 72-1. Eight Steps of Procedural Skill Learning

1. Identify an acceptable skill level.
2. Identify when to perform the procedure.
3. Select the instruments and equipment needed to perform the procedure.
4. Identify the critical steps of the procedure.
5. Memorize the sequential order of the steps.
6. Develop a mental image of performing the procedure.
7. Practice procedural movements with feedback.
8. Assess procedural competence.

From Chapman[11]

PROCEDURAL TRAINING IN THE EMERGENCY DEPARTMENT

Bedside Teaching

Procedural training at the bedside is an important part of learning a new skill in the ED (Fig. 72-1). Ideally the trainee has undergone formal training in the procedure prior to attempting the new skill on a human patient. This may include listening to lectures, watching videotapes, using computerized instructional materials, and reading and reviewing procedural texts and atlases. Having an appropriate clinical setting and adequate time to explain the procedure in detail optimizes bedside teaching. The instructor should review the procedure beforehand with the trainee. This may include such components as the indications, contraindications, relevant anatomy, procedural steps, and complications. The review may take place outside the patient's room or at the bedside. The trainee then performs the procedure while the instructor observes and provides guidance and assistance if needed. Following the procedure, the instructor should examine the patient and assess the adequacy of the procedure. This may then be followed by a discussion of problems that occurred during the procedure, suggestions for improvement, and a review of postprocedural care.

Figure 72-1 Procedural training at the bedside is an important part of learning a new skill. *A,* This ankle dislocation requires prompt relocation in the ED. *B,* The instructor first reviews the procedure with the trainee, including indications, contraindications, procedural steps, and complications. The trainee then performs the reduction while the instructor observes and provides guidance during the procedure. *C,* Following the procedure, the instructor examines the patient and assesses the adequacy of reduction.

PROCEDURAL TRAINING DURING EMERGENCIES

Procedural training in the ED is often complicated by the exigent circumstances under which many procedures are performed. When a patient arrives with a life-threatening condition that mandates emergent intervention, procedures must be accomplished as quickly and competently as possible, and they are frequently done by the most experienced member of the resuscitation team.[29] [61] Consequently, emergency medicine (EM) faculty are seldom afforded the time and circumstances necessary to explain the rationale and details of life-saving surgical procedures to residents in training. [48] [49] The adage "see one, do one, teach one" is particularly unconscionable in the ED, [67] where procedures must be performed rapidly and competently in order to be lifesaving. Hedges [26] wrote that in the case of an unfavorable teaching scenario, it may be better for the educator to teach while he or she does the procedure. He observes that while this may be less satisfying for the trainee, there are still many things to be learned from observing the patient-clinician interaction, procedural setup, critical actions, and postprocedural care.

PROCEDURAL TRAINING FOR UNCOMMON PROCEDURES

Furthermore, the ability for clinicians to practice certain critical resuscitative procedures on human patients in the ED may be limited because they are performed so infrequently. Residents, therefore, have limited opportunity to train and acquire procedural competency and speed in their performance.

There has been a decline in the rate of performance of certain resuscitative procedures in recent years due to a number of factors. Recent critical analyses of patient outcomes following ED thoracotomy have identified key predictors of successful outcome, most notably penetrating trauma to the chest, which have also virtually eliminated performing this procedure in victims of blunt trauma. [5] [16] With clinicians now using a more selective approach for thoracotomy, procedural competency is more difficult to obtain in the ED setting. In addition, Chang et al. [9] reported a significant decline in the rate of cricothyroidotomies performed on trauma patients following the beginning of a new EM residency training program. They attribute this to several possible causes, including the widespread application of rapid sequence intubation techniques, the presence of supervisory EM faculty 24 hours a day, and the diminished concern regarding orotracheal intubation of patients whose cervical spines have not been radiographically cleared. There is also competition for procedures between EM residents and residents from other specialties. [59] In fact, a 1995 survey completed by program directors of EM residencies found that, overall, emergency clinicians perform only 50% of 10 index procedures in the ED while residents from other specialties perform the remainder. [22] Finally, how often residents have the opportunity to perform surgical procedures is often determined by chance.[38]

A recent survey of the experience of EM residents found that a significant number of residents perform fewer than five each of certain critical resuscitative procedures during their training. [24] This confirms the findings of earlier published reports that certain emergency procedures, particularly venous cutdown, thoracotomy, and cricothyroidotomy, are performed infrequently. [20] [54]

ASSESSING PROCEDURAL COMPETENCY

Chapman and others have argued that, with so few procedures being done and without training alternatives, it is unlikely that emergency medicine residents will have achieved procedural competency during their training. [9] [14] The actual number of procedures necessary to ensure competency remains unknown. A study by Chapman failed to show a significant correlation between the clinician's recollection of previous procedural experience and actual thoracotomy performance as assessed by written, computerized, or animal models. Similarly, knowledge of thoracotomy content and procedural steps did not predict procedural competency. [10] Typically, the number of procedures previously performed is taken as predictive of procedural competency; however, these findings suggest that procedural competency cannot be predicted by previous experience. Despite these findings, many hospitals use the number of procedures previously performed as a criterion for hospital credentialing and thereby granting the privilege to perform procedures independently. [12] Some surgical residencies have adopted competency-based education and report success using fresh cadavers as models to achieve rapid improvement in surgical skills. [44]

The acquisition of complicated motor skills is highly individualized and may depend upon the quality of each procedural experience rather than the number of procedures performed.[24] For example, if procedures have been taught or practiced incorrectly, experience is not a useful predictor of procedural competency. It has been demonstrated that when one performs a manual skill incorrectly, even if only once, it is much more difficult to relearn the correct technique. [63] Therefore it is critically important to observe students closely and correct them as they practice a procedure. If procedures are learned incorrectly without the benefit of testing and remediation, these errors may be passed on to other residents and students through the teaching process. [12] In the words of Red Auerbach, the legendary coach of the Boston Celtics, "Practice does not make perfect... . Perfect practice makes perfect." [63]

The learning curve is steep for certain procedures. In a report by Konrad, initial intubation success rates for anesthesia residents in the operating room may be as low as 50% with their first 10 patients, and the curve does not rise to 90% until a mean of 57 attempts. [36]

Regardless of the reasons, when procedures are performed infrequently, competency becomes an issue and complications may be prevalent. Cricothyroidotomy is an example of an uncommon procedure and published reports of complication rates vary widely. [33] [45] [50] [56] However, despite a high incidence of complications, successful cricothyroidotomy is an essential skill to be able to perform, because the alternative is failing to establish an airway, which in many situations results in certain death.[60]

Chapman is an advocate of establishing procedural competency expectations for emergency procedures and resuscitations to ensure the competency of EM graduates. [14] There are currently no published competency criteria for emergency procedures and resuscitations and a minimum number of procedures required by the American Board of Emergency Medicine (ABEM) has not been established. ABEM has likewise not established a mechanism for testing procedural competency, and must rely upon residencies to provide the necessary training, evaluation and assurance of competency. [4] Braen and Munger[4] described early efforts of the ABEM to evaluate procedural skills, but these were not implemented, primarily due to a lack of reliable equipment and resources to examine large pools of candidates in a high-stakes national examination. To standardize testing there must be an assurance that examiners will be able to reliably evaluate candidates. Bullock et al. [7] demonstrated good inter-rater reliability by both expert and non-expert observers when they were given structured checklists to assess procedural skills. Custalow et al.[17] likewise observed excellent inter-rater reliability among expert reviewers for the evaluation of critical step performance of saphenous vein cutdown, thoracotomy, and cricothyroidotomy. Ideally, a national procedural competency examination might incorporate animal, cadaver, and virtual reality simulation laboratories to evaluate candidates. [14]

EDUCATIONAL ALTERNATIVES FOR PRACTICING PROCEDURES

To ensure residents' procedural competency upon completion of residency training and with limited available clinical experience, educators must explore alternative methods for training. Many educational methods have been tried. Unfortunately, many alternatives to clinical experience have substantial limitations and few have been tested for their efficacy and applicability to the performance of procedures

on human patients. The following is a description of the currently available educational techniques. As mentioned earlier, it is ideal to introduce the procedure via formal review before the trainee practices the skill using one of the following procedural models. This may include listening to lectures, watching videotapes, using computerized instructional materials, and reading and reviewing procedural texts and atlases.

Volunteers

Human volunteers (paid or unpaid) are commonly used for teaching procedures. They are useful for practicing noninvasive procedures such as casting and splinting (Fig. 72-2) and certain minimally invasive procedures such as intravenous catheter or nasogastric tube insertion but they are clearly not appropriate for most invasive procedures.

Living Patients in Operating Rooms

Many EM residency programs provide opportunities for residents to practice endotracheal intubations during anesthesia rotations in the controlled setting of the operating room. However, when there is also an anesthesia residency training program at the hospital, residents may compete for these cases.

Mannequins

Mannequins, such as the popular "Resusci-Annie," are available to teach many procedures including cardiopulmonary resuscitation, peripheral venipuncture, arterial puncture, intraosseous infusion, umbilical vessel catheterization, central line catheterization, lumbar puncture, endotracheal intubation (Fig. 72-3), needle thoracostomy, urinary catheter placement, suturing, and emergency childbirth. Stratton found that paramedics trained in endotracheal intubation using a mannequin-only teaching program achieved equal success rates in field intubations compared to those receiving additional training on human cadavers. [62] Mannequins can serve as useful adjuncts

Figure 72-2 Volunteers are ideal models for teaching certain noninvasive procedures such as splinting and casting.

Figure 72-3 Mannequins are available to teach many procedures, including endotracheal intubation.

for teaching procedures but are limited by the lack of certain physical properties of living tissue, including hemorrhage, a beating heart, and breathing lungs. Most mannequins are designed for durability and not for realistic simulation. They are very different from the human patient in which pliable structures (such as the tongue and epiglottis) bend easily and move with the instruments. [41]

Video Imaging

Levitan developed the Airway Cam Direct Laryngoscopy Video System in which a miniature video camera is worn by the trainee, thus allowing a supervisor to assist. The advantage is that instructors can provide real-time feedback to trainees. The trainee's performance can be recorded and reviewed. [40] The complicated anatomy of the larynx can also be demonstrated better with a camera directed on an actual patient than on a mannequin. In a study of initial success rates of paramedic trainees in an operating room setting, Levitan et al. [42] observed a mean improvement in intubation success rates of 41% after paramedics watched a 26-minute instructional videotape made using this video camera system.

In another study medical students were found to perform emergent thoracotomy on the dog and pig models with surprising accuracy after only watching a 30-minute videotape demonstration of this procedure. The presentation of complicated anatomy to novices appears to be an important prerequisite to performing procedures accurately.[11] [12]

Virtual Reality and Medical Simulators

Virtual reality is a promising technology that has enormous educational potential for teaching procedures, but it is still in the early stages of development. [27] In a review of virtual reality and simulation technology, Reznek et al. note that to be an effective teaching tool, a simulator must provide both educationally sound and realistic feedback to a user's questions,

decisions, and actions.[55] Force and tactile feedback have proven to be the most difficult parts of the virtual environment to simulate. While not in widespread use in emergency medical education at this time, modern human patient simulators have been developed or are currently under development for endotracheal intubation, chest compression, electrical cardioversion, cricothyroidotomy, chest tube insertion, pericardiocentesis, diagnostic peritoneal lavage, emergency thoracotomy, lumbar puncture, skin suturing, insertion of peripheral venous/arterial catheters, and insertion of central venous lines (Fig. 72-4).[55]

Cadaver Laboratories

Fresh cadavers (bodies of individuals who have given consent for their bodies to be used for teaching) can be useful to teach certain procedures. The disadvantages are cost, limited availability, and the potential risk for transmission of disease. [48] Preserved cadavers are more readily available and these laboratories offer the

advantage of a standardized reproducible laboratory experience under the guidance of an instructor with no risk to patients. [66] Disadvantages of preserved cadavers are that they do not bleed and they suffer from tissue adherence due to the preservation process, so while excellent for learning the anatomy of procedures, they may not completely simulate the in vivo experience. [13]

Newly Deceased Patients

Newly deceased patients (those who have not expressly given consent for the use of their bodies) have also been used to practice performing procedures. A survey of program directors of EM and critical care training programs found that 63% of EM programs allow procedures to be performed on newly dead patients. [8]

The performance of invasive procedures on the newly dead may be limited by certain debated ethical concerns. [1] [8] [23] [25] [30] [31] [32] [47] [53] Whether consent should be obtained prior to performing procedures on the newly dead is a question that has been discussed extensively in the literature. Advocates of practicing procedures without consent believe that the dead

Figure 72-4 Human patient medical simulator. *A,* In the control room the educator is able to create and monitor clinical scenarios. *B,* The trainee performs electrical cardioversion on a human patient simulator and receives feedback from his actions by watching the monitor (successful conversion of ventricular tachycardia to sinus rhythm).

have no claim to autonomy and that this is a function of personhood. Iserson states that consent for procedures on the newly dead is therefore an inappropriate extension of patient autonomy. Secondly, given the absence of suitable alternative training models, it is in society's best interest to have adequate numbers of medical care providers who are experienced in life-saving procedures. Finally, families are often less altruistic on behalf of their relatives than the individual would be, and requesting permission from relatives may supersede the individual's own wishes and create excessive emotional barriers between the provider and a distraught family.[30] [31] [32]

Those who advocate obtaining consent claim that practicing procedures on the newly dead without consent is unlawful and unethical. Goldblatt [23] wrote that proxy consent by a family member is required when patients cannot give consent themselves and that the next of kin have "quasi-property rights" for the body of a dead family member. He suggested that by framing a request to the family such as, "What would the deceased have wanted?" the protective instincts of the next of kin may be decreased and permission granted.

In a survey involving theoretical clinical scenarios, people responded that they would agree to after-death procedures on themselves in 75% of cases and on their relatives in 70% of cases. However, without prior consent they would allow such procedures only 40% of the time on themselves and 50% on their family members. [43] In actual clinical practice, consent given by family members has traditionally been lower. Families gave consent for intubation of newly deceased infants in 73% of cases,[3] for retrograde wire intubation of newly deceased adults in 59% of cases, [46] and for cricothyroidotomy of newly deceased adults in 39% of cases. [51]

Isolated Animal Tissues

Many schools teach basic wound closure techniques using fresh animal tissue such as pig's feet (Fig. 72-5).[34] Isolated sheep or pig tracheas are useful to practice the technique of cricothyroidotomy but lack the external anatomy of the cricothyroid membrane in situ. Others have experimented with the use of chicken or turkey bones to teach the technique of intraosseous line placement.

Figure 72-5 Isolated pig's feet are useful models to teach basic wound closure techniques.

Live Animal Laboratories

Live animal laboratories provide for a realistic, stimulating teaching environment that imparts a level of understanding vastly different from other educational methods.[18] Although no alternative to performing procedures on a human patient is completely suitable, animal laboratories can provide a reasonable training alternative in which procedures may be performed with close supervision and under controlled conditions (Fig. 72-6).[61] Animal laboratories offer the advantages associated with performing procedures on living, bleeding tissues. Many feel that there is no substitute for this experience and that these learning experiences cannot be duplicated by

Figure 72-6 In the live animal laboratory an instructor assists while the trainee performs a venous cutdown.

simulations.[18] Students experience a feeling of responsibility and receive immediate feedback for their actions. [35] Moreover, animal laboratories may instill confidence in performing procedures on real patients. A survey of clinicians participating in a swine procedure laboratory reported a significant change in their comfort level in performing six resuscitative procedures.[52]

A survey of American medical colleges found that 92 of 126 medical schools (73%) use live animal laboratories at some point in their regular curriculum. [34] In this study, more than half of the schools without animal laboratories cited increasing expense of animals and equipment as the primary reason for not continuing them. Only two schools noted pressure from animal rights activists or student complaints as significant issues in discontinuing animal laboratories. [34]

The time, space, and money required to provide animal laboratory training for residents are considerable, yet the effectiveness of animal laboratory training as compared with other training techniques has not been well investigated. In one study, an animal procedure laboratory emphasizing skill repetition improved tube thoracostomy procedural skills and speed, and these skills were retained on retesting of subjects 18 days later. However, all participants in this study received animal laboratory training and there was no comparison to subjects receiving instruction using conventional training techniques. [29] A 2002 study by Custalow et al.[17] compared residents who had received animal laboratory training to those without animal laboratory training and found significant long-term improvements in procedural competency and speed in the performance of resuscitative procedures in those who received animal laboratory training.

One disadvantage of using animals for medical training, however, is the considerable cost involved. Furthermore, many question whether an animal model provides the best available simulation of the performance of procedures in humans. Finally, debate continues on the appropriate balance between animal rights and the benefits of using them for medical training and research. [15] [21] [29] [65]

CONCLUSION

There are numerous educational alternatives for teaching ED procedures, each with advantages and disadvantages. Optimally, residencies will have the space and resources to use a combination of training techniques to ensure competent performance of procedures by EM graduates. Educators may then find new ways to teach time-proven techniques, refine these techniques, or even develop new ones such as the Brofeldt four-step cricothyrotomy. [6] [28] Many questions remain unanswered regarding the best educational methods, but EM has the foundation for building a comprehensive instructional system to ensure the competency of trainees and maintenance of procedural skills throughout life. With repetition and reinforcement, these skills may then be committed to long-term memory for retrieval when they are most needed in the ED.

Emergency clinicians are frequently required to perform conversions and calculations in the emergency department (ED). Several formulas and tables are presented to guide those computations.

TEMPERATURE-CONVERSIONS FROM CELSIUS TO FAHRENHEIT

Fahrenheit (F) and Celsius (C) are the units most commonly used. Table A-1 is a list of approximate F/C equivalents. The formulas for conversion between units are as follows:

°F = (°C × 1.8) + 32

°C = (°F - 32) / 1.8

Example: A mother reports her child's temperature is 104°F. To convert to °C:

°C = (104°F - 32) / 1.8 = 40°C

Example: A child's temperature in the ED is 39.6°C. His mother wants to know what the temperature is in °F. To convert to °F:

°F = (39.6°C × 1.8) + 32 = 103.3°F

TABLE 1 -- Approximate Fahrenheit and Celsius Equivalents

°C	***°F***
30	86
32	89.6
34	93.2
35	95
35.5	95.9
36	96.8
36.5	97.7
37	98.6
37.5	99.5
38	100.4
38.5	101.3
39	102.2
39.5	103.1
40	104
40.5	104.9
41	105.8

WEIGHT-CONVERSION FROM POUNDS TO KILOGRAMS

Patients frequently express body weight in pounds, but many medical calculations require conversion to kilograms. The formulas for conversion between these two units are

1 kg = 2.2 lb

kg = lb/2.2 lb

Example: A dehydrated child requires intravenous fluid. The clinician plans to infuse a fluid bolus of 20 mL per kilogram. The patient's mother states that the child weighs 35 lb.

kg = 35 lb/2.2 = 16 kg

The fluid bolus is 16 kg × 20 mL = 320 mL

ESTIMATION OF A CHILD'S WEIGHT

Weight in kg = (2 × age) + 8

Example: A 3-year-old child needs rehydration. The estimated weight in kg is (2 × 3) + 8 = 14 kg.

CALCULATION OF THE MEAN ARTERIAL PRESSURE

Calculation of the mean arterial pressure (MAP) provides a weighted average of the systolic blood pressure (SBP) and the diastolic blood pressure (DBP). It is a determination of tissue perfusion pressure and is normally 70 to 100 mm Hg in adults. To determine the MAP:

MAP = [SBP + (2 × DBP)]/3

Example: An elderly, hypertensive patient is diagnosed with an acute hemorrhagic stroke. The neurologist recommends lowering the MAP to <130 mm Hg. The patient's current blood pressure is 210/120. To calculate the current MAP:

MAP = [210 + (2 × 120)]/3 = 150 mm Hg

QT AND QTC INTERVALS

The QT interval on the electrocardiogram (ECG) represents the period of ventricular electrical activity from activation to repolarization. The most important determinant of the QT interval is the heart rate. As the heart rate increases, the QT interval shortens. To calculate the rate-corrected QT interval (QTc), divide the QT interval by the square root of the R-R interval (the interval between the R on two consecutive QRS complexes). The interval is represented in sec or msec:

QTc = QT/vR-R

QTc = the normal corrected QT interval, which is normally =0.40 sec for men and =0.44 sec for women.

R-R = the R-R interval is calculated as 60 divided by the heart rate (in beats per minute).

Table A-2 shows the normal range of the QT interval for adults.

Example: A 21-year-old male ingested a large quantity of amitriptyline (tricyclic antidepressant) tablets. His ECG reveals a QT interval of 0.37 seconds and a heart rate of 120 beats/min. The QTc is calculated as follows:

QTc = QT interval/vR-R

R-R interval = 60/120 = 0.50

QTc = 0.37/v0.50 = 0.37/0.71 = 0.53 sec = 520 msec

The patient's QTc is significantly prolonged for his heart rate and indicates significant cardiac effects from a tricyclic antidepressant overdose.
Causes of prolonged QT interval are shown in Table A-3 .

TABLE 2 -- Normal Range of QT Interval for Adults

Heart Rate (bpm)	***Normal QT Range (sec)***
40	0.42–0.53
50	0.37–0.48
60	0.34–0.44
70	0.31–0.41
80	0.29–0.38
90	0.28–0.36
100	0.27–0.34
110	0.25–0.32
120	0.24–0.31
130	0.23–0.30
140	0.22–0.29
150	0.21–0.28

TABLE 3 -- Conditions/Medications That May Cause QT Prolongation and/or Induce Torsades de Pointes

Conditions That May Cause QT Prolongation	
Metabolic abnormalities	• Hypokalemia
	• Hypocalcemia
	• Hypomagnesemia
Bradyarrhythmias	• Complete atrioventricular block
	• Any bradyarrhythmia, even transient
Starvation	• Anorexia nervosa
	• "Liquid protein" diets
	• Gastroplasty and ileojejunal bypass
	• Celiac disease
Nervous system injury	• Subarachnoid hemorrhage
	• Thalamic hematoma
	• Right neck dissection or hematoma
	• Pheochromocytoma
Medications That Can Prolong the QT Interval and/or Induce Torsades de Pointes	

Antipsychotics	• Chlorpromazine*
	• Haloperidol—QT, TdP
	• Mesoridazine—QT, TdP
	• Pimozide—QT, cases
	• Quetiapine—QT
	• Risperidone—QT
	• Thioridazine—QT, TdP
	• Ziprasidone—QT
Antiarrhythmics	• Amiodarone—QT, TdP
	• Disopyramide—QT, TdP
	• Dofetilide—QT, TdP
	• Flecainide† —QT, TdP
	• Ibutilide—QT, TdP
	• Procainamide—QT, TdP
	• Quinidine—QT, TdP
	• Sotalol—QT, TdP
Antidepressants	• Amitripyline‡ -cases
	• Desipramine‡ -cases
	• Doxepin‡ -cases
	• Fluoxetine—QT, TdP
	• Imipramine‡ —cases
	• Paroxetine—TdP
	• Sertraline† —QT, TdP
	• Venlafaxine—QT
Anticancer	• Arsenic Trioxide—QT, TdP, cases
	• Tamoxifen—QT
Misc. cardiac	• Bepridil—QT, TdP
	• Isradipine—QT
	• Moexipril/hetz—QT
	• Nicardipine—QT
GI stimulant	• Cisapride—QT, TdP
Antibiotics	• Clarithromycin-cases
	• Erythromycin—QT, TdP
	• Gatifloxacin—QT
	• Levofloxacin—TdP
	• Moxifloxacin—QT
	• Sparfloxacin—QT, TdP
Antimigraine	• Naratriptan—QT
	• Sumatriptan—QT
	• Zolmitriptan—QT
Miscellaneous	• Dolasetron—QT
	Droperidol—QT, TdP, cases
	• Fascarnet—QT
	• Felbamate—TdP
	• Fosphenytoin—QT
	• Halofantrine—QT, TdP
	• Indapamide—QT, cases
	• Levomethadyl—QT
	• Octreotide—QT
	• Pentamidine—QT, TdP
	• Salmeterol—QT
	• Tacrolimus-cases
	• Tizanidine—QT

QT: Prolongation is mentioned in the FDA-approved labeling as a known action of the drug.

TdP: The FDA-approved labeling includes mention of cases or a risk of Torsades de Pointes.

Cases: There are case reports of TdP in the medical literature.

Reference: Drugs that prolong the Q-T interval and/or induce Torsades de Pointes. (Resource on World Wide Web) http://www.torsades.org accessed September 12, 2000.

From Viskin S: Long QT syndromes and torsade de pointes. Lancet 354:1625, 1999.

*Nonspecific QT changes
†Association not clear
‡Tricyclic antidepressants used alone or in combination with drugs that prolong the QT interval may predispose patients to cardiac arrythmias.

PREDICTED PEAK EXPIRATORY FLOW RATE

The peak expiratory flow rate (PEFR), measured in liters/minute (L/min) is a useful means of assessing airway obstruction. It is measured by having a patient exhale maximally through a peak flow meter. Normal values range from 350 to 600 L/min. A patient's prognosis in asthma exacerbations can be followed by comparing the initial and post-treatment PEFR. Patients with an initial PEFR of <20% predicted or with a subsequent value of <60% predicted after initial therapy may require further evaluation or treatment, or both. Many patients monitor PEFR on themselves and are able to state a personal best, which is the preferred standard for that individual. Other patients may be monitored using an estimated PEFR. PEFR is primarily based on a patient's gender, age, and height. While graphs and tables are available to provide values across a range of ages and heights, PEFR can also be approximated using the following formulas for adults:

PEFR in males (L/min) = {[(Height in inches × 0.139) + 1.58] - (Age × 0.041)} × 60

PEFR in females (L/min) = {[(Height in inches × 0.094) + 2.24] - (Age × 0.03)} × 60

Example (male): A 50-year-old male is 72 inches tall.

PEFR in males (L/min) = {[(72 in × 0.139) + 1.58] - (50 × 0.041)} × 60 = (11.59 - 2.05) × 60 = 572 L/min

Example (female): A 45-year-old female is 62 inches tall.

PEFR in females (L/min) = {[(62 in × 0.094) + 2.24] - (45 × 0.03)} × 60 = (8.07 - 1.35) × 60 = 403 L/min

ENDOTRACHEAL INTUBATION AND MECHANICAL VENTILATION

Patients with respiratory failure may require endotracheal intubation and mechanical ventilation in the ED. The following are guidelines for choosing the endotracheal (ET) tube size and for calculating the initial ventilator settings.

Selecting the Endotracheal Tube Size (Also See Chapter 4)

Adults: Select the largest diameter ET tube that can be tolerated for adults.
Size 7.5 mm cuffed ET tube is well tolerated by most adult female patients.
Size 8.0 mm cuffed ET tube is well tolerated by most adult male patients.
An uncuffed ET tube should be used for children under the age of 8. There are a number of techniques for estimating the appropriate ET tube size in children. The formula most commonly used is:

ET size (mm) = (Age in years/4) + 4

Example: A 5-year-old male needs emergent intubation. To select the appropriate size tube:

ET size (mm) = (5/4) + 4 ˜ 5.0 endotracheal tube (uncuffed)

To estimate the depth of insertion for a child older than 2 years:

Depth of insertion = 3 × internal diameter of the endotracheal tube

Determining Initial Ventilator Settings (See Chapter 8)

The recommended initial ventilator settings follow. Adjustments in these ventilator settings may be made according to the patient's clinical situation:
Tidal volume (TV) = 6–12 mL/kg

Rate = 10–12 breaths per minute for adults, 16–20 breaths per minute for children and 20–30 breaths per minute for infants.

FiO_2 = 50%–100% initially. Reduce the FiO_2 as quickly as possible to avoid oxygen toxicity to the lungs.

I:E ratio = 1:2. To allow complete exhalation, the inspiratory to expiratory ratio should be at least 1:2.

Example: A 6-year-old female with asthma has respiratory distress and altered mental status, requiring ET intubation. Her weight is 20 kg. To prepare for intubation and mechanical ventilation:

ET tube size = 6/4 + 4 = 5.5 mm tube, uncuffed

Tidal volume = 12 mL/kg × 20 kg = 240 mL
Respiratory rate = 16 breaths per minute
FiO_2 = 100%
I:E ratio = 1:2

RENAL FUNCTION

Creatinine Clearance

Creatinine clearance (Cl_{Cr}) is best calculated using a collection of urine over a 24-hour period. However, if the patient's creatinine clearance is in steady state (i.e., without recent change), it is possible to estimate Cl_{Cr} by using a formula that incorporates serum creatinine, weight, age, and gender:

Cl_{Cr} (men) = [(140 - age in years) × (lean body weight, kg)]/[72 × (serum creatinine in mg/dL)]

Cl_{Cr} (women) = [(140 - age in years) × (lean body weight, kg)]/[72 × (serum creatinine in mg/dL)] × 0.85

Normal values: 74–160 mL/min

Mild renal impairment: 40–60 mL/min

Moderate renal impairment: 10–40 mL/min

Severe renal impairment: <15 mL/min (= indication for renal dialysis)

Example: A 64-year-old woman has upper abdominal pain tenderness. A CT scan is planned, but the radiologist is concerned about the risk of intravenous contrast. The patient's serum creatinine is 1.8 mg/dL and she weighs 75 kg. To calculate her Cl_{Cr}:

Cl_{Cr} (women) = [(140 - 64) × (75 kg)/72 × (1.8 mg/dL)] × 0.85 = 37.4 mL/min

The patient has moderate renal impairment.

Fractional Excretion of Sodium

The fractional excretion of sodium (Fe_{Na}) calculation predicts the likelihood that a patient with acute renal failure has acute tubular necrosis (ATN). In ATN, the kidneys have difficulty reabsorbing sodium and concentrating urine. The following formula takes advantage of this by using plasma sodium and creatinine concentrations (P[Na] and P[Cr]) and spot urine sodium and creatinine levels (U[Na] and U[Cr]):

$Fe_{Na} = (U[Na] \times P[Cr])/(P[Na] \times U[Cr]) \times 100$

Fe_{Na} > 2% suggests post-glomerular failure

Fe_{Na} < 1% suggests prerenal azotemia (volume depletion).

Example: A middle-aged male was found lying on the ground and has ulcers on all pressure points on his back, buttocks, and legs. A urinary catheter is placed and yields a small amount of dark urine, which tests positive for blood on dipstick. He is found to have acute renal failure. Plasma and urine electrolytes and creatinine analyses are performed. The results are P[Na] = 134 mmol/L, P[Cr] = 3.5 mg/dL, U[Na] = 108 mmol/L, U[Cr] = 68 mg/dL. What is the most likely cause of his renal failure, ATN/myoglobinuria, or dehydration?

$Fe_{Na} = [(108 \times 3.5)/(134 \times 68)] \times 100 = 4.1$

The patient's Fe_{Na} is 4.1 (which is >2%) and suggests that ATN is the most likely the cause of his renal failure and myoglobinuria.

Calculation of the Anion Gap

The anion gap (AG) is an estimate of the amount of negatively charged (unmeasured) ions in the serum that are not bicarbonate (HCO_3^-) and chloride (Cl^-). The AG is calculated by subtracting the sum of HCO_3^- and Cl^- values from the sodium (Na^+), which is the major positive charge in the serum. Potassium (K^+) is not used in the calculation because most of the body's potassium is intracellular and there is a relatively small amount of K^+ in the serum. An elevated AG usually means that there is some unmeasured anion, toxin, or organic acid in the blood. The AG is normally 8 to 12 mmol/L:

$AG = Na^+ - (Cl^- + HCO_3^-) = 8$ to 12 mmol/L

An increase in the AG is usually associated with acidosis, referred to as an anion gap acidosis.
Table A-4 lists many substances that can cause an anion gap acidosis.

Example: A suicidal young male drank an unknown amount of antifreeze. His electrolyte levels are Na^+ 144, K^+ 3.1, Cl^- 108, and HCO_3^- 14. The anion gap is calculated as follows:

$AG = [144 - (108 + 14)] = 22$ mmol/L

The anion gap is abnormally elevated, presumably due to ethylene glycol ingestion.

TABLE 4 -- Substances Associated with High Anion Gap*

Aspirin
Methanol, metformin
Uremia
Diabetic ketoacidosis
Paraldehyde, phenformin
Isoniazid, iron
Lactate (multiple causes)
Ethylene glycol
Carbon monoxide, cyanide
Alcoholic ketoacidosis
Toluene

*Follows the mnemonic A MUDPILE CAT.

Calculating the Osmolal Gap

Serum osmolality can be measured in the laboratory by freezing point depression. The measured serum osmolality is normally higher than the calculated osmolality and the difference is termed the osmolal gap (OG). The osmolal gap is normally 5 to 10 mOsm/kg. If there is a higher gap, the osmols unaccounted for may represent methanol, ethylene glycol, isopropyl alcohol, or other solutes (Table A-5). To calculate serum osmolaity (Osm_{calc}) and the osmolal gap:

$Osm_{calc} = 2 \times (Na^+) + [BUN\ (mg/dL)/2.8] + [glucose\ (mg/dL)/18] =$ normally 280—295

$OG = Osm_{meas} - Osm_{calc}$

TABLE 5 -- The Effect of Some Solutes on Serum Osmolality

Each mg/dL of:	*Increases Serum mOsm/kg by:*	*For Each Serum mOsm/kg Increase Due to:*	*The Corresponding mg/dL Change is (= mol wt/10):* t
Methanol	0.31	Methanol	3.2
Ethanol	0.22	Ethanol	4.6
Acetone	0.17	Acetone	5.8
Isopropyl alcohol	0.17	Isopropyl alcohol	6.0
Ethylene glycol	0.16	Ethylene glycol	6.2
Glycerol	0.11	Glycerol	9.2
Mannitol	0.05	Mannitol	18.2

Adapted from Kullig K, Duffy JP, Linden CH, et al: Toxic effects of methanol, ethylene glycol and isopropyl alcohol. Top Emerg Med 6(2):16, 1984.

Table A-5 shows the effect of some solutes on serum osmolality. In general, the increase in osmolality caused by a solute can be calculated by dividing its serum concentration by the tabulated value.

Example: An intoxicated patient has serum chemistry results as follows: Na^+ 142, K^+ 4.5, Cl^- 100, HCO_3^- 22, Glucose 90, BUN 14. His ethanol level is 240 and his measured serum osmolality is 348. To calculate his serum osmolaity:

$$\text{Osm}_{\text{calc}} = 2\,(142) + (14/2.8) + (90/18)$$
$$= 284 + 5 + 5$$
$$= 294\ \text{mOsm/kg}$$

To evaluate for the effect of ethanol, refer to Table A-5 , adding the alcohol level divided by 4.6:

$$= 240/4.6 + 294\ \text{mOsm/kg}$$
$$= 52 + 294\ \text{mOsm/kg}$$
$$= 346\ \text{mOsm/kg}$$

Finally, calculate the osmolal gap:

$OG = Osm_{meas} - Osm_{calc} = 348 - 346 = 2$

Factitious Hyponatremia

Factitious hyponatremia may be due to hyperglycemia. In this hyperosmolal state, glucose tends to stay in the extracellular fluid, drawing water out of the cells and into the extracellular fluid. Serum sodium is decreased by about 1.6 mmol/L for each 100 mg/dL of excess glucose. To calculate the corrected sodium:

Corrected Na^+ (mmol/L) = Measured Na^+ (mmol/L) + [1.6 × [(measured glucose in mg/dL - 100)/100]

Many labs automatically make this adjustment so it is important to check with your lab to determine the necessity of this correction.

Example: An obtunded elderly man appears dehydrated. His sodium level is 126 mmol/L and his glucose is 1000 mg/dL.

$$\text{Corrected } Na^+ = 126\ \text{mmol/L} + [1.6 \times (1000 - 100)/100]$$
$$= 126 + 14.4 = 140.4\ \text{mmol/L}$$

His corrected Na^+ suggests that he has factitious hyponatremia due to hyperglycemia.

Free Water Deficit in Hypernatremia

Elevation of serum sodium concentration is proportionate to free water deficit when volume is depleted. Since 60% of the adult body is water, total body free water deficit is calculated using measured Na^+ , desired Na^+ , and body weight in kg. To calculate the free water deficit:

Ideal total body water (TBW) = 60% × weight in kg

Current TBW = (desired serum Na^+ × ideal TBW)/measured Na^+

Free water deficit = ideal TBW - current TBW

Example: An elderly man is brought to the ED in a coma. He has signs of severe dehydration. His ideal body weight is 70 kg. His serum Na^+ is 165 mmol/L. To determine his free water deficit:

Ideal TBW = 0.6 (70 kg) = 42 L

Current TBW = 140 mmol/L × 42 L/165 mmol/L = 35.6 L

Free water deficit = 42 L - 35.6 L = 6.4 L

Fluid correction for hypernatremia should take place over 48 to 72 hours to avoid the potential for cerebral edema.

Calculation of the Sodium Deficit In Hyponatremia

The following formula may be used to calculate the Na^+ deficit in hyponatremia:

Na^+ deficit = 60% × (weight in kg) × (desired Na^+ - measured Na^+)

Symptoms related to hyponatremia are variable and the severity of symptoms should guide therapy. Sodium replacement is most commonly given as isotonic saline, which contains 154 mmol of Na^+ per liter. Patients who are severely symptomatic may require 3% saline solution that contains 513 mmol of Na^+ per liter. The volume of solution needed to replace the Na^+ deficit (in mmol) can be calculated using the concentrations in the saline solutions listed earlier.

Example: A young man is seizing on arrival to the ED. He is known to have schizophrenia and compulsive water drinking. His Na^+ is 116 mmol/L. He weights 65 kg. To determine his sodium deficit:

$$Na^+\ \text{deficit} = 0.6 \times (65\ \text{kg}) \times (140 - 116)$$
$$= 936\ \text{mmol of } Na^+$$

This amount of Na^+ deficit can be administered as approximately 6 liters of isotonic saline or 1.8 liters of hypertonic saline. Na^+ should be replaced very slowly to

avoid the possibility of inducing central pontine myelinolysis (CPM), which results from overaggressive correction of sodium.

pH and Changes in Serum Potassium Levels

Serum potassium (K^+) levels change with the acid-base status. In acidemic states, K^+ moves out of cells as H^+ moves in, thus raising serum K^+ levels. In alkalemic states, K^+ moves into cells as H^+ moves out, thus lowering serum K^+ levels. The change in K^+ varies inversely with pH at the following rate:

Serum K^+ concentration increases 0.6 mmol/L for each 0.1 unit decrease in pH.

Serum K^+ concentration decreases 0.6 mmol/L for each 0.1 unit increase in pH.

Calculating the Corrected Calcium Level

Approximately 50% of serum calcium is bound to serum proteins (primarily albumin), 40% is in the free ionized state (the physiologically active form), and 10% is mixed with serum anions (phosphate, bicarbonate, citrate, and lactate). For this reason, serum calcium is lowered about 0.8 mg/dL for every decrease in albumin of 1 g/dL. To correct for decreased albumin (at levels <4 g/dL), the following formula can be used:

Corrected Ca^{2+} (mg/dL) = serum Ca^{2+} (mg/dL) + (0.8 × [4.0 - serum albumin {g/dL}])

Example: A malnourished man has a serum calcium level of 7.5 mg/dL and a serum albumin level of 2 g/dL. To calculate his corrected calcium level:

Corrected Ca^{2+} (mg/dL) = 7.5 mg/dL + [0.8 × (4.0 - 2.0 g/dL)] = 7.5 + 1.6 = 9.1 mg/dL

Calculating Pediatric Intravenous Maintenance Fluids

To calculate maintenance intravenous fluids for a pediatric patient, use the following formula:

4 mL/kg/hr for the first 10 kg, plus
2 mL/kg/hr for the second 10 kg, plus
1 mL/kg/hr for each further kg

Example: A 5-year-old boy weighs 19 kg and requires maintenance intravenous fluids. To calculate his intravenous fluid rate:

4 mL/kg/hr for the first 10 kg = 4 mL × 10 kg/hr = 40 kg/hr, plus
2 mL/kg/hr for the second 10 kg = 2 mL × 9 kg/hr = 18 kg/hr
40 kg/hr + 18 kg/hr = 58 kg/hr

Fluid Replacement for Burn Victims

Various formulas for intravenous fluid resuscitation in burns have been recommended. The Parkland formula is commonly used, and is calculated as follows:

Replacement fluid = (4 mL) × (weight in kg) × (% body surface area burned)

The total volume should be given in the first 24 hours with half the fluid given in the first 8 hours and the remaining half given in the next 16 hours. Clinical parameters including urine output, vital signs, and central venous pressure or pulmonary capillary wedge pressure should be monitored carefully to assess the adequacy of resuscitation.

Example: A 65-kg woman has second- and third-degree burns covering 35% of her body. To determine her anticipated 24-hour fluid resuscitation needs:

Replacement fluid (in liters) = (4 mL) × (65) × (35) = 9100 mL

ARTERIAL BLOOD GAS ANALYSIS

The Alveolar-Arterial Oxygen Gradient

The alveolar-arterial oxygen gradient (A-a gradient) is the difference between the partial pressure of oxygen in the alveolar air ($P_A O_2$) and the arterial blood ($P_a O_2$). It is used primarily to differentiate between hypoxia due to hypoventilation (in which the A-a gradient is normal) and hypoxia due to ventilation-perfusion mismatch (in which the A-a gradient is abnormal). In conditions where there is abnormal oxygen exchange between the alveoli and the arterial blood, the A-a gradient will be increased.

Calculating the Partial Pressure of Oxygen in the Alveolar Air ($P_a O_2$)

The partial pressure of oxygen in the alveolar air ($P_A O_2$) cannot be directly sampled and is therefore calculated from the alveolar air equation. Because it is difficult to determine the actual amount of oxygen delivered to the alveoli when the patient is breathing supplemental oxygen, the equation is most accurate when the patient is breathing room air.

$P_A O_2 = [FiO_2 \times (\text{barometric pressure} - PH_2O)] - PCO_2/RQ$

*Administer 50% of volume over first 8 hours and remainder over subsequent 14 hours post burn.

$P_A O_2$ = partial pressure of oxygen in the alveolar air

FiO_2 = 0.21 = fraction of the inspired air that is oxygen (21% for room air)

Barometric pressure (at sea-level) = 760 mm Hg

PH_2O = 47 mm Hg (partial pressure of water vapor at 37° and sea level)

PCO_2 = as measured by arterial blood gas (ABG) analysis

RQ = 0.8 (respiratory quotient, the ratio of CO_2 produced per unit of oxygen consumed)

To simplify the equation assuming sea-level barometric pressure and room air:

$P_A O_2 = [0.21 \times (760 - 47)] - (PCO_2/0.8)$
$P_A O_2 = 150 - (PCO_2/0.8)$

Calculating the A-a Gradient

To determine the A-a gradient, the partial pressure of oxygen in the arterial blood ($P_a O_2$) (as determined by the ABG) is subtracted from the calculated partial pressure of oxygen in the alveolar air ($P_A O_2$):

A-a gradient = $P_A O_2 - P_a O_2 = [150 - (PCO_2/0.8)] - P_a O_2$

Calculating the Age Correction for the A-a Gradient

The normal A-a gradient is less than 10 mm Hg in a young person; however, since alveolar oxygen diffusion decreases with age, an increase in the A-a gradient is expected with age. To estimate this change, use the following formula:

Age-corrected A-a gradient = [(age/4) + 4]

Example: A 60-year-old man is found confused at home. He is tachypneic and diaphoretic. Oxygen saturation is 92% by pulse oximetry. A room air ABG showed: pH = 7.48, PCO_2 = 27, PO_2 = 72. To calculate the A-a gradient:

A-a gradient = (150 - 27/0.8) - 72 = 116 - 72 = 44 mm Hg

Age adjusted A-a gradient: (age/4) + 4 = (60/4) + 4 = 19

The A-a gradient is abnormally elevated beyond the adjustment for age, suggesting a ventilation-perfusion (V/Q) mismatch.

ACID-BASE BALANCE

Using the combination of an ABG sample and serum electrolyte levels, a patient's acid-base status can be evaluated. Faced with pH, PCO_2, and HCO^-_3 data, the clinician may determine the primary acid-base disturbance and whether the compensation is appropriate. The following basic steps are required.

Knowledge of normal values:

Normal serum pH = 7.40

Normal PCO_2 = 40 mm Hg

First, determine the pH status. Acid-base changes are either metabolic or respiratory. Simple disturbances are categorized by examining the pH and the PCO_2 and HCO^-_3 (Table A-6). If the pH is less than normal (below 7.35), the patient is acidemic. If the pH is above normal (above 7.45), the patient is alkalemic. If the patient is acidemic and the PCO_2 is elevated (>45 mm Hg) as a primary disorder, then respiratory acidosis is present. If the patient is alkalemic and the PCO_2 is decreased (<35 mm Hg) as a primary disorder, then respiratory alkalosis is present. If the patient is acidemic and the arterial HCO^-_3 level is less than normal (<22 mm Hg) as a primary disorder, then a metabolic acidosis is present. If the patient is alkalemic and the HCO^-_3 level is greater than normal (>26 mm Hg) as a primary disorder, then a metabolic alkalosis is present.

Acid-base homeostasis is normally maintained because the disruption of one element provokes a proportional change, or compensation, in the other. Alteration of pH is limited and not entirely corrected by normal mechanisms. The degree and timing of compensation is determined by the primary disturbance itself and by individual physiology. Respiratory compensation for metabolic disorders is rapid and occurs by adjusting the PCO_2. Full metabolic compensation for a respiratory disturbance requires renal adjustment of HCO^-_3 and takes 3 to 5 days. The predicted compensatory responses for the primary disturbances are shown in Table A-6 . It is important to remember that

physiologic compensatory mechanisms may themselves be compromised or overwhelmed by the acid-base disorder (Fig. A-1).

TABLE 6 -- Acidosis and Compensatory Response

Primary Disturbance	***Predicted Compensatory Response***
Metabolic acidosis	? in PCO_2 = 1.3 × ? in HCO^-_3
Metabolic acidosis	? in PCO_2 = 0.6 × ? in HCO^-_3
Respiratory acidosis	*Acute:* For every PCO_2 ? of 10 mm Hg, ? by 1 mmol/L
	Chronic: For every PCO_2 ? of 10 mm Hg, HCO^-_3 ? by 4 mmol/L
	Acute: For every PCO_2 ? of 10 mm Hg, HCO^-_3 ? by 2 mmol/L
	Chronic: For every PCO_2 ? of 10 mm Hg, HCO^-_3 ? by 5 mmol/L

Adapted from Rutecki GW, Whittier FC: Acid-Base interpretation. Consultant, Nov 1991, pp 44–59.

Example 1: A 58-year-old woman has had profuse diarrhea for 1 week. Initial laboratory data include the following:

Sodium, 133 mmol/L

Potassium, 2.8 mmol/L

pH, 7.26

Chloride, 118 mmol/L

PCO_2 , 13 mm Hg

HCO^-_3 , 5 mmol/L

1. Acidemia is present (pH < 7.40)
2. The primary process is metabolic (HCO^-_3 < 22 mmoL, and PCO_2 is not increased)
3. Compensation: In primary metabolic acidemia, the formula that checks for compensation is

? PCO_2 = 1.3 × ? HCO^-_3
? PCO_2 = 1.3 × (25 - 5) = 26 mm Hg
The predicted PCO_2 is 40 - 26 = 14
The actual PCO_2 is 13 mm Hg
Compensation is normal

Example 2: A 74-year-old nursing home resident is admitted to the hospital with hypotension (96/70) and fever (39°C). He has had a positive urine culture for *Escherichia coli* and two positive blood cultures with the same organism. The laboratory values are as follows:

Sodium, 138 mmol/L

Potassium, 3.2 mmol/L

Chloride, 105 mmol/L

pH, 7.49

PCO_2 , 25 mm Hg

HCO^-_3 , 22 mmol/L

1. Alkalemia is present (pH > 7.44)
2. The primary process is respiratory (PCO_2 <40 mm Hg and the HCO^-_3 was not increased).
3. Compensation: The decrease in the PCO_2 is 40 - 25 or 15 mm Hg. The formula for an expected decrease in HCO^-_3 is 2 mmol for every 10 torr decrease in the PCO_2 . In this instance the expected decrease in HCO^-_3 , for the 15 mm Hg decrease in PCO_2 is 3 mmol/L, which is nearly identical to the actual decrease (i.e., 25 – 22). Therefore, only acute respiratory alkalemia is present with normal compensation.

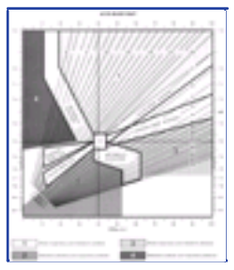

Figure 1 Acid-base map.

THE TRAUMATIC LUMBAR PUNCTURE

A traumatic lumbar puncture is suggested by progressive clearing of the cerebrospinal fluid (CSF) and a decreasing red blood count (RBC) from tubes one to three. The ratio of RBC to white blood count (WBC) should reflect the ratio in the peripheral blood. Subarachnoid hemorrhage is considered if cerebrospinal fluid (CSF) is markedly bloody and unchanged after several milliliters of fluid are removed from the puncture site. The centrifuged sample in subarachnoid hemorrhage is frequently xanthochromic. The following formula may be used to estimate the true CSF WBC:

True CSF WBC = Measured CSF WBC × [(CSF RBC × peripheral blood WBC)/peripheral blood RBC]

The approximate normal ranges for whole blood in adults (male and female):

RBC = 3.5-6 × 10^6 /µL approximate normal range for peripheral blood RBC

WBC = 5-11 × 10^3 /µL approximate normal range for peripheral blood WBC

When peripheral blood cell counts are normal, the CSF from a traumatic lumbar puncture should contain around 1 WBC per 700 RBCs.

DIAGNOSTIC PROBABILITY

The probability of obtaining a certain test result, in the presence or absence of a particular disease entity, for a given population with a given disease prevalence is represented by Table A-7 .

No medical test is totally accurate. The parameters listed in Table A-7 , when available, can help guide a clinician's test selection. When this information is not available, it may be difficult to identify random laboratory errors or detection failures. Knowledge of disease prevalence, combined with the sensitivity and specificity of the test, yields the positive (or negative) predictive value of that test. For a given sensitivity and specificity, predictive value is directly proportional to prevalence. Hence, even a test with high sensitivity and specificity may not detect a rare disease. This underscores the importance of pre-test clinical evaluation.

TABLE 7 -- Definitions of Commonly Used Epidemiologic Terms

Prevalence	= (a + c)/(a + b + c + d)	= incidence of disease in population tested
Sensitivity	= a/(a + c)	= probability of positive test result, disease present
Specificity	= d/(b + d)	= probability of negative test result, disease absent
False-negative rate	= c/(a + c)	= probability of negative test result, disease present
False-positive rate	= b/(b + d)	= probability of positive test result, disease absent
Positive predictive value	= a/(a + b)	= probability of disease presence, test positive
Negative predictive value	= d/(c + d)	= probability of disease absence, test negative
Overall accuracy	= (a + d)/(a + b + c + d)	= probability of a "true" test result

	Disease State		
Test Result	**Present**	**Absent**	
Positive	a (true positive)	b (false positive)	a + b = all positive tests
Negative	c (false negative)	d (true negative)	c + d = all negative tests
	a + c = all patients with disease	b + d = all patients without disease	a + b + c + d = all patients tested

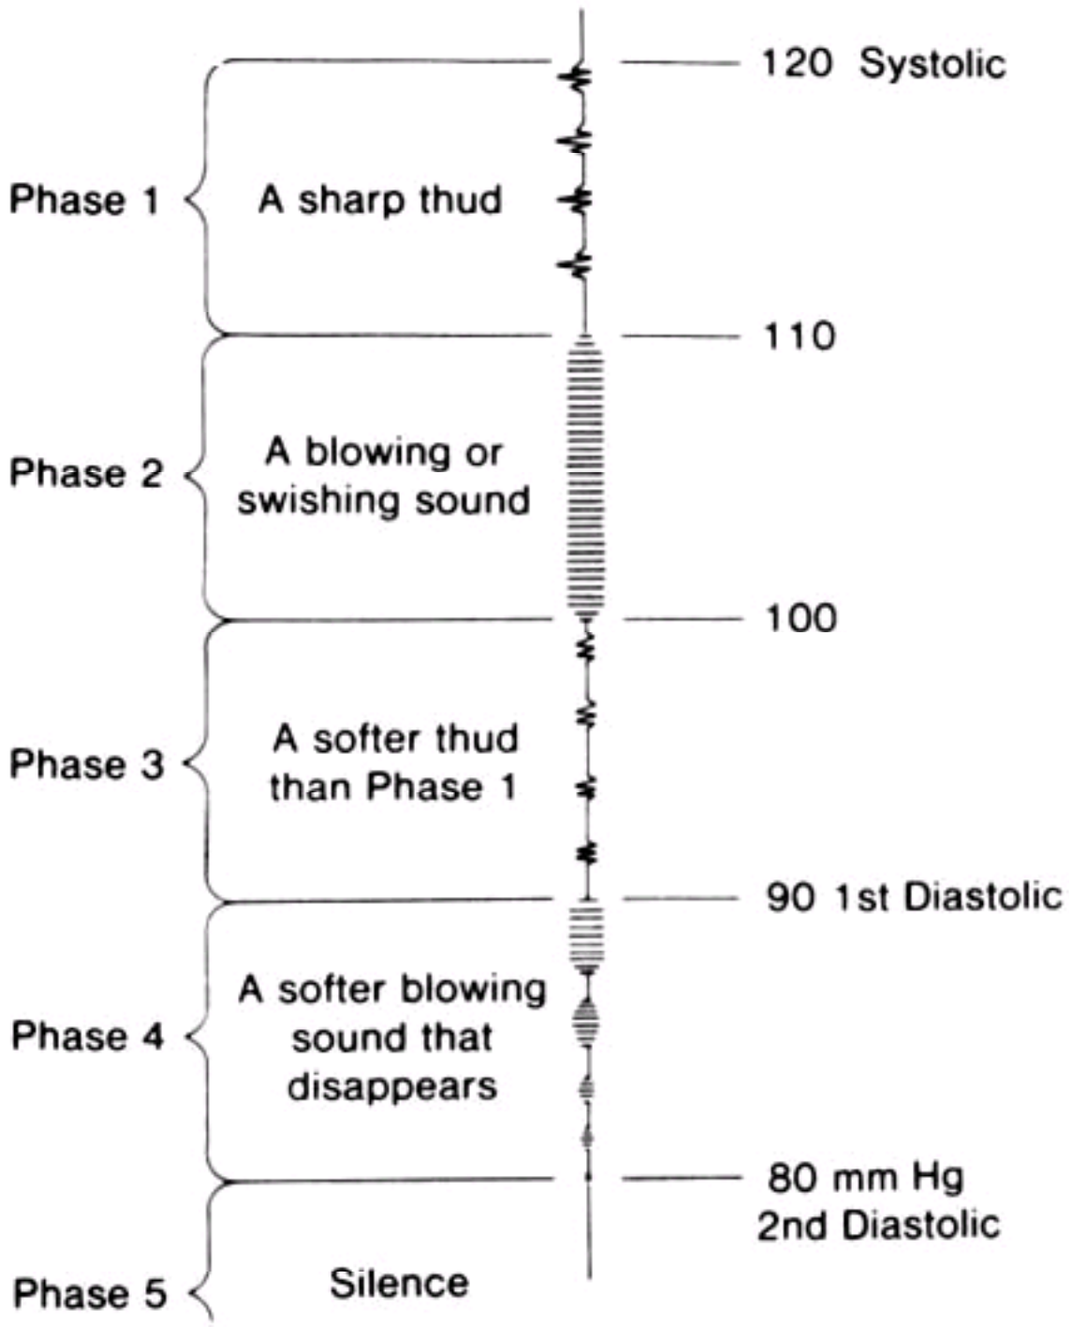

Figure 1-3 *A*, Measurement of pulsus paradoxus. Note that the systolic pressure varies during the respiratory cycle. *(From Stein L, Shubin H, Weil M: Recognition and management of pericardial tamponade. JAMA 225:504, 1973. Copyright 1973, American Medical Association. Reproduced by permission.)* *B*, Technique for the measurement of pulsus paradoxus.

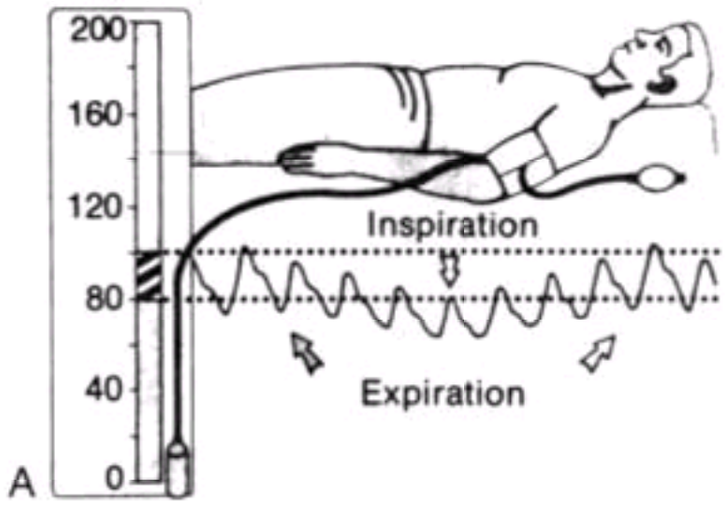

A

PROCEDURE FOR THE MEASUREMENT OF PULSUS PARADOXUS

Patient should be reclining at a 30 to 45° angle and instructed to breathe normally.

1. Inflate standard blood pressure cuff until Korotkoff sounds over brachial artery disappear.
2. Lower pressure in cuff a few millimeters of mercury per second until first Korotkoff sounds appear during expiration.
3. Maintain pressure at this level and observe disappearance of sounds during inspiration. Record this cuff pressure.
4. Very slowly lower cuff pressure unitl Korotkoff sounds are heard throughout the respiratory cycle. Record this cuff pressure.
5. The difference between pressures recorded in the 2 previous steps is then recorded as the measurement (in mm Hg) of pulsus paradoxus. A pulsus paradoxus >12 mm Hg is abnormal. (see text).

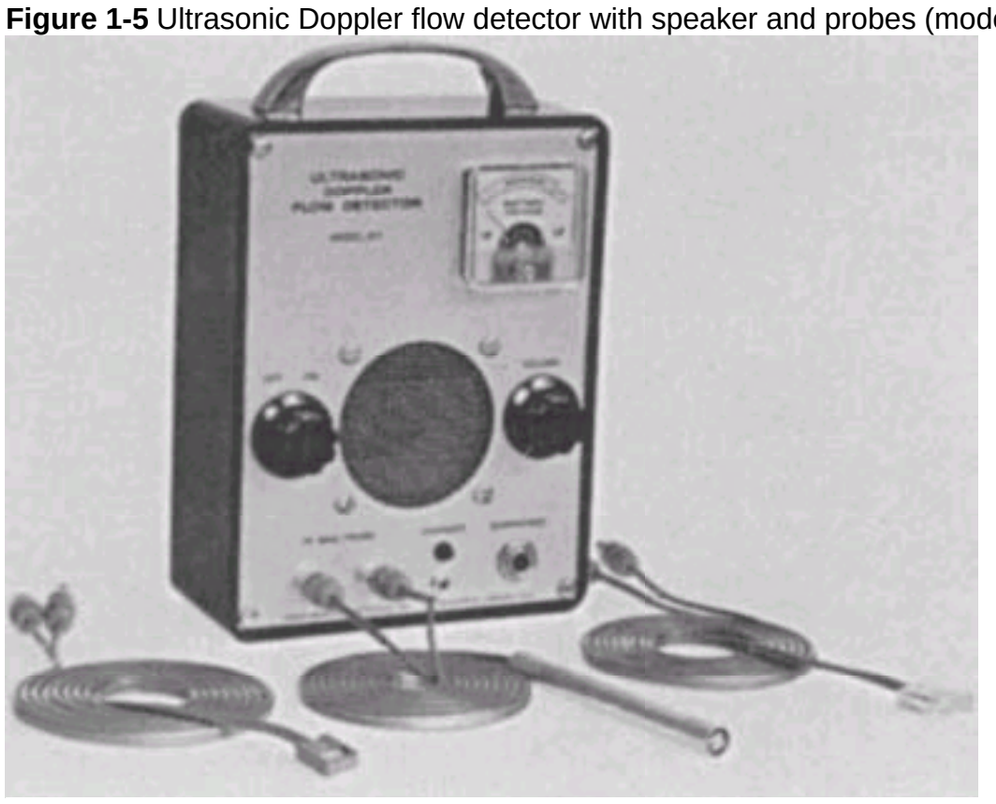

Figure 1-6 Typical pressures in a normal subject. Findings, based on resting pressures, show no evidence of occlusive disease of the large- or medium-sized arteries. Significant findings (normal) are as follows: (1) Ankle-to-brachial pressure index =1.0. (2) All pressure gradients <30 mm Hg. (3) Upper thigh pressure at least 40 mm Hg above brachial pressure. *(From Doppler Evaluation of Peripheral Arterial Disease: A Clinical Handbook. Fredericksburg, VA, Sonicaid, Inc. Reproduced by permission.)*

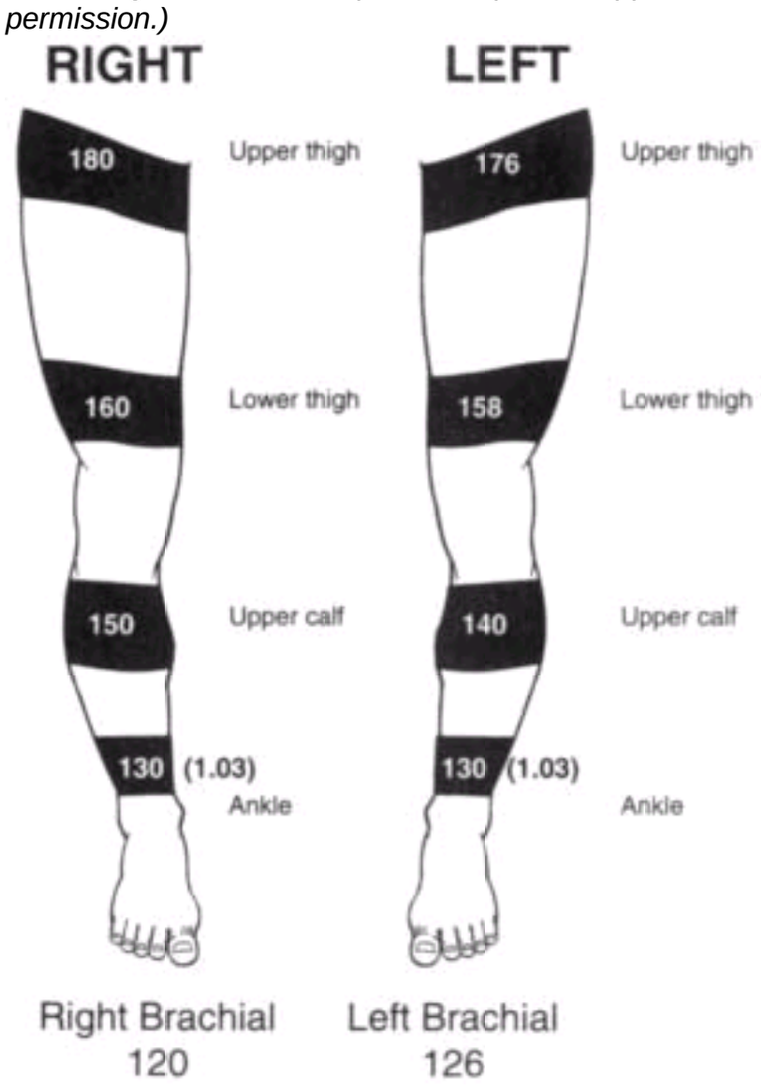

Figure 1-7 Typical pressures in a patient with obstruction of the popliteal or tibial arteries. Significant findings are as follows: (1) Ankle-to-brachial pressure index <0.9 in right leg. (2) Abnormally high gradient from ankle to below knee and again from below to above knee in right leg. (3) Upper thigh pressures are 50 mm Hg higher than brachial pressures, consistent with normal flow at the aorta-iliac level. Findings are suggestive of a right popliteal occlusion or an anterior and posterior tibial occlusion, or both. *(From Doppler Evaluation of Peripheral Arterial Disease: A Clinical Handbook. Fredericksburg, VA, Sonicaid, Inc. Reproduced by permission.)*

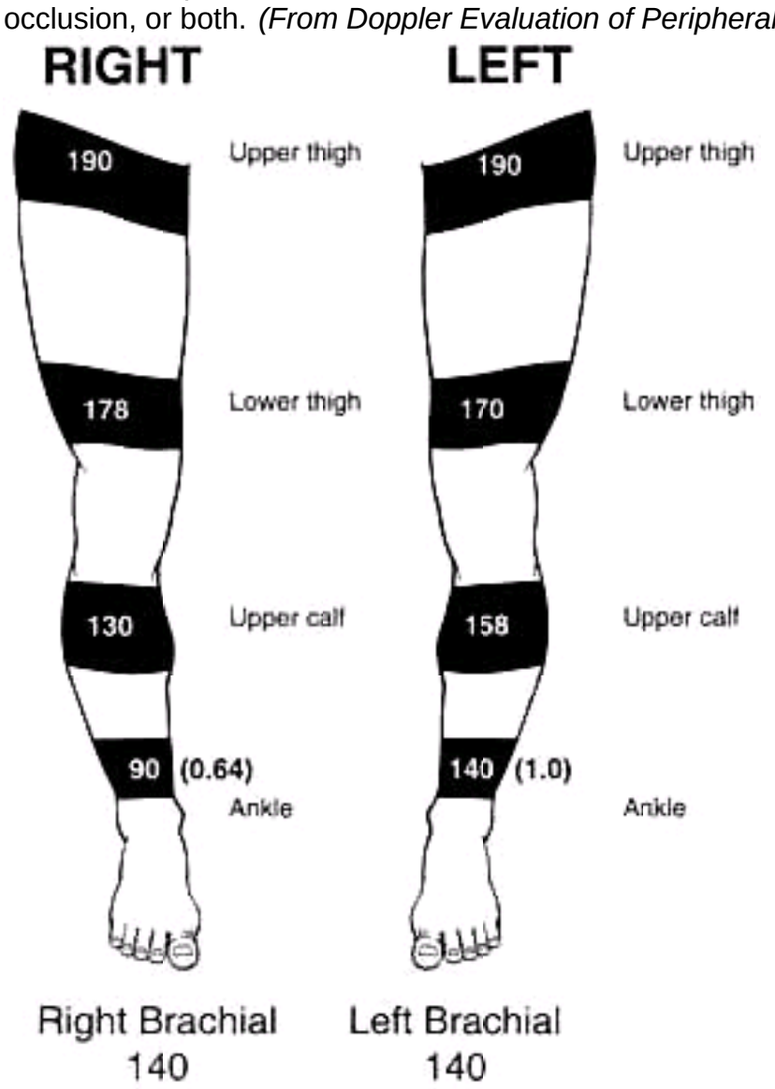

Figure 1-8 Typical pressures in a patient with obstruction of the abdominal aorta or bilateral iliac obstruction. Significant findings are as follows: (1) Ankle-to-brachial pressure index <0.9. (2) All segmental gradients <30 mm Hg. (3) Both upper thigh pressures relatively low with respect to brachial pressure. Findings are suggestive of severe aorto-iliac occlusive disease. *(From Doppler Evaluation of Peripheral Arterial Disease: A Clinical Handbook. Fredericksburg, VA, Sonicaid, Inc. Reproduced by permission.)*

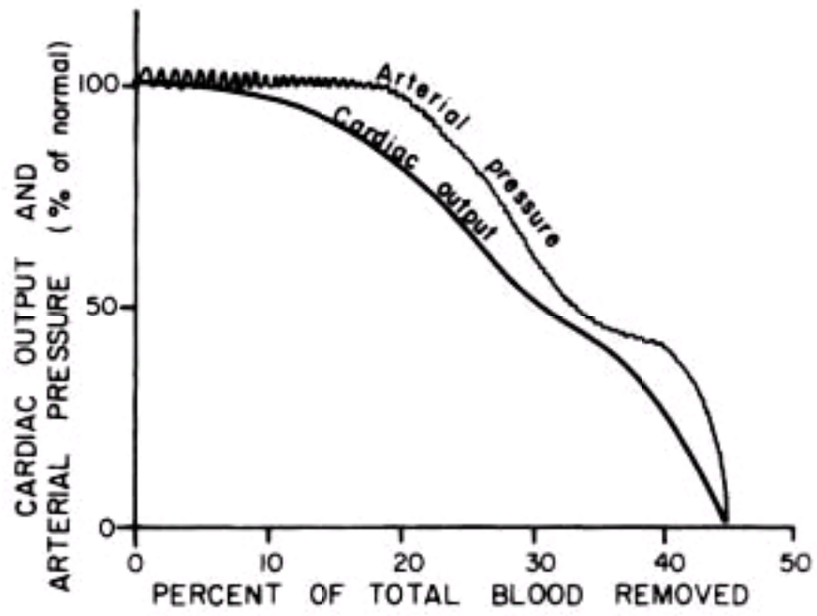

Figure 1-10 Relationship between oral and urinary temperatures constructed as a nomogram. Urinary temperatures are consistently within 1 to 1.5°C of simultaneously obtained oral temperatures and within 2°C of rectal temperatures. To use the nomogram, locate the oral temperature on the horizontal axis (*A*) and draw a perpendicular line to intersect the diagonal border of the graph (*B*). Follow the dotted horizontal line to the right to determine the expected urinary temperature on the longitudinal axis (*C*). The far right-hand scale (*D*) provides a 99% confidence level for the lower range of expected urinary temperatures and finding a value below the 99% confidence level is essentially diagnostic of a factitious fever. *(From Murray HW, Tuazon CU, Guerrero IC, et al: Urinary temperature: A clue to early diagnosis of factitious fever. N Engl J Med 296:23, 1977. Reproduced by permission of the New England Journal of Medicine.)*

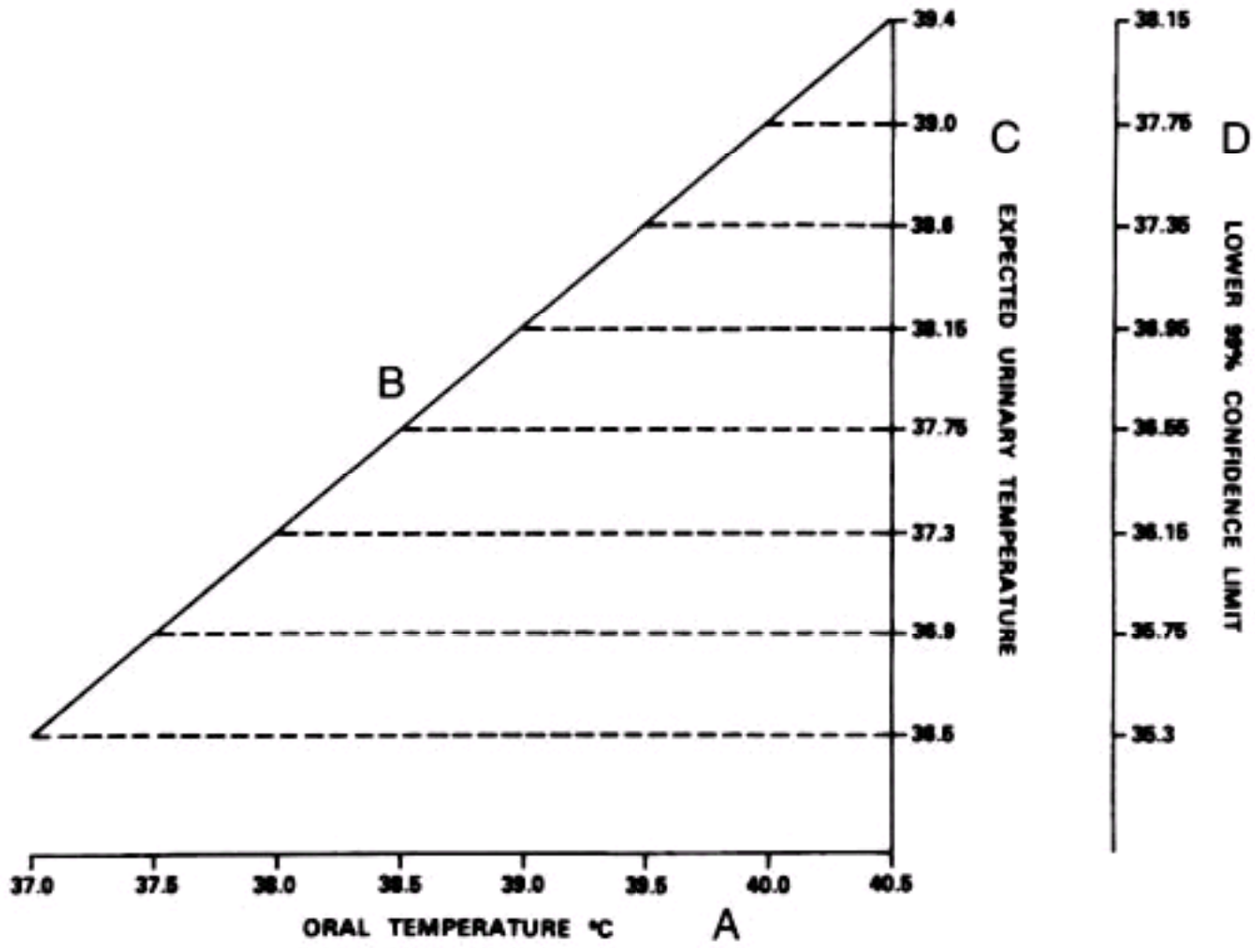

Figure 1-11 Temperature conversion scale. To change Celsius (centigrade) to Fahrenheit, multiply the Celsius temperature by 9/5 and add 32. To change Fahrenheit to Celsius, subtract 32 from the Fahrenheit number and multiply by 5/9.

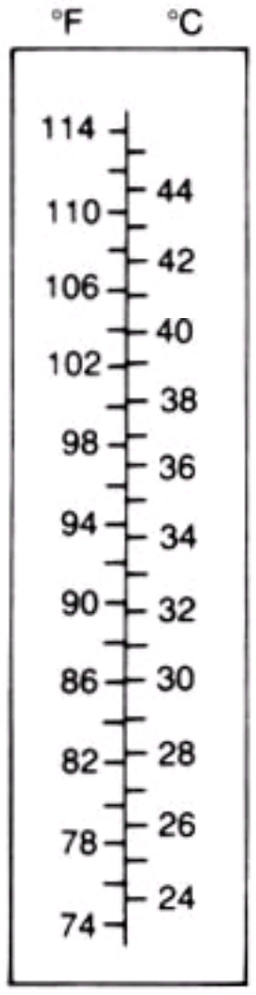

Figure 2-1 Time-forced vital capacity (FVC) is the volume of gas forcibly expelled following a maximal inspiration. Forced expiratory volume in 1 second (FEV_1) is the volume of gas expelled during the first second of the forced expiration. The other lung volumes obtainable are the tidal volume (TV), which is the volume of gas moved during quiet respiration; the inspiratory reserve volume (IRV), which is the volume of gas that can be inspired in addition to the tidal gas volume; and the expiratory reserve volume (ERV), which is the volume of gas that can be forcibly expired at the end of a tidal expiration. Some gas cannot be expired and remains in the chest. This is known as the residual volume (RV).

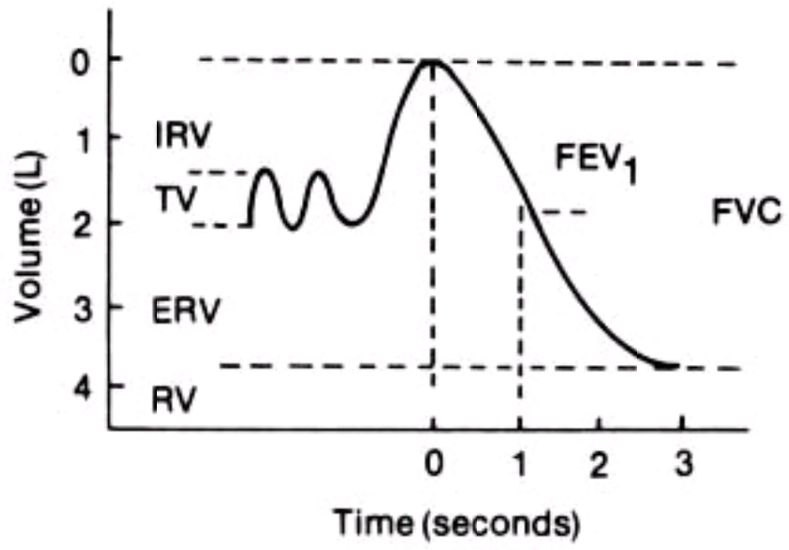

Figure 2-2 Wright peak flow meter. After resetting the dial to zero, the patient inhales fully and exhales forcefully through the disposable paper mouthpiece. The best of three attempts is recorded. A tight seal of the lips around the mouthpiece is required.

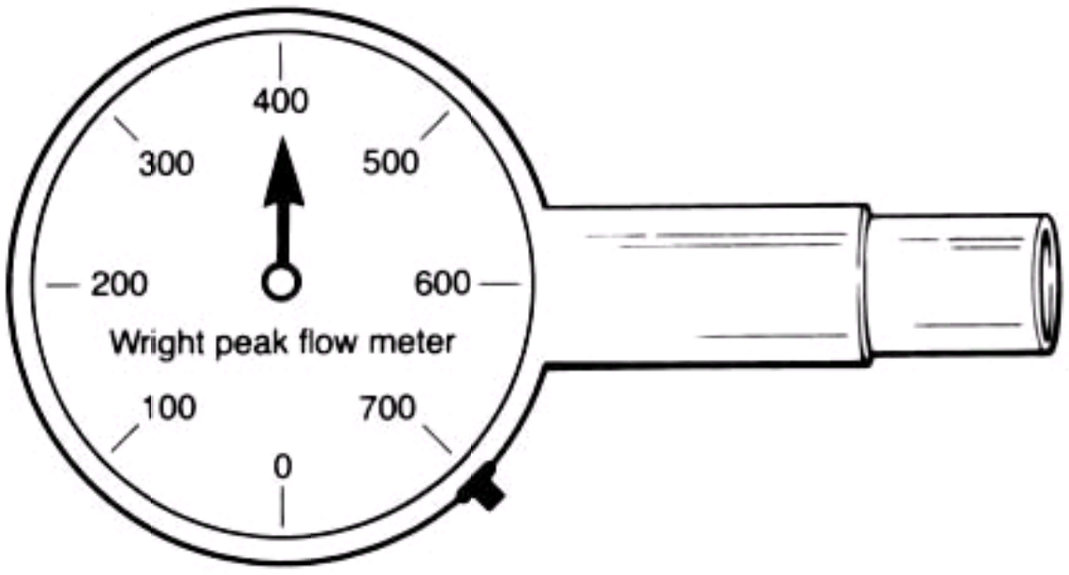

Figure 2-3 Mini-Wright peak flow meter. The indicator arrow is moved back to zero. The patient inhales fully and then exhales forcefully through the disposable paper mouthpiece. The best of three attempts is recorded. Patient cooperation and a tight seal of the lips around the mouthpiece are required.

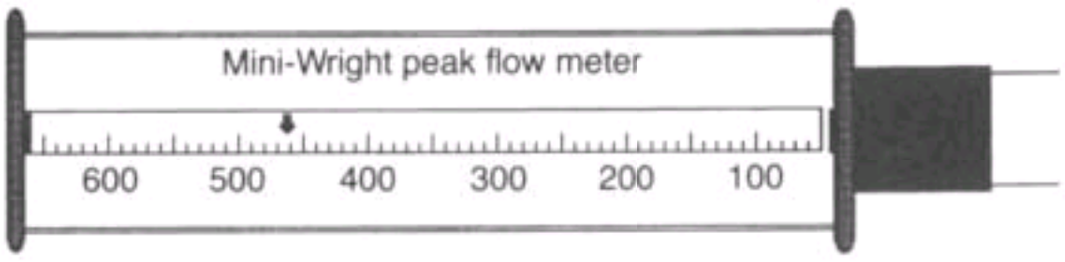

Figure 2-4 The Respiradyne portable spirometer. The device is turned on or "cleared" from the last effort. The patient exhales forcefully into the handheld mouthpiece following maximal inhalation. The "sequence" button permits selection of the desired spirometry measurements. The best of several tries should be recorded.

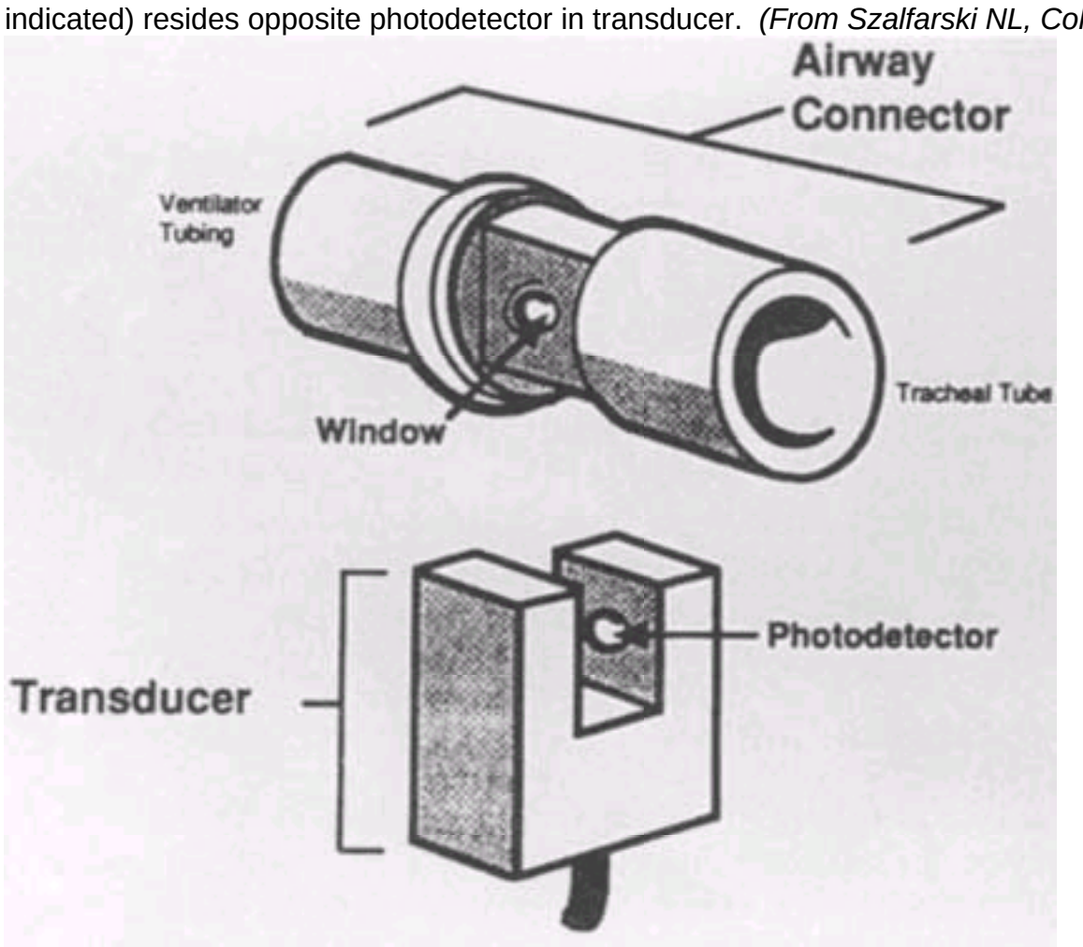

Figure 2-10 Schema of side-stream CO_2 sampling technique in capnography. *(From Szalfarski NL, Cohen NH: Use of capnography in critically ill adults. Heart Lung 20:363, 1991.)*

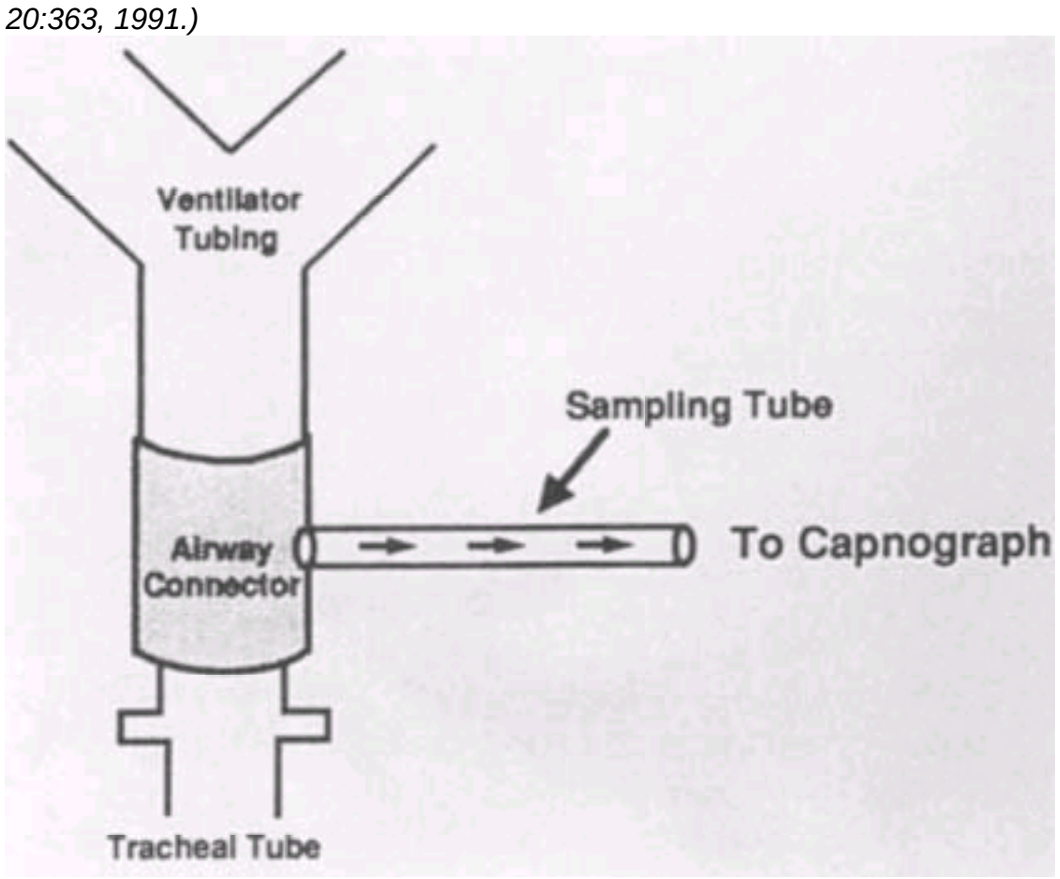

Figure 2-11 The four phases of a normal capnogram. Exhalation begins at point *B*. The steep ascending limb (segment *B–C*) represents rapidly exchanging alveoli. Segment *C–D* is the alveolar plateau representing uniformly ventilated alveoli, with a nearly constant CO_2 concentration. $PetCO_2$ is the highest point on the alveolar plateau (point *D*) and immediately precedes the next inspiration. Segment *D–E* rapidly descends to the original baseline (zero in normal subject) during inspiration (segment *A–B*). *(Courtesy of Novametrix Medical Systems, Inc., Wallingford, CT.)*

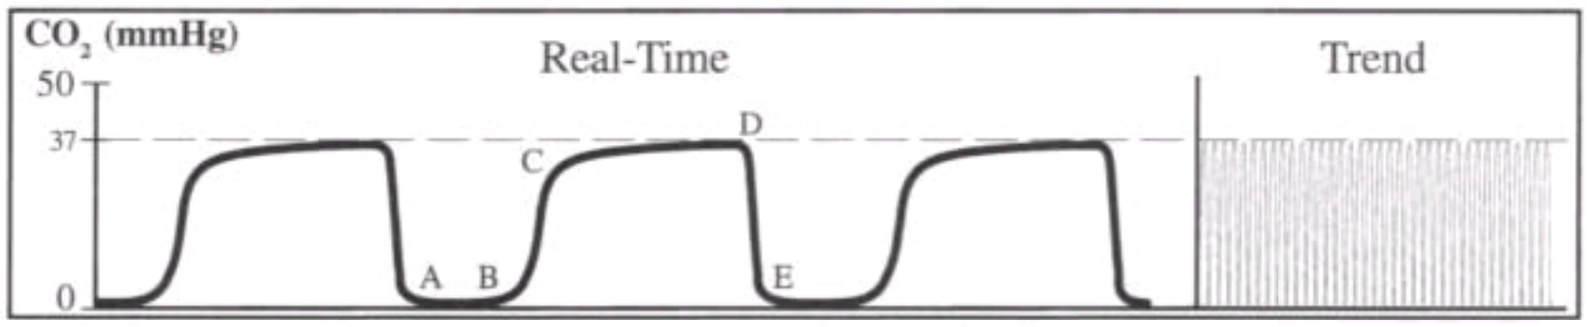

The "normal" capnogram is a waveform which represents the varying CO_2 level throughout the breath cycle.

Waveform Characteristics:

A–B	Baseline
B–C	Expiratory Upstroke
C–D	Expiratory Plateau
D	End Tidal Concentration
D–E	Inspiration Begins

Figure 2-12 Capnogram of patient with adult respiratory distress syndrome and pneumonia. Lack of a normal alveolar plateau is evident. *(From Szalfarski NL, Cohen NH: Use of capnography in critically ill adults. Heart Lung 20:369, 1991.)*

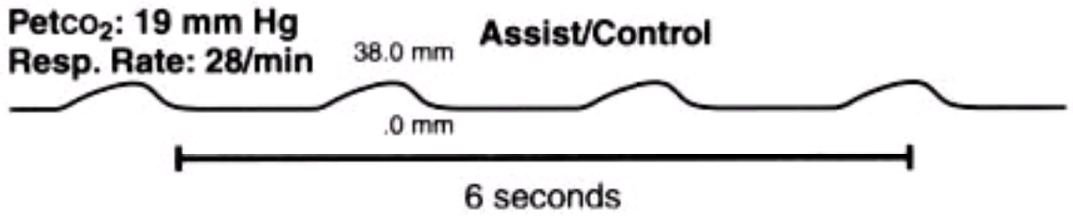

Figure 2-13 Esophageal capnogram after ingestion of carbonated beverage. *A*, CO_2 is clearly present as the esophagus is ventilated. The CO_2 concentration rapidly dissipates to the nonphysiologic range. *B*, The normal tracheal capnogram obtained simultaneously from the same experimental animal is shown. *(Modified from Garnett AR, Gervin CA, Gervin AS: Capnographic waveforms in esophageal intubations: Effect of carbonated beverages. Ann Emerg Med 18:387, 1989.)*

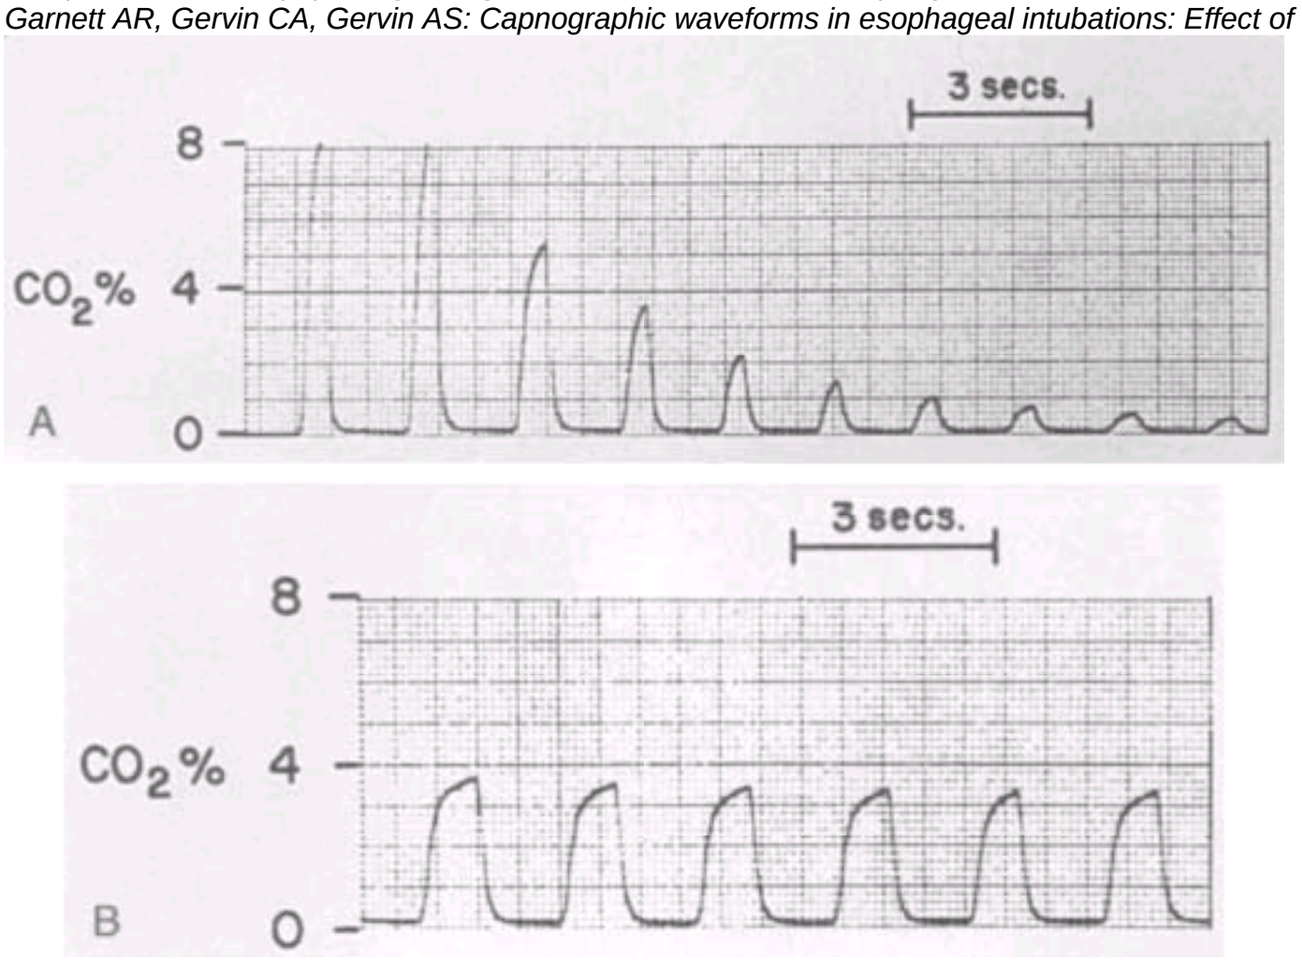

Figure 2-14 Partial endotracheal tube occlusion and other obstructions in the breathing circuit or airway. Note slurred upstroke of CO_2 waveform and absence of expiratory plateau. *(Courtesy of Novametrix Medical Systems, Inc., Wallingford, CT.)*

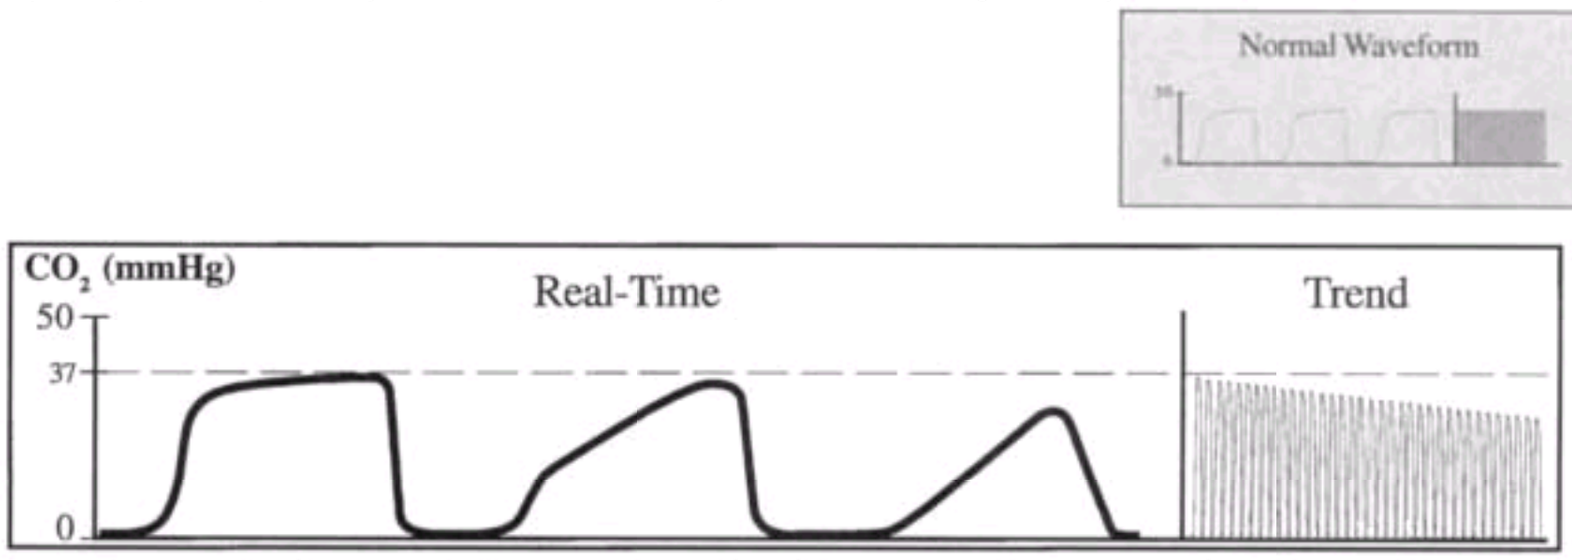
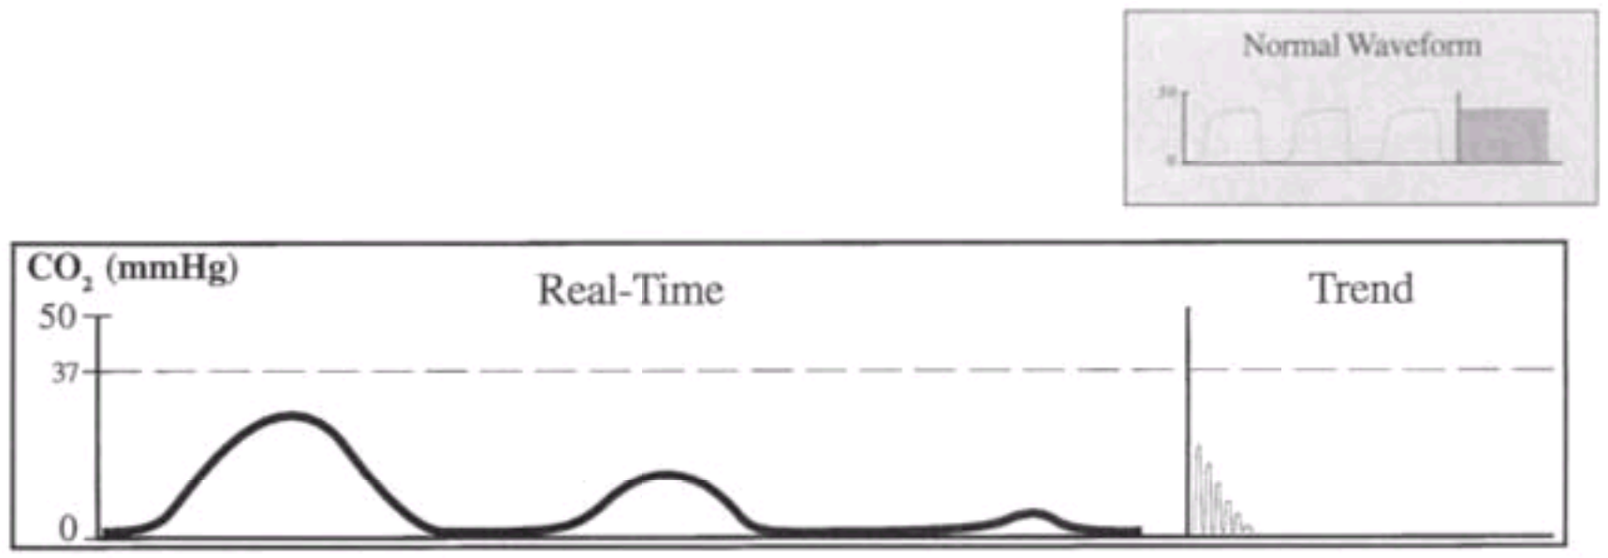


Obstructed expiratory gas flow is noted as a change in the slope of the ascending limb of the capnogram (the expiratory plateau may be absent).

Possible Causes:

- Obstruction in the expiratory limb of the breathing circuit
- Presence of a foreign body in the upper airway
- Partially kinked or occluded artificial airway
- Bronchospasm

Figure 2-15 Malposition of endotracheal tube in the esophagus. Note loss of capnographic waveform. *(Courtesy of Novametrix Medical Systems, Inc., Wallingford, CT.)*



Waveform Evaluation:

A normal capnogram is the best available evidence that the ET tube is correctly positioned and that proper ventilation is occurring. When the ET tube is placed in the esophagus, either no CO_2 is sensed or only small transient waveforms are present.

Figure 2-16 Occlusion of the endotracheal tube. Note that occlusion of a properly placed tube yields the same flat capnogram as esophageal intubation or accidental extubation. *(From Murray IP, Modell JH: Early detection of endotracheal tube accidents by monitoring carbon dioxide concentration in respiratory gas. Anesthesiology 59:345, 1983.)*

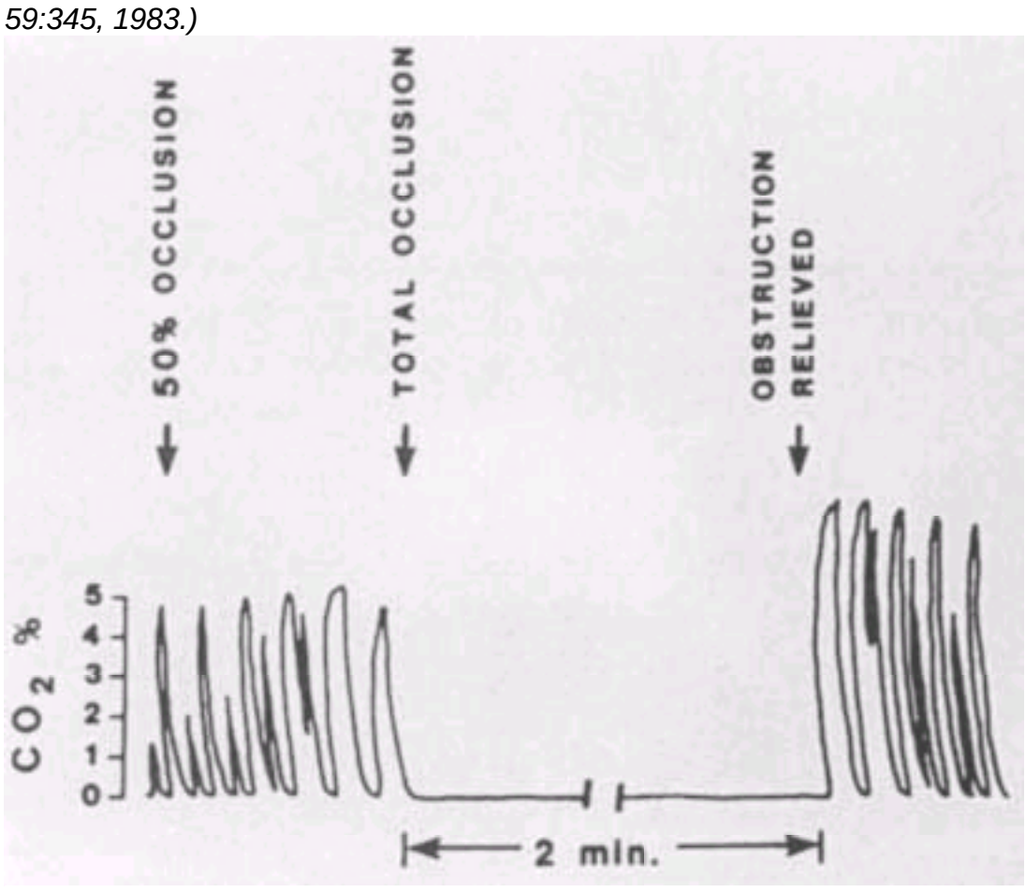


Figure 2-17 Capnogram of patient receiving assist-control ventilation and vecuronium paralyzation. *(Courtesy of Novametrix Medical Systems, Inc., Wallingford, CT.)*

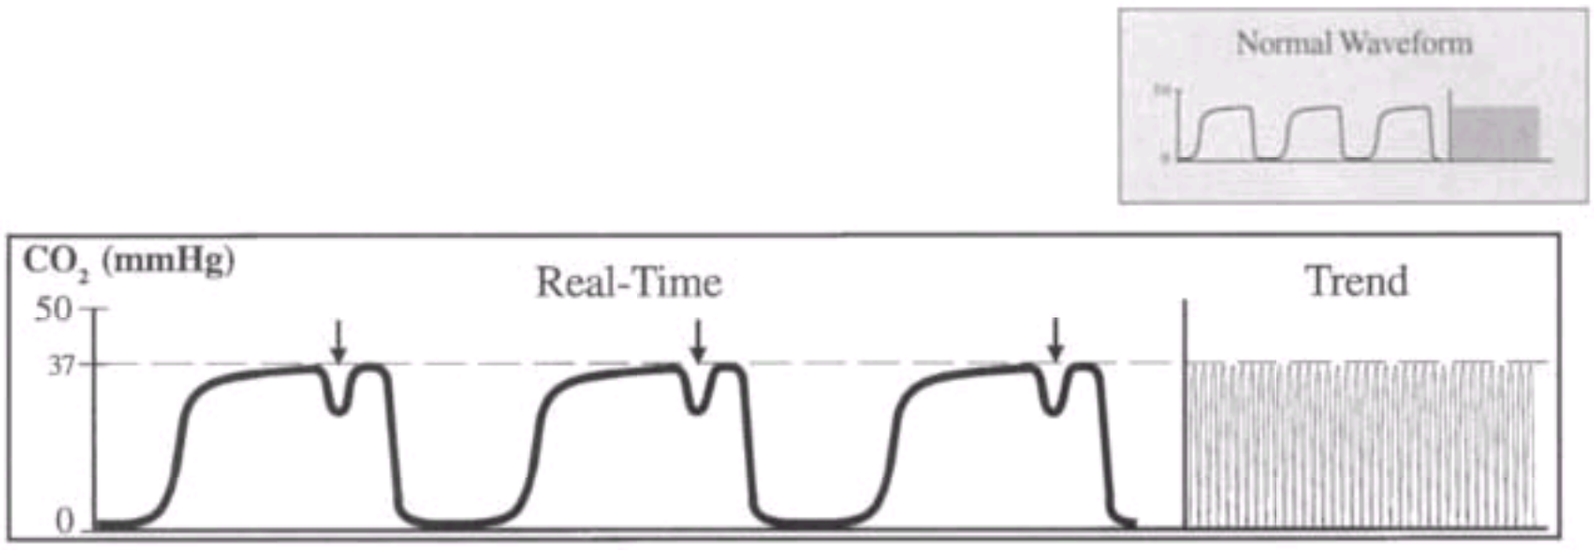
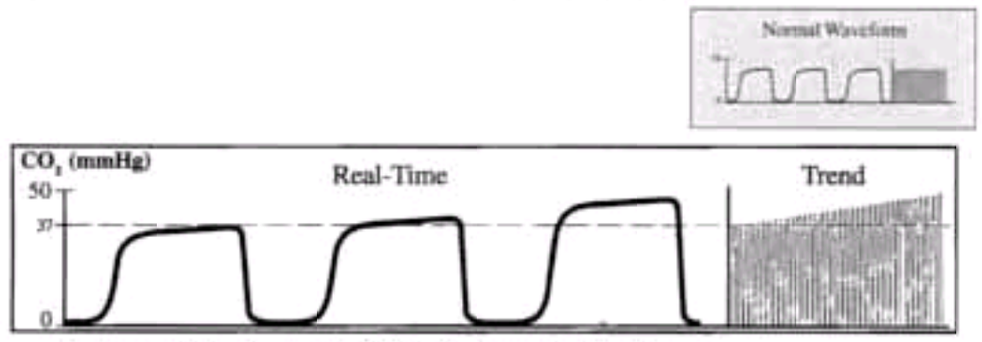


Clefts are seen in the plateau portion of the capnogram. They appear when the action of the muscle relaxant begins to subside and spontaneous ventilation returns.

Characteristics:

- Depth of the cleft is inversely proportional to the degree of drug activity
- Position is fairly constant on the same patient but not necessarily present with every breath

Figure 2-18 *A–F,* Various abnormal capnography patterns and their causes. *(Courtesy of Novametrix Medical Systems, Inc., Wallingford, CT.)*

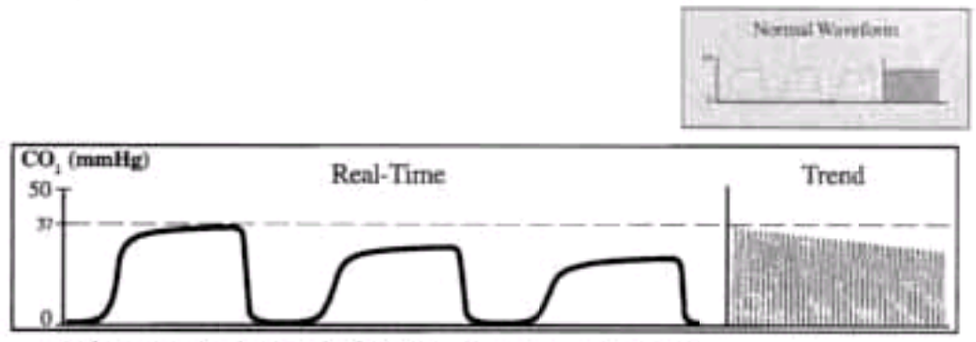


An increase in the level of $ETCO_2$ from previous levels.

Possible Causes:

- Decrease in respiratory rate (hypoventilation)
- Decrease in tidal volume (hypoventilation)
- Increase in metabolic rate
- Rapid rise in body temperature (malignant hyperthermia)

A

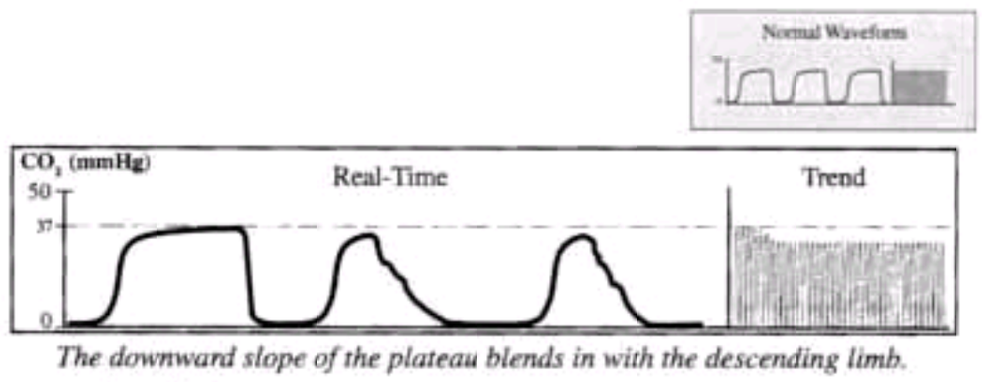


A decrease in the level of $ETCO_2$ from previous levels.

Possible Causes:

- Increase in respiratory rate (hyperventilation)
- Increase in tidal volume (hyperventilation)
- Decrease in metabolic rate
- Fall in body temperature

B

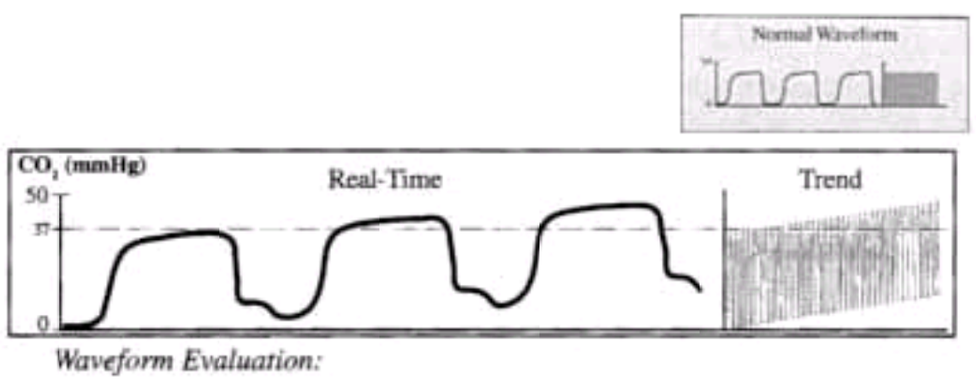


The downward slope of the plateau blends in with the descending limb.

Possible Causes:

- A leaky or deflated endotracheal or tracheostomy cuff
- An artificial airway that is too small for the patient

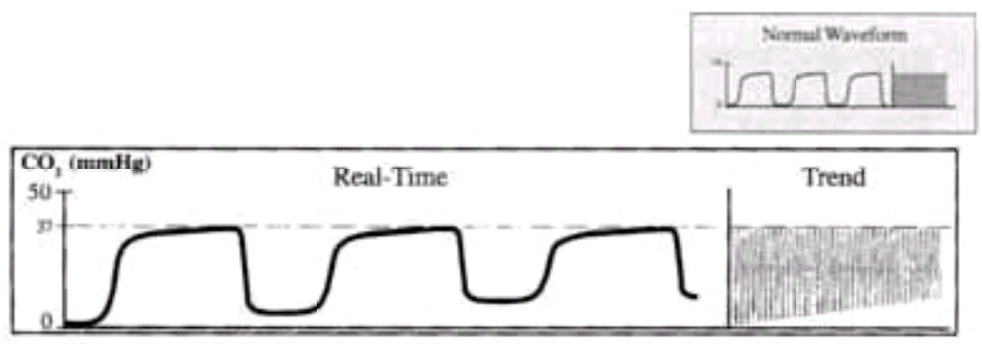
C



Waveform Evaluation:

- Baseline elevated
- Abnormal descending limb of capnogram
- Allows patient to rebreathe exhaled gas

D

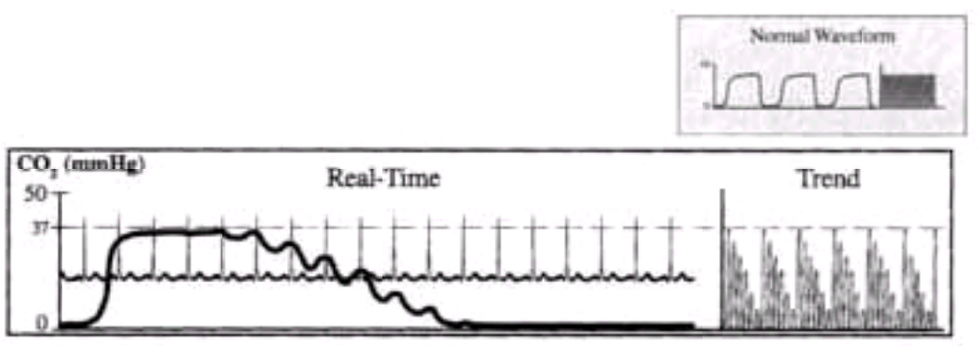


Elevation of the baseline indicates rebreathing (may also show a corresponding increase in $ETCO_2$).

Possible Causes:

- Faulty expiratory valve
- Inadequate inspiratory flow
- Malfunction of a CO_2 absorber system
- Partial rebreathing circuits
- Insufficient expiratory time

E



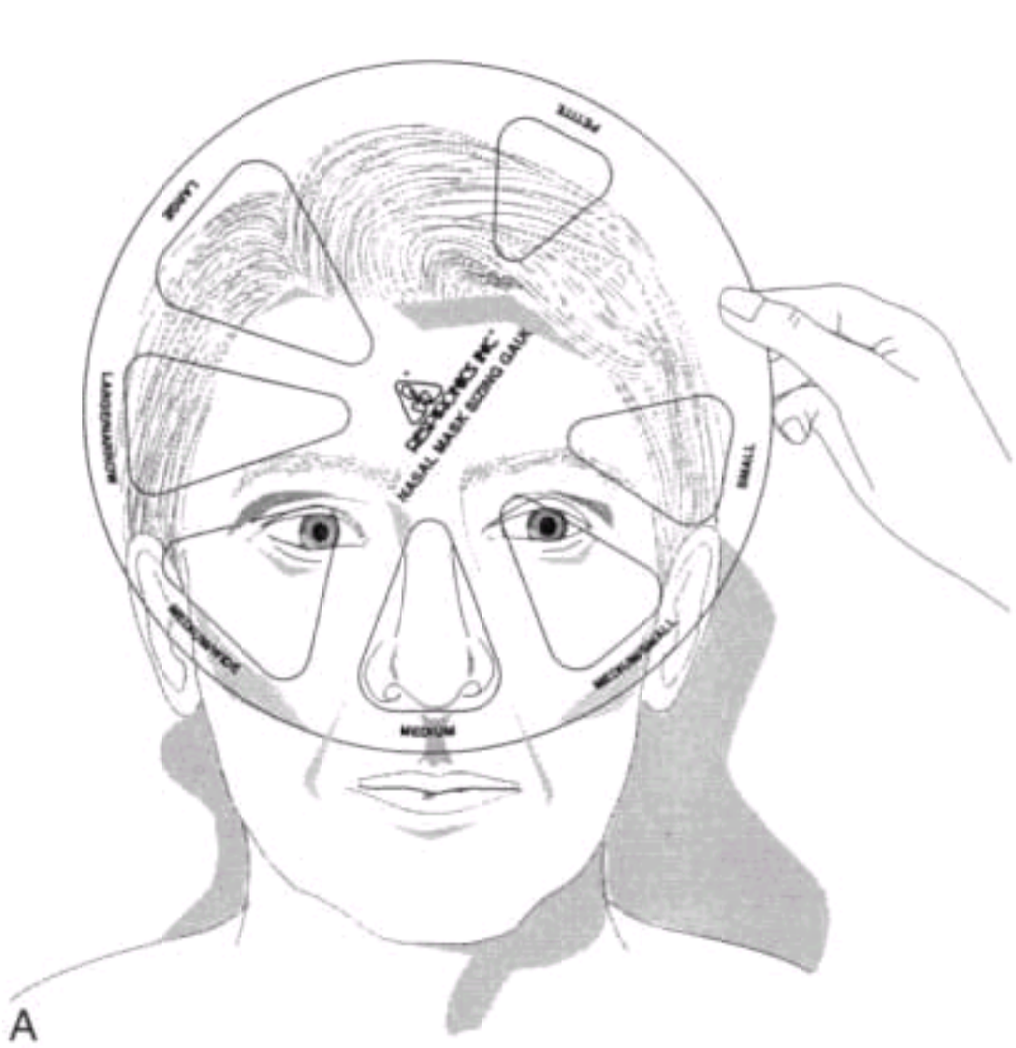
Cardiogenic oscillations appear during the final phase of the alveolar plateau and during the descending limb. They are caused by the heart beating against the lungs.

Characteristics:

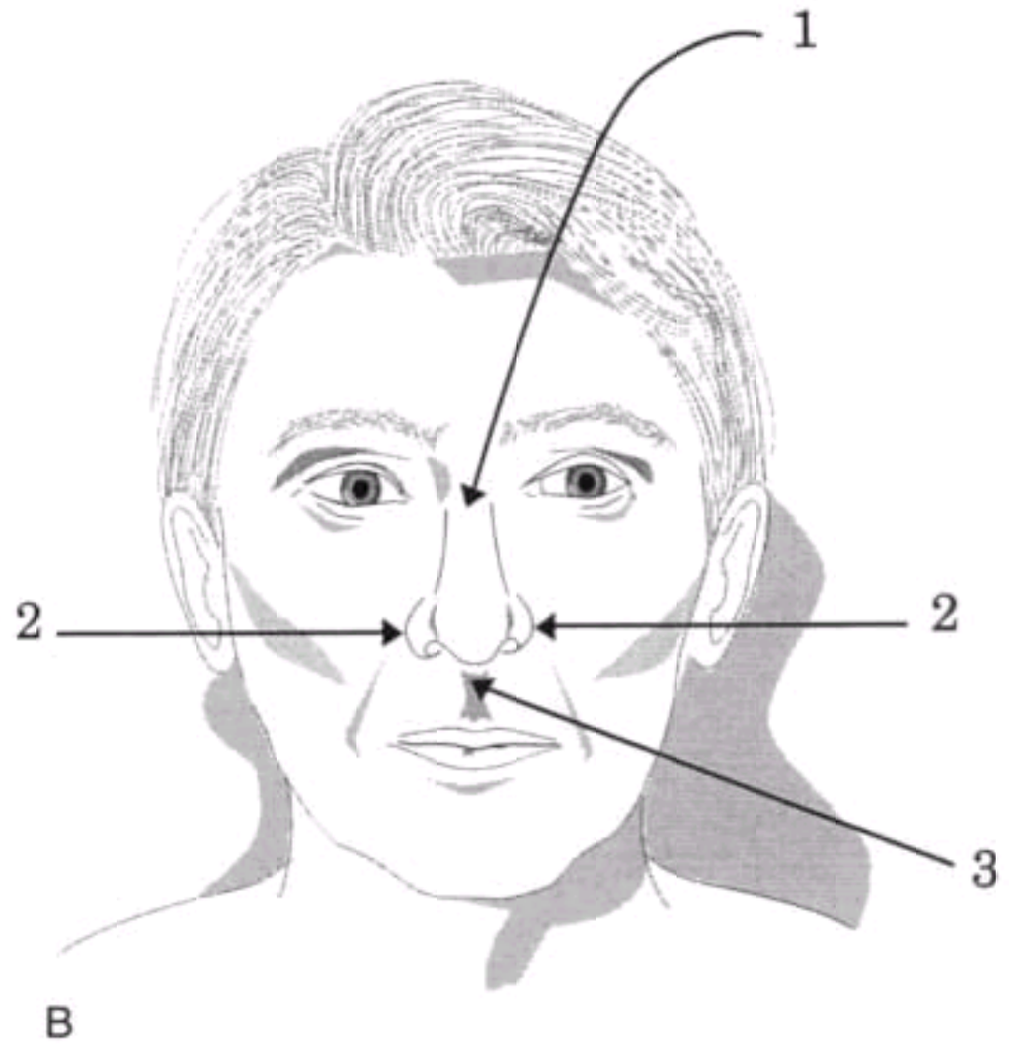
- Rhythmic and synchronized to heart rate
- May be observed in pediatric patients who are mechanically ventilated at low respiratory rates with prolonged expiratory times

F

Figure 2-19 Use of template to size nasal mask for BiPAP System. *A*, The nasal mask sizing gauge is placed over the patient's nose. The size that comes close to, but does not touch, the nose in three locations is selected. *B*, The sites to avoid direct contact: (1) just above the junction of the nasal bone and cartilage; (2) on the sides of both nares; and (3) just below the lowest point of the nose, above the lip. *Remember to use the smallest size mask that will sufficiently cover the nasal area.* Too small a mask will produce skin discomfort or injury. Too large a mask will increase air leak. *(Courtesy of Respironics Inc., Murrysville, PA.)*

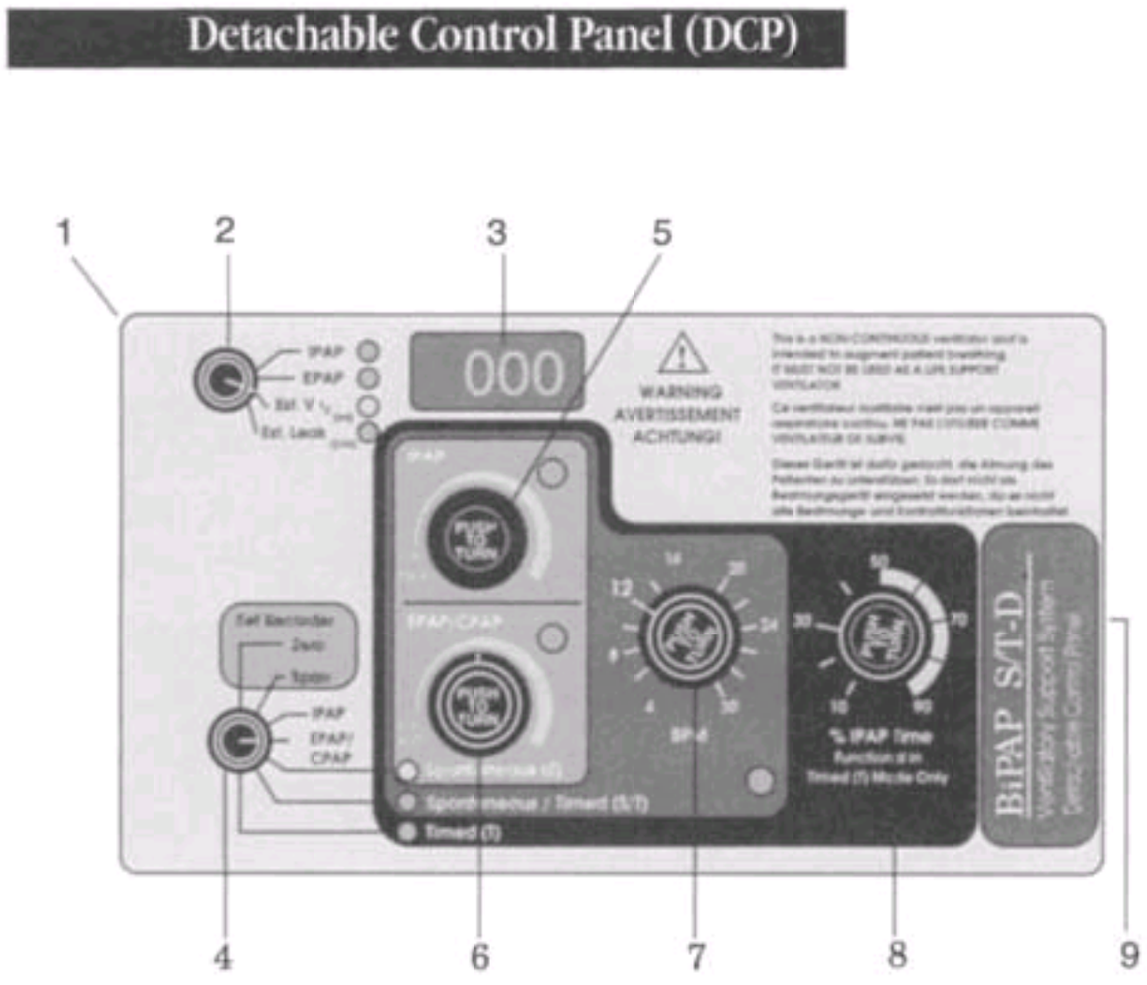


A



B

Figure 2-20 Control panel of BiPAP System. Note control setting for ventilation mode in lower left corner (see text for use of settings). For spontaneously breathing patients in respiratory distress, the "spontaneous" mode is generally selected and IPAP and EPAP settings selected. *(Courtesy of Respironics Inc., Murrysville, PA.)*



1 Puts controls at fingertips of hospital staff.

2 **Display Selector** determines the type of information shown on the Digital Display:
- **IPAP** setting displays delivered inspiratory pressure level
- **EPAP** setting displays delivered expiratory pressure level
- **Estimated Tidal Volume** setting displays estimated exhaled tidal volume
- **Estimated Leak** setting displays estimated circuit leak

3 **Digital Display** provides data for patient monitoring:
- Provides continuous monitoring of estimated exhaled tidal volume
- Allows verification of circuit pressures
- Offers capability to monitor circuit leaks
- Indicator lights specify which display parameter is active

4 **Function Selector** sets one of four different modes of operation:
- **Spontaneous (S) mode.** The unit cycles between IPAP and EPAP in response to the patient rate. The difference between IPAP and EPAP is the delivered pressure support level.
- **Spontaneous/Timed (S/T) mode.** The unit cycles as in the S mode. In addition, if the patient fails to initiate an inspiration within the timed interval, the unit will cycle to IPAP based on the Breaths Per Minute (BPM) control setting.
- **Timed (T) mode.** The unit cycles between IPAP and EPAP levels based solely on set BPM and % IPAP Time Controls.
- **Continuous Positive Airway Pressure (CPAP) mode.** Allows system to be used for CPAP delivery.

5 **IPAP control** sets prescribed inspiratory pressure level. Range: 4 cm H_2O to 20 cm H_2O.

6 **EPAP control** sets prescribed PEEP level. Range: 4 cm H_2O to 20 cm H_2O.

7 **Breaths Per Minute (BPM) control** sets the number of breaths per minute. Range: 4 to 30 breaths per minute. Active in S/T and T modes.

8 **% IPAP Time control** works in conjunction with the BPM control and determines the fraction of the respiratory cycle spent in IPAP. Range: 10% to 90%. Active only in T mode.

9 **Isolated DC analog outputs** (on side) for recorder include:
- Estimated Tidal Volume
- Pressure
- Total Flow
- Estimated Patient Flow

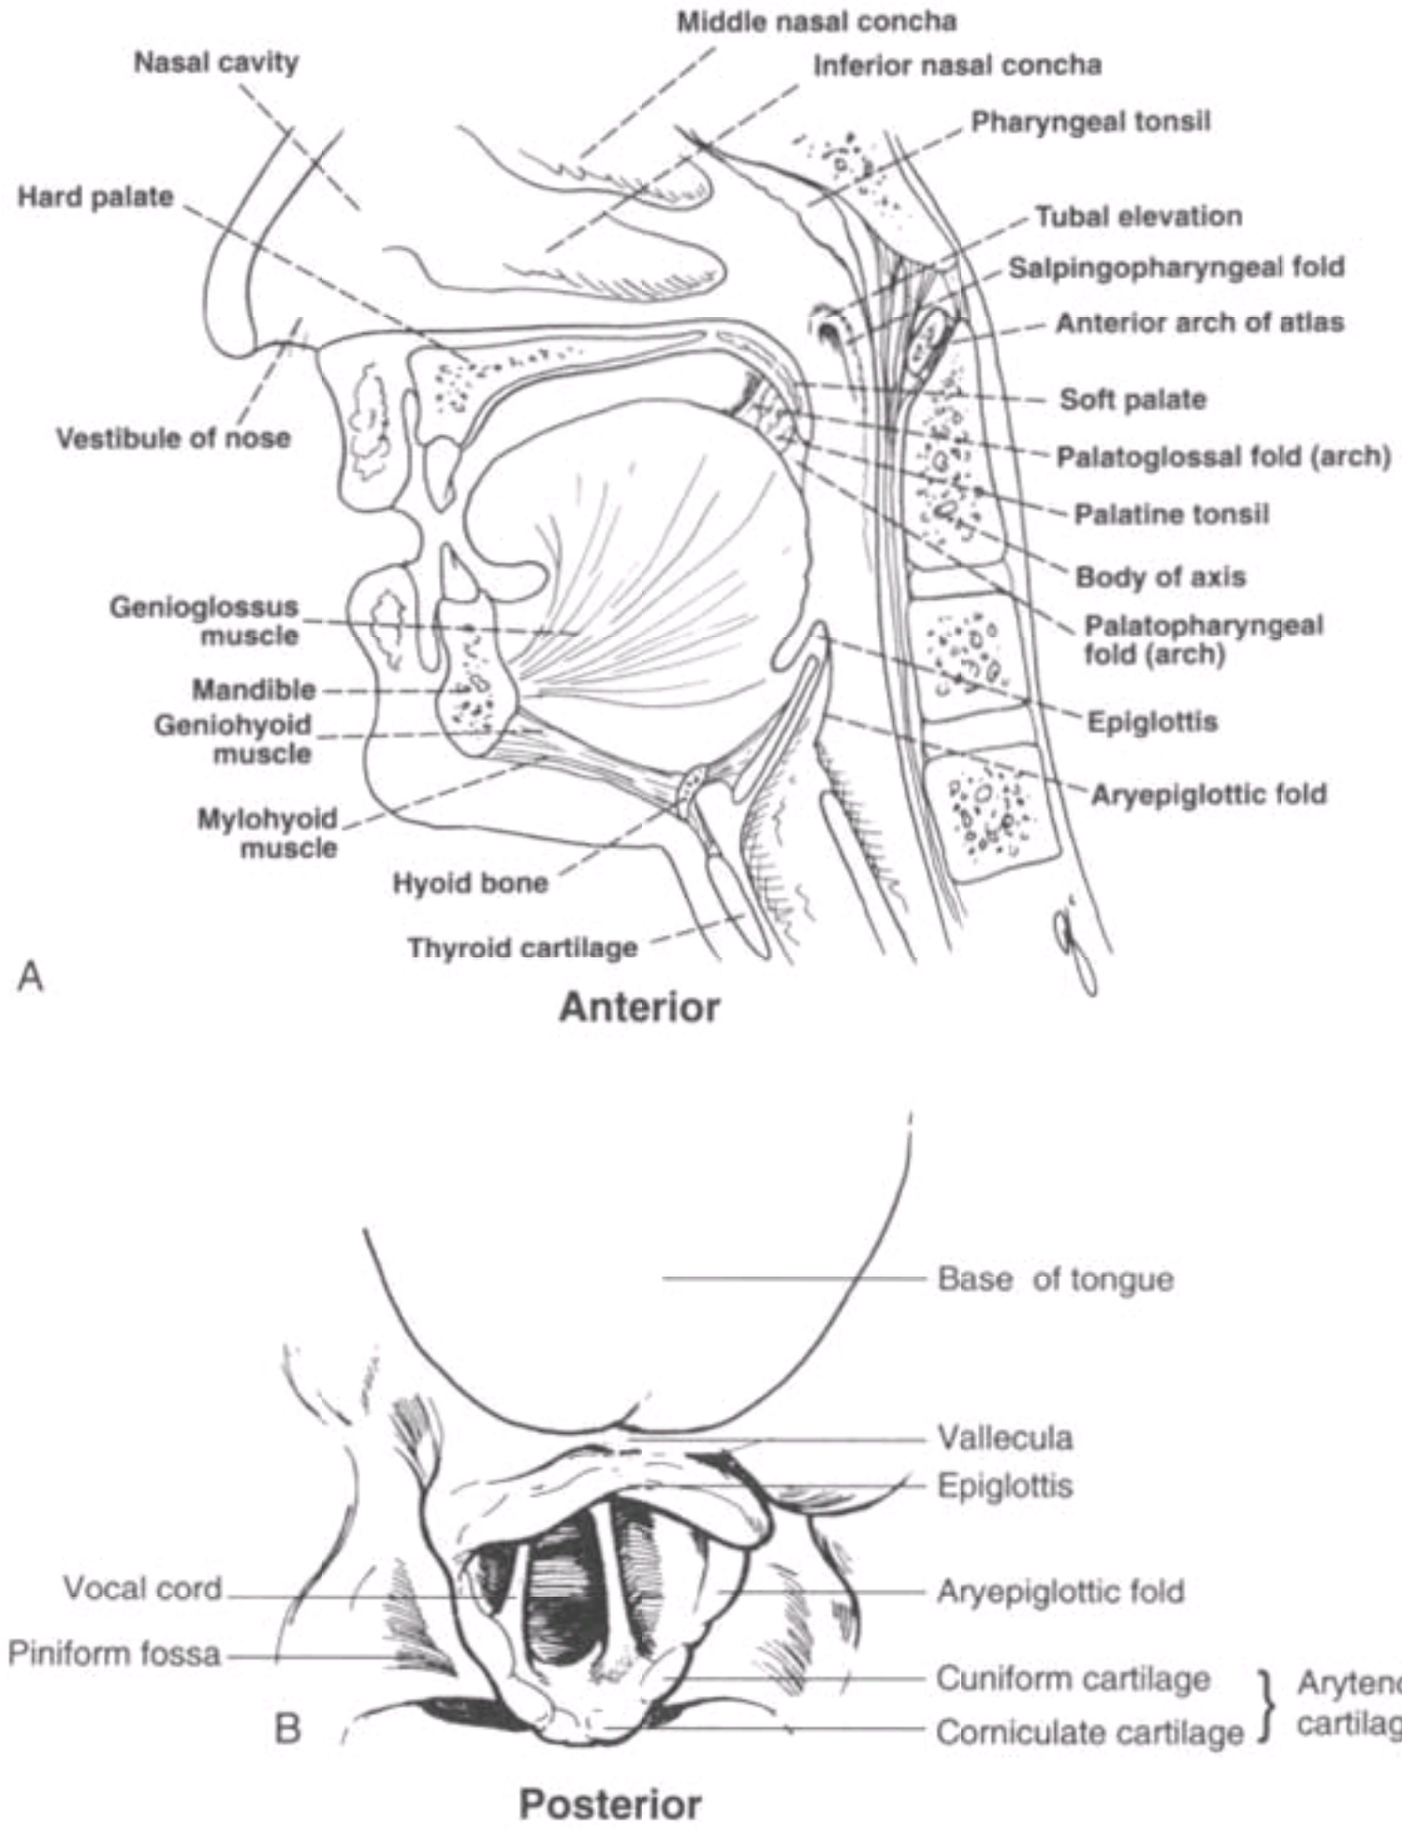

Figure 4-3 Pediatric endotracheal tube size estimation using fingernail width of the 5th finger.

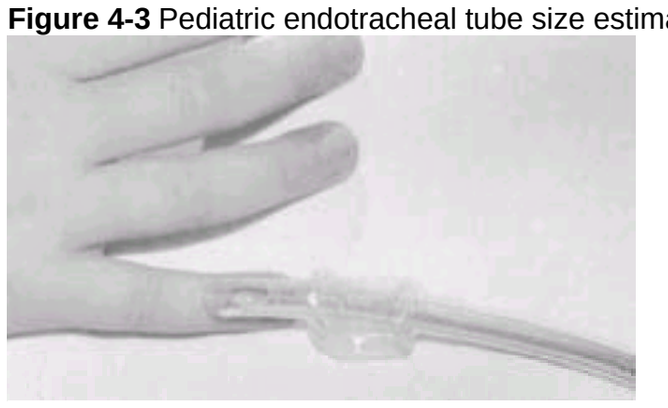

Figure 4-4 Head positioning for tracheal intubation. *A,* Neutral position. *B,* Head elevated. *C,* "Sniffing" position, with flexed neck and extended head. Note how flexing the neck and extending the head to line up the various axes allows for intubation. This position creates the shortest distance and straightest line between the teeth and vocal cords.

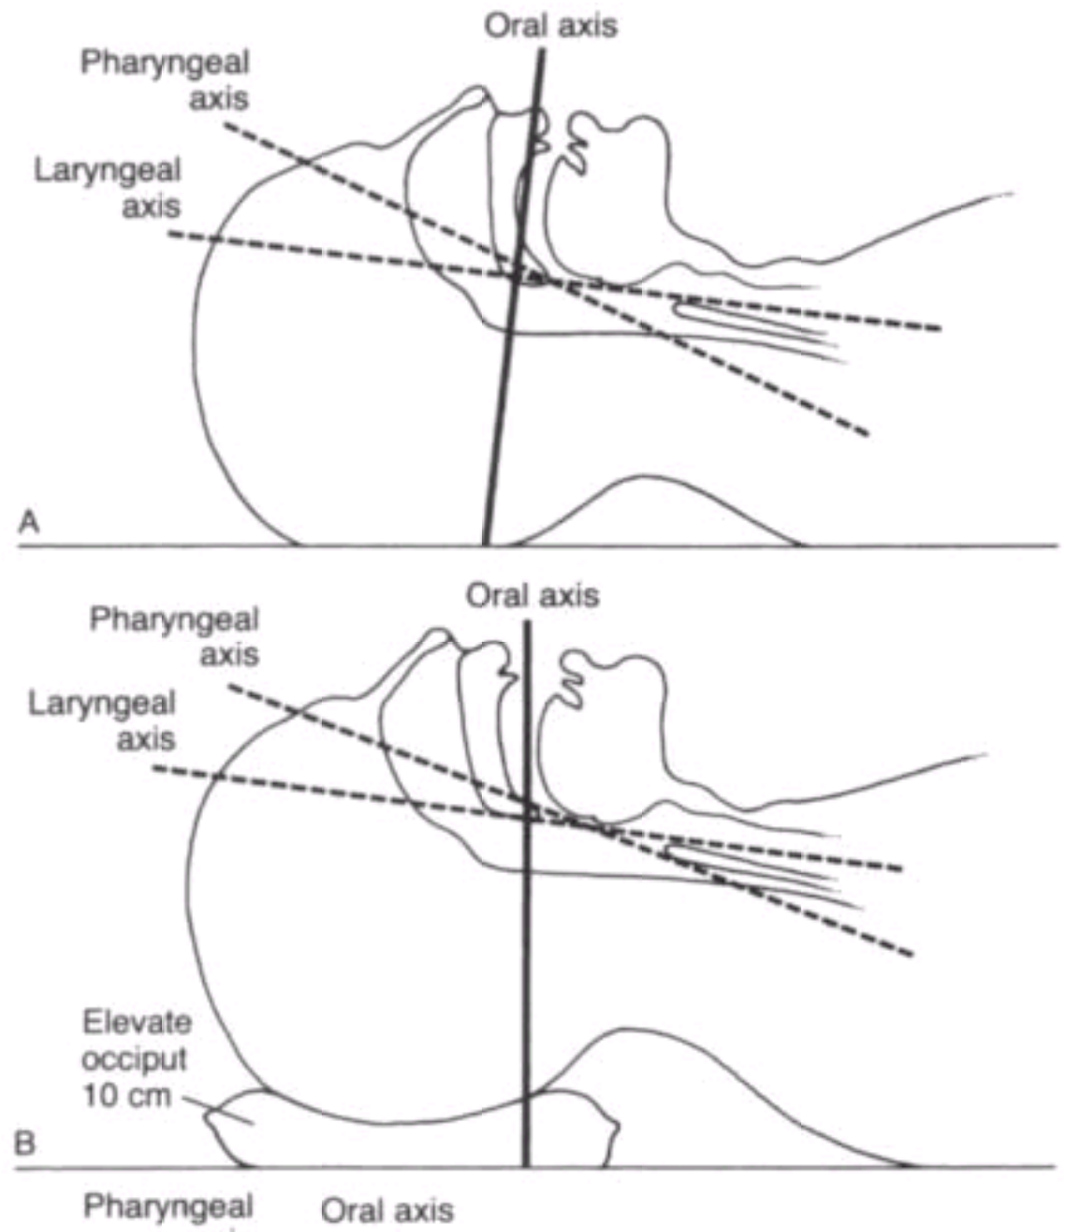

Figure 4-5 *A*, Mallampati classification predicting difficulty of intubation based on visibility of intraoral structures: Intubation should pose no difficulty in patient in class I or II, moderate difficulty in class III, and severe difficulty in class IV. *(A from Whitten CE: Preintubation evaluation: Predicting the difficult airway. Emerg Med 21:111, 1989.) B*, A difficult intubation also may be expected if the distance from the mentum of the chin to the hyoid bone in an adult is less than three fingerbreadths when the head is extended. Patients with a shortened distance often have a hypoplastic or poorly developed mandible or a short, thick neck, resulting in an anterior larynx that may be best approached with the straight blade and cricoid pressure.

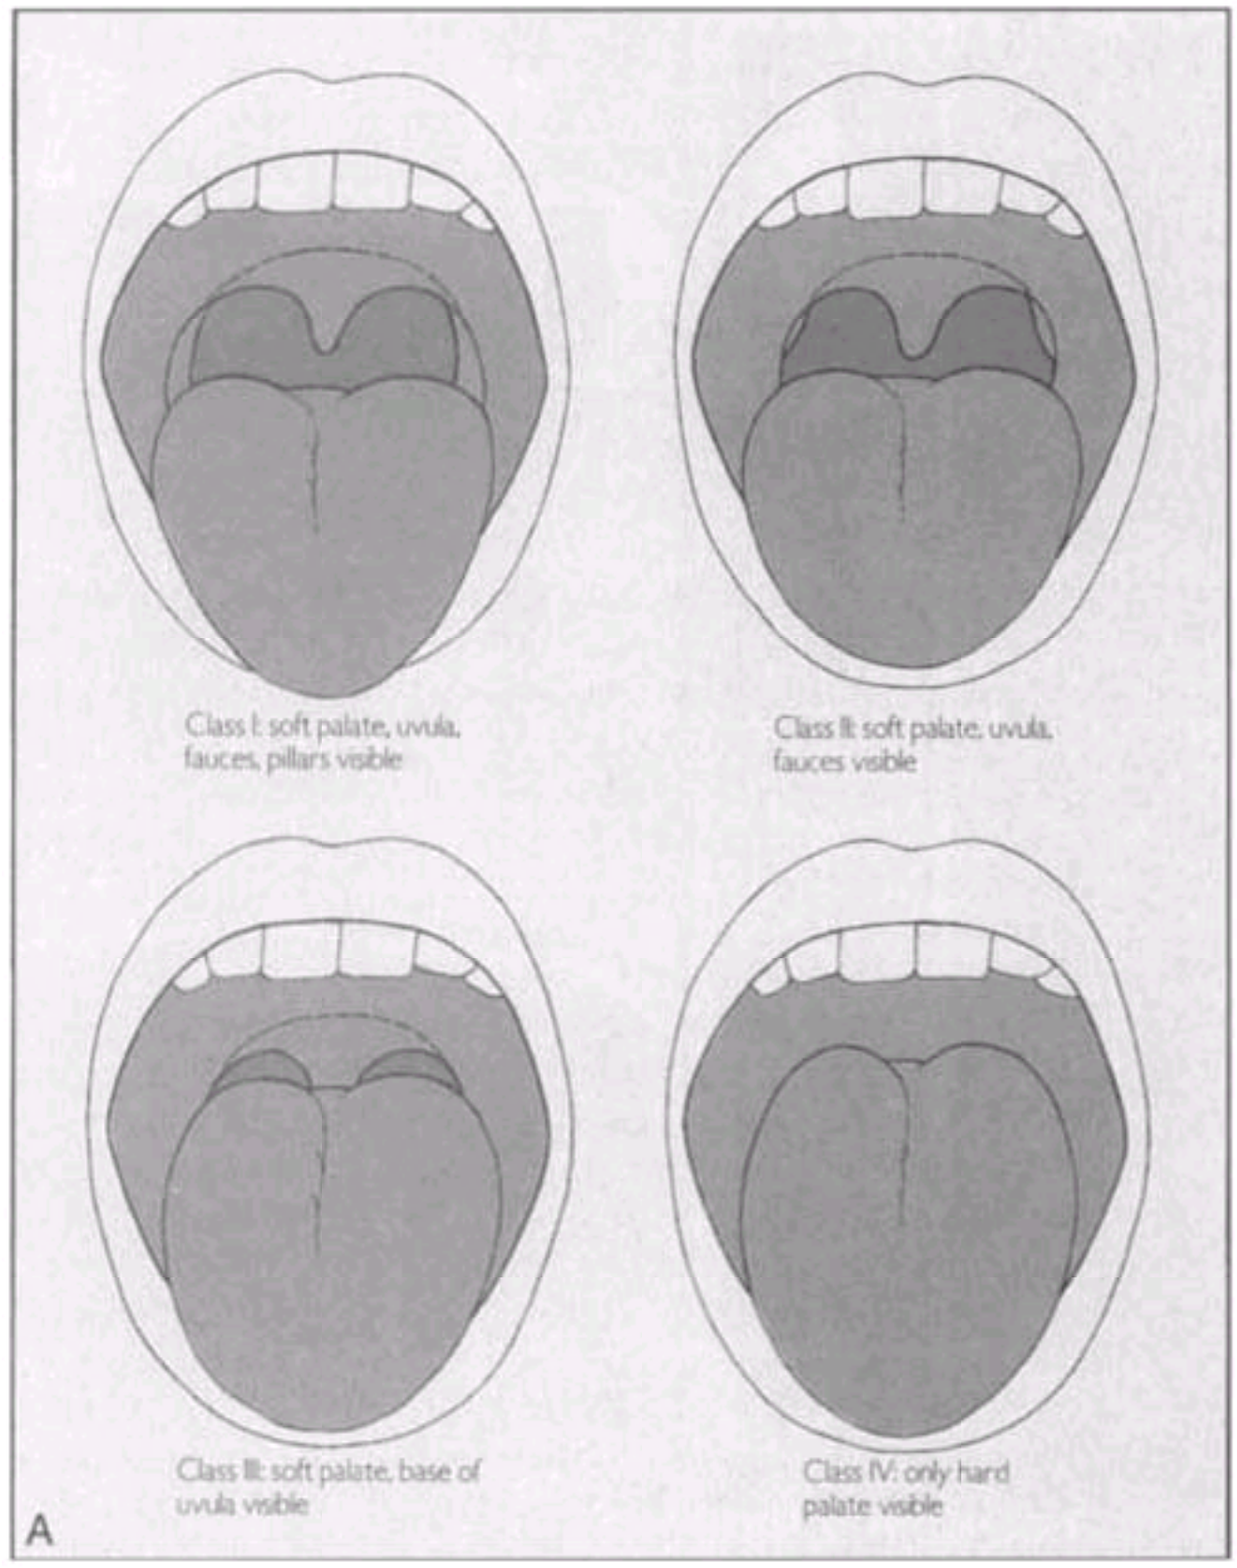

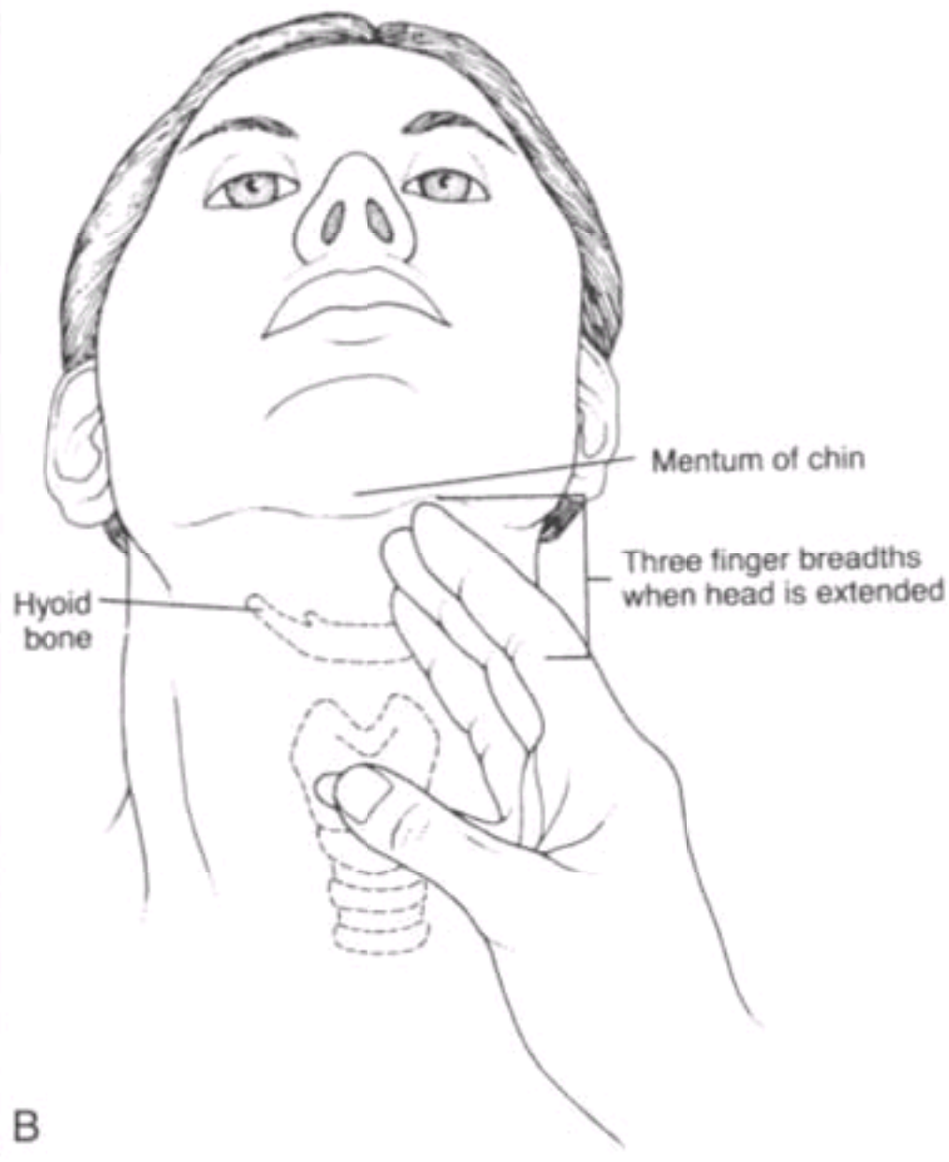

Figure 4-6 Proper positioning of clinician, patient, and assistant for tracheal intubation.

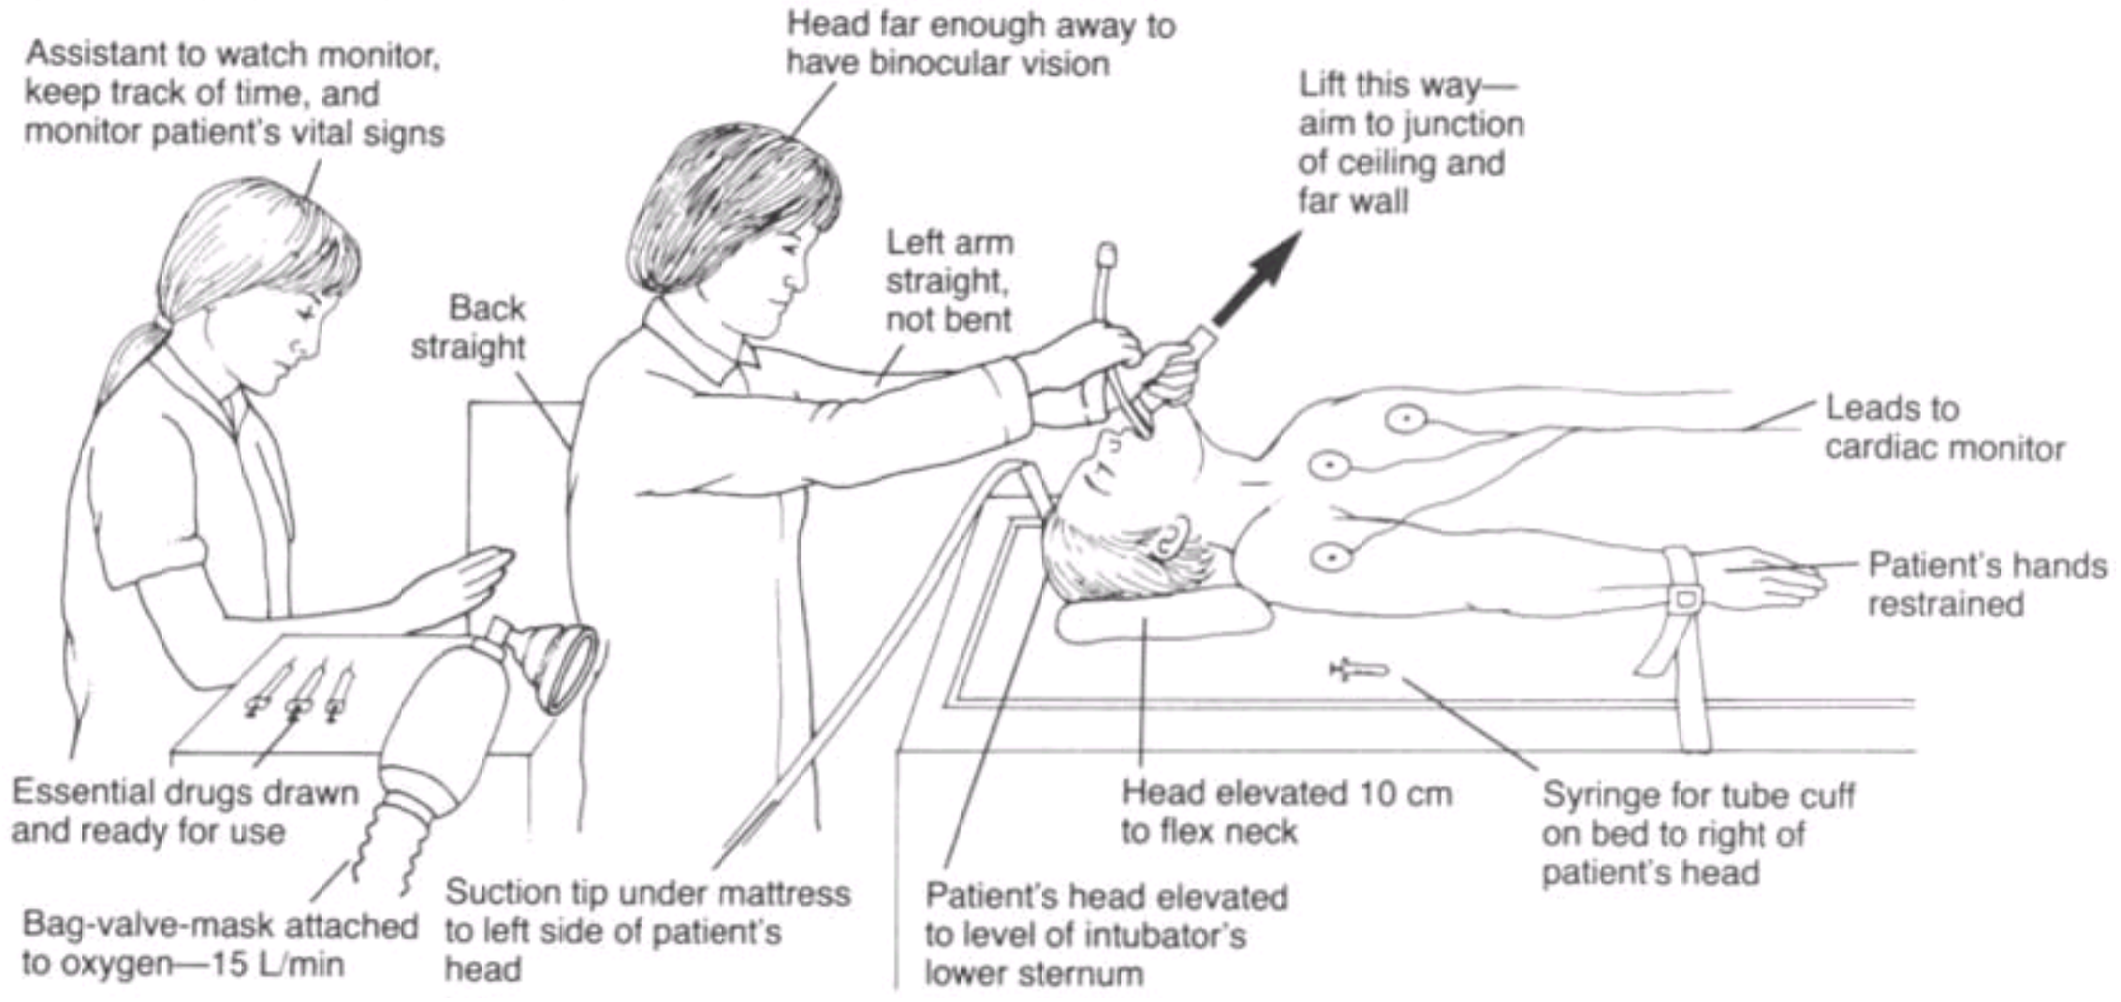

Figure 4-7 Common problems encountered with the laryngoscope: *A,* Laryngoscope blade under the middle of the tongue, with the sides of the tongue hanging down and obscuring the glottis. *B,* Tongue not pushed far enough to the left, obscuring the glottis. *C*, Correct blade position with tongue elevated and to the left. *D,* Use of the curved (MacIntosh) laryngoscope blade. *E,* Use of the straight (Miller) blade.

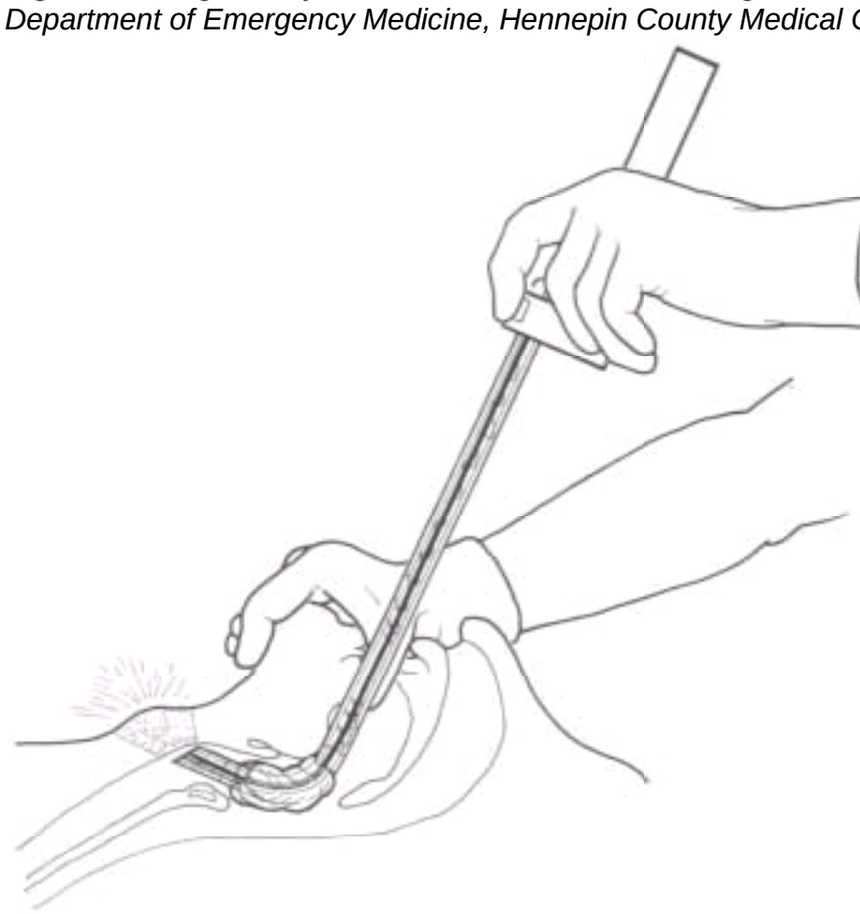

Figure 4-21 Fiberoptic nasotracheal intubation. Note use of the fiberoptic scope as a guide over which the tracheal tube is passed. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

Figure 4-22 Fiberoptic orotracheal intubation. A fiberoptic scope is passed through a hollow oral airway device to help position the scope and tube and to protect them from being bitten during fiberoptic oral intubation. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

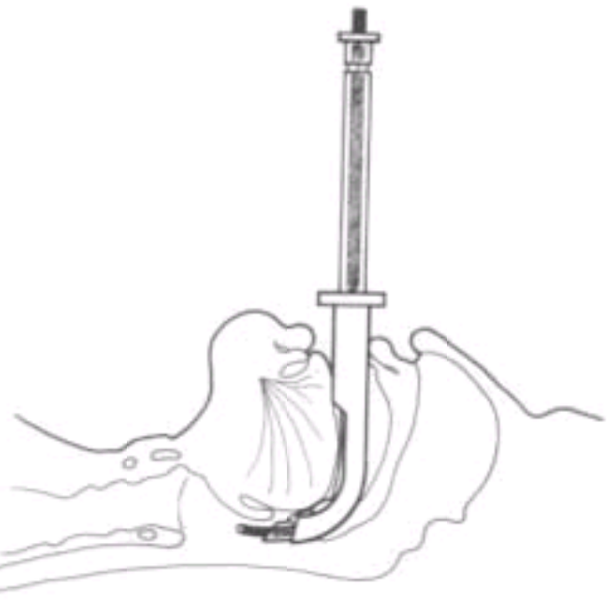

Figure 4-23 Retrograde intubation using guidewire and antegrade sheath. *A*, Placement of a needle through the cricothyroid membrane (note: needle bevel is oriented cephalad). *B*, Placement of the J-wire directed cephalad through the translaryngeal needle. *C*, Passing antegrade sheath over the guidewire. *D*, Removal of guidewire with advancement of sheath into trachea. *E*, Advancement of tracheal tube over sheath into trachea. *F*, Removal of the sheath. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

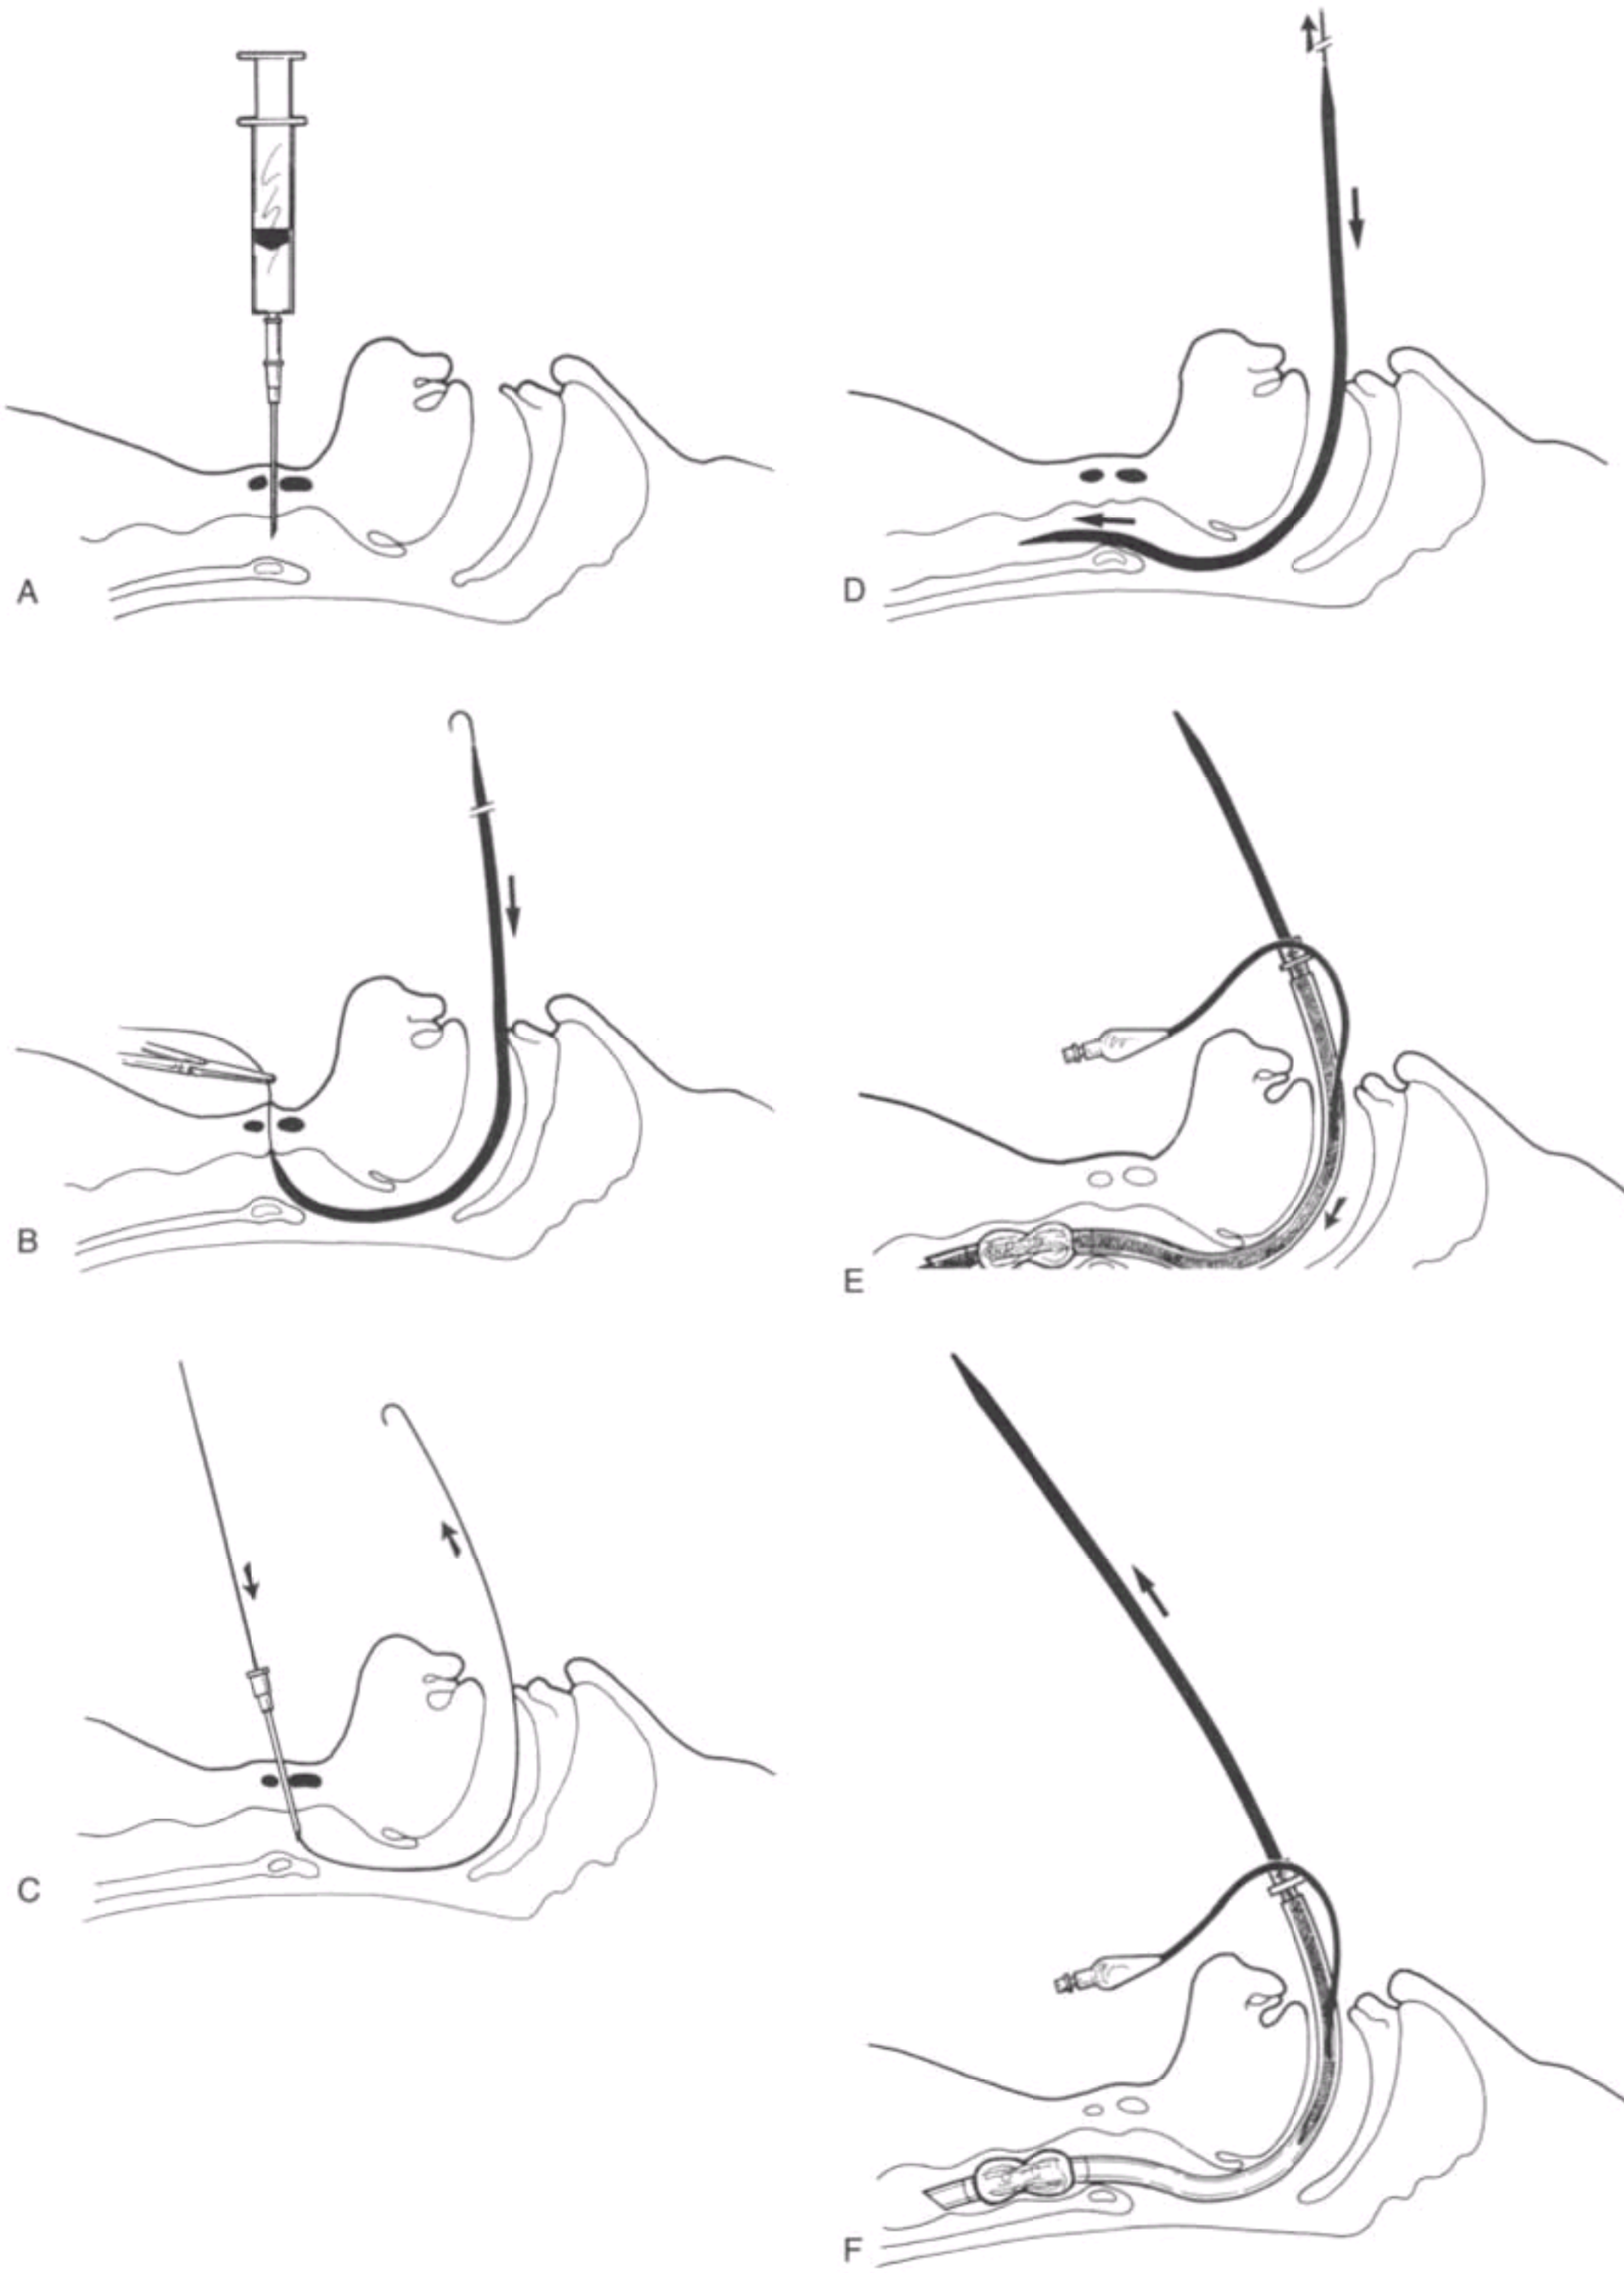

Figure 4-24 Fiberoptic scope as an aid in retrograde intubation. Once the retrograde wire (long) is placed and retrieved superiorly, the wire is threaded through the tip of the fiberoptic scope and out through the suction port. The scope is then advanced until it passes through the vocal cords, stopping at the anterior laryngeal wall. The wire is withdrawn through the suction port, the fiberoptic scope is advanced into the trachea, and the tracheal tube advanced over the scope into the trachea. The fiberoptic scope is then withdrawn. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

Figure 4-25 Replacing damaged tracheal tube. *A,* Placement of tracheal tube exchanger down damaged tube and deep into trachea (*open arrow*) followed by removal of tracheal tube (*solid arrow*). *B,* Replacement tube is passed over tube exchanger into trachea, followed by removal of tube exchanger. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

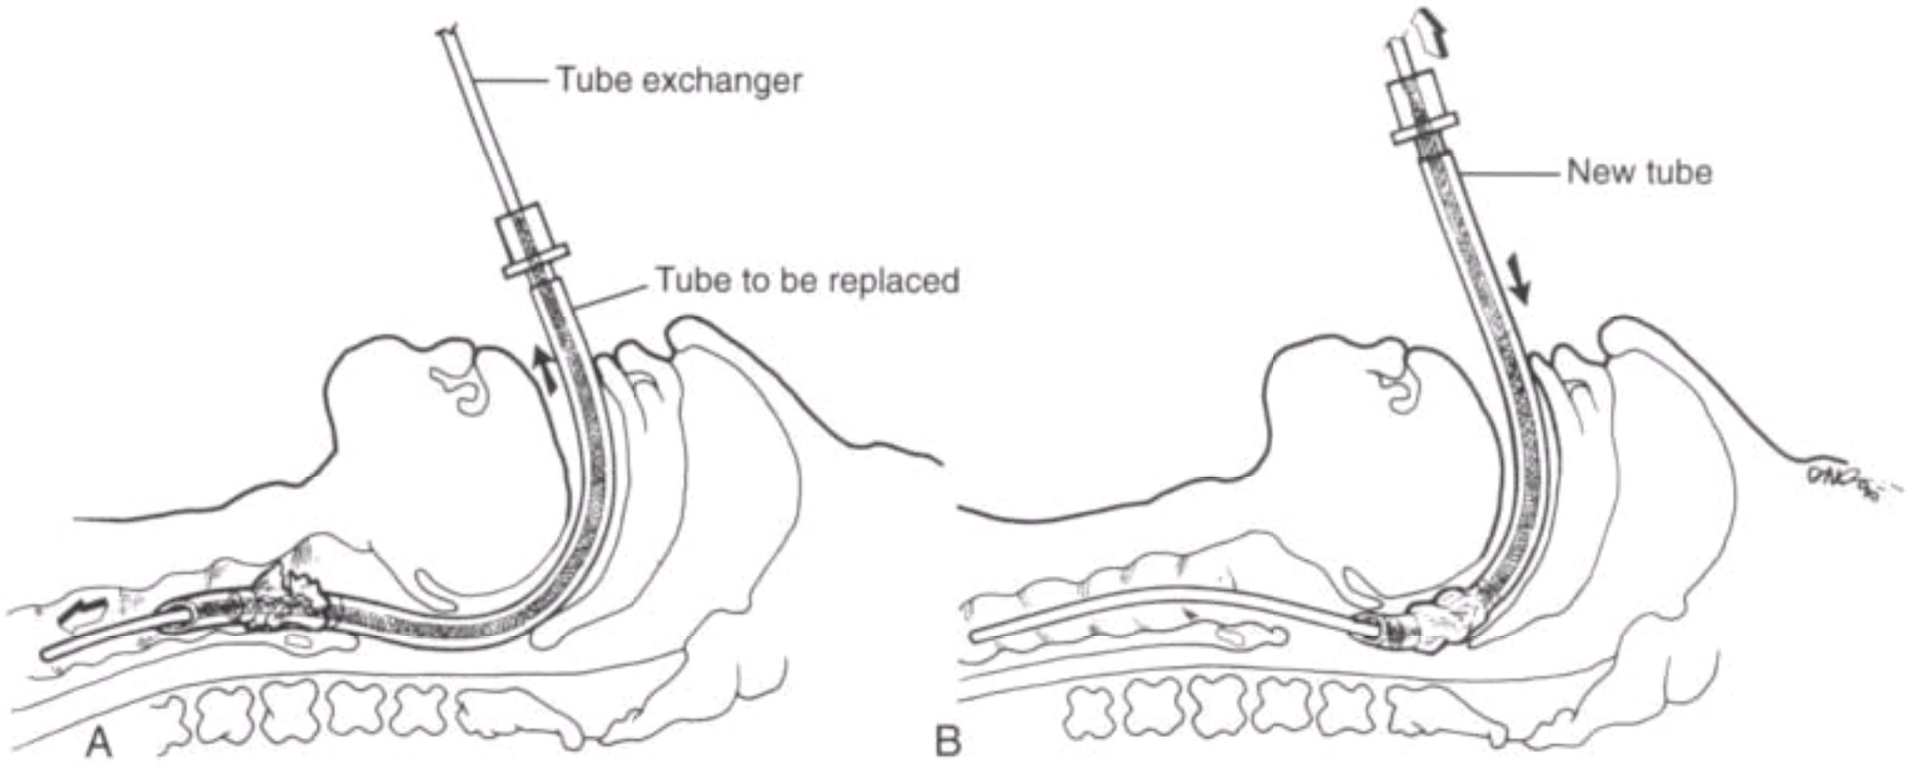

Figure 6-1 Anatomy of the neck. *A*, Surface anatomy of the neck, showing important external landmarks. *B*, Anterior view of the neck, showing various internal structures (overlying superficial skin and structures removed to show cricothyroid membrane). *C*, Lateral view of the neck, showing various structures.

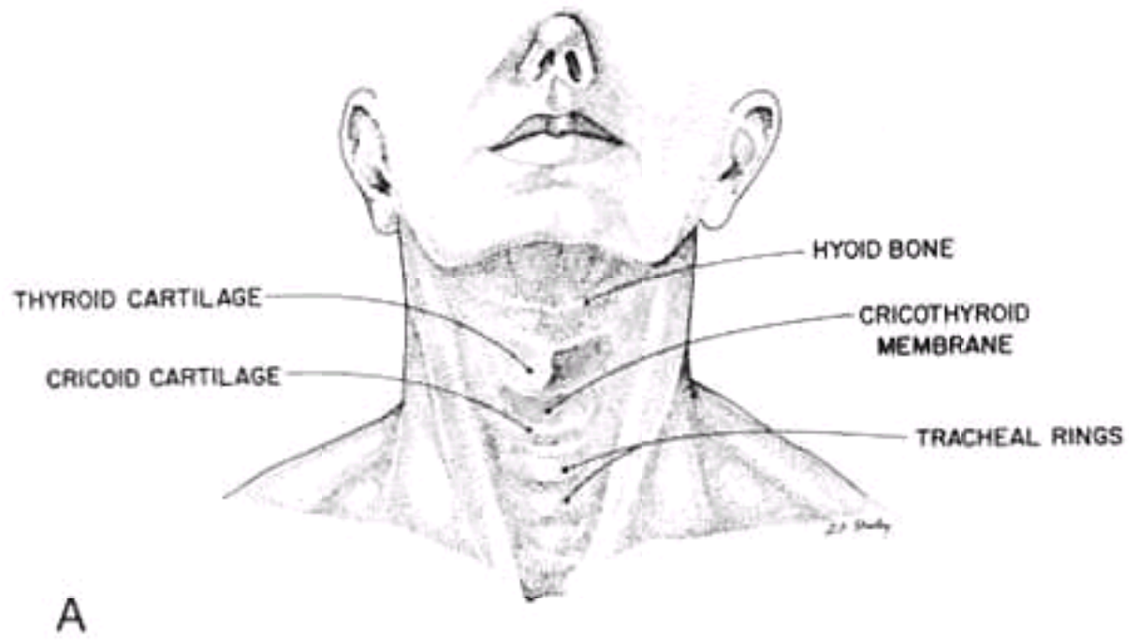

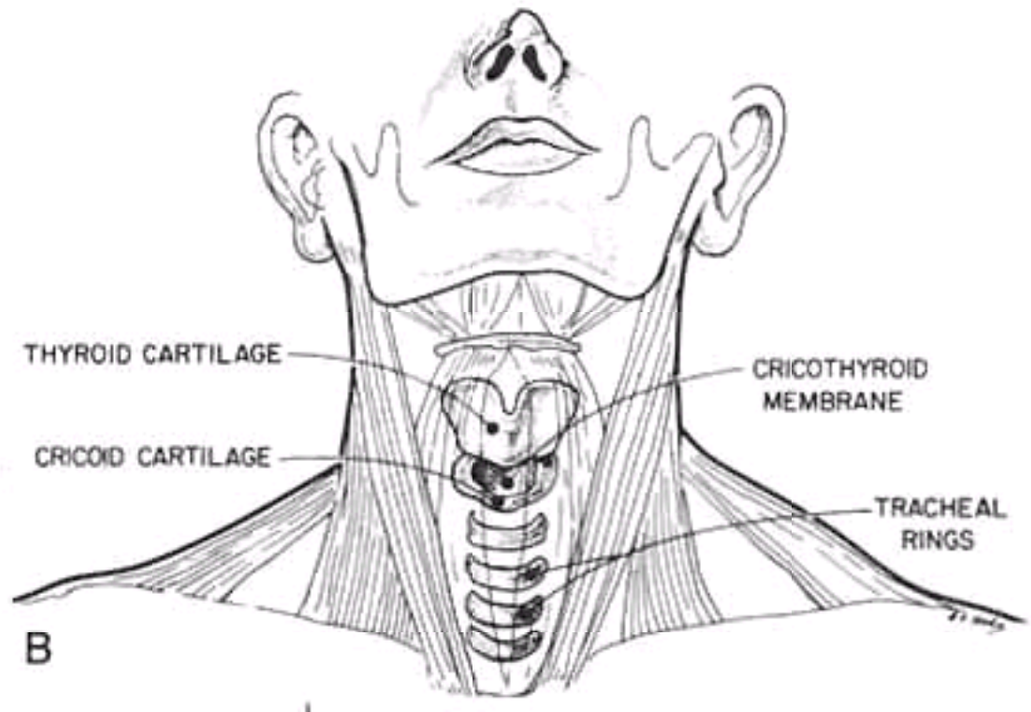

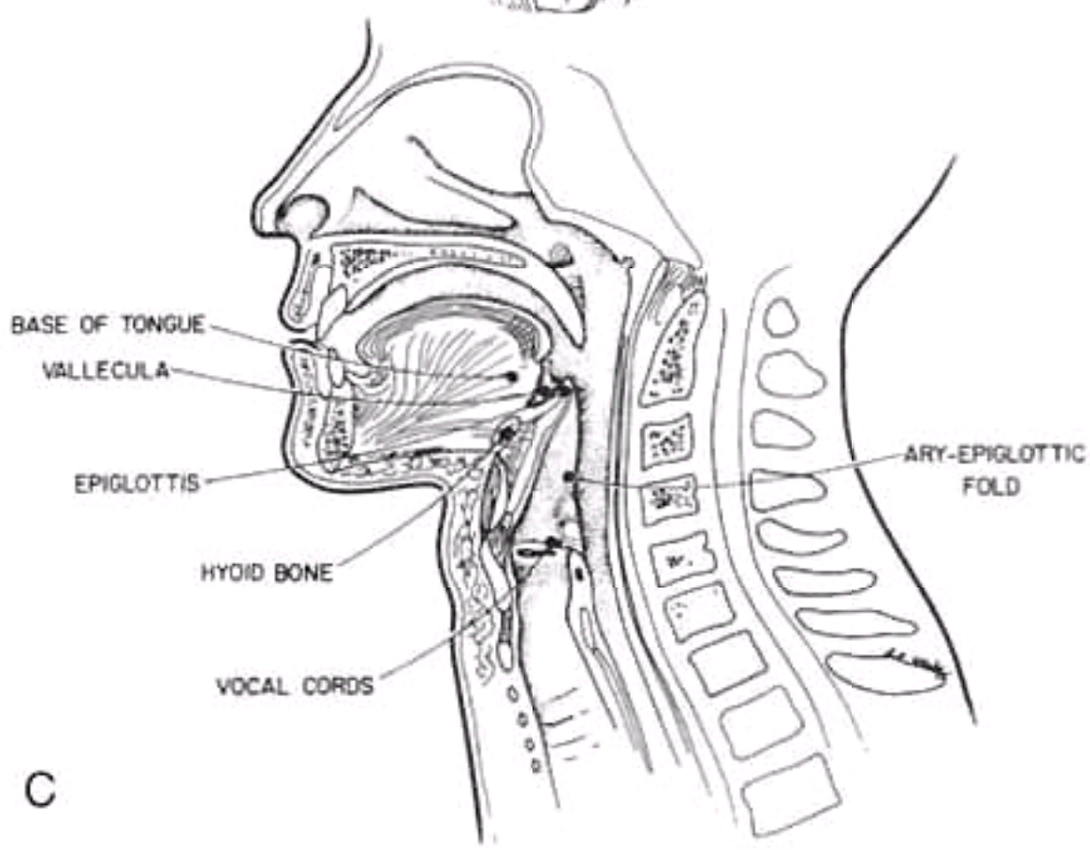

Figure 6-2 Modification of an endotracheal tube for use as a tracheostomy tube. *A*, An appropriate-sized endotracheal tube is cut to an appropriate length. *B*, An adapter is attached to the cut end before the modified endotracheal tube is inserted into the larynx via the opening in the cricothyroid membrane.

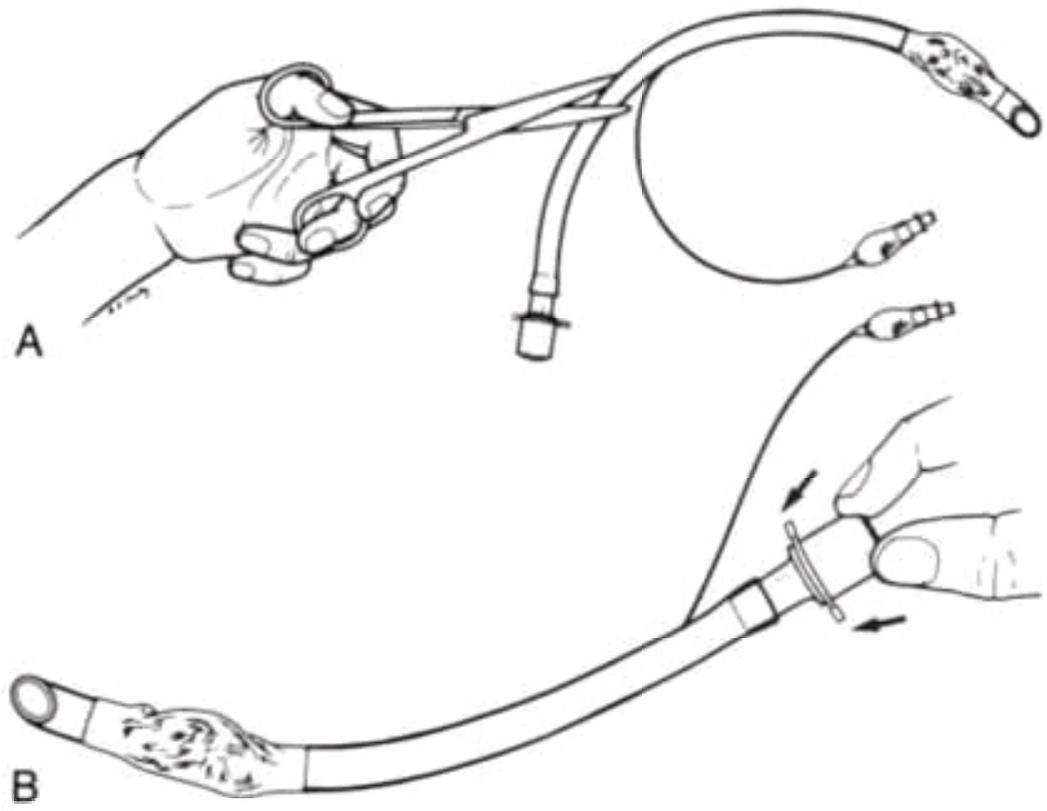

Figure 6-3 The procedure for surgical cricothyrotomy. *A*, Locate the cricothyroid membrane. The insert shows further anatomic details of the region. *B*, A longitudinal skin incision is made over the cricothyroid membrane. *C*, The larynx is stabilized with the thumb and middle finger or a tracheal hook (held in the nondominant hand) while an incision is made in the cricothyroid membrane. *D*, The surrounding anatomy of the neck is shown, with the incision being made in the cricothyroid membrane. *E*, After the incision in the cricothyroid membrane is widened using hemostats, curved Mayo scissors, or the blunt end of the scalpel, the tracheostomy tube is inserted between the curved hemostats or tracheal dilator. *F*, Lateral view, showing insertion of the tracheostomy tube.

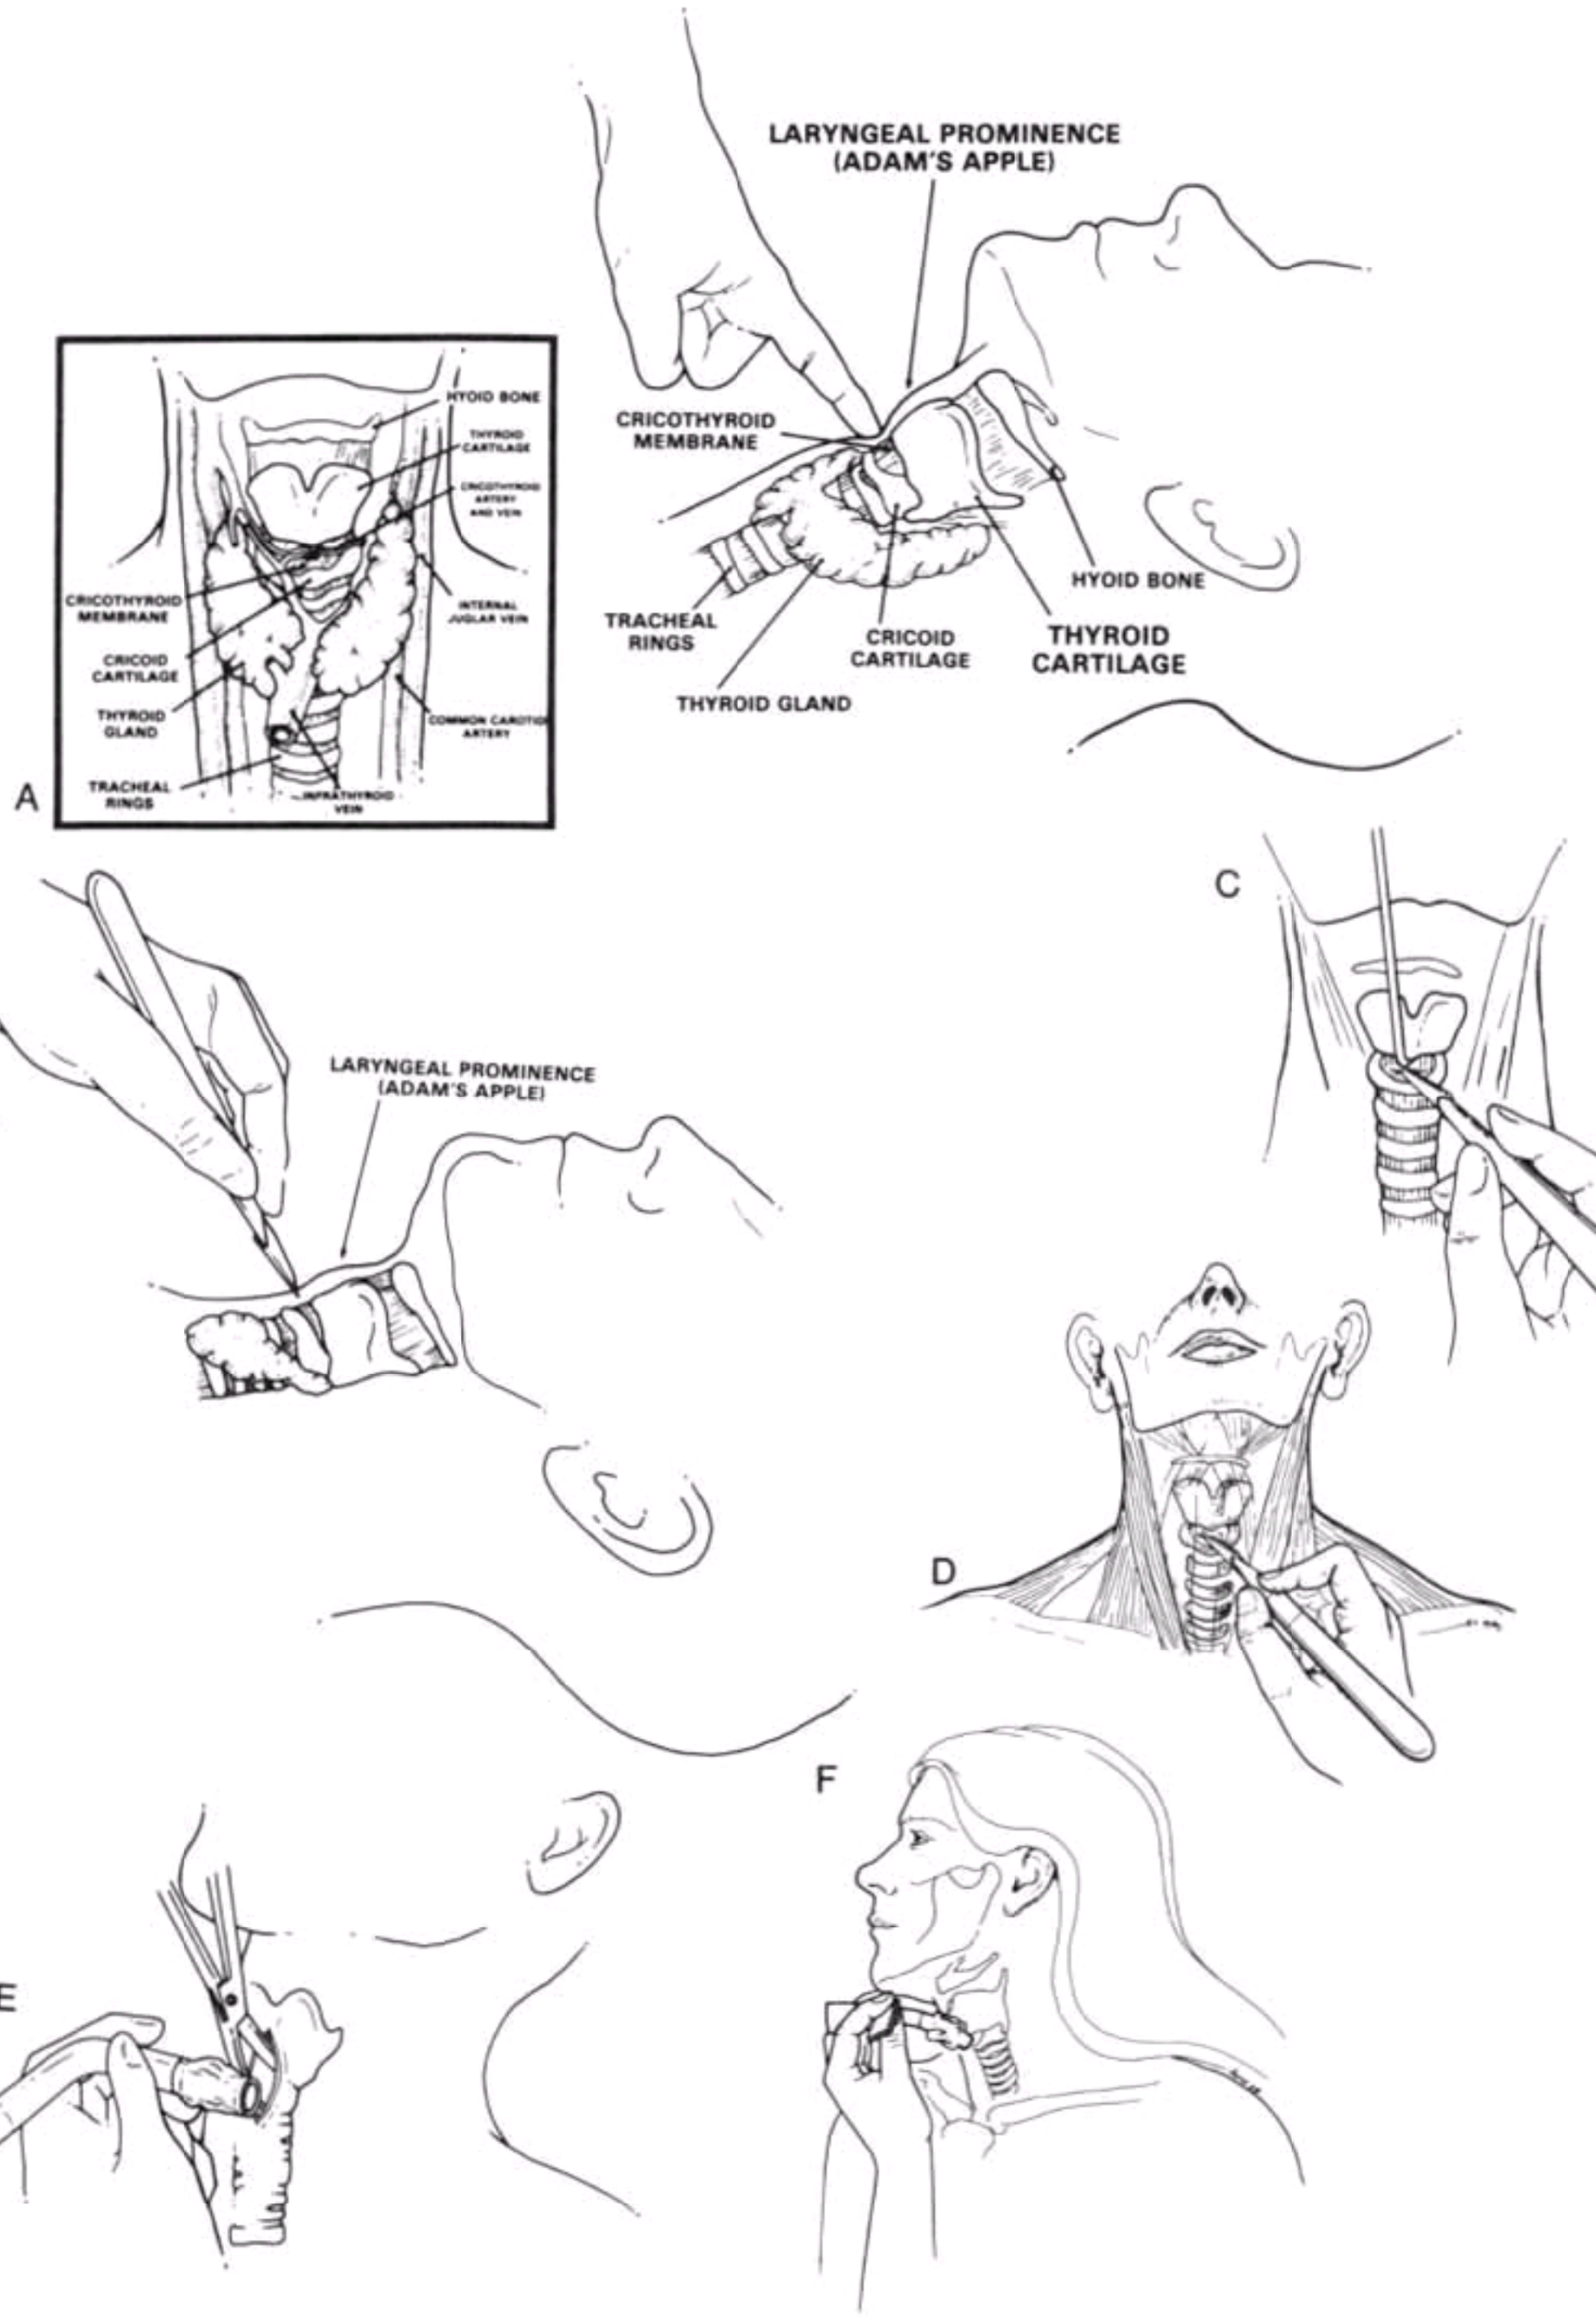

Figure 6-4 Rapid, four-step cricothyrotomy technique. *A,* Step 1: Palpation (location of cricoid membrane externally). *B,* Step 2: Incision (horizontal incision of skin and soft tissues through cricoid membrane). *C,* Step 3: Traction (caudal traction on cricoid ring). *D,* Step 4: Intubation (passage of tracheal tube). *(Reproduced from Brofeldt BT, Panacek EA, Richards JR. An easy cricothyrotomy approach: the rapid four-step technique. Acad Emerg Med 3:1060, 1996.)*

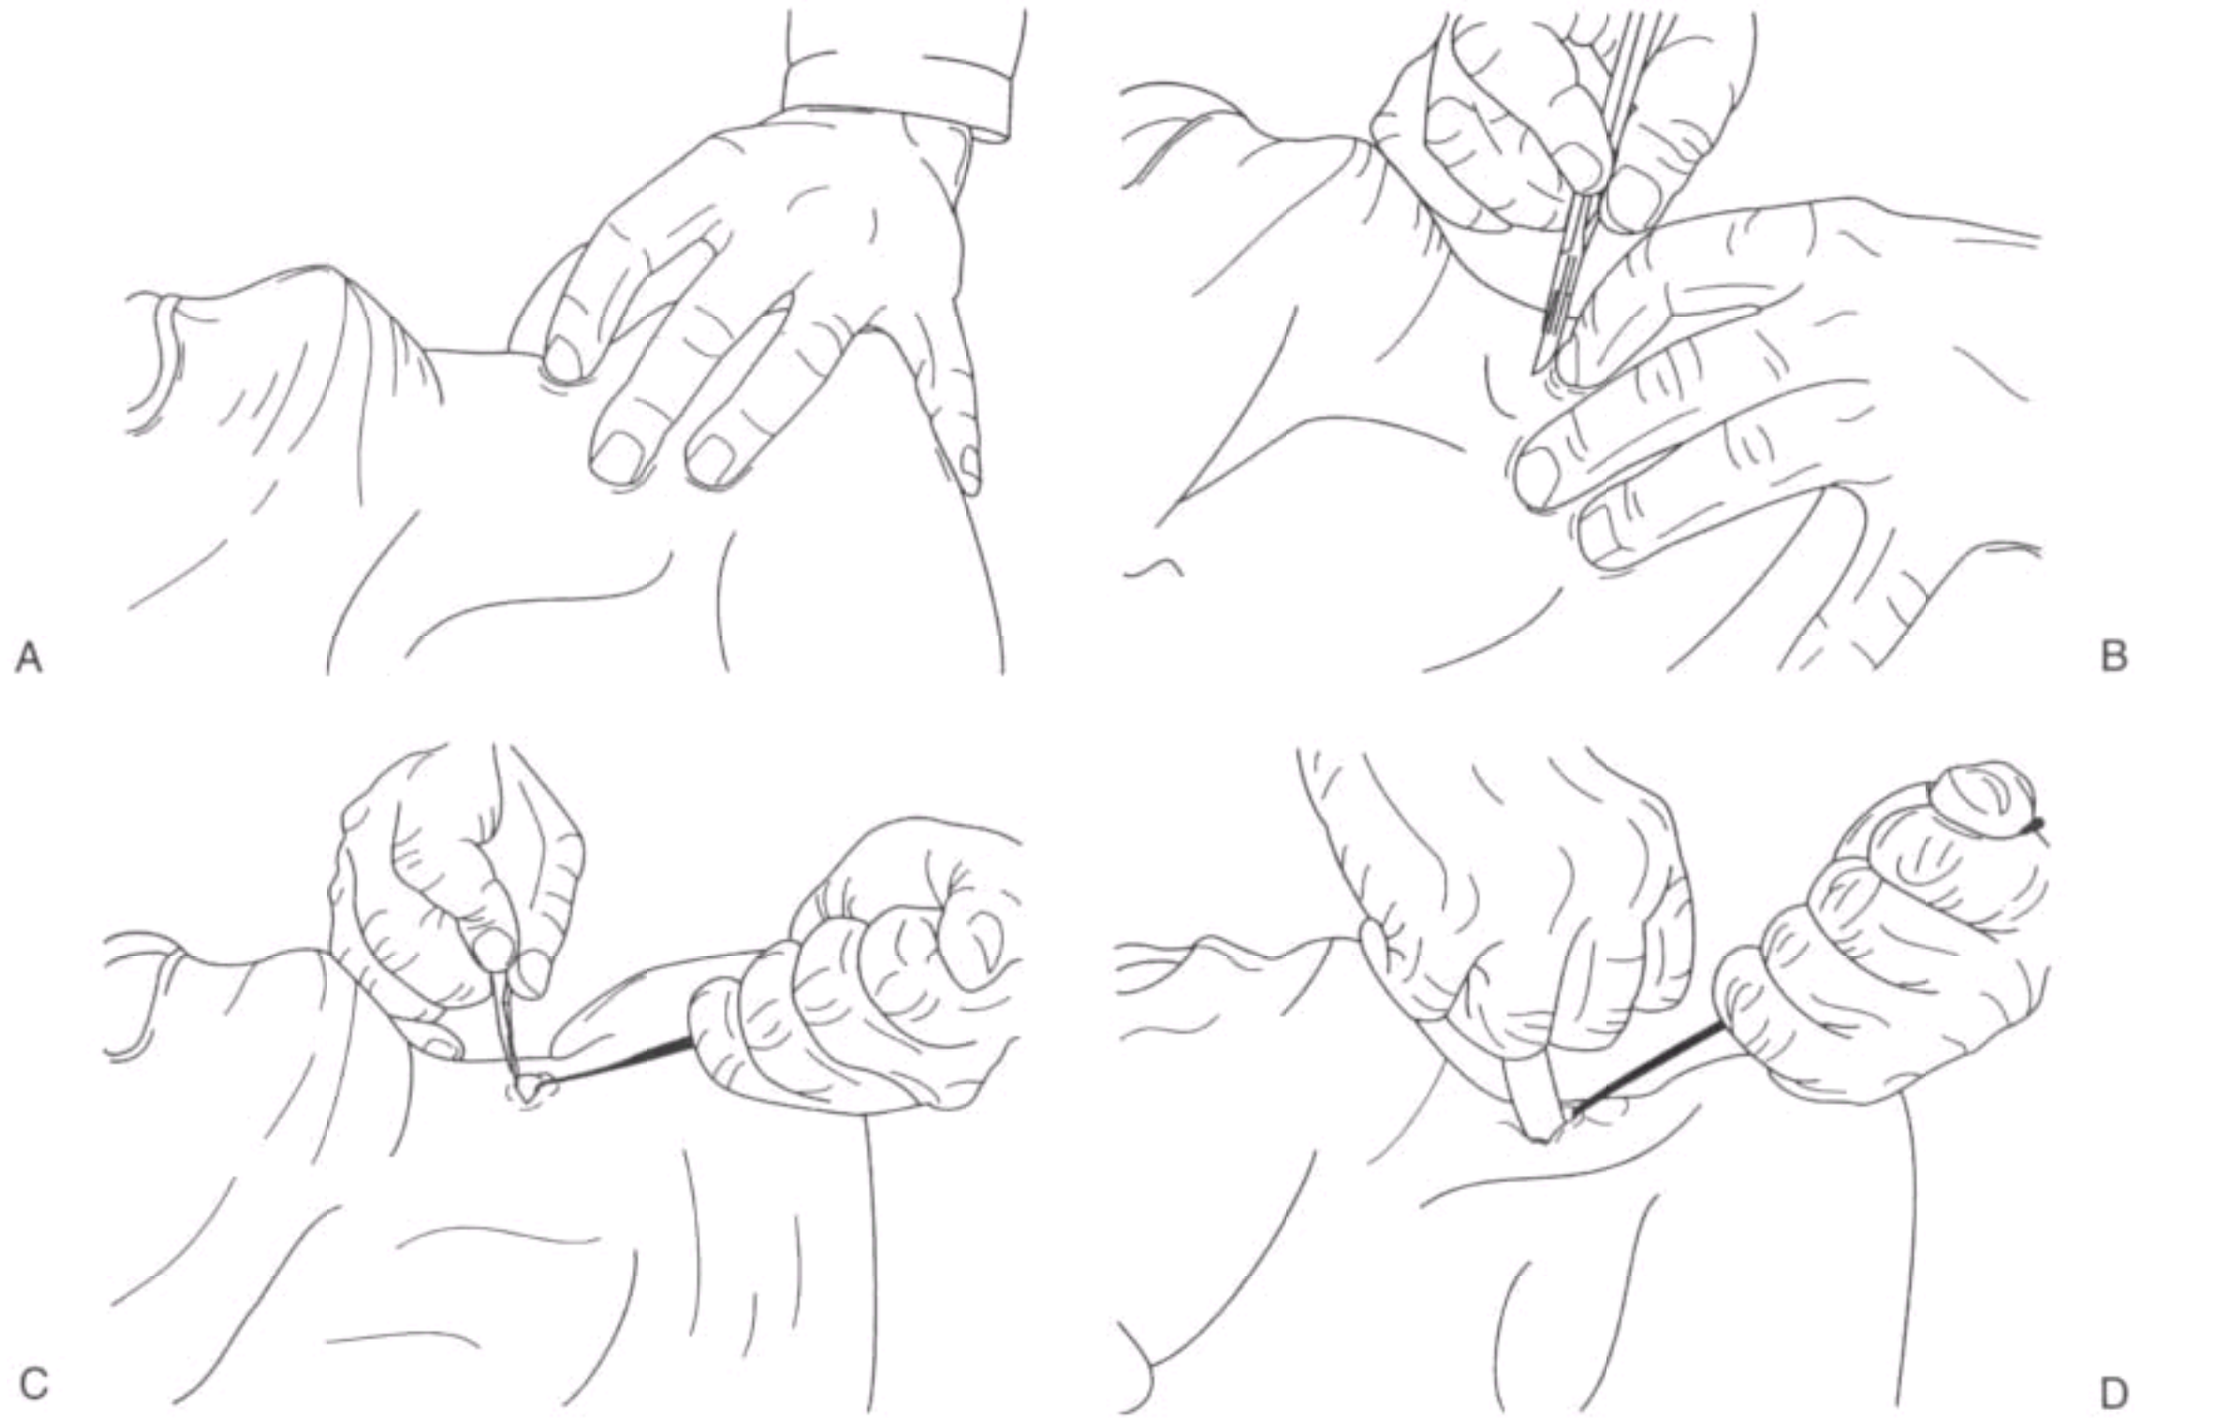

Figure 6-5 "Bair Claw" device. *A,* Device shown without scalpel. During the tracheal tube intubation procedure, the device is used as a caudally directed tracheal hook with slight spreading of the arms of the hook. In this manner the device both stabilizes the distal trachea and provides exposure of the lumen. *B,* Device shown attached to scalpel. During the initial incision, the device is attached to the No. 20 scalpel and passively placed through the cricothyroid membrane during the initial horizontal incision. The "claws" of the device are then released and the scalpel removed. The device is then rotated into position and used as outlined above. *(Davis DP, Bramwell KJ, Hamilton RS, et al. Safety and efficacy of the rapid four-step technique for cricothyrotomy using a Bair Claw. J Emerg Med 19:125, 2000.)*

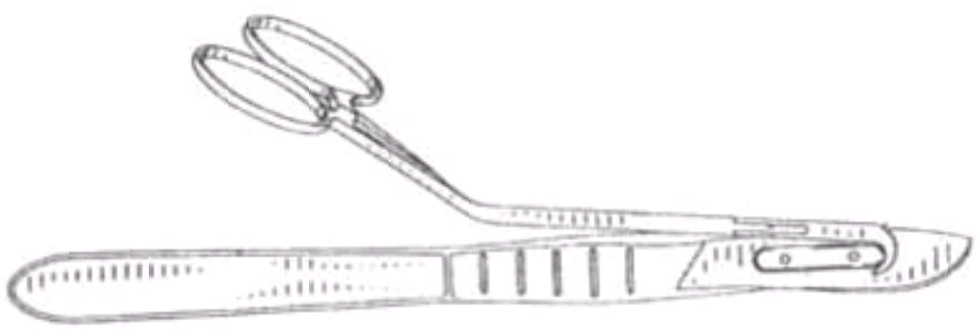
A



B

Figure 6-6 Modification for a patient with a massive neck swelling (see text). *A*, Landmarks in the neck. *B*, The procedure for a patient with a massive neck swelling uses a spinal needle to find and identify the hyoid bone; the skin incision is then made in the midline, moving inferiorly from the midpoint of the hyoid bone past the thyroid cartilage until the cricothyroid membrane is exposed. Care is needed to *avoid* a high incision through the thyrohyoid membrane above the thyroid cartilage.

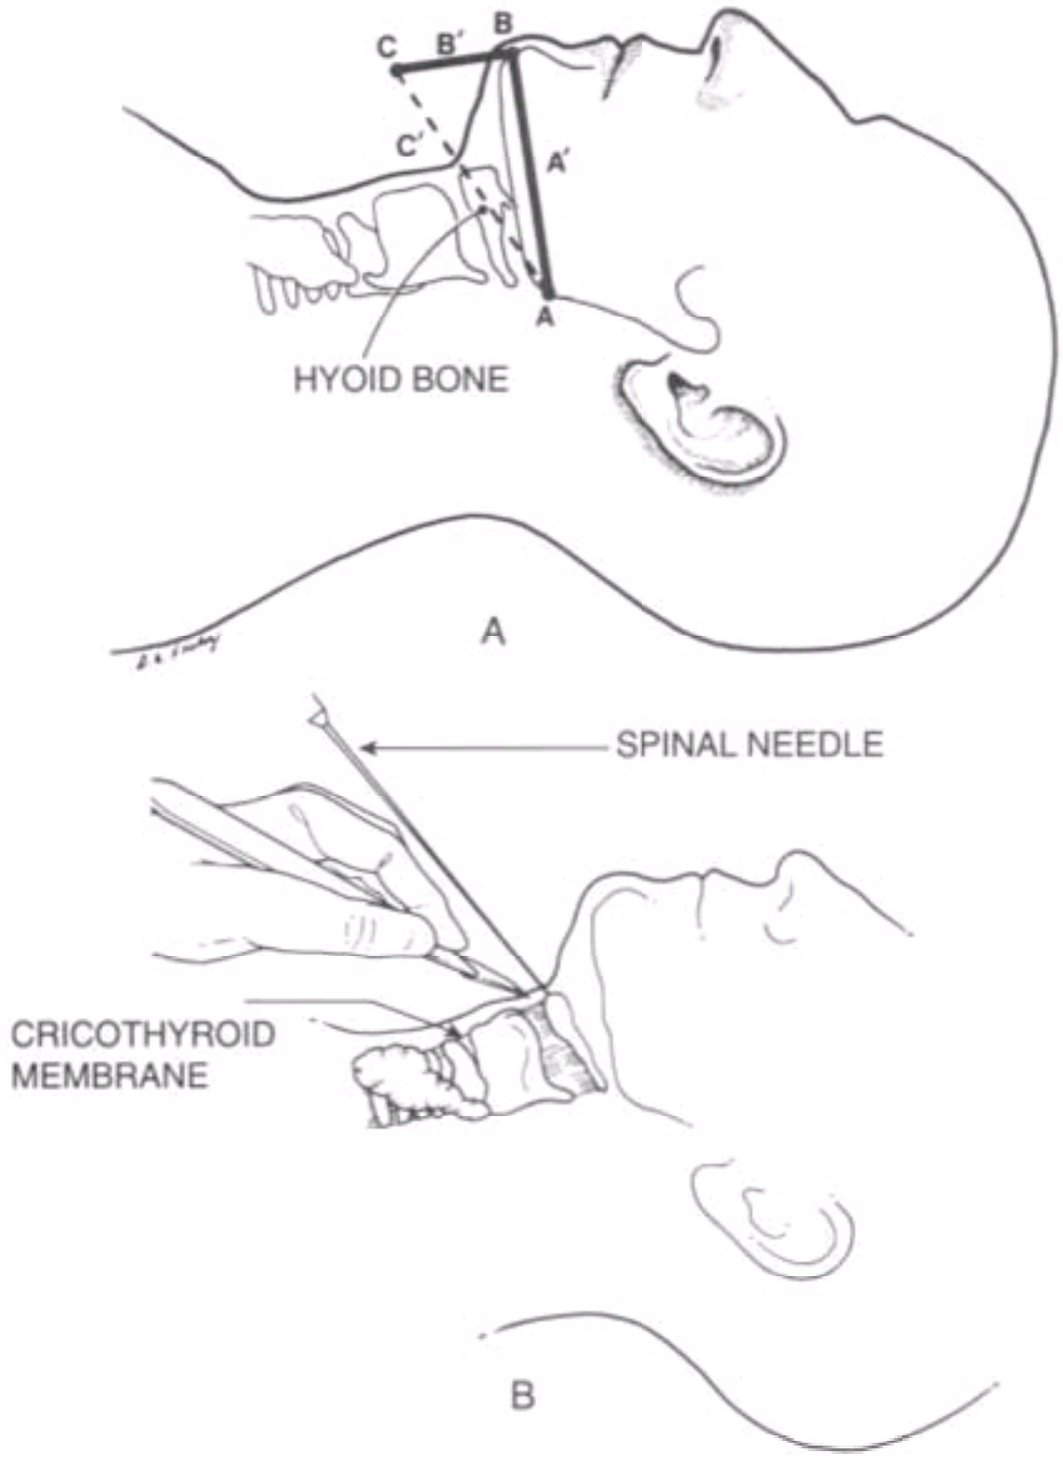


Figure 6-7 The equipment for translaryngeal ventilation. One-way valve used to control ventilation. Note that tubing is attached at the neck to the hub of the cricothyrotomy device, or if a tracheostomy is in place, the insufflation catheter can be passed into the tracheostomy tube.

Figure 6-8 A simple setup for translaryngeal ventilation using standard equipment found in any emergency department. This setup is inadequate for adults. High-pressure (50 psi) ventilation systems (see Fig. 6-7) are optimal. Even with the pressure relief valve on the bag-valve device turned off, only a suboptimal pressure can be developed. However, this technique may be satisfactory in infants and small children.

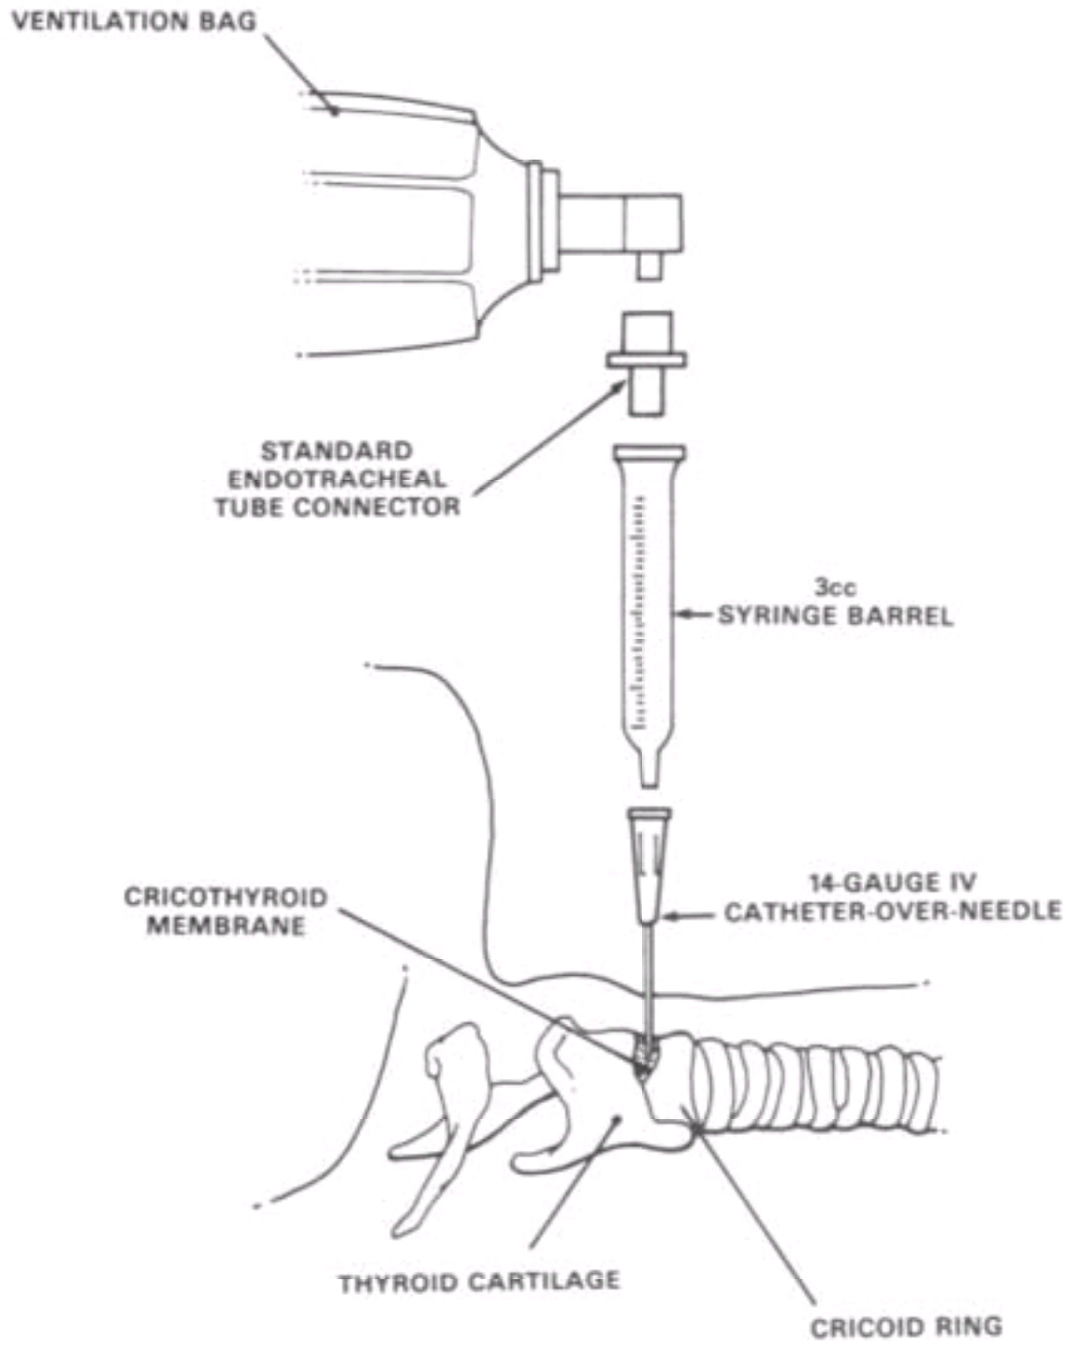

Figure 6-9 *A*, Commercial device used in performing a cricothyrotomy with a modified Seldinger technique. The adult Pertrach percutaneous emergency airway provides a means of rapidly inserting a tube into a patient's trachea (through either the cricothyroid membrane or trachea) in certain clinical situations. It provides an adequate airway that can, by its standard 15-mm adapter, be used to allow the patient to breathe. The unit allows full control of the airway with inflation of the cuff. The pediatric device is provided uncuffed in three sizes for infants and children of various sizes. The 15-mm adapter is part of each unit. (Tracheostomy *only* is recommended in children and infants.) *B*, Method of establishing an airway with the Pertrach cricothyrotomy kit: (1) The 14-ga needle is inserted into the trachea through a cricothyroid membrane or upper trachea. Placement in the airway is verified by drawing air. The syringe is removed. (2) The dilator is placed to its hilt into the tracheostomy tube, and both are inserted as a single unit. The leader of the dilator is inserted into the trachea through the needle, which is then split and removed. The dilator and trachea tube are inserted into the trachea. Note that a small skin incision at the puncture site is needed to facilitate passage of the tracheal tube. (3) The dilator is removed. The cuff can then be inflated and a respirator applied. *(Courtesy of Pertrach, Inc., Clarksburg, WV 26301.)*

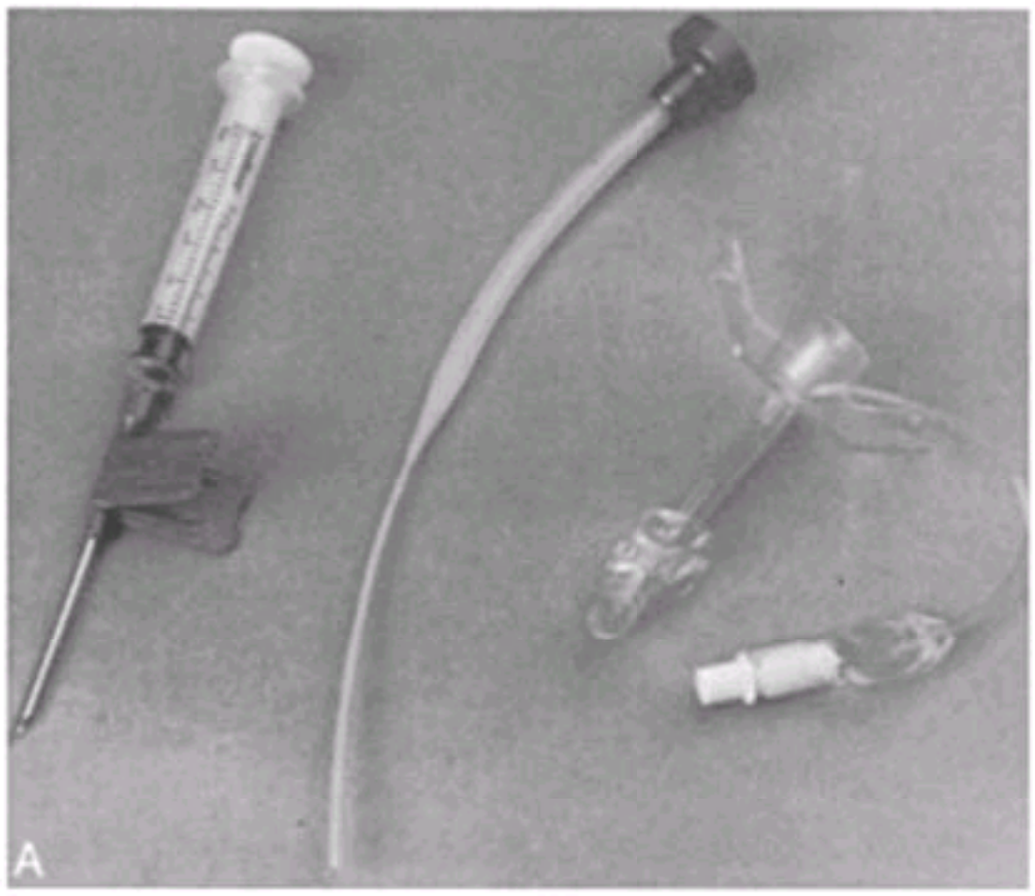

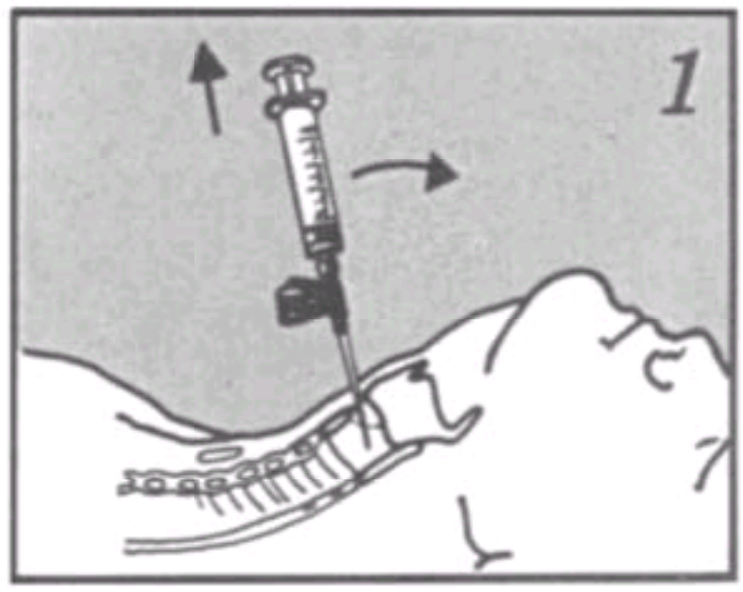

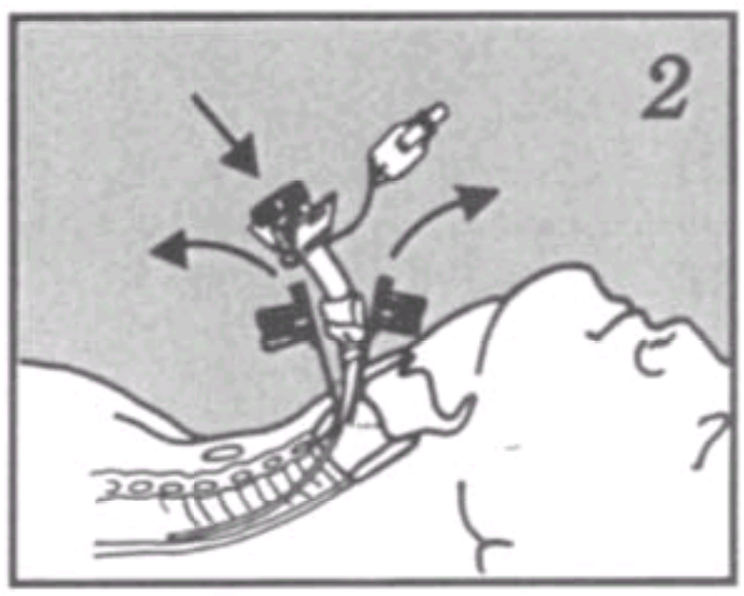

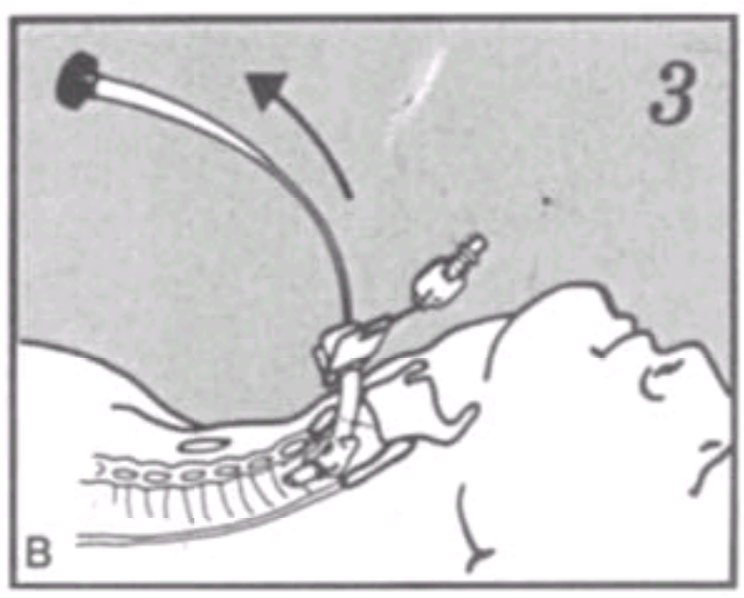

Figure 6-10 The procedure for transtracheal ventilation. *A*, The cricothyroid membrane is punctured with the needle or catheter aimed caudally at approximately a 45° angle. *B*, The inner needle has been removed, and the catheter is hooked up to a manual in-line device and then to a source of oxygen. A valve device or tubing modification as shown in Figure 6-7 is also required.

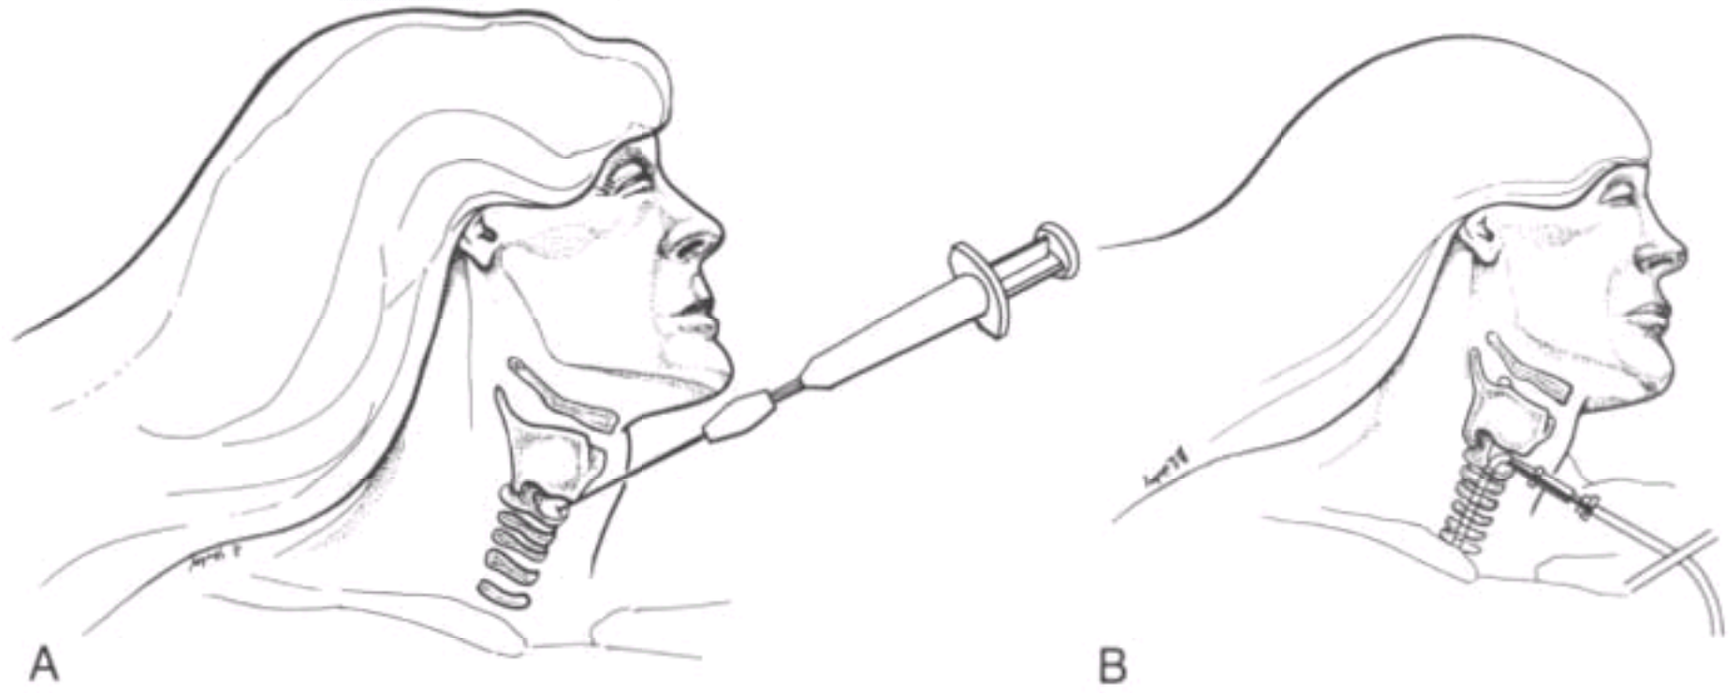

Figure 7-1 Control of innominate artery bleed by digital pressure. When major bleeding occurs and a cuffed tracheostomy tube is present, overinflation of the tube cuff may temporize (see text). When unsuccessful or a cuffed tube is not available, use the illustrated maneuver; digital pressure should be applied to the anterior tracheal wall through the tracheostomy. The index finger is placed within the trachea and then pulled against the anterior tracheal wall, allowing the airway to remain partially open. The artery is compressed between the index finger and the thumb—placed over the anterior neck. Digital compression of the innominate artery is a temporizing procedure, until definitive (operative) management of the bleed is obtained.

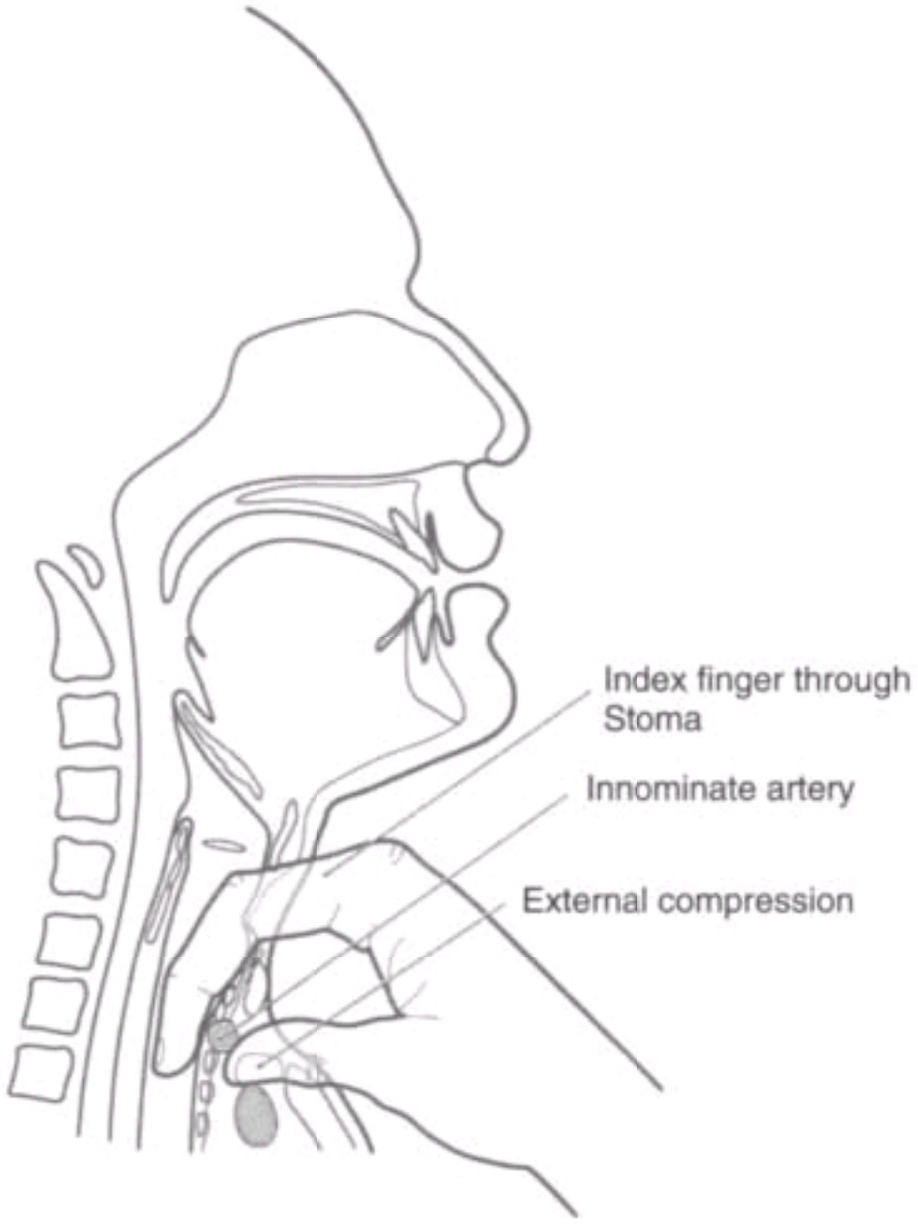

Figure 7-2 Tracheostomy tube *(top)* with inner cannula and attached ambu bag adaptor *(middle)* and obturator *(bottom)*.

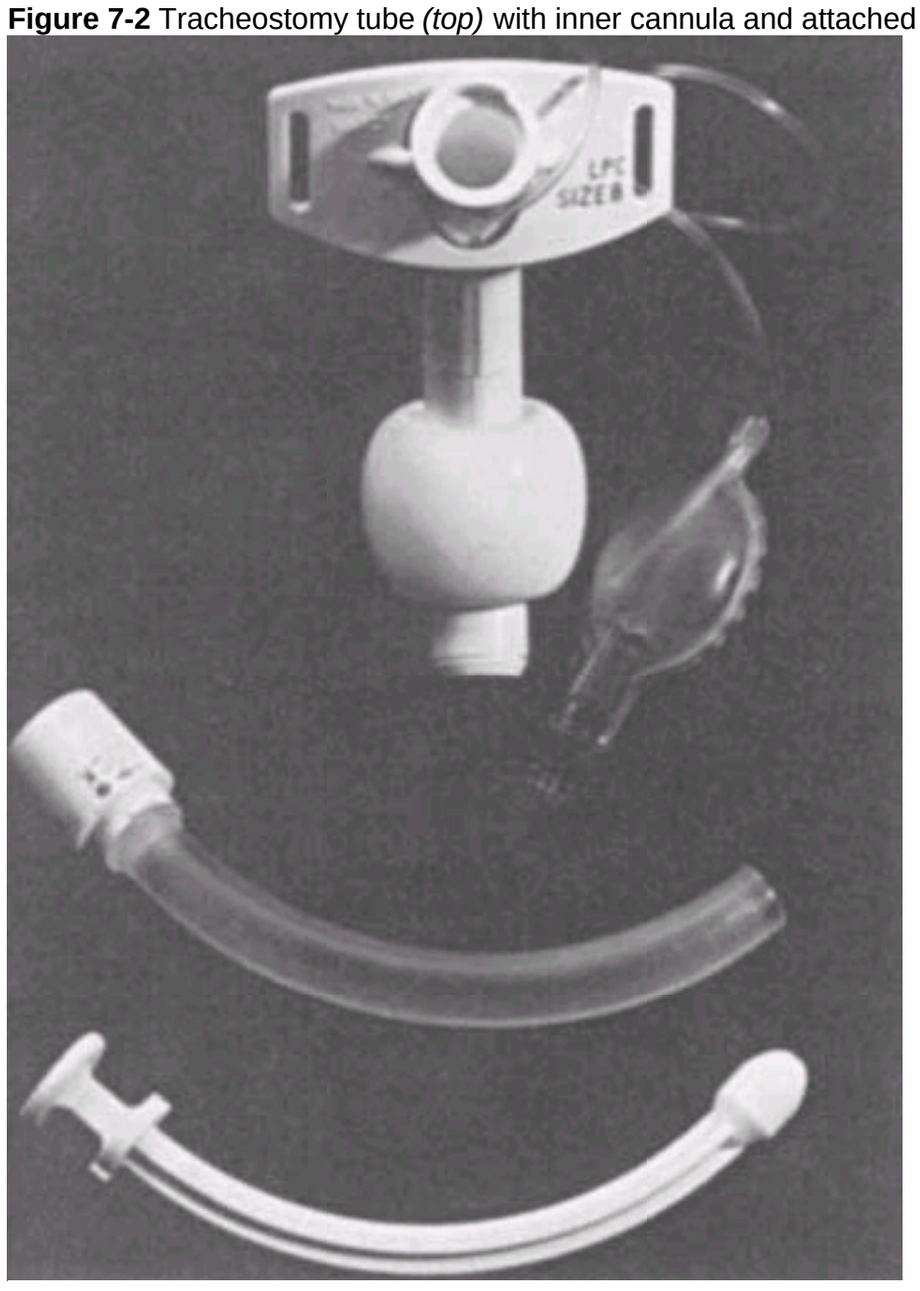

Figure 7-3 Changing a tracheostomy tube. *A,* Before the old tube is removed, a small red rubber catheter (or other guide catheter) is passed into the proximal trachea. *B,* The tracheostomy tube has been removed over the catheter, and only the catheter remains in the trachea. The catheter serves as a guide for easy and atraumatic insertion of a new tube. Note that the neck should be slightly hyperextended. *C,* A new tracheostomy tube, without the obturator is threaded over the guide catheter; once the tube is in place, the catheter is removed. Similarly, if the tracheostomy tube has already been removed, the catheter may be passed through the stoma before a new tube is advanced. Note that an obturator or inner cannula is *not* used when changing a tube with this technique.

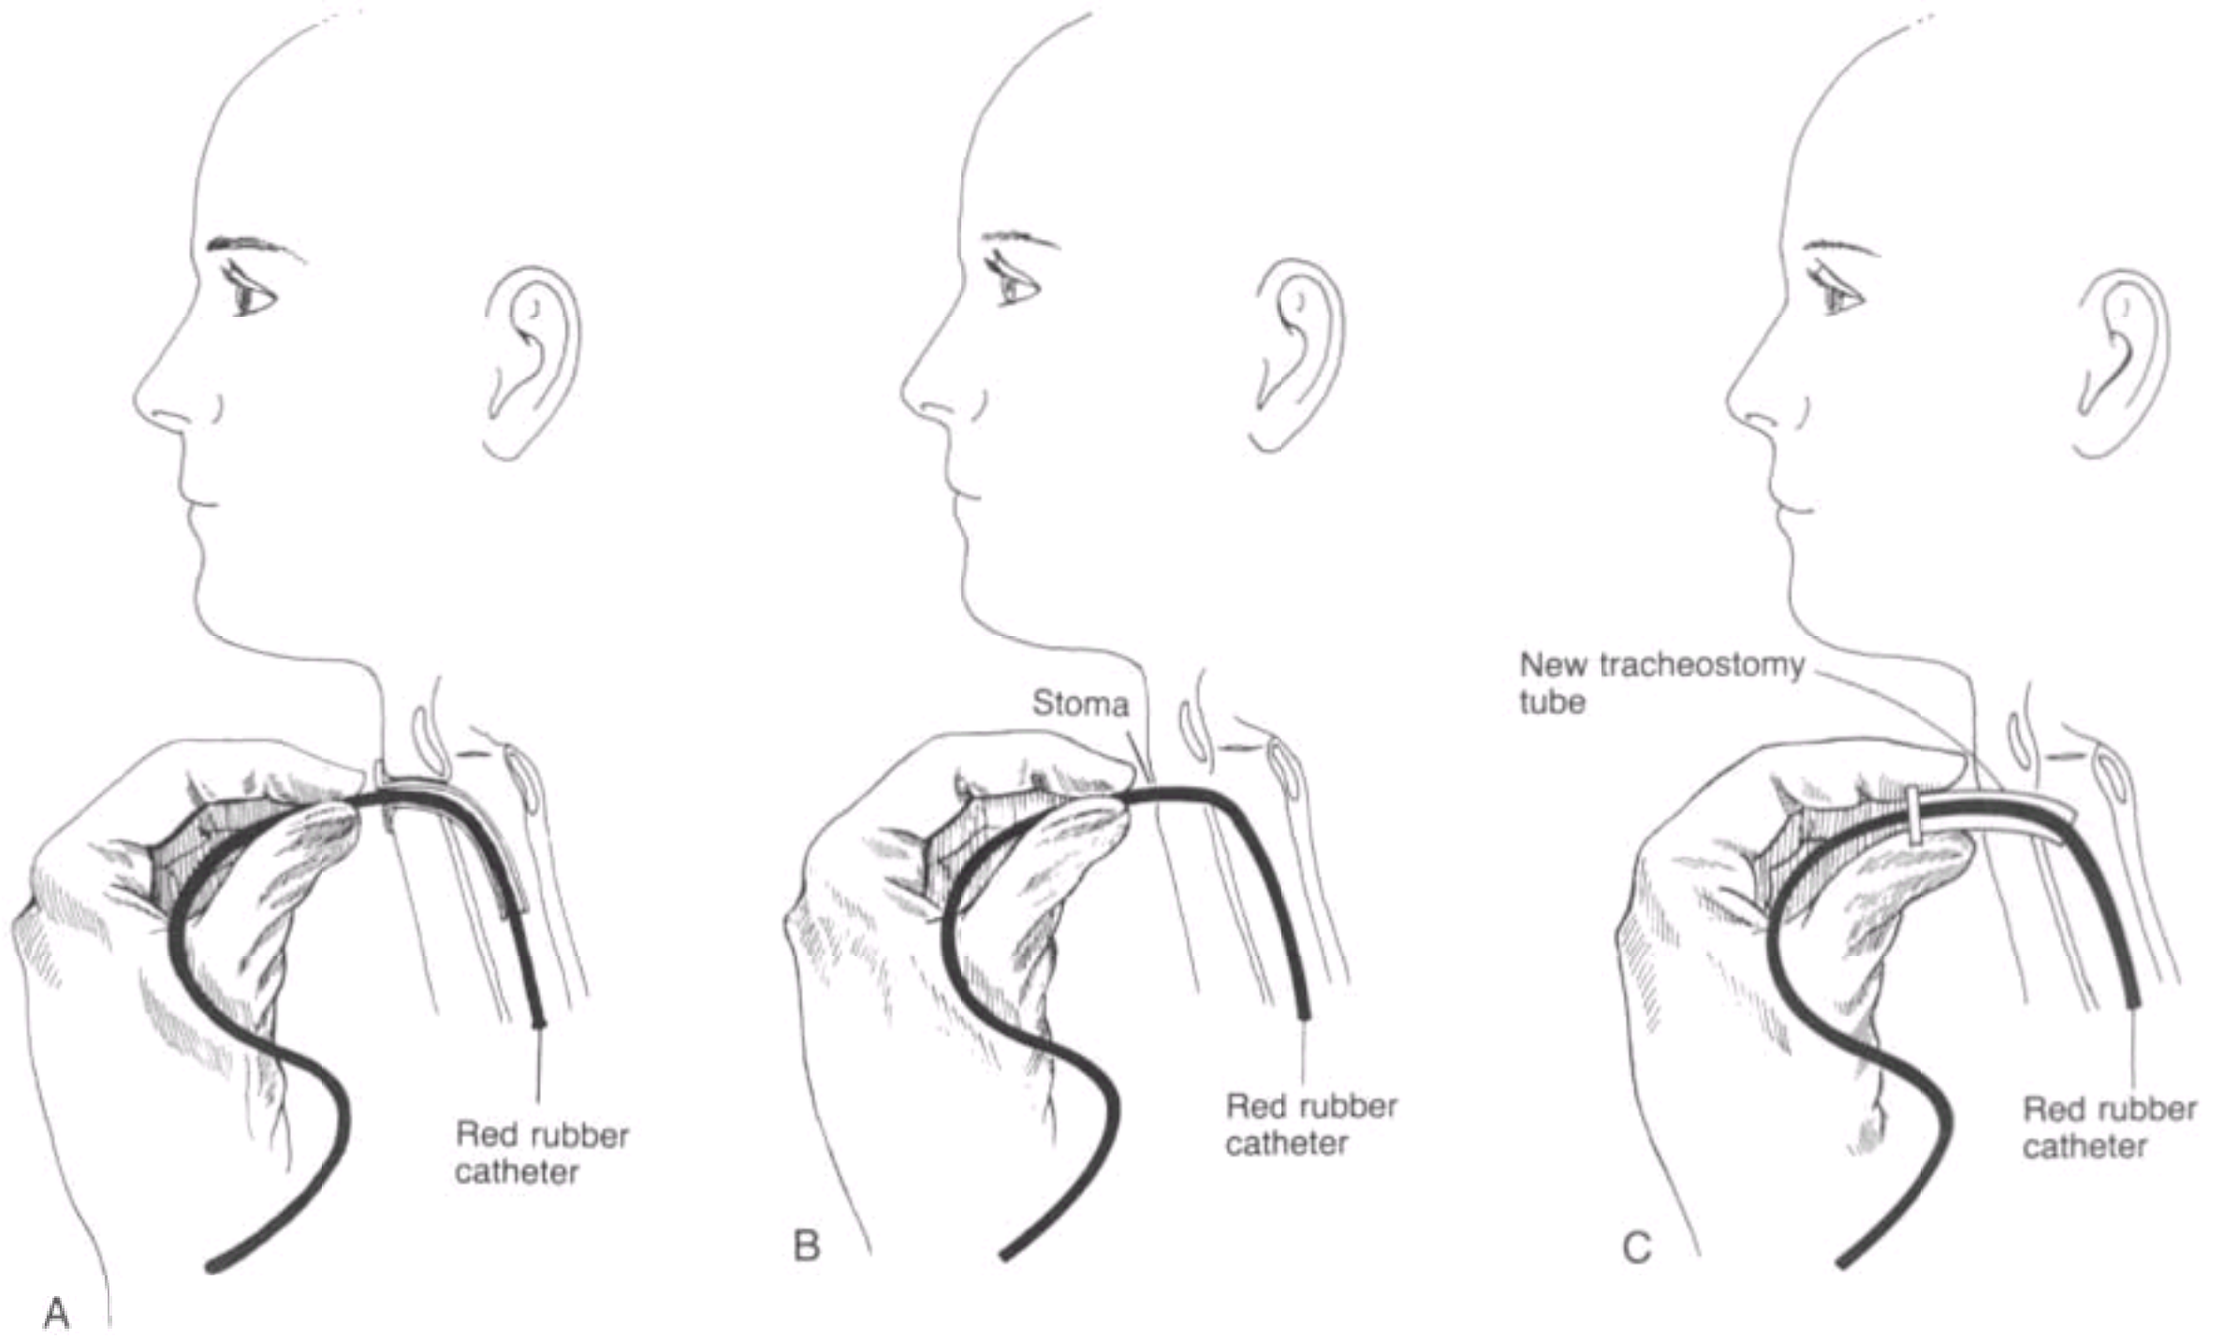

Figure 7-4 The tracheostomy tube should be inserted with a gentle rocking motion of the wrist. Insertion should follow the curve of the tube, as diagrammed above. If any resistance is met during insertion, the clinician should discontinue insertion and identify the obstruction. A pediatric laryngoscope or other light source may be helpful in visualizing the tracheal lumen prior to insertion. *(Adapted from Hackeling et al: Emergency care of patients with tracheostomies: A 7-year review. Am J Emerg Med 16:681, 1998.)*

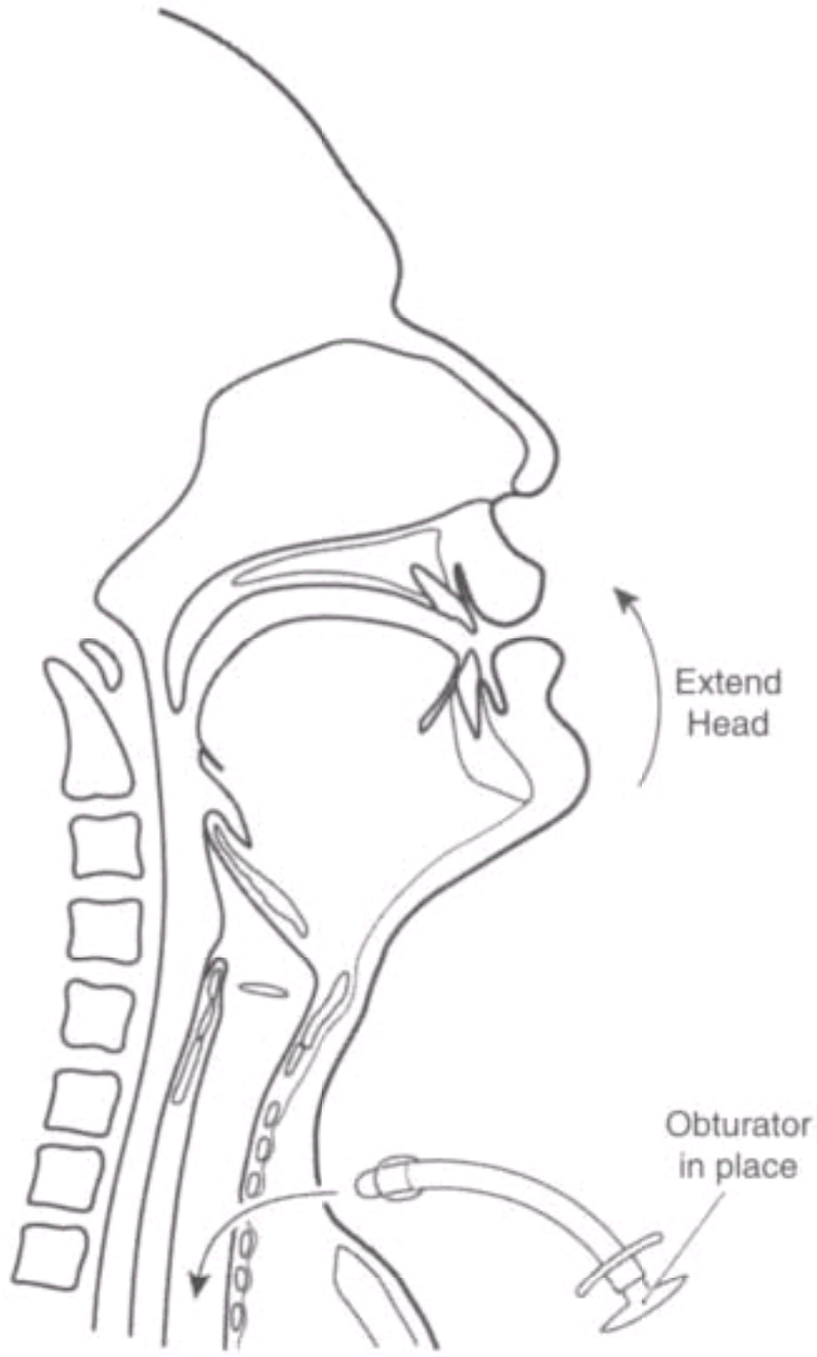

Figure 7-5 Transtracheal aspiration. *A*, Position of patient. *B*, Anatomic landmarks. *C*, Technique of puncture. The Intracath needle or J-wire introducer needle is inserted just above the cricoid cartilage through the cricothyroid membrane with its bevel up at a 45° angle to the skin. *(From Eknoyen G: Medical Procedures Manual. Chicago, Year Book Medical Publishers, 1981. Reproduced by permission.)*

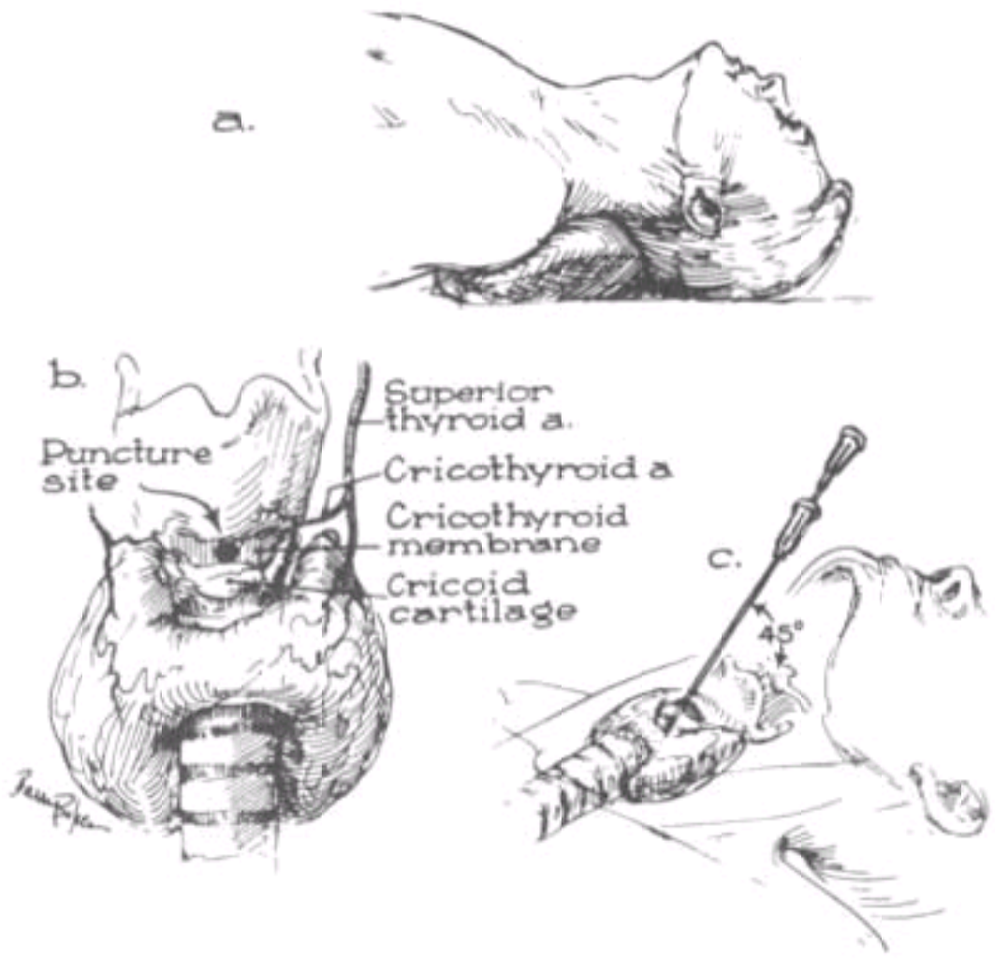

Figure 8-1 Alveolar interdependence. Note that alveoli are not round in shape; instead, they are polygons. Polygons have corners and may have two opposing surfaces that may adhere to one another via surface tension. Surfactant works to reduce this surface tension and allow alveoli to open with reduced shear stress at the junction of closed and open alveoli. Alveoli are connected via the pores of Kohn. This allows opening alveoli to pull a relatively closed alveolus open while equalizing pressure between adjacent alveoli. The central alveolus on the right is fairly closed in the upper diagram, but is pulled open by its neighbors as they expand and accept gas.

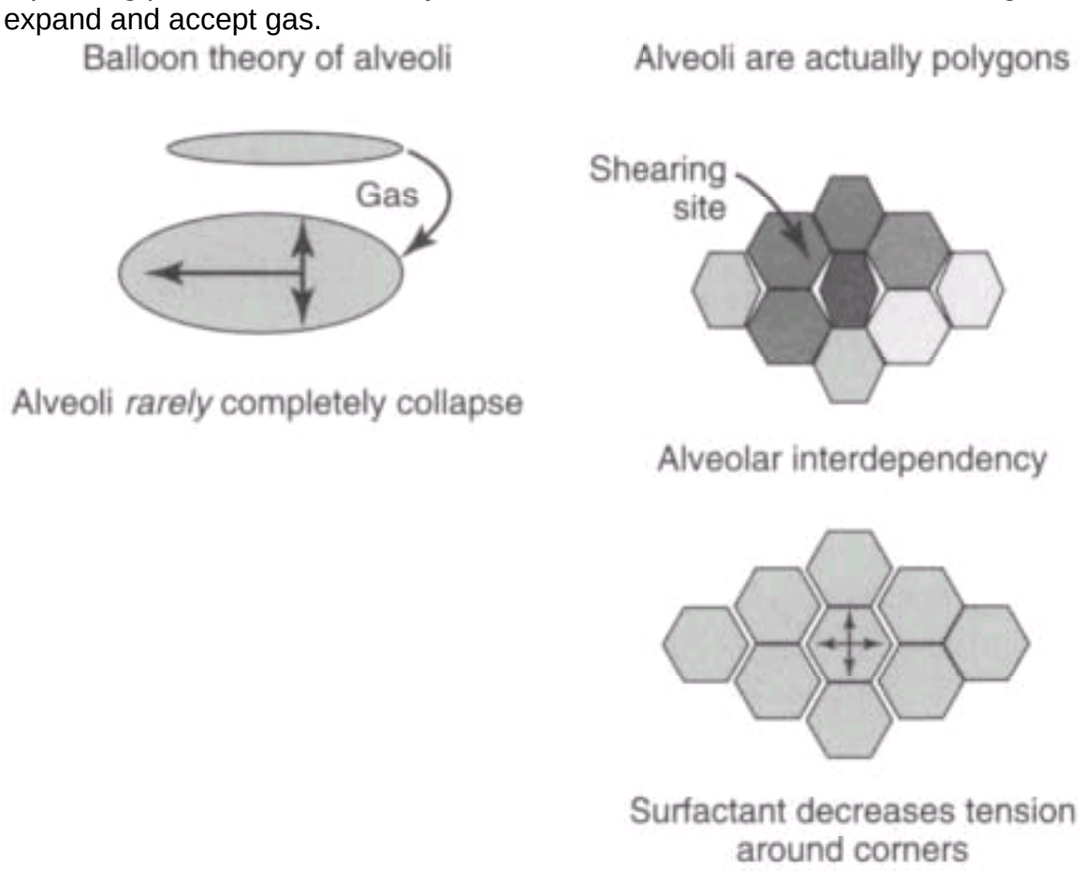

Figure 8-2 Dynamic pressure-volume loop. Note that as soon as there is delivered pressure to the airway, there is an increase in measured tidal volume. The lower arrow denotes inspiration while the upper arrow indicates exhalation. This indicates that the airways are open and do not need to be forced open by increasing the pressure in the airway. If this latter case were true, then the P-V loop would initially be flat along the X-axis.

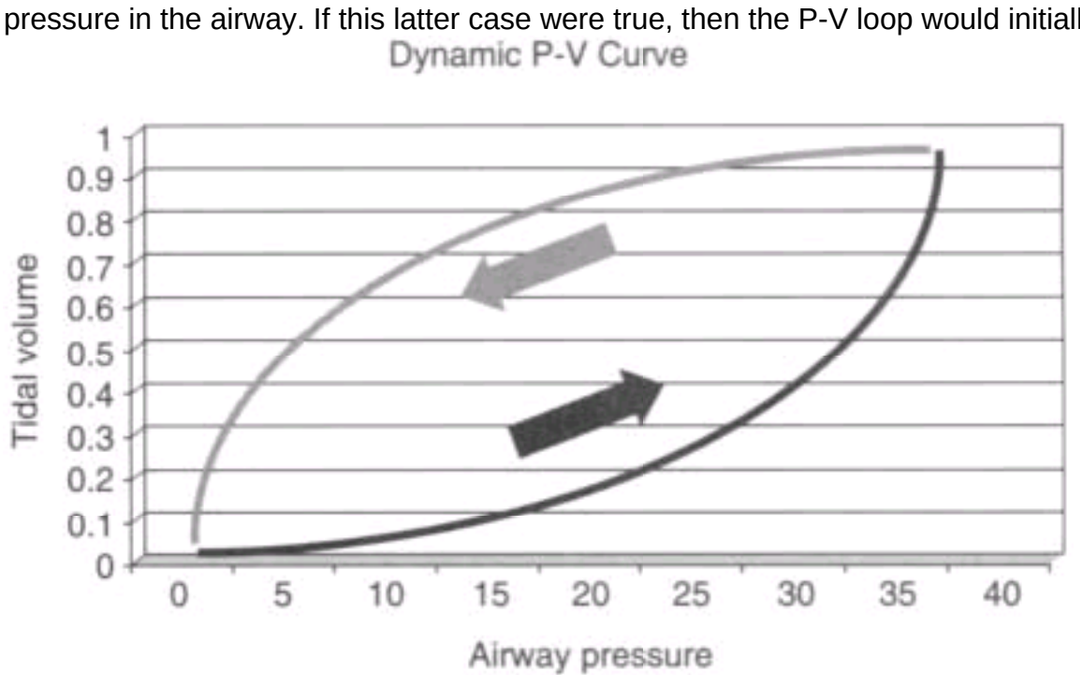

Figure 8-3 Inadequate PEEP and the P-V loop. Compare this curve to that in Figure 8-2 . Note that the loop is initially flat (lower segment) along the X-axis. Once the airway pressure is high enough to open the alveolar units, each increase in airway pressure is matched by a corresponding increase in tidal volume.

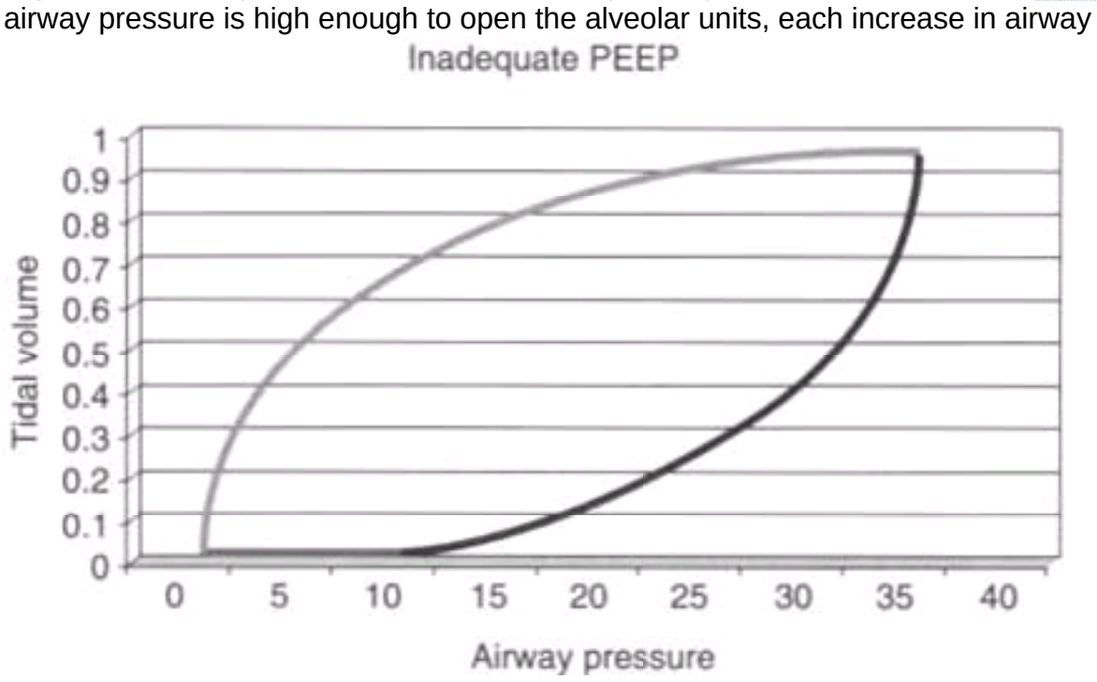

Figure 8-4 Identifying auto-PEEP with the flow-time trace. The X-axis is time while the Y-axis is flow rate in L/min. Deflections above the X-axis indicate inspiration, while deflections below represent exhalation. In this example, the flow pattern is ramp (decelerating). Note that as the respiratory rate increases (decreased time for exhalation), the flow has not yet returned to baseline (a), indicating incomplete exhalation when compared to the following breath (b).

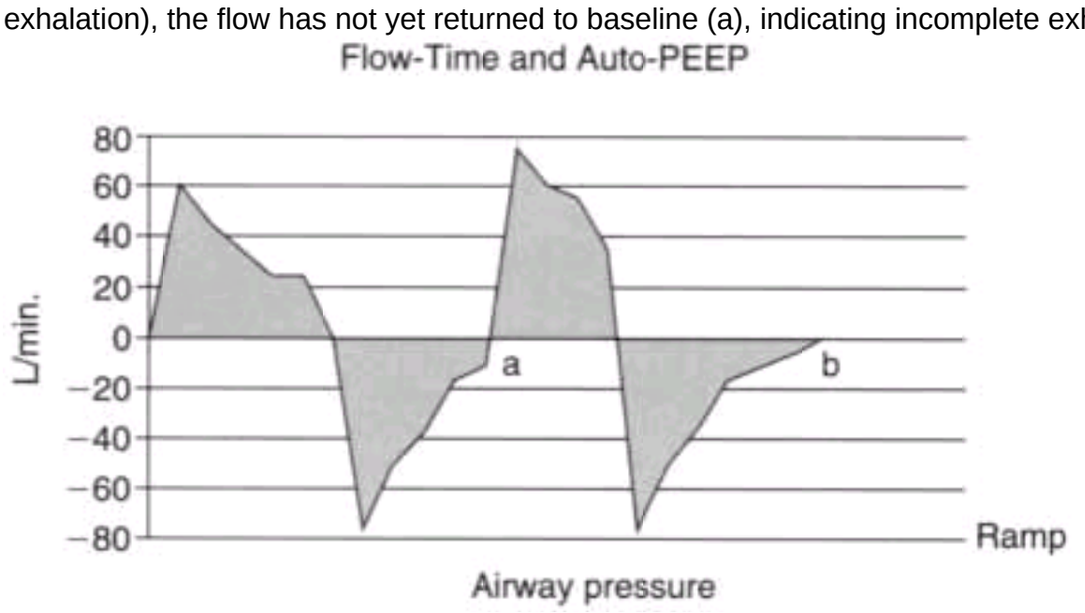

Figure 8-5 Effect of flow rate on inspiratory and expiratory times. Note that as the flow rate changes, there are corresponding alterations in the effective time for inspiration and exhalation. Deflections above the X-axis (time) indicate inspiration, while those below indicate exhalation. The delivered tidal volume for each cycle is the same, but the inspiratory and expiratory times are different.

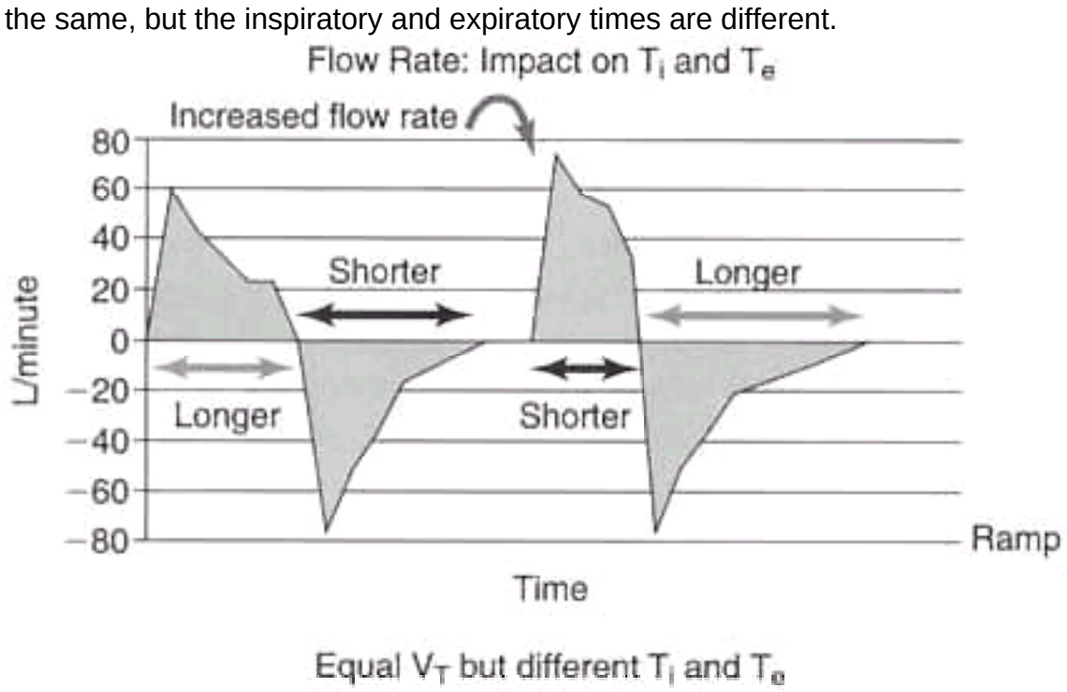

Figure 8-6 Airway Pressure Release Ventilation (APRV)—airway pressure-time and flow-time traces. Note that the peak airway pressure (P_{aw}-high) is maintained for a long period. This phase establishes oxygenation (T_{high}). There is a short period of release when most CO_2 is cleared (T_{low}). Note that the bottom trace is flow over time. The combined time for the T_{high} and T_{low} is known as a phase cycle. Note that the number of phase cycles is not the respiratory rate as patients breathe within the entirety of the T_{high}. As the release phase is initiated, the flow rate is identified as negative and is of a high rate (here approximately 7.5 L/min), consistent with significant alveolar recruitment. During the high CPAP phase, the patient is allowed to exhale (negative deflections on the flow-time trace). Thus, APRV is quite dissimilar from traditional cyclic ventilation. This unique mode is made possible by a floating valve system.

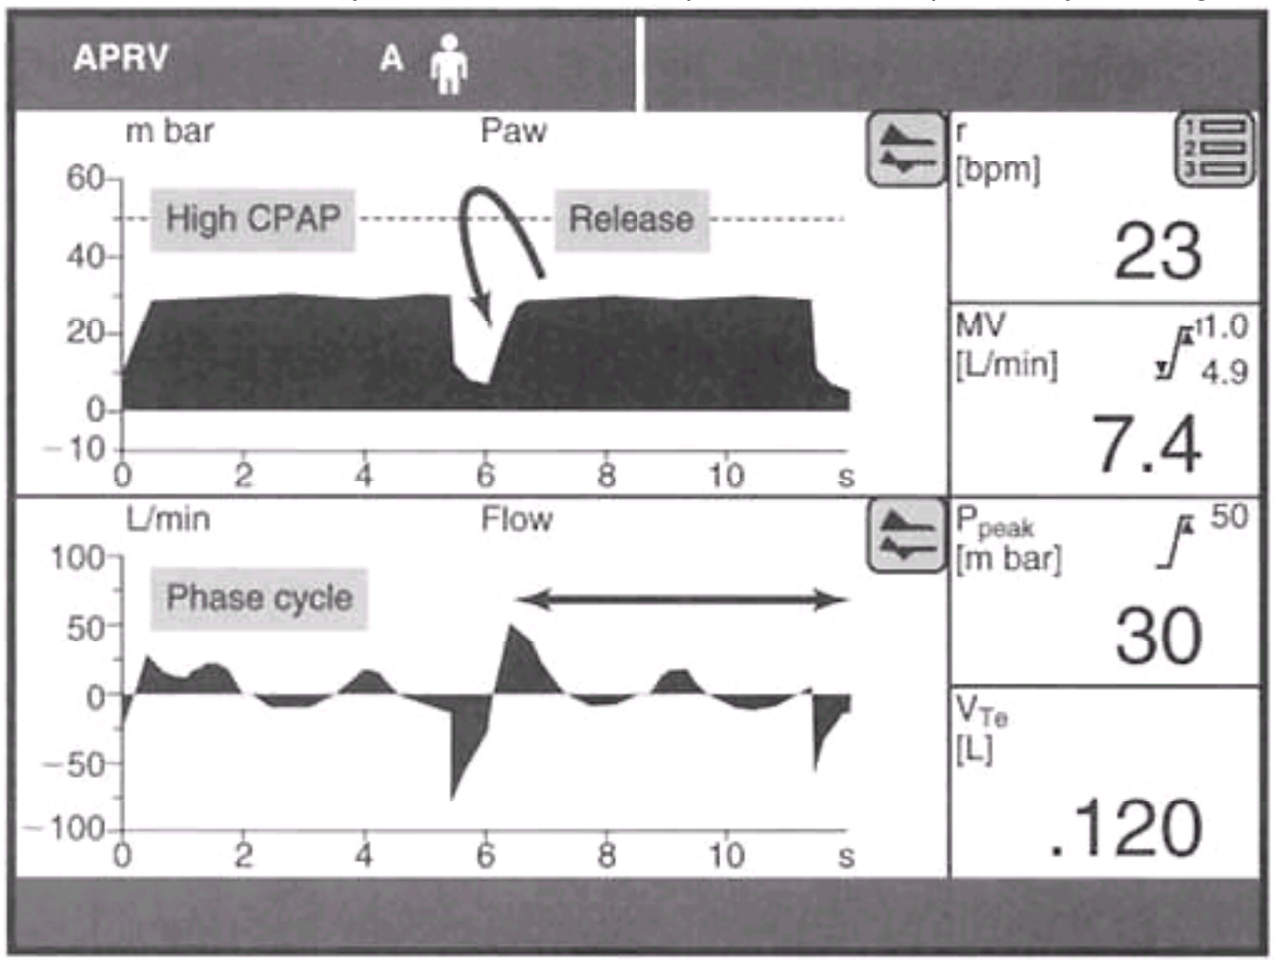

Figure 8-7 Chest geometry and prone position. Note that ovoid chest geometry results in equal volumes above and below the transverse axis leading to no change in recruited lung volume with pronation. Triangular chest geometry leads to a significant increase in lung volume with prone positioning. This is by virtue of the large volume of lung that lies posterior to the transverse plane with the patient in the supine position. Increases in cardiac volume reduce the available retrocardiac lung volume and impair the effectiveness of prone positioning with regard to pulmonary recruitment.

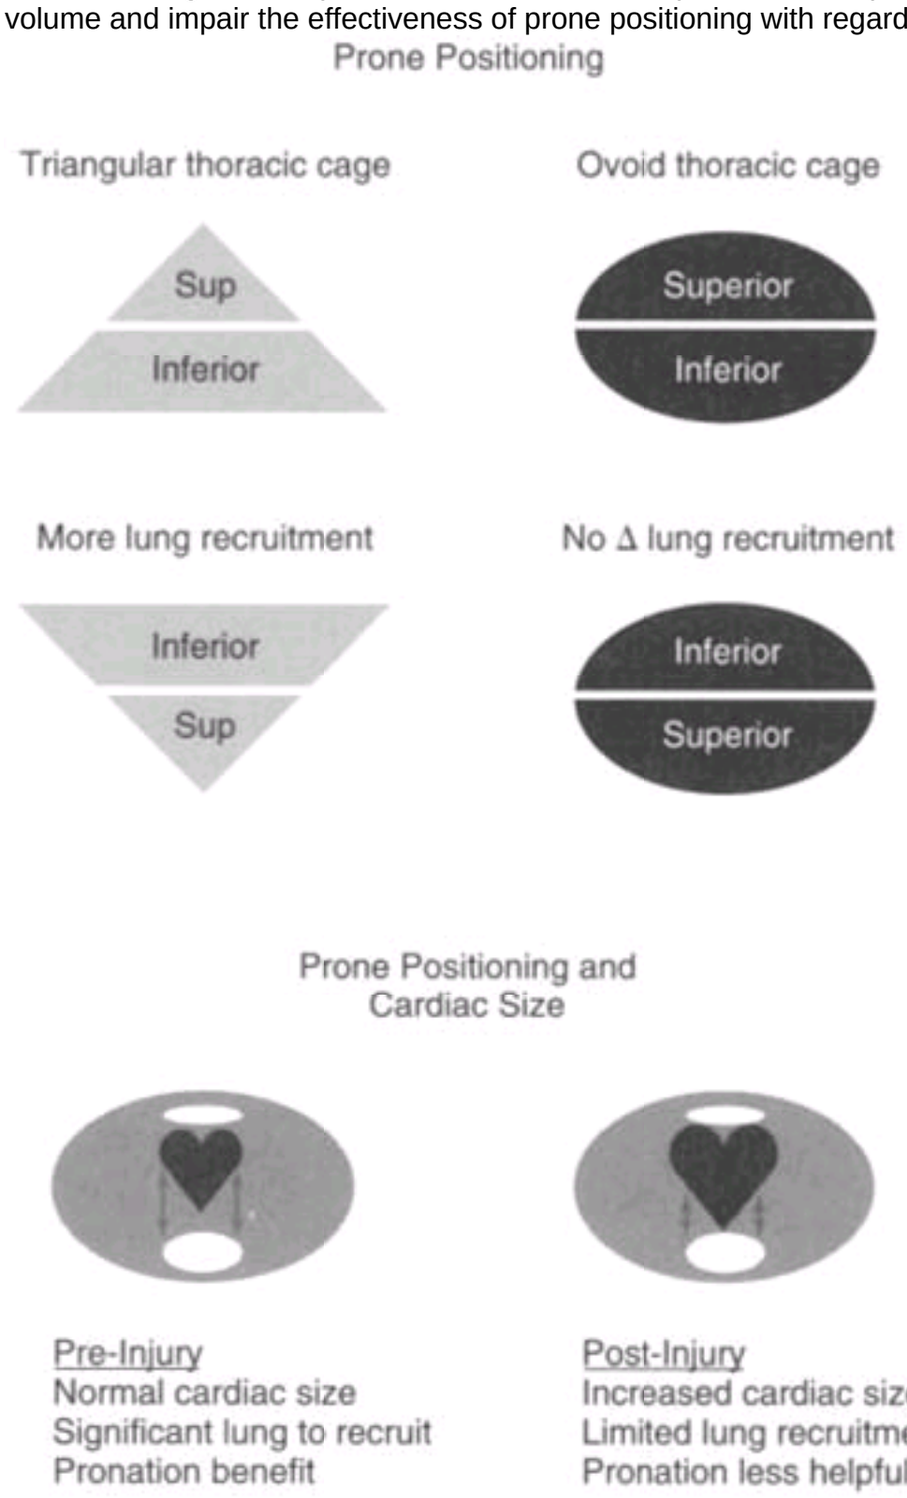

Figure 8-8 Alveolar overdistension is reflected in the increase in airway pressure without any concomitant increase in tidal volume. This pressure-volume curve pattern approximates a "bird's beak" profile.

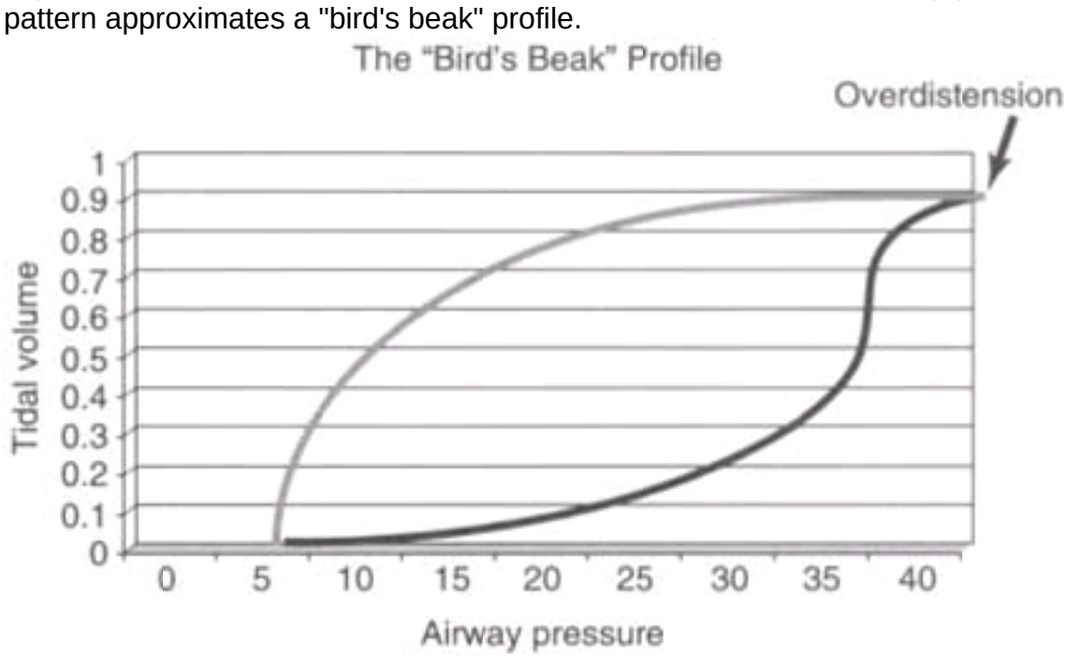

Figure 8-9 Mean airway pressure and the pressure-time trace. Note that the greater the maximum airway pressure and the longer the T_i, the greater the area under the curve (AUC) described by the positive-pressure (inspiratory) limb of the respiratory cycle. The increase in mean airway pressure (area under the curve) is the principal correlate of oxygenation in volume or pressure-cycled ventilation.

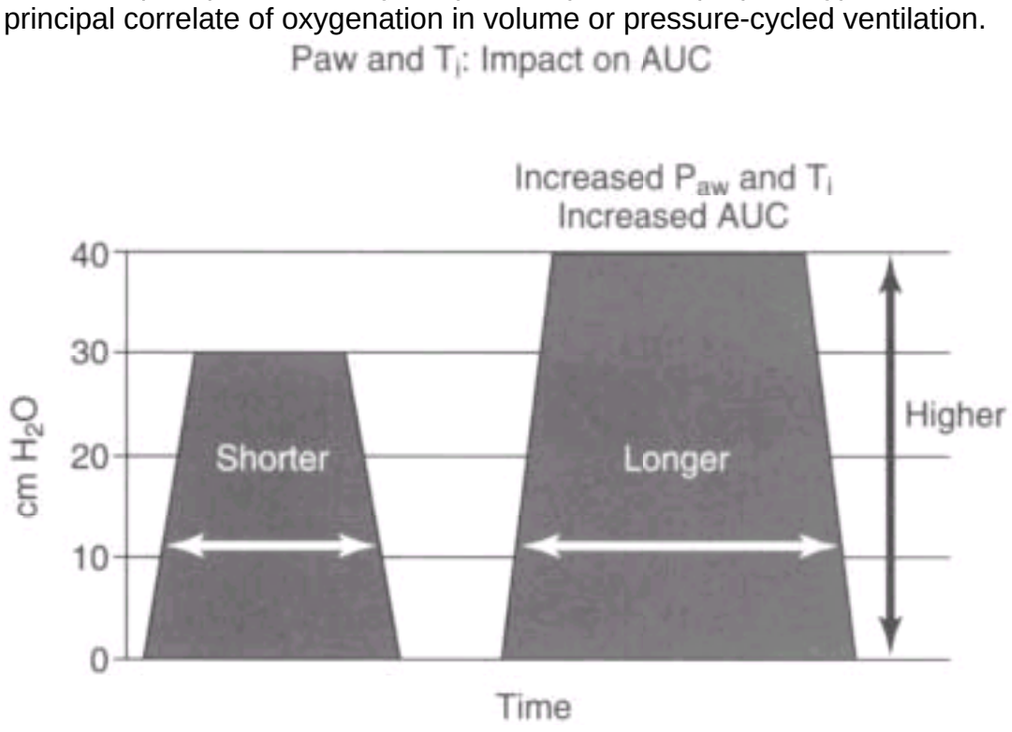

Figure 8-10 Confounders in the diagnosis of pneumonia. Fever, leukocytosis, radiographic infiltrate, and sputum production do not necessarily indicate the diagnosis of pneumonia. Multiple other causes should be considered as well so that one does not apply antibiotics when there is no infectious agent to address. ALI = acute lung injury, ARDS = acute respiratory distress syndrome.

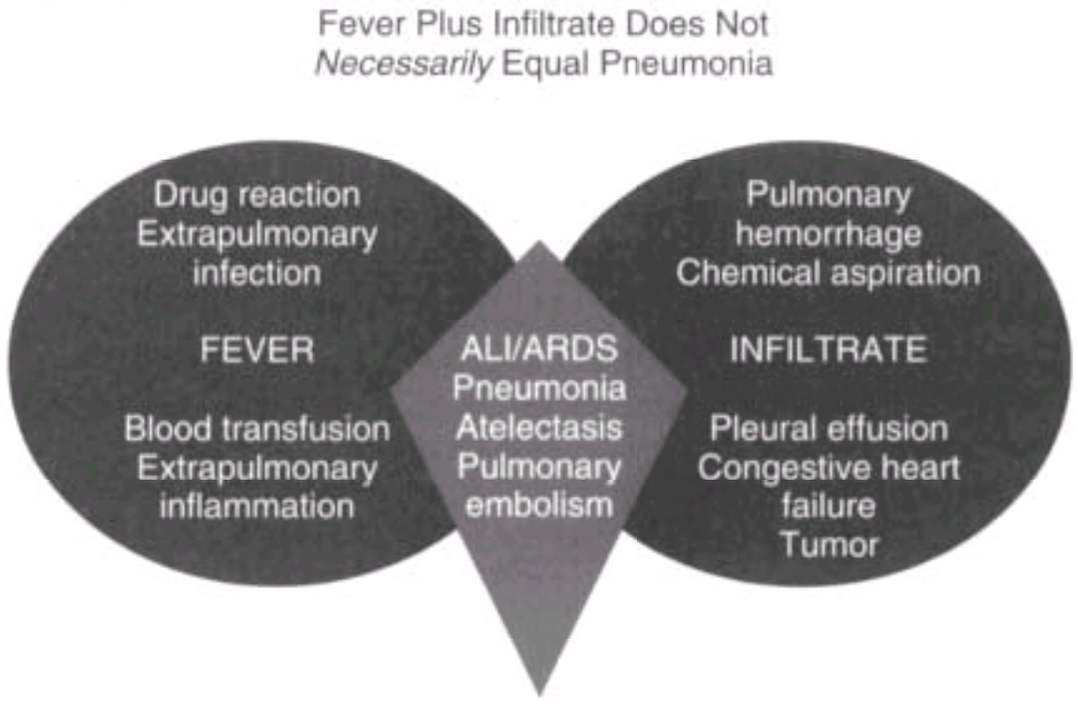

Figure 8-11 The Bispectral Index monitor (Aspect Medical, Nantucket, MA). This is a pole-mounted device that attaches to the patient's forehead and provides a modified single-lead electroencephalogram whose power spectrum undergoes a Fourier transformation to yield a numeric representation of the level of sedation.

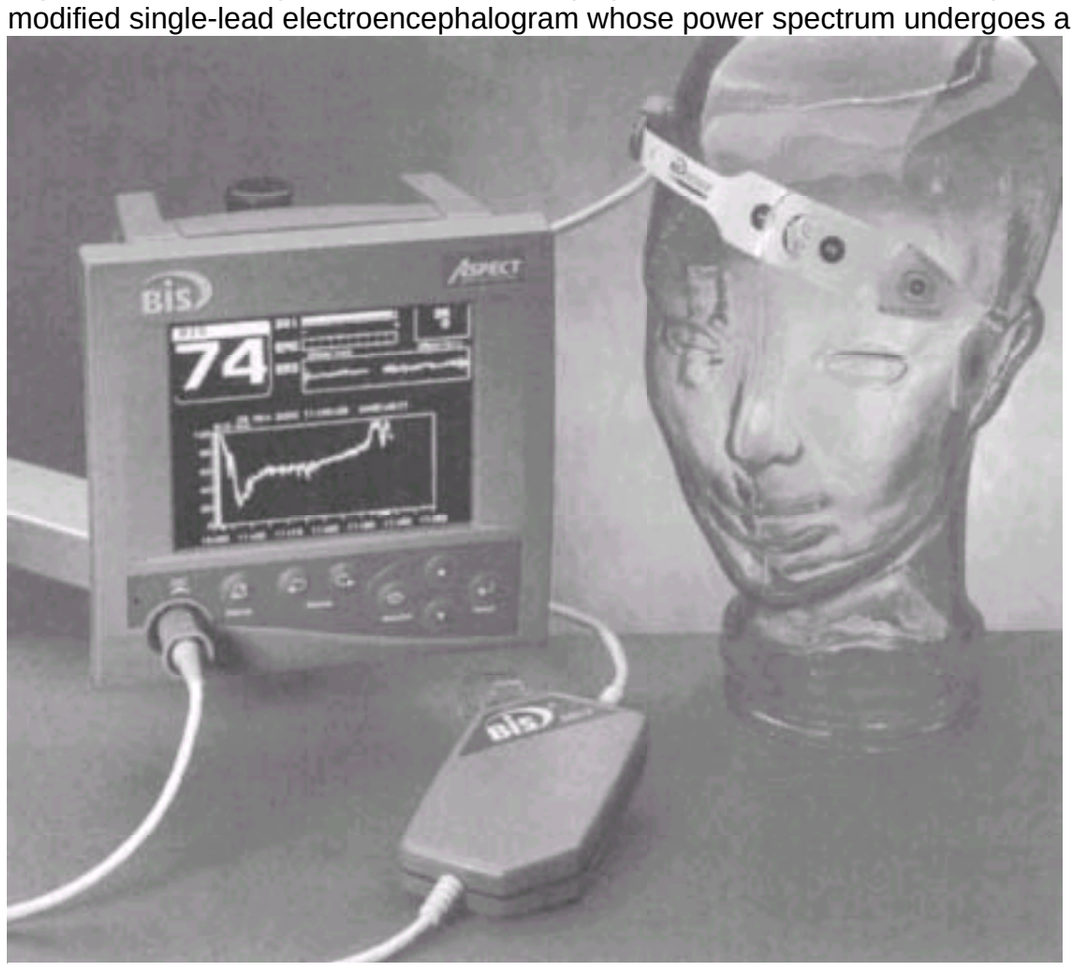

Figure 8-12 Volume guarantee ventilation. Note that the ventilator uses the prior breath to determine how much support is required to achieve the desired tidal volume and remain within the set pressure limit.

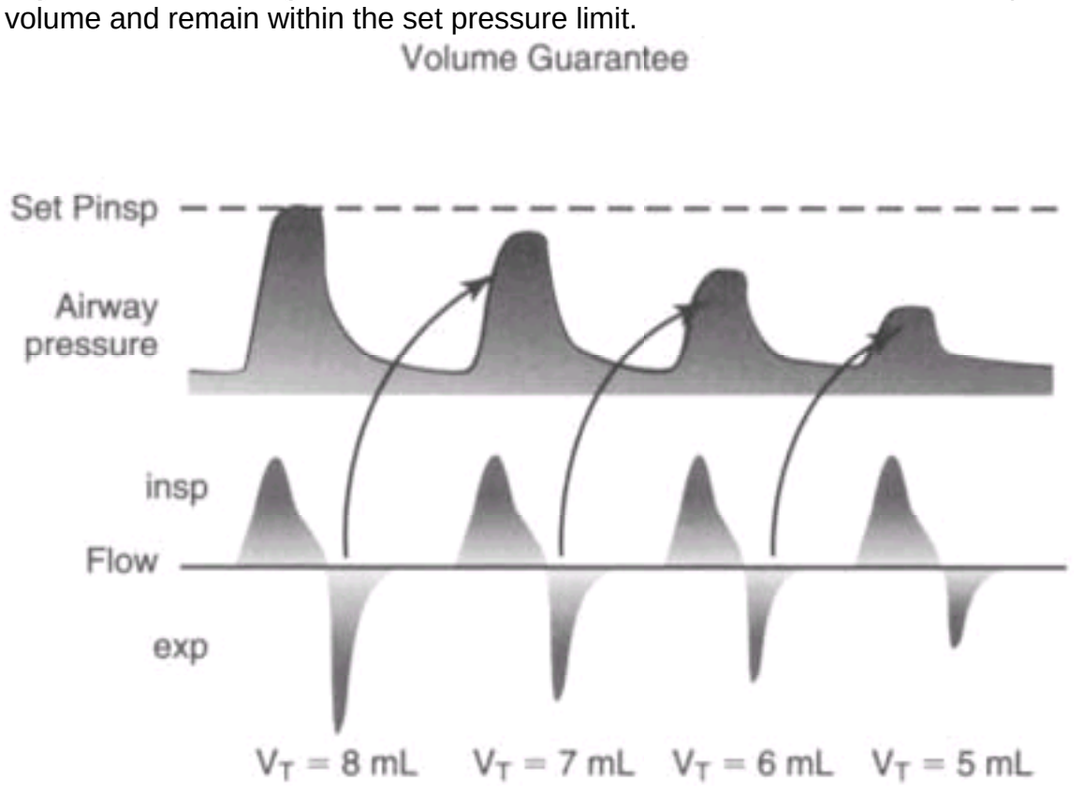

Figure 8-13 Pressure support volume guarantee ventilation. As the compliance of the lung (C lung) improves, the positive inspiratory pressure (PIP) decreases while maintaining a constant tidal volume (V_T). When the pressure support volume is reduced to an acceptable minimum level, weaning has been achieved and the patient should be evaluated for liberation from mechanical ventilation.

PSV + VG: The Concept of "Autoweaning"

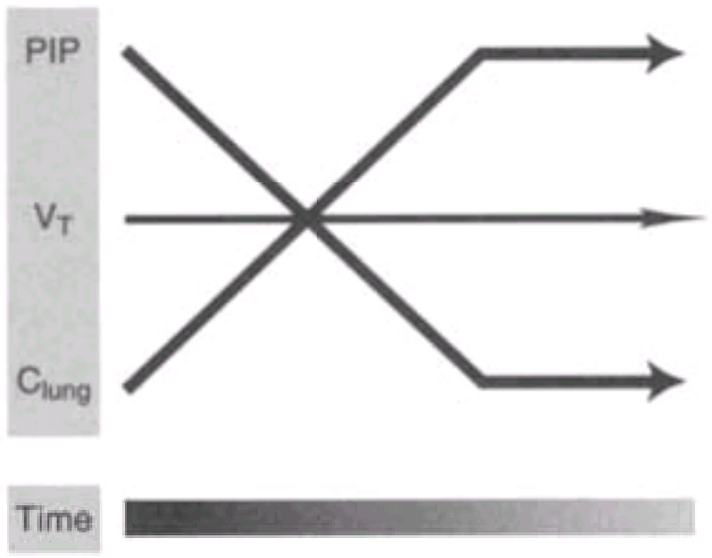

Figure 8-14 *Continuous positive airway pressure* (CPAP) mask. This is a nasal CPAP mask and has a low-pressure bladder around the rigid mask. There is a hook-and-loop closure strap system to secure the mask to the patient. Care must be taken to ensure a proper fit. The goal is to achieve a tight seal without creating undue pressure on the skin, nose, or other bony prominences of the head, thus avoiding pressure necrosis.

Figure 8-15 The BiPAP machine. Each hospital may have a different BiPAP device. The key features are an O_2 connection to bleed-in O_2, a rate control, and separate controls for the level of inspiratory positive pressure (IPAP) and expiratory positive pressure (EPAP), as well as separate timing controls for IPAP and EPAP. Clinicians should familiarize themselves with the unique features of the device available at their institutions.

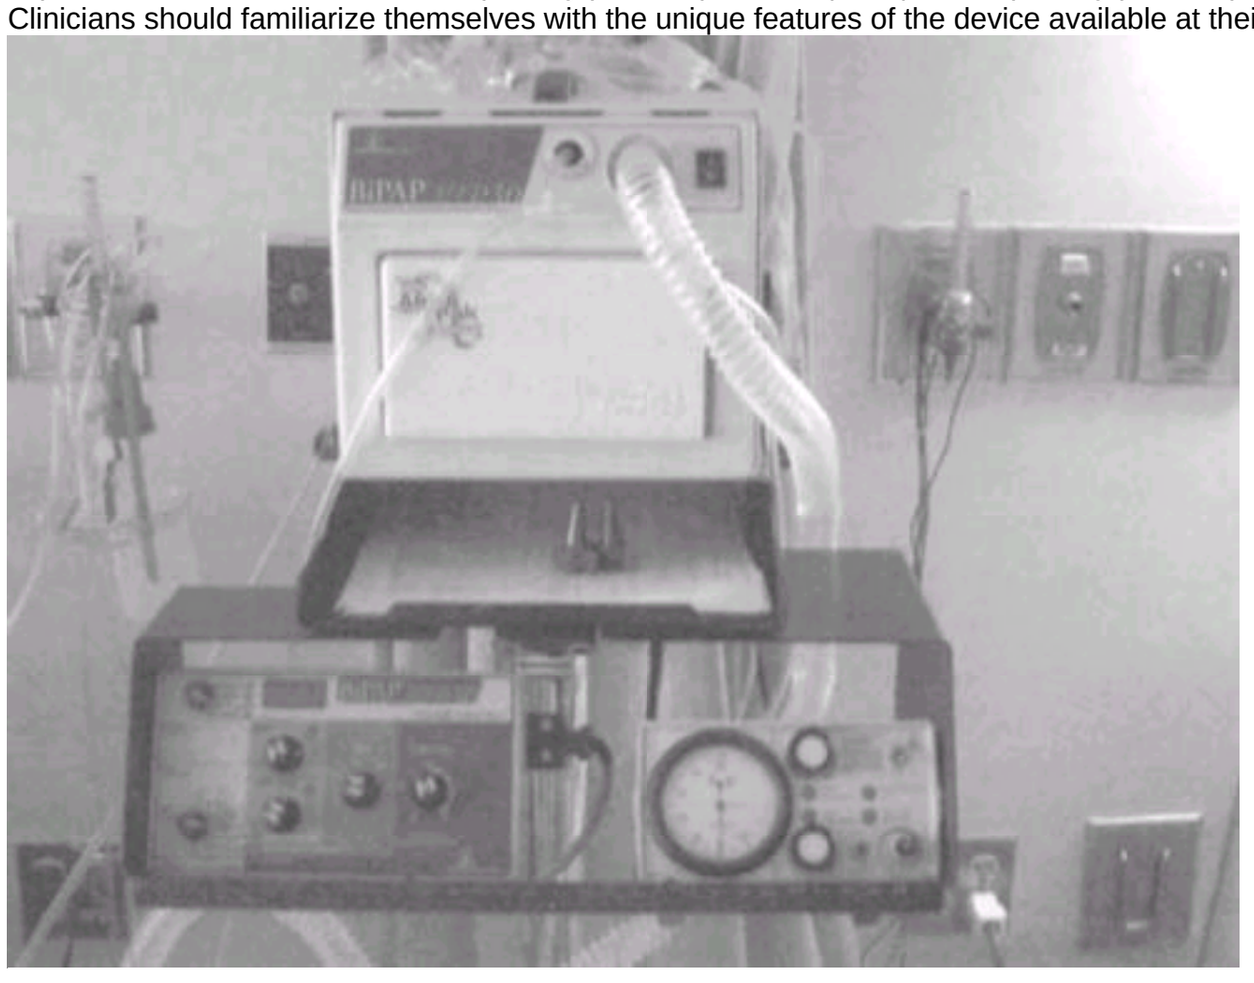

Figure 8-16 The end-tidal CO_2 ($ETCO_2$) trace. This diagram of an $ETCO_2$ capnograph represents normal exhalation flow dynamics. As exhalation progresses, the measured CO_2 rises and eventually plateaus. At the end of the plateau, immediately before the downstroke of the trace is the point at which the $ETCO_2$ value is measured and reported (i.e., point "D"). No other values are reported on the $ETCO_2$ capnometer. Thus in the absence of the capnograph, all other information is unavailable to the clinician. Abnormalities in endotracheal tube position, blockage of the airway (complete or partial), as well as correct endotracheal tube placement, are identifiable by evaluating the $ETCO_2$ tracing. *(Reproduced with permission from Drager Medical.)*

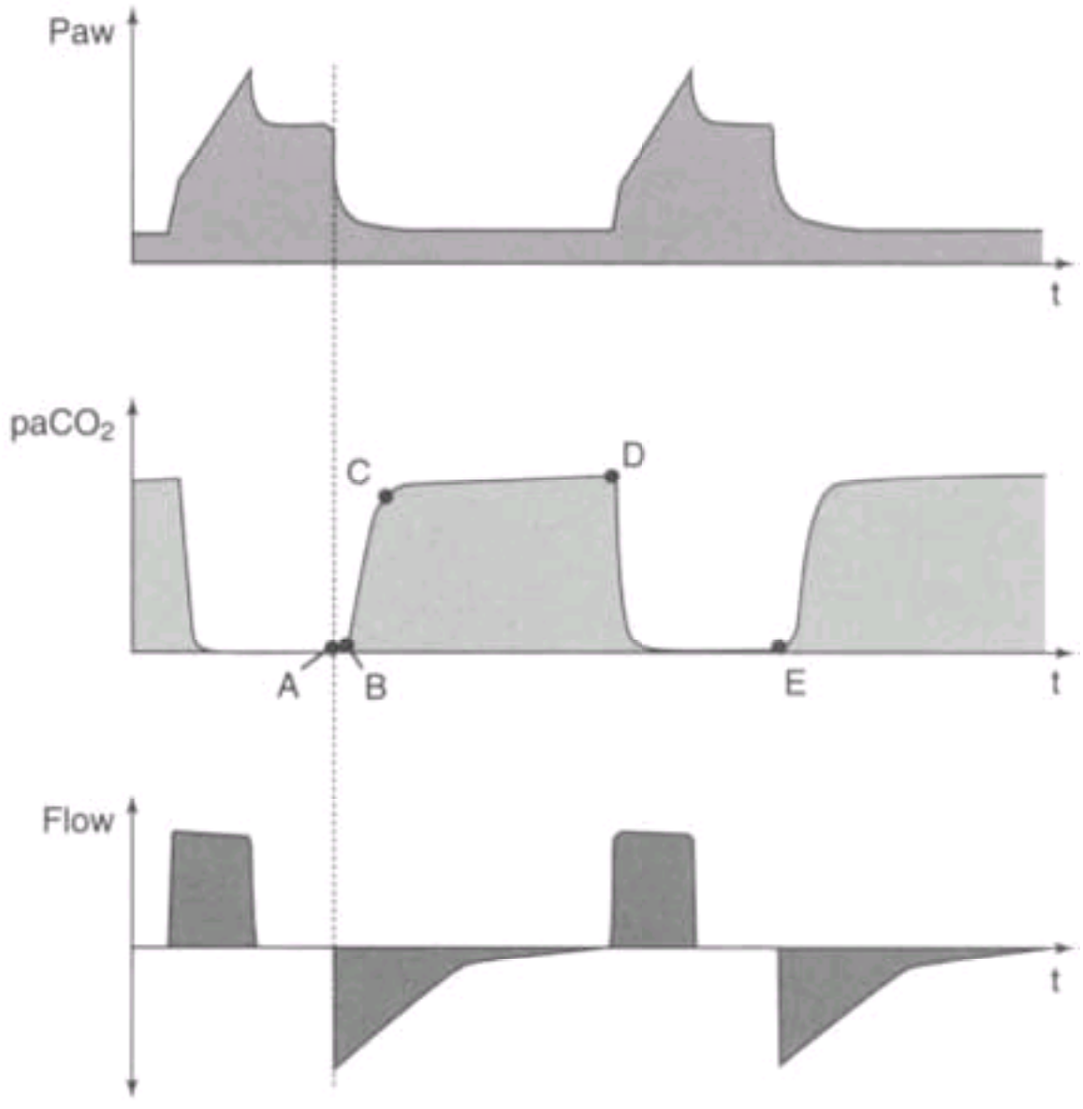

Figure 8-17 The $ETCO_2$ tracing in COPD—identification of auto-PEEP. In this diagram of an $ETCO_2$ trace in a patient with COPD who is being ventilated at a high respiratory rate, one may detect the presence of auto-PEEP based on the abnormal expiratory flow pattern. A similar suggestion could be obtained by interrogating the flow-time trace as well.

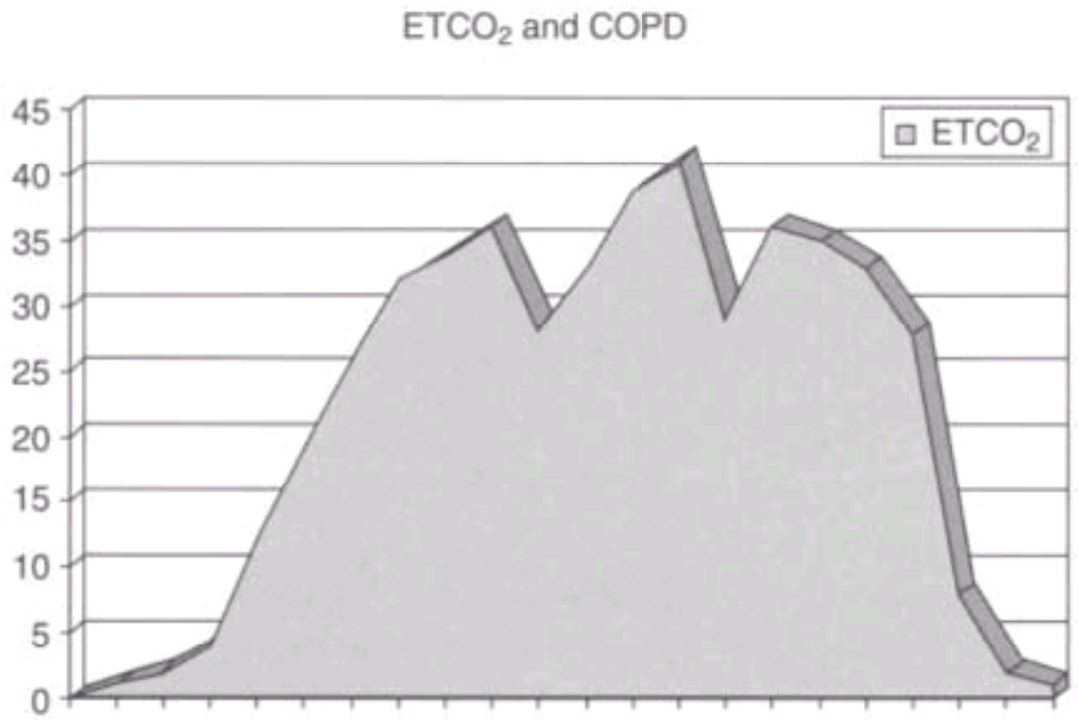

Figure 8-18 The Puritan-Bennett 7200 Model ventilator. Note that on this particular ventilator, the controls are grouped into three distinct areas of the ventilator faceplate. To the left of the picture are display areas in green that indicate pressures (top), rate and I:E ratio (middle), and volumes (bottom). At the very top of the green section is an analog pressure meter to confirm pressures in the case of a liquid-crystal display (LCD) malfunction. The center portion (blue) houses the data entry keypad, the alarm limit-setting buttons, waveform selection, sighs, and 100% O_2 for suctioning button. Note that the "++" button is the selector to change between options that are displayed in the horizontal LCD bar above the keypad. Function 10 is the function to set the pressure support and is accessed by using the "++" key until the number 10 appears. One must then press Enter to access the function. The top of the blue section has the PEEP/CPAP knob, as well as the displays for peak flow, FIO_2 , set rate, and tidal volume. The gray section to the right indicates the alarm status as well as the alarm silence button.

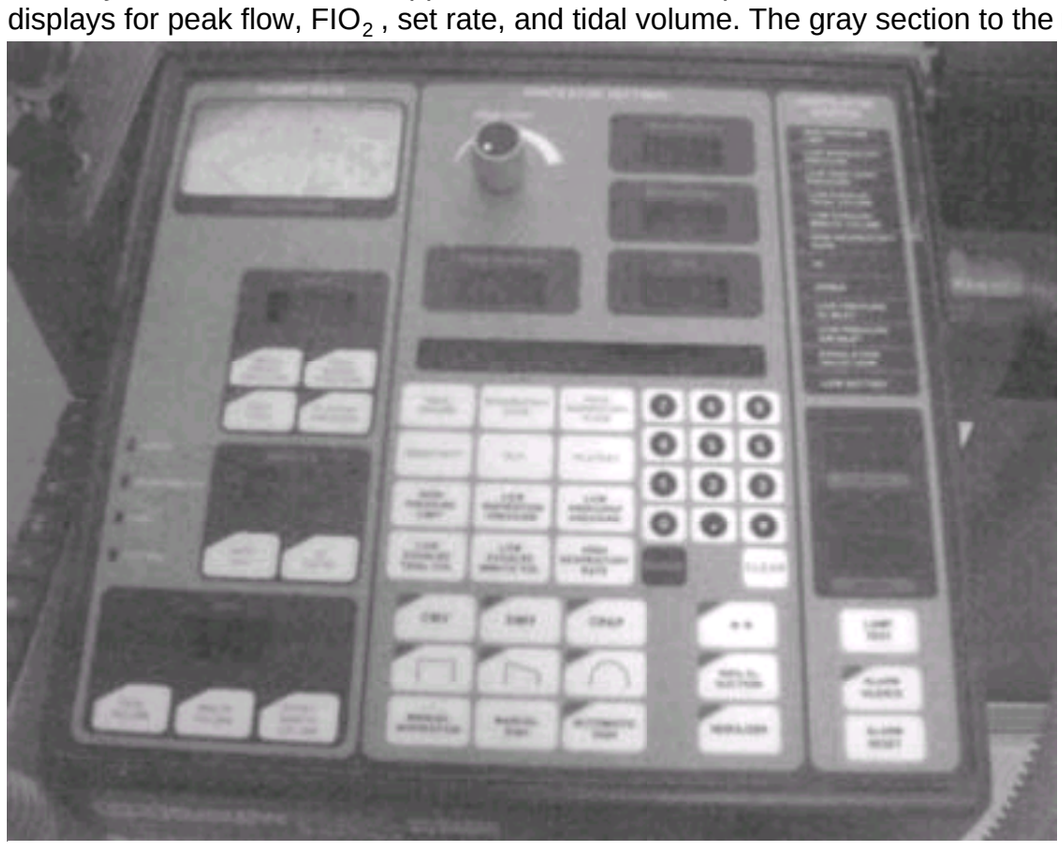

Figure 8-19 Faceplate for the Drager Evita 4 Pulmonary Workstation. Note that the liquid-crystal display (LCD) screen is colored and has controls embedded in the screen to adjust the individual mode settings. The righthand controls on the front of the device control the kind of screen display, the silence button, and the standby button.

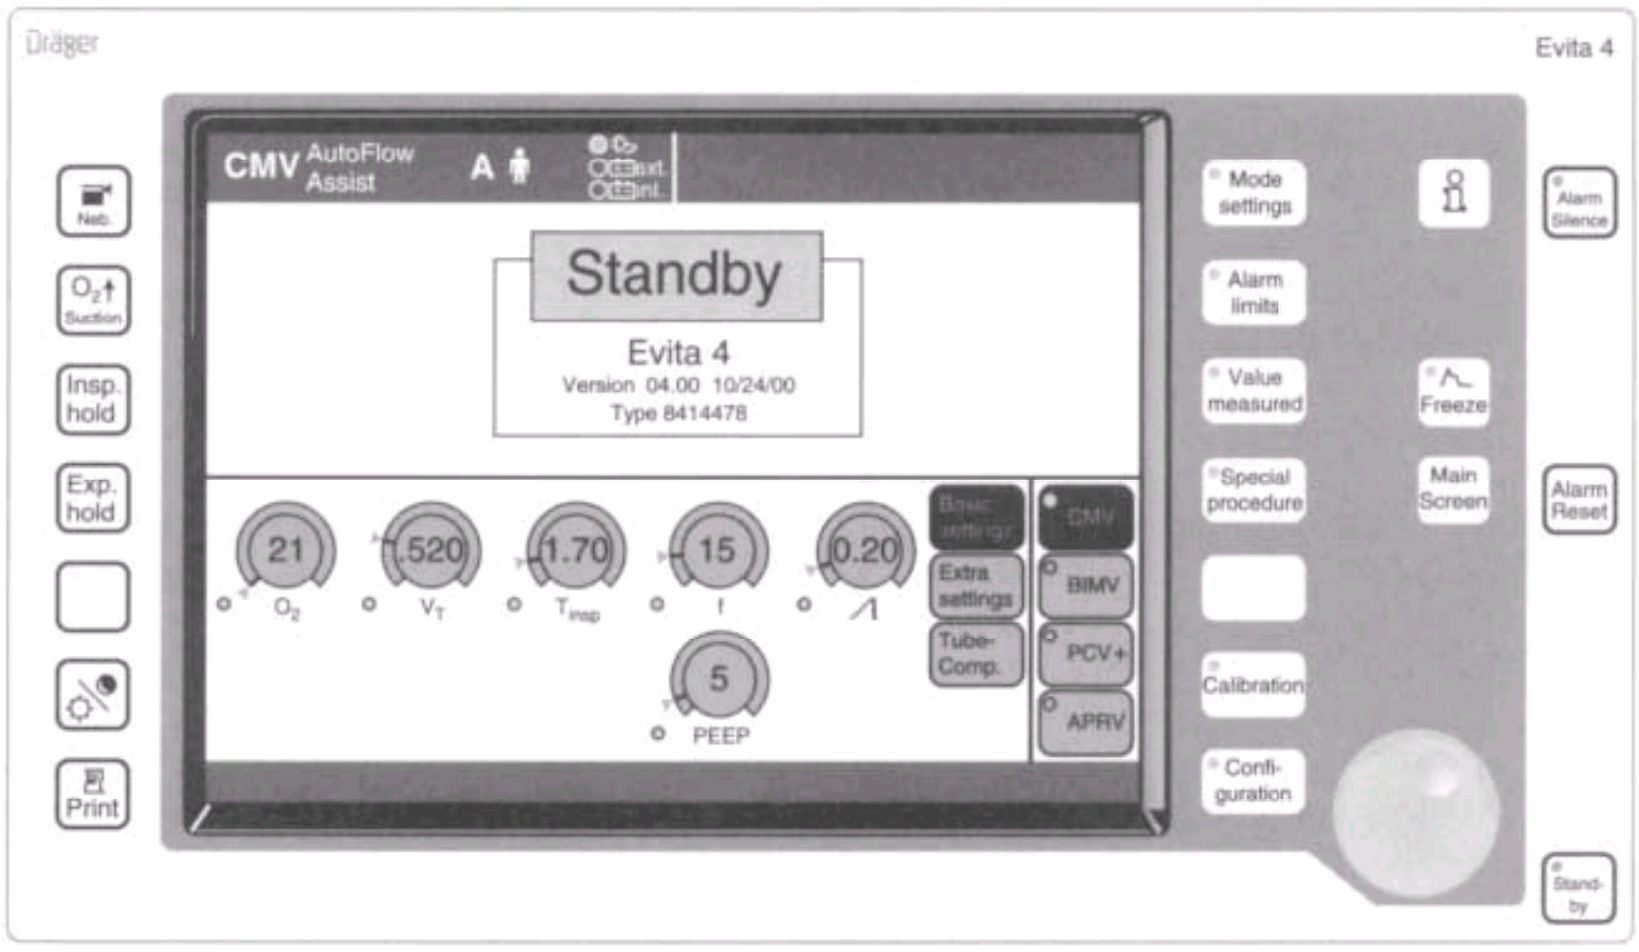

Figure 8-20 The pressure-volume curve on the Adult Star ventilator. Note that the curve is identical to the type of curve one would obtain on the E $_4$ with the exception of color and the ability to freeze a reference curve for comparison. Here it is accompanied by the flow-time loop, as well.

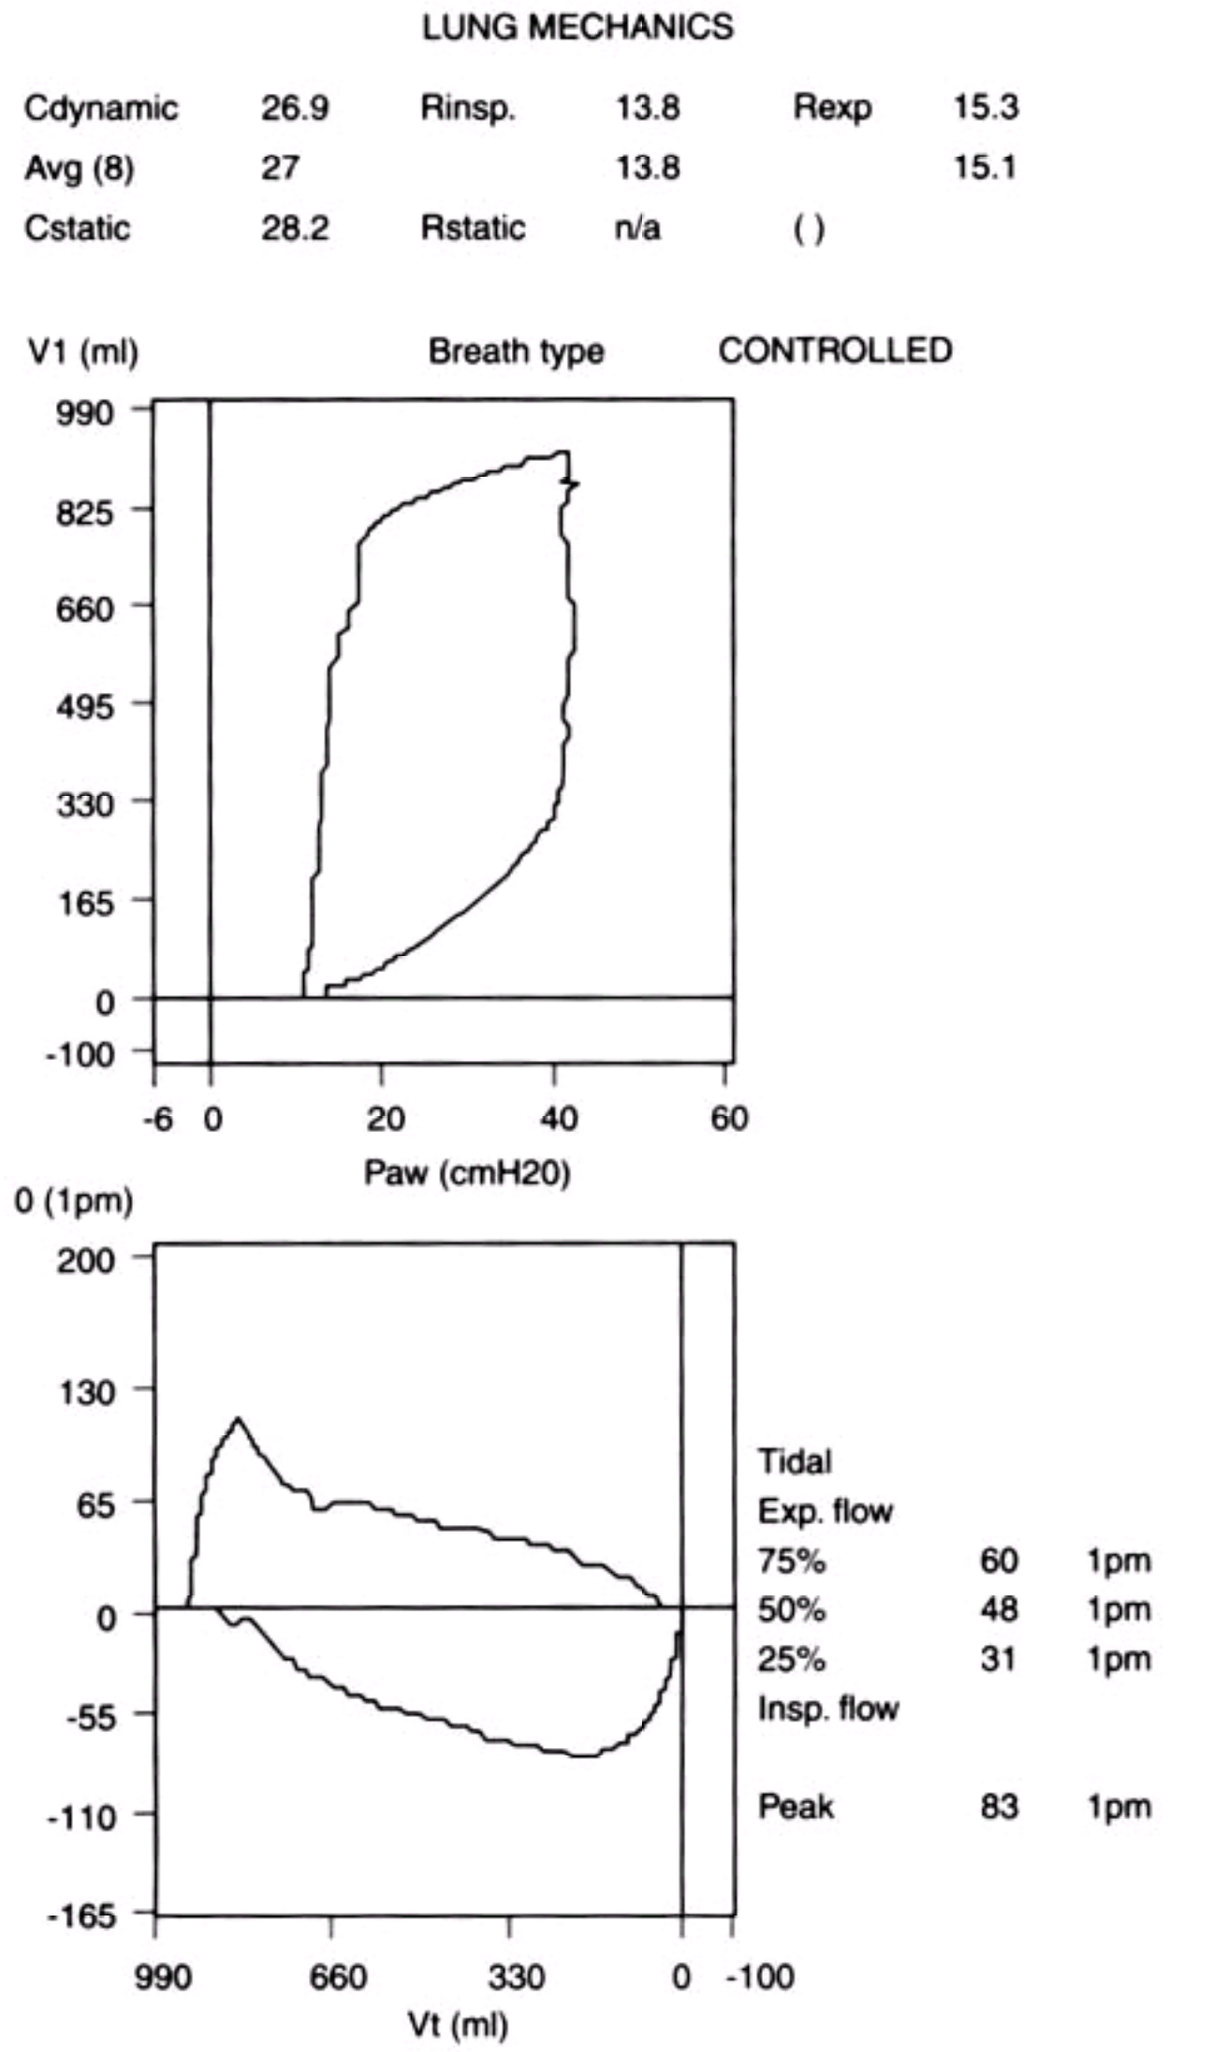

Figure 8-21 Pressure-volume curve on the E_4 . This display may be brought up as a solo display, or integrated into other multi-display screens as indicated above. One accesses the menu on the lower right of the screen by activating the "values measured" button on the right of the faceplate (not the liquid-crystal display [LCD] screen). Then press Loops. The device will either display a continuous set of loops, or a reference and a single breath (yellow button illuminated on the appropriate green icons).

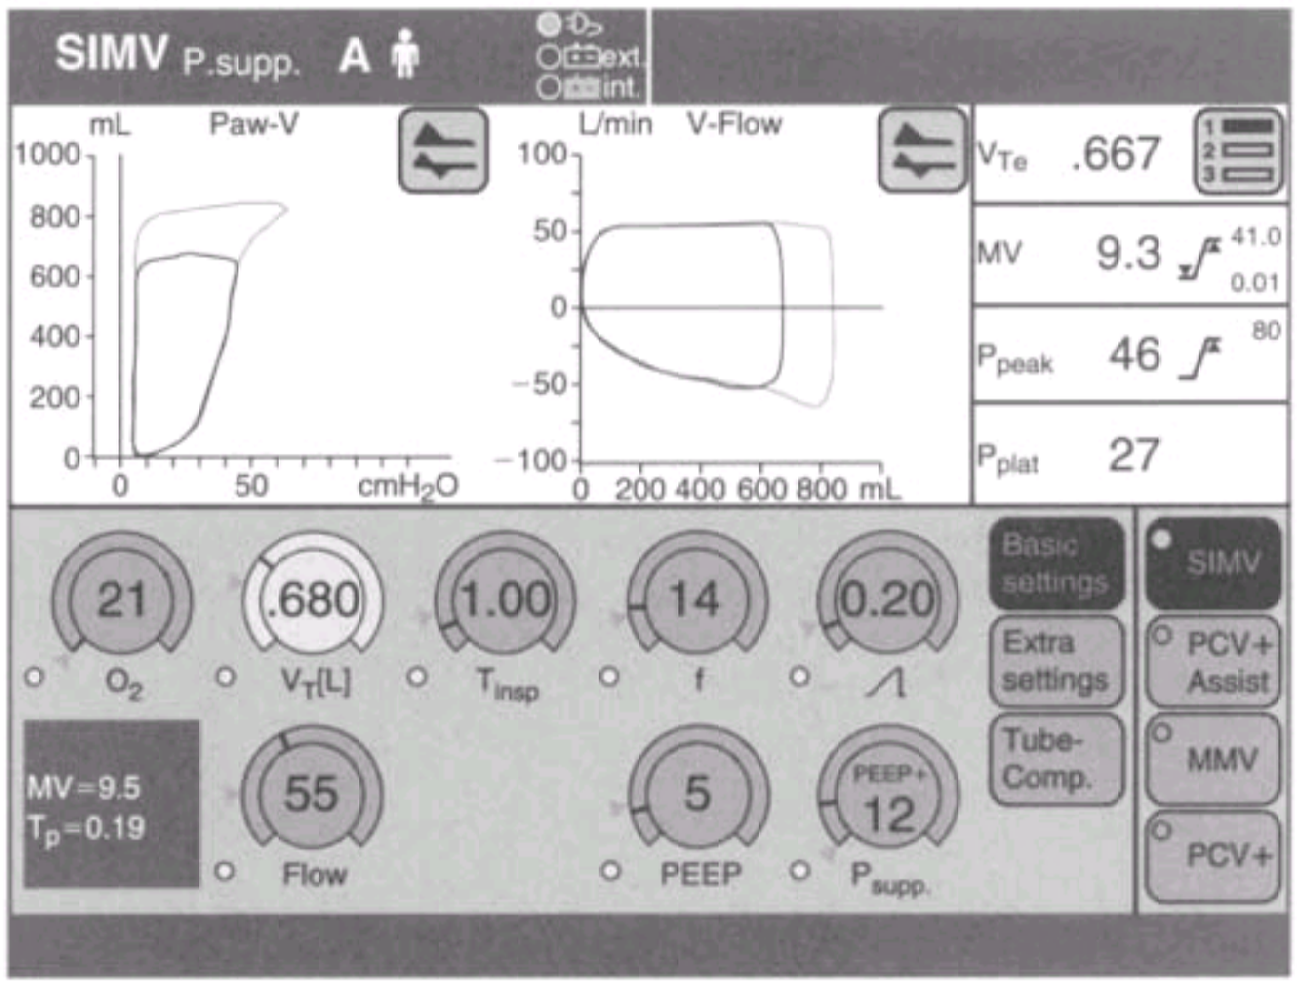

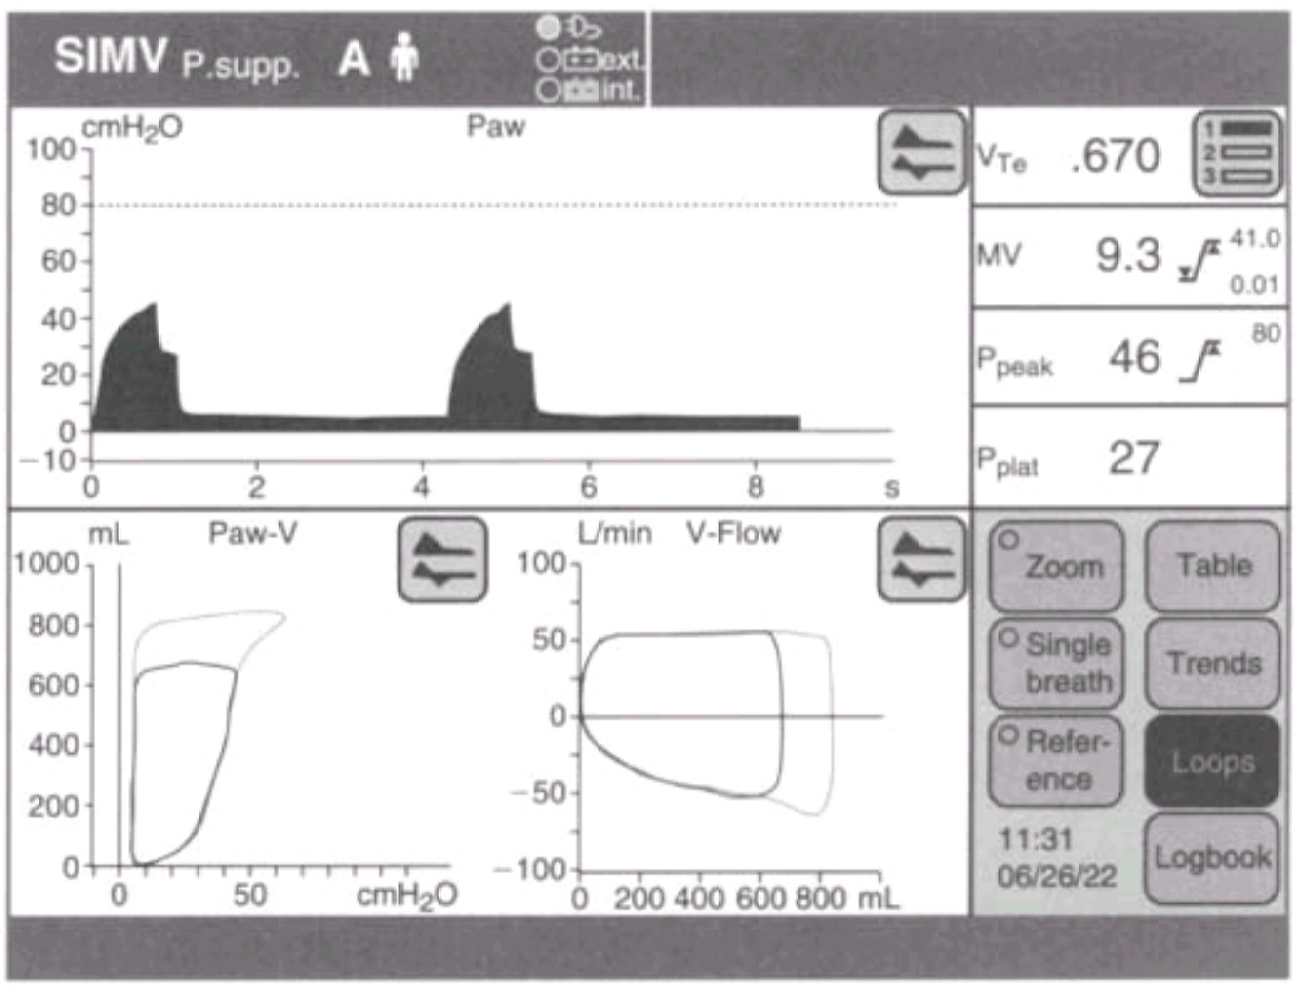

Figure 8-22 Intrinsic PEEP (PEEPi). The E_4 will measure the intrinsic PEEP as well as the trapped volume responsible for that PEEPi. The function is accessed by using the "special procedure" button on the righthand side of the faceplate, activating the "start" button on the liquid-crystal display [LCD] screen, and then depressing the knob to initiate the procedure. In this example, the PEEPi is 0.4 cm H_2O pressure and represents a volume of 155 mL (0.155L) of gas.

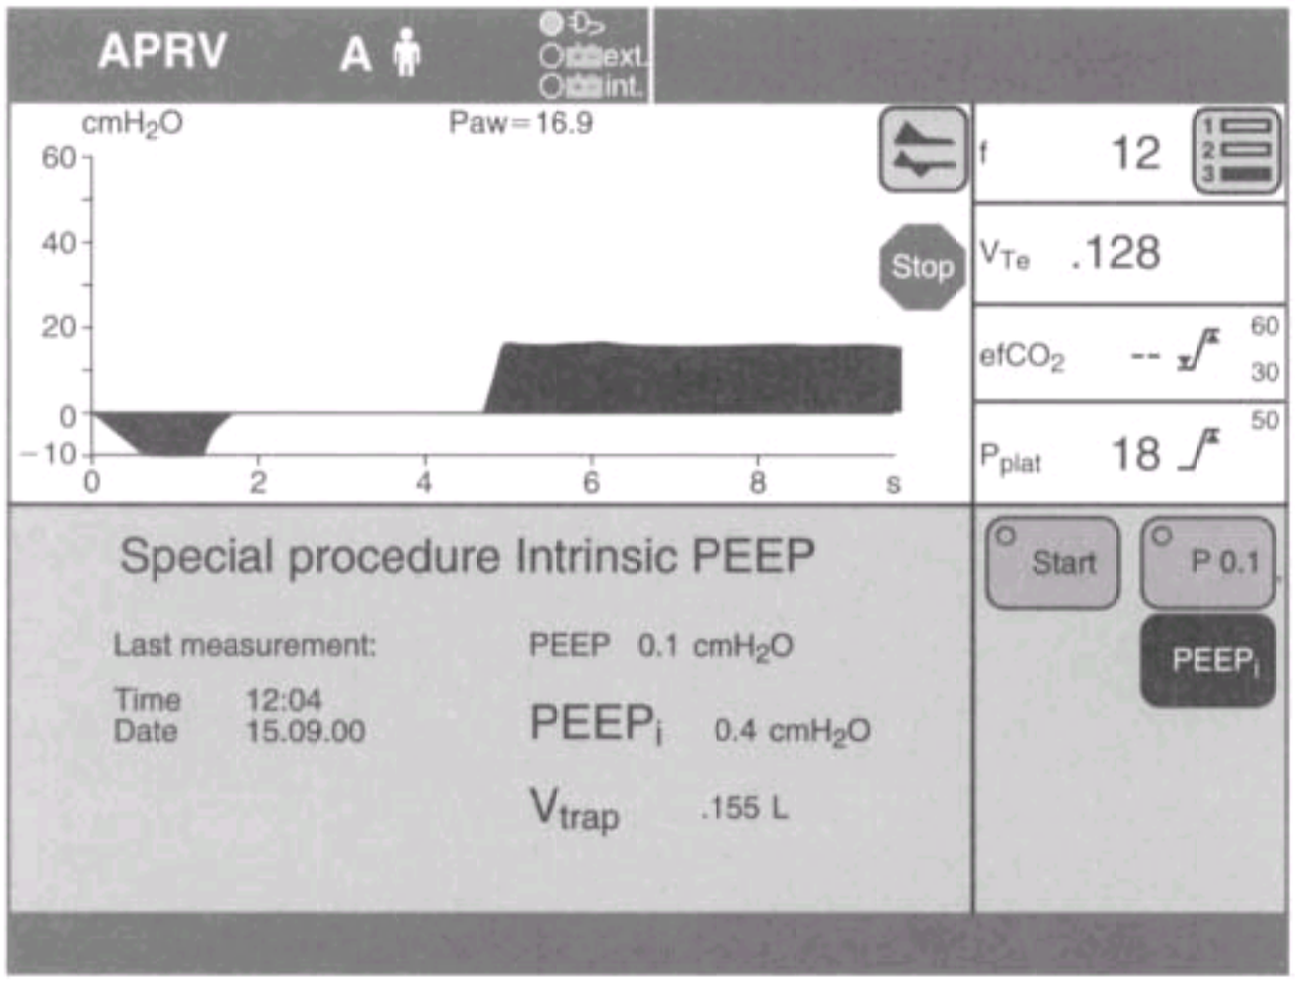

Figure 9-1 Schematic of relationships between the parietal and visceral pleura.

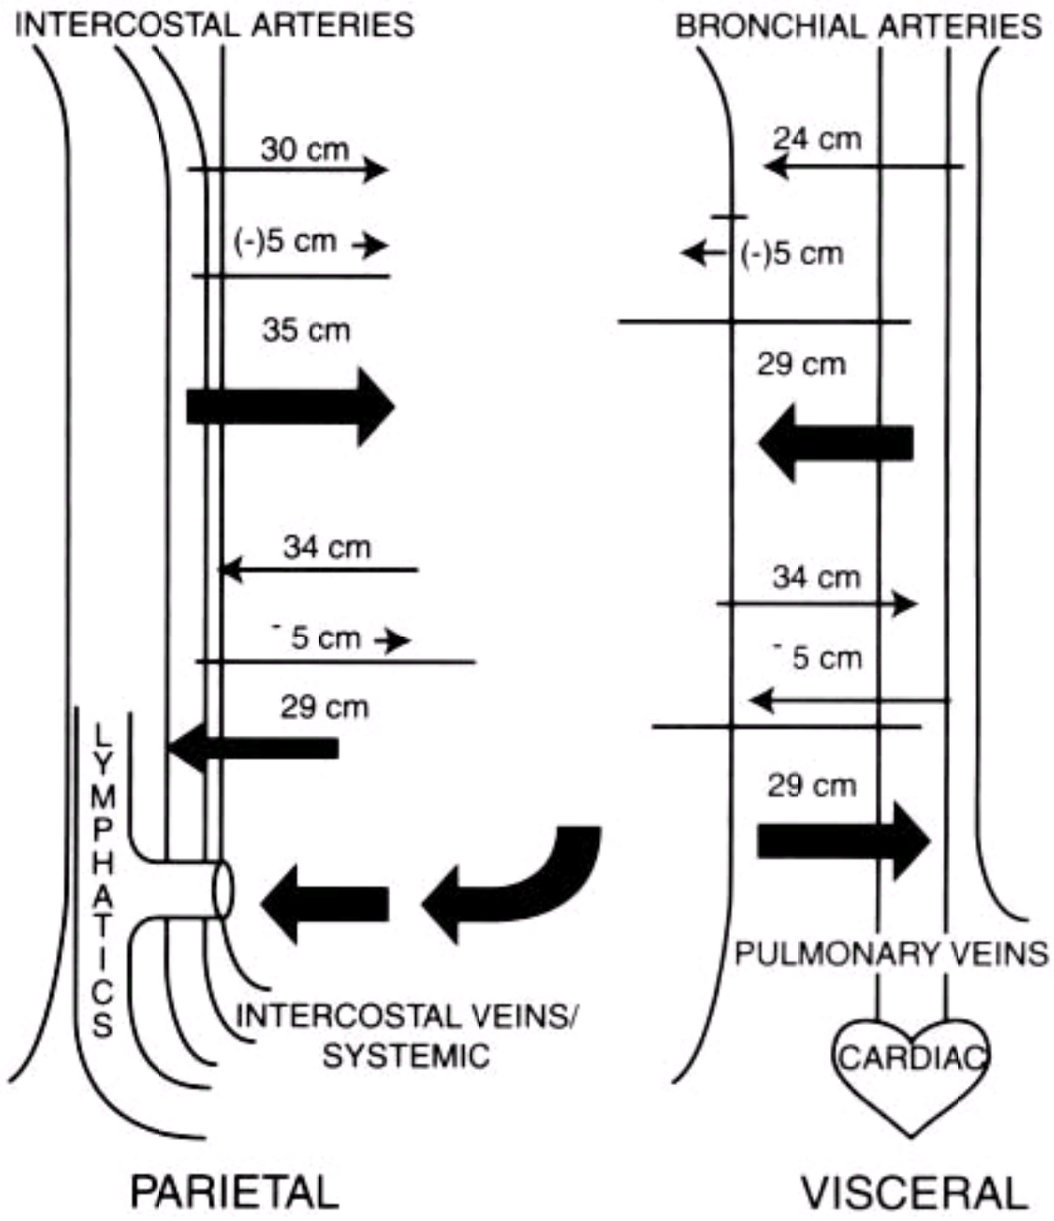

Figure 9-2 Right-sided pleural effusion. Posterior-anterior (PA) radiograph demonstrates blunting of right costophrenic angle. Both PA and lateral radiographs demonstrate the appearance of a meniscus.

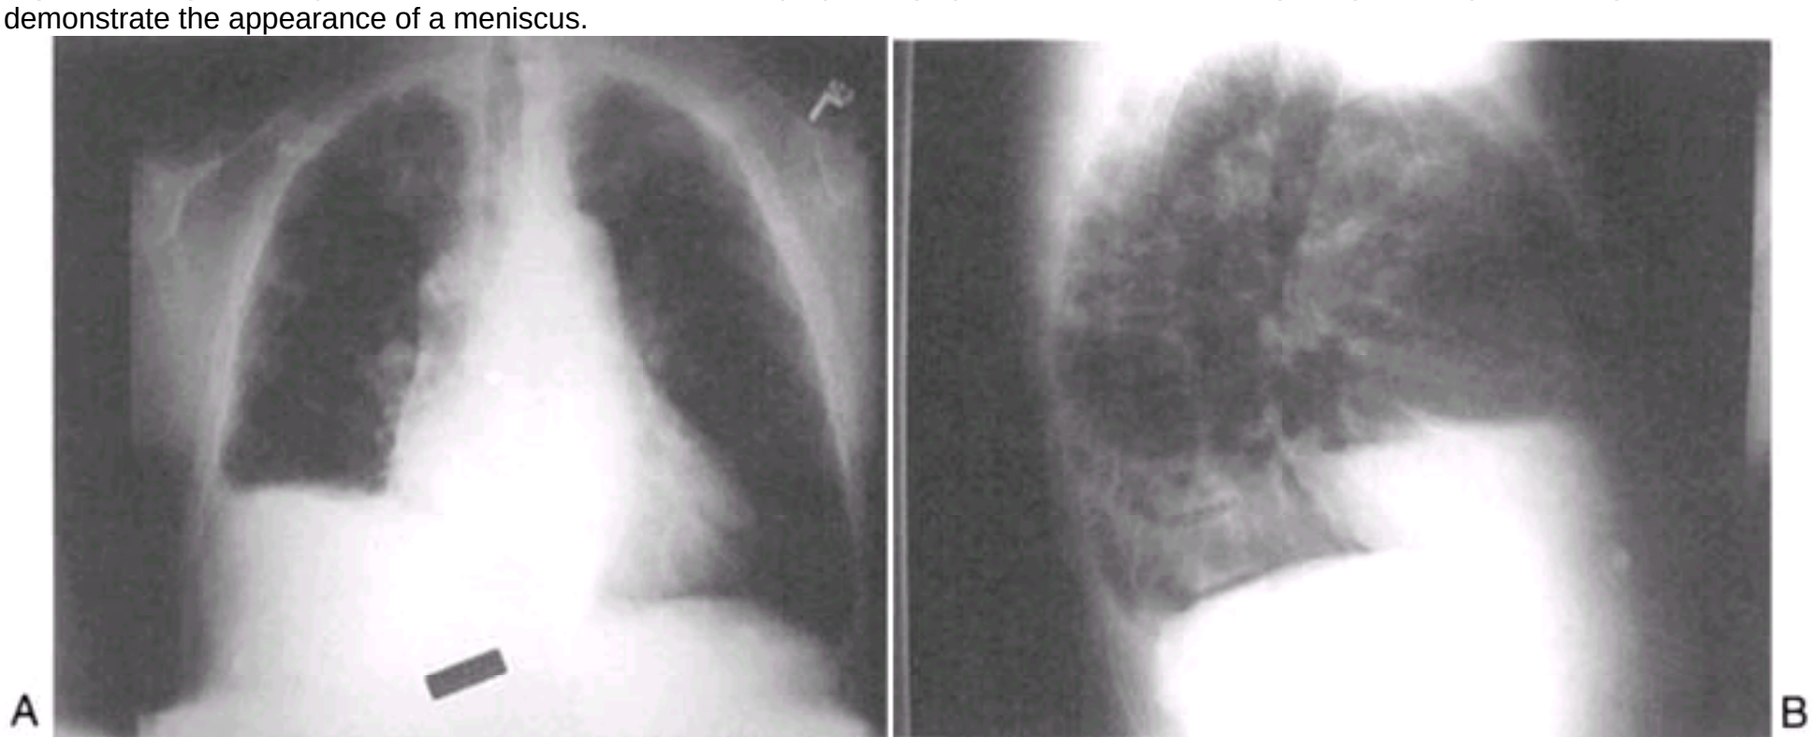

Figure 9-3 Loculated pleural effusion. This posterior-anterior radiograph demonstrates the D-shaped appearance of a right-sided loculated pleural effusion.

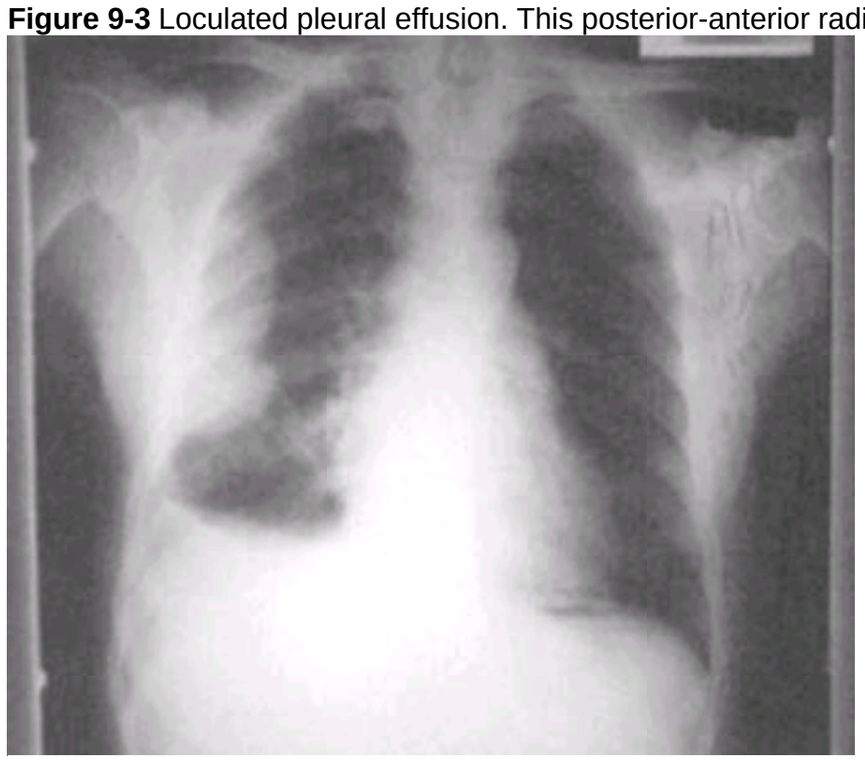

Figure 9-4 Subpulmonic effusion. This posterior-anterior radiograph demonstrates an elevated left hemidiaphragm that peaks more laterally than expected. A decubitus radiograph in the same patient demonstrates the free-flowing fluid.

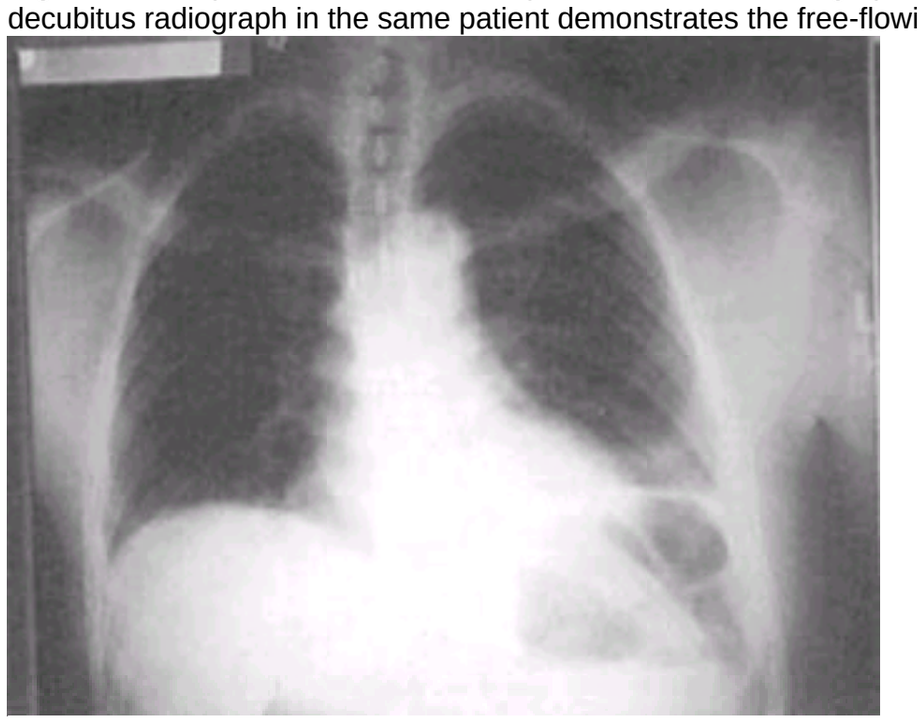

Figure 9-5 Bilateral decubitus radiographs. This patient's right-sided pleural effusion appeared on the posterior-anterior radiograph. Bilateral decubitus views demonstrate the free-flowing nature of the effusion and allow visualization of the lung parenchyma.

Figure 9-6 Massive pleural effusion. A repeat radiograph after thoracentesis demonstrates underlying mass.

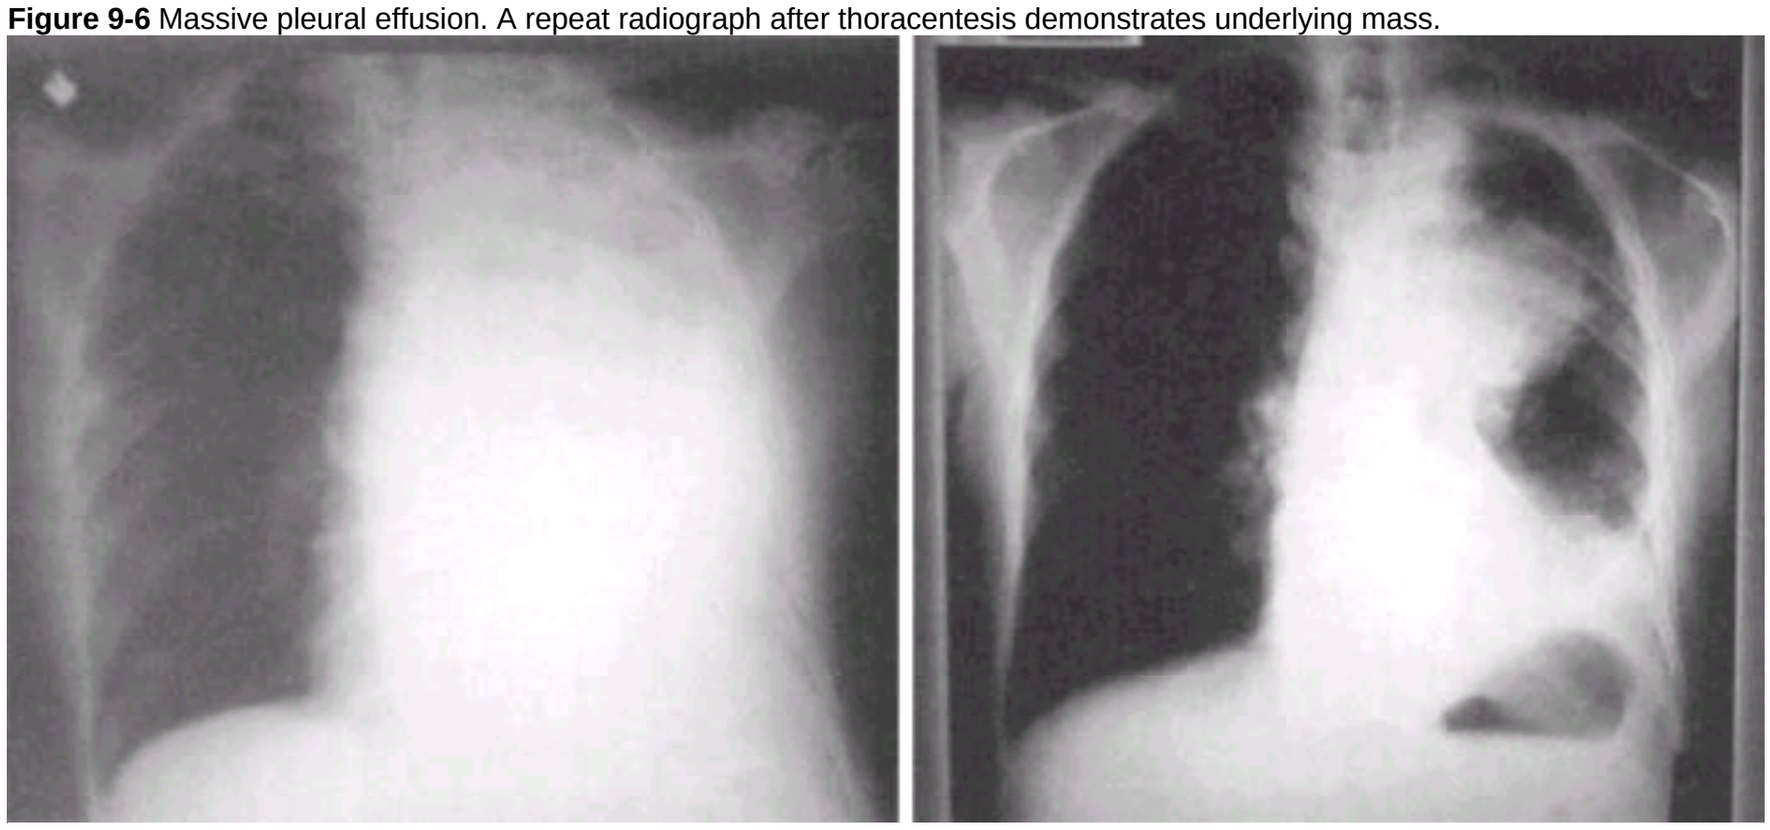

Figure 9-7 Pleural effusion. Sickle appearance of a free-flowing pleural effusion on computed tomography scan.

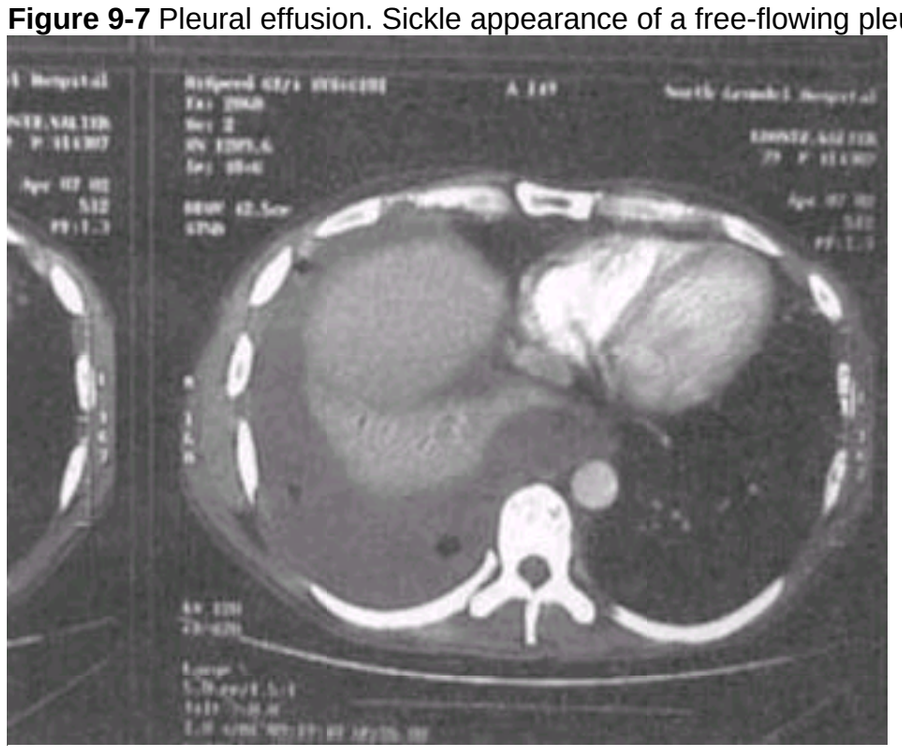

Figure 9-8 The bare area sign. A computed tomography scan demonstrates the obliteration of the potential space behind the liver with pleural fluid.

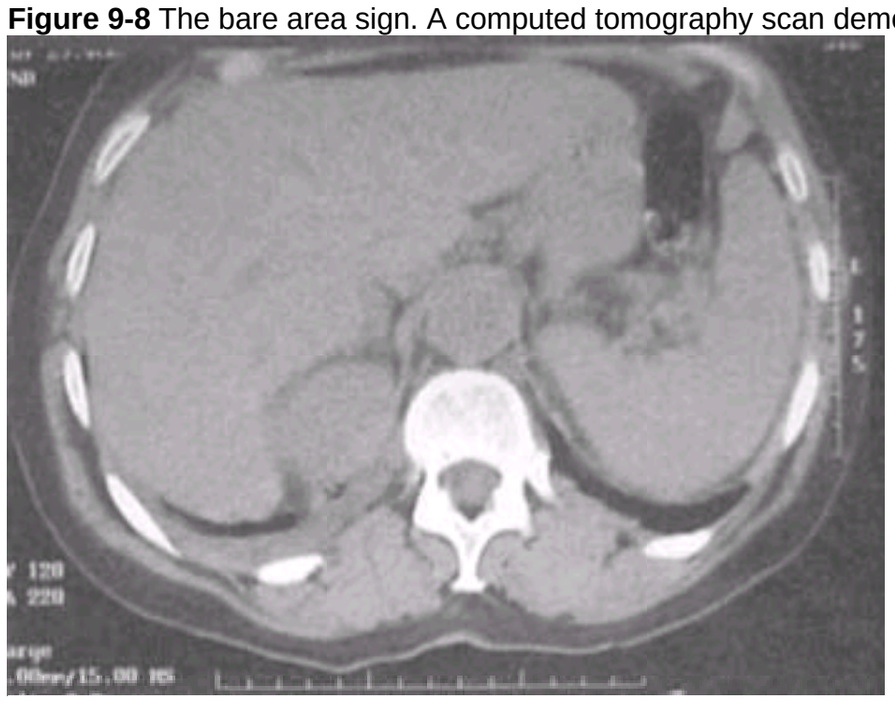

Figure 9-9 Pleural effusion. Ultrasound demonstrates the appearance of pleural fluid.

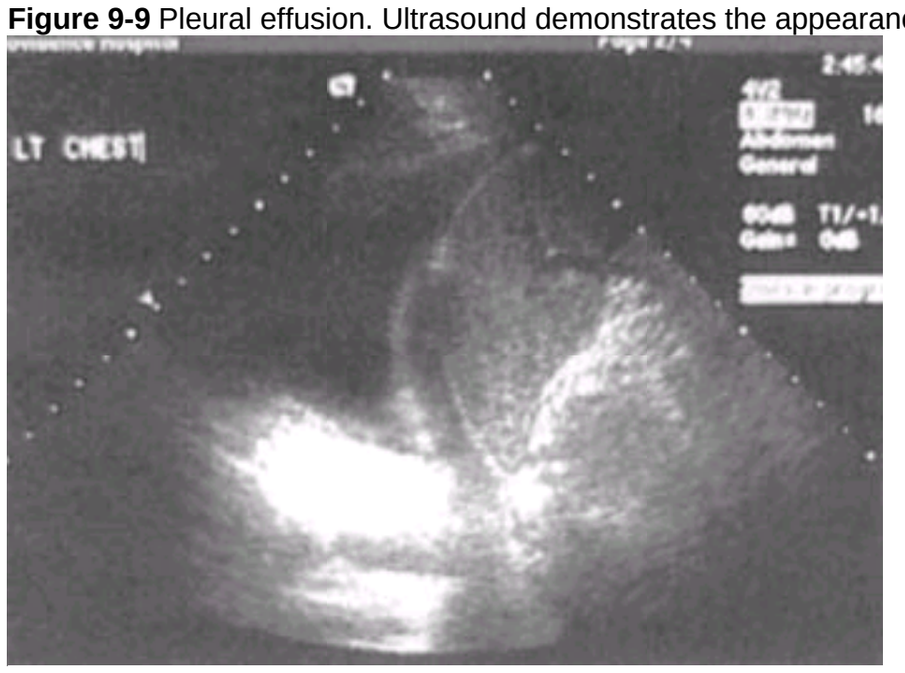

Figure 9-10 Techniques for through-the-needle catheter thoracentesis. Separate intercostal spaces depict the steps. *A,* Needle placement into pleural space. *B,* Catheter insertion through needle. *C*, Withdrawal of needle after catheter advancement.

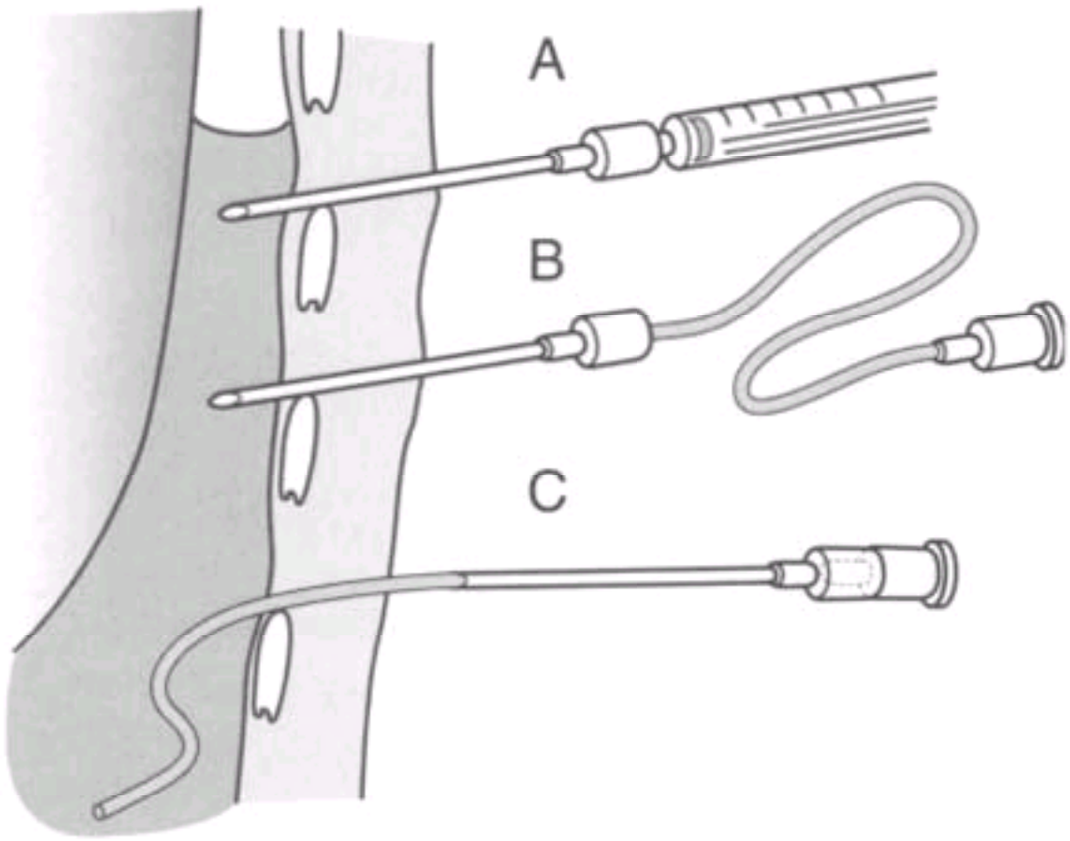

Figure 9-11 Positioning of patient for drainage of pleural effusion. *A,* Upright positioning. The broken line indicates midscapular line. *B,* Lateral decubitus positioning. The broken line indicates posterior axillary line. *C,* Supine patient positioning. The broken line indicates mid-axillary line.

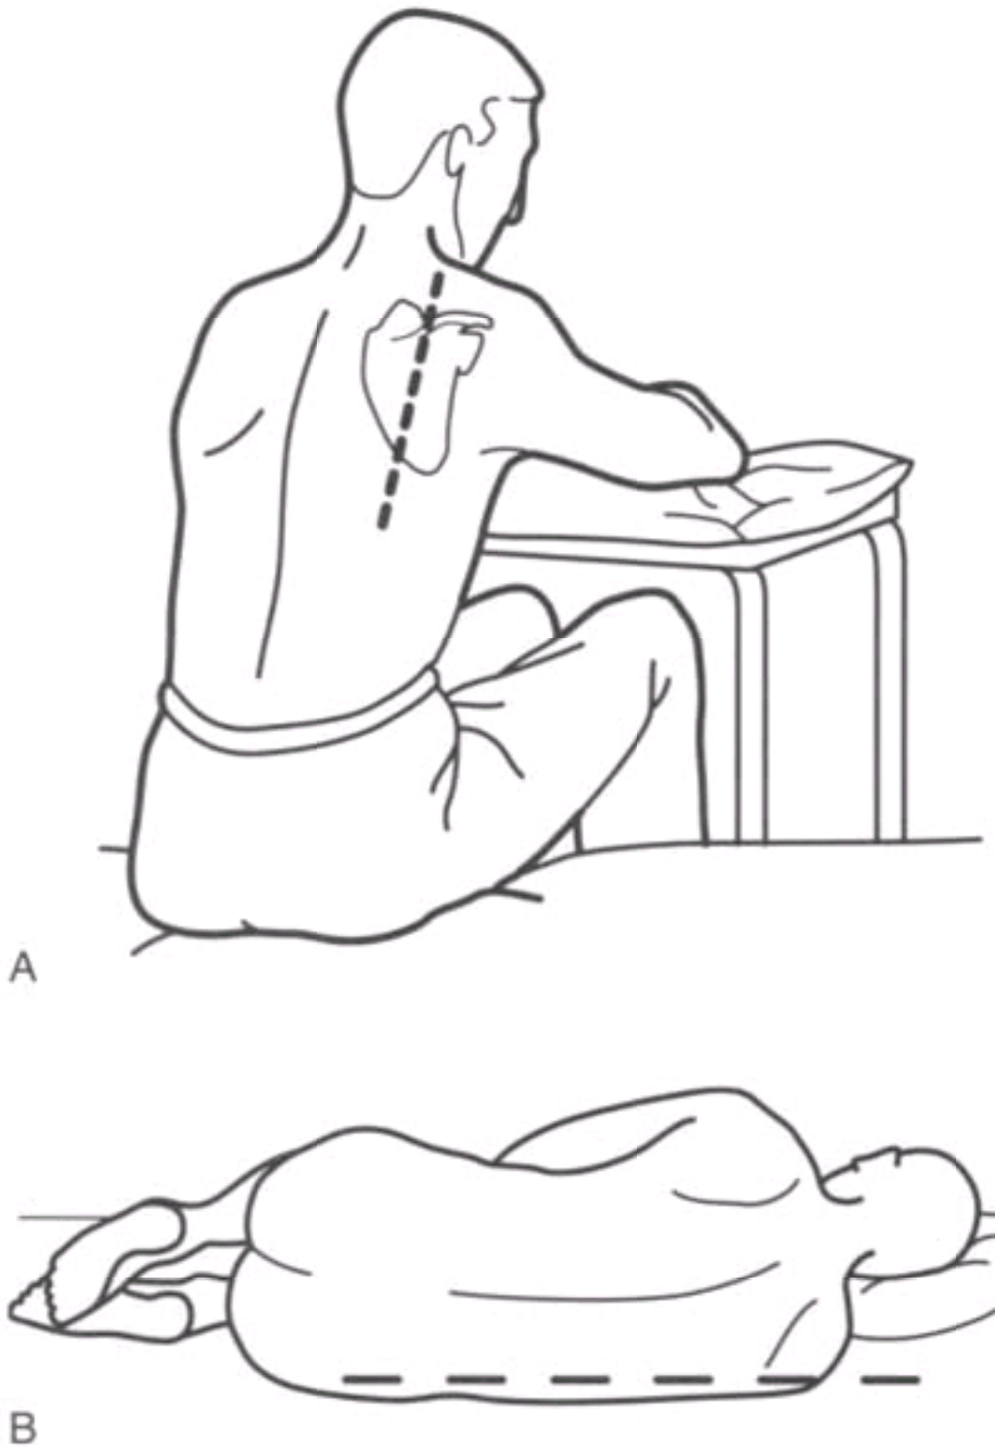

Figure 9-12 "Walking" the anesthetic needle over the superior aspect of the rib.

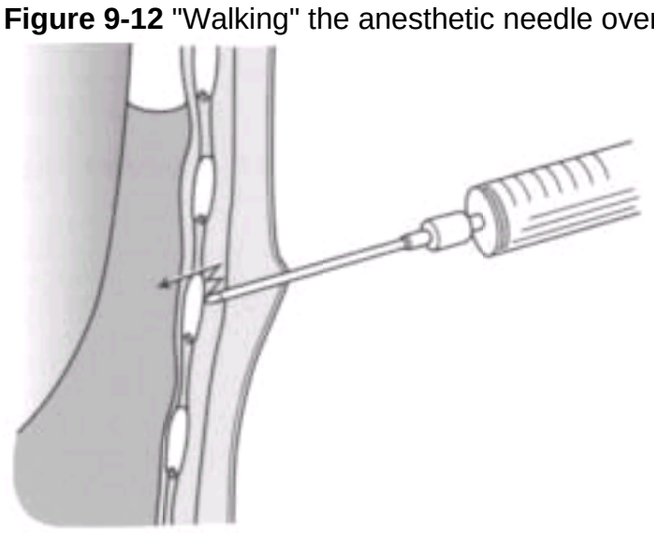

Figure 10-1 Simple pneumothorax, anteroposterior chest radiograph view. Note absence of lung marking on the affected side and deviation of the trachea contralaterally.

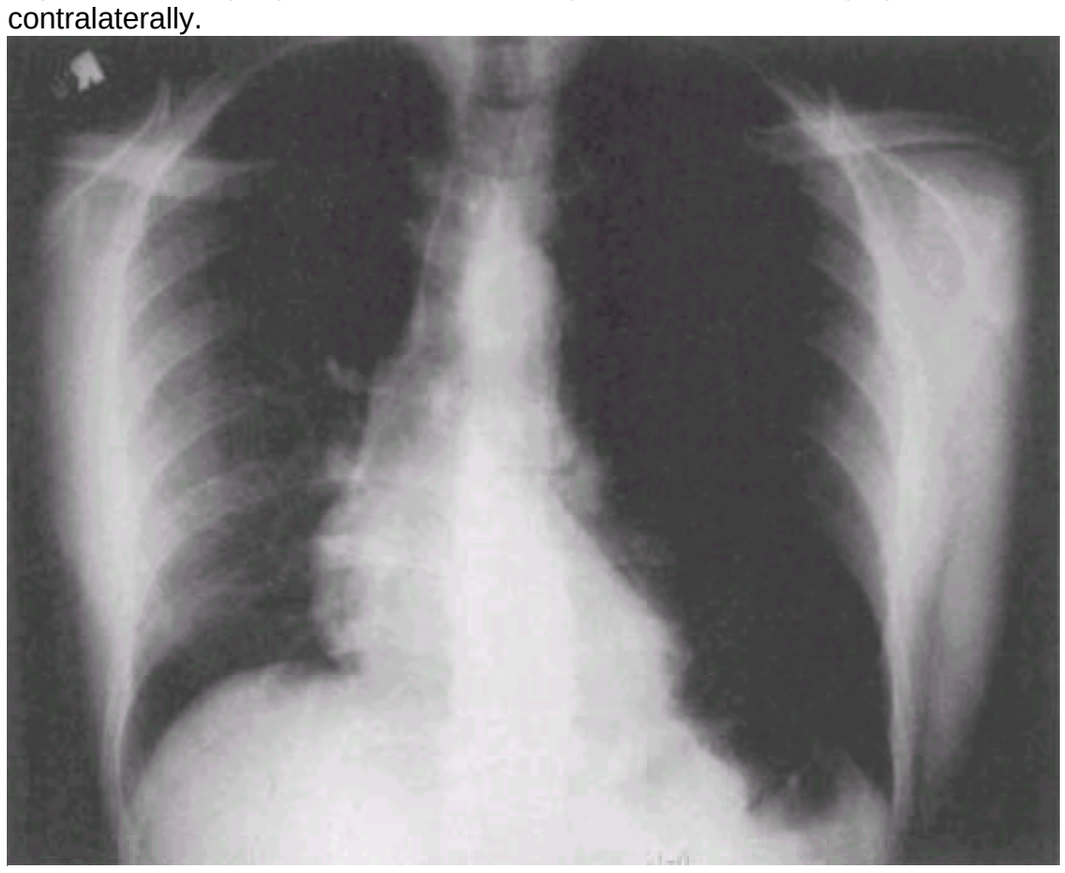

Figure 10-2 *A*, Tension pneumothorax. With inspiration air enters the pleural space from the outside or from a puncture in the lung, or both. Upon expiration, the air leaks are closed, trapping increasing amounts of air in the pleural space. Cardiac filling and eventually cardiac output are compromised. *(From Vukich DJ, Markovchick VJ: Pulmonary and chest wall injuries. In Rosen P, Barkin RM, Braen CR, et al (eds): Emergency Medicine: Concepts and Clinical Practice. St Louis, Mosby-Year Book, 1988. Reproduced by permission.) B*, A thoracic computed tomography (CT) scan demonstrating a tension pneumothorax. In general, whenever a tension pneumothorax is suspected, treatment should be initiated before obtaining a CT scan *(Courtesy of H.K. Liang).*

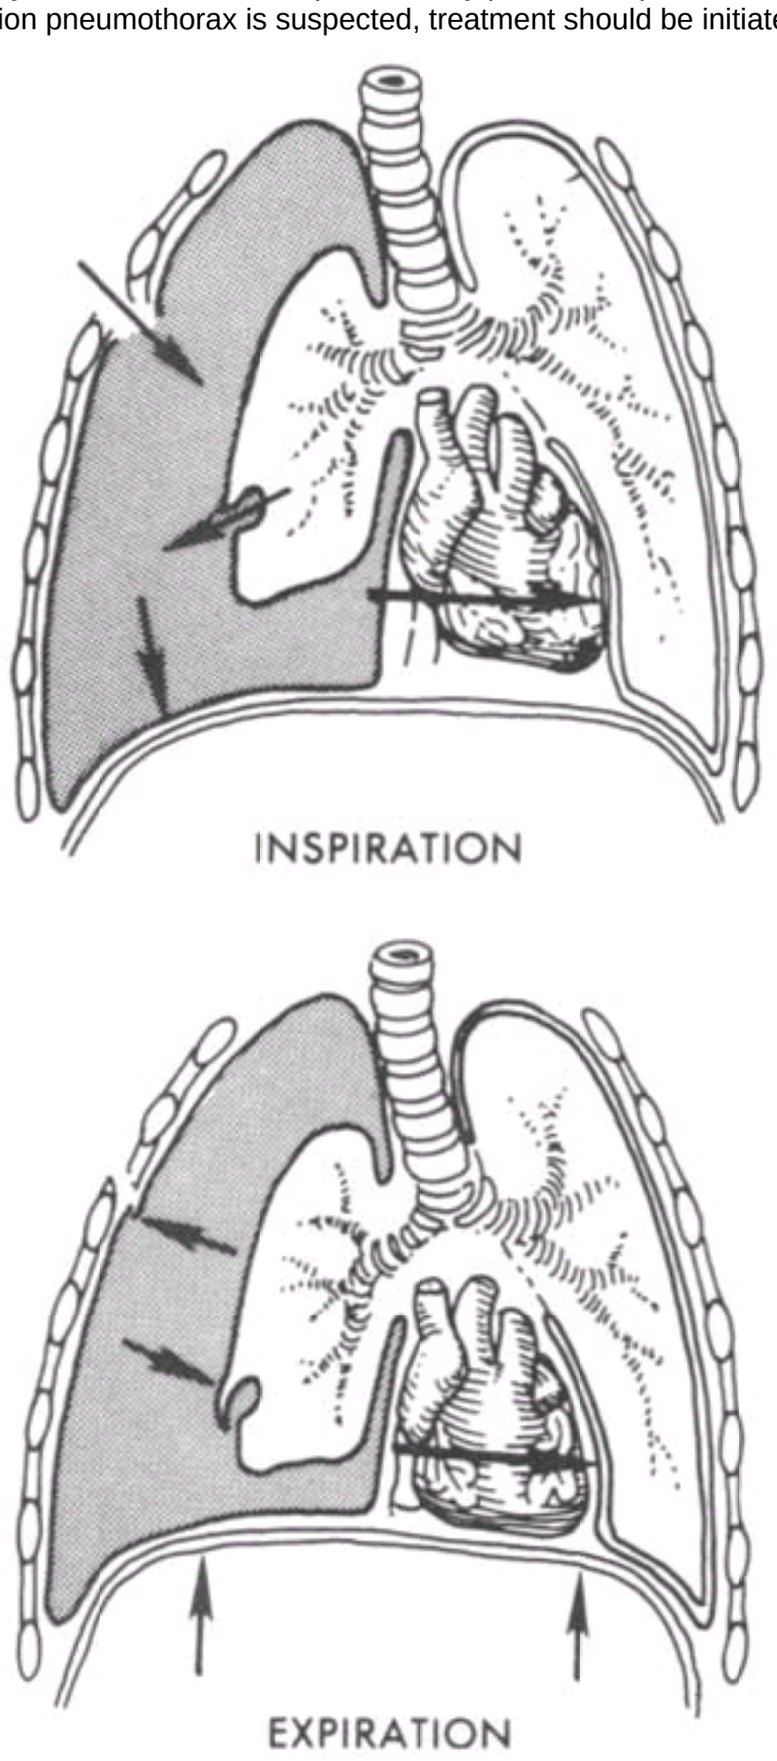
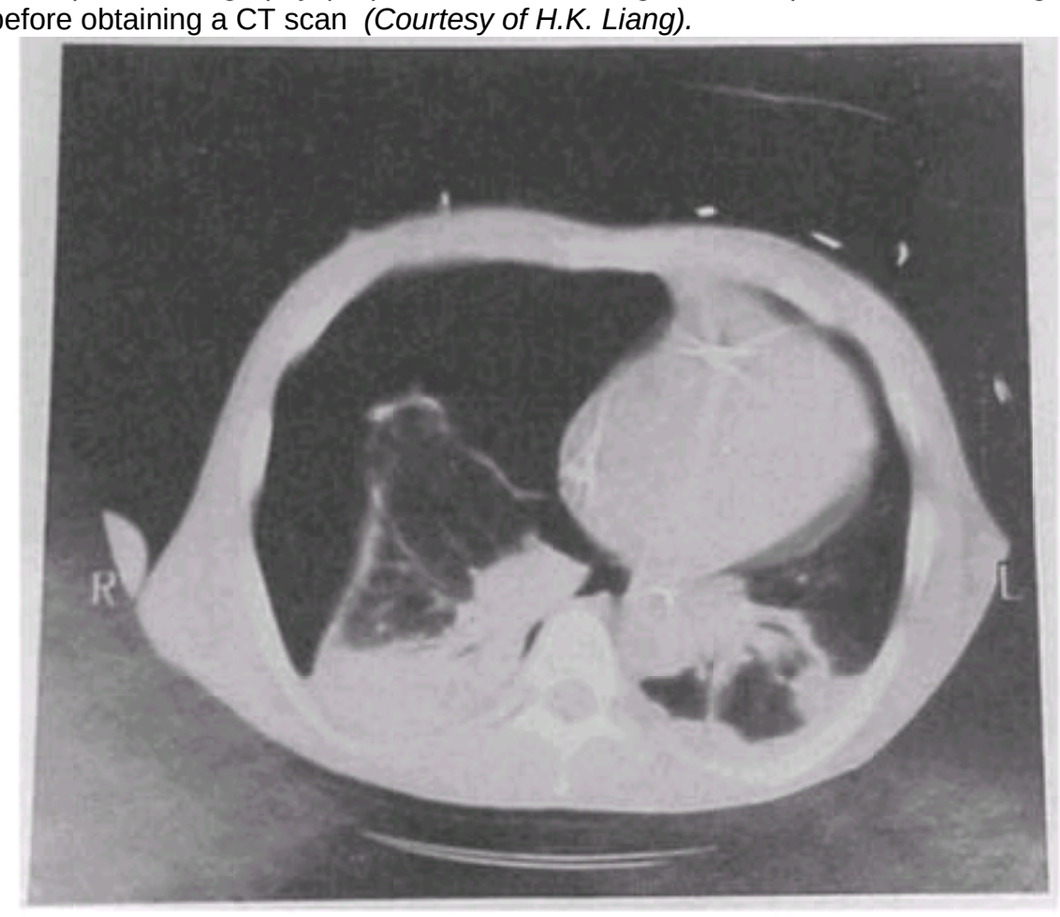




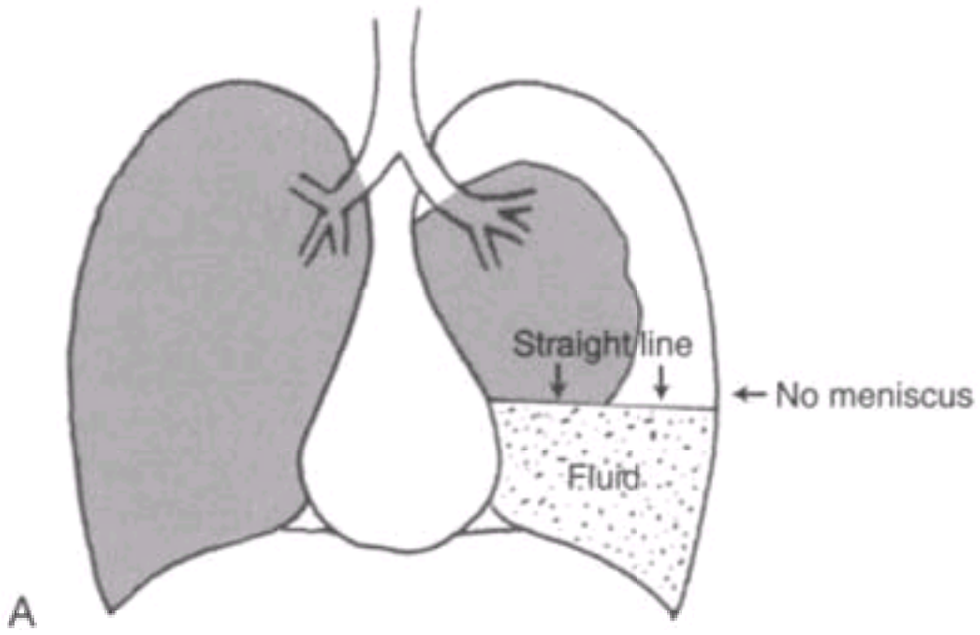
B

Figure 10-3 *A*, Following a successful cardiopulmonary resuscitation and intubation from respiratory arrest, this patient began to deteriorate. Marked subcutaneous emphysema was noted in the scrotum and abdominal wall. Curiously, little air could be palpated in the chest or neck, the usual place for air to accumulate. Assuming that the air must have come from the lungs, the scenario led to the clinical diagnosis of a tension pneumothorax. *B*, Following the placement of a chest tube, the vital signs quickly stabilized. Due to the urgency of the situation, the thoracostomy tube was performed before obtaining an x-ray, and the rush of air obtained upon entering the pleural cavity, and the normalization of vital signs, retrospectively confirmed the tension pneumothorax.

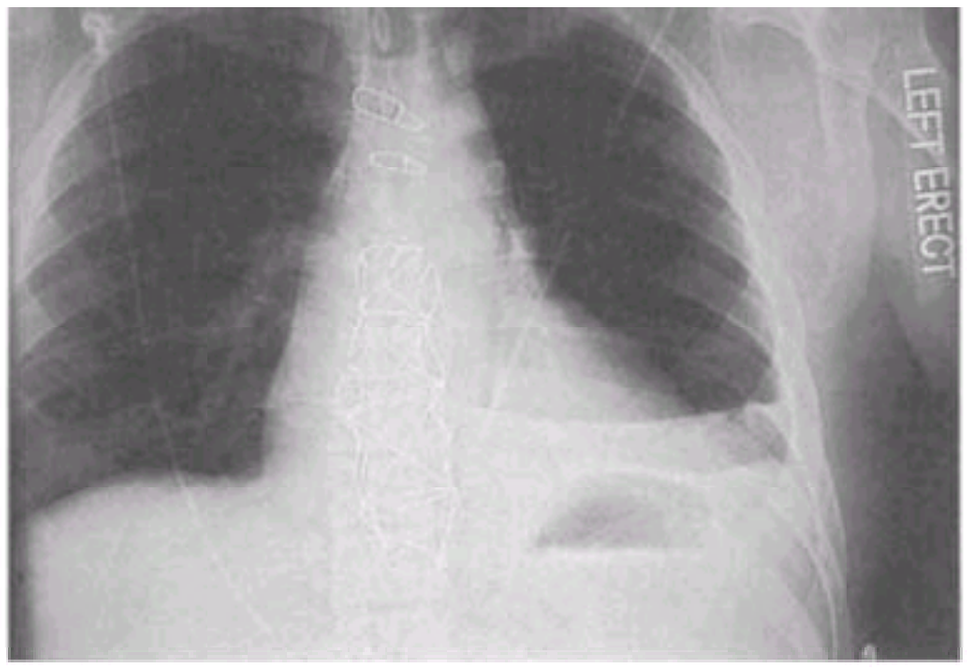
A

B

Figure 10-4 *A*, Hemopneumothorax. Note that whenever the top of the accumulated fluid is seen as a straight line as opposed to a meniscus, a pneumothorax must also be present. *B*, Following a stab wound to the chest, this radiograph demonstrated an air-fluid level (straight line) in the left hemithorax. A 10% pneumothorax is difficult to see on the poor quality film, but the air-fluid level means that a pneumothorax must be present. Otherwise, the fluid would form a meniscus tracking up the lateral chest wall. On a supine film, this subtle finding may not be appreciated.



A



B

Figure 10-5 Nomogram for the prediction of pneumothorax size from an average interpleural distance (see text). The interpleural distance is measured in centimeters from the outer edge of the collapsed lung to the inner aspect of the chest wall (i.e., parietal pleura to visceral pleura). *(From Rhea JT, DeLuca SA, Greene RE: Determining the size of pneumothorax in the upright patient. Radiology 144:733, 1982. Reproduced with permission.)*

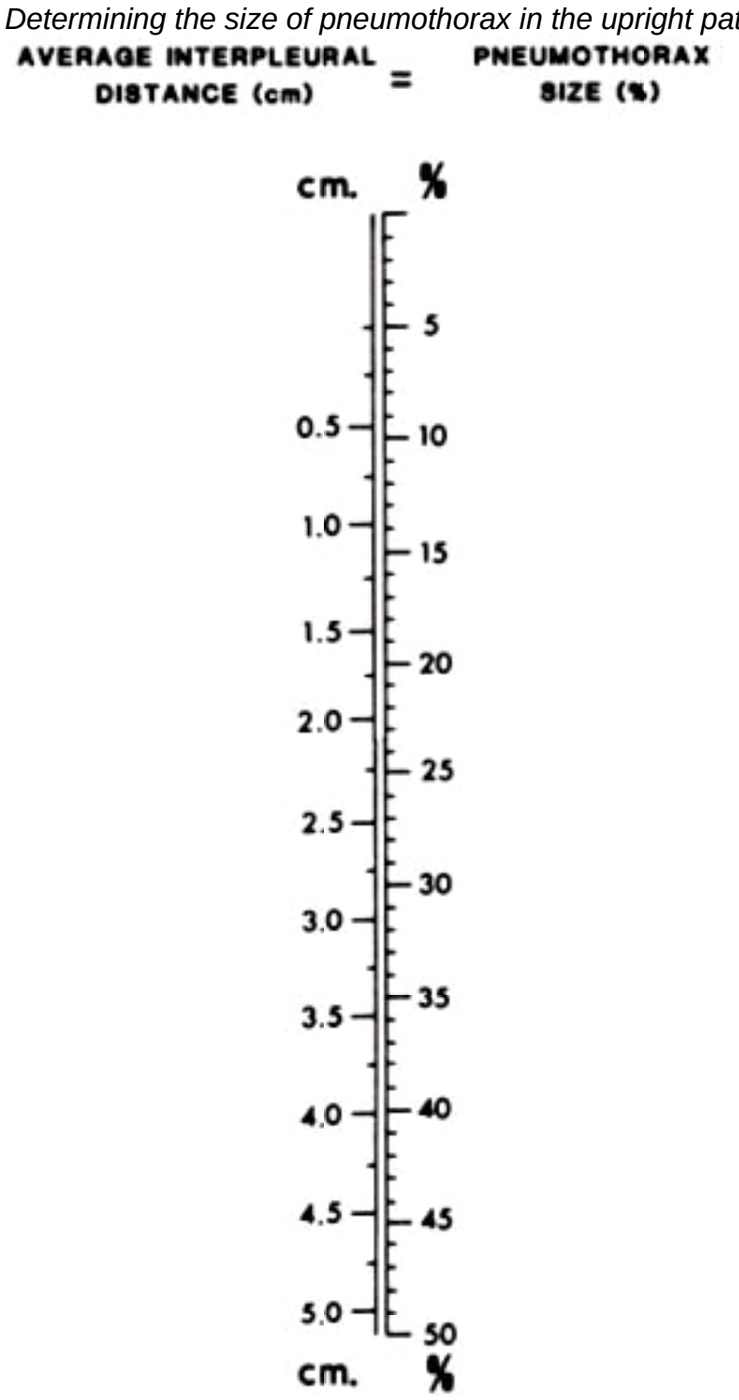


Figure 10-6 During a resuscitation involving a tension pneumothorax, there may be no time for a chest tube and needle decompression may not be effective rapidly enough. Under these circumstances the pleural cavity can be vented in seconds. This assumes that the patient is intubated. *A*, A No. 10 scalpel is used to make a deep incision in the skin and subcutaneous tissue over the fourth or fifth rib in the anterior axillary line. *B*, A long *closed* Kelly clamp (or scissors) is inserted over the top of the rib and stabbed into the pleural space. A pop is usually felt. *C*, Once the instrument is in the pleural space, it is opened wide to create a rent in the parietal pleura. Air should immediately vent. If the patient is intubated, normal cardiorespiratory function can be maintained. A chest tube is then inserted. (See also Figure 10-11 Figure 10-12 Figure 10-13 Figure 10-14 .)

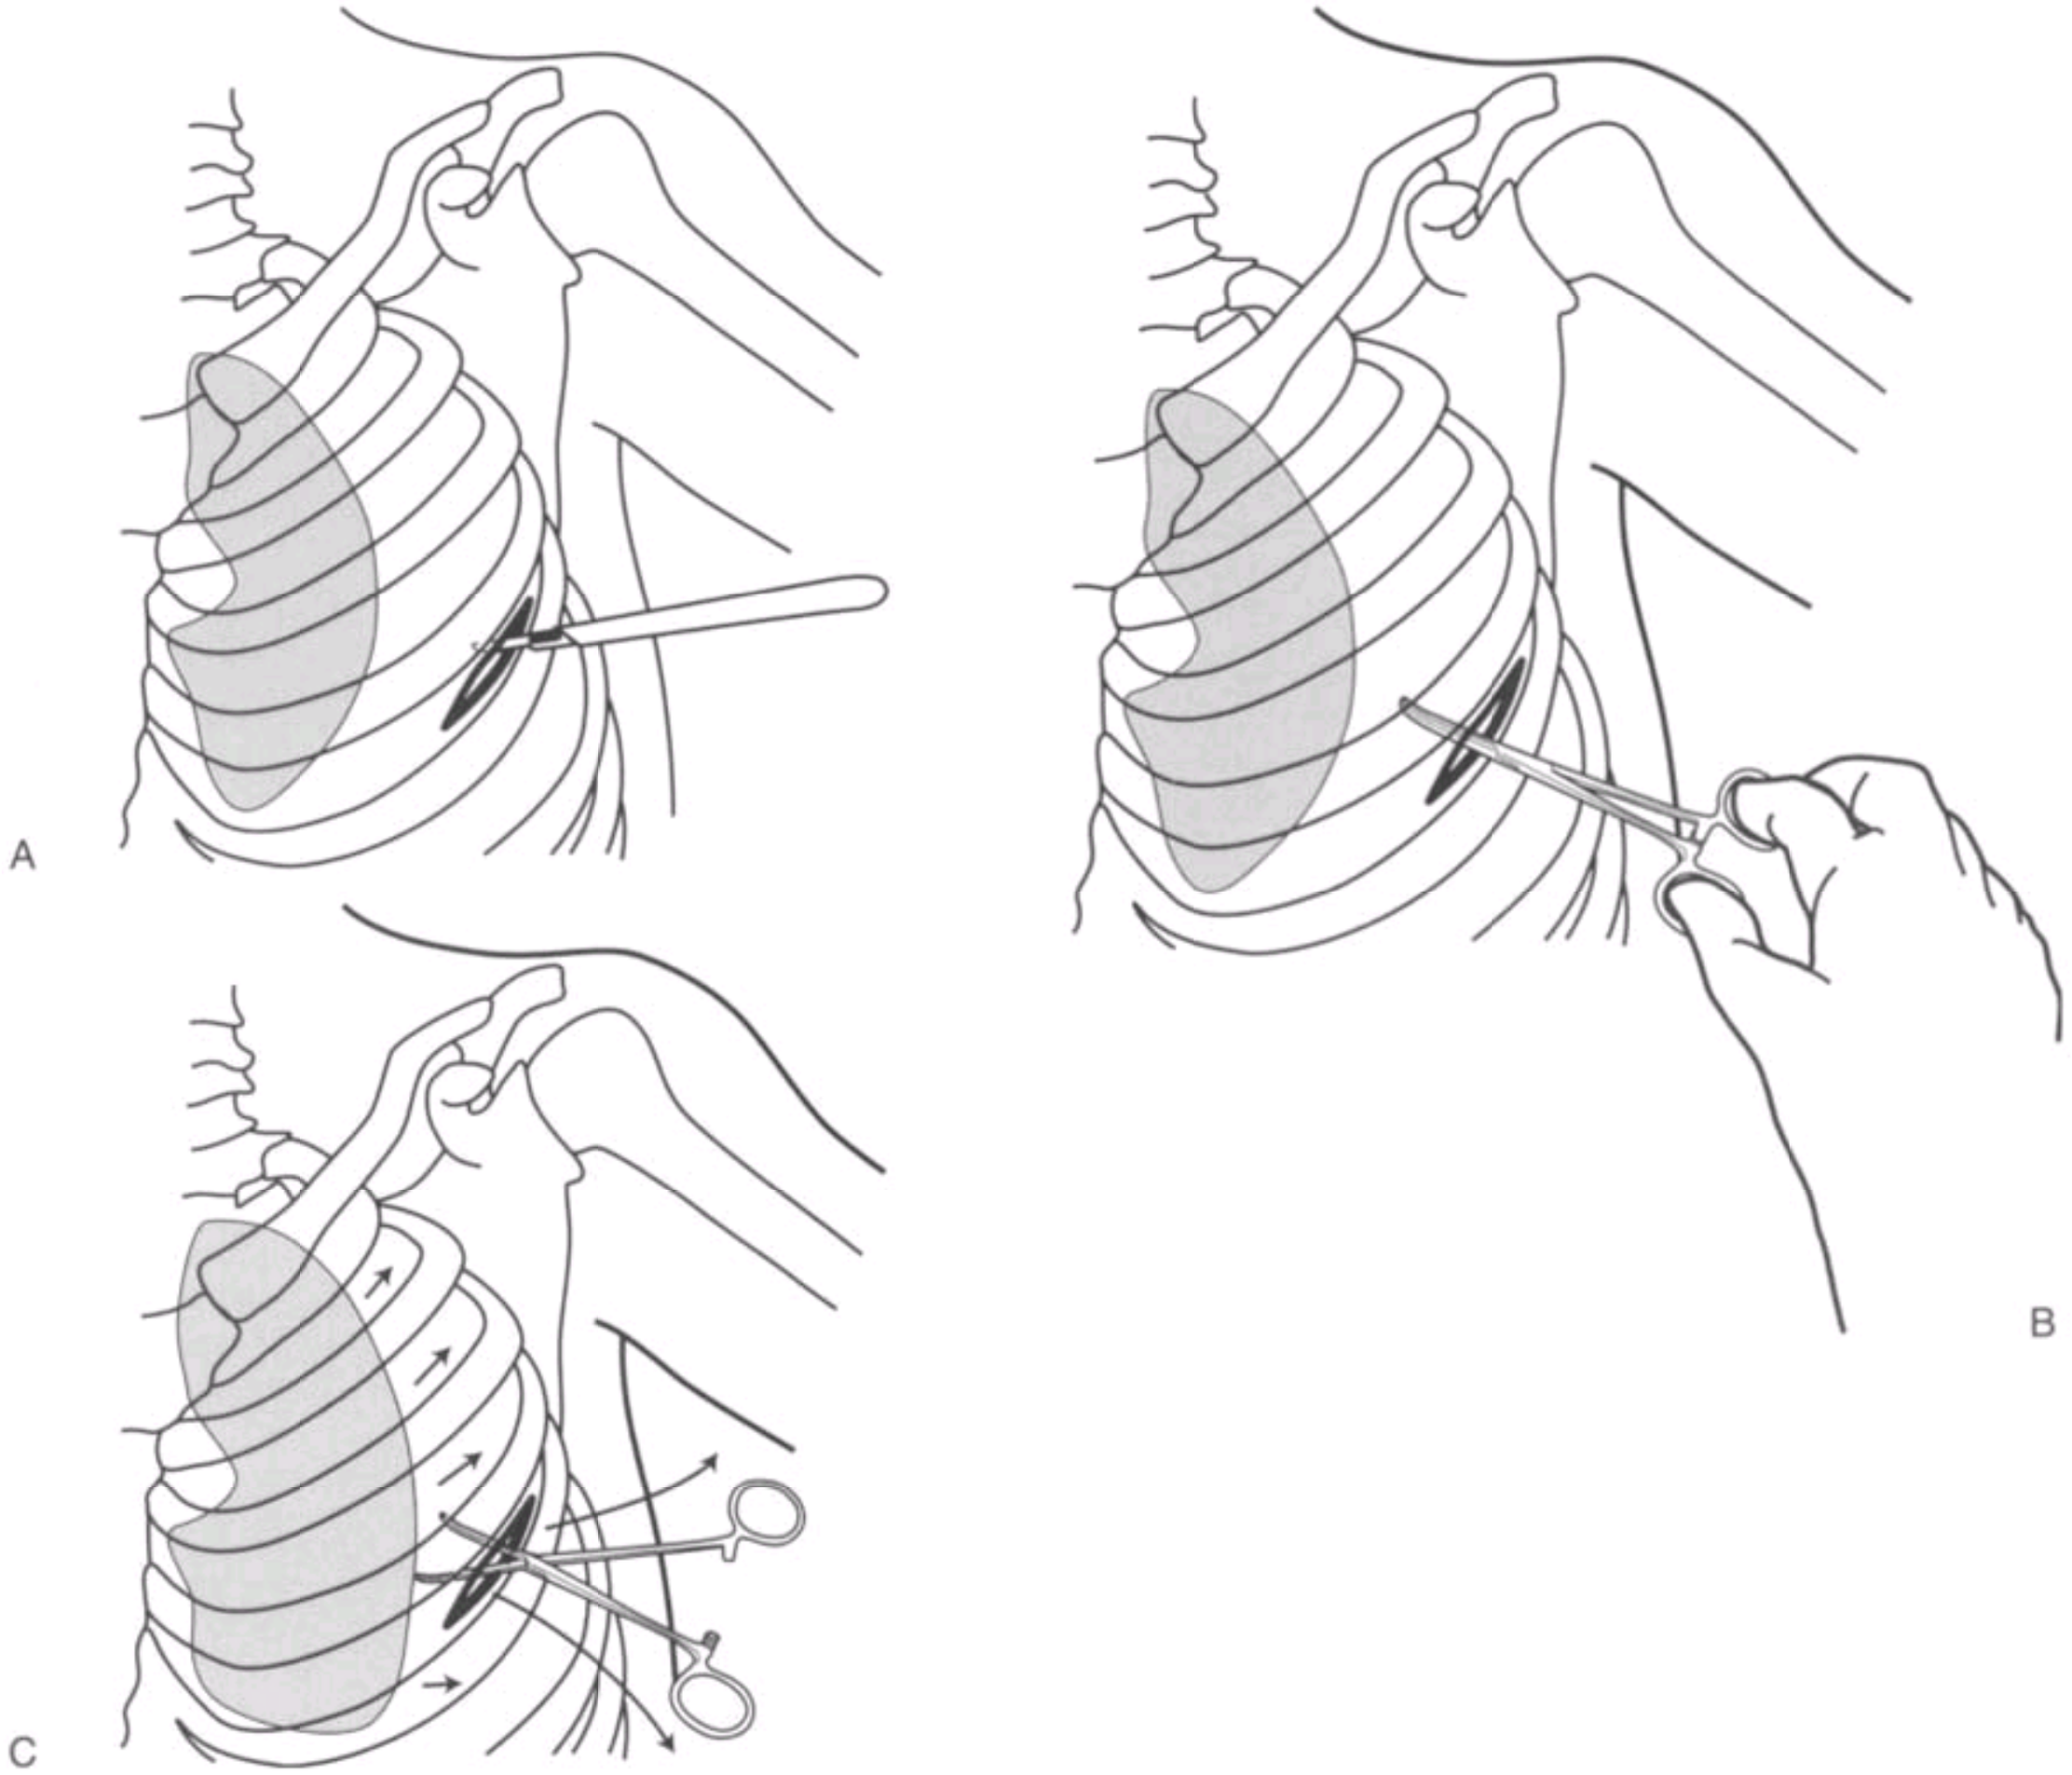

Figure 10-7 Standard sites for tube thoracostomy. *A*, The second intercostal space, midclavicular line. *B*, The fourth or fifth intercostal space, midaxillary line. The midaxillary line placement is usually preferable for all chest tubes, regardless of pathology. Always avoid the breast tissue, even in prepubescent girls. Note that placing the tube too far posteriorly will not allow the patient to lie down comfortably.

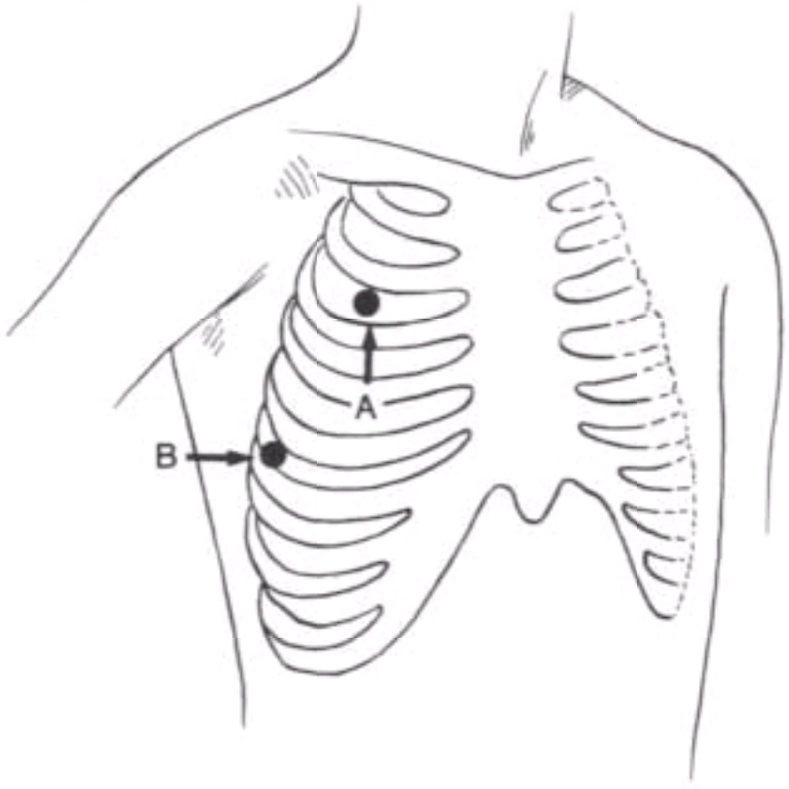

Figure 10-8 To insert a chest tube, the patient is placed semi-erect with the ipsilateral shoulder abducted and preferably restrained. Supplemental oxygen is recommended.

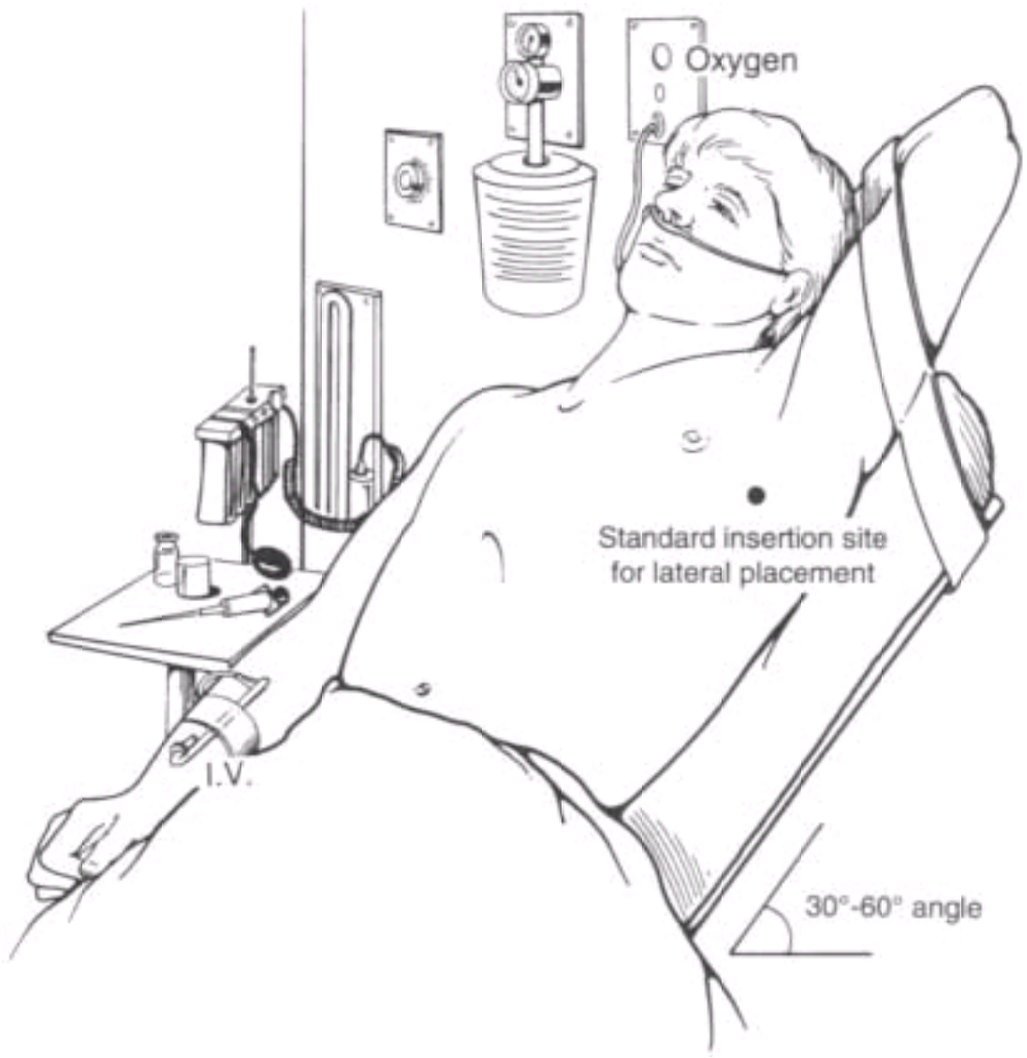

Figure 10-9 Insertion of a chest tube can be relatively painless with proper infiltration of the skin *and pleura* with local anesthetic. The liberal use of 1% lidocaine with epinephrine (maximum lidocaine dose, 5 mg/kg) is recommended. *(Redrawn from Hughes WT, Buescher ES: Pediatric Procedures, 2nd ed. Philadelphia, WB Saunders, 1980, p 234.)*

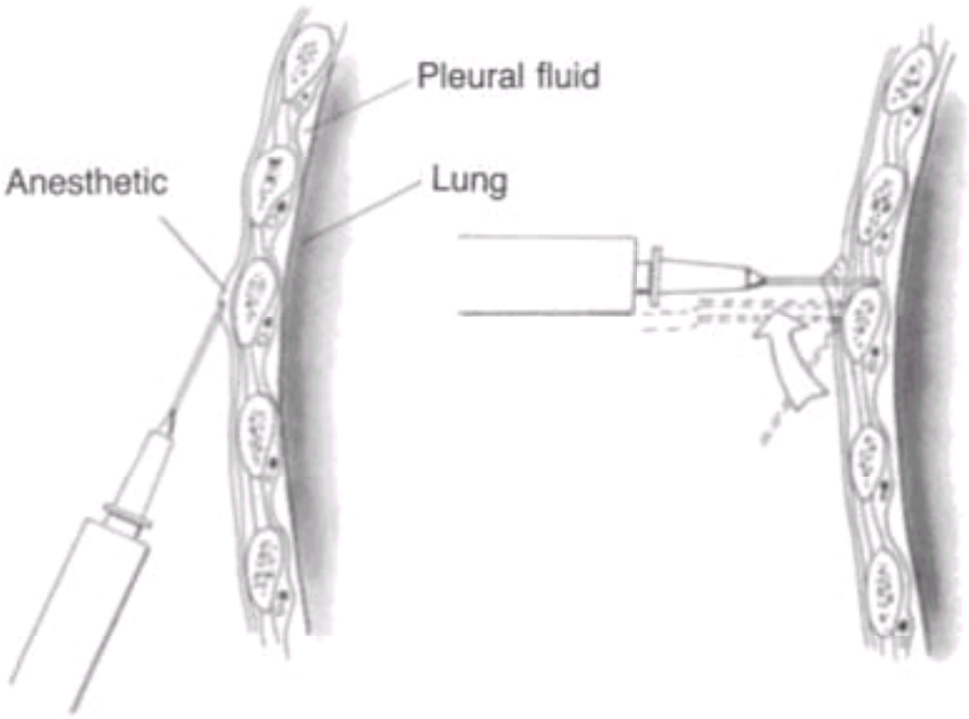

Figure 10-10 Use of the anesthetic needle to puncture the parietal pleura and establish the presence of blood or air in the pleural space. This procedure is not only diagnostic, but also may be a temporary therapeutic maneuver in a patient with tension pneumothorax. *(Redrawn from Richards V: Tube thoracostomy. J Fam Pract 6:631, 1978.)*

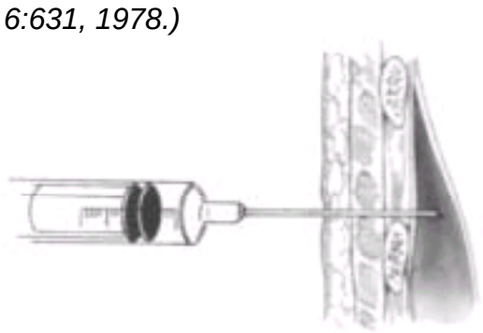

Figure 10-11 The skin wound is made one intercostal space below the space through which the tube will pass *(A)*. By spreading tissue with scissors *(B)*, dissection is carried subcutaneously to the pleural lining. The pleura is entered with a blunt Kelly or Tonsillar clamp *(C)*. A common error in technique is to attempt to insert a large chest tube through a skin incision that is too small. *(Redrawn from Hughes WT, Buescher ES: Pediatric Procedures, 2nd ed. Philadelphia, WB Saunders, 1980, p 237.)*

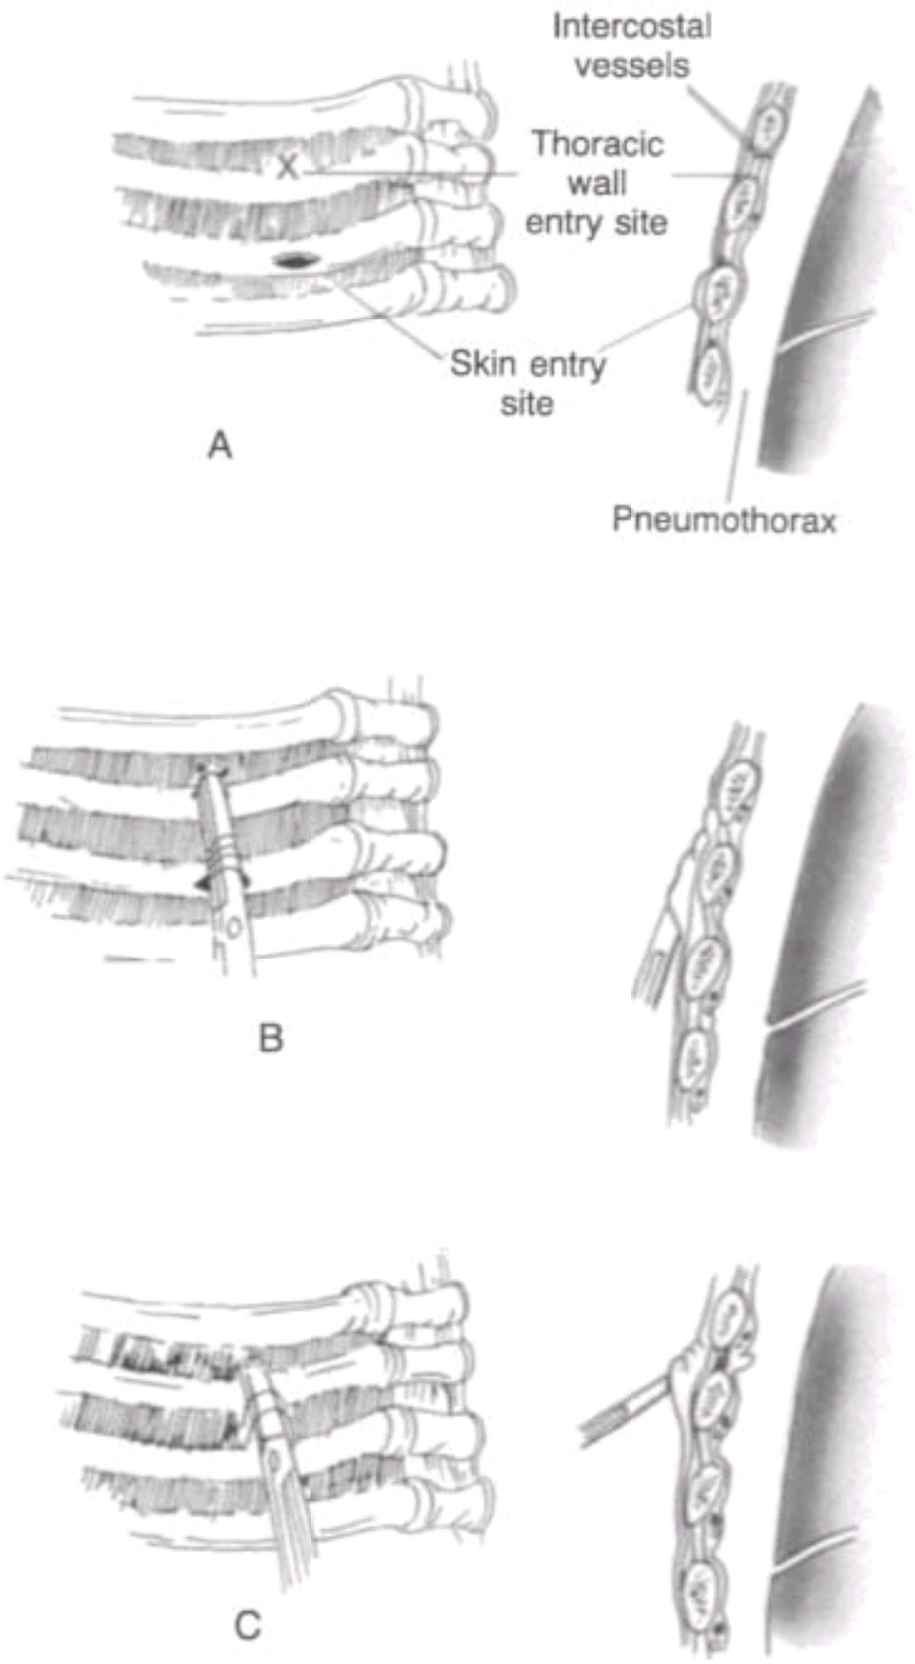

Figure 10-12 Location of the intercostal neurovascular bundle, running inferiorly and slightly medial to the rib. *(From Millikan JS, Moore EE, Steiner E: Complications of tube thoracostomy for acute trauma. Am J Surg 140:739, 1980.)*

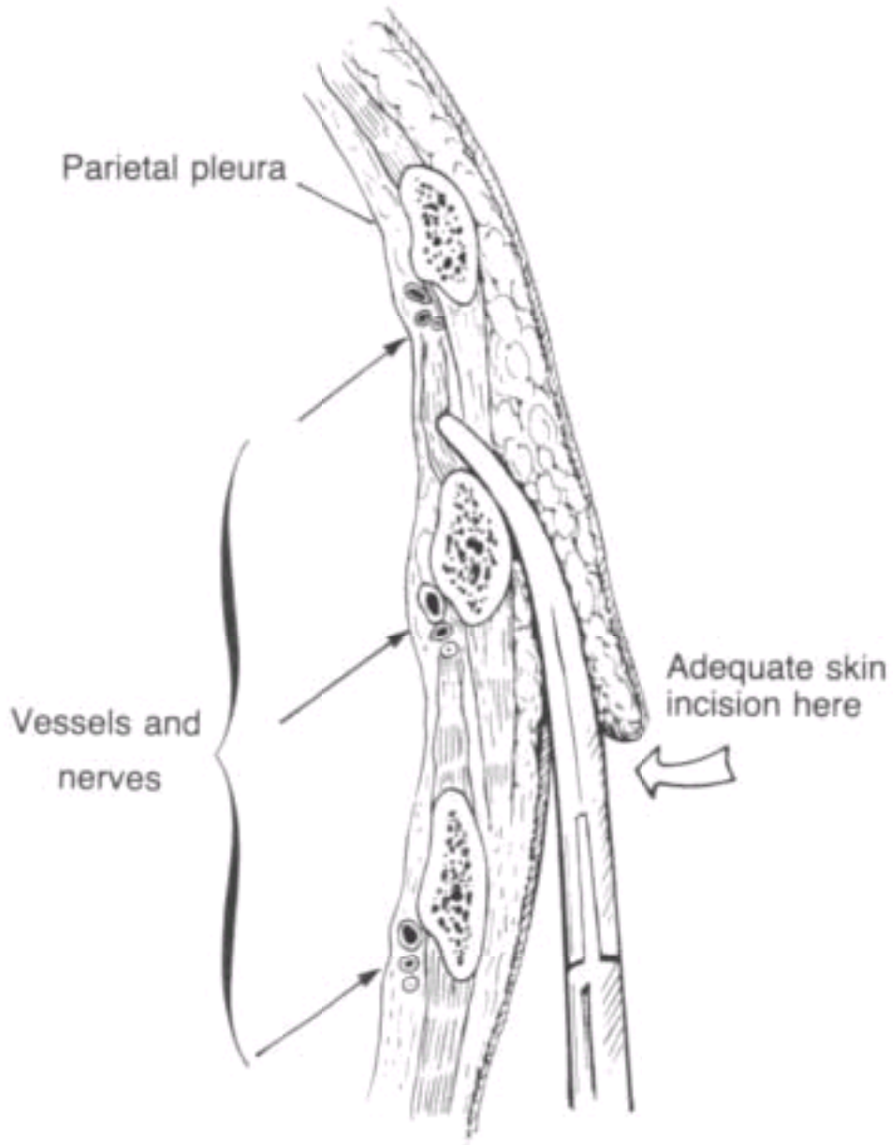

Figure 10-13 One accomplishes blunt dissection by forcing the closed points of the clamp forward, then spreading the tips and pulling back with the points spread. Note that the clamp should be spread in a direction parallel with the ribs (See Fig. 10-6); not perpendicular to the ribs as suggested in the figure. The drawing emphasizes the placement of the instrument *over* the rib. A rush of air or fluid signifies penetration into the pleural space. *(From Bricker DL: Safe, effective tube thoracostomy. ER Reports 2:49, 1981.)*

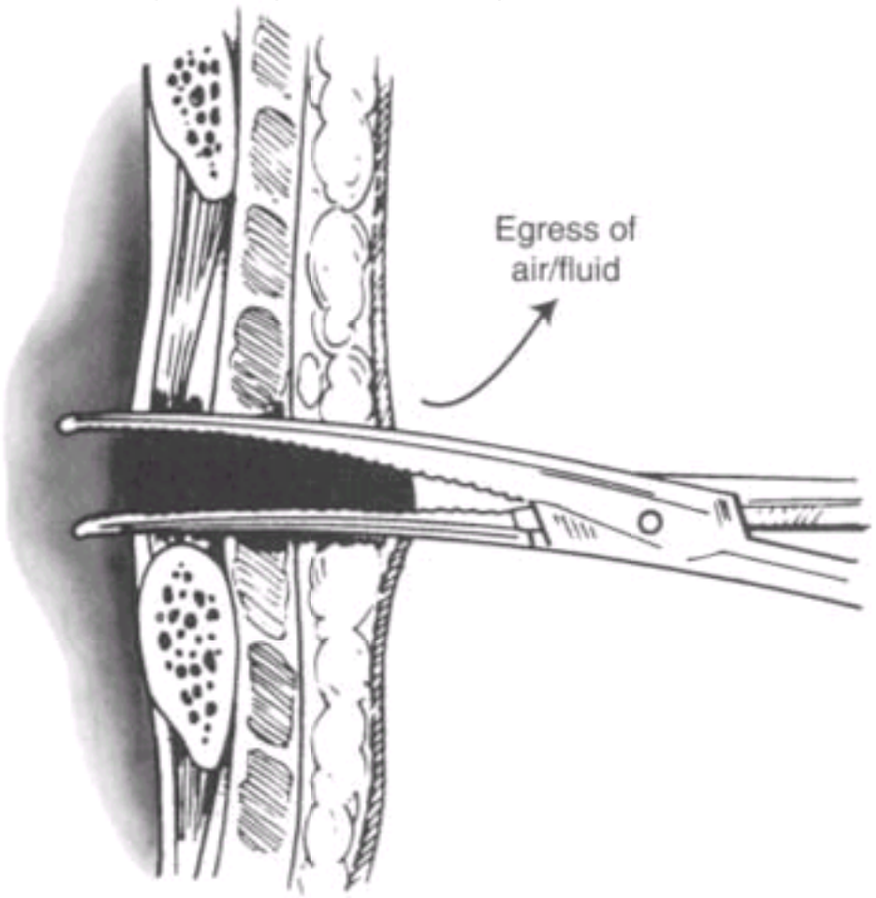

Figure 10-14 Using the finger as a guide to ensure entry into the pleural cavity, one places the tip of the tube into the pleural cavity. *(From Millikan JS, Moore EE, Steiner E: Complications of tube thoracostomy for acute trauma. Am J Surg 140:739, 1980.)*

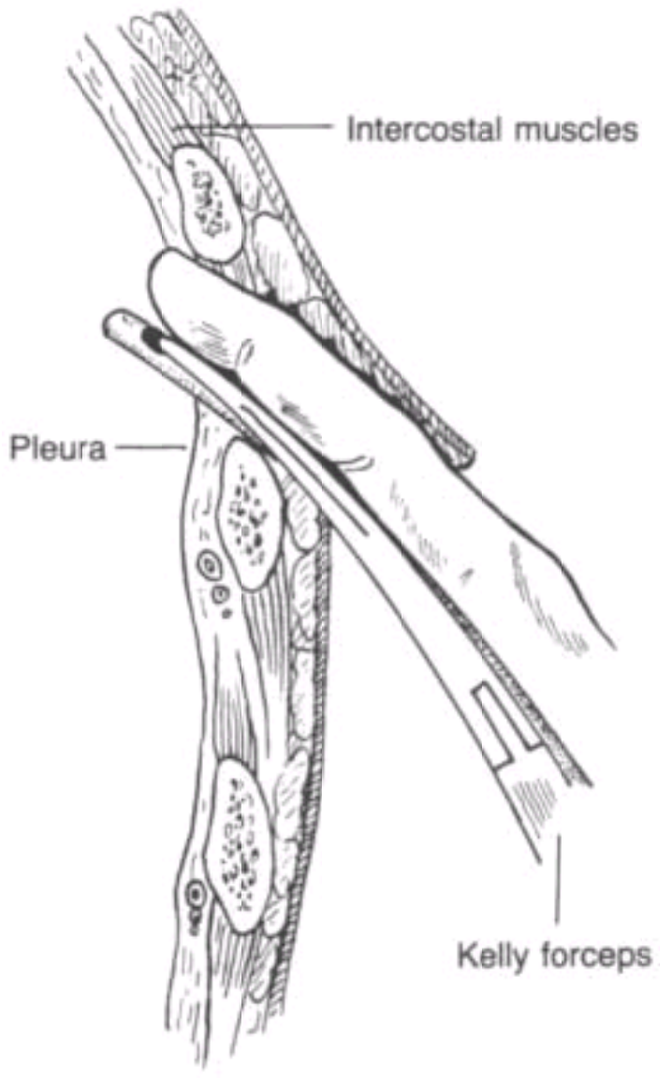

Figure 10-15 The tube is grasped with the curved clamp, with the tube tip protruding from the jaws.

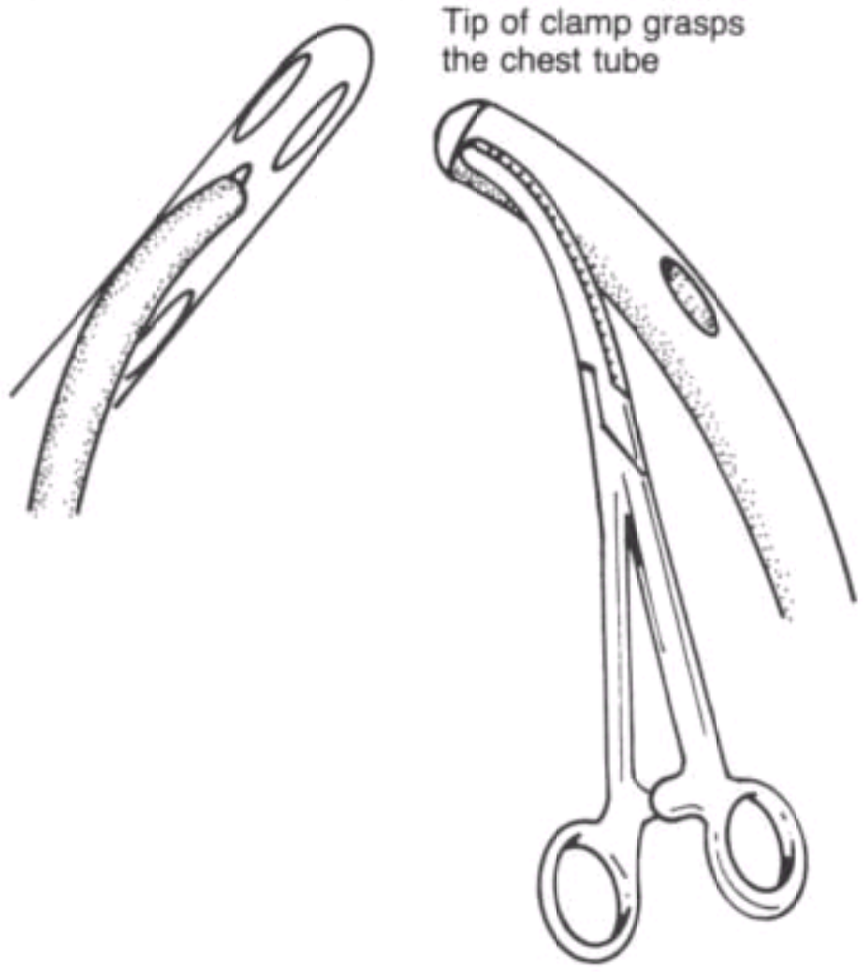

Figure 10-16 Subcutaneous (SQ) placement of a chest tube (*arrows*) can occur, as the tube can dissect through tissue planes with relative ease. If this tube had been directed posteriorly, the radiograph would erroneously "confirm" intrapleural placement despite the tube being SQ throughout its entire course.

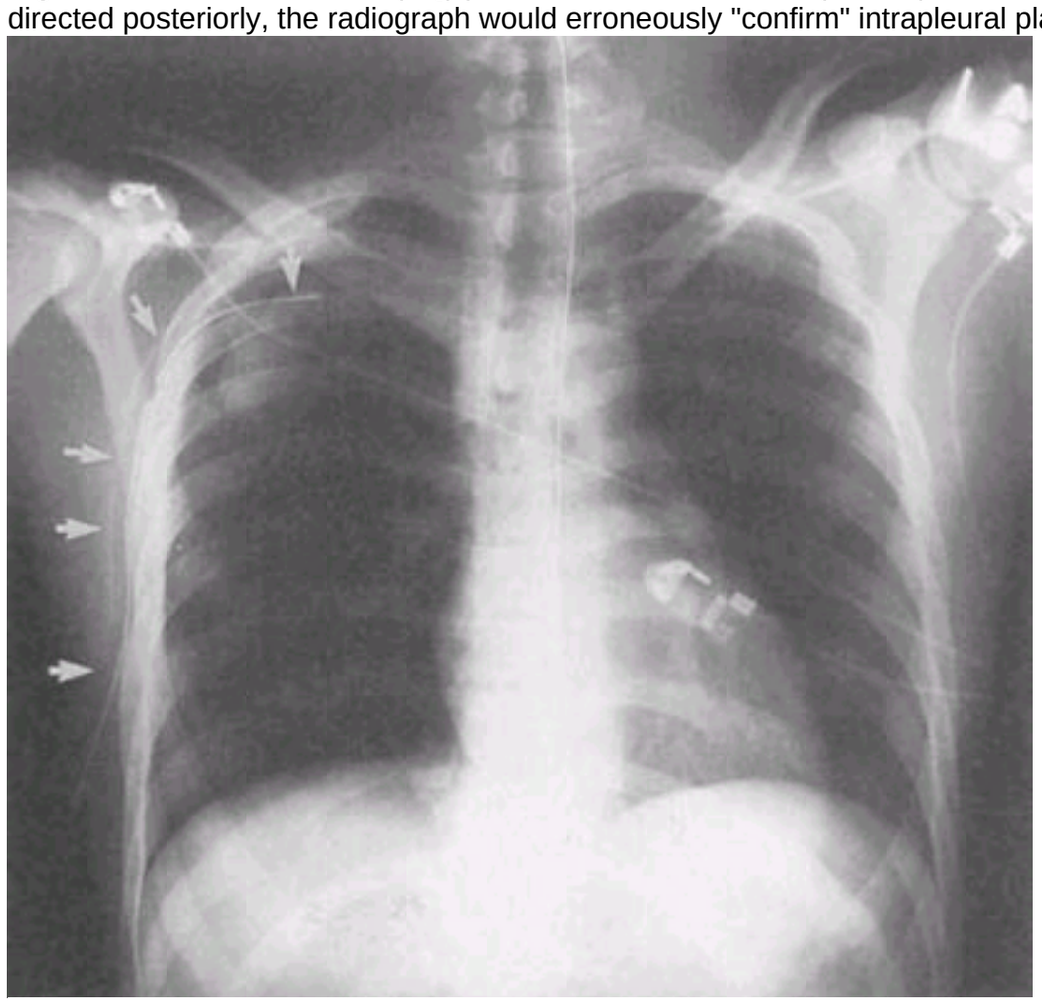

Figure 10-17 A "stay" suture is first placed next to the tube to close the skin incision. *A,* The knot is tied securely and the ends, which will subsequently be wrapped around the chest tube, are left long. *B,* The ends of the suture are wound twice about the tube tightly enough to indent the tube slightly and are tied securely.

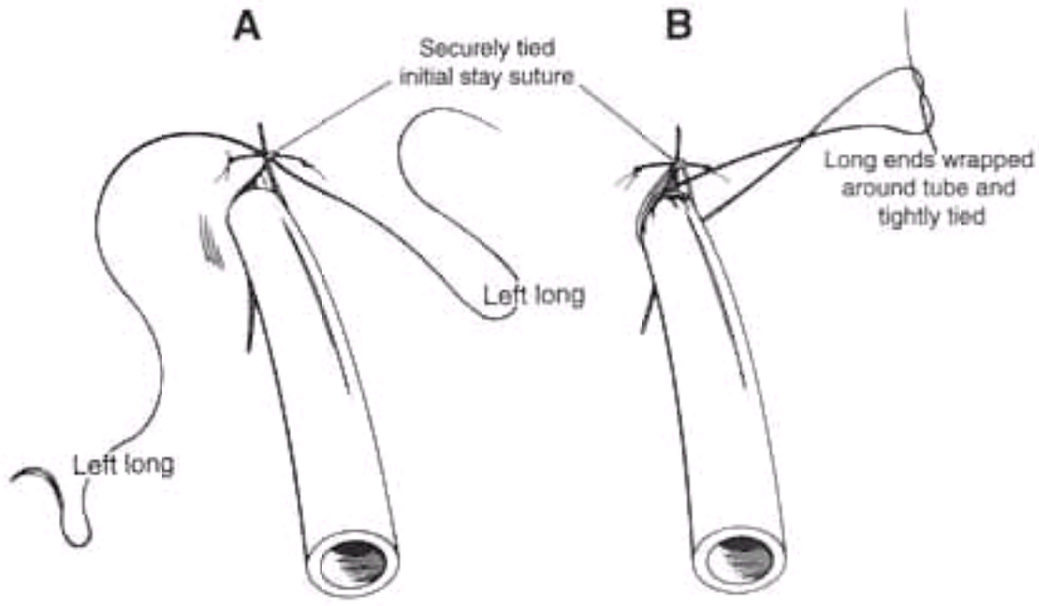

Figure 10-18 *A,* A horizontal mattress suture is placed around (above and below) the tube and is held only with a surgeon's knot. *B,* The loose ends are also wrapped around the tube and are tied loosely in a bow to identify the suture. This suture will be untied and used to close the skin incision after tube removal.

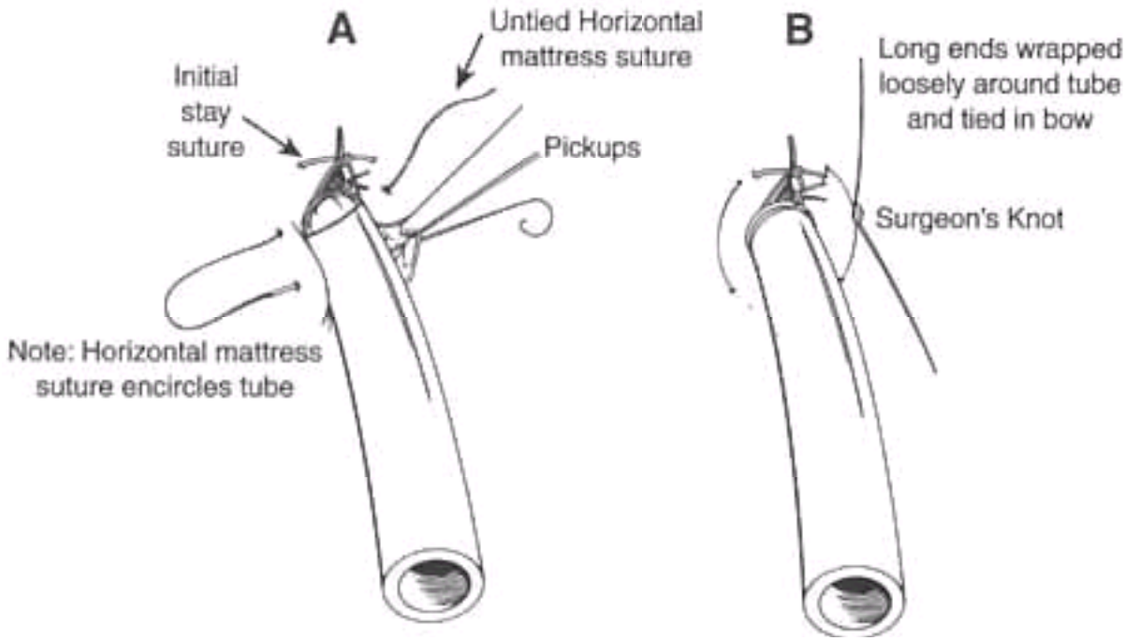

Figure 10-19 A dressing consisting of gauze sponges with a Y-cut is applied to the entry site to provide an air-tight seal. Two pieces are placed at angles.

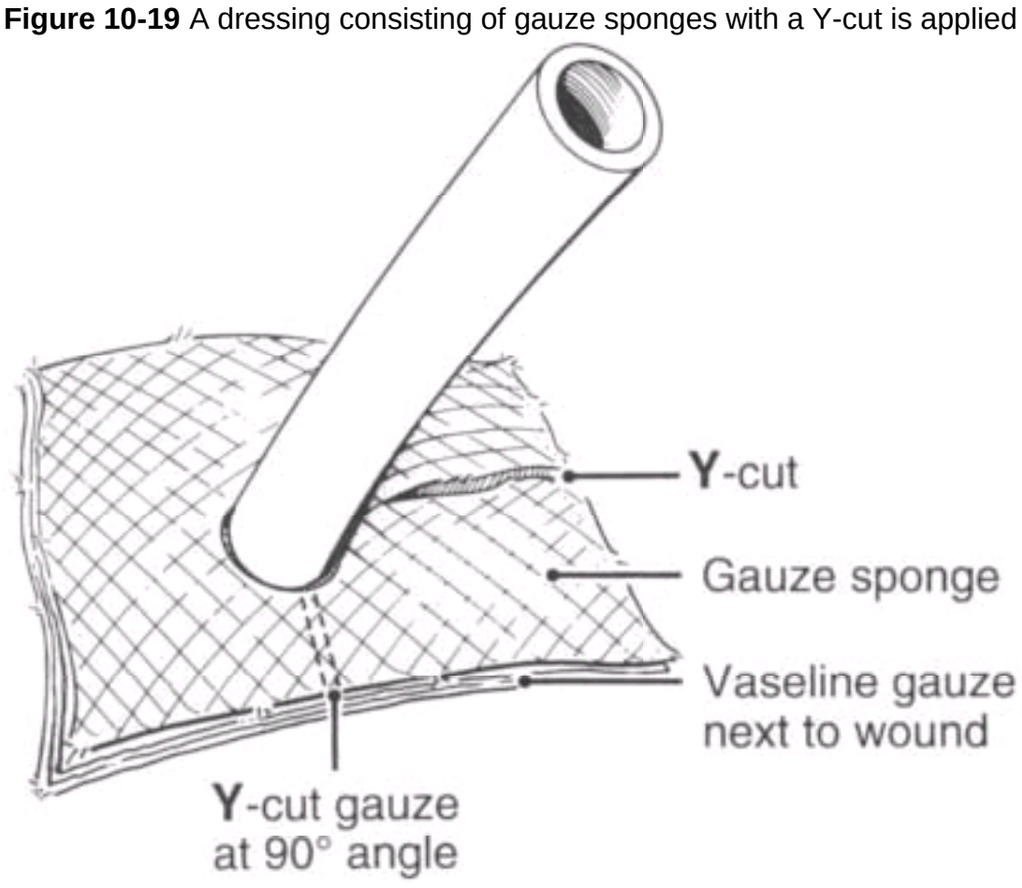

Figure 10-20 *A*, The distal half of a wide piece of tape is longitudinally split into three pieces. The two outside pieces are placed on the skin on either side of the tube, and the center strip is wrapped around the chest tube itself. *B*, This process may be repeated with a similar piece of tape placed at a 90° angle. The tape is securely anchored to the skin (benzoin is optional, but the skin must be clean and dry), and the torn tape is wrapped around the tube. Each anchoring piece is covered by another piece of tape.

B.

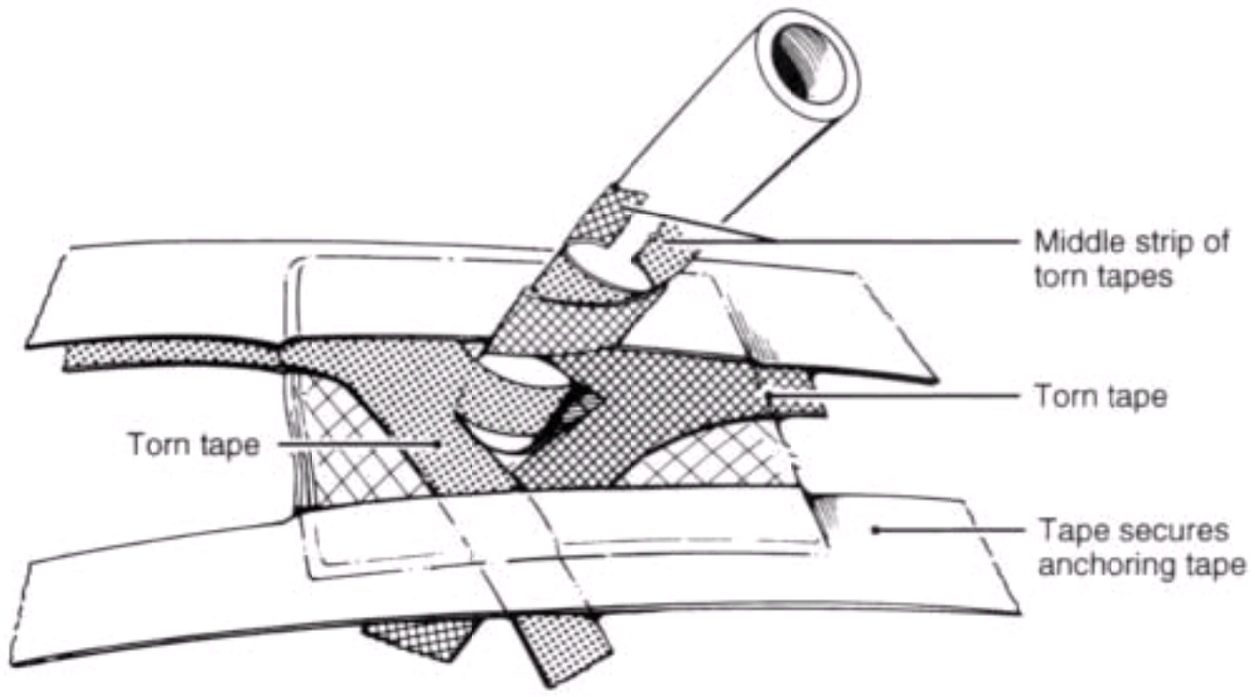

Figure 10-21 A one-way Heimlich valve alone is usually sufficient to treat a pneumothorax, but should *not* be used to treat a hemothorax.

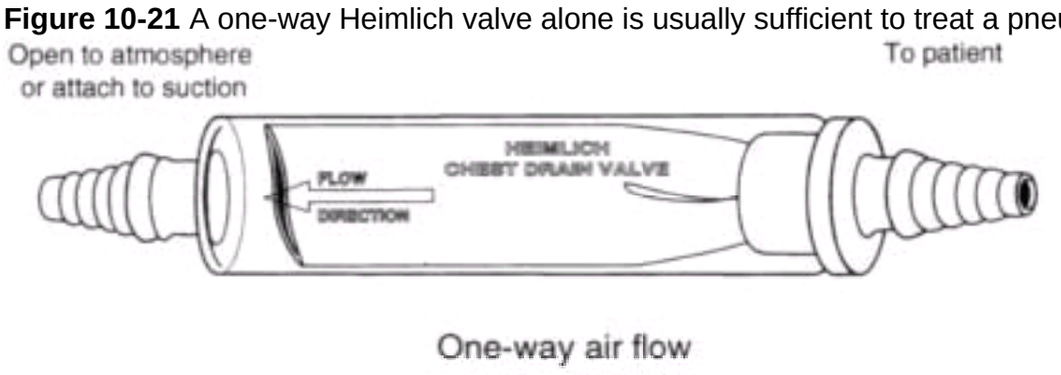

Figure 10-22 Single-bottle (water seal) collection device.

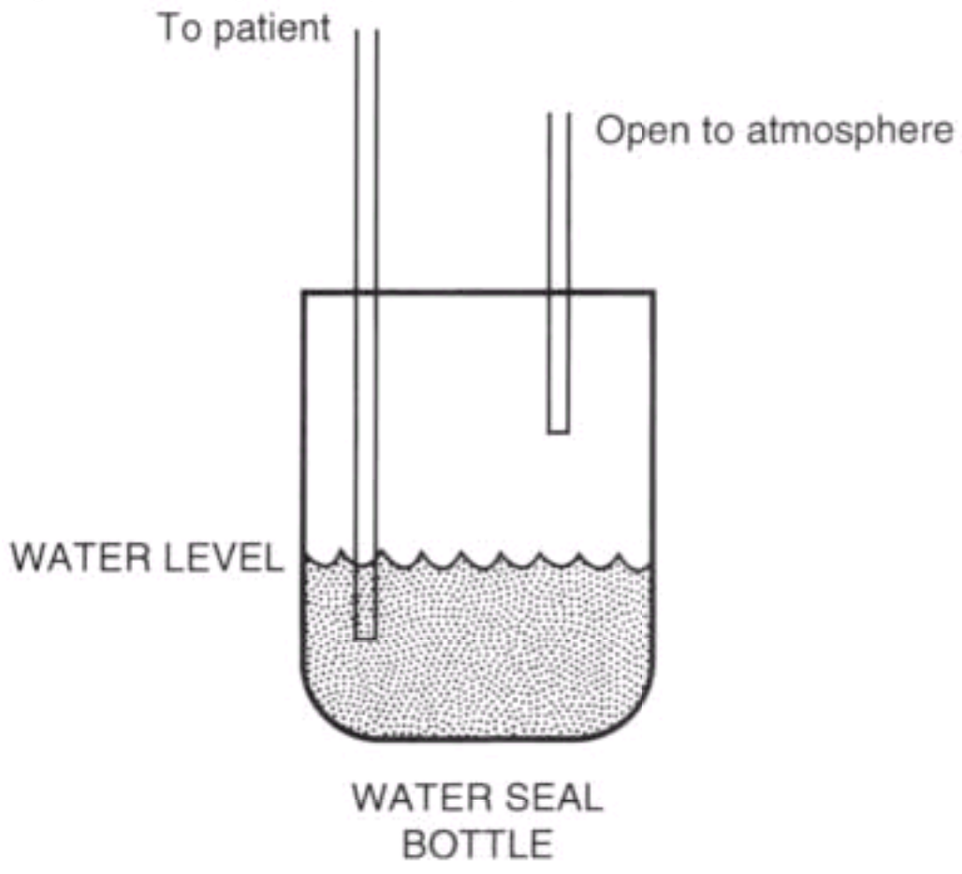

Figure 10-23 A two-bottle system. The "trap" reservoir proximal to the water seal keeps the accumulating drainage from affecting the water seal pressure.

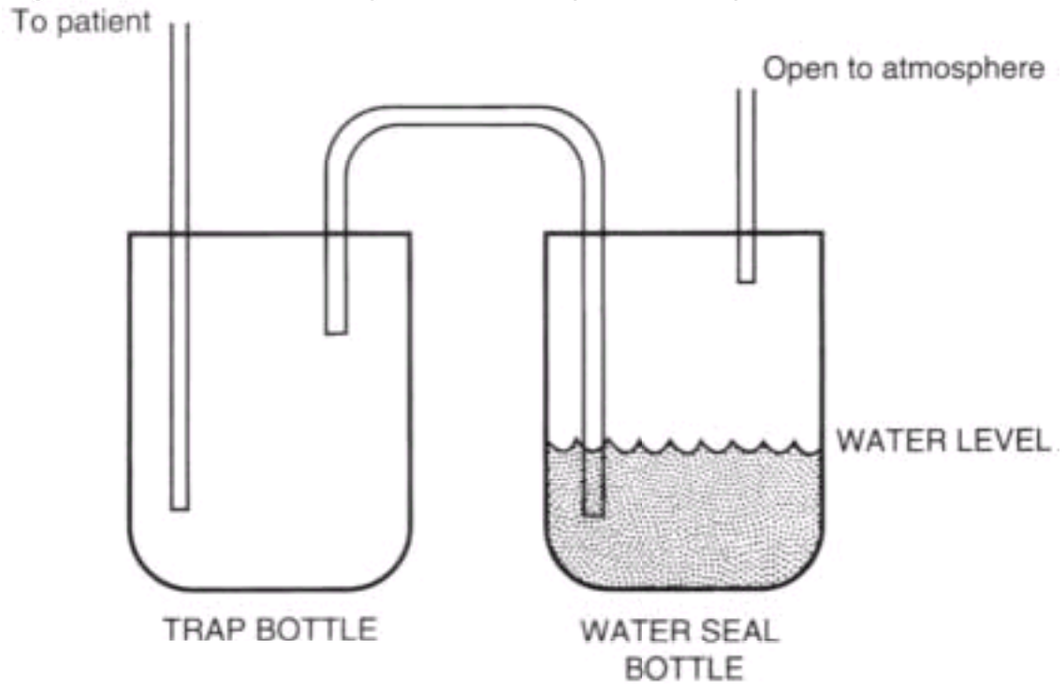

Figure 10-24 A 3-bottle system with fluid trap bottle, water seal, and adjustable vent tube. The height of the column of water in bottle 2 regulates the amount of suction applied, independent of the pressure on the suction valve. *(From Miller KS, Sahn SA: Chest tubes: Indications, technique, management and complications. Chest 91:258, 1987.)*

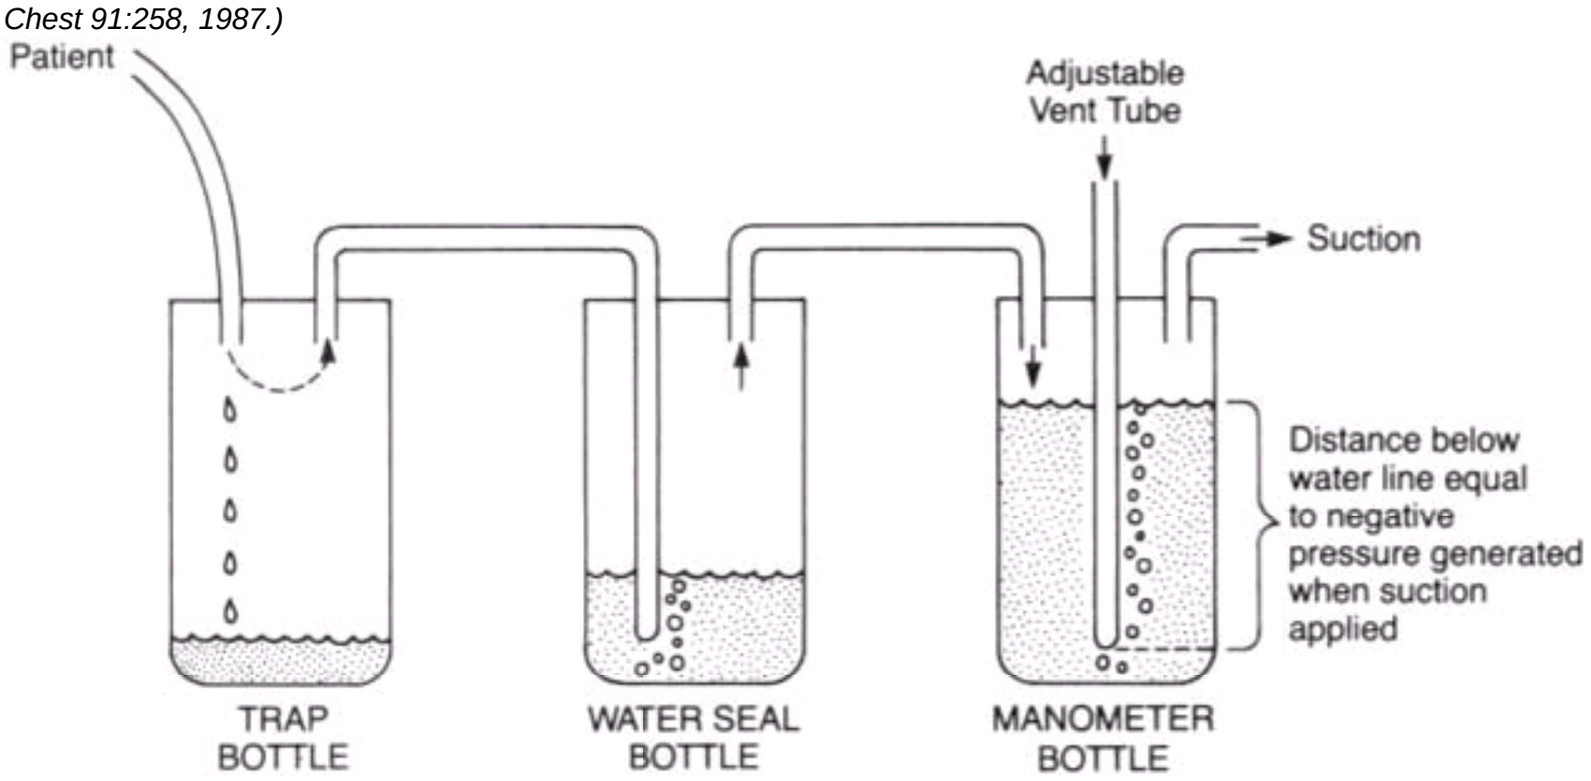

Figure 10-25 Diagram of a commercially available chest drainage system. Included is a 2500-mL fluid collection chamber, a suction control device, an air leak indicator, and a fluid sampling port. A separate attachment is available for autotransfusion. *(Courtesy of Davol, Inc, a division of CR Bard, Cranston, RI.)*

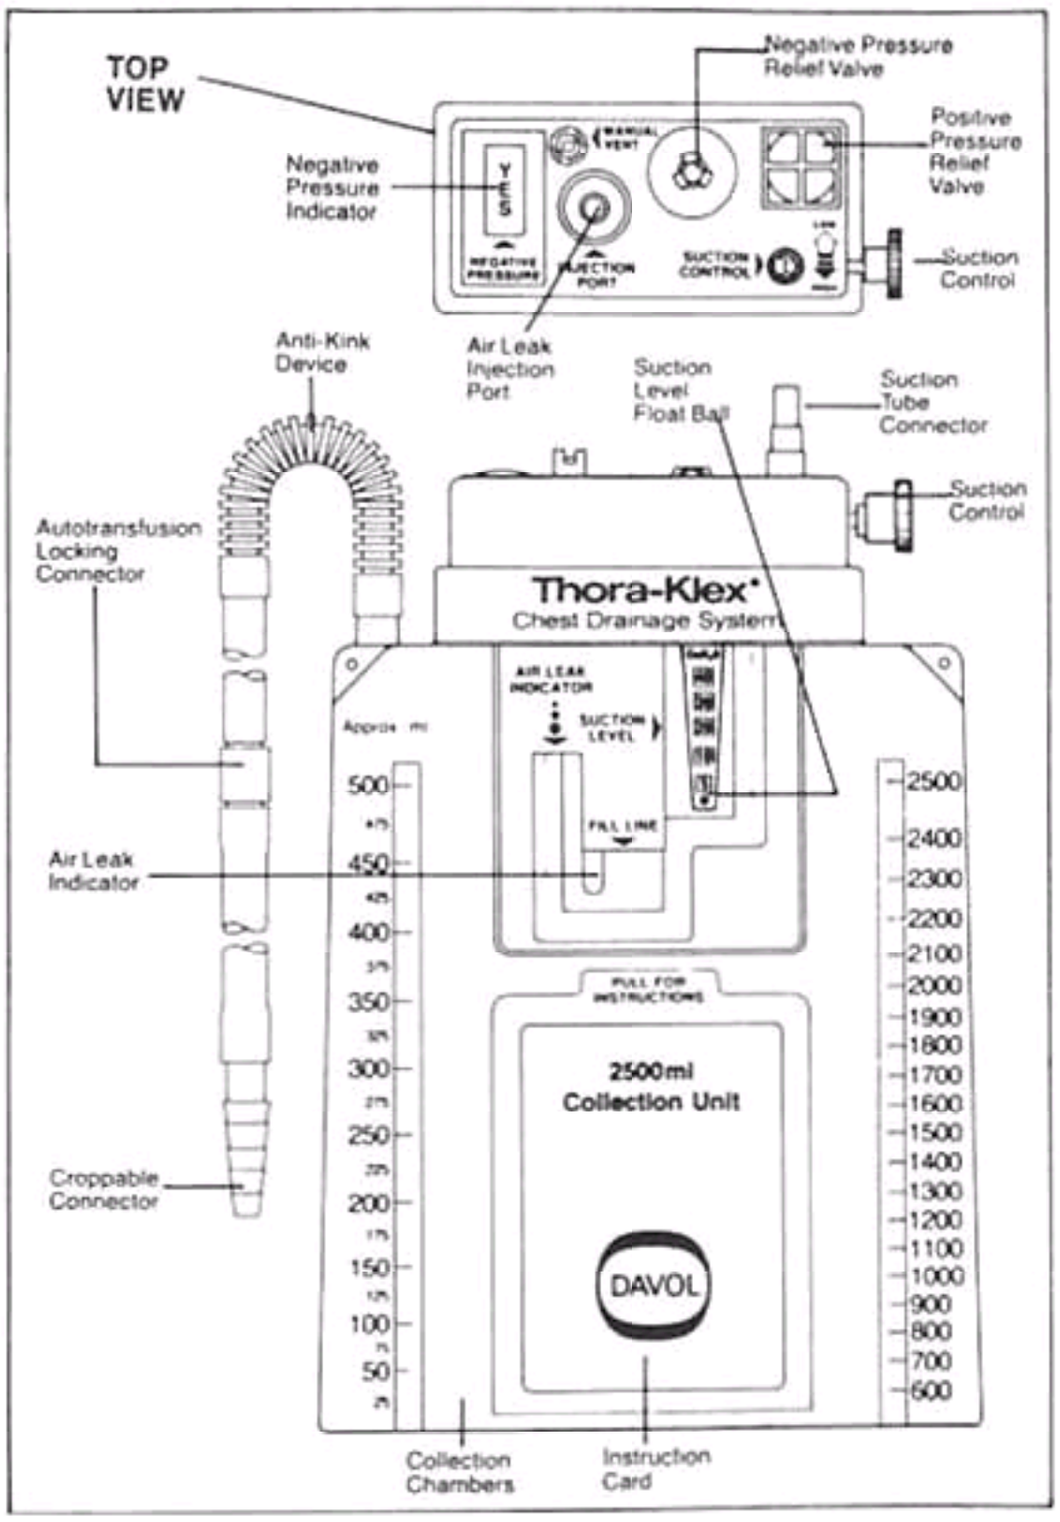

Figure 10-26 Dependent loops of fluid-filled tubing require positive intrapleural pressure greater than the vertical height of the fluid-filled loop for drainage to occur. *(From Batchelder TL, Morris KA: Critical factors in determining adequate pleural drainage in both the operated and non-operated chest. Am Surg 28:298, 1962.)*

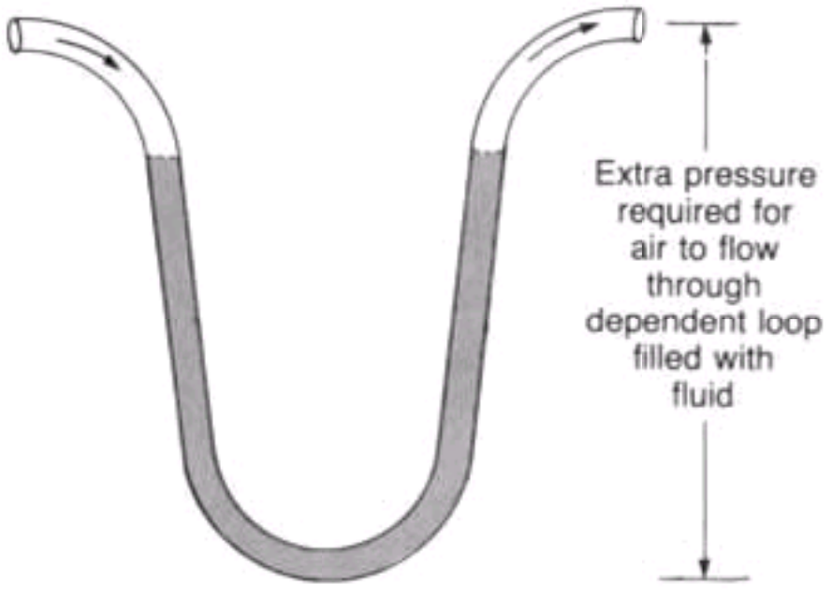

Figure 10-27 Aspiration of a pneumothorax (caused by subclavian vein catheterization) with an Arrow 14 Fr Percutaneous Cavity Drainage Catheterization Kit. This 23-cm pigtail multi-hole catheter is ideal for such purposes. Air can be aspirated from the catheter part with a syringe or the catheter can be attached to suction or a Heimlich valve. This catheter is not used for patients on a ventilator, those with continuing air leaks, or with a hemothorax. It is ideal for stable patients who have a primary pneumothorax or a collapse that can be expected to be stable if the lung is reexpanded (such as intravenous drug use induced, minor blunt trauma, secondary to central venous catheter insertion). *A*, Seldinger-type catheter kit demonstrating pigtail catheter and all necessary equipment, including local anesthesia, introducing needle and syringe, scalpel, guidewire, and dilator. *B*, After generous local anesthesia, the introducing syringe is advanced in *a straight line over the top of the fifth rib* until air is aspirated. Unless a straight track is created it will be difficult to advance the floppy catheter, and a tunneling approach cannot be used. *C*, The guidewire is advanced into the pleural space and the introducing needle is removed. *D*, Following puncture of the skin at the site of wire insertion with a scalpel, a dilator is advanced over the wire to create a track for the catheter. *E*, The pigtail catheter is advanced over the wire through the dilated tract, assuming its pigtail configuration when it is in the pleural space. A twisting motion may be needed to advance the catheter through the subcutaneous tissues. *F*, The catheter is advanced to the hilt and secured to suction. This catheter may be removed after a period of observation or the suction may be maintained for a few days. If used for a few days, the catheter will become clogged with mucus or blood, which may be cleared by injecting sterile saline through the device.

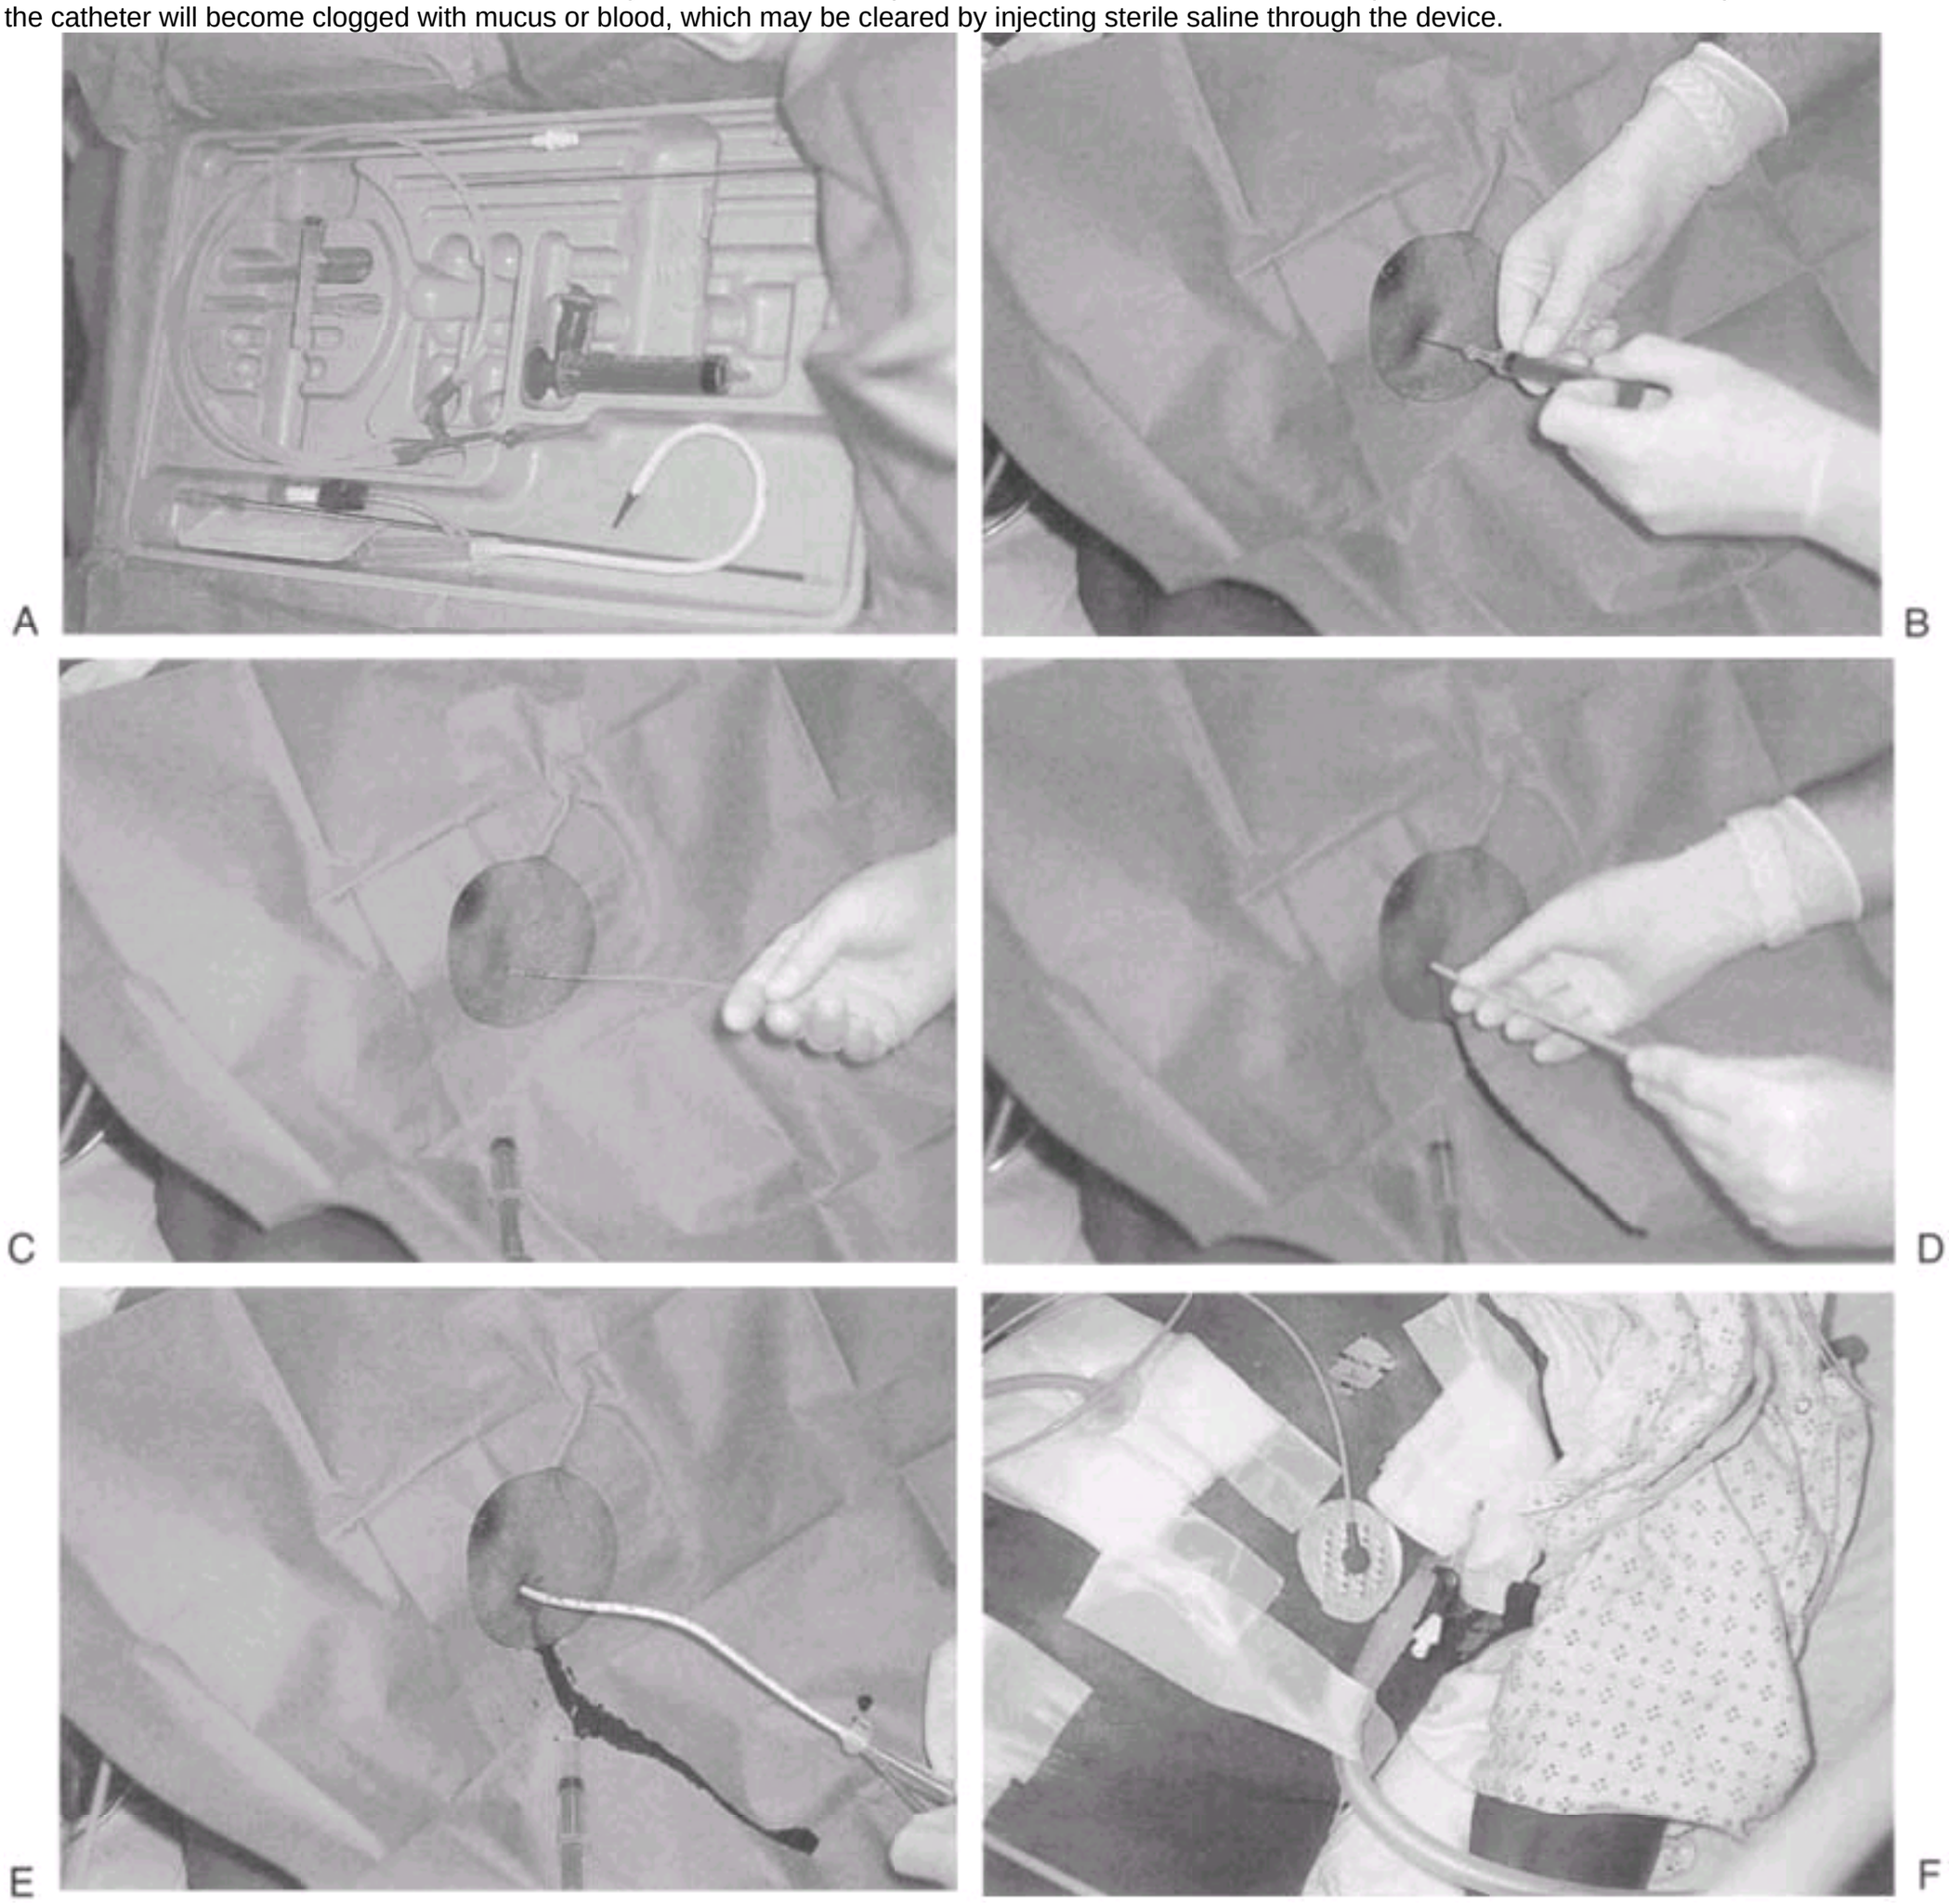

Figure 10-28 Seldinger technique for aspiration catheter insertion. *A*, Guidewire is passed through a needle over the rib into the pleural space. *B*, The needle is removed with the wire in the pleural space. *C* and *D*, A nick is made in the skin with a No. 11 blade, and the introducer and catheter are threaded into the pleural space. A twisting motion may be helpful. *E*, The guidewire and introducer are removed, leaving the catheter in the pleural space.

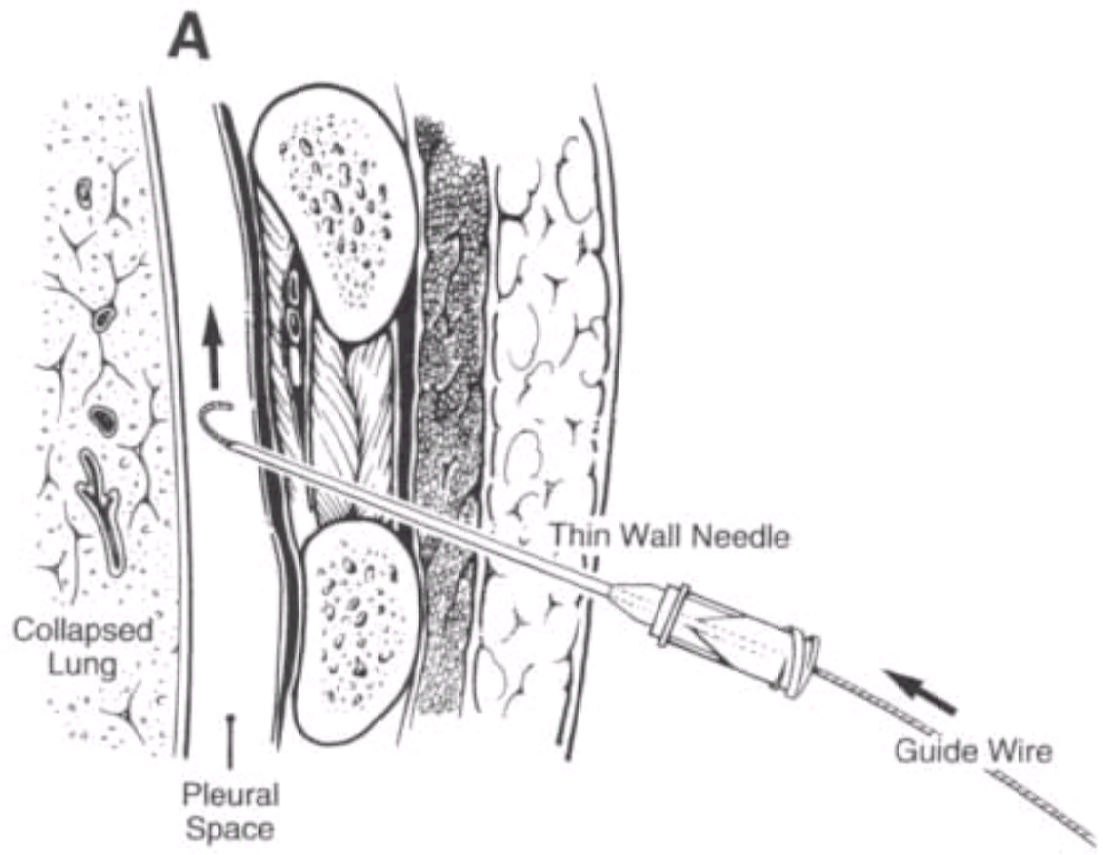

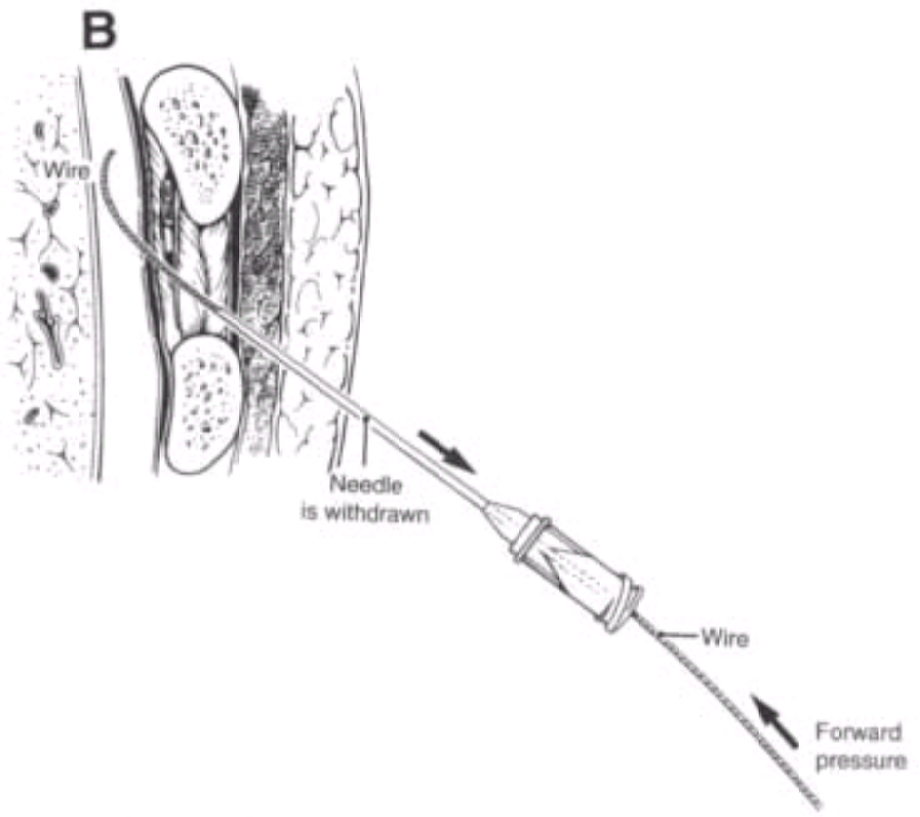

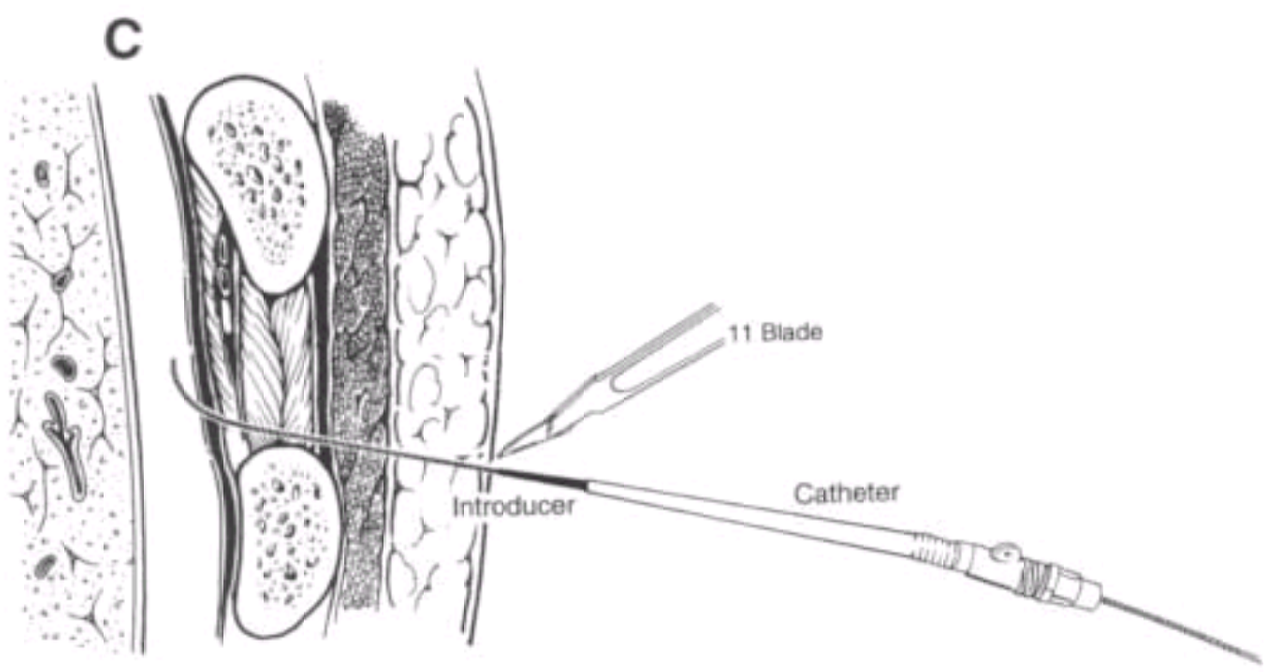

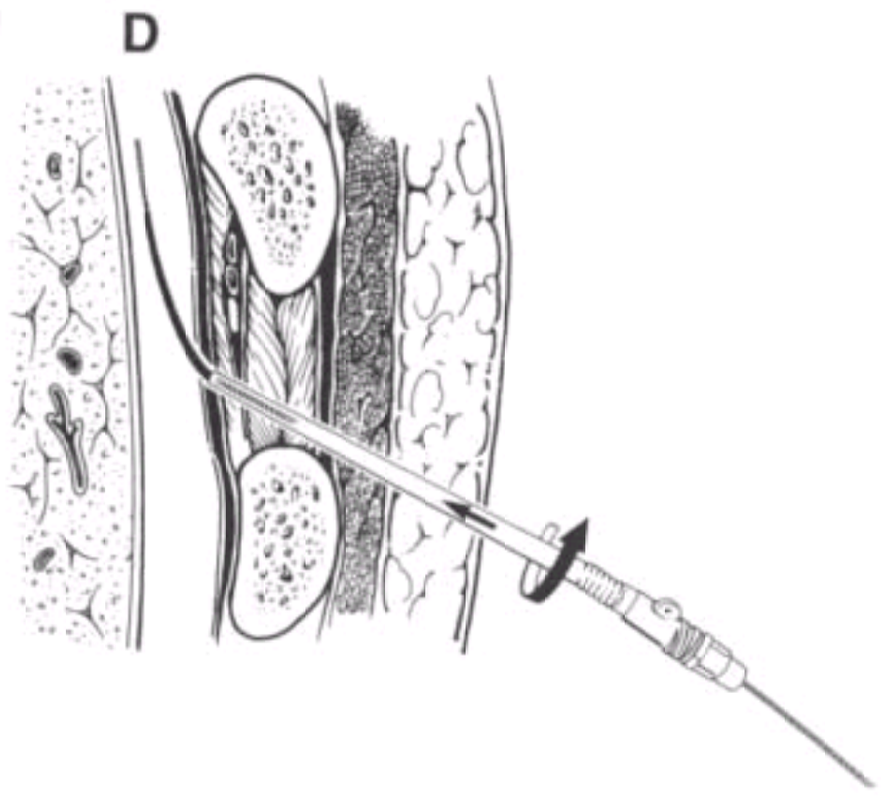

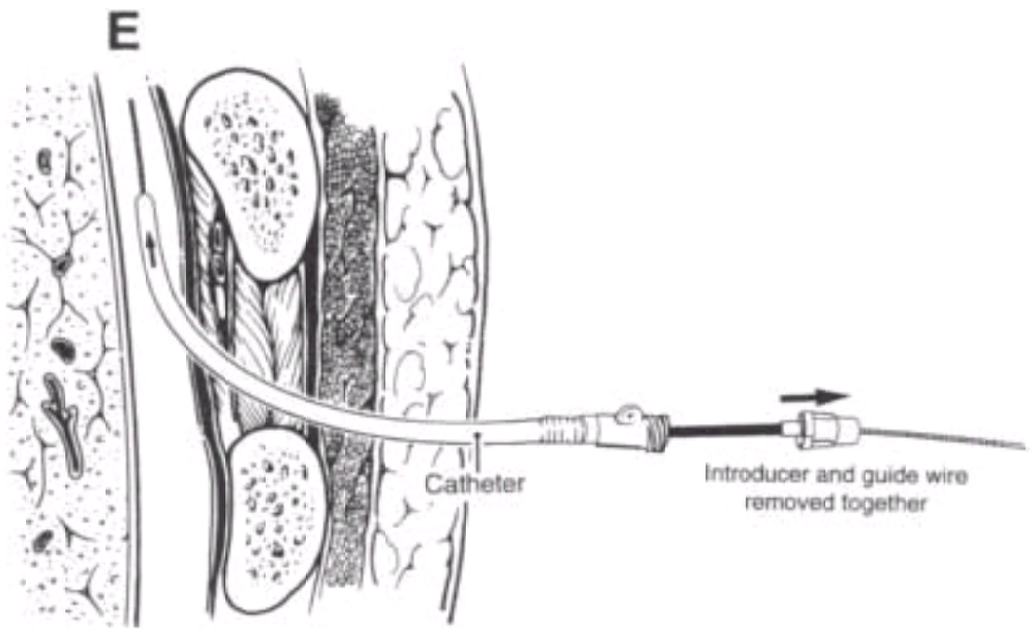

Figure 10-29 Over-the-needle catheter aspiration. *A,* A small nick is made in the skin with a No. 11 blade. The over-the-needle catheter is inserted through the nick into the pleural space. Proper placement is confirmed by the free flow of air into the attached syringe. *B,* The catheter is then threaded over the needle into the pleural space, and the needle is withdrawn.

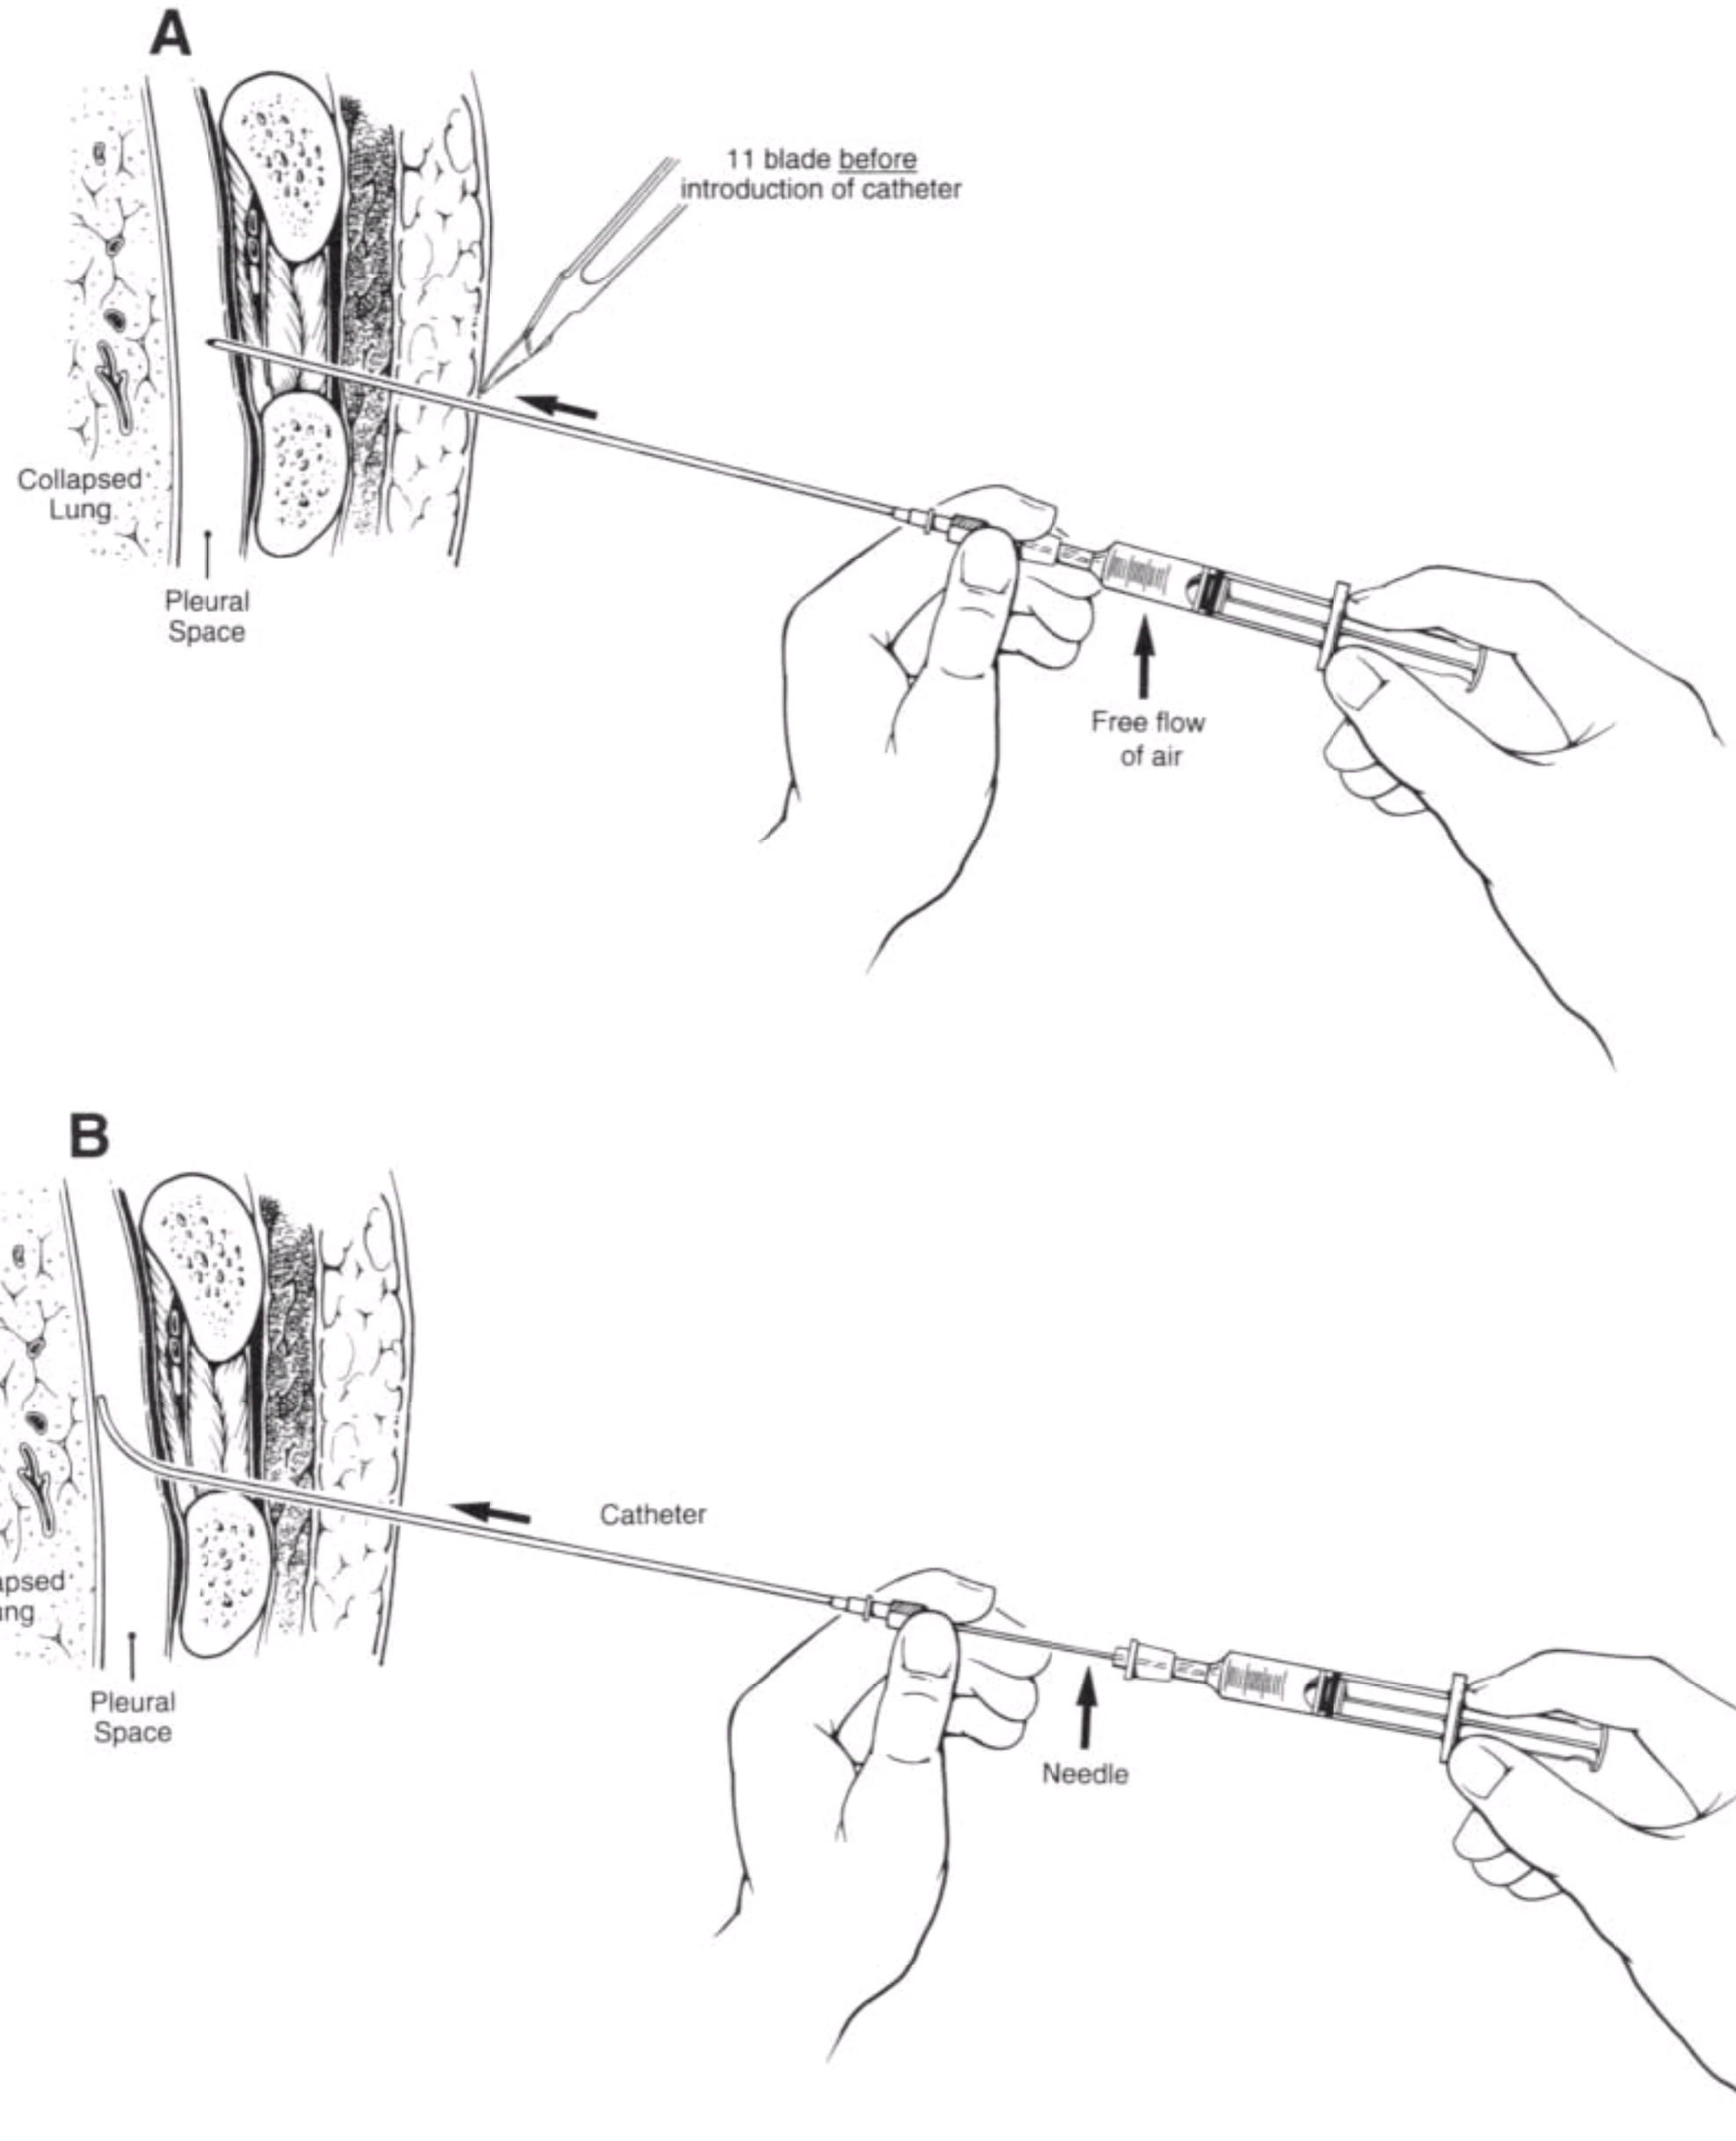

Figure 11-1 Anatomy of the carotid sinus reflex. Carotid receptors send impulses to the medulla by way of the sinus nerve of Hering and cranial nerve IX. Efferent nerves are shown on the right. *(Adapted from Scher AM: Control of arterial blood pressure. In Ruch TC, Patton HD: Physiology and Biophysics, vol 2, 20th ed. Philadelphia, WB Saunders, 1974.)*

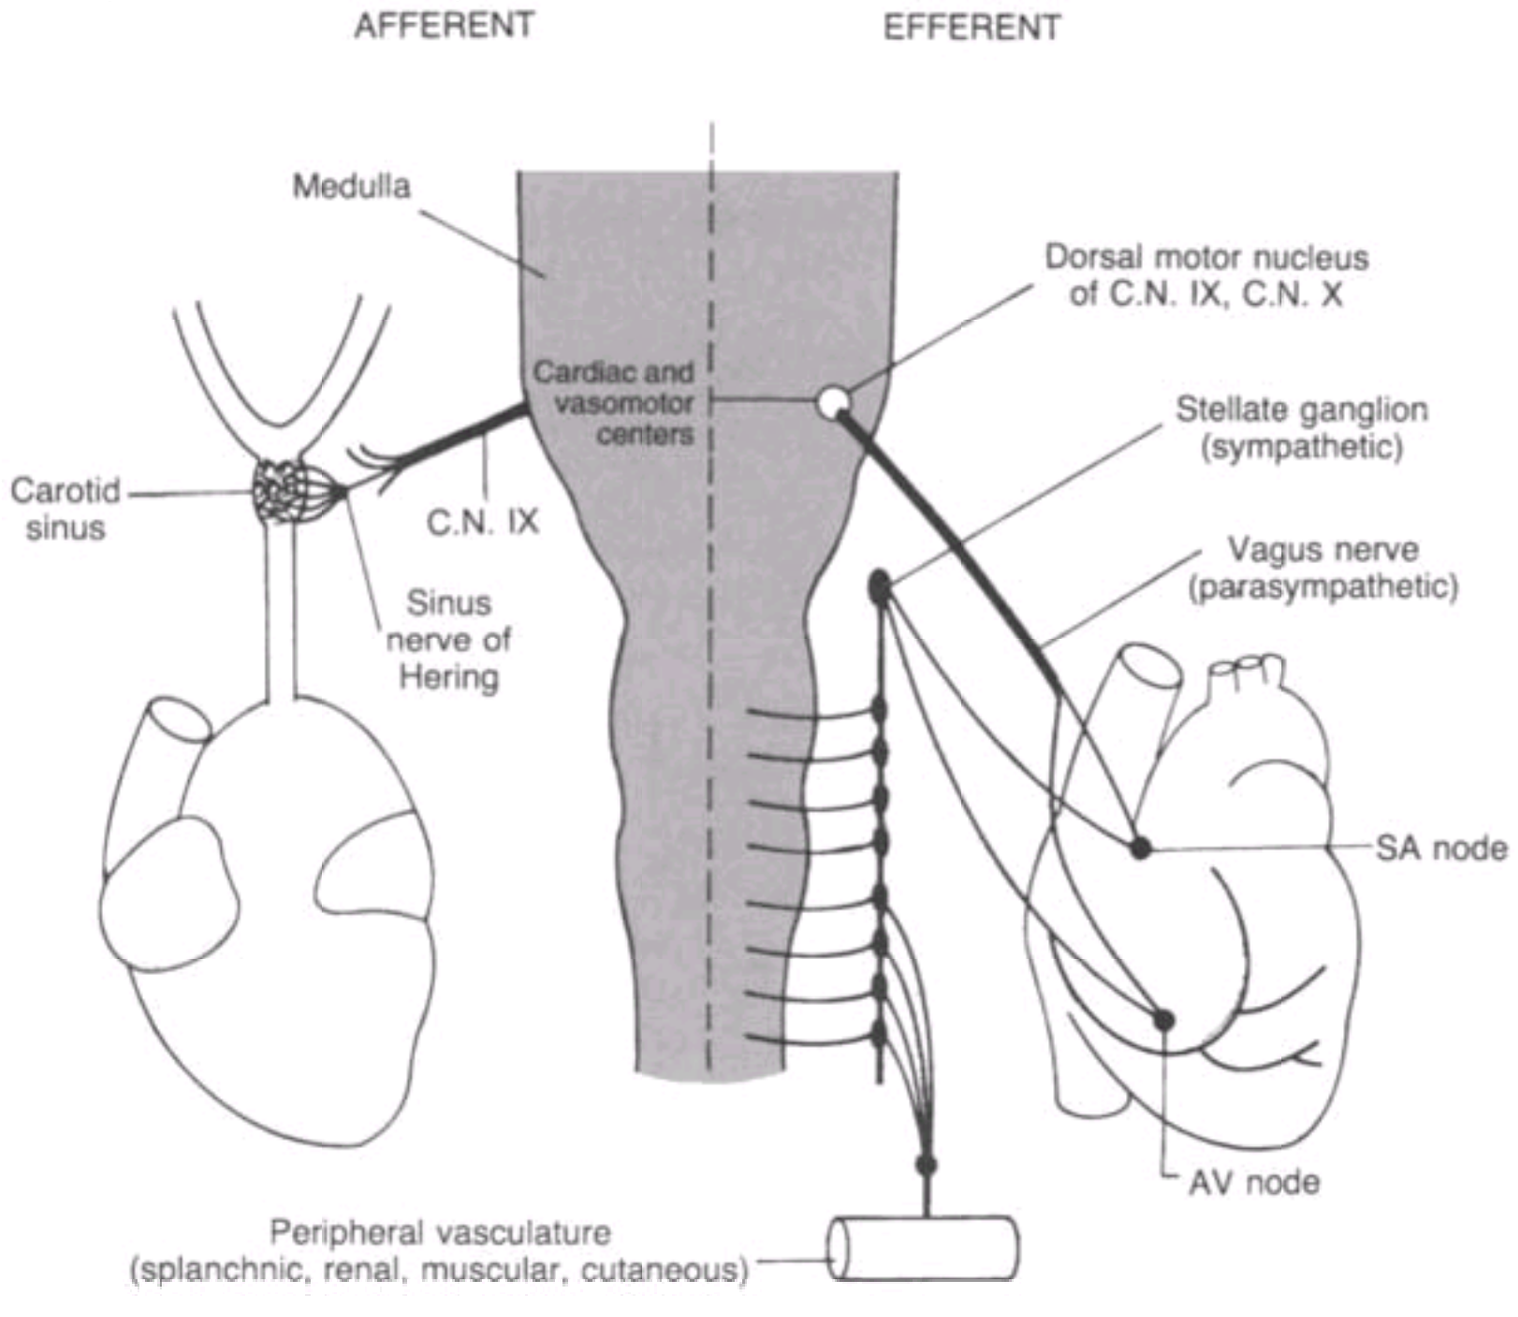

Figure 11-2 Ventricular Tachycardia. Carotid sinus massage (CSM) slows atria but not ventricles, thus establishing the presence of atrioventricular dissociation, supporting the diagnosis of ventricular tachycardia. The QRS measures 0.16 sec. Note the atrial rate slowing from 102 to 88 beats/min while the ventricular rate is unaffected. *(From Lown B, Levine SA: Carotid sinus—Clinical value of its stimulation. Circulation 23:766, 1961. Reproduced by permission.)*

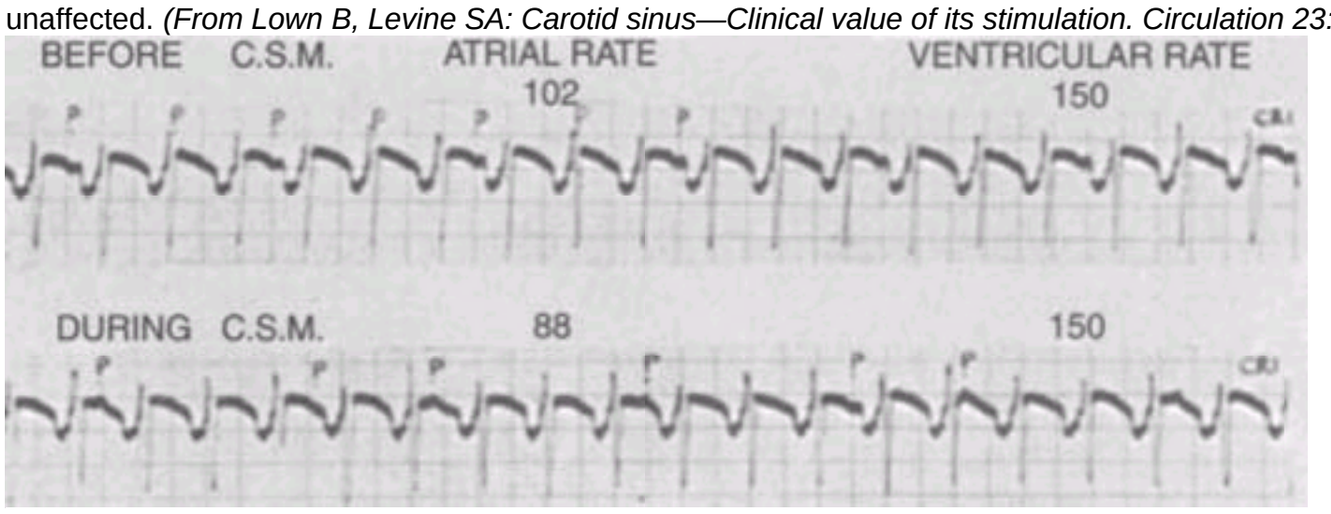

Figure 11-3 Paroxysmal atrial tachycardia with variable block. Carotid sinus pressure uncovers P waves hidden in the ventricular complex. The upper strip resembles atrial flutter or atrial fibrillation with ventricular ectopic beats. The lower strip shows paroxysmal atrial tachycardia with variable block at an atrial rate of 166 beats/min. *(From Lown B, Levine SA: Carotid sinus—Clinical value of its stimulation. Circulation 23:766, 1961. Reproduced by permission.)*

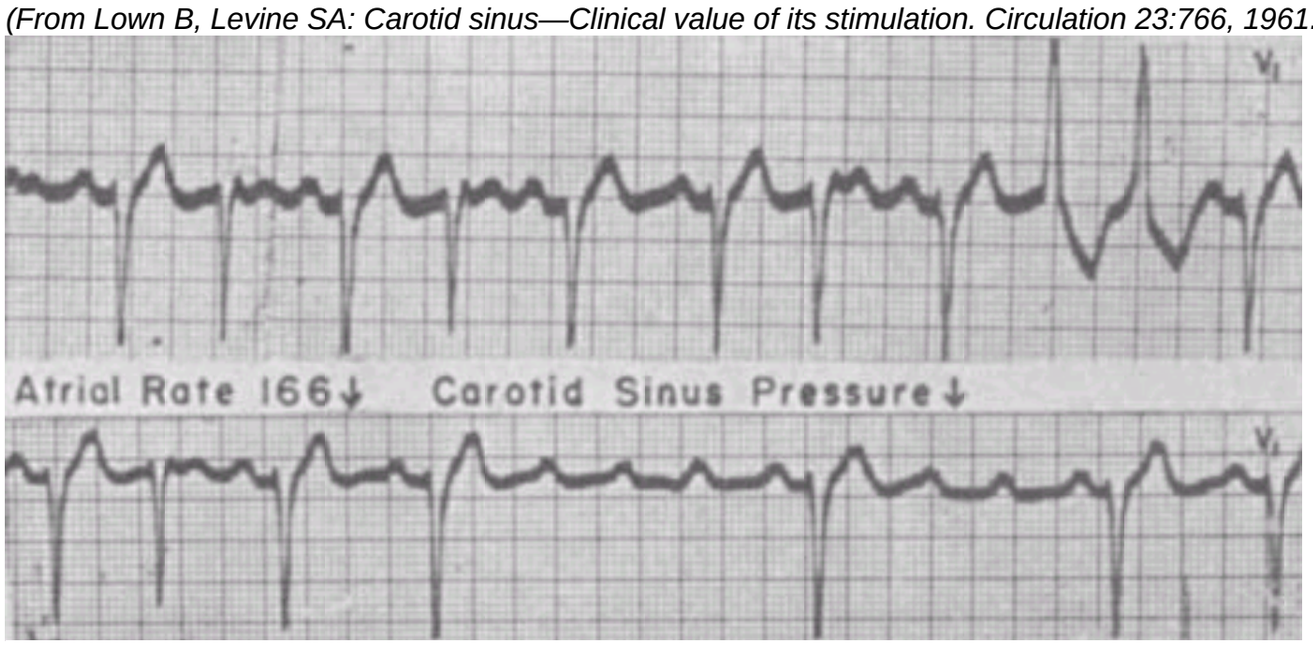

Figure 11-4 Sinus tachycardia. The sinus P wave is obscured within the descending limb of the T wave. Carotid sinus massage (CSM) transiently slows the sinus rate and exposes the P wave. The rate then increases. The strips are continuous. *(From Silverman ME: Recognition and treatment of arrhythmias. In Schwartz GR, Safar P, Stone JH, et al (eds): Principles and Practice of Emergency Medicine, vol. 2. Philadelphia, WB Saunders, 1978. Reproduced by permission.)*

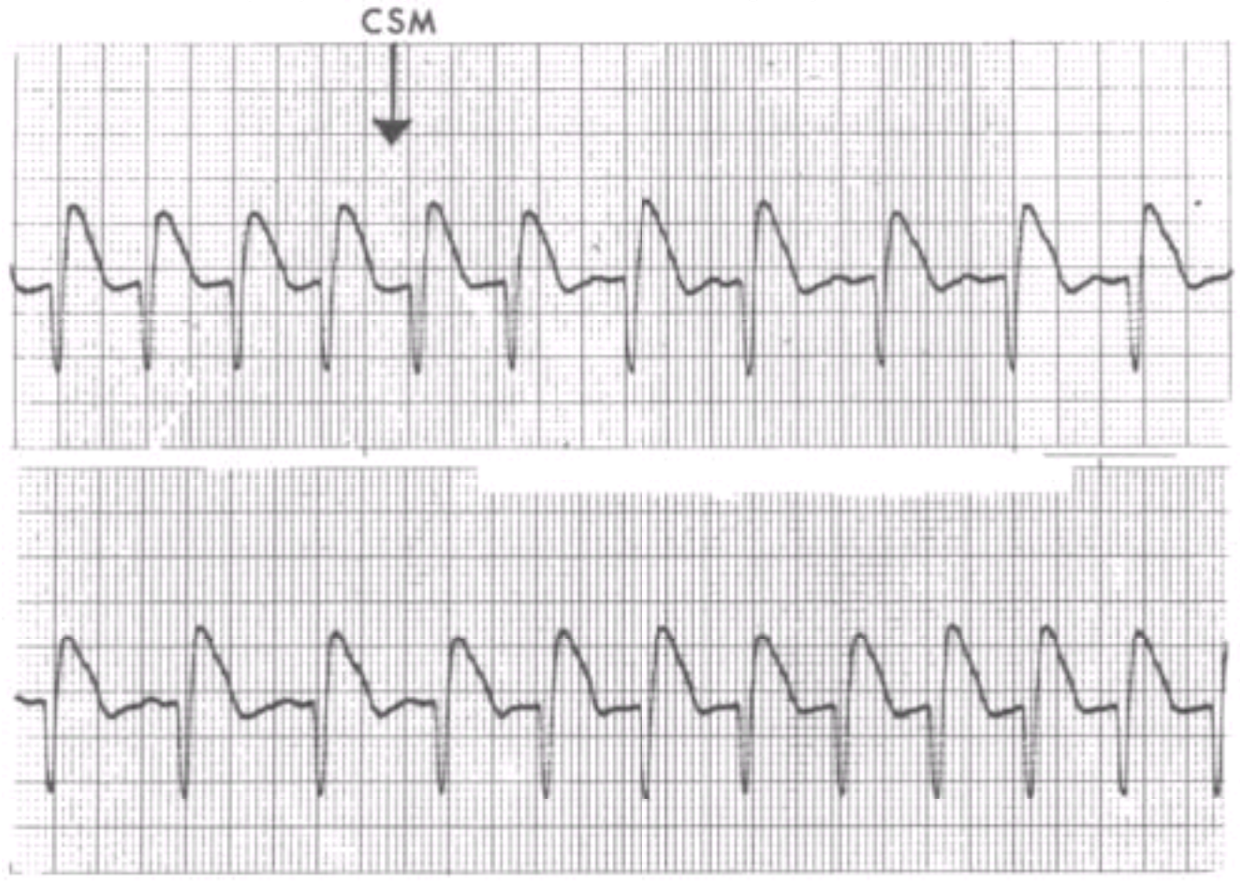

Figure 11-5 Sinus tachycardia with high-degree atrioventricular block. Arrows indicate sinus P waves. Strips II-a to II-d are continuous. The basic rhythm is sinus, but marked first-degree atrioventricular block is present. High-degree (advanced) atrioventricular block associated with transient slowing of sinus rate is produced by carotid sinus stimulation (CSS). *(From Chung EK: Electrocardiography, 2nd ed. New York, Harper & Row, 1980. Reproduced by permission.)*

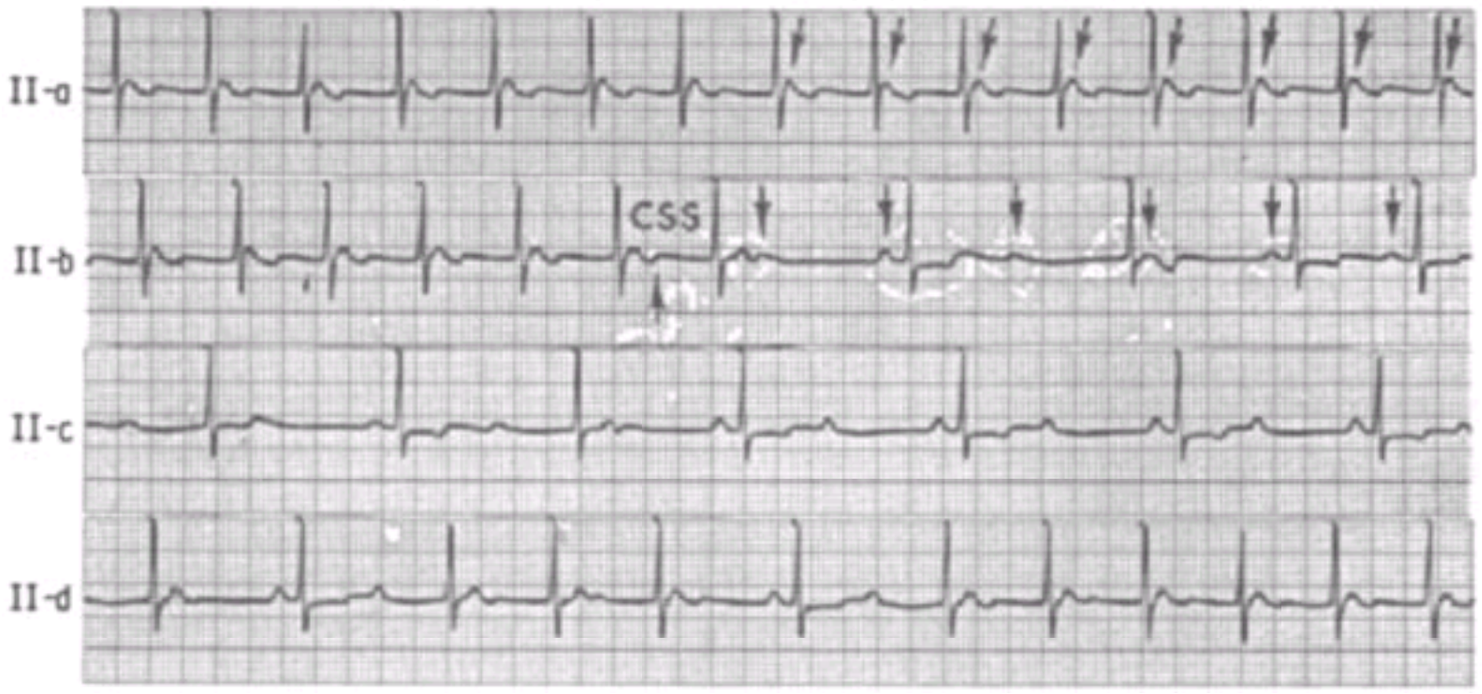

Figure 11-6 Paroxysmal atrial tachycardia. Carotid sinus massage (CSM) abolishes the dysrhythmia and results in a period of sinus suppression with a junctional (J) escape beat, followed thereafter by a sinus rhythm. Prolonged periods of asystole may produce anxiety in the clinician who is waiting for the resumption of a sinus pacemaker. *(From Silverman ME: Recognition and treatment of arrhythmias. In Schwartz GR, Safar P, Stone JH, et al (eds): Principles and Practice of Emergency Medicine, vol 2. Philadelphia, WB Saunders, 1978. Reproduced by permission.)*

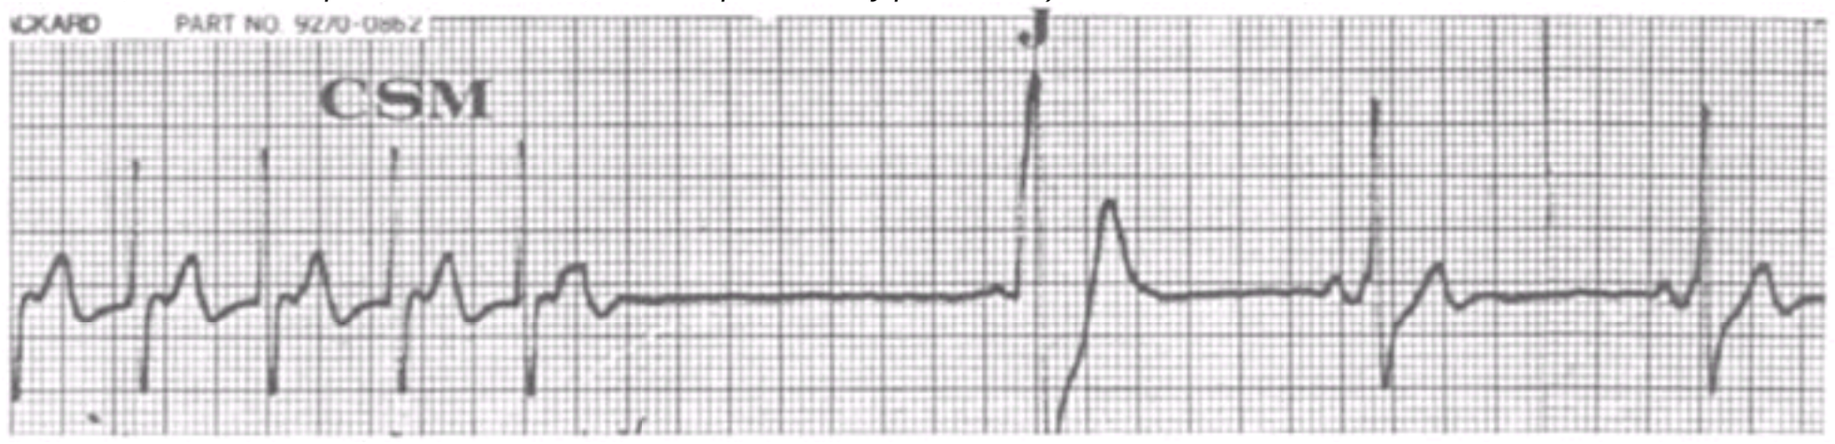

Figure 11-7 Atrial flutter. Carotid sinus stimulation (CSS, *downward arrow*) produces marked slowing of the ventricular rate in atrial flutter. Note the obvious flutter waves with an atrial rate of 300 and a long period of ventricular standstill. Strips are continuous. *(From Chung EK: Electrocardiography, 2nd ed. New York, Harper & Row, 1980. Reproduced by permission.)*

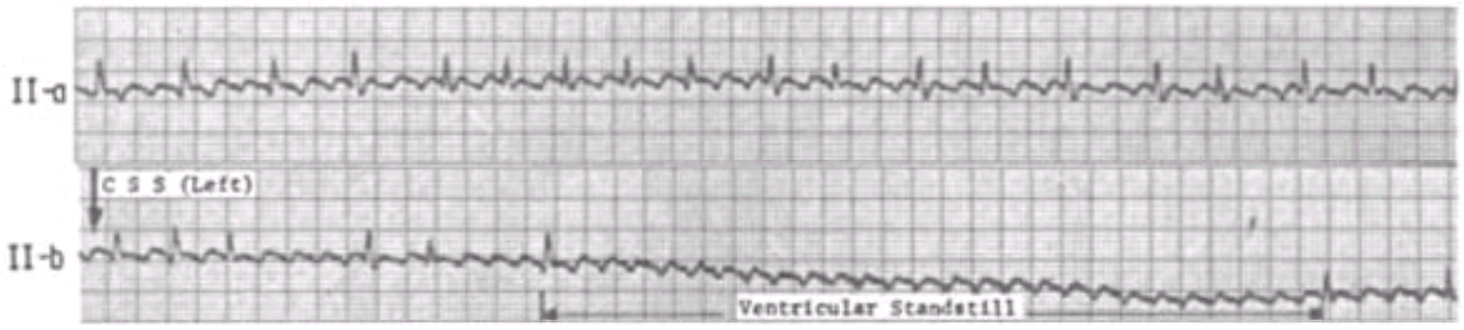

Figure 11-8 Atrial fibrillation. Carotid sinus massage (CSM) slows the ventricular response transiently, revealing the fibrillating baseline. The ventricular rate subsequently accelerates. *(From Silverman ME: Recognition and treatment of arrhythmias. In Schwartz GR, Safar P, Stone JH, et al (eds): Principles and Practice of Emergency Medicine, vol. 2. Philadelphia, WB Saunders, 1978. Reproduced by permission.)*

Figure 11-9 Occult premature ventricular contractions. Carotid sinus massage (CSM) reveals ventricular extrasystoles, thereby explaining the cause of palpitation in this case. *(From Lown B, Levine SA: Carotid sinus—Clinical value of its stimulation. Circulation 23:766, 1961. Reproduced by permission.)*

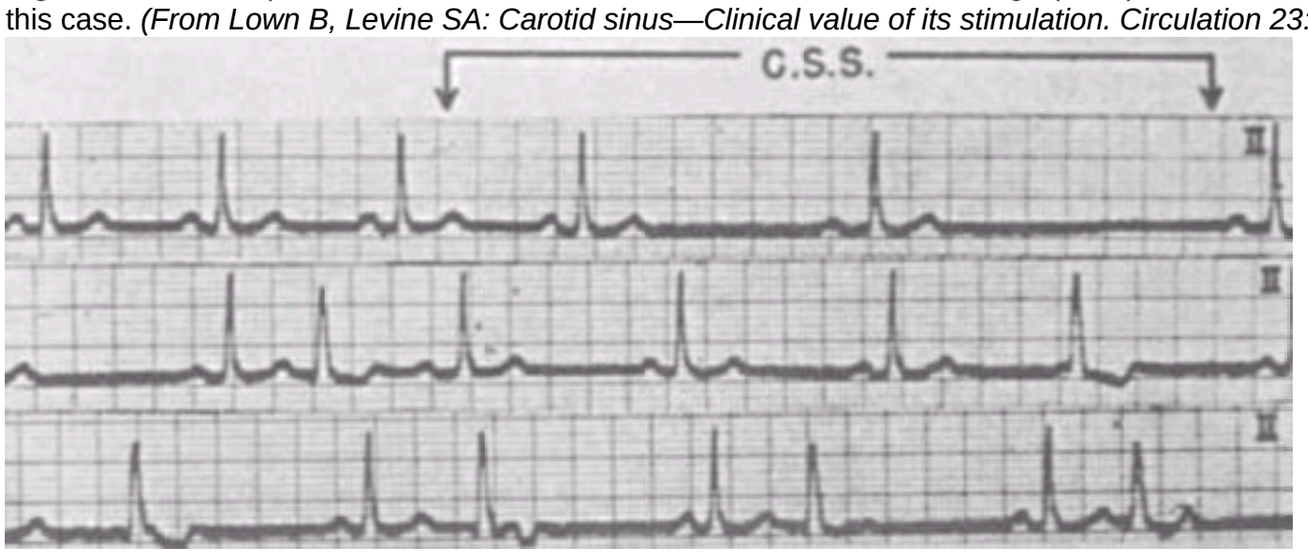

Figure 11-10 A run of ventricular tachycardia is seen immediately after a supraventricular dysrhythmia is terminated by cardiac sinus massage (CSM). The patient remained asymptomatic, and a normal sinus rhythm was established spontaneously within a few seconds.

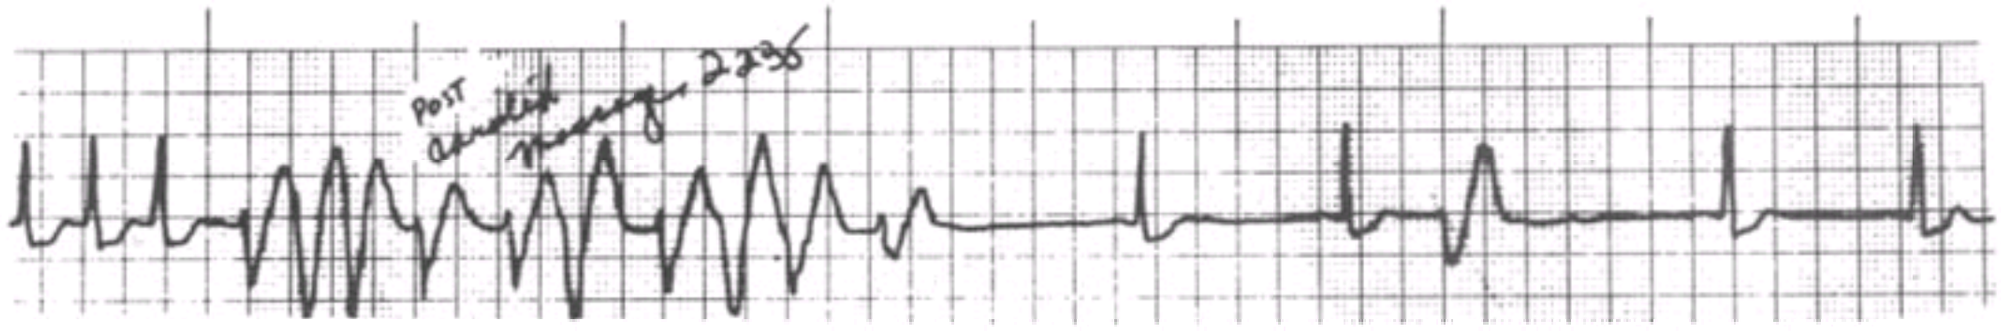

Figure 11-11 Hyperreactive carotid sinus reflex. Gentle pressure was applied to the carotid sinus for 3 seconds, resulting in a pause in sinus rhythm of approximately 7 seconds. This syndrome may be the cause of syncope. *(From Bigger JT Jr: Mechanisms and diagnosis of arrhythmias. In Braunwald E (ed): Heart Disease, vol 1. Philadelphia, WB Saunders, 1980. Reproduced by permission.)*

Figure 11-12 Acceleration of ventricular rate by carotid sinus stimulation (CSS). Continuous tracing. Upper strip shows 2:1 atrioventricular block: Atrial rate at approximately 102/min; ventricular rate at approximately 51/min. The second and third strips were recorded during and after CSS, when the atrial rate was reduced to 68/min; a 1:1 response occurs. *(From Lown B, Levine SA: Carotid sinus—Clinical value of its stimulation. Circulation 23:766, 1961. Reproduced by permission.)*

Figure 12-1 Success versus time; graph depicting relationship between survival to hospital discharge after ventricular fibrillation (VF) cardiac arrest and time interval between collapse and defibrillation. There is a 7% to 10% decrease in survival for each minute of VF duration. *(From Larsen MP, Eisenberg MS, Cummins RO, Hallstrom AP: Predicting survival from out-of-hospital cardiac arrest: A geographic model. Ann Emerg Med 22:1652, 1993. Reproduced with permission.)*

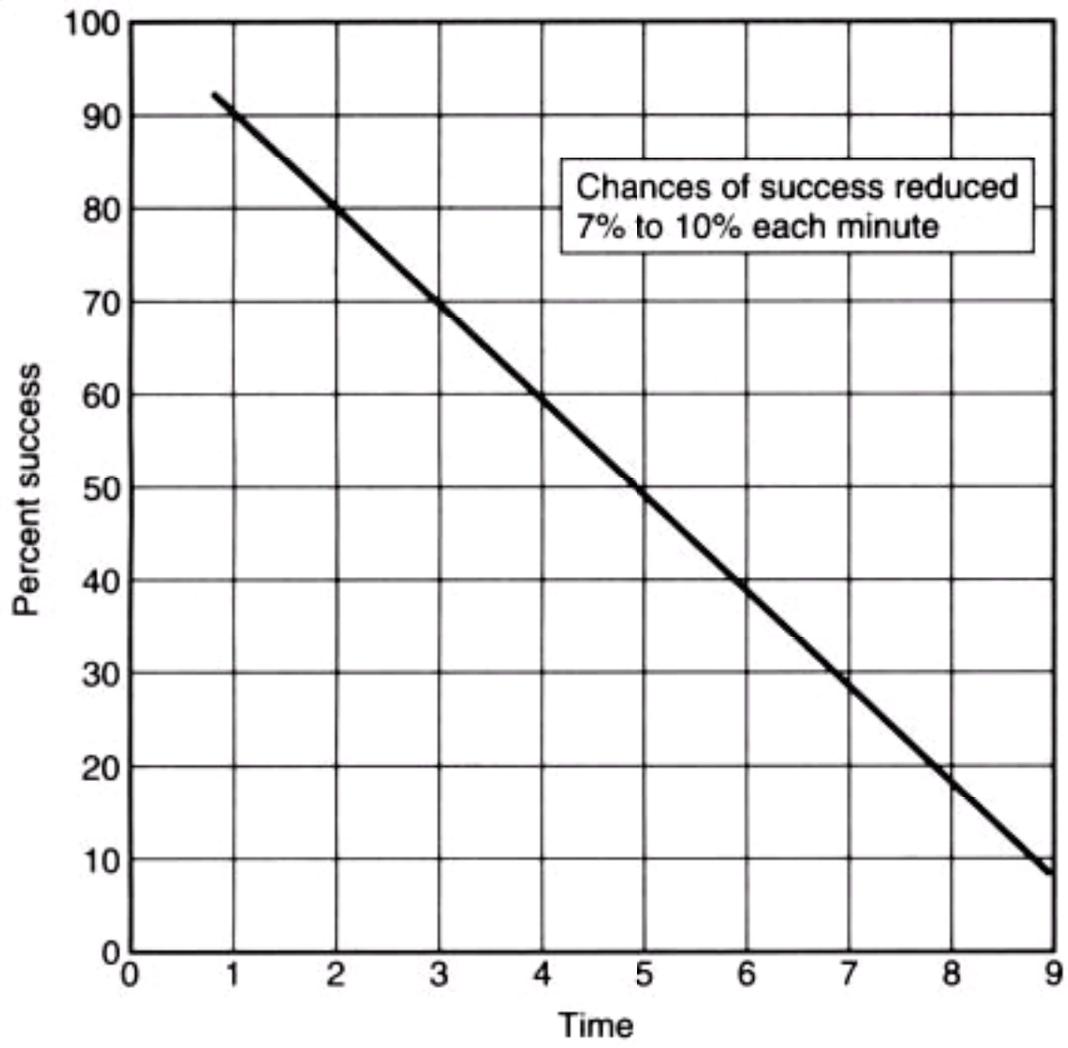

Figure 12-2 Leads aVR, aVL, and aVF from an animal with electrically induced ventricular fibrillation (VF). From onset to 4.5 minutes, VF waves were obvious in all 6 frontal plane leads. At 5.0 and 5.5 minutes, lead aVR was a straight line. Note that aVR is the electrical sum of leads aVL and aVF. By 6 minutes, the null vector had changed, and VF was again evident in all 6 frontal plane leads. *(From Ewy GA, Dahl CF, Zimmerman M, et al: Ventricular fibrillation masquerading as ventricular standstill. Crit Care Med 9:841, 1981. Reproduced by permission.)*

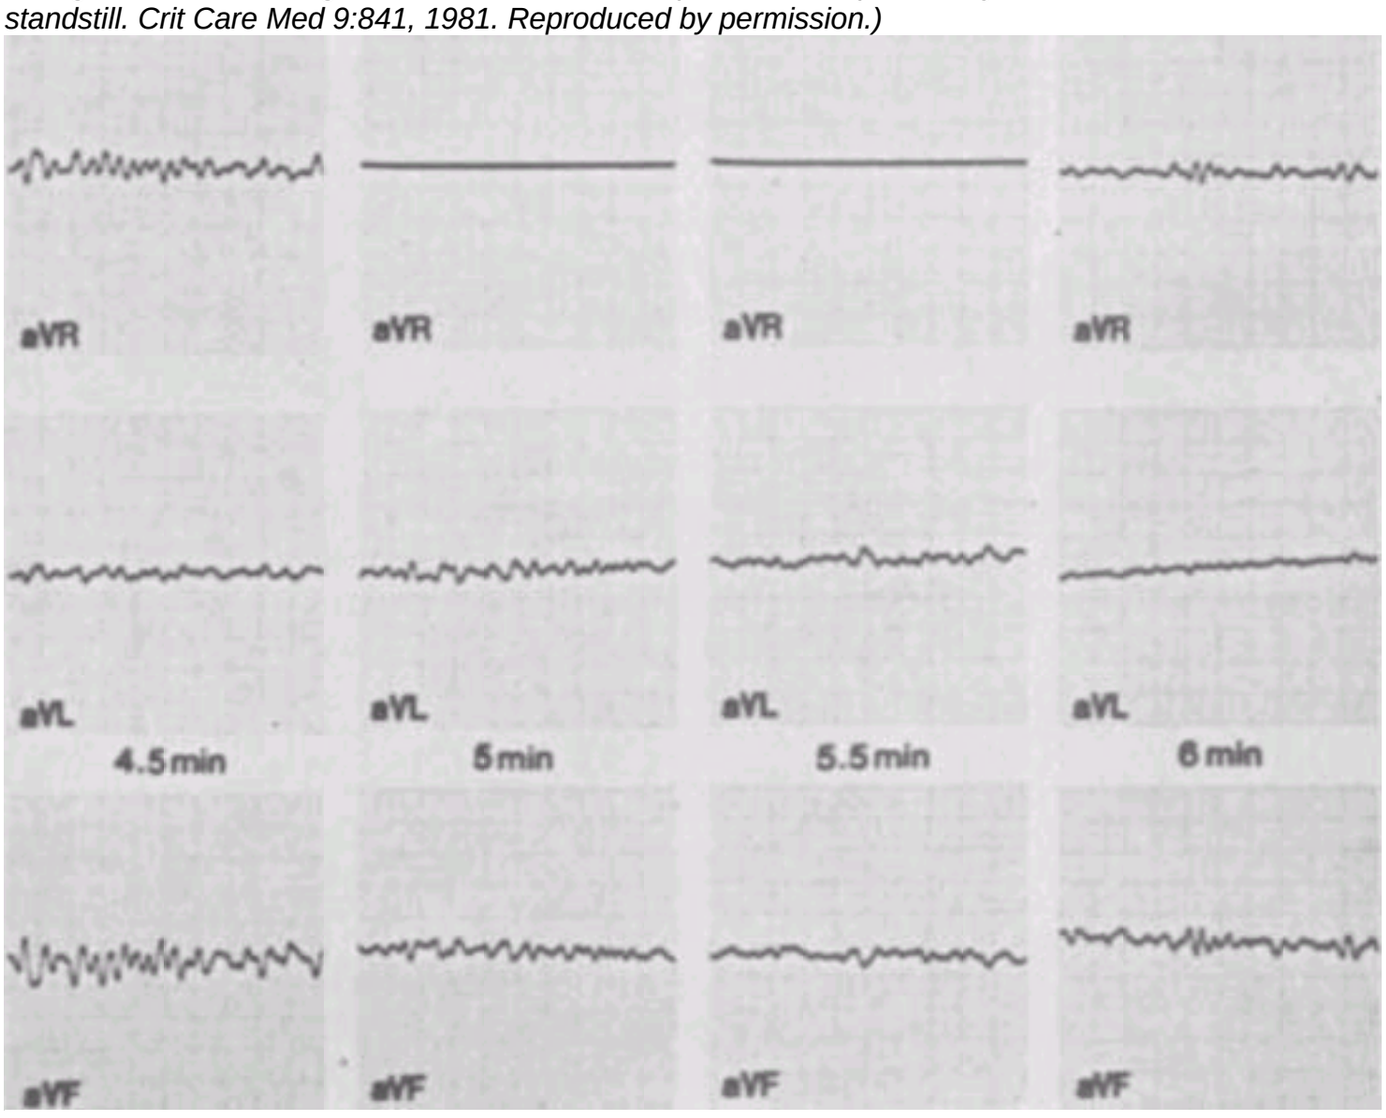

Figure 12-3 Phases of vulnerability for atrium and ventricle. Note that an alternating current shock of 0.20 seconds may end at the T wave even when synchronized with the R wave of the electrocardiogram. *(From Resnekov L: Theory and practice of electroversion in cardiac dysrhythmias. Med Clin North Am 60:325, 1976. Reproduced by permission.)*

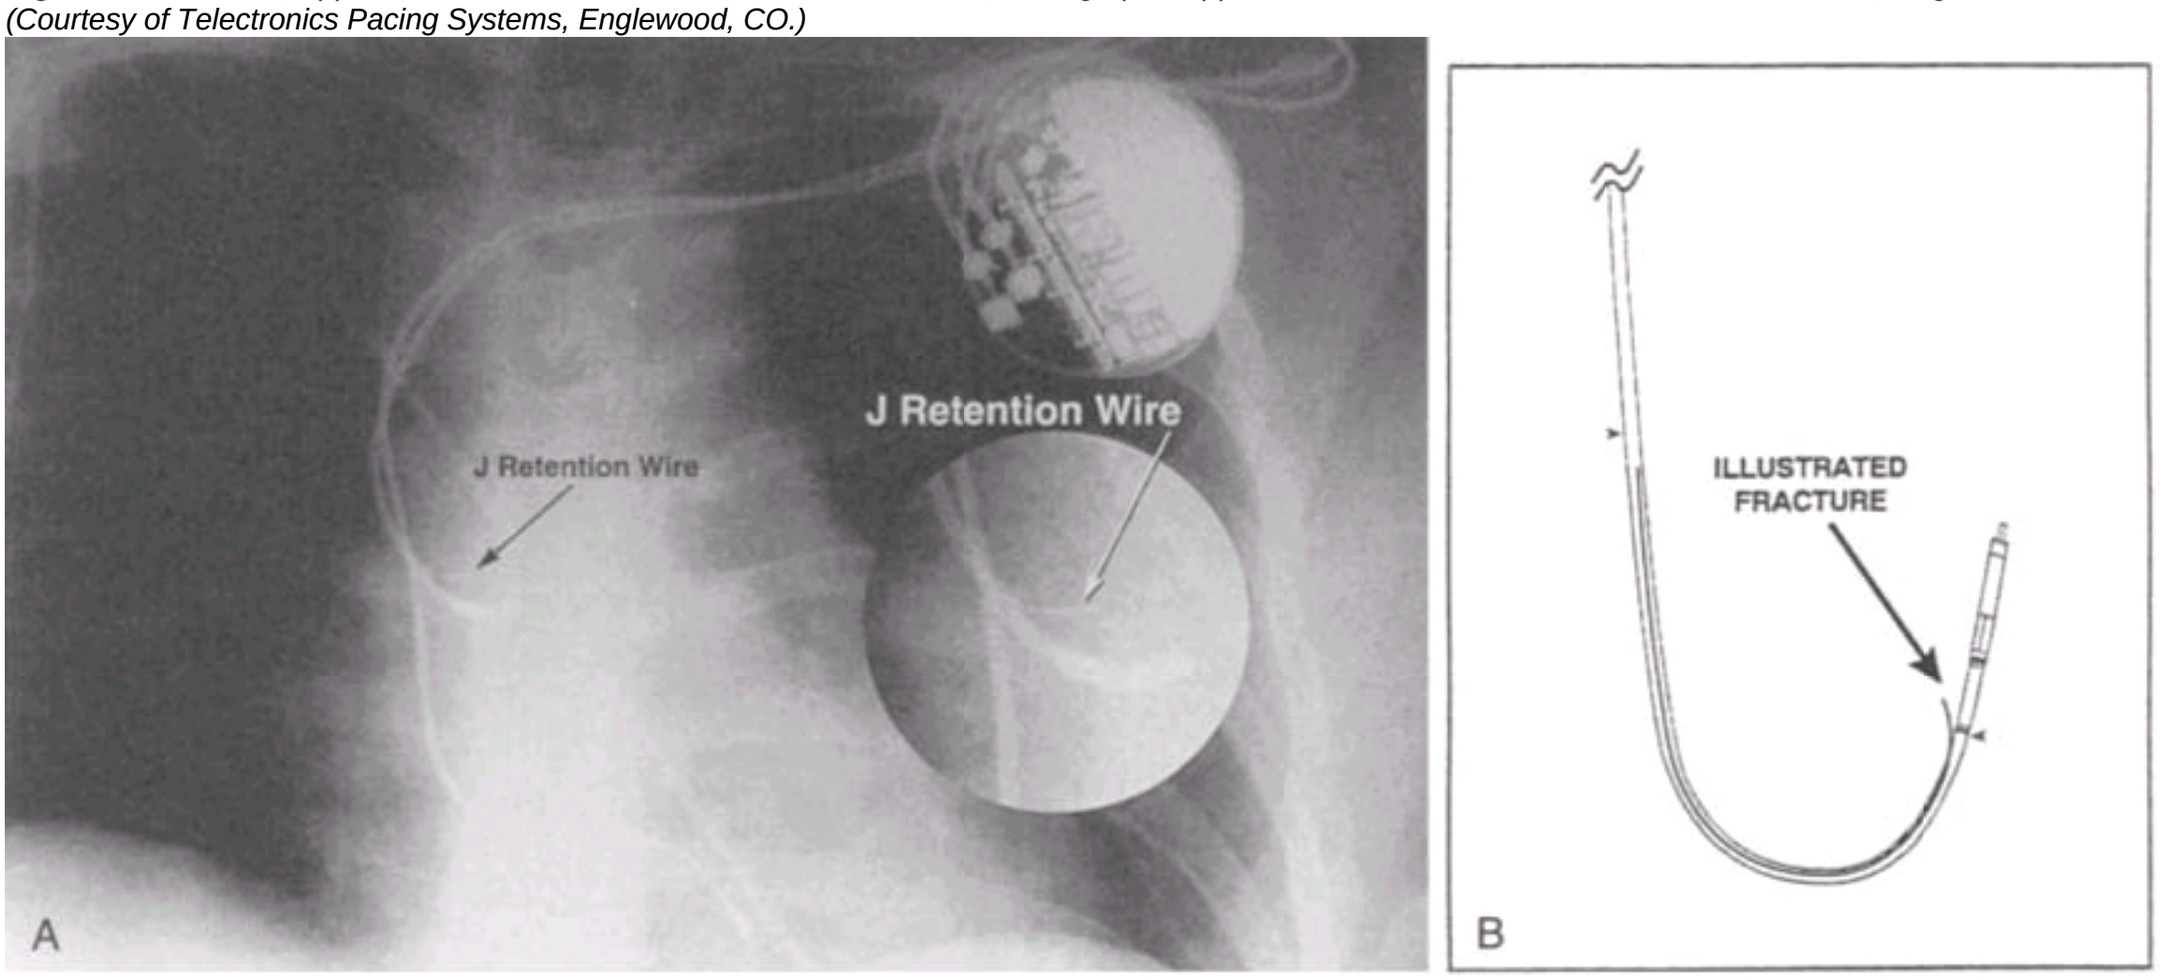

Figure 13-8 Ring magnet.

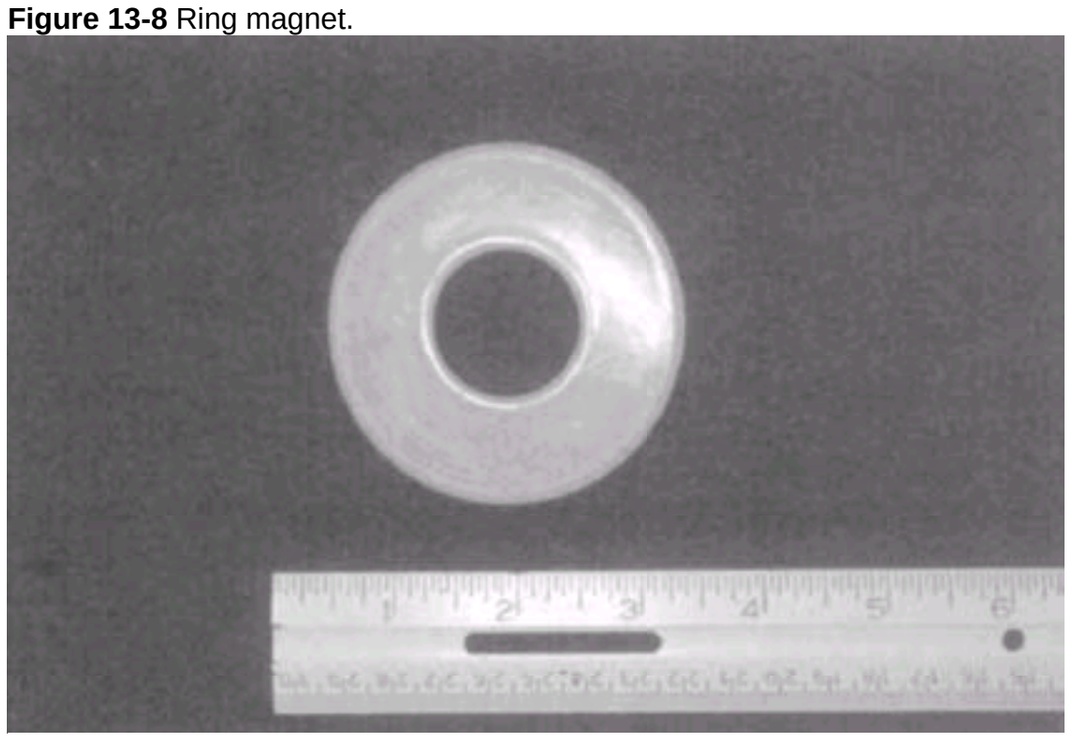

Figure 13-9 Typical location of pacemaker pocket in upper chest wall.

Figure 13-10 Application of ring magnet over pacemaker generator.

Figure 13-11 Electrocardiogram of patient with a nonfiring pacemaker. Intrinsic cardiac rate is 80 beats/min, and no pacemaker activity is seen.

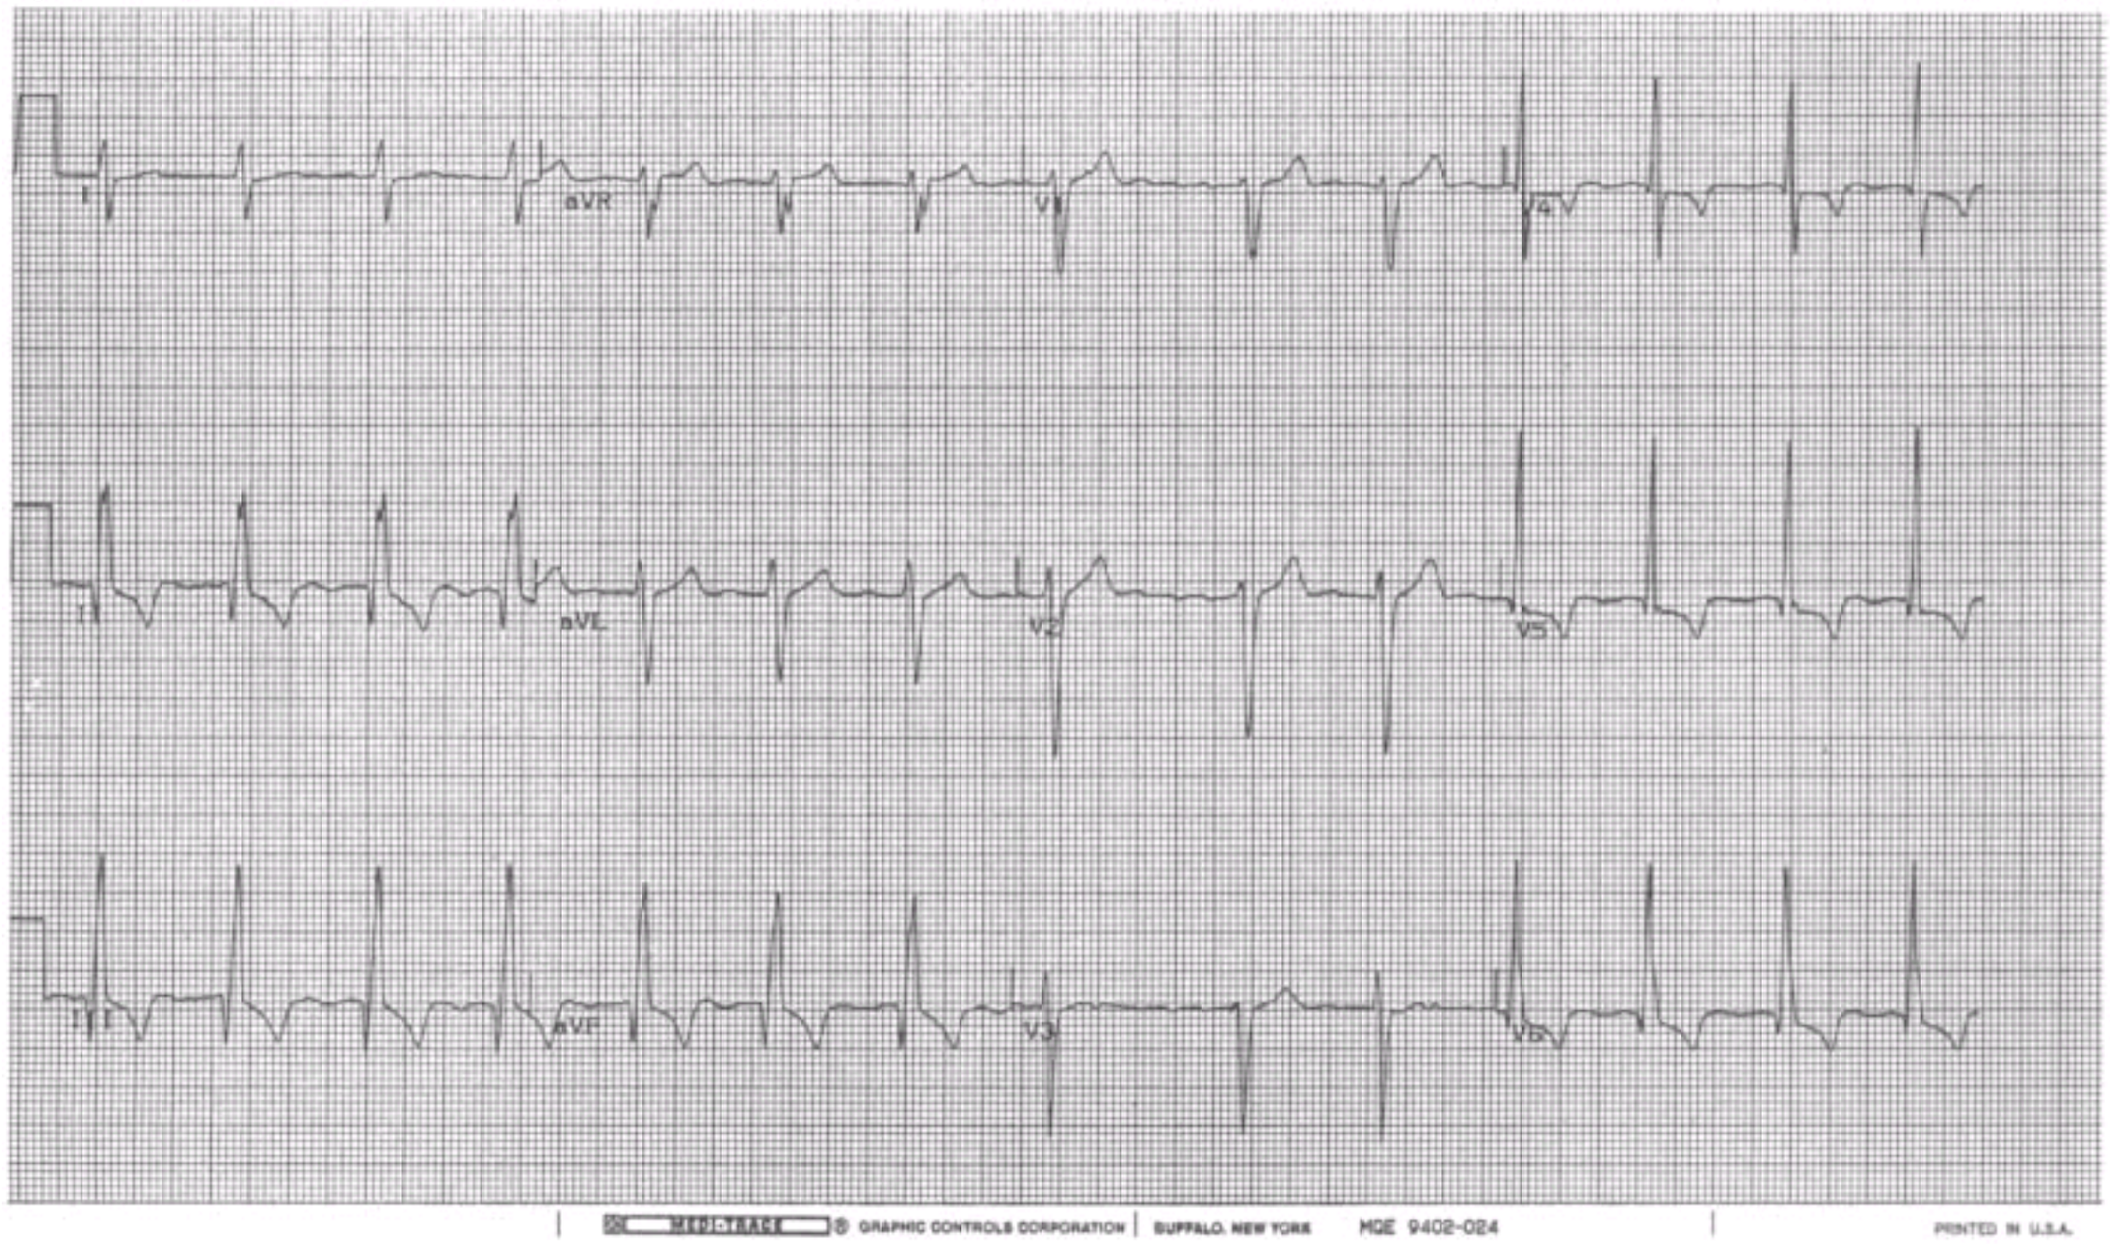

Figure 13-12 Electrocardiogram of same patient with magnet applied over pacemaker, producing a paced rhythm. Pacer spikes are evident (*arrows*) and the magnet rate is 85 beats/min. Note the left bundle-branch bundle typical of a pacer lead in the right ventricle.

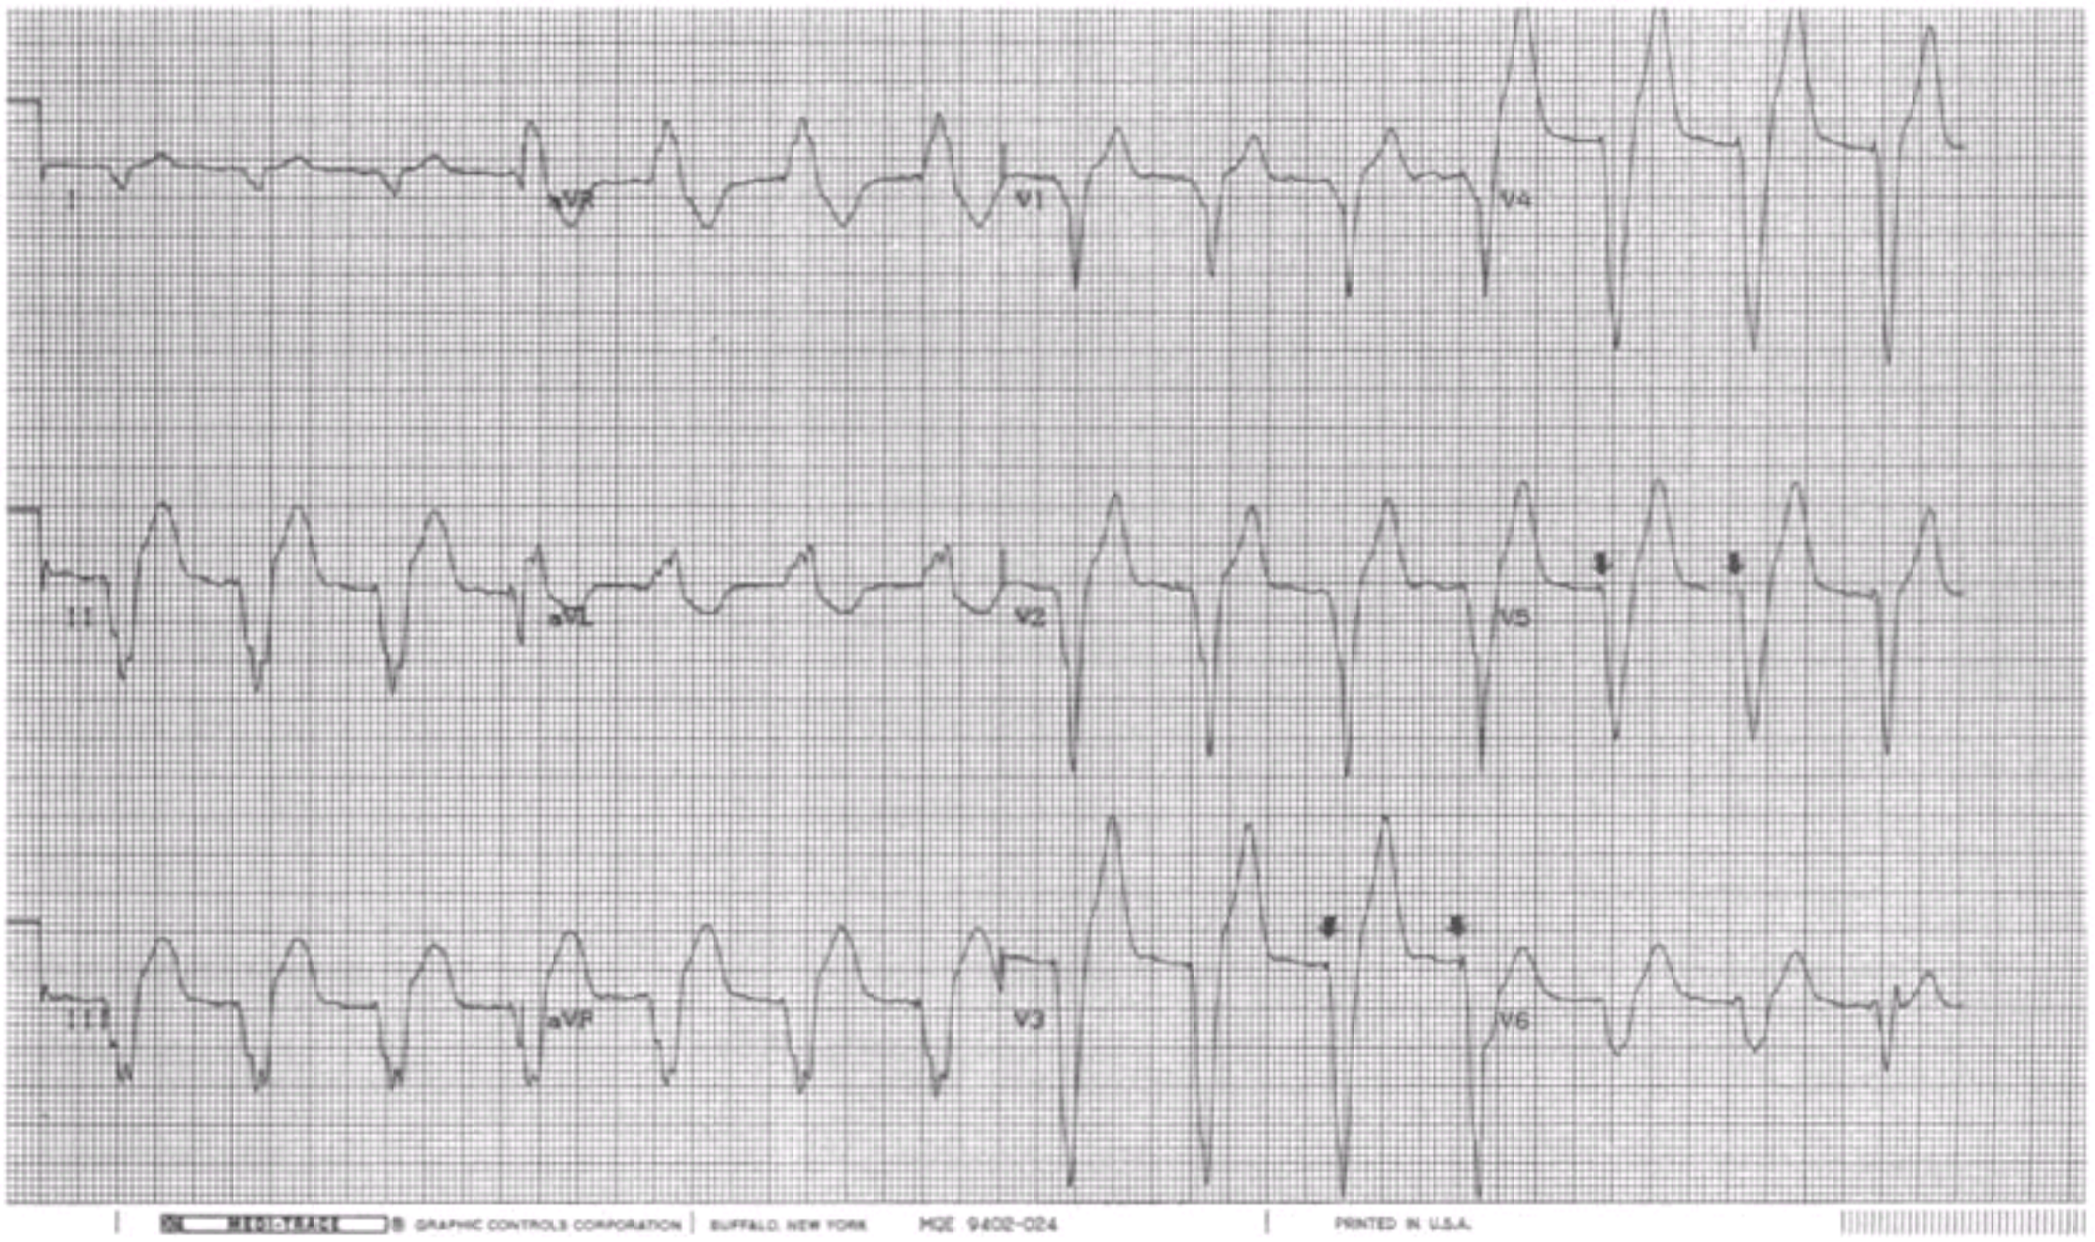

Figure 13-13 Placement of magnet on AICD.

Figure 14-1 Bipolar limb leads. Leads I, II, and III are shown as a triangle, known as Einthoven's triangle. Left arm (LA), right arm (RA), and left leg (LL) placement is shown. These bipolar leads are oriented such that the positive poles lie inferiorly and to the left (given that the bottom apex of the triangle is directed toward the left leg)—as does the major electrical vector of the heart.

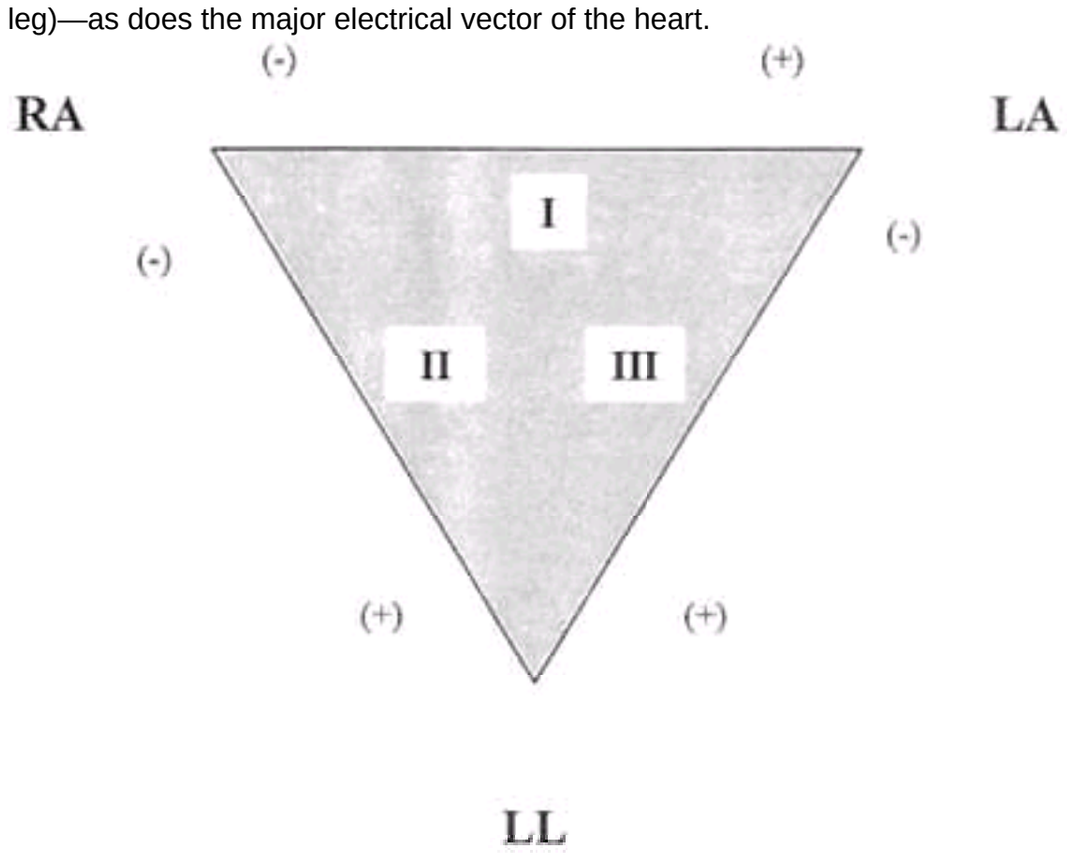

Figure 14-2 Hexaxial system of limb and augmented leads in the frontal plane. Each lead is separated by 30° in this frontal plane representation of the limb and augmented leads. Augmented leads are shown in boldface. Arrows denote positive polarity. Note that the inferior leads (II, III, aVF) logically lie at the bottom of this figure, and the lateral leads (I, aVL) lie on the left side of the figure, where the lateral aspect of the heart is located were this to be superimposed on a patient.

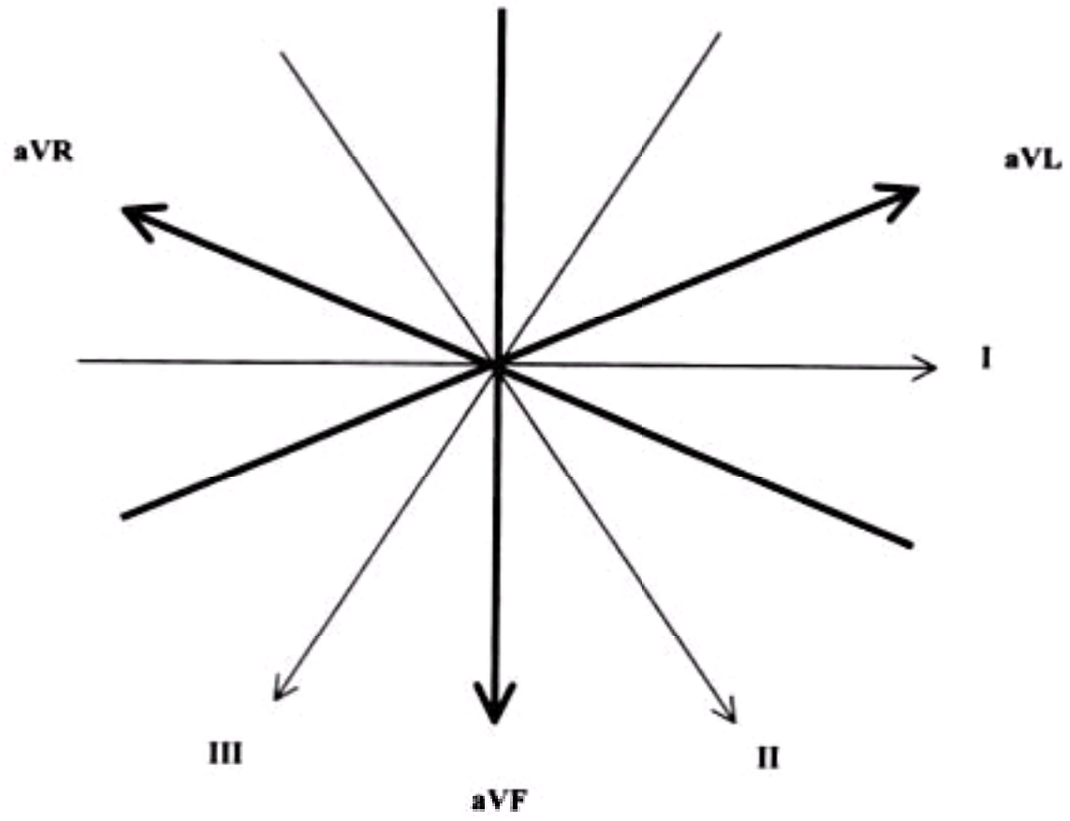

Figure 14-3 Precordial lead placement for the standard 12-lead ECG. If multiple or repeat ECG tracings are anticipated, the original lead placements should be marked on the patient's chest wall or stick-on leads should be left in place after the ECG wires are removed.

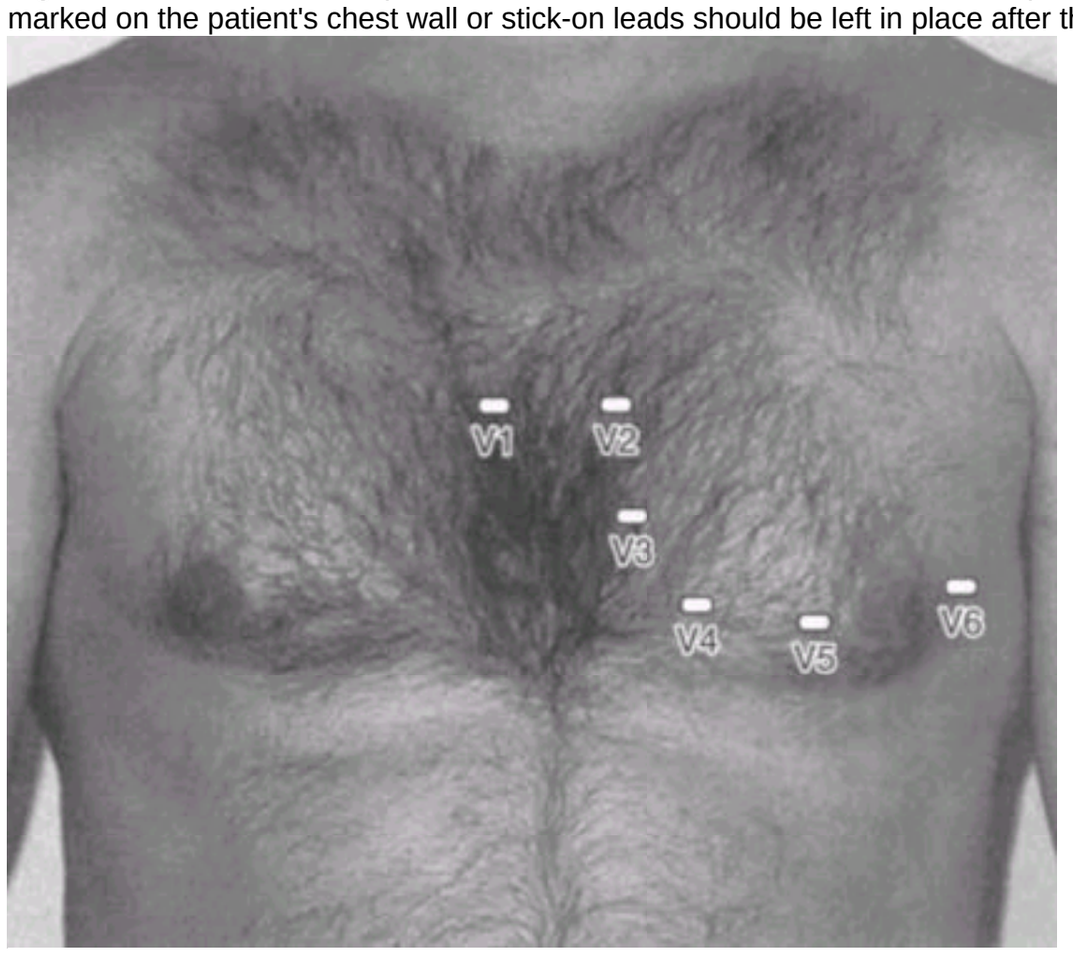

Figure 14-4 *A,* Normal 10 mm/mV calibration. Note the box-shaped mark to the left of the complexes; this is a graphic representation of the calibration for the tracing. This parameter should be routinely noted before ECG interpretation. Note the change in *B*. *B,* Abnormal 20 mm/mV calibration. The calibration in this tracing was (inexplicably and unexpectedly) changed to 20 mm/mV by the ECG, not by the operator. When compared with a baseline ECG, it appeared that the patient had developed voltage criteria for left ventricular hypertrophy as well as ST segment elevation. *A,* which was recorded minutes later with correction of calibration to the standard 10 mm/mV, was unchanged from baseline tracings.

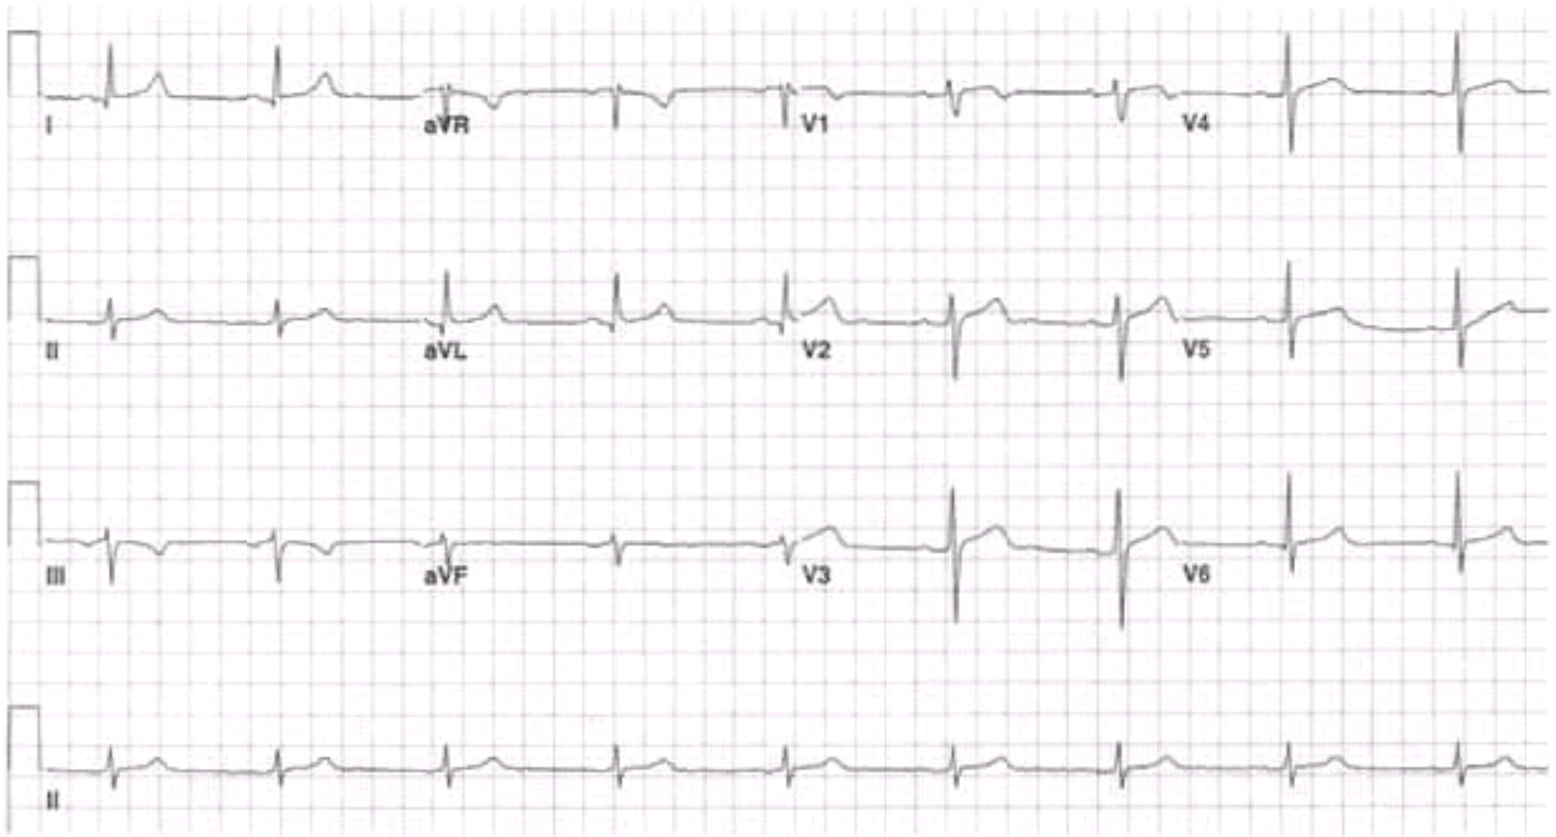

Figure 14-5 Posterior lead placement. Leads V7, V8, and V9 are placed on the same horizontal plane as V6, with V7 at the posterior axillary line, V8 at the tip of the left scapula, and V9 near the border of the left paraspinal muscles.

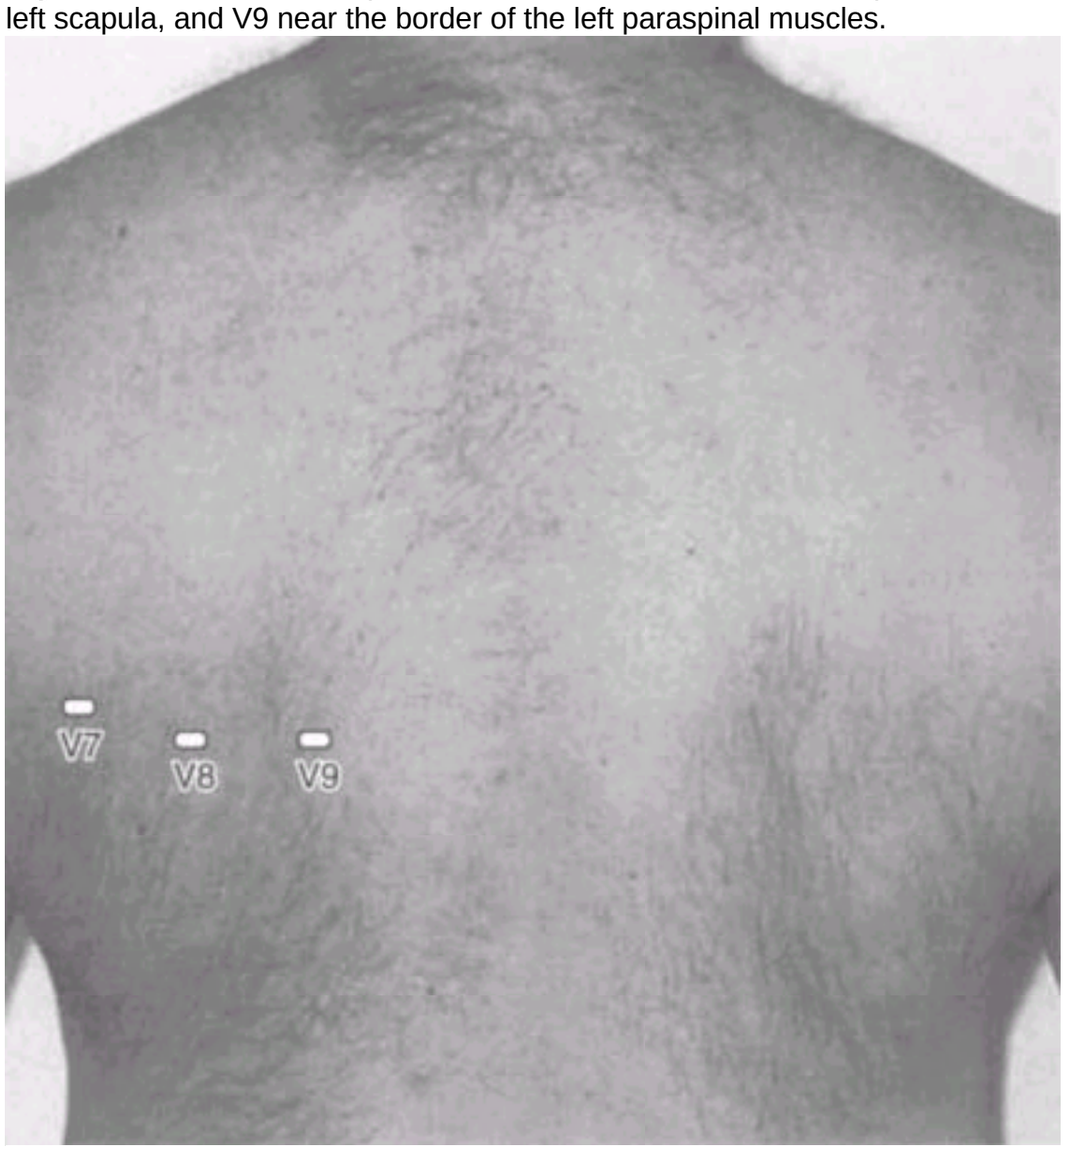

Figure 14-6 Right-sided lead placement. Right-sided leads RV1–RV6 are placed on the chest as a mirror image of the standard precordial leads.

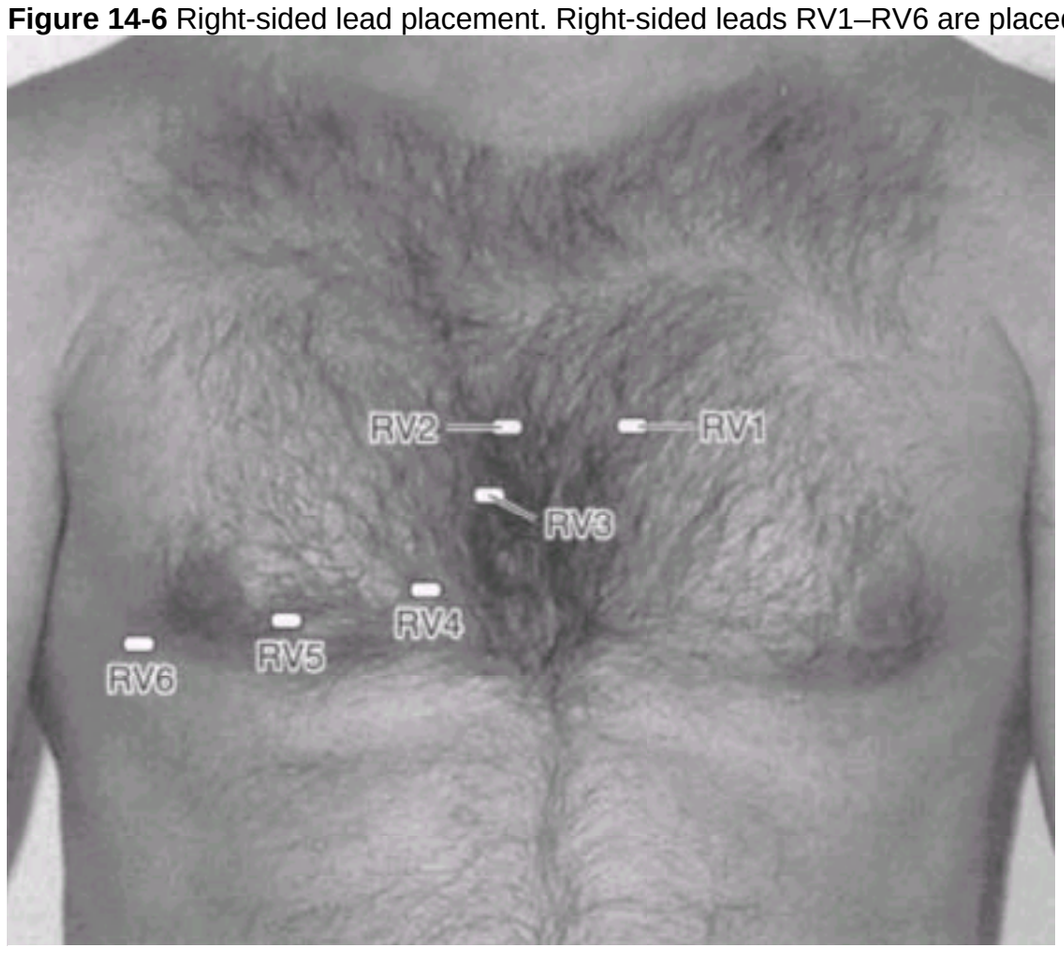

Figure 14-7a *A,* Baseline ECG of patient before development of abnormal rhythm (10 mm/mV). Note the P wave morphologies, especially in leads I, II, and V1. *B,* ECG during ectopic atrial tachycardia (10 mm/mV). Note the change in P wave morphology, especially in lead V1.

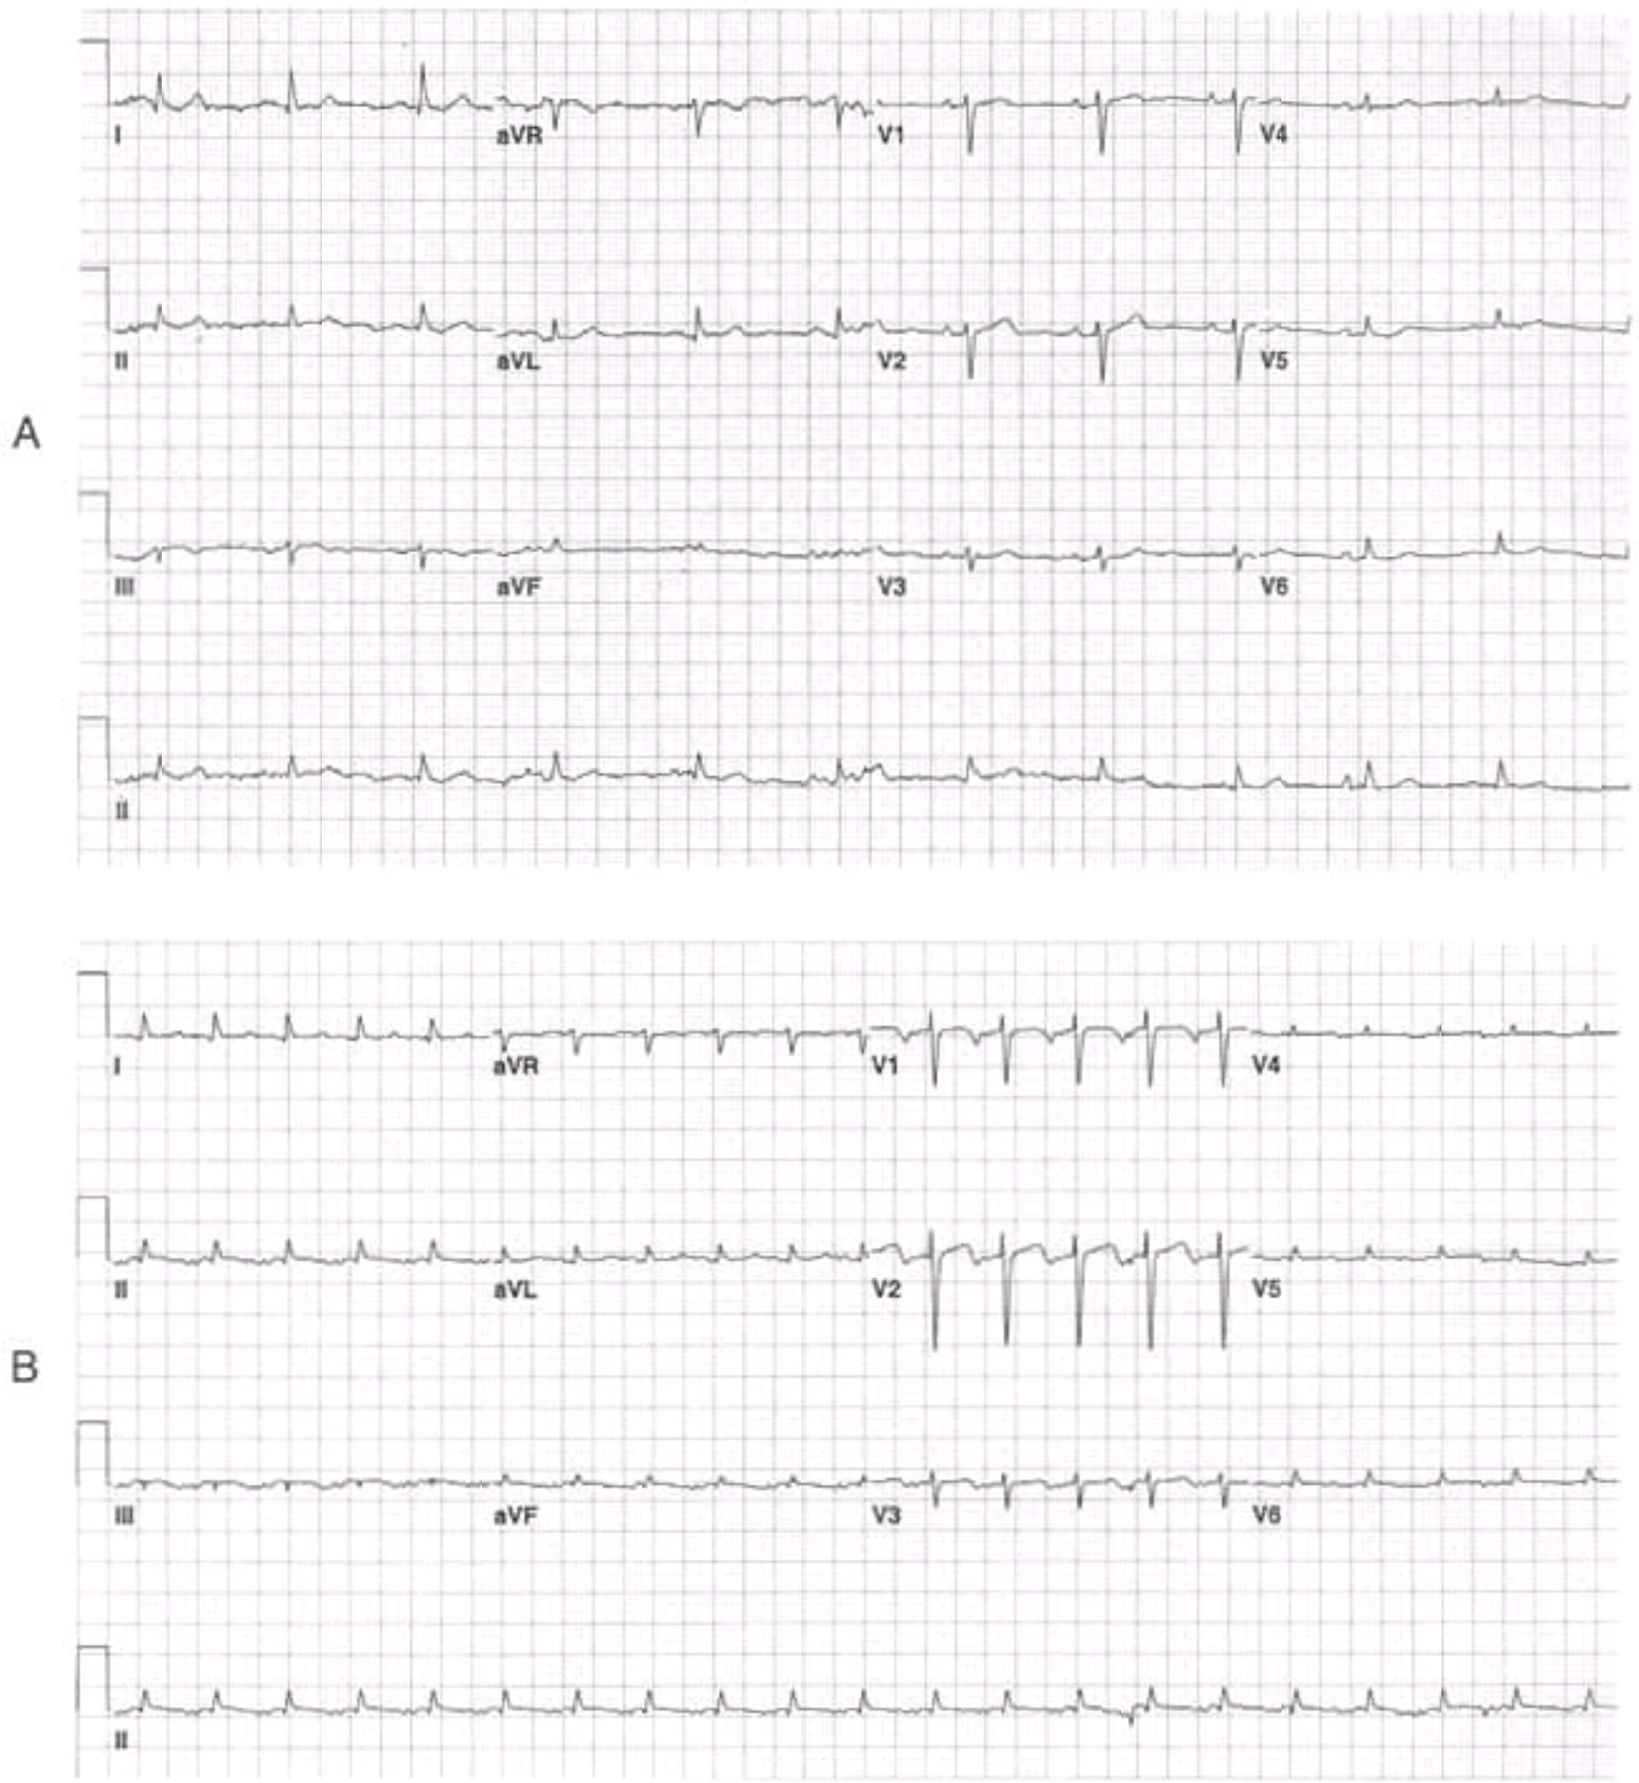

Figure 14-7b *C,* ECG during ectopic atrial tachycardia (20 mm/mV). The P waves are now easier to see in all leads. *D,* ECG after reversion to normal atrial focus (20 mm/mV). Contrast these accentuated P waves to those in *C*.

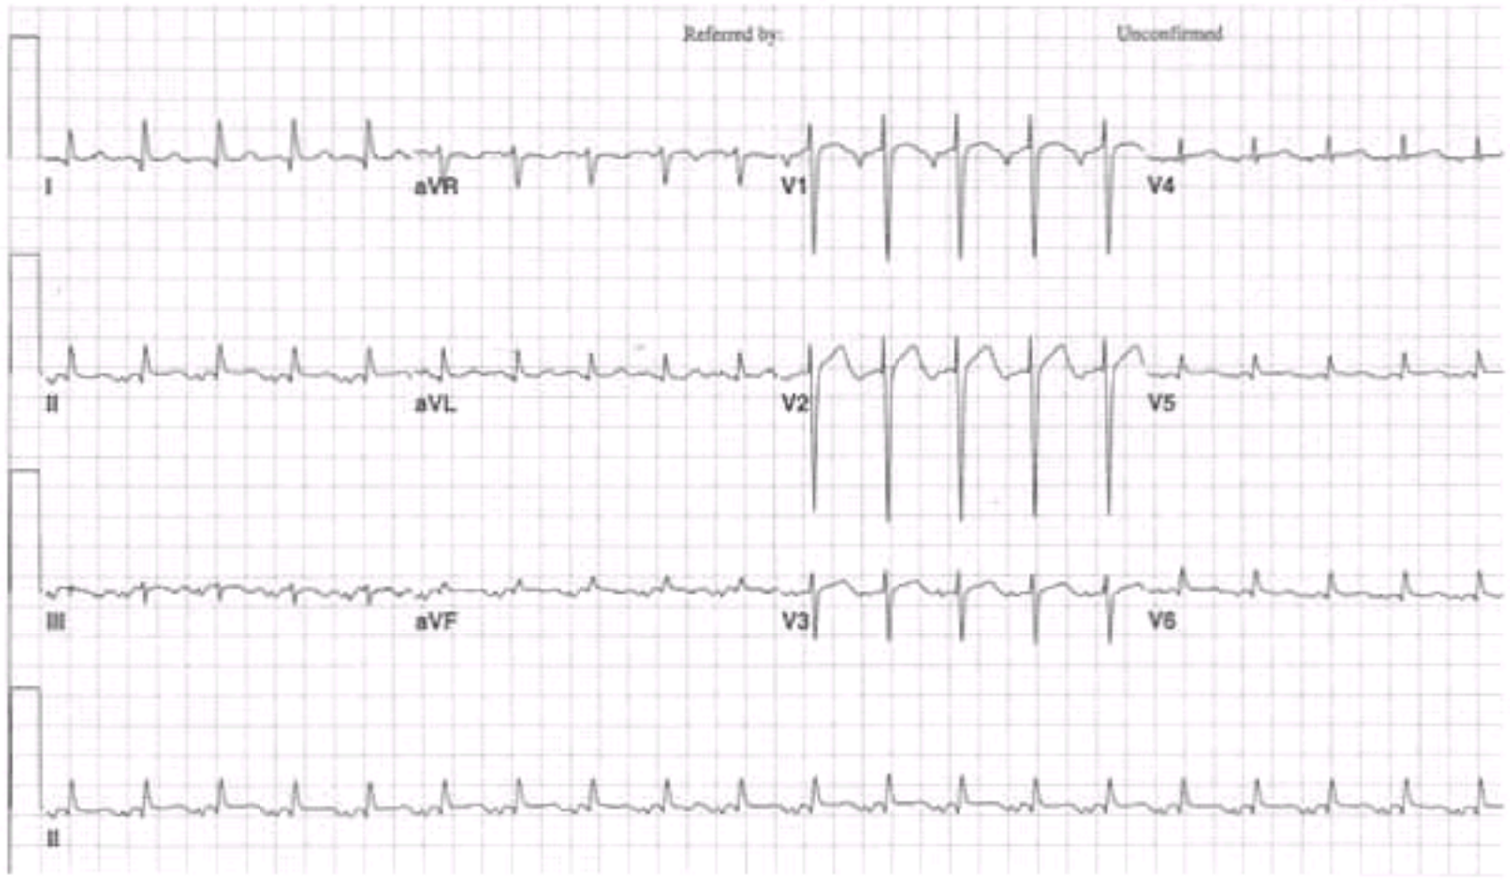
C



D

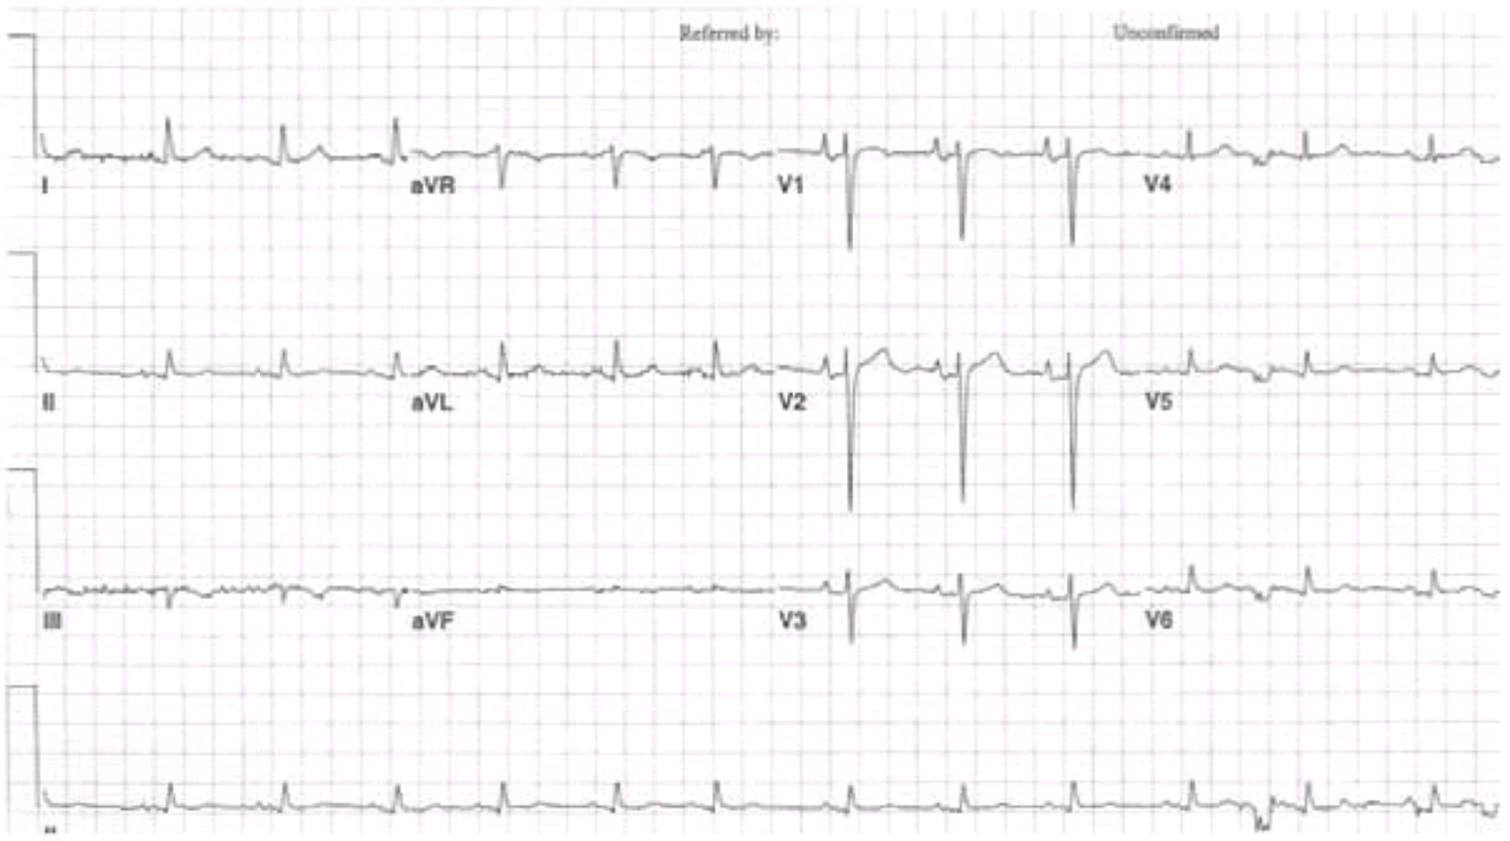


Figure 14-8 *A,* ECG with tachycardia at normal paper speed (25 mm/sec). Because of the rapid rate, the actual P waves are difficult to discern, thus making rhythm determination difficult. The computerized interpretation is sinus tachycardia with first-degree AV block. *B,* ECG with tachycardia at double paper speed (50 mm/sec). With increased paper speed, atrial P wave activity is accentuated, demonstrated atrial flutter with a 2:1 AV block.

A

B

Figure 14-9 Alternative leads. The figure displays three of the more commonly used alternative lead strategies for atrial rhythm clarification (Lewis leads, vertical sternal or Barker leads, and MCL1), and ST/T wave monitoring (MCL6).

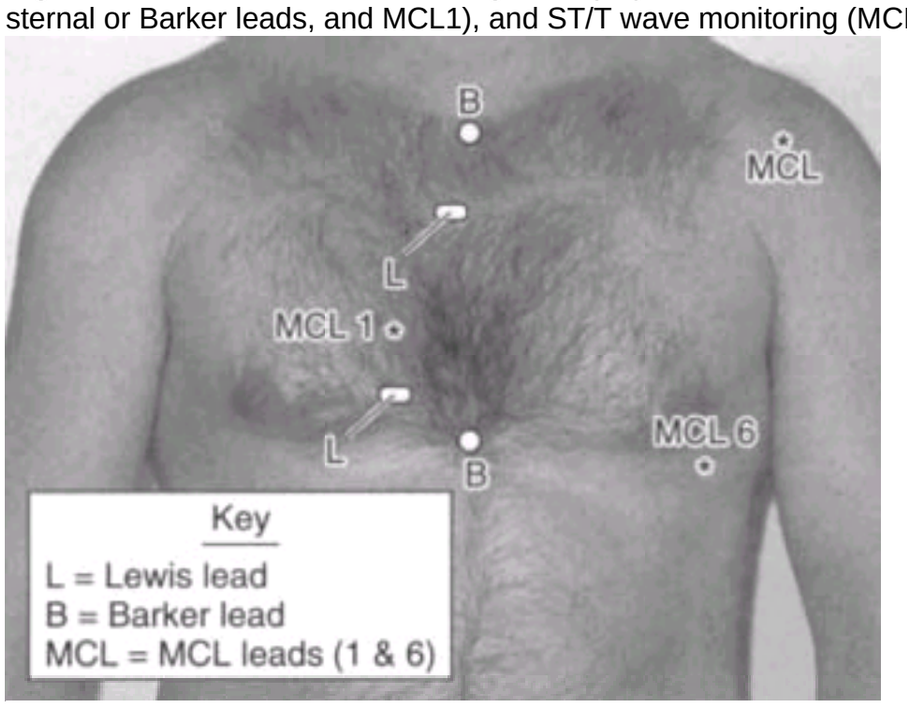

Figure 14-10 Arm lead reversal (LA ⟷ RA). The most common of limb lead reversals, the clues lie in leads I and aVR. Lead I features a negative P wave, as well as a principally negative QRS complex and T wave. This could suggest dextrocardia, but the precordial leads demonstrate normal transition, which is not consistent with dextrocardia. Note also the unusual appearance of aVR in this tracing.

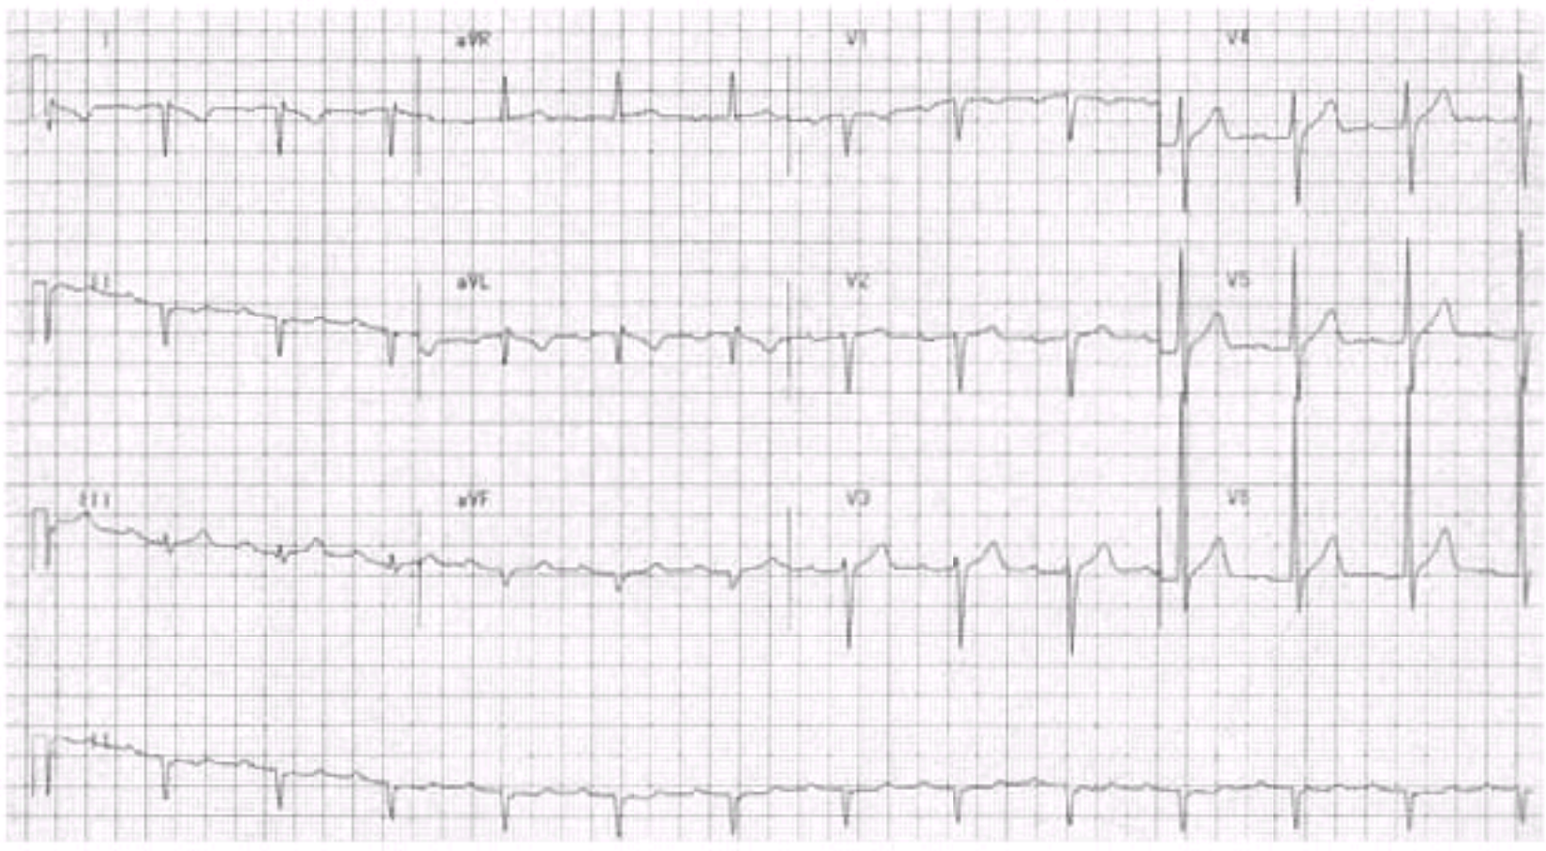

Figure 14-11 *A,* Limb lead reversal (LA ⟷ LL). A patient with a history consistent with ACS was brought to the ED after this ECG was recorded in a clinic. Leads I and aVL suggest an acute high lateral infarct but, surprisingly, there are no corresponding changes in leads V5 and V6. The deep T wave inversions in III and aVF were at first thought to be inferior ischemia or reciprocal changes (see also *B*). *B,* Correction of lead reversal (LA ⟷ LL). After the leads were reconnected, this tracing reveals an acute inferior wall MI, as well as deep T wave inversion in aVL—a harbinger of acute inferior MI. Comparing this tracing with that in *A,* note the following: lead I ⟷ lead II; lead aVL ⟷ aVF, and lead III is inverted. Thus, inferior changes become lateral, and lateral become inferior.

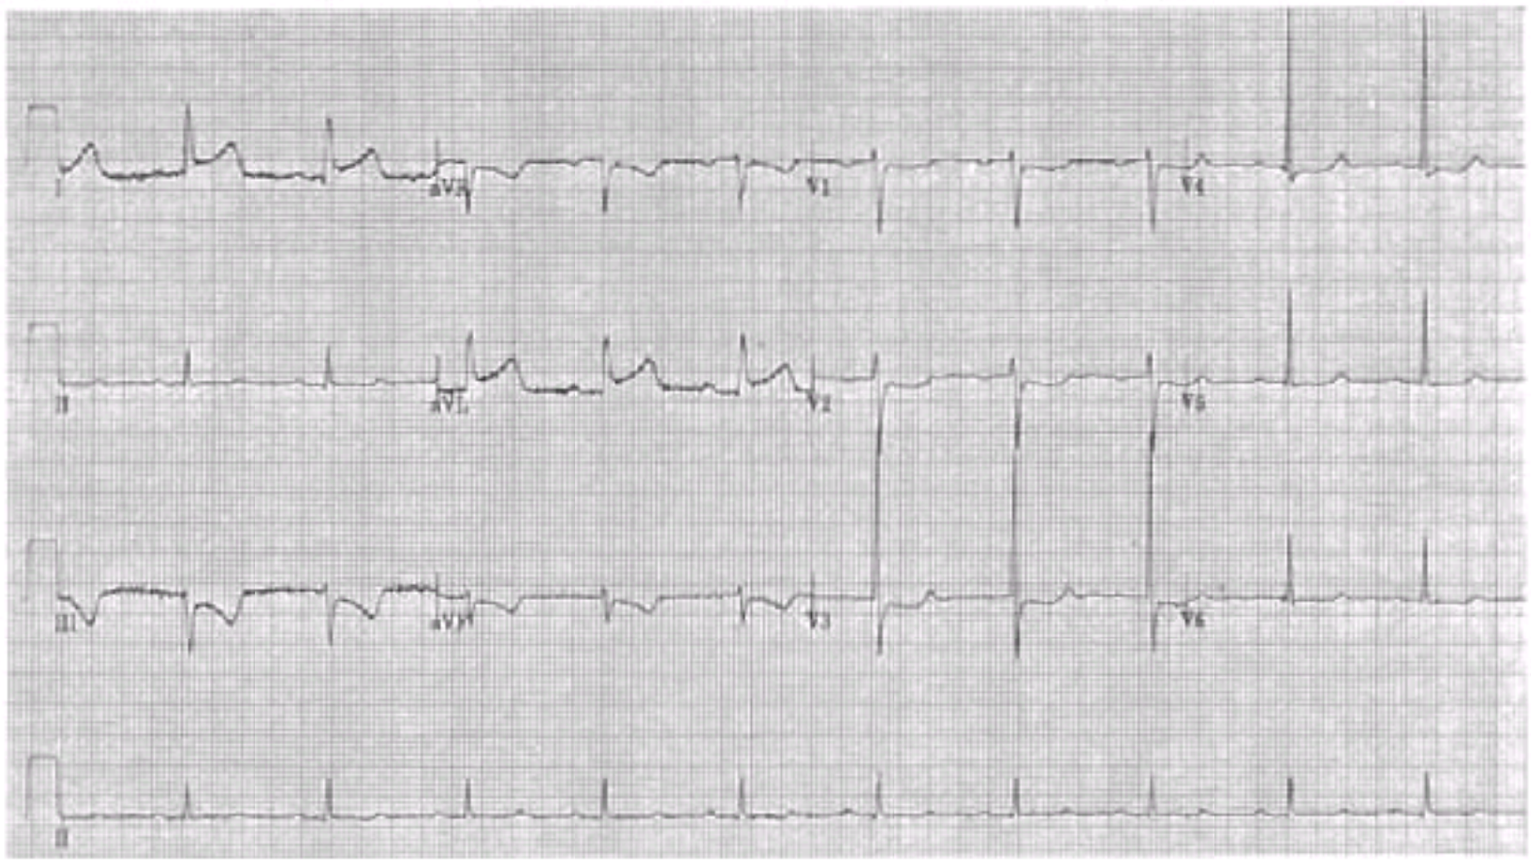
A



B

Figure 14-12 *A* and *B*, Precordial lead reversal (V2 ⟷ V3). Note the usual precordial progression of R wave growth in leads V2 and V3 is disrupted in the tracing displayed in *A; B* shows a return to a normal V3 transition zone.

Figure 15-14 Combined defibrillator-transcutaneous pacemaker unit (Zoll-PD). The unit defibrillates through standard hand held paddles and has additional cable connections for electrocardiograph monitoring electrodes and for pacing electrodes. *(Courtesy of ZMI Corporation, Cambridge, Mass.)*

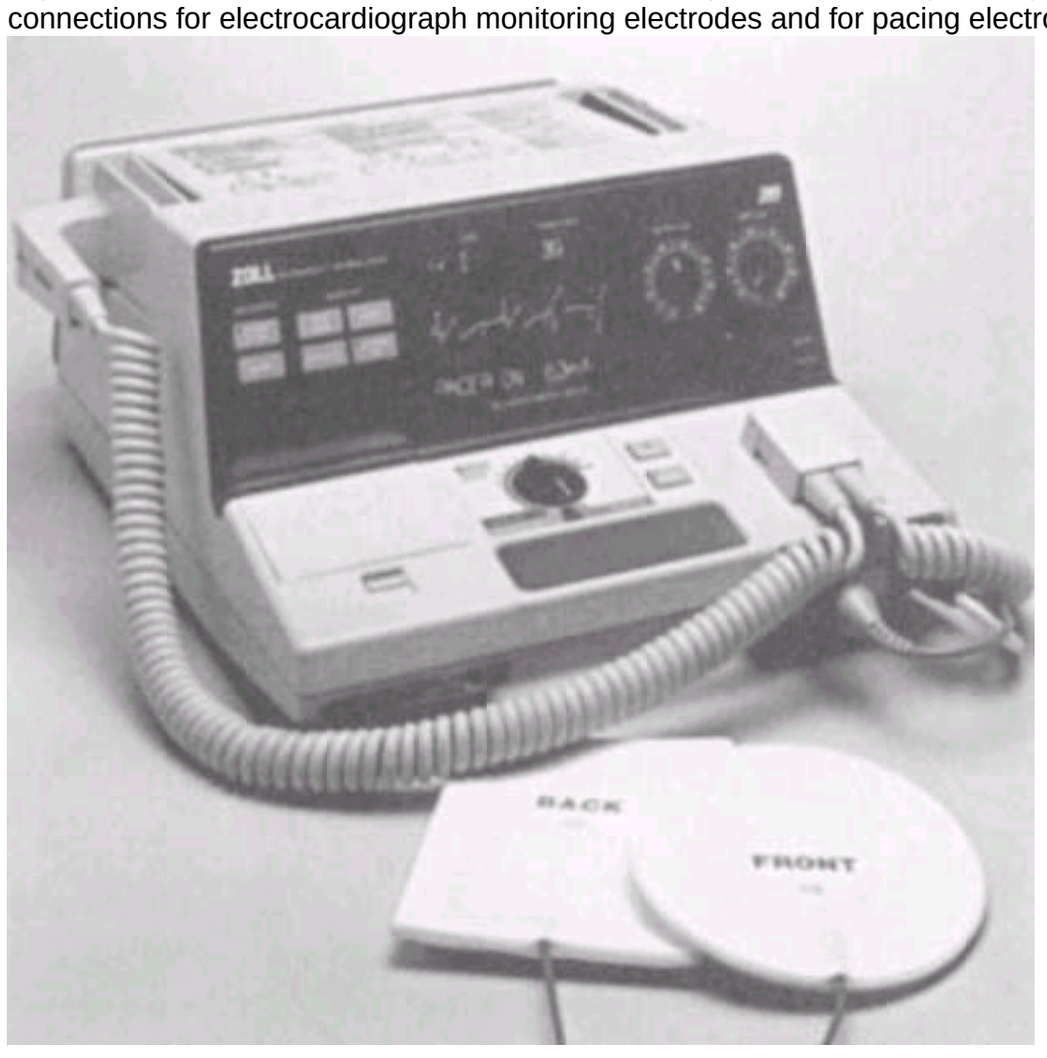

Figure 15-15 "Stand alone" transcutaneous pacemaker (Zoll NTP). This unit has a built-in monitor and strip chart recorder. *(Courtesy of ZMI Corporation, Cambridge, Mass.)*

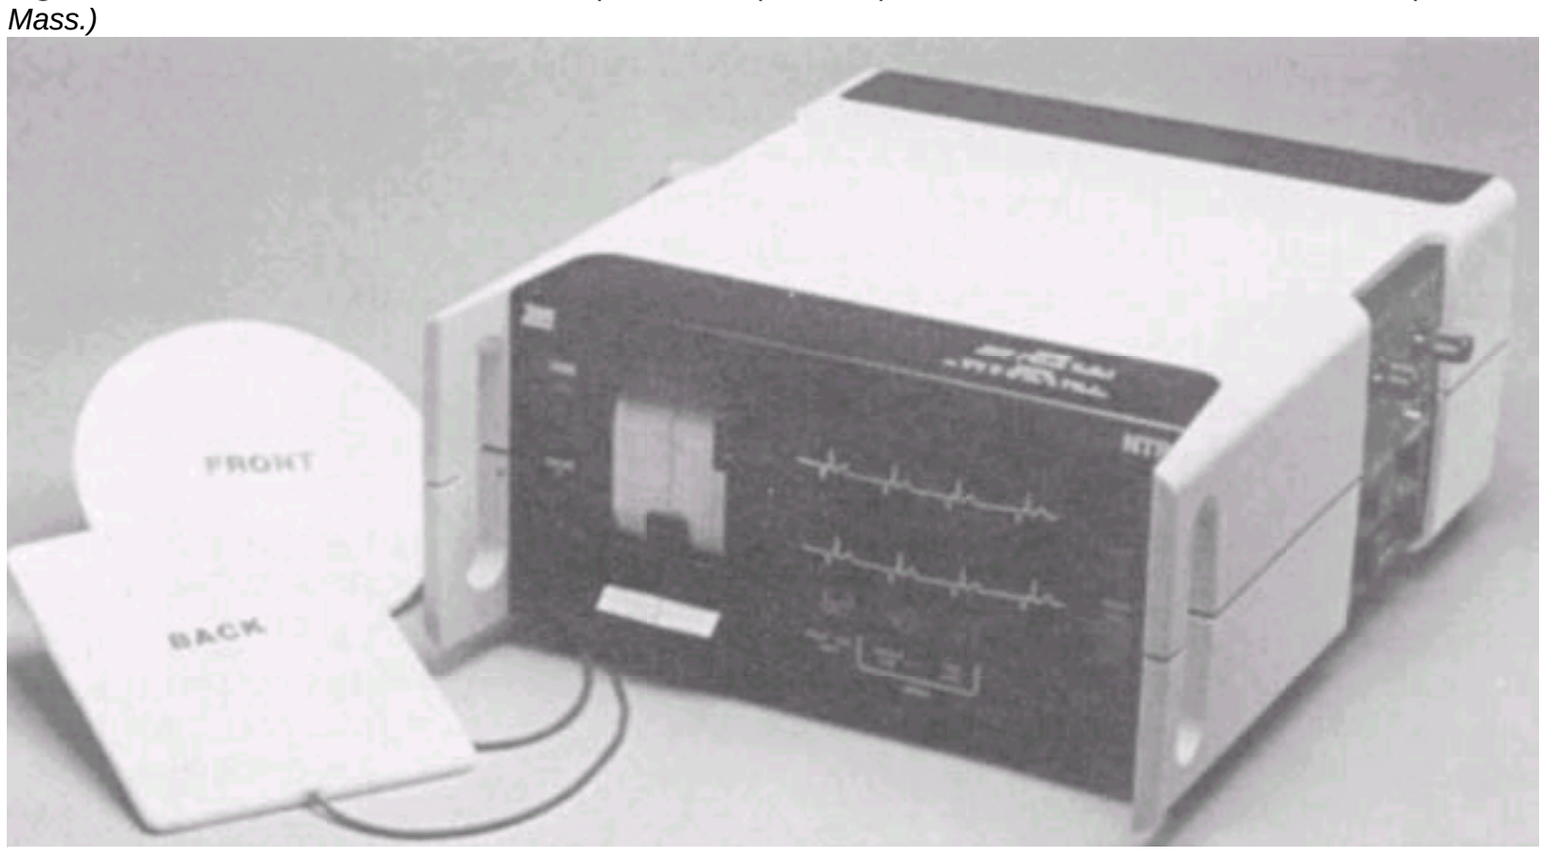

Figure 15-16 The top three rhythm strips *(A–C)* are taken from a standard wall-mounted electrocardiograph monitor. They all demonstrate large pacer spikes without capture. The underlying rhythm cannot be determined and could be treatable ventricular fibrillation. The bottom rhythm strip *(D)* demonstrates a tracing on the same patient with the external pacer monitor (special dampening). Note that the pacing spikes are much smaller, and it is easily seen that the underlying rhythm is asystole, without pacer capture. The presence of a T-wave after the QRS complex is a good indicator of ventricular capture.

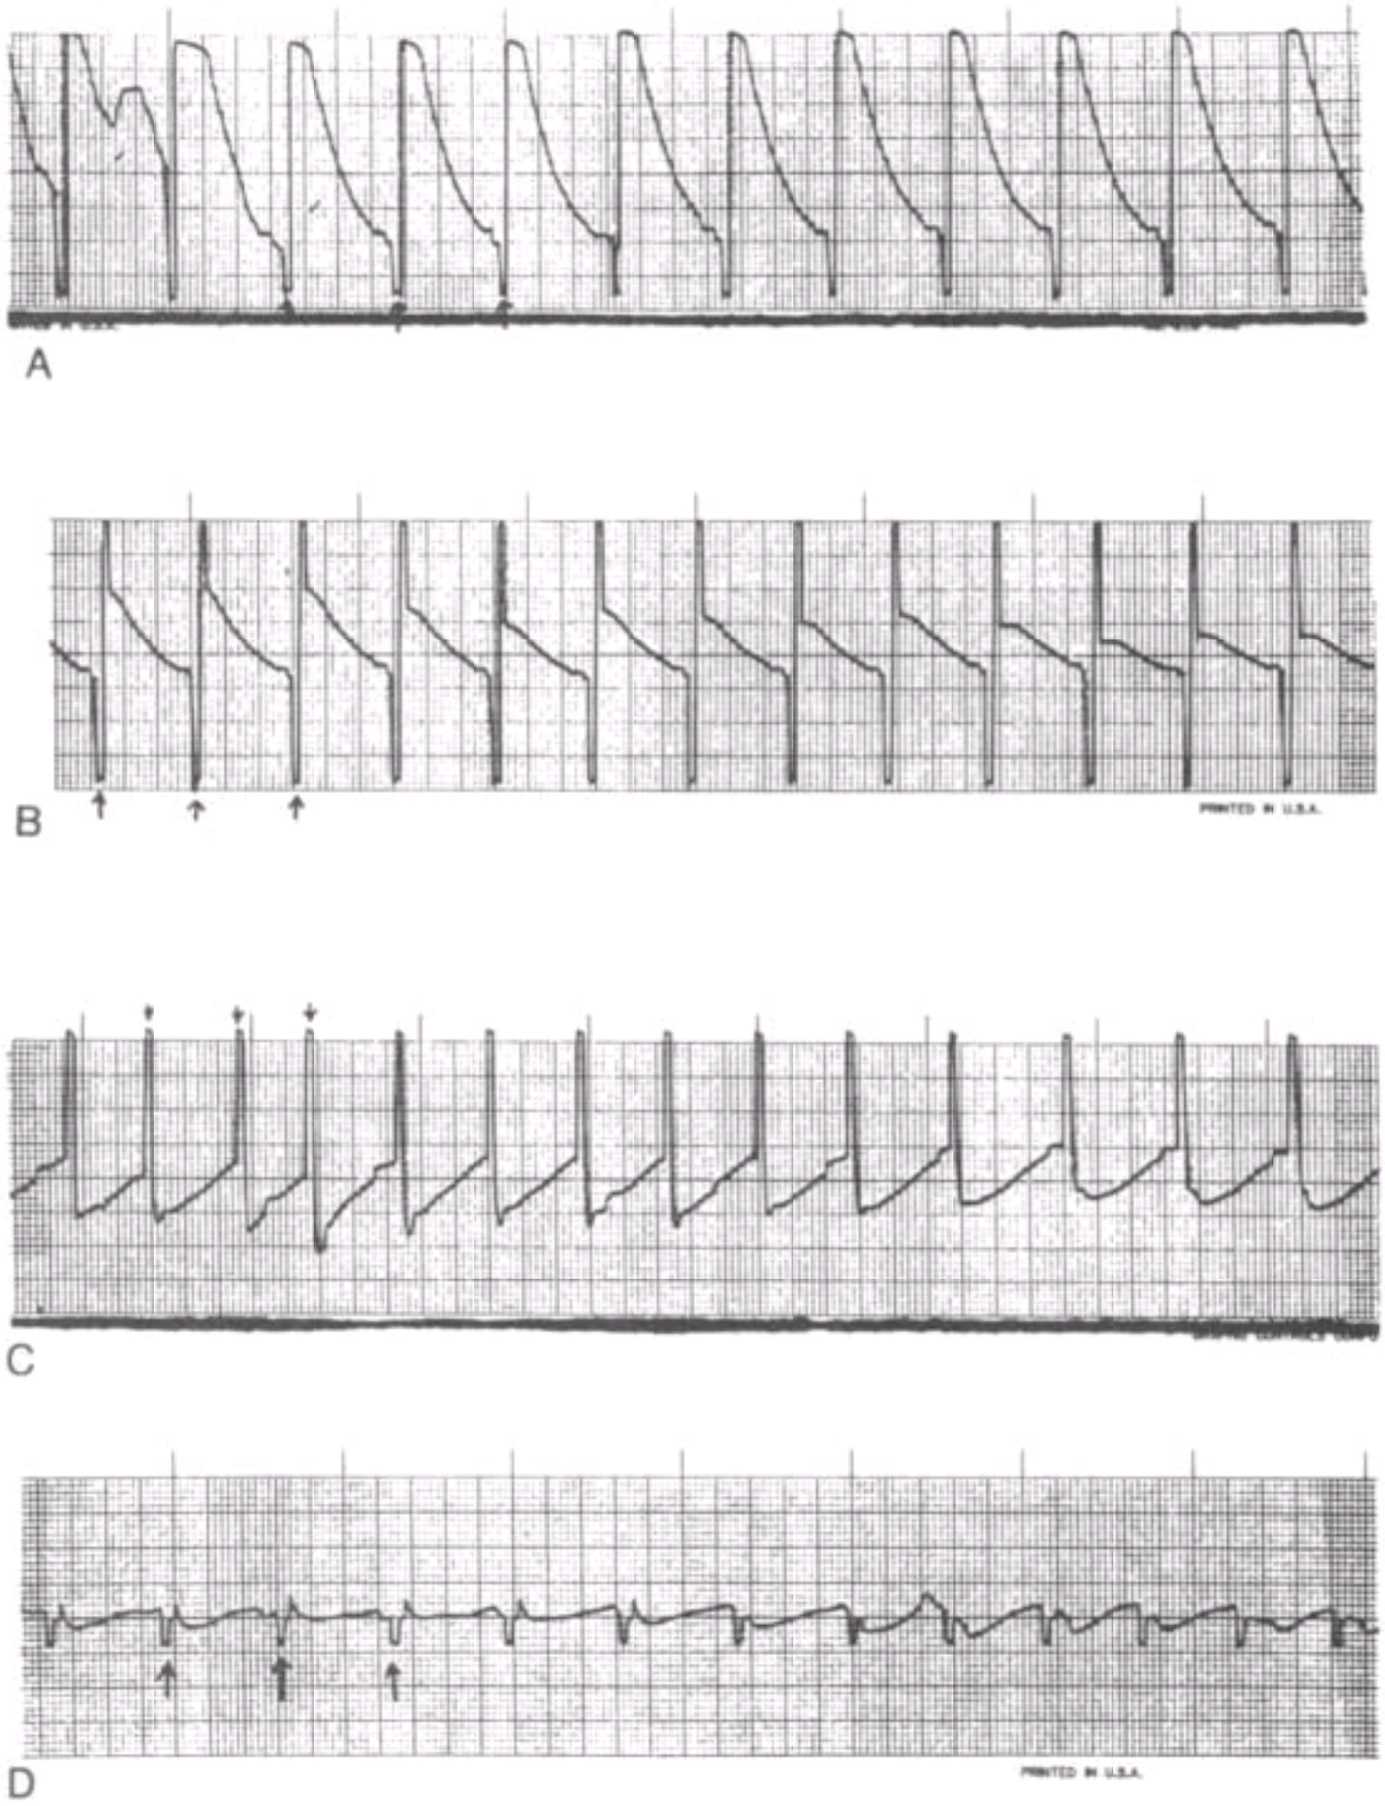

Figure 15-17 Correct placement of transcutaneous pacemaker electrodes (see text). *(Courtesy of ZMI Corporation, Cambridge, Mass.)*

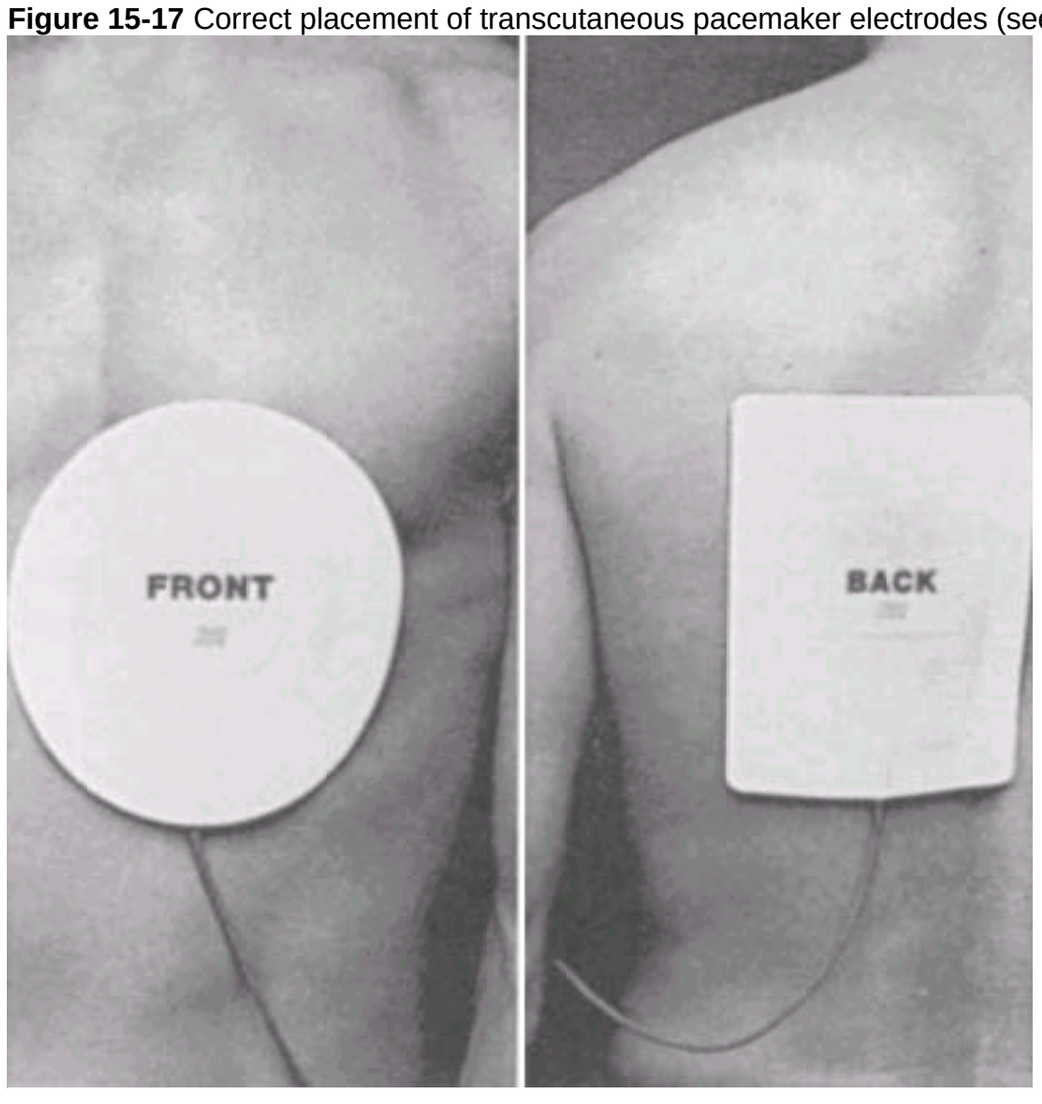

Figure 15-18 Rate and output selections.

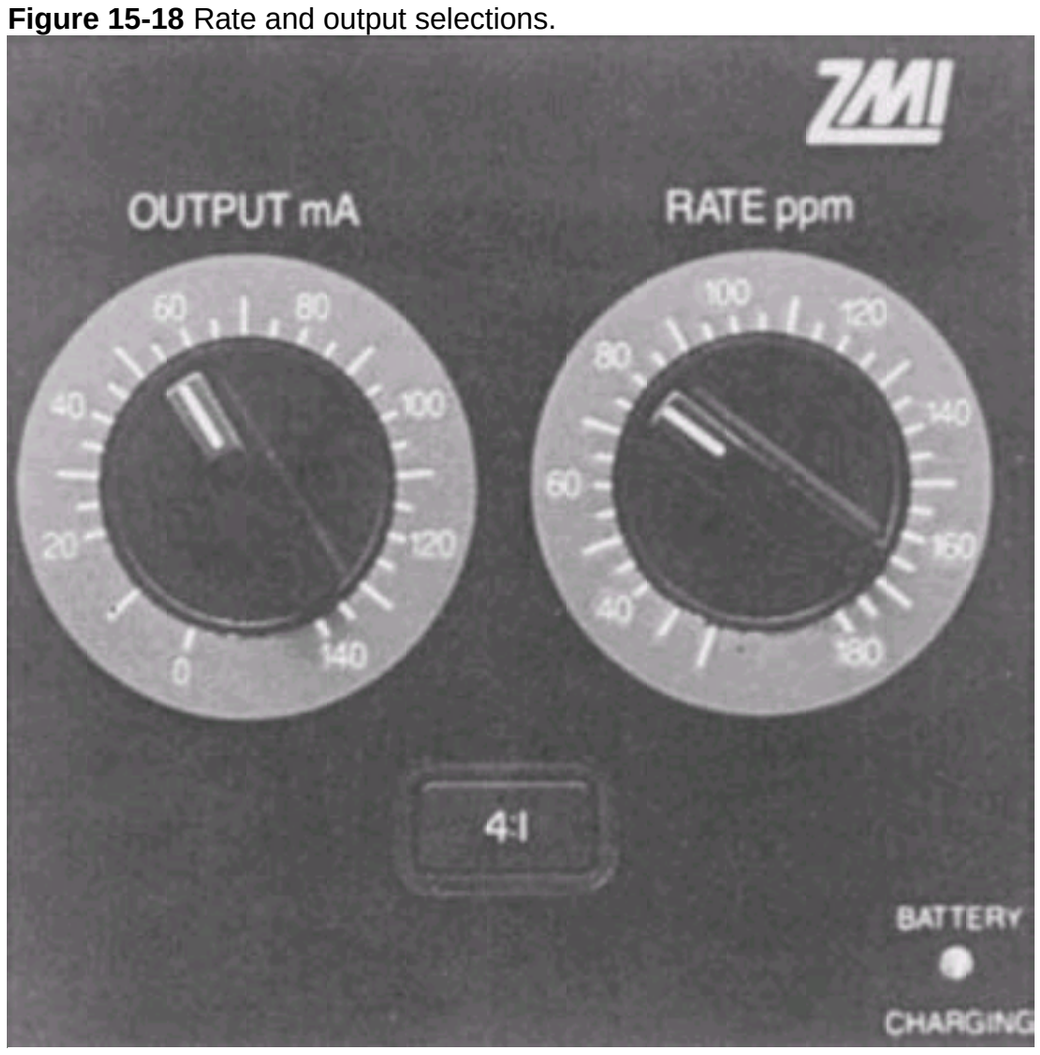

Figure 15-19 Assessing electrocardiogram capture with TCP. Note that the monitor has been adapted to accommodate the large pacing artifact so as not to obscure the underlying ventricular activity.

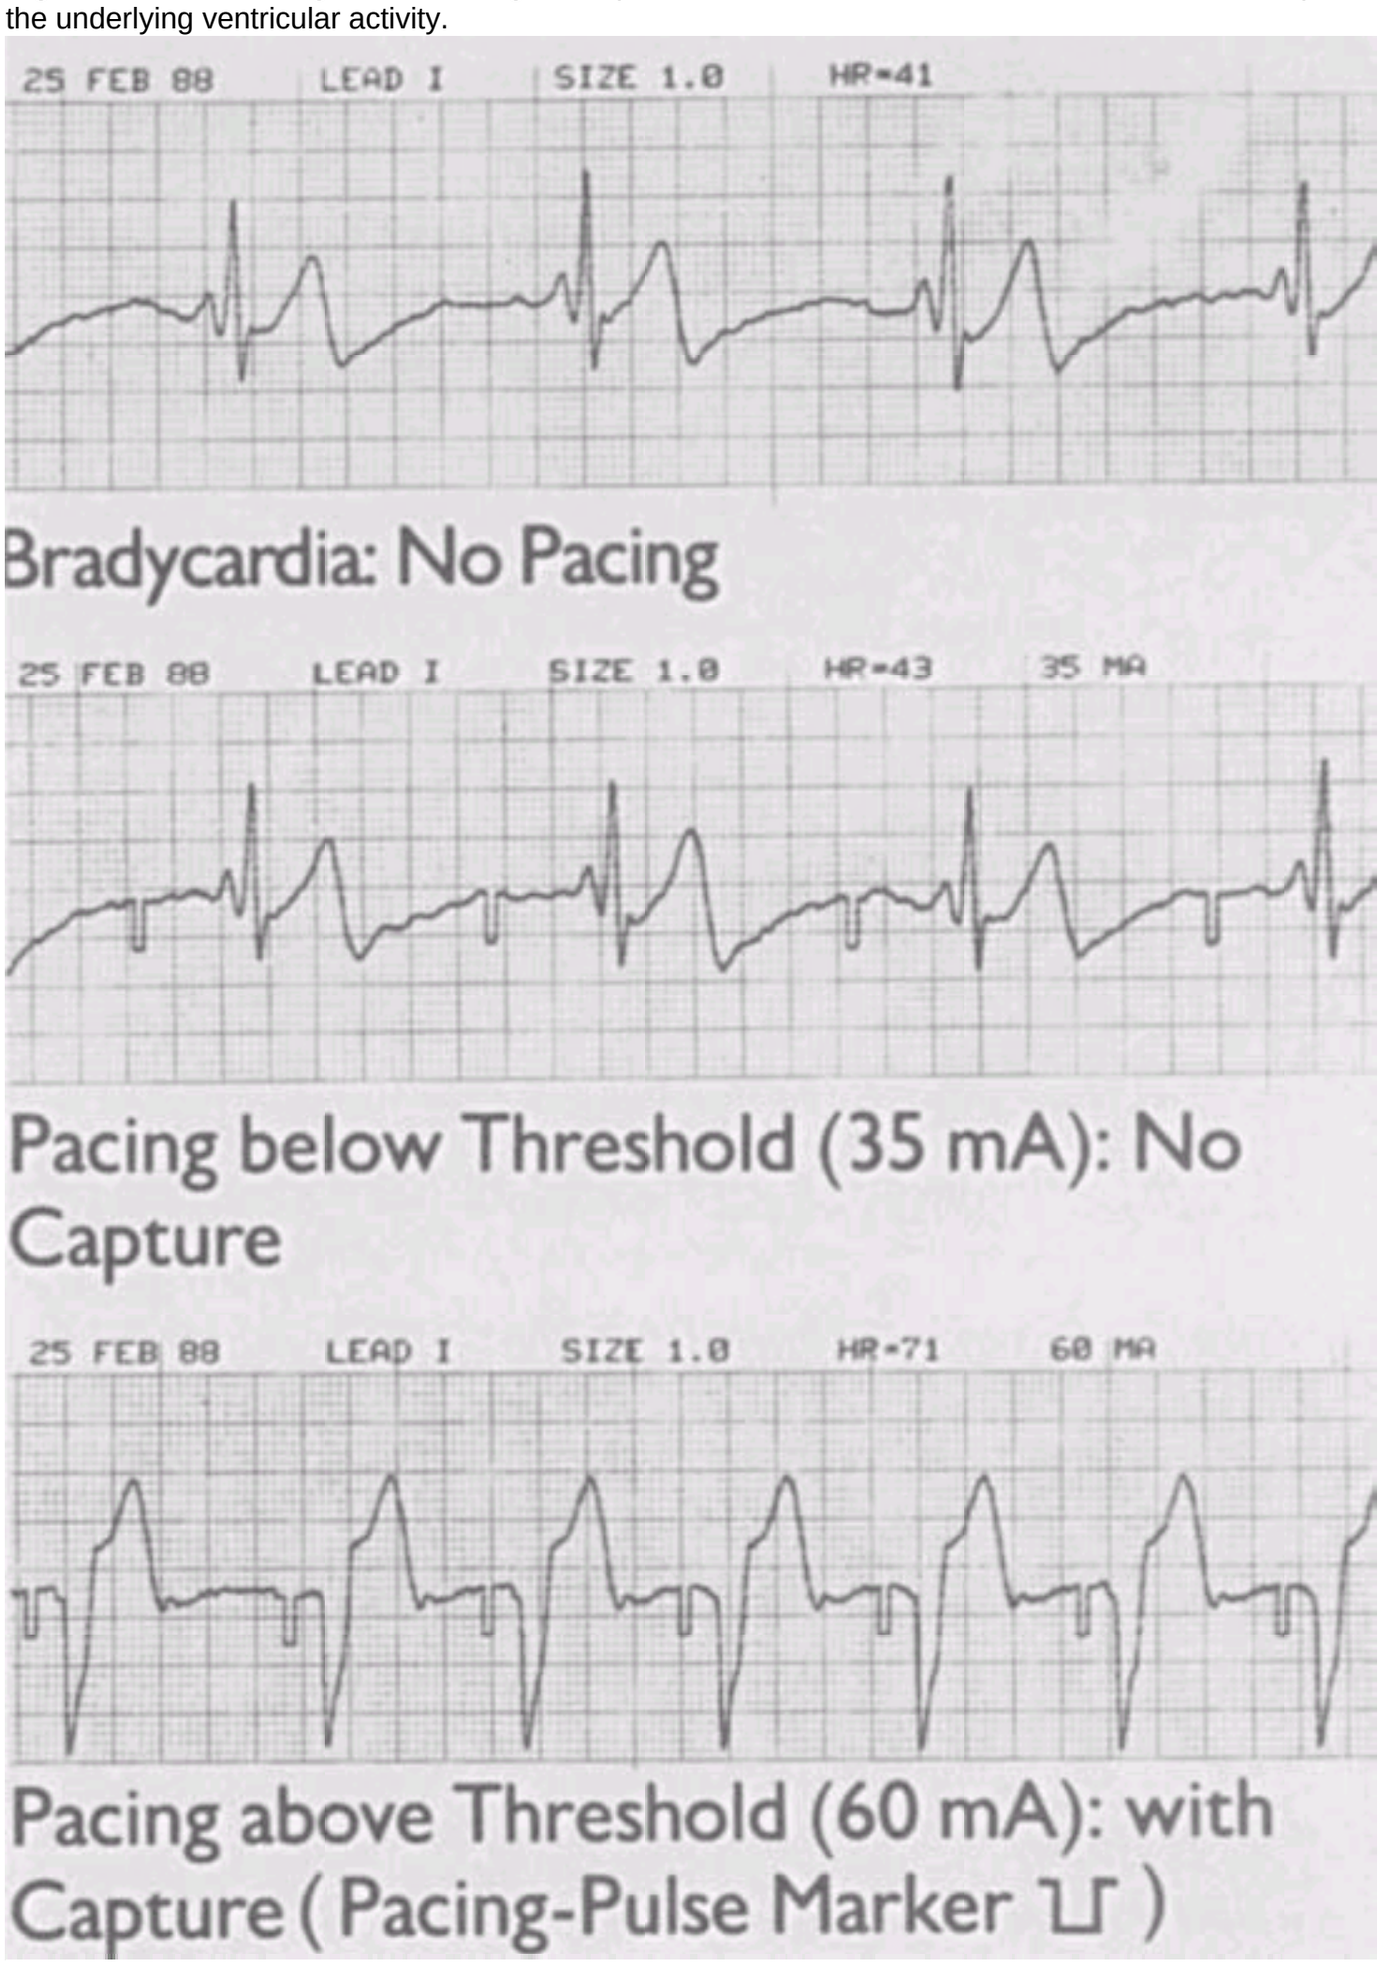

Figure 16-1 Production of cardiac tamponade by injections of saline into the pericardial sac. Although pericardial space can acutely accommodate 80 to 120 mL of fluid without a significant increase in pericardial pressure, note steep increases in pressure and drop in blood pressure at about 200 mL of saline. Once critical volumes are reached, very small increases cause significant hemodynamic compromise. *(From Fowler NO: Physiology of cardiac tamponade and pulsus paradoxus. II: Physiological, circulatory, and pharmacological responses in cardiac tamponade. Mod Concepts Cardiovasc Dis 47:116, 1978. Reproduced by permission of the American Heart Association, Inc.)*

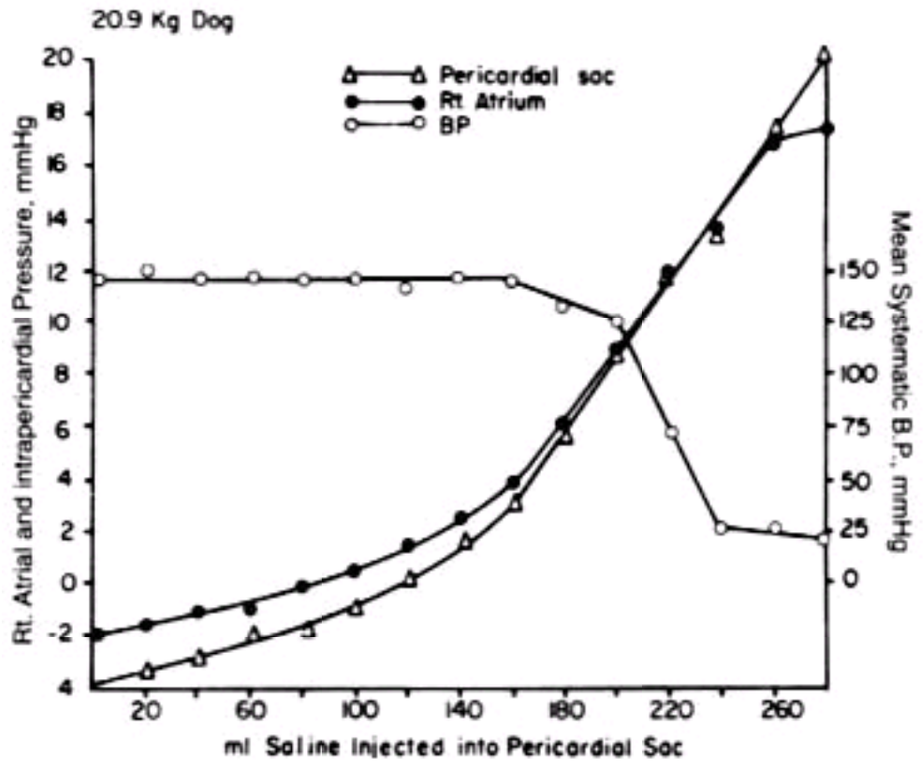

Figure 16-2 Relationship of intrapericardial pressure to volume of pericardial fluid. Note that pressure drops rapidly when a small amount of fluid is removed. *(From Pories W, Gaudiani V: Cardiac tamponade. Surg Clin North Am 55:573, 1975. Reproduced by permission.)*

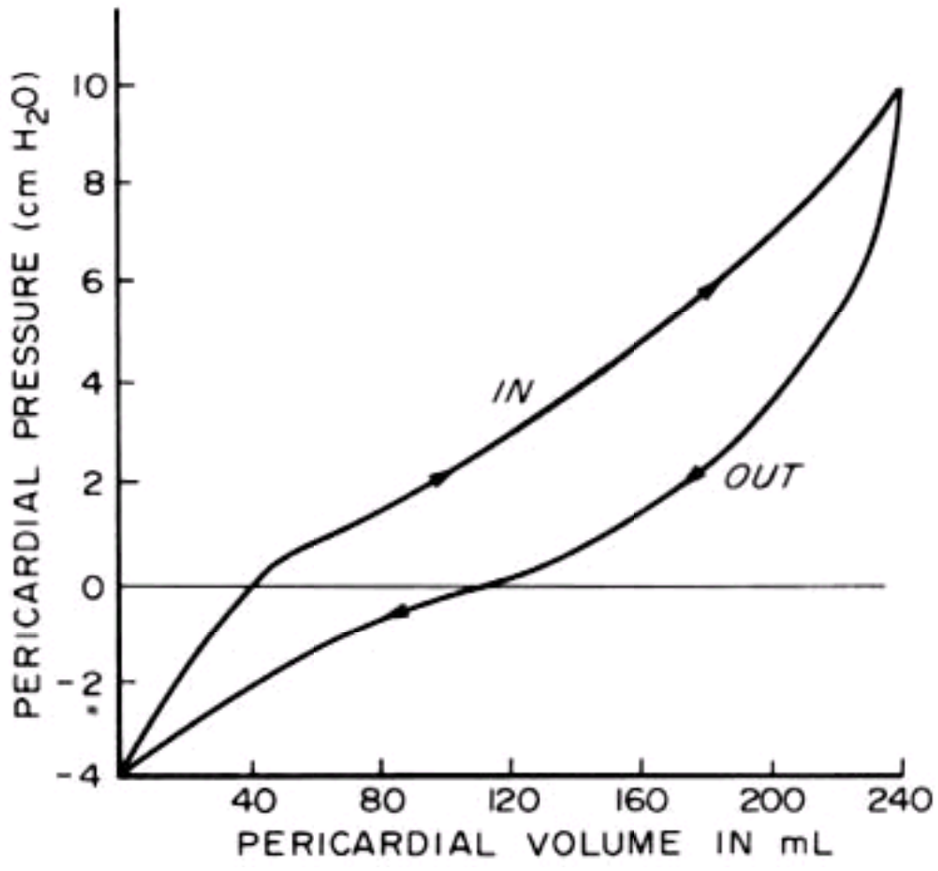

Figure 16-3 Summary of physiologic changes in tamponade. RV, right ventricle. *(From Shoemaker WC, Carey JS, Yao ST, et al: Hemodynamic monitoring for physiological evaluation, diagnosis, and therapy of acute hemopericardial tamponade from penetrating wounds. J Trauma 13:36, 1973; and Spodick D: Acute cardiac tamponade: Pathologic physiology, diagnosis, and management. Prog Cardiovasc Dis 10:65, 1967. Reproduced by permission.)*

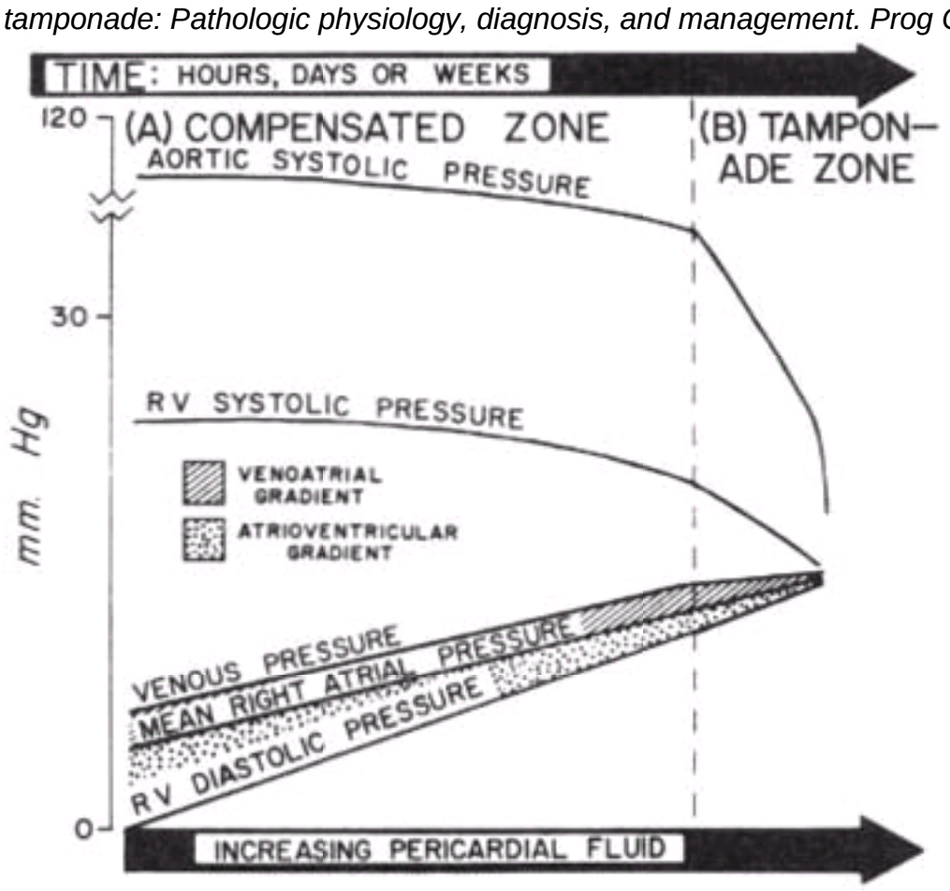

Figure 16-4 Normally systolic blood pressure drops slightly during inspiration. To measure *pulsus paradoxus*, the patient breathes normally while lying at a 45-degree angle. The blood pressure cuff is inflated well above systolic pressure and slowly deflated. When the pulse is first heard only during expiration, this is the upper value. The cuff is deflated until the pulse is heard during both inspiration and expiration, and this is the lower value. The difference in the two values is the amount of *pulsus paradoxus*. A difference of more than 12 mm Hg is abnormal.

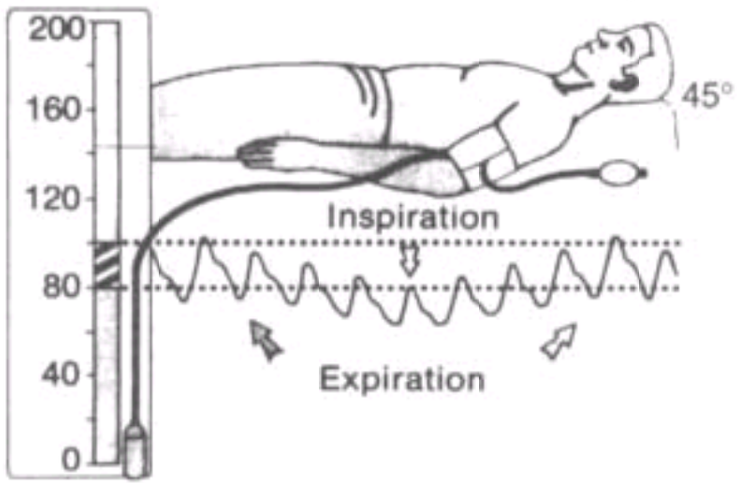

Figure 16-5 Epicardial fat pad sign. The water density space between the radiolucent epicardial fat and the mediastinal fat represents the pericardium and its contents and should be 2 mm or less. An increase suggests pericardial fluid or thickening. *A,* Left anterior-oblique chest film. *B,* Lateral chest film. In acute tamponade, the chest radiograph has very minimal diagnostic value.

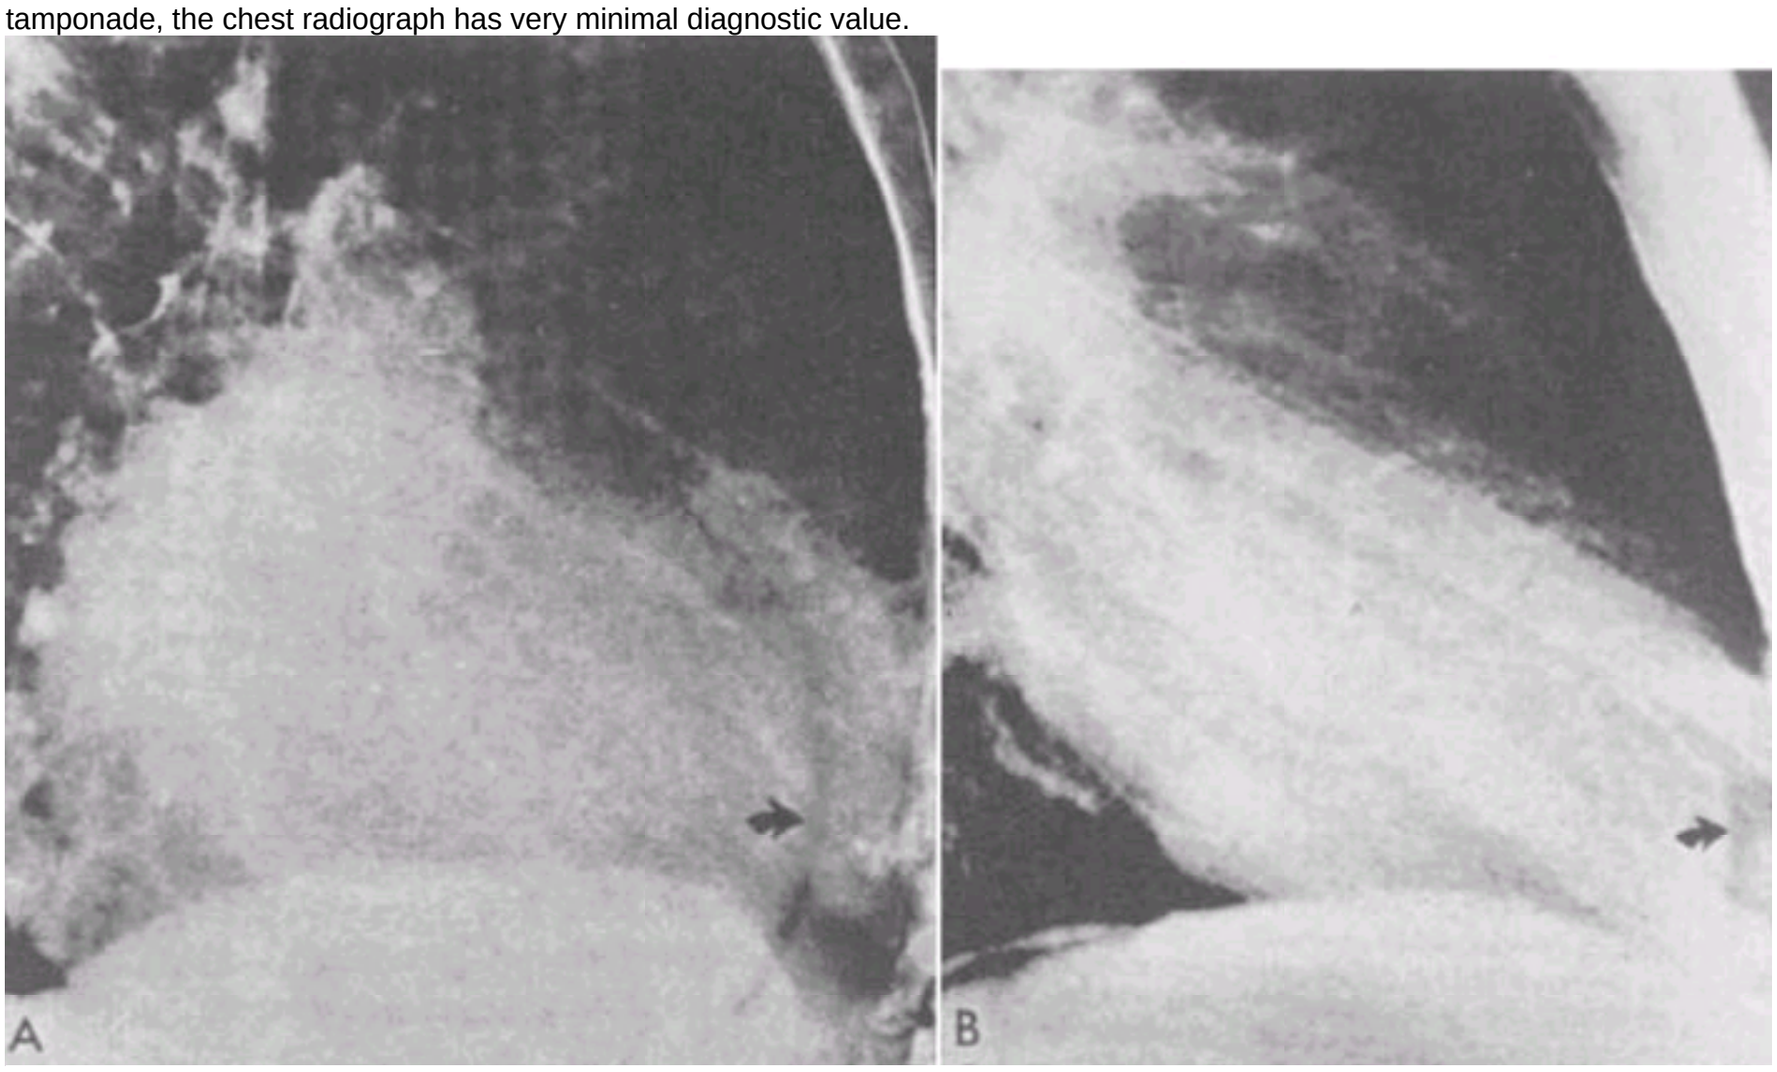

Figure 16-6 Overall, the electrocardiogram (ECG) has a low sensitivity for pericardial effusion or tamponade, but PR depression, low voltage, or electrical alternans may be seen. Lewis lead ECG showing total electrical alternans of both amplitude and configuration of P and QRS complexes. This is rarely seen but is highly suggestive of tamponade. Note that electrical alternans may not be evident in standard ECG leads. *(From Sotolongo RP, Horton JD: Total electrical alternans in pericardial tamponade. Am Heart J 101:854, 1981. Reproduced by permission.)*

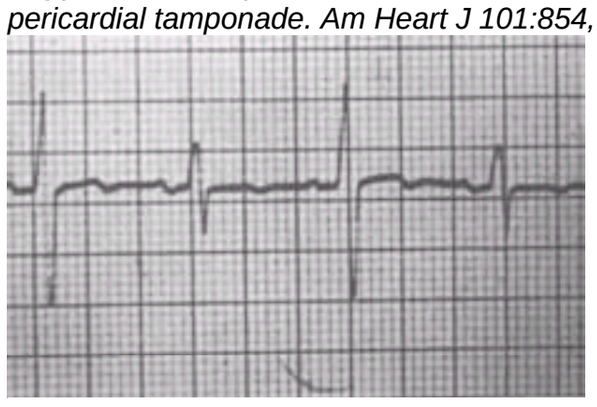

Figure 16-7 Management of *nontraumatic* cardiac tamponade. IV, intravenous line; CVP, central venous pressure; ECG, electrocardiogram.

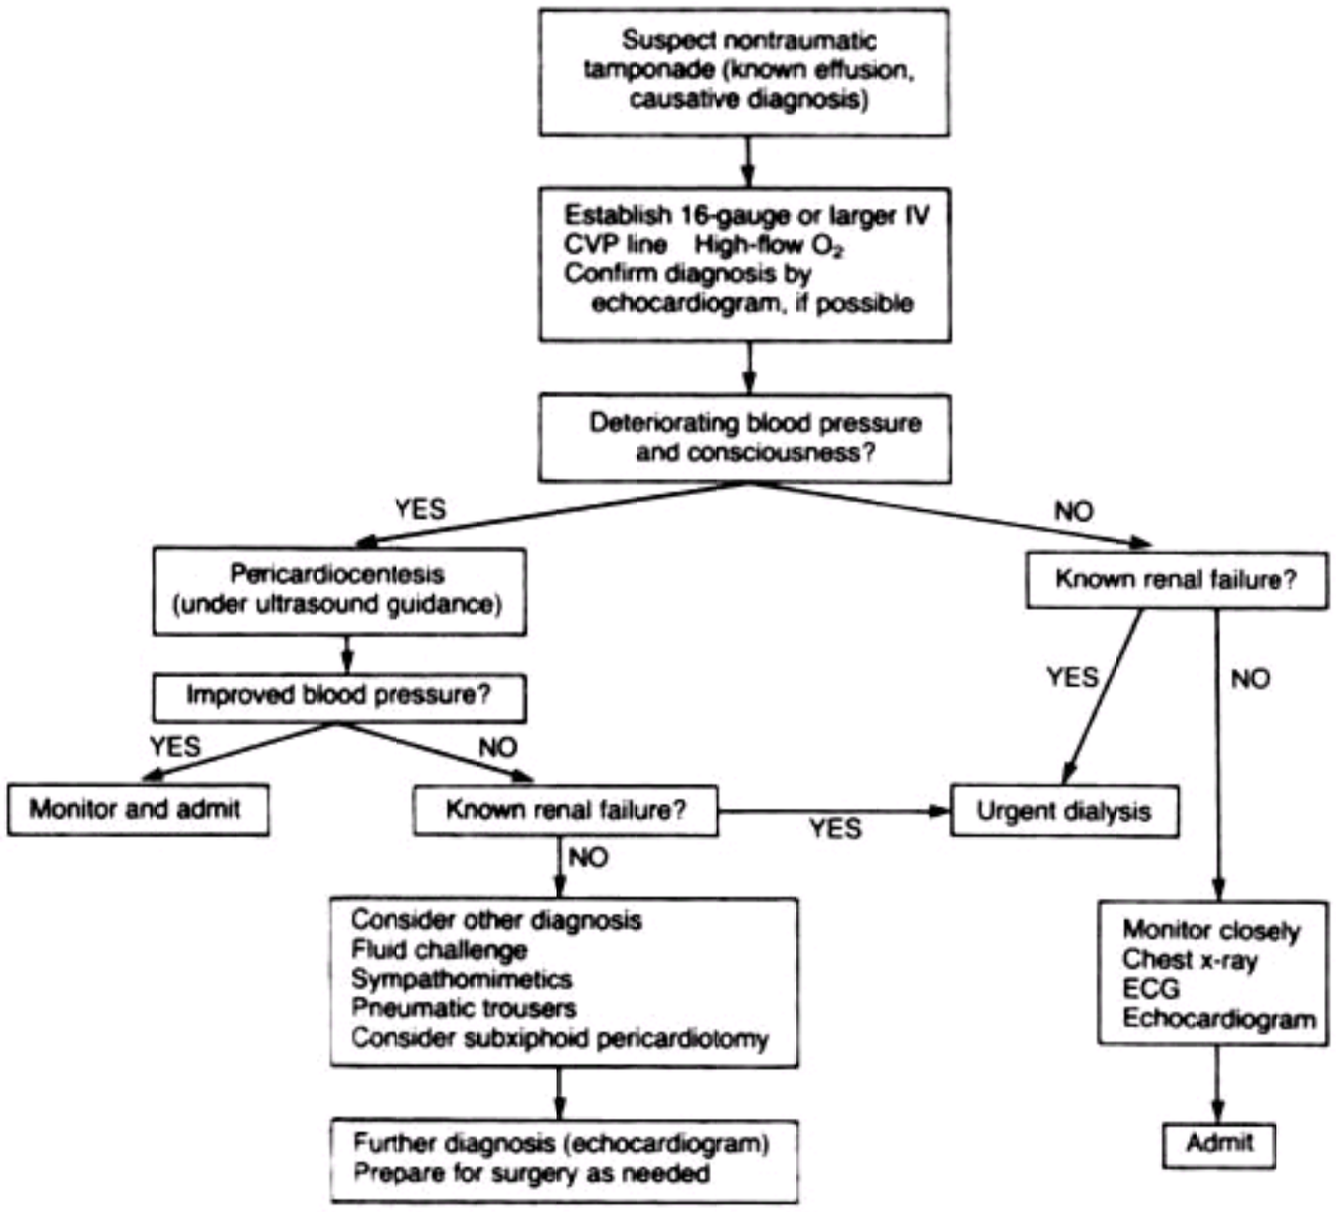

Figure 16-8 Management of *traumatic* cardiac tamponade. IV, intravenous lines; CVP, central venous pressure; ECG, electrocardiogram; R/O, rule out.

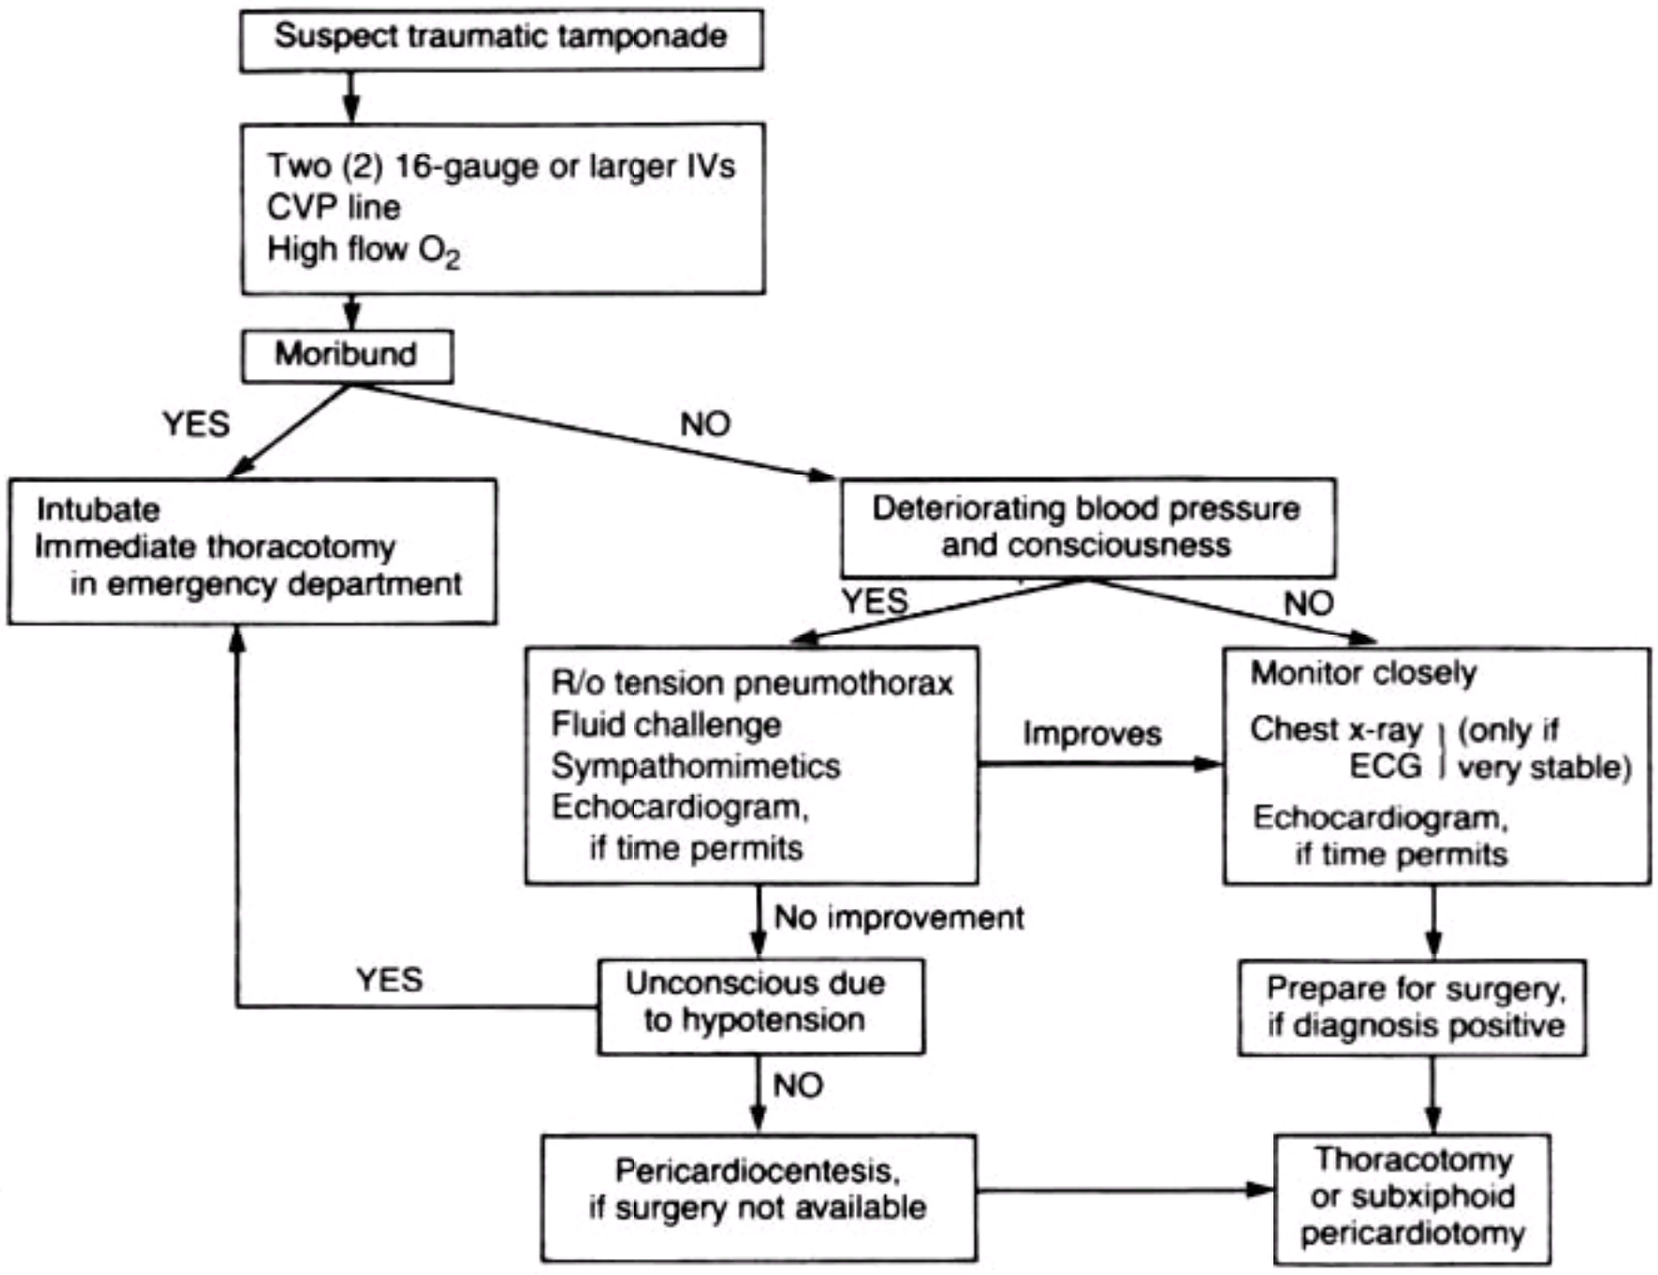

Figure 16-9 Equipment for emergent pericardiocentesis: long, 18-ga spinal needle; wire with alligator clips for connection to the electrocardiograph machine; and syringe (three-way stopcock optional). Sterile skin preparation and local anesthetic are also required.

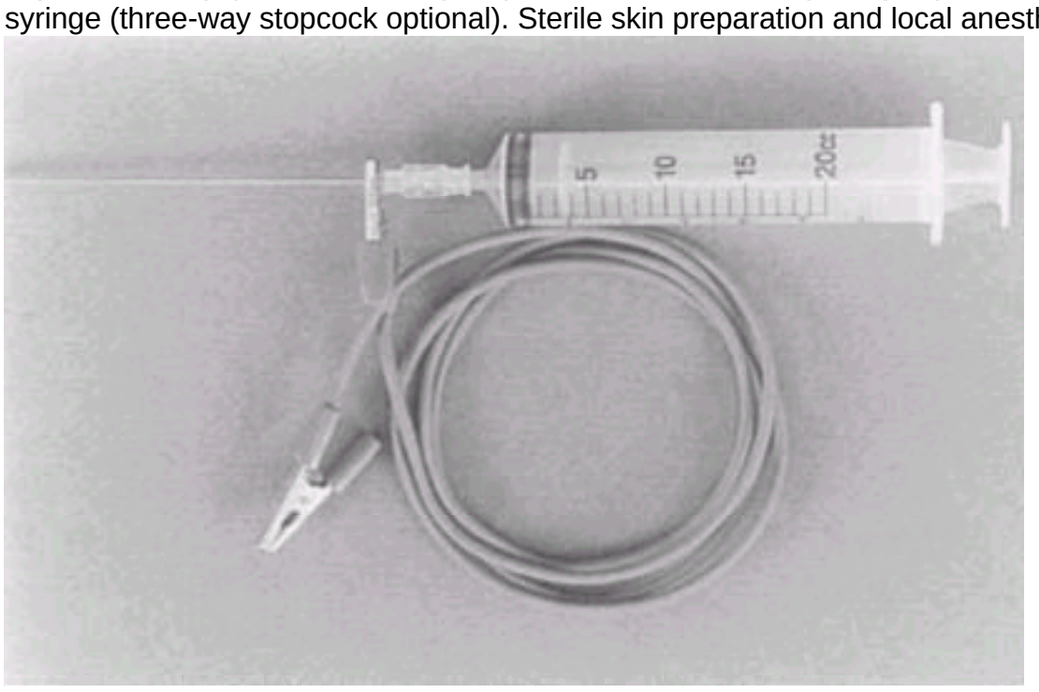

Figure 16-10 An example of the contents of a prepackaged pericardiocentesis set: finder needle, Seldinger wire, dilator, catheter guide, and pigtail catheter. Sterile skin preparation and local anesthetic are also required.

Figure 16-11 Parasternal approach for pericardiocentesis. The patient is depicted in a supine position, although a preferable position would be sitting at a 45° angle, if the patient's clinical condition permits. Note ECG monitoring via alligator clamp attached to lead.

Figure 16-12 *A* and *B*, Xiphosternal approach for pericardiocentesis. The needle is aimed for the sternal notch or the left shoulder. Note the electrocardiography monitor. Although the patient is shown in a supine position, a preferable position would be sitting at a 45° angle, if the patient's condition permits. This general approach is also used for intracardiac injection of advanced cardiac life support drugs.

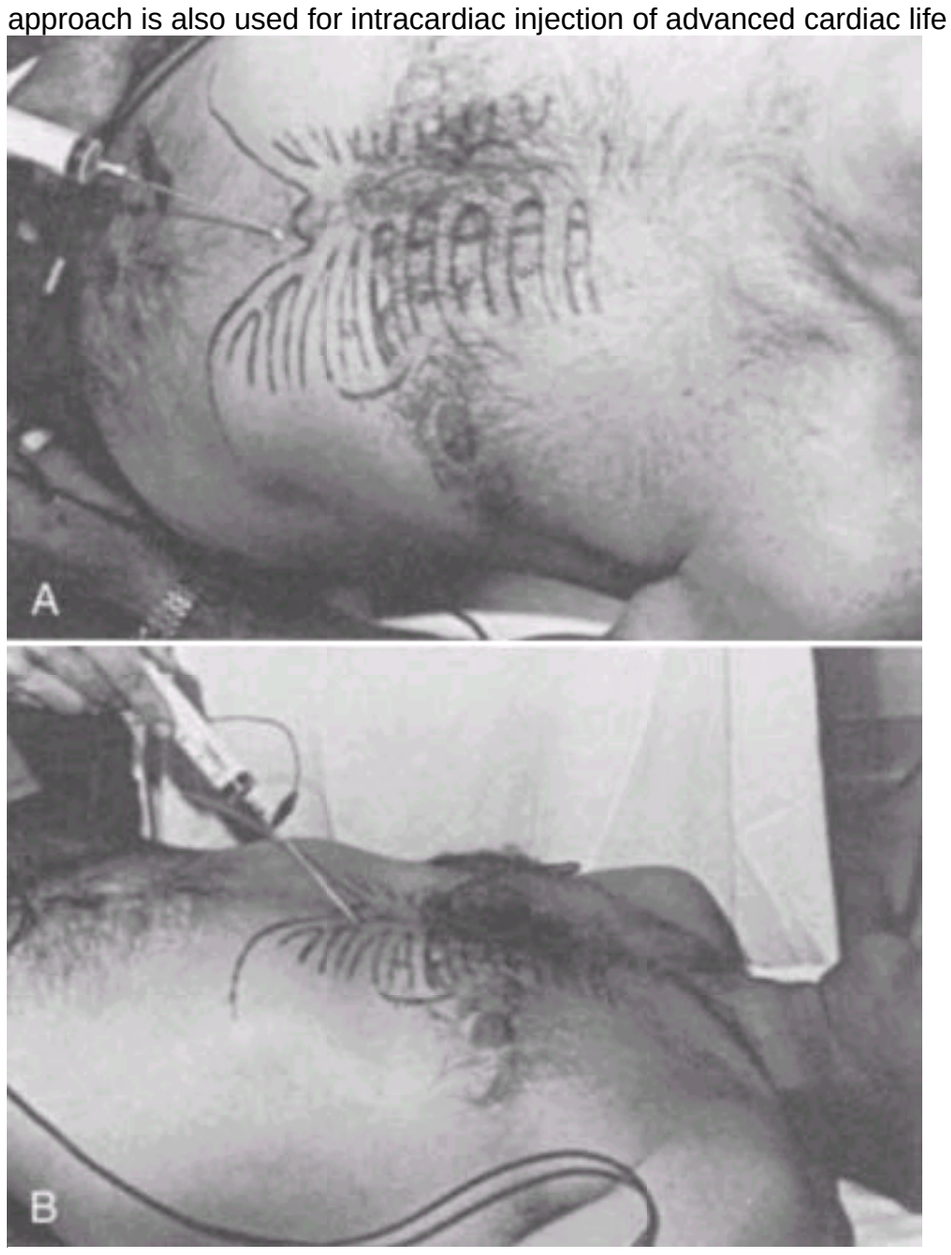

Figure 16-13 Subxyphoid approach to catheter placement into pericordial space. A short needle (16- or 18-ga) is inserted into the left xiphocostal angle perpendicular to the skin and 3 to 4 mm below the left costal margin *(A)*. After advancing the needle to the inner aspect of the rib cage, the needle's hub is depressed so that the needle points toward the patient's left shoulder. The needle is then cautiously advanced about 5 to 10 mm until fluid is reached *(B)*. The fingers may sense a distinct "give" when the needle penetrates the parietal pericardium. Successful removal of fluid confirms the needle's position. The syringe is then disconnected from the needle, and the flexible tip of the guide wire is advanced into the pericardial space *(C)*. The needle is withdrawn and replaced with a soft, multihole pigtail catheter (No. 6 to 8 Fr) using the Seldinger technique. After dilating the needle tract, the catheter is advanced over the guide wire into the pericardial space *(D)*. Once the catheter is properly positioned, aspiration of fluid should result in rapid improvement in blood pressure and cardiac output, a decrease in atrial and pericardial pressures, and a decrease in the degree of any paradoxical pulse *(E)*. Electrical alternans, if present, also decreases or disappears. *(From Spodick DH: The technique of pericardiocentesis. J Crit Illness 2:91, 1987.)*

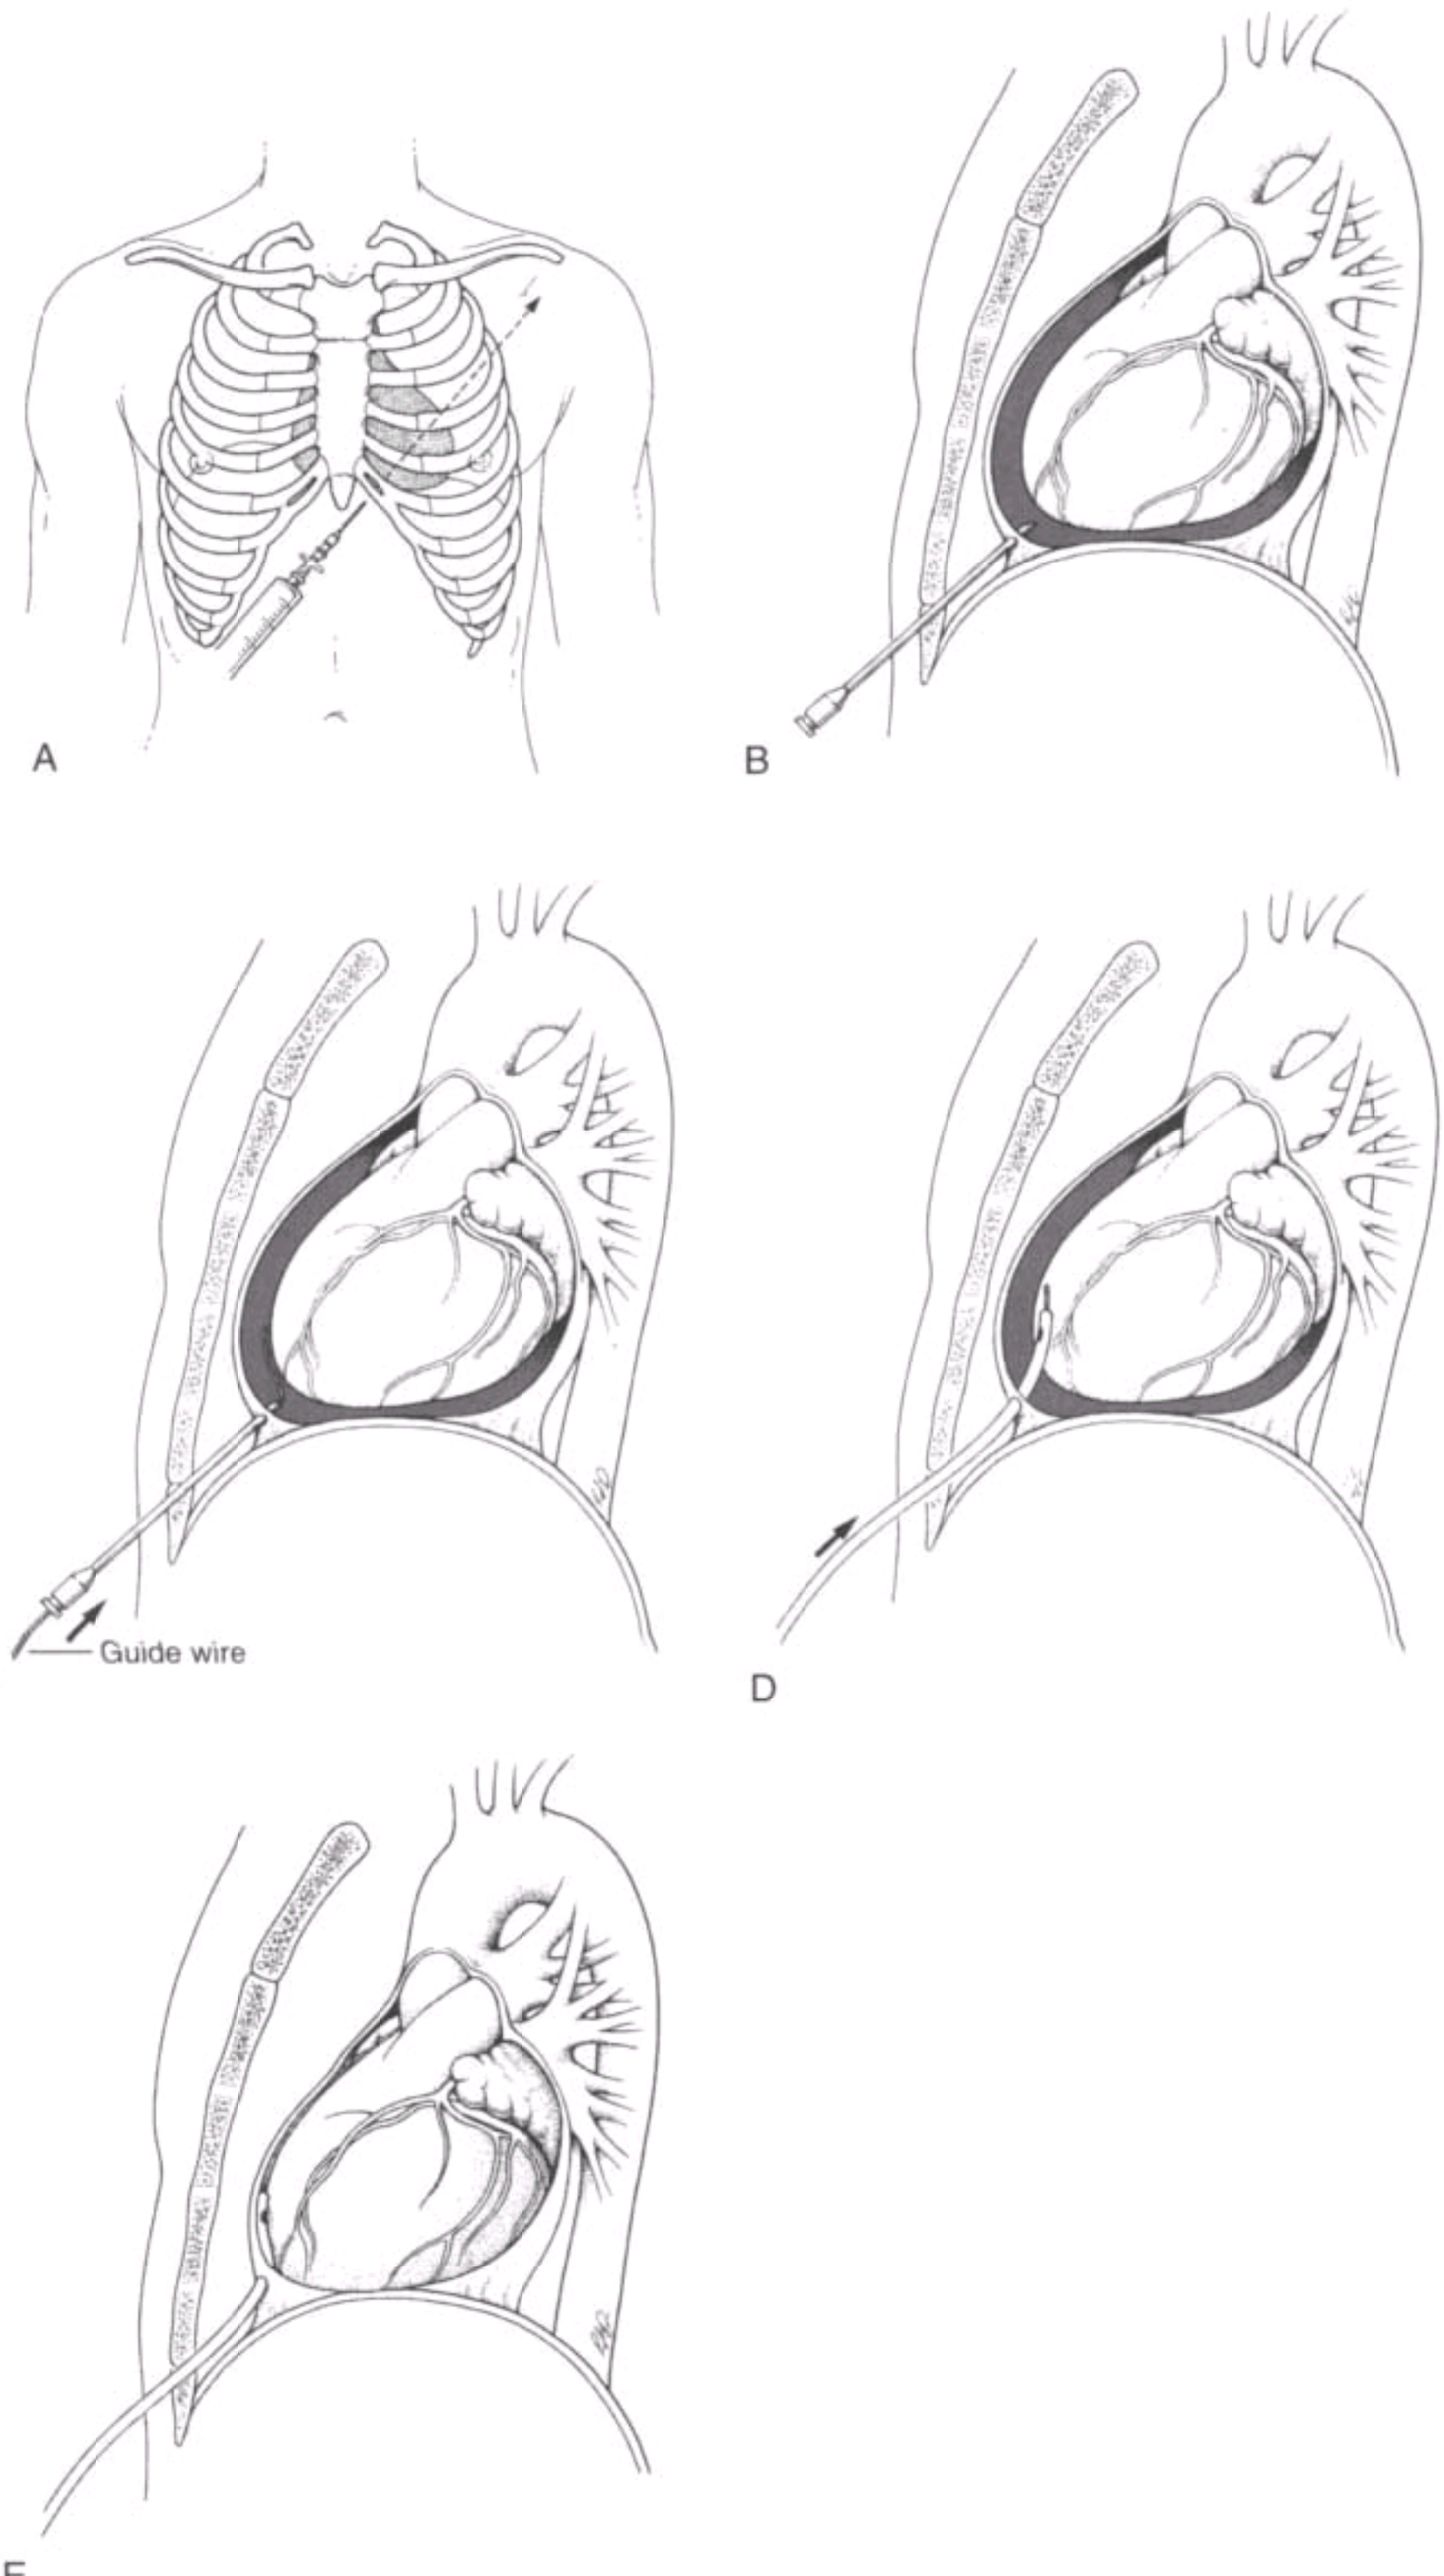

E

Figure 16-14 Current of injury. There is an obvious change in the electrocardiogram when the pericardiocentesis needle touches the epicardium. Following slight withdrawal *(arrow)*, the ST-segment elevation diminishes.

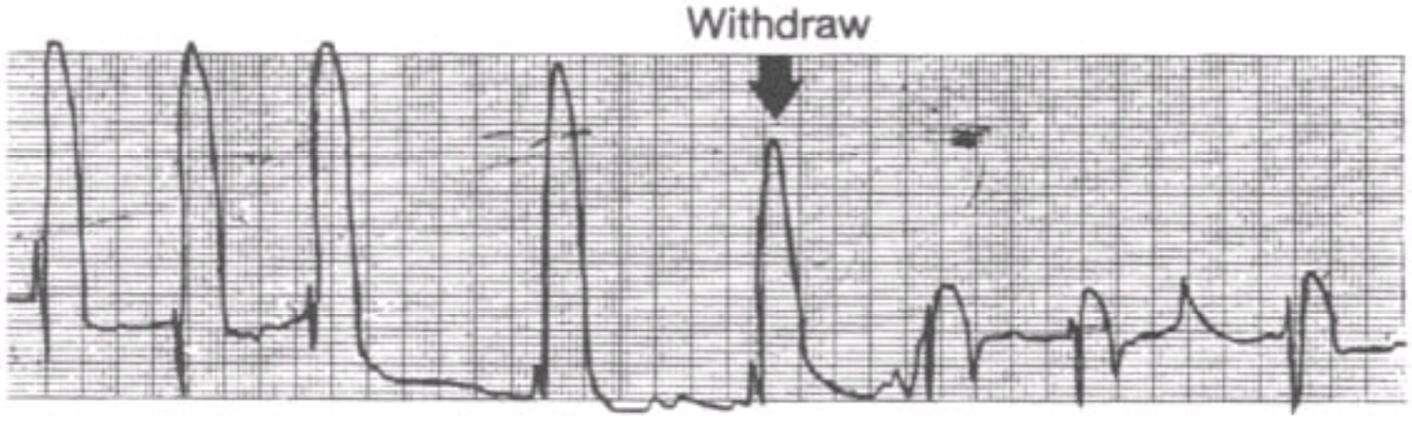

Figure 17-3 The Thumper Cardiopulmonary Resuscitator.

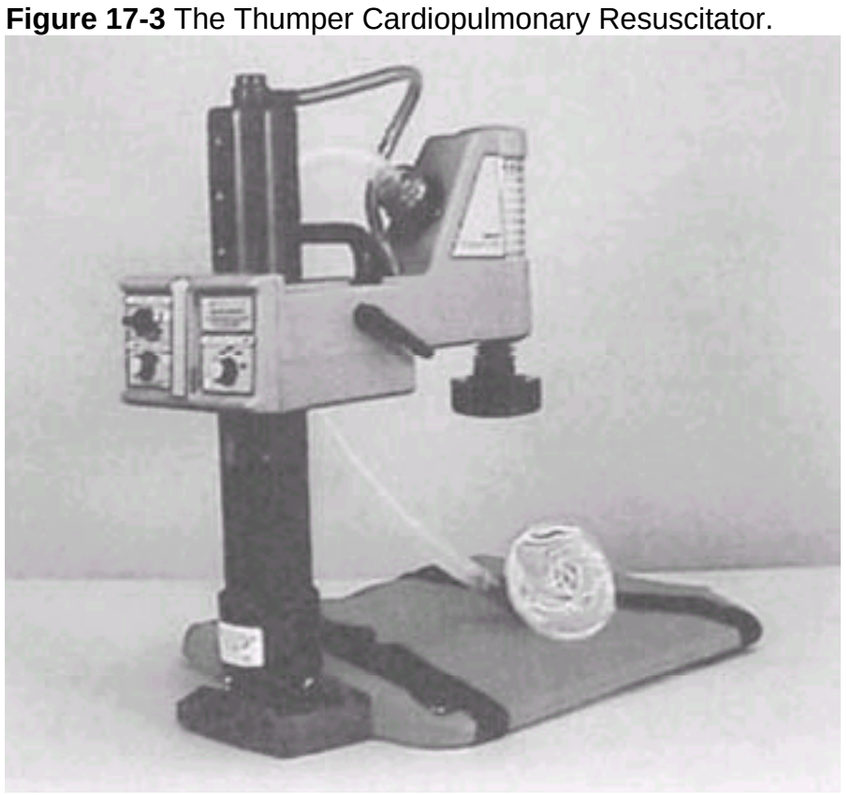

Figure 17-4 An artist's conception of basic rescuers performing interposed abdominal compression cardiopulmonary resuscitation. For clarity, both rescuers are shown on the same side of the victim. With two rescuers, the first compresses the chest and performs ventilation while the second compresses the abdomen. With three rescuers, ventilation, chest compression, and abdominal compression are performed by each individual. Ideally, the rescuer performing chest compressions is on the victim's right side and the rescuer performing abdominal compressions is on the victim's left side. *(From Voorhees WD, Niebauer MJ, Babbs CF: Improved oxygen delivery during cardiopulmonary resuscitation with interposed abdominal compressions. Ann Emerg Med 12:128, 1983. Reproduced by permission.)*

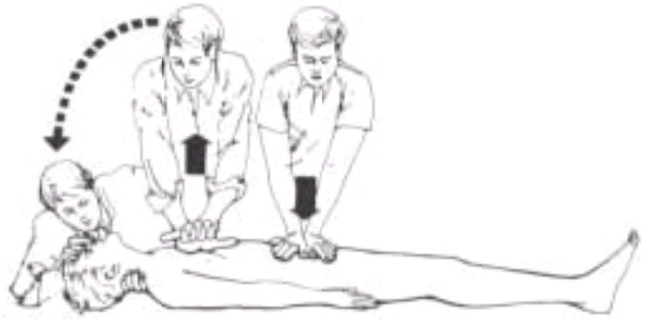

Figure 17-5 A comparison of vest cardiopulmonary resuscitation (CPR) and standard manual CPR. With vest CPR, a pneumatic system inflates and deflates a bladder surrounding the chest. The compression phase results in circumferential compression as opposed to point compression during manual CPR. The vest CPR system is equipped with defibrillator electrodes that monitor the patient's electrocardiogram as well as allow defibrillation without removal of the vest.

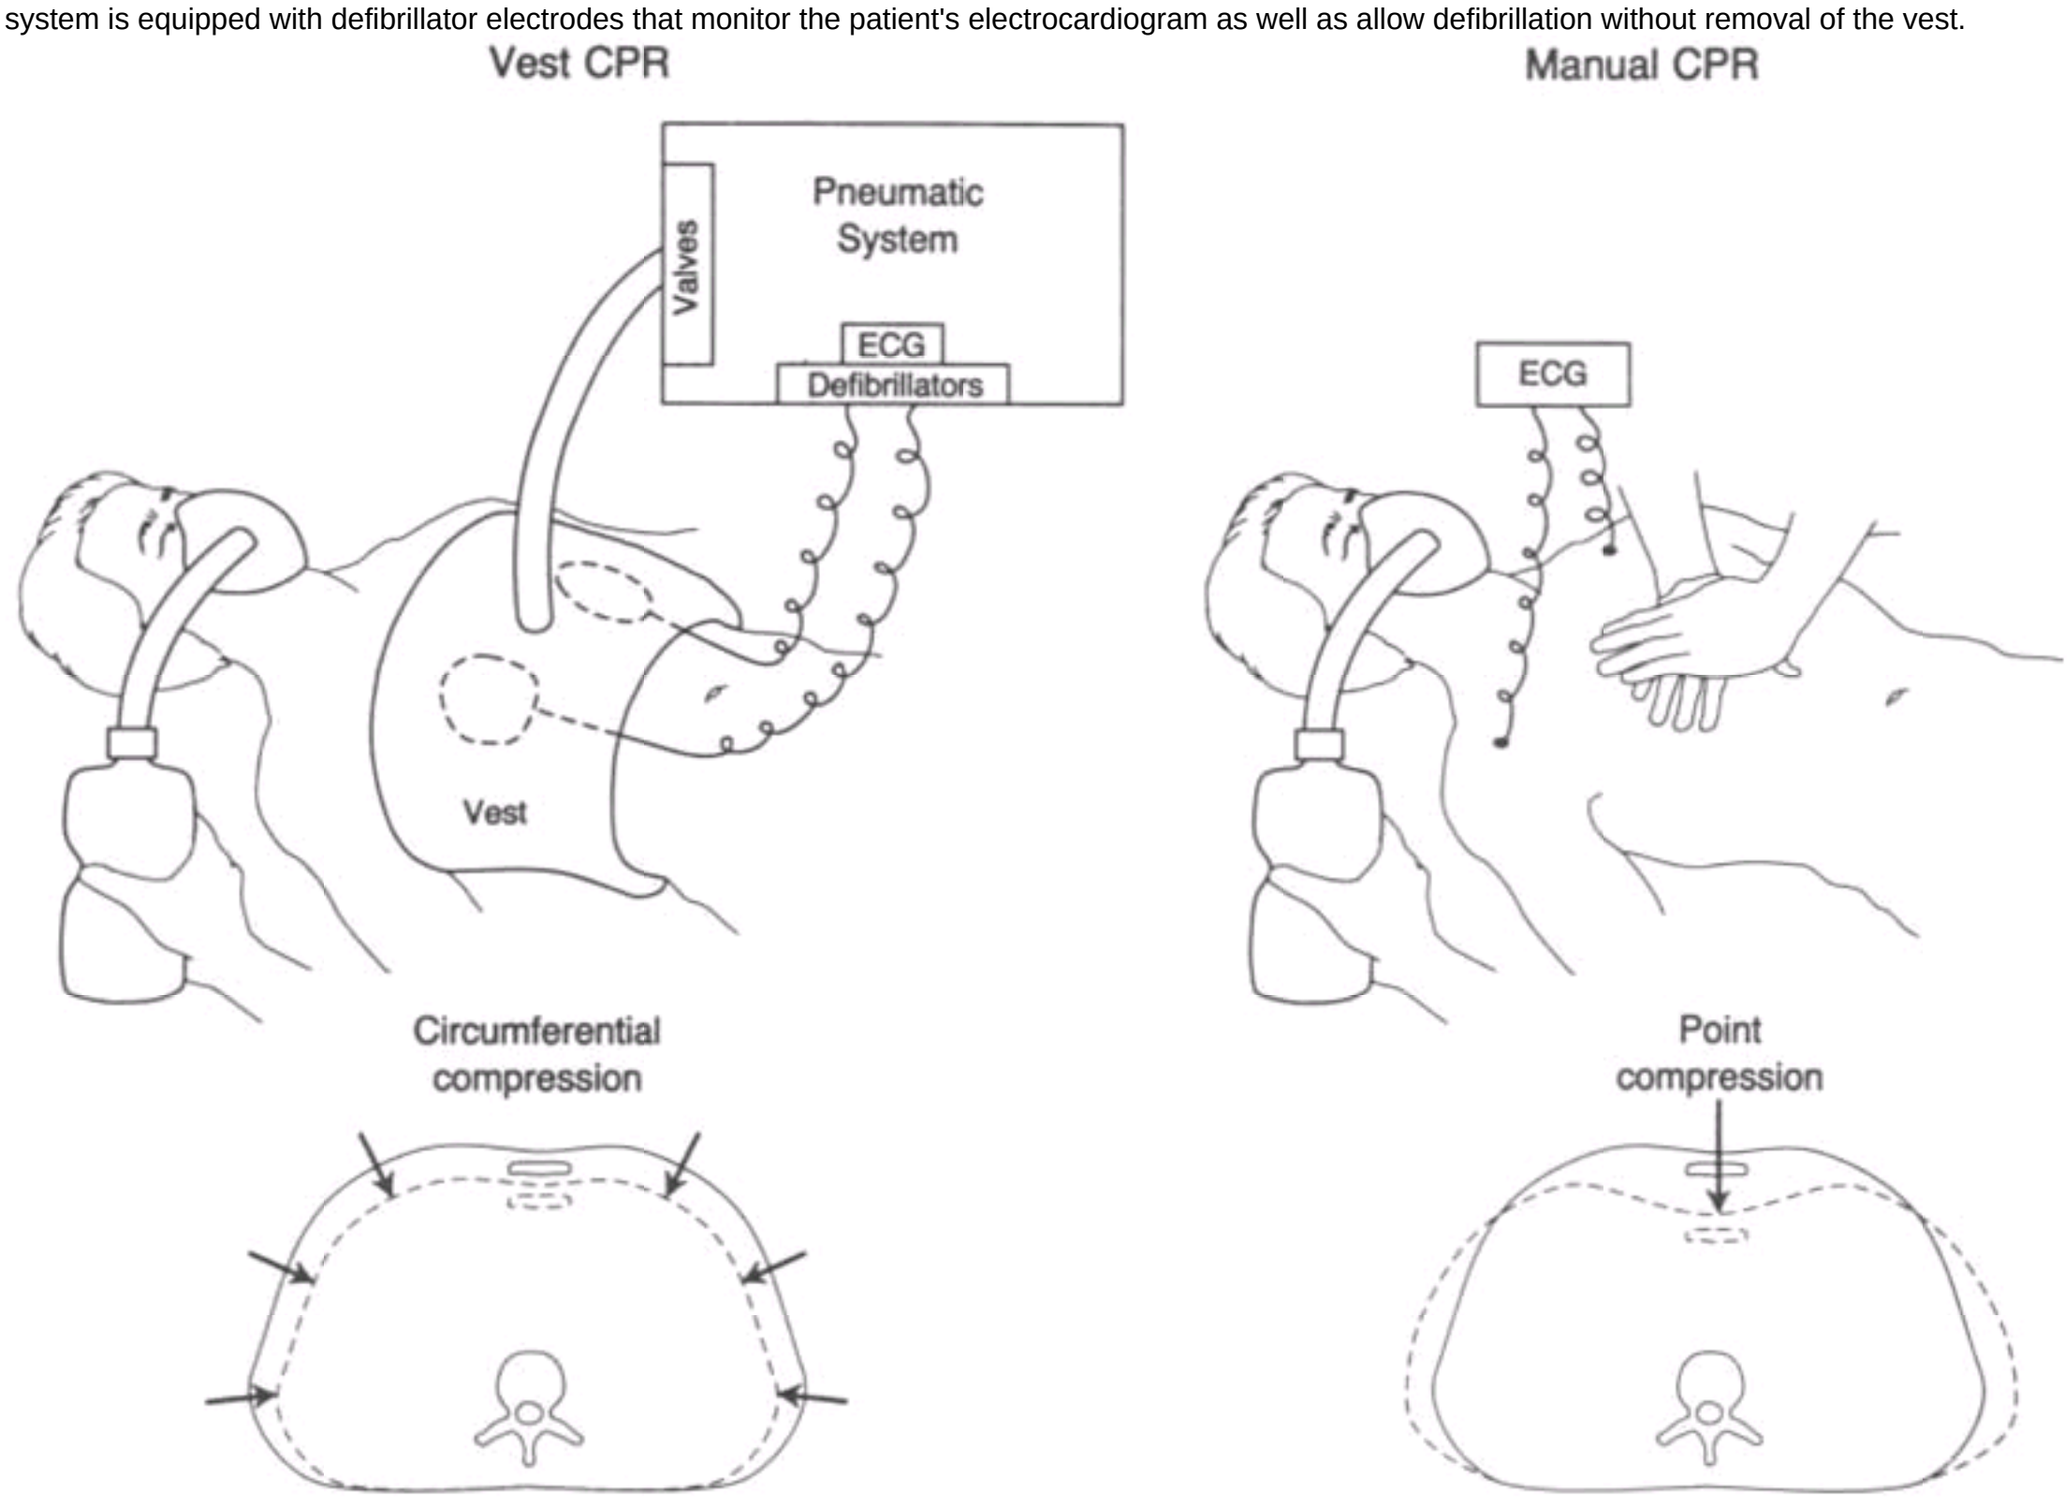

Figure 17-6 The active compression-decompression (ACD) device uses a suction cup positioned at mid-chest at the level of the nipples. The device is pushed downward into the chest during the compression phase of CPR. The force of compression can be approximated by the gauge within the handle. During the decompression phase, the handle is actively pushed up and away from the chest while the suction keeps the device attached. This active withdrawal characterizes the decompression phase of CPR. The value of this adjunct is uncertain.

Figure 17-7 Lifestick Resuscitator used for active compression-decompression cardiopulmonary resuscitation (ACD-CPR).

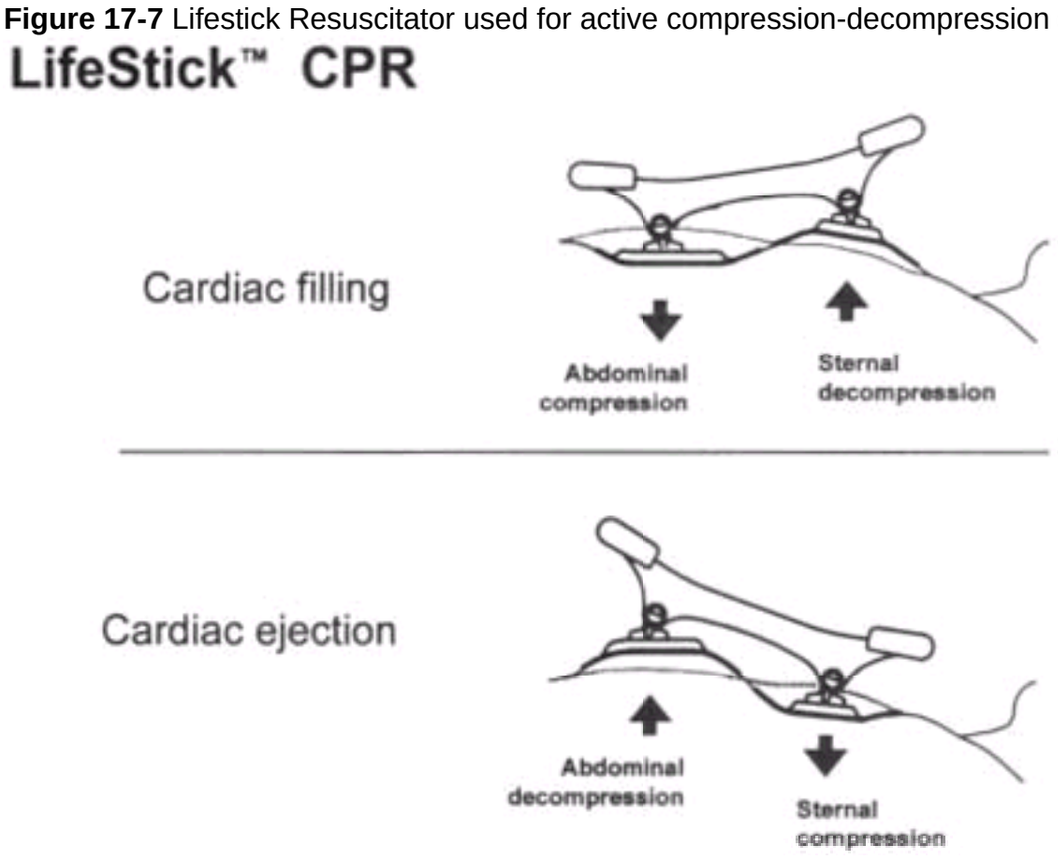

Figure 18-1 An emergency department thoracotomy is a dramatic and heroic intervention that has a very low survival rate. In the proper setting, its use can be advocated (see text). In this case of multiple gunshots, the abdomen was also opened in an attempt to cross-clamp the abdominal aorta, but no readily reversible pathology of the chest or abdomen was found.

Figure 18-2 Bedside ultrasound demonstrating hemopericardium.

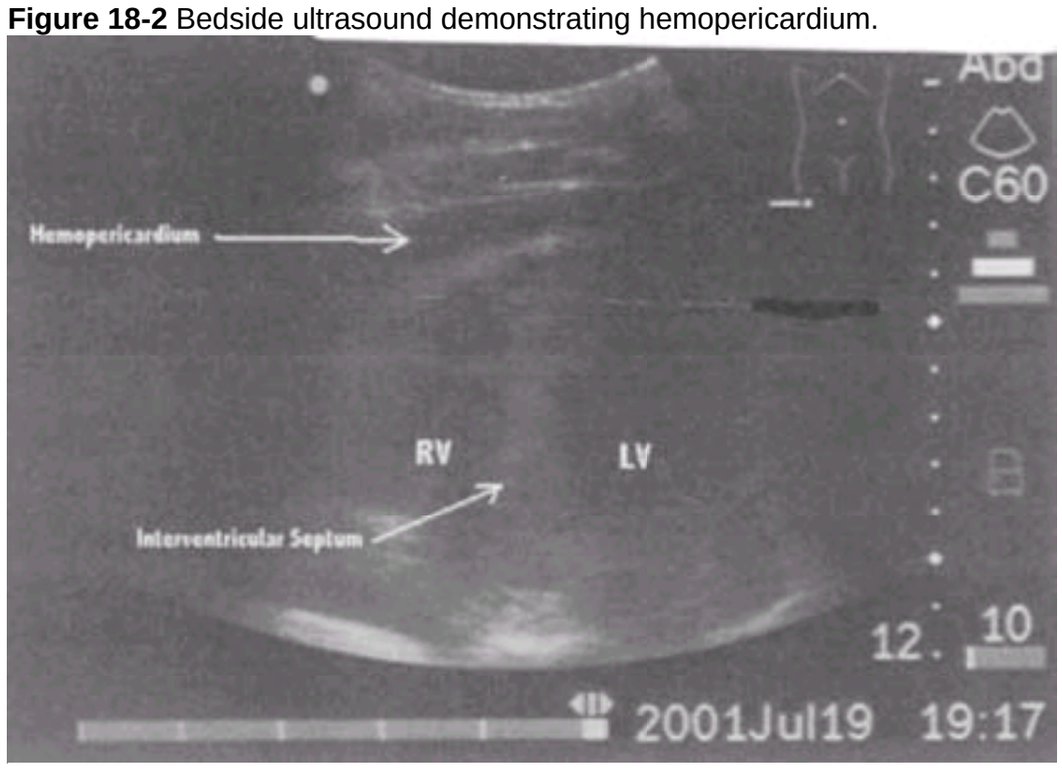

Figure 18-3 An algorithmic approach to chest trauma. QRS, organized electrical activity; VFib, ventricular fibrillation; (+)TAP, pericardial tap yielding blood; US, ultrasonography.

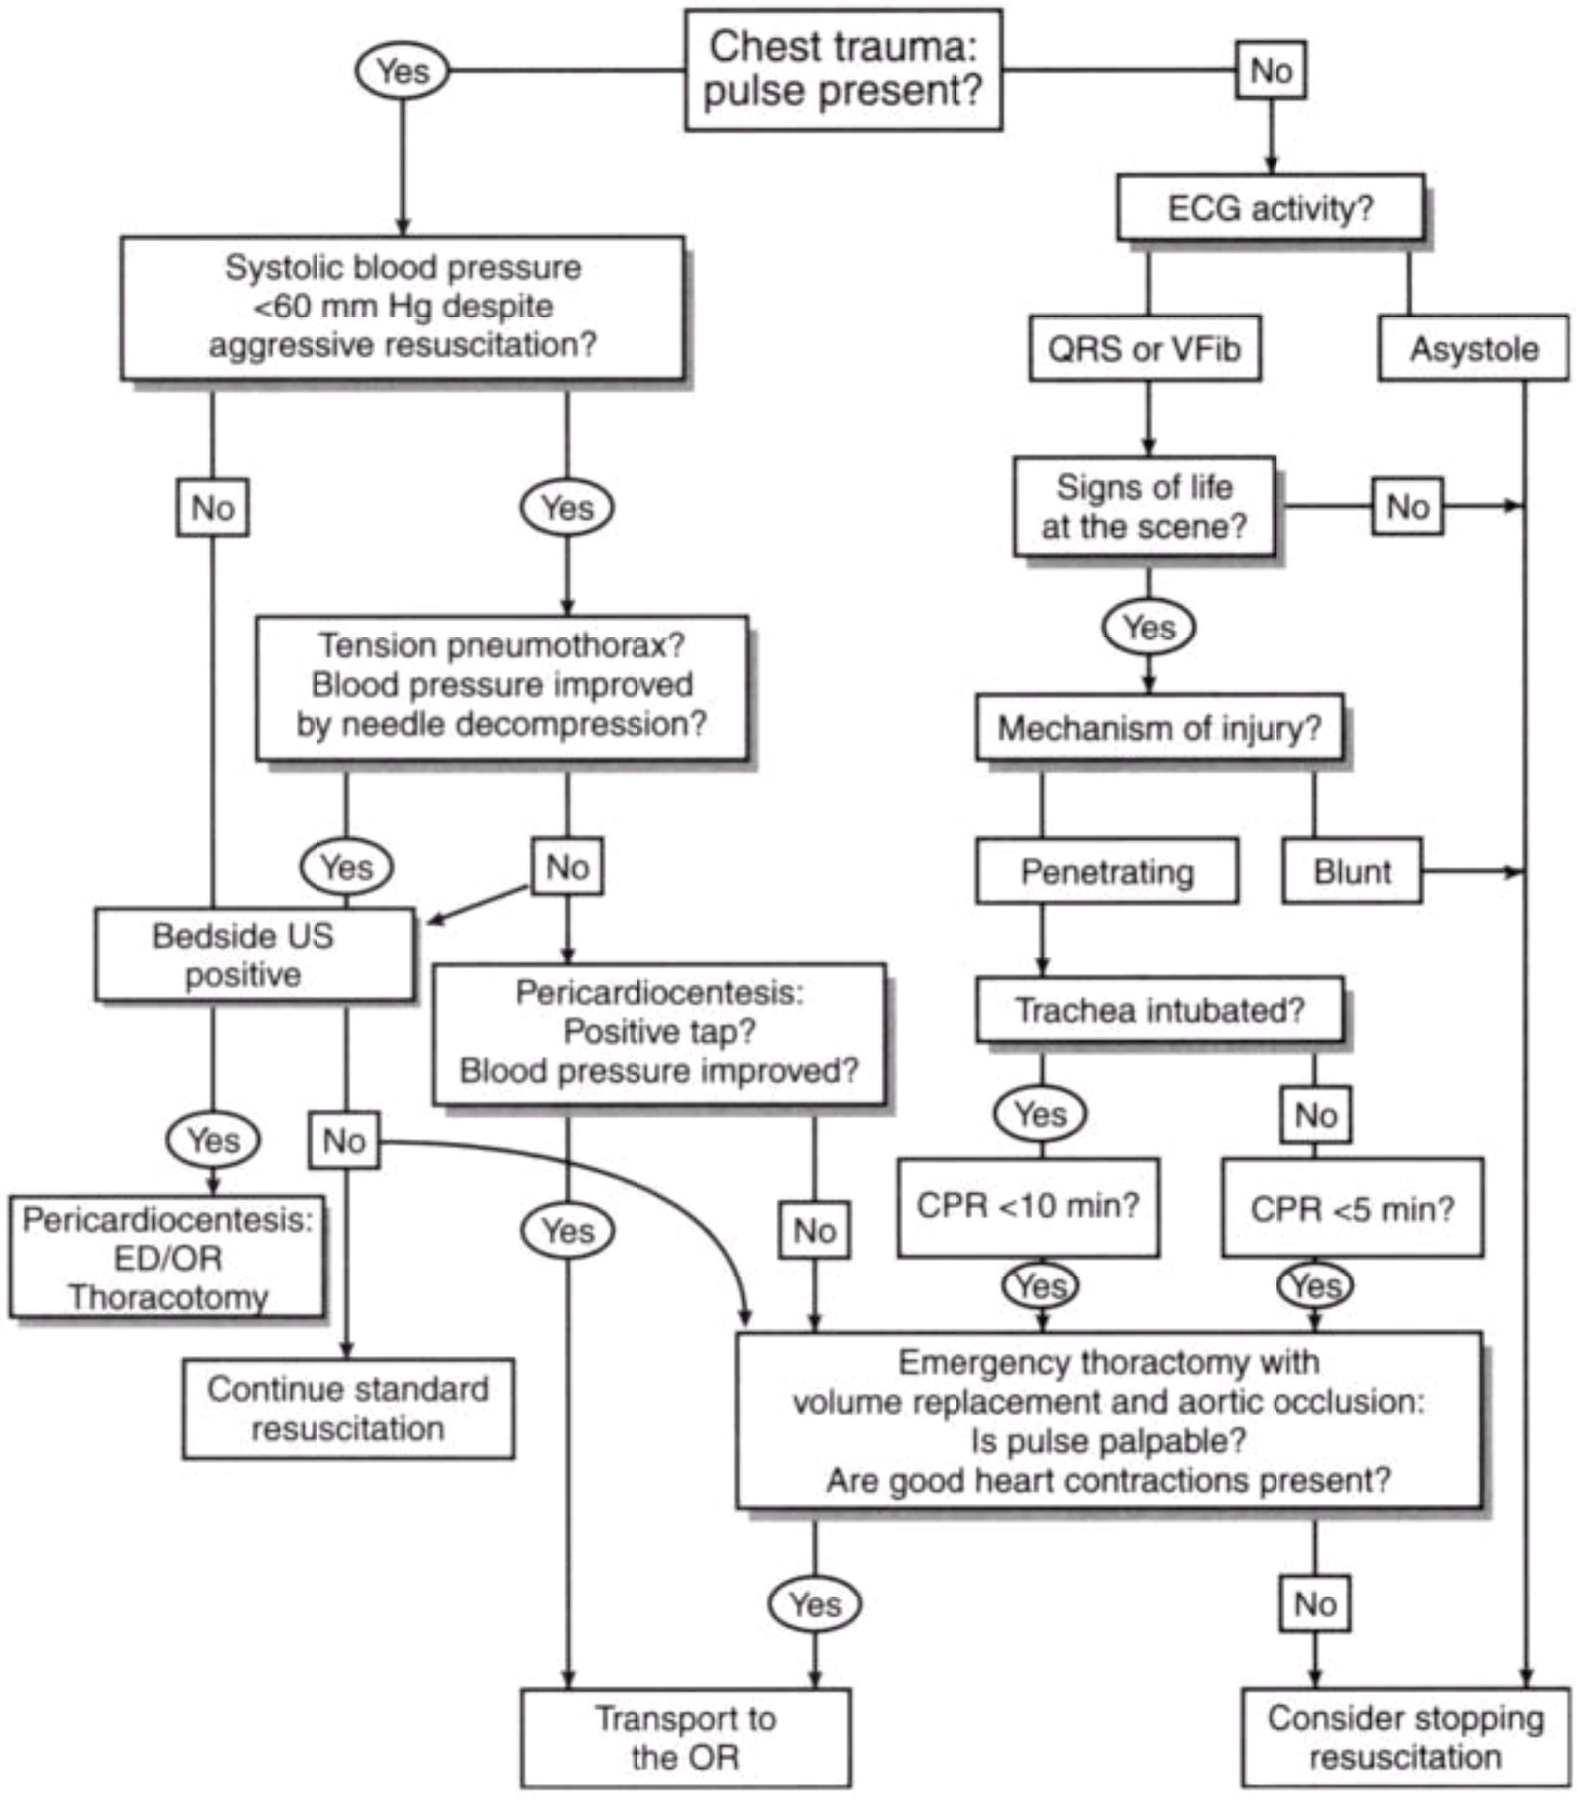

Figure 18-4 Left anterolateral thoracotomy. *A,* Several towels or sandbags are placed under the left scapula and the arm is raised above the head. The patient should be intubated. A nasogastric tube can be inserted to facilitate differentiation of the esophagus from the aorta. *B,* The left anterolateral submammary incision is the suggested initial approach. Ideally the incision is made between the fourth and fifth ribs. Generally the incision is just inferior to the nipple (male) or along the inframammary fold (female). The incision begins on the sternum and extends to the posterior axillary line, where it should be deep enough to partially transect the *latissimus dorsi* muscle. *C, Dashes* indicate the incision site of the inframammary fold in women.

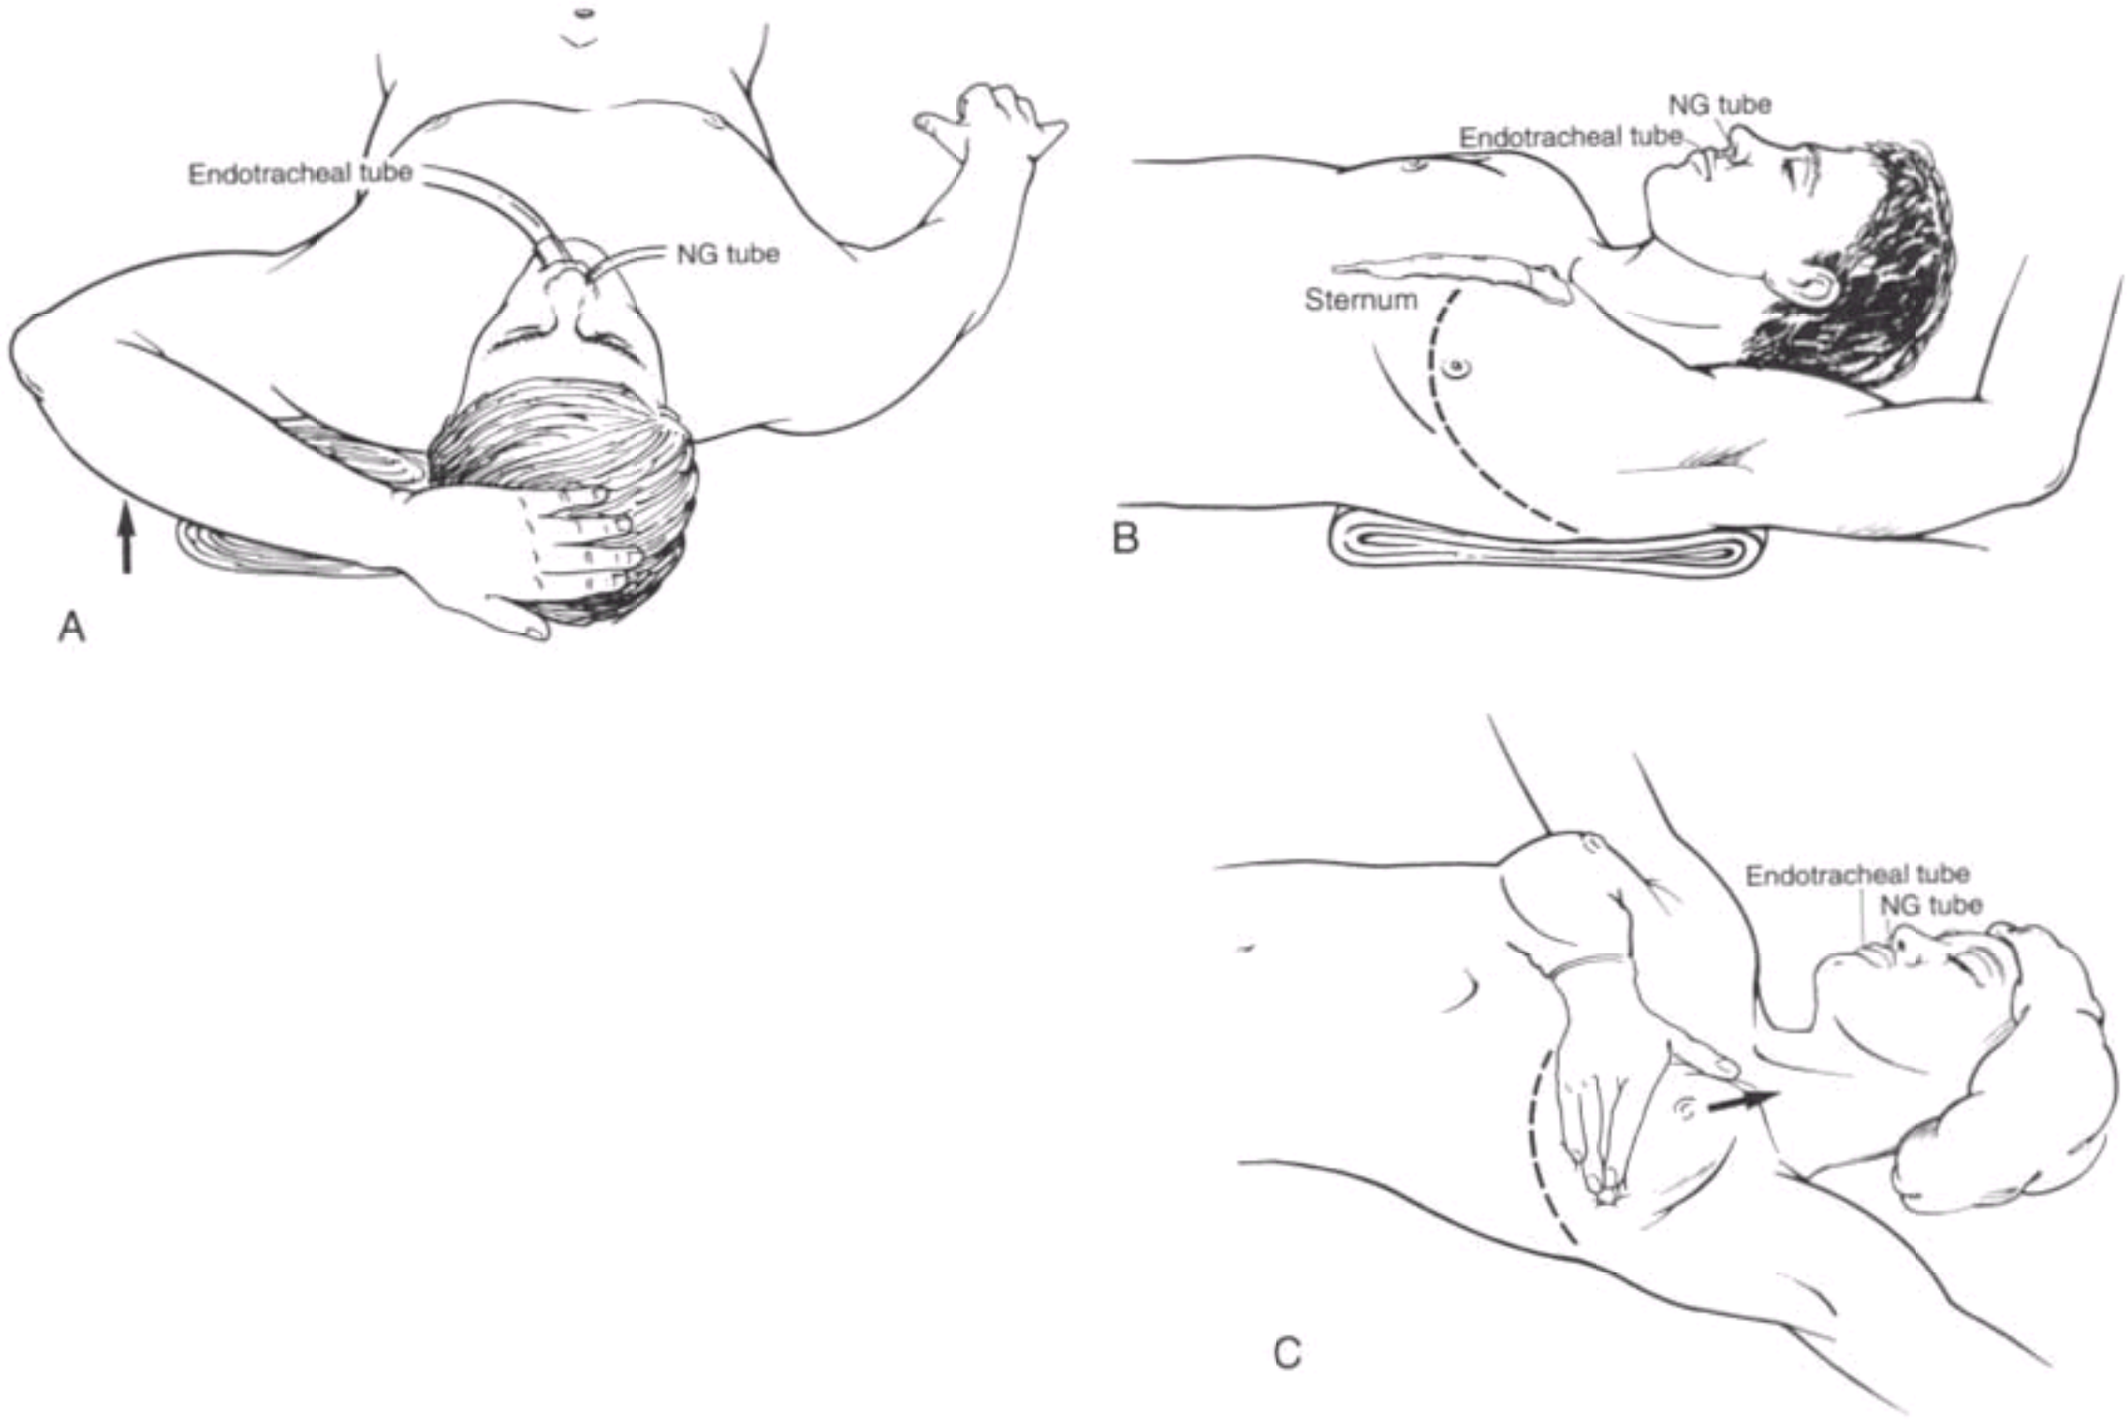

Figure 18-5 *A*, When entering the pleural cavity, it is important to make the incision on top of the rib to avoid the intercostal vessels. Once a hole has been made into the pleural space, the incision is widened with blunt scissors by cutting the intercostal muscles. The fourth and fifth fingers of the operator's free hand are inserted into the pleural space to fend off the lung as the scissors divide the intercostal muscle. Momentary cessation of ventilation will collapse the lung. Alternatively, the right mainstem bronchus can be intubated, which permits continuous ventilation and oxygenation without inflating the left lung into the operating field. *B,* The incision must always be carried to the posterior axillary line to maximize exposure. The rib spreader should be placed with the handle laterally. Because it can be difficult to determine if tamponade has occurred using visual inspection alone, the pericardium must be opened to definitively determine if tamponade is present. Using tissue pick ups with teeth, the operator must press hard against the pericardium to engage it within the tissue pick ups. The incision is started near the diaphragm and anterior to the phrenic nerve, which is easily identified as a thick tendon-like structure. Using blunt scissors, the incision is carried to the root of the aorta.

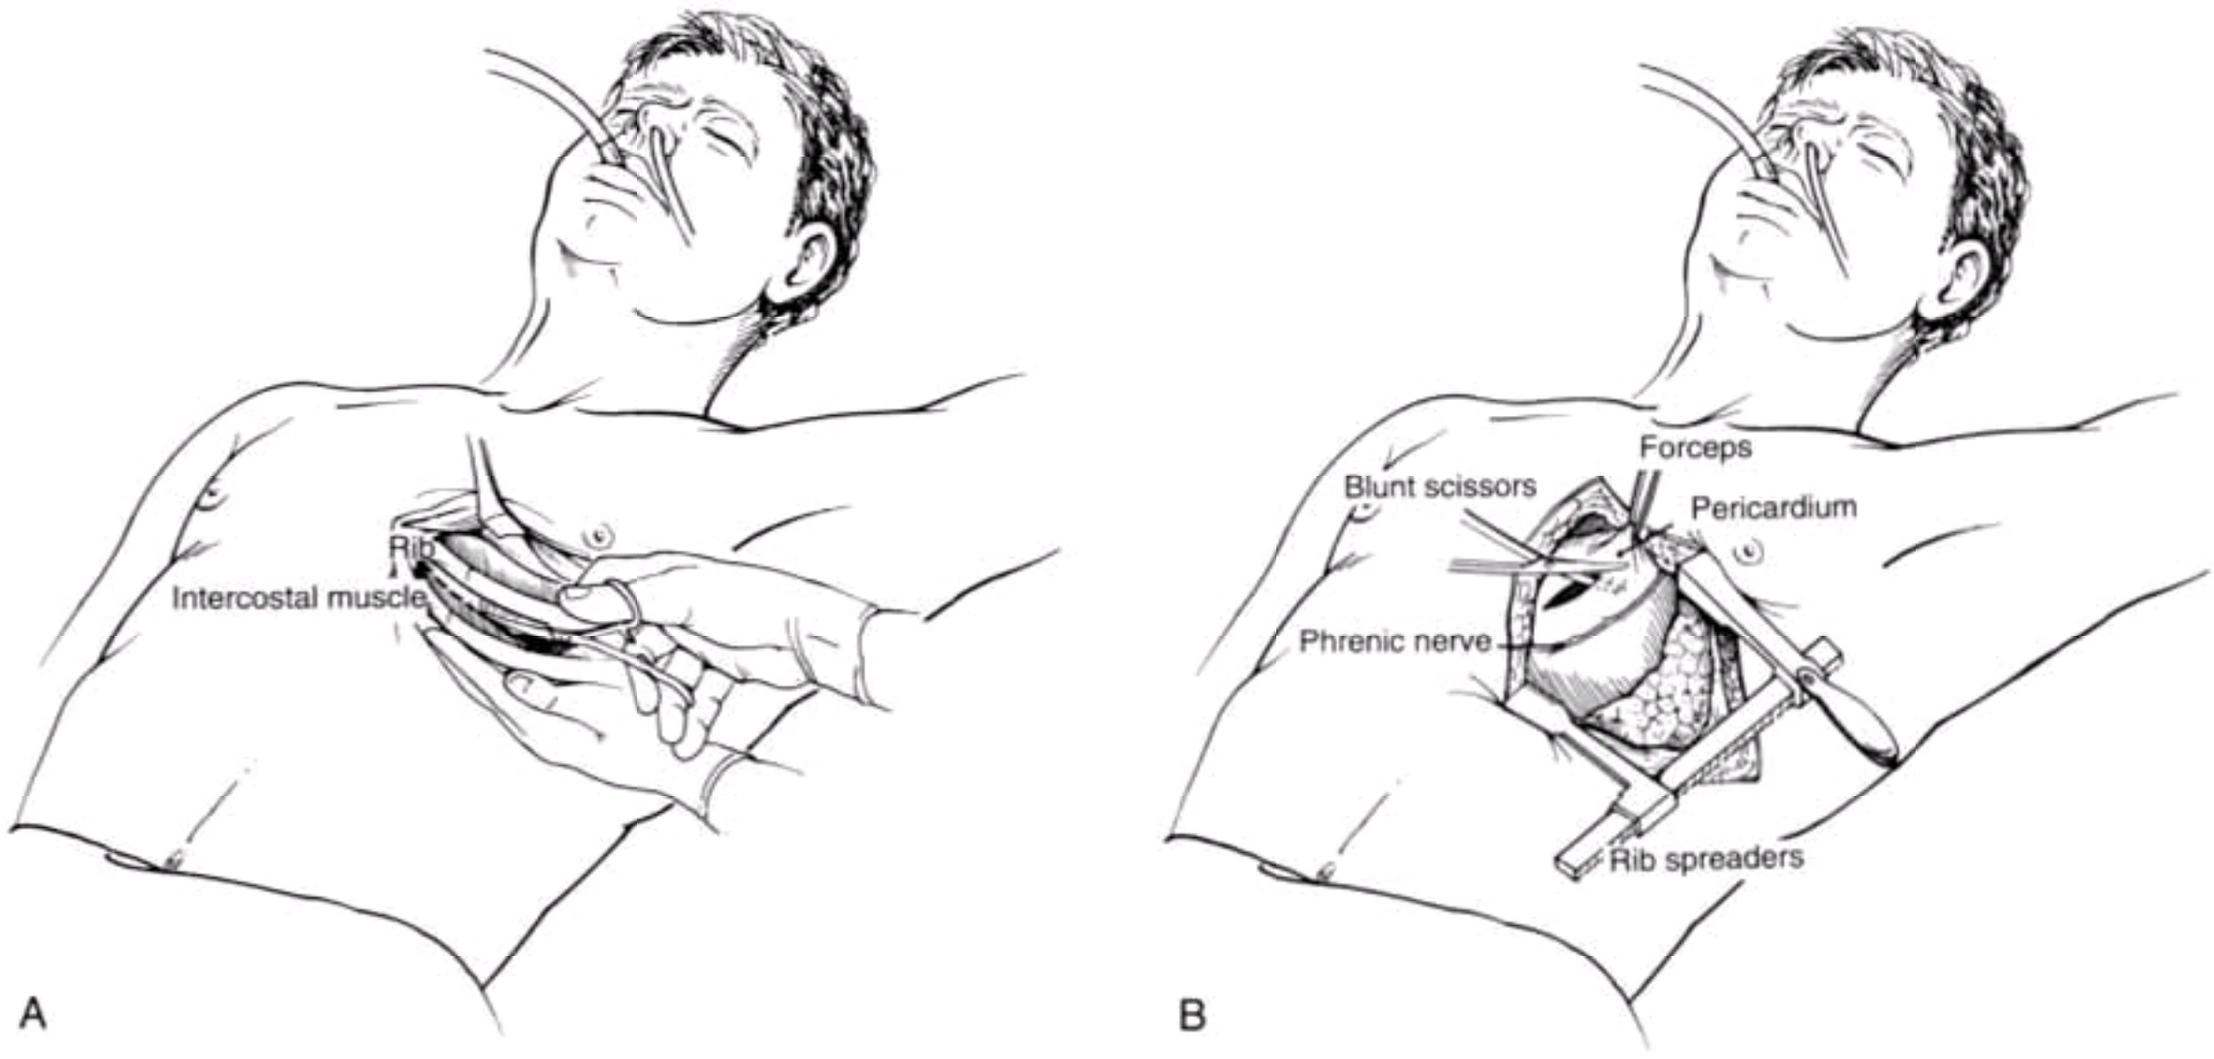

Figure 18-6 Two-handed method of cardiac massage. The ventricles are compressed toward the interventricular septum. Note how the hands flank the left anterior descending artery, which overlies the septum. Avoid using excessive finger *tip* pressure or lifting the heart, which slows ventricular filling by distorting the soft atrial caval junction.

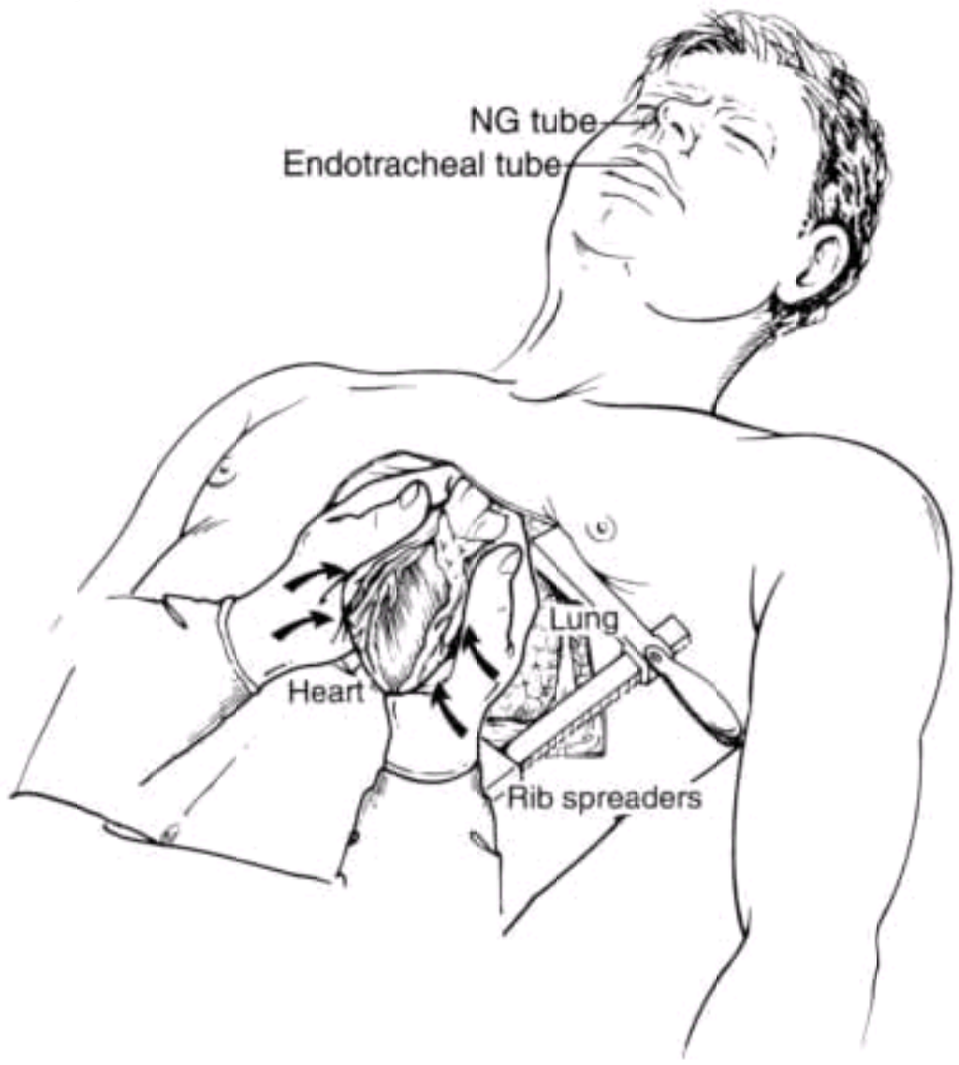

Figure 18-7 Technique of cardiac stapling to temporarily control hemorrhage. An assistant can approximate tissues with fingertip pressure or, as illustrated, two half-horizontal sutures can be used to approximate the wound edges and reduce bleeding. A skin stapler with wide (6 mm) staples is used to place staples 5 mm apart. This technique may be used for atrial and ventricular lacerations. Following stabilization of the patient's condition, the wound is revised in the operating room.

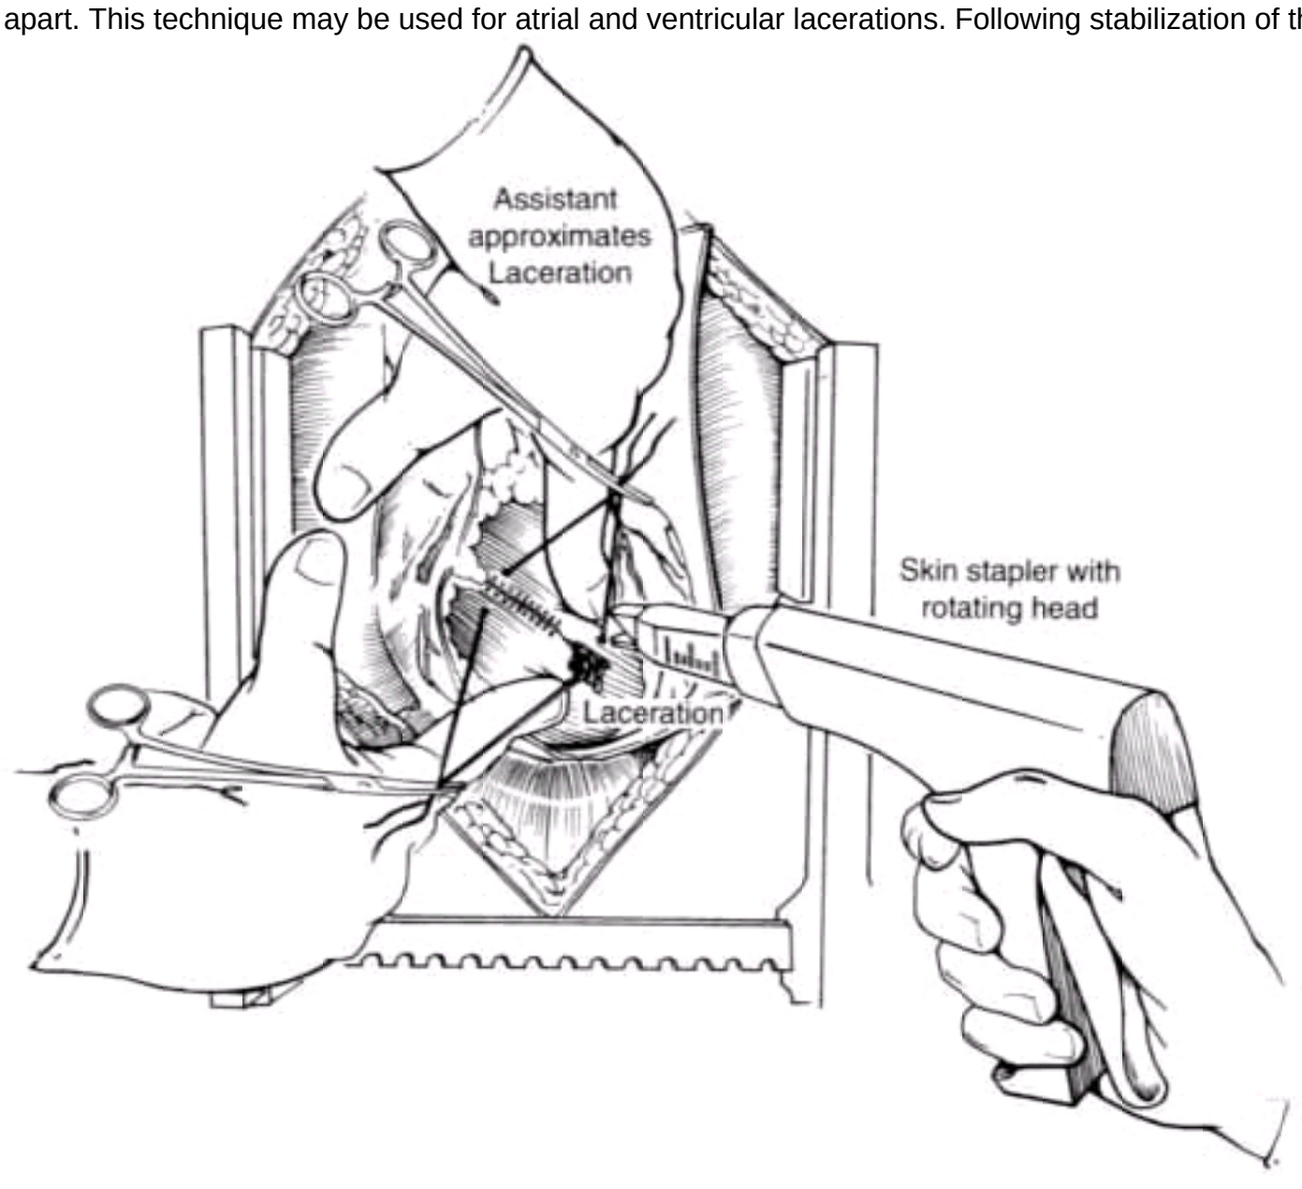

Figure 18-8 *A*, Technique of repair. Multiple horizontal mattress sutures are placed 6 mm from the wound edge before tying. The wound is closed just enough to stop the bleeding. Teflon pledgets are used for reinforcement. Closure without pledgets incurs the risk of sutures ripping through the contracting myocardium. Similarly, the use of simple vertical sutures should be discouraged because of the risk of suture dissection through the myocardium. *B,* For repairs near a coronary artery, care is taken to pass the suture under the artery. Note that rectangles of pericardial tissue may be substituted for ready made Teflon pledgets.

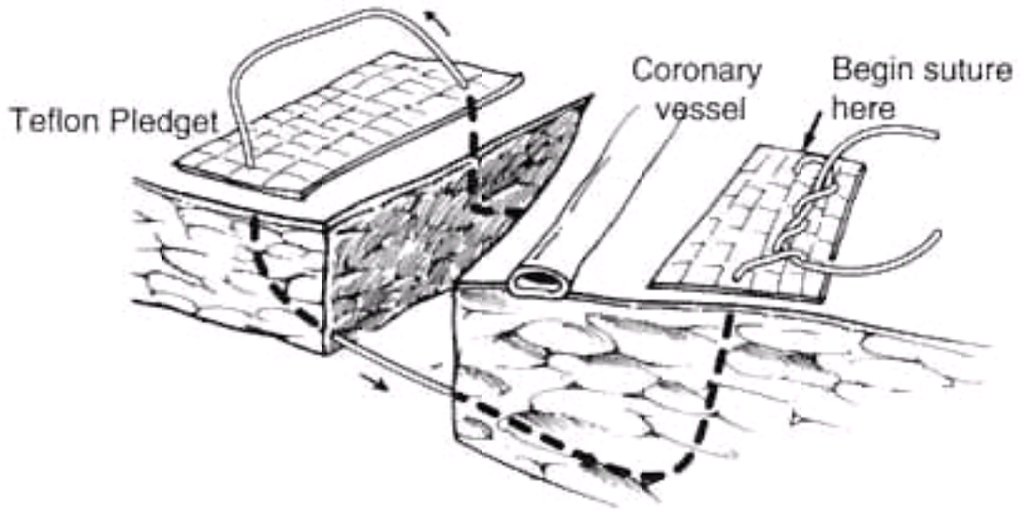

Figure 18-9 Hemorrhage control using two widely placed incomplete mattress sutures. An assistant then crosses the two "half-horizontal" sutures to bring the wound edges into apposition. By controlling the hemorrhage in this manner, the assistant's hands are outside of the operative field, fully exposing the wound edges. This facilitates a more orderly closure of the wound. Following repair of the wound, the sutures may either be removed or tied to each other.

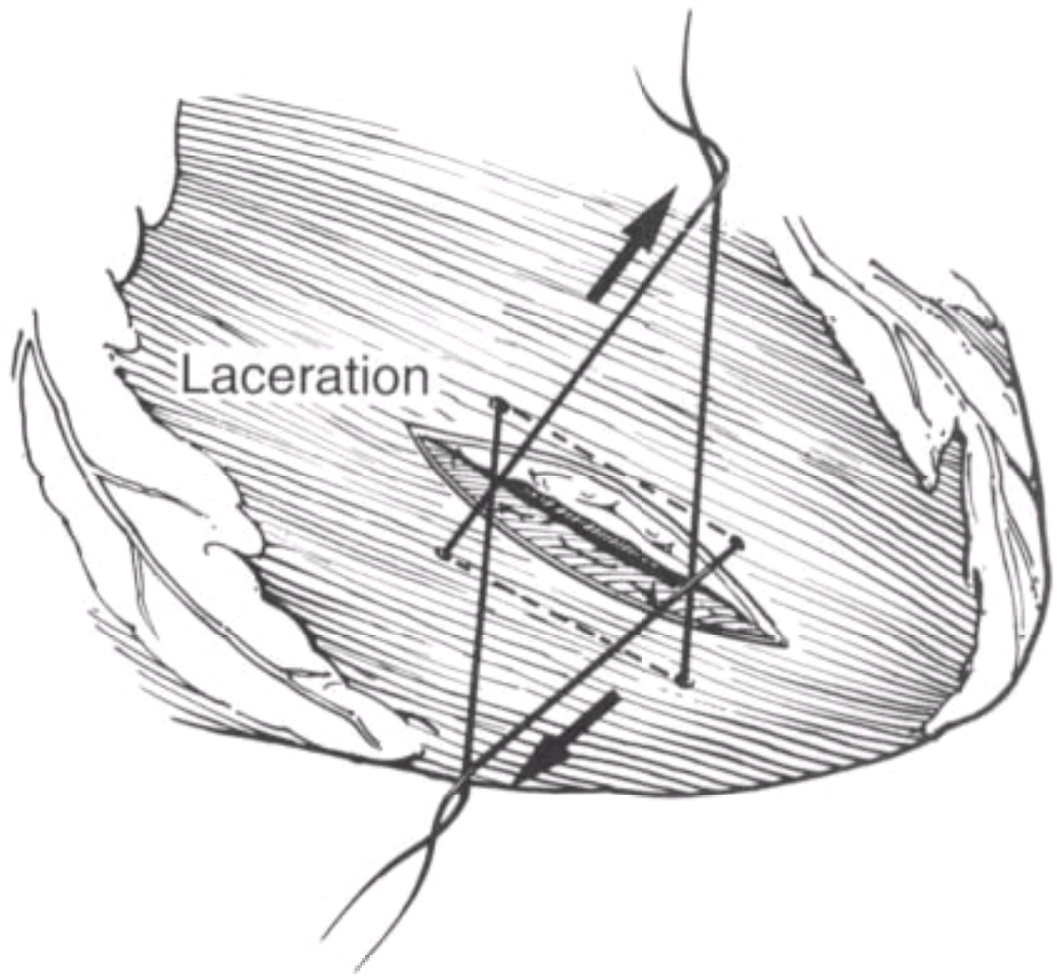

Figure 18-10 Sauerbruch maneuver: the *method of choice* for reducing heavy bleeding from cardiac wounds. Venous inflow occlusion is achieved by using the first and second or second and third fingers as a clamp.

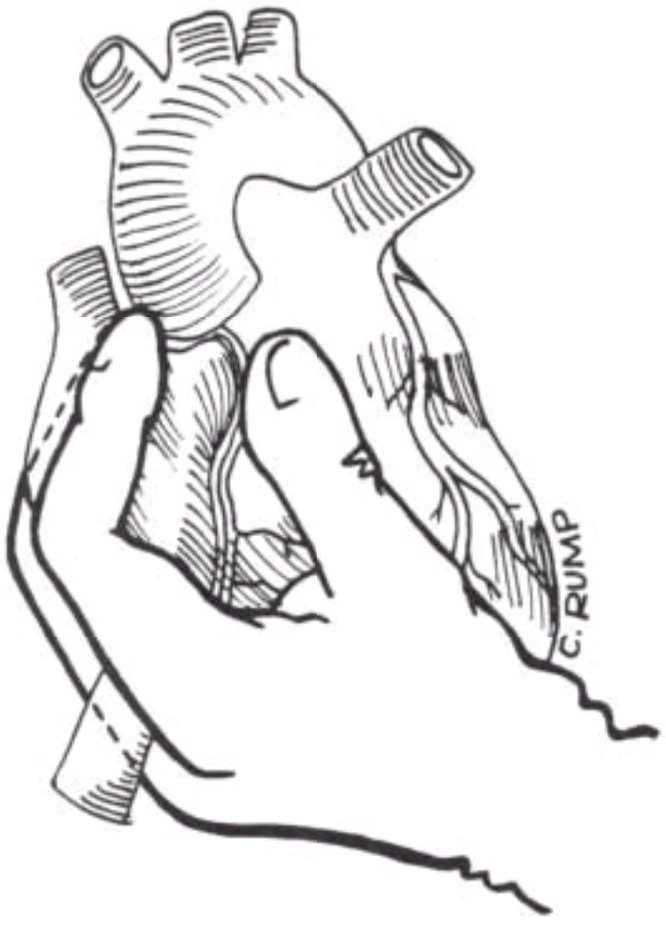

Figure 18-11 Serial illustration. Gentle traction on an inflated Foley catheter will control hemorrhage and allow easy repair. The balloon is inflated with saline, and care is taken to avoid rupturing the balloon with the suture needle. This technique is particularly useful with injuries of the inferior cavoatrial junction, with posterior wounds, and during cardiac massage. Volume loading can be obtained by infusion of blood or crystalloid solutions through the lumen of the catheter. Care should be taken to avoid an air embolus through the lumen of the catheter during placement.

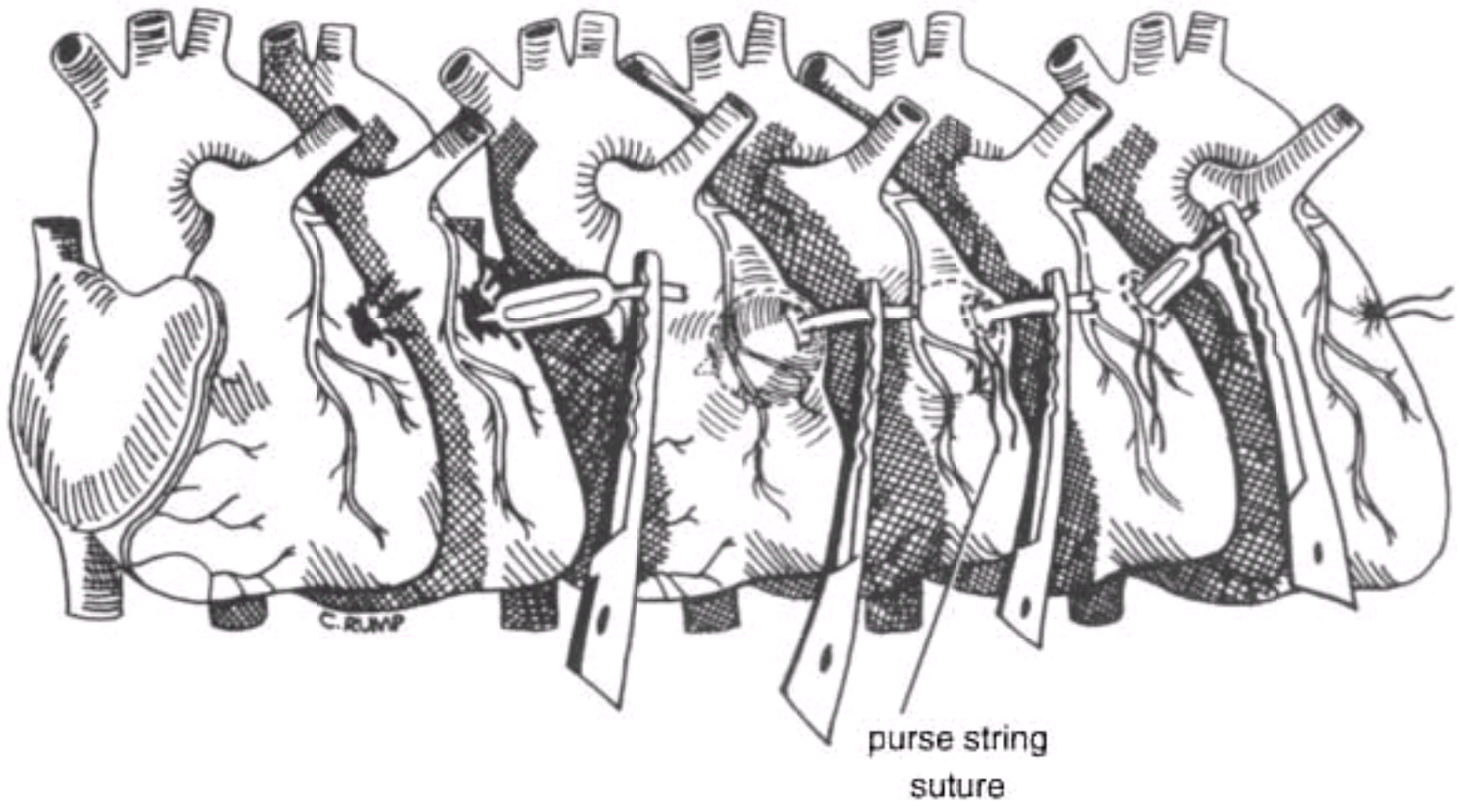

Figure 18-12 Technique for elective fibrillation: 20 J (watt-sec) is delivered through internal defibrillating paddles placed perpendicular to the epicardium. Coronary vessels should be avoided during paddle placement.

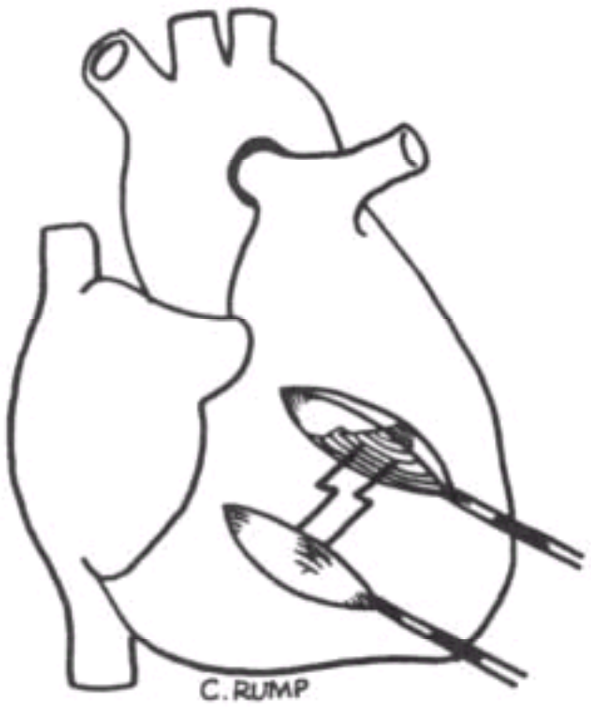

Figure 18-13 Use of a partial occluding clamp in different locations for control of bleeding and subsequent repair.

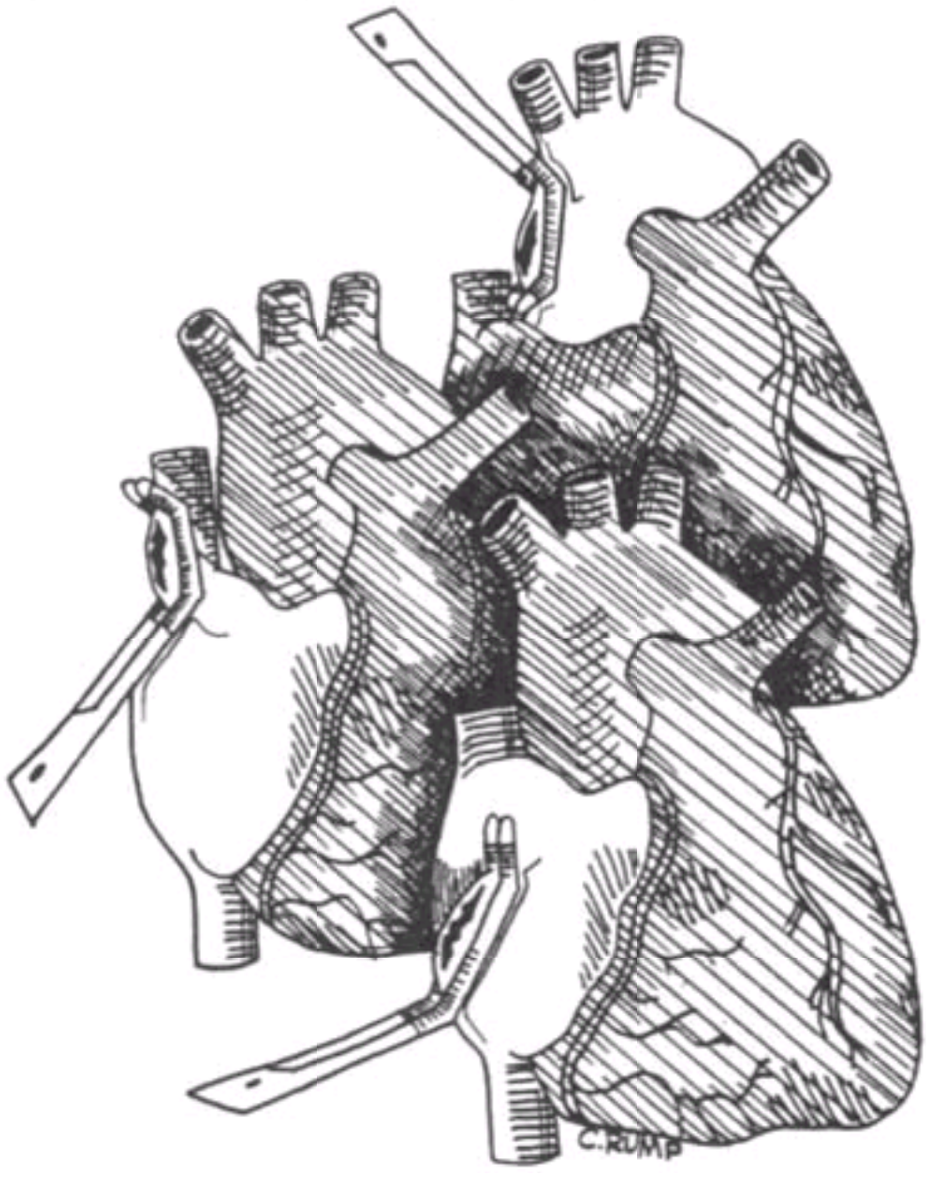

Figure 18-14 Wounds of the inferior cavoatrial junction are difficult to manage with simple vascular clamping. *A–D,* Use of a Foley catheter provides satisfactory control.

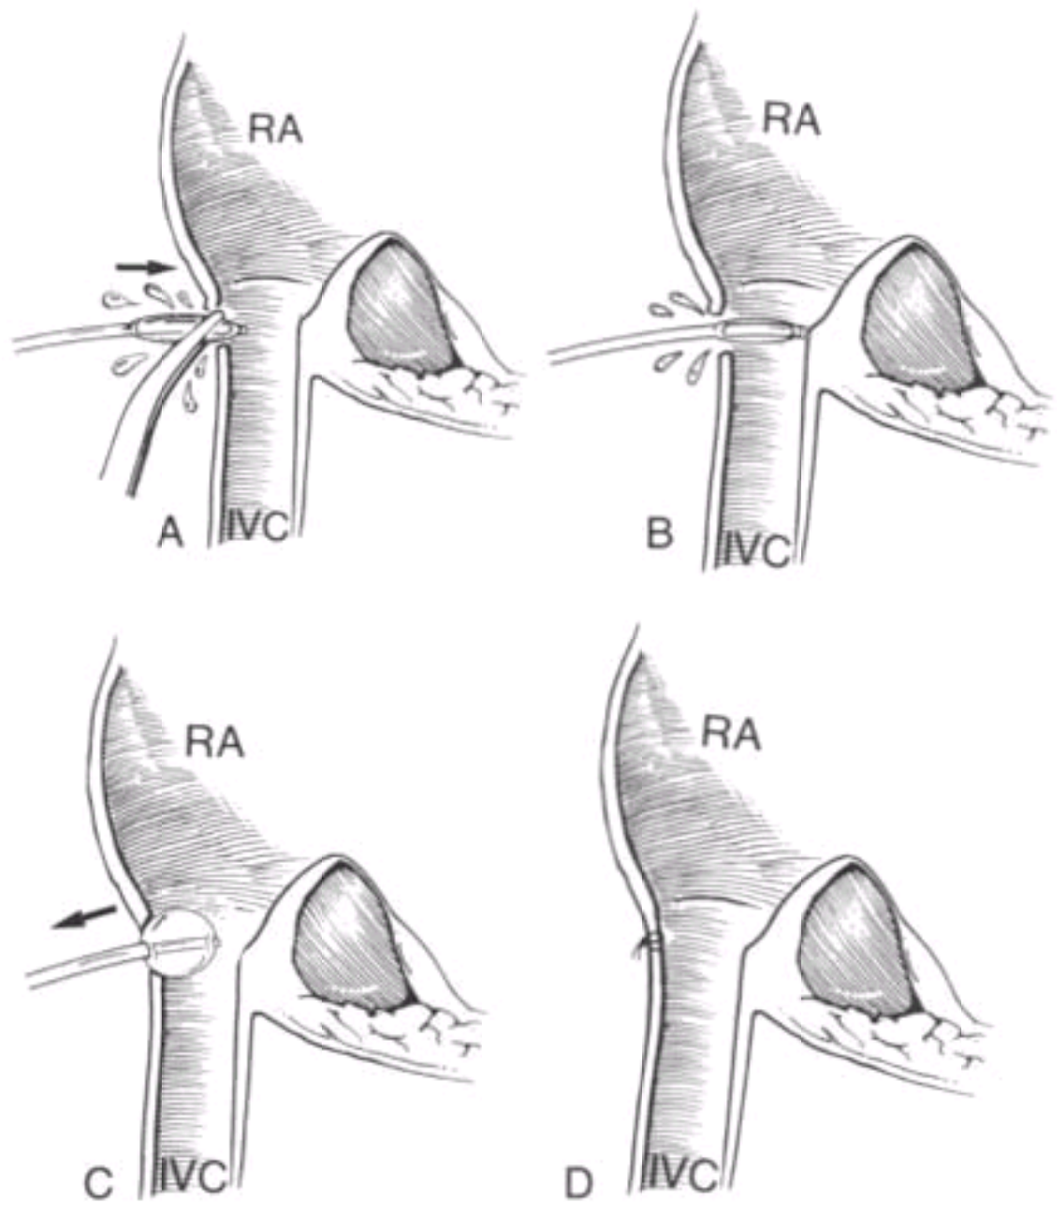

Figure 18-15 Cross-clamping for control of subclavian bleeding is difficult and time-consuming. Compression with laparotomy pads in the apical pleura from below and the supraclavicular fossa from above will control hemorrhage while the patient's condition is stabilized and the patient is transported to the operating room.

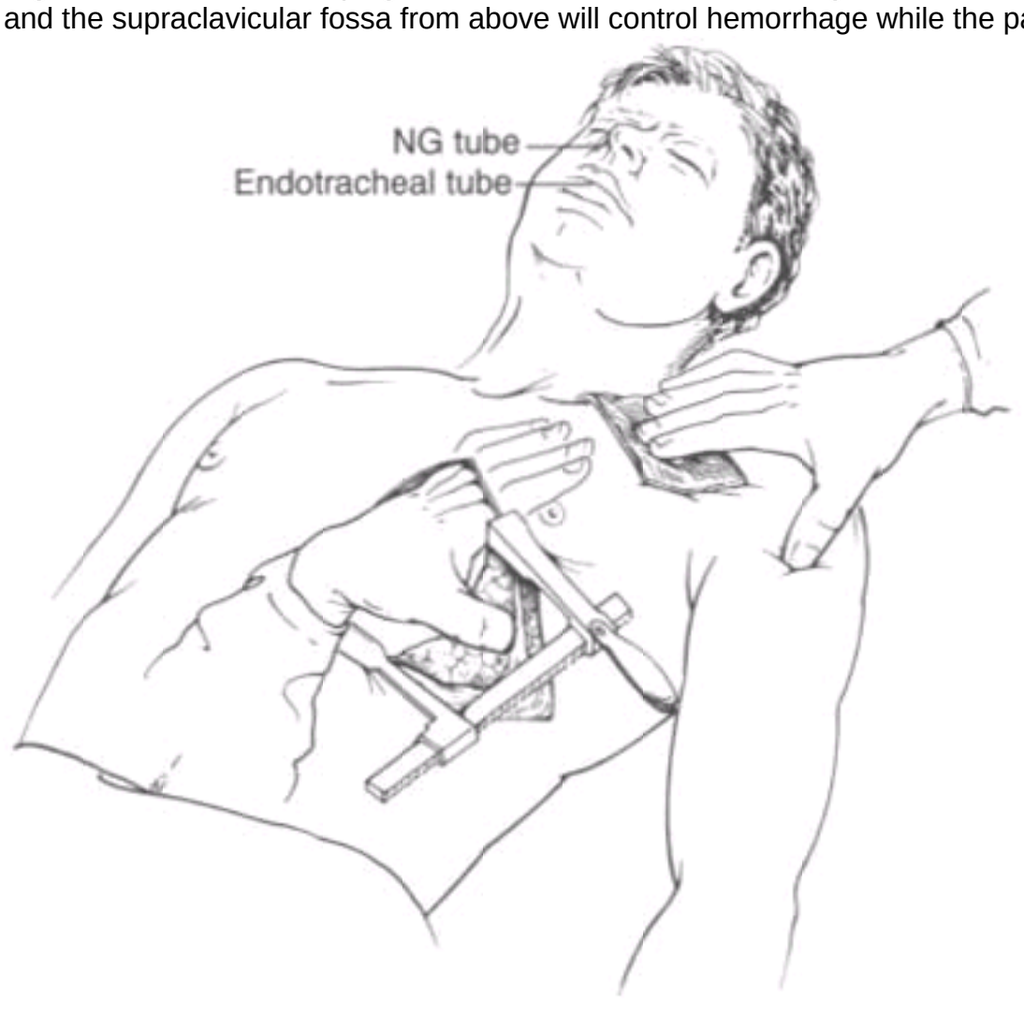

Figure 18-16 *A*, Modified umbilical cord clamp. *B,* Modified umbilical cord clamp securing a catheter in the right atrial appendage.

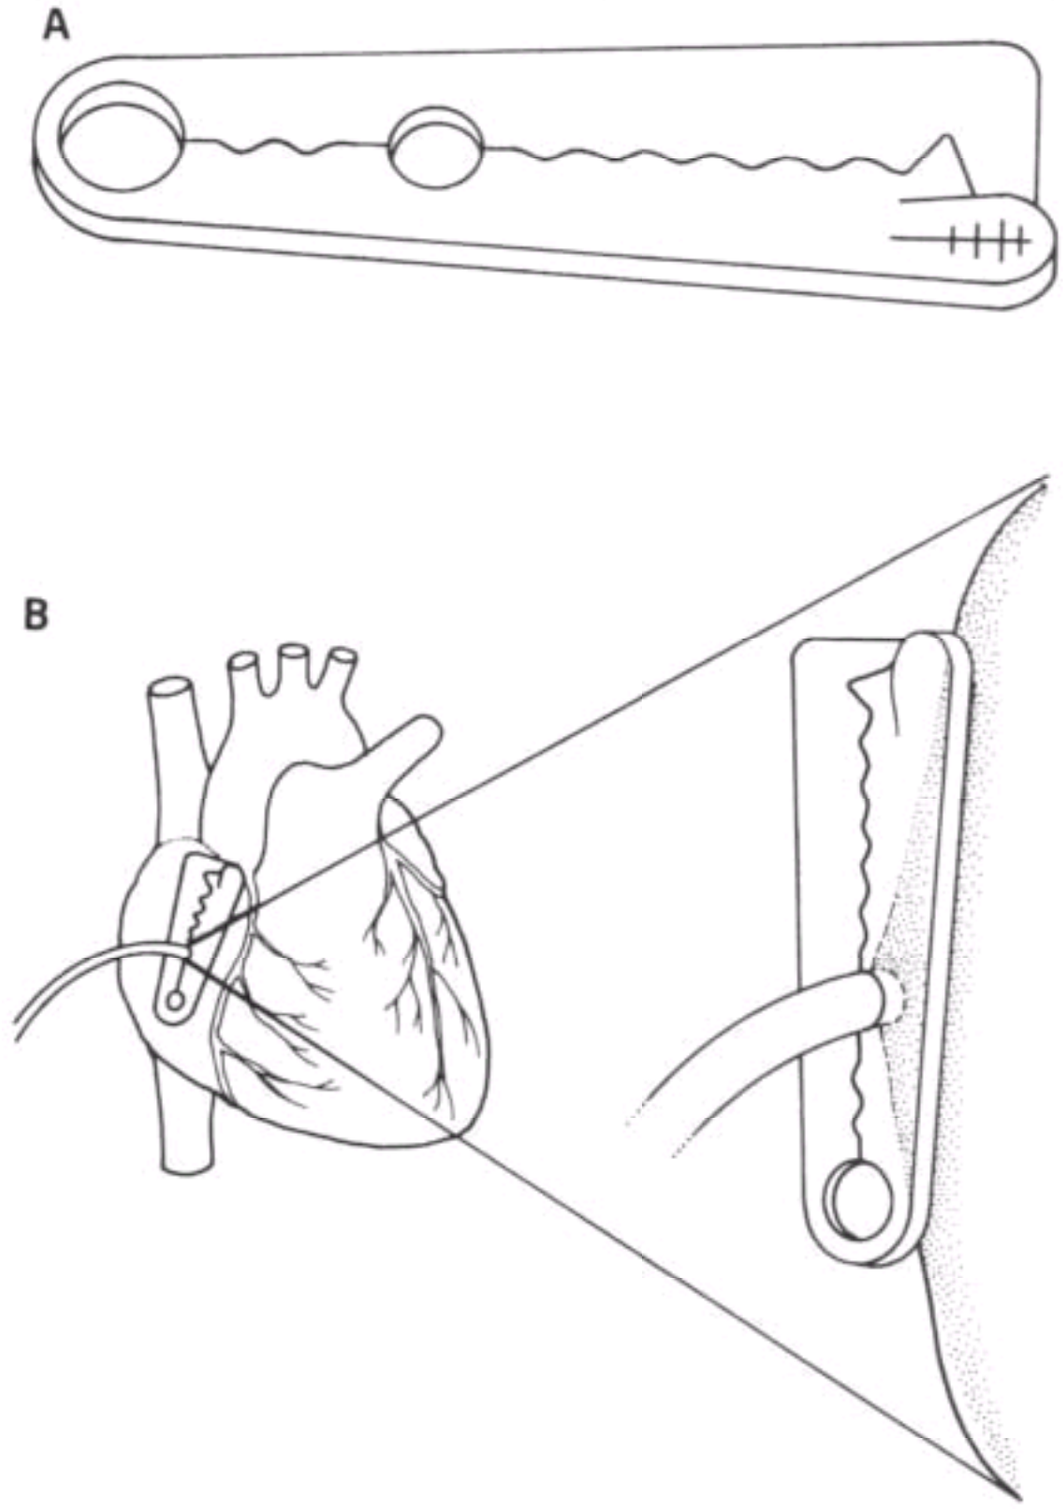

Figure 18-17 Manual cardiac massage and cross-clamping of the aorta to increase coronary and cerebral perfusion selectively.

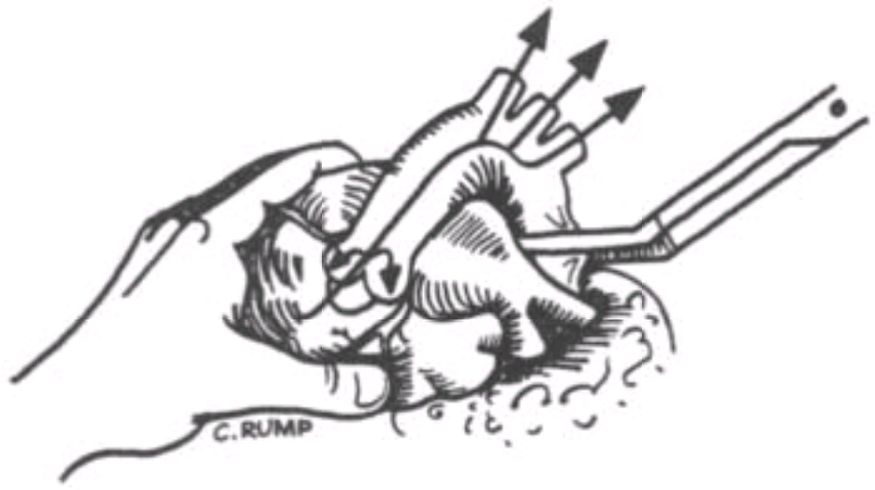

Figure 18-18 Traumatic rupture of the aorta. Three clamps are required for control. Back-bleeding will occur if fewer than three clamps are used.

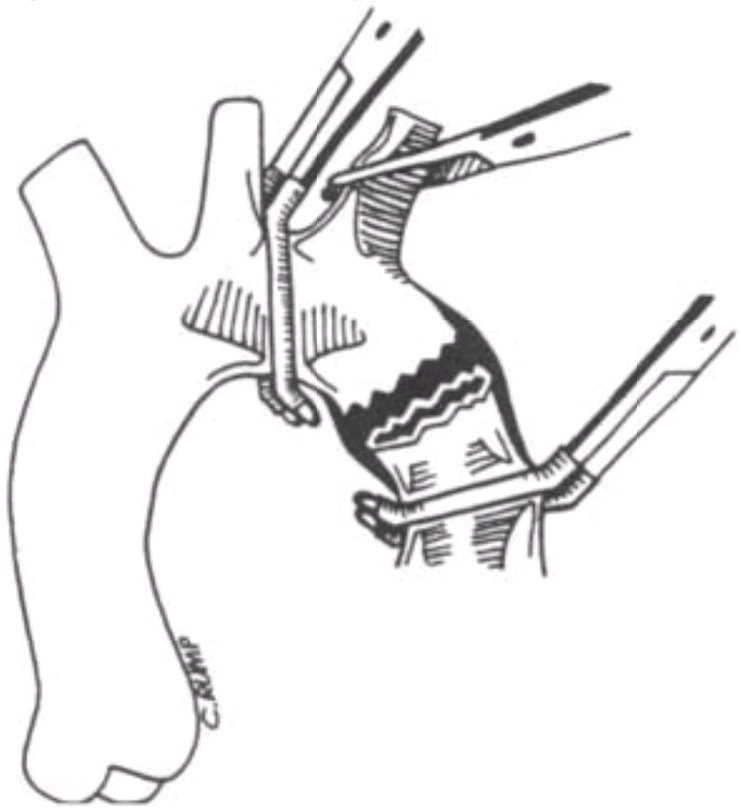

Figure 18-19 Adequate exposure of the descending aorta may require division of the inferior pulmonary ligament.

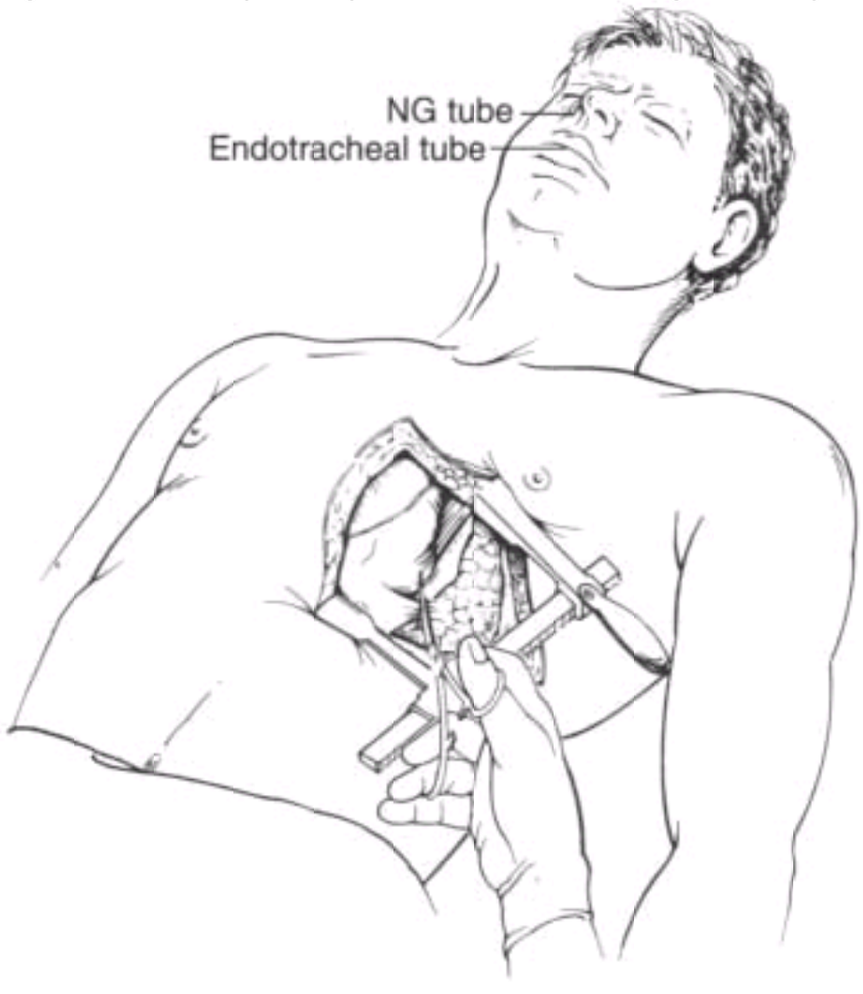

Figure 18-20 *A*, Identification of the aorta: in the posterior mediastinum the aorta lies directly anterior to the vertebral bodies. The esophagus is anterior and slightly medial to the aorta. In the lower thorax, both are covered on the anterolateral surface by mediastinal pleura, which must be dissected prior to isolating the aorta for cross-clamping. *B,* Aortic cross-clamping: Using blunt dissection, one spreads the pleura above and below the aorta. The vessel should be fully mobilized and clearly separated from the esophagus before clamping. It may be difficult to differentiate the aorta from the esophagus. The aorta is the more posterior structure and is in contact with the vertebral bodies. Passage of a nasogastric tube from above will often aid the rapid identification of the esophagus.

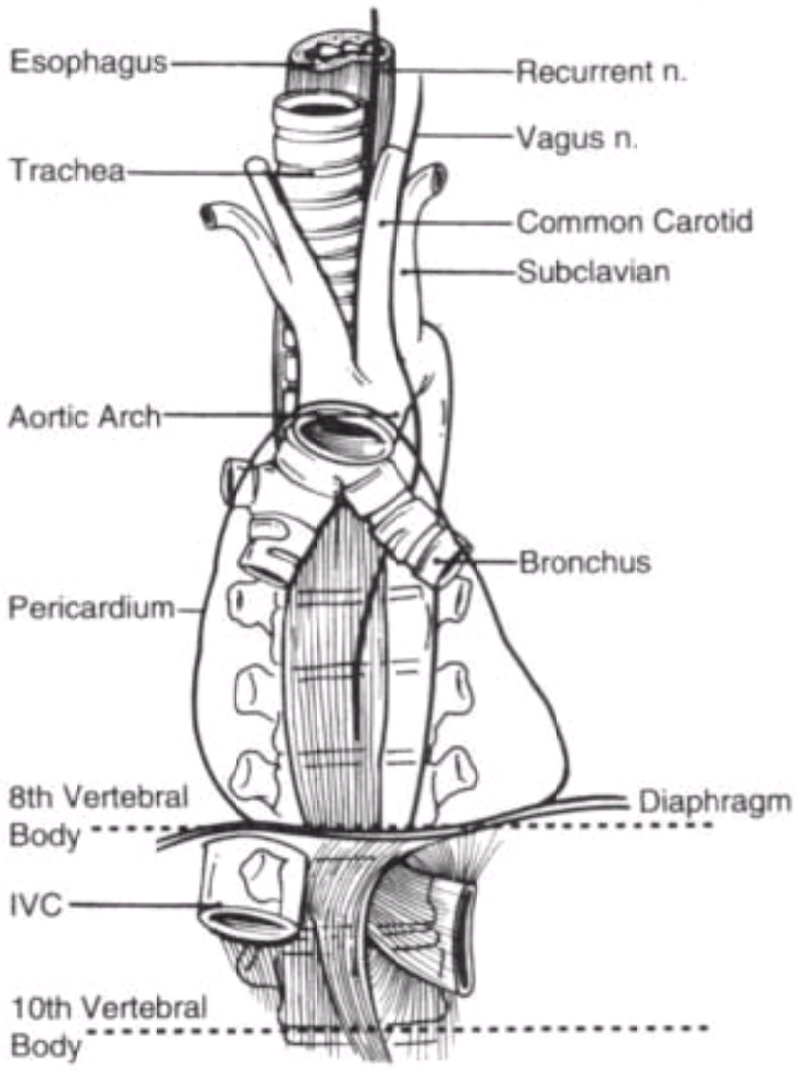

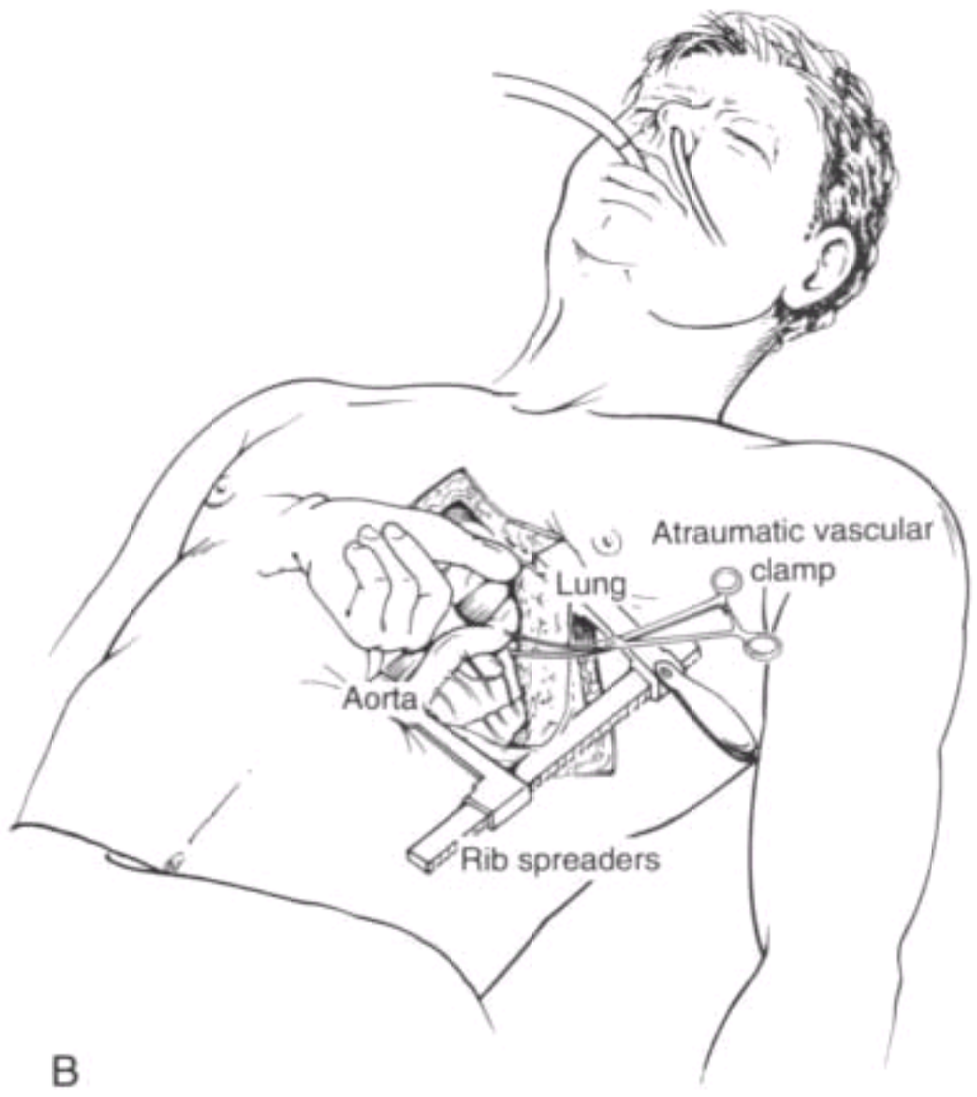

Figure 18-21 The use of a Conn aortic compressor is the method of choice for aortic occlusion because it is fast, does not interfere with the operative field, and is associated with minimal risk of injury. Alternatively, the more awkward technique of direct digital occlusion can be used. *(Courtesy of Pilling Company, Ft. Washington, PA.)*

Figure 19-1 Acceptable sites for heel stick puncture illustrated by shaded areas. *(Adapted from the Textbook of Pediatric Emergency Procedures; Henretig FM, King C [eds]. Philadelphia, Williams & Wilkins, 1997.)*

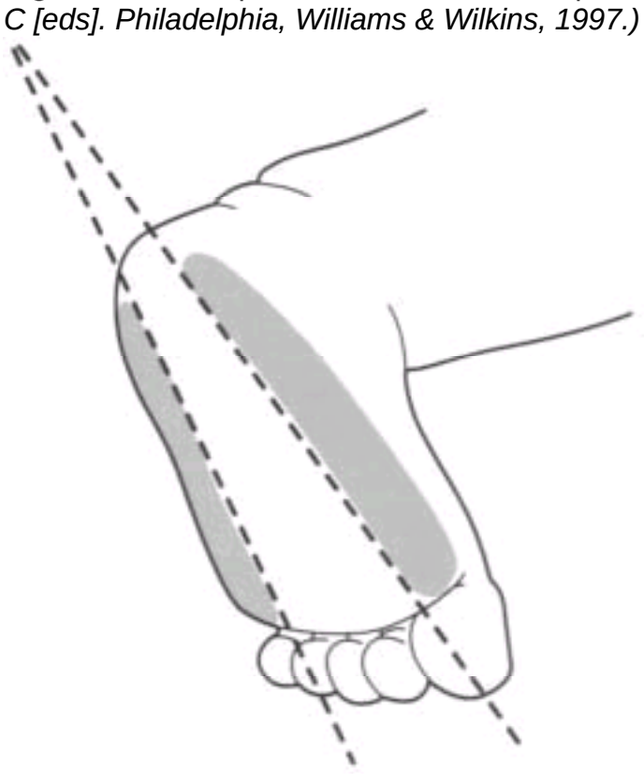

Figure 19-2 *A*, The heel stick is performed on the lateral or medial aspect of the heel. *B*, The collector end of the Microtainer is touched to the drop of blood, and blood is allowed to flow down the wall of the tube to the bottom; or *C*, a heparinized capillary tube is placed in the drop of blood, and the proximal end of the inverted tube is allowed to fill by capillary action. *D*, The blood is maintained in the capillary tube using the index finger to maintain capillary tension on the end of the tube. *E*, When using a microtainer tube, the Microtainer is capped. *F*, when using a capillary tube, the ends are capped or (*G*) sealed with wax or clay. Avoid squeezing the foot, and keep the proximal end of the Microtainer below the puncture site. *(Adapted from the Textbook of Pediatric Emergency Procedures; Henretig FM, King C [eds]. Philadelphia, Williams & Wilkins, 1997.)*

Figure 19-3 Venous access sites in the neonate and young infant. If venous access is unavailable, arterial blood may be used for most laboratory tests, including blood cultures.

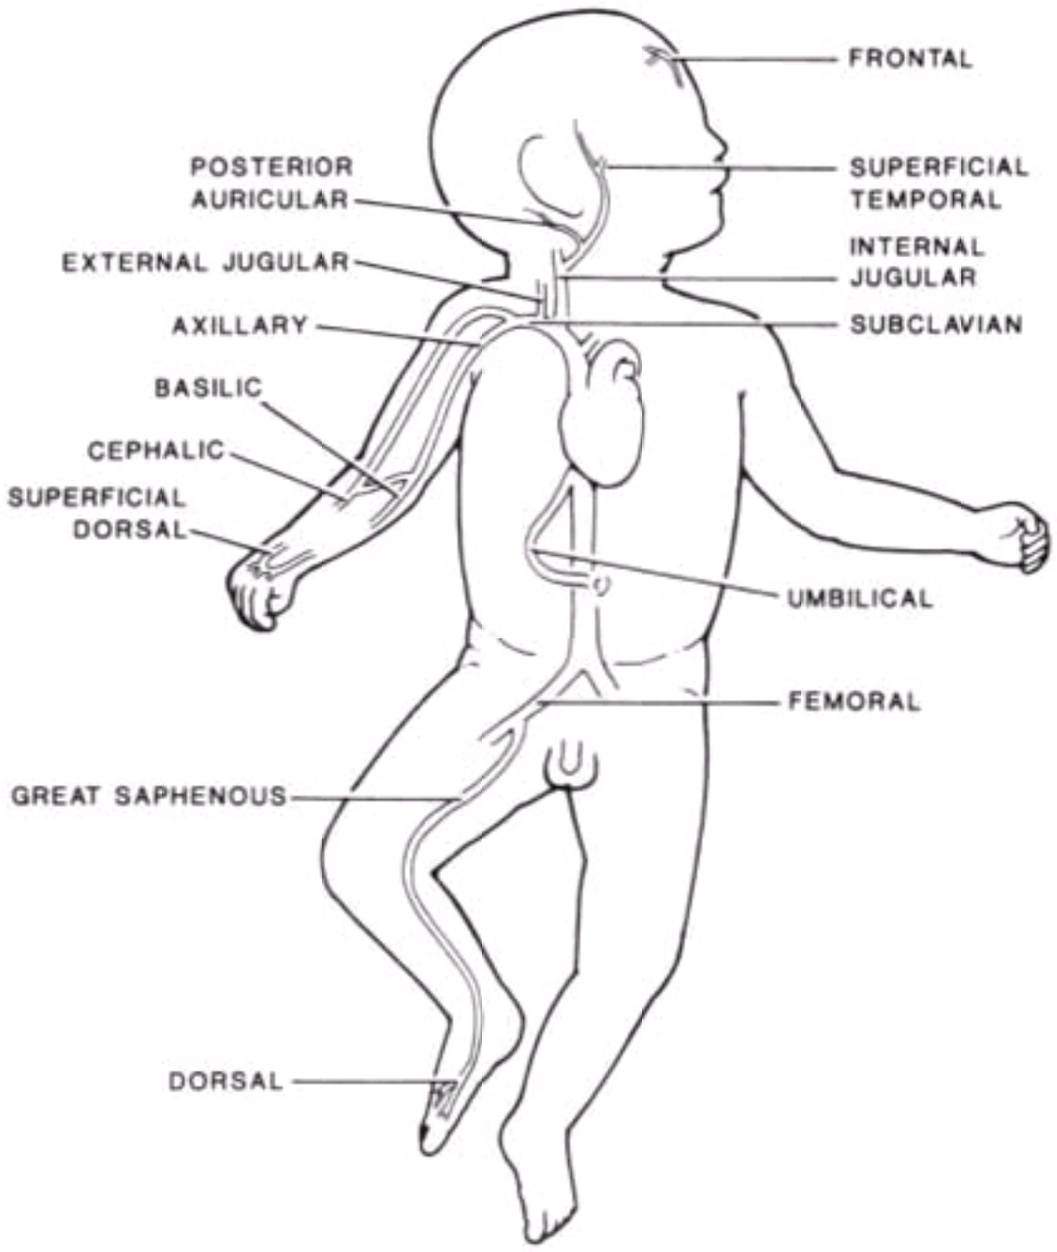

Figure 19-4 *A*, Technique for obtaining blood by antecubital venipuncture with a butterfly needle and a syringe. Once blood is obtained, the butterfly needle may serve as an infusion site. Note that this procedure often requires two persons to carry it out—one to hold the arm and insert the needle and the other to aspirate the blood. *B*, As an alternative to a syringe, a Vacutainer system may be used to apply suction. The Vacutainer needle punctures the sealed end of the butterfly set. Use of this method helps to prevent the premature clotting of blood that may occur if there is a delay in filling the collection tubes.

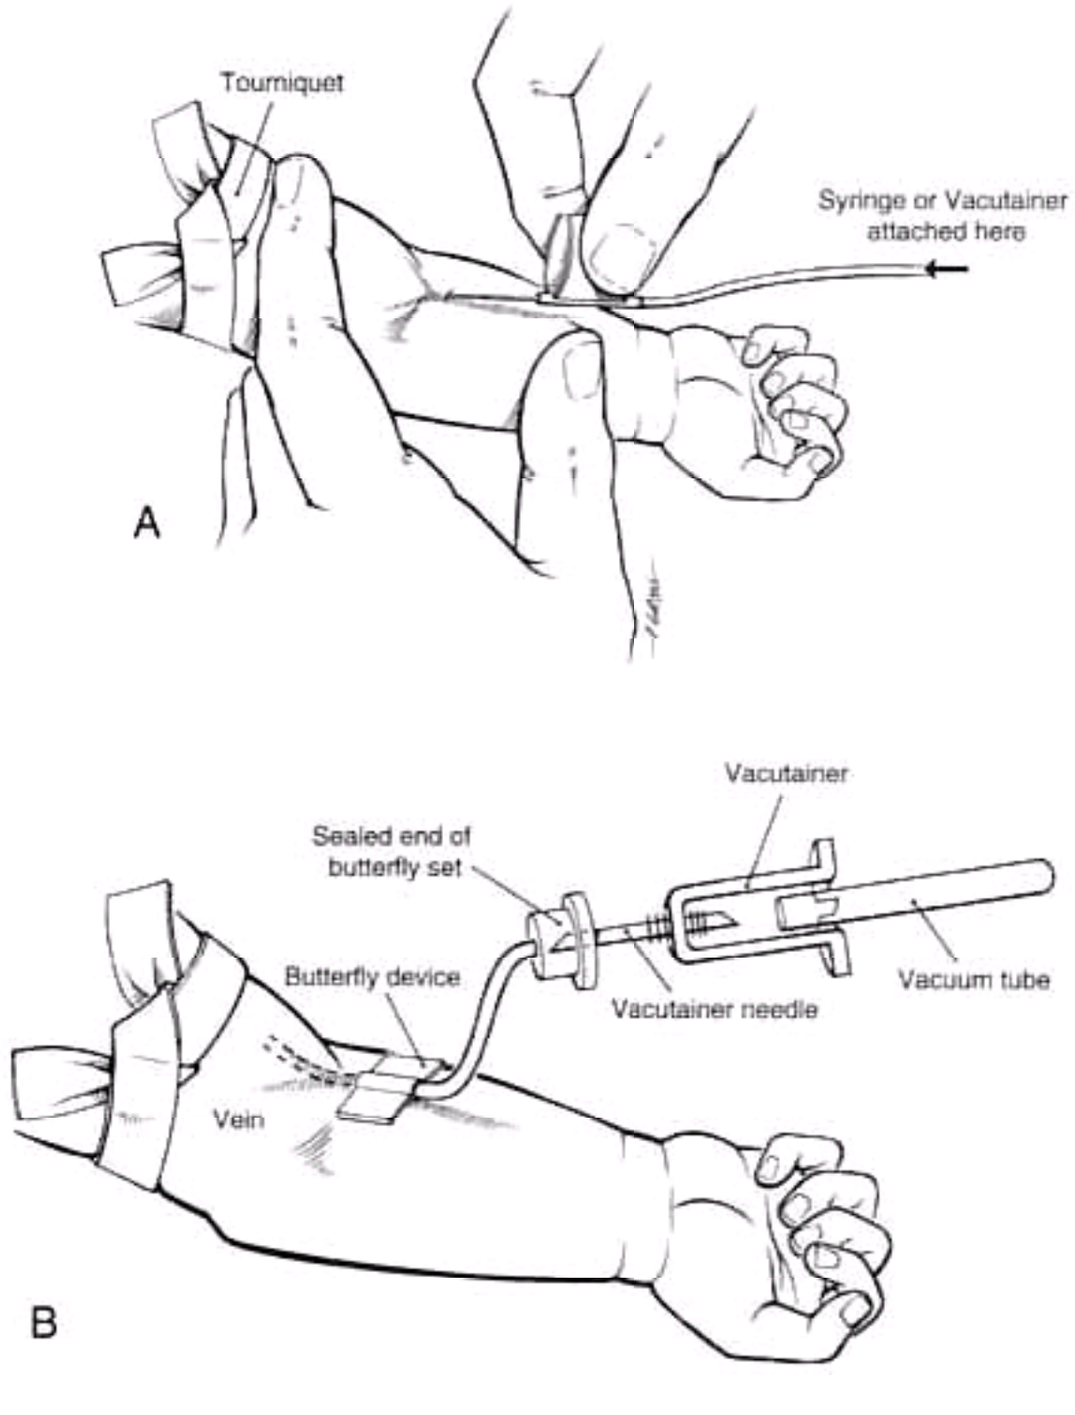

Figure 19-5 External jugular venipuncture. A syringe or a butterfly needle may be used. Venous distention is aided when an assistant's finger occludes the vein, or when the infant cries. The neck is extended, either over the side of the bed or by placing a rolled towel under the shoulders. This procedure requires two persons. Gloves should be worn.

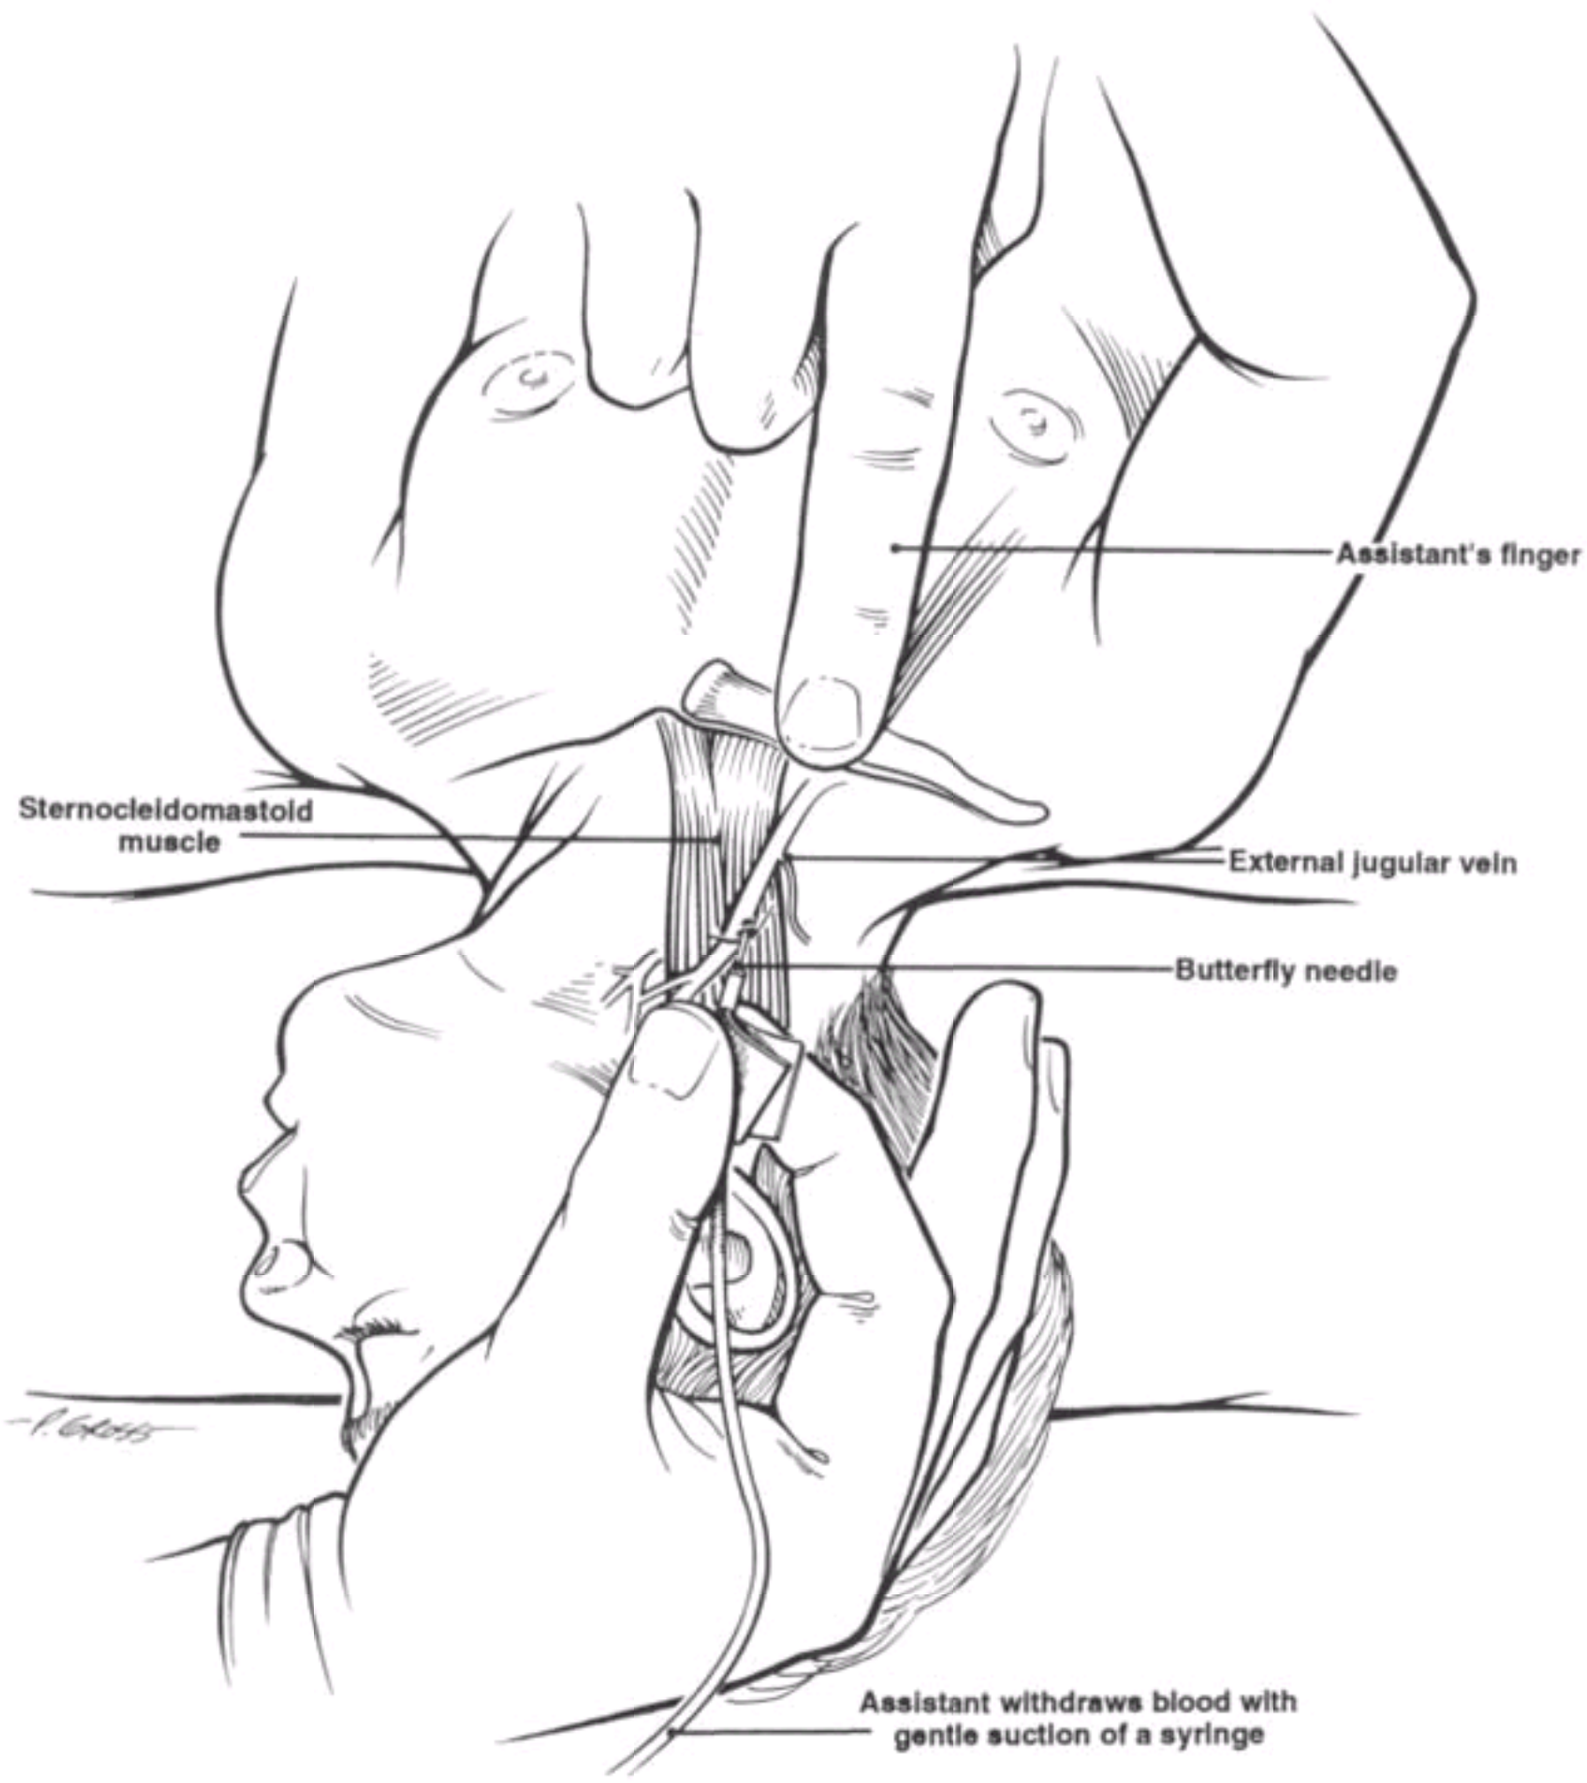

Figure 19-7 Anatomy of the volar surface of the wrist and the palm. The radial artery is preferred for sampling procedures.

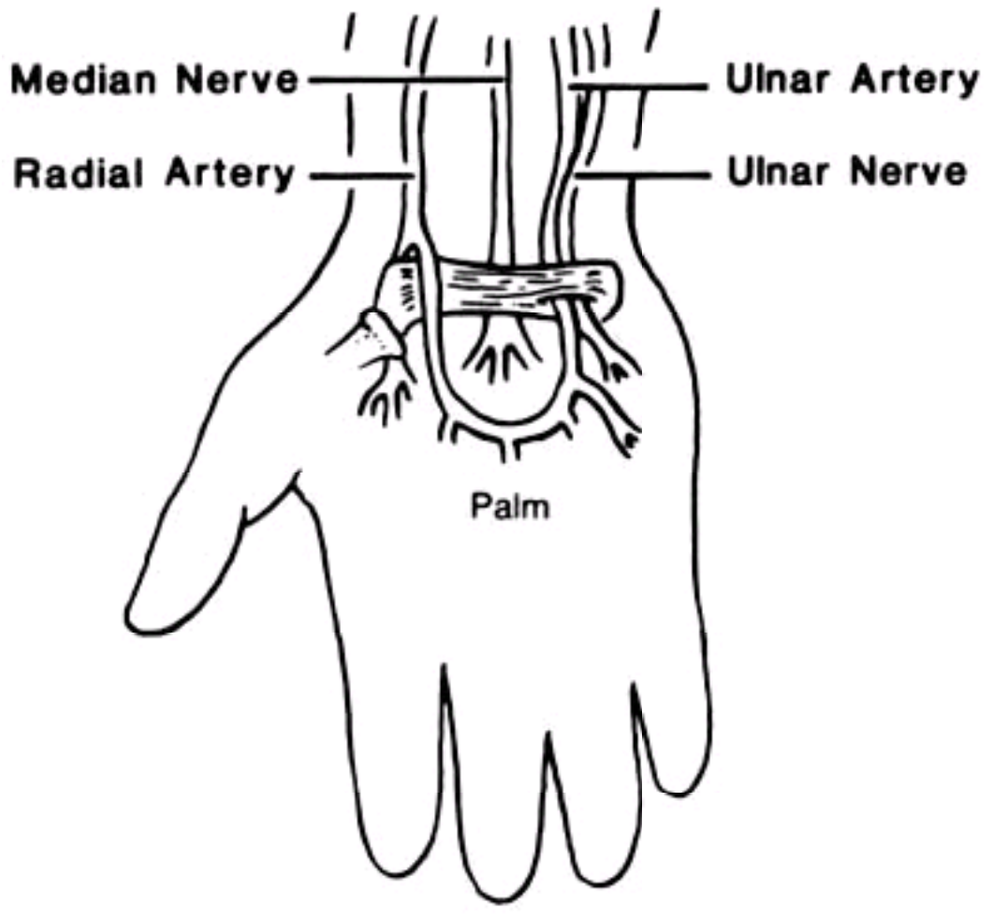

Figure 19-8 For arterial blood sampling, the needle should be inserted under the skin at a 30° to 45° angle. A butterfly needle and syringe are used if larger volumes of blood are required. The wrist is held dorsiflexed by the nondominant hand.

Figure 19-9 Resistance met during passage of the blood gas needle usually indicates contact with bone. The needle should be withdrawn slowly. If the needle has traversed both walls of the artery, blood will be obtained as the needle is slowly withdrawn into the arterial lumen.

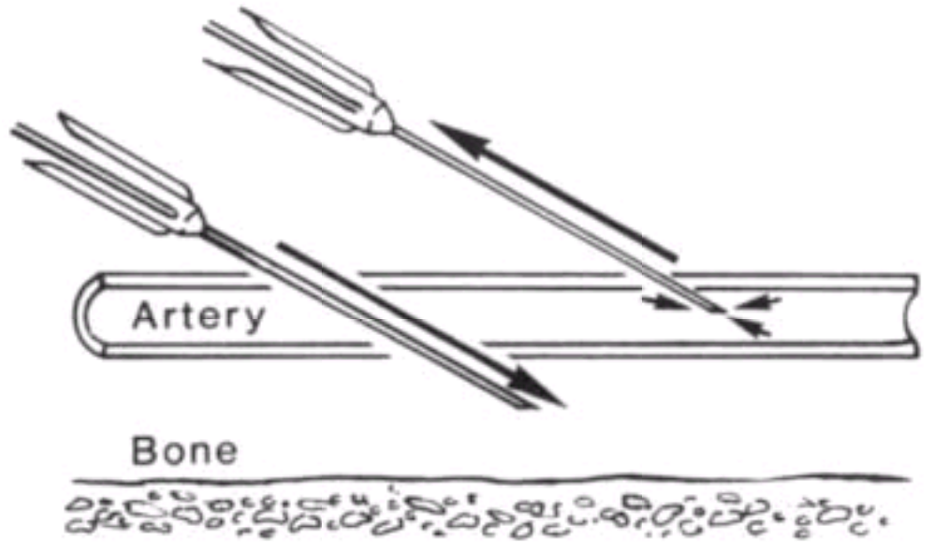

Figure 19-10 Technique for peripheral venous catheterization. *A*, The catheter is directed at a 10° to 20° angle toward the insertion site and advanced until blood return is seen in the catheter and hub. The stylet is removed, and the T-extension tubing is attached. *B*, Taping technique for butterfly and intravascular catheters using a crisscross pattern. *C*, Hand and forearm secured to an arm board. *D*, Covering with the plastic wrapper from the T-extension tubing for protection.

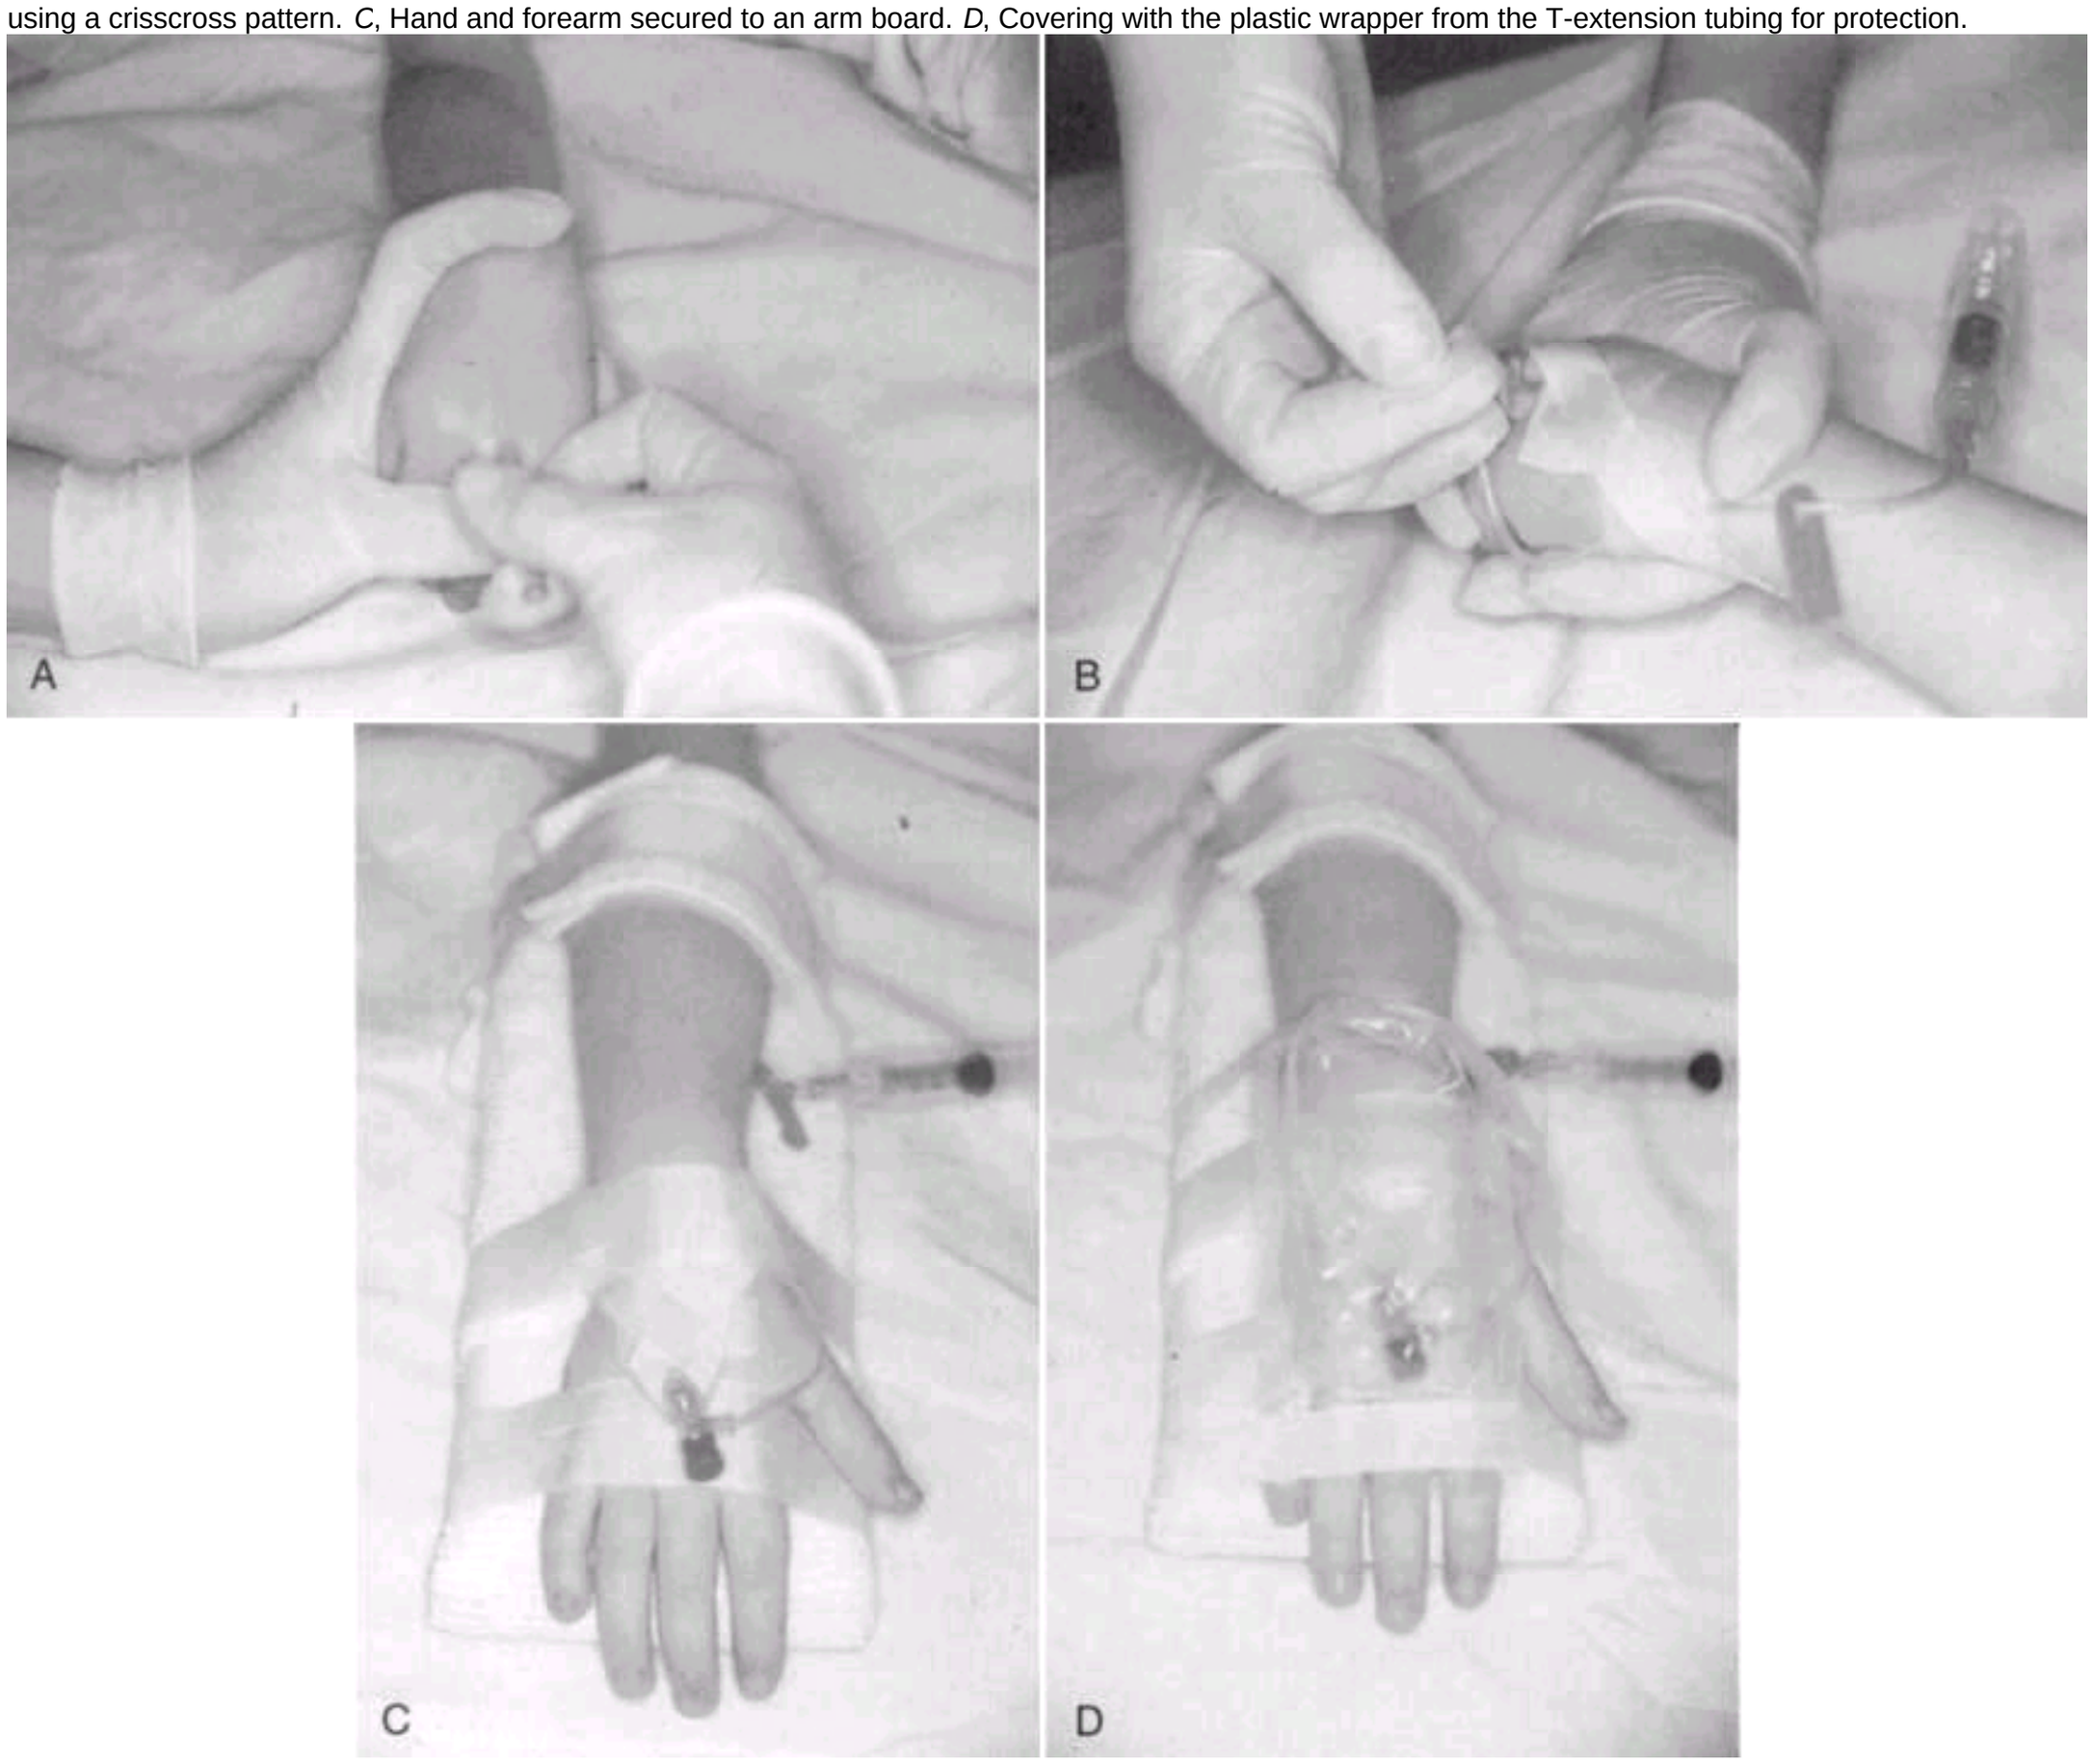

Figure 19-11 Using a rubber band as a tourniquet to distend the scalp veins, the needle is introduced approximately 0.5 cm distal to the anticipated site of the vessel puncture. Gloves should be worn.

Figure 19-12 Protecting the intravenous line with a plastic medicine cup.

Figure 19-13a Venous cutdown (saphenous vein). *A*, Immobilization of the ankle and the site of skin incision. *B*, A curved hemostat scoops up the vein. The point of the hemostat should be kept against the bone. *C*, The vein is dissected free. *D*, With a proximal and distal tie to stabilize the vein and control bleeding, an incision is made in the upper one third of the vein. *E* and *F*, The infusion catheter is threaded into the vein lumen and advanced.

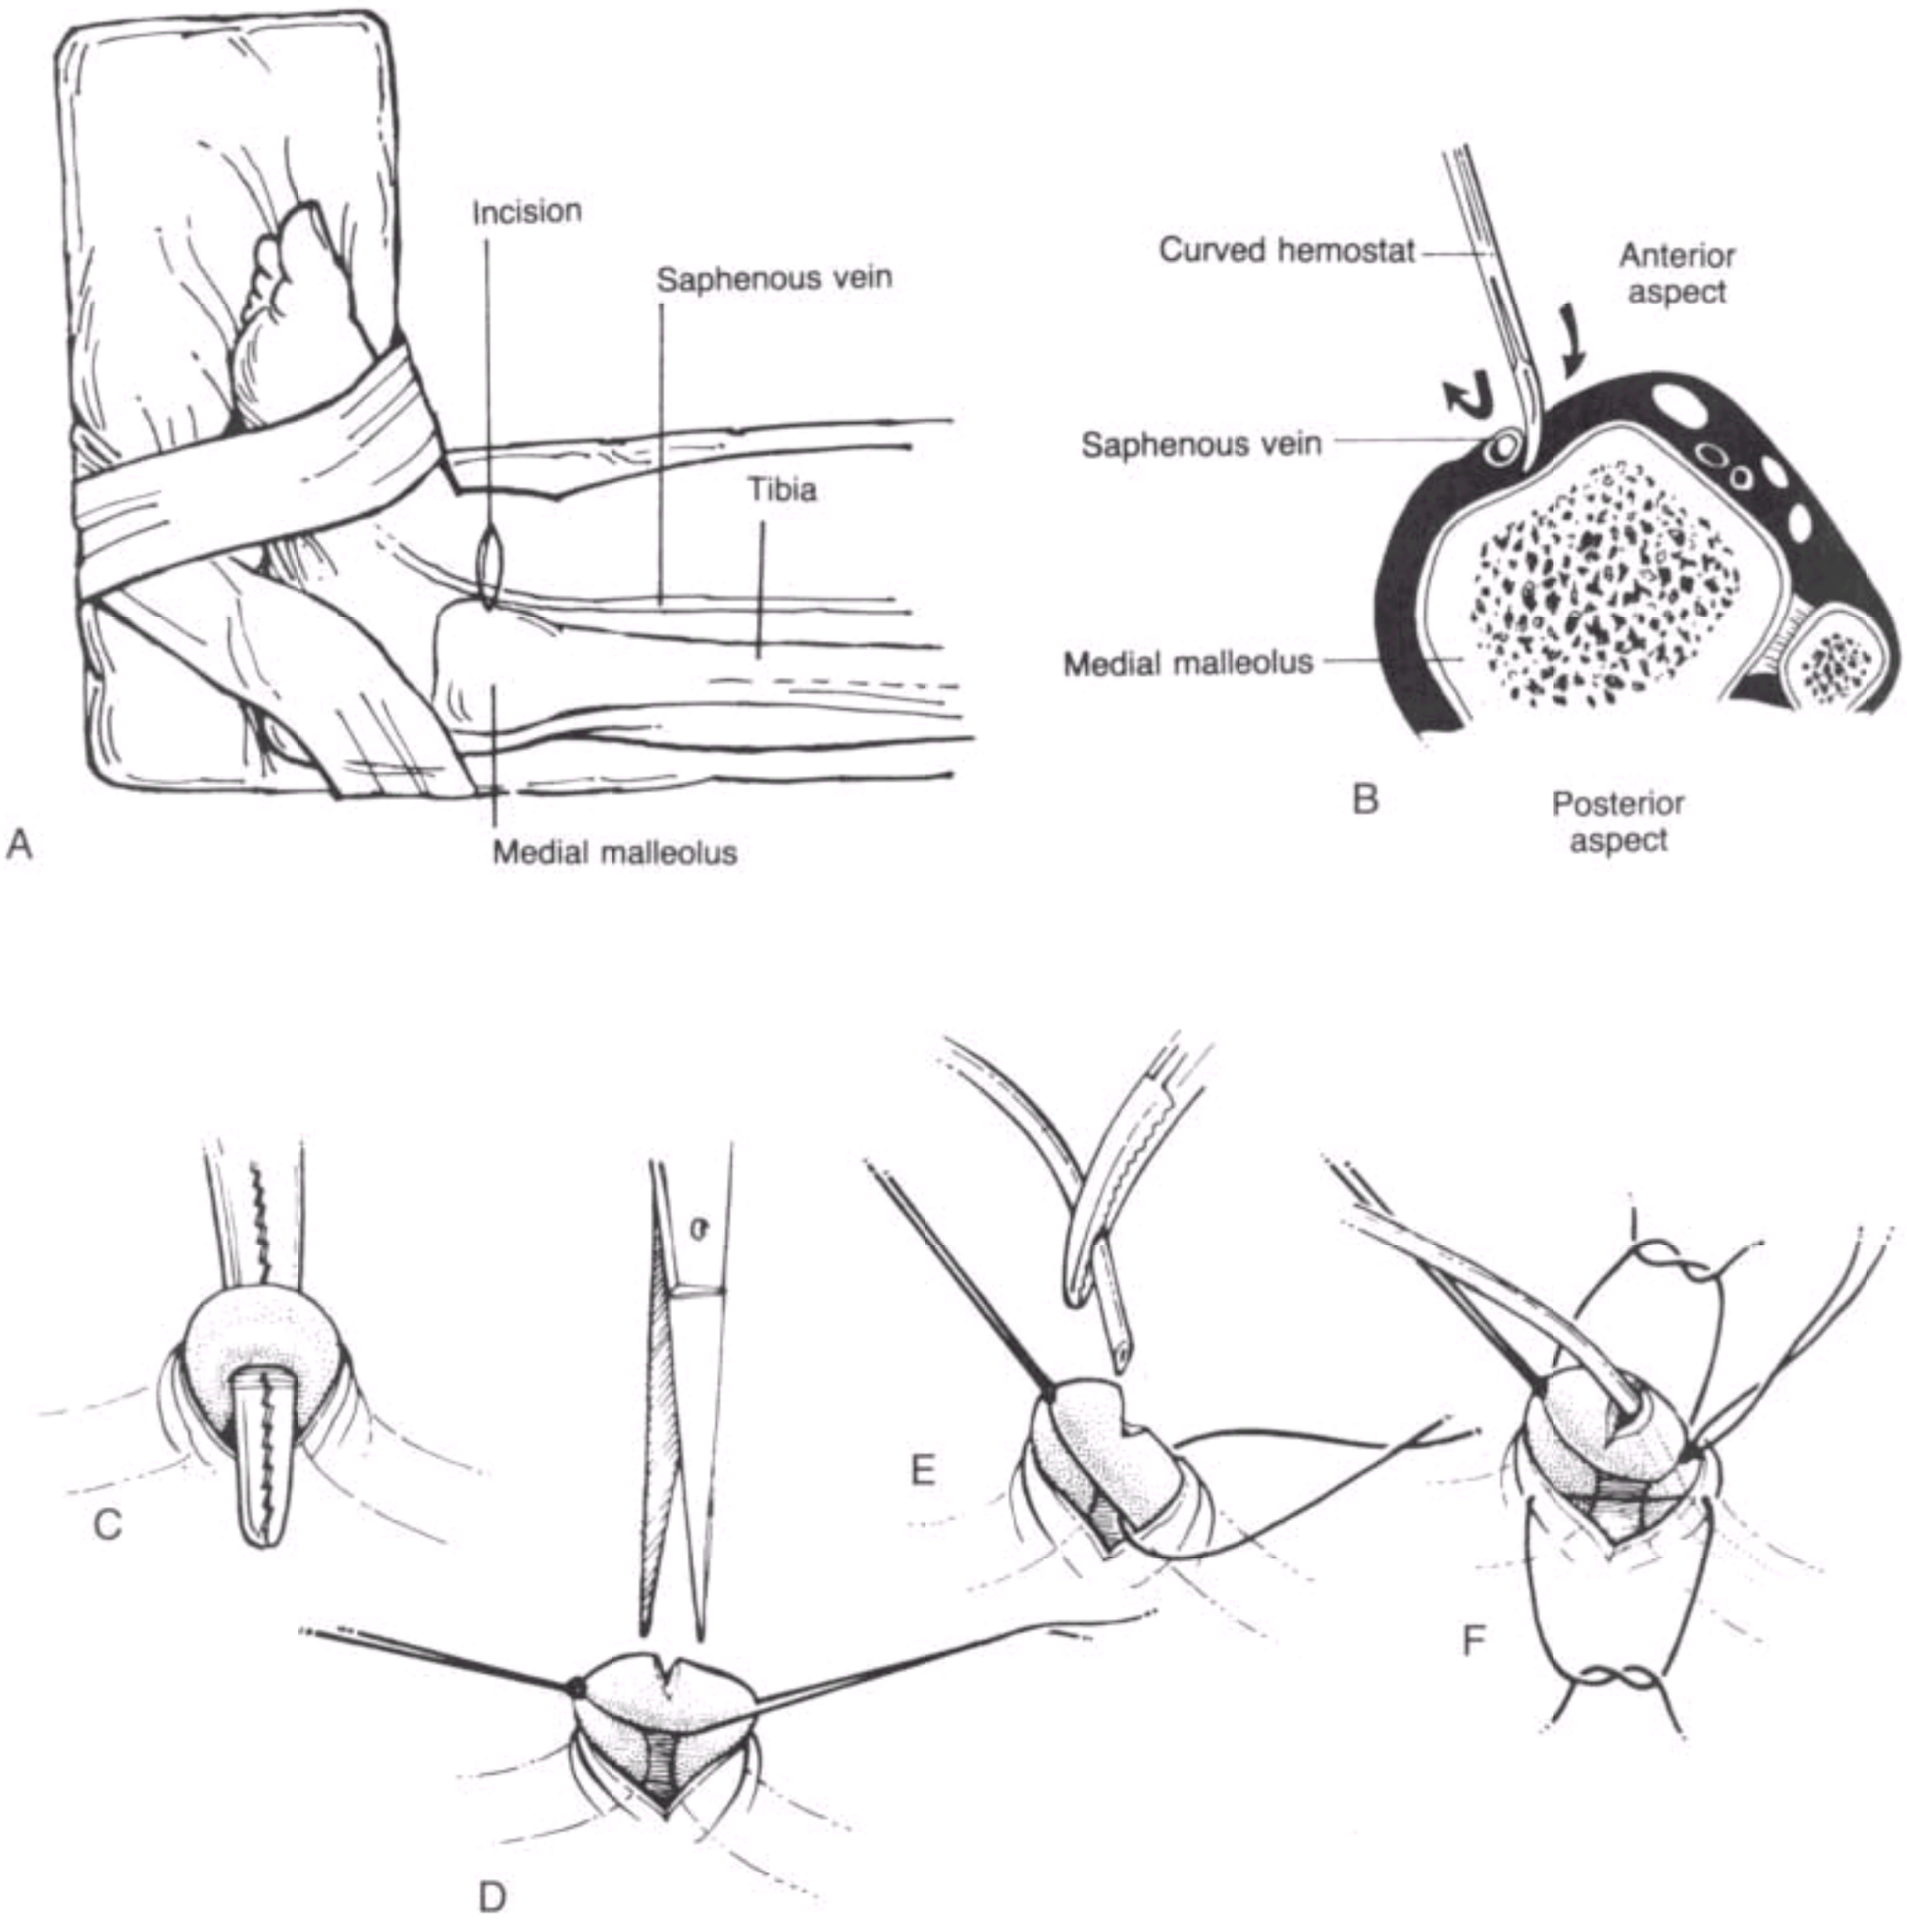

Figure 19-13b *G*, A vein lifter/dilator facilitates placement of the catheter into the vein lumen. *H*, The incision is sutured, and the catheter is secured. *(C from Suratt PM, Gibson RS: Manual of Medical Procedures. St. Louis, CV Mosby, 1982. Reproduced by permission.)*

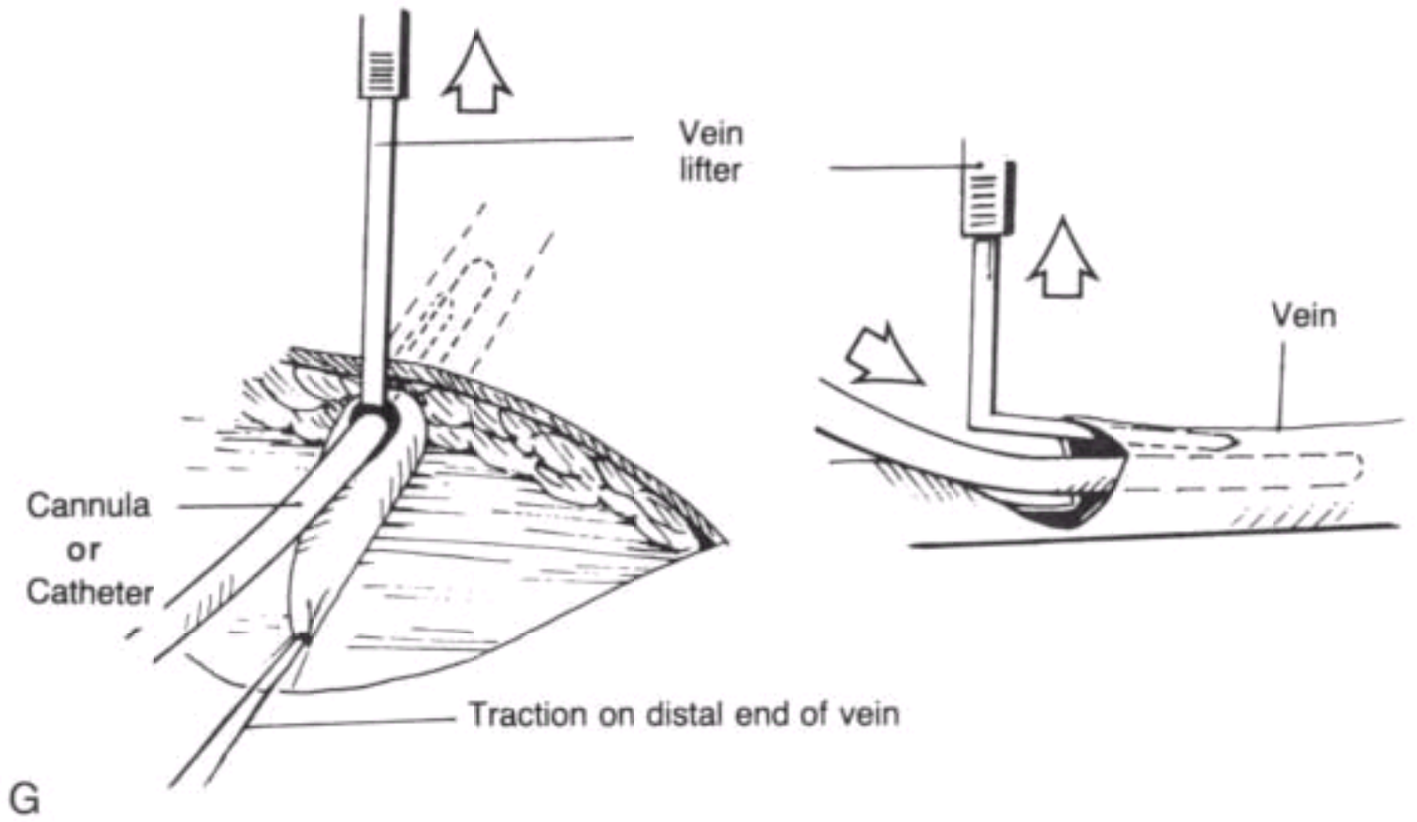

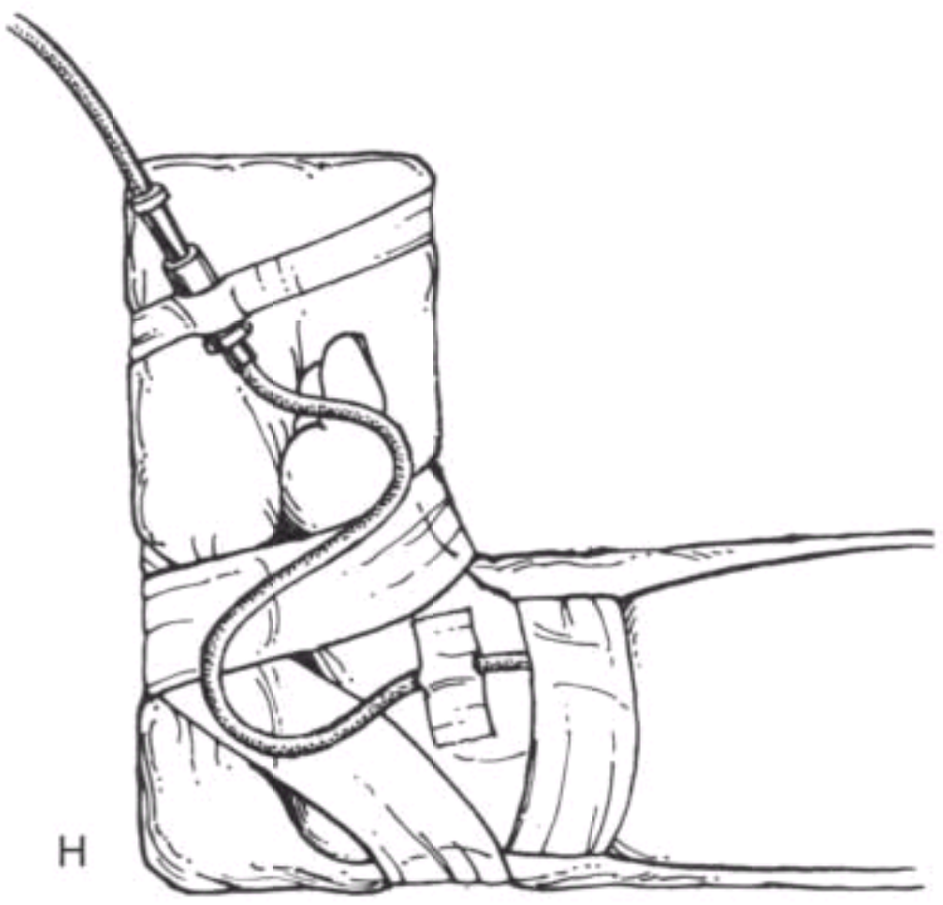

Figure 19-14 The mini-cutdown procedure using a standard intravenous catheter over-the-needle system is technically easier than the full cutdown and may be preferred in an emergency.

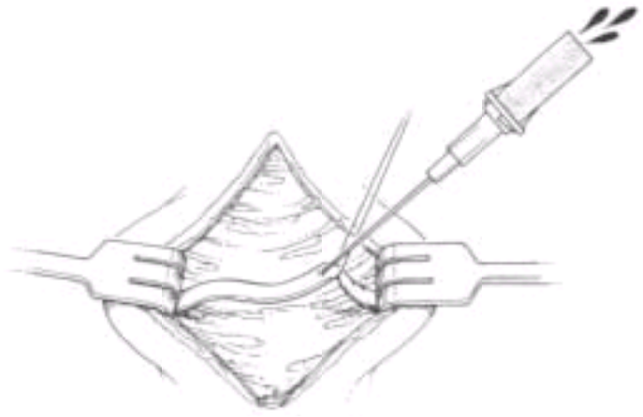

Figure 19-15 Technique for inserting a femoral venous catheter. *A*, A 21-ga butterfly catheter is used to enter the femoral vein, and the guidewire is passed through the butterfly needle into the proximal vein. Note that the tubing has been removed from a standard butterfly set. *B*, A small incision is made alongside the wire, and the dilator is advanced over the wire and into the vein. *C*, The catheter is advanced over the wire and into the vein. *D*, The wire is removed and the catheter secured. Note that many commercial kits have a self-contained 21-ga needle, making modification of a butterfly needle catheter unnecessary.

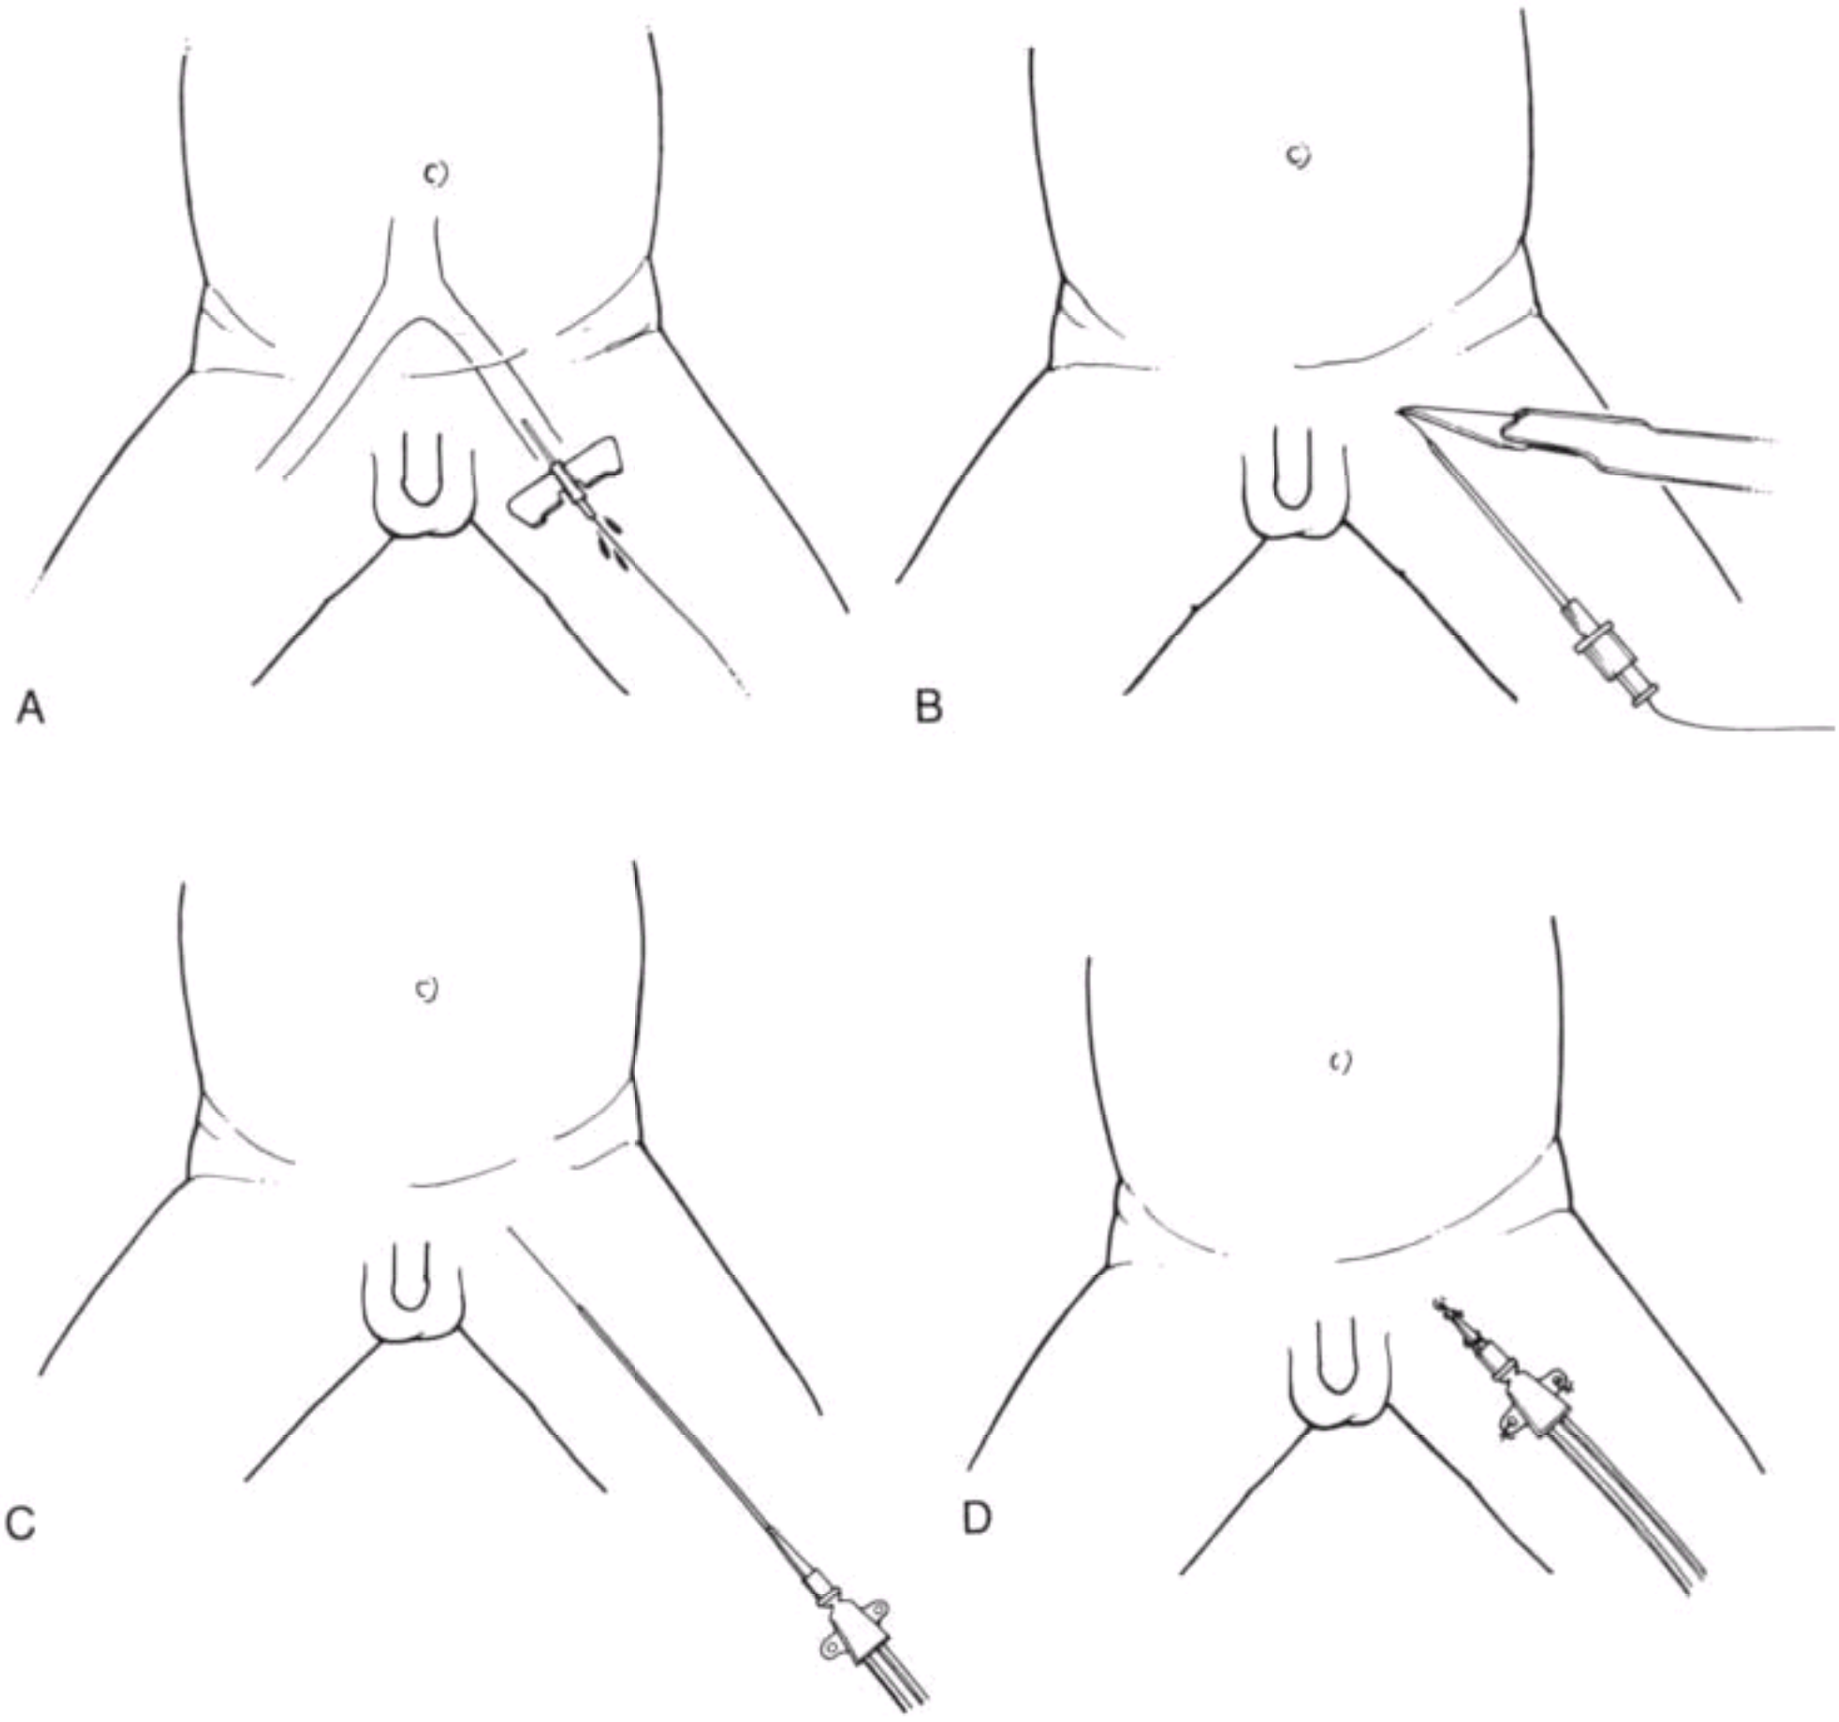

Figure 19-18 Techniques for insertion of central catheters from peripheral veins. *A*, A tape measure is used to determine the catheter length. *B*, Placement of the catheter through the specialized breakaway butterfly-type introducer needle.

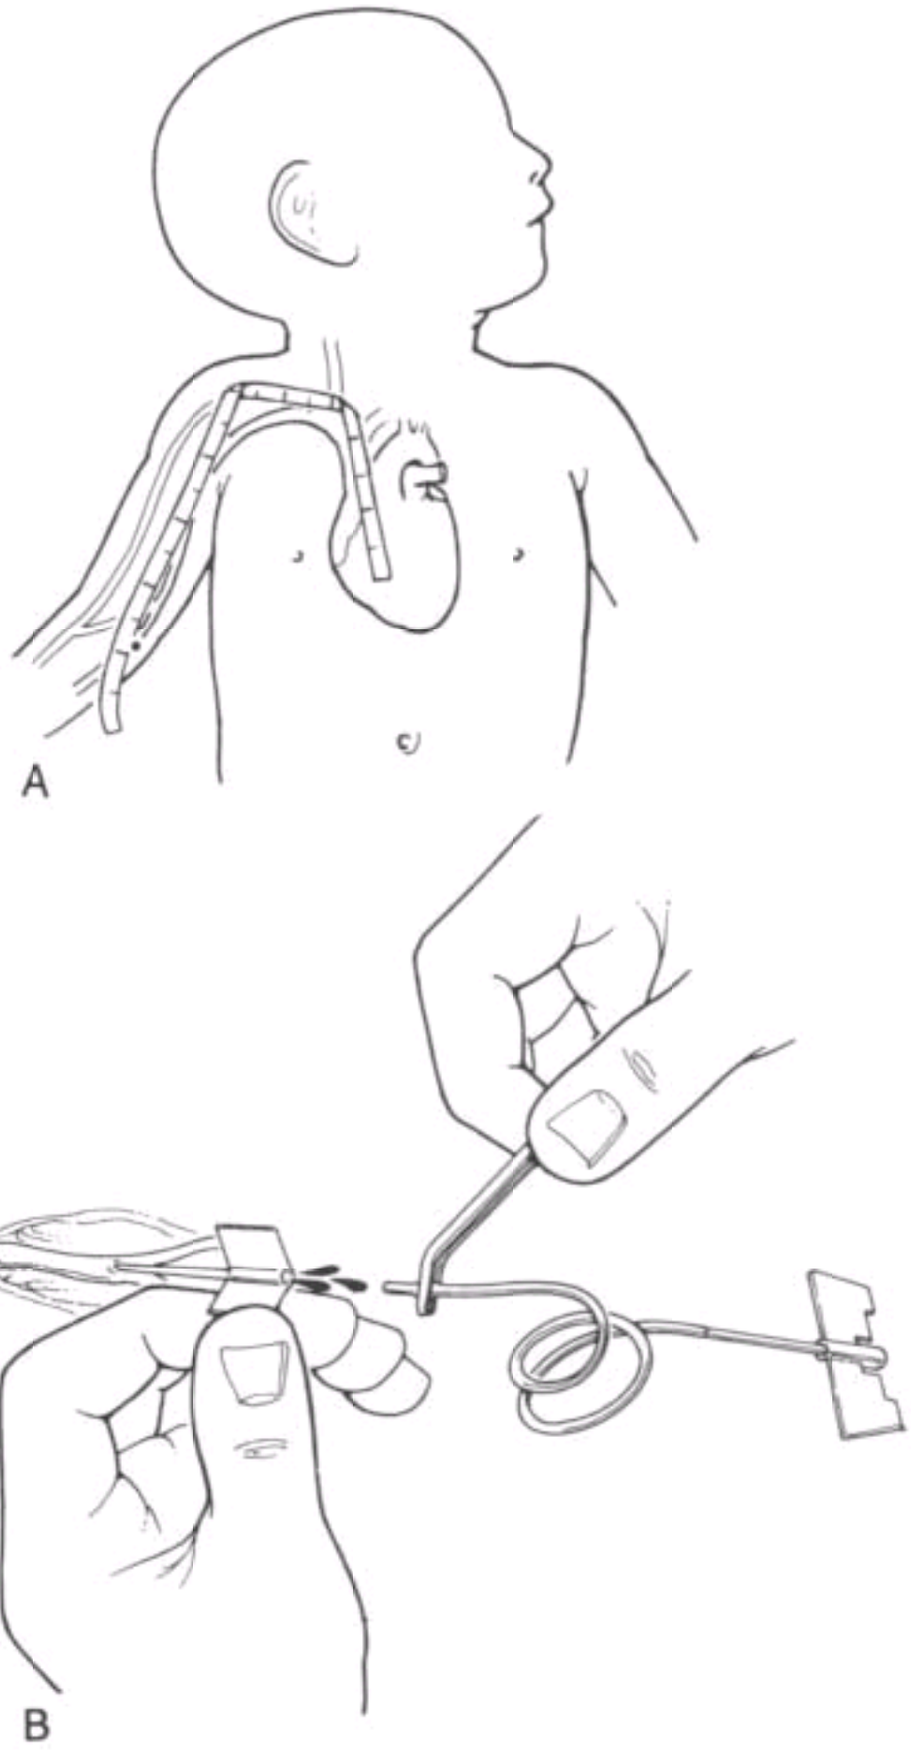

Figure 19-19 When placing an umbilical vein catheter, a pursestring suture or umbilical tape is passed around the base of the cord to provide hemostasis and to anchor the line.

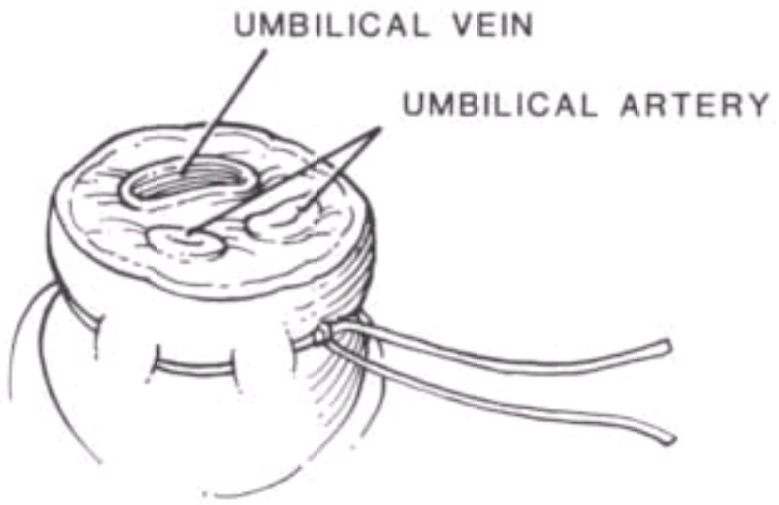

Figure 19-20 An umbilical vein catheter is directed toward the head and remains anterior until it passes through the *ductus venosus* into the inferior vena cava. *(From Ludwig S, Fleisher GR: Textbook of Pediatric Emergency Medicine. Baltimore, Williams & Wilkins, 1994.)*

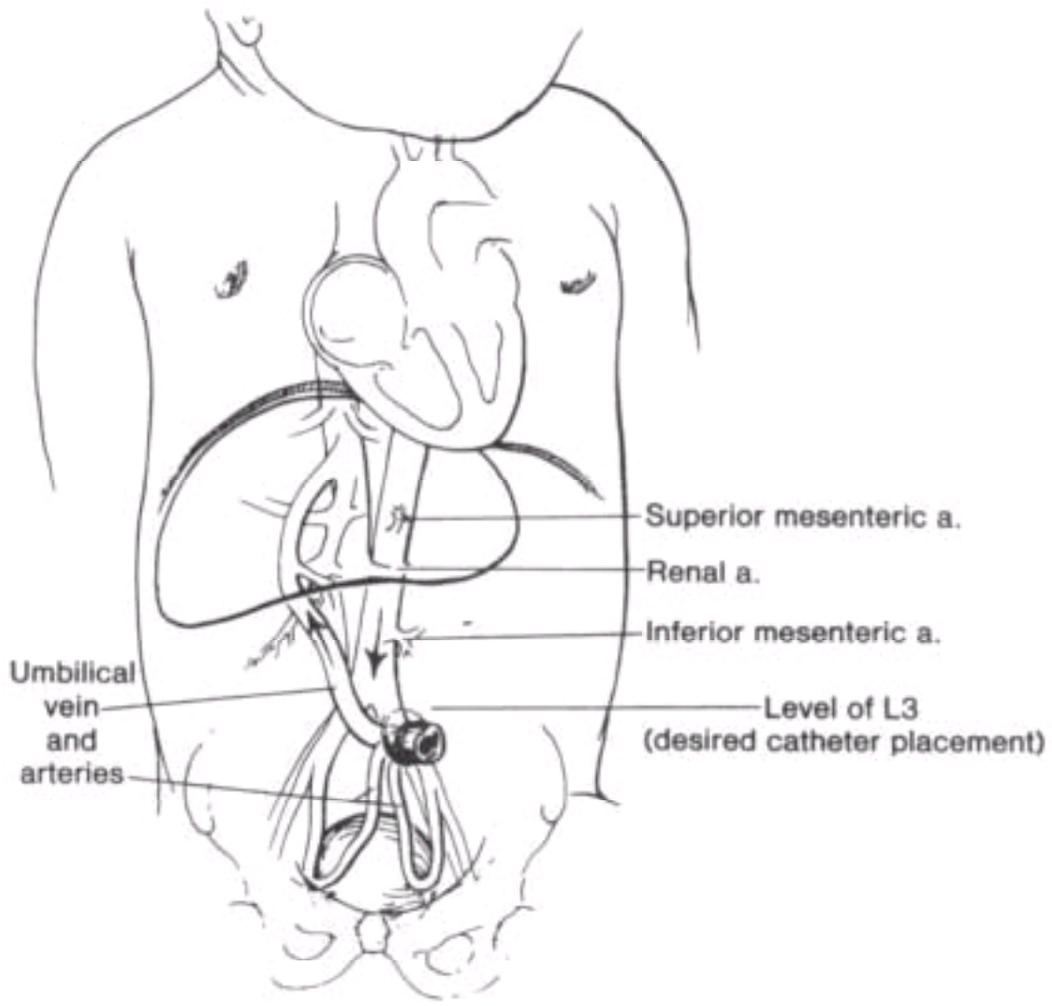

Figure 19-21 After measuring the shoulder-to-umbilicus length, a standardized graph can be used to determine the appropriate length of the umbilical venous catheter (*A*), or umbilical arterial catheter (*B*). The venous catheter should be inserted into the inferior vena cava below the level of the right atrium. The appropriate length of the arterial catheter depends on whether a "high" or "low" line is desired (see text for explanation). *(From The Johns Hopkins Hospital, Nechyba C, Gunn VL: The Harriet Lane Handbook: A Manual for Pediatric Home Officers, 16th ed. St. Louis, CV Mosby, 2002.)*

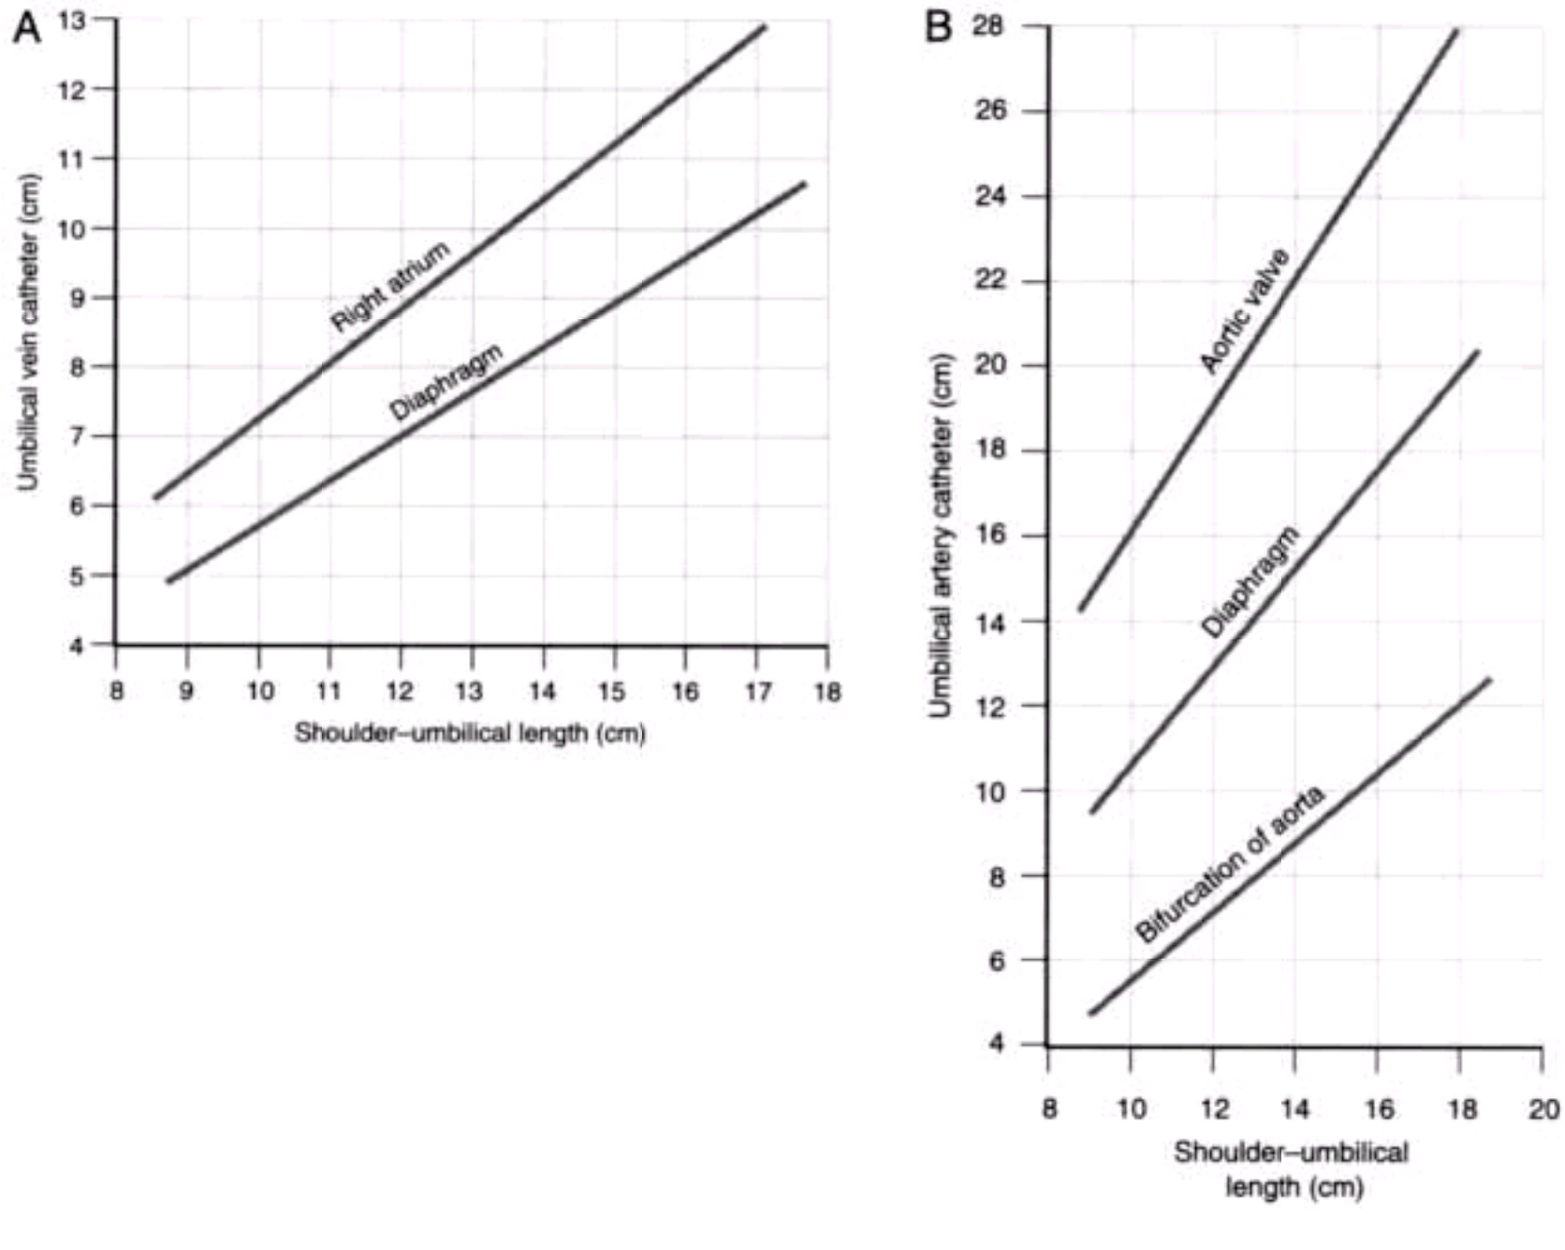

Figure 19-22 The umbilical cord is grasped with a curved hemostat near the selected artery. The umbilical artery is then dilated with a curved iris forceps.

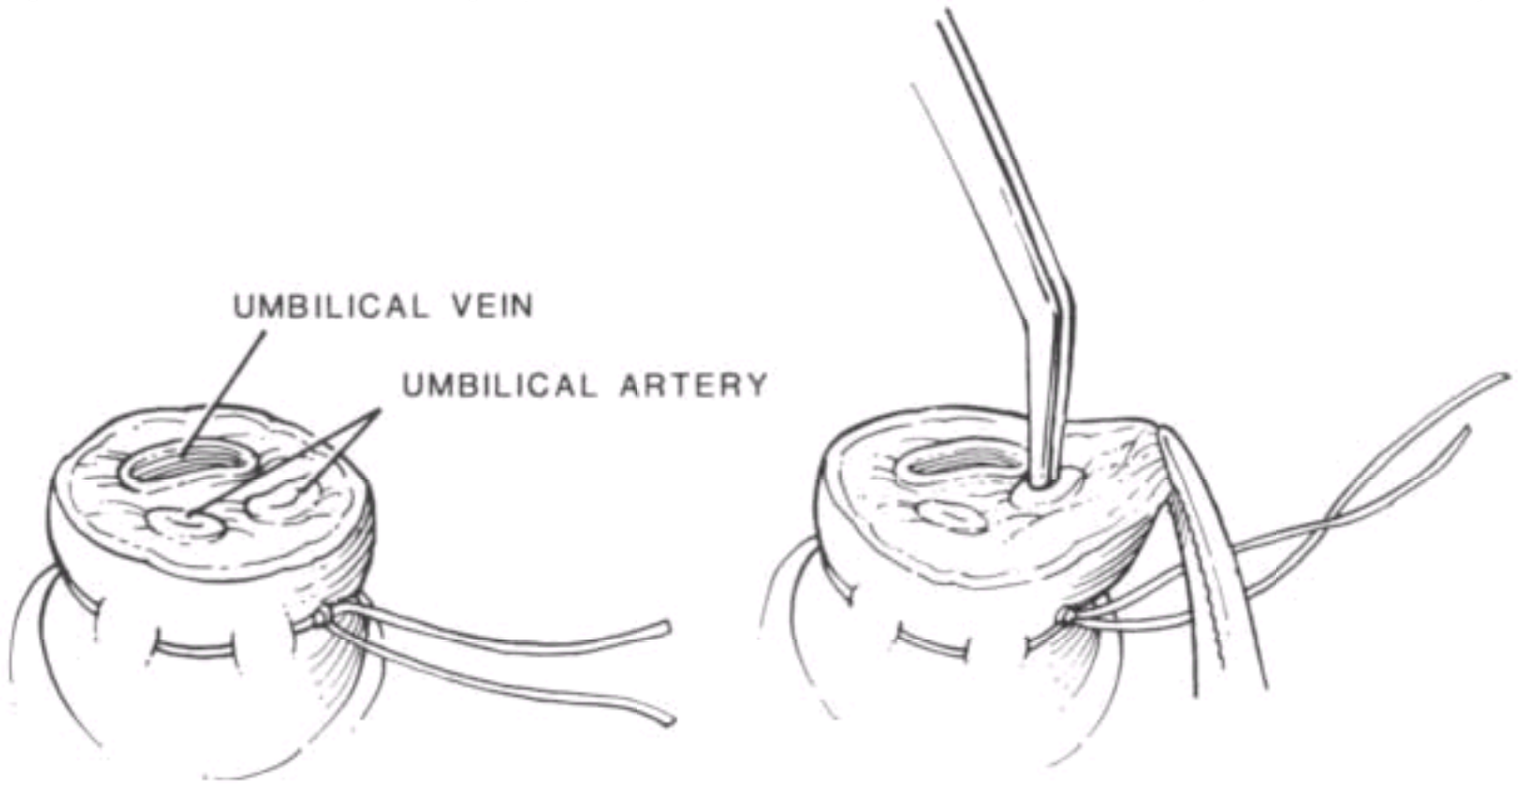

Figure 19-23 The catheter is introduced into the dilated artery and advanced toward the feet. The suture placed around the base of the cord is tied to the catheter.

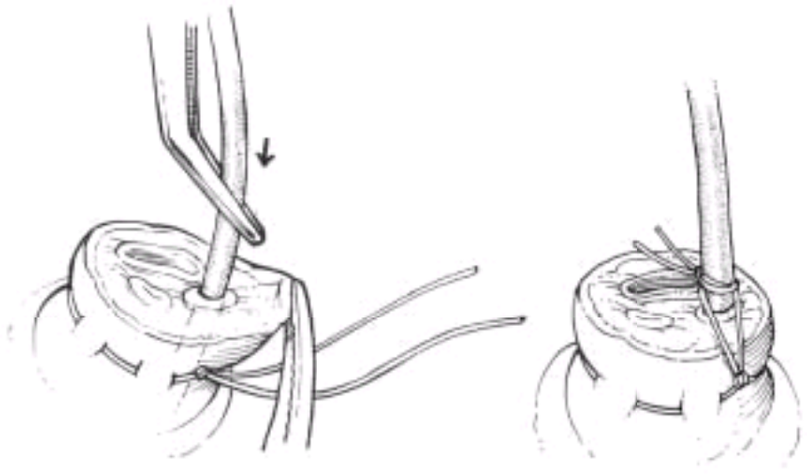

Figure 19-24 The tape is pleated above and below the catheter.

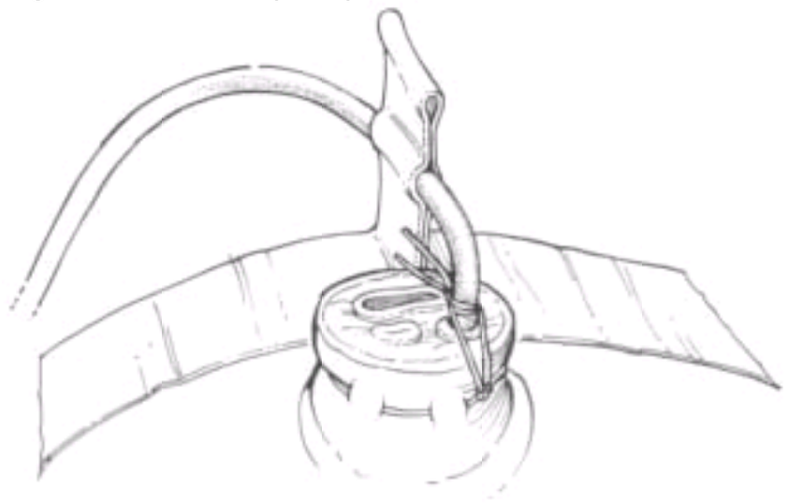

Figure 19-25 The umbilical artery catheter makes a loop downward before heading cephalad (schematic drawing of a radiograph interpretation).

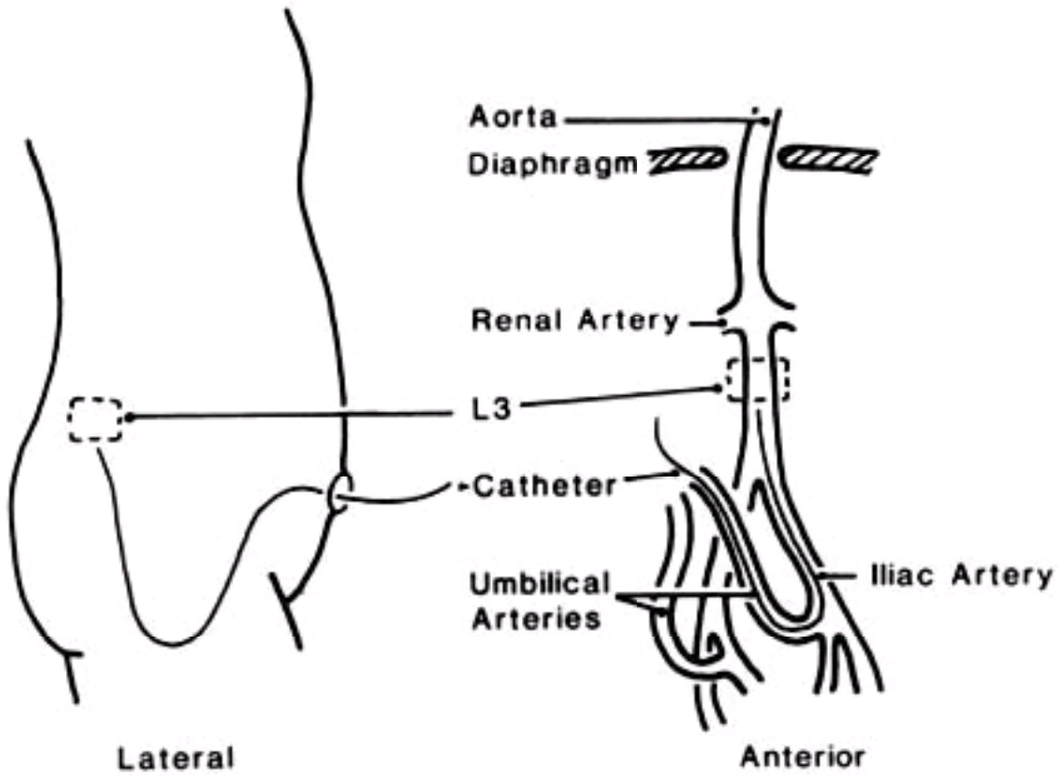

Figure 19-26 The catheter assembly is introduced into the radial artery through skin at a 10- to 20-degree angle. This is a smaller angle than is used for simple arterial puncture. Gloves should be worn.

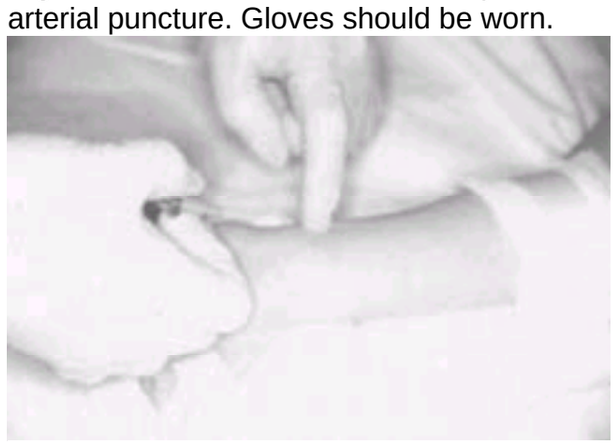

Figure 19-27 One technique of taping the arterial catheter. The arm board should be well padded and secured.

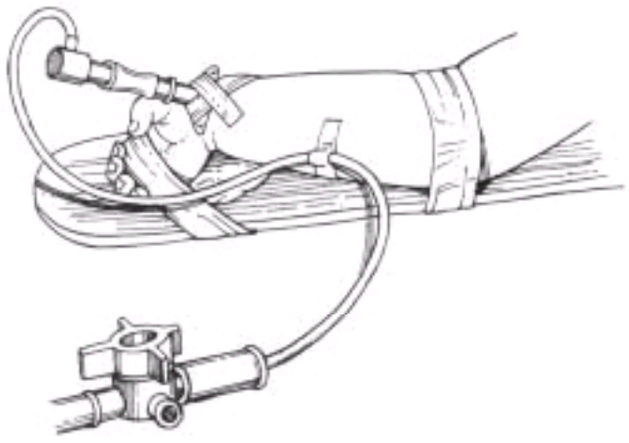

Figure 19-28 Anatomy of the posterior tibial artery and surrounding structures.

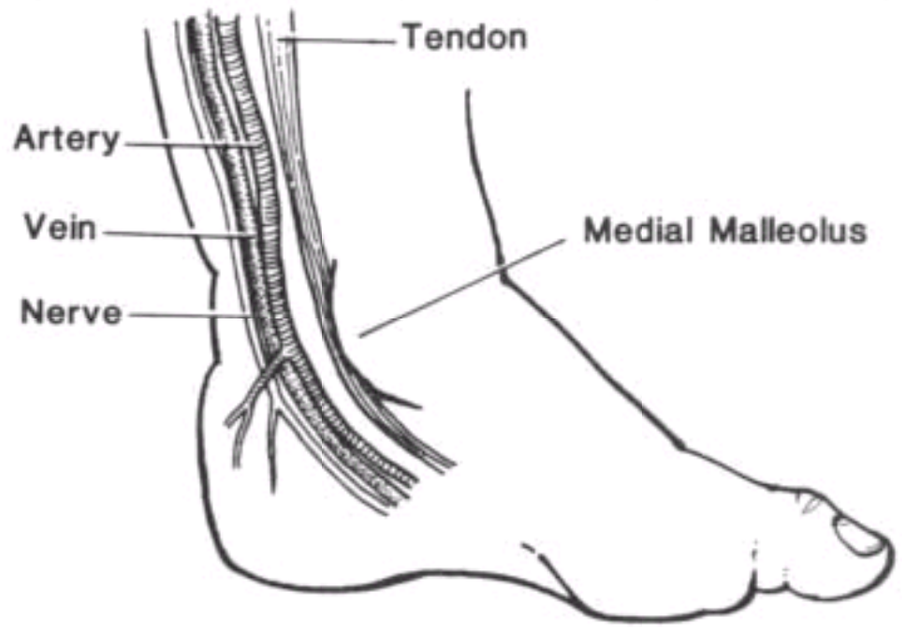

Figure 19-29 *A*, Posterior tibial artery cutdown technique. With the foot prepared and immobilized, a 5- to 7-mm incision is made in the skin posterior to and at the midline of the medial malleolus. *B*, A curved forceps and a silk suture are inserted beneath the posterior tibial artery, which courses just posterior to the medial malleolus.

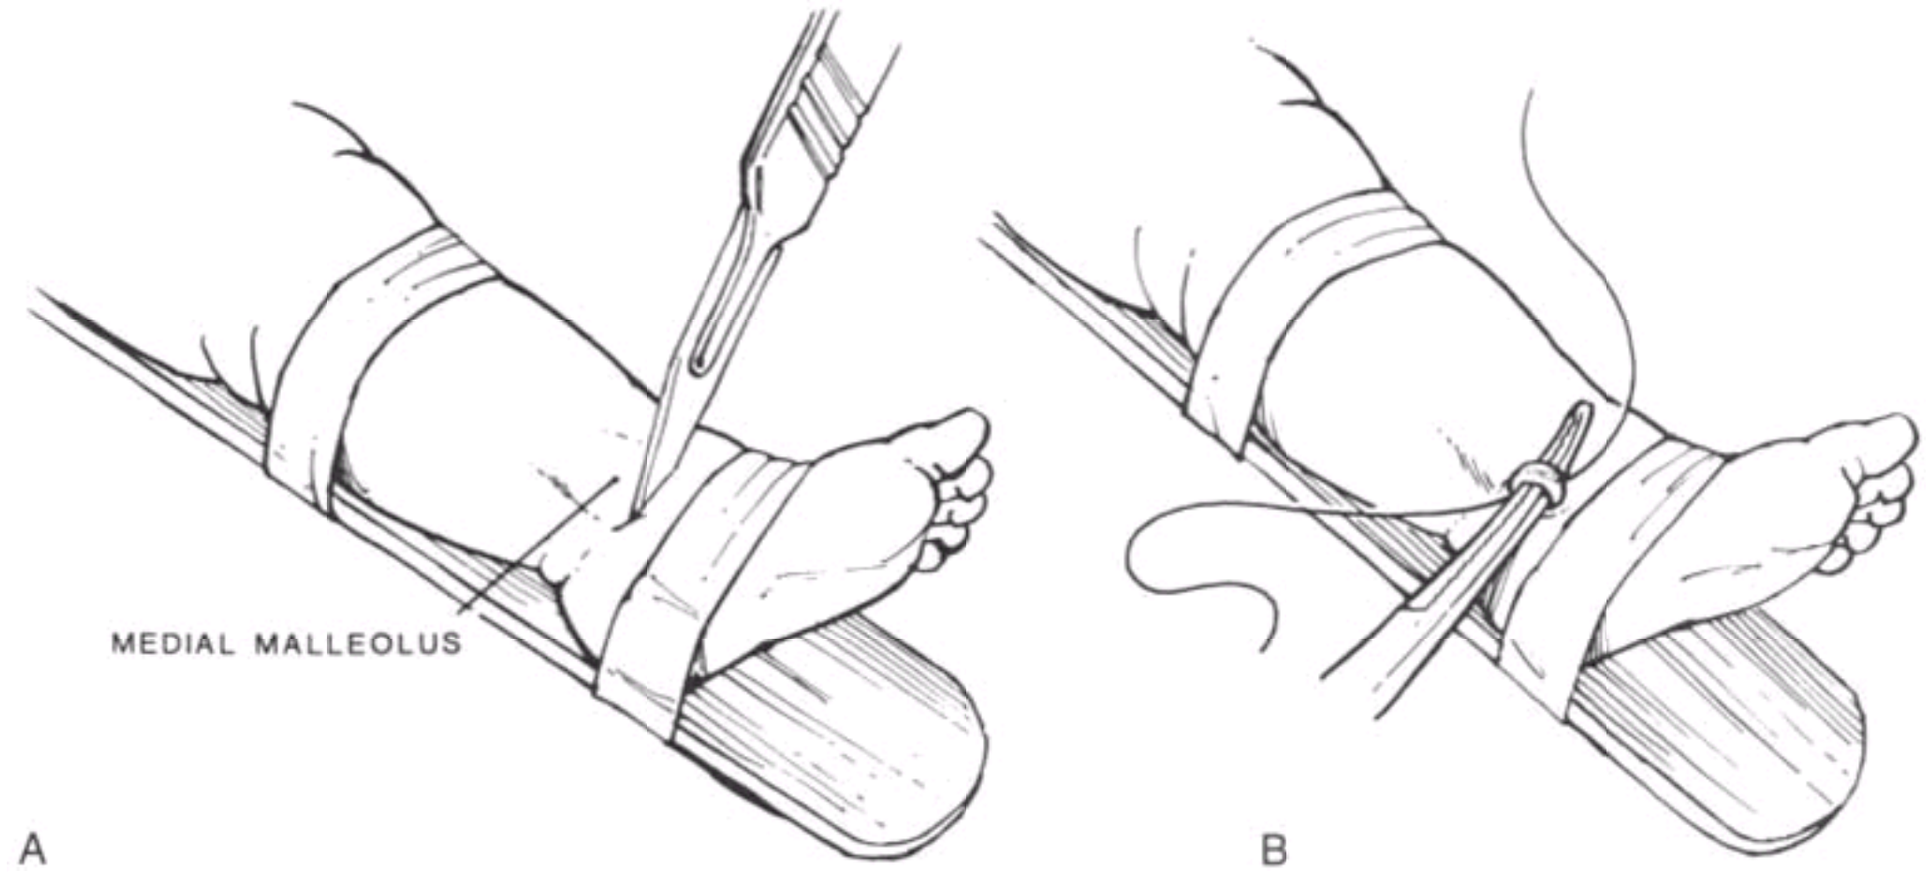

Figure 19-30 Technique of inserting the arterial catheter. A silk tie is used *only to stabilize the artery during cannulation*. It is never tied. The catheter is inserted under direct vision without making an incision in the vessel.

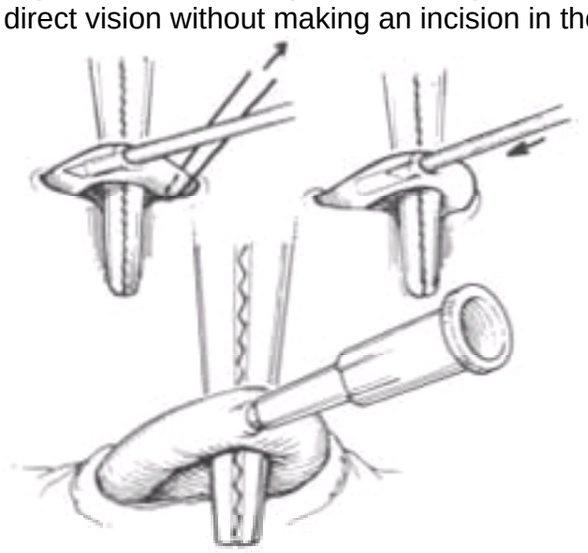

Figure 19-31 The skin incision is closed, and the catheter and connector are secured to the heel with tape.

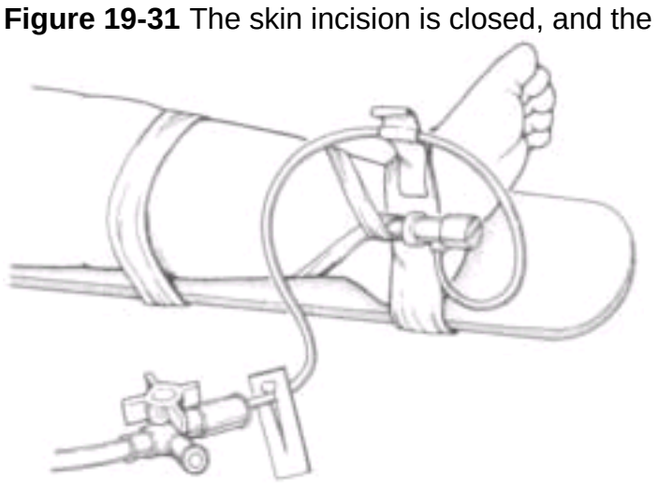

Figure 20-1 Catheters for arterial cannulation. A standard intra-catheter for arterial cannulation may be used for direct vessel cannulation. Newer devices with a modified guidewire and quick-flash identifier (Arrow International, Inc. Reading, PA) or a needle with an attachable guidewire to aid cannulation are also available.

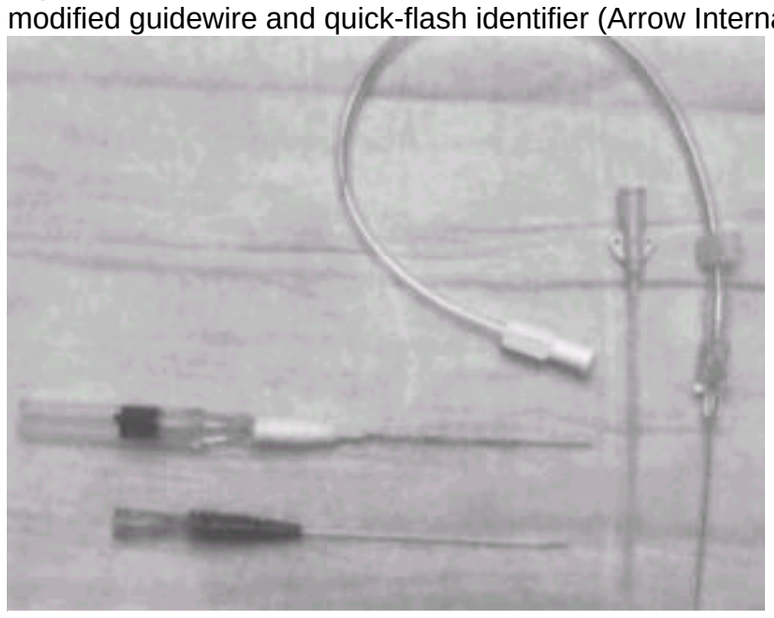

Figure 20-2 Assembly technique for anaeroid manometer system. The middle and proximal extension tubings contain heparinized saline. The middle extension tubing is arranged to form a fluid meniscus at the same level as the heart when the proximal stopcock is closed to the middle tubing (i.e., no pressure input). The distal extension tubing is filled with air and held vertically so that there is no saline contamination of the manometer at maximal pressures. Approximately 10 to 12 cm of air in the distal and middle tubings is optimal. The same system can be used with a mercury manometer in place of the anaeroid manometer. Sterility of the extension tubing and stopcocks is essential. *(From Zorab JSM: Continuous display of the arterial pressure: A simple manometric technique. Anaesthesia 24:433, 1969. Copyright © 1969 by the Association of Anaesthetists of Great Britain and Ireland. Reproduced by permission.)*

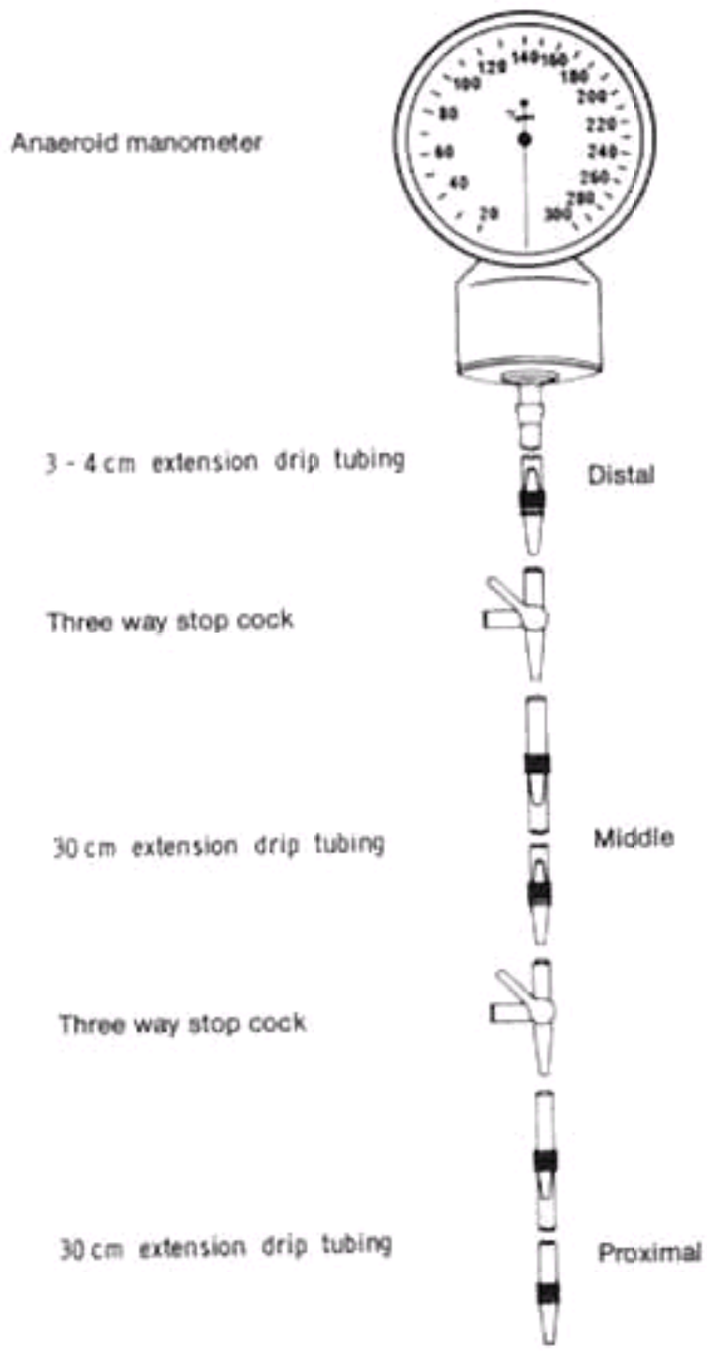

Figure 20-3 Arterial pressure monitoring systems. *A,* System for continuous flush. Heparin (2 mL of a 1:1000 unit solution) is added to a 1-L bag of normal saline, and the bag is pressurized to 300 mm Hg using a metered blood pump (not shown). The continuous flush device is set to deliver 3 mL/hour of the heparinized saline. A mechanical pressure transducer is depicted. The transducer device is a sterile, inexpensive, fully assembled monitor that can be used during patient transfer. Alternatively, the electronic transducer depicted in *B* may be used. *B,* System for manual flush. A heparinized saline flush solution can be injected manually through a syringe at the proximal or distal port. The transducer dome should be maintained at the level of the patient's heart. *(From Beal JM [ed]: Critical Care for Surgical Patients. New York, Macmillan, 1982. Reproduced by permission.)*

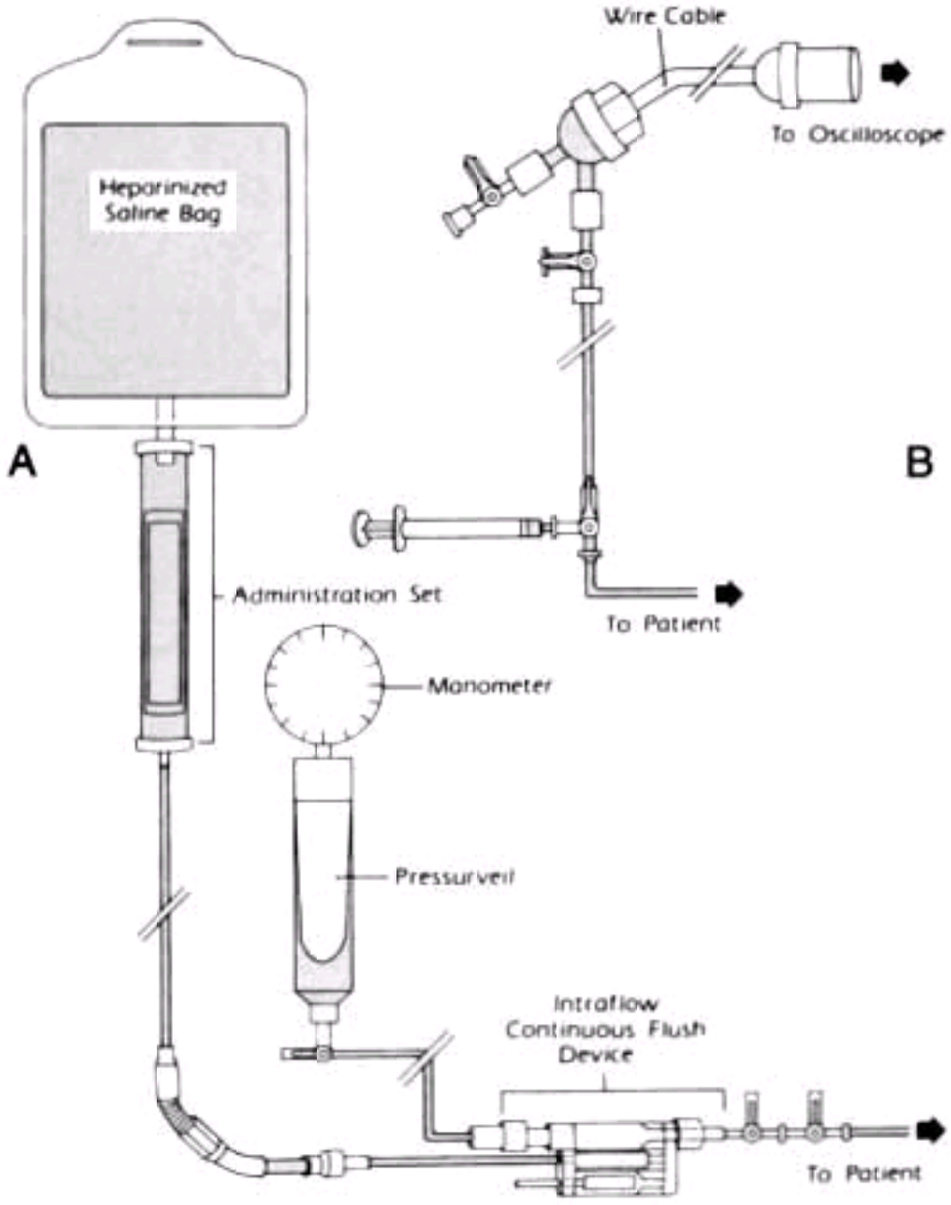

Figure 20-4 Arterial puncture: The syringe-needle is held at a 30 to 45° angle and should enter with the bevel up and advanced slowly. The landmark is best located by palpating the pulse using the index and middle fingers placed immediately proximal to the needle entry site. The needle should *not* be passed between the fingers due to risk of operator self-injury. *(Picture courtesy of JMM, with permission.)*

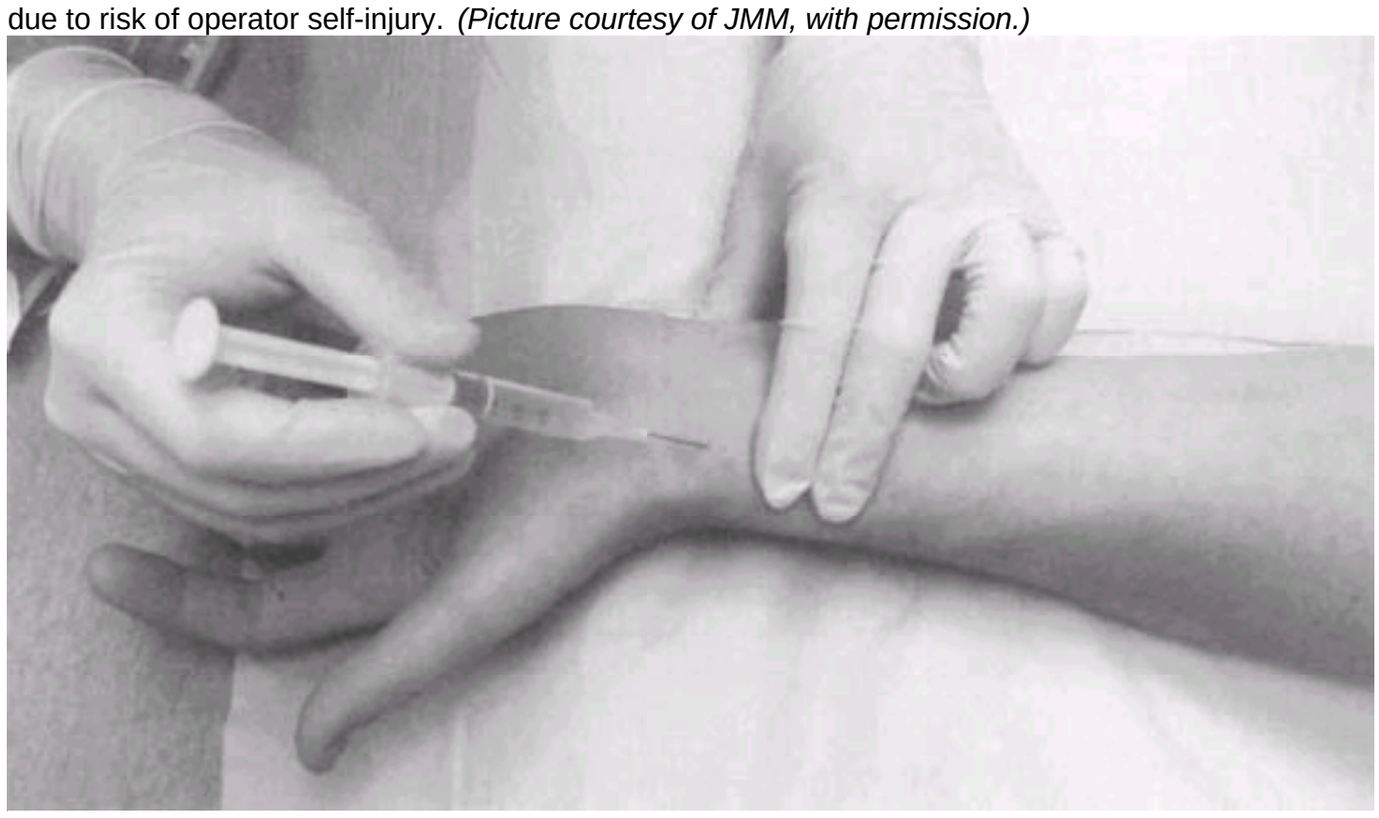

Figure 20-5 Removal of air bubbles from the syringe. Air bubbles are finger-tapped to the top of the syringe. An alcohol swab is placed over the top of the needle. The plunger is advanced to expel air while drops of blood are collected on the alcohol swab. After removal of the bubbles, the syringe is capped and sent to the laboratory.

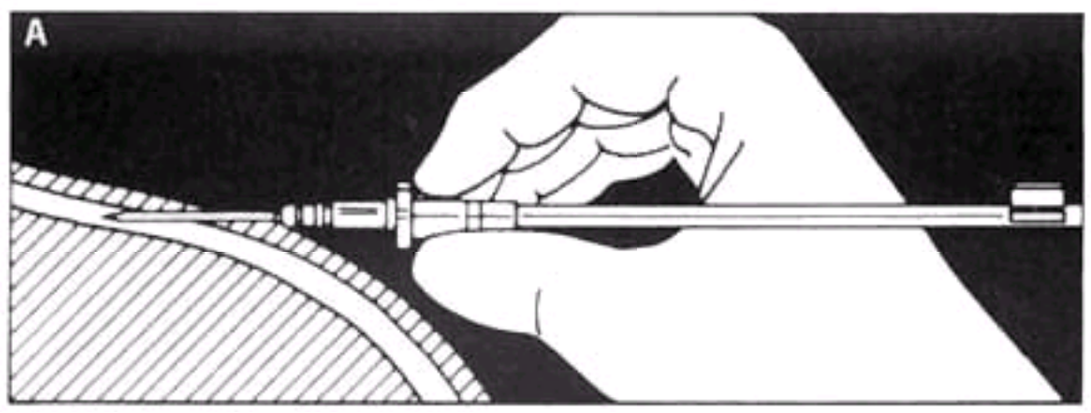
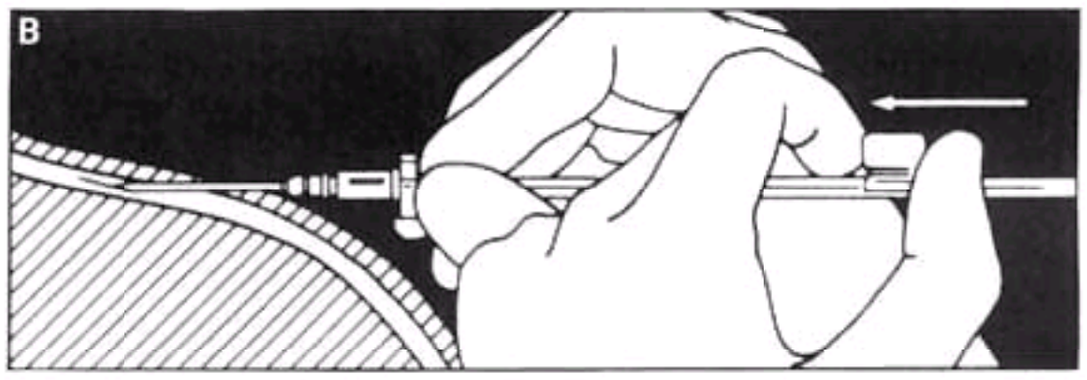
Figure 20-6 Step-by-step arterial cannulation, using the guidewire technique (Arrow arterial catheterization kit). *(Courtesy of Arrow International, Inc., Reading, PA.)*

General instructions for use of Radial Artery set.

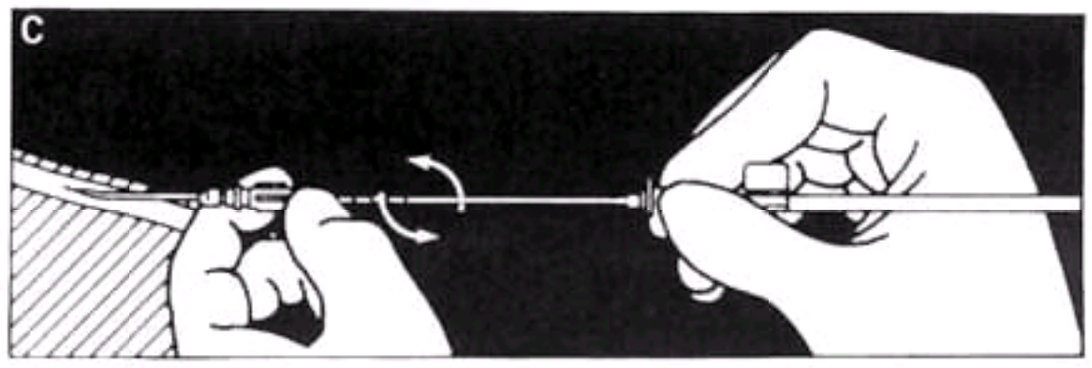
1. Prepare puncture site in preferred manner.
2. Peel open package and remove entire unit.
3. Remove protective shield. Trial advance and retract spring-wire guide through needle via actuating lever to ensure proper feeding. *Note:* Catheter hub wing clip can be "snapped" out of groove and removed if desired. This allows suture ring on hub to be optionally used for attachment to skin after placement.
   CAUTION: Before insertion, actuating lever must be retracted proximally as far as possible so as not to inhibit blood flashback.
4. Puncture vessel using a continuous, controlled, slow forward motion, being careful to avoid transfixing both vessel walls. Blood flashback in clear hub of introducer needle indicates successful entry into vessel *(A)*.
   CAUTION: If both vessel walls are punctured, advancement of spring-wire guide could result in inadvertent subarterial placement.



5. Stabilize position of introducer needle and carefully advance spring-wire guide (via actuating lever) distally as far as possible into vessel *(B)*. Reference mark on clear feed tube indicates approximate actuating lever advancement position at which soft tip of spring-wire guide coincides with tip of needle.
   CAUTION: If resistance is encountered while advancing spring-wire guide, *do not force feed and do not retract spring-wire guide while in vessel* (to avoid damaging wire). Withdraw entire unit and attempt new puncture.



6. Advance the entire placement unit a maximum of 1 to 2 mm farther into the vessel.
7. Firmly hold clear introducer needle hub in position and advance catheter forward to track spring-wire guide into vessel. If difficulty is encountered during catheter advancement, a slight rotating motion of catheter hub may be helpful *(C)*.



8. Hold catheter in place and remove introducer needle, spring-wire guide, and feed tube assembly. Free blood flow indicates successful placement in vessel.
   CAUTION: Do not reinsert needle into catheter.
9. Attach desired stopcock, injection cap, or connecting tubing to catheter hub.
10. Secure catheter to patient in preferred manner, using wing clip or suture ring as described in Step 3.
11. Cover puncture site with suitable dressing.

Figure 20-7 Femoral vessel cannulation kit. (Arrow International, Inc., Reading, PA.) A 16-ga single lumen vessel with a guidewire for Seldinger placement includes entire procedural needs with local anesthetic, subcutaneous puncture syringe, needle, scalpel, and suture material.

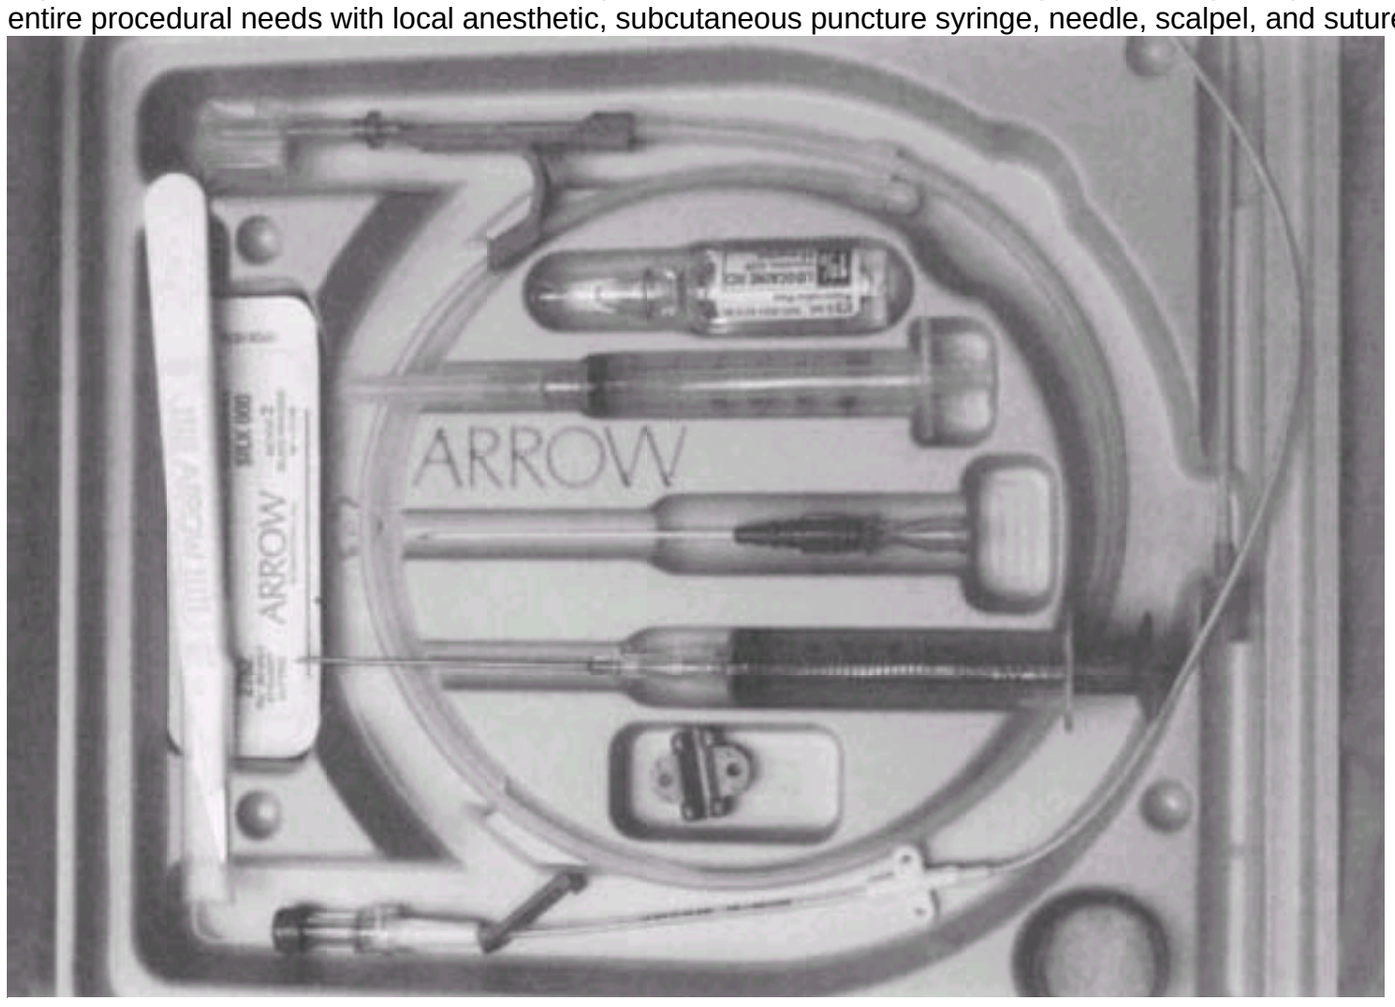


Figure 20-8 Placement of an arterial line using the cutdown technique. Note that the catheter enters the surgical wound percutaneously to minimize bacterial entry into the healing wound and permit better stabilization of the catheter. Catheter entry of the vessel is more parallel to the vessel than is illustrated. Ligatures are used only to *temporarily* isolate the artery and to control bleeding. *The artery should not be tied off.* The catheter is secured by suturing the hub to the skin (see Fig. 20-9).

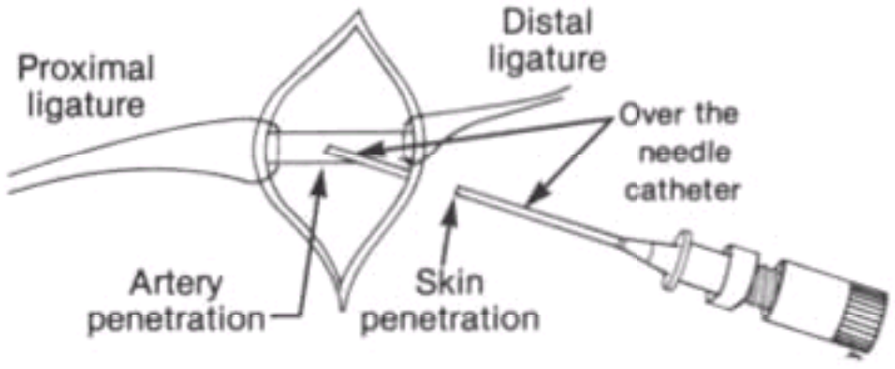

Figure 20-9 Illustration of a technique for securing a vascular catheter to adjacent skin.

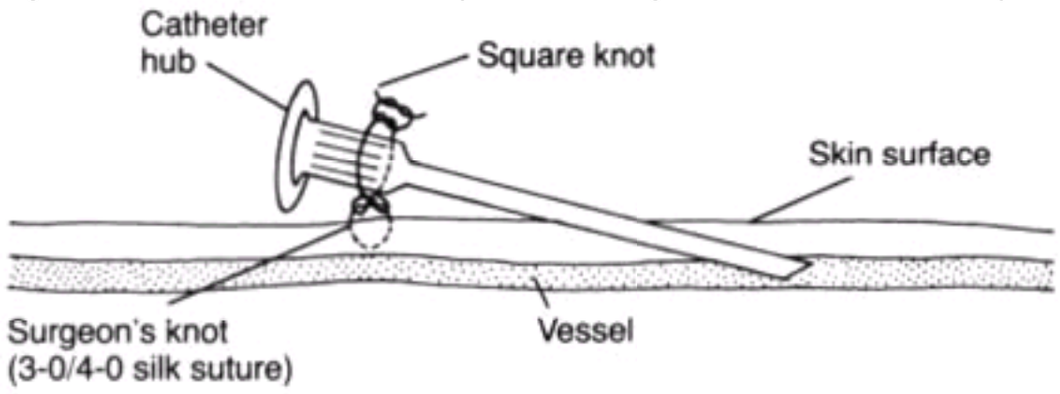

Figure 20-10 Pressure transducer fluid monitoring set; a pressurized saline (heparinized solution may be substituted) connected to an intravascular line and arterial catheter, which is then fixed to a three-way stopcock. The fluid wave is directly monitored by the electormechanical transducer, which records pressure cycles and displays multiple hemodynamic values.

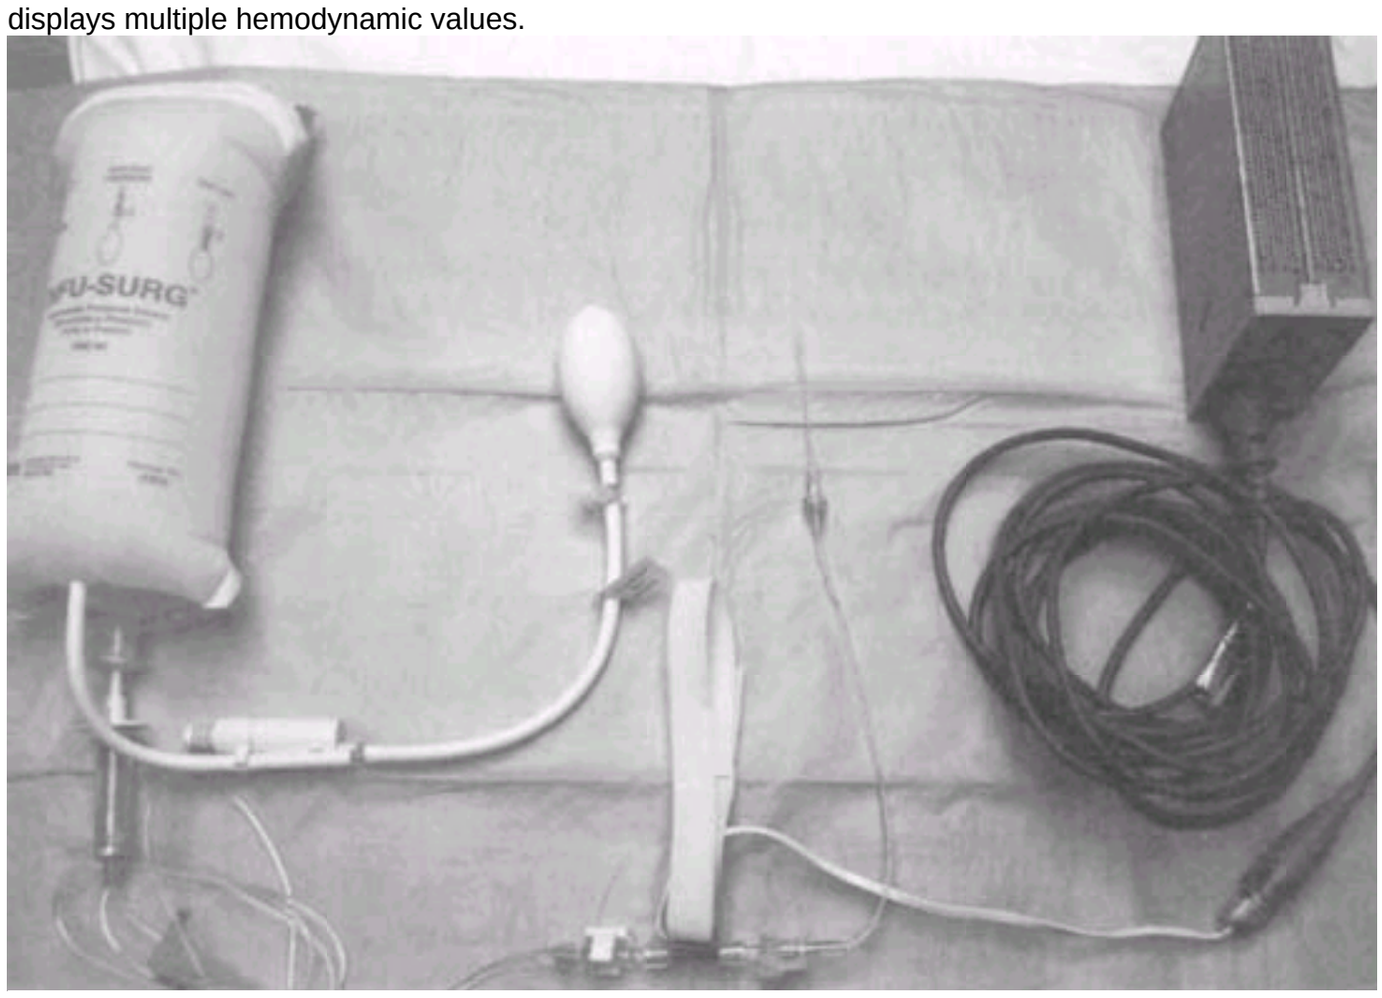

Figure 20-11 Arterial anatomy of the hand and wrist. *(From Ramanathan S, Chalon J, Turndorf H: Determining patency of palmar arches by retrograde radial pulsation. Anesthesiology 42:758, 1975. Reproduced by permission.)*

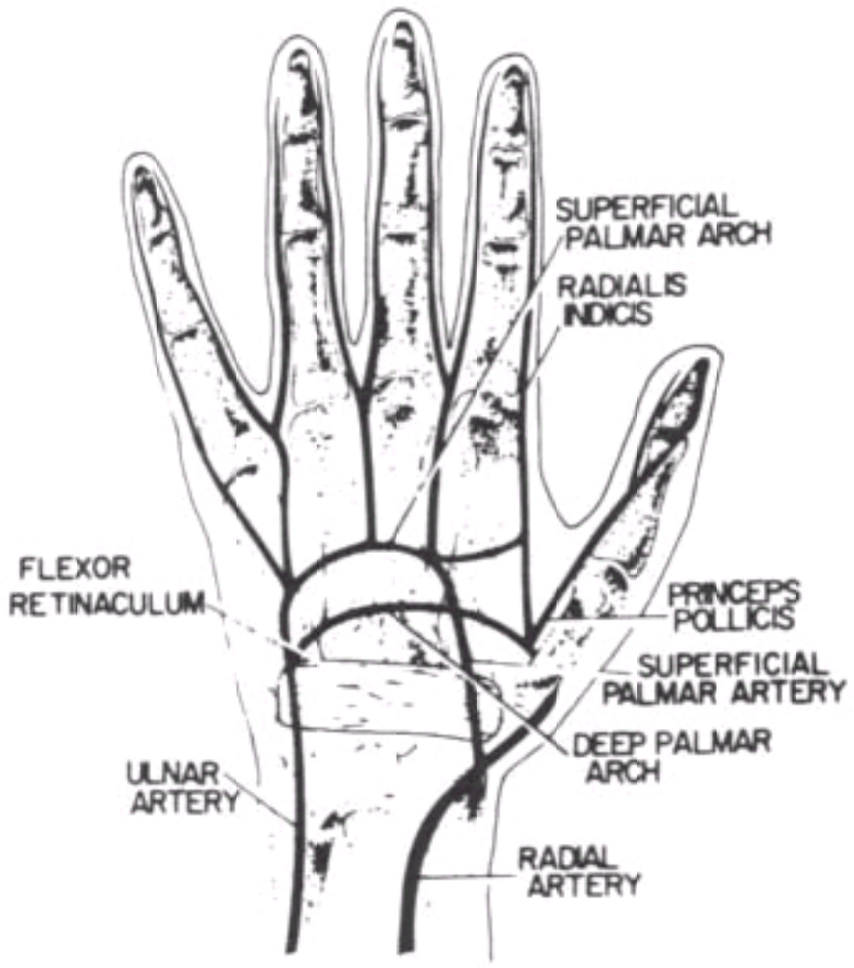

Figure 20-12 Allen test. Before puncturing the radial artery it is important to identify a competent ulnar artery. This can be done as follows: (*1*) The examiner compresses both arteries, and the patient repeatedly makes a tight fist to squeeze all the blood out of the hand. (*2*) The patient then extends the fingers, and the examiner observes the blanched hand. (*3*) Compression of the ulnar artery is released, and the examiner observes the hand filled with blood. If filling does not occur within 5 to 10 seconds, radial artery puncture should not be done. If brisk filling occurs, the test is then repeated with release of the radial artery to assess radial artery patency. If both radial and ulnar arteries demonstrate patency, the wrist may be used for arterial puncture. *(From Schwartz GR [ed]: Principles and Practice of Emergency Medicine. Philadelphia, WB Saunders, 1978, p 354. Reproduced by permission.)*

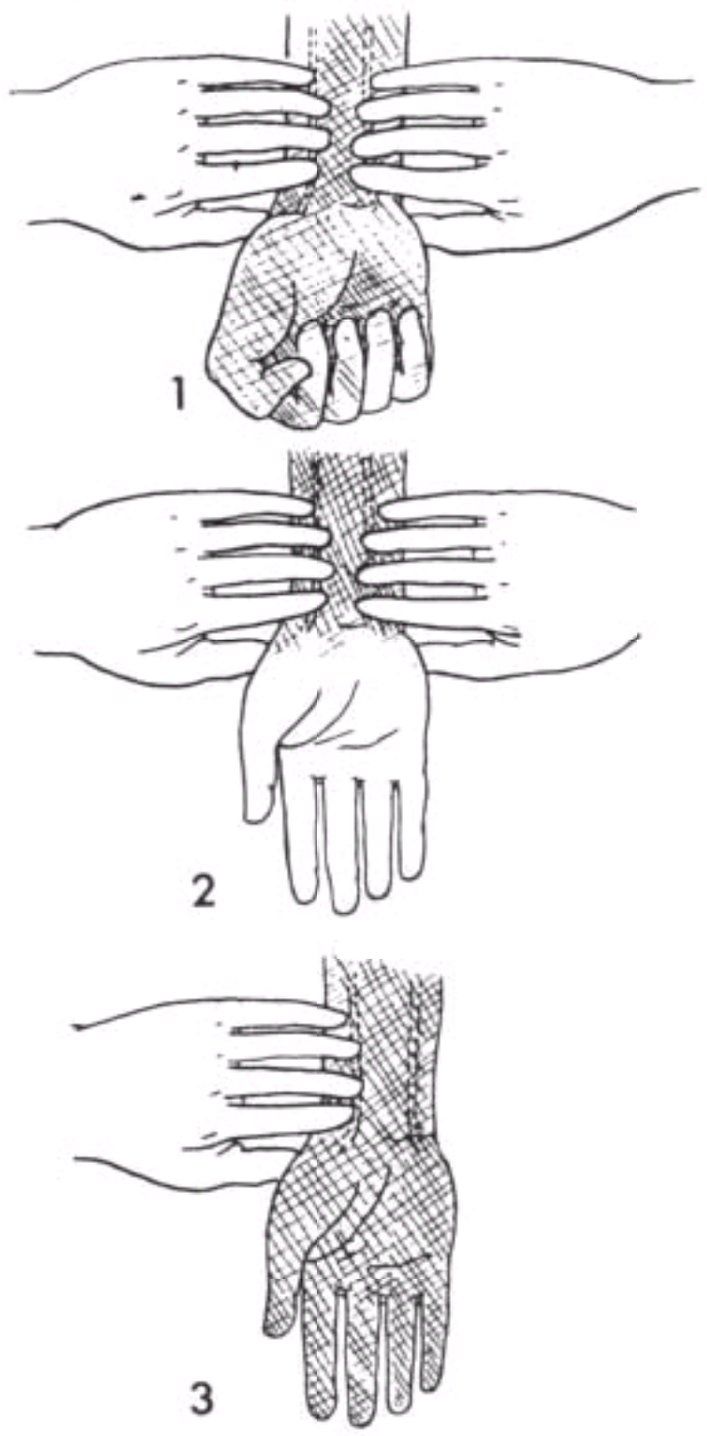

Figure 20-13 Percutaneous arterial cannulation at the wrist. The catheter unit is advanced 1 to 2 mm into the vessel lumen after blood first appears in the flash chamber. While the needle is fixed, the catheter is threaded over the needle. *(From Beal JM [ed]: Critical Care for Surgical Patients. New York, Macmillan, 1982. Reproduced by permission.)*

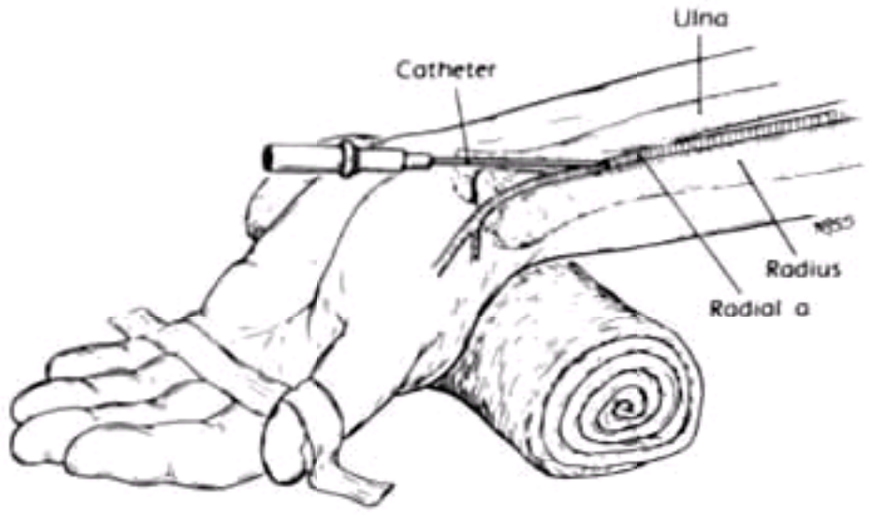

Figure 20-14 The right brachial artery and its branches. *(From Christensen JB, Telford IR: Synopsis of Gross Anatomy. New York, Harper & Row, 1966. Reproduced by permission.)*

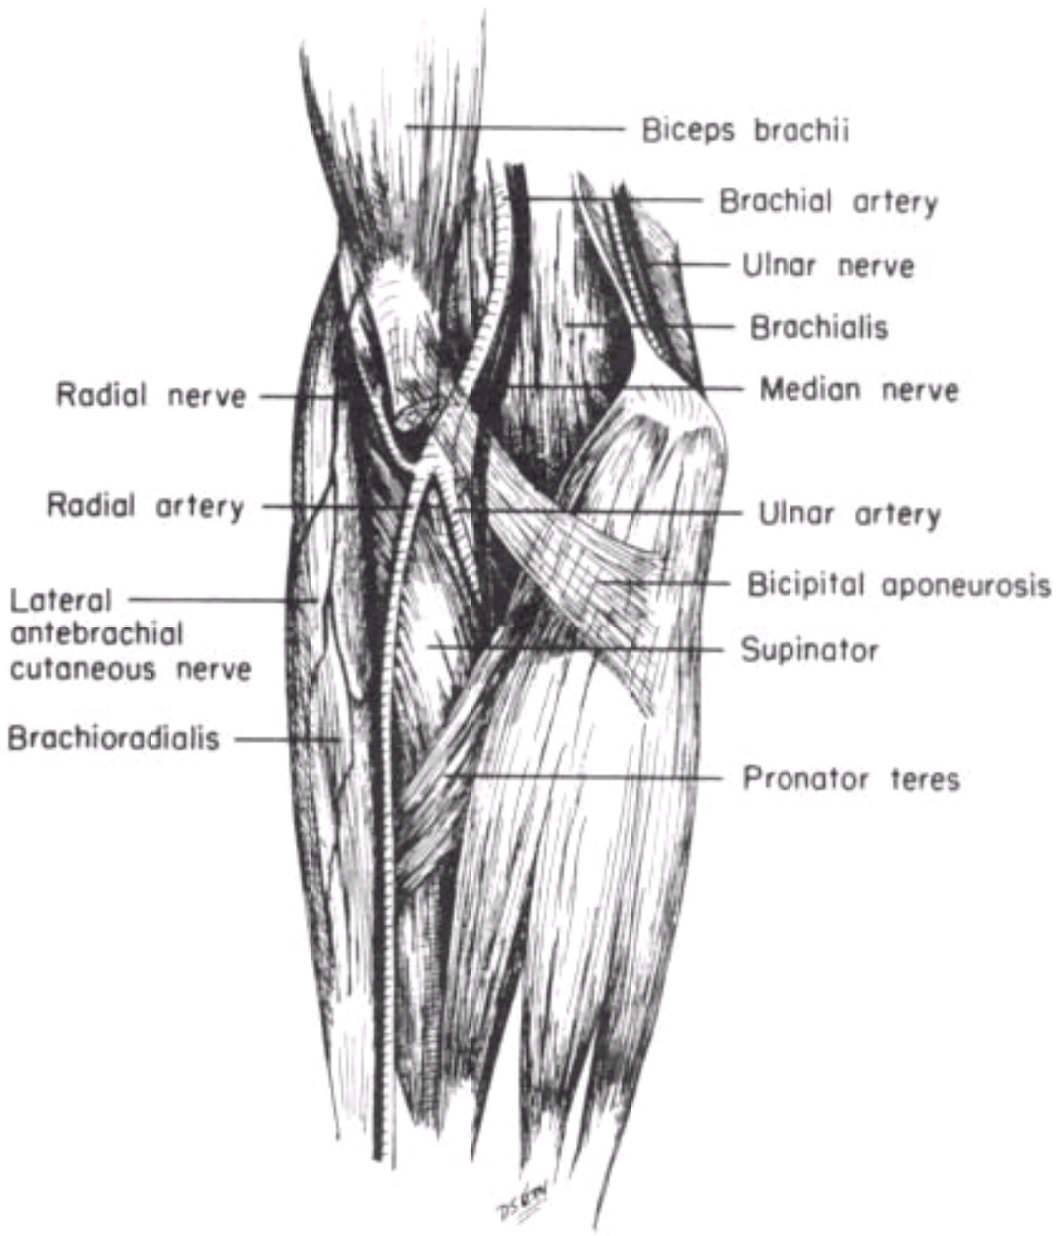

Figure 20-15 A 20-ga catheter in the dorsalis pedis artery, illustrating the relationship to surrounding tendons. The catheter is secured with Steri-Drape. Splinting is not needed. *(From Johnstone RE, Greenhow DE: Catheterization of the dorsalis pedis artery. Anesthesiology 39:655, 1973. Reproduced by permission.)*

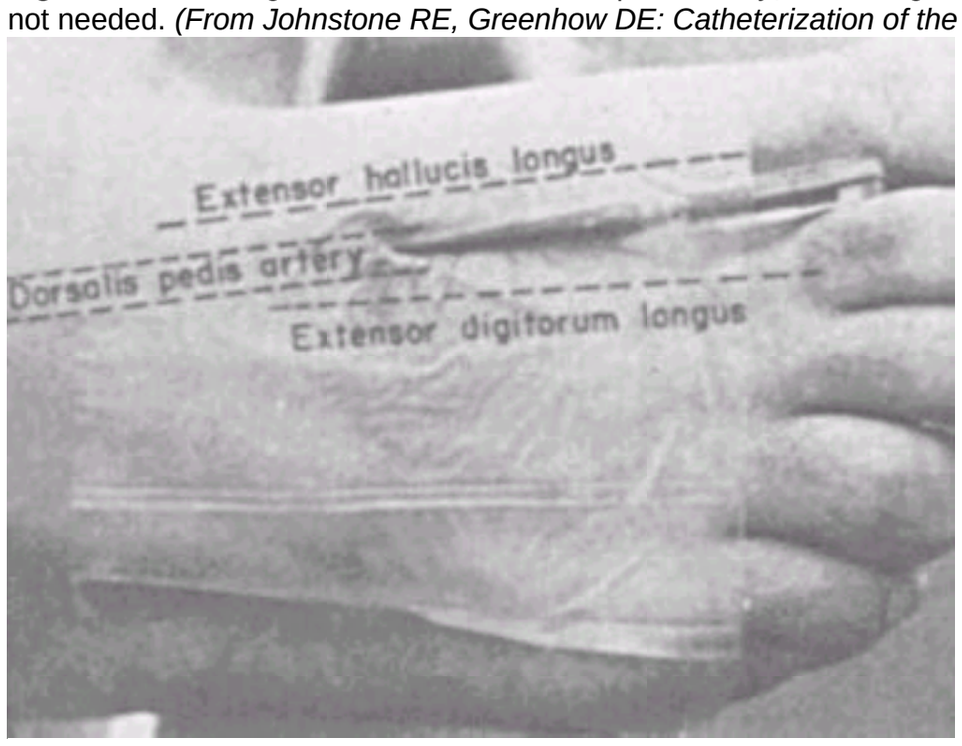

Figure 20-16 The right femoral vessels and some of their branches. The femoral nerve (not shown) lies lateral to the artery and may be deep to the artery. *(From Warwick R, Williams PL [eds]: Gray's Anatomy, 35th ed. Edinburgh, Churchill Livingstone, 1973, p 676. Reproduced by permission.)*

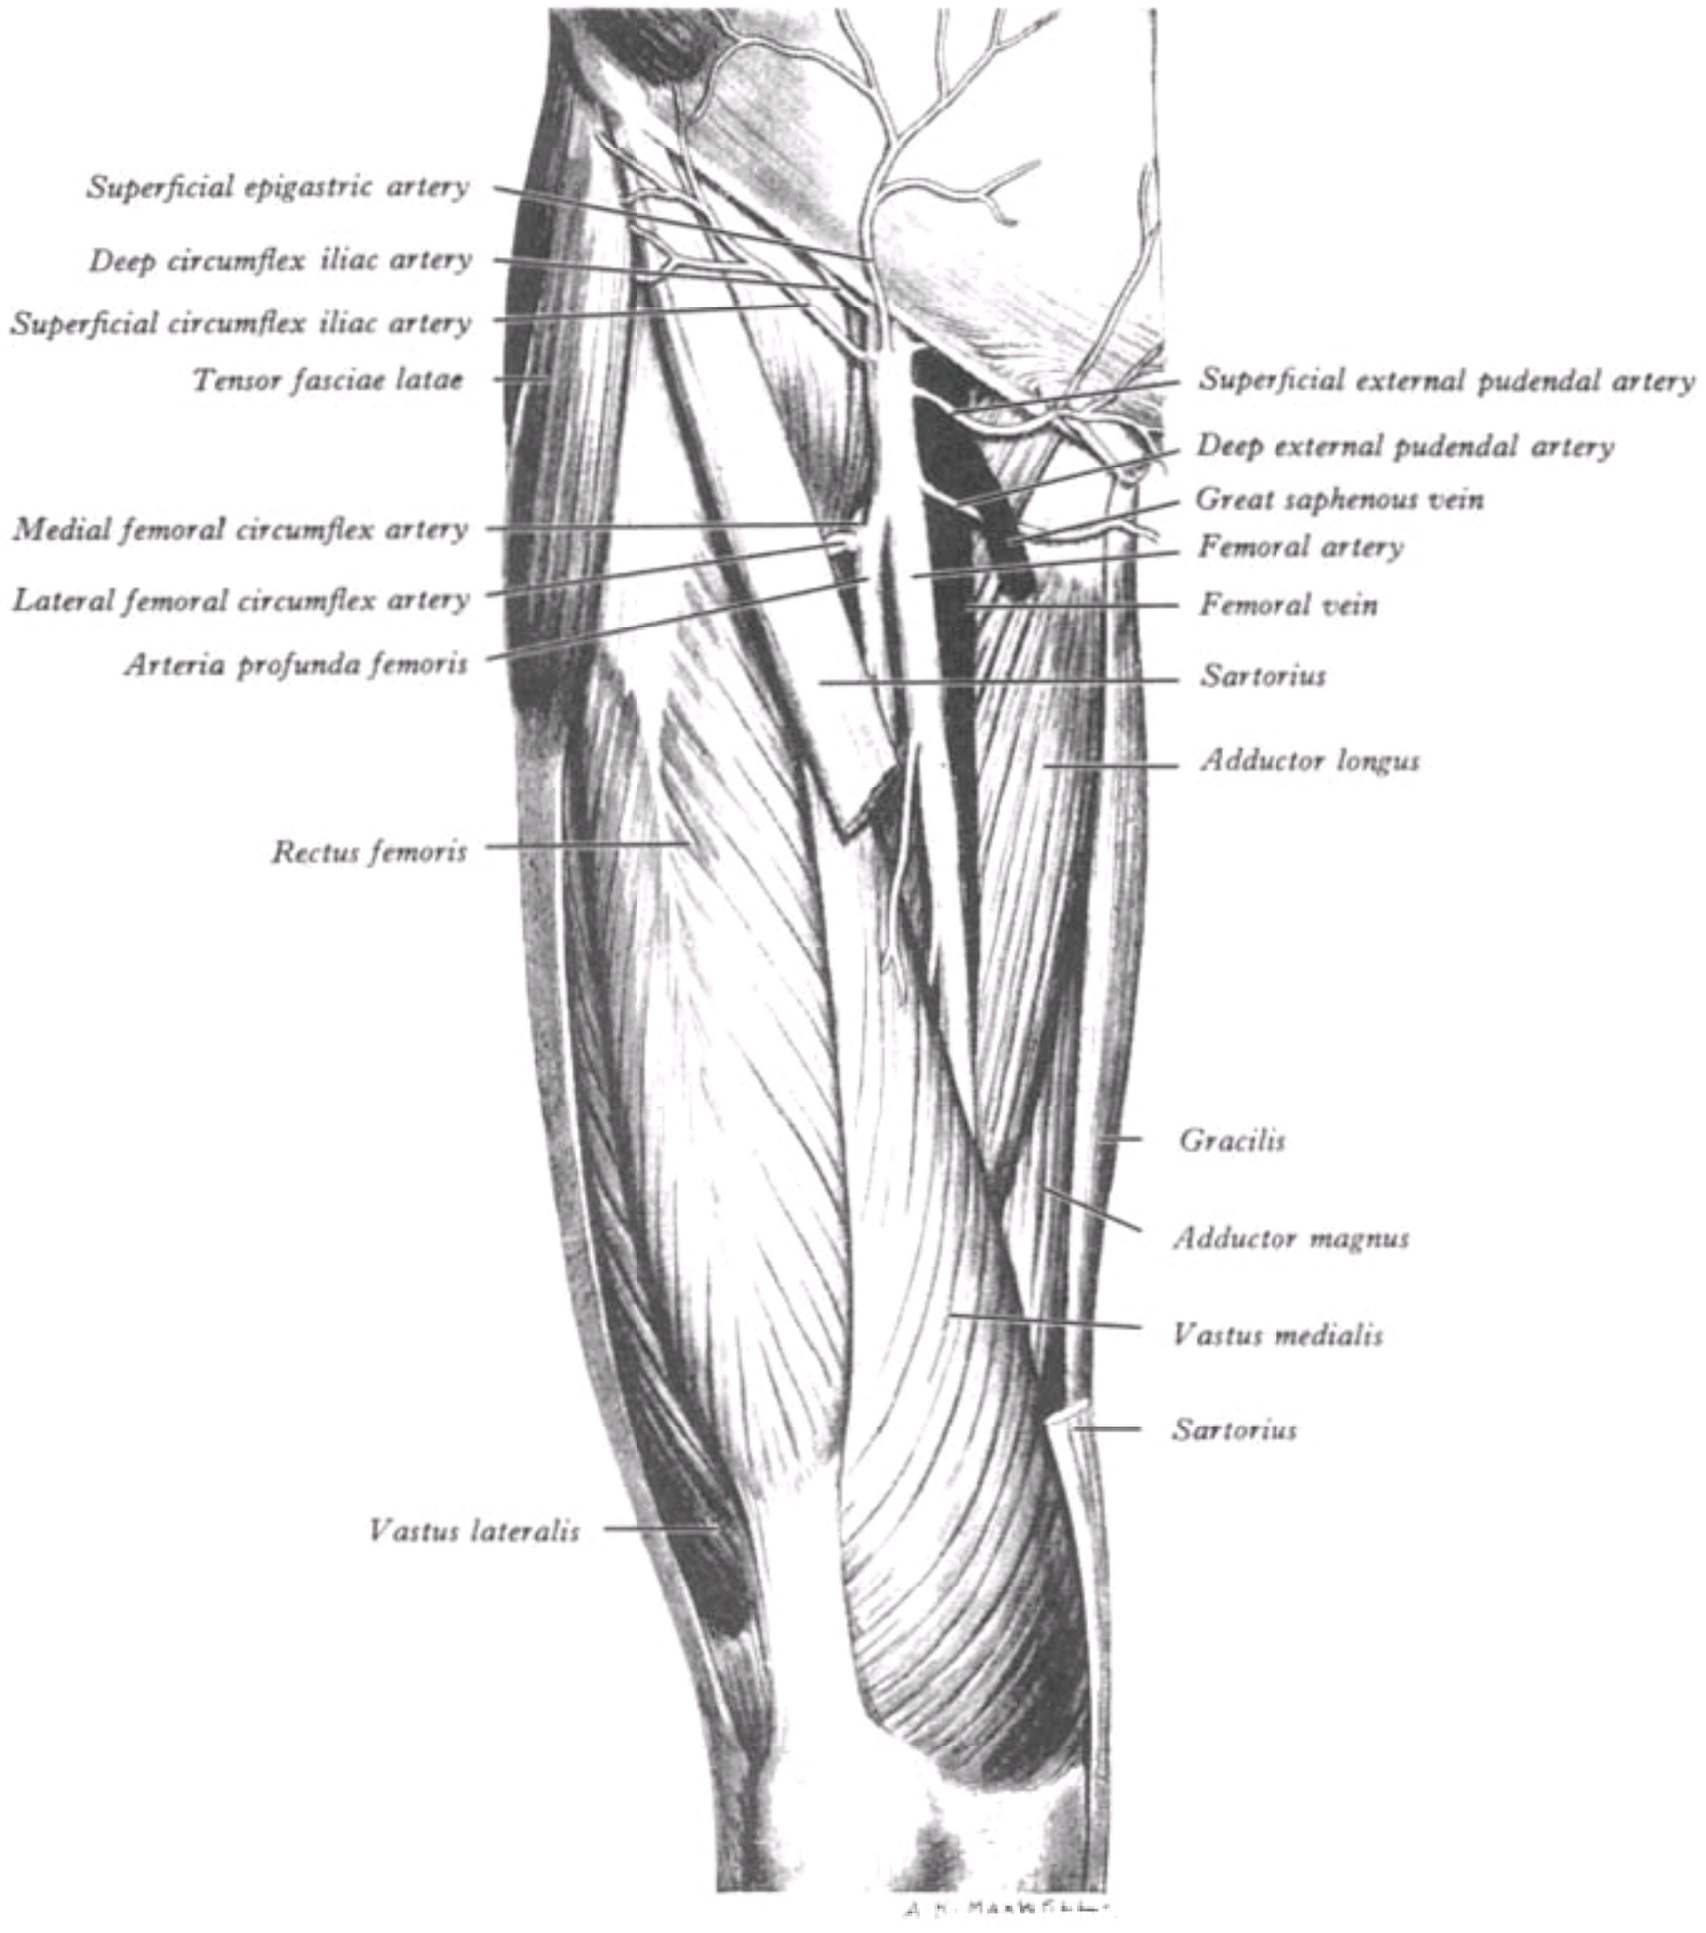

Figure 21-1 Anatomy of veins in hands and arms for intravenous cannulation. *(Adapted from Millam DA: How to insert an IV. Am J Nurs 79:1268, 1979.)*

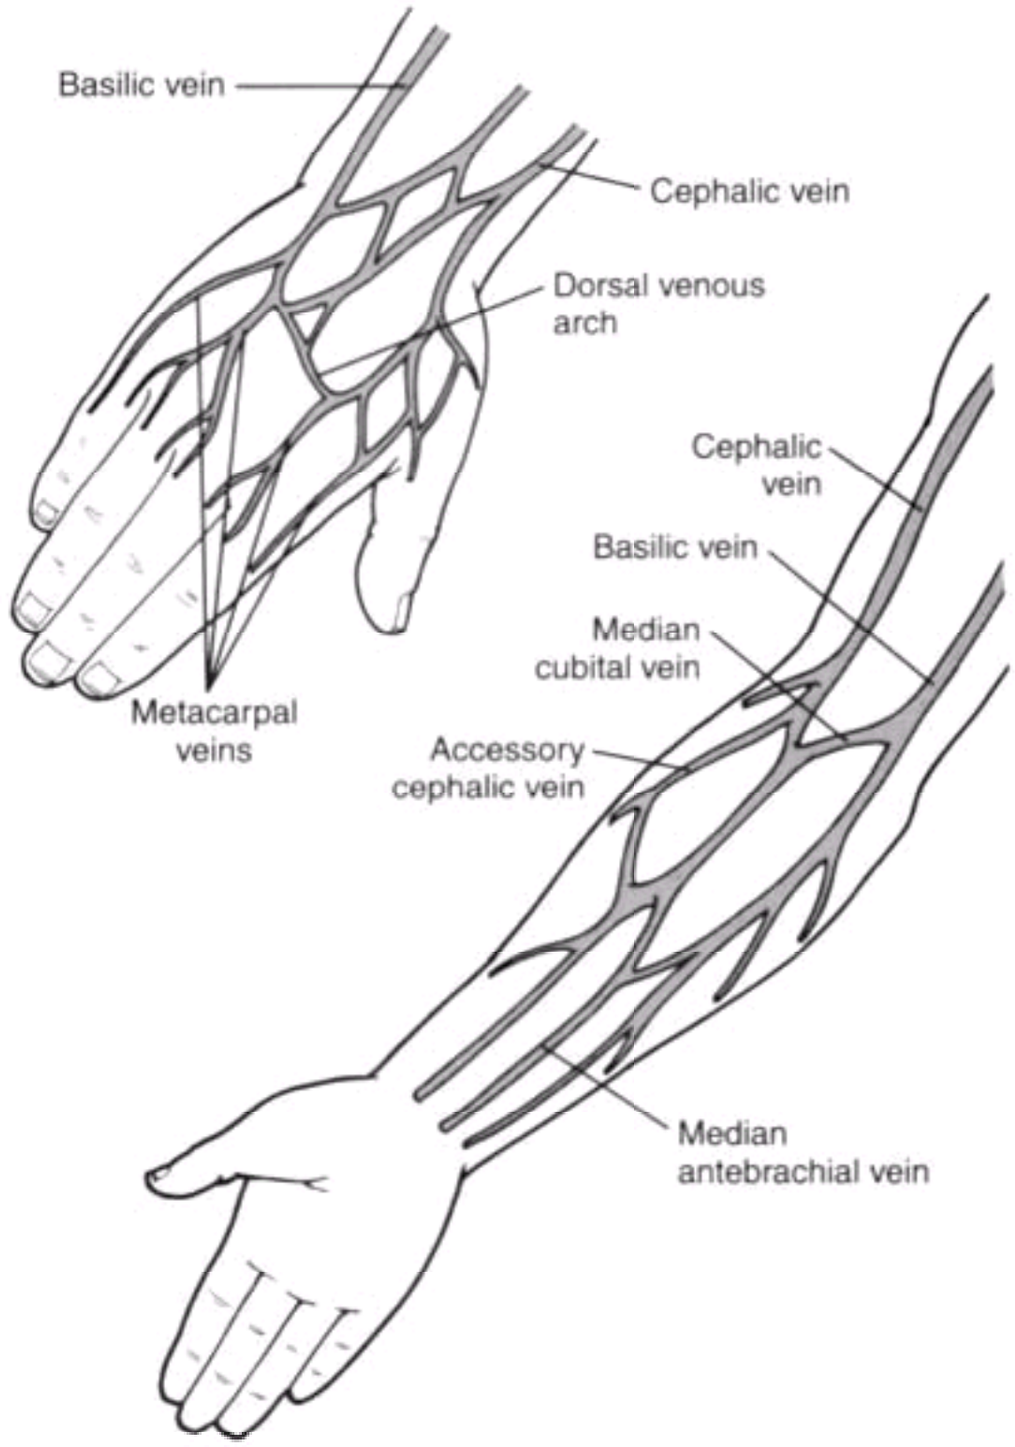

Figure 21-2 The external jugular vein may be cannulated in the same manner as any other peripheral vein, which often negates the need for central venous catheterization. This site is especially useful to obtain blood and to infuse fluids and medication in obese adults, infants, and IV drug users. The major disadvantages are that flow is very dependent on the position of the neck (a significant problem in children and obtunded or restless adults), and valves may abut against the tip of the catheter. Air embolism from a disconnected catheter is another potential hazard with this access route.

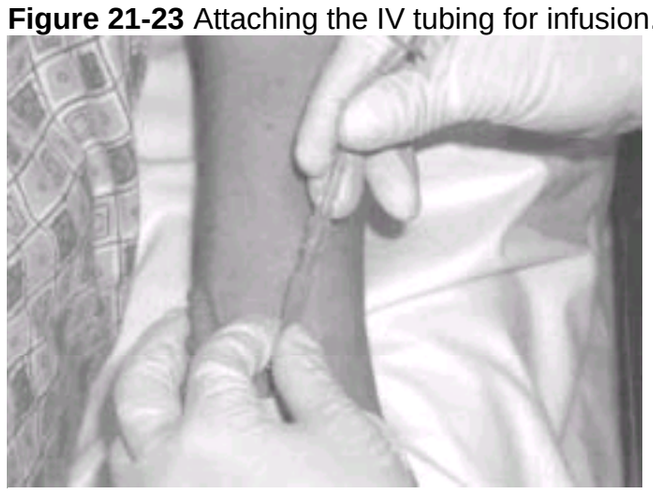

Figure 21-24 *A*, Anatomy of the vessels of the arm. *B*, Corresponding ultrasound image obtained with an Aloka 7.5-MHz ultrasound probe on the right arm. BA, brachial artery; BAV, basilic vein; DBV, deep brachial vein. *(From Keyes LE, et al: Ultrasound-guided brachial and basilic vein cannulation in emergency department patients with difficult intravenous access. Ann Emerg Med 34:711, 1999.)*

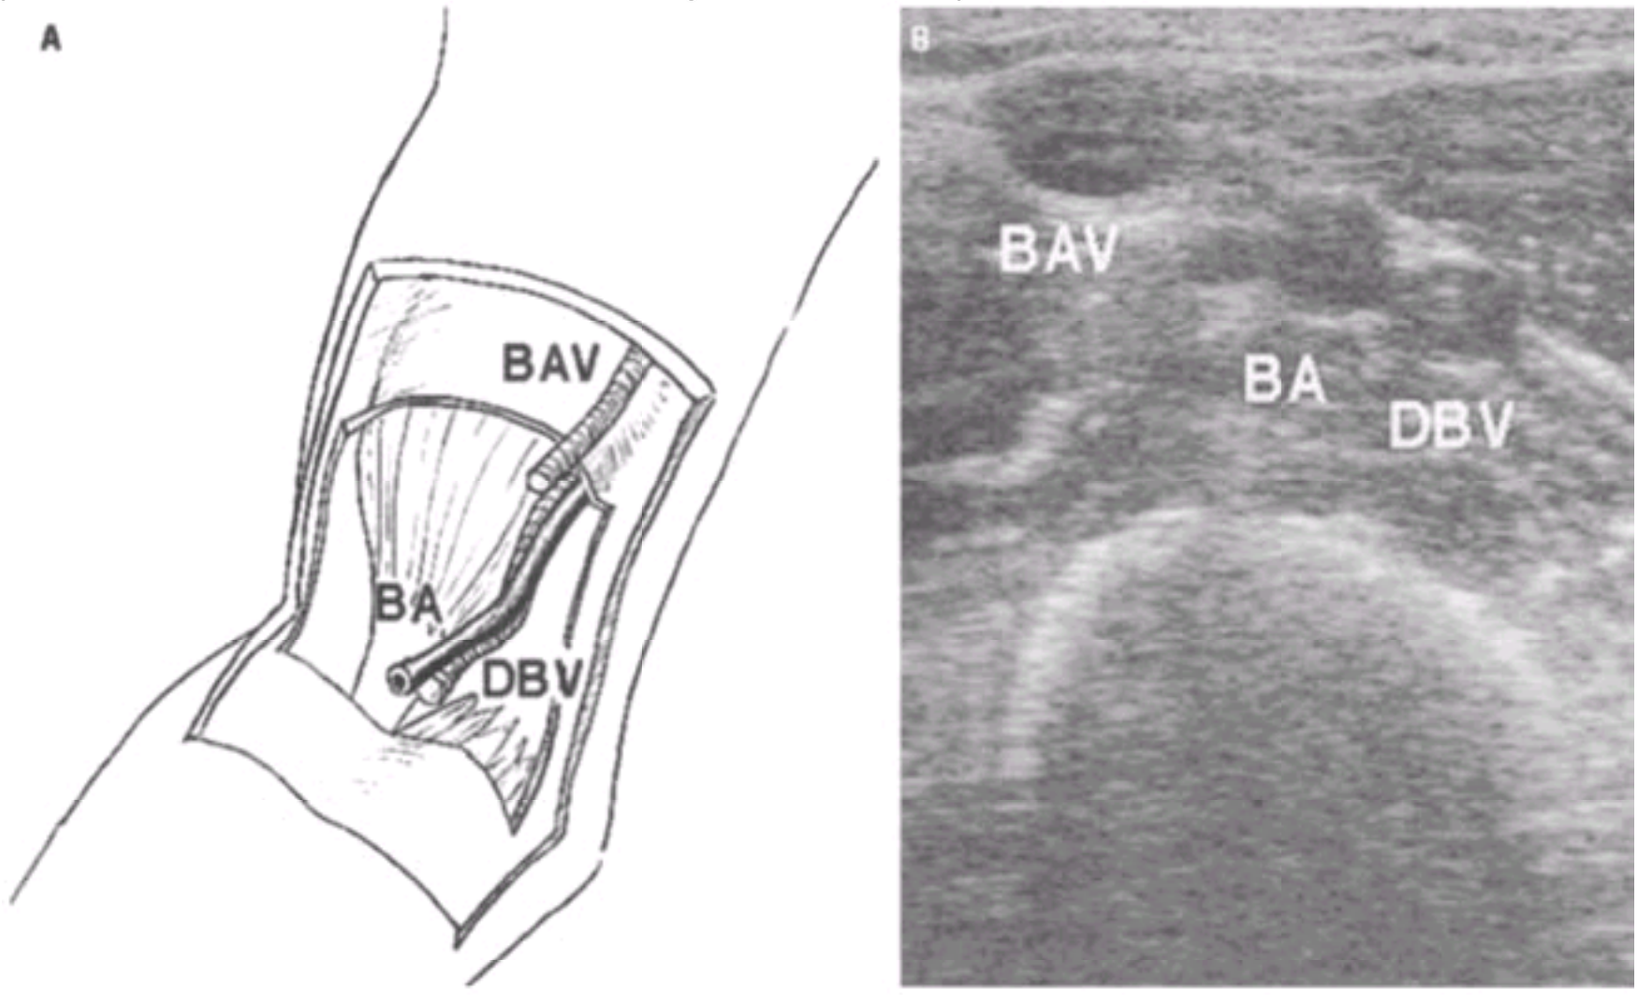

Figure 21-25 Extravasation of phenytoin. Pain at the infusion site or the alarm of an infusion pump requires inspection of the IV site for extravasation when irritating solutions are infused. In this case, an unconscious patient received a concentrated phenytoin infusion for status epilepticus, but his comatose state did not allow him to complain of pain. Over a few days, a skin slough occurred, requiring many weeks to resolve. This could have been avoided with the use of a more dilute solution (i.e., <1 mg/mL phenytoin to saline solution) or a central vein. The top panel shows the site one day after the phenytoin extravasation. The bottom panel was taken on follow up approximately a month later. *(Pictures courtesy of Dr. Mahesh Shrestha.)*

a, Point of insertion and direction of needle.
b, Oblique anterosuperior veiw of root of neck.

Figure 22-2 Structures in a dissection of the neck. The superficial veins and the sternocleidomastoid muscle have been removed, as have the submandibular gland and a segment of the facial vein. The cutaneous nerves have been cut down to short stumps arising from the second, third, and fourth cervical nerves. The internal jugular vein is drawn somewhat more medial in this illustration than is commonly found. *(From Hollinshead WH: Textbook of Anatomy, 3rd ed. New York, Harper & Row, 1974, p 765. Reproduced by permission.)*

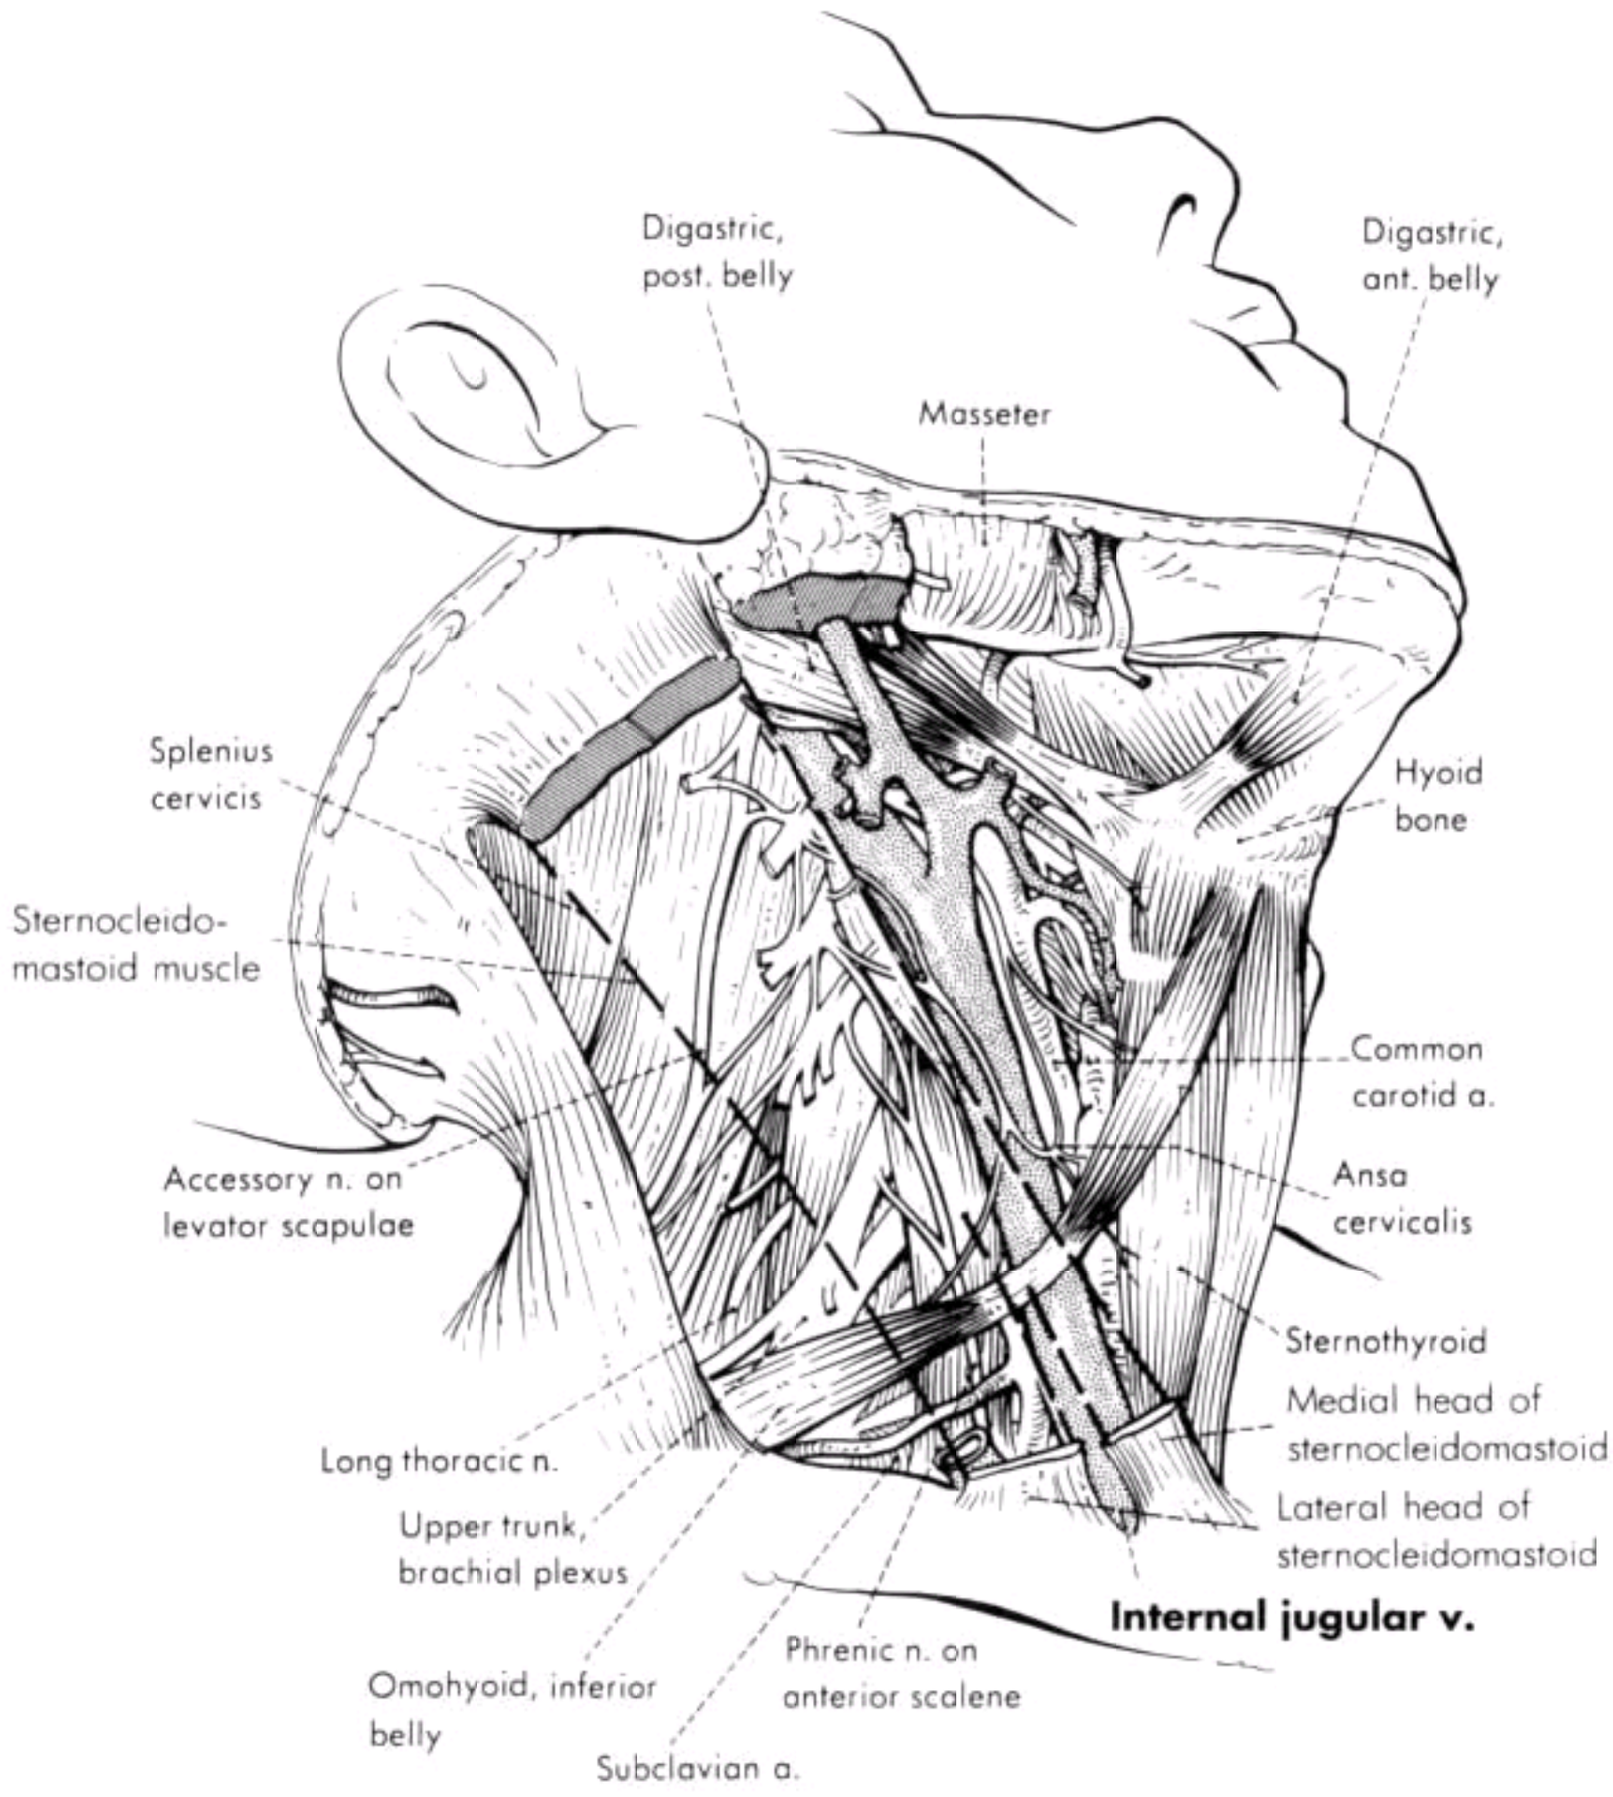

Figure 22-3 The right femoral vessels and some of their branches. The femoral nerve (not shown) lies lateral to the artery and may be deep to the artery. *(From Warwick R, Williams PL [eds]: Gray's Anatomy, 35th ed. Edinburgh, Churchill Livingstone, 1973, p 676. Reproduced by permission.)*

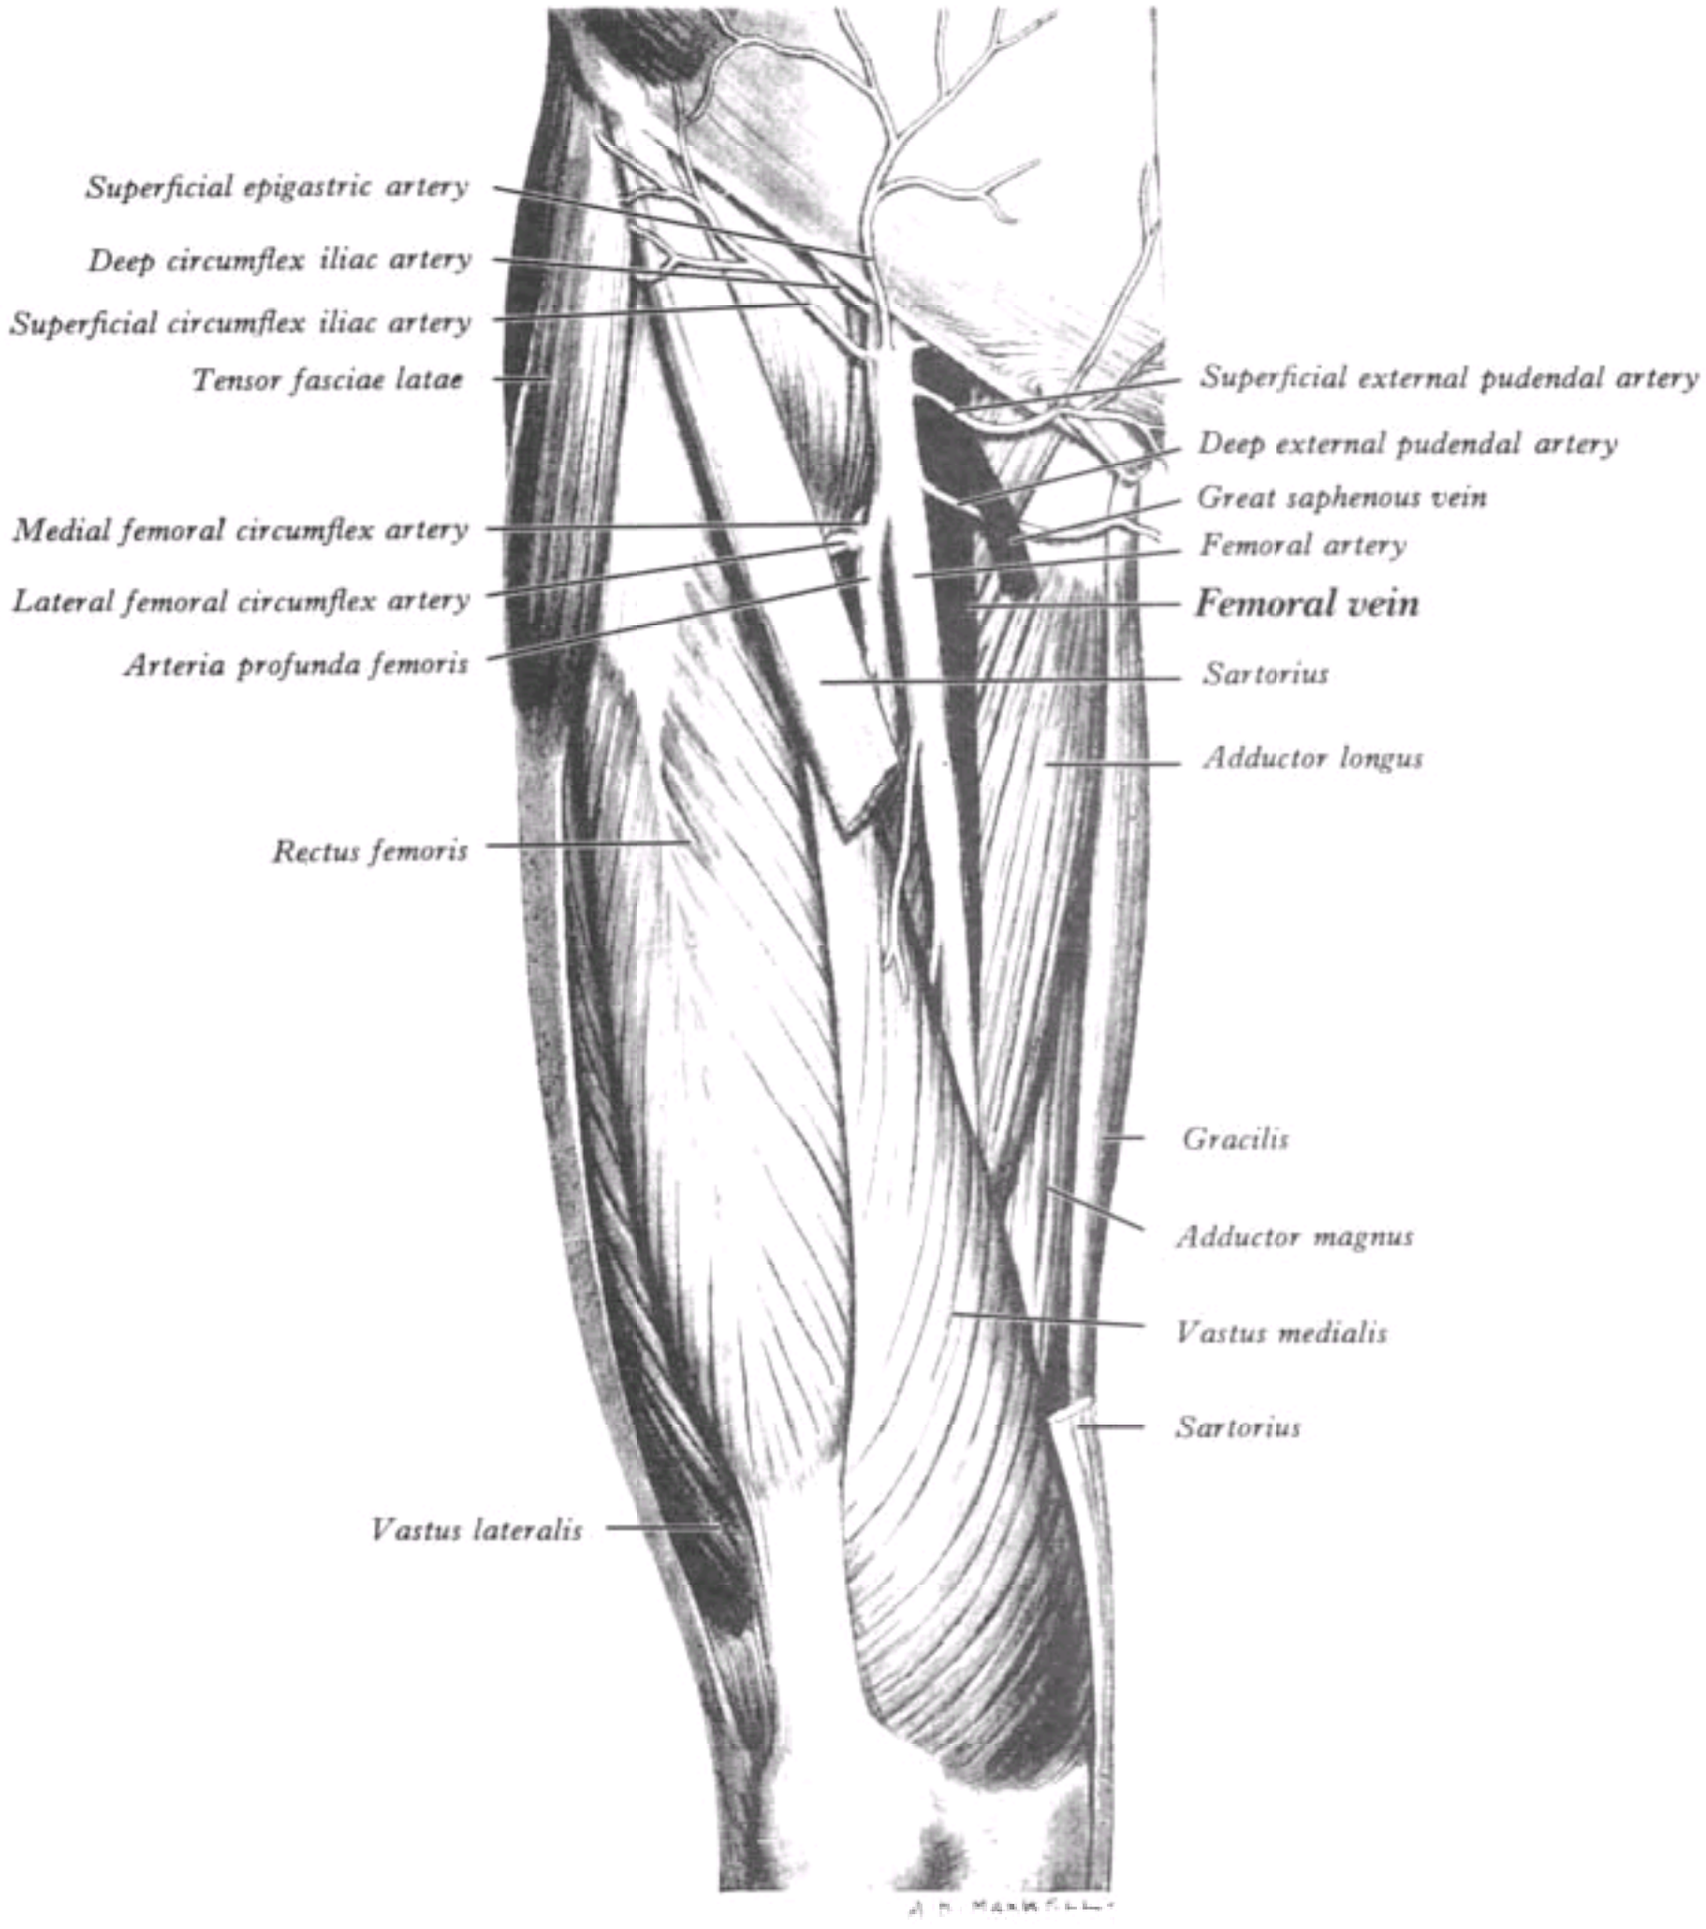

Figure 22-4 Major veins of the upper half of the body. *(From Hedges JR: Vascular access. Curr Top Emerg Med 2:1, 1981. Reproduced by permission.)*

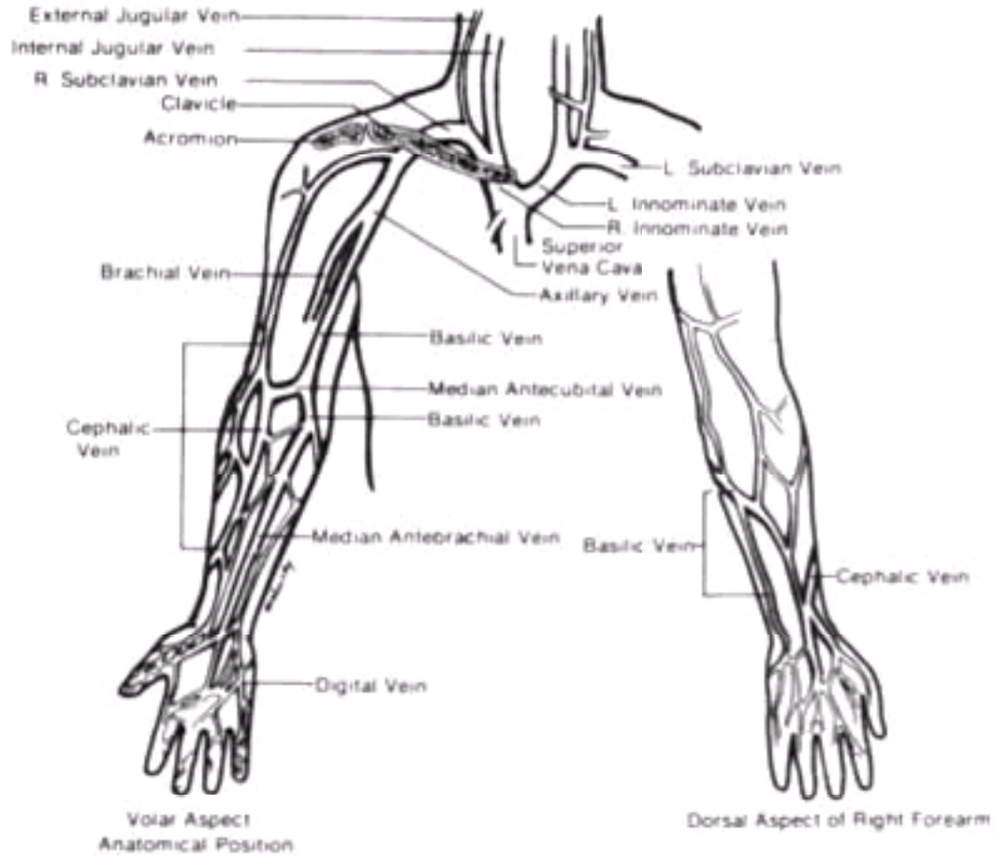

Figure 22-5 Introducing needles. *A,* Ordinary needle with a straight-bore lumen. *B,* Seldinger needle with a tapered lumen, allowing easy entry of the guidewire.

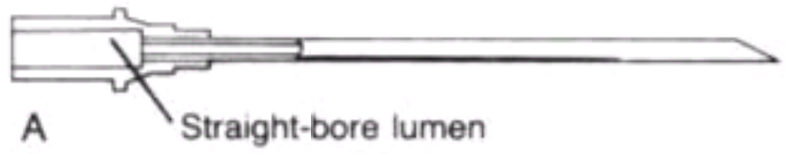

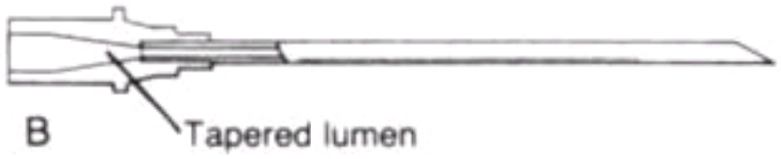

Figure 22-6 *A*, Guidewire internal structure: safety wire (a), core wire (mandrel) (b), coiled wire (c), flexible tip (d). *B*, Flexible end of a straight-spring guidewire knotted on a vessel dilator (a), bent junction of the rigid and flexible portions of a straight-spring guidewire with protrusion of the central core (arrow) (b), partially fractured tip (arrow) of a J-spring guidewire (c). *(From Schwartz AJ, Horrow JL, Jobes DR, Ellison N: Guide wires—A caution. Crit Care Med 9:348, 1981. ©1981 Williams & Wilkins, Baltimore. Reproduced by permission.)*

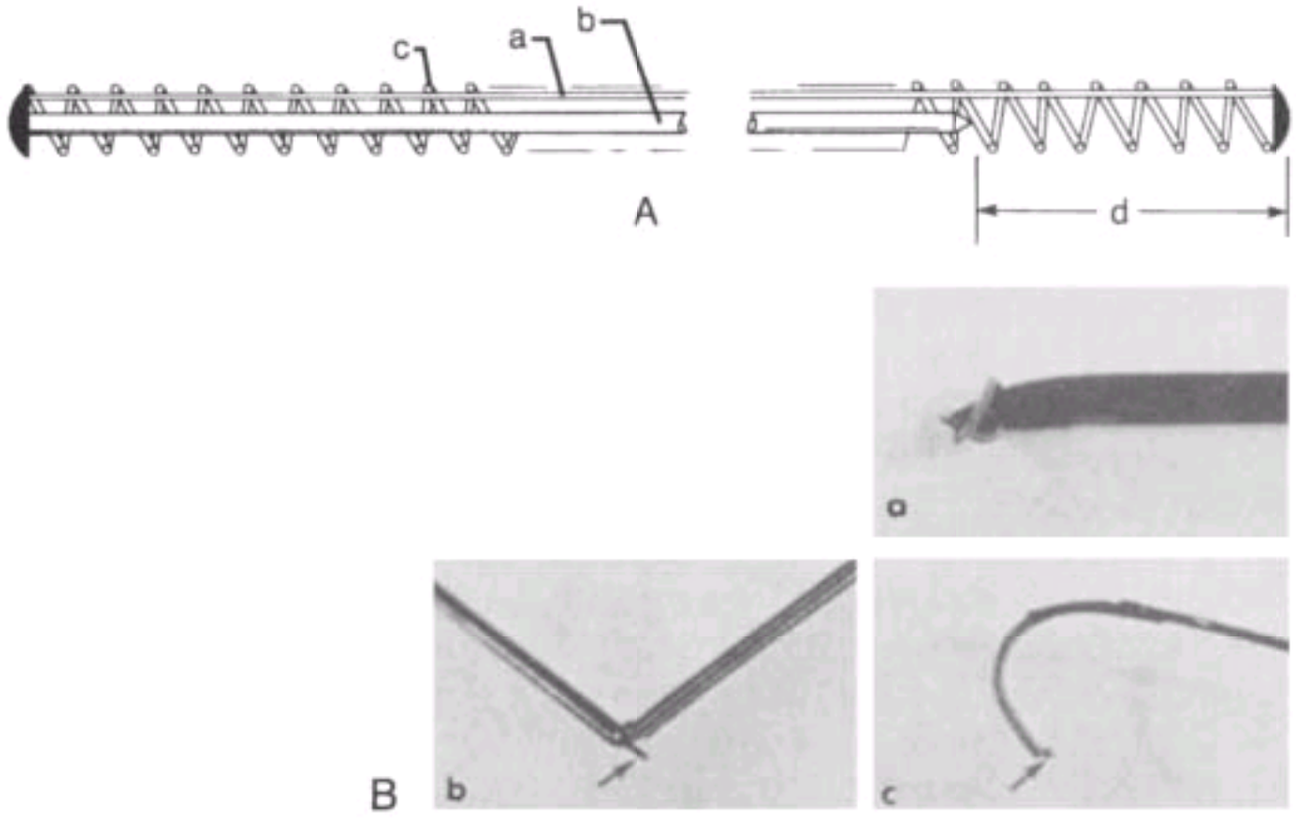

Figure 22-7 Desilets-Hoffman sheath introducer. *A*, Guidewire. *B*, Sheath-introducer. *C*, Dilator. *D*, Assembled device.

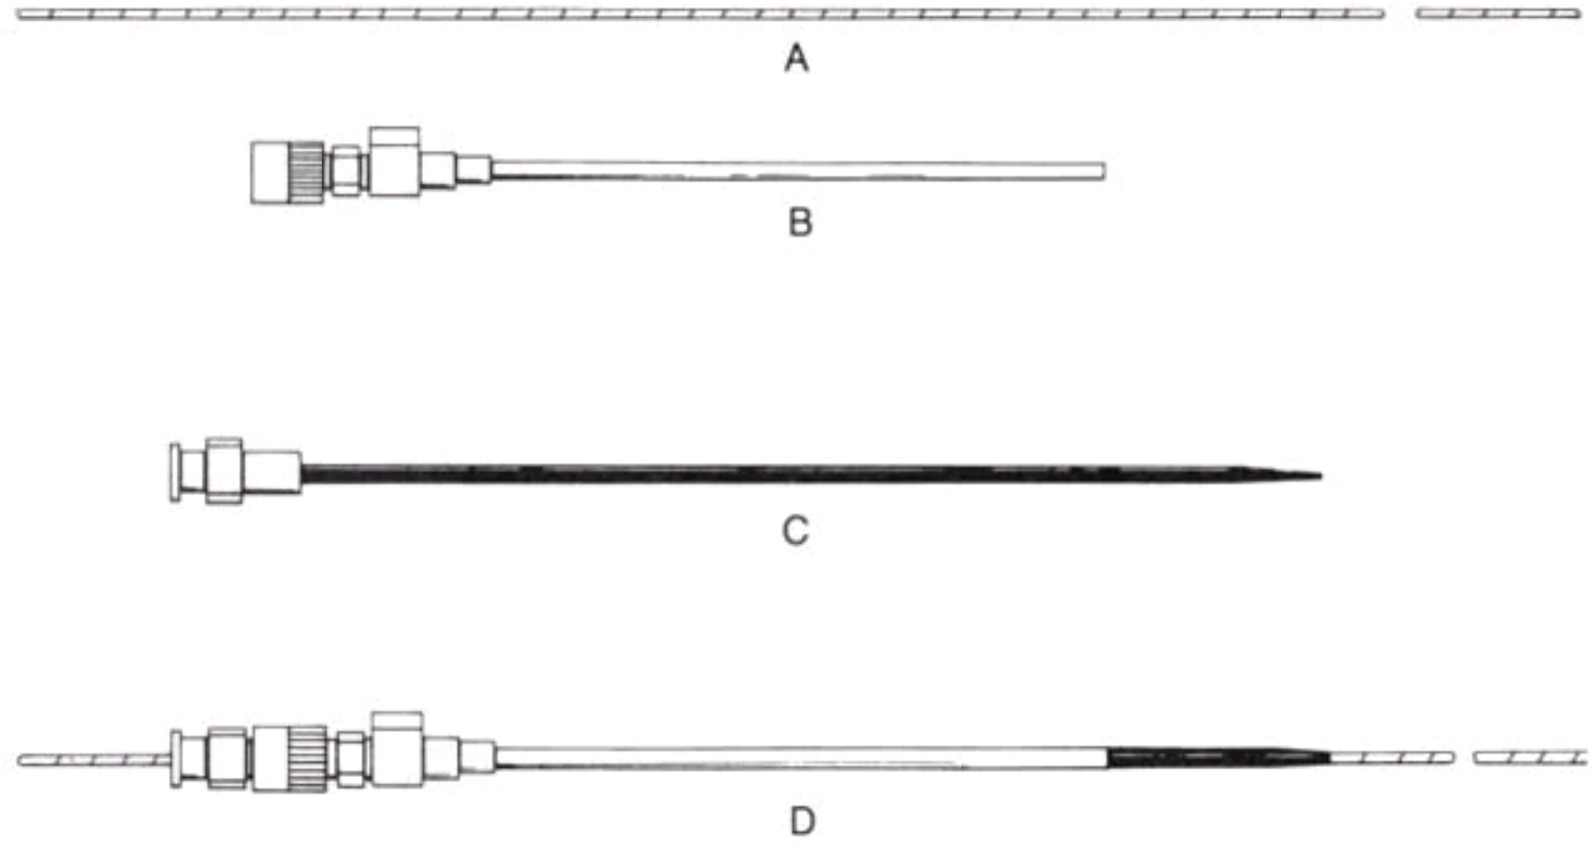

Figure 22-8 Procedure for placement of Seldinger-type guidewire catheter. *A*, The selected vessel is cannulated with a thin-walled needle, or an existing IV catheter is chosen to be changed with the wire technique. *B*, The guidewire is threaded through the vessel, with the flexible end first, into the lumen of the vessel. If a J wire is used, a sleeve will facilitate entry into the needle (see Fig. 22-9). *C*, The needle is removed so that only the wire now exits from the vessel. *D*, The skin entry site is enlarged with a No. 11 scalpel. *E*, The catheter sheath and the dilator are threaded over the wire and advanced to the skin. The wire must be visible through the back of the device. *F*, If the proximal wire is not visible, it is pulled from the skin through the catheter until it appears at the back of the catheter. *G*, The sheath and the dilator are advanced as a unit into the skin with a twisting motion. It is best to grasp the unit at the junction of sheath and dilator to prevent bunching up of the sheath. The wire (at the back of the catheter) must be held while the sheath and dilator are advanced as a unit. *H*, Once the sheath and the dilator are well within the vessel, the guidewire and the dilator are removed. Contrary to the illustration, latex gloves should be worn.

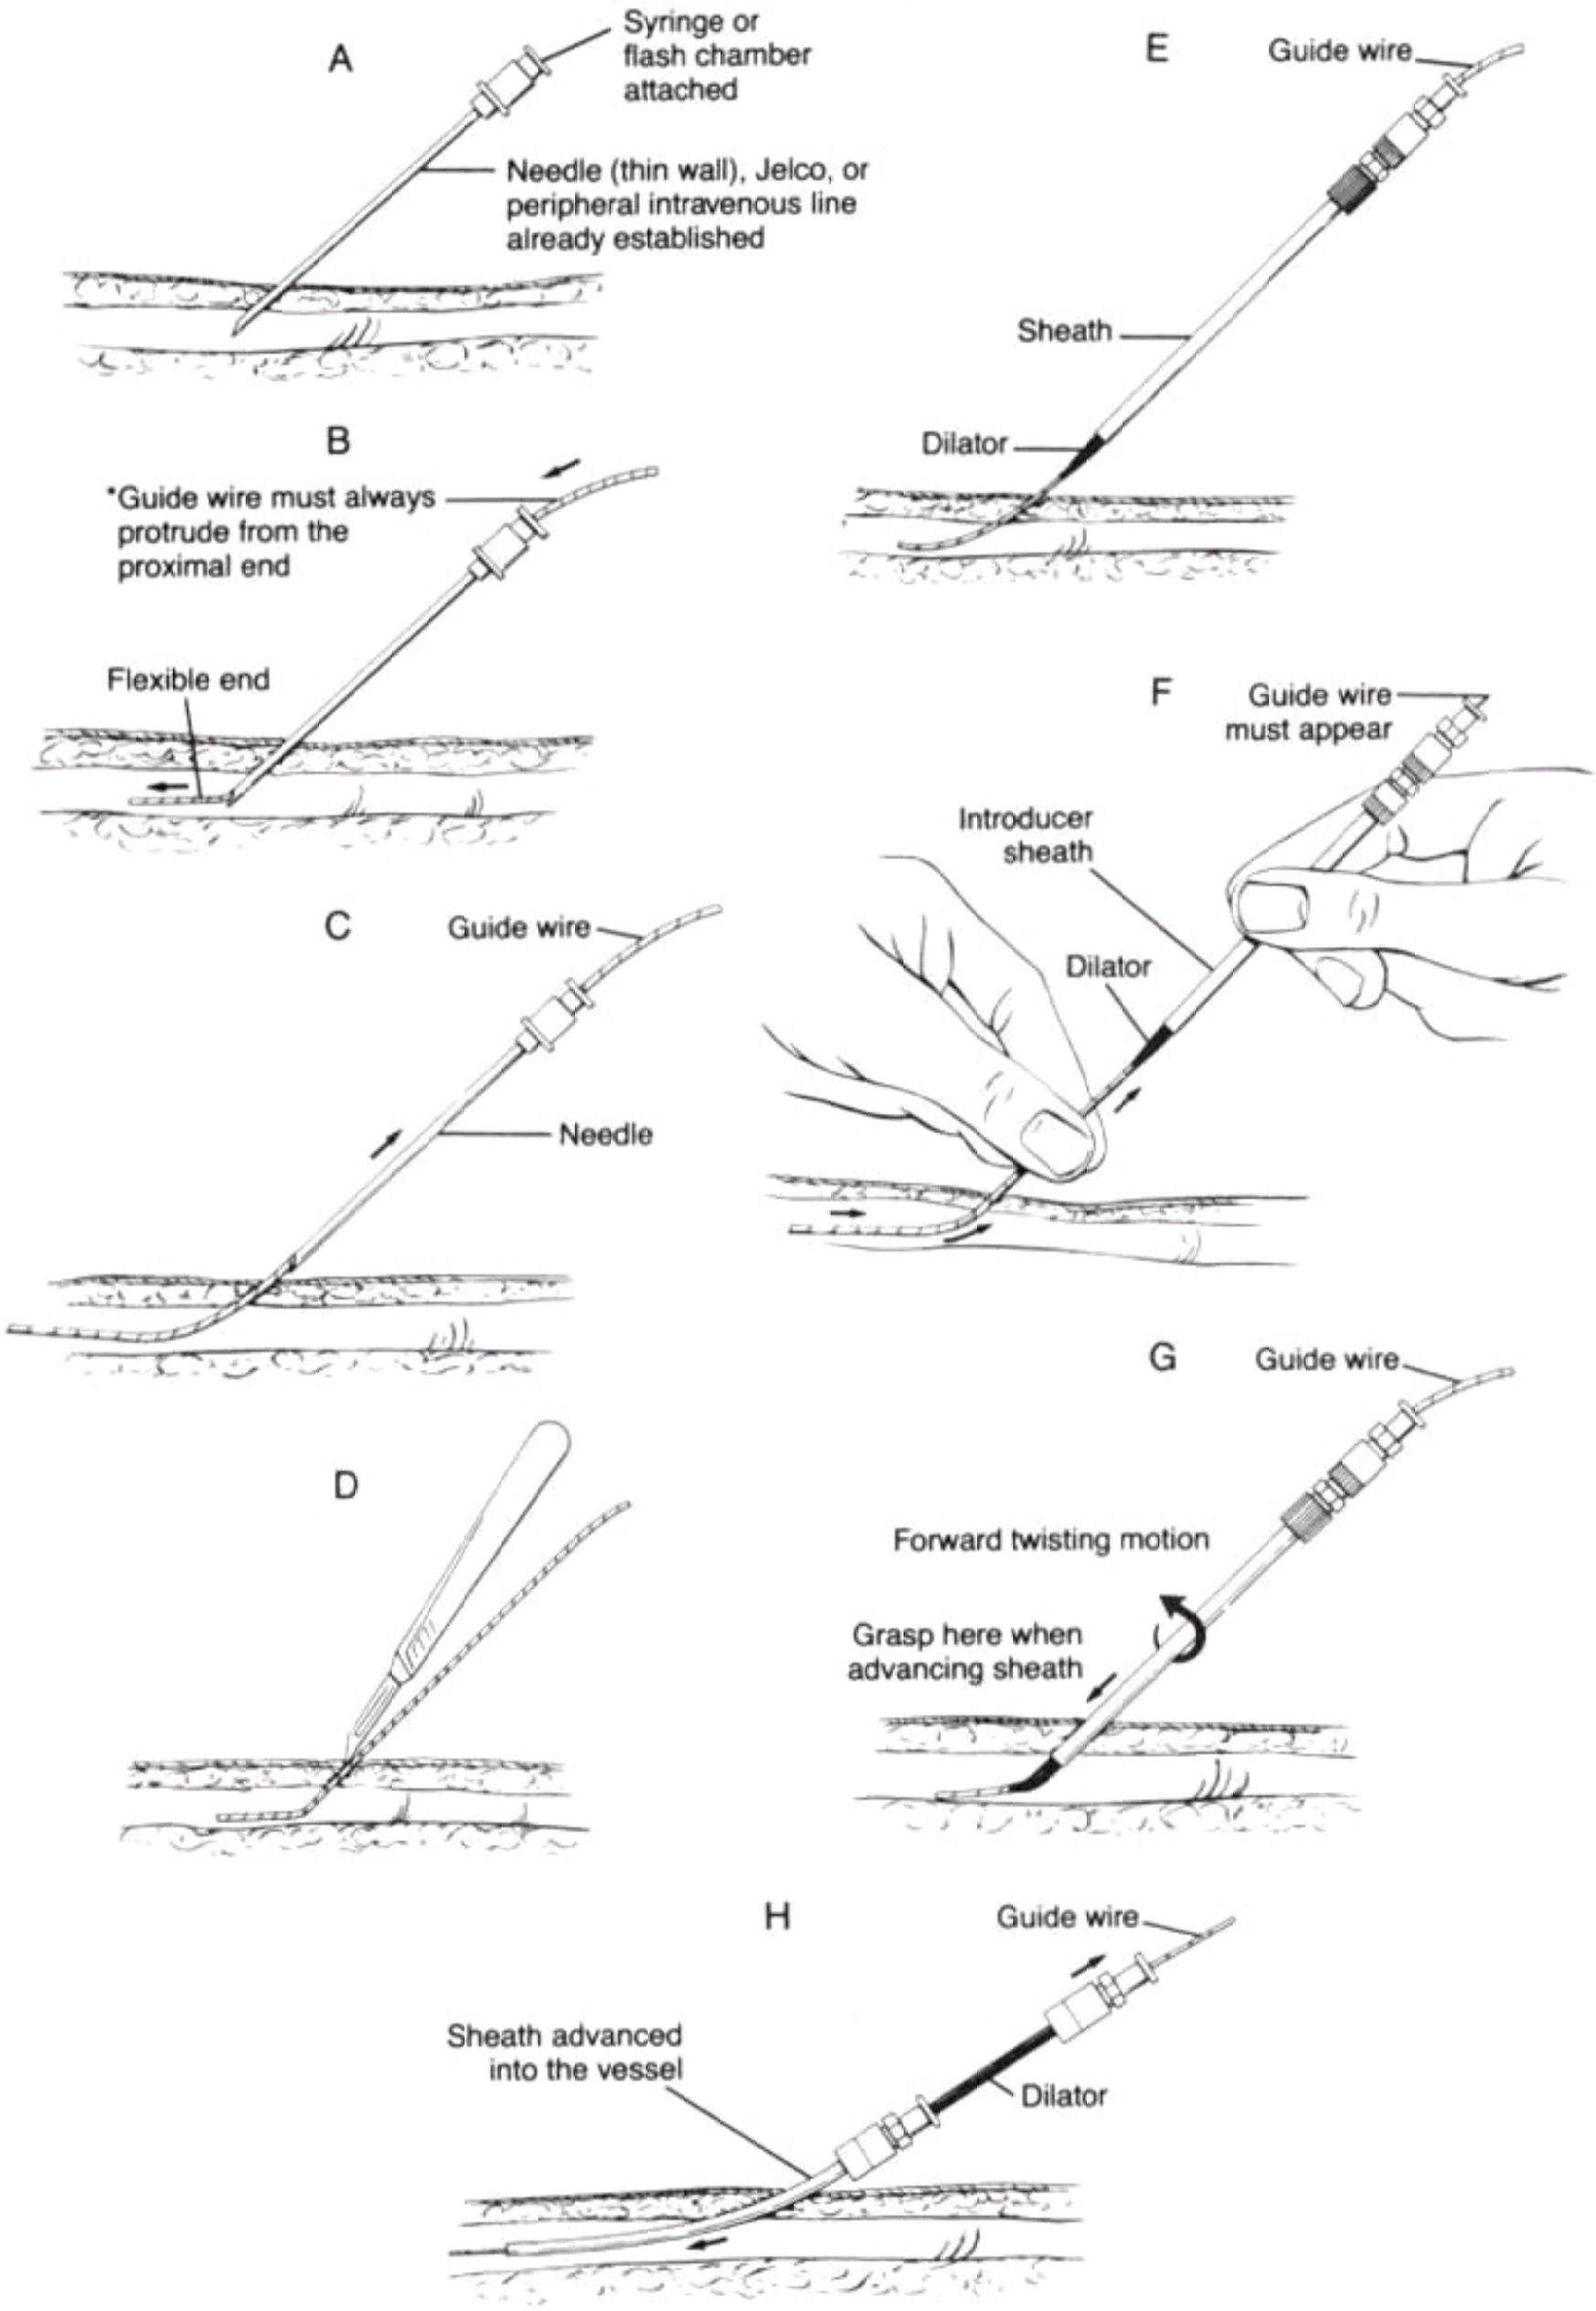

Figure 22-9 J wire. *A*, Plastic sleeve in retracted position, demonstrating the J tip. *B*, Plastic sleeve is advanced to straighten the curve to allow easy introduction into the needle hub. In an emergency, care must be taken to not misplace or throw away the sleeve. Without it, placing the J wire into the hub of the needle is very difficult.

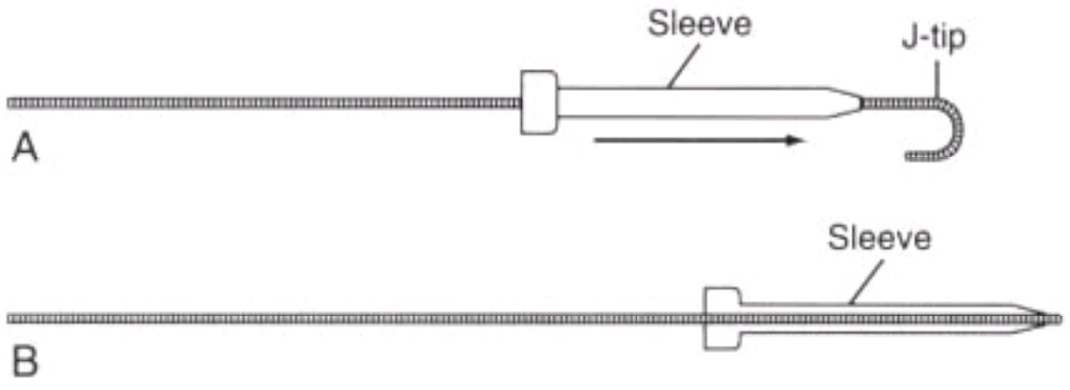

Figure 22-10 Although newer guidewires are more resistant to shearing, if a guidewire will not advance, it is best to withdraw both the needle and wire in one motion. These pictures demonstrate a permanently deformed guidewire that could not be advanced. Withdrawing the wire with the indwelling introducer needle in place within a vessel may shear off a portion of the wire, resulting in systemic embolization.

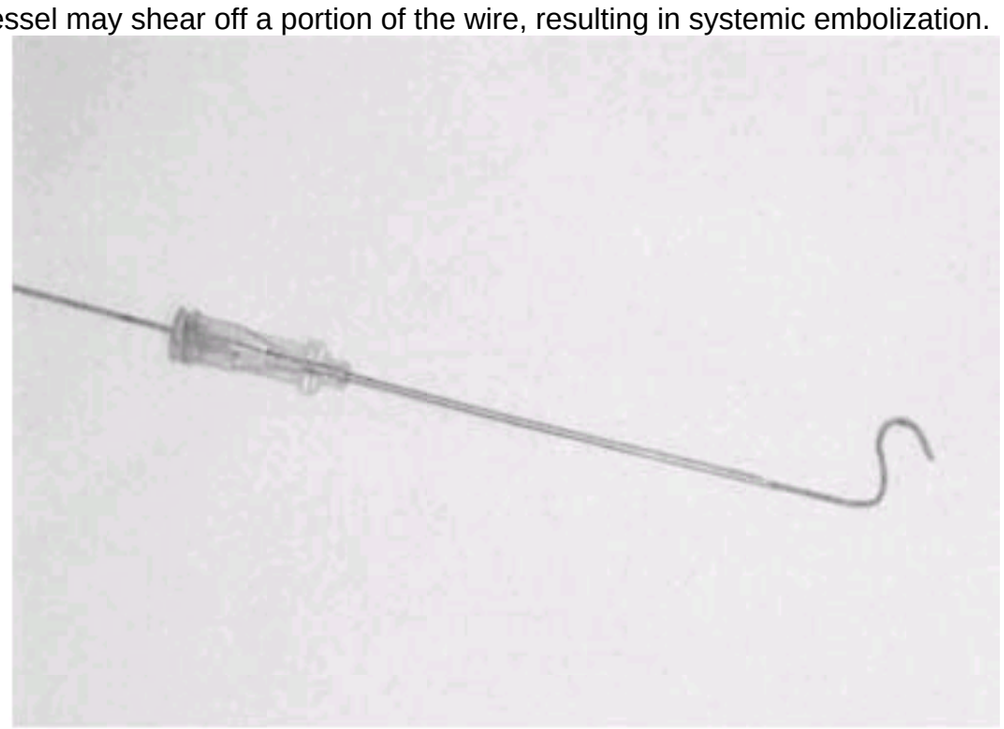
A



B

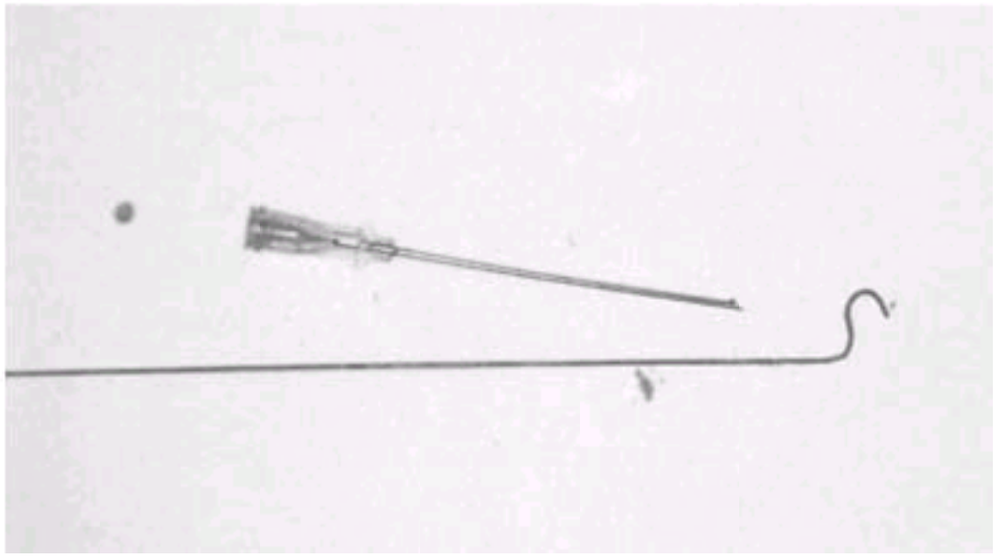


Figure 22-11 Needle bevel orientation using supraclavicular and infraclavicular venipuncture. The orientation of the needle bevel may help in positioning the catheter properly by guiding the direction of the catheter during advancement. If the bevel is aligned with the markings on the syringe, the orientation of the bevel is always certain.

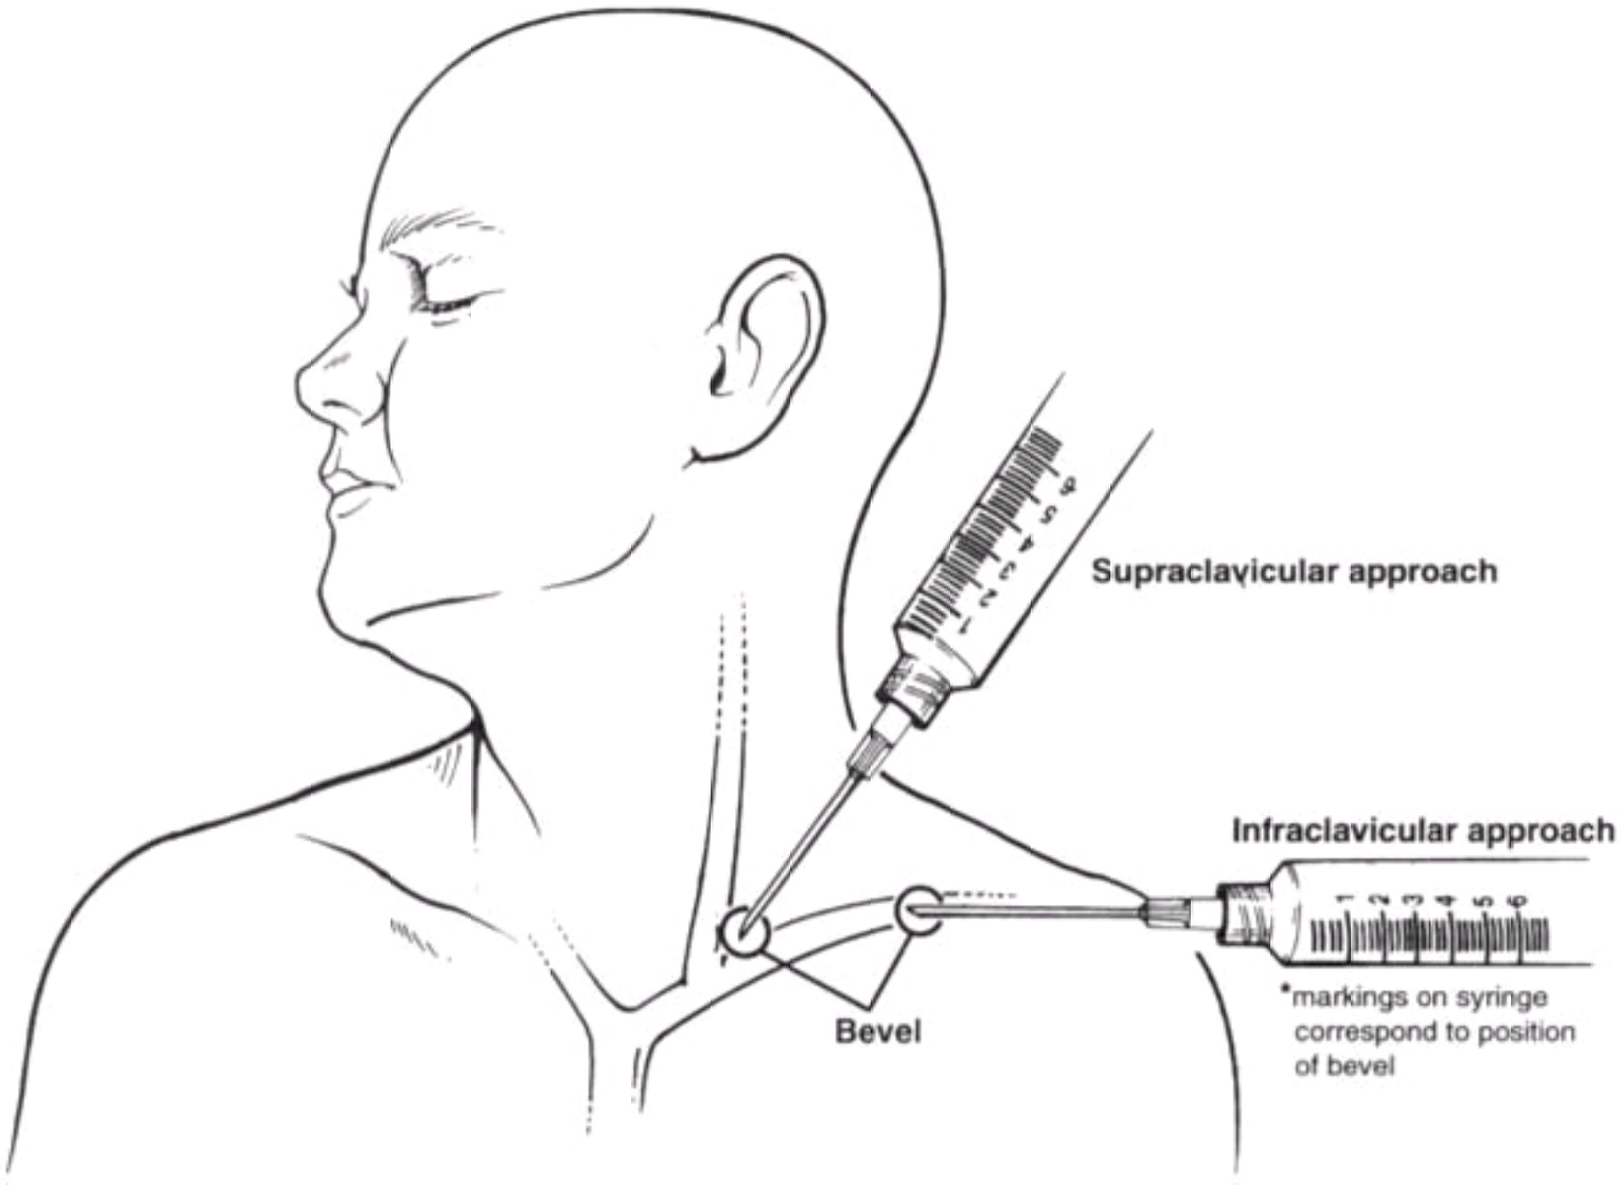

Figure 22-12 Hand position during subclavian venipuncture. Note that surgical gloves should be worn during this procedure, in contrast to the illustration. *(From Linos D, Mucha P, von Heerden J: Subclavian vein: A golden route. Mayo Clin Proc 55:318, 1980. Reproduced by permission.)*

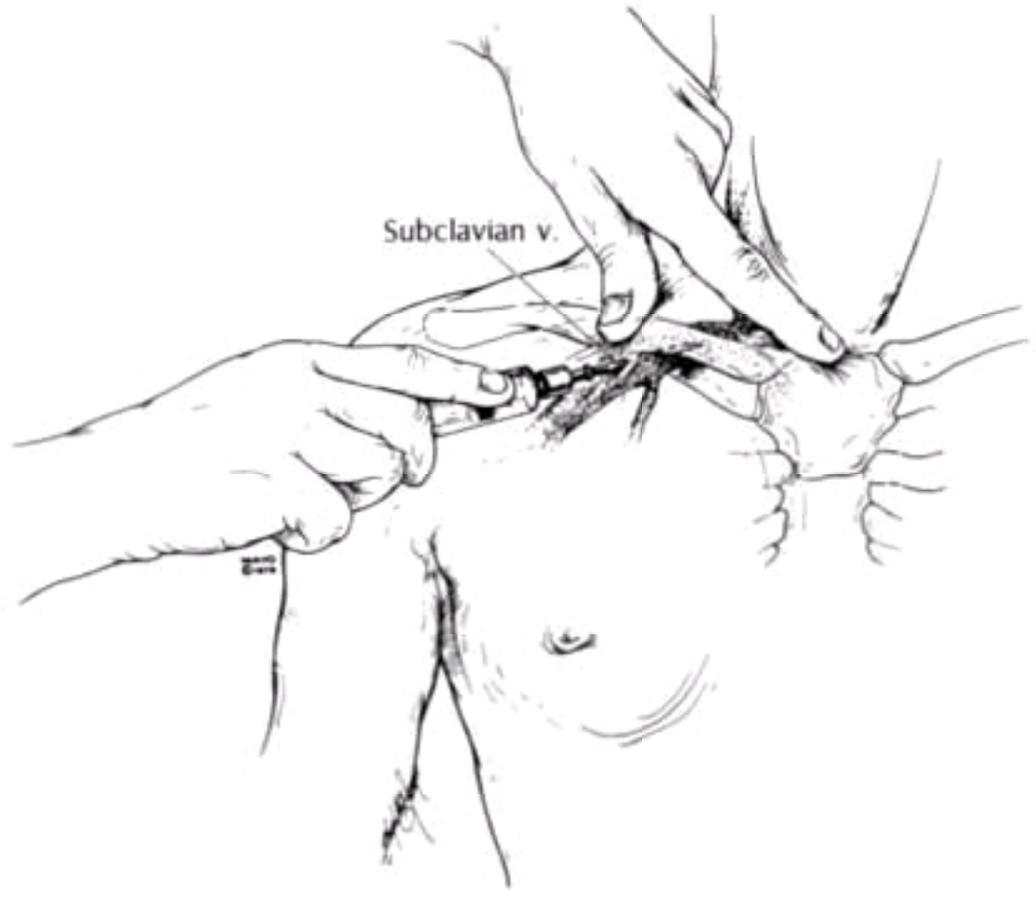

Figure 22-13 *A* and *B*, For the supraclavicular approach, the needle is inserted above and behind the clavicle, bisecting the angle made by the clavicle and the lateral border of the sternocleidomastoid muscle (clavisternomastoid angle). The point of entry is 1 cm lateral to the clavicular head of the muscle and 1 cm posterior to the clavicle. The needle traverses an avascular plane, puncturing the junction of the subclavian and internal jugular vein behind the sternoclavicular joint. The right side is preferred because of a direct route to the superior vena cava and the absence of the thoracic duct. The needle is directed 45° from the sagittal plane and 10° to 15° upward from the horizontal plane, aiming toward the contralateral nipple. Note that the vein is just posterior to the clavicle at this juncture. *C*, Sagittal view of the supraclavicular area. As the subclavian vein passes over (and somewhat anterior to) the first rib, it is separated from the subclavian artery by the anterior scalene muscle. The dome of the pleura is posterolateral to the confluence of the great veins.

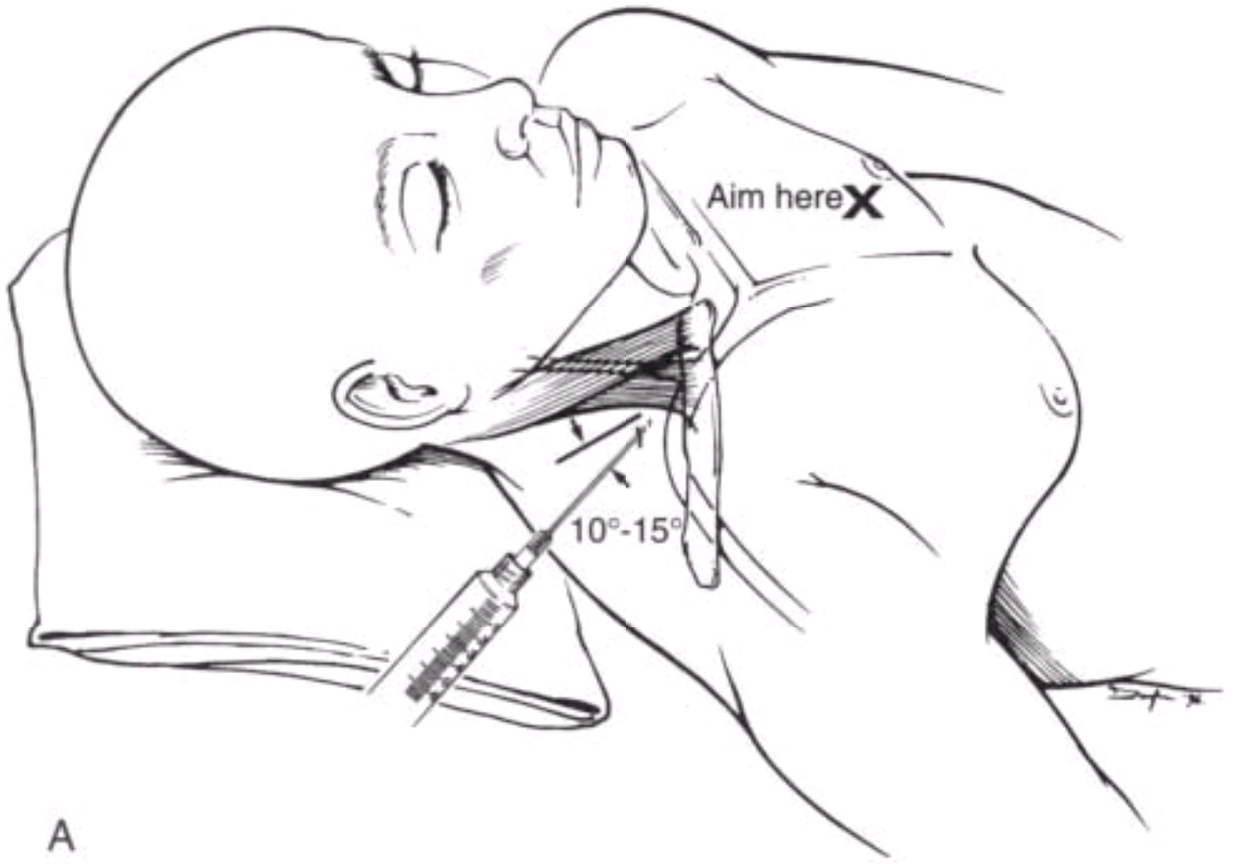

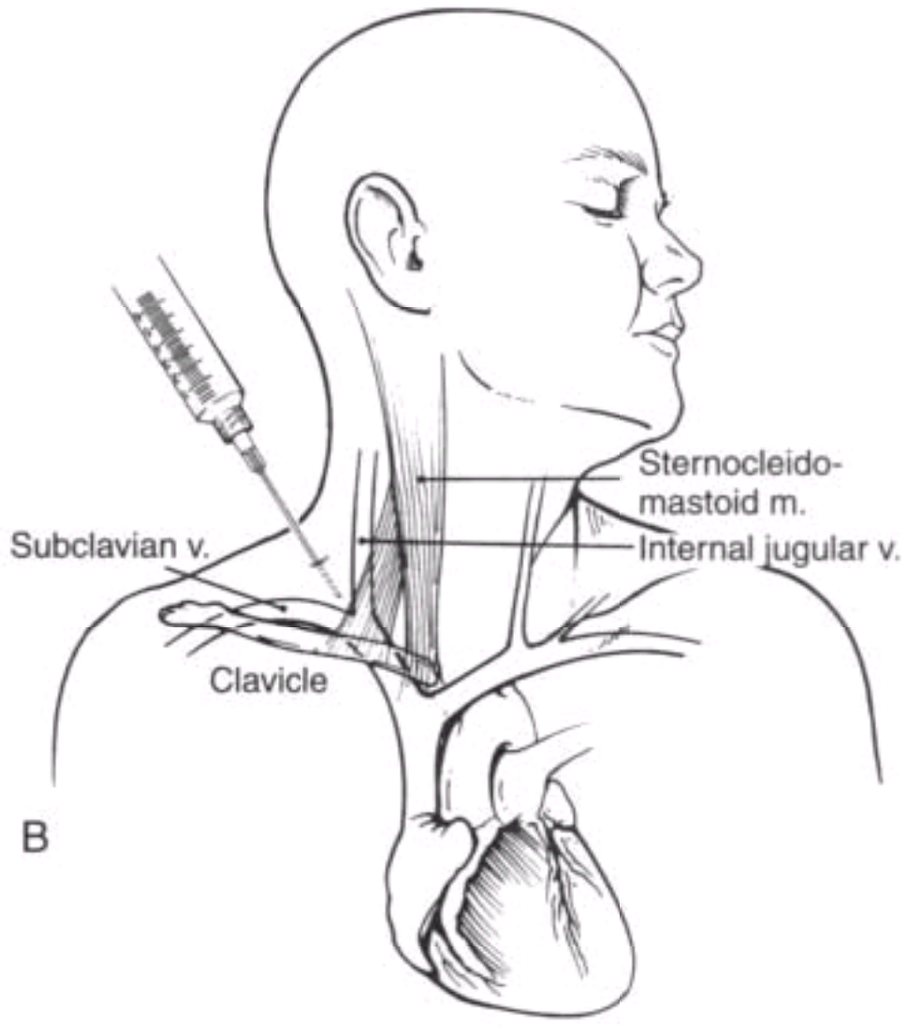

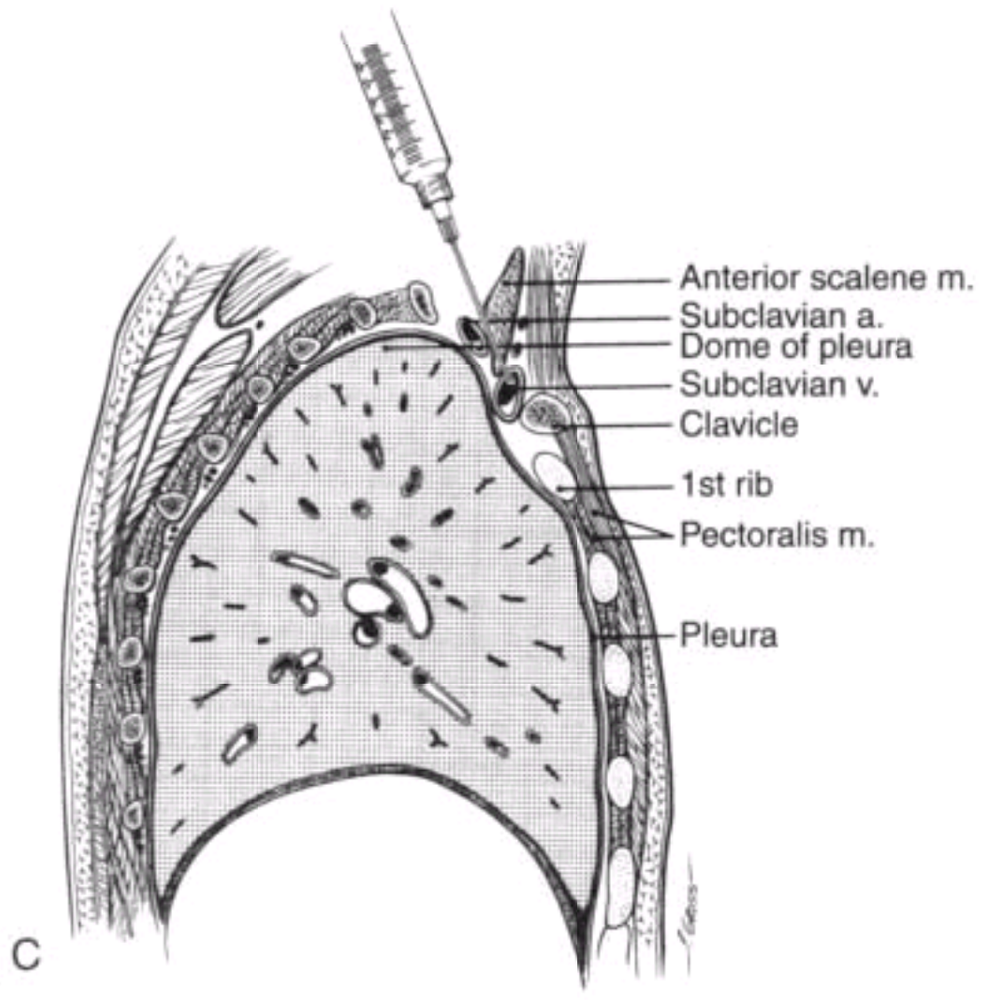

Figure 22-14 Internal jugular vein approaches. *A*, Central approach. *B*, Posterior approach. *C*, Anterior approach. Note that contrary to the photographs, gloves should be worn during the procedure.

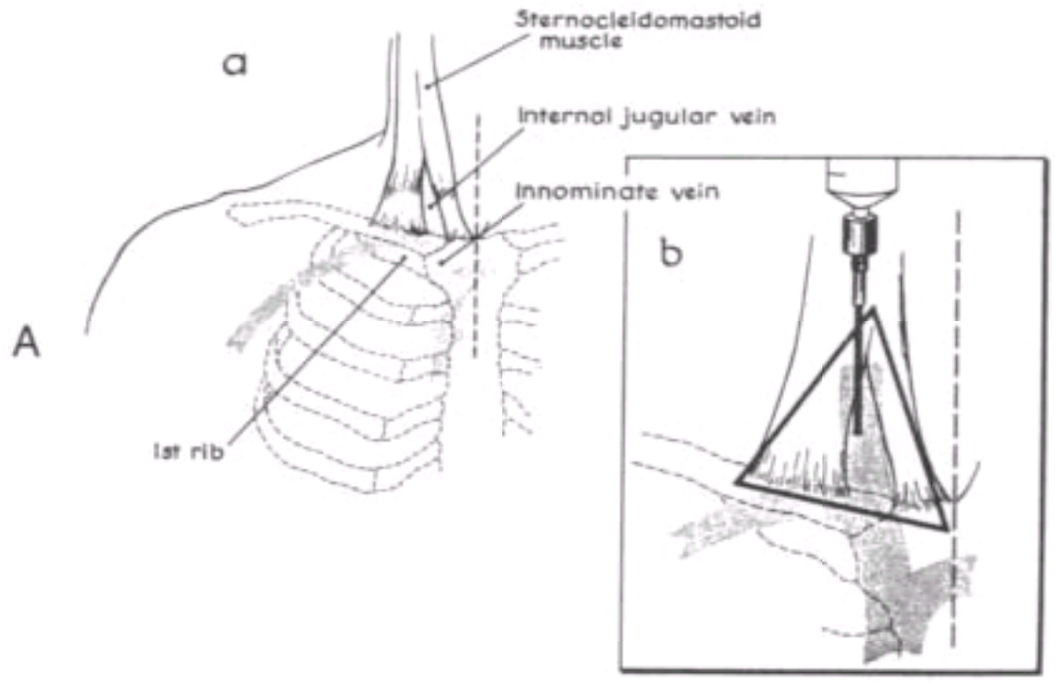
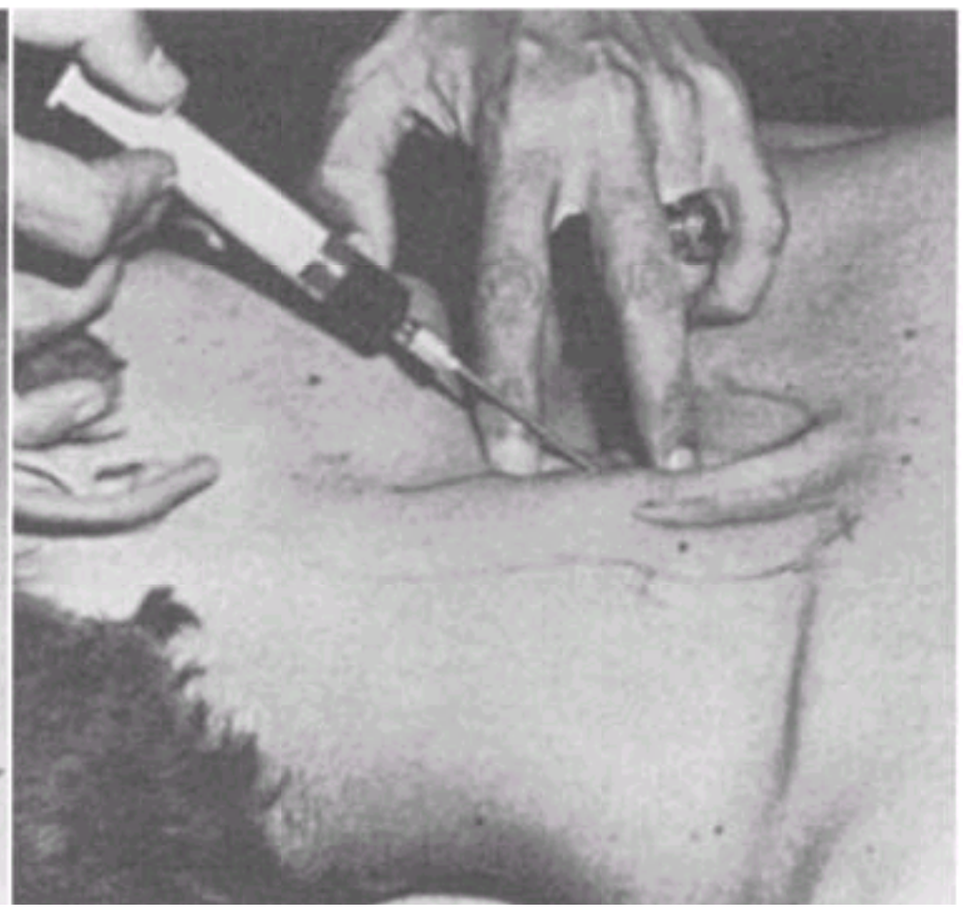


B



C

Figure 22-15 Insertion of a catheter over a wire via the external jugular vein. Successful passage may require many attempts and manipulations of the J wire to navigate turns and valves. *(From Blitt CD, Wright WA, Petty WC: Central venous catheterization via the external jugular vein, a technique employing the J-wire. JAMA 229:817, 1974. Reproduced by permission.)*

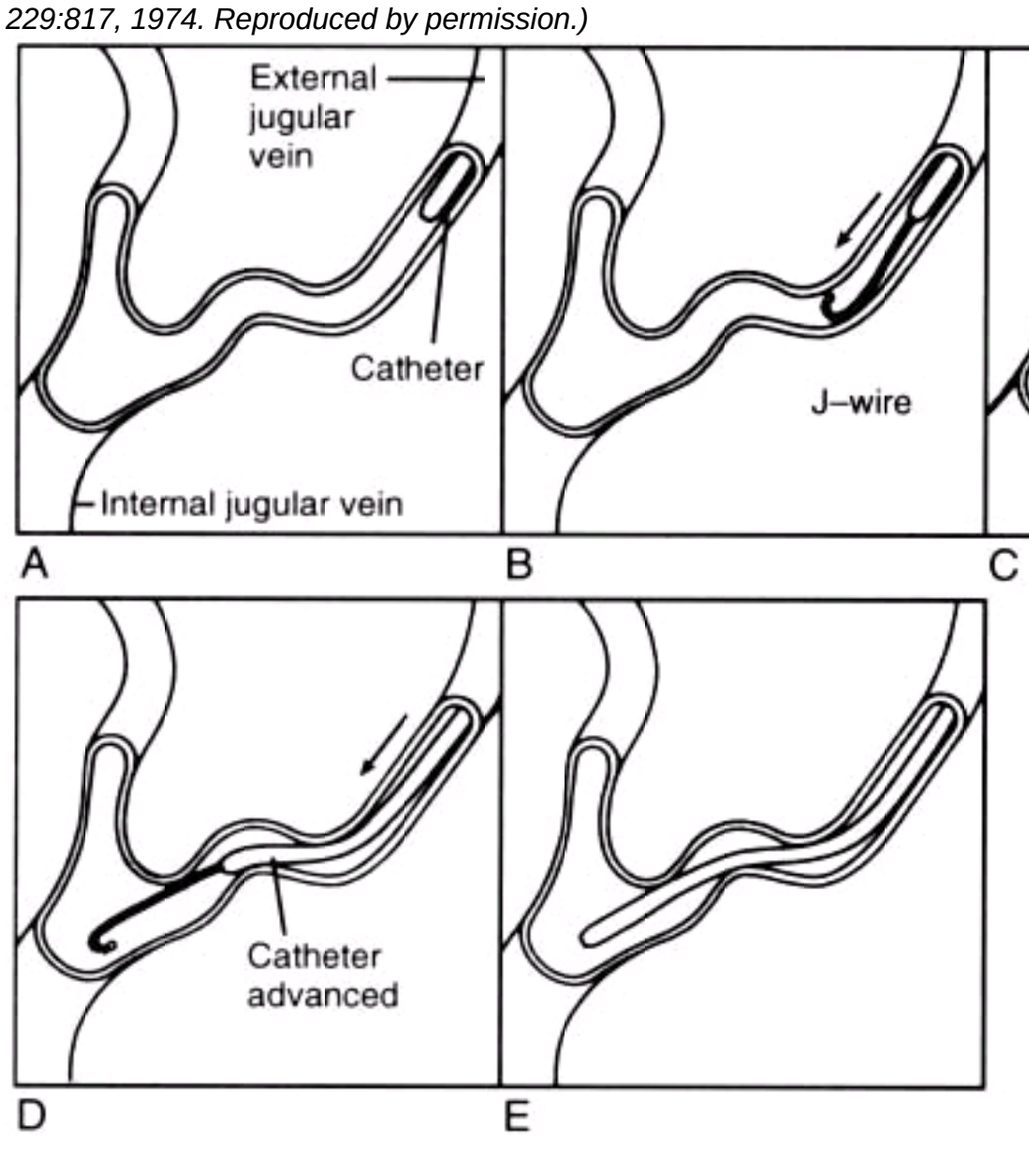


Figure 22-16 Internal jugular line secured by looping around the ear. *(From Boulanger M, et al: Une nouvelle voie d'abord de la veine jugulaire interne. Can Anaesth Soc J 23:609, 1976. Reproduced by permission.)*

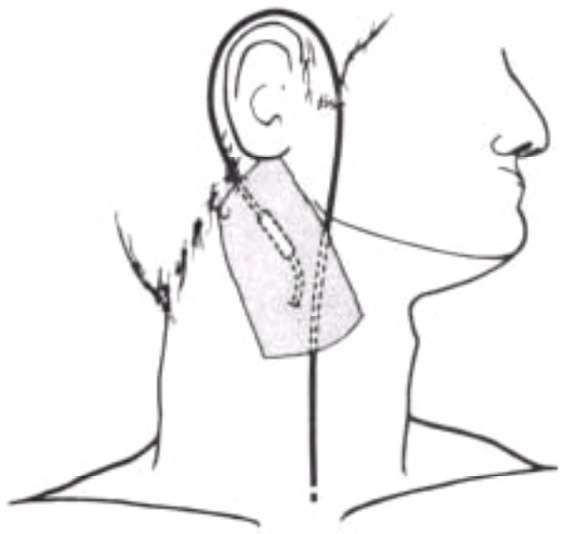

Figure 22-17 A chest film showing the proper catheter tip placement in the superior vena cava *(arrow)*. The tip should not lie within the right atrium or the right ventricle.

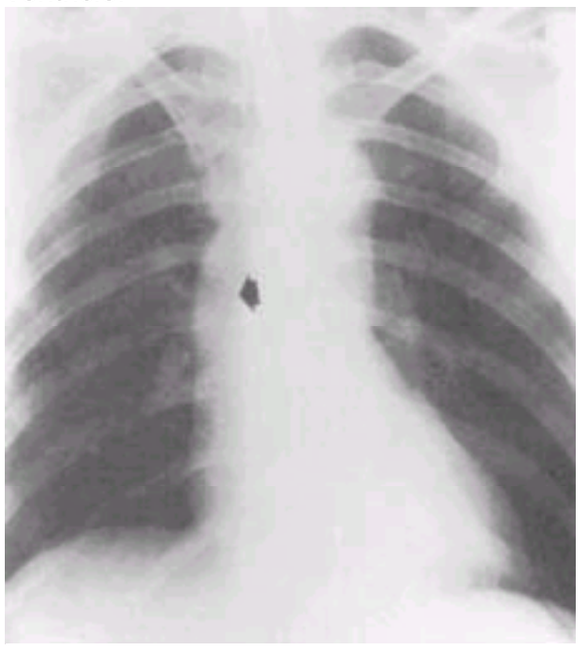

Figure 22-18 A chest radiograph should be routinely taken to assess position of a central catheter introduced via the chest or neck. *A*, In this case a poorly positioned patient produced a rotated and oblique film, and the catheter (black arrow) appeared, at first glance, to be in the correct position in the right subclavian vein. The supine position of the patient did not allow identification of an early hydrothorax (white arrow). *B*, A repeat radiograph shows the obvious intrapleural position of the catheter, and a large hydrothorax after infusion of 2 liters of saline.

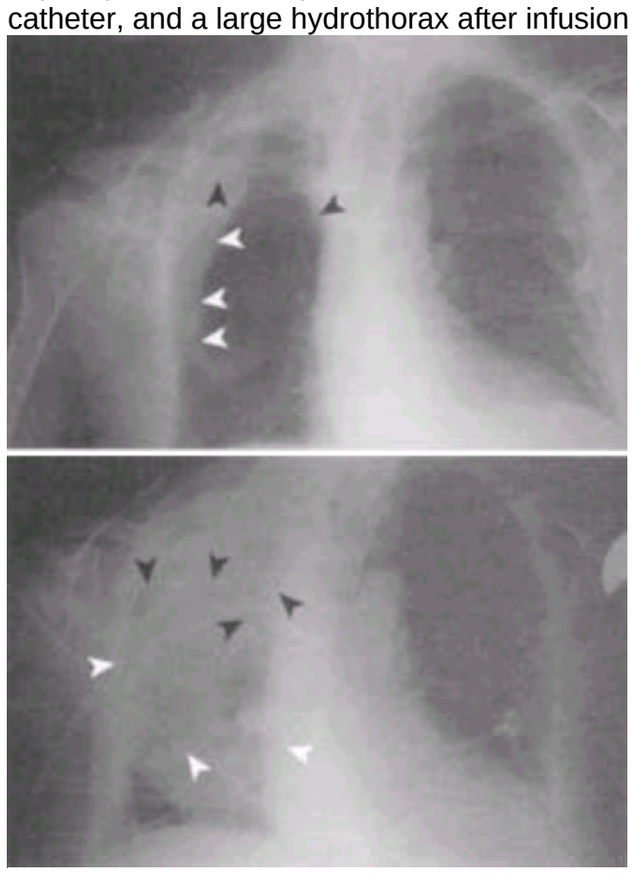

Figure 22-19 *A*, Surface ultrasound-directed central vein identification. A handheld transducer allows noninvasive localization of veins, in this case the subclavian. The device shown includes a needle guide, which allows simultaneous visualization and penetration of a targeted vessel. *B,* Surface ultrasound image of the subclavian artery (left) and vein (right). *(Courtesy of Irene R. Skolnick, Dymax Corp, Pittsburgh.)*

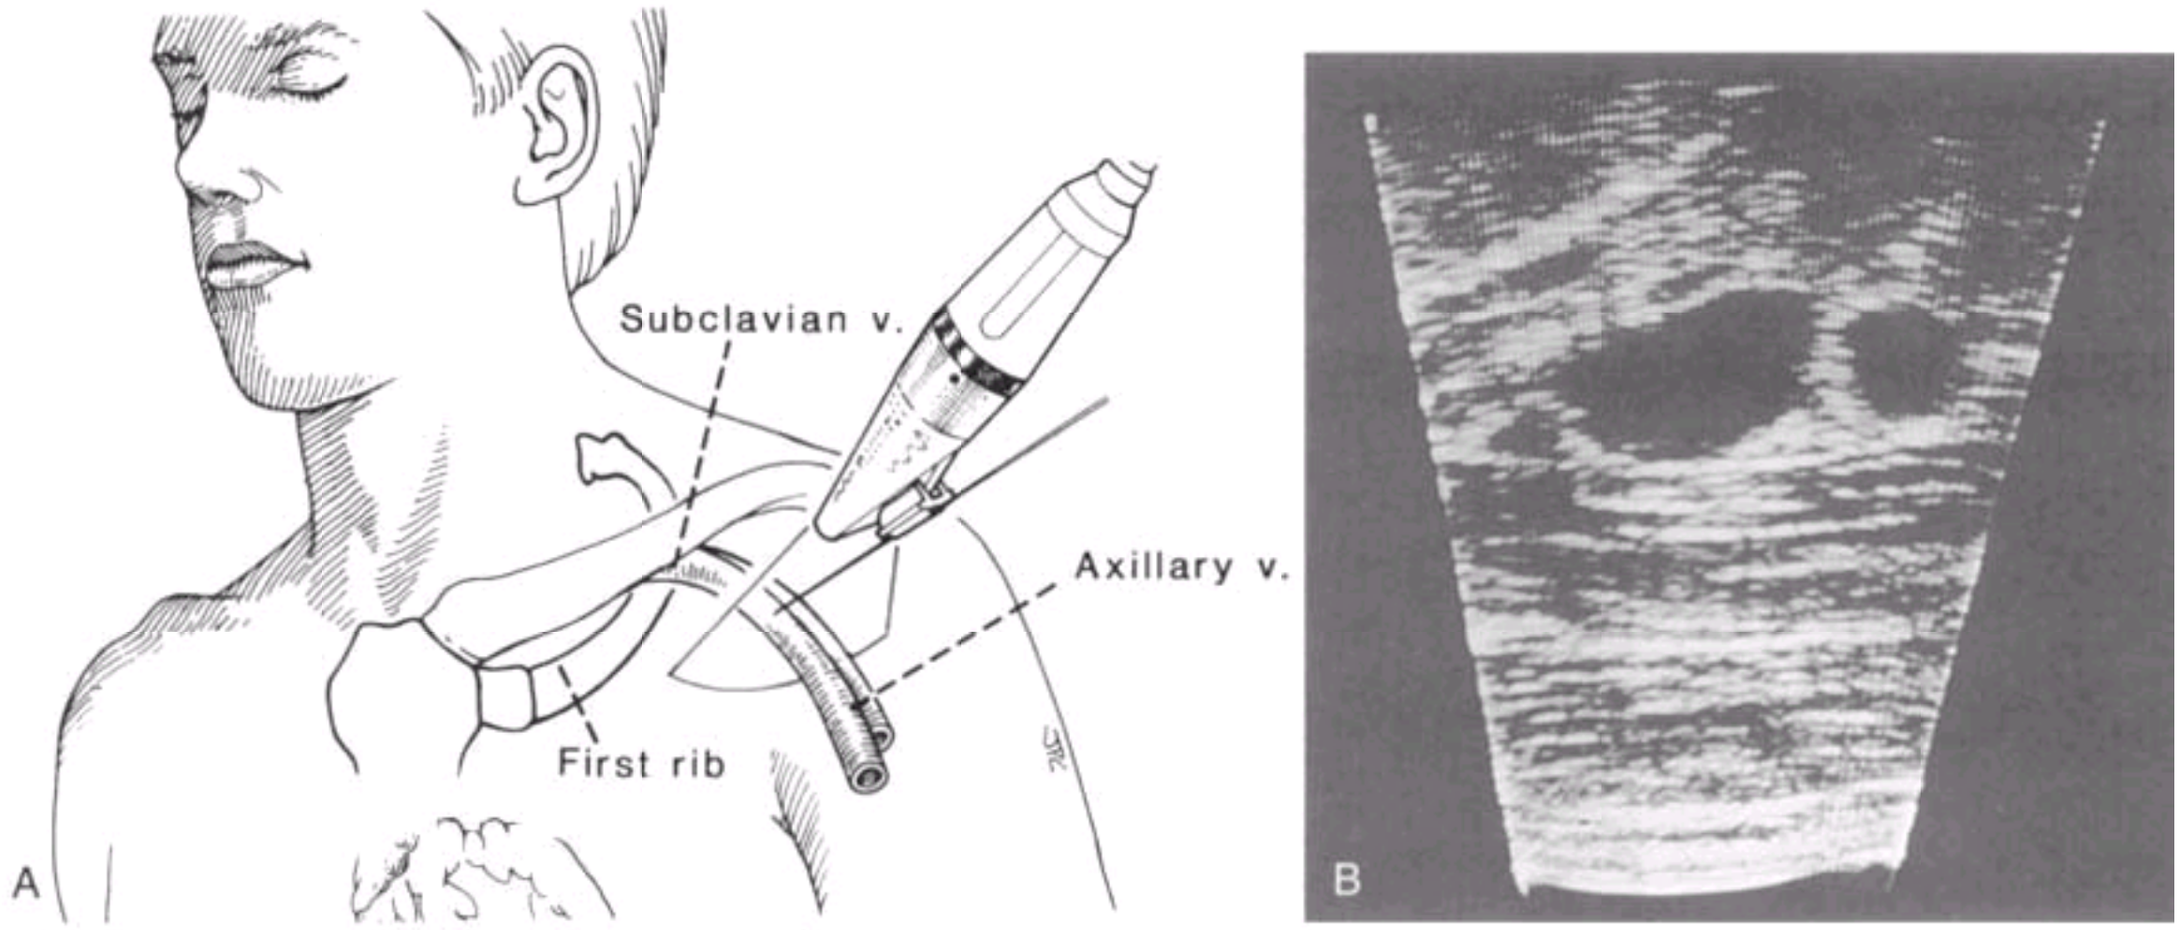

Figure 22-20 *A,* A femoral vein catheter is more prone to deep vein thrombosis and infection than a subclavian/internal jugular line, but it is a standard access route in the emergency department. Strict attention to sterile procedure and limiting use for a few days will negate most of the negatives of this approach. *A*, Significant hemorrhage can occur after puncture of the femoral artery, but this area is readily compressed. The femoral route may be the route of choice in the patient with a coagulopathy who requires a central line. The femoral vein will accept: (*B*) a triple-lumen catheter or (*C*) a large sheath introducer.

Figure 22-21 A subclavian line can easily be advanced into the neck (internal or external jugular vein). Malpositioned catheters should be discovered and replaced as soon as possible. Infusing saline into this catheter is not harmful, but hyperosmotic and vasoactive medications should not be given through this catheter for prolonged periods of time.

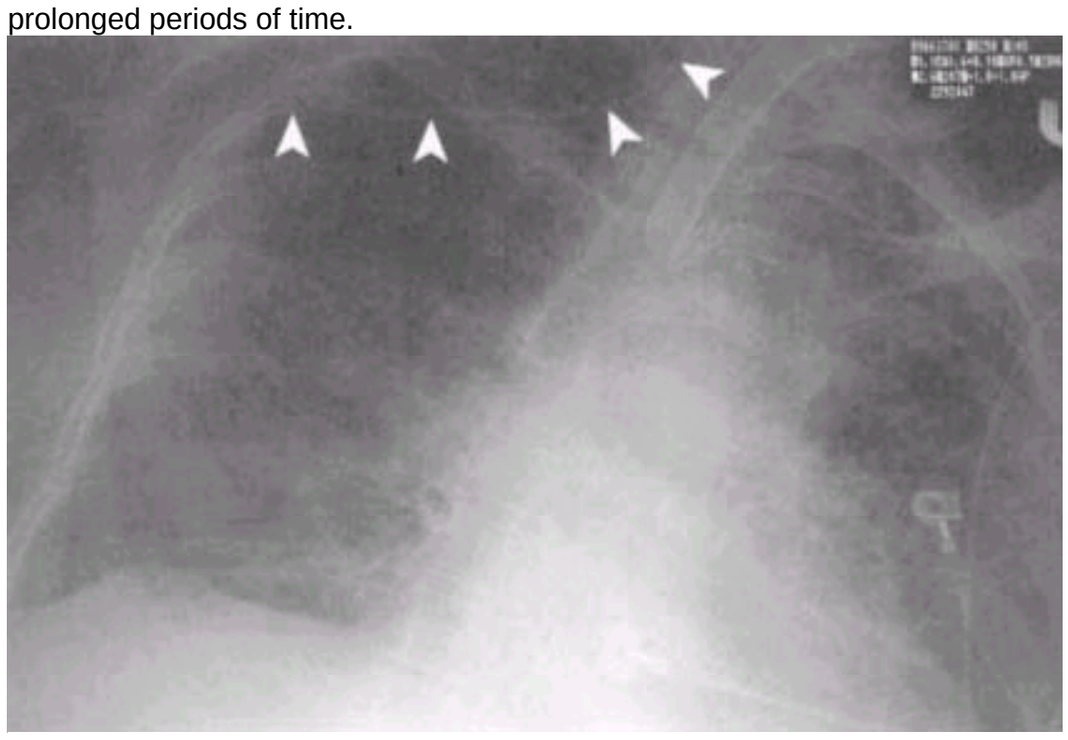

Figure 22-22 *A*, Simple manometry column used to measure CVP at the bedside. The stopcock is turned to direct the flow to the patient, bypassing the manometer. This is the position that is maintained to keep the catheter patent. The tubing is always flushed before connecting it to the patient's central venous pressure catheter. *B*, The stopcock is turned to fill the manometer to 25 cm H_2O. *C*, The stopcock is opened to the patient, and the column of water in the manometer is allowed to fall and stabilize before a reading is taken. Note that the zero mark is horizontally aligned with the tricuspid valve (midaxillary line in a supine patient).

C

Figure 22-23 General configuration of an intravascular pressure transducer. A working understanding of these devices, particularly regarding proper setup, zeroing, and line debubbling, will maximize their effectiveness and accuracy.

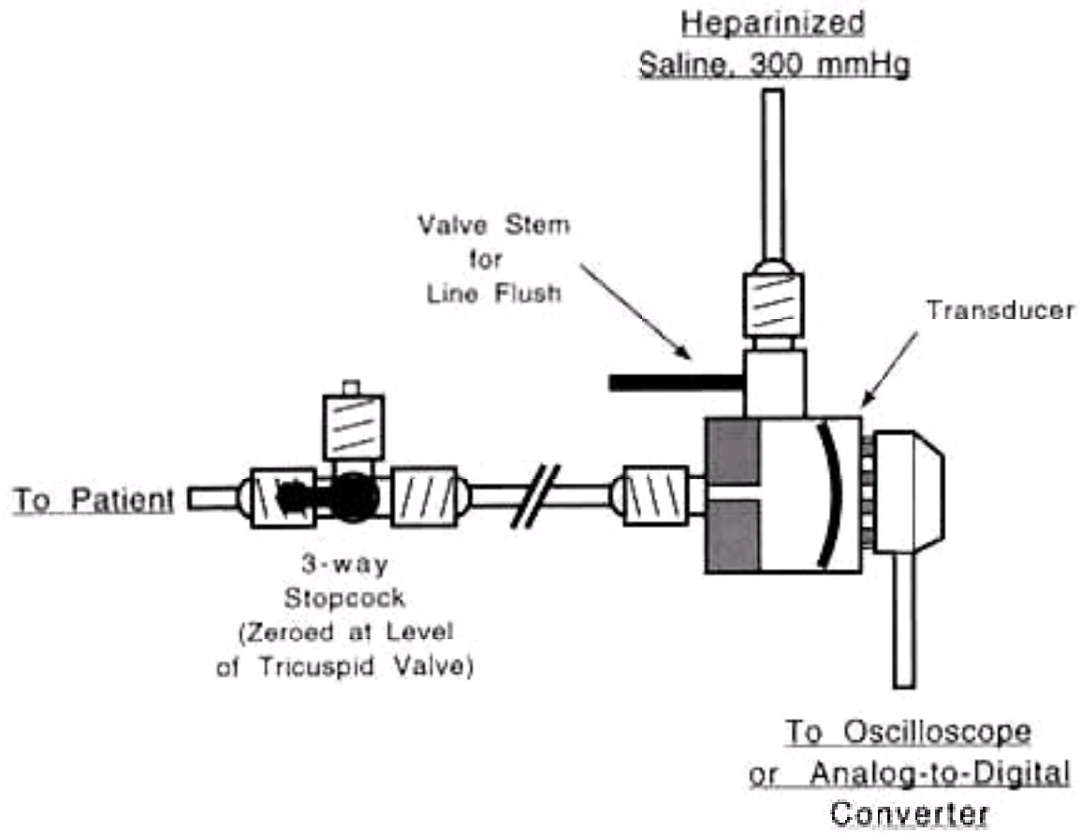

Figure 23-1 Superficial veins of the lower limb.

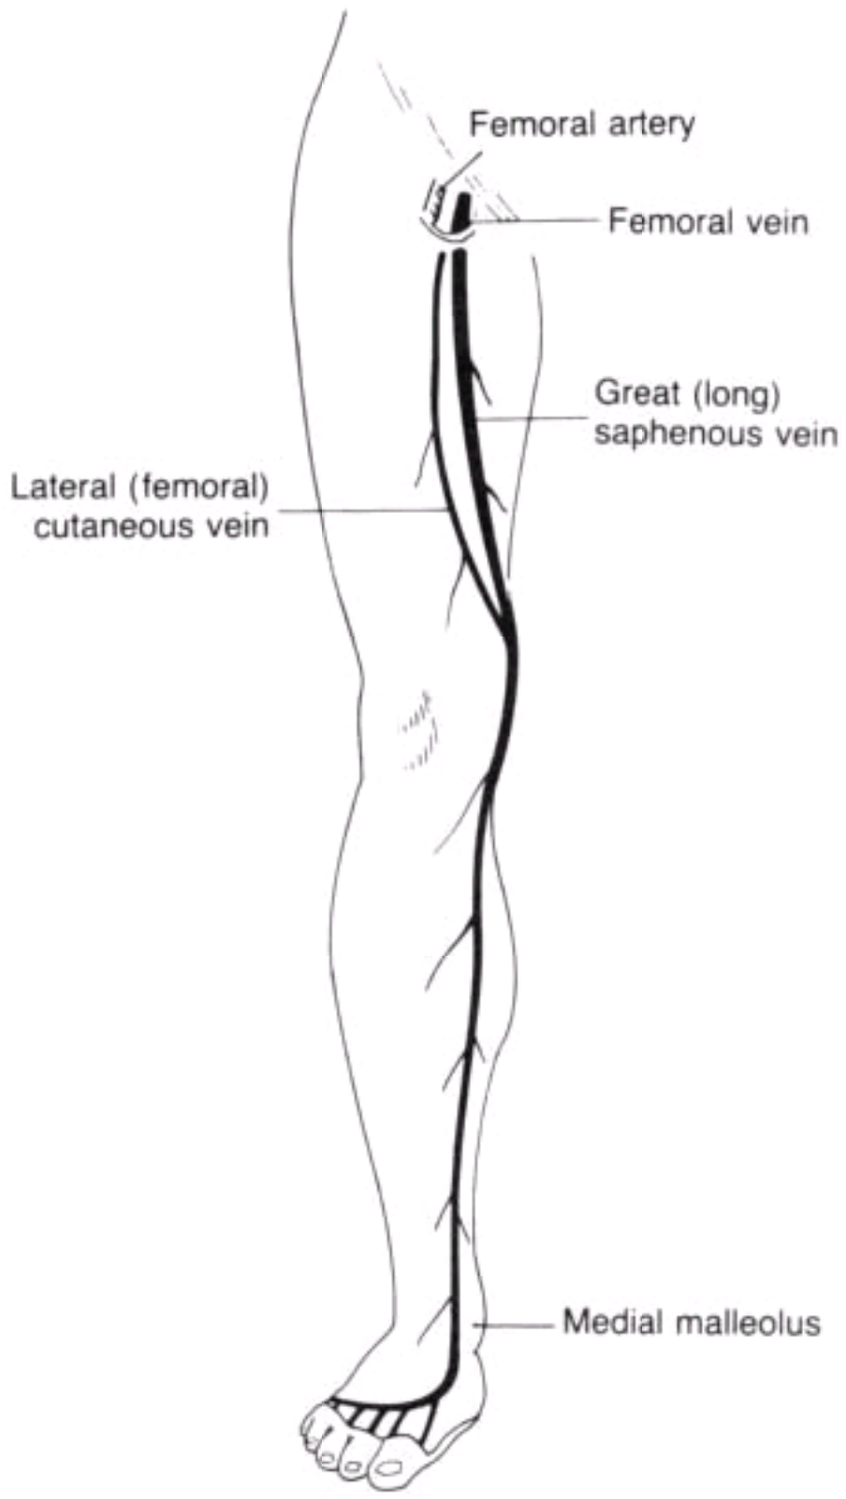

Figure 23-2 Veins of the upper limb.

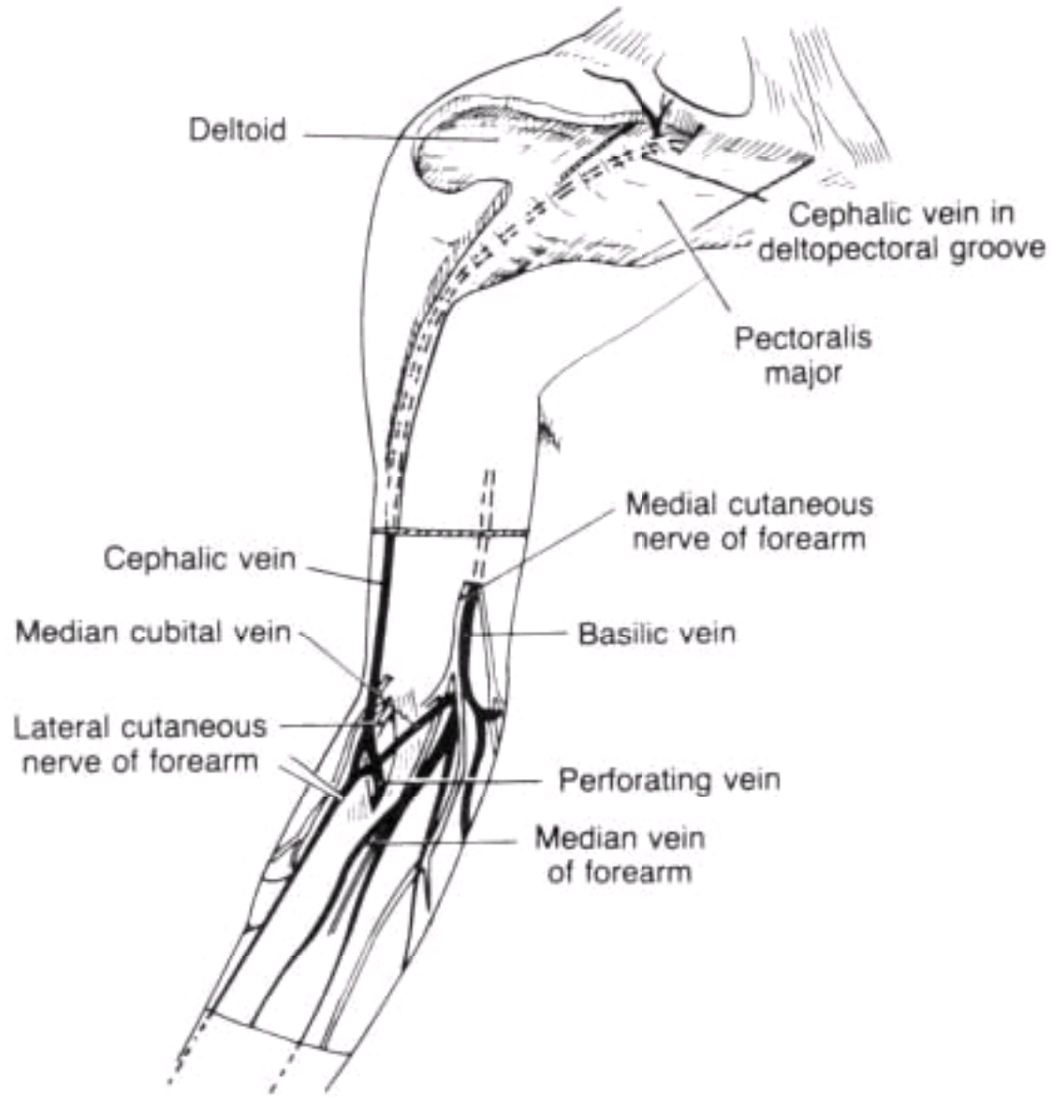

Figure 23-3 Venous cutdown tray. Note the small plastic vein dilator-lifter *(arrows)*, which is especially useful in children.

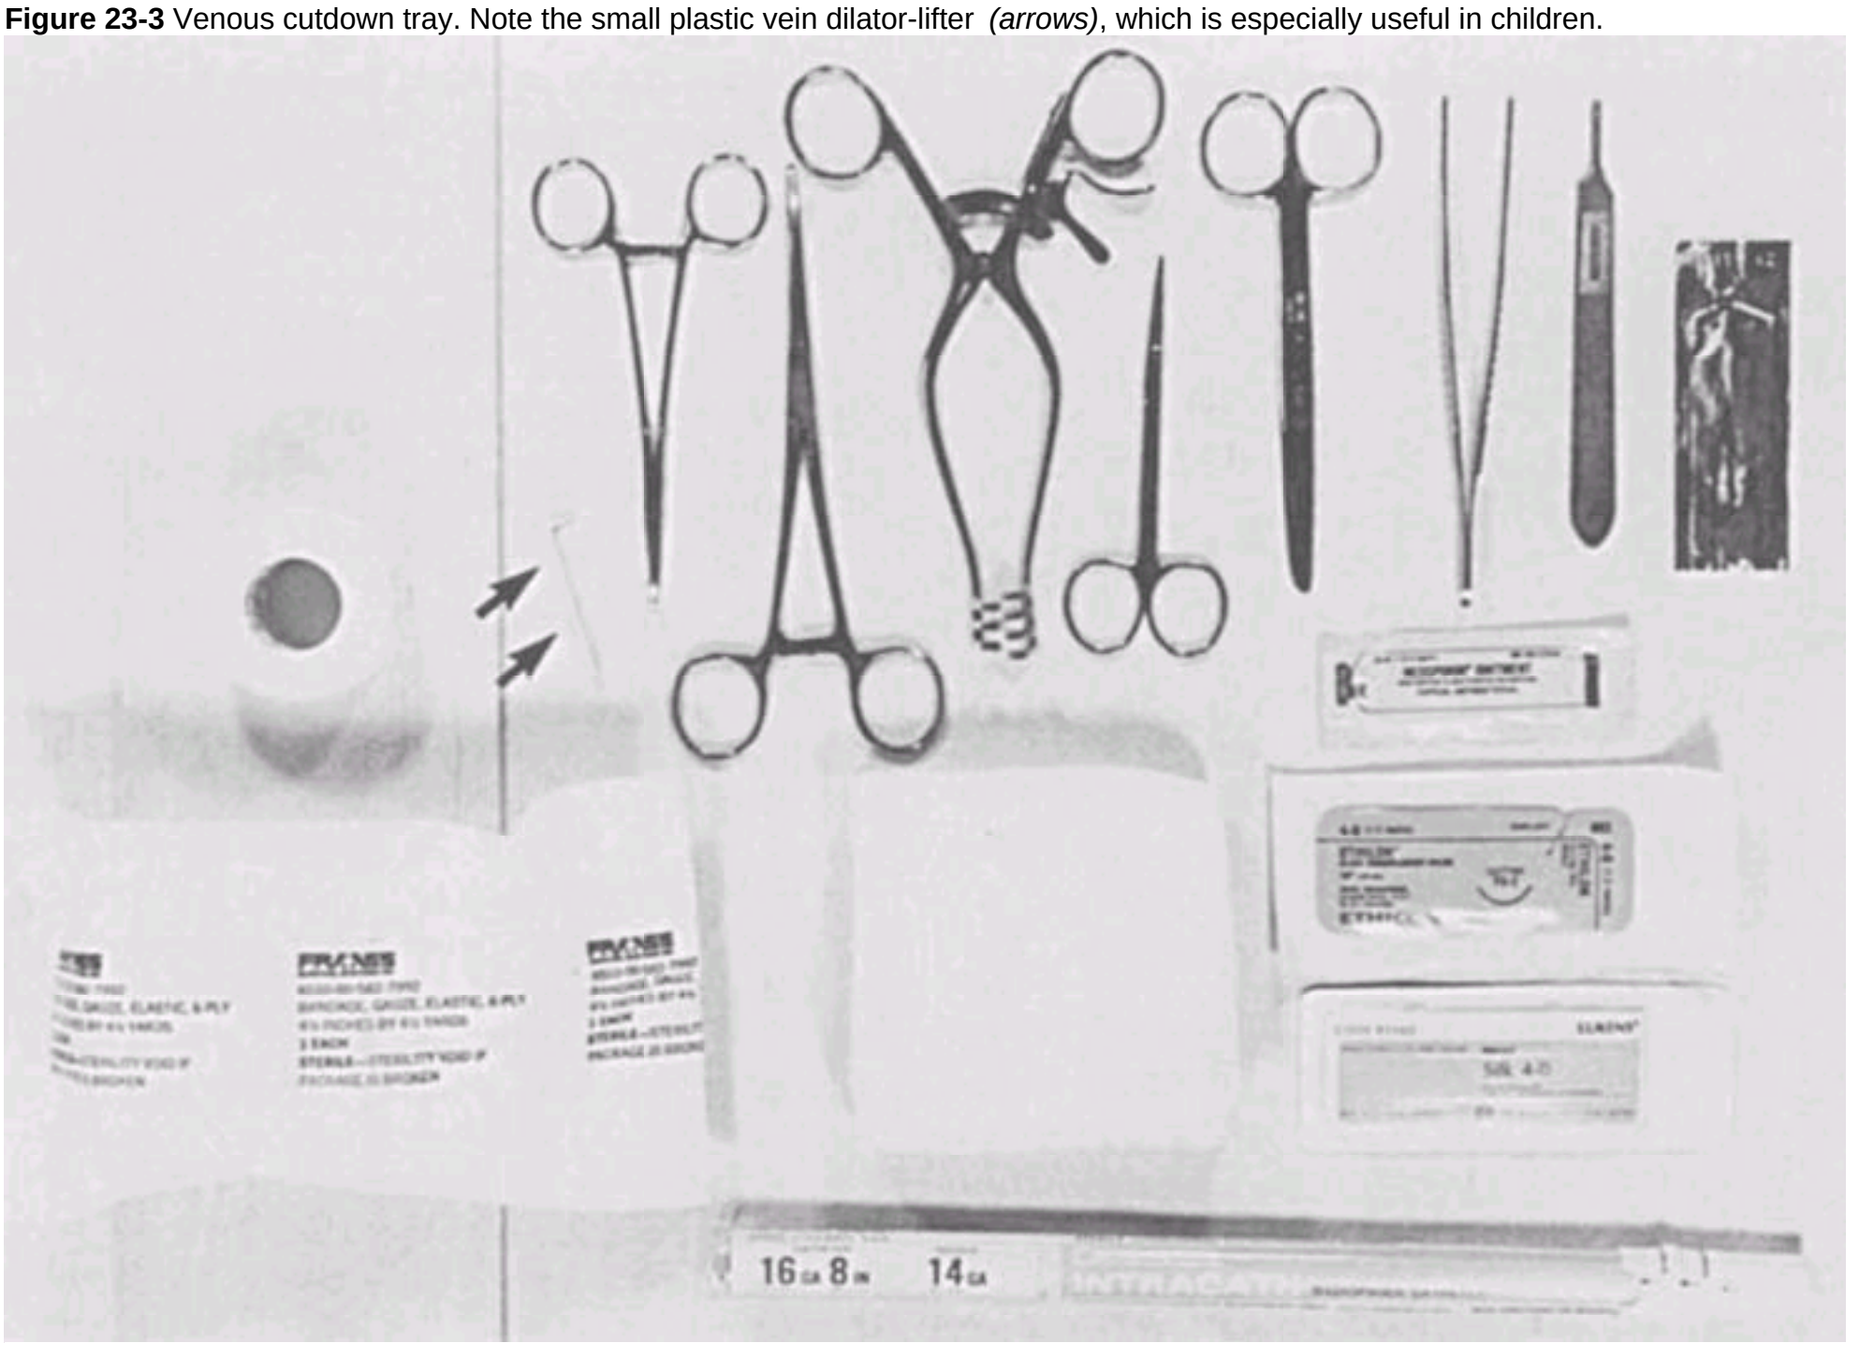

Figure 23-4 A skin incision is made perpendicular to the course of the vein.

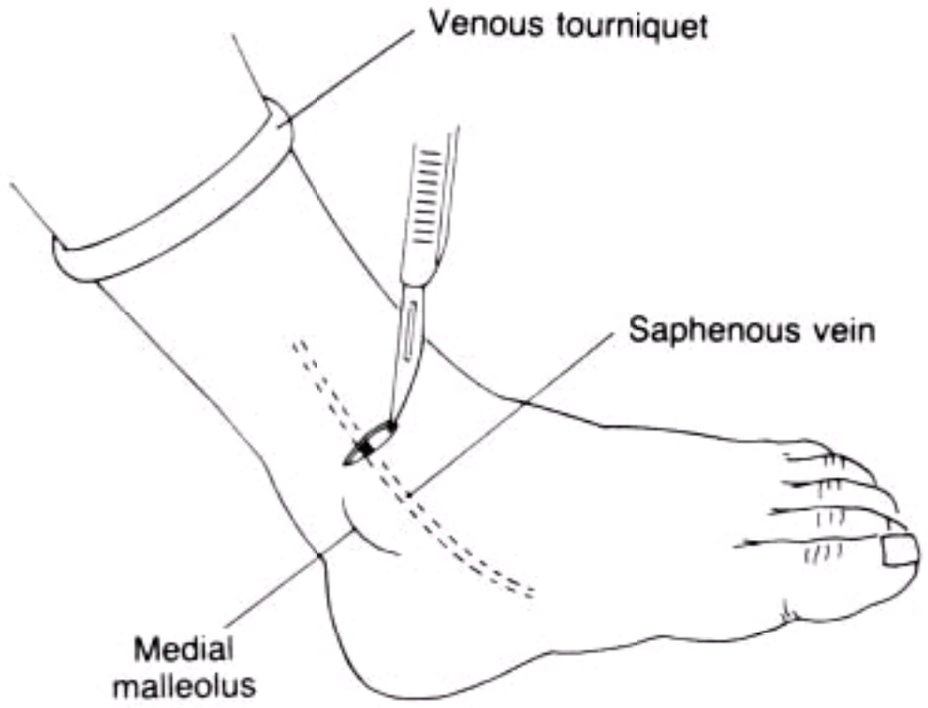

Figure 23-5 The skin is retracted and the vein exposed by blunt dissection. *(From Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

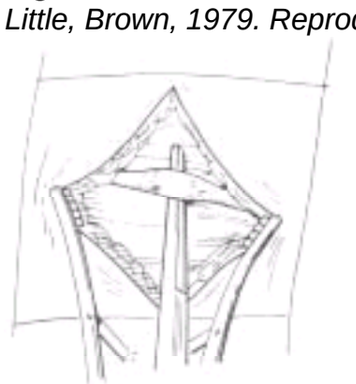

Figure 23-6 Proximal and distal ties are passed under the vein. If the vein is to be sacrificed, the distal suture is tied to prevent bleeding, and the ends are left long to help stabilize the vein during cannulation. The proximal tie is not tied at this point, but traction on it will control back-bleeding. *(From Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

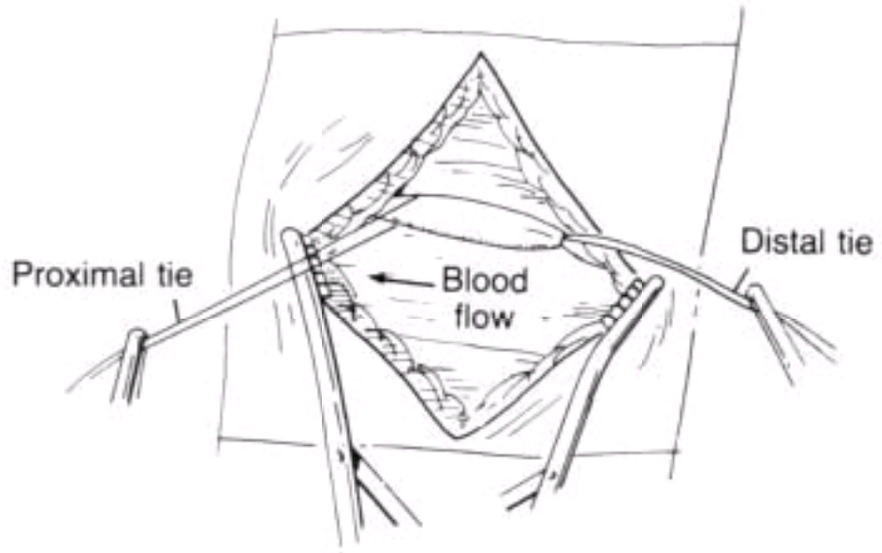

Figure 23-7 The vein is stretched flat and incised at a 45° angle. Approximately one third of the lumen must be exposed. Traction on the proximal tie will control back-bleeding. *(From Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

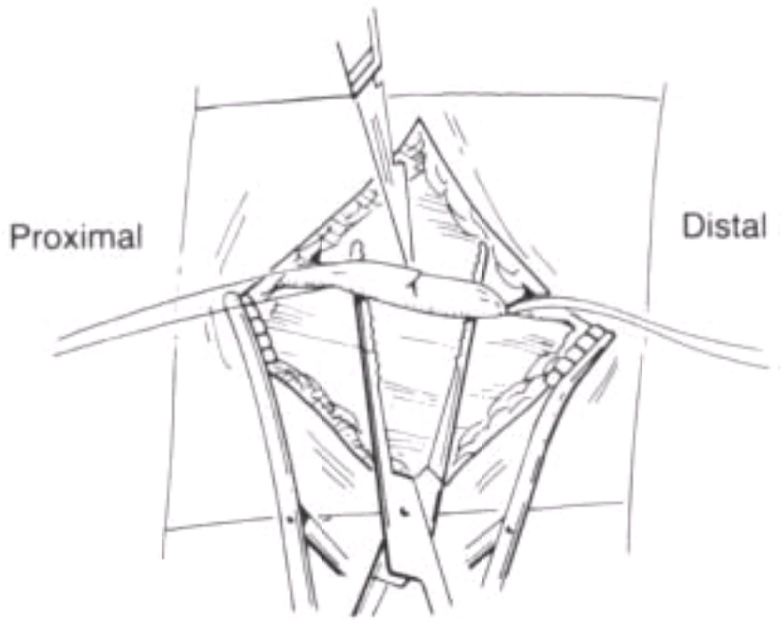

Figure 23-8 Use of the Intracath needle to produce a separate stab incision. The cannula is introduced into the wound by retrograde passage through the introducing needle. *(From Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

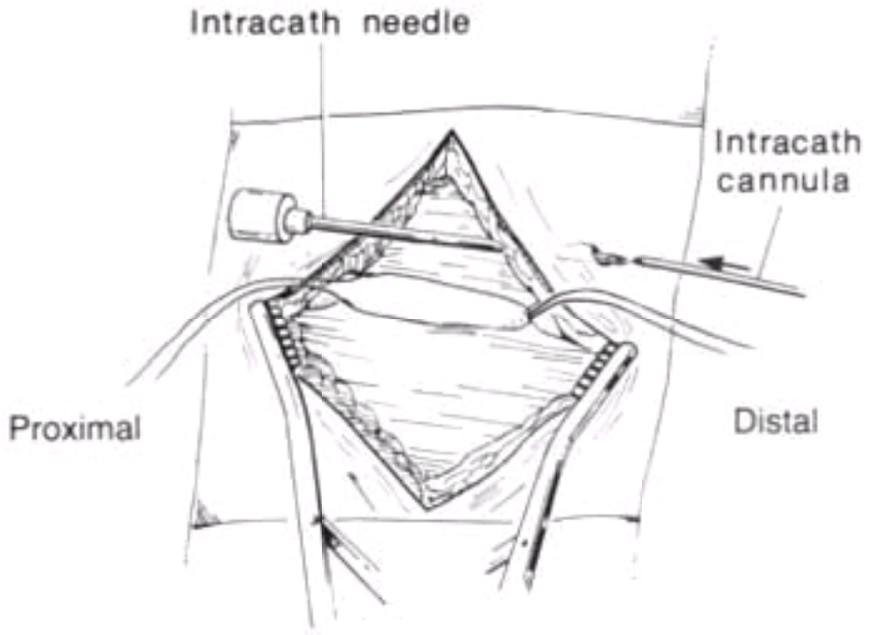

Figure 23-9 A cannula threaded through the stab incision. The Intracath needle has been withdrawn following introduction of the cannula into the wound. *(From Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

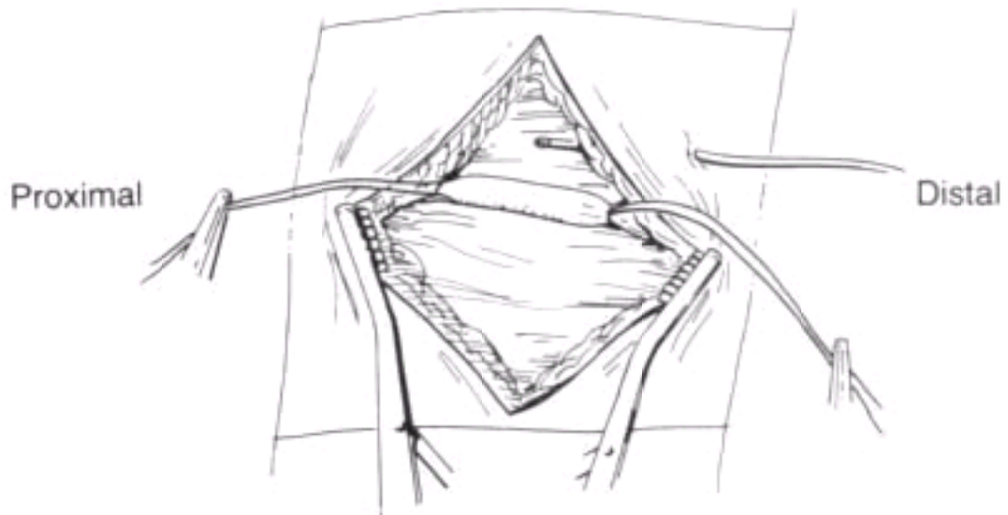

Figure 23-10 Threading the catheter with the aid of a venous dilator (lifter). This is technically the most difficult part of the procedure. The lifter is especially helpful in small veins.

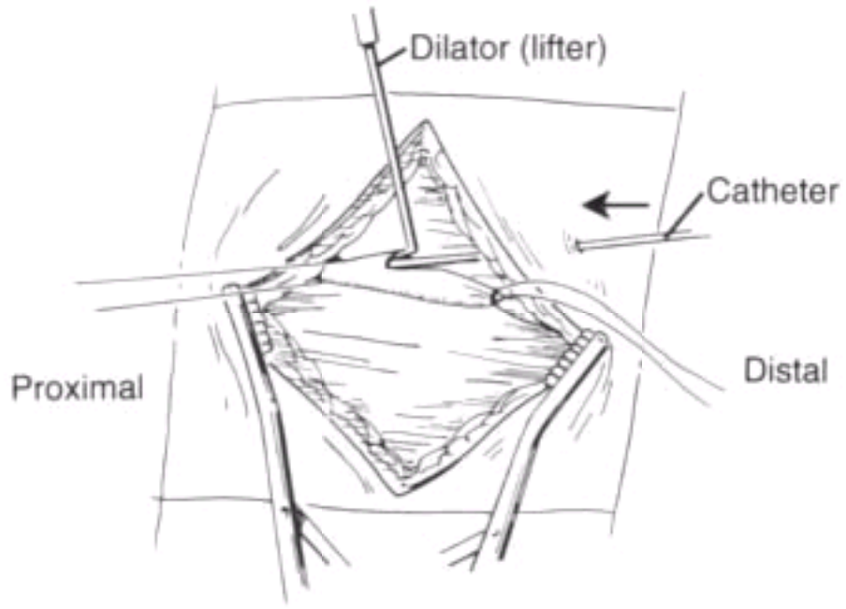

Figure 23-11 In larger veins, a mosquito hemostat can facilitate the placement of the cannula by opening the lumen and providing countertraction.

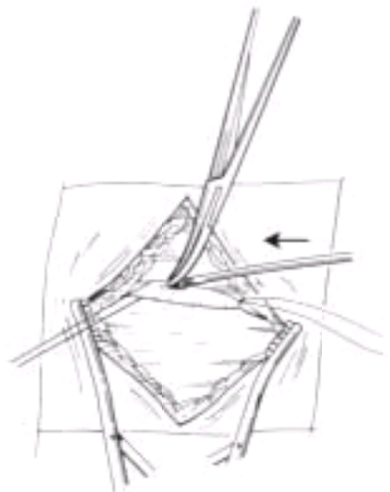

Figure 23-12 The incision is closed, and the catheter is sutured in place.

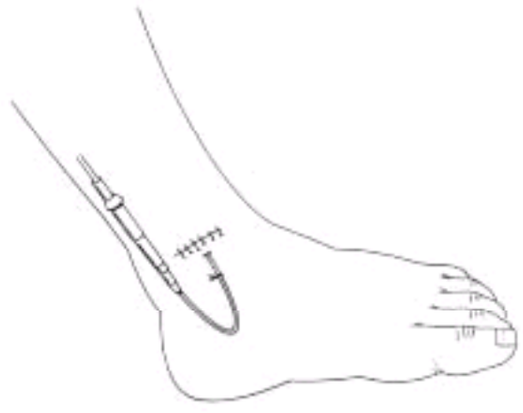

Figure 23-13 The cutdown site is securely dressed and splinted.

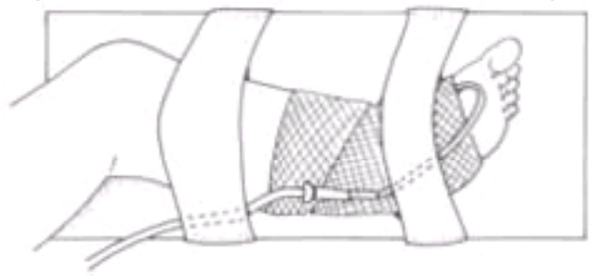

Figure 23-14 The mini-cutdown technique is an alternative to the venous cutdown method. The vein is cannulated under direct vision using standard percutaneous catheters. A separate entry site (shown) may be used, or the vein can be cannulated through the skin incision. Note that the vein is not tied off with this technique. A standard Angiocath IV set also may be used instead of the through-the-needle catheter shown here.

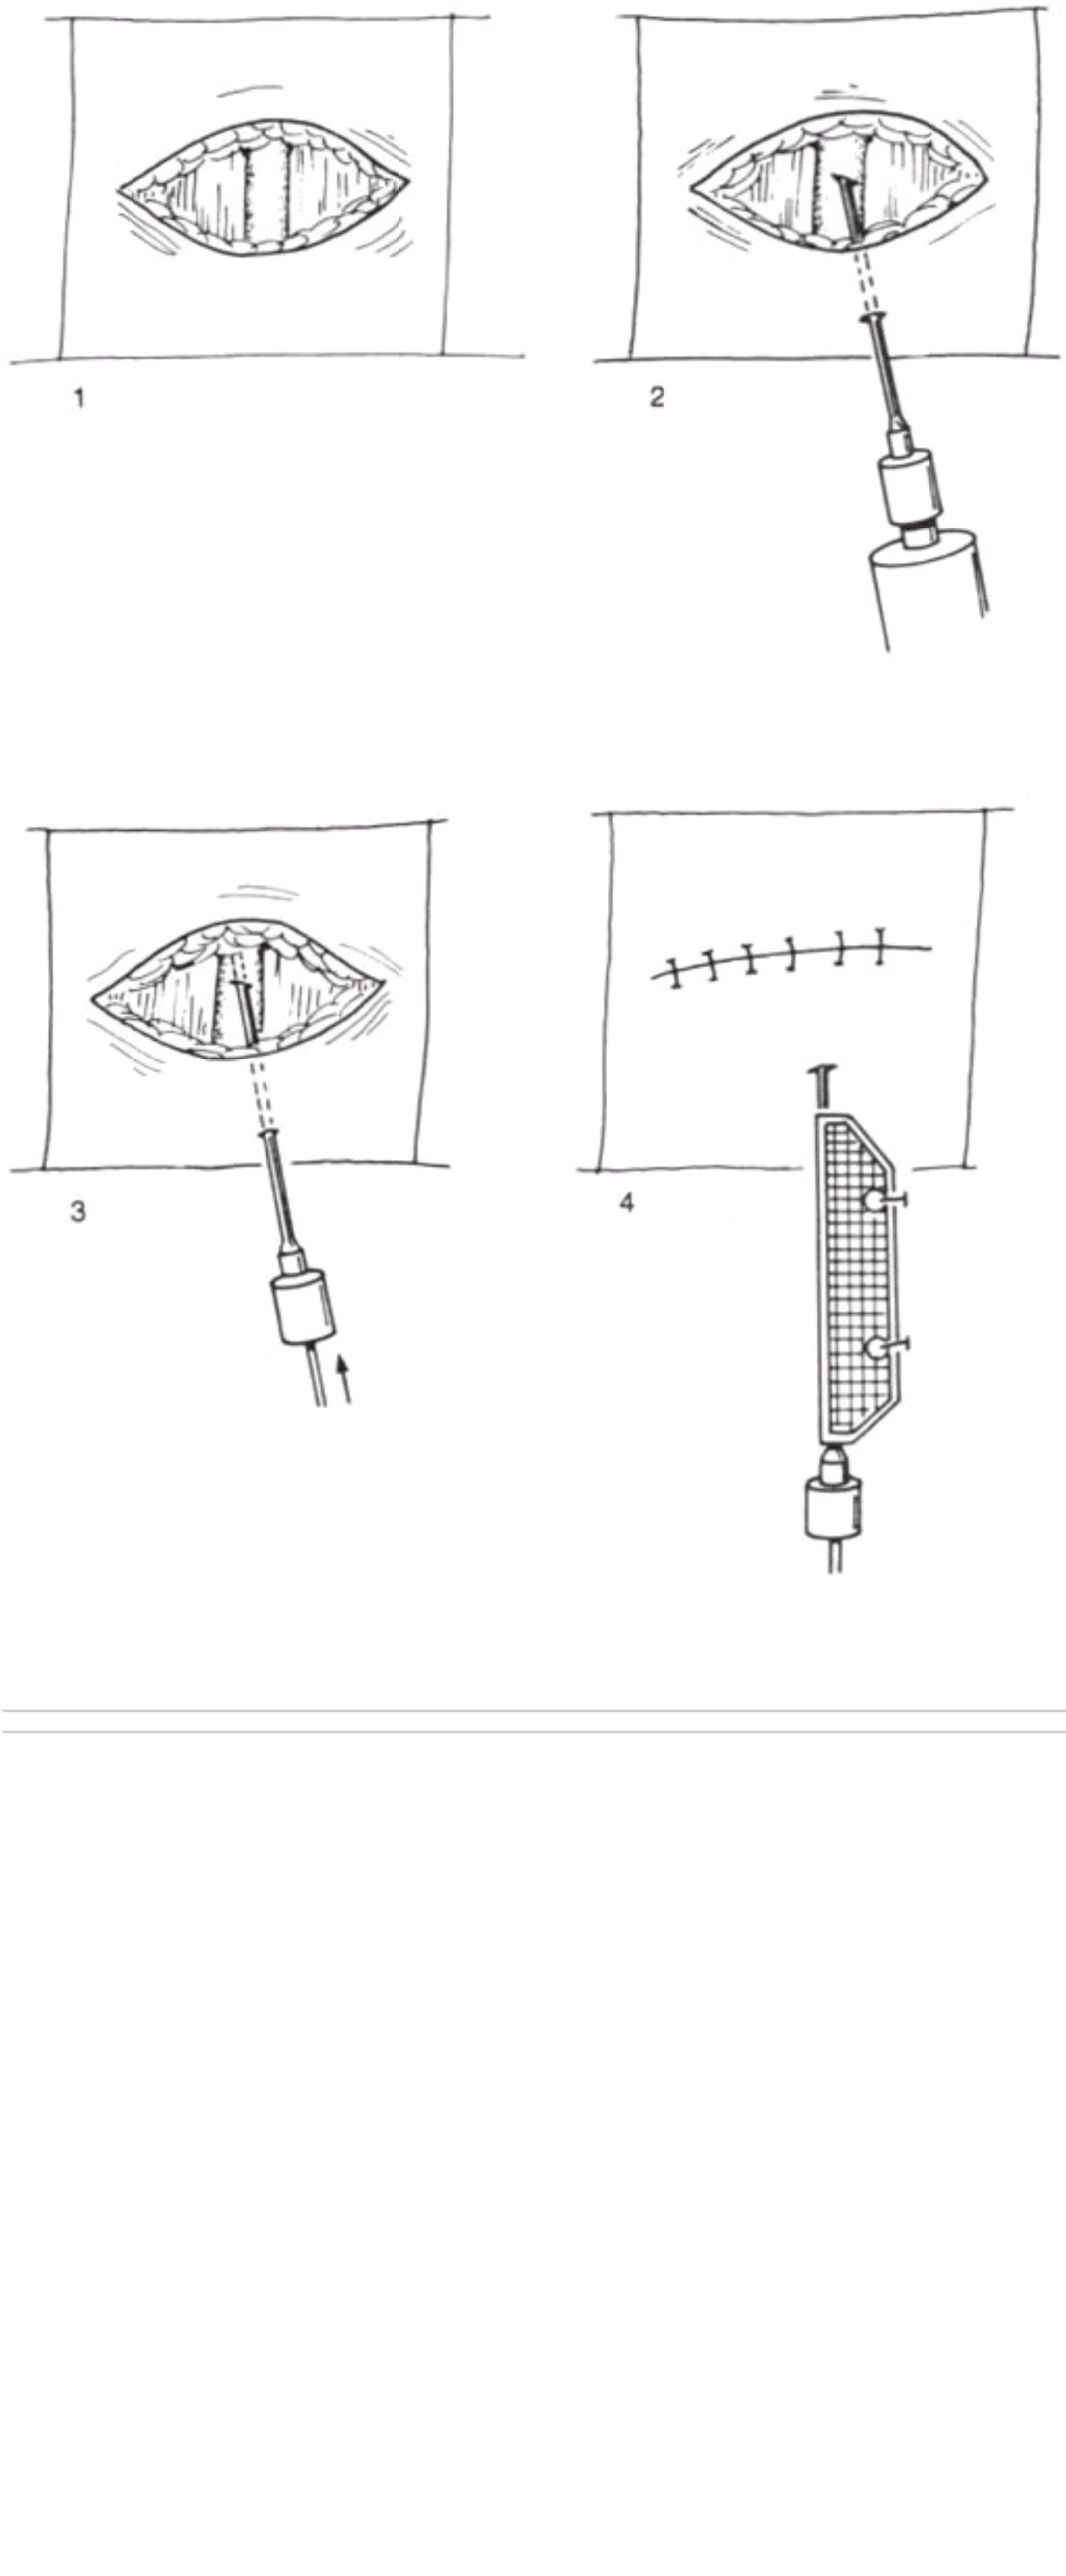

Figure 24-1 Three types of external pressure devices. *A*, Infuser-1. *(As modified in Iserson KV, Reeter A, Woods W, Criss E: Pressurization of IV bags: A new configuration and evaluation for use. J Emerg Med 3:89, 1985.) B*, Infusable *(Biomedical Dynamics Corp., Minneapolis, MN)*. *C*, Alton Dean infuser *(North Salt Lake City, UT)*.

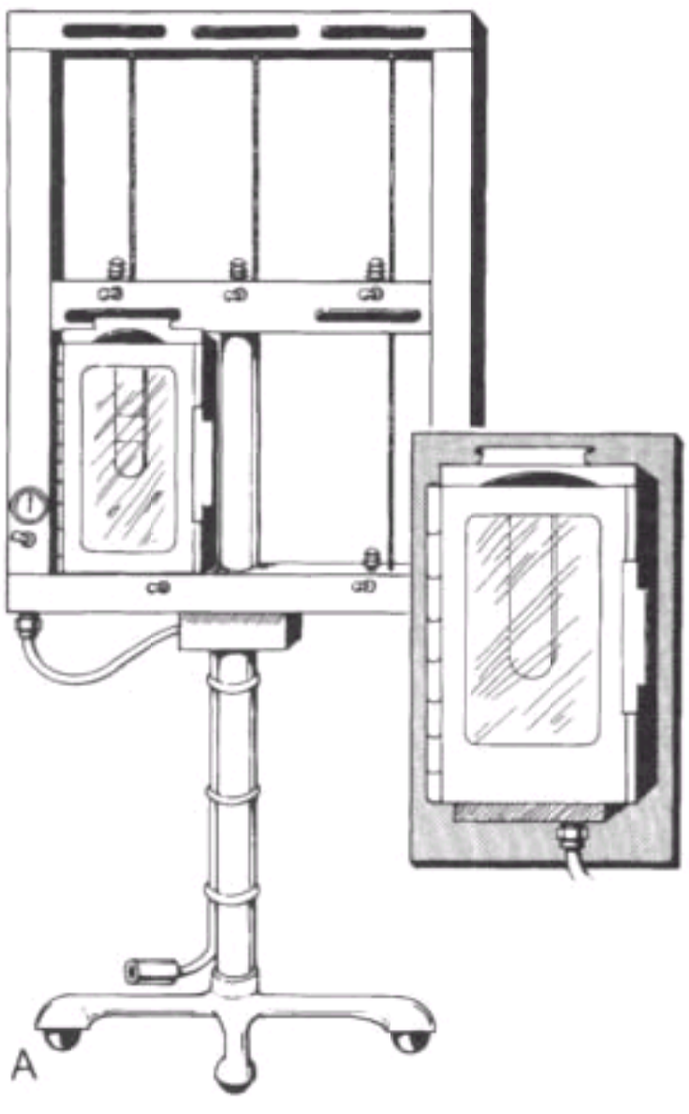

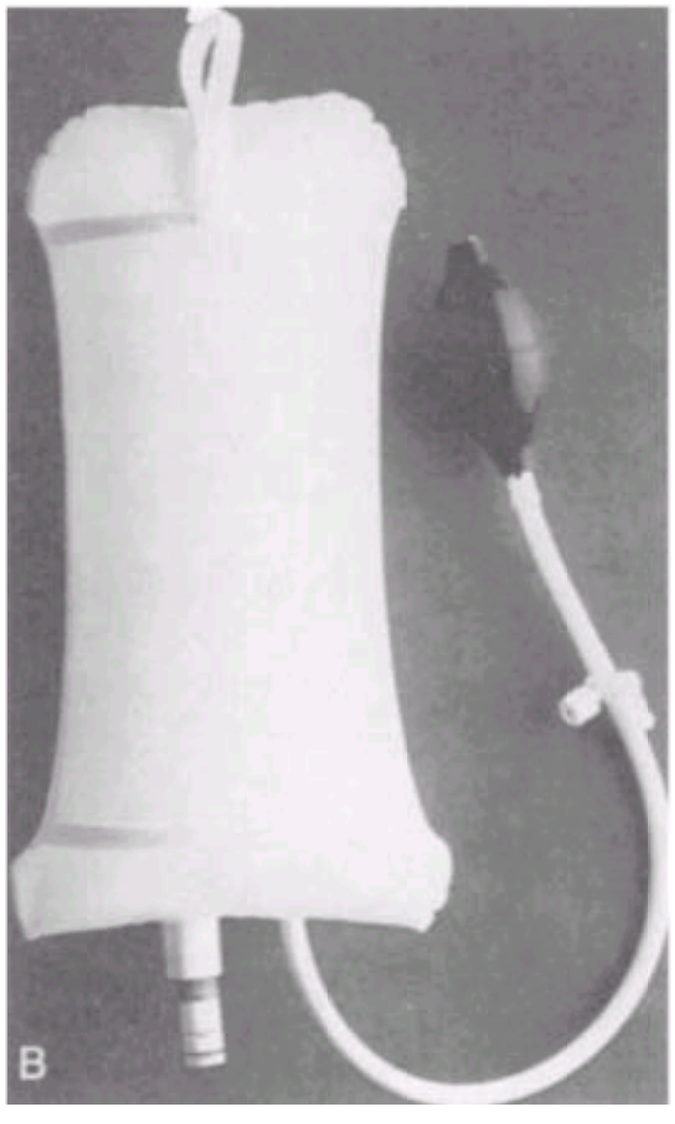

Figure 24-2 (1) During all handling of blood, standard universal precaution procedures should be followed. (2) Remove a 250-mL bag of normal (N) saline from the 70°C incubator. Check the bag for clarity, discoloration, particulate matter, obvious decreased volume, and cracking of the outer wrapper. Do not use if problems are found. (3) Check the incubator thermometer to ensure that its temperature is between 65° and 75°C. Do not use if above 75°C. (4) "Spike" the packed red blood cell (PRBC) unit from the blood bank with one end of a Fenwal plasma transfer set (No. 4C2243). Spike the other end of the transfer set into the 70°C, 250-mL N saline bag. Open the clamp, raise the saline bag above the level of the PRBC bag, and manually squeeze the saline (or use external pressure bag or other external pressure device) into the PRBC bag. (5) A towel or potholder-type kitchen glove may be used to squeeze the 70°C saline bag, if desired. (6) After all of the 70°C saline is transferred into the PRBC bag, tightly close the clamp on the transfer set tubing. (7) Do not remove the transfer set tubing spike from the PRBC bag (to prevent contamination). The now-empty saline bag may be removed from the other end of the transfer set and discarded, or simply left in place. (8) On the patient's side, spike the unused part of the PRBC bag (now admixed with 70°C saline) with one limb of the Y-type blood set already attached to the patient. The admixture temperature will be approximately 37°C. (9) Close the clamp on the other limb of the Y set, which has been infusing standard warm or room-temperature normal saline into the patient. (10) If the blood is to be rapidly infused, pressurize the external pressure bag or device. (11) Open the clamp on the PRBC admixture bag to begin infusion of 37°C PRBC unit into the patient. (12) Additional units of warm-admixed PRBC may be prepared using the same technique. Close the Y set clamp, remove the empty admixed PRBC bag, and replace it with the second unit. Open the clamp and begin infusing the second unit. (13) Infuse the blood into the patient as rapidly as necessary. (14) For each unit of warm-admixed PRBC infused, document in the patient's record that the patient received "1 unit of PRBC admixed with 250 mL of N saline at an infusion temperature of approximately 37°C." Include start/stop times of infusion and the name of the person preparing and administering the infusion. *(From Iserson KV, Knaut MA, Anhalt D: Rapid admixture blood warming: Technical advances. Crit Care Med 18:1138, 1990. © 1990, Williams & Wilkins, Baltimore.)* Following admixture, the infused blood will be between 35° and 40°C. *Cautions:* (1) Keep the blood bag hanging when adding saline. (2) If the blood is admixed, it must be infused or discarded to avoid contamination. (3) Do not mix the blood manually or shake the bag. (4) *Do not* infuse 70°C saline *directly* into patients!

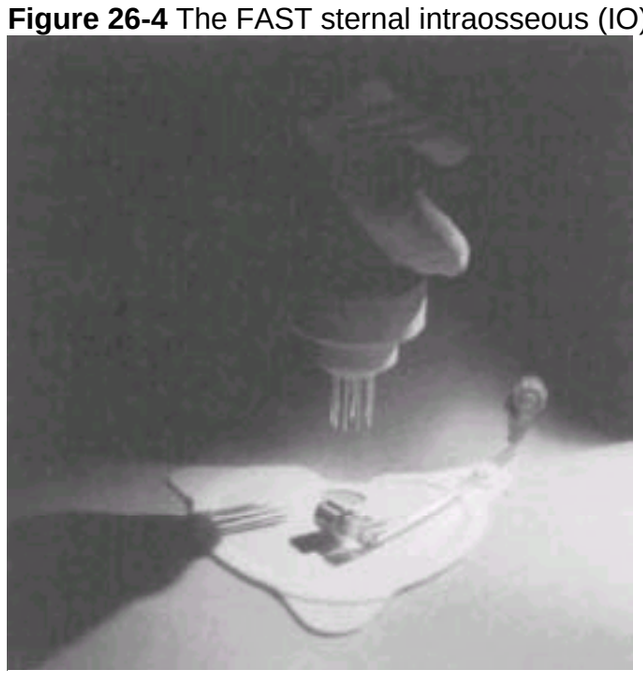

Figure 26-5 The Bone Injection Gun (BIG).

Figure 26-6 Schematic diagram demonstrating intraosseous (IO) insertion sites. *A*, The proximal tibia. The IO needle is inserted 1 to 3 cm distal to the tibial tuberosity and over the medial aspect of the tibia. *The bevel of the needle is directed away from the joint space. B,* The distal tibia. The IO needle is inserted on the medial surface of the distal tibia at the junction of the medial malleolus and the shaft of the tibia, posterior to the greater saphenous vein. The needle is directed cephalad, away from the growth plate. *C,* The distal femur. The IO needle is inserted 2 to 3 cm above the external condyles in the midline and directed cephalad away from the growth plate.

Figure 26-7 Insertion of an intraosseus (IO) needle. The fingers and thumb are wrapped around the proximal tibia to stabilize it. A towel (not shown) may be placed behind the knee for support. The needle is grasped firmly in the palm, and a rotary motion is applied with moderate pressure. The plastic sleeve can be adjusted to prevent it from being forced too deeply into the bone or through the bone. Note that the needle is directed away from the joint space.

Figure 26-8 Intraosseus (IO) needle in situ. *A*, The needle and tubing are secured with tape and the extremity is immobilized on a leg board. A long leg board may be needed with an active child. *B*, The needle is protected from accidental dislodgement by wrapping a stretch bandage around the extremity and placing a small plastic drinking cup around the needle.

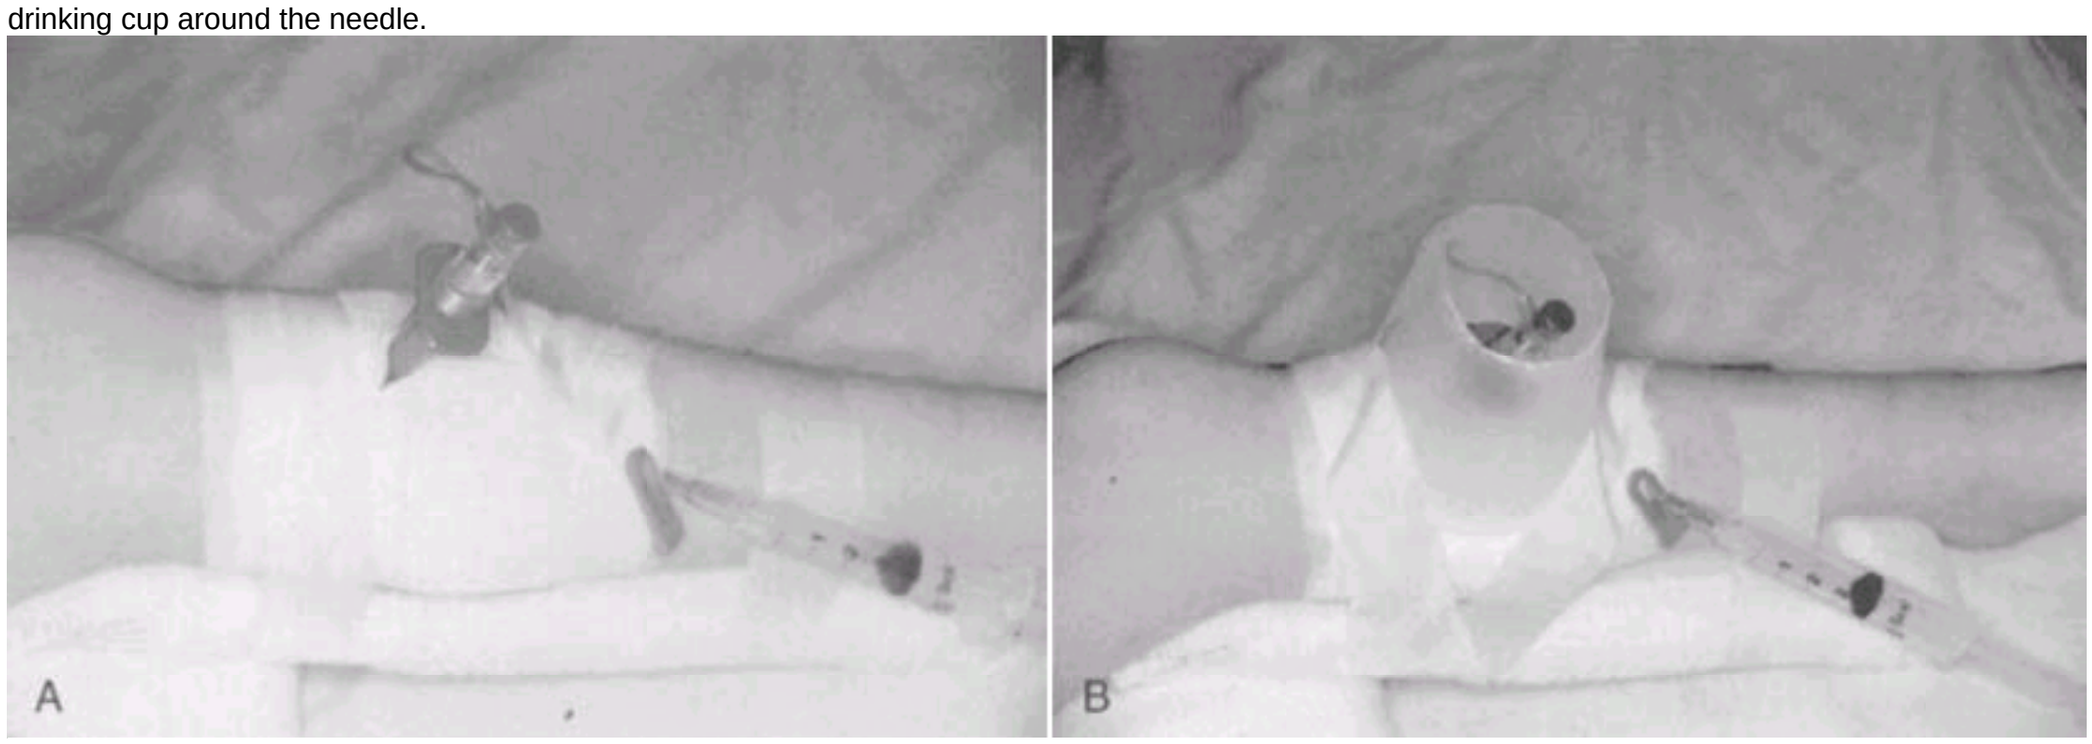

Figure 26-9 The FAST sternal intraosseous (IO) infusion device comes packaged with all necessary equipment.

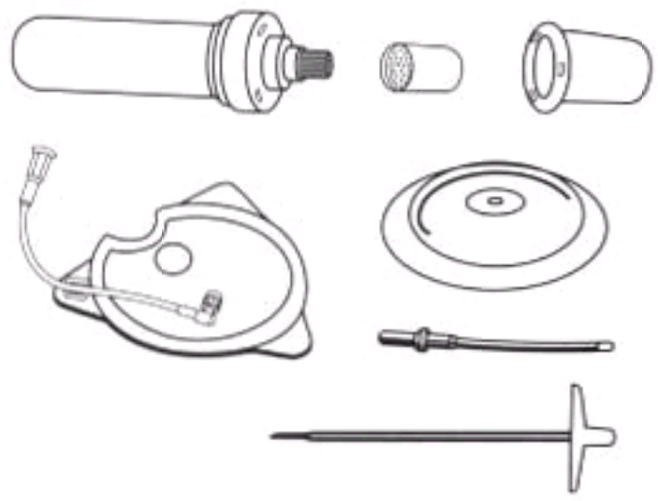

Figure 26-10 *A*, After prepping the overlying skin with iodine and alcohol, an adhesive target patch is placed over the midline of the manubrium with the target zone hole approximately 1.5 cm below the sternal notch. *B*, The introducer, which contains a "bone cluster" of needles, is placed in the center of the target zone. *C*, Pressure on the handle releases an inner needle upon which a plastic infusion tube with a small metal tip is loaded. The central needle advances exactly 5 mm beyond the circular cluster of needles, stopping at the cortex. The metal tip is now positioned in the cortex-medullary junction. Withdrawal of the handle leaves only the plastic infusion tube protruding from the insertion site. A plastic dome is attached via Velcro fasteners to the target patch, securing the tube in place.

Figure 30-6 *A,* Except in the setting of gross contamination, wounds should be anesthetized by inserting the needle through the cut edges, not through the intact skin. Patients often will not feel a 25-gauge or smaller needle passed into the subcutaneous tissue when it is advanced slowly through the cut edge. However, pain generally occurs with tissue distention by the anesthetic, and hence, injection should be slow and deliberate. *B,* If a wound is grossly contaminated, the anesthetic may be introduced through the intact skin. The operator should limit the number of needle sticks. The needle is first introduced at a point in line with the wound and beyond the wound edge (*1*), and while the anesthetic is slowly injected, the needle is advanced to include 1 entire side of the wound (if possible) to a point well past the opposite end of the wound. The other side may be anesthetized by passing the needle through the area already infiltrated by the first injection (*3*), making the skin puncture painless. A 3.8-cm (1.5-in.) 27-gauge needle is a good choice. If the needle is not long enough to encompass the entire wound, the skin is painlessly punctured at a midway point that has already been anesthetized (*2*).

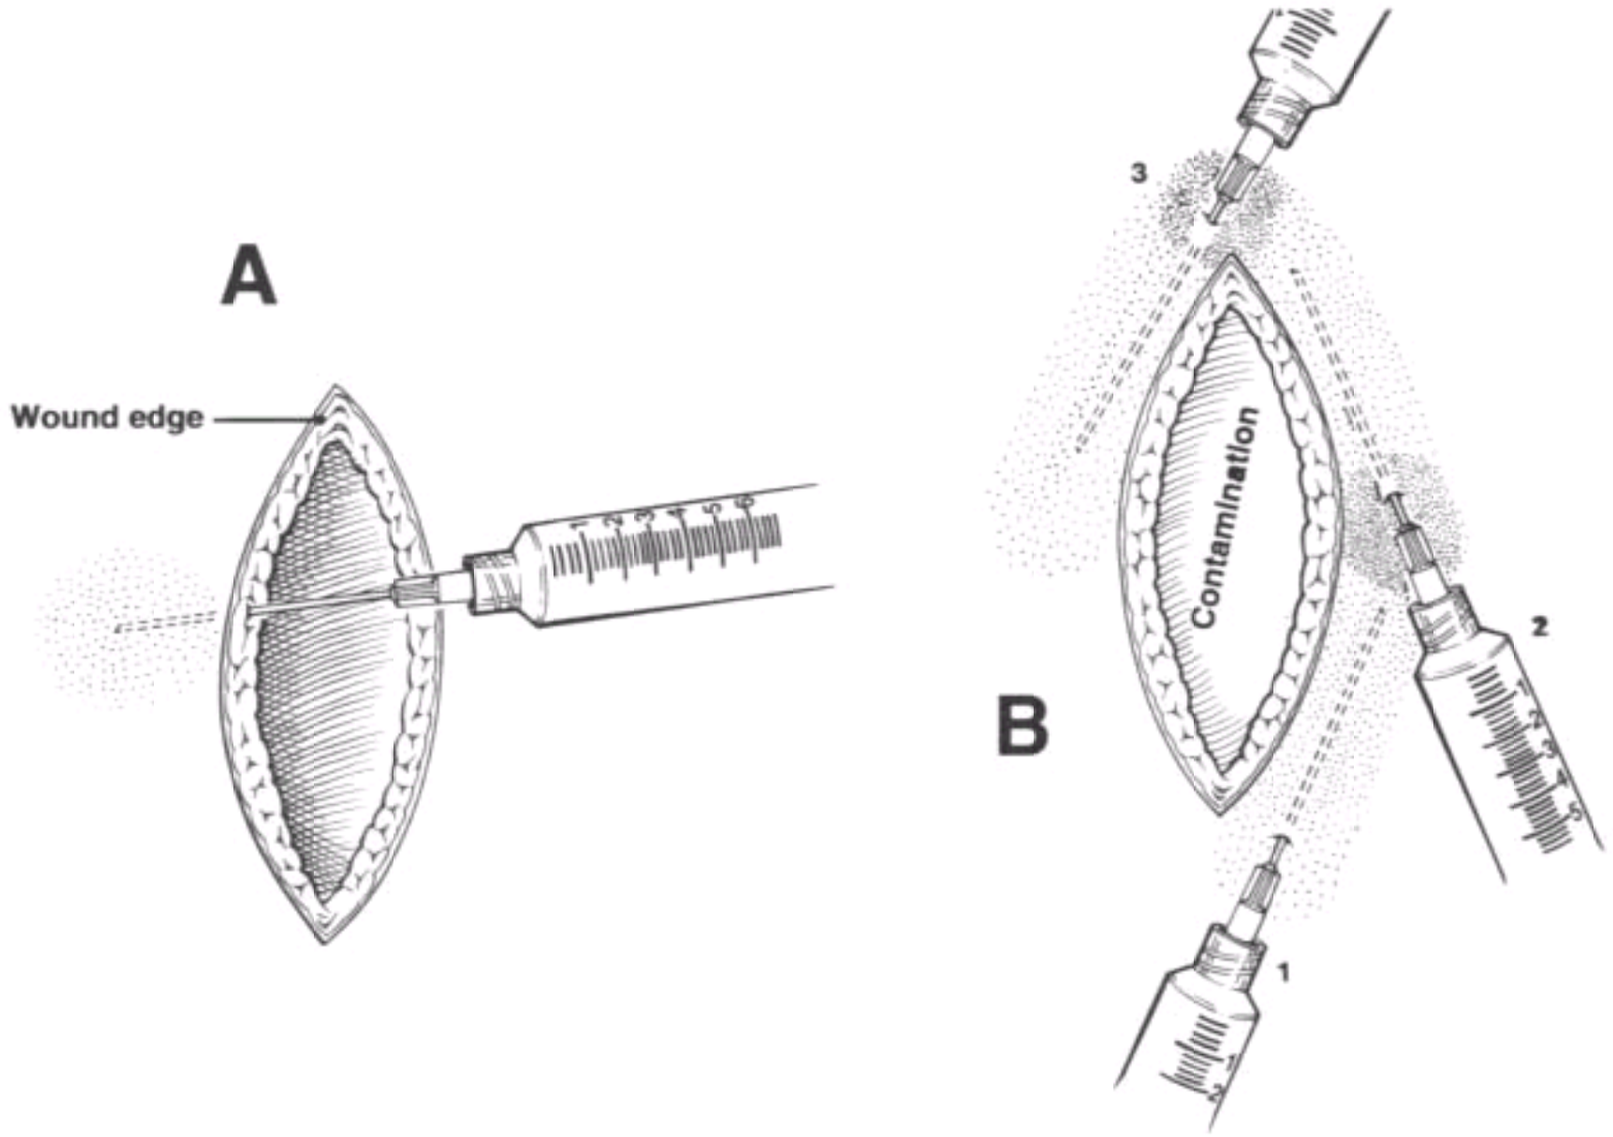

Figure 31-3 *A,* Local anesthesia—basic setup for intraoral application using an aspirating dental syringe. An alternative for a dental syringe is a 3-mL Luer-Lok syringe with a 1 ½ inch 25- or 27-ga needle. *B* and *C,* Intraoral dental blocks may be minimally painless if a topical anesthetic numbs the mucosa. Topical anesthesia is applied prior to injection, illustrated here for an inferior alveolar nerve block. After drying the mucosa with gauze, the pterygomandibular triangle is painted with topical anesthetic. Benzocaine is liberally sprayed into two cotton swabs and held in place by closing the teeth and lips for a few minutes after painting the area of needle penetration. The mucosa is dried with gauze before applying the topical anesthetic.

B

Figure 31-7 Posterior superior alveolar nerve block.

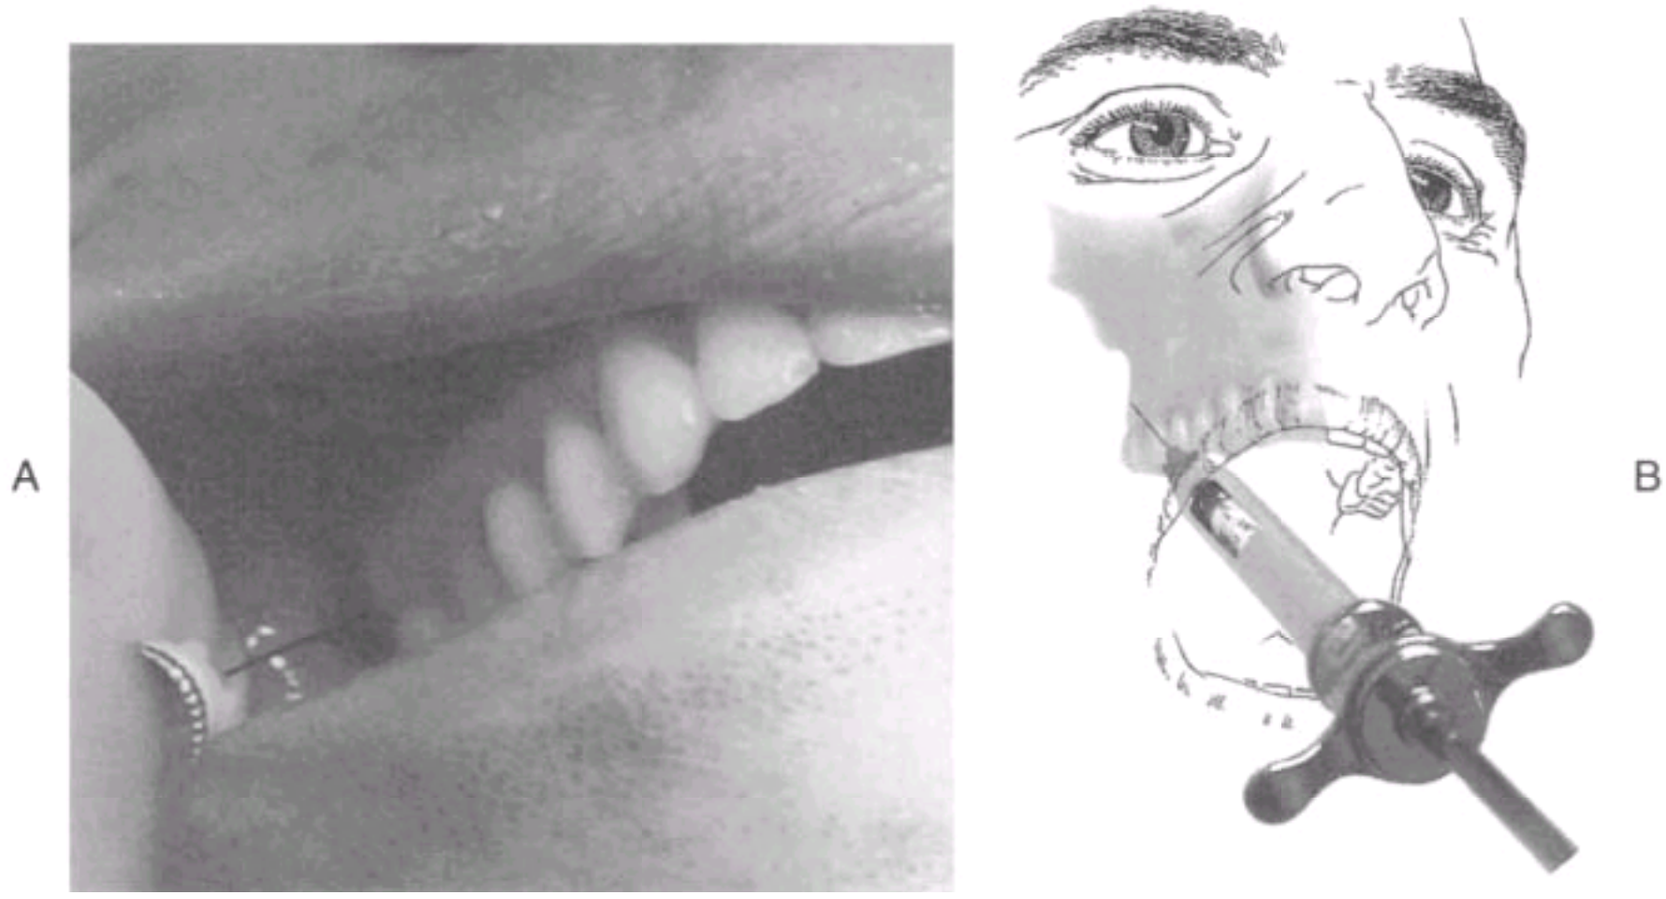

Figure 31-8 Middle superior alveolar nerve block.

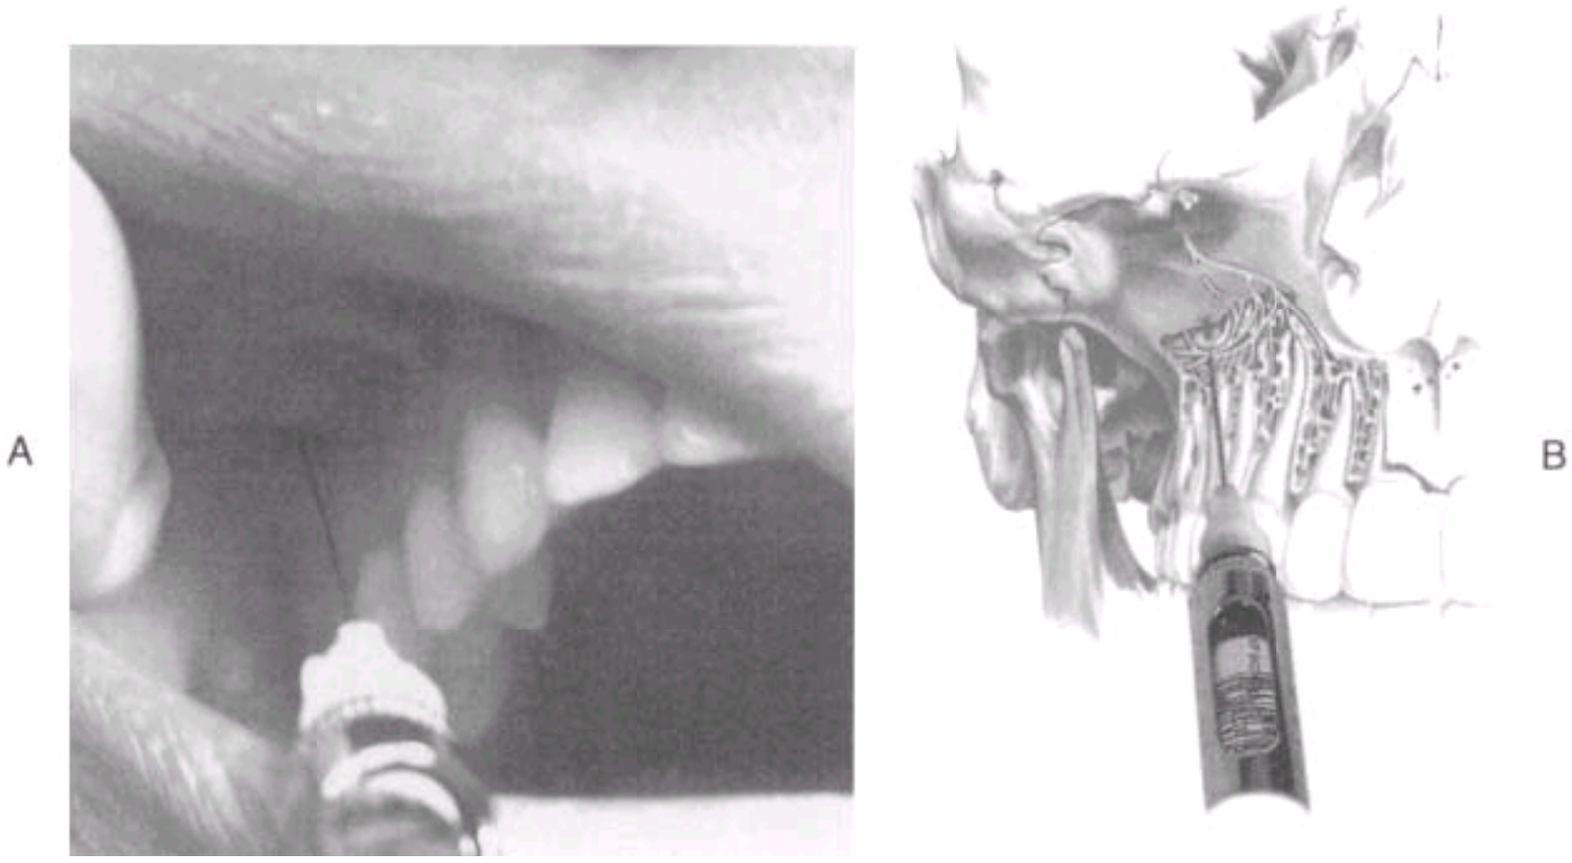

Figure 31-9 Anterior superior alveolar nerve block.

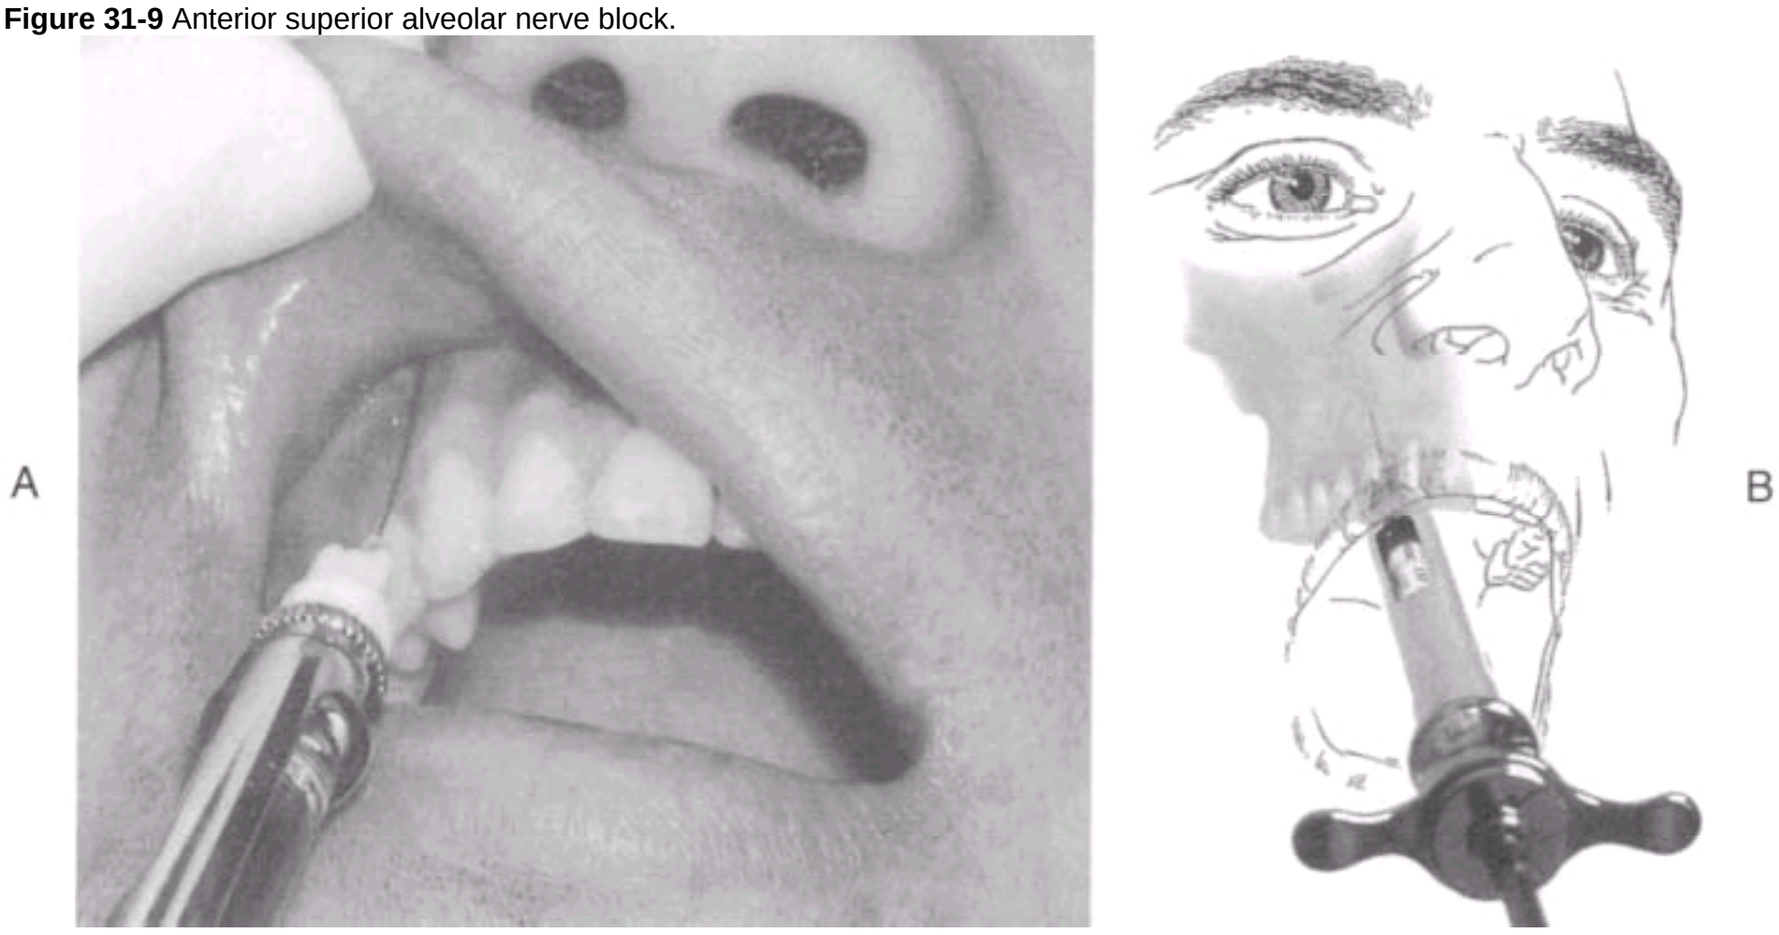

Figure 31-10 Area of anesthesia of a unilateral infraorbital nerve block. Anesthesia includes the lower eyelid and the upper lip.

Figure 31-11 *A,* Intraoral approach for infraorbital nerve block. *B,* The position of the infraorbital foramen *(arrow)* on the inferior portion of the infraorbital ridge. During infiltration, the needle should be near but not within the foramen. *C,* Incorrect infraorbital injection technique may result in needle entry into the orbit. *(Adapted from Eriksson E: Illustrated Handbook in Local Anesthesia. Philadelphia, WB Saunders, 1980.)*

A

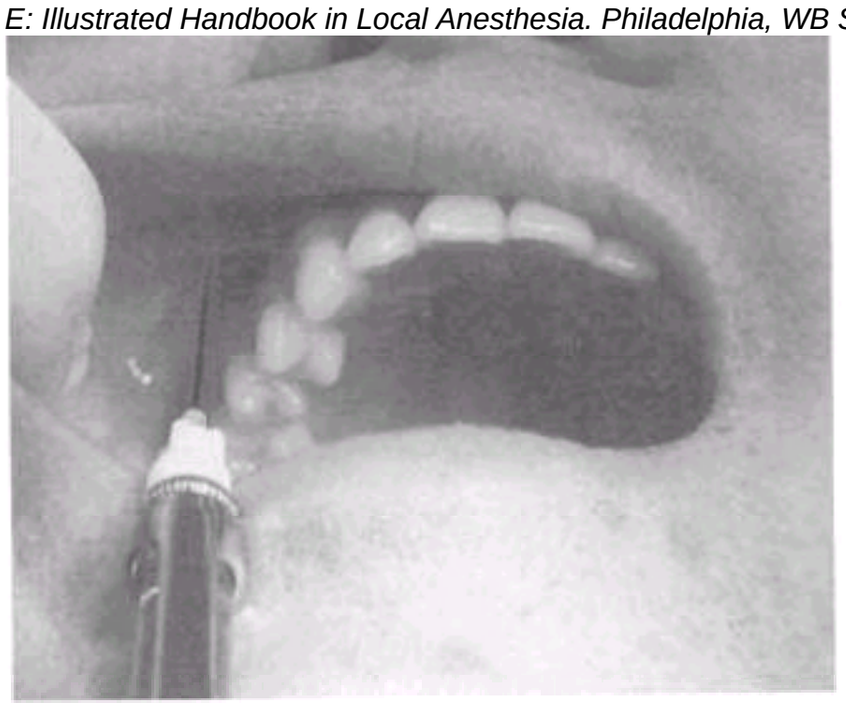

Figure 31-12 *A,* The extraoral approach to the infraorbital nerve. This procedure is more difficult than the intraoral approach, especially when attempting to obtain anesthesia of the upper lip. *B,* During injection, a finger placed above the needle and below the eyelid will limit swelling of the lower lid. Continual pressure with a finger during injection limits edema of the lower eyelid from the anesthetic solution.

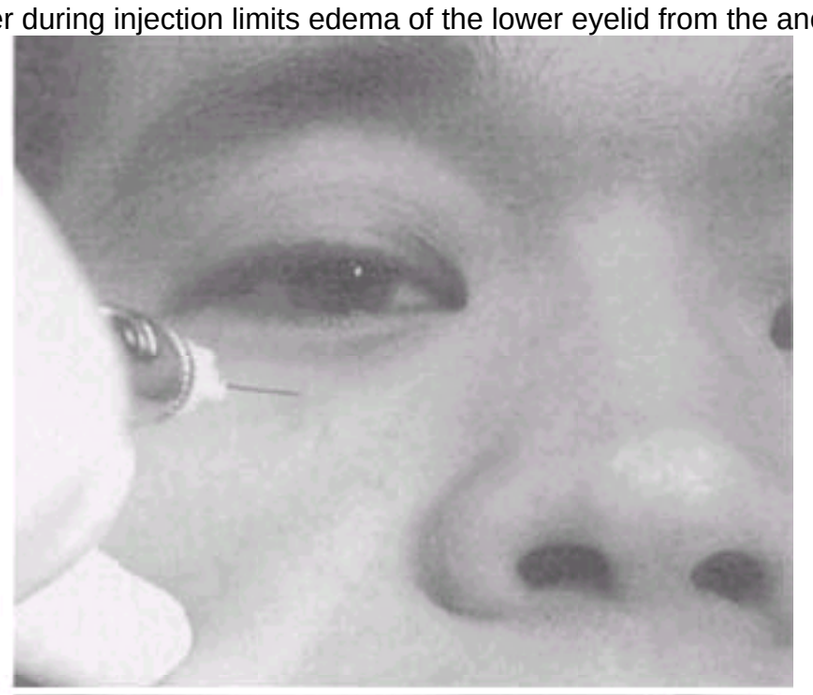
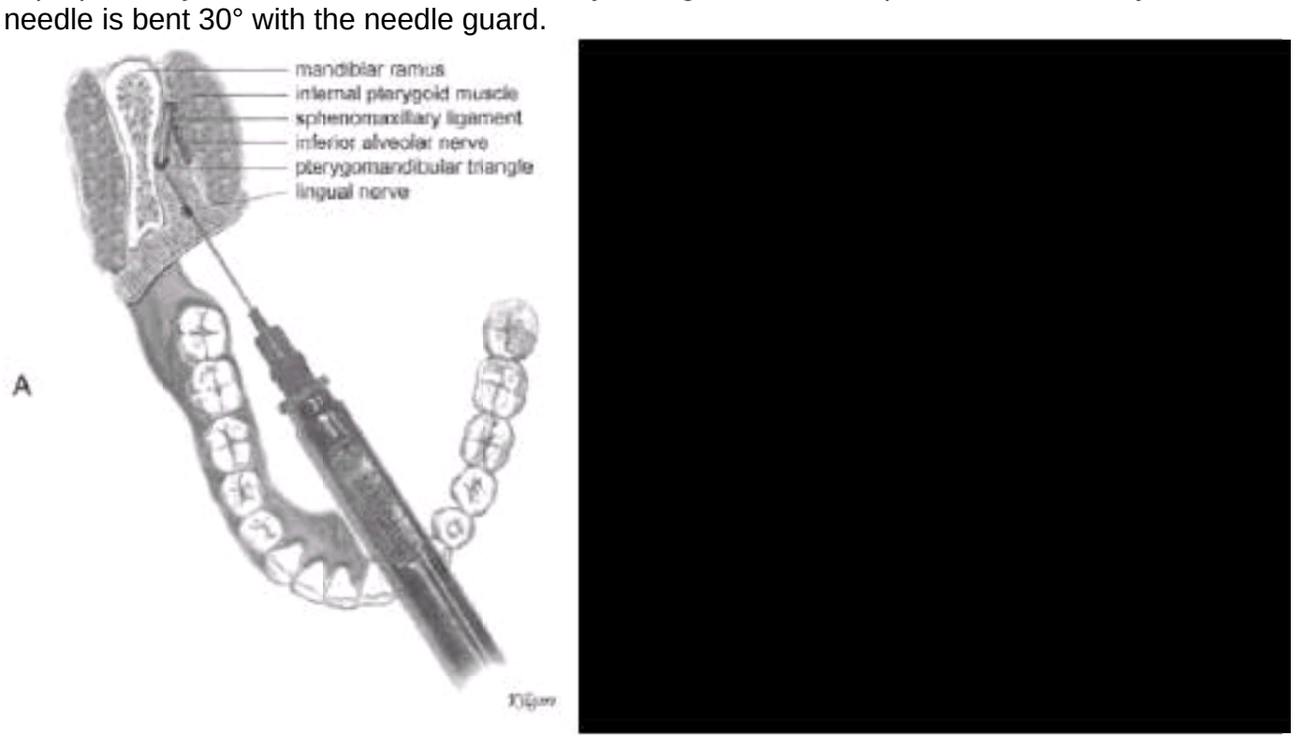
A



B

Figure 31-13 Inferior alveolar nerve block. *A,* Transverse illustration of the anatomy of the pterygomandibular triangle and direction of needle *before injection*. *B,* Anatomy of the inferior alveolar nerve block (intraoral approach) *(Adapted from Eriksson E: Illustrated Handbook in Local Anesthesia. Philadelphia, WB Saunders, 1980. Reproduced with permission)*. The greatest depth of the anterior border of the ramus of the mandible, the coronoid notch, is identified with the left index finger or left thumb. *C,* The ramus is grasped between an intraorally placed thumb (positioned on the coronoid notch) and extraorally positioned index finger. The pterygomandibular triangle may then be well visualized. Note the angle of the syringe during injection, with the syringe overlying the first and second premolars on the opposite side of the mandible. Failing to appreciate this orientation is one common cause of failure. The operator should be able to feel the needle contacting the bony surface of the inner mandible. Also note that the injection is 1 cm *above* the level of the teeth. *D,* Directing the needle too far posteriorly during the inferior alveolar nerve block technique will result in entry into the area of the parotid gland. Anesthesia of the seventh nerve may result. This occurs because from an improper entry orientation and is corrected by noting *C*. *E,* To compensate for difficulty in obtaining the correct approach with a straight needle, a 25-ga 1 ½-inch needle is bent 30° with the needle guard.



C

D

E

Figure 31-14 Mental infiltration technique. *A,* The correct supraperiosteal approach is an *infiltration* technique. *B,* Actual introduction of the needle into the mental foramen may produce neurovascular damage, and therefore infiltration only is recommended. *(Adapted from Eriksson E: Illustrated Handbook in Local Anesthesia. Philadelphia, WB Saunders, 1980.)*

Median Nerve (7)

Ulnar Nerve (8)

Figure 32-5 Cross section of the wrist looking cephalad. The arrow points to the (covered) median nerve. Shaded triangle depicts the area infiltrated with anesthetic. Note the relatively superficial position of the median nerve, just radial to the palmaris longus. *(Redrawn from Adriani J: Labat's Regional Anesthesia: Techniques and Clinical Applications. 3rd ed. Philadelphia, WB Saunders, 1967, p 234. Reproduced with permission.)*

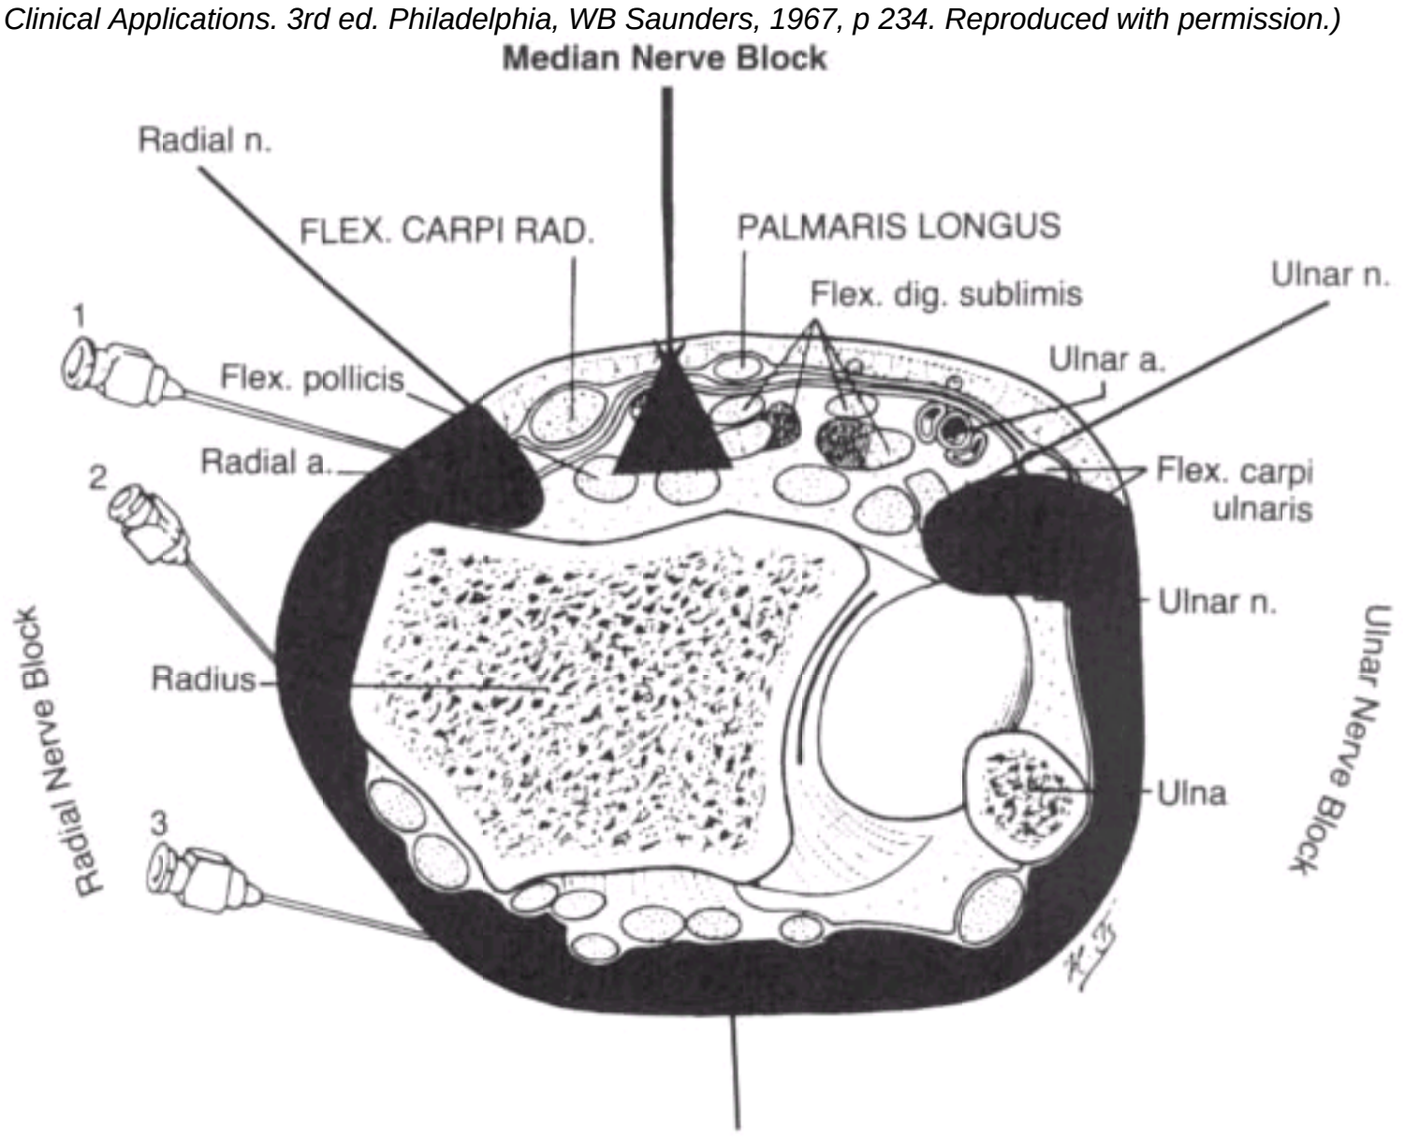

Figure 32-6 Landmarks and anatomy of the median and ulnar nerve block. The median nerve is more superficial than often expected. It lies to the radial side of the palmaris tendon.

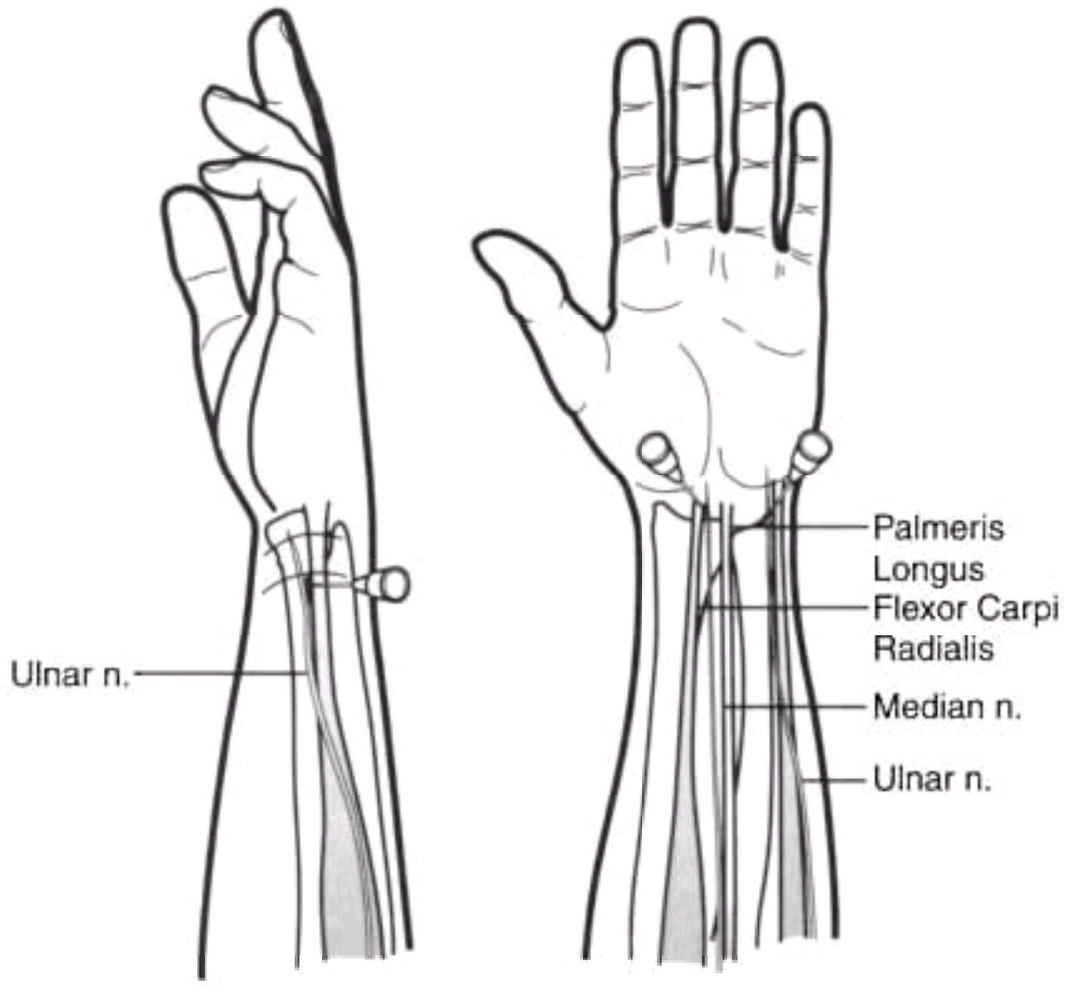

Figure 32-7 Ulnar nerve block at the elbow. *A,* Positioning patient for ulnar nerve block at the elbow. The patient is supine, the elbow flexed, and the medial epicondyle and ulnar groove are exposed. *B,* The ulnar nerve passes between the olecranon (*) and medial epicondyle (•) of the humerus. Avoid injecting large amounts of anesthesia directly into the ulnar groove. Instead, place anesthetic proximal to the groove. Alternatively, the ulnar nerve may be blocked at the wrist.

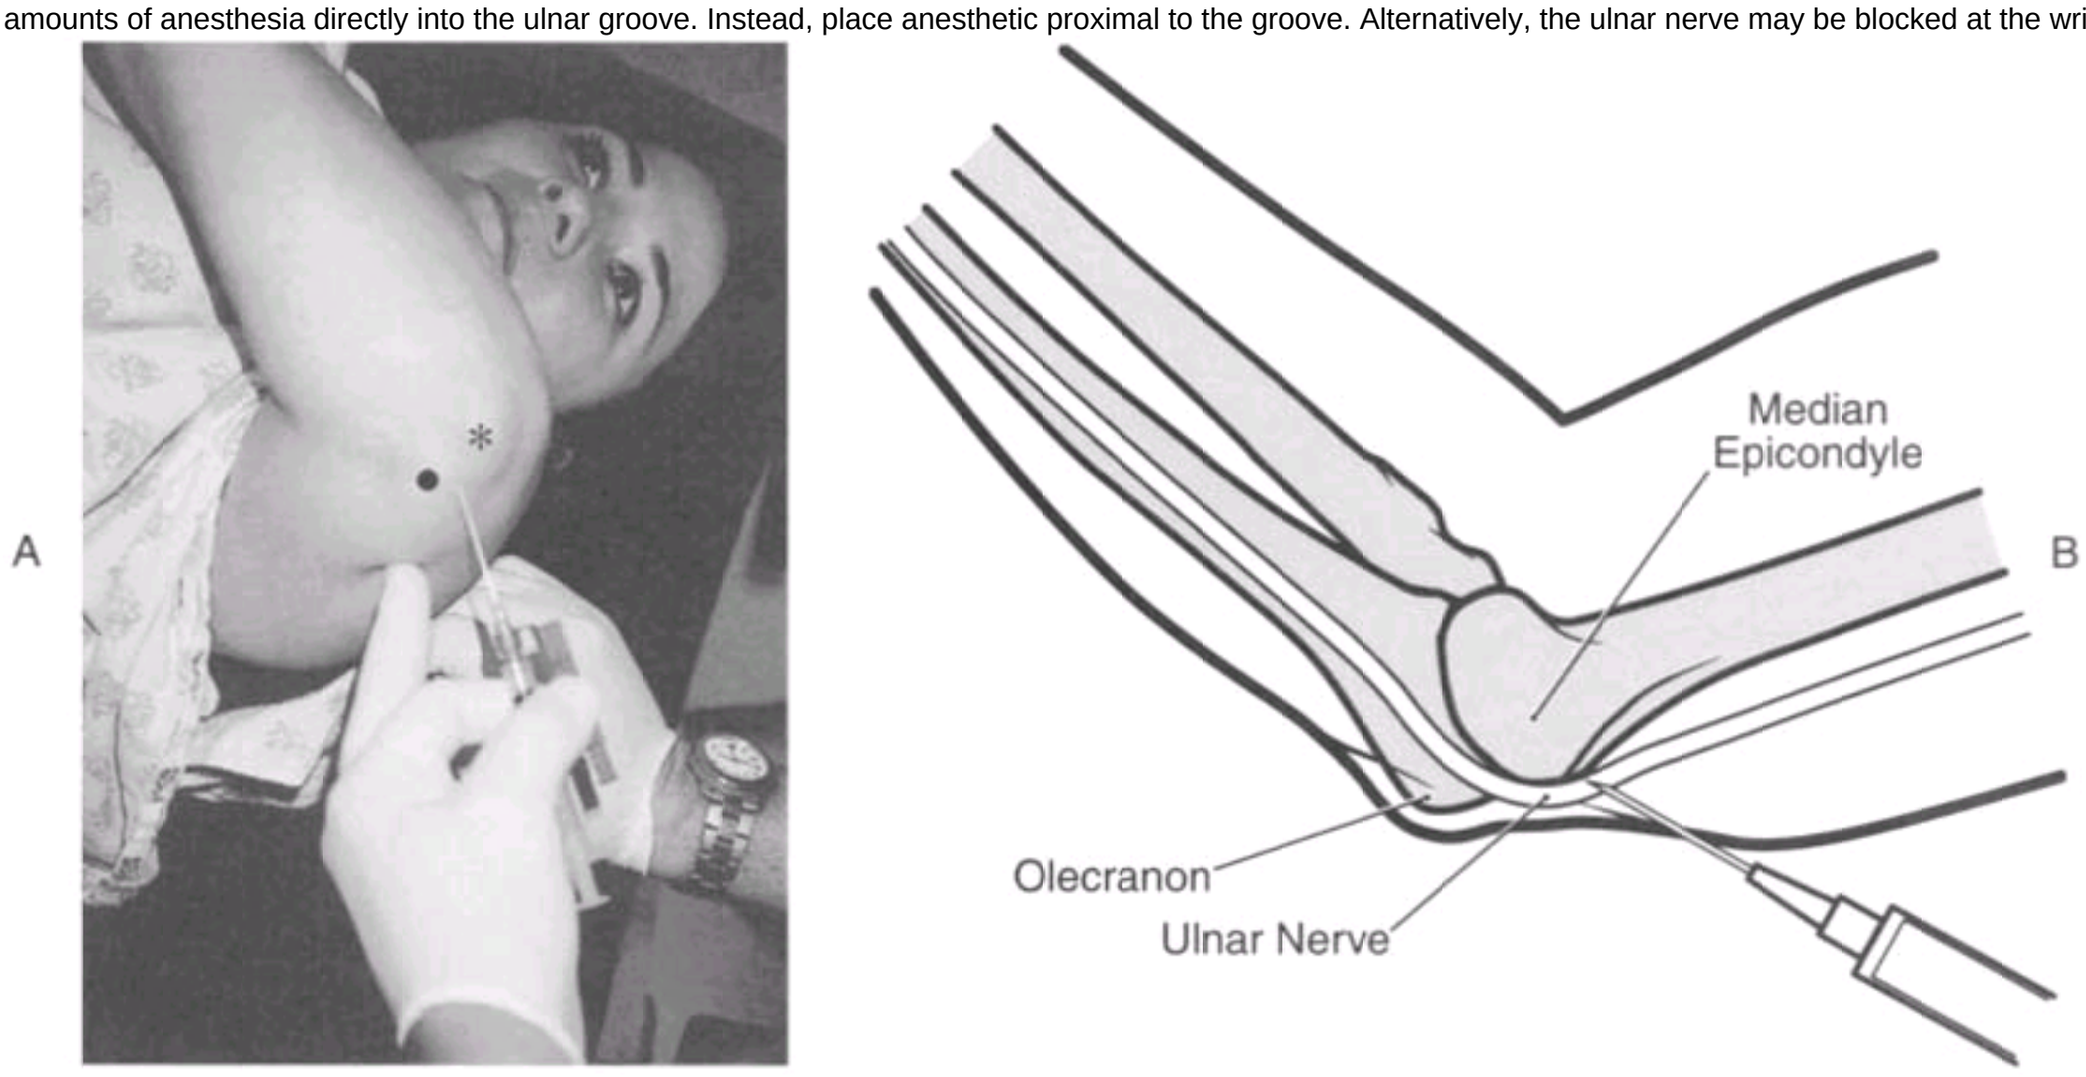

Figure 32-8 Cross section of the elbow, demonstrating (1) the median nerve, (2) the radial nerve, and (3) the ulnar nerve. *(From Adriani J: Labat's Regional Anesthesia: Techniques and Clinical Applications. 3rd ed. Philadelphia, WB Saunders, 1967, p 234. Reproduced with permission.)*

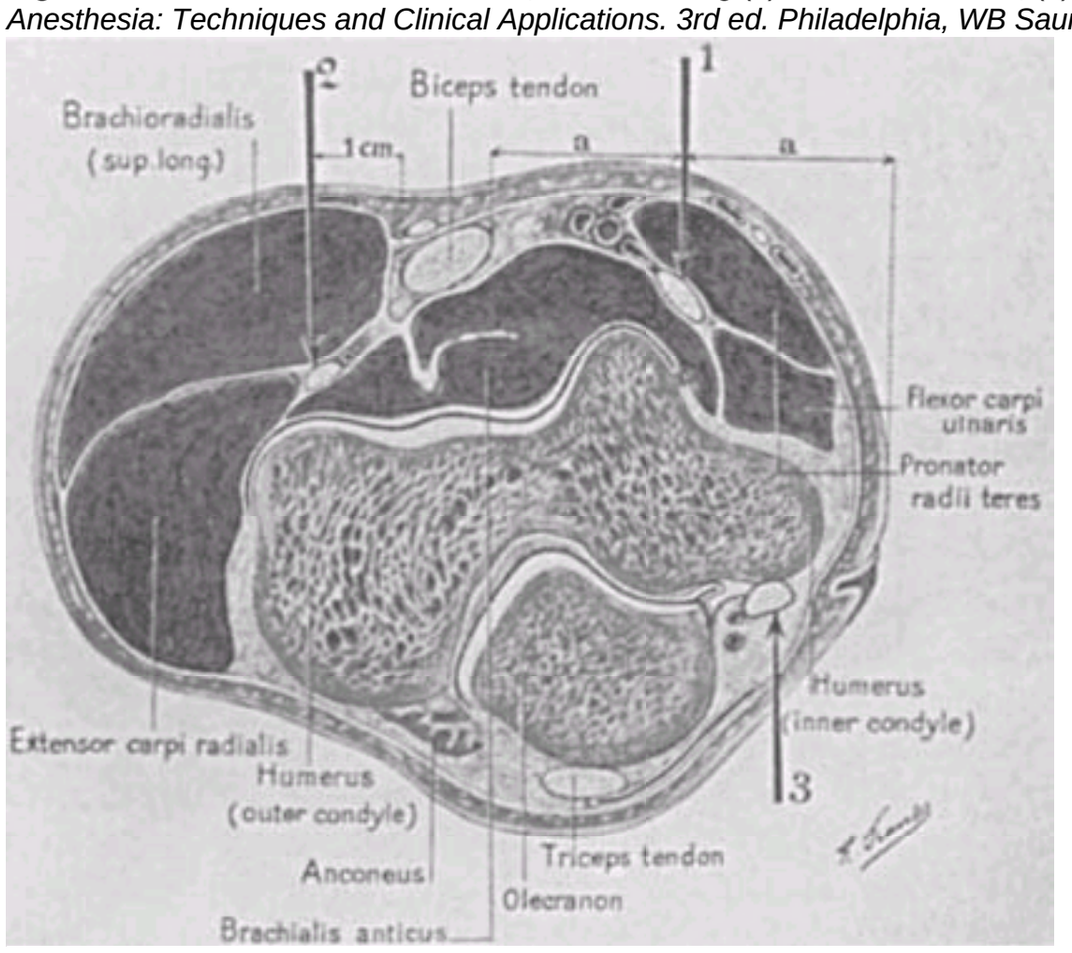

Figure 32-9 Anatomy for nerve blocks at the elbow and wrist. Black circles on skin indicate site of puncture. *(From Adriani J: Labat's Regional Anesthesia: Techniques and Clinical Applications, 3rd ed. Philadelphia, WB Saunders, 1967, p 226. Reproduced with permission.)*

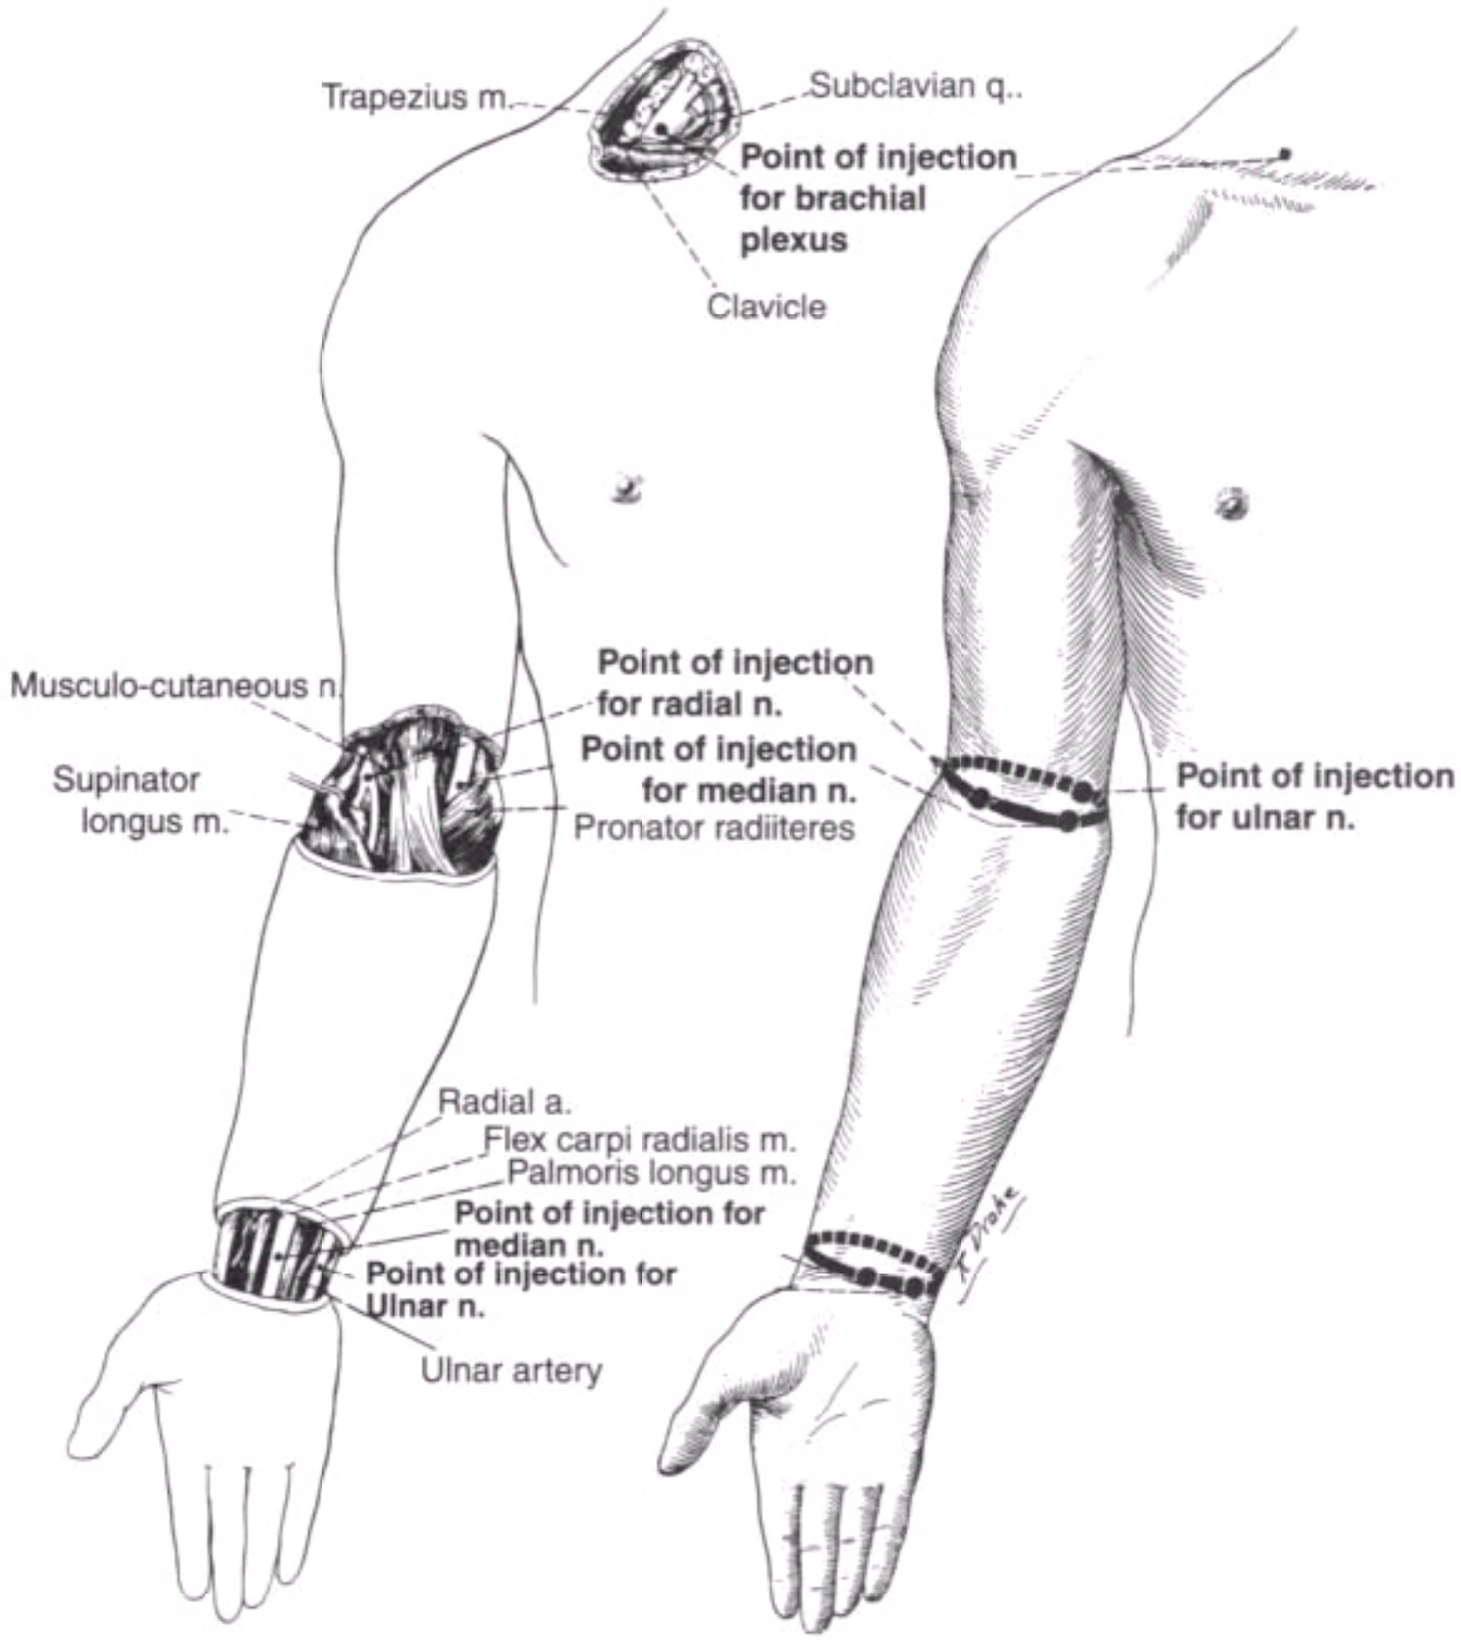

Figure 32-10 Distribution, anatomy, and blockade of the radial nerve at the wrist.

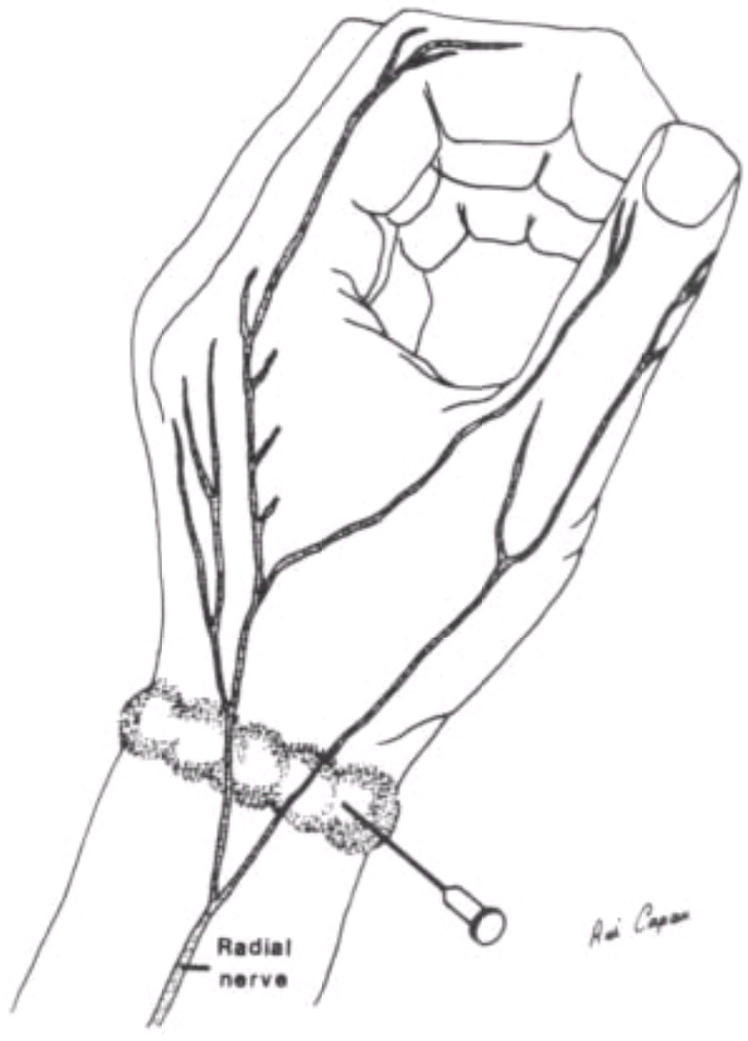

Figure 32-11a *A,* Schematic cross section of the phalanx, demonstrating the relationship of the nerves to the bone. If the anatomy is examined (*B* and *C*), it is obvious that in order to perform a digital block of the thumb and fifth finger, all four digital nerves (two volar, two palmar) must be blocked. Since almost the entire second, third, and fourth fingers are supplied by only the palmar branch (note that each palmar nerve curves around to the dorsum from the palmar surface), only the palmar nerves must be blocked to obtain anesthesia for all but the skin of the proximal dorsal digit. The exception is the ulnar side of the fourth finger, which receives some of its distal dorsal innervation from the dorsal nerve. *D,* On the palmar aspect, the digital nerves are almost adjacent to the flexor tendon, a position that is more palmar than is usually appreciated. *(From Grant's Atlas of Anatomy, 9th ed. Baltimore, Williams & Wilkins, 1978. Reproduced with permission.)*

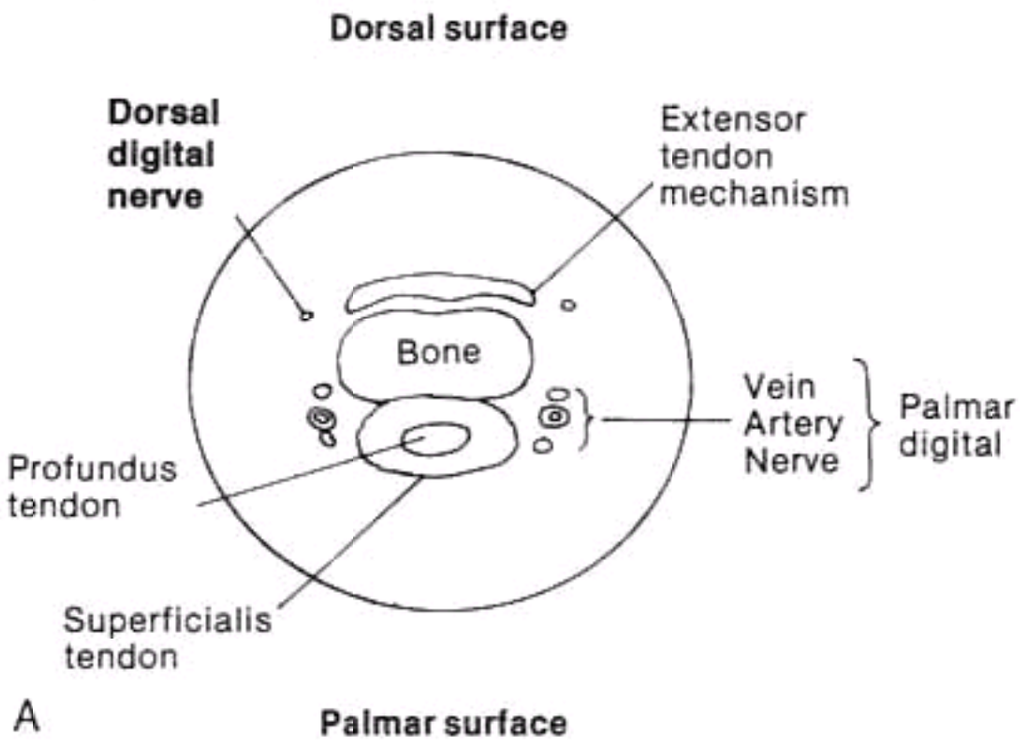

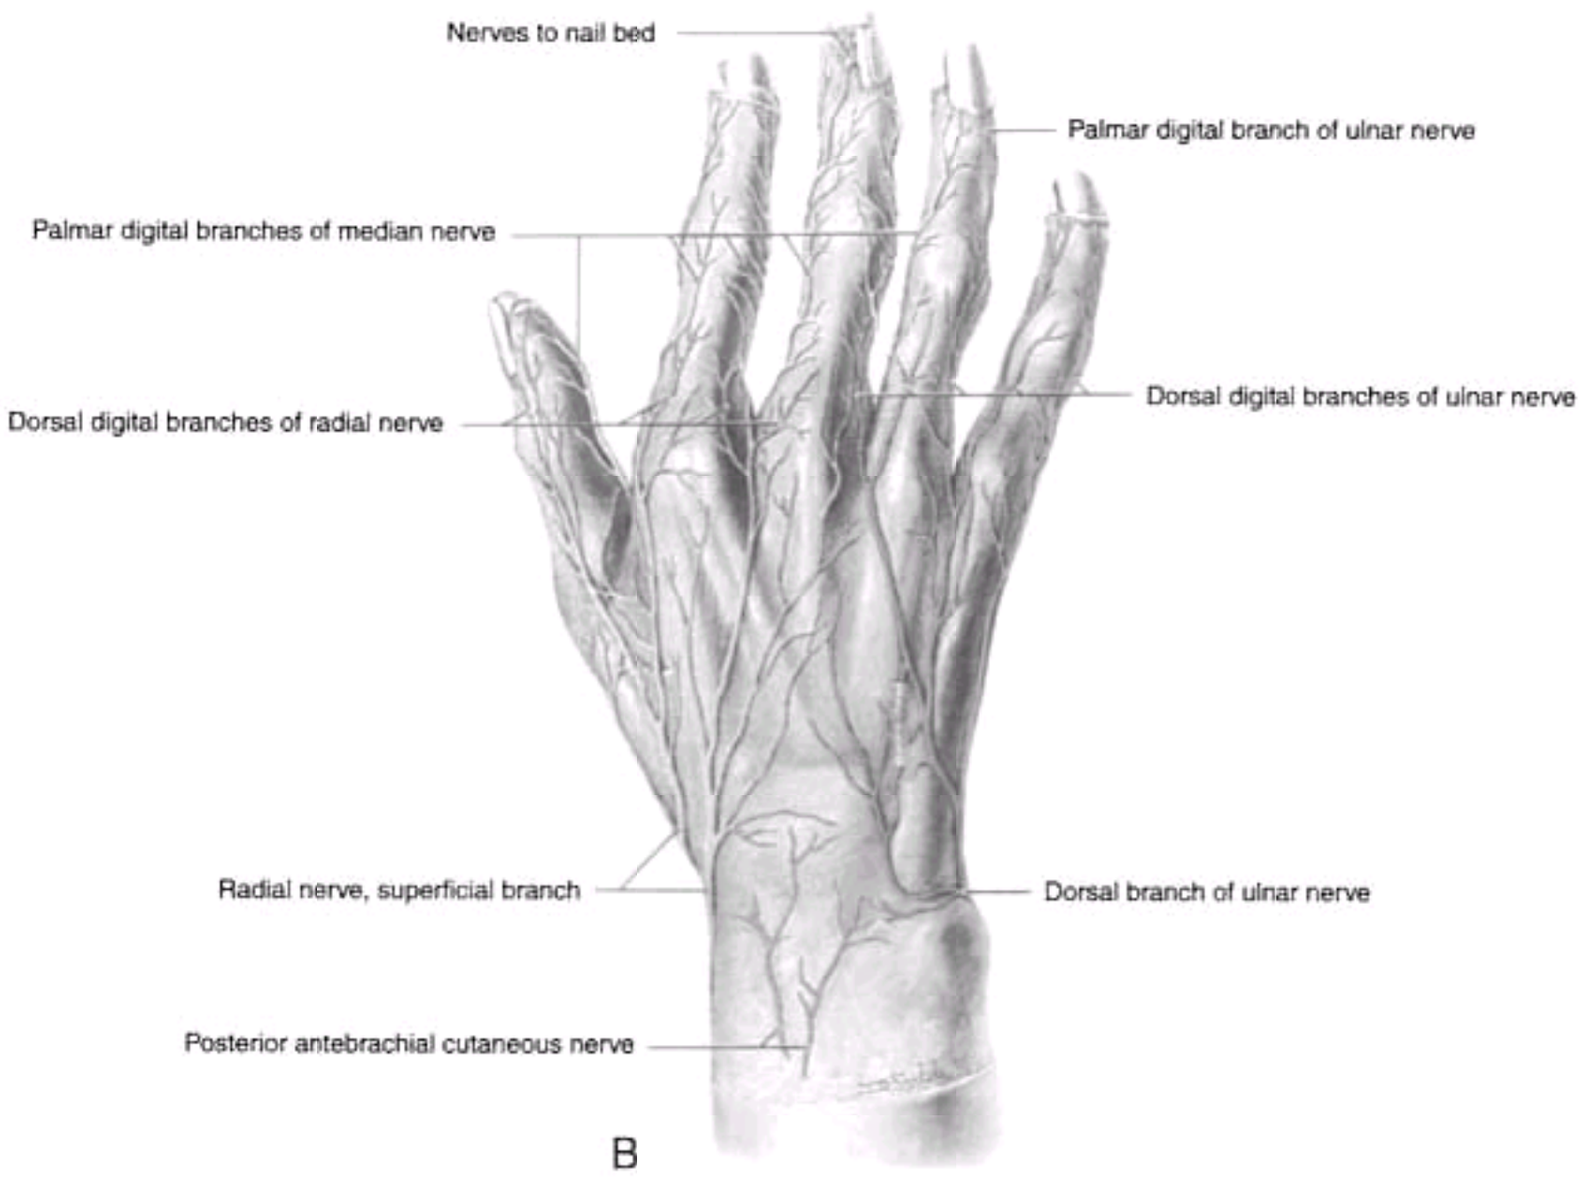

Figure 32-11b

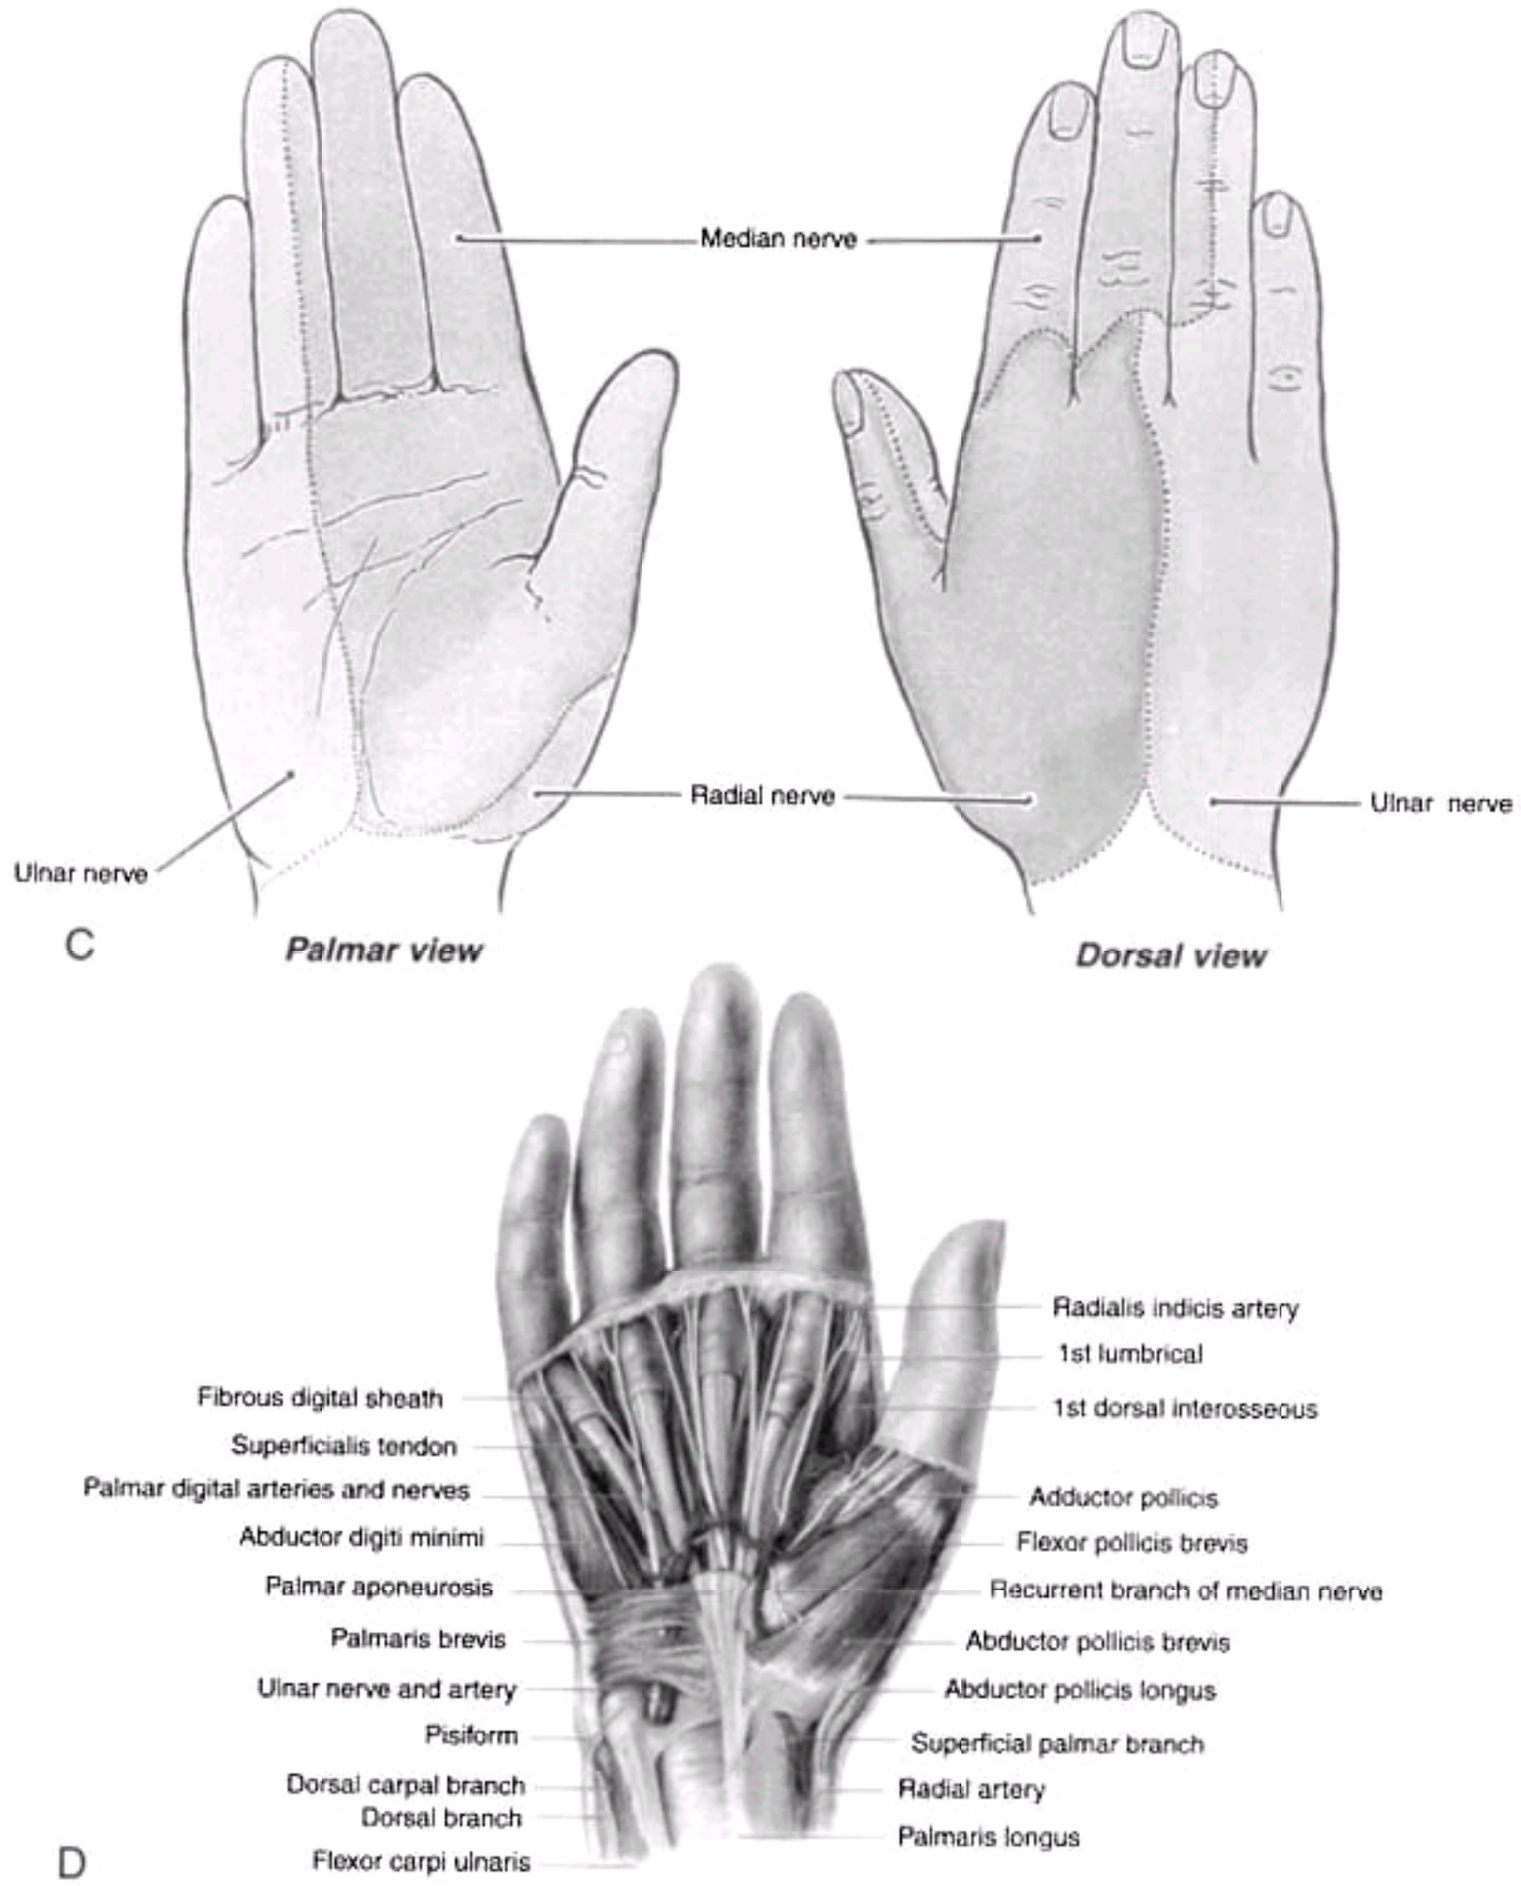

Figure 32-12a *A,* Each finger has four digital nerves: two palmar and two dorsal nerves. The palmar nerves travel in a line connecting the top of the skin creases made by flexing the proximal interphalangeal and distal interphalangeal joints *(black line)*. The nerves are more palmar than often appreciated, and are almost adjacent to the flexor tendon, so injecting the true lateral portion of the finger may miss the nerve. If the anesthesia needle is inserted at the tip of the skin creases (see probe) the nerve will be blocked. *B,* When performing a digital nerve block on the thumb, all four digital nerves must be blocked. As in the other fingers, the palmar nerve travels in a line made by connecting the top of the skin creases produced by flexing the digit *(black line)*. The anesthetizing needle (see probe) must be placed almost adjacent to the flexor tendon to block the nerve. *C,* Sites of digital nerve blocks at the base of the finger. *D,* Technique of anesthetizing the second injection site. *(From Adriani J: Labat's Regional Anesthesia: Techniques and Clinical Applications, 3rd ed. Philadelphia, WB Saunders, 1967, p 445. Reproduced with permission.)*

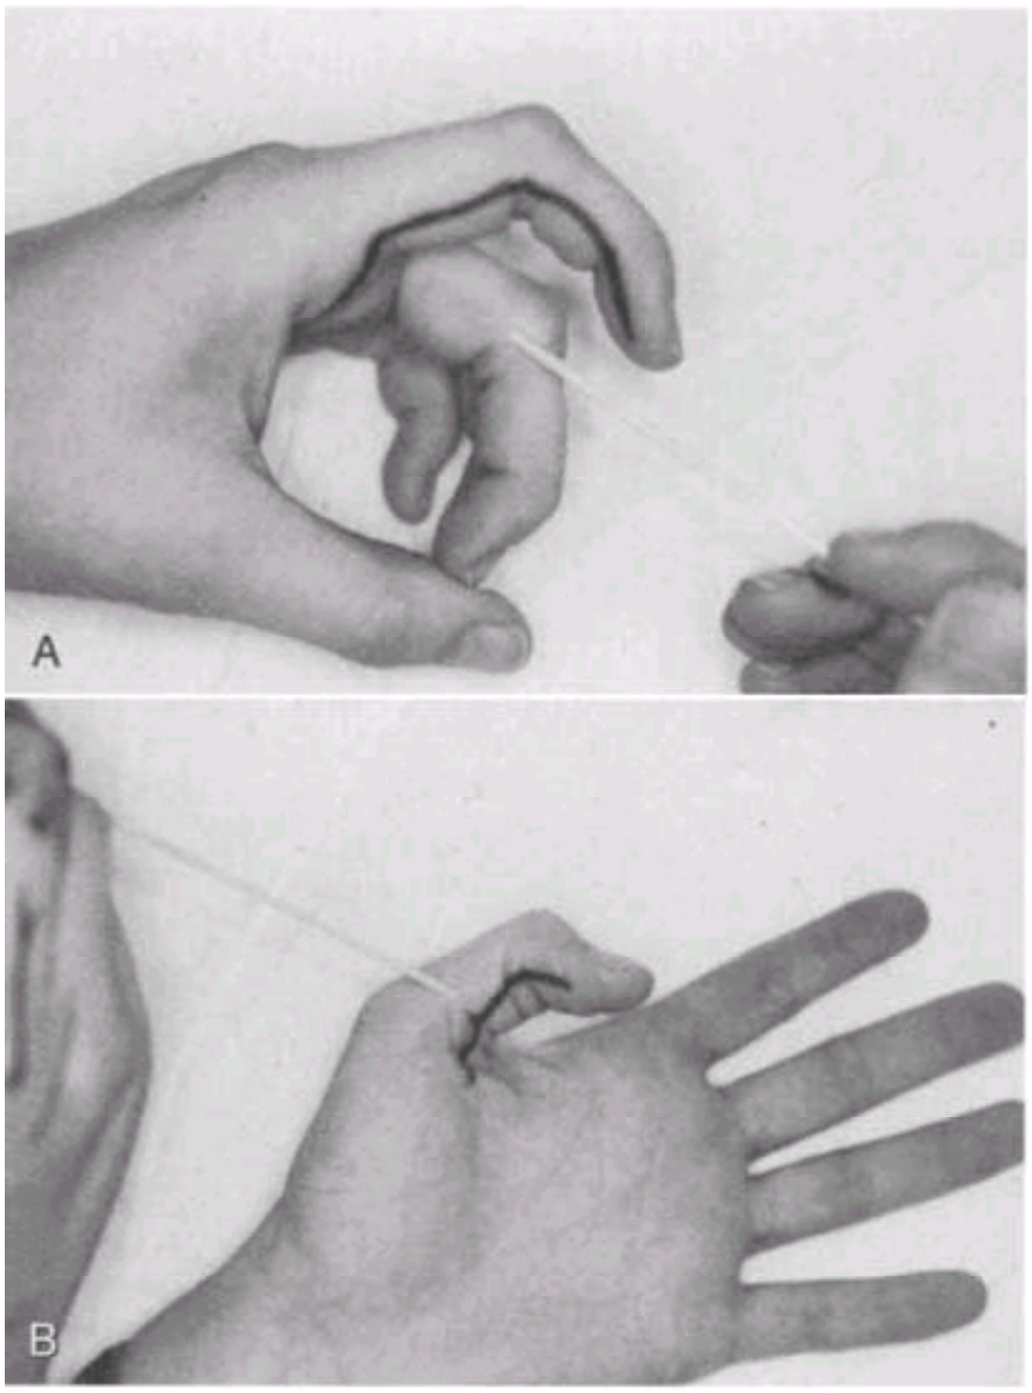

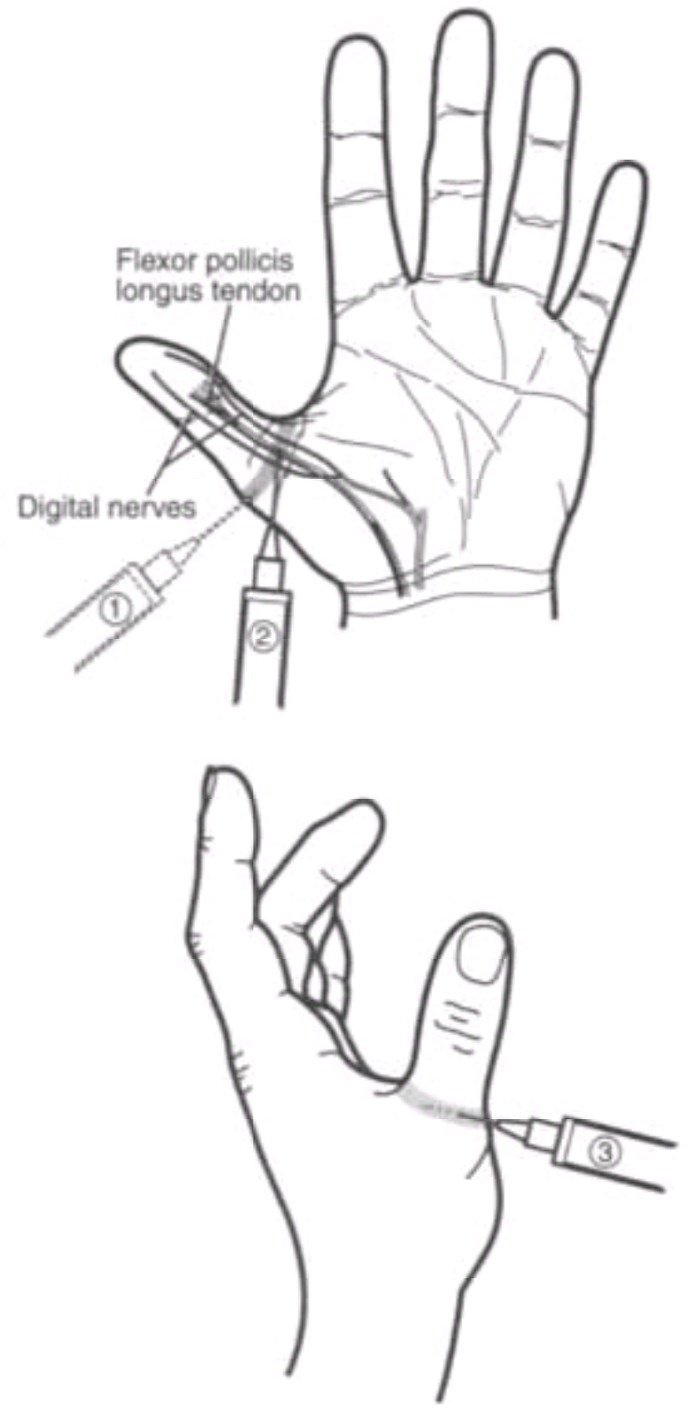

Figure 32-12b

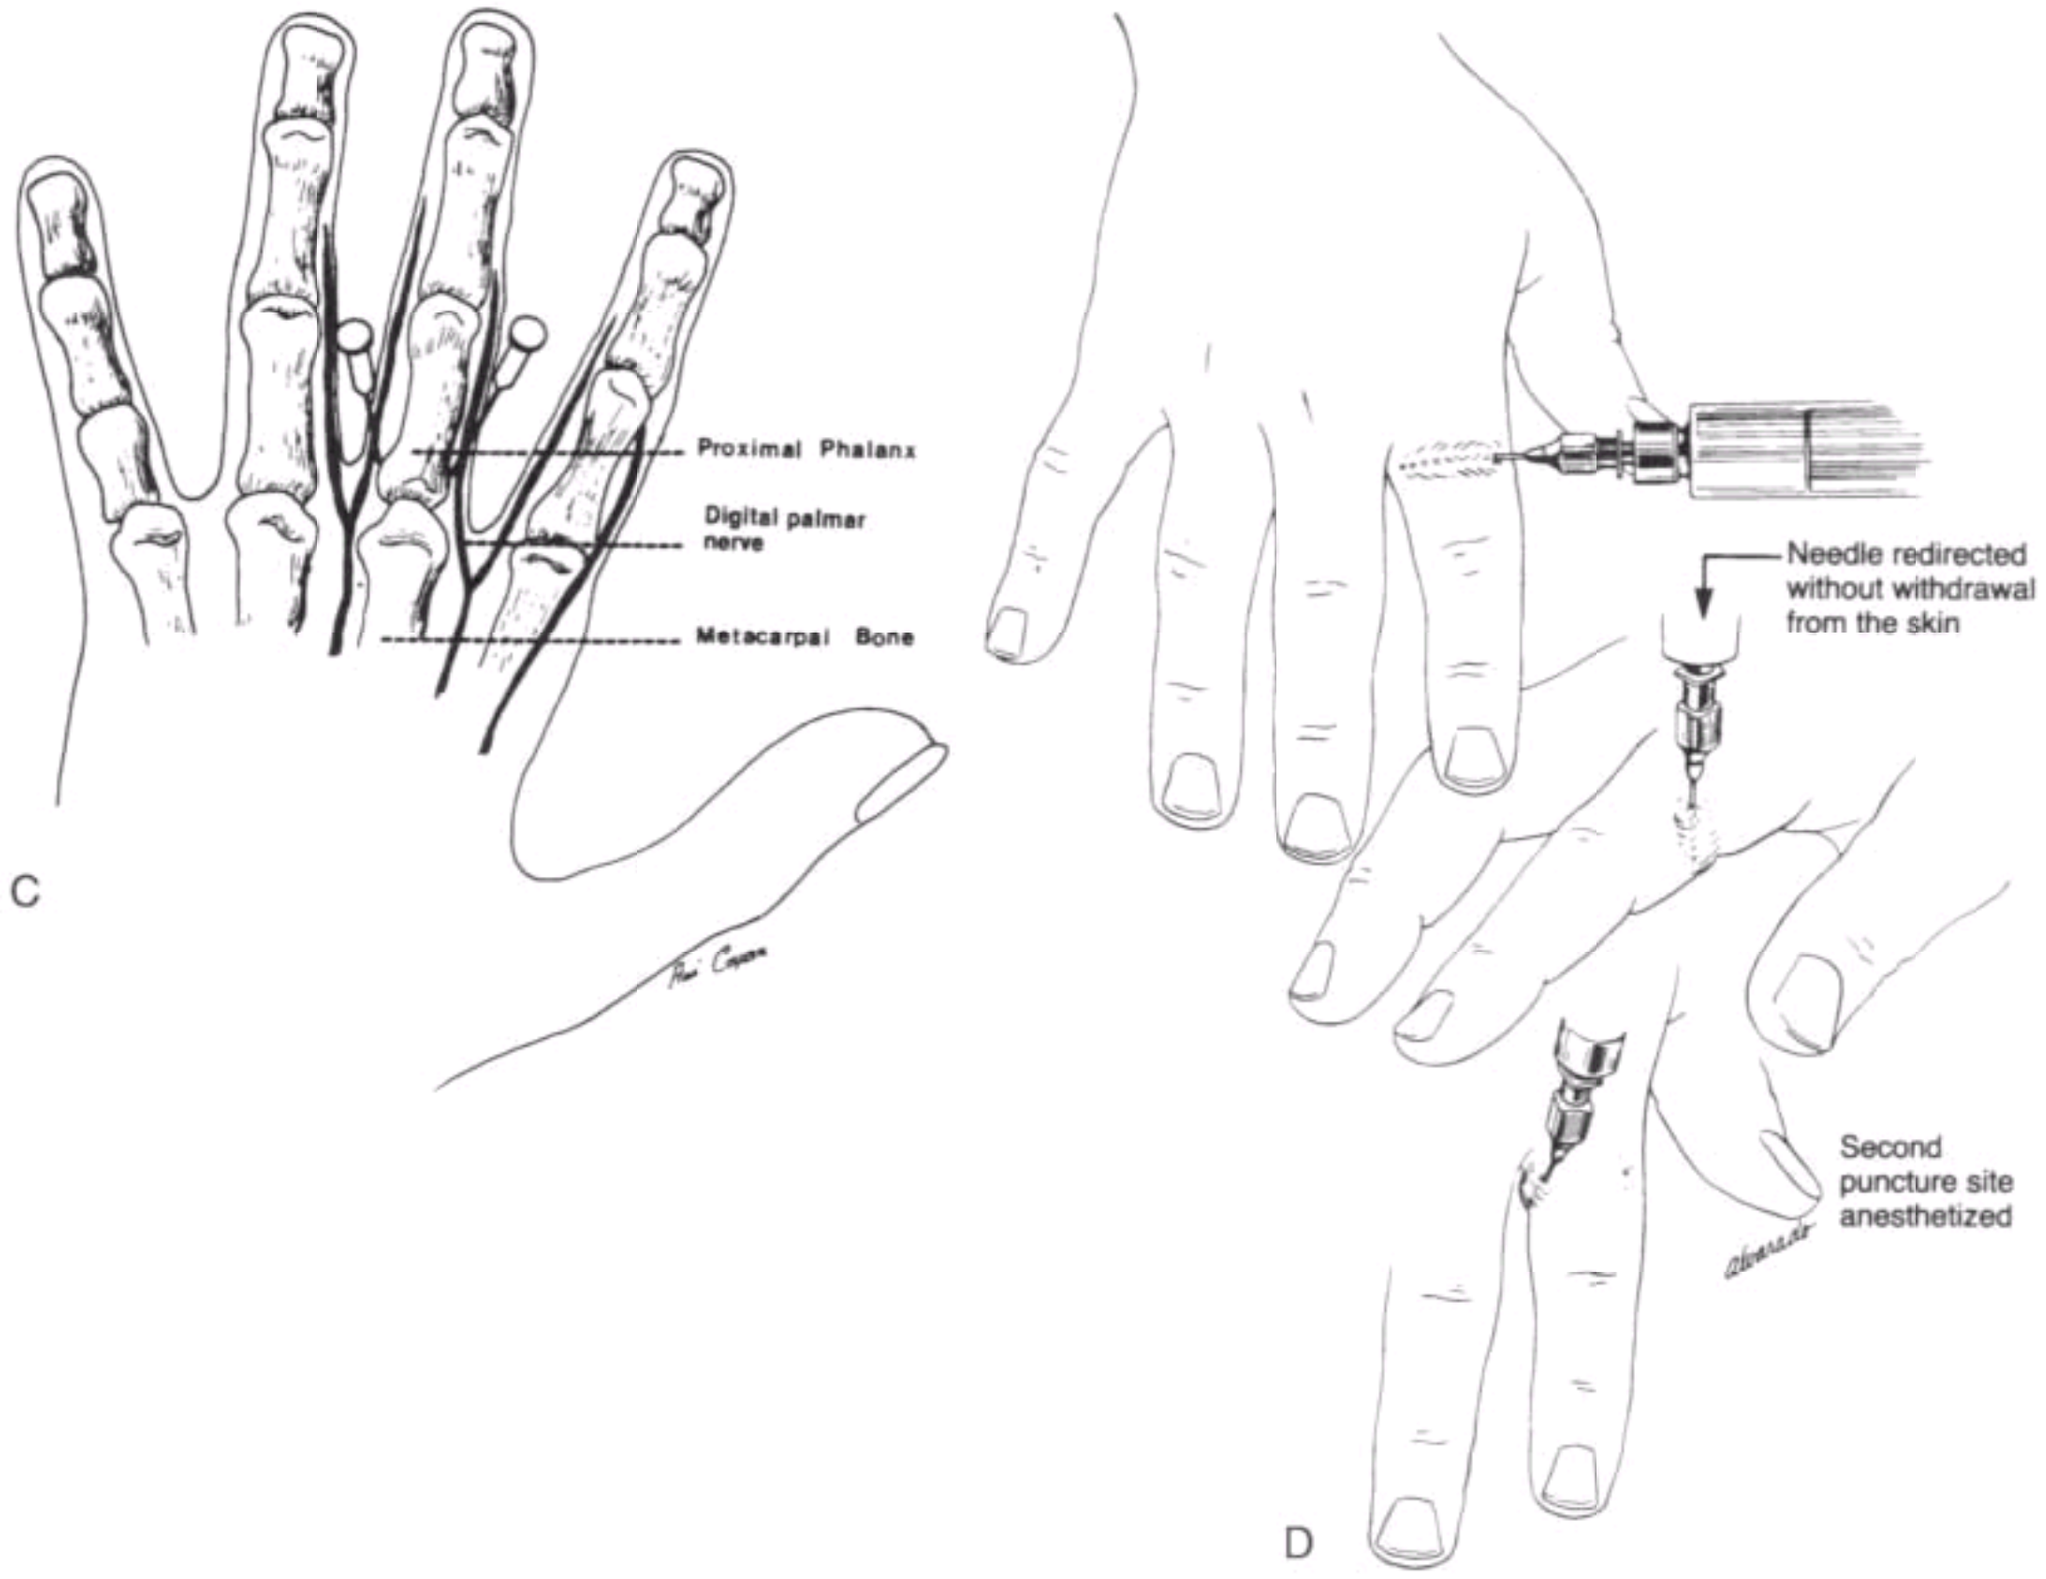

Figure 32-13 Palmar approach to the metacarpal head. After needle puncture in the midline, the needle is directed slightly to the right and left, and anesthetic is deposited along the course of both volar digital nerves. The needle is not withdrawn until both nerves are blocked. This technique blocks only the palmar nerves.

Figure 32-14 The palmar digital nerves (*N*) are adjacent to the head of the metacarpal (*MC*) in the palm. For a metacarpal head block the anesthetizing needle punctures the palm in the middle of the MC (see probe), and anesthetic is deposited both laterally and medially, blocking both nerves with a single puncture. Injection in this area is usually more painful than injecting in the web space, but it is almost foolproof for obtaining anesthesia.

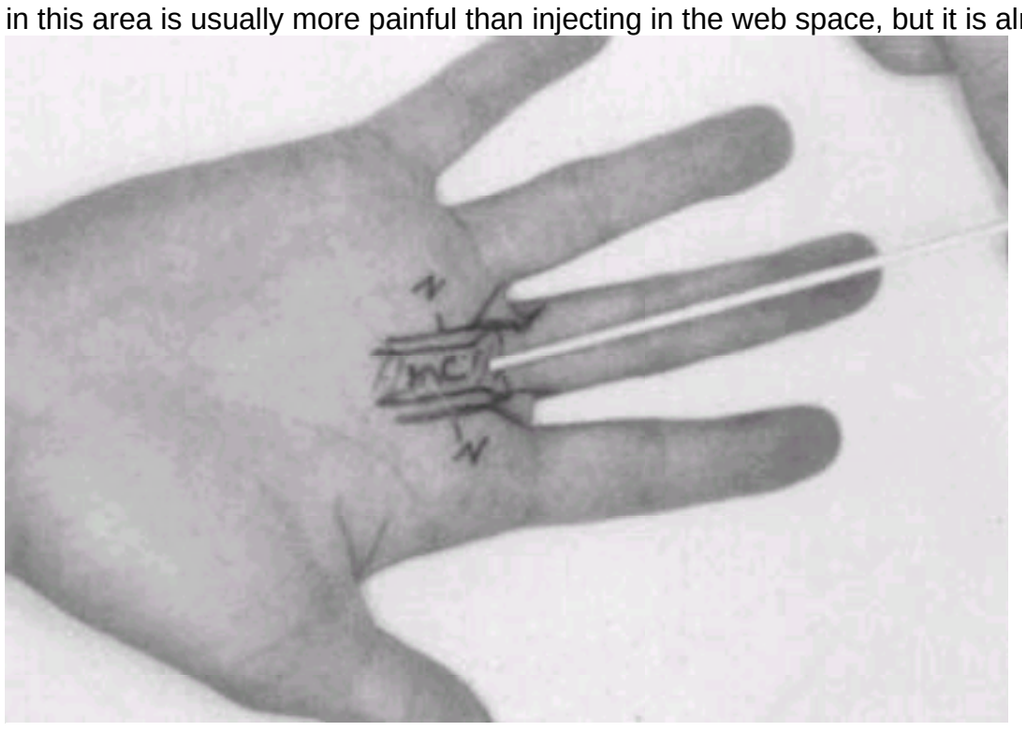

Figure 32-15 The palmer web space metacarpal head block allows two of the three inner fingers to be anesthetized with a single needle puncture. The clinician's index finger palpates the patient's metacarpal head on the patient's palm while the injured finger is supported and the web space is exposed. The index finger can feel the tissue distention by the anesthetic, but care must be taken to avoid passing the needle through the skin and puncturing the operator's finger. About 3 to 5 mL of anesthetic is deposited. To anesthetize the adjacent finger the needle is partly withdrawn and redirected to the other metacarpal head. Bending the needle to 30° allows easier access to the proper position without the syringe getting in the way.

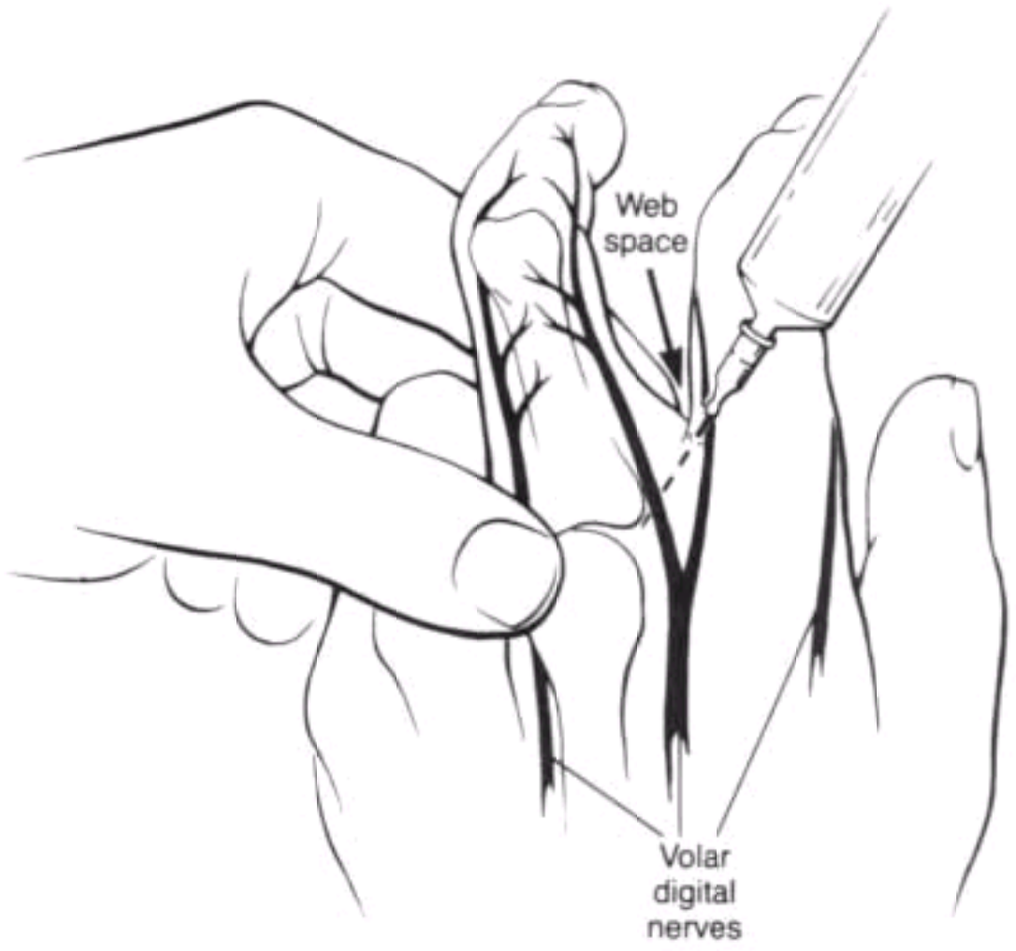
Figure 32-16 Nerve block of the third digit. After injection of anesthetic into the web space skin, the needle is advanced to the digital nerve, where it passes just lateral to the volar metacarpal head. Anesthetic is injected, and the needle is advanced to the opposite digital nerve. This procedure requires about 3 to 5 mL of anesthetic. If the index finger also must be blocked, the needle is redirected without withdrawal from the skin. Thus, both fingers are blocked with a single needle puncture.



M

Figure 32-17 Transthecal block. The flexor tendon sheath is entered volarly just proximal to the metacarpophalangeal joint. With the use of a 25-ga needle on a 3-mL syringe the fluid should flow easily. Inject 2 mL of anesthetic and apply proximal tendon sheath pressure.

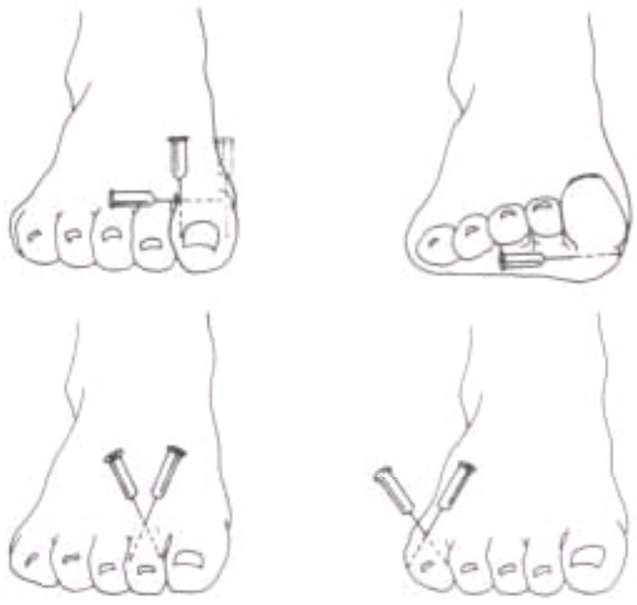

Figure 33-1 Preparation for induction of anesthesia in a patient with a fracture of the right radius. Note precautionary IV line and deflated tourniquet in place. The procedure has been explained, and preoperative sedation or analgesia has been given if required. *(From Roberts JR: Intravenous regional anesthesia. JACEP 6:263, 1977.)*

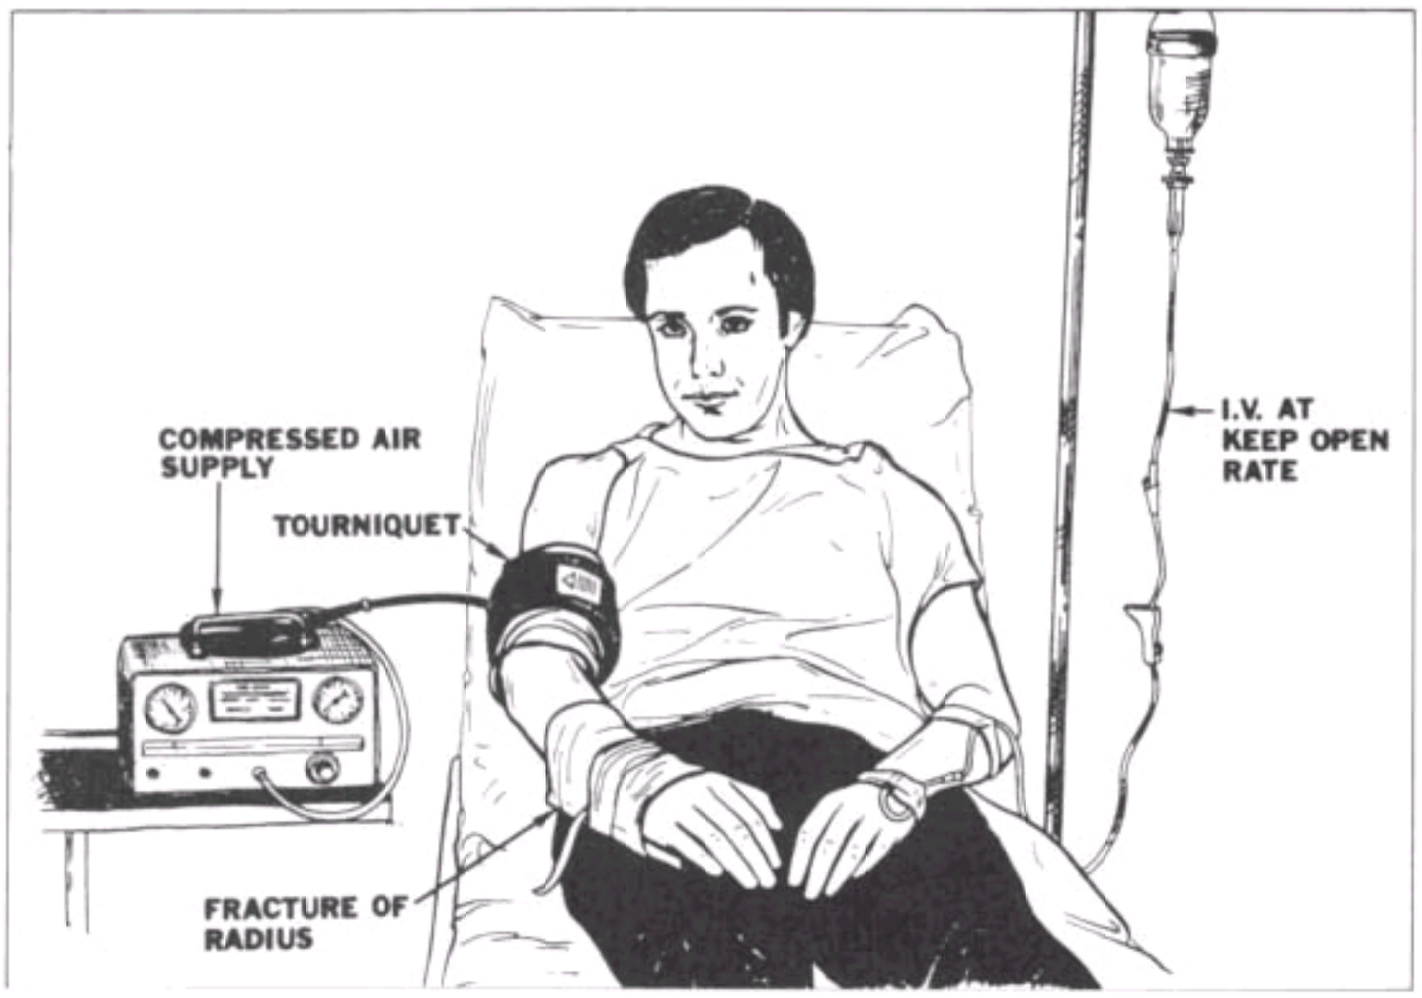

Figure 33-2 Double-cuff apparatus with two-way valves allows longer tourniquet time without pain. A standard blood pressure cuff should never be used. *(From Roberts JR: Intravenous regional anesthesia. JACEP 6:263, 1977.)*

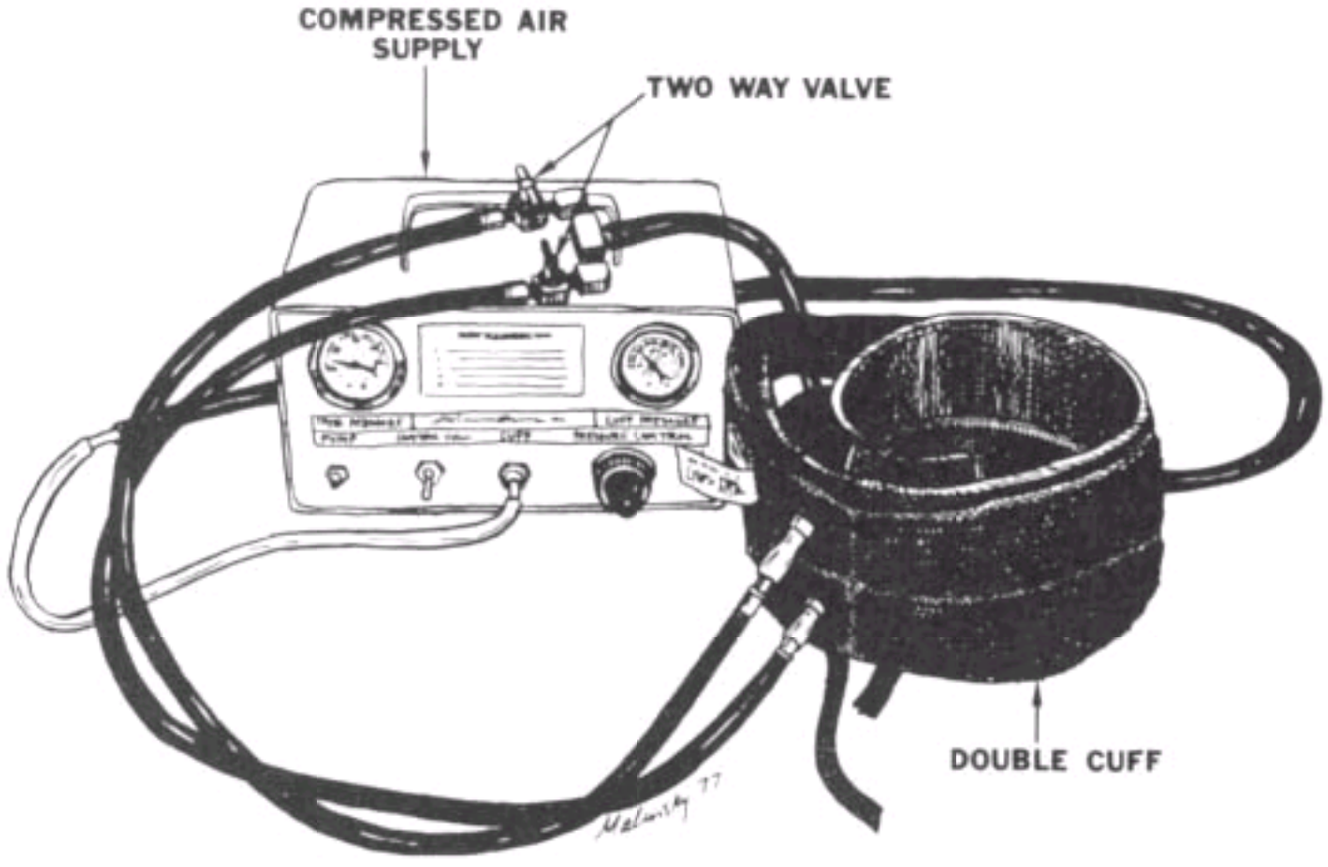

Figure 33-3 Infusion cannula securely taped in the dorsum of hand. A butterfly needle is shown here, but a plastic catheter with the hub attached may also be used. *(From Roberts JR: Intravenous regional anesthesia. JACEP 6:263, 1977.)*

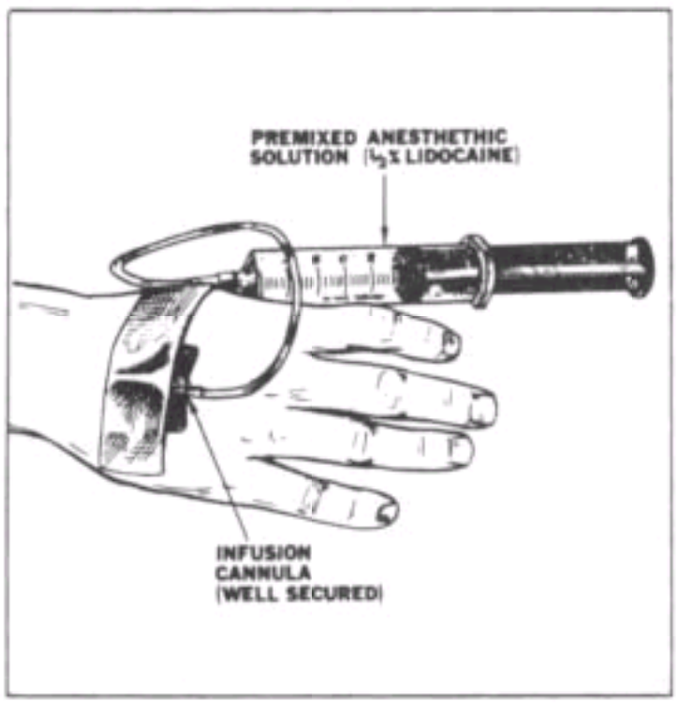

Figure 33-4 Exsanguination by elevation and elastic bandage. The tourniquet has yet to be inflated at this point. Care must be taken not to dislodge the infusion cannula. *(From Roberts JR: Intravenous regional anesthesia. JACEP 6:263, 1977.)*

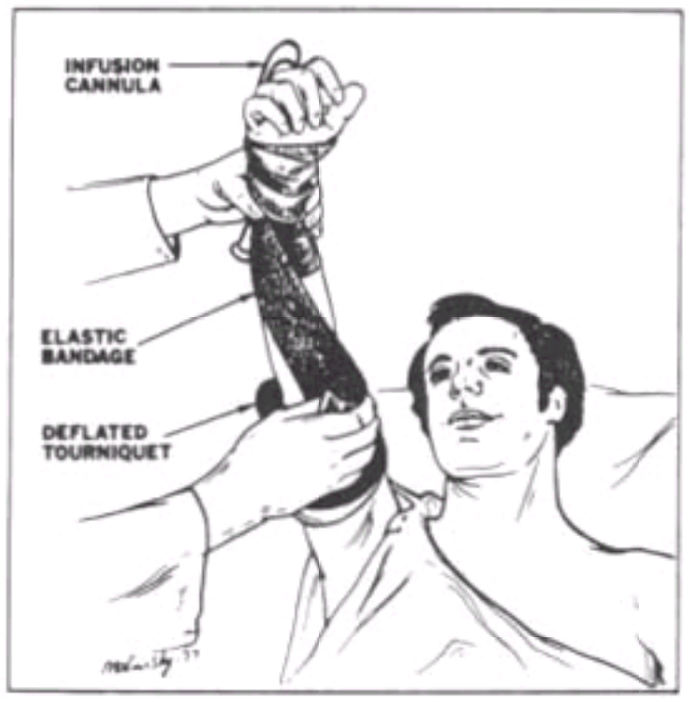

Figure 33-5 A cast is applied under anesthesia. Because the tourniquet is portable, postreduction radiographs may be obtained without losing anesthesia. *(From Roberts JR: Intravenous regional anesthesia. JACEP 6:263, 1977.)*

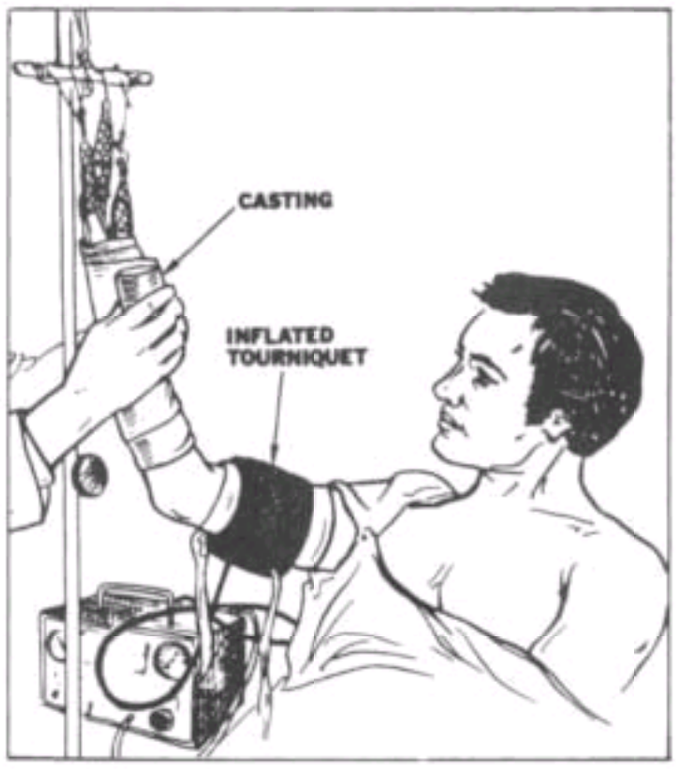

Figure 34-1 A child undergoing repair of a laceration while dissociated with ketamine. The blank stare is typical.

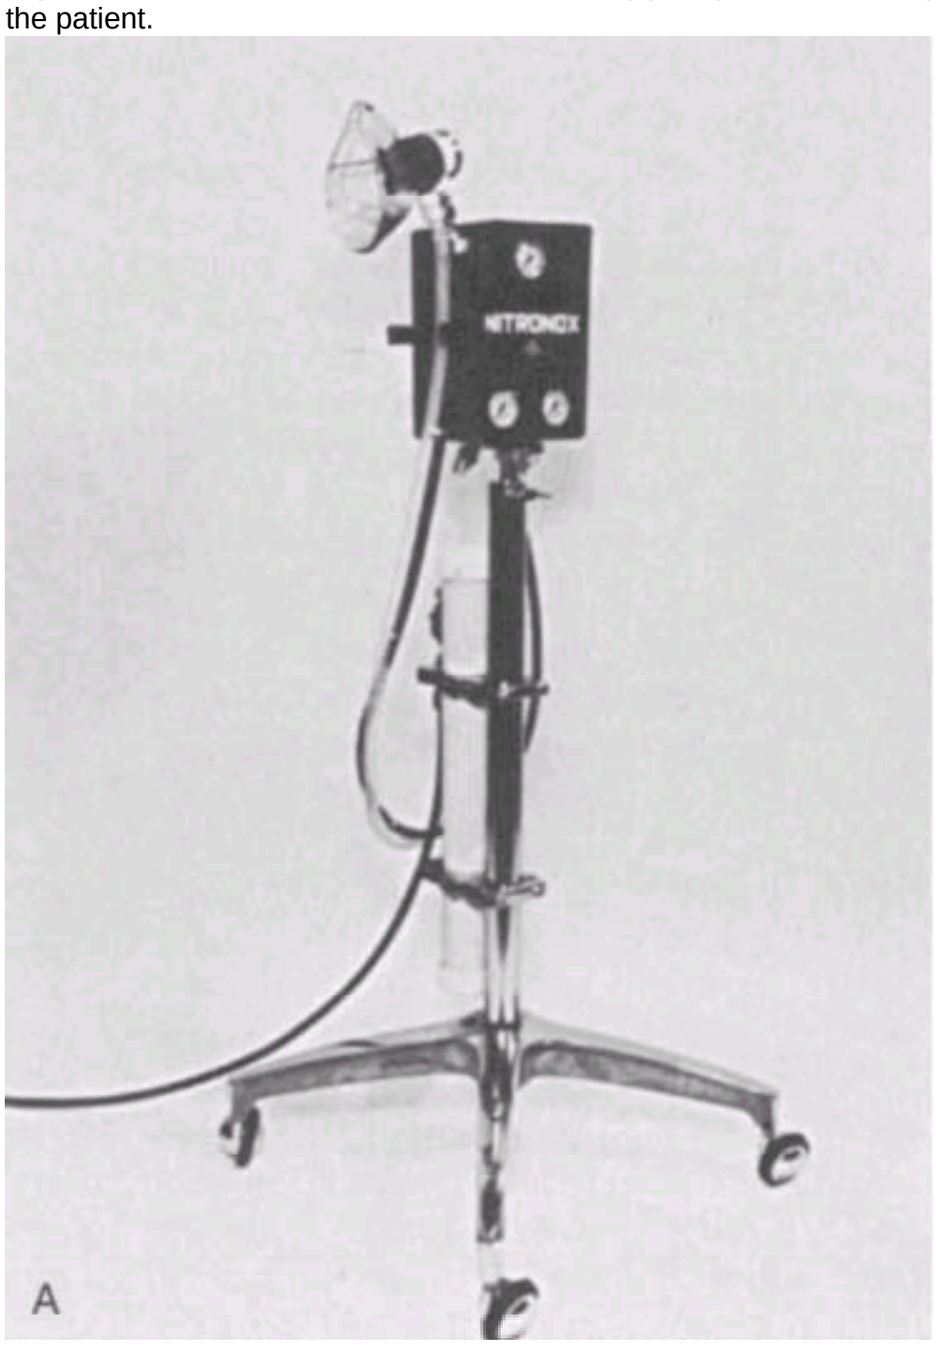
Figure 34-2 *A*, A demand-flow nitrous oxide/oxygen system. *B*, Example of a face mask for a nitrous oxide system. The mask must be held in contact with the face by the patient.



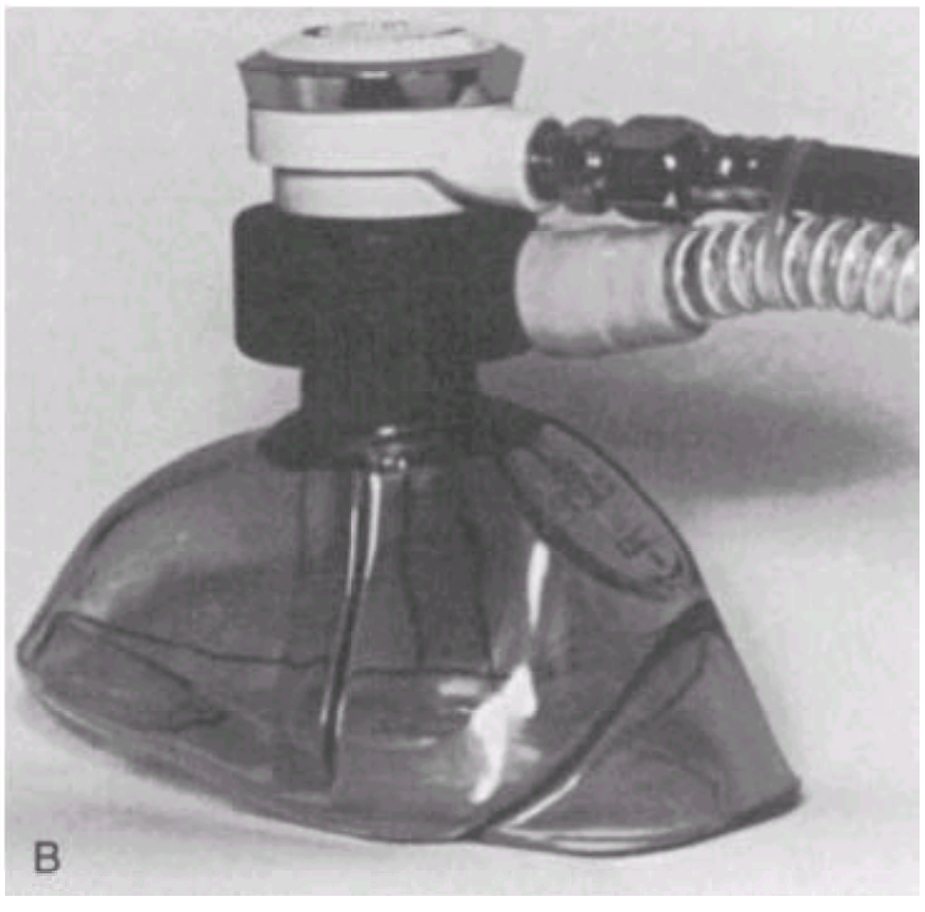


Figure 34-4 The downward spiral of fatal cocaine-induced delirium starts long before the chronic cocaine user is brought to the hospital, but physical restraints applied by police, security guards, and medical personnel only aggravate the situation. When it takes leather restraints and a bevy of personnel to subdue a delirious, violent, and totally out-of-control patient, it's time for aggressive and effective parenteral sedation and evaluation for and rapid correction of hyperthermia and acidosis. In the scenario shown here, it is impossible to even begin to adequately evaluate or treat this patient. The sagacious clinician knows, however, that this individual is an acute medical emergency.

Figure 34-5 The postulated downward spiral of agitated delirium in a cocaine-intoxicated patient. An adverse outcome may theoretically be ameliorated with the aggressive use of chemical restraint.

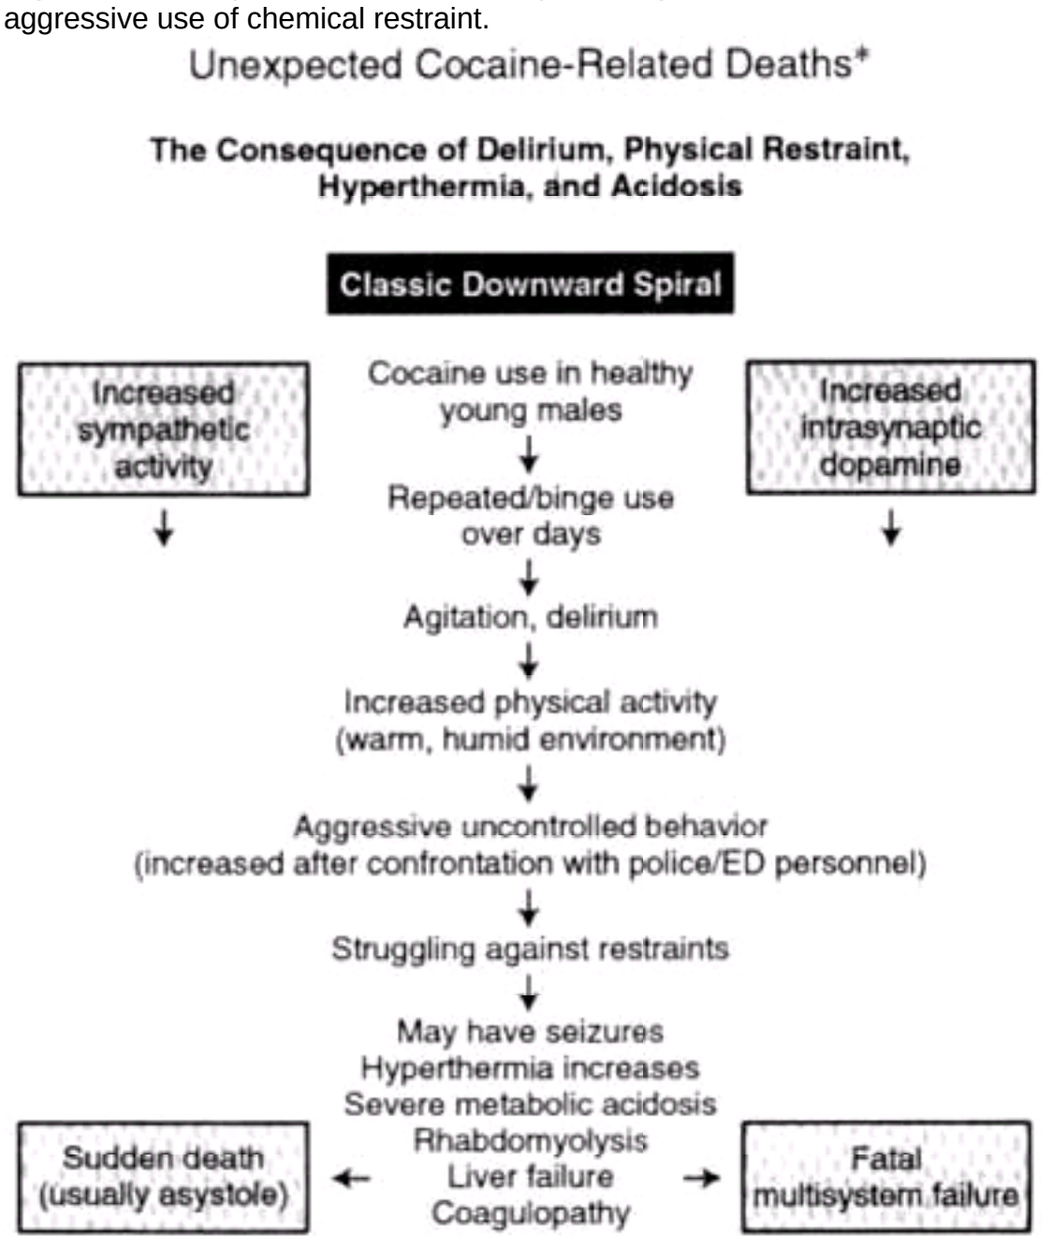

Figure 34-6 When an indwelling venous catheter cannot be obtained in the violent patient, the clinician may mainline the appropriate medications. By enlisting the help of security personnel, the arm or foot is immobilized by brute force, and medication is given by bolus injection into a large anticubital (*A*) or saphenous vein (*B*). Alternatively, two security guards lie across the upper thighs and lower stomach, and the clinician injects directly into the femoral vein (being careful to avoid an intra-arterial injection).

Figure 35-1 Graphic representation of the various phases of wound healing. Note that the tensile strength of scar tissue never reaches that of unwounded skin. Displayed values of tensile strength are approximate and demonstrate the general concept of wound healing.

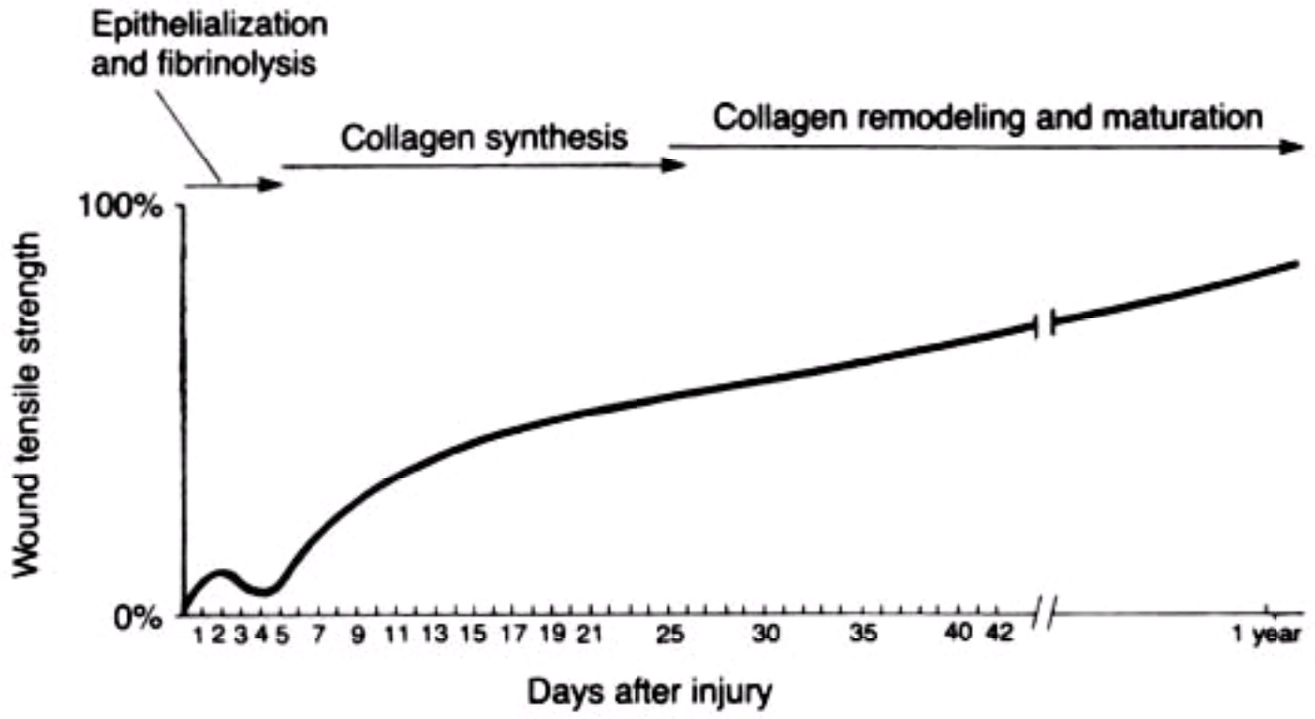

Figure 35-2 This laceration illustrates that there is no specific time frame (the so-called golden period) during which a laceration must be closed, or else relegated to an unsightly scar or a revision months later. *A*, This woman was punched in the face, suffered a laceration of the cheek, and presented to the ED 36 hours later. The wound was not infected, had contracted, and was beginning to heal by granulation. Under local anesthesia the wound was opened, irrigated, minimally debrided, and the skin edges were trimmed. *B*, Using a No. 15 blade, a 1-mm skin edge was incised. *C*, The trimmed edges were then cut by scissors. *D*, The wound was undermined to relieve tension on the skin. *E*, The wound was closed with 6-0 interrupted sutures that were removed in 5 days. No antibiotics were used and only a small linear scar resulted.

Figure 35-3 What's wrong with this picture? The patient is sitting up during laceration repair. Shortly after this picture was taken the patient fainted and nearly fell off the chair. Even the bravest patients should be *supine* for surgical procedures.

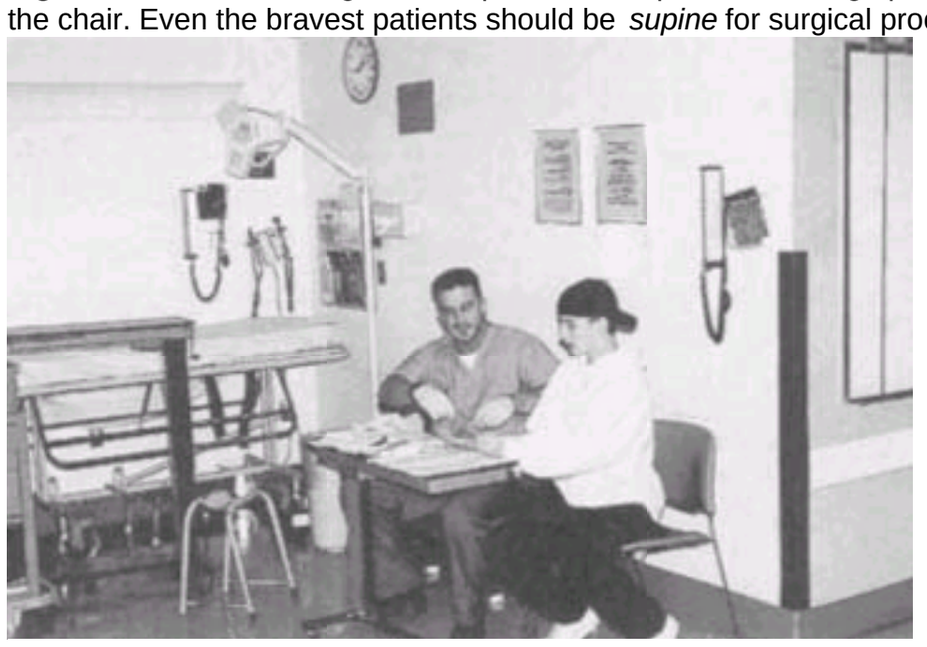

Figure 35-4 An easy method of high-pressure irrigation. IV tubing with an in-line, one-way valve is attached to a bottle of sterile 0.9% saline solution. The other end is connected to a stopcock. Saline solution is aspirated into the syringe. Maximal force is exerted on the plunger of the syringe, delivering the solution in a fine stream through an attached 19-ga needle held close to the wound. A splash shield may be used instead of a needle (see Fig. 35-6).

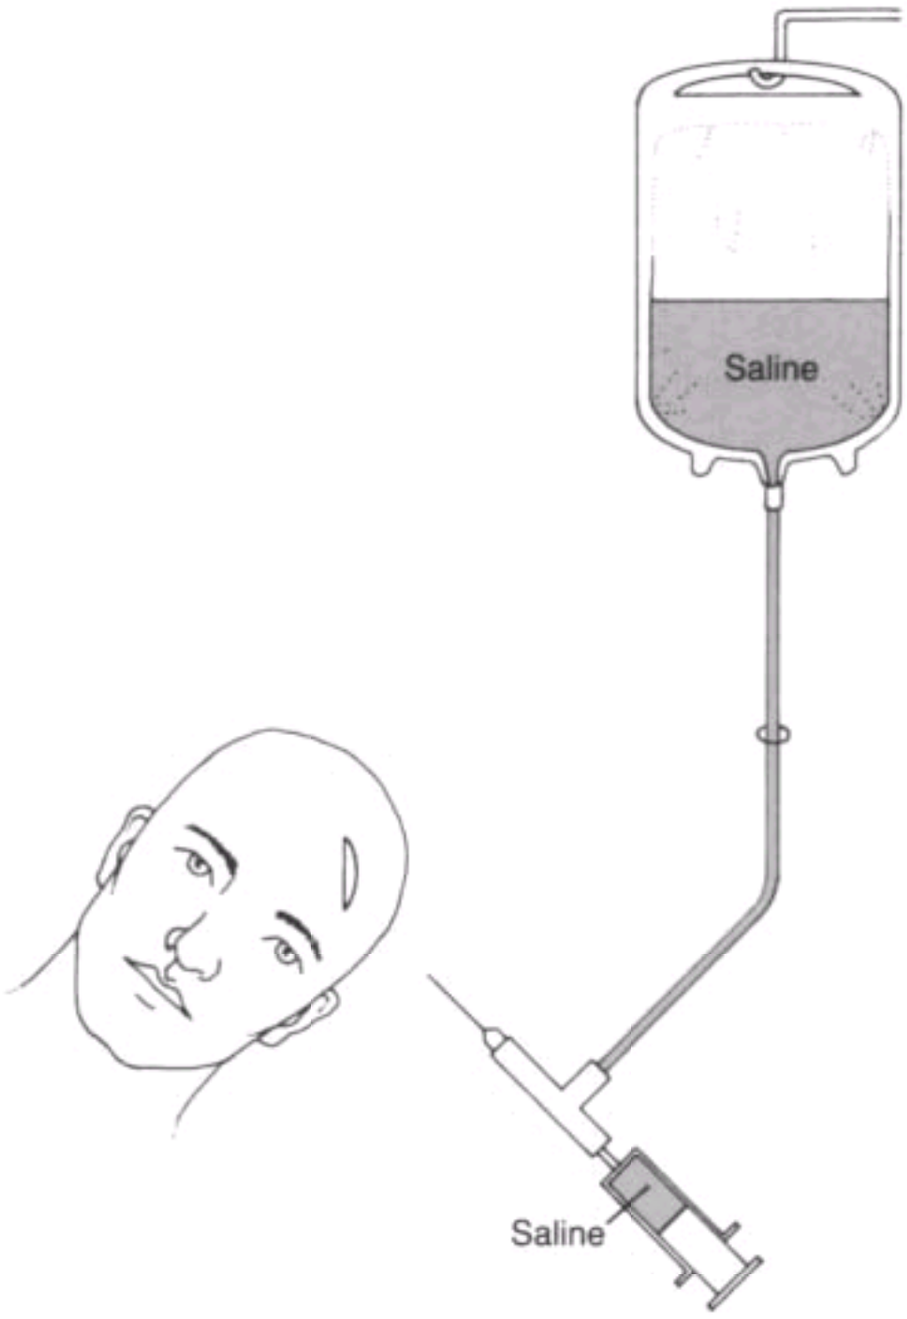

Figure 35-5 A spring-loaded irrigation device with ring handles speeds the somewhat tedious process of wound irrigation. *(Courtesy of Canyons International, Inc., Salt Lake City, UT.)*

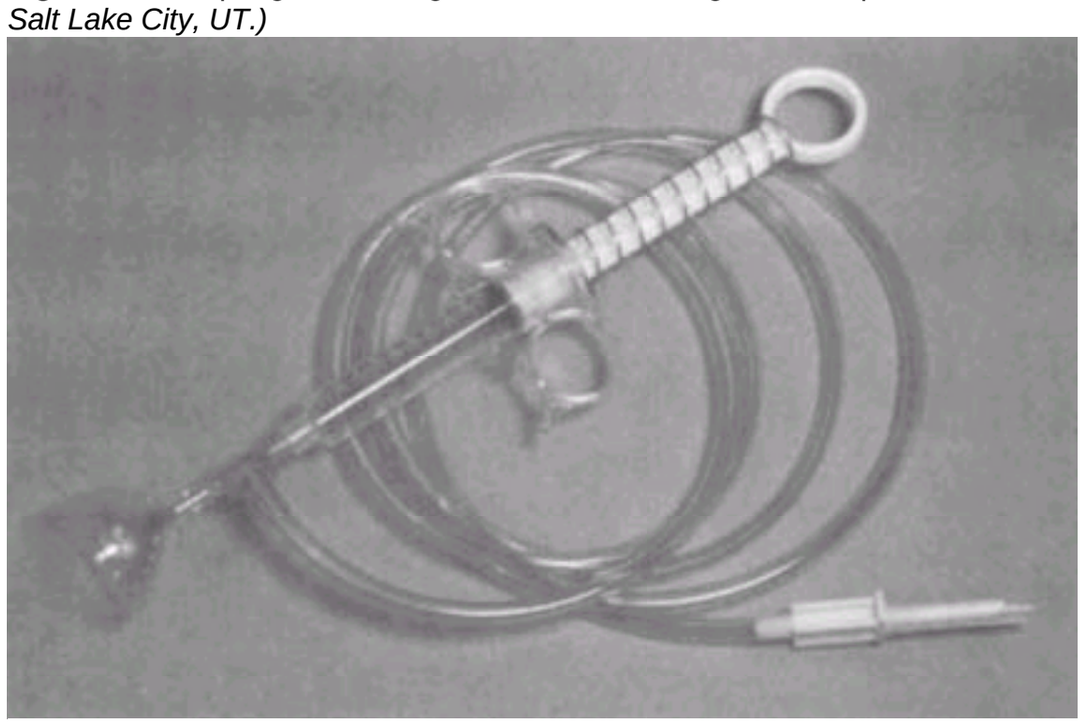

Figure 35-6 *A*, ZeroWet Splashield attached to end of a syringe. This device is used in lieu of a needle. The shield is held near the skin, and the tip of the syringe directs the irrigating solution. *B*, This protective shield allows forceful irrigation without splatter of infectious fluids. *Note that the clinician is holding open the laceration with forceps to allow irrigation of the deep structures. The margins of this small laceration were also extended to allow for better irrigation.*

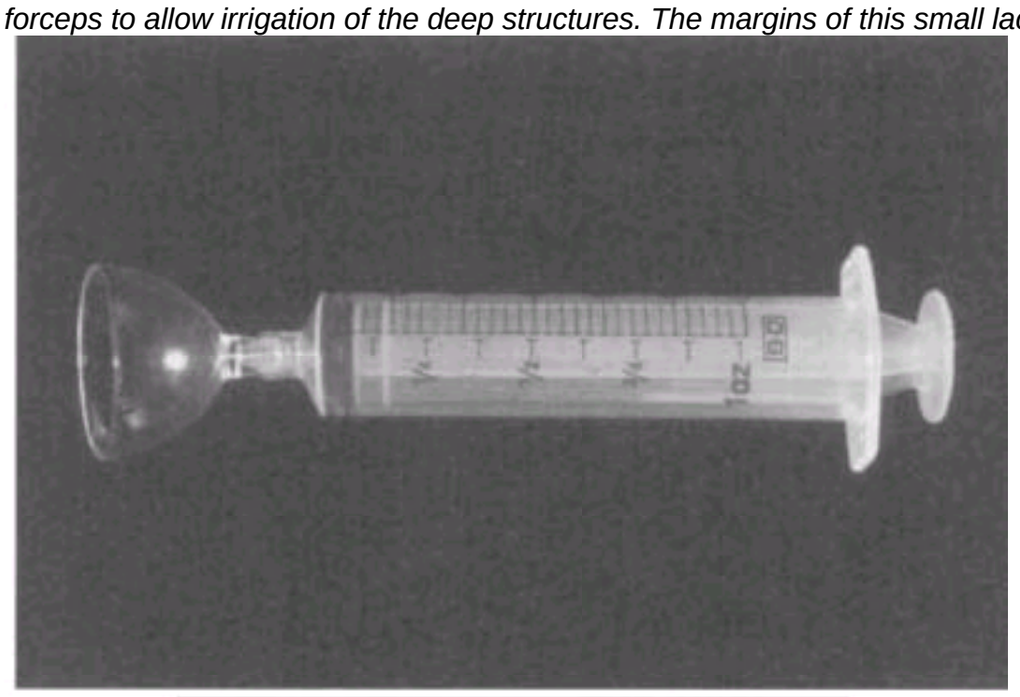
A



B

Figure 35-7 A sterile glove on the hand with the finger cut out, instead of an annoying drape, and a finger tourniquet to provide a bloodless field make examination and suturing of a wound easier.

Figure 35-8 *Do not* probe a wound with a finger looking for foreign bodies! If the clinician's skin is broken, the patient's blood may introduce HIV, hepatitis, viruses, and other infectious agents. Betters ways to find a foreign body are obtaining radiographs and exploring wounds with metal probes. Extending the wound edges and performing the examination under a bloodless field and with good lighting will find most foreign bodies.

Figure 35-9 *A–C,* Complete excision of a wound. Grossly contaminated wounds may be excised and sutured primarily.

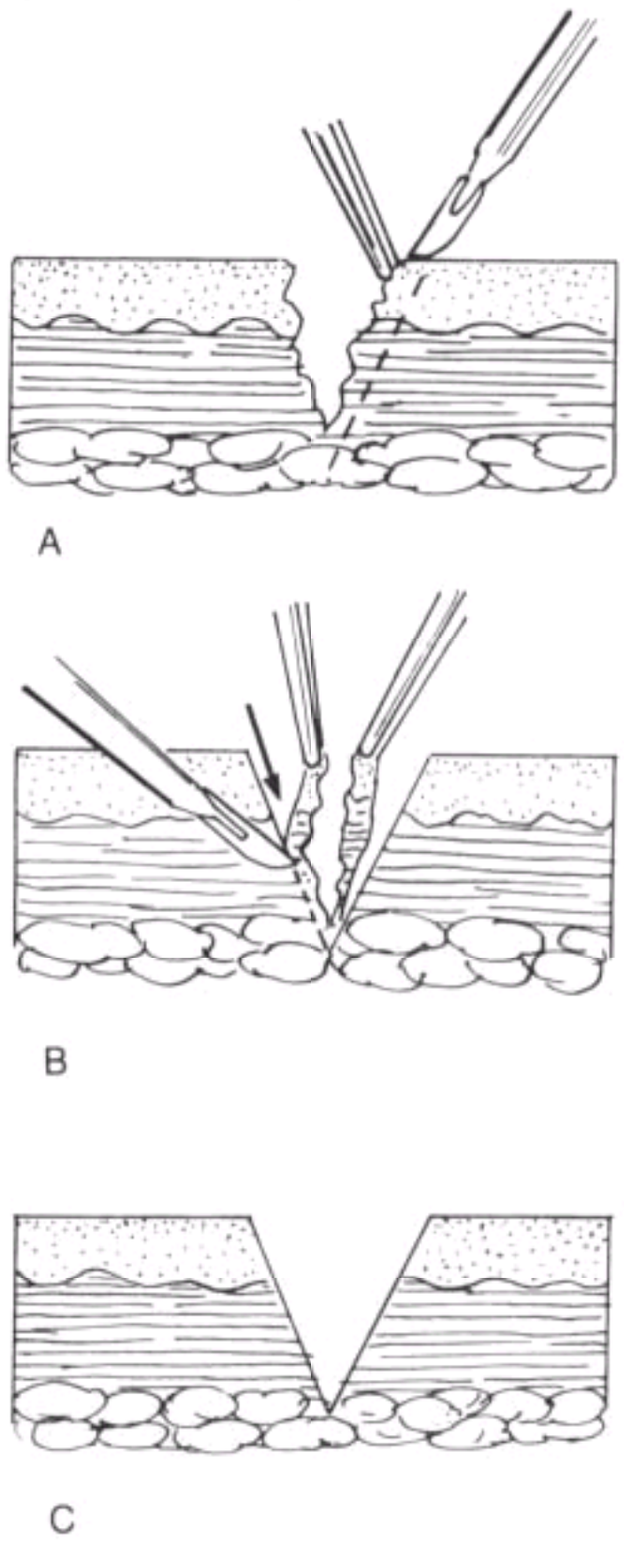


Figure 35-10 Excision through an eyebrow. Use an angled incision to remove tissue in the eyebrow, thus avoiding further injury of hair follicles. *(From Dushoff IM: A stitch in time. Emerg Med 5:2, 1973. Reproduced by permission.)*

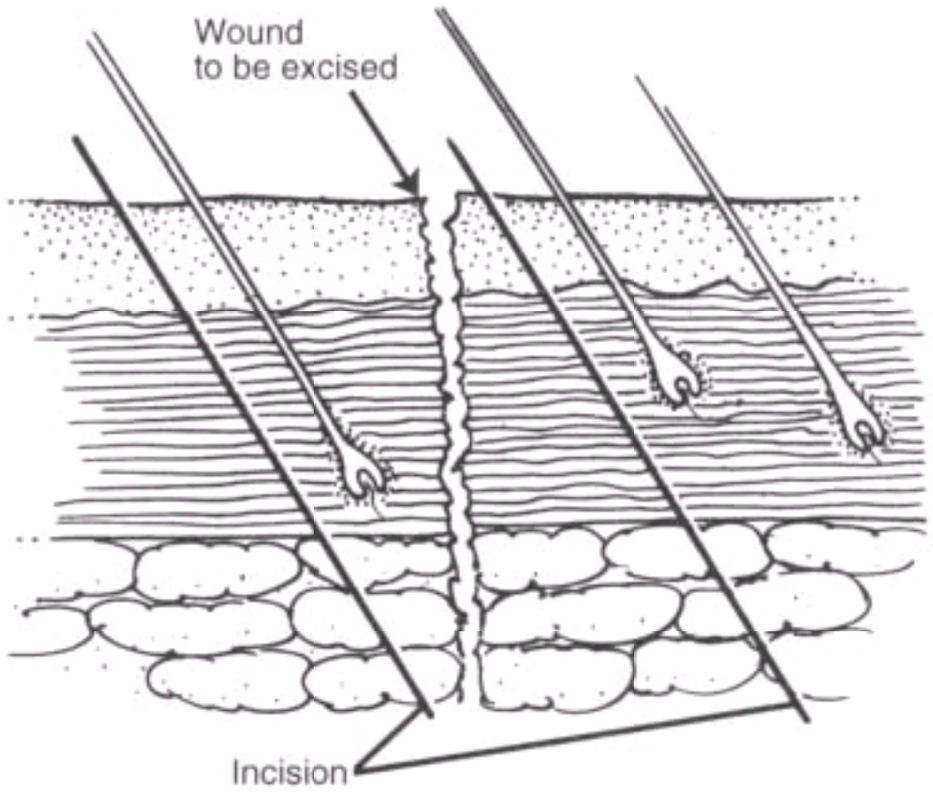

Figure 35-11 When one attempts to tie off a bleeding vessel, the tip of the hemostat should project beyond the clamped vessel.

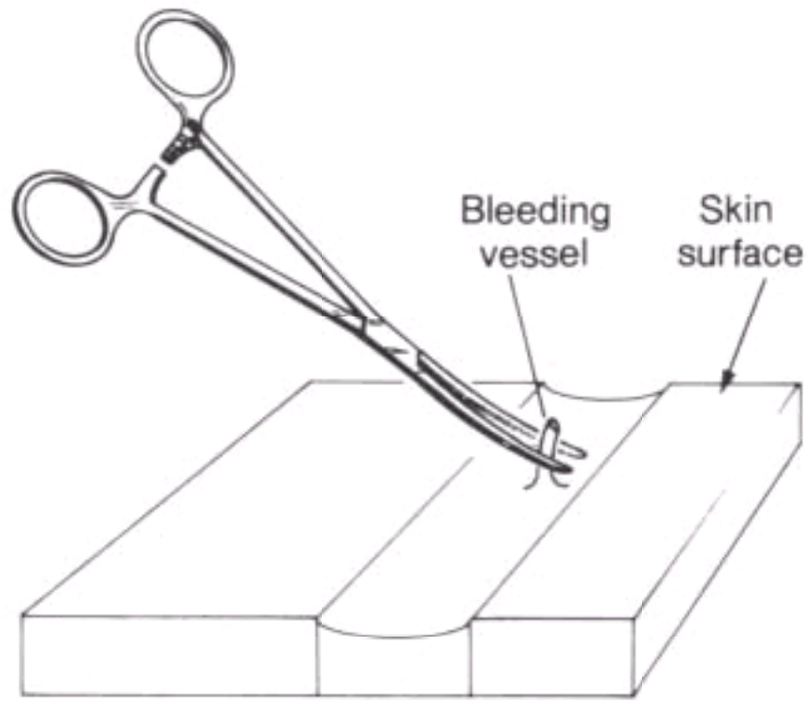

Figure 35-12 *A,* The handles of the hemostat are raised by an assistant as a ligature is passed under them. *B,* The ligature thread stretched between the index fingertips is carried under the projecting tips of the hemostat. *(Modified from Kirk RM: Basic Surgical Techniques. Edinburgh, Churchill Livingstone, 1978, p 50. Reproduced by permission.)*

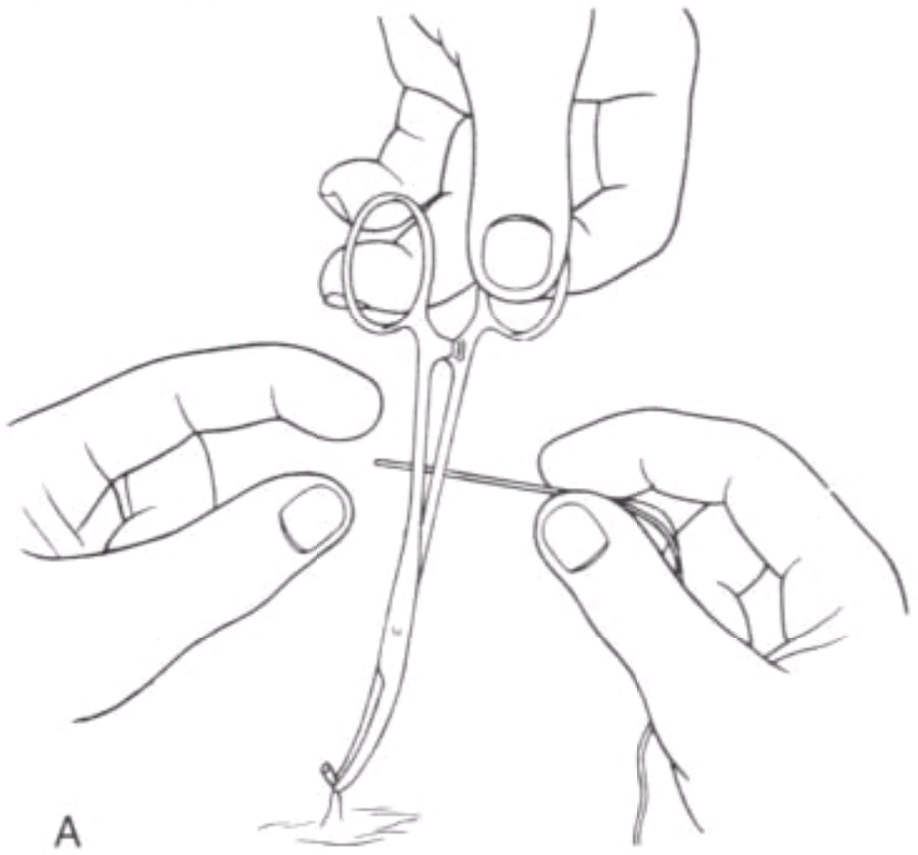

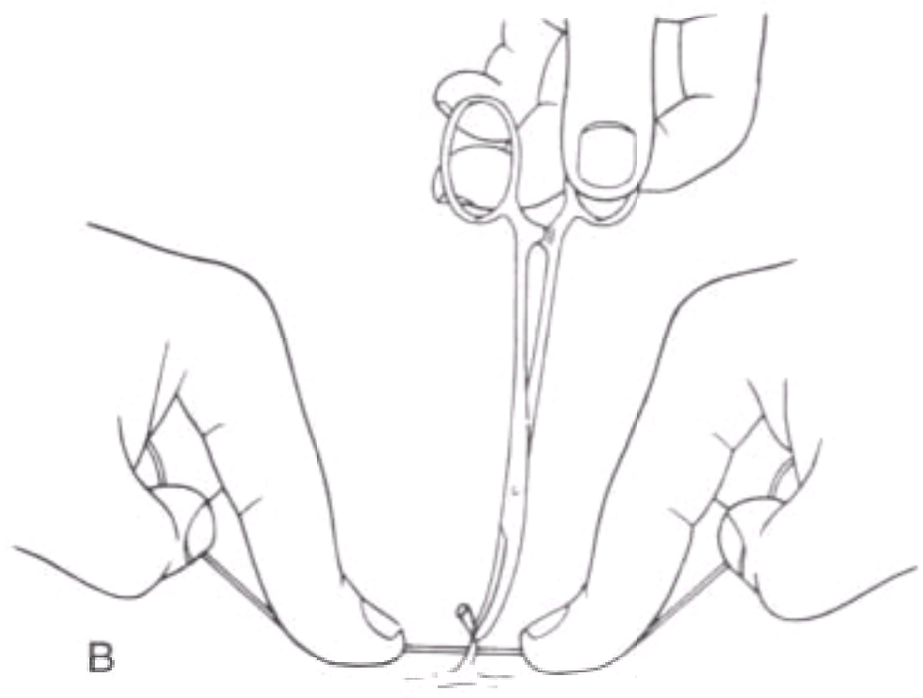

Figure 35-13 *A,* Ligature tension is maintained with one hand by grasping one tail of the suture with a clamp and keeping its base between the thumb and the forefinger. *B,* As the pedicle clamp is removed with the other hand, the ligature is tightened by extending the flexed thumb and index finger to the desired tension. Then the pedicle clamp is discarded from the right hand, and further knots are applied in the usual fashion. *(Modified from MacDonald RT: Maintenance of ligature tension by a single operator with simultaneous removal of a hemostatic clamp. Am J Surg 143:770, 1982. Reproduced by permission.)*

Figure 35-21 A common three-layer dressing, consisting of antibiotic ointment, Adaptic, and gauze.

Figure 35-22 Snugness of the bandage is increased by 180° rotation of the bandage roll after each circular turn to create a reverse spiral. *(From Norton LW: Trauma. In Hill GJ II: Outpatient Surgery. Philadelphia, WB Saunders, 1980. Reproduced by permission.)*

Figure 35-23 Finger dressing. *A,* The inner layer is nonadherent gauze or whatever is required for soft tissue care. The middle layer is 2 × 2 in. gauze sponges wrapped circumferentially and held in place with a small strip of tape. *B,* Begin No. 2 tube gauze at the base of the finger. It is useful to hold this end with one finger while the tube gauze applicator is pulled toward the fingertip. A twisting motion firms the wrap about the digit; generally about 90° is necessary. Excessive stretch or twisting can compromise circulation. *C,* When the fingertip is reached, make a 360° twist. *D,* Pass the applicator toward the finger base with an additional 90° twist. Repeat once more; thus, three layers are in place. *E,* Cut enough gauze to reach the base of the finger, and tape it there. As an alternative, pull the final layer beyond the tip, leaving it long enough to reach to and around the wrist (about three times the finger length). Split this gauze into two strands; bring them dorsally to the wrist, knot, and loosely wrap around the wrist. *(Redrawn from Kaplan EN, Hentz VR: Emergency Management of Skin and Soft Tissue Wounds: An Illustrated Guide. Boston, Little, Brown, 1984, p 86. Reproduced by permission.)*

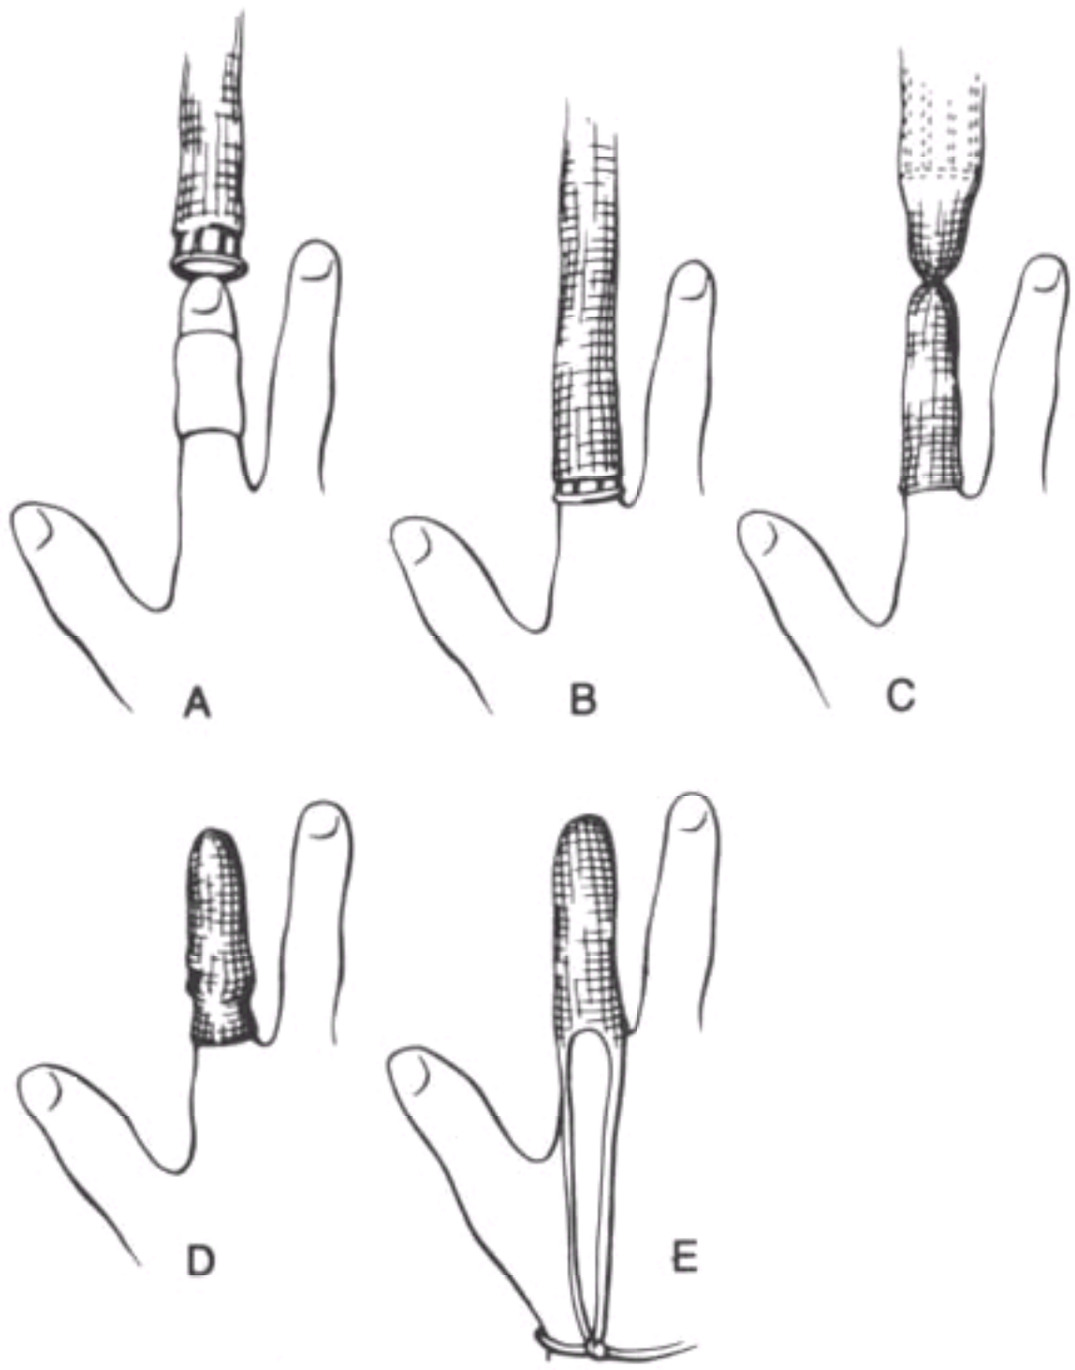

Figure 35-24 *A,* When a Kling or Kerlix wrap must be applied to an area such as the forearm, start by putting a strip of tape on opposite sides of the arm, leaving the ends free. *B,* Wrap the bandage around the arm, covering the portions of the tape that are attached to the skin. *C,* After completing one layer of wrapping, tuck the free ends of the tape down so that the nonadhesive side faces the first layer of wrapping and the sticky side faces out. Place another layer of wrapping around the arm. *D,* After completing a second layer of wrapping, the dressing will not slip because it is adhered to itself as well as to the skin. *(From Lazo J: Non-slip dressing technique. Res Staff Physician 22:103, 1976. Reproduced by permission.)*

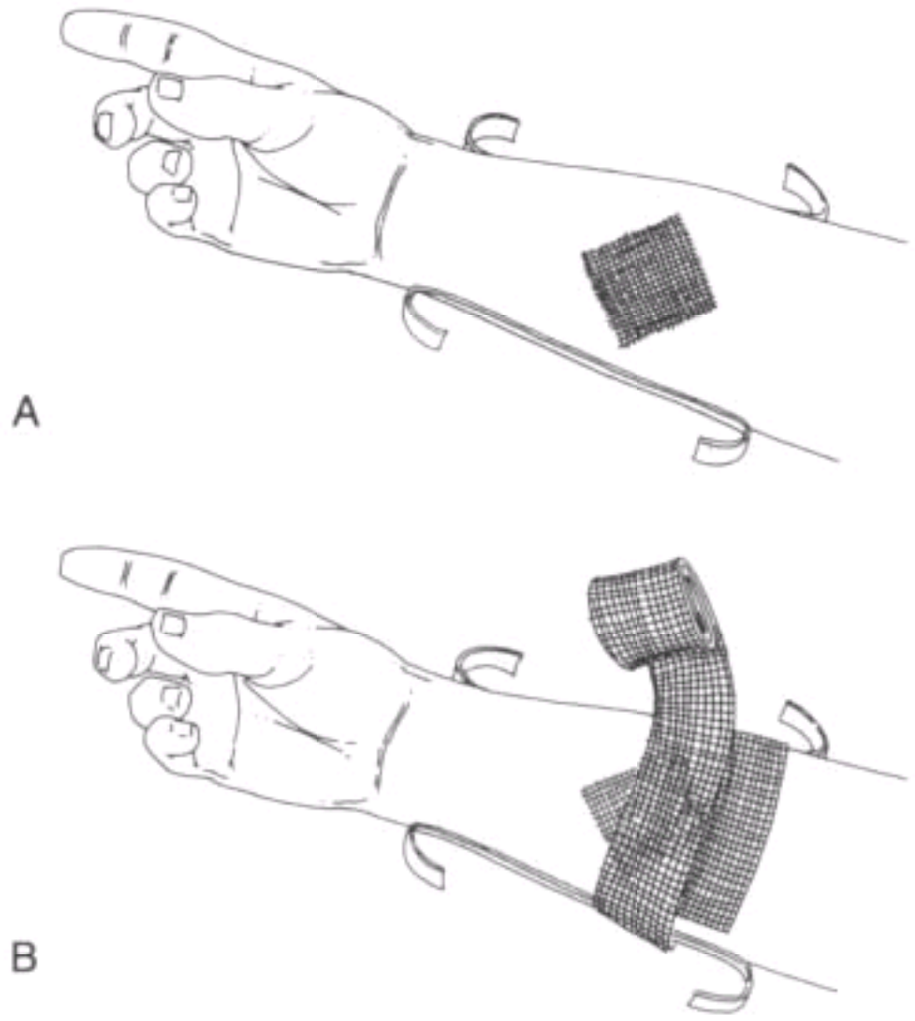

Figure 35-25 *A–E,* Technique for bandaging the head. A strip of bandage (the "tie strip") 3 inches wide and 3 feet long is placed over the head in the frontal plane (*A)*. While the patient maintains downward tension on the first strip of bandage, the clinician places a full-length gauze bandage at the forehead level in a horizontal plane, winding the bandage around the head (*B)*. (The "Kling"-type bandage is preferred.) The main bandage is stabilized with several turns, passing near the patient's ear, then wrapped around one side of the tie in a full turn (*C)*. The main bandage is then taken across the front of the head, wrapped full-turn around the other side of the tie bandage (*D)*. The main bandage is wrapped around the head, from front to back, overlapping with each pass. The dressing is secured in place by tying the ends of the tie strip under the chin (*E)*. This dressing can be removed easily by untying the chin straps and gently pulling both ends of the tie strip upward (*F)*.

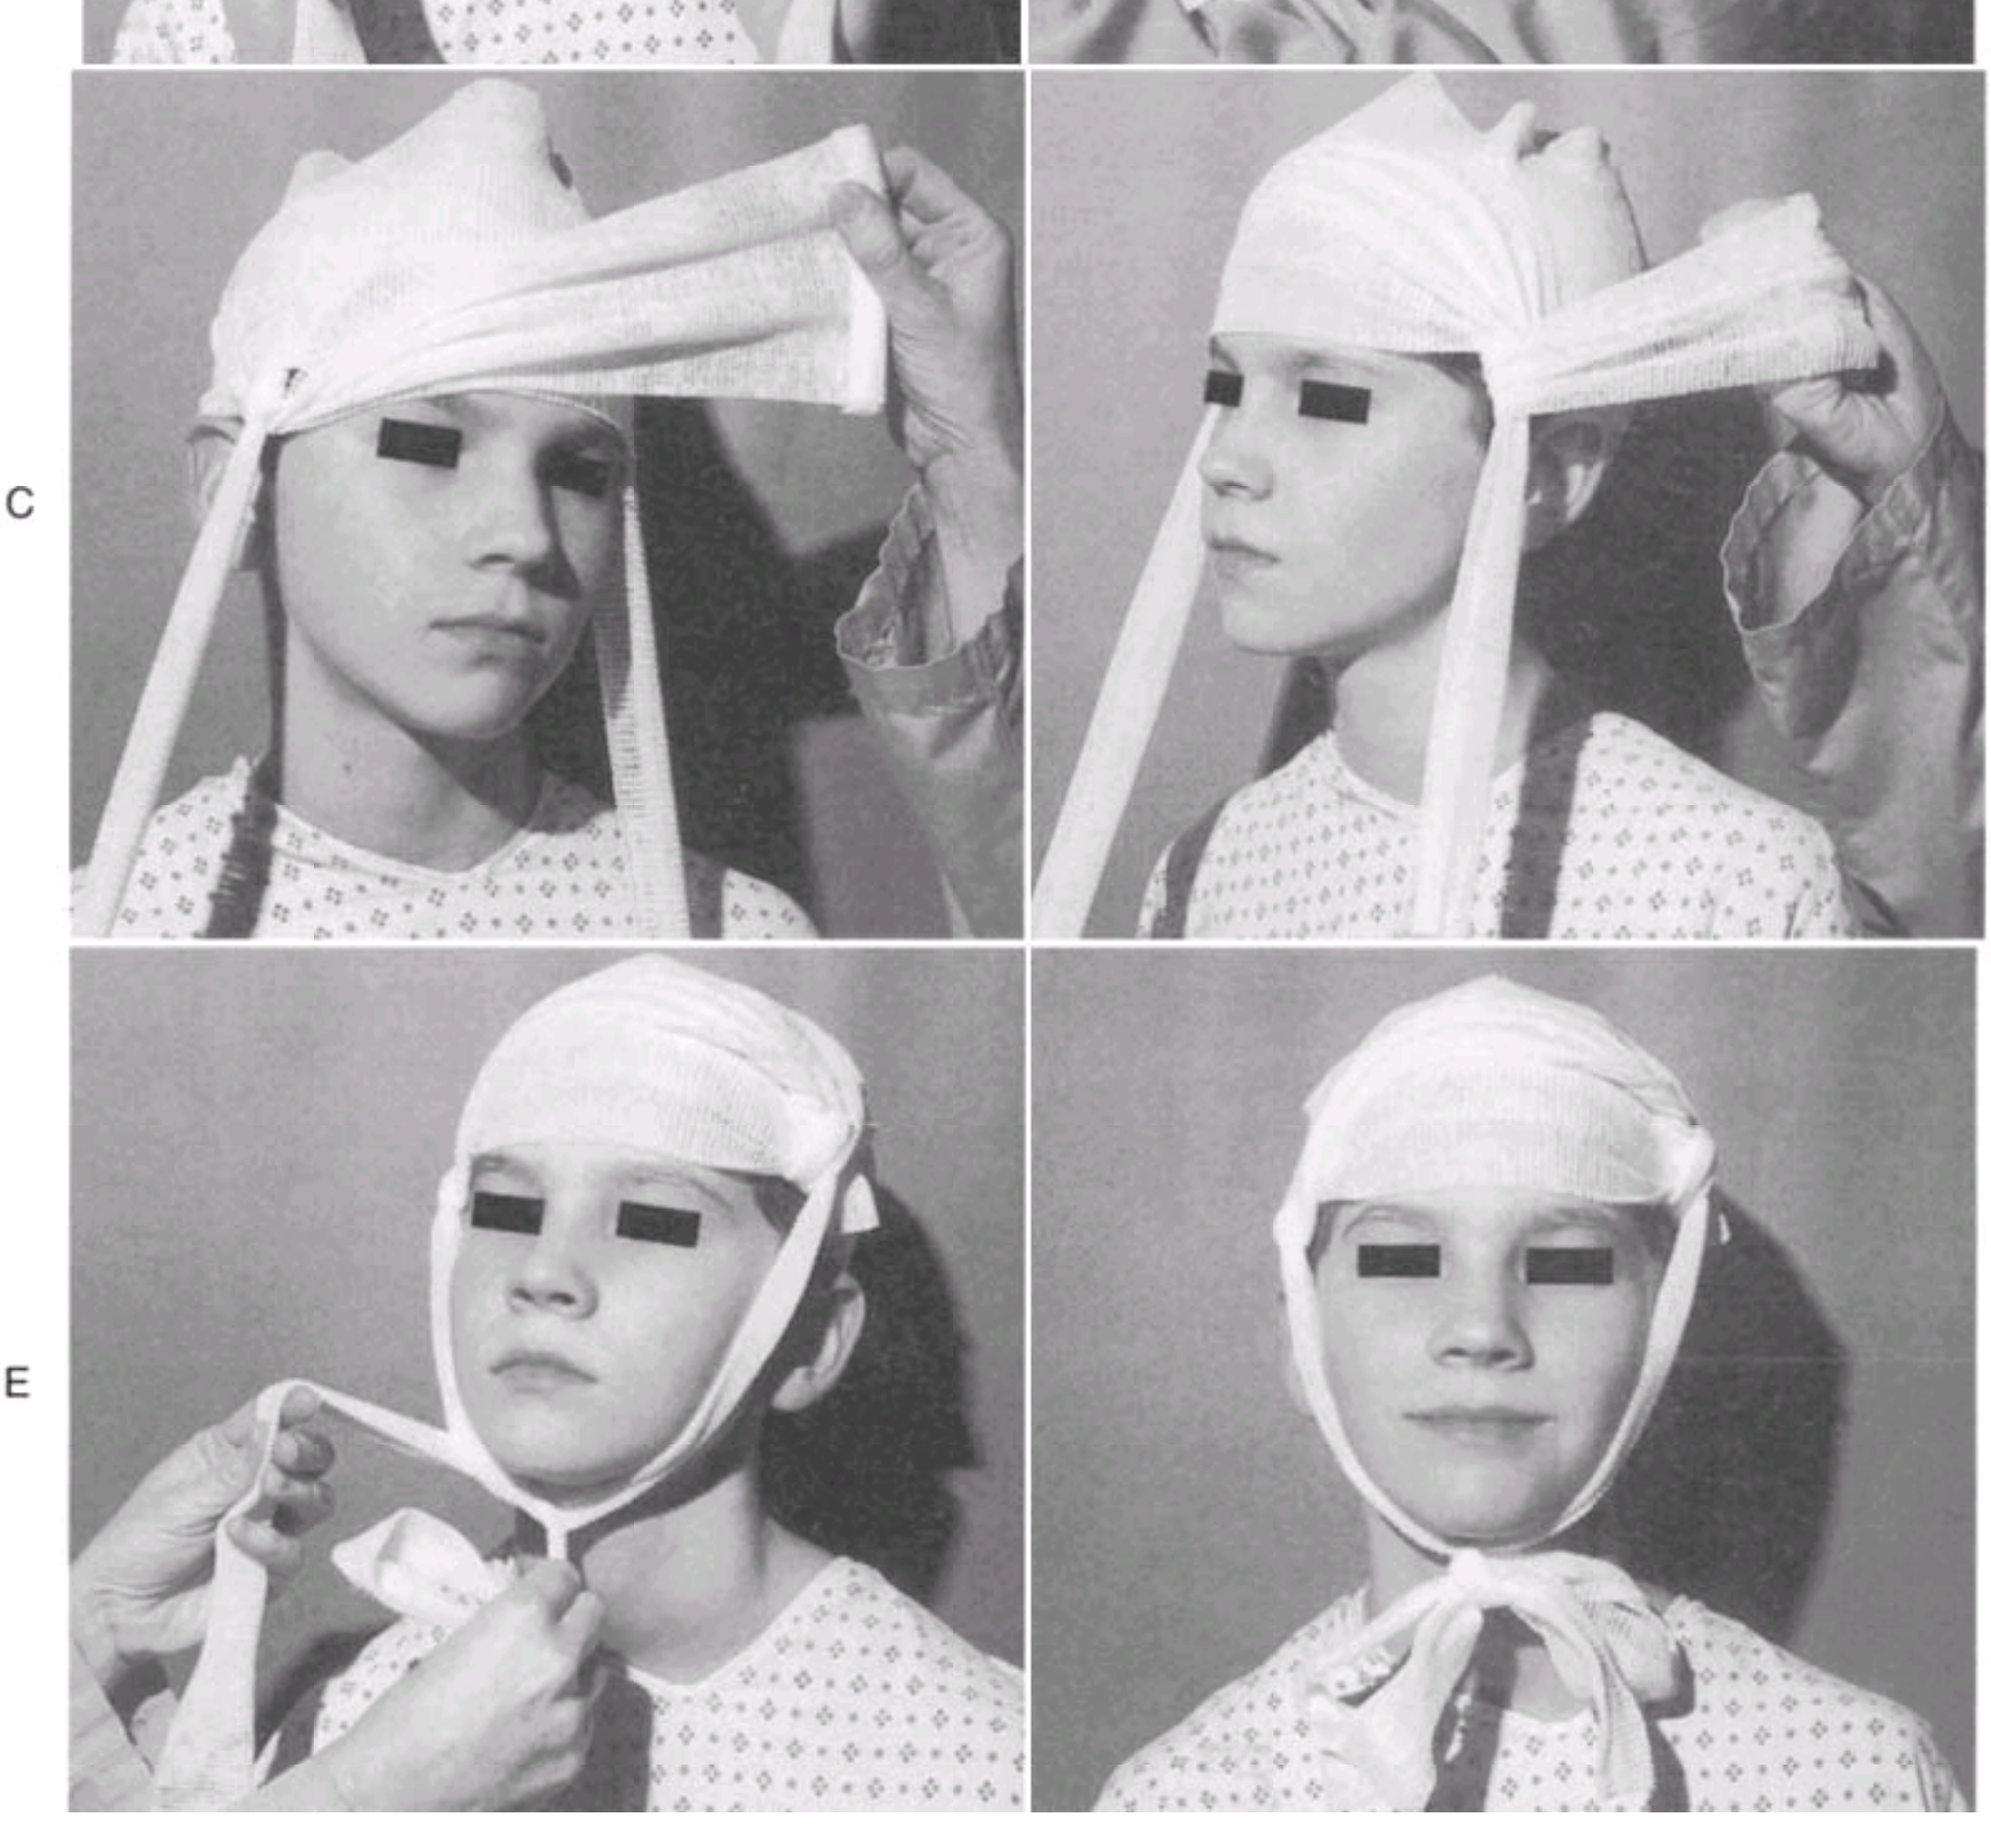

Figure 35-26 This patient used a neomycin-containing ointment on a minor wound, and developed redness, swelling, pruritis, and skin changes. The patient thought it was an infection but it was a contact dermatitis from the neomycin. Plain bacitracin ointment will not do this.

Figure 35-27 Tetanus immunization guidelines.

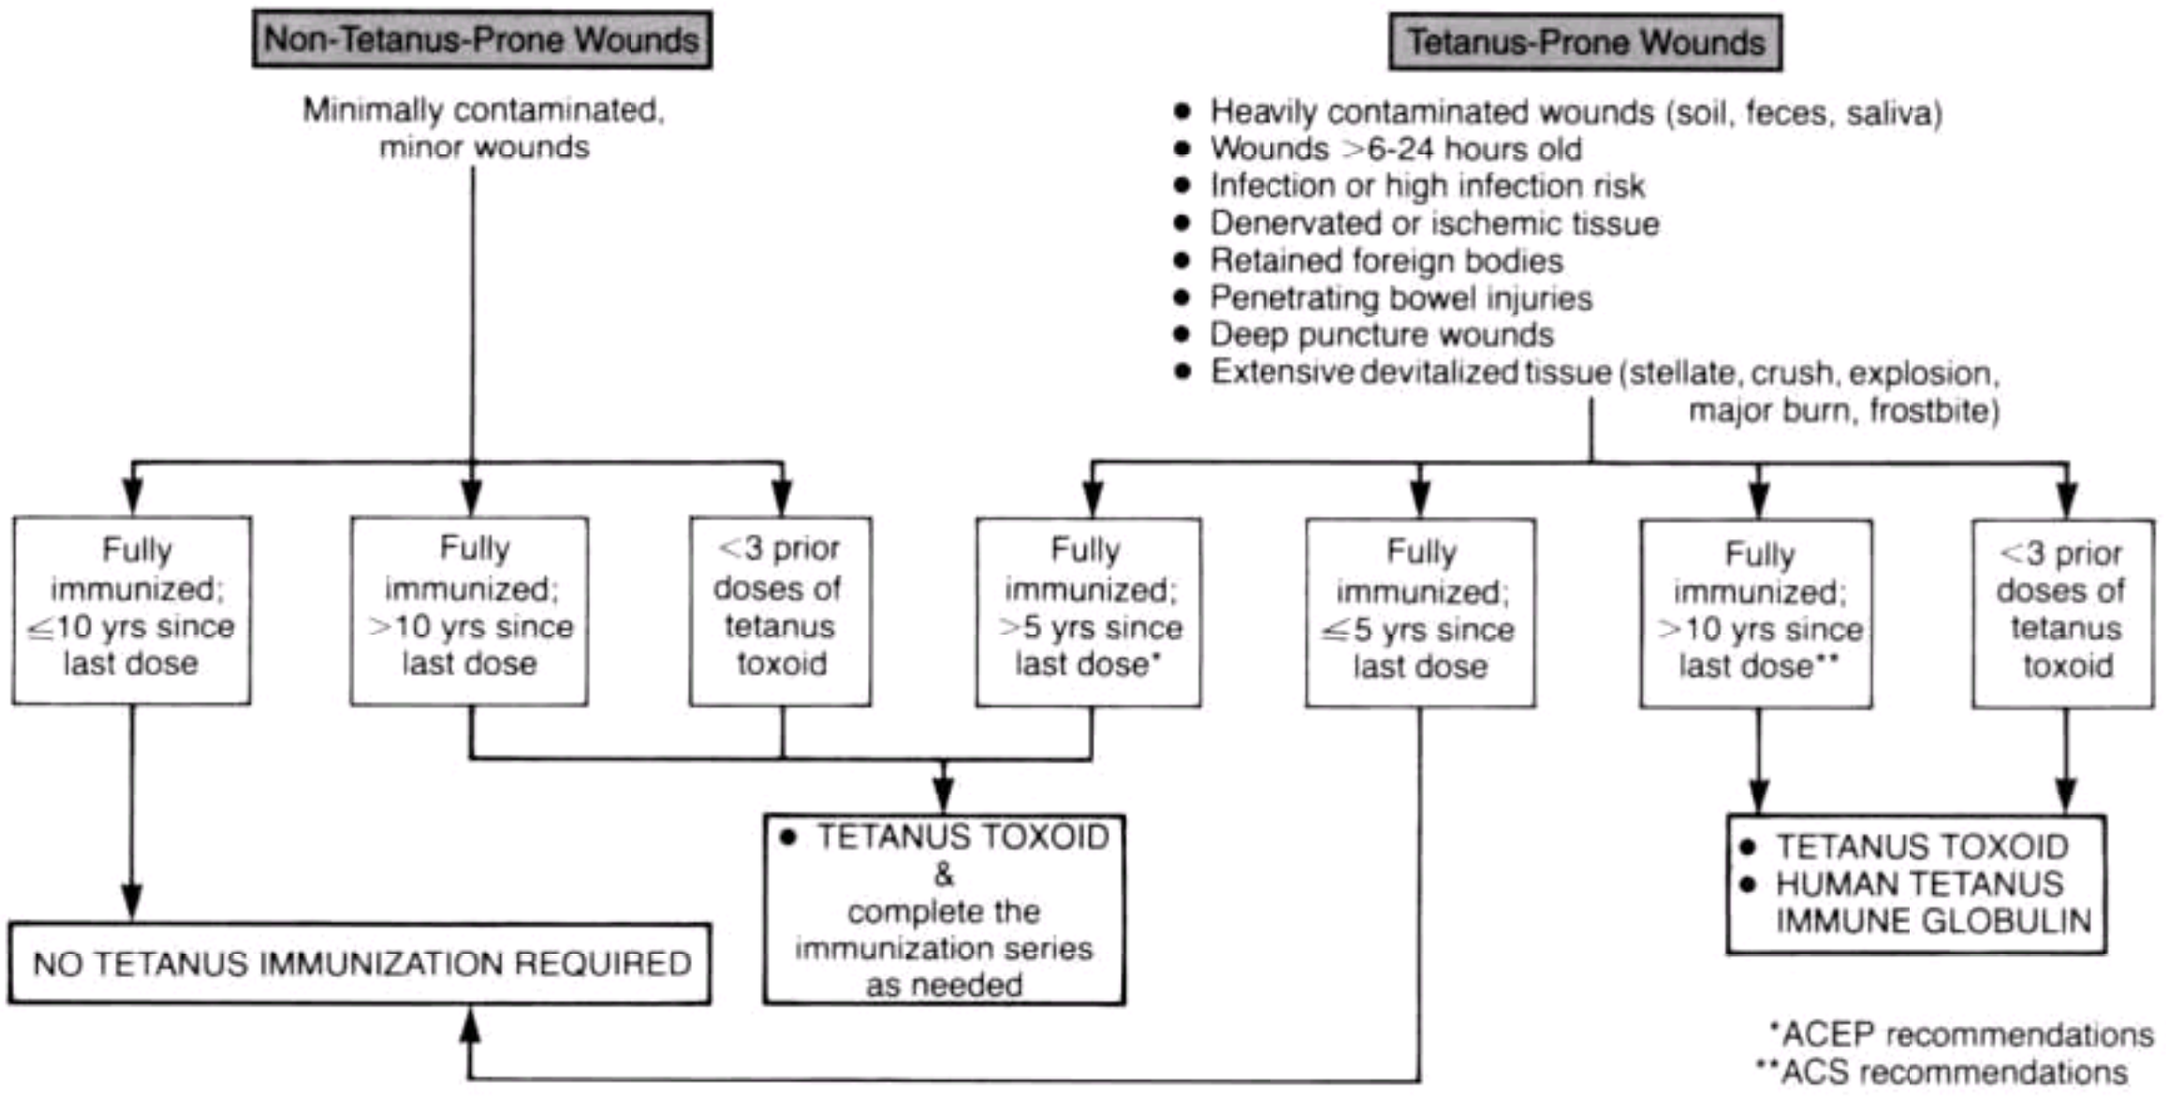

Figure 35-28 Technique for suture removal. Pull should be toward the wound line *(A)* rather than away from it *(B),* which causes the wound to tear apart. *(Modified from Stuzin J, Engrav LH, Buehler PK: Emergency treatment of facial lacerations. Postgrad Med 71:81, 1982.)*

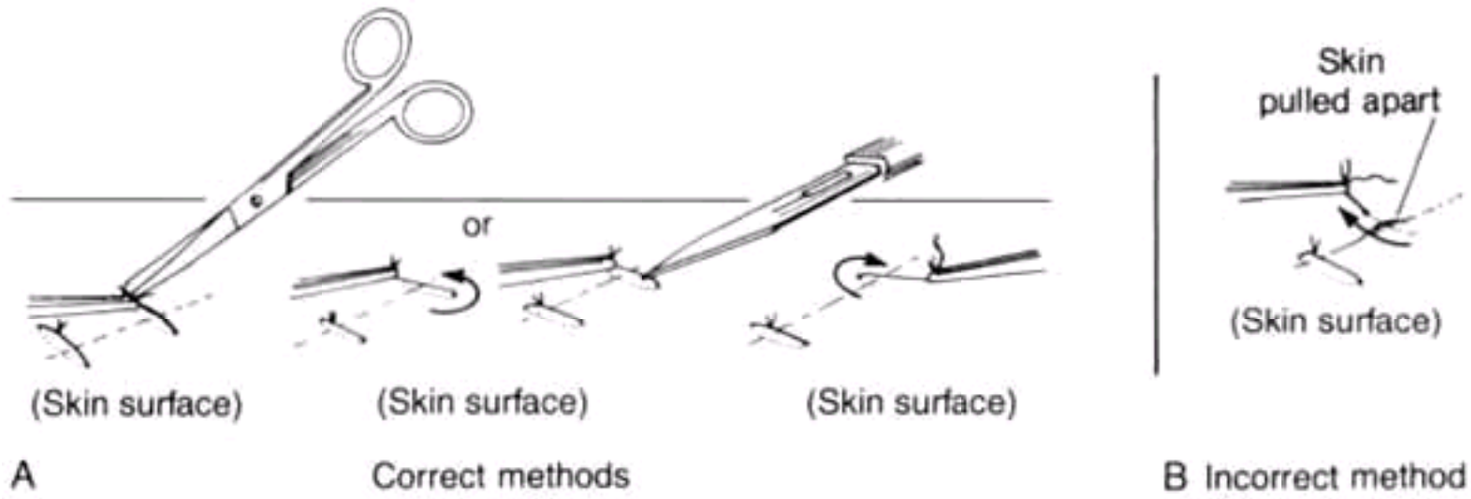

Figure 35-29 Support of the wound with surgical tape.

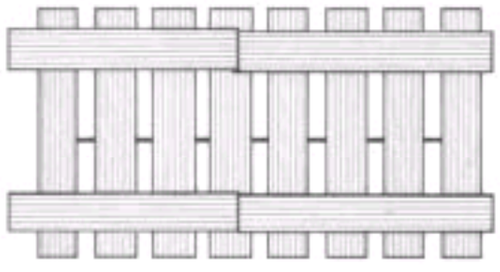

Figure 35-30 At the time of suture removal, the suture is cut at the midpoint of the relief *(A)*. The proximal portion is removed at the point of original entry into the skin *(B),* and the distal portion is removed through the original exit point *(C)*. *(From Grimes DW, Garner RW: "Reliefs" in intracuticular sutures. Surg Rounds 1:48, 1978. Reproduced by permission.)*

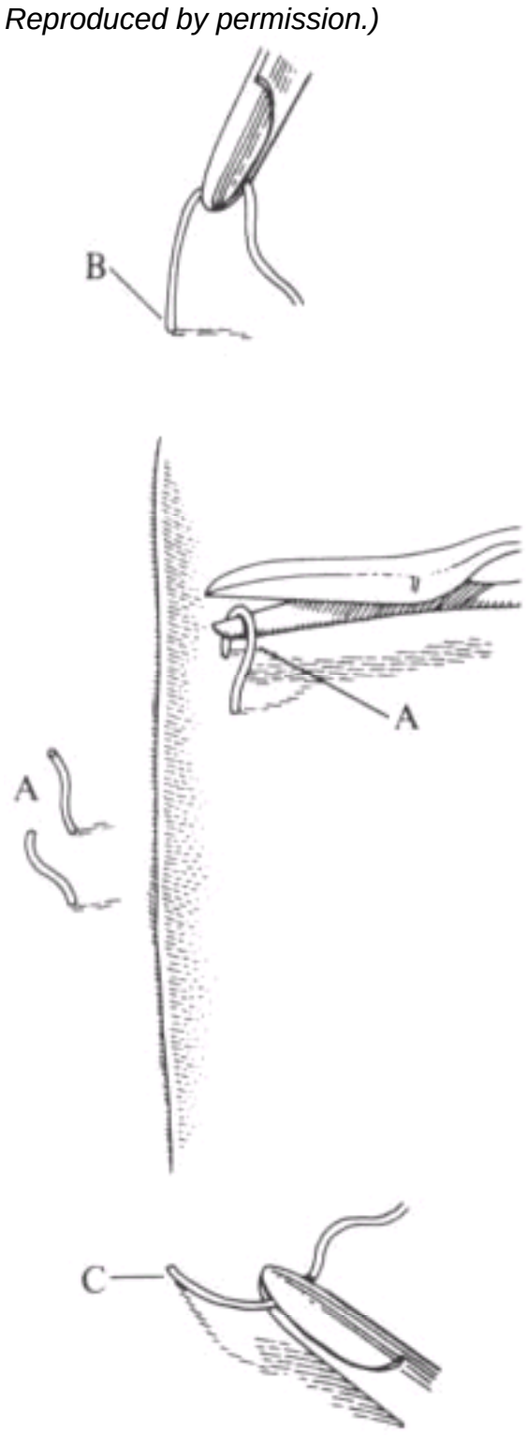

Figure 35-31 Minor gunshot wounds may be treated as outpatients, even when bullet fragments remain and there are *minor* fractures. *A* and *B*, This through-and-through injury transversed the hypothenar eminence. No bullet remained and no bones were involved. *C*, Usually it is impossible to irrigate a puncture wound, but in this case note the saline at the exit site. *D*, After the entrance wound is debrided of the powder burn, a hemostat is passed through the wound. *E*, The instrument grasps gauze packing and pulls it into the wound. The gauze was pulled back and forth to debride the wound tract, and then a clean gauze was left in place. No antibiotics were given, the pack was removed at wound check in 24 hours, and the patient did well. Many gunshot wounds cannot be irrigated to this extent but the treatment principles are similar.

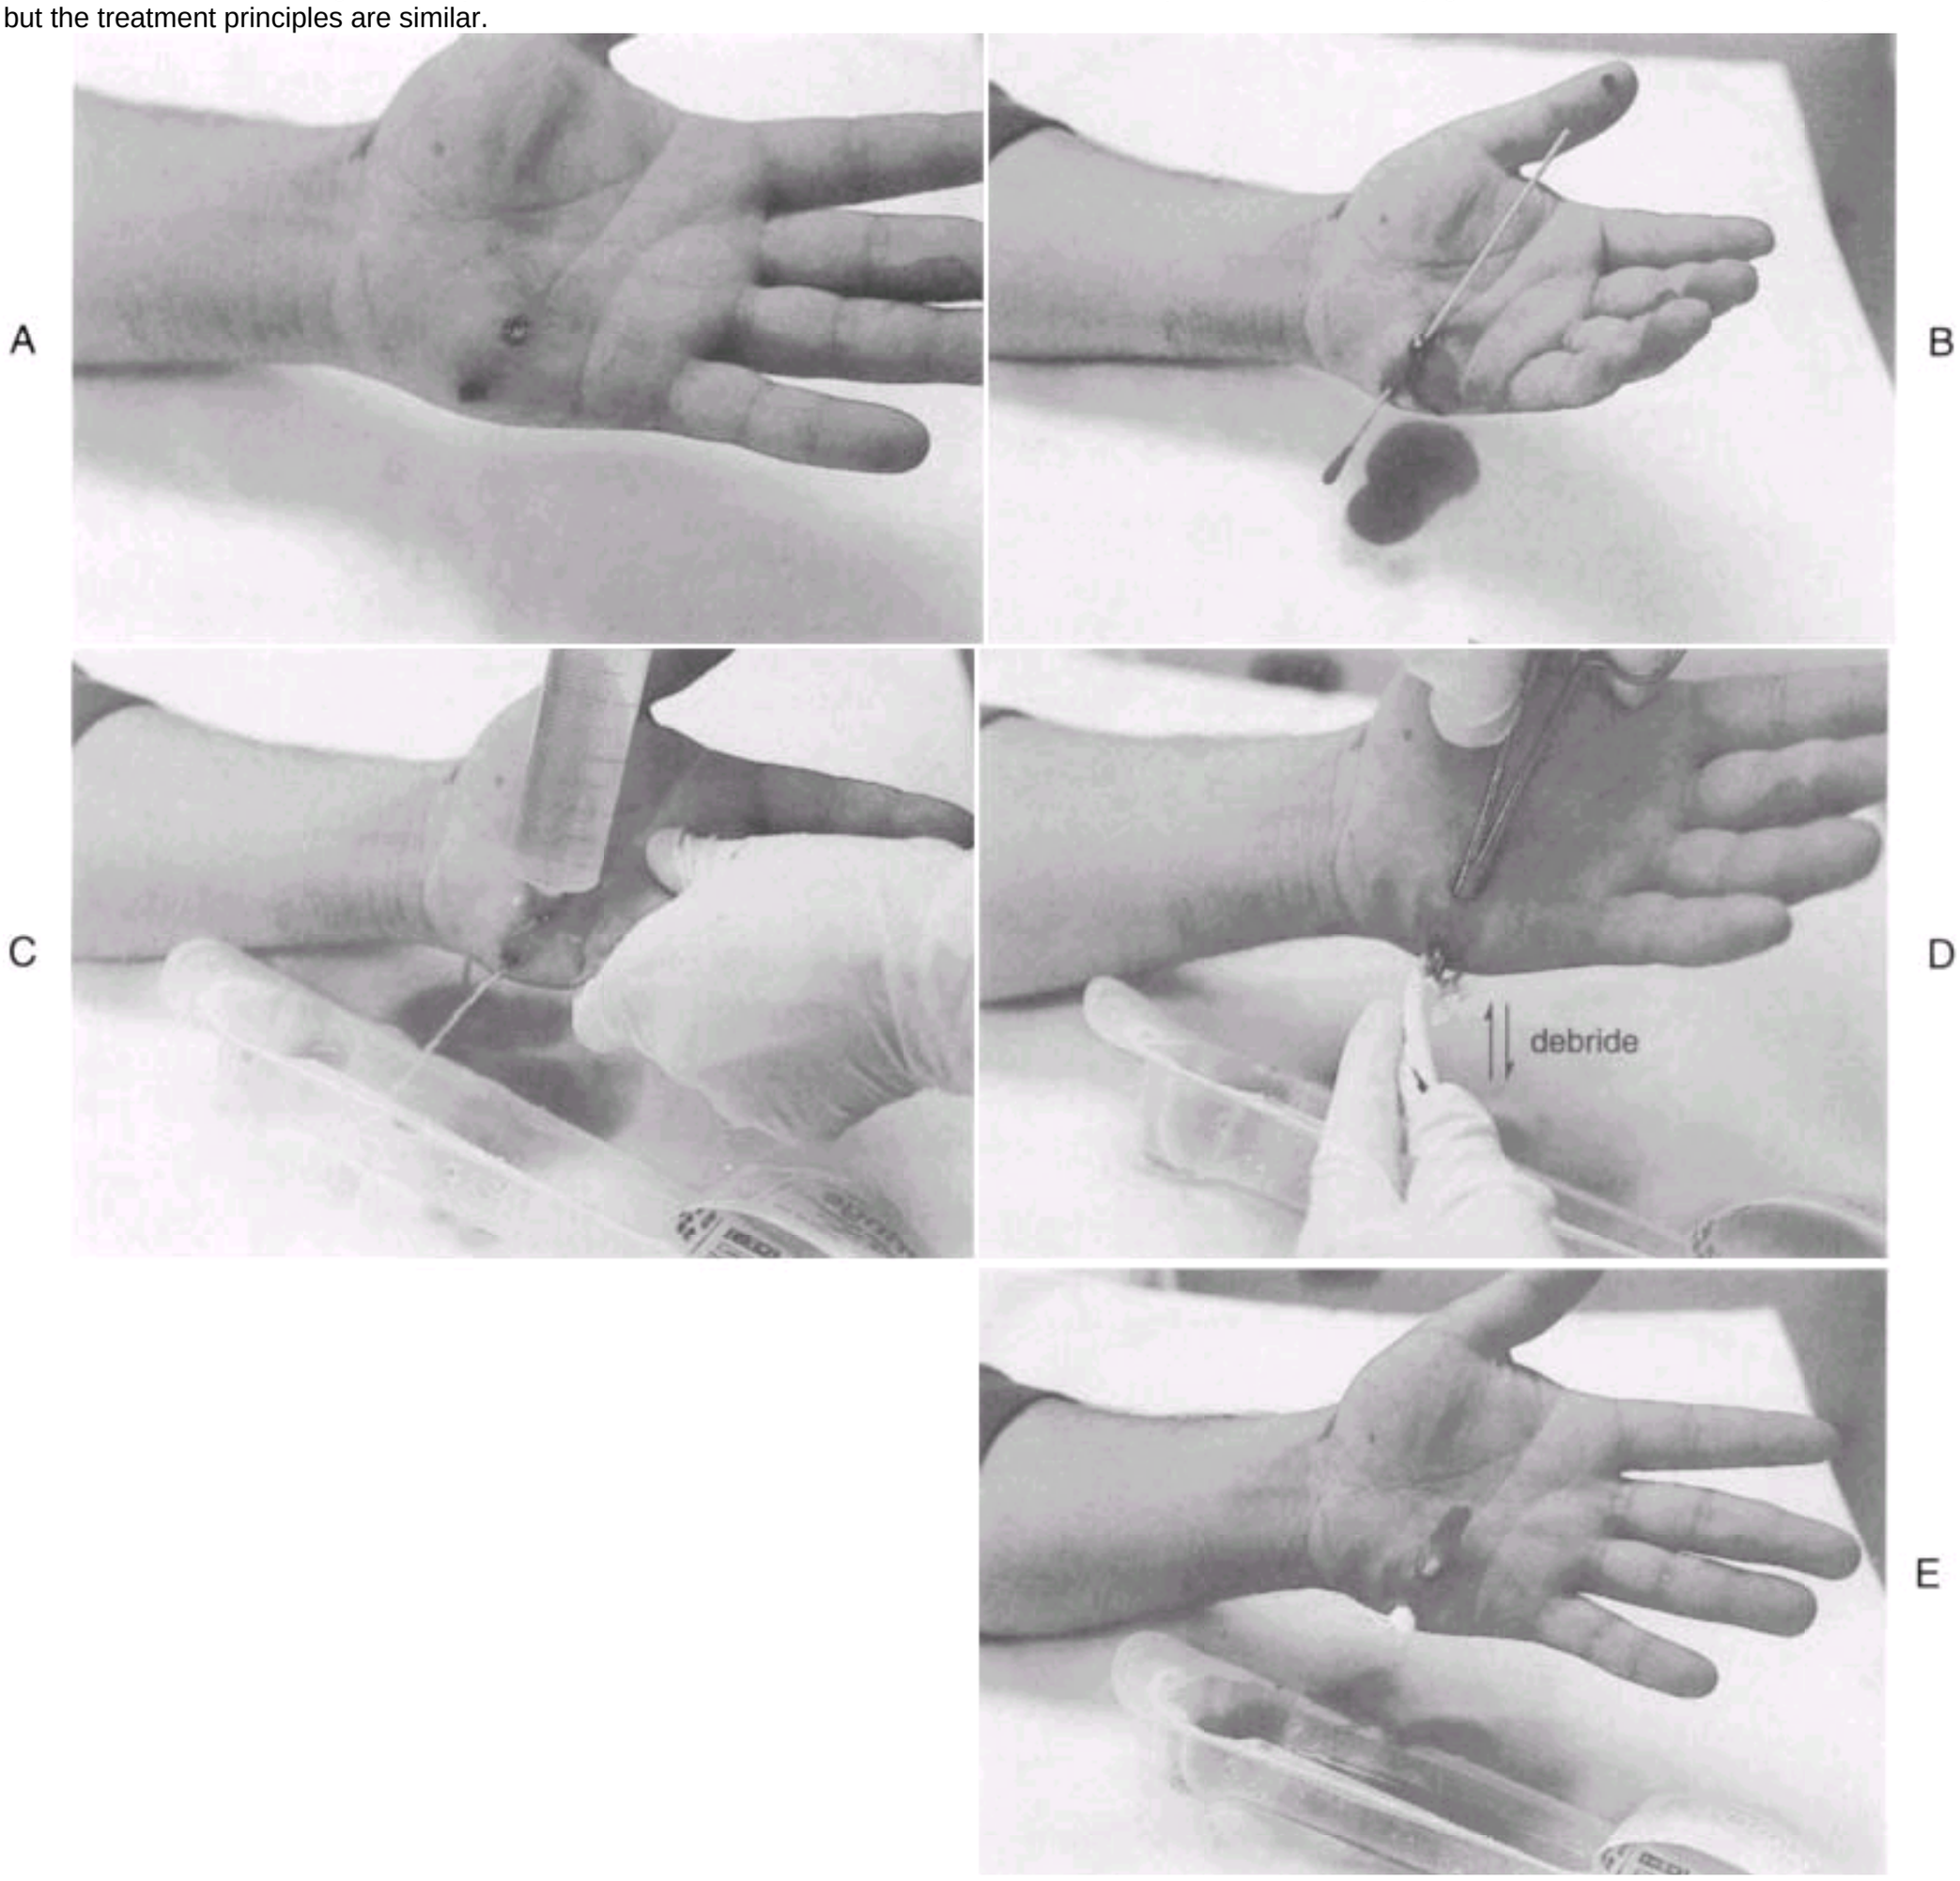

Figure 36-1 *A,* Hair on each side of a laceration is twisted to form "ropes" of hair. *B,* The "roped" strands are tied across the wound in a surgical knot along with additional throws to oppose the skin edges.

Figure 36-2 *A,* A skin avulsion is an ideal wound to close with closure tapes. An elderly woman who was on steroids had extremely thin skin and suffered an anterior tibial skin avulsion that could not be replaced with sutures. *B,* The skin edges are uncurled, stretched, and anatomically replaced. *C,* The wound should heal when closure tapes keep the skin in place. A compression dressing, such as an elastic bandage or a Dome paste (Unna) boot dressing, can be applied to minimize flap movement and decrease fluid buildup under the flap. *D,* Tape should be placed in a semicircular or spiral pattern on digits to avoid constriction.

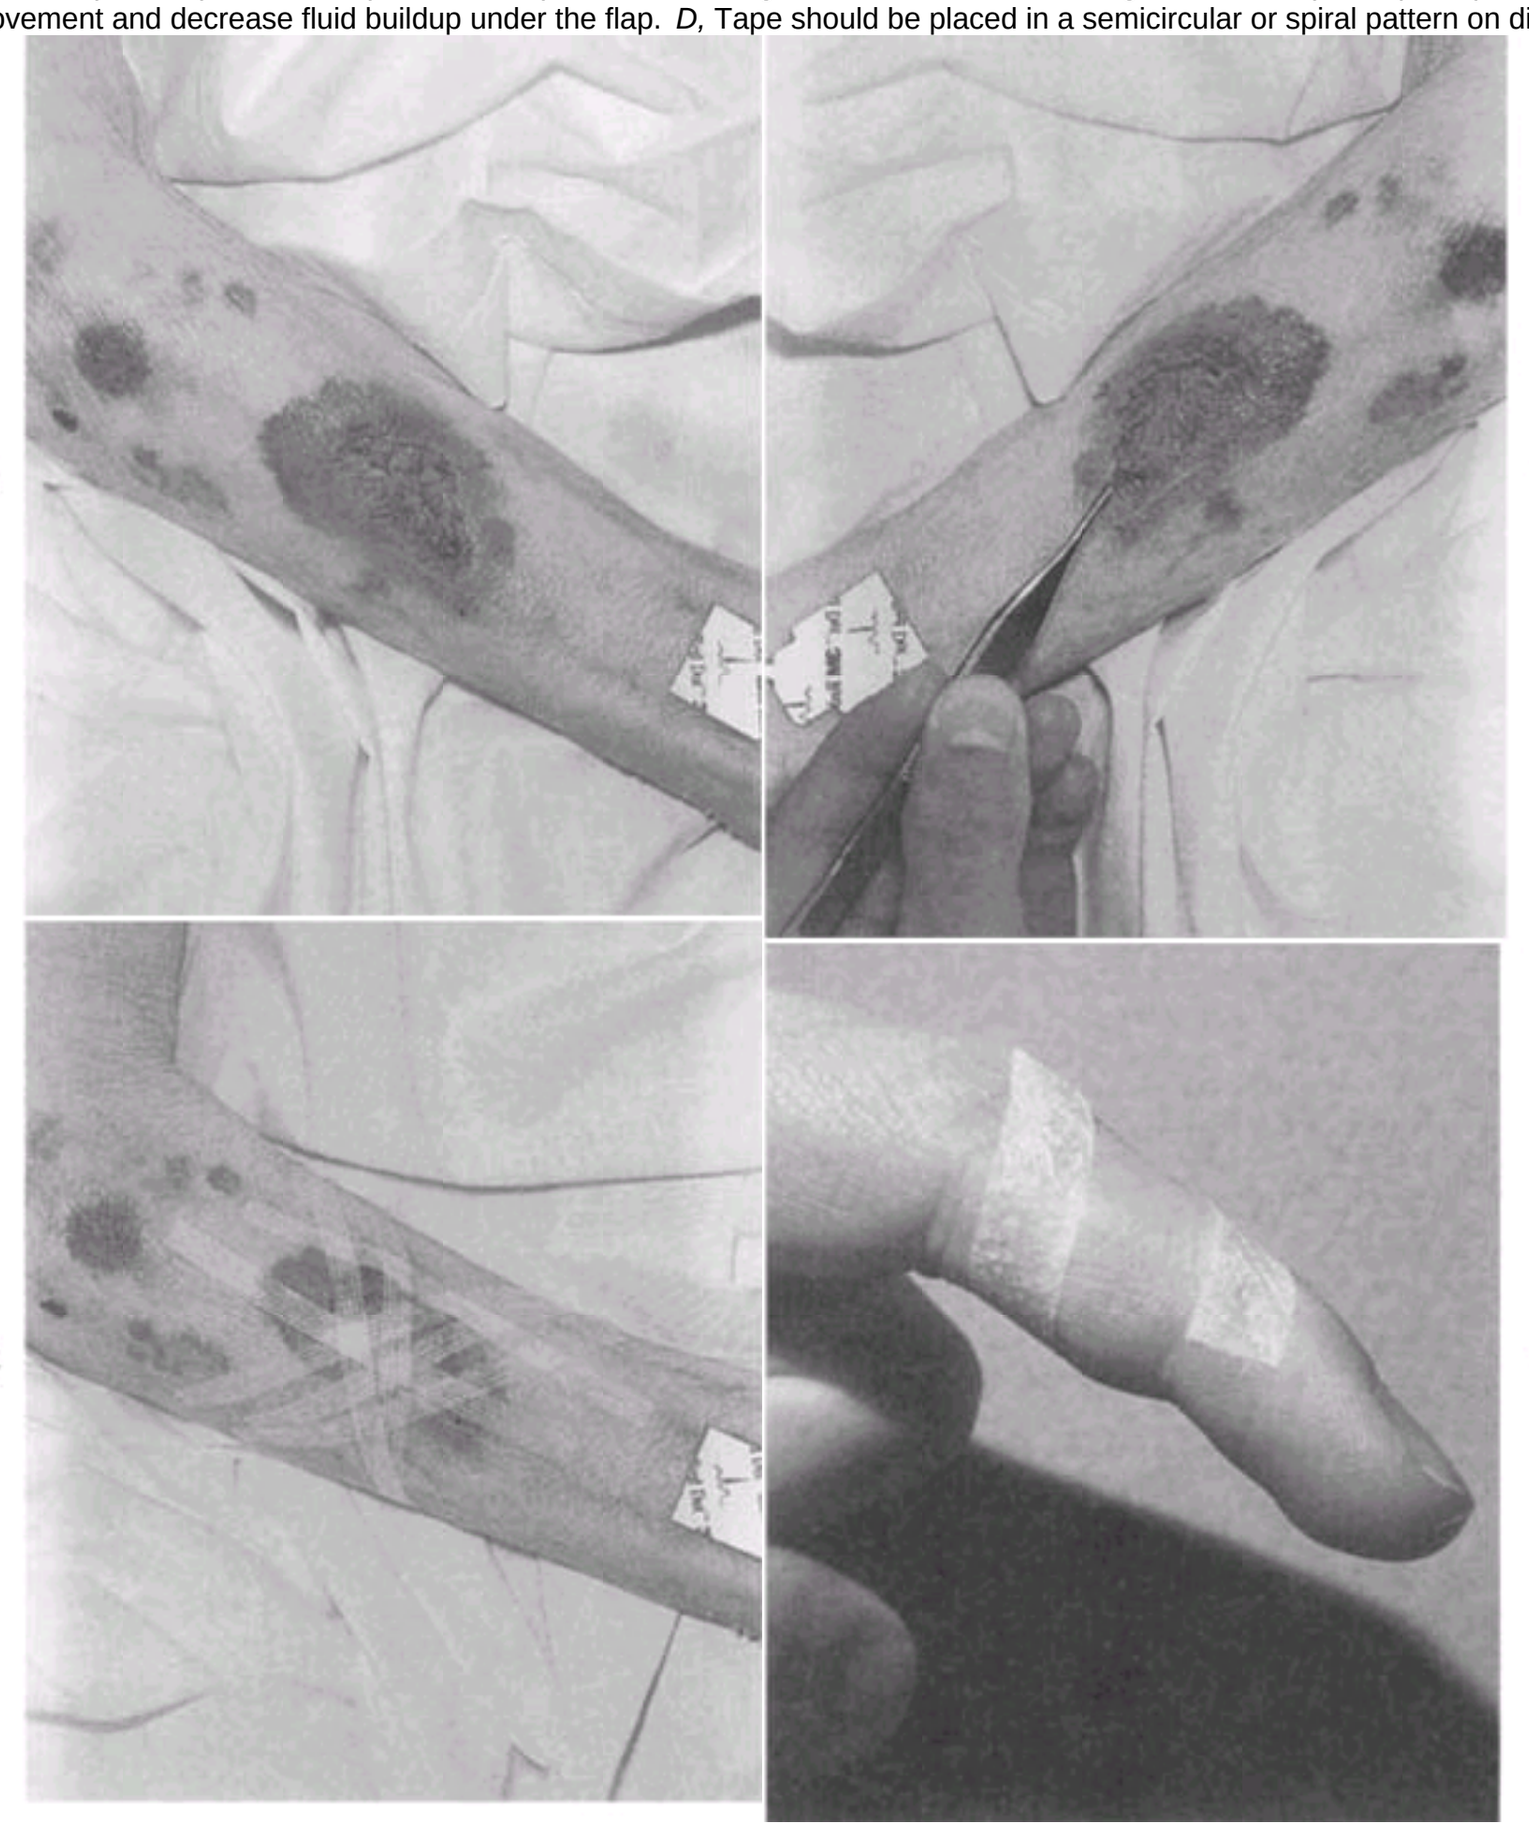

Figure 36-3a Proper technique for application of tapes for skin closure. *A,* After wound preparation (and placement of deep closures, if needed), dry the skin thoroughly at least 2 inches around the wound. Failure to dry the skin and failure to obtain perfect hemostasis are common causes of failure of tapes to stick to the skin. *B,* If desired, apply a thin coating of tincture of benzoin around the wound to enhance tape adhesiveness. Benzoin should not enter the eye, and it causes pain if it seeps into an open wound. *C,* Cut the tapes to the desired length before removing the backing. *D,* The tapes are attached to a card with perforated tabs on both ends. Gently peel the end tab from the tapes.

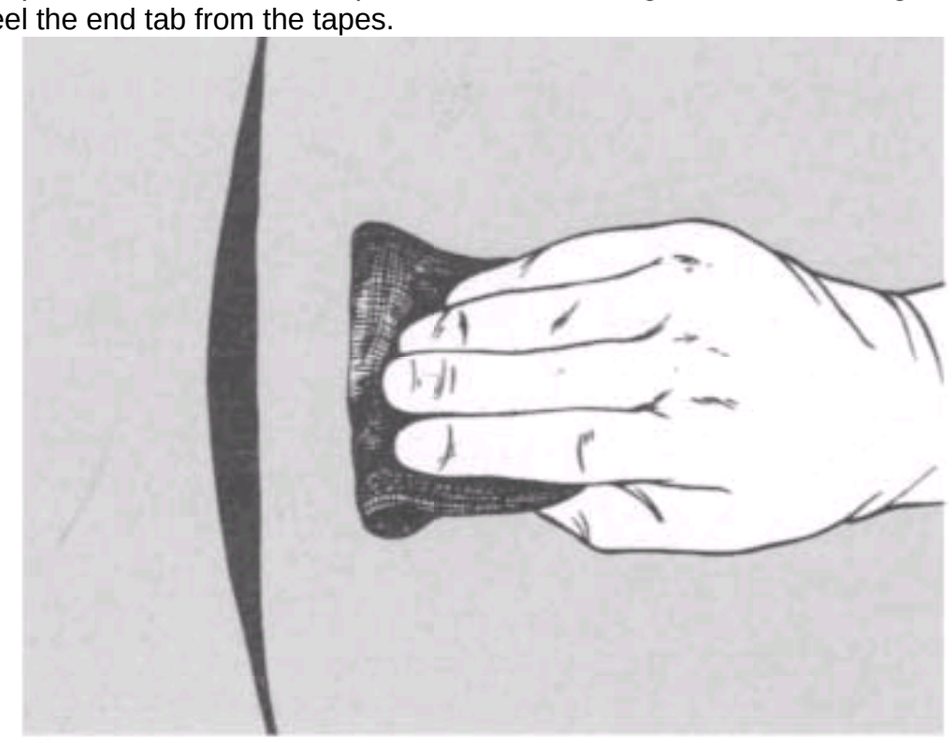
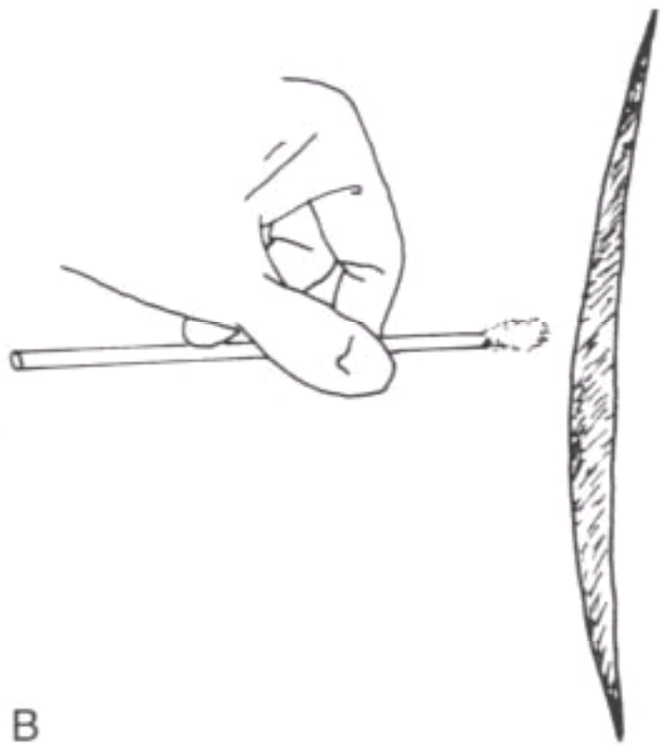
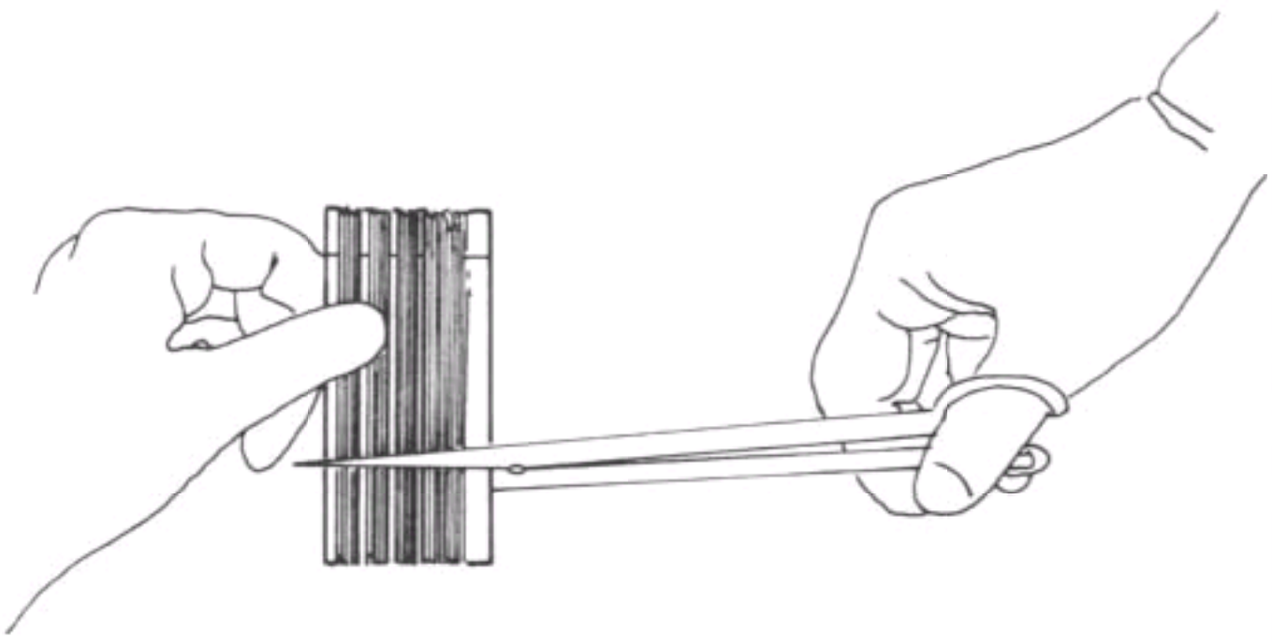


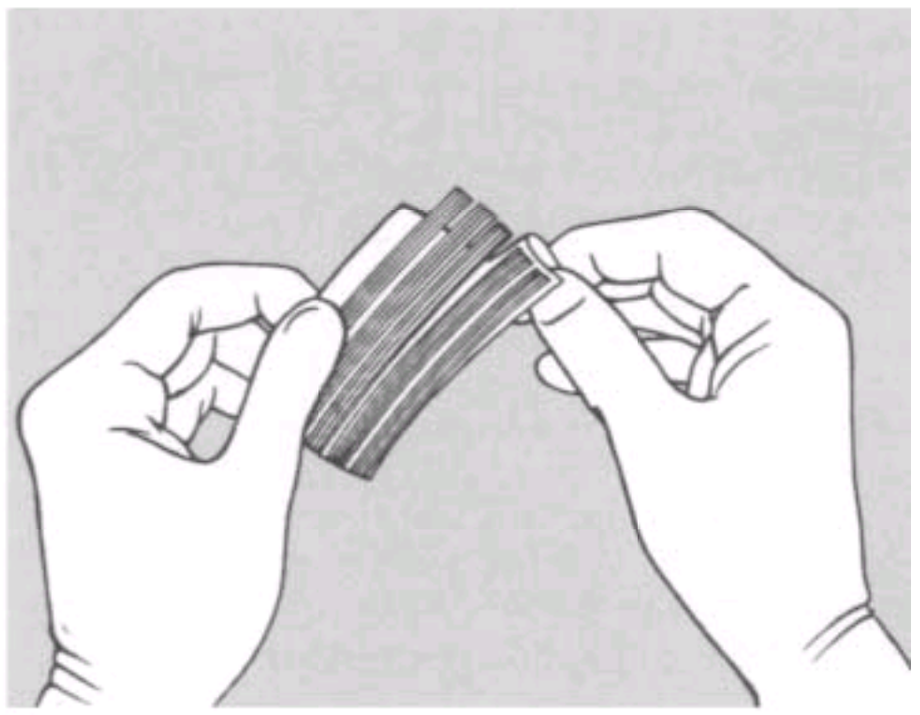
A



B

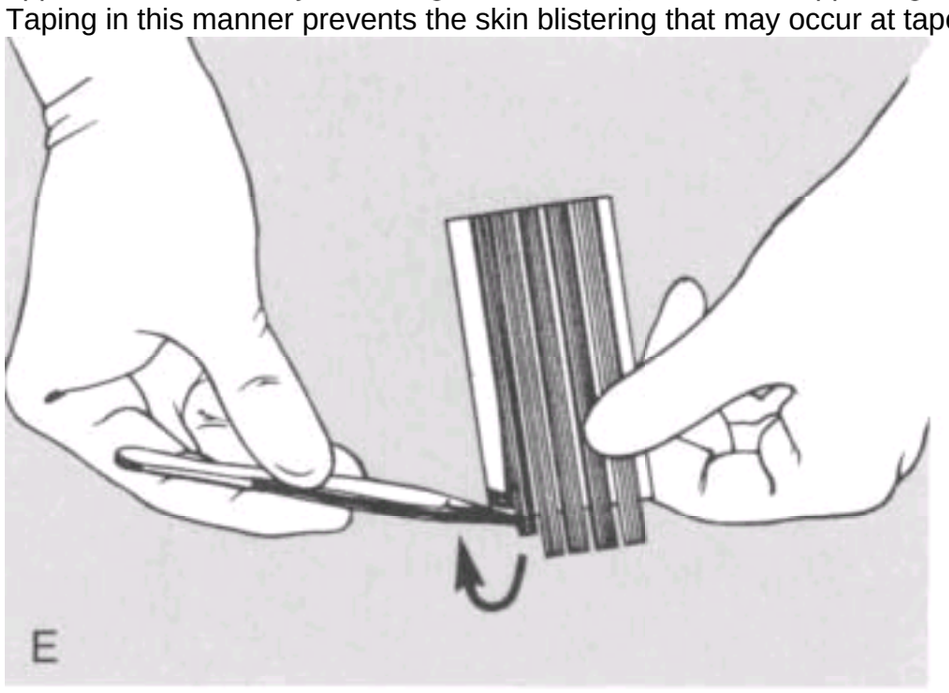


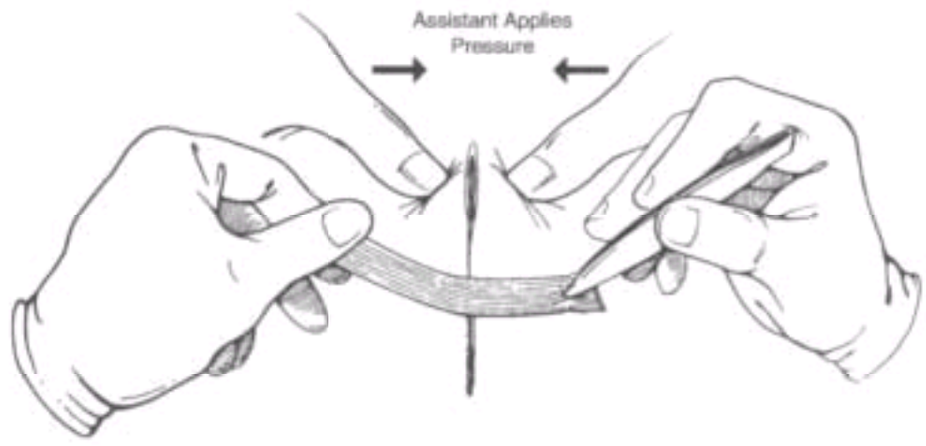
C

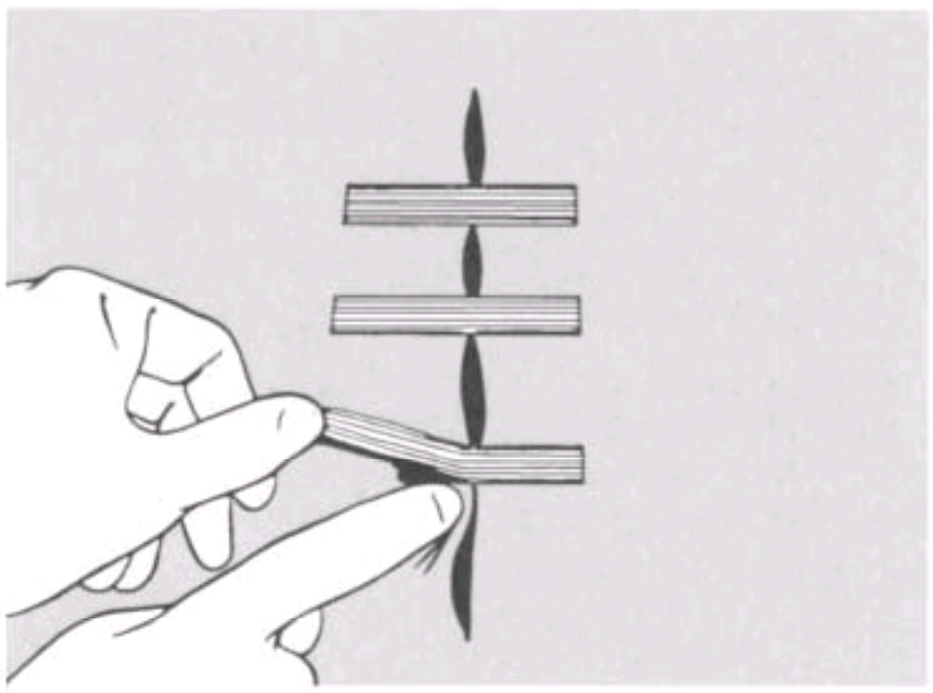


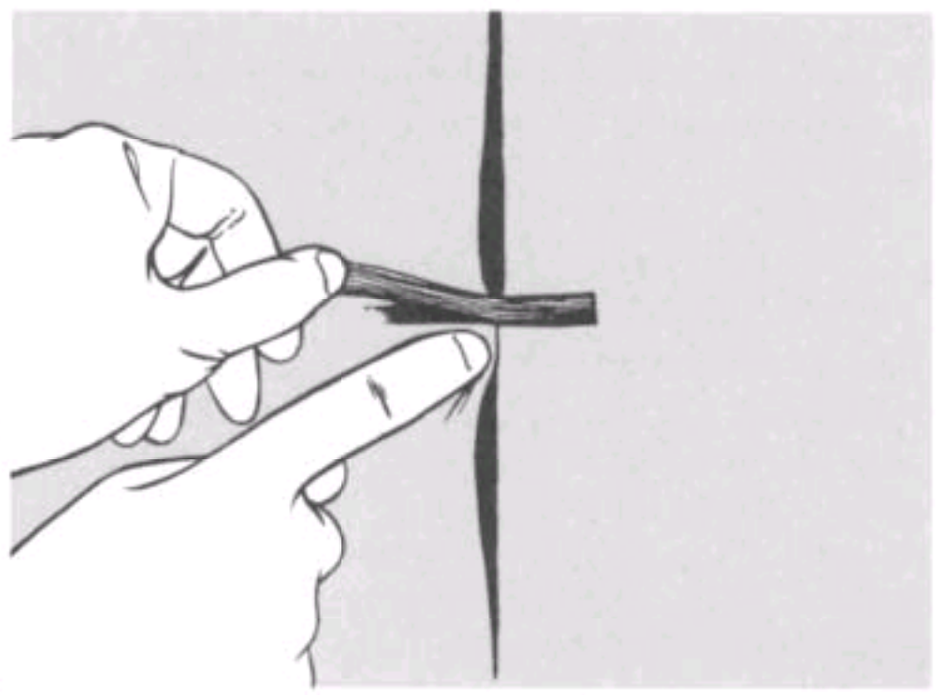
D

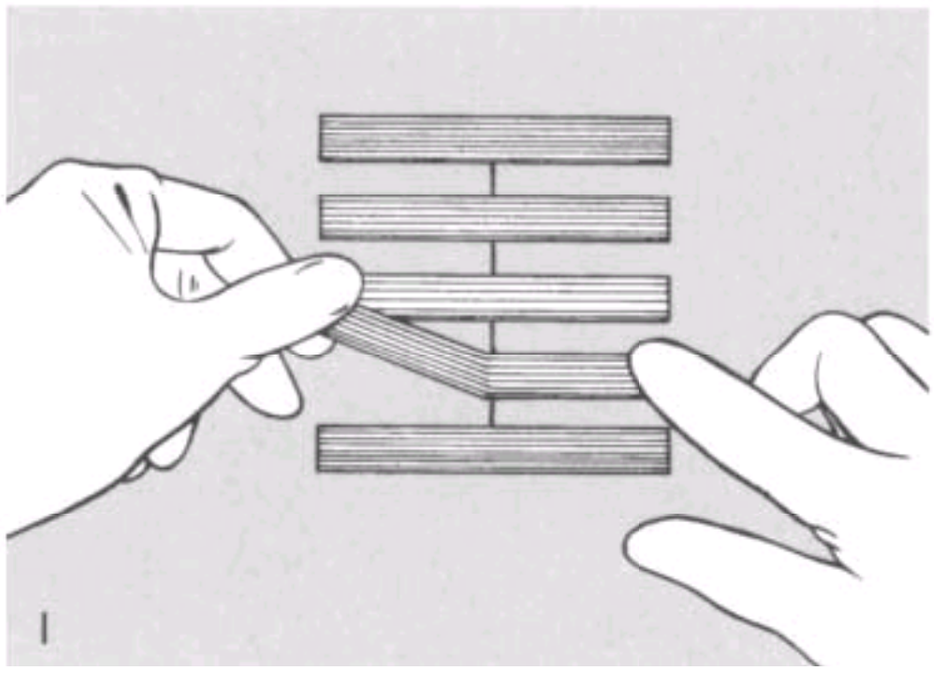
Figure 36-3b *E,* Use forceps to peel the tape off the card backing. Pull directly backward, not to the side. *F,* Place one half of the first tape at the midportion of the wound; secure firmly in place. *G,* Gently but firmly oppose the opposite side of the wound, using the free hand or forceps. If an assistant is not available, the operator can approximate the wound edges. *H,* The tape should be applied by bisecting the wound until the wound is closed satisfactorily. *I,* Wound margins are completely opposed without totally occluding the wound. *J,* Additional supporting tapes are placed approximately 2.5 cm from the wound and parallel to the wound direction. Taping in this manner prevents the skin blistering that may occur at tape ends.











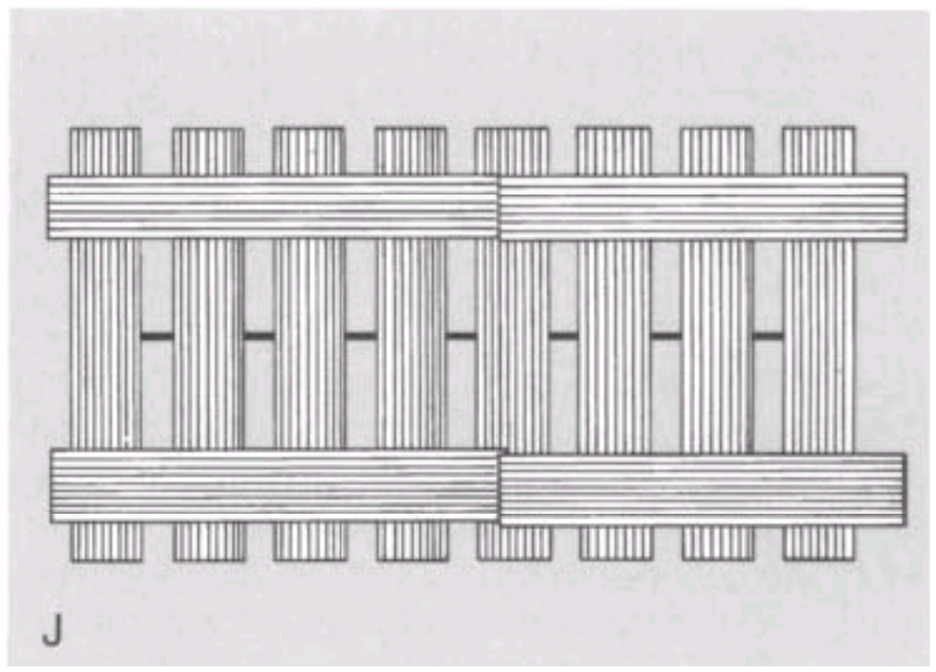


Figure 36-4 Tissue adhesive, 2-octyl cyanoacrylate in a commercially available application dispenser.

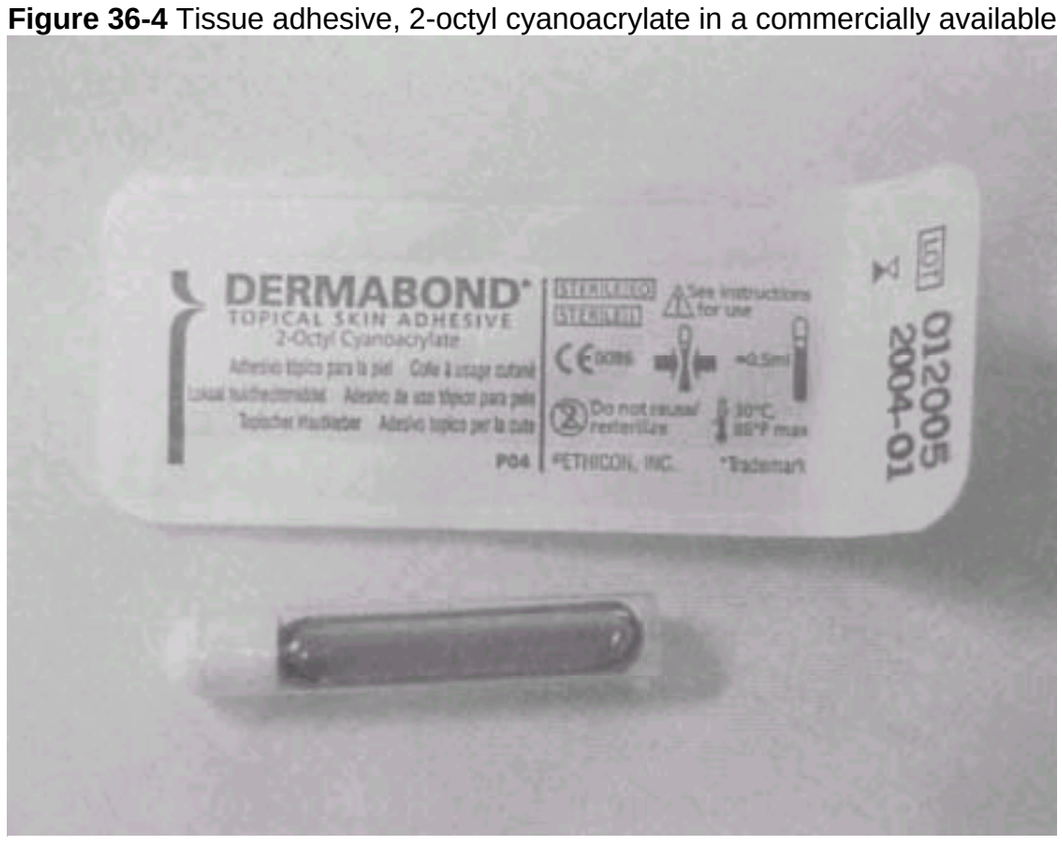

Figure 36-5 The skin edges must be approximated and everted by hand or with forceps before they are secured with staples. Failure to evert the wound edges is a common error that may cause an unacceptable result. *(Adapted with permission from Edlich RF: A Manual for Wound Closure. St. Paul, MN, 3M Medical-Surgical Products, 1979. Reproduced by permission.)*

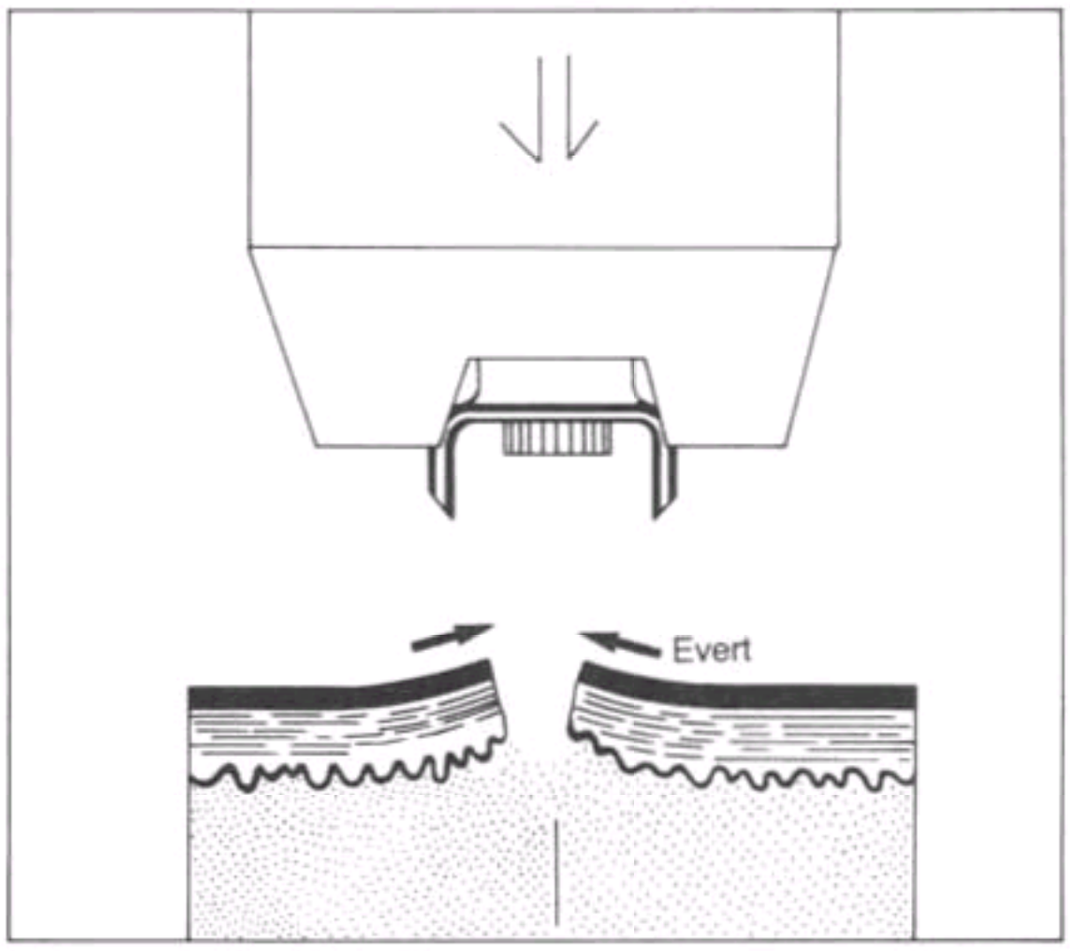

Figure 36-6 By squeezing the stapler handle, a plunger advances one staple into the wound margins. *(From Edlich RF: A Manual for Wound Closure. St. Paul, MN, 3M Medical-Surgical Products, 1979. Reproduced by permission.)*

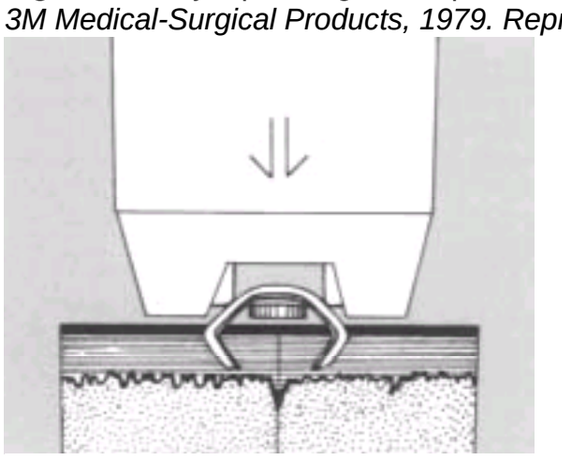

Figure 36-7 An anvil automatically bends the staple to the proper configuration. *(From Edlich RF: A Manual for Wound Closure. St. Paul, MN, 3M Medical-Surgical Products, 1979. Reproduced by permission.)*

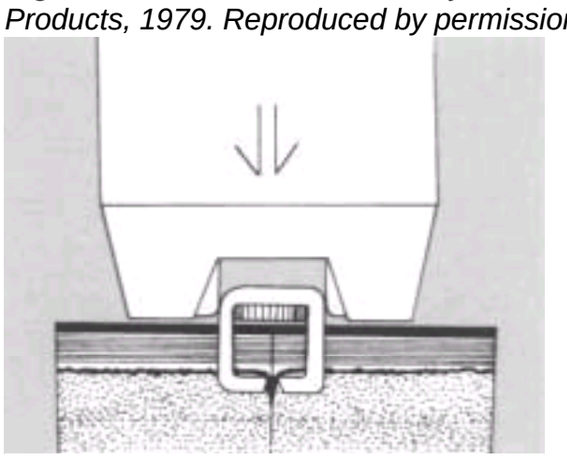

Figure 36-8 Care should be taken to ensure that a space remains between the skin and the crossbar of the staple. Excessive pressure created by placing the staple too deep causes wound edge ischemia, as well as pain on removal. Note that the staple bar is 2 to 3 mm above the skin line. *(From Edlich RF: A Manual for Wound Closure. St. Paul, MN, 3M Medical-Surgical Products, 1979. Reproduced by permission.)*

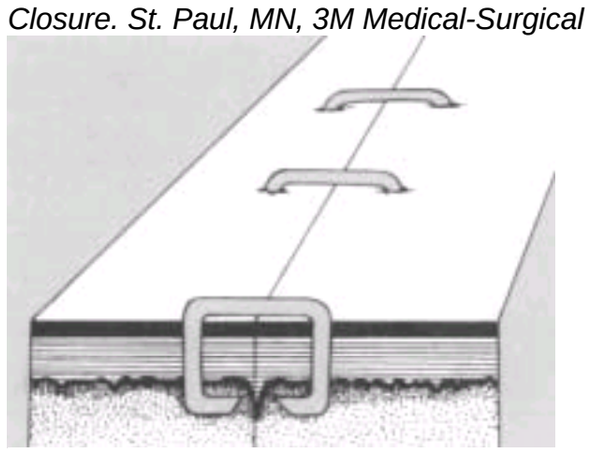

Figure 36-9 The lower jaw of the staple remover is placed under the crossbar of the staple. *(From Edlich RF: A Manual for Wound Closure. St. Paul, MN, 3M Medical-Surgical Products, 1979. Reproduced by permission.)*

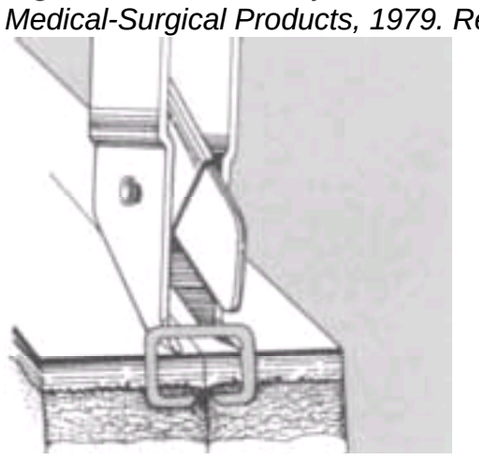

Figure 36-10 By squeezing the handle gently, the upper jaw compresses the staple and allows it to exit the skin. *(Adapted from Edlich RF: A Manual for Wound Closure. St. Paul, MN, 3M Medical-Surgical Products, 1979. Reproduced by permission.)*

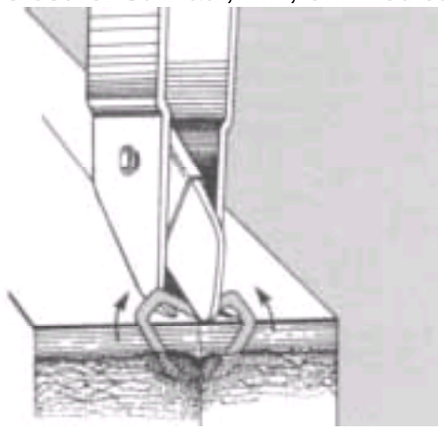

Figure 36-11 A very poor result occurred when staples (*some marked with arrows*) were used to close this deep scalp laceration (*A*). The wound edges were not everted (in fact, the skin overlapped significantly), and poor hemostasis was obtained because the galea was not closed by the superficial staples. Three days later during a wound check, the staples were removed, and the laceration was closed with 3-0 interrupted nylon sutures (*B*). The clinician should attempt to obtain a cosmetic closure on all scalp lacerations, because as patients lose their hair, a previously hidden, unsightly scar emerges. In general, staples should not be used to close full-thickness scalp lacerations, especially wounds that are actively bleeding.

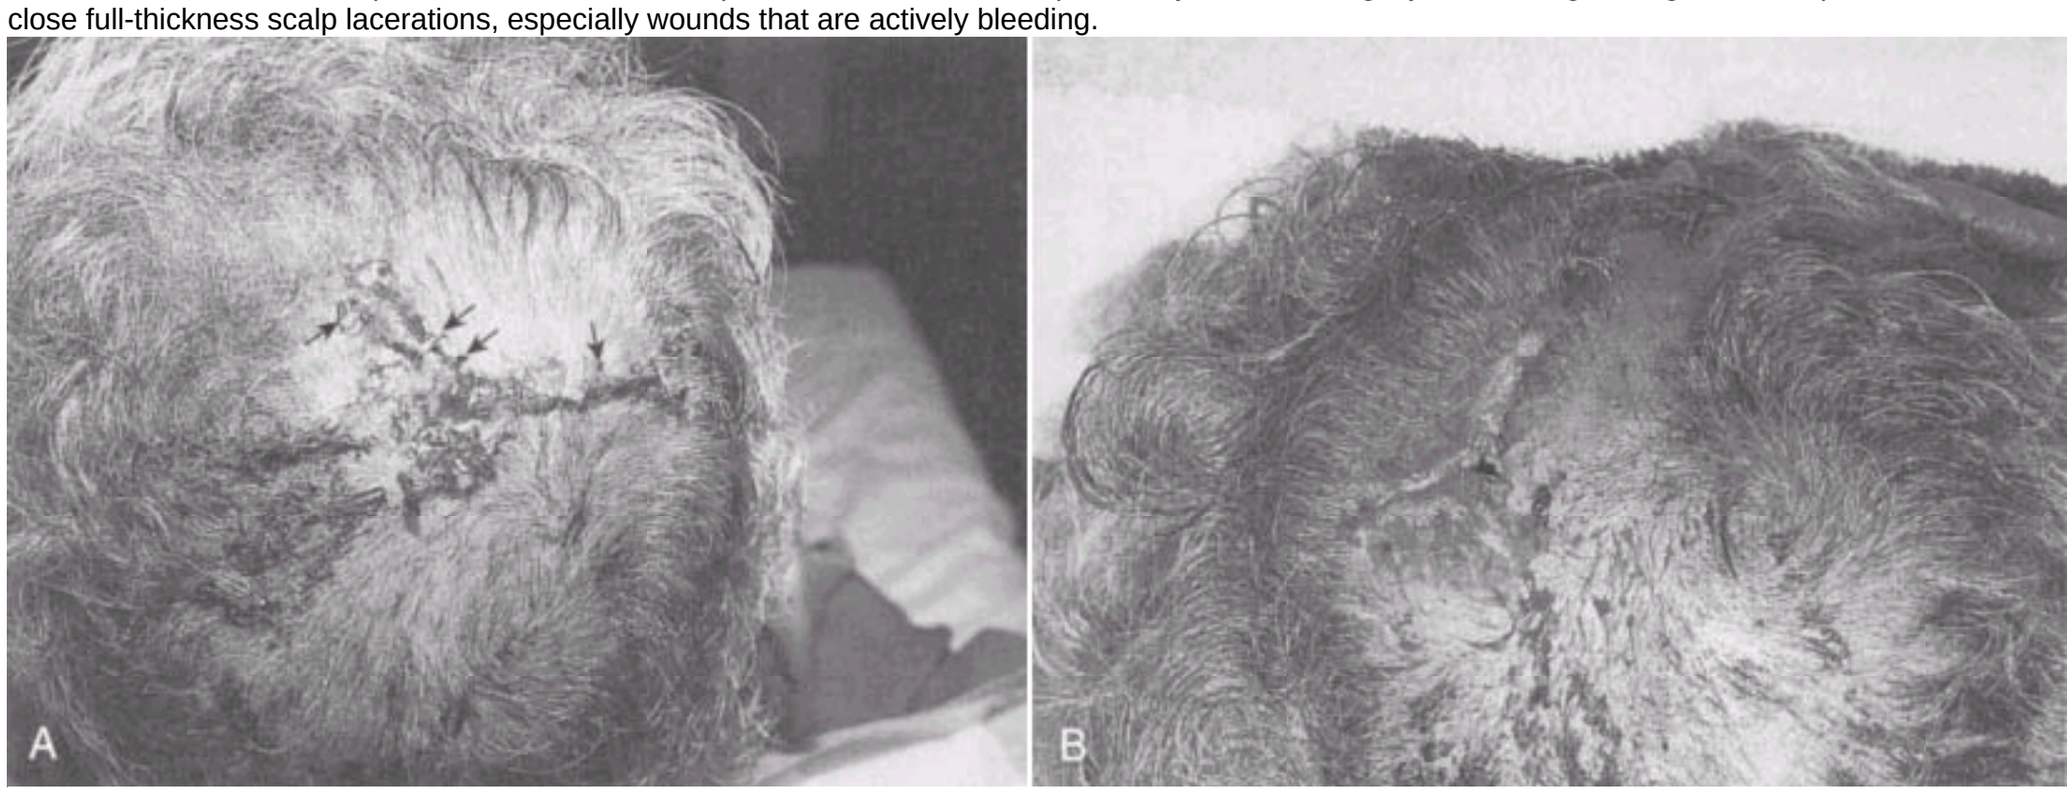

Figure 36-12 The eyeless, or "swaged," needle. *(From Suture Use Manual: Use and Handling of Sutures and Needles. Somerville, NJ, Ethicon, Inc., 1977, p 29. Reproduced by permission.)*

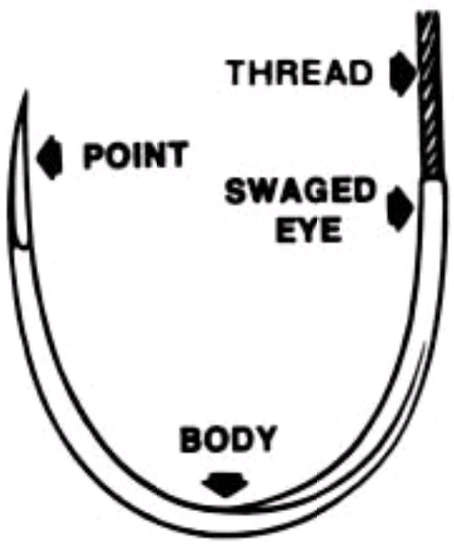

Figure 36-13 The needle should be large enough to pass through tissue and should exit far enough to enable the needle holder to be repositioned on the end of the needle at a safe distance from the point.

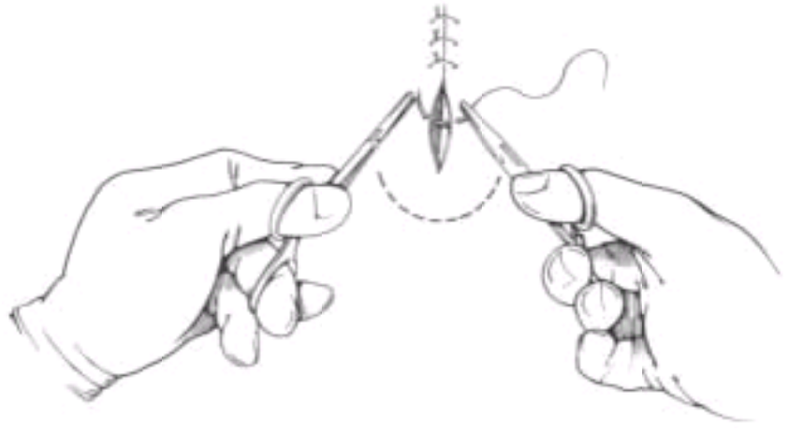

Figure 36-14 One-half and three-eighths circle needles, used for most traumatic wound closures.

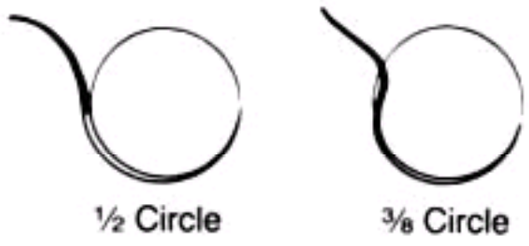

Figure 36-15 Types of needles. *A,* The conventional cutting needle has two opposing cutting edges, with a third edge on the inside curvature of the needle. The conventional cutting needle changes in cross section from a triangular cutting tip to a flattened body. *B,* The reverse cutting needle is used to cut through tough, difficult-to-penetrate tissues, such as fascia and skin. It has two opposing cutting edges, with the third cutting edge on the outer curvature of the needle. The reverse cutting needle is made with the triangular shape extending from the point to the swage area, with only the edges near the tip being sharpened. *(From Suture Use Manual: Use and Handling of Sutures and Needles. Somerville, NJ, Ethicon, Inc., 1977, p 31. Reproduced by permission.)*

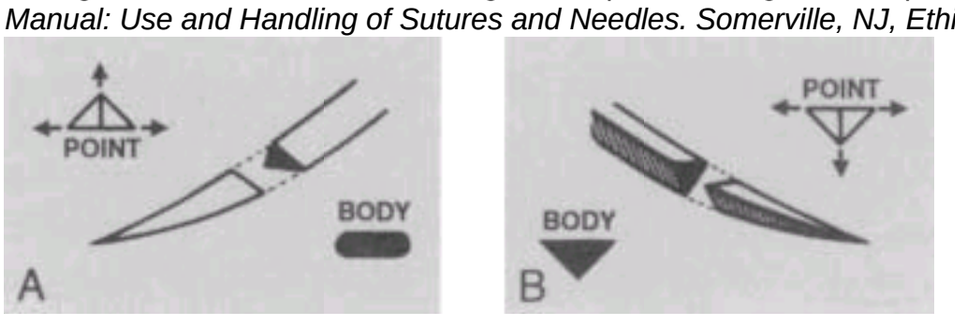

Figure 36-16 *A–D,* Technique for wrapping the scalp to keep stray hair from falling into the operating field. A scrub hat is an acceptable alternative.

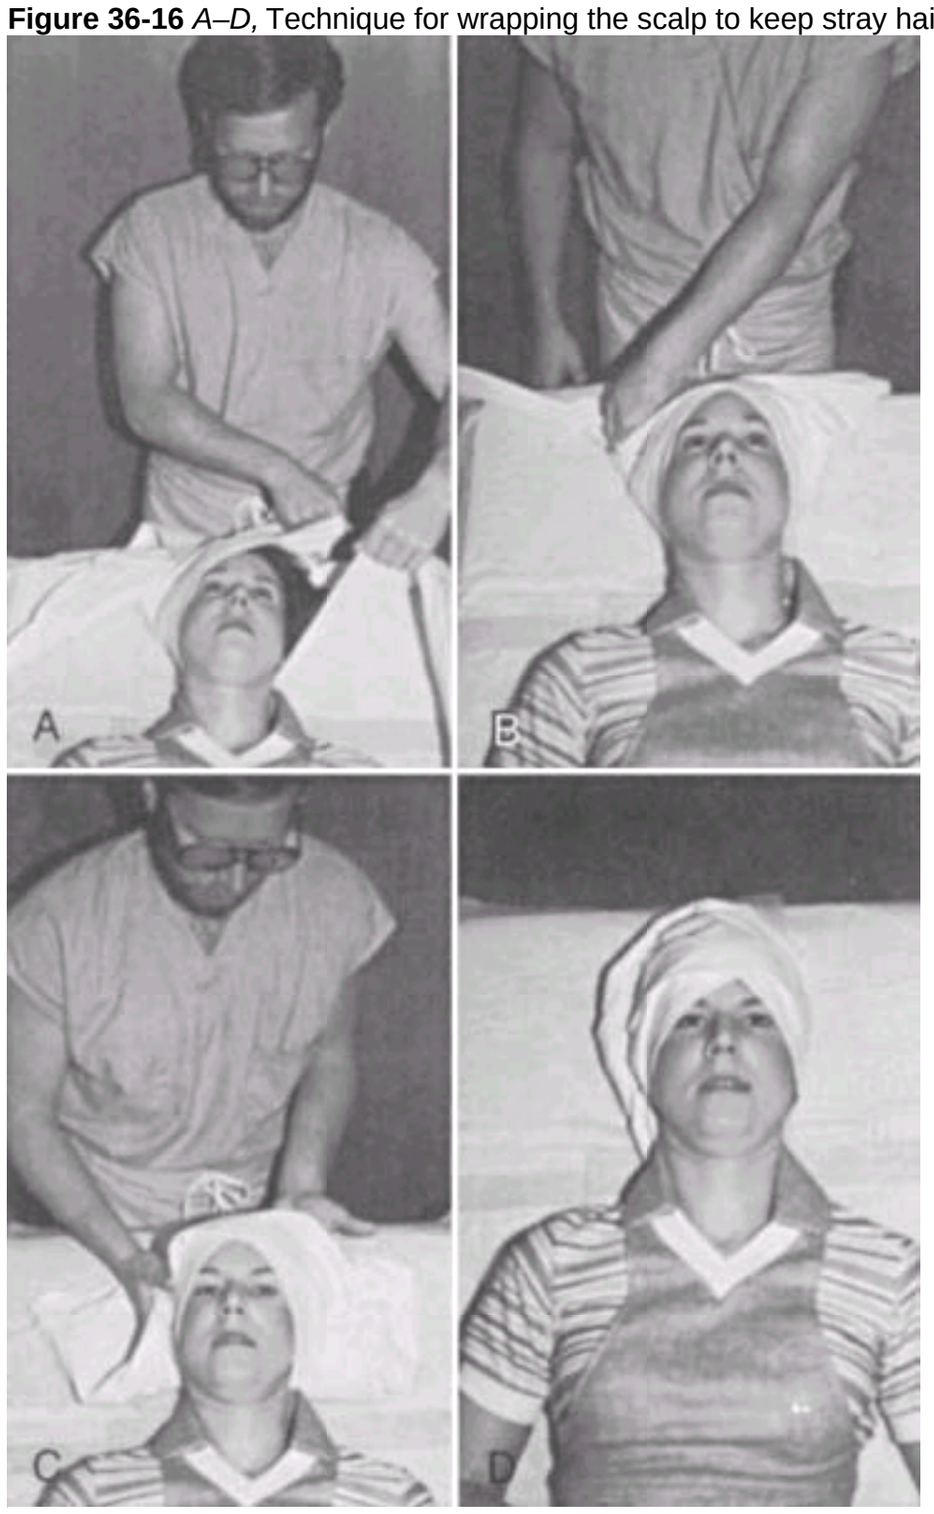

Figure 36-17 The technique of undermining. The scalpel is used to find an appropriate site; a natural plane often exists at the epidermis-dermis junction. Undermining relieves tension on the wound and renders a better cosmetic result. This technique is simple to master, but sometimes overlooked.

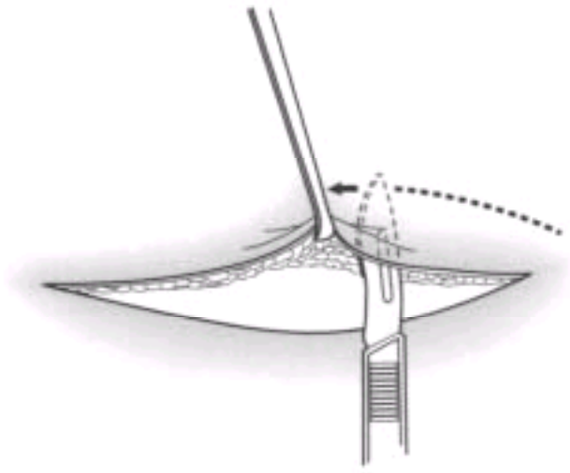

Figure 36-18a Variation in the structure of skin. *A,* Section of the skin of the scalp, ×15. *B,* Skin of the human fingertip, illustrating a very thick stratum corneum. Hematoxylin and eosin, ×65.

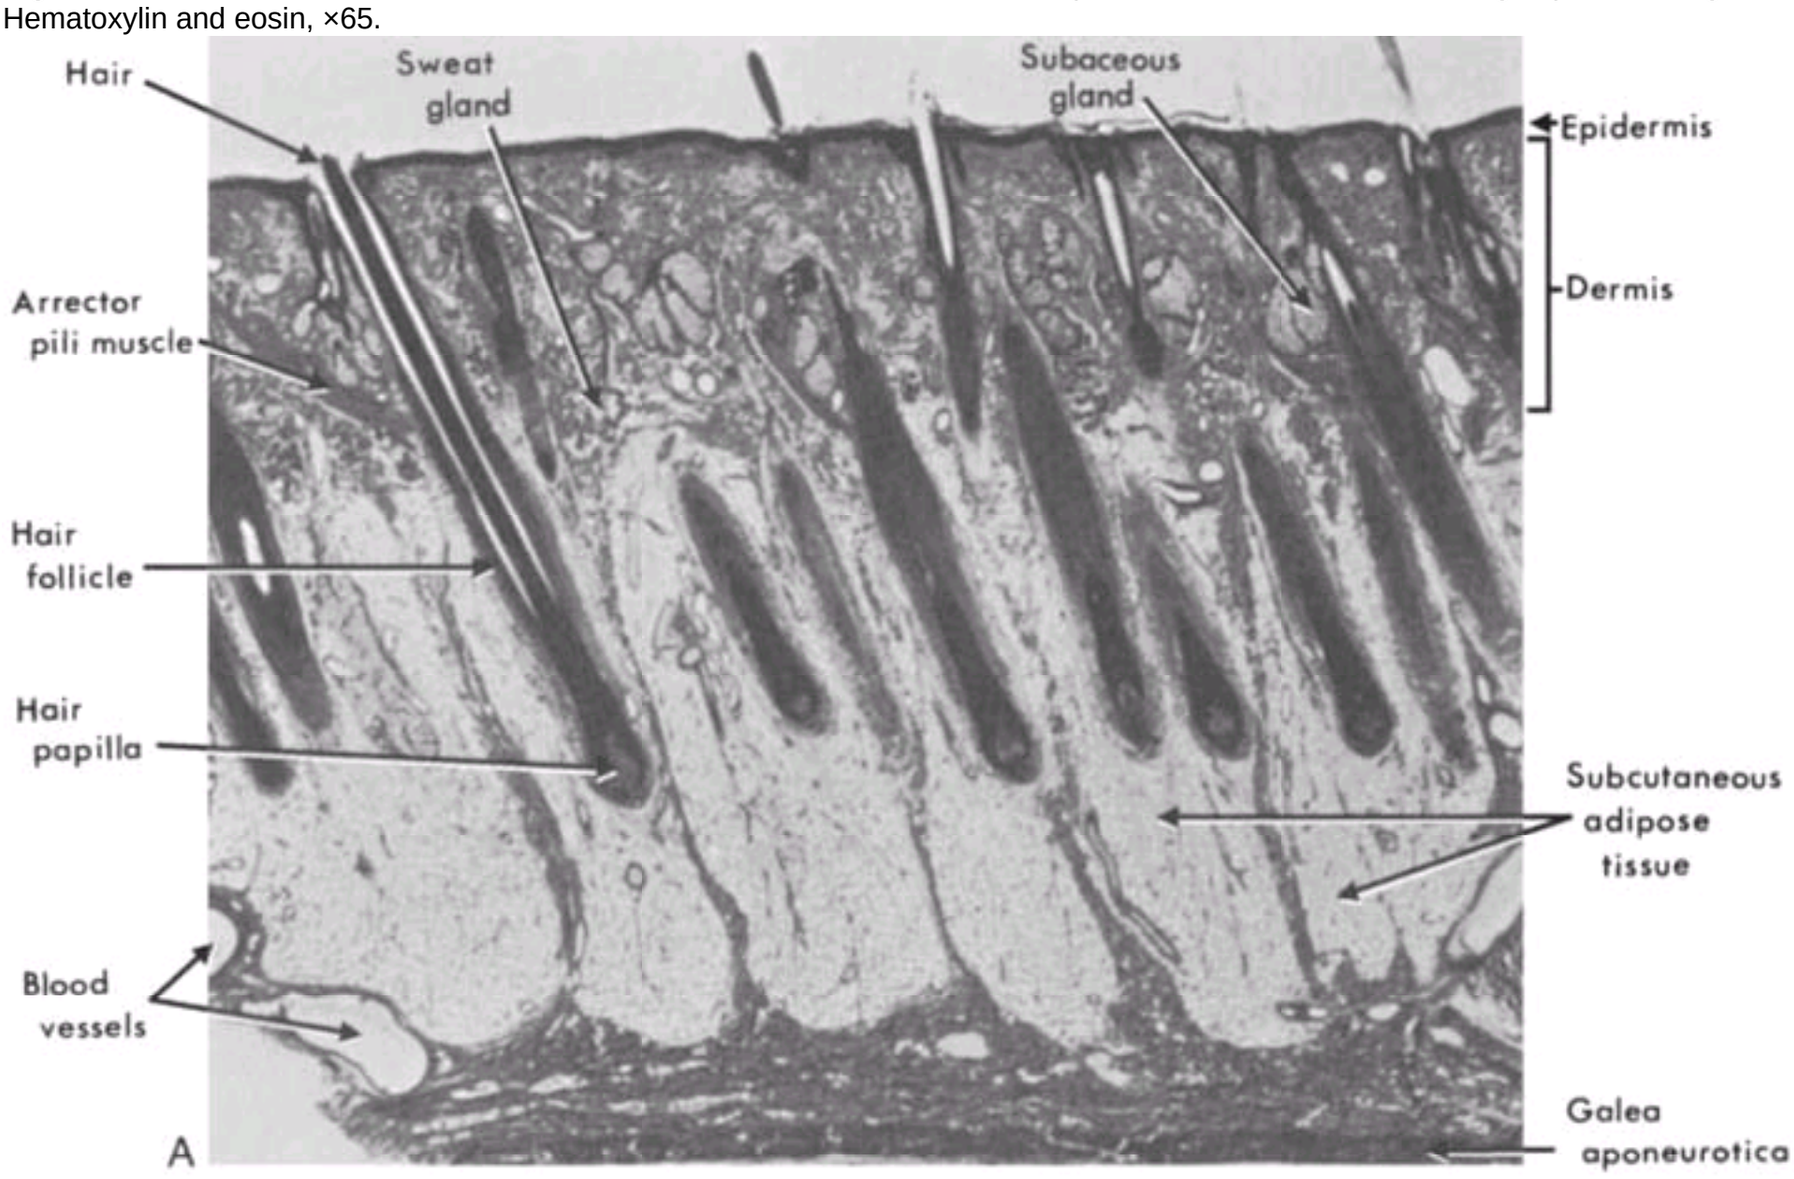

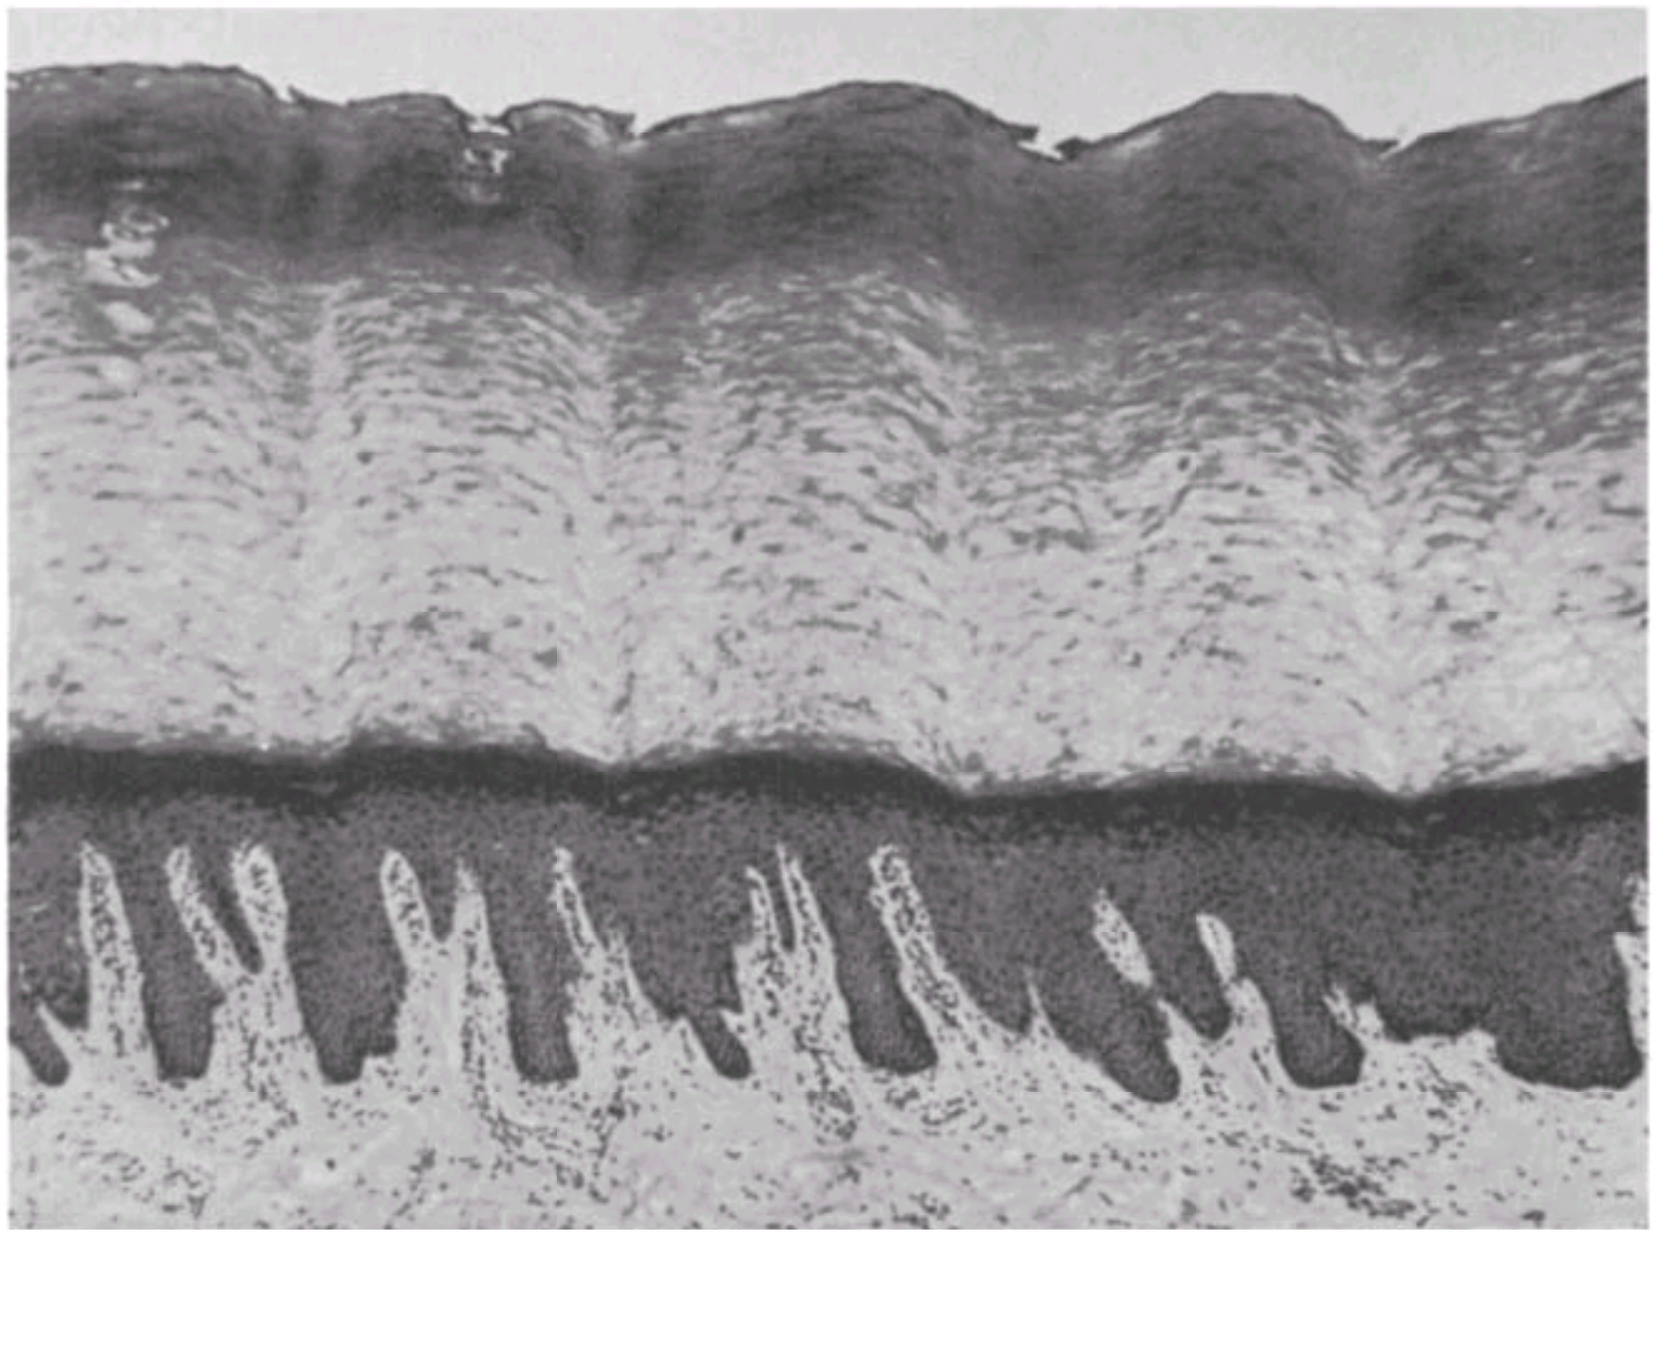

Figure 36-18b *C,* Section of human sole perpendicular to the free surface, ×100. *D,* Section through human thigh perpendicular to the surface of the skin. Blood vessels are injected and appear black. Low magnification. *(A Courtesy of H Mizoguchi. C and D after AA Maximow. From Bloom W, Fawcett DW: A Textbook of Histology, 10th ed. Philadelphia, WB Saunders, 1975. Reproduced by permission.)*

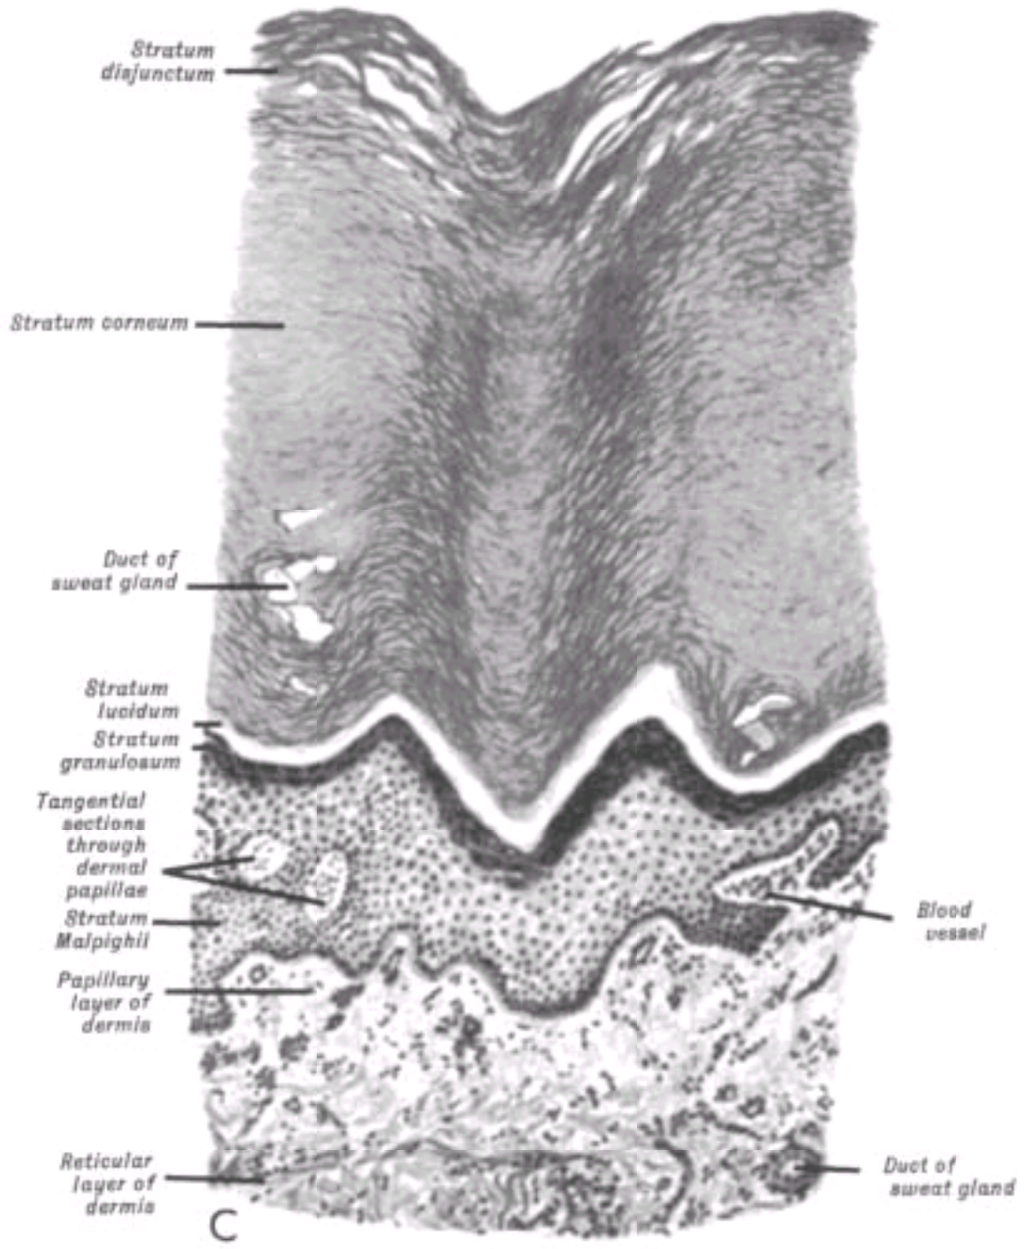

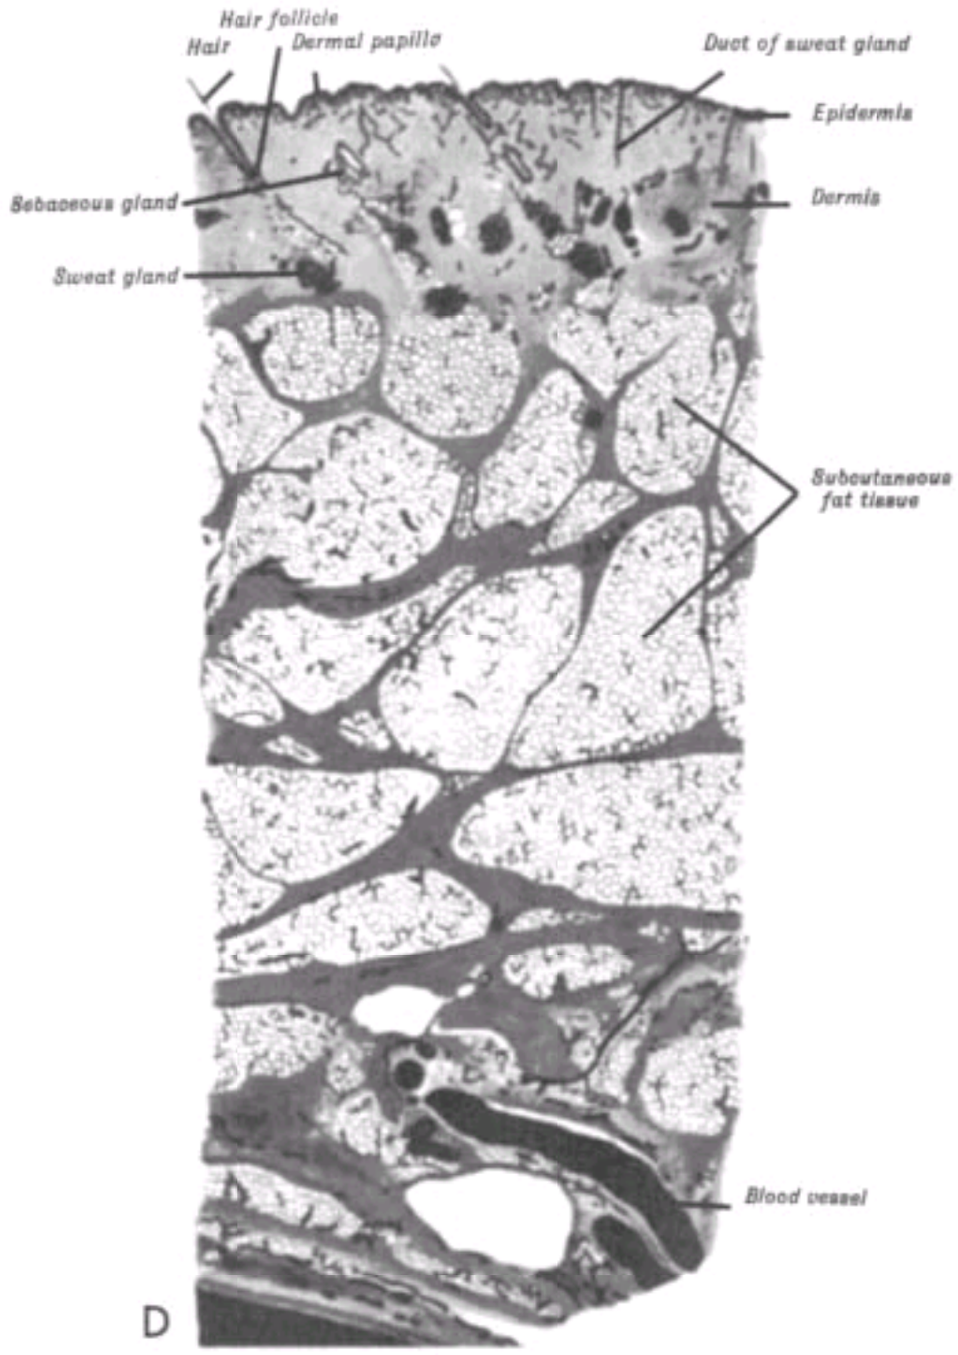

Figure 36-19 The thenar grip technique of handling the needle holder. The index finger is placed on the side of the needle holder, where it guides the placement of the needle. Neither the index nor the middle finger is placed in the ringlet hole. An alternate method (the thumb-ring finger grip) is shown in Figure 36-27 .

Figure 36-20 *A* and *B,* Inverted subcutaneous stitches.

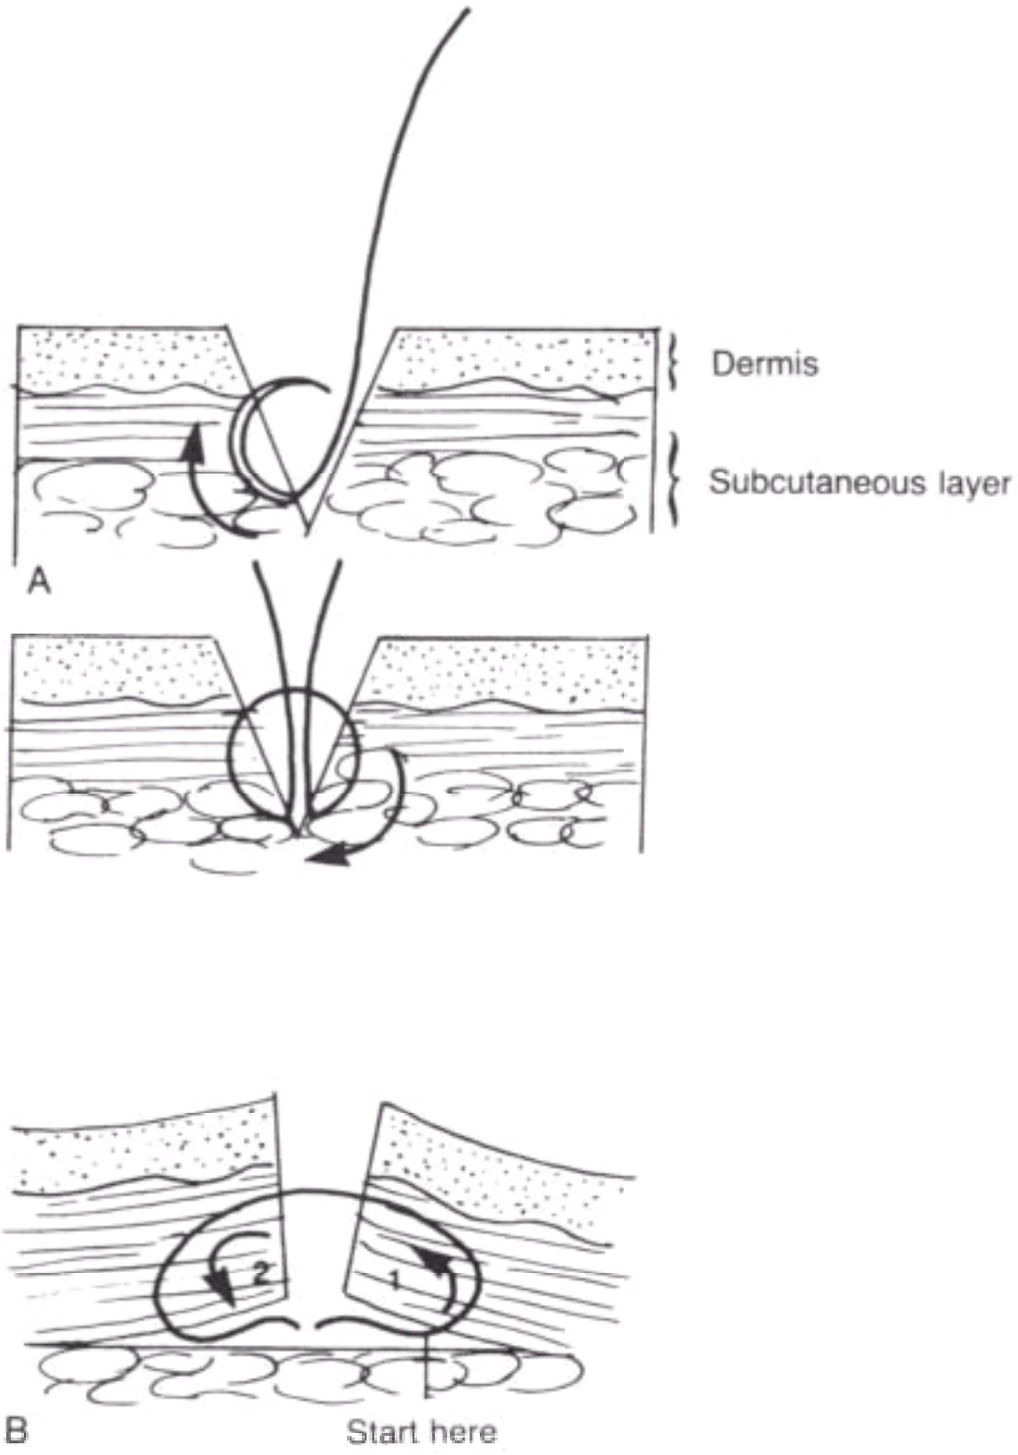

Figure 36-21 The two tails of the subcutaneous suture are pulled in the same direction, tightly opposing the edges of the wound.

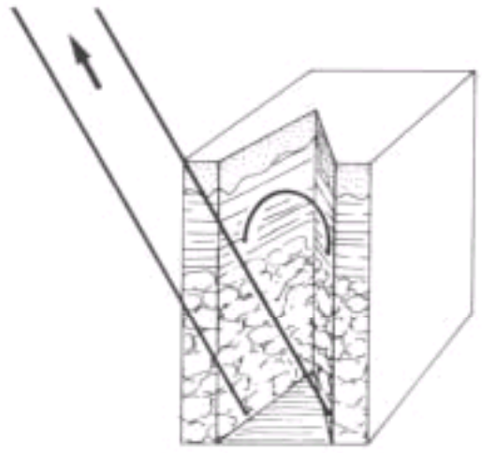

Figure 36-22 Cutting the tails of the subcutaneous suture. Note that the cutting blade is tilted away from the knot to avoid cutting it. *(Modified from Anderson CB: Basic surgical techniques. In Klippel AP, Anderson CB (eds): Manual of Outpatient and Emergency Surgical Techniques. Boston, Little, Brown, 1979. Reproduced by permission.)*

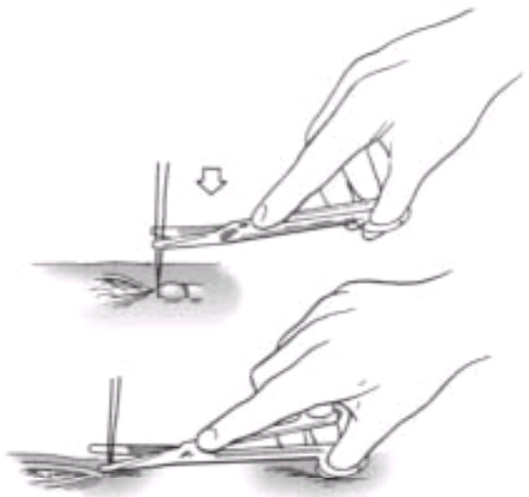

Figure 36-23 Horizontal dermal stitch. (A vertical suture also closes the deep tissue.)

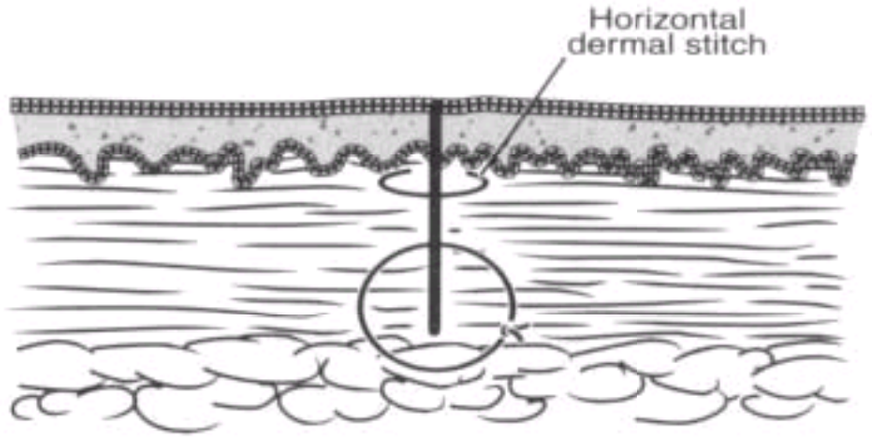

Figure 36-24 Closure of the surface of the wound in segments.

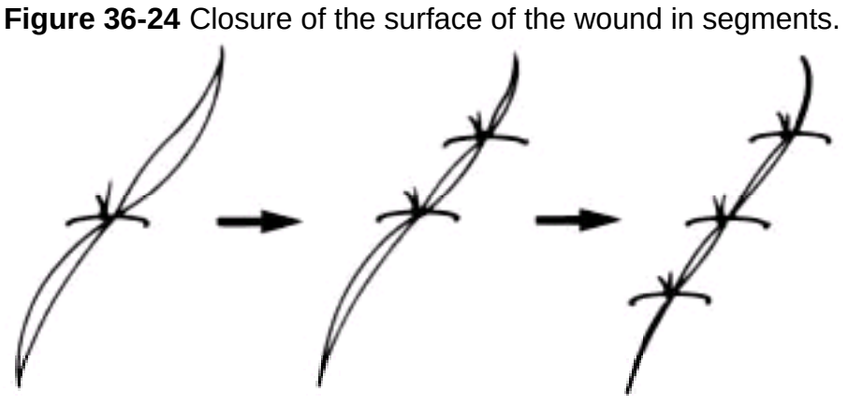

Figure 36-25 *A,* Too few stitches used. Note gaping between sutures. *B,* Too many stitches used. *C,* Correct number of stitches used for a wound under an average amount of tension.

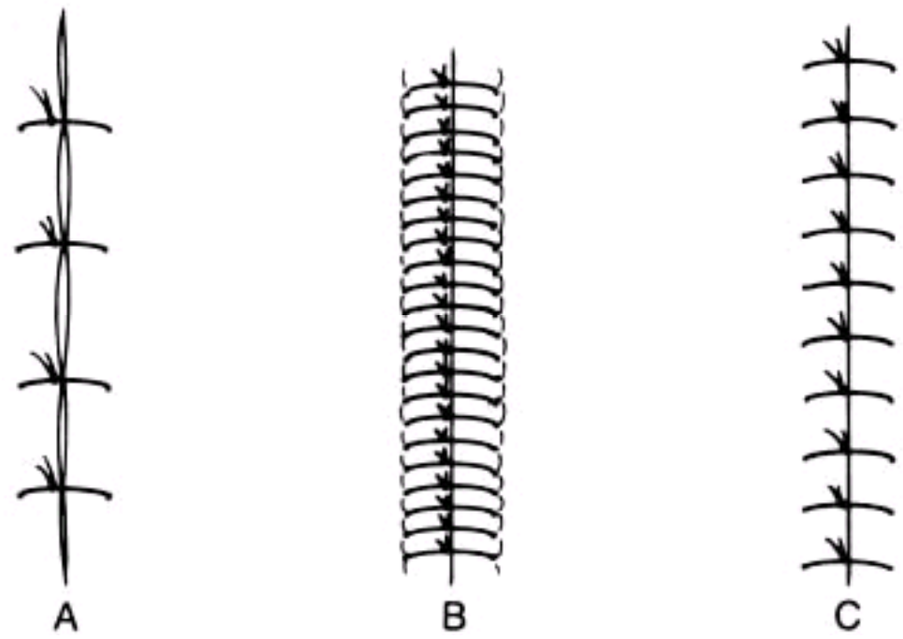

Figure 36-26 The simple suture. *A,* Hold the needle pointing down by excessively pronating the wrist so that the needle tip initially moves farther from the laceration as the needle penetrates deeper into the skin. Thus, there is more dermis in the depth of the wound than at the surface. Drive the needle tip downward and away from the cut edge, into the fat. *B,* Advance the needle into the laceration. The needle tip can be advanced directly into the opposite side. This can be achieved by rolling the needle holder as the needle enters the opposite side at the same level, and the arc pathway of the needle is controlled by retracting the skin edge. This causes more dermis to be incorporated into the depths than at the surface. As an alternative, if a small needle is used in thick skin or the distance across the wound is great, the needle can be removed from the first side, remounted on the needle holder, and advanced to the opposite side. *C,* Advance the needle upward toward the surface so that it exits at the same distance from the wound edge as on the contralateral side of the wound. Grasp the needle behind the tip and roll it out in the arc of the needle. *D,* The final position, with more tissue in the depth than the surface. The distance from each suture exit to the laceration is one half the depth of the dermis. *(Redrawn from Kaplan EN, Hentz VR: Emergency Management of Skin and Soft Tissue Wounds: An Illustrated Guide. Boston, Little, Brown, 1984, p 86. Reproduced by permission.)*

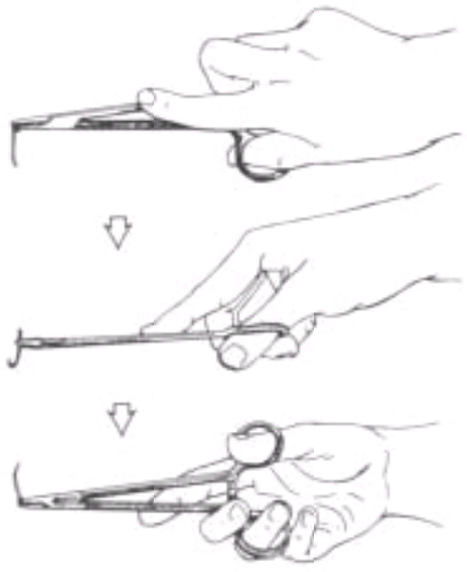

Figure 36-28 Skin edges that are everted will gradually flatten to produce a level wound surface. *(From Grabb WC: Basic technique of plastic surgery. In Grabb WC, Smith JW: Plastic Surgery: A Concise Guide to Clinical Practice. Boston, Little, Brown, 1979. Reproduced by permission.)*

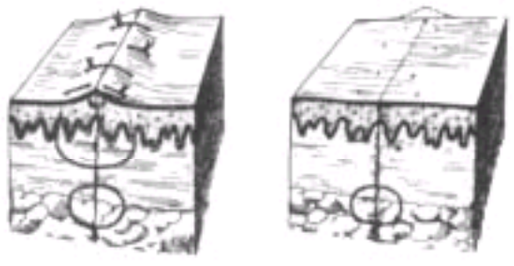

Figure 36-29 The use of a skin hook to evert the wound edge. This technique allows the operator to see the needle path, ensuring that the proper depth has been reached, and promotes eversion of the skin edges.

Figure 36-30 Eversion can often be obtained by slight thumb pressure. Care should be taken to avoid a needle stick, a common complication of this technique. *(From Converse JM: Introduction to plastic surgery. In Converse JM: Reconstructive Plastic Surgery: Principles and Procedures in Correction, Reconstruction, and Transplantation, vol 1, 2nd ed. Philadelphia, WB Saunders, 1977. Reproduced by permission.)*

Figure 36-31 The vertical mattress suture is the best technique for producing skin edge eversion. *A,* Usual type of mattress suture for approximating and everting wound edges. *B,* "Tacking" type of vertical mattress suture, extending into deep fascia to obliterate dead space under wound. Note that only a small bite of skin is included on the inner suture. *(Modified from Converse JM: Introduction to plastic surgery. In Converse JM: Reconstructive Plastic Surgery: Principles and Procedures in Correction, Reconstruction, and Transplantation, vol 1, 2nd ed. Philadelphia, WB Saunders, 1977. Reproduced by permission.)*

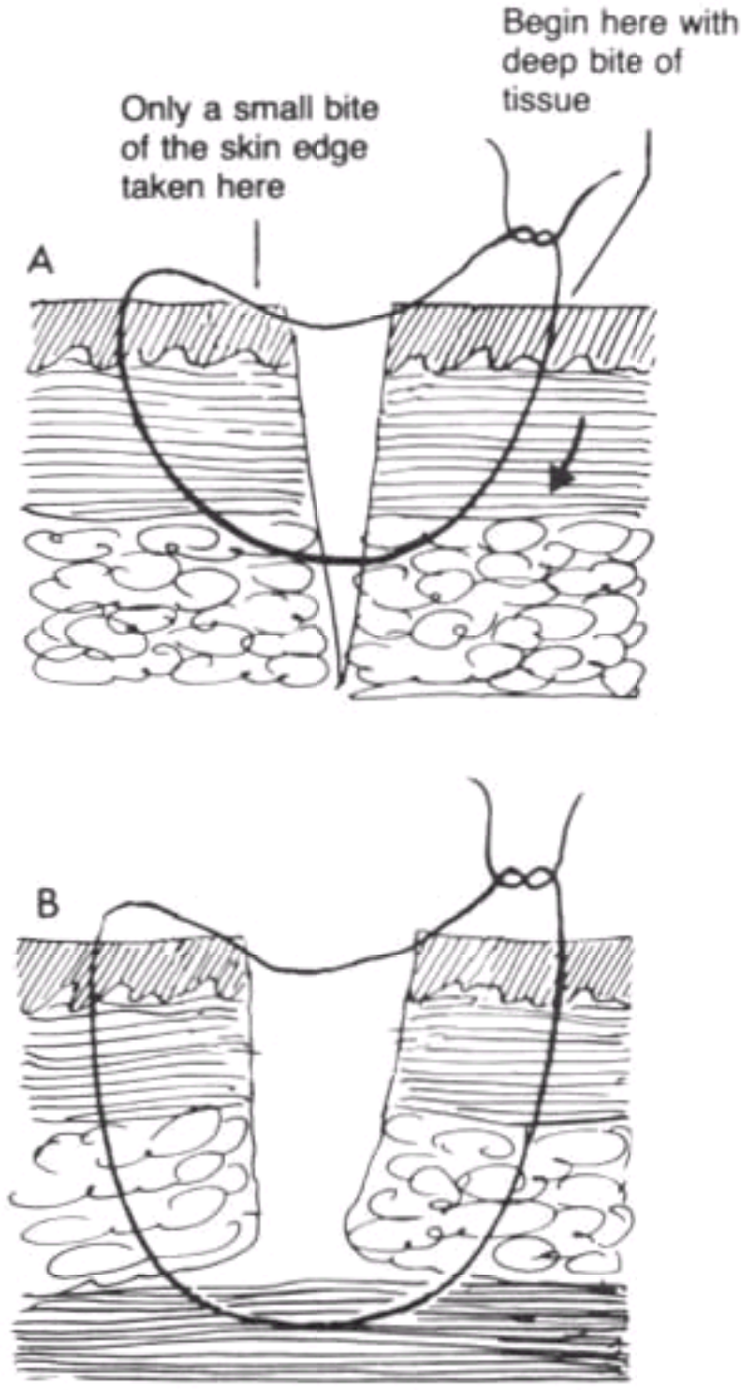

Figure 36-33 Simple interrupted stitch. Additional throws in a partially tied knot are not shown. *(From Grabb WC: Basic techniques of plastic surgery. In Grabb WC, Smith JW (eds): Plastic Surgery: A Concise Guide to Clinical Practice. Boston, Little, Brown, 1979. Reproduced by permission.)*

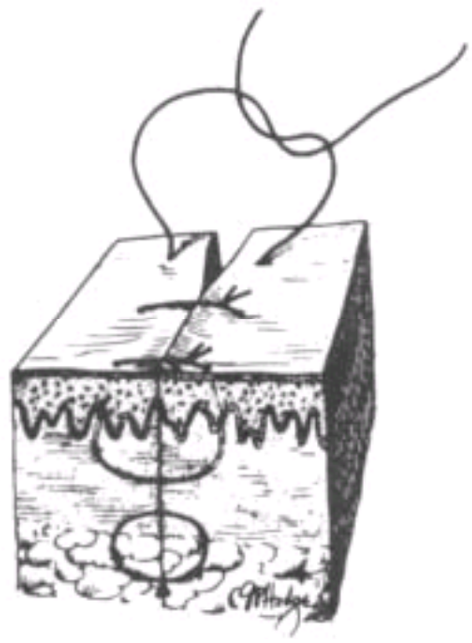

Figure 36-34 Simple continuous stitch. *(From Grabb WC: Basic techniques of plastic surgery. In Grabb WC, Smith JW (eds): Plastic Surgery: A Concise Guide to Clinical Practice. Boston, Little, Brown, 1979. Reproduced by permission.)*

Figure 36-35 Completing the simple continuous stitch. A series of square knots is tied, with the loop as one of the ties.

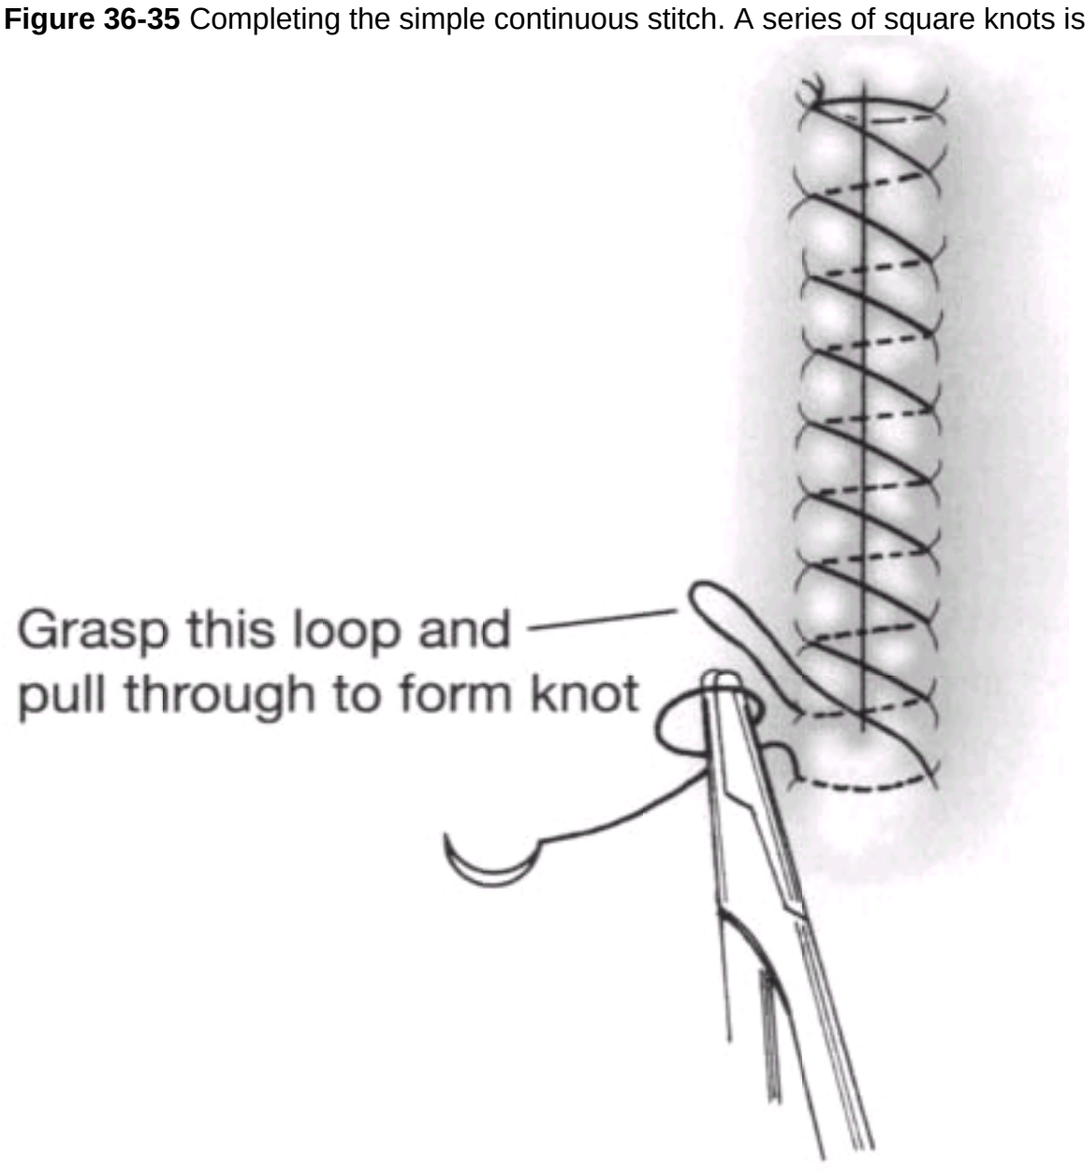

Figure 36-36 Continuous interlocking stitch. *(Modified from Suture Use Manual: Use and Handling of Sutures and Needles. Somerville, NJ, Ethicon, Inc, 1977. Reproduced by permission.)*

Figure 36-37 *A,* Pullout subcuticular stitch. The suture is introduced into the skin in line with the incision, approximately 1 to 2 cm away. *(From Grimes DW, Garner RW: "Reliefs" in intracuticular sutures. Surgical Rounds 1:46, 1978. Reproduced by permission.) B,* By backtracking each stitch slightly, one can produce a straight scar. *(From Grabb WC: Basic techniques of plastic surgery. In Grabb WC, Smith JW (eds): Plastic Surgery: A Concise Guide to Clinical Practice. Boston, Little, Brown, 1979. Reproduced by permission.)*

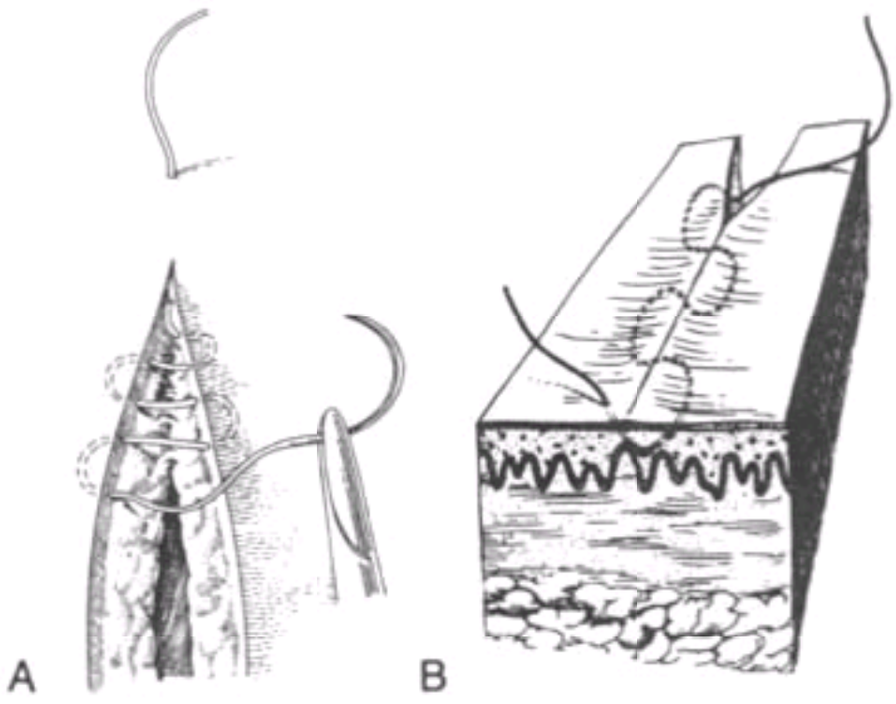

Figure 36-38 In constructing the relief to facilitate suture removal, the suture is crossed to the opposite side, going into the subcuticular area beneath the skin for approximately 2 cm before exiting *(A)*. The suture is then carried over the epidermis for approximately 2 cm *(B)* and then back under the dermis again *(C)*. Reentry is made into the wound area *(D)* at approximately the same location where the next "bite" would have been placed had the relief not been used. *(From Grimes DW, Garner RW: "Reliefs" in intracuticular sutures. Surgical Rounds 1:47, 1978. Reproduced by permission.)*

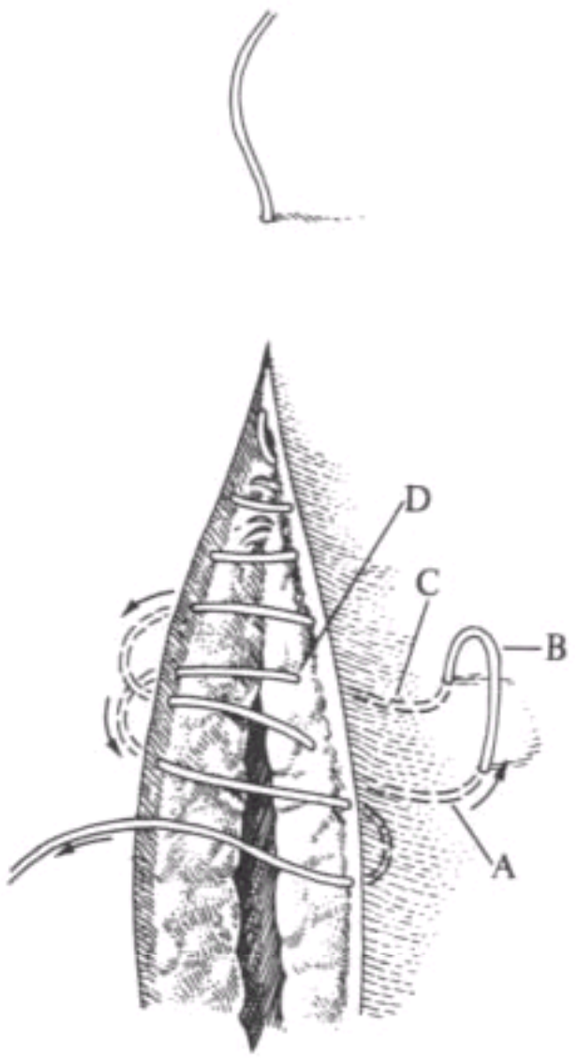

Figure 36-39 Subcuticular closure without epidermal penetration. *A,* The initial knot is secured in the dermal or subcutaneous tissue. *B,* The short strand is cut, and the needle is inserted into the dermis at the apex of the wound. *C,* The needle in the dermis, close to the corner of the wound and exiting the wound at the same horizontal level. *D,* After the subcuticular stitch has been completed, a knot is tied with the tail and the loop of the suture. *(Modified from Stillman RM: Wound closure: Choosing optimal materials and methods. ER Reports 2:43, 1981.)*

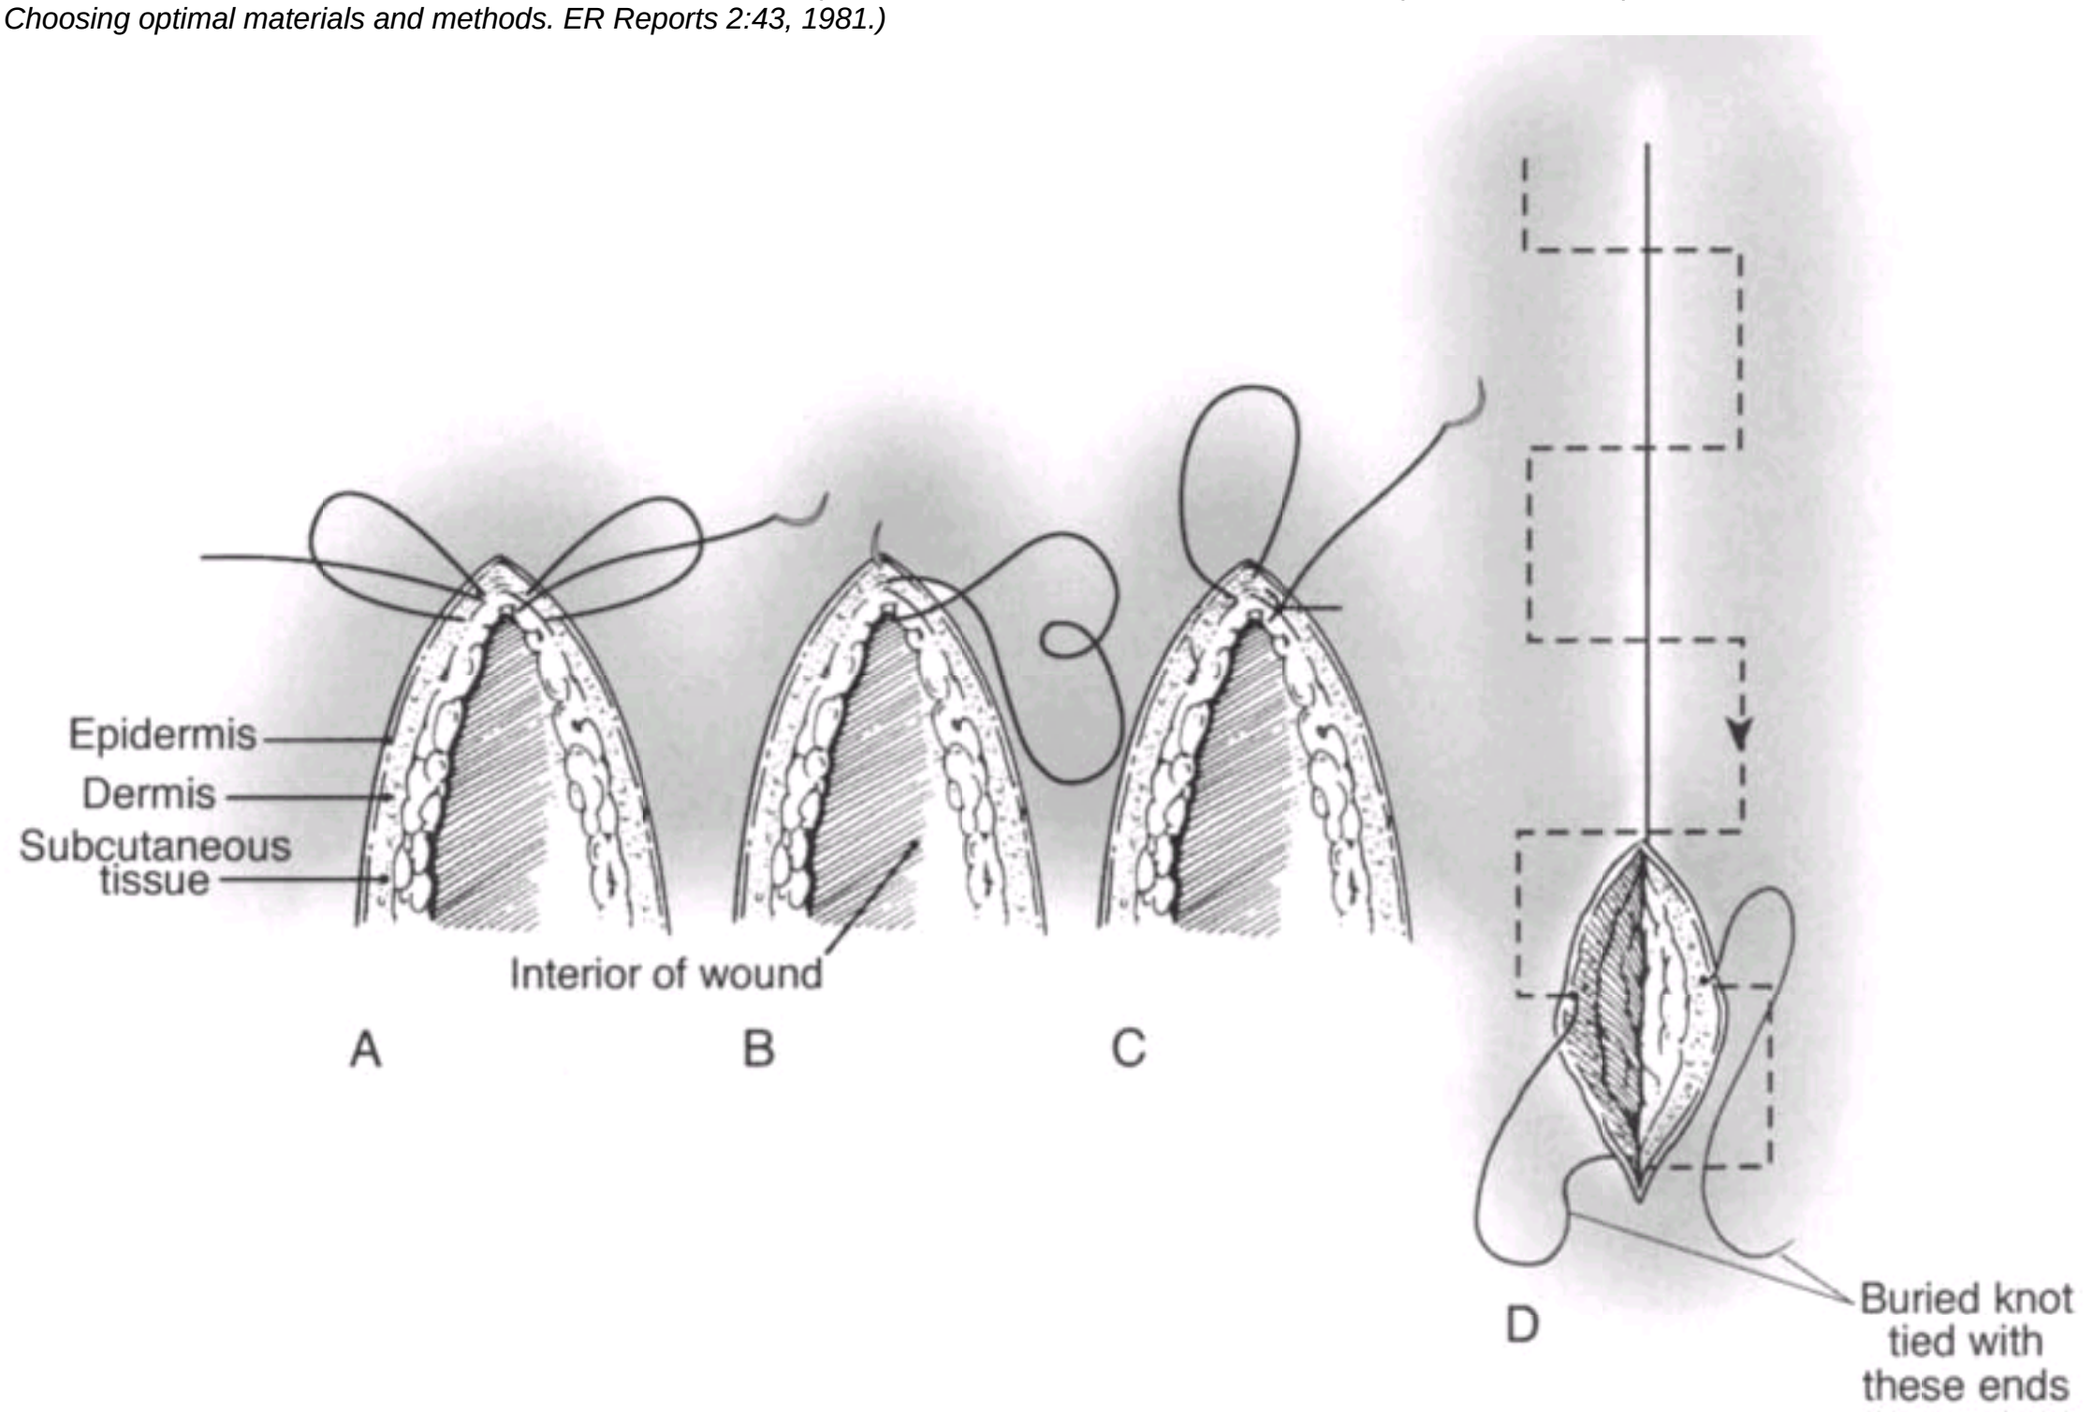

Figure 36-40 Interrupted subcuticular stitch (also called a *horizontal dermal stitch*). Absorbable sutures are used. A deep vertical suture is also shown.

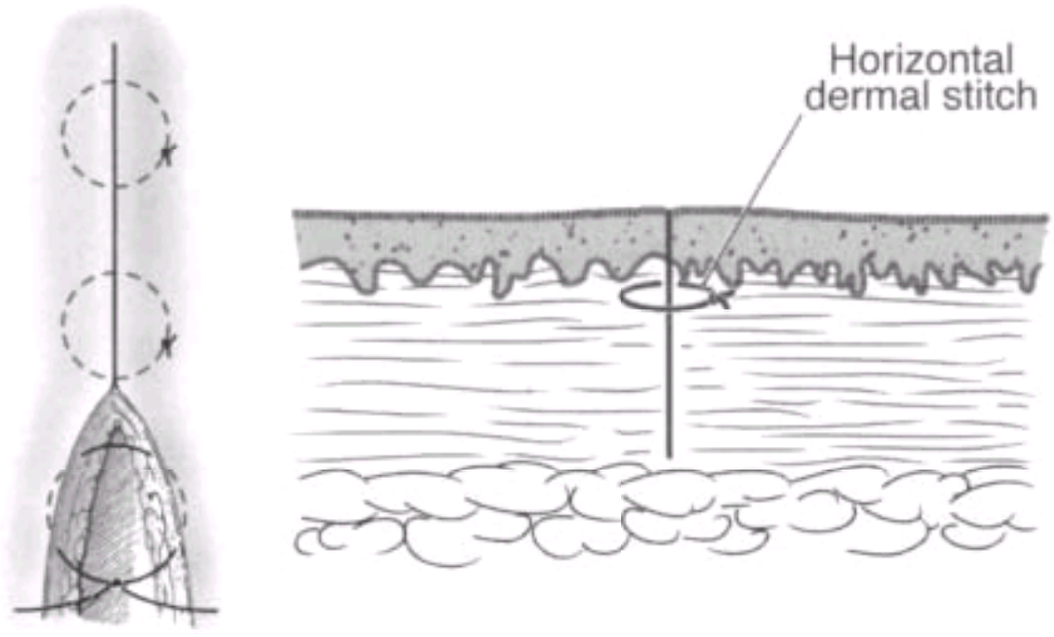

Figure 36-41 Vertical mattress stitch. The key to a tight closure is to place the inner sutures very close to the suture line (wound edge). *(From Grabb WC: Basic techniques of plastic surgery. In Grabb WC, Smith JW (eds): Plastic Surgery: A Concise Guide to Clinical Practice. Boston, Little, Brown, 1979. Reproduced by permission.)* See also Fig. 36-31 .

Figure 36-42 *A*, Horizontal mattress stitch. *B,* The dorsum of the hand, foot, or finger is an ideal place for a horizontal mattress suture to evert the wound edges. The relatively thin skin in these areas precludes the use of vertical mattress sutures. *(A from Grabb WC: Basic techniques of plastic surgery. Grabb WC, Smith JW (eds): Plastic Surgery: A Concise Guide to Clinical Practice. Boston, Little, Brown, 1979. Reproduced by permission.)*

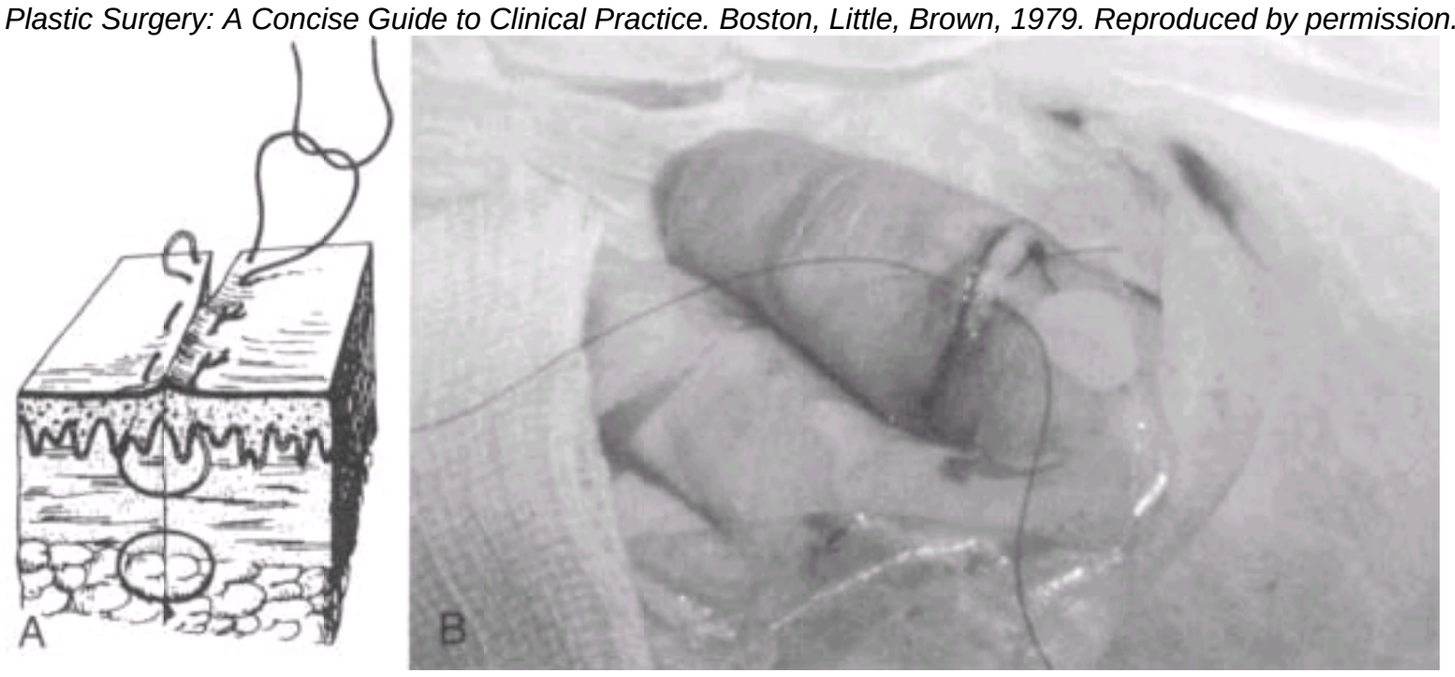

Figure 36-43 Half-buried horizontal mattress stitch. *(From Grabb WC: Basic techniques of plastic surgery. In Grabb WC, Smith JW: Plastic Surgery: A Concise Guide to Clinical Practice. Boston, Little, Brown, 1979. Reproduced by permission.)*

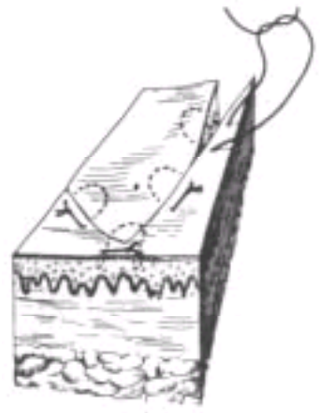

Figure 36-44 *A* and *B,* Approximation of a corner flap with a half-buried horizontal mattress stitch. Because of its applicability to this closure, the stitch is often called a *corner stitch*.

Figure 36-49 *A* and *B,* V-Y advancement flap. *(From Rosen P, Sternbach G: Atlas of Emergency Medicine. Baltimore, Williams & Wilkins, 1979, p 132. Reproduced by permission.)*

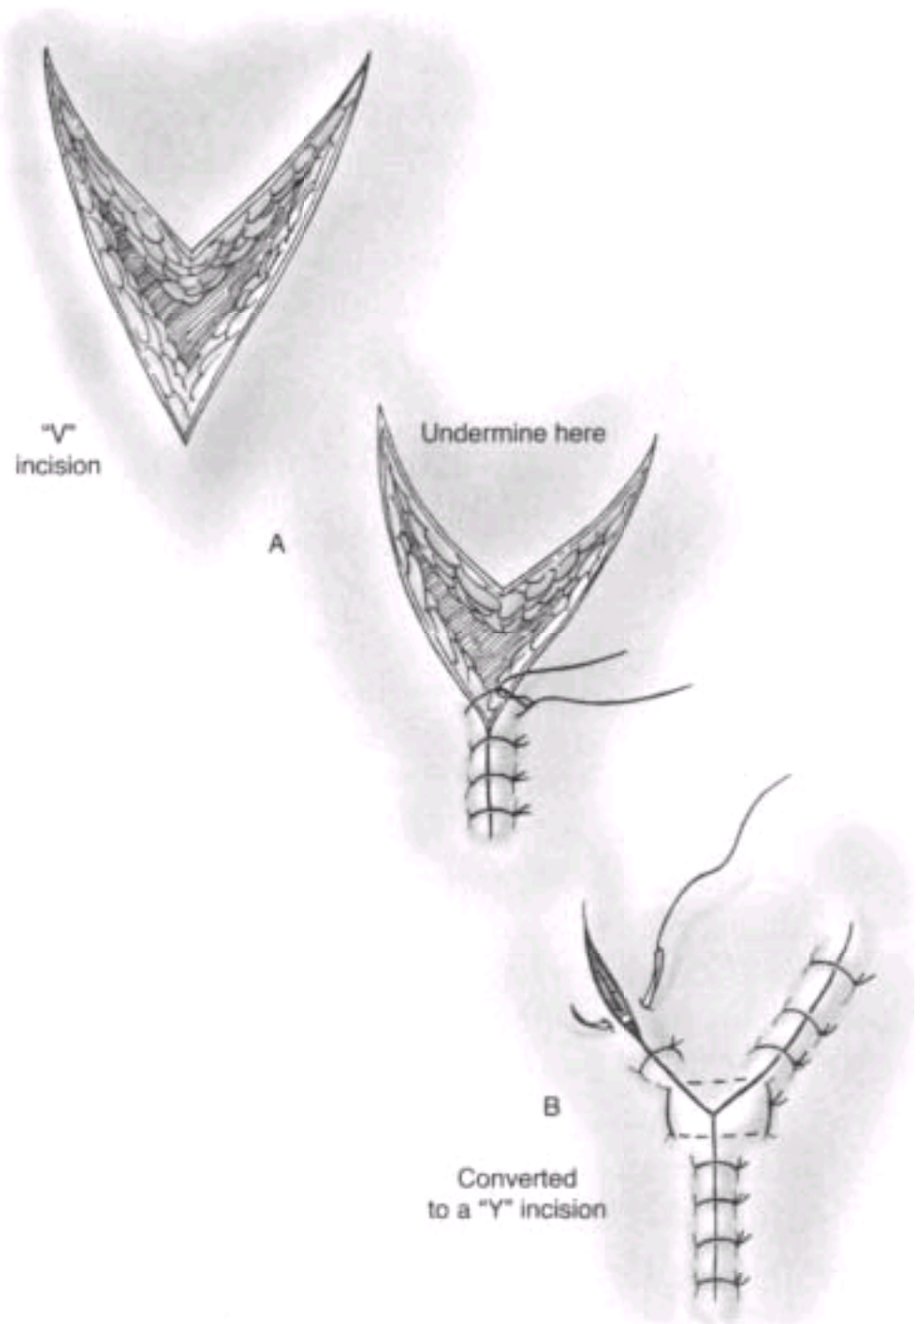

Figure 36-50 View from *above* stellate laceration, showing closure with half-buried mattress stitches.

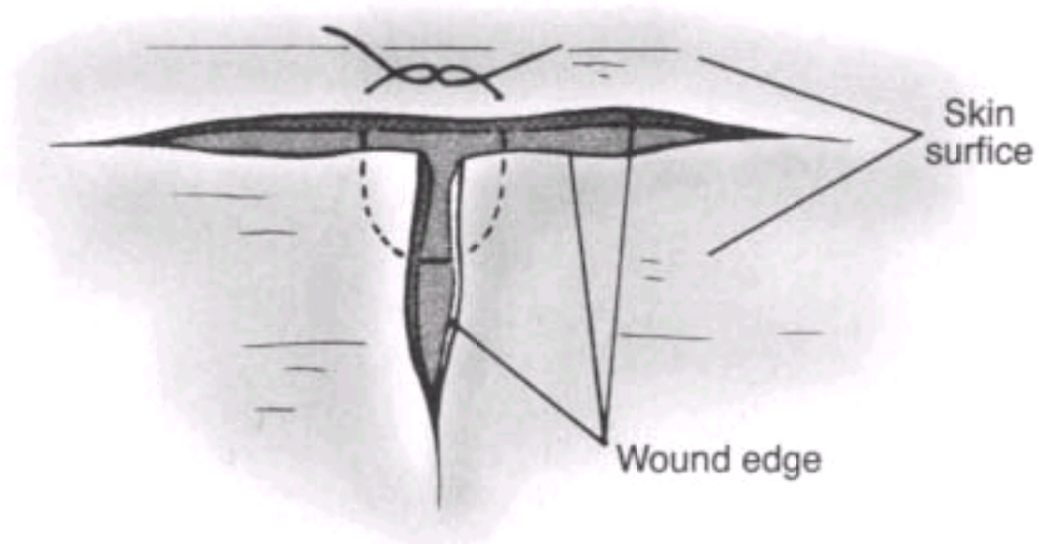

Figure 36-51 Lacerations following natural skin lines (shown here) heal with a less noticeable scar than those that are oblique or perpendicular to natural lines (or wrinkles).

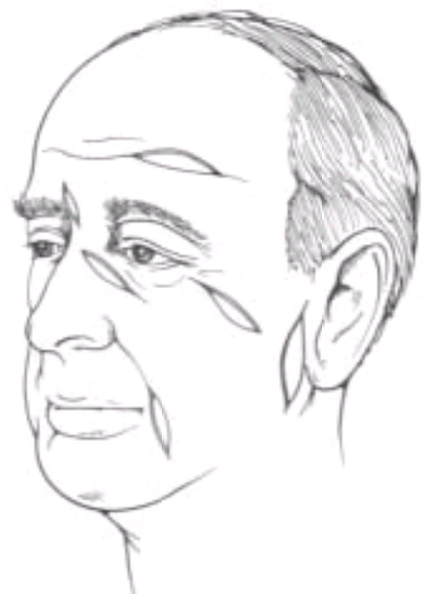

Figure 36-52 Wound closure tape can be used to provide additional support while sutures are in place and after they are removed. This may be especially useful in cosmetic areas, such as the face.

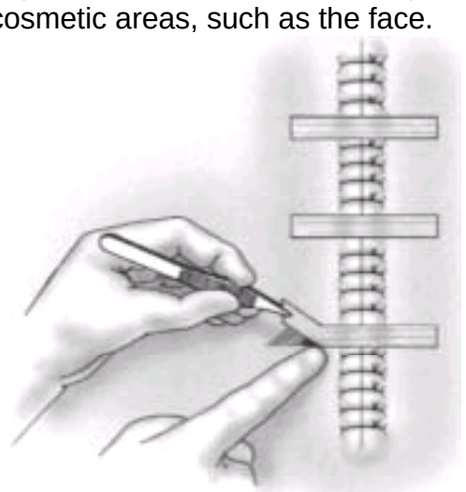

Figure 36-53 *A*, Elevation of a forehead flap. The "trap-door effect" is a natural healing process of elliptical or round lacerations. Patients should be advised of this phenomenon. *B,* This flap-type laceration of the knee will heal with a puffed-up center (trap door), even under the best of circumstances. *(A from Grabb WC, Kleinert HE: Technics in Surgery: Facial and Hand Injuries. Somerville, NJ, Ethicon, Inc., 1980. Reproduced by permission.)*

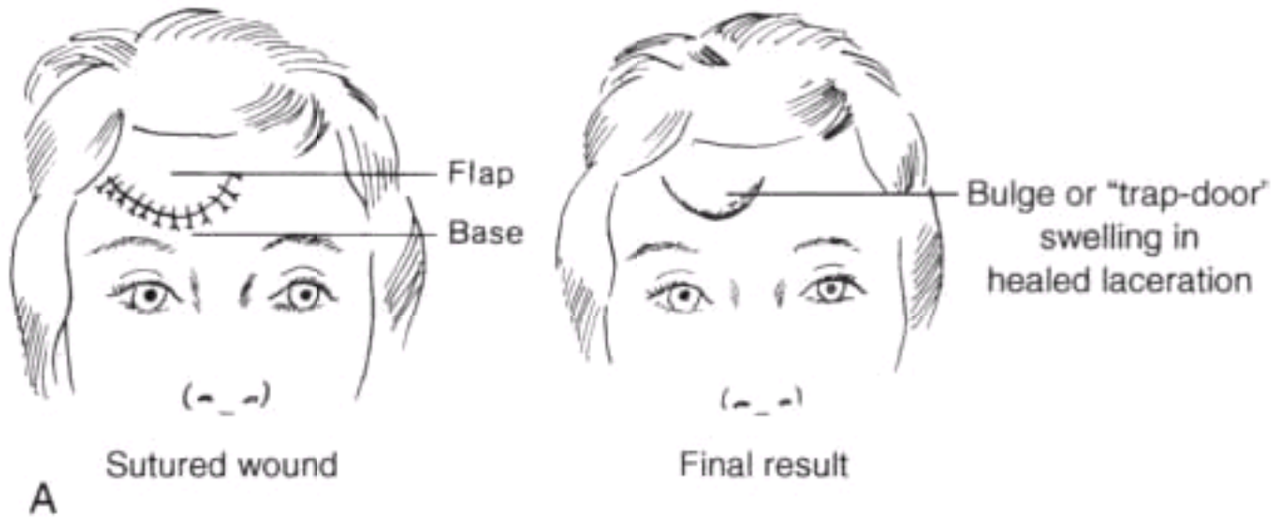

Figure 36-54 *A,* Repair of a U-shaped flap laceration with a superiorly oriented base to minimize the trap door effect. *A,* Excision of edges. *B,* undermining. *C,* Approximation of SQ tissue on the flap to SQ tissue at a deeper level on the base; *D,* skin closure. *B* and *C,* When a laceration in the thin skin of the forehead borders the thicker skin of the scalp, a horizontal mattress suture with an intradermal component can enhance healing by bringing tissues to the same plane. These figures show eversion of thinner skin to obtain adequate approximation with thicker scalp tissue. *(B from Converse JM: Introduction to plastic surgery. In Converse JM (ed): Reconstructive Plastic Surgery: Principles and Procedures in Correction, Reconstruction, and Transplantation, vol 1, 2nd ed. Philadelphia, WB Saunders, 1977. Reproduced by permission.)*

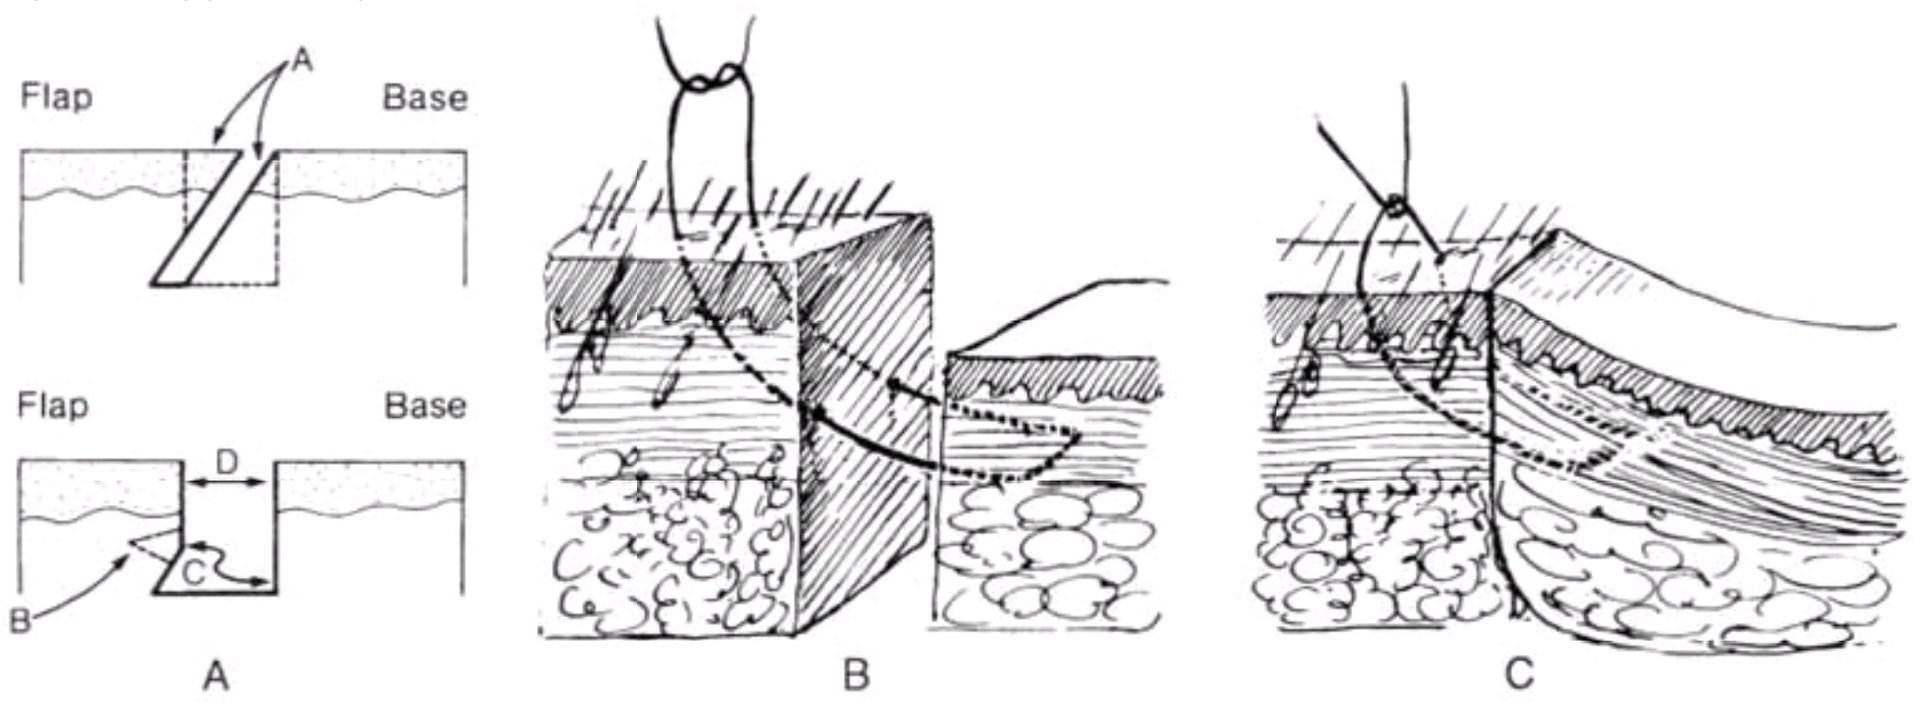

Figure 36-55 *A,* Repair of a simple lid laceration. The first sutures are placed at the lid margin so that the lid can be extended by traction with a hemostat. Interrupted absorbable sutures are used to close the tarsus (1), followed by separate closure of the muscle layer with absorbable sutures (2), and finally by closure of the skin with interrupted 8-0 black silk or synthetic sutures (3). Such a repair should not be performed by the novice. *B*, A method of identifying and repairing the canaliculus. This repair is best left to the ophthalmologist, but recognizing the potential for a canaliculus injury is the task at hand in the emergency department. *C,* Deep laceration of the left upper lid with herniation of orbital fat. For fat to prolapse, the orbital septum (and potentially the globe itself) must have been perforated. This is a wound requiring operating room exploration and repair. *D*, Lacerations of the ear require a special repair aimed at covering cartilage and preventing hematoma formation. With this through-and-through laceration of the margin of the pinna, the cartilage is trimmed just enough to allow the skin to be approximated to cover all exposed cartilage. The repair is easiest if the posterior pinna is sutured first.

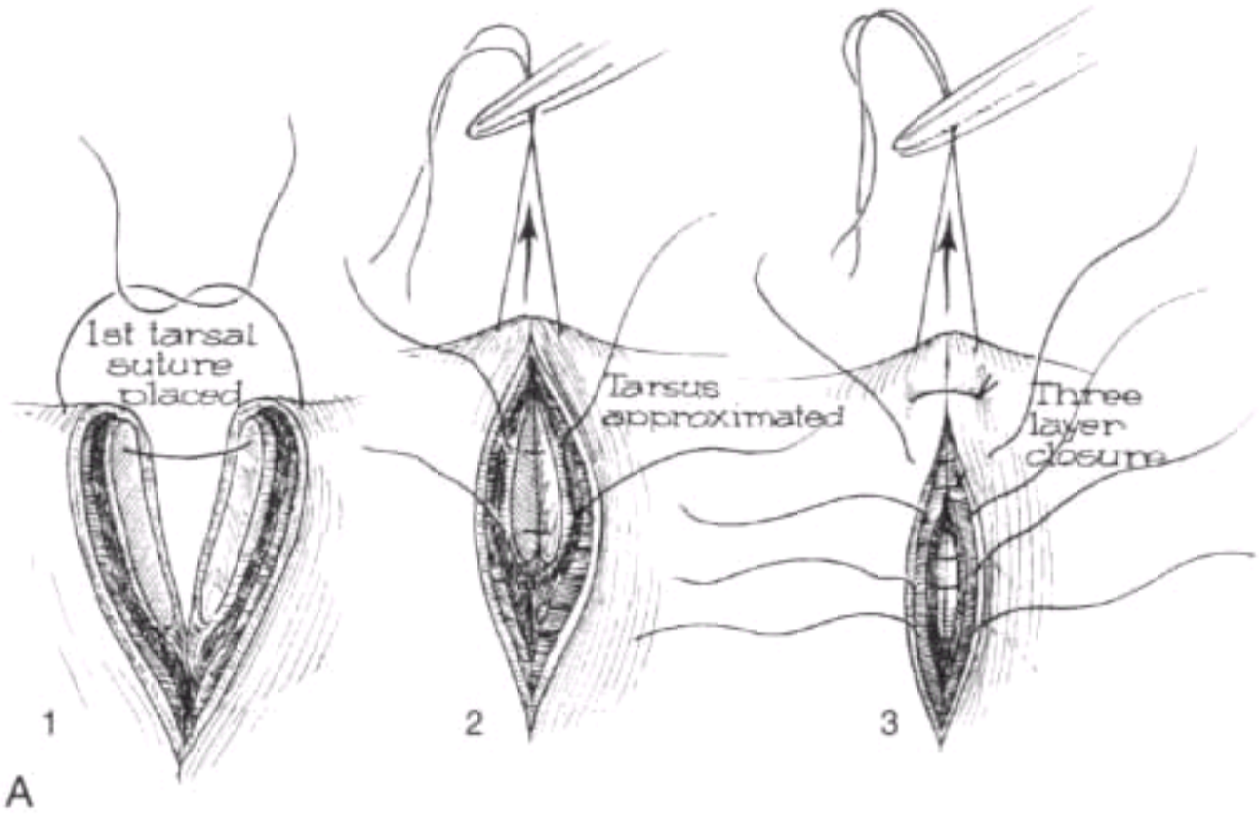

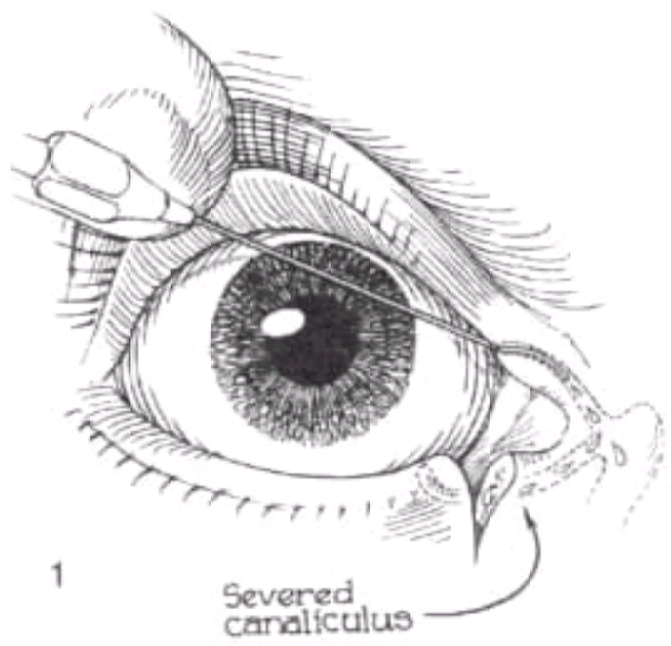

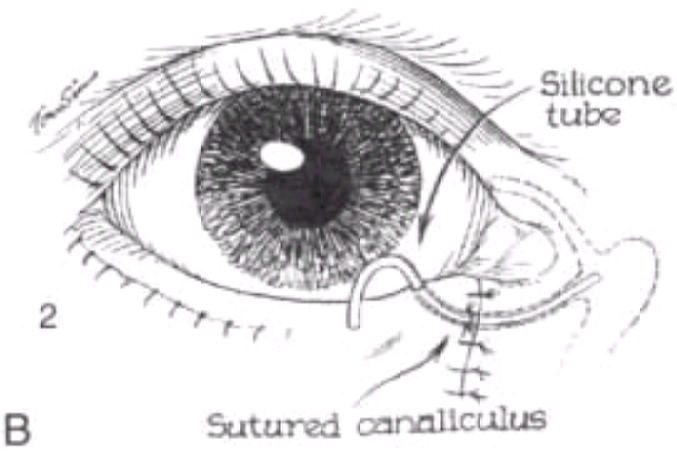

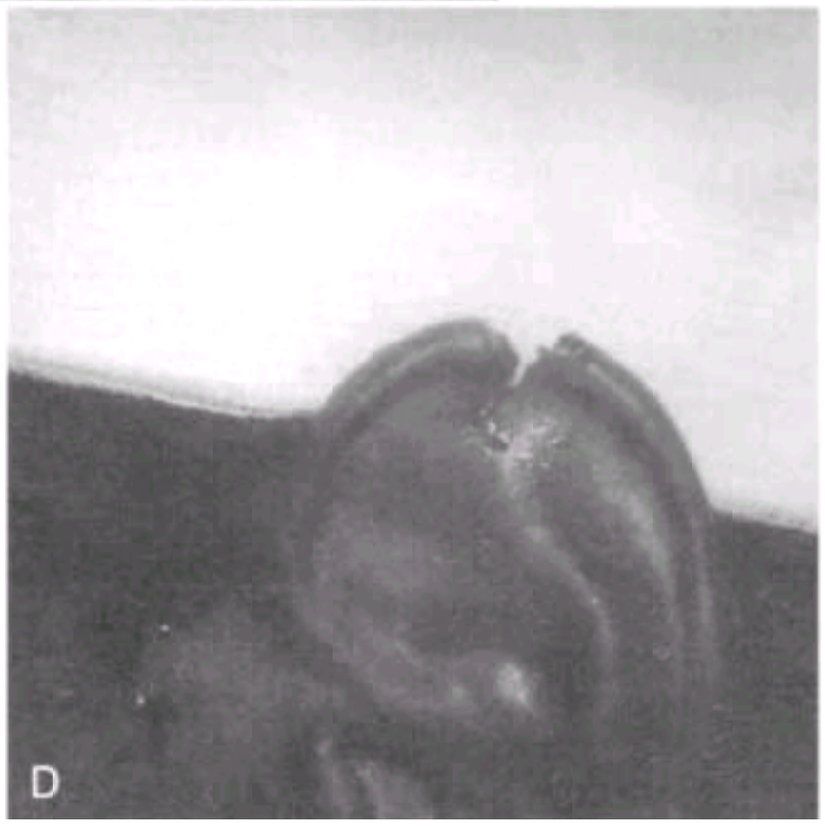

Figure 36-56 *A,* In the repair of lip lacerations, the first stitch should be placed at the vermilion-cutaneous border to obtain proper alignment. *(A from Grabb WC, Kleinert HE: Technics in Surgery: Facial and Hand Injuries. Somerville, NJ, Ethicon, Inc., 1980. Reproduced by permission.)*

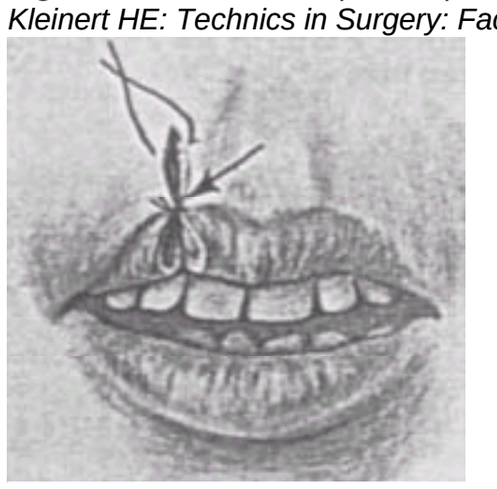

Figure 36-57 Through-and-through injuries and lacerations of the tongue margins require sutures to achieve anatomic healing. Dexon, Vicryl, or silk sutures are ideal for suturing the tongue surface. Bleeding is usually controlled with direct pressure and local infiltration of lidocaine with epinephrine. For through-and-through lacerations, the muscle layer should be closed separately (with absorbable sutures) to prevent hematoma formation. In general, buried sutures are better tolerated by the patient.

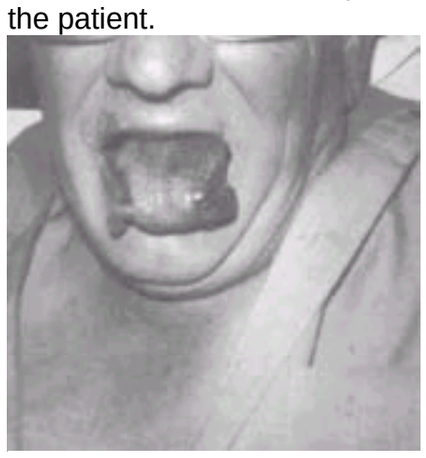

Figure 36-58 *A*, Anatomy of the scalp. Note that the skin, superficial fascia, and galea are adherent and constitute the outer layer. Blood vessels in the fascia are the major source of the blood loss noted in scalp lacerations. *B,* To temporarily control bleeding from vessels in the fascia, the galea can be everted to compress the fascia. *C,* The galea has been transected in wounds that gape open like this one, and to achieve hemostasis and obtain the best closure, the galea should be sutured. This is most easily accomplished with the use of a long needle, forceps, and 3-0 sutures that incorporate the skin, SQ tissue, and galea in a single bite *(D)*. In this figure, the needle is passing through the galea from the underside, having traversed all three layers on the other side of the laceration. If this technique is used, individual buried sutures in the galea are not required, and hemostasis is ensured. At the base of this wound is the periosteum, a tissue-like covering of the skull. In *C*, the galea is actually adherent to the avulsed flap; the anesthetic needle is touching the underside of the galea. A simple laceration that does not gape open *(E)* means the galea is intact. It can be easily closed with superficial sutures or staples.

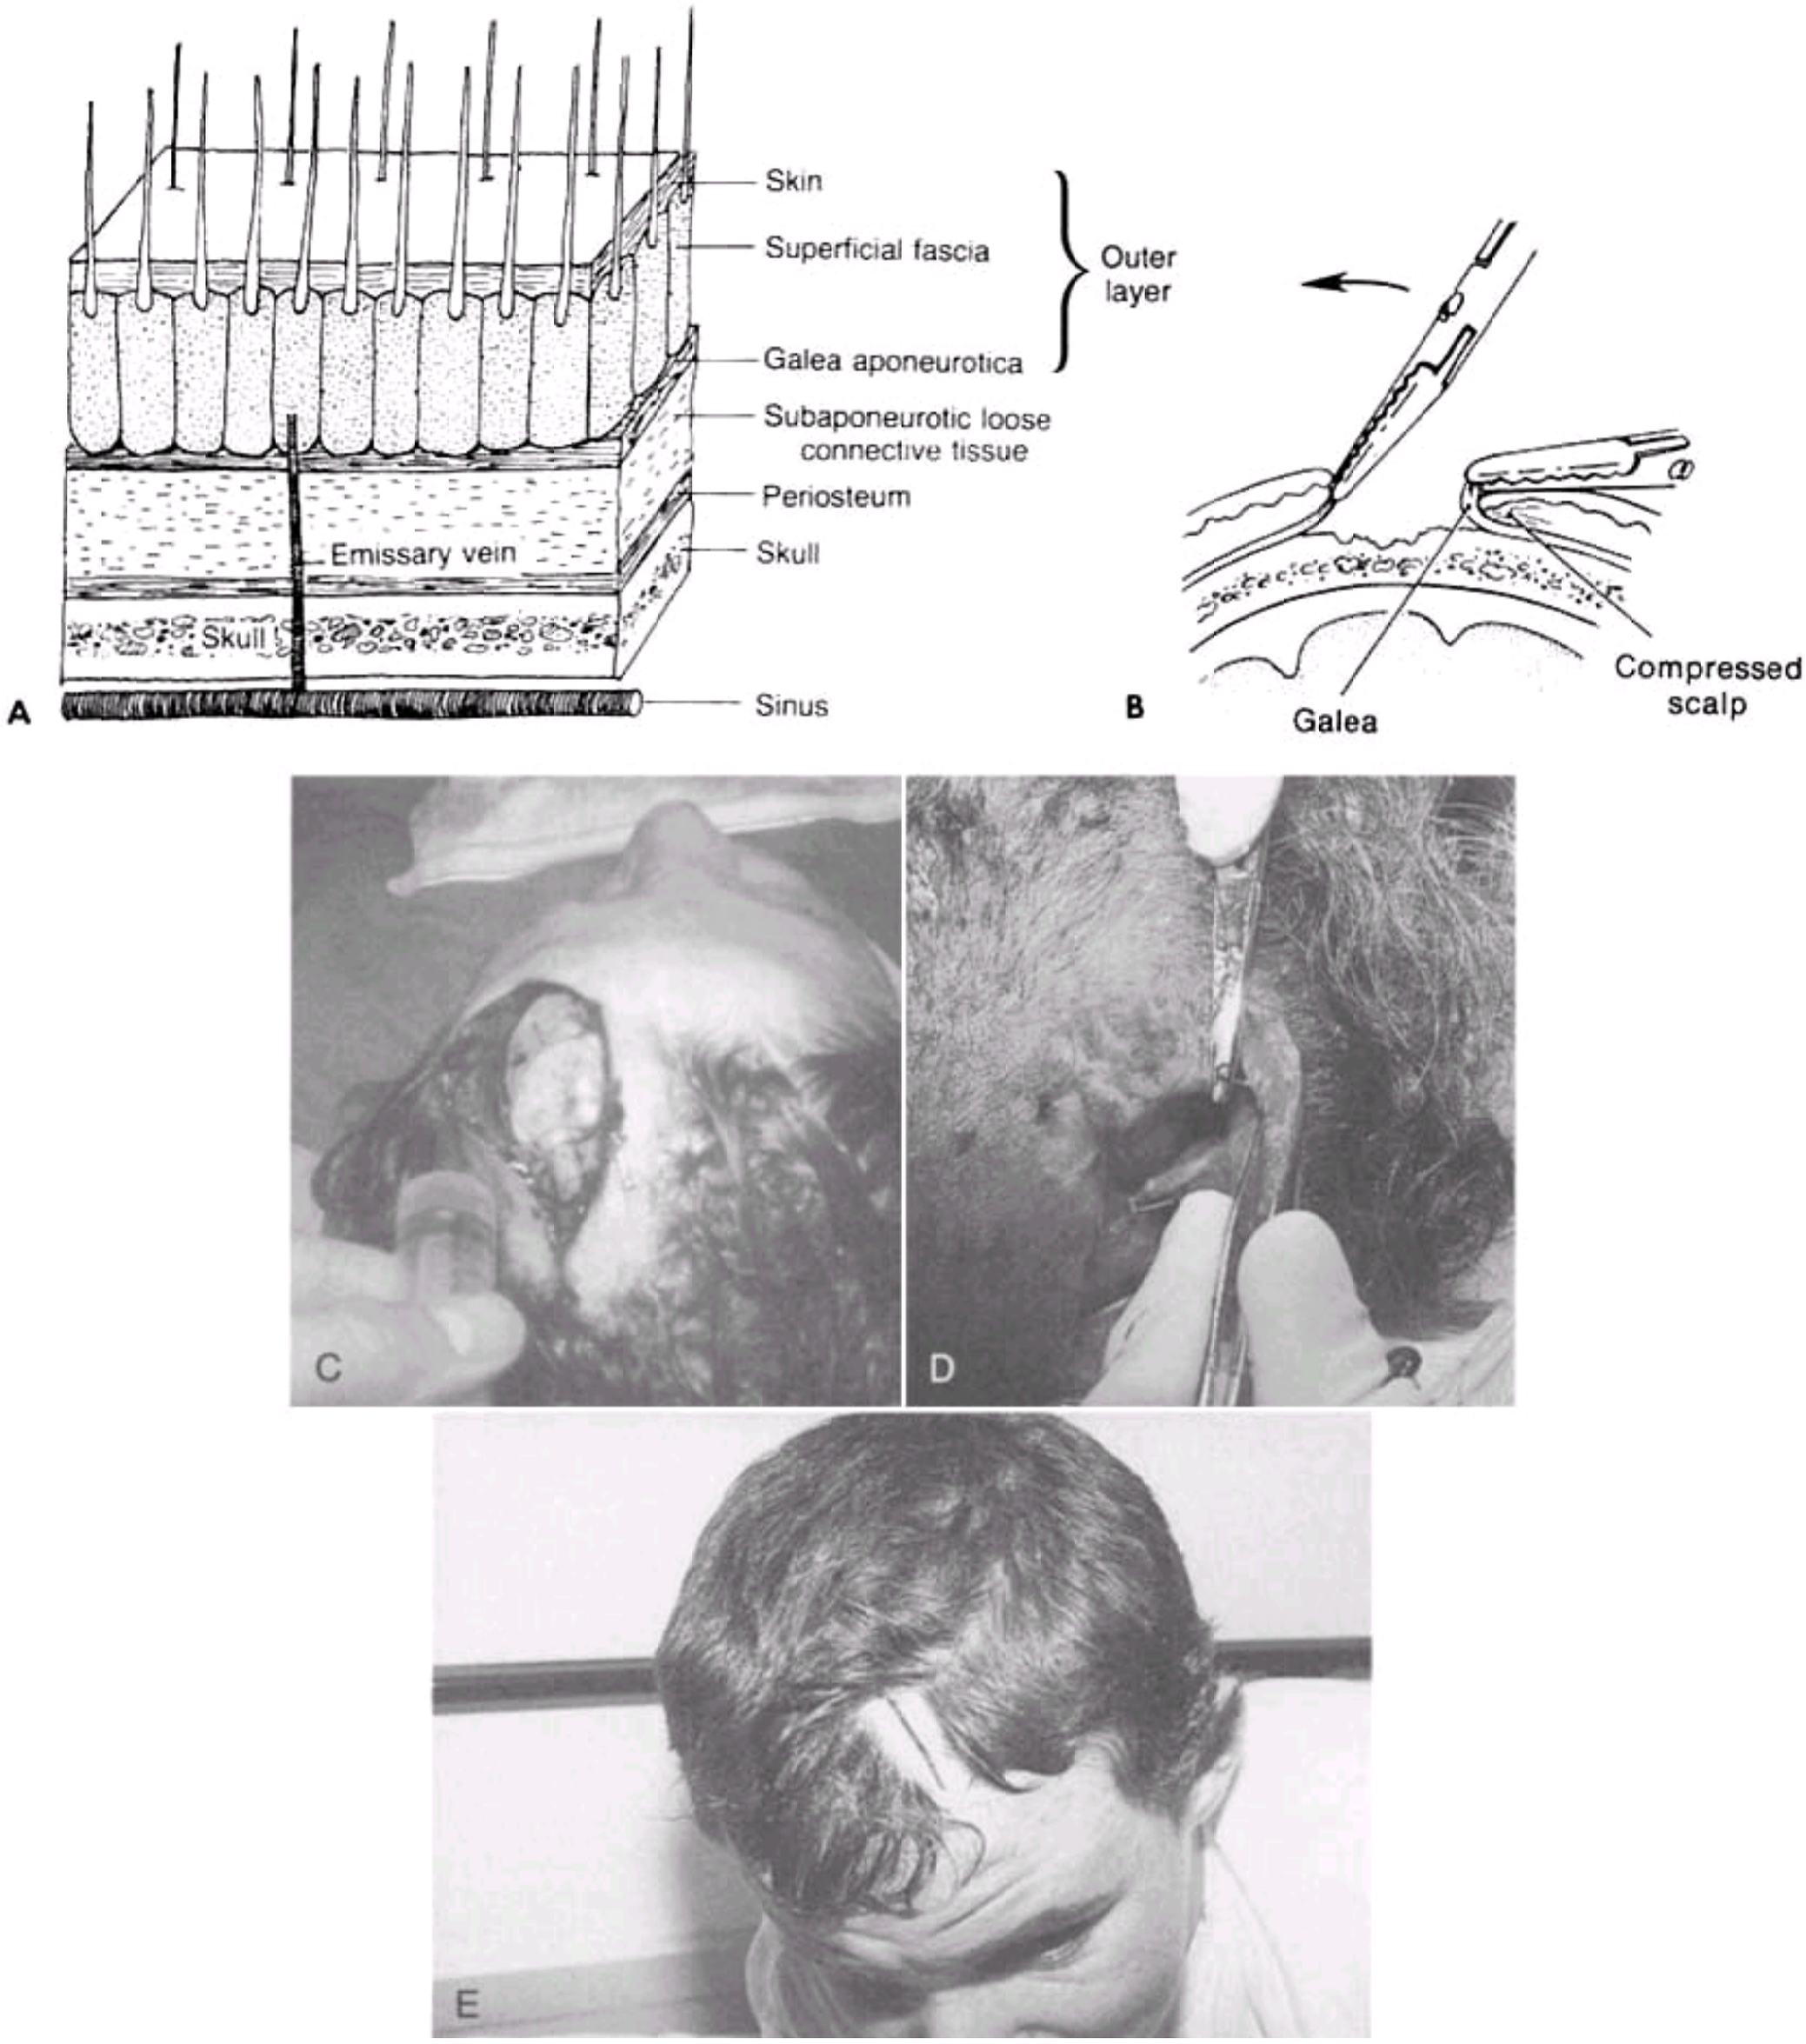

Figure 36-59 Large partial scalp avulsion.

Figure 36-60 *A,* To achieve hemostasis of a scalp laceration, a wide, tight, sterilized rubber band or Penrose drain may be placed around the forehead and occiput. This compresses the arterial supply to the scalp. *B,* Alternatively the wound margins can be temporarily clamped to control hemorrhage. Raney scalp clips and accompanying instrument for application to scalp wound edges are shown.

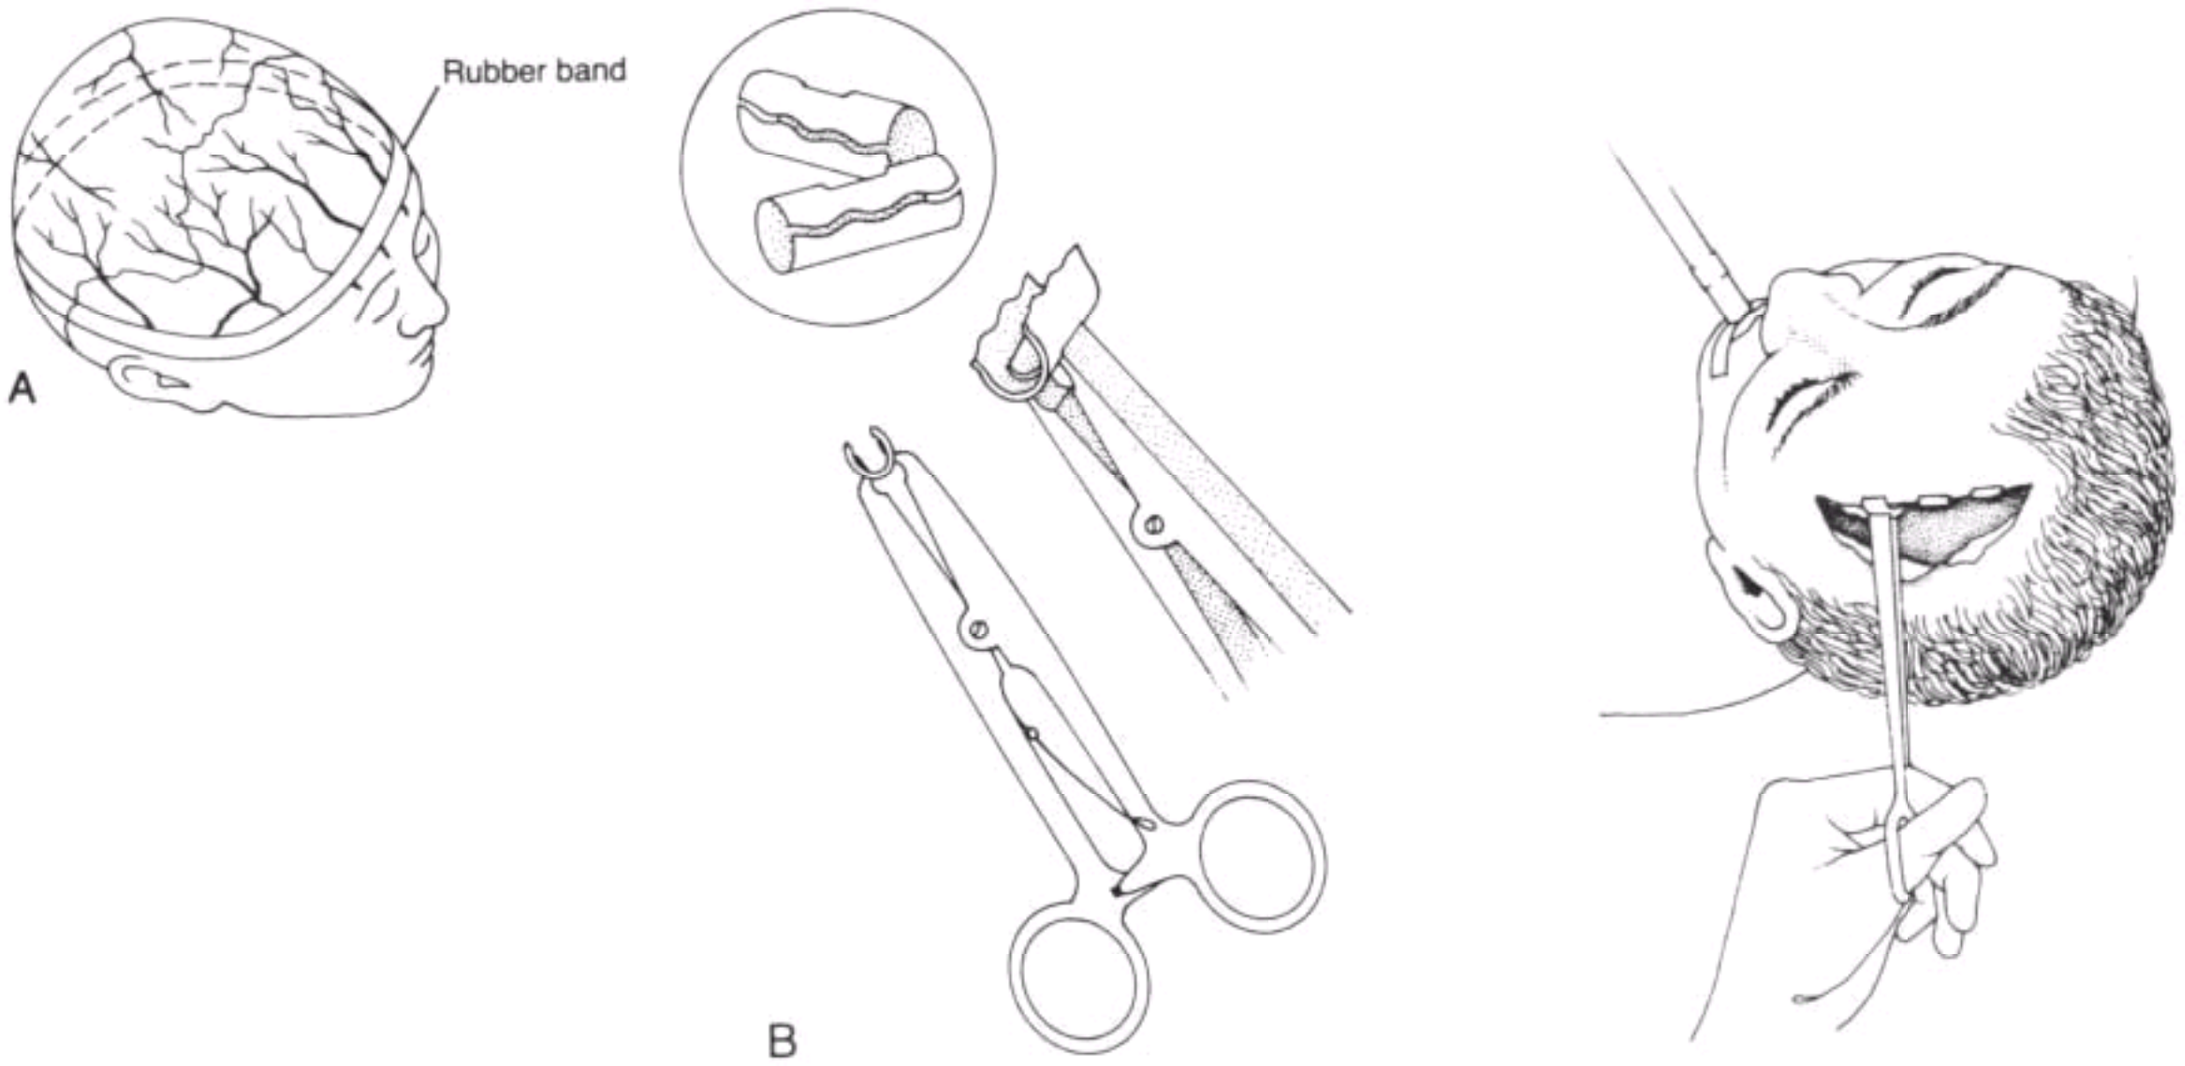

Figure 36-61 Anatomy of the fingernail. The fingernail rests on the nailbed, also termed the *matrix*. The distal nail covers the sterile matrix; the proximal nail arises from and covers the germinal matrix. The tissue adherent to the proximal dorsal nail is the eponychium (also termed the *cuticle*), and the potential space between the nail and the eponychium is the nail fold.

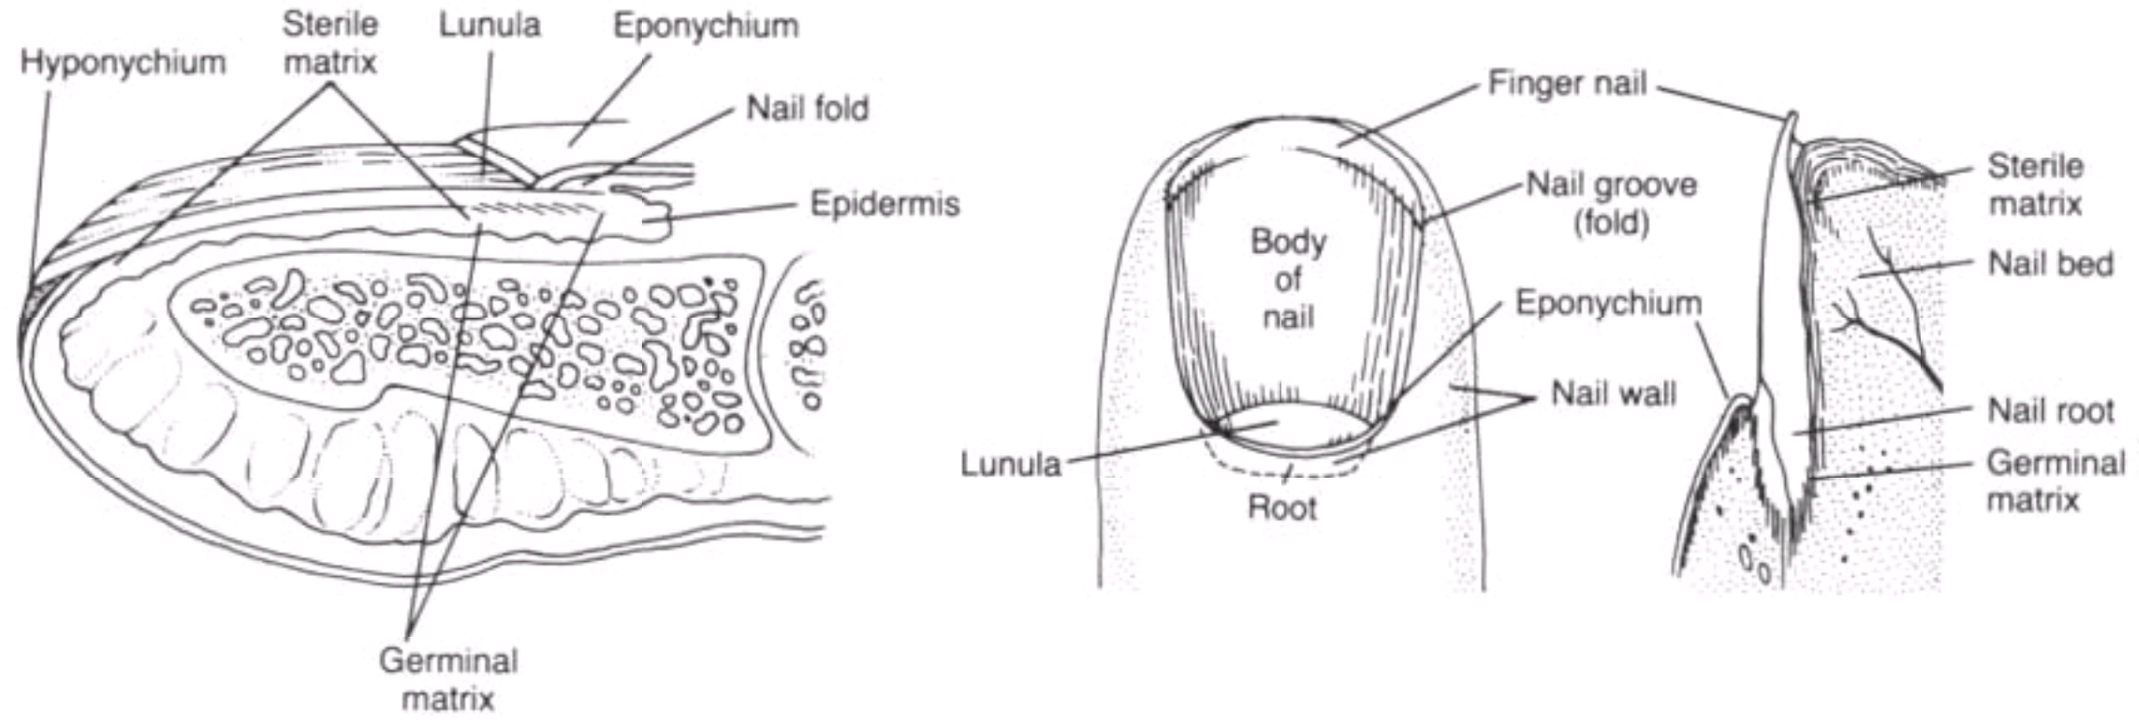

Figure 36-62 This subungual hematoma occupies about two thirds of the nail and should be drained by simple nail trephination. The injury does not require nailbed repair, because the nail is still firmly attached to the matrix. Even though there must be a nail matrix laceration (the source of the bleeding), the cosmetic result will be excellent. The presence of an underlying digital tuft fracture does not change management (see also description of nail trephination in Chapter 38).

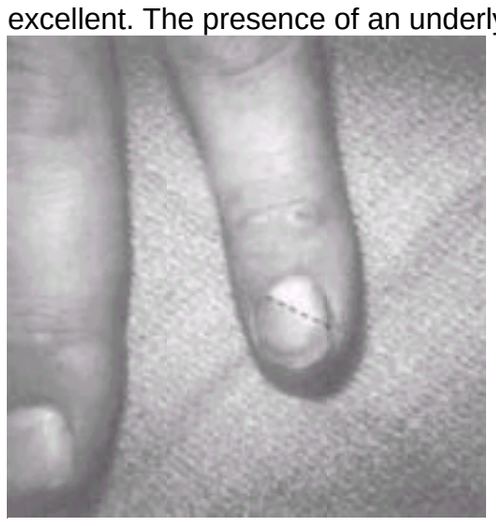

Figure 36-63 This fingernail was avulsed at the base *(A)*, a common result of having a door slam on the digit. Since the nail is mobile *(B)* and there is subungual bleeding, the nail can be removed and the nailbed inspected. Any large laceration should be meticulously repaired. Absorbable sutures size 6-0 or smaller should be used. After repair, the nail is replaced under the eponychium (cuticle). See Figure 36-68 for a simple technique for removal of the fingernail.

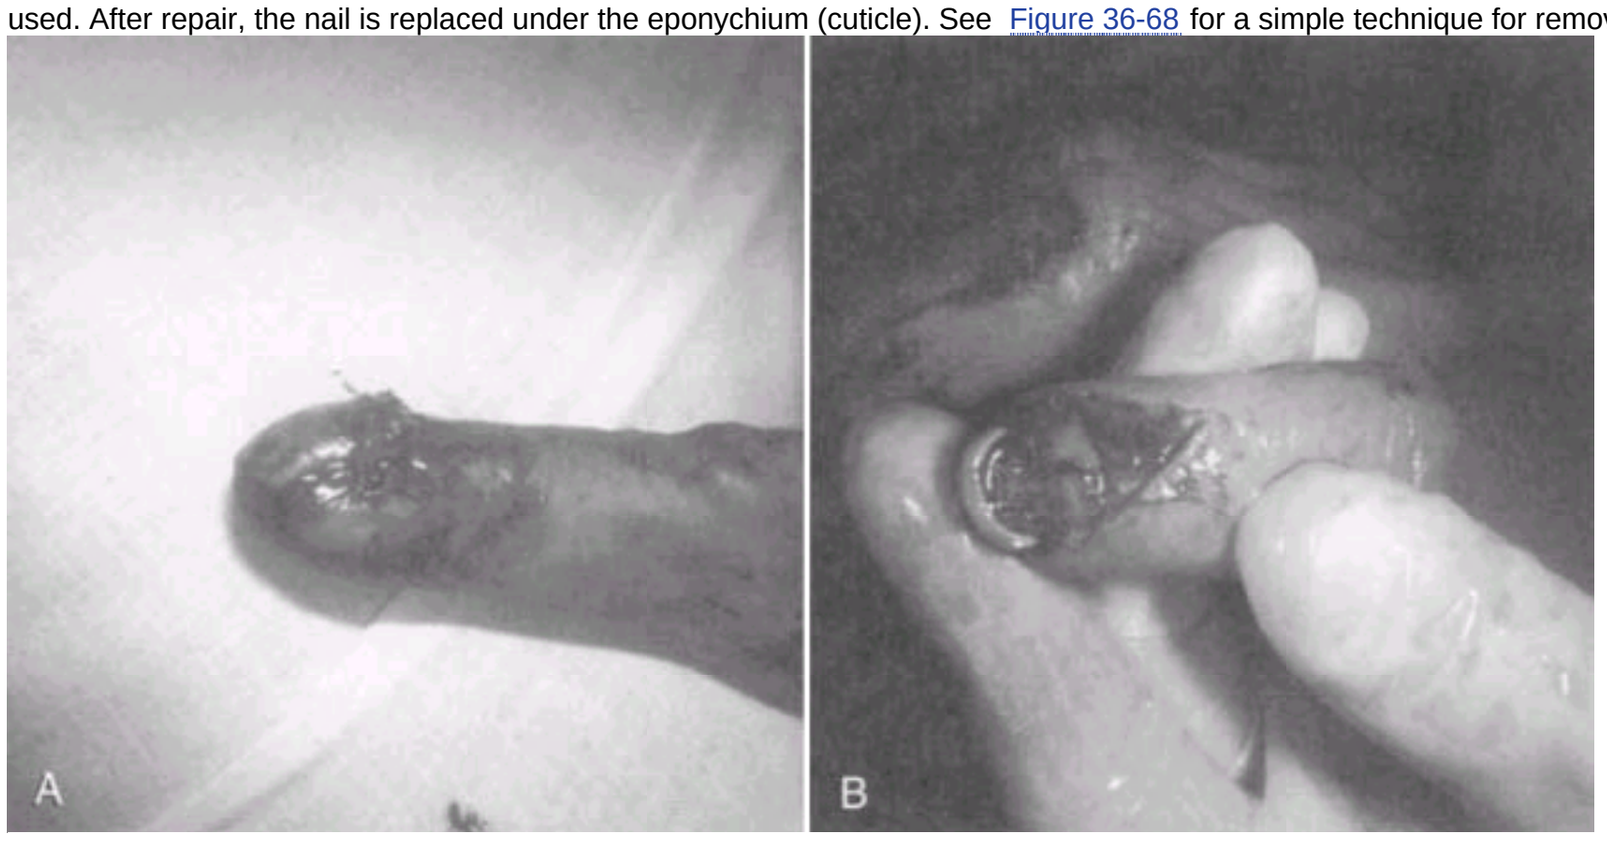

Figure 36-64 This nail is permanently deformed with ridges. Although crush injury to the nailbed is likely responsible for this deformity, nailbed repair is believed to minimize the resultant deformity.

Figure 36-65 A laceration involving the nailbed, germinal matrix, and skinfold must be carefully approximated. First the nail is completely removed. (see Fig. 36-68). Fine, absorbable sutures are used to repair the nailbed under a bloodless field provided by a finger tourniquet. The avulsed nail (trimmed at the base) or a gauze pack is gently placed between the matrix and eponychium for 2 to 3 weeks to prevent scar formation *(A)*. If the original nail is replaced (the best option), it may be sutured or taped in place *(B)*. A large hole in the nail will allow drainage. The old nail is gradually pushed out by a new one. If the nail matrix is replaced quickly and atraumatically, the nail may act as a free graft and grow normally. Note: Only absorbable sutures are used to repair the nailbed.

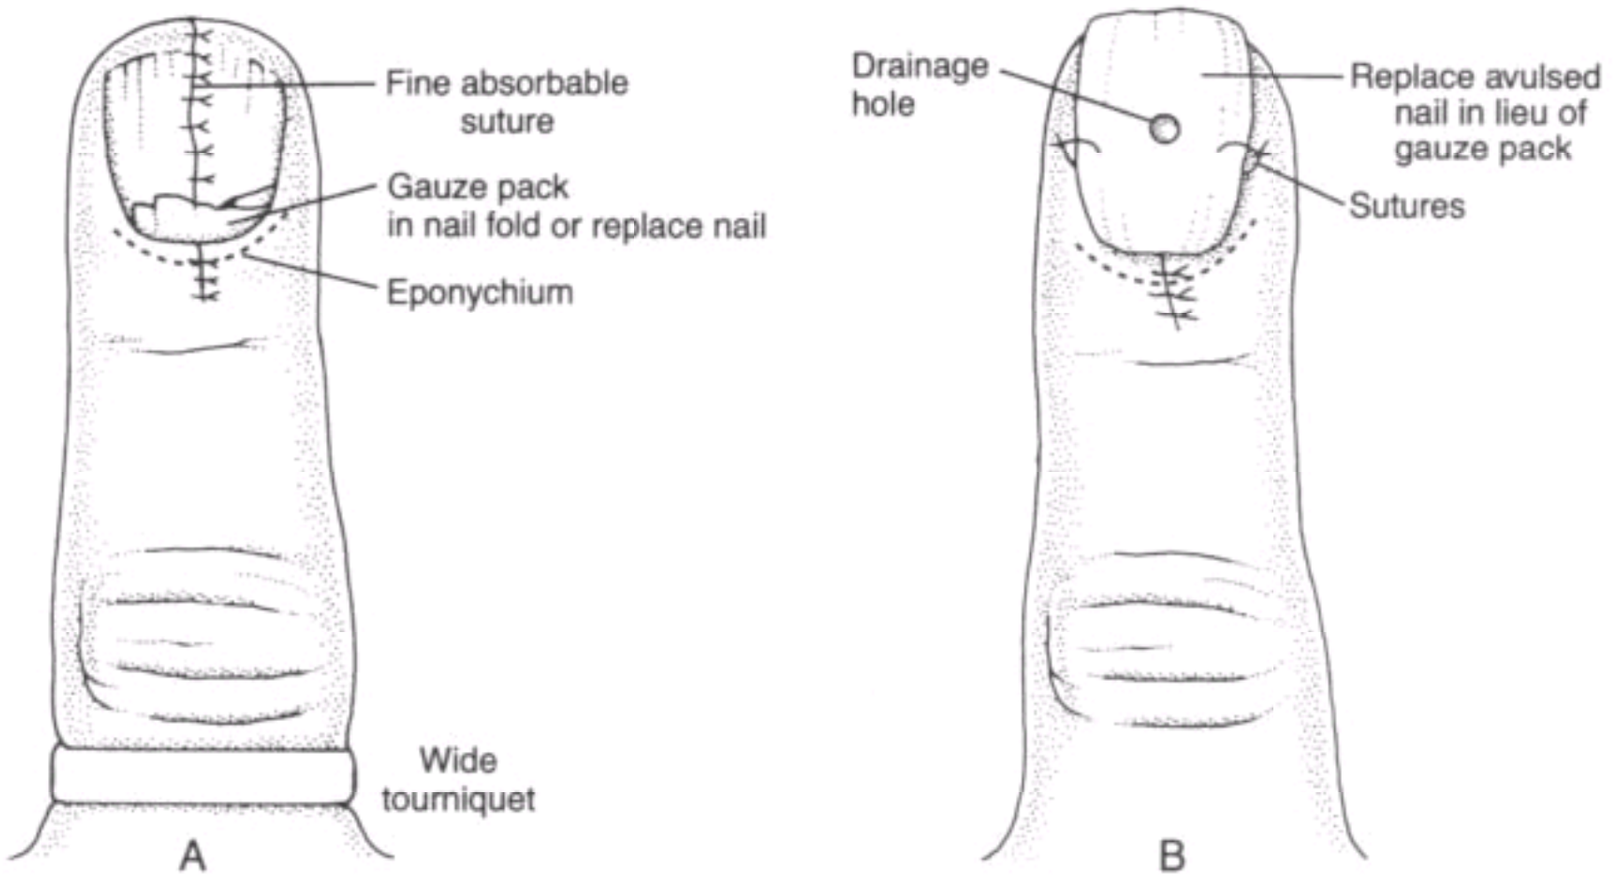

Figure 36-66 Avulsion of the nail, leaving the matrix intact, requires only a nonadherent dressing to separate the skinfold from the nailbed. If the germinal matrix is avulsed, as shown in this figure, it should be replaced to its original position under the eponychium with 6-0 plain absorbable sutures. *(From Grabb WC, Kleinert HE: Technics in Surgery: Facial and Hand Injuries. Somerville, NJ, Ethicon, Inc., 1980. Reproduced by permission.)*

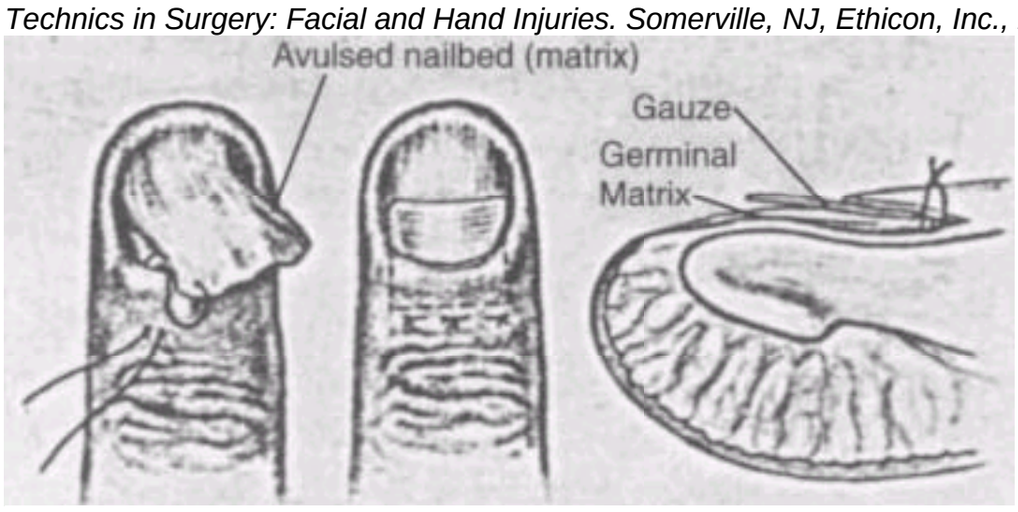

Figure 36-67 Repair of a distal finger laceration involving the nail and the onychial fold. In this case the nail is still adherent to the nail matrix and acts as a natural splint. If the nail is loose or completely transected, it is prudent to remove the entire nail and then carefully suture the nailbed under direct vision. *(From Dushoff IM: Handling the hand. Emerg Med 1976, p 111. Reproduced by permission.)*

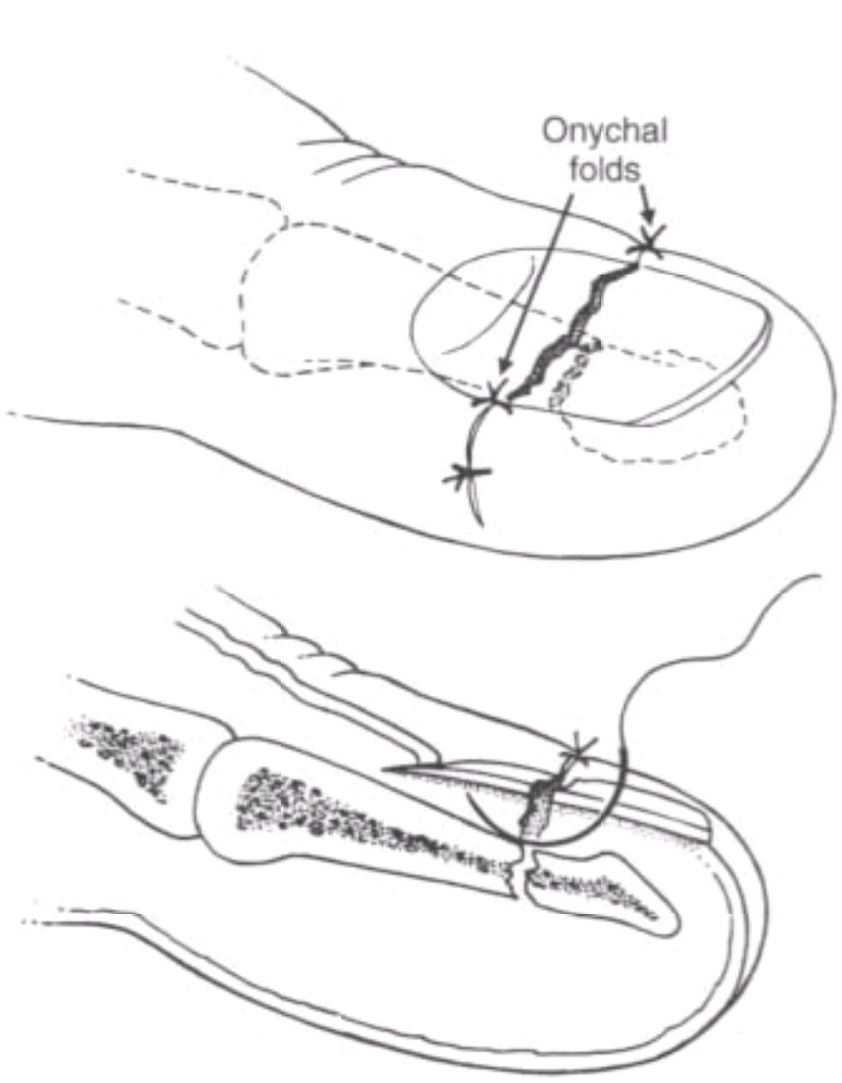

Figure 36-68 To remove a fingernail or toenail atraumatically, the blades of iris scissors are held parallel to the nailbed to avoid lacerating the matrix. A digital block is usually performed to make the procedure painless. The closed blades are slowly advanced in the plane between the nail and the nailbed *(A)* and then gently spread *(B)* to loosen the nail. The scissors are advanced and spread in stages until the base of the nail is reached and the entire nail is loose. The nail is grasped with a hemostat and pulled from the base *(C)*, exposing the nail matrix *(D)*. The nail can be replaced, if desired, once the nailbed laceration has been repaired.

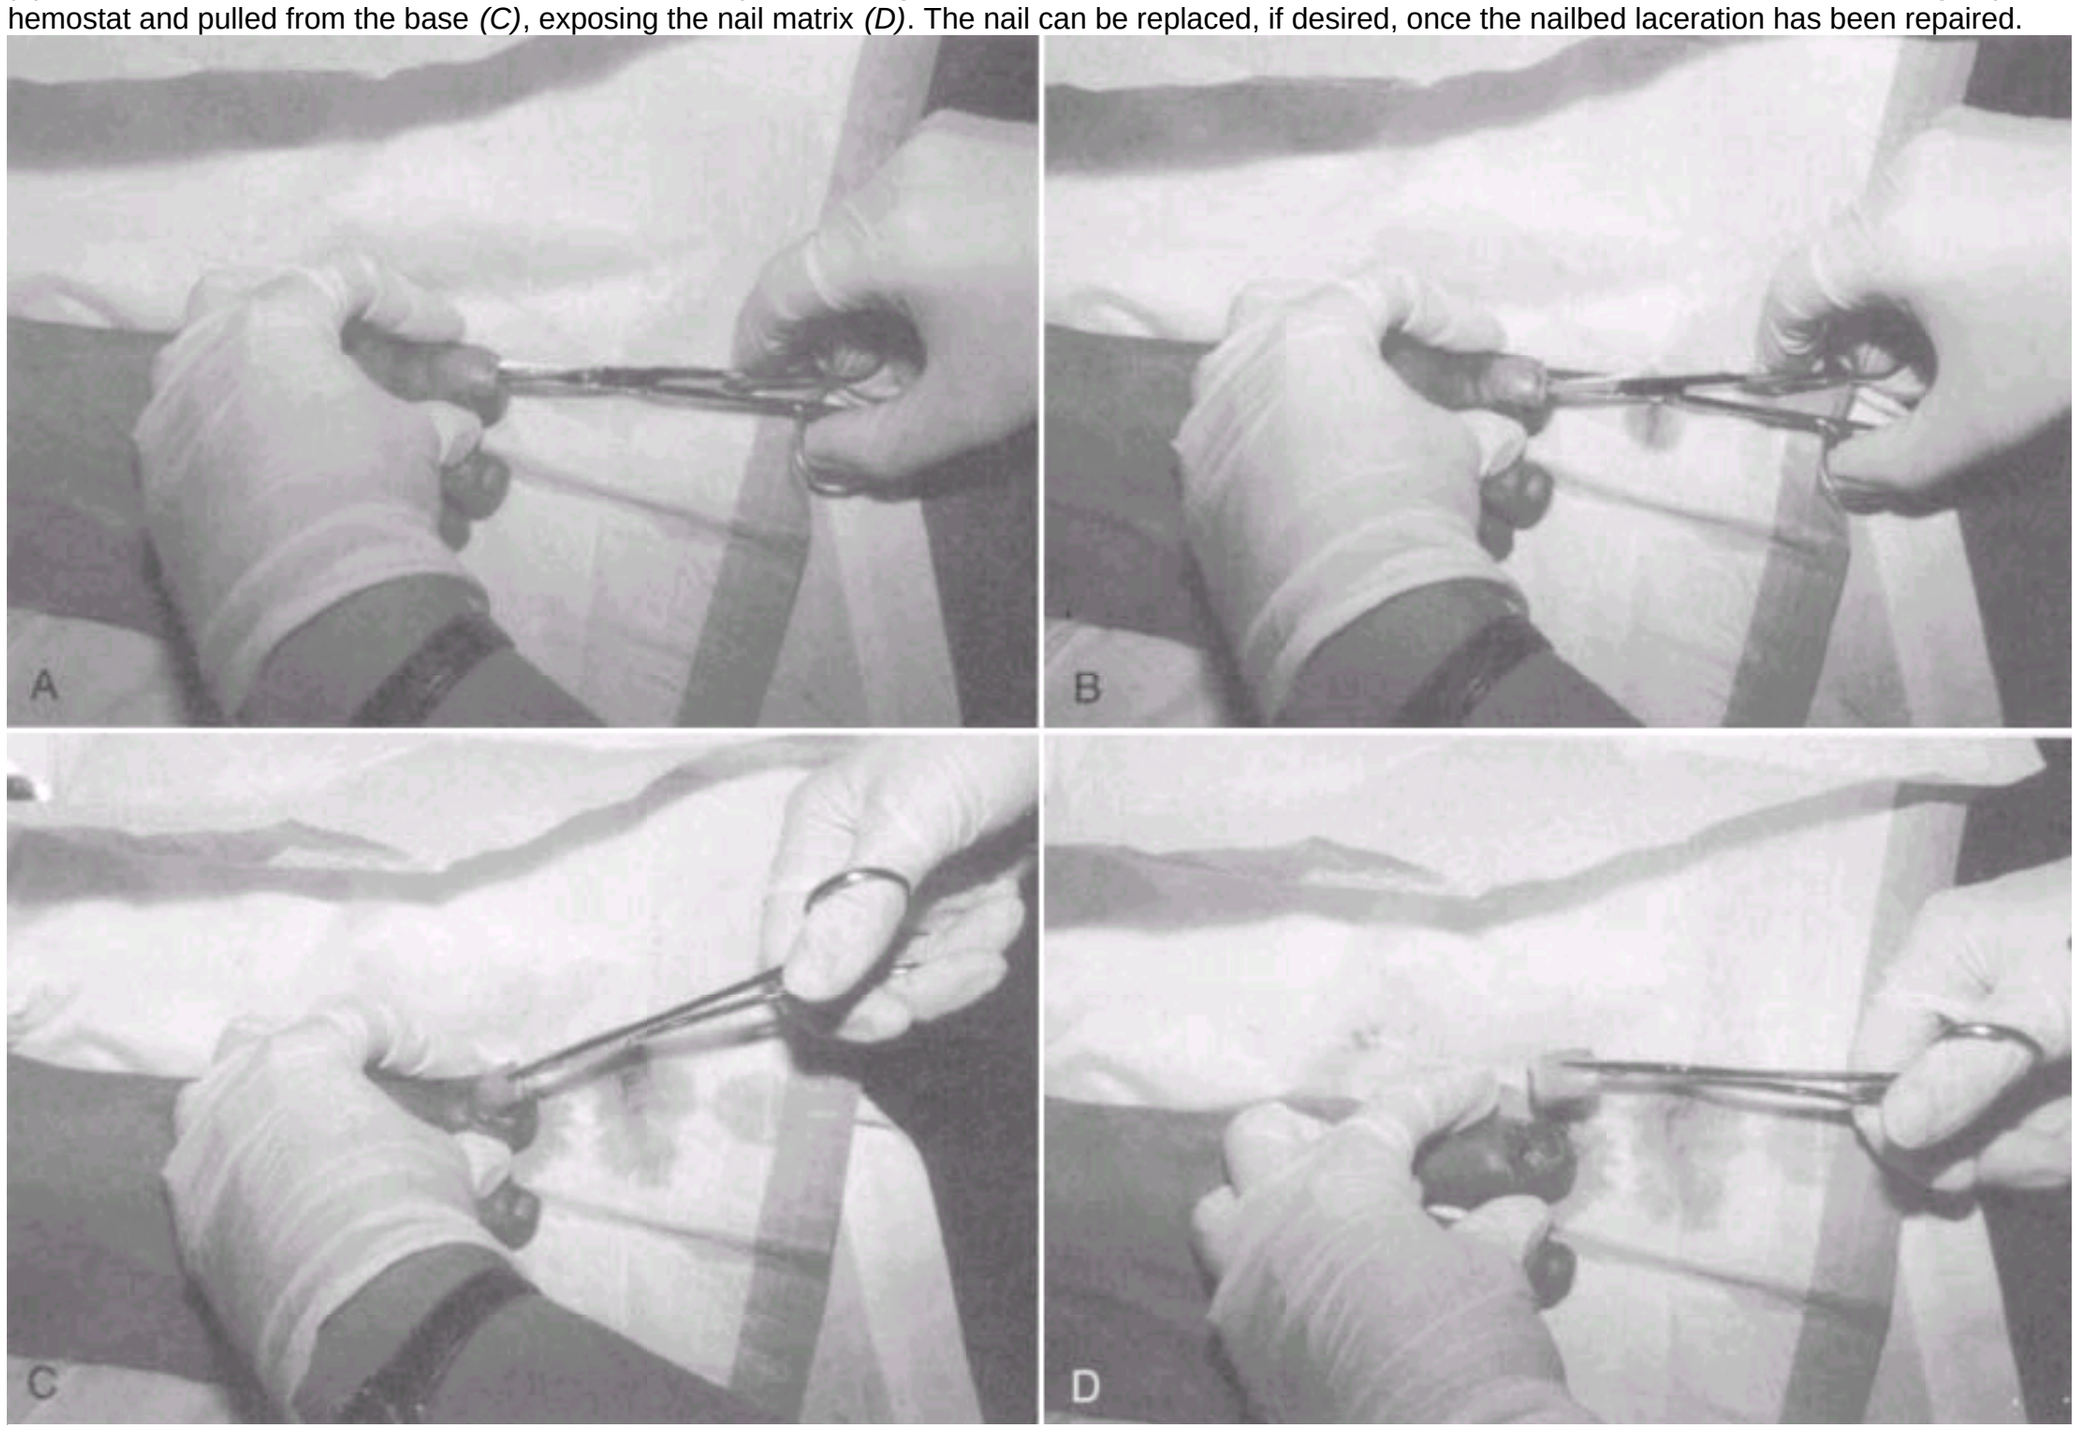

Figure 37-1 A common foreign body (FB) of the foot is a splinter, toothpick, pin, or needle that is impaled while walking barefoot on a carpet. This sewing needle was obvious, but some FBs may be mistaken for a heel spur, contusion, or tendinitis. Preoperative *(A)* and postoperative *(B)* radiographs demonstrate complete removal.

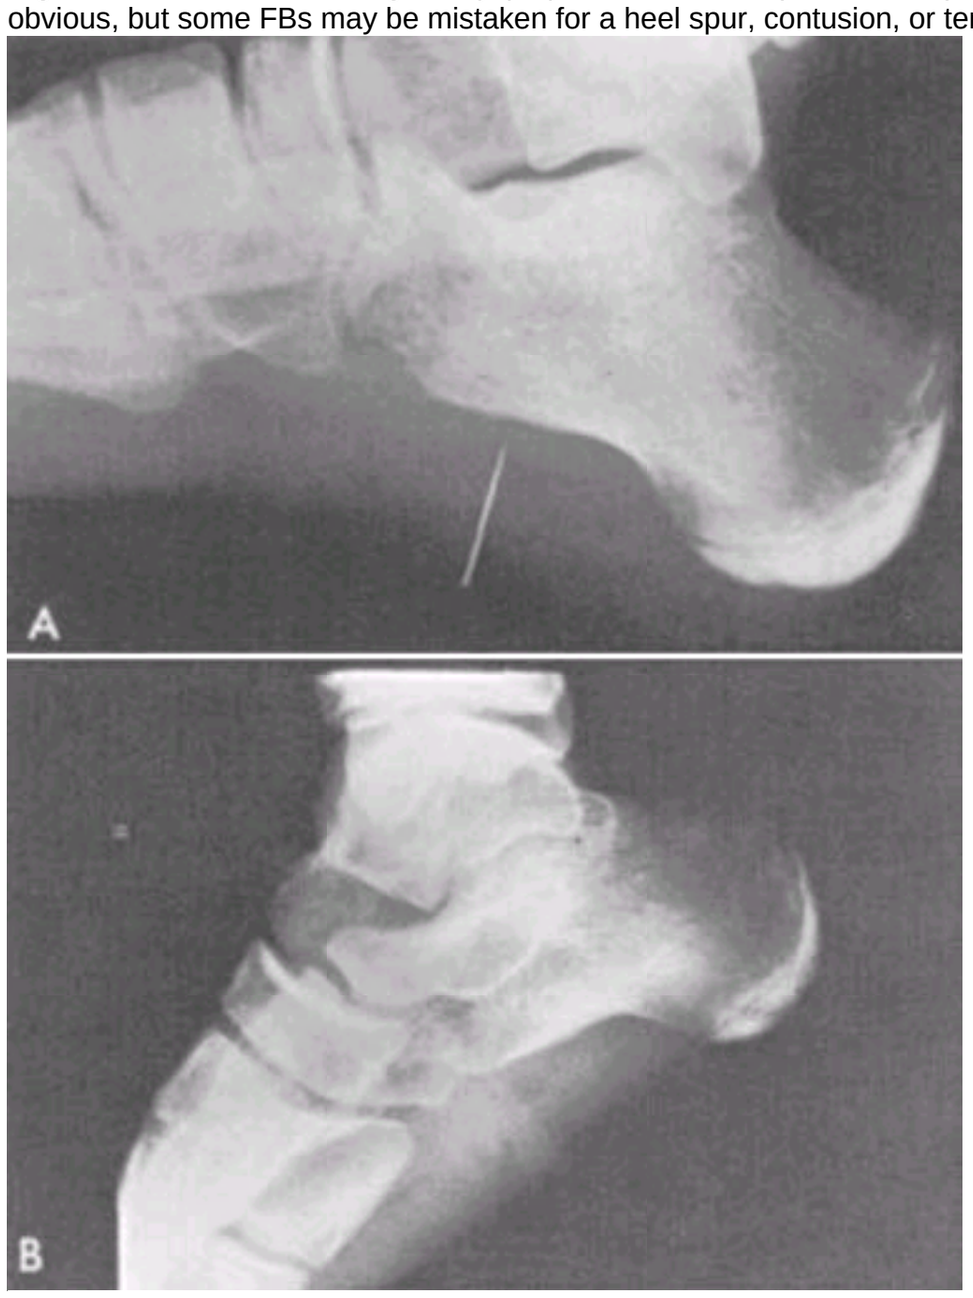

Figure 37-2 This patient fell, landed on a metal pipe, and suffered a laceration to the thigh. A radiograph was taken to rule out a fracture, and the key was seen but thought to be an artifact (i.e., an item left on the backboard). During the examination the key was found embedded in the wound. It had been in the patient's pants pocket and was forced into the wound by the pipe during the injury.

Figure 37-3 Most lead foreign bodies are well tolerated, but if a bullet is bathed in synovial, pleural, peritoneal, or cerebrospinal fluid, the lead may leach out over time and produce a significant elevation in blood lead levels. Symptoms are often vague, and the relation between the retained lead and the patient's clinical scenario may be difficult to sort out. *(From Schwartz DT, Goldfrank LR: Toxicologic imaging. In Goldfrank LR, Flomenbaum NE, Lewin NA, et al [eds]: Goldfrank's Toxicologic Emergencies. 5th ed. Norwalk, CT, Appleton & Lange, 1994, p 116. Reproduced with permission.)*

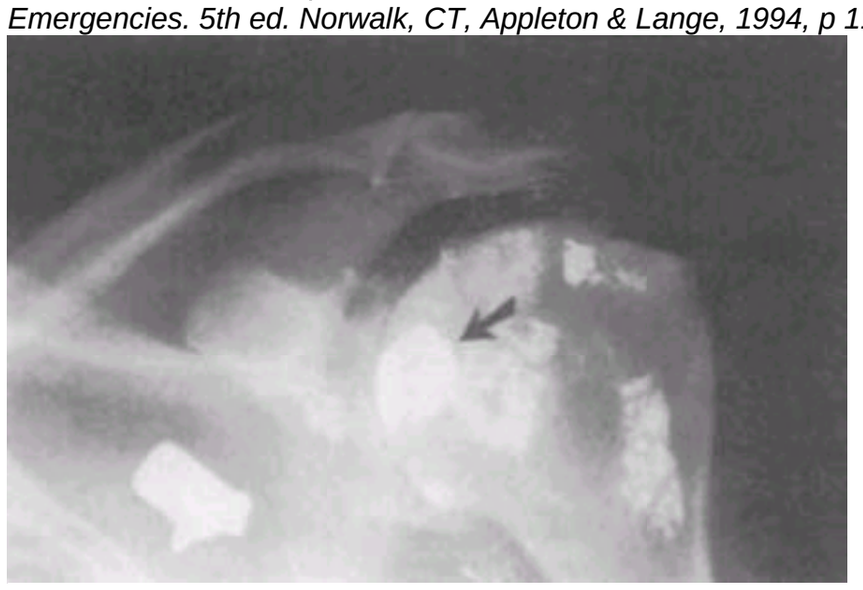

Figure 37-4 Comparison of plain radiography, computed tomography, and ultrasonography in imaging wooden, glass, and plastic foreign bodies (FBs) in an in vitro preparation. Computer manipulation of a digitized radiograph may aid in FB assessment. *(From Ginsburg MJ, Ellis GL, Flom LL: Detection of soft-tissue FBs by plain radiography, xerography, computed tomography, and ultrasonography. Ann Emerg Med 19:701, 1990. Reproduced with permission.).*

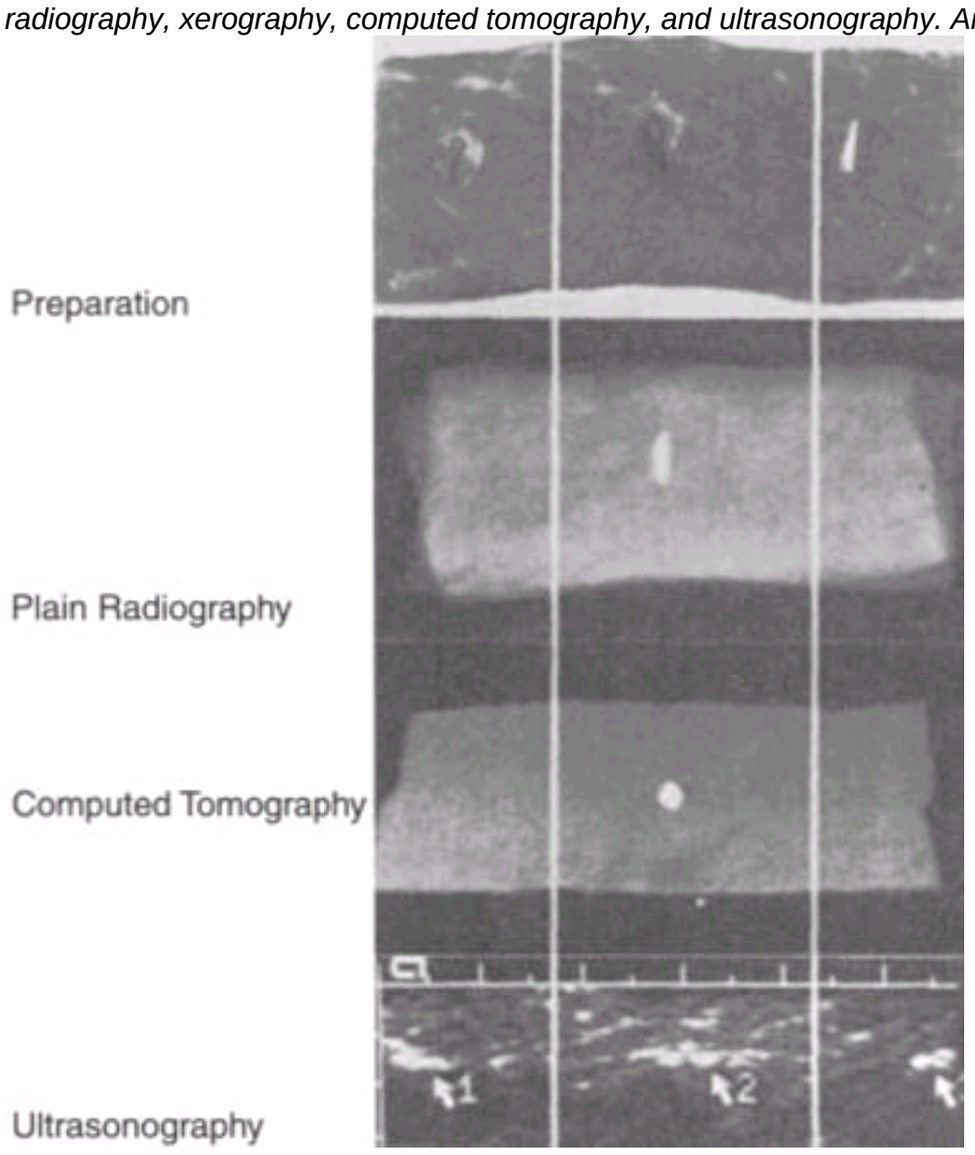

Figure 37-5 Almost all glass is visible on a plain radiograph. Small size is the major limiting factor, not the lead content. If glass is superimposed over bone, it may be obscured, so multiple projections are required. Samples of glass are superimposed on the abdomen and exposed to x-rays. *(Reproduced with permission from Zatzkin HR: The Roentgen Diagnosis of Trauma. Copyright © 1965 by Year Book Medical Publishers, Chicago. Reproduced with permission.)*

Figure 37-6 This foreign body (FB) granuloma developed after the FB was stable for 6 months in this laborer's hand. There was no gross infection, but the pain was quite bothersome. The FB and reactive tissue were excised under local anesthesia.

Figure 37-7 This intoxicated patient punched out a window and sustained seemingly minor puncture wounds *(A)*. He did not believe that glass was in the wound, there was little pain, and no FB could be palpated externally. A radiograph *(B)* revealed a large shard of glass deeply embedded in the wound *(C)*.

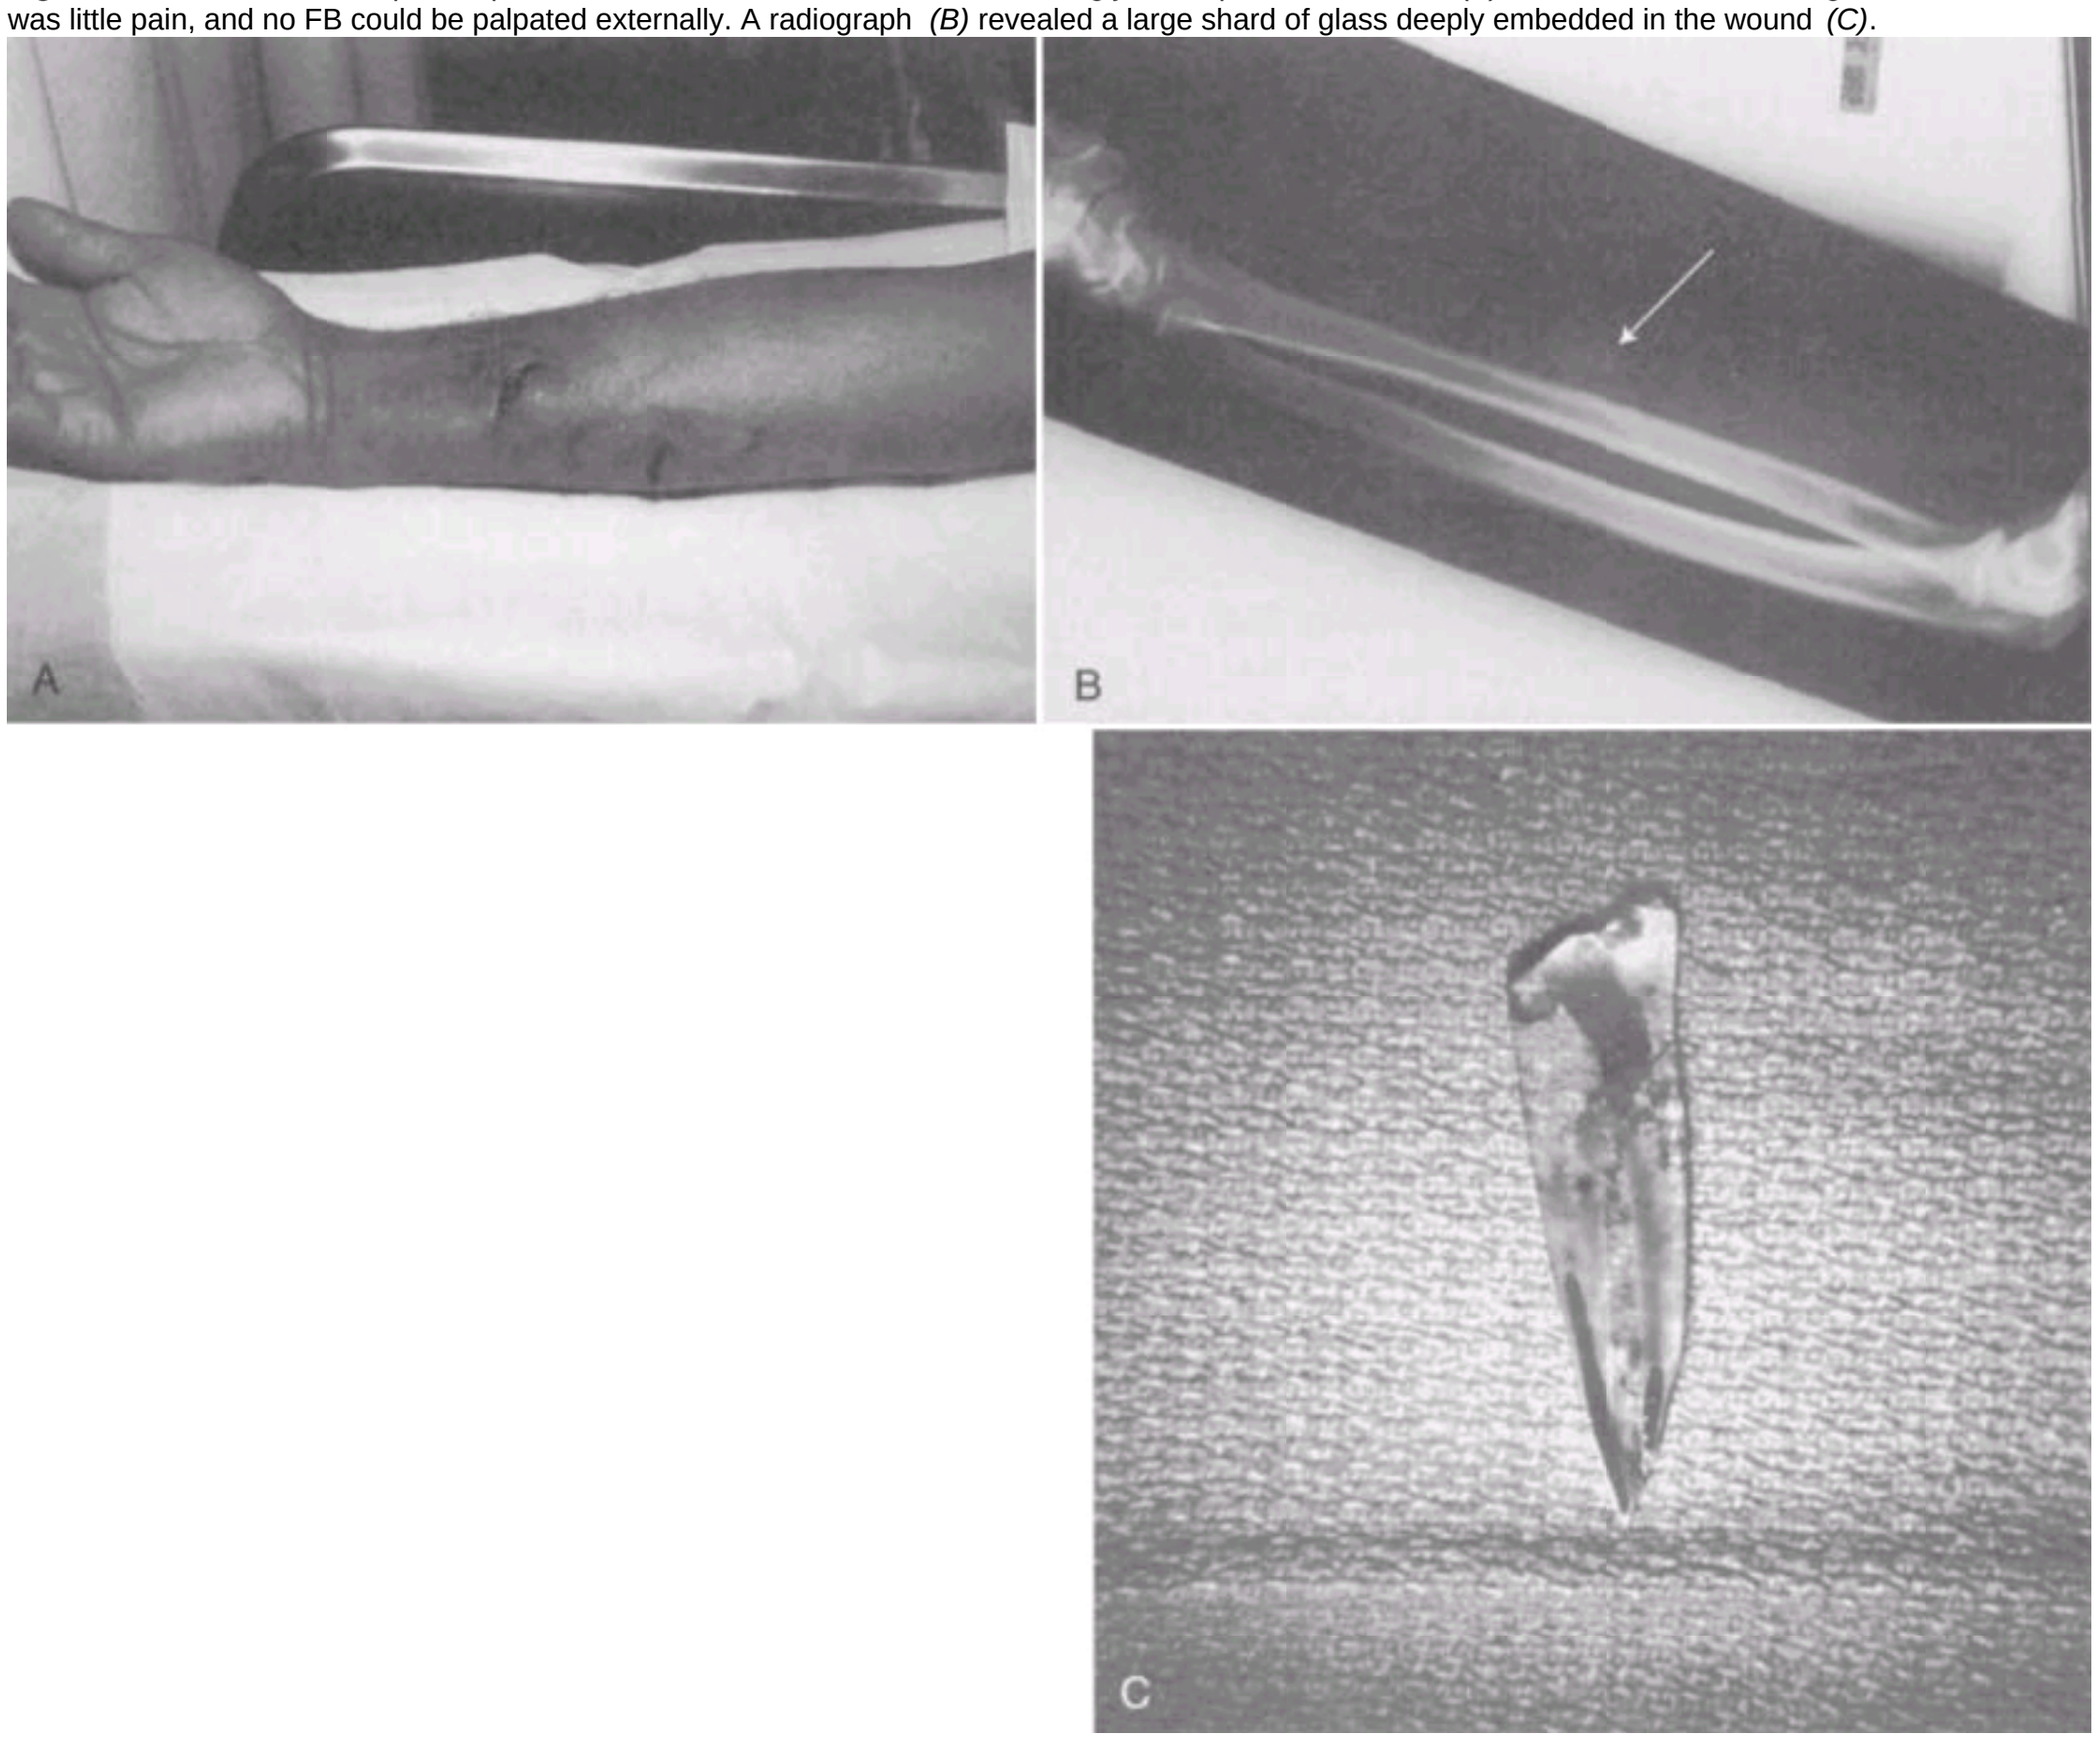

Figure 37-8 What's wrong with this picture? Although historically suggested as a useful technique to find FBs, probing the depths of a wound with a gloved finger may result in a puncture wound in the operator. The practice is strongly discouraged because of the prevalence of hepatitis and human immunodeficiency virus infections.

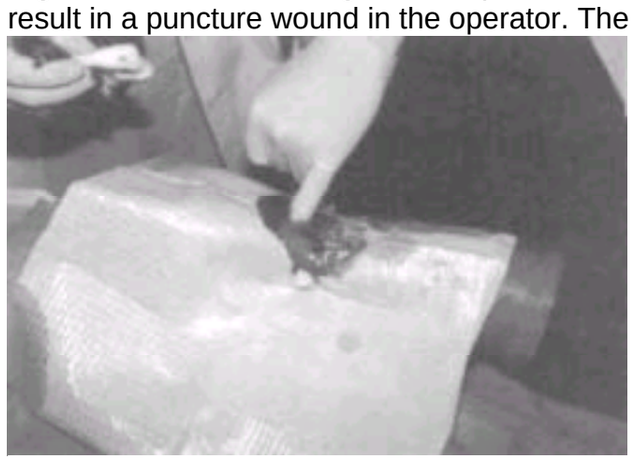

Figure 37-9 When a small entrance wound *(A)* is noted but the foreign body (FB) is not seen, noninvasive localization is preferable to blind probing. Metal markers taped to the skin or needles inserted close to the FB under local anesthesia *(B)* and radiographed at different angles provide a guide to FB localization and extraction. *(Reproduced from Hospital Medicine, © January 1981, with permission of Cahner's Publishing Co.)*

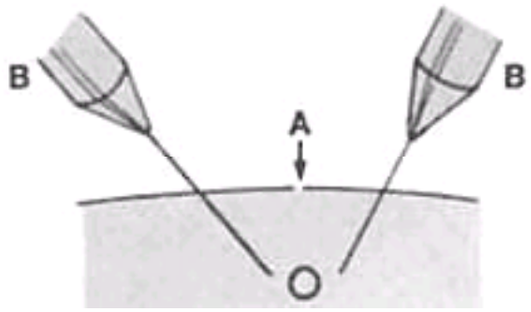

Figure 37-10 A sewing needle completely embedded below the surface *(A* and *B)* is easily located by a radiograph. Following local anesthesia, a small incision over the superficial end permits removal with a hemostatic forceps *(C)*. The hemostat is introduced through an adequate incision, spread to open the tissue, and used to "feel" the foreign body as the hemostat is advanced. *(Reproduced from Hospital Medicine, © January 1981, with permission of Cahner's Publishing Co.)*

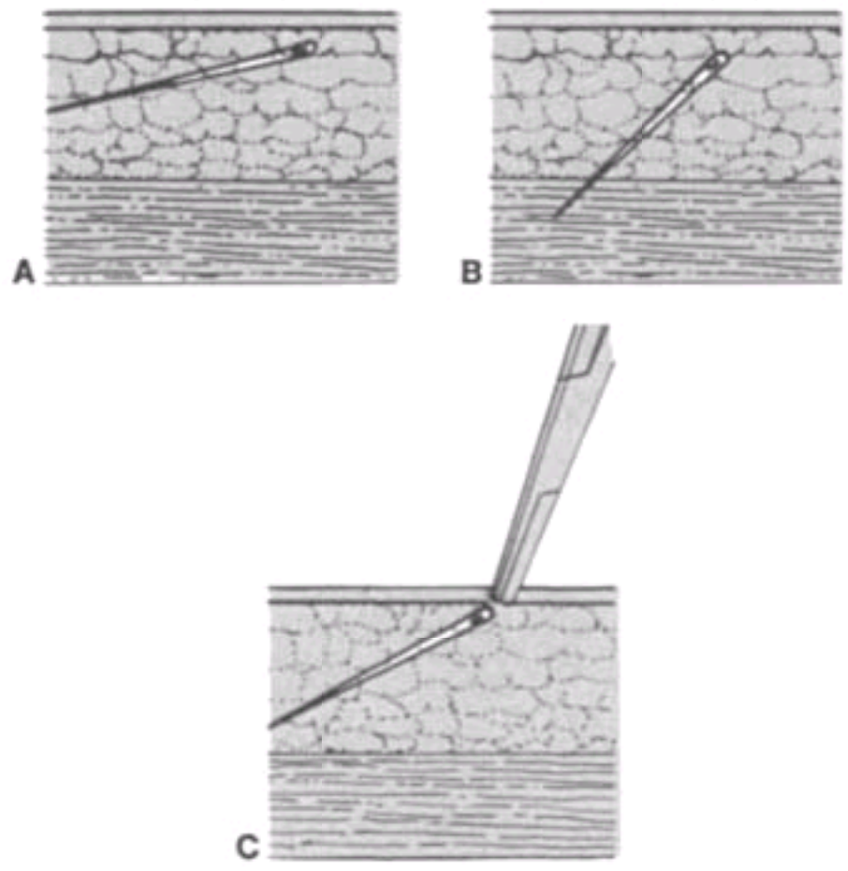

Figure 37-11 If a linear skin incision is used to locate a mobile foreign body (FB) that is perpendicular to the skin in the subcutaneous fat *(A),* the FB may be displaced *(B)*. A modified elliptical incision is made *(C),* and the skin edges are undermined, displacing the FB into the middle of the wound. Pressure with the thumbs may be applied to the skin to force the FB into view. *(From Rees CE: The removal of FBs: A modified incision. JAMA 113:35, 1939. Copyright 1939, American Medical Association. Reproduced with permission.)*

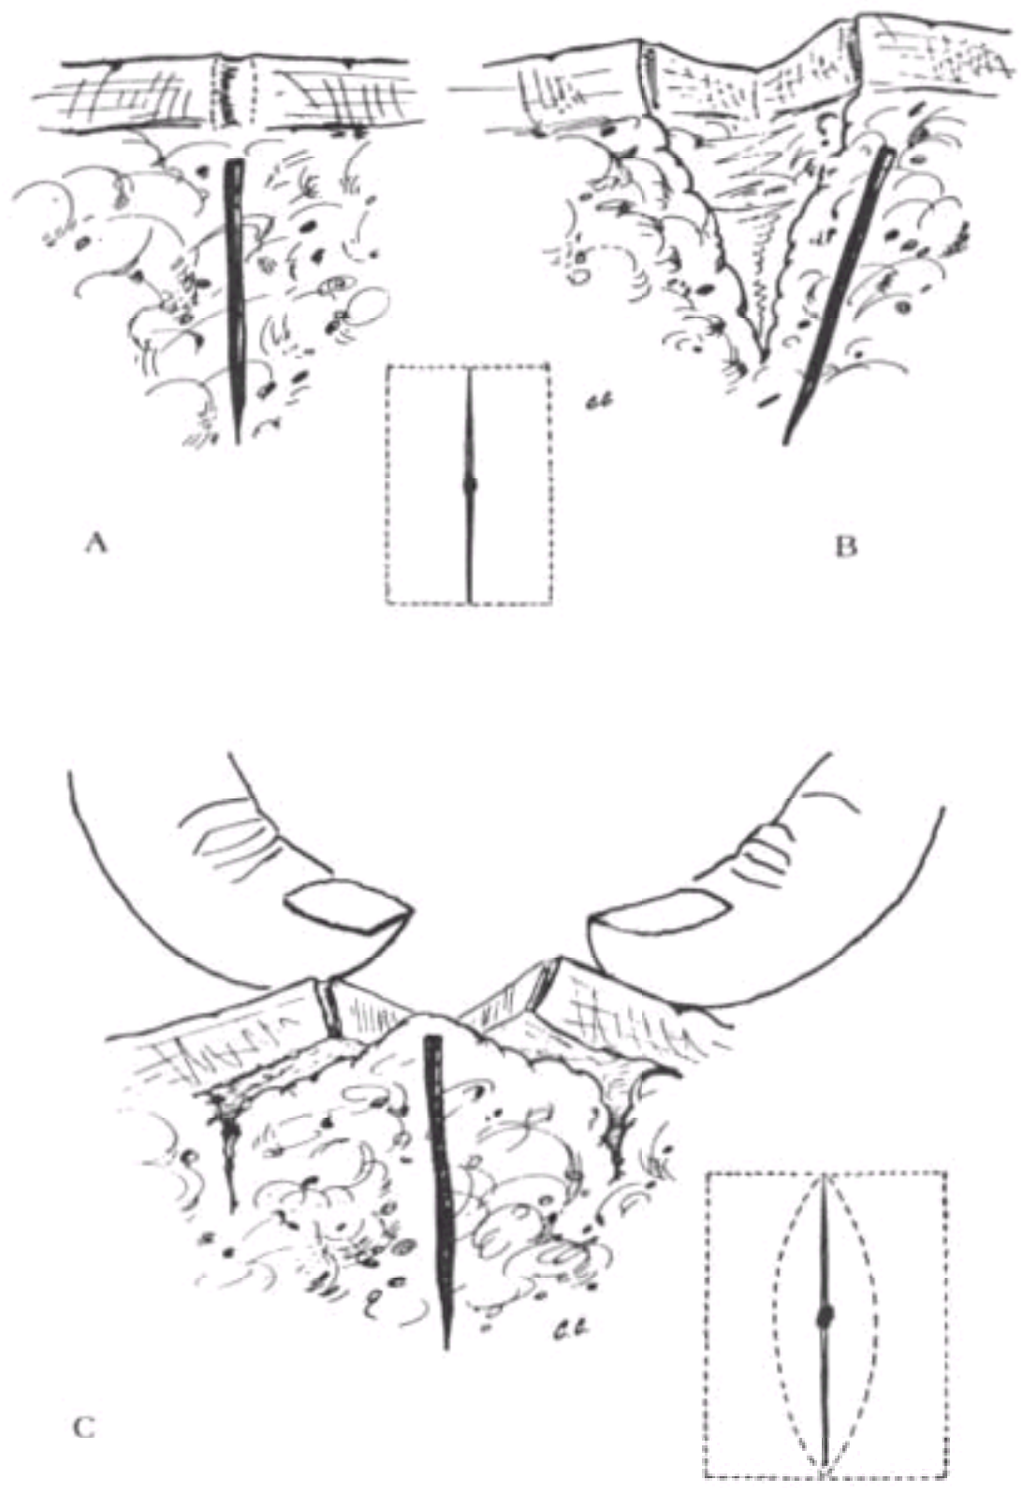

Figure 37-12 Foreign bodies (FBs) in deep fat *(A)* may be approached by a small elliptical incision around the entry point *(B)*. The incision is then laterally undercut and grasped (without pulling) with an Allis clamp *(C)*. The ellipse is then further undercut until contact with the FB is made *(D)*. The FB may be grasped and removed along with the entry tract and the soiled local fat *(E)*. *(Reproduced from Hospital Medicine, © January 1981, with permission of Cahner's Publishing Co.)*

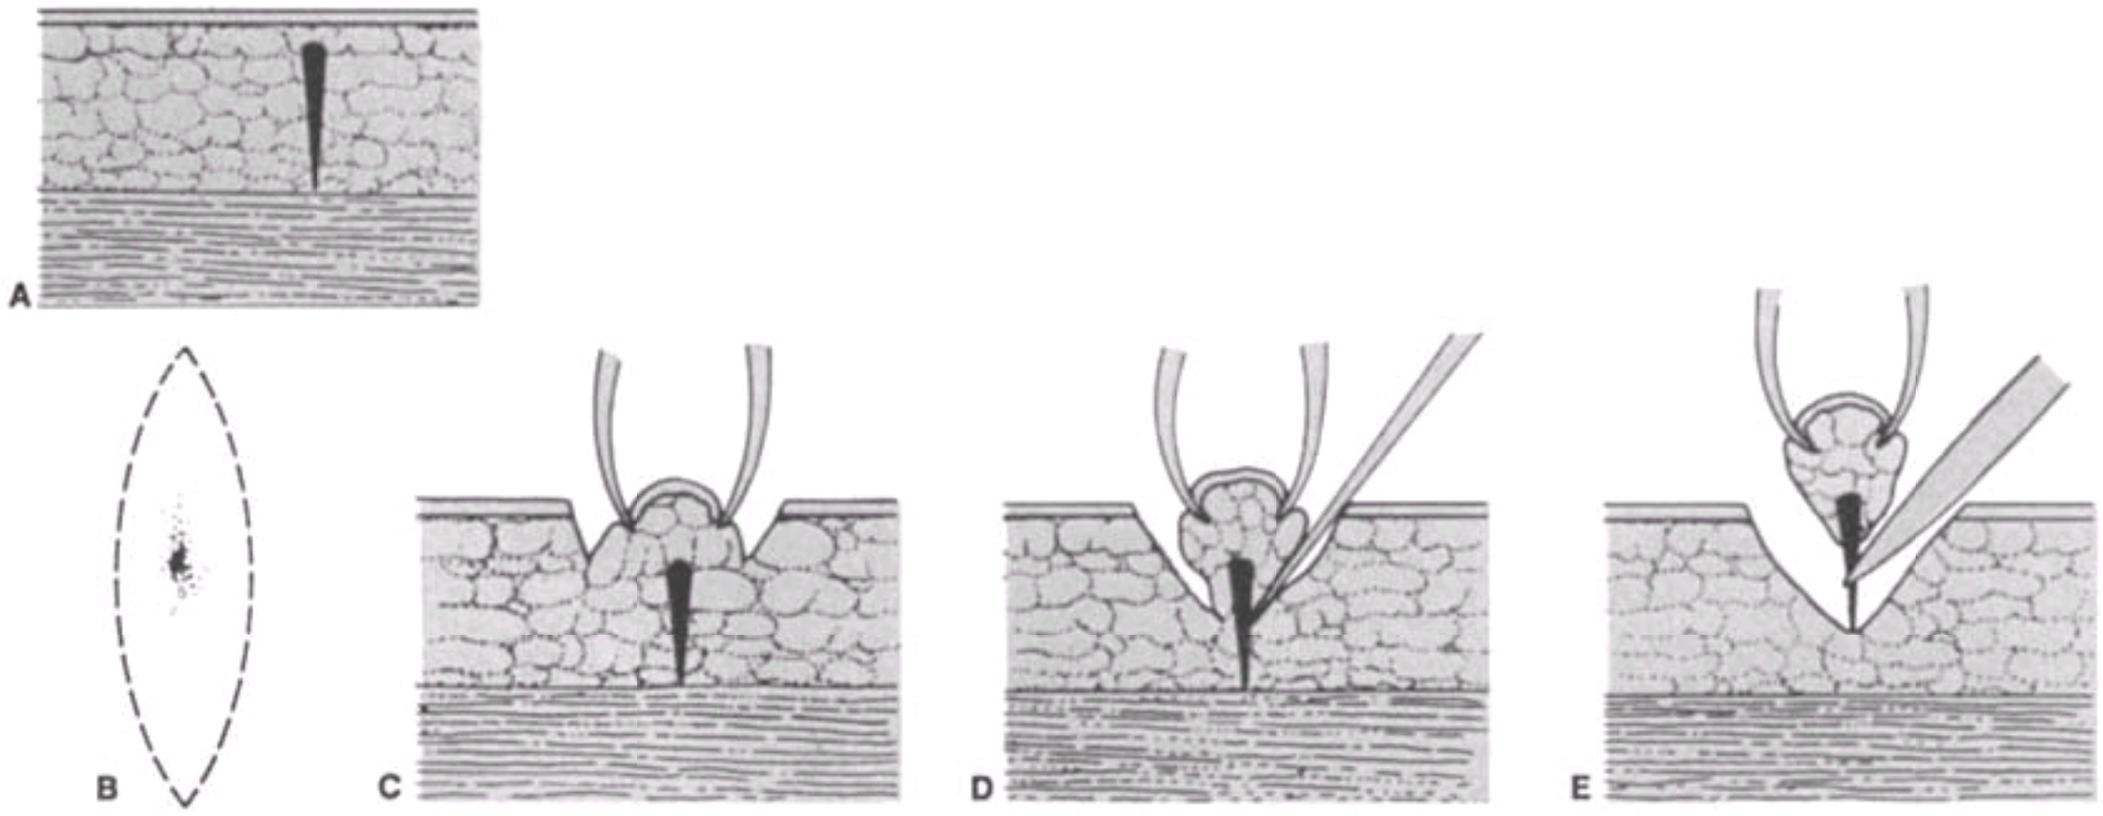

Figure 37-13 The vast majority of patients who step on a nail have no long-term consequences, but a few experience soft tissue infections or serious and debilitating osteomyelitis. The depths of a fresh puncture wound are not routinely explored, but key to avoid missing a superficial foreign body (FB) is to examine the patient under good lighting, supine, and with an arterial tourniquet if necessary (*A*). If the patient was wearing socks or tennis shoes, a small FB, like this piece of rubber, may be introduced into the wound. It may only be evident when the edges of the skin are trimmed and the wound is explored (*B*). Coring out the puncture wound tract is controversial and unproven, but it is one way to remove foreign material. In this case a No. 11 blade is inserted to the hilt and a 2 to 3 mm core of tissue is removed with the FB (*C*). This tract may be left open or a small packing applied. If a patient returns with an infection within a few days after a seemingly simple puncture wound (*D*), it is most likely a soft tissue infection, but persistent pain demands a search for osteomyelitis or a deep FB.

Figure 37-14 For an FB deep in the nailbed, take as small a wedge of nail as will allow access to the proximal end of the splinter, then extract the FB with splinter forceps. All wood particles should be removed. A digital nerve block is usually necessary. *(Reproduced from Hospital Medicine, © January 1981, with permission of Cahner's Publishing Co.)*

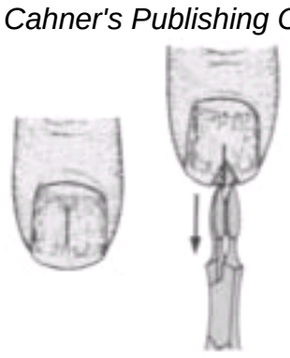

Figure 37-15 Method of removing an embedded fishhook when anesthesia is available and when the point of the fishhook is close to the skin. *A,* Obtain local anesthesia overlying the point of the hook. *B,* Force the point through the anesthetized skin. *C,* Clip off the barb. *D,* Remove the rest of the hook by reversing the direction of entry. *(Reproduced from Hospital Medicine, © July 1980, with permission of Cahner's Publishing Co.)*

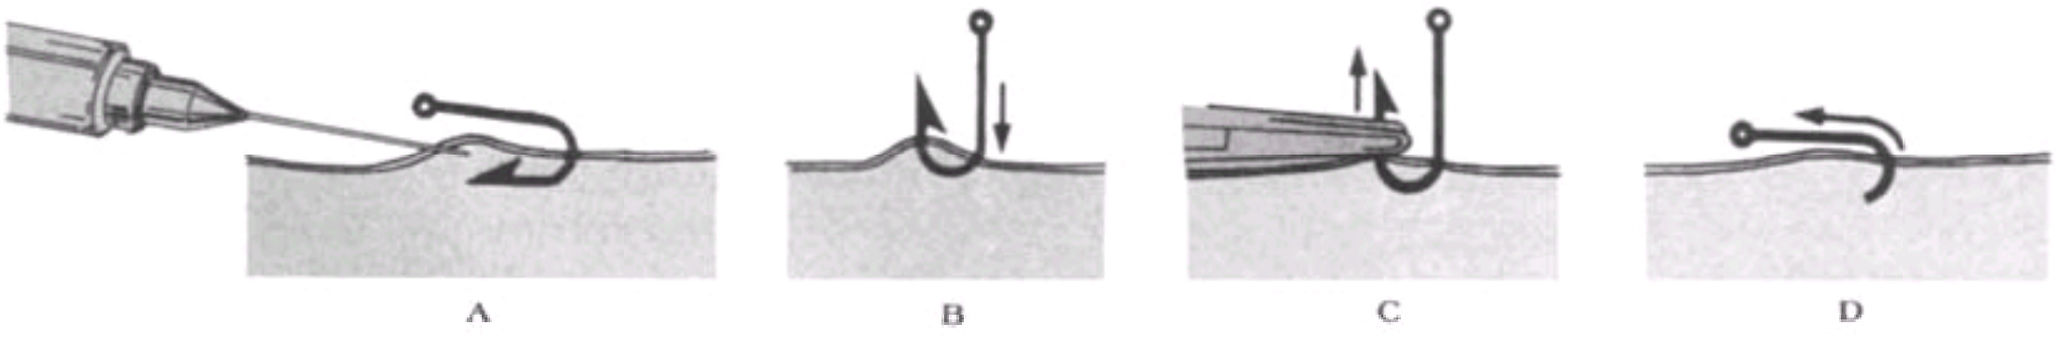

Figure 37-16 Method of removing an embedded fishhook when anesthesia is unavailable or when the barb of the fishhook lies too deep to force it out through a second wound without causing significant additional damage. Loop a piece of string (or thick suture material) around the belly of the hook and hold it down against the skin with the index finger of the left hand *(A)*. Depress the shaft of the hook against the skin with the middle finger and thumb while applying light downward pressure with the index finger of the left hand to disengage the barb from the subcutaneous tissue *(B)*, and pull *sharply* on the ends of the string with the right hand *(C)* to remove the hook through its entry wound. Bystanders should be out of the expected path of the hook. *(Reproduced from Hospital Medicine, © July 1980, with permission of Cahner's Publishing Co.)*

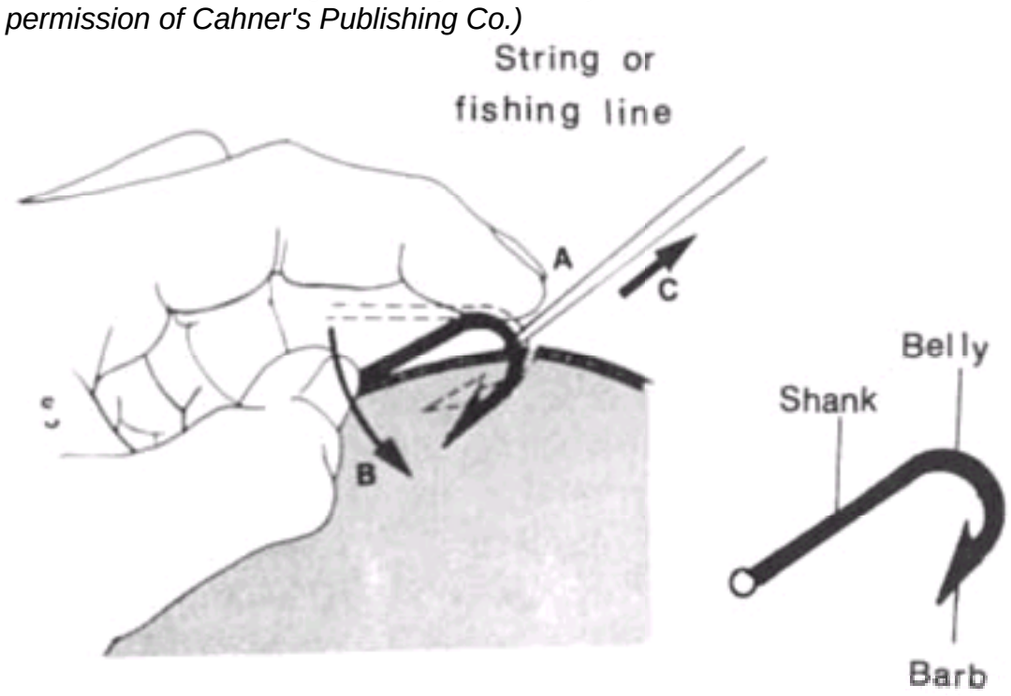

Figure 37-17 Method of removing an embedded fishhook using anesthesia when the hook is large and not too deep in the skin. After anesthetizing the area with 1% lidocaine *(A),* insert a short-bevel 18-ga needle through the entry wound of the hook and attempt to sheathe the barb of the hook within the needle *(B)*. If this is done correctly, the hook and needle may then be backed out together *(C)*. *(Reproduced from Hospital Medicine, © July 1980, with permission of Cahner's Publishing Co.)*

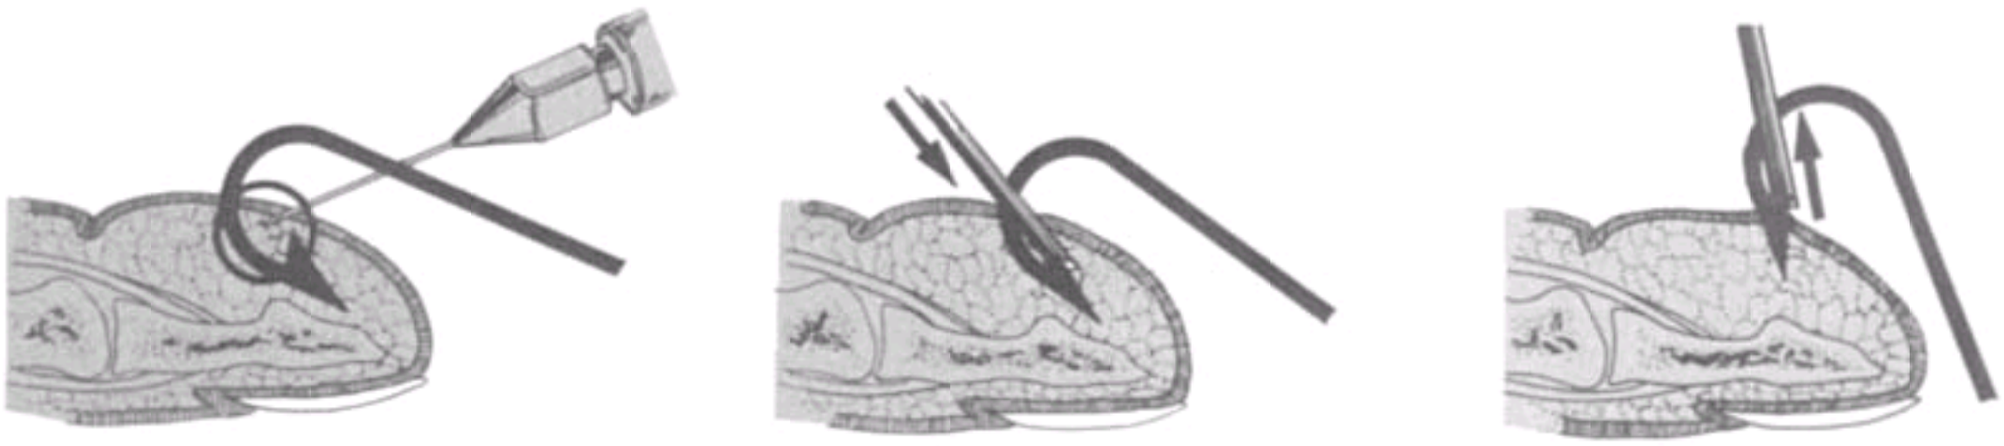

Figure 37-18a The course and depth of penetration of this large wood splinter of the leg *(A)* is uncertain, but it is axiomatic that all pieces of wood must be removed to prevent infection. To ensure complete FB removal, an incision is made over the entire course of the splinter *(B)* (*see inset*). All pieces of wood are carefully removed under direct vision *(C),* and the laceration is sutured primarily *(D)*. While it may be tempting to simply pull out the splinter and irrigate the puncture tract, such actions often lead to retained particles and complications.

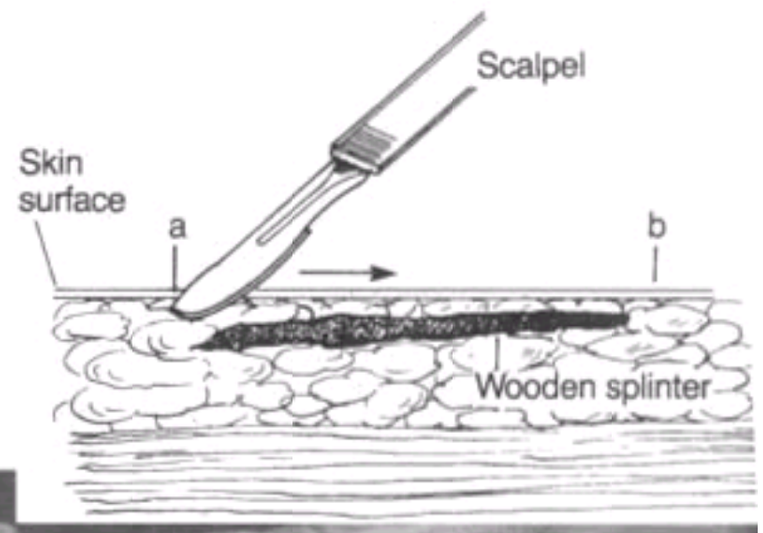

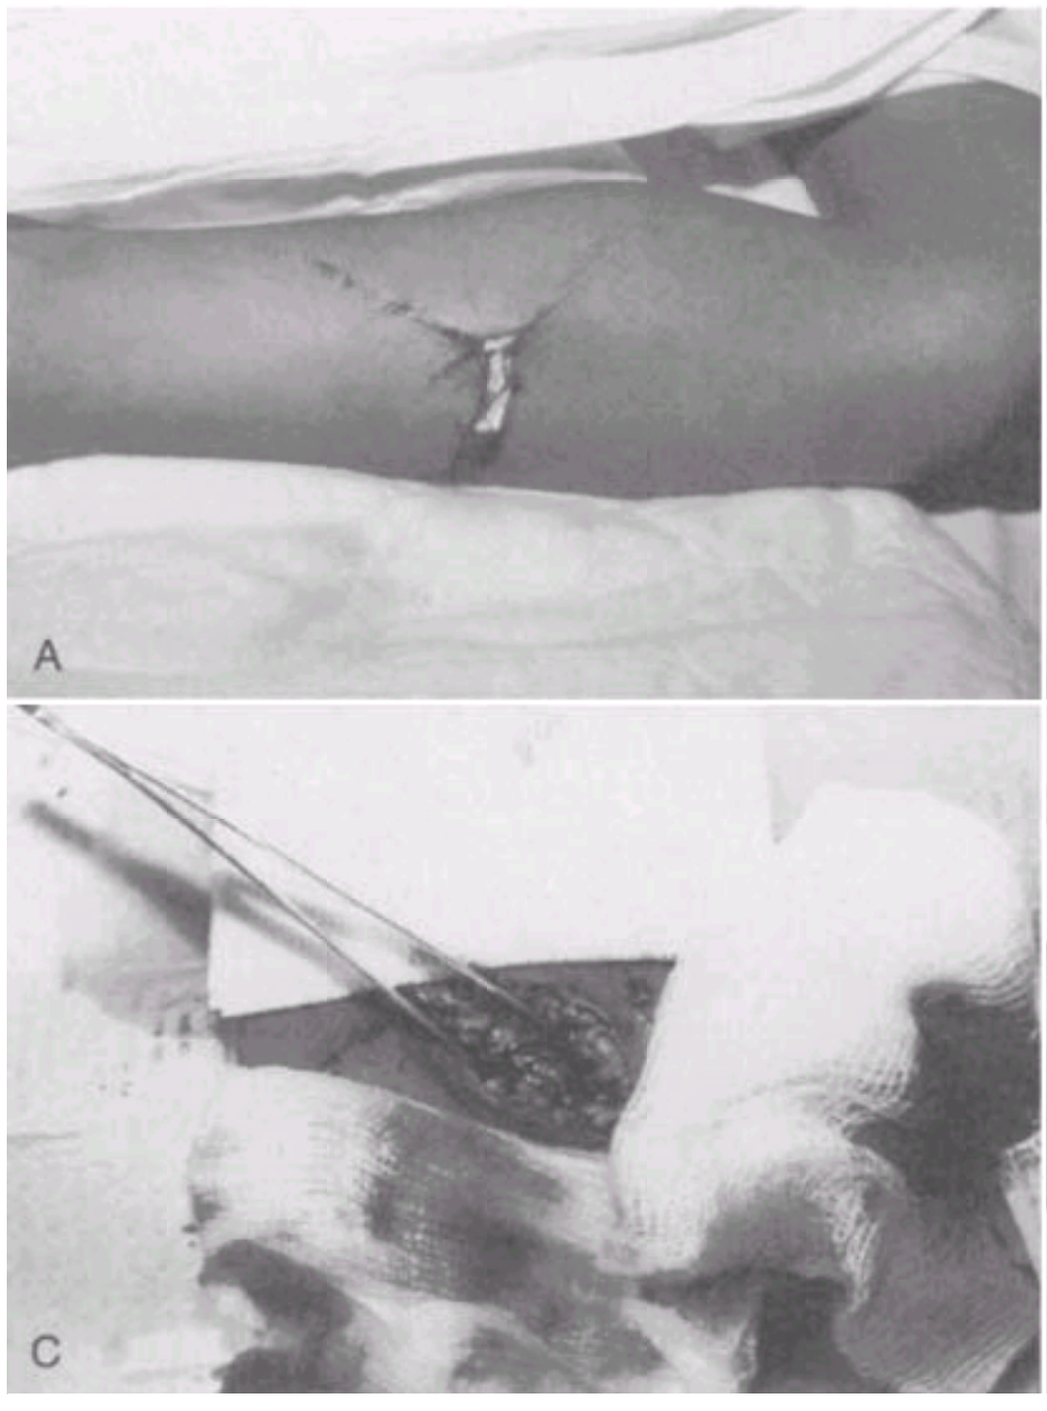

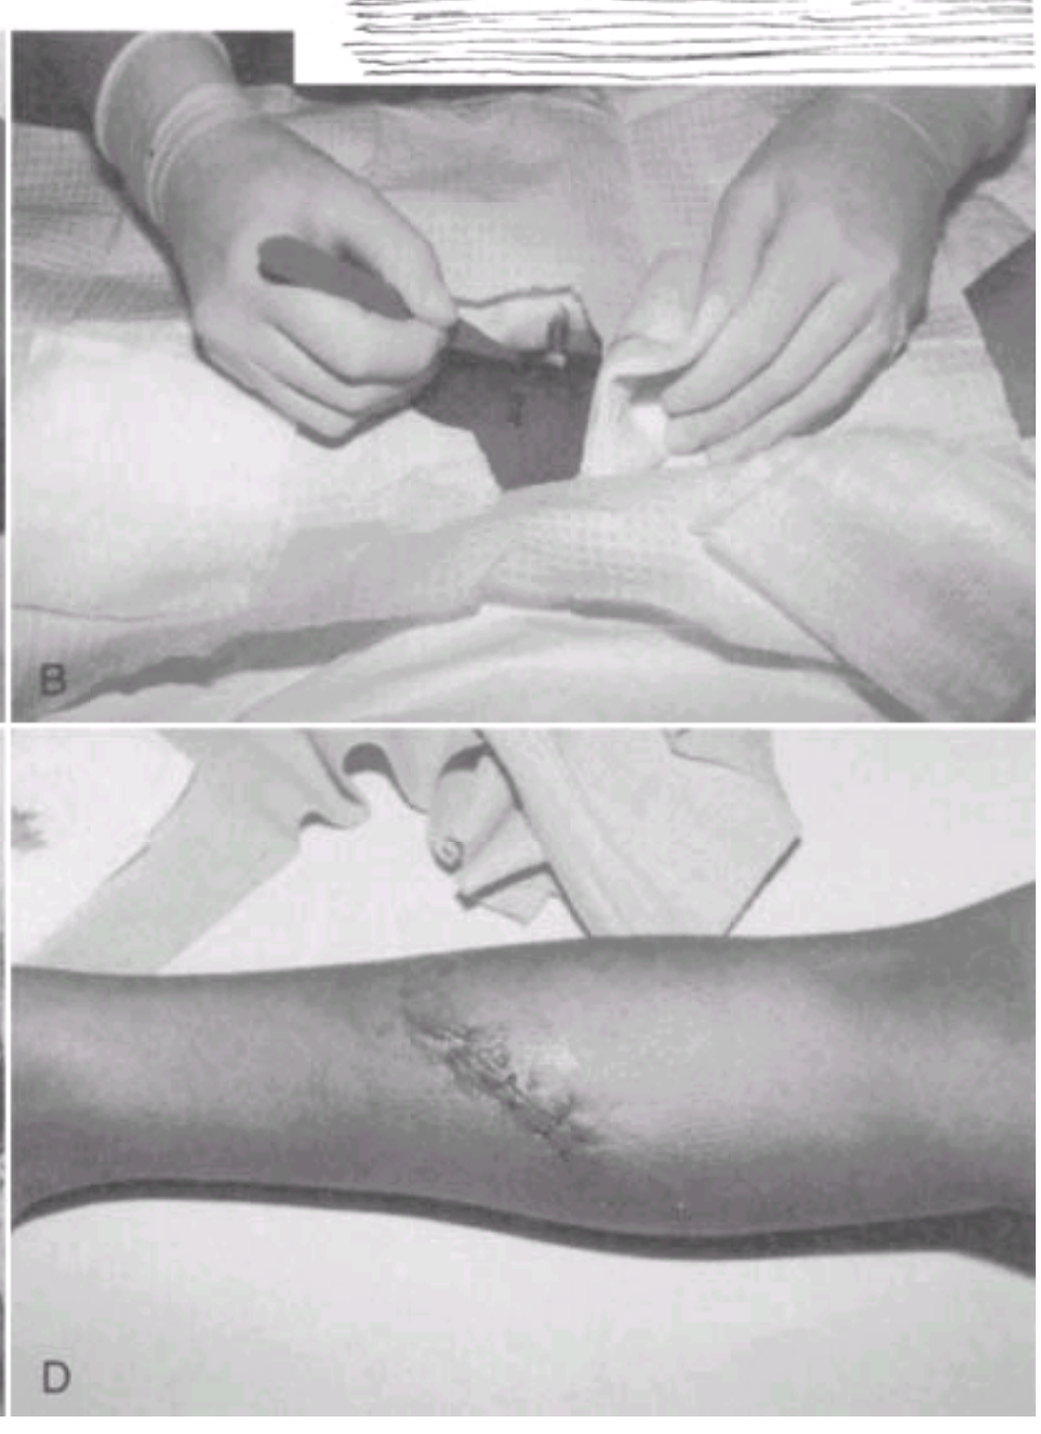

Figure 37-18b Here is another example of longitudinal incision of the overlying skin followed by withdrawal of a wood foreign body en mass to avoid retained fragments (*E*, *F*, *G*, and *H*.)

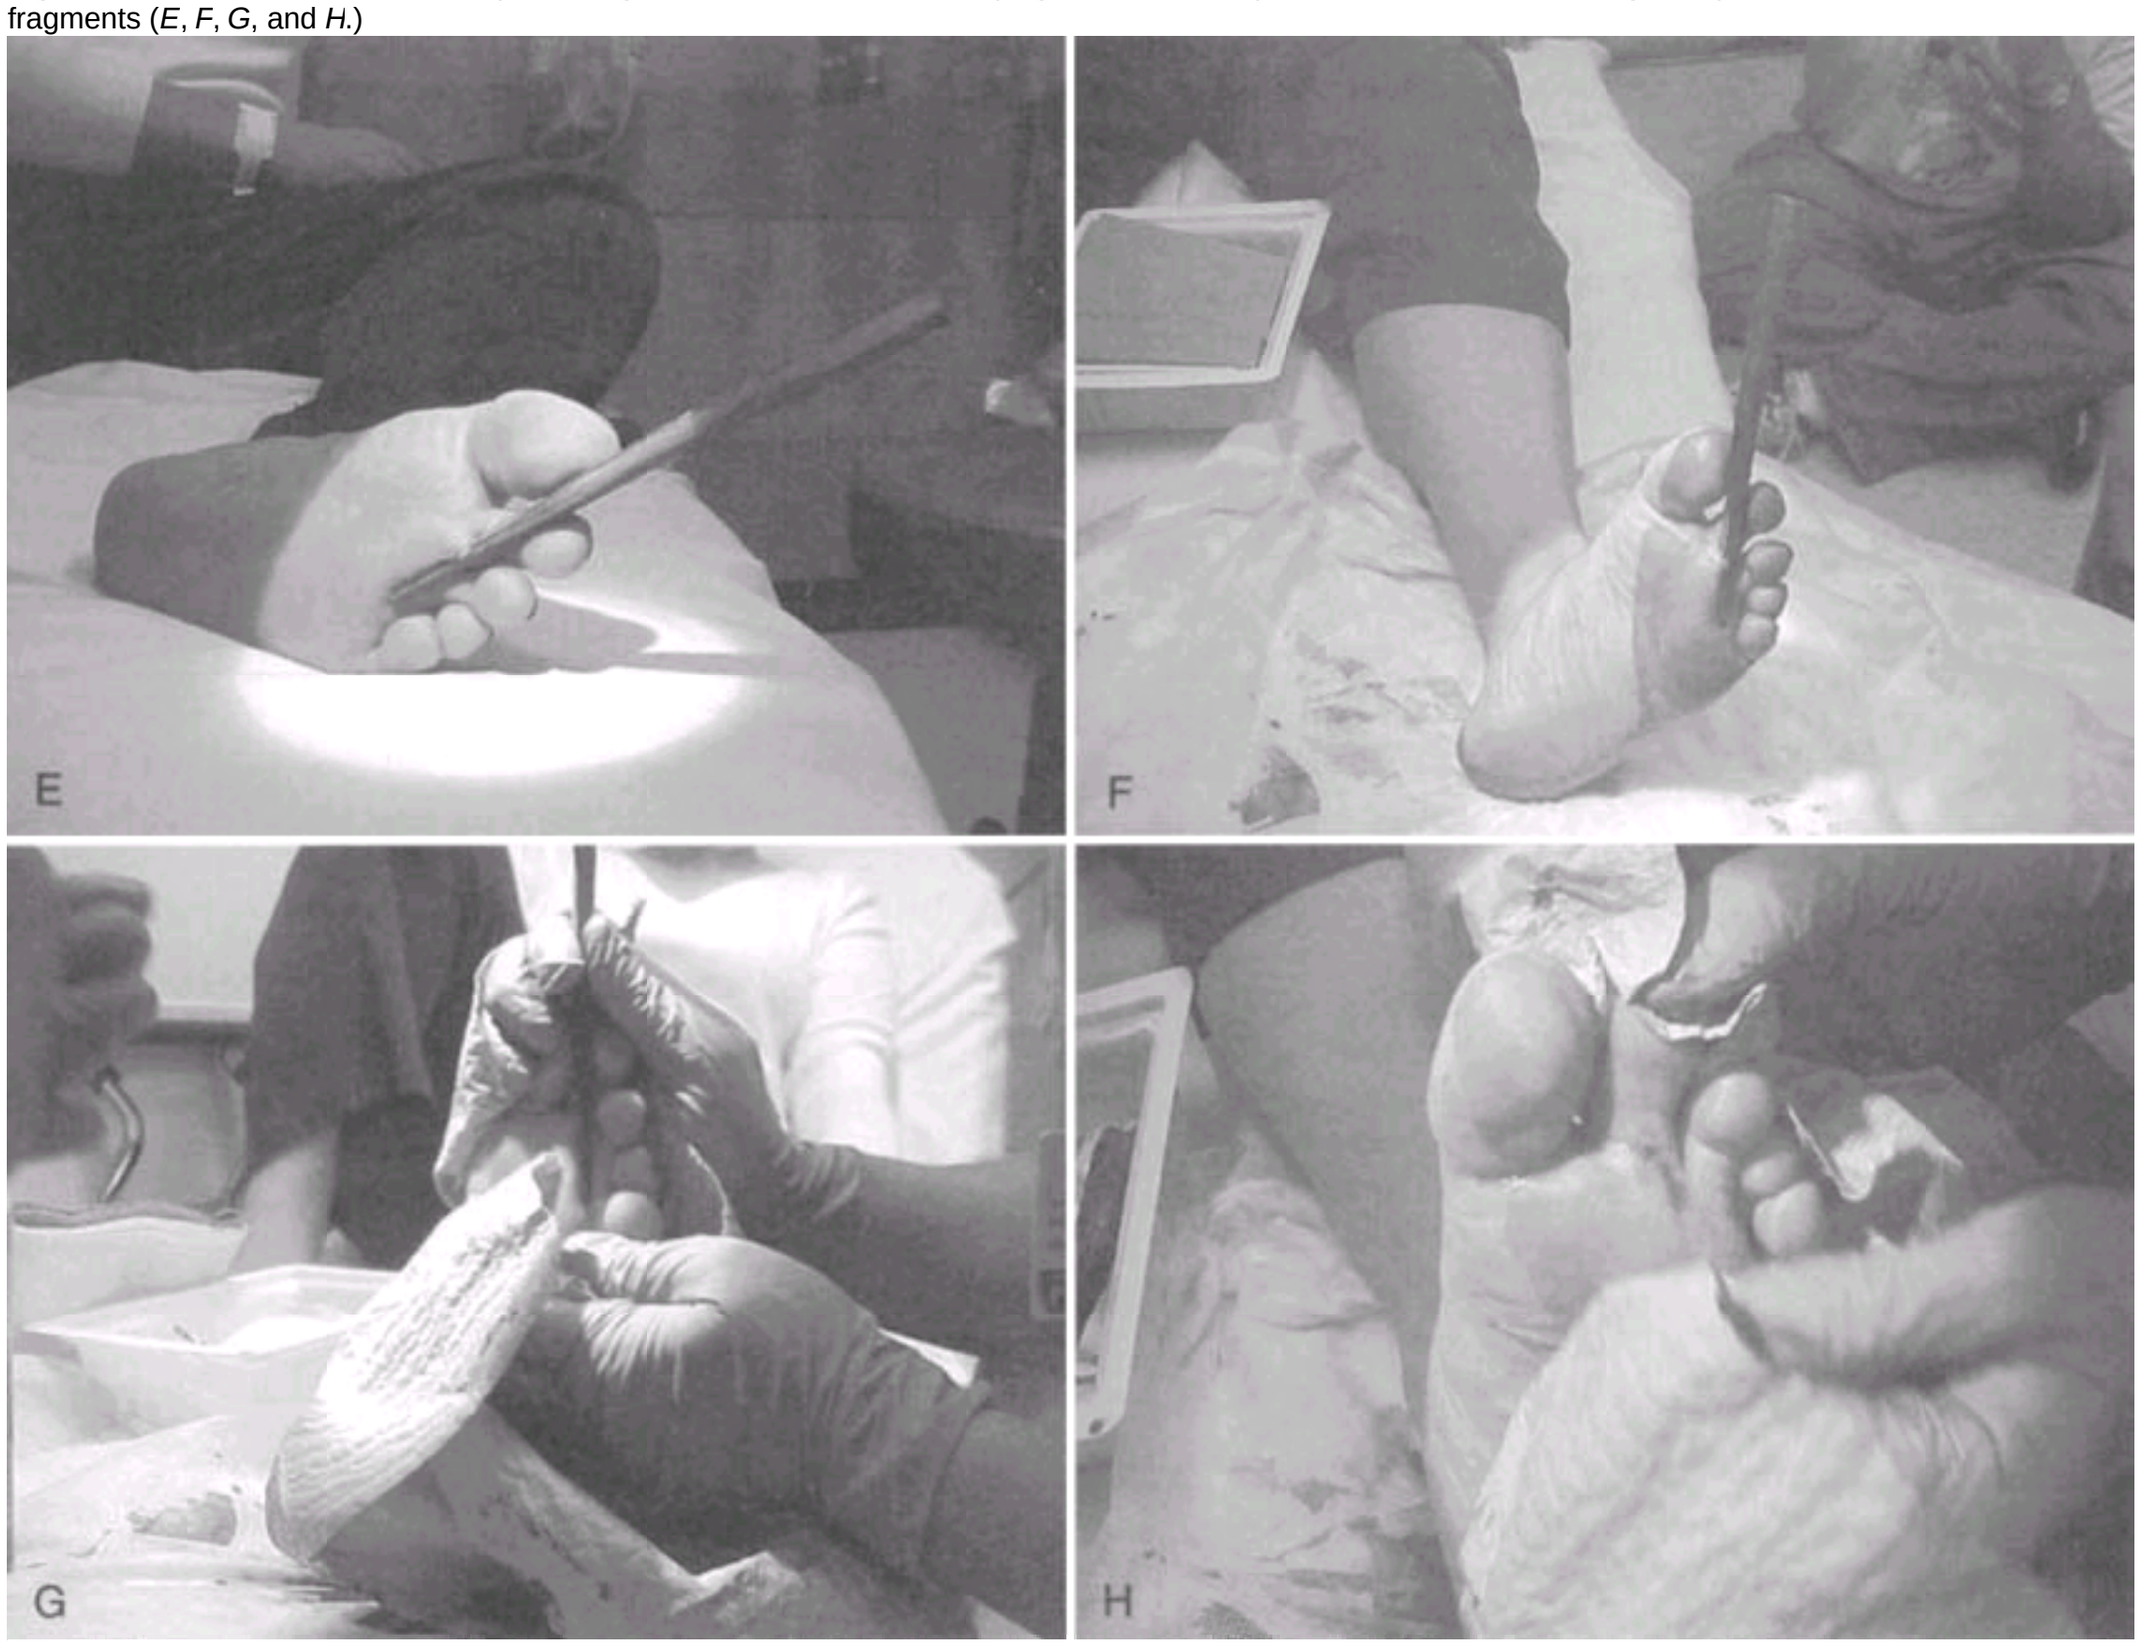

Figure 37-19 Magnified view of venom-containing nematocyst in its resting or "cocked" state *(A)*. After contact with the skin, a dart-like tail is extended and penetrates the dermis *(B),* and venom is injected *(C)*. Further stimulation of the attached nematocyst can expel more venom (see decontamination/removal technique in text).

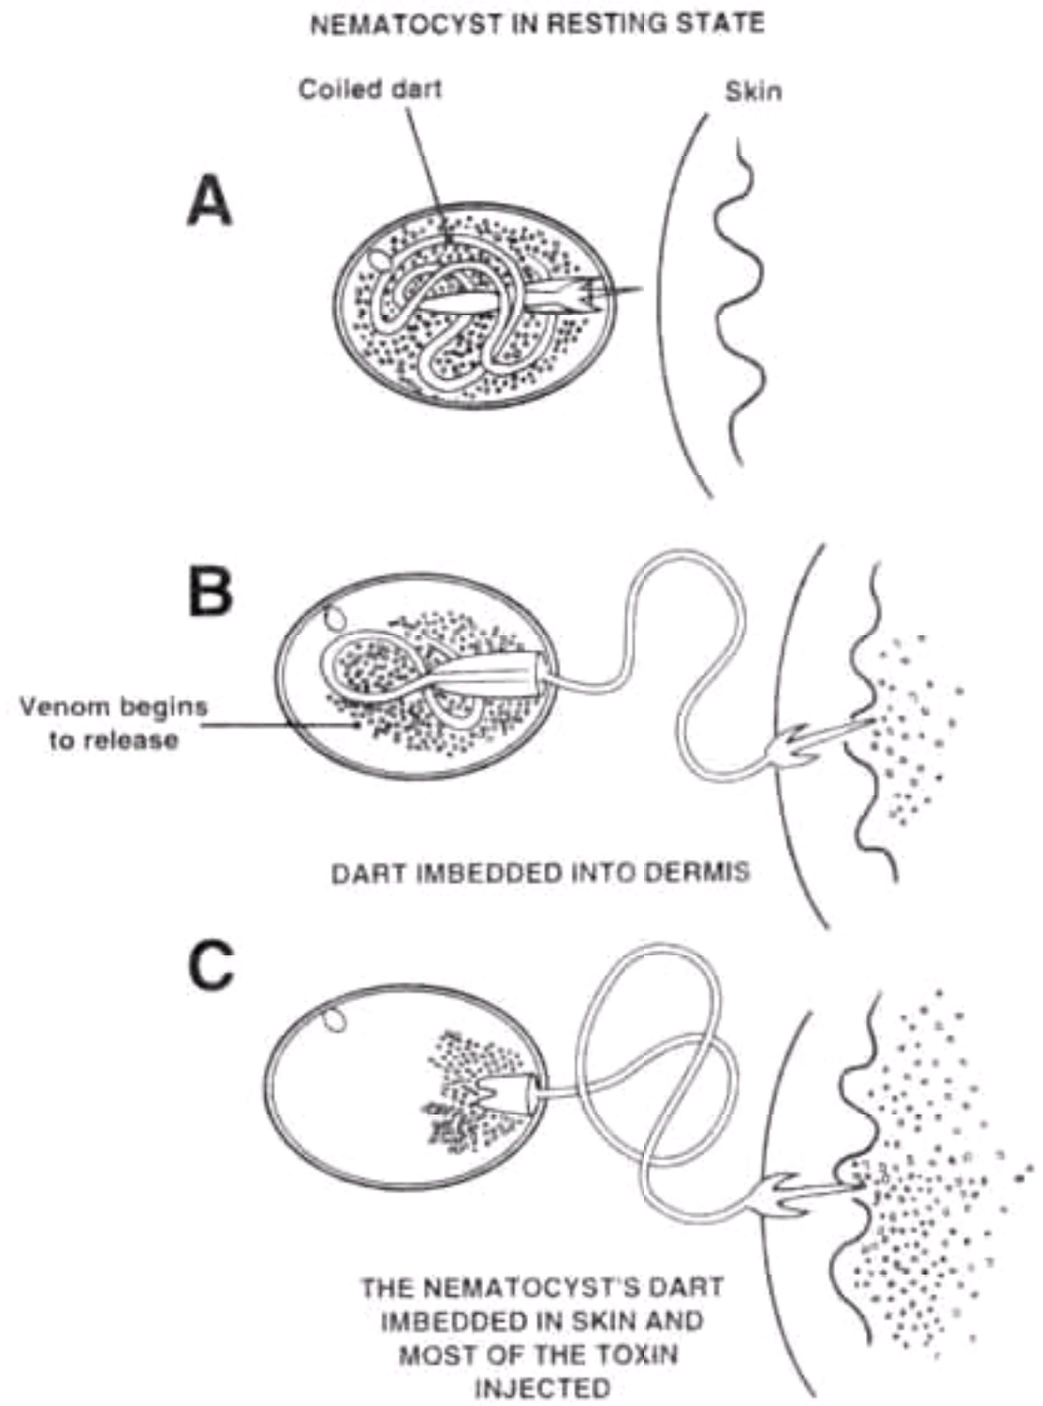

Figure 37-20 *A,* Stingray resting on the bottom of the ocean, usually covered by a layer of sand. An unsuspecting victim steps on the stingray, and the whiplike tail impales the foot (even through a heavy boot) with one or more spines *(B)*. The spine has backward-facing barbs covered by a sheath with venom-containing cells (*C*), causing a toxic envenomation and the potential for multiple FBs.

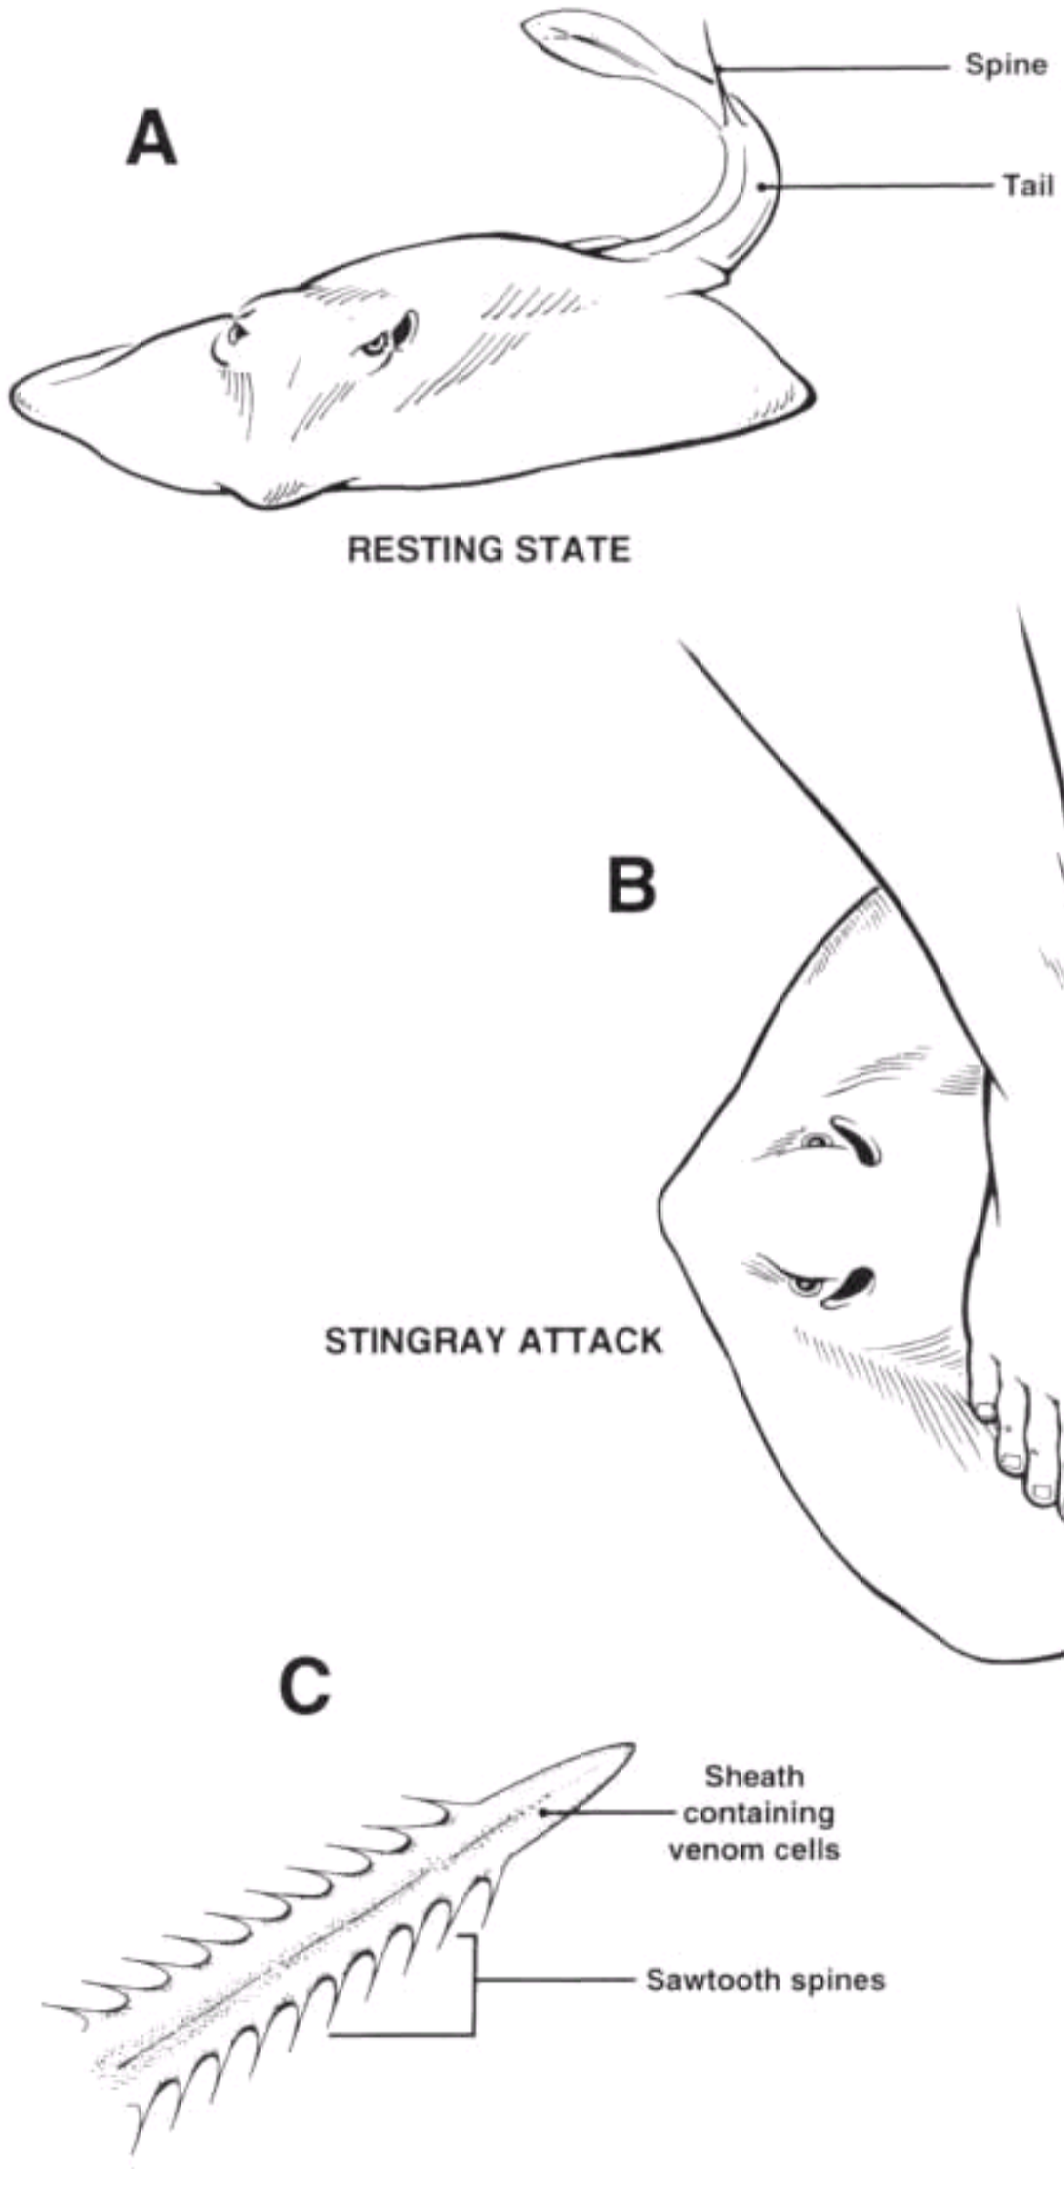

Figure 37-21 *A,* A thousand or more glochids affixed to the skin by contact with a single pad of polka dot cactus. *B,* The *professional* facial gel is spread with a fan brush. *C,* The gel is spread thin at the edges. *D,* The gel rollup is started by picking at the edge with the fingernails. *E,* When the *professional* gel is peeled off, all of the very small spines come with it. *(From Lindsey D, Lindsey WE: Cactus spine injuries. Am J Emerg Med 6:362, 1988. Reproduced by permission.)*

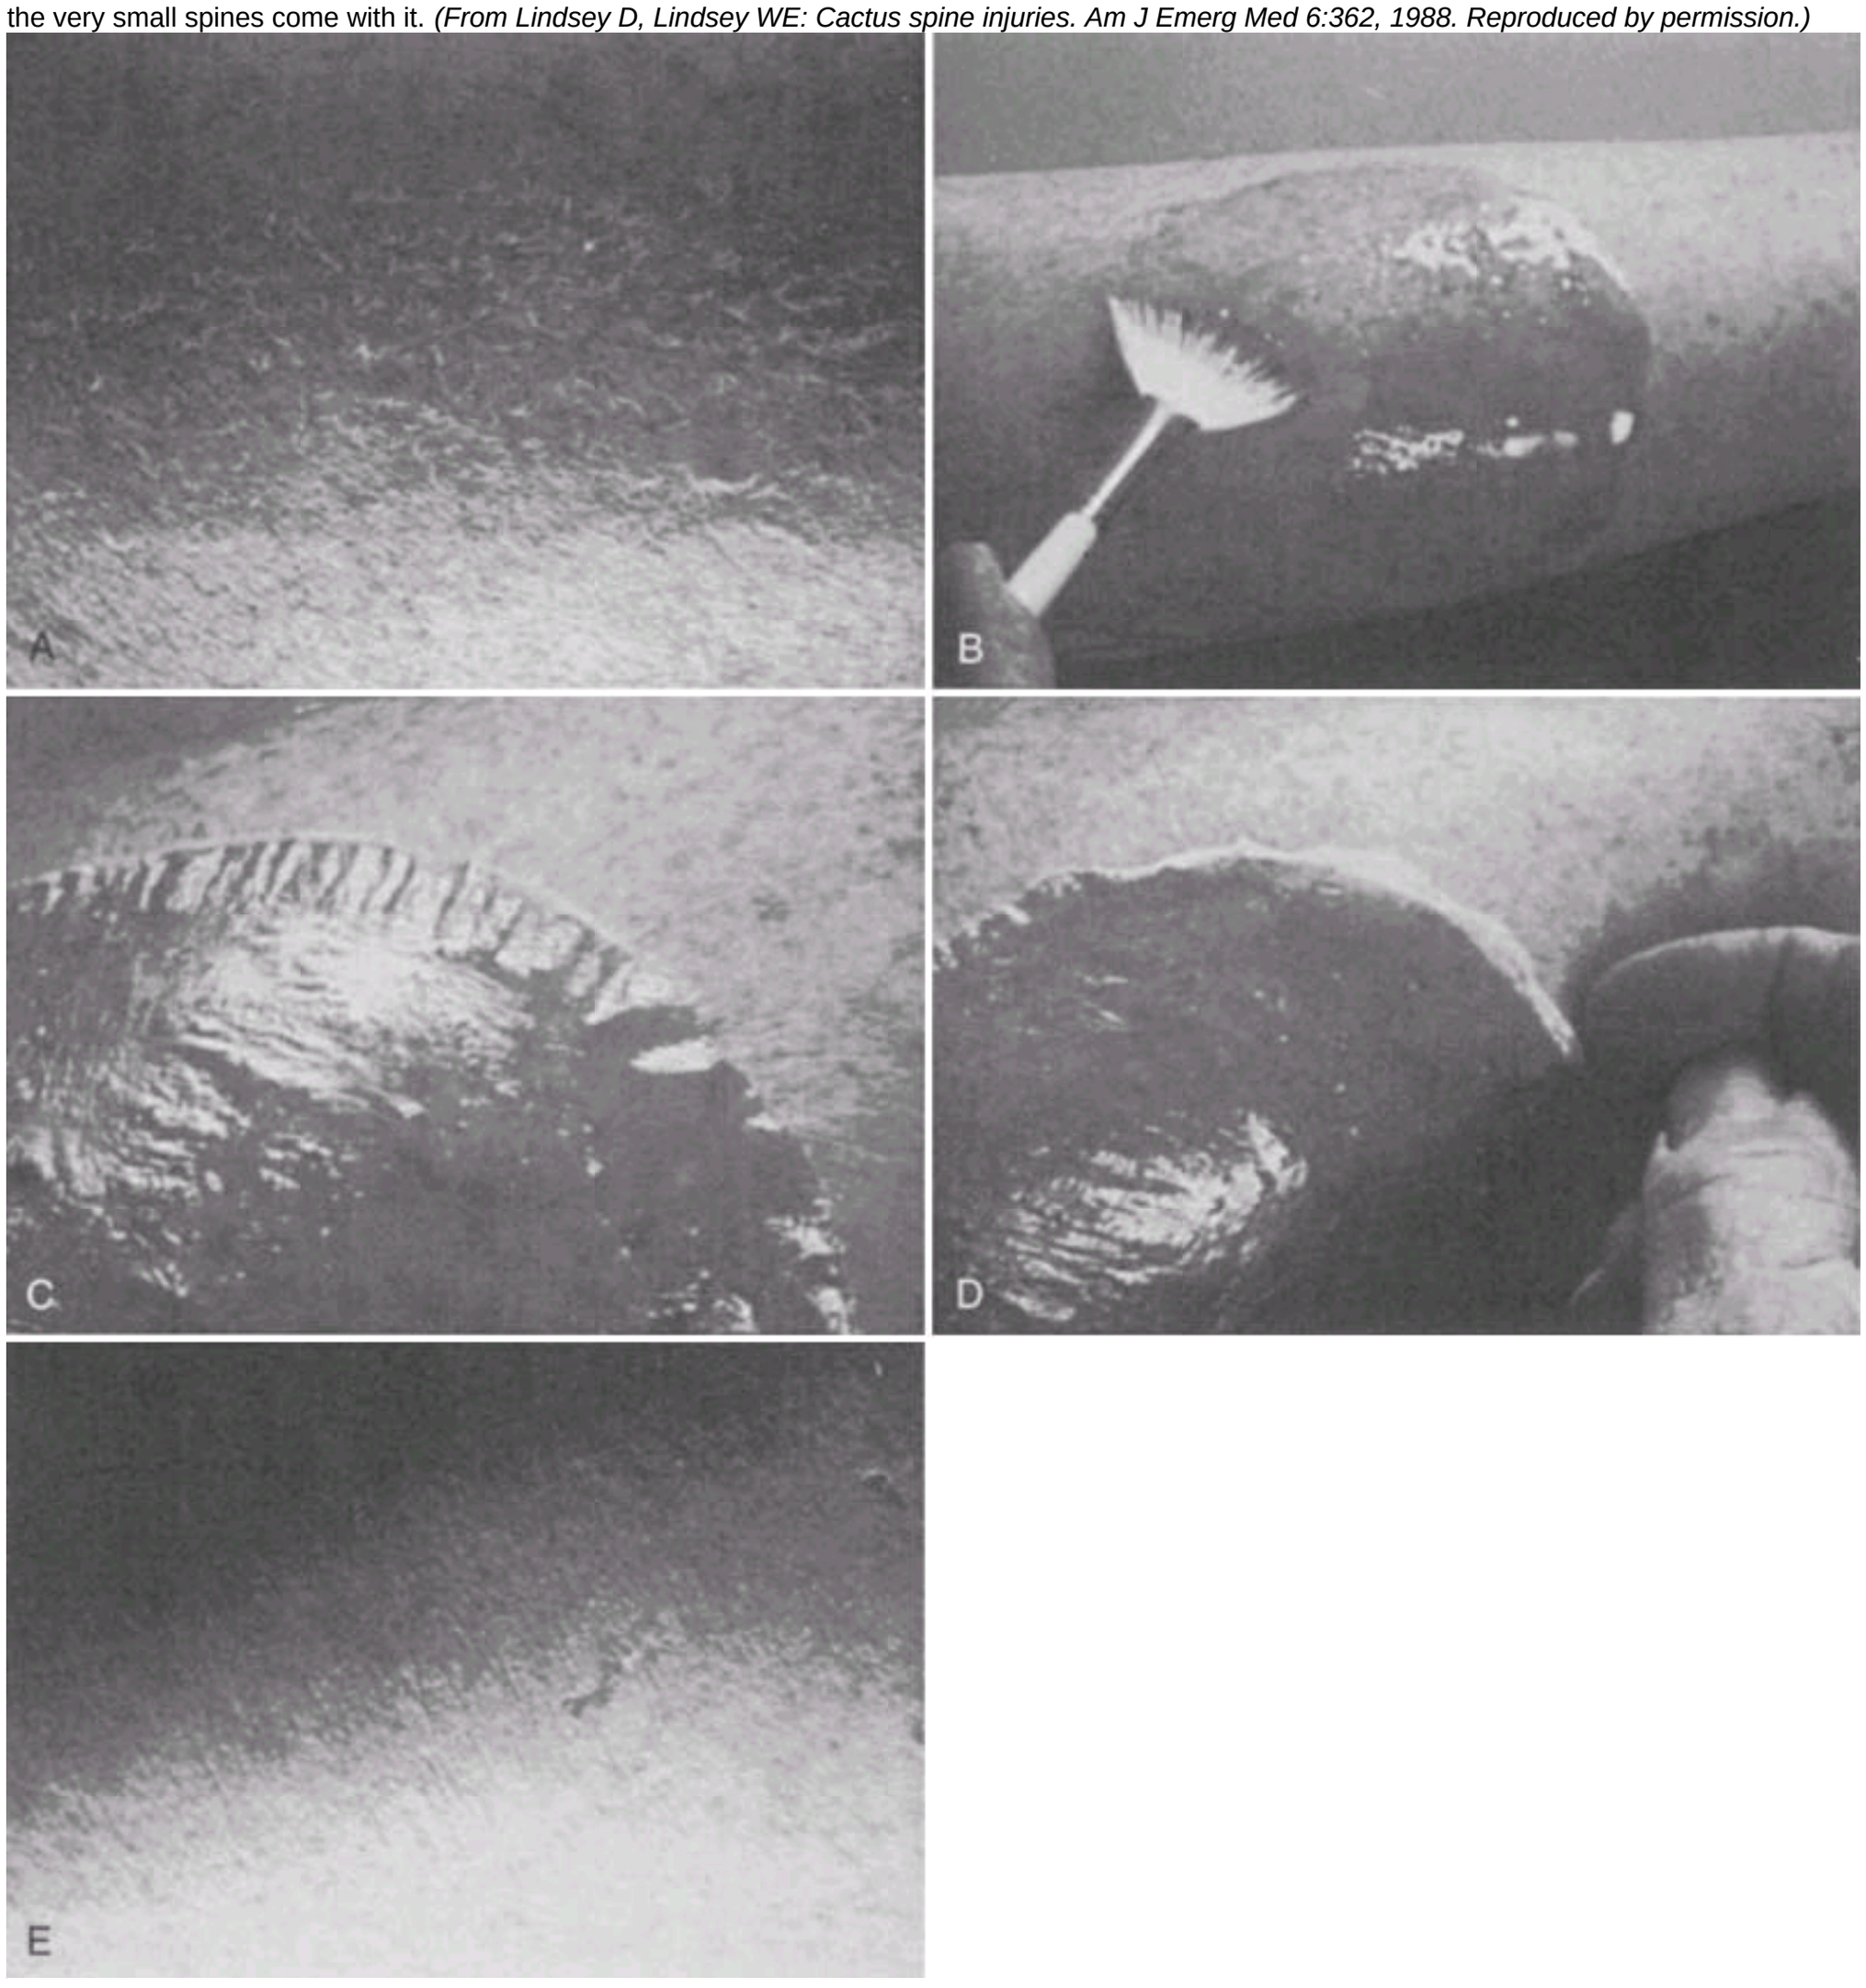

Figure 37-22a String removal technique for a tight ring. Note the absence of a laceration or underlying fracture *(A)*. A digital or metacarpal block is suggested. Edema is lessened by compression of the finger with a Penrose drain *(B)*. A long piece of umbilical tape is placed under the ring with the winding portion left long *(C)*.

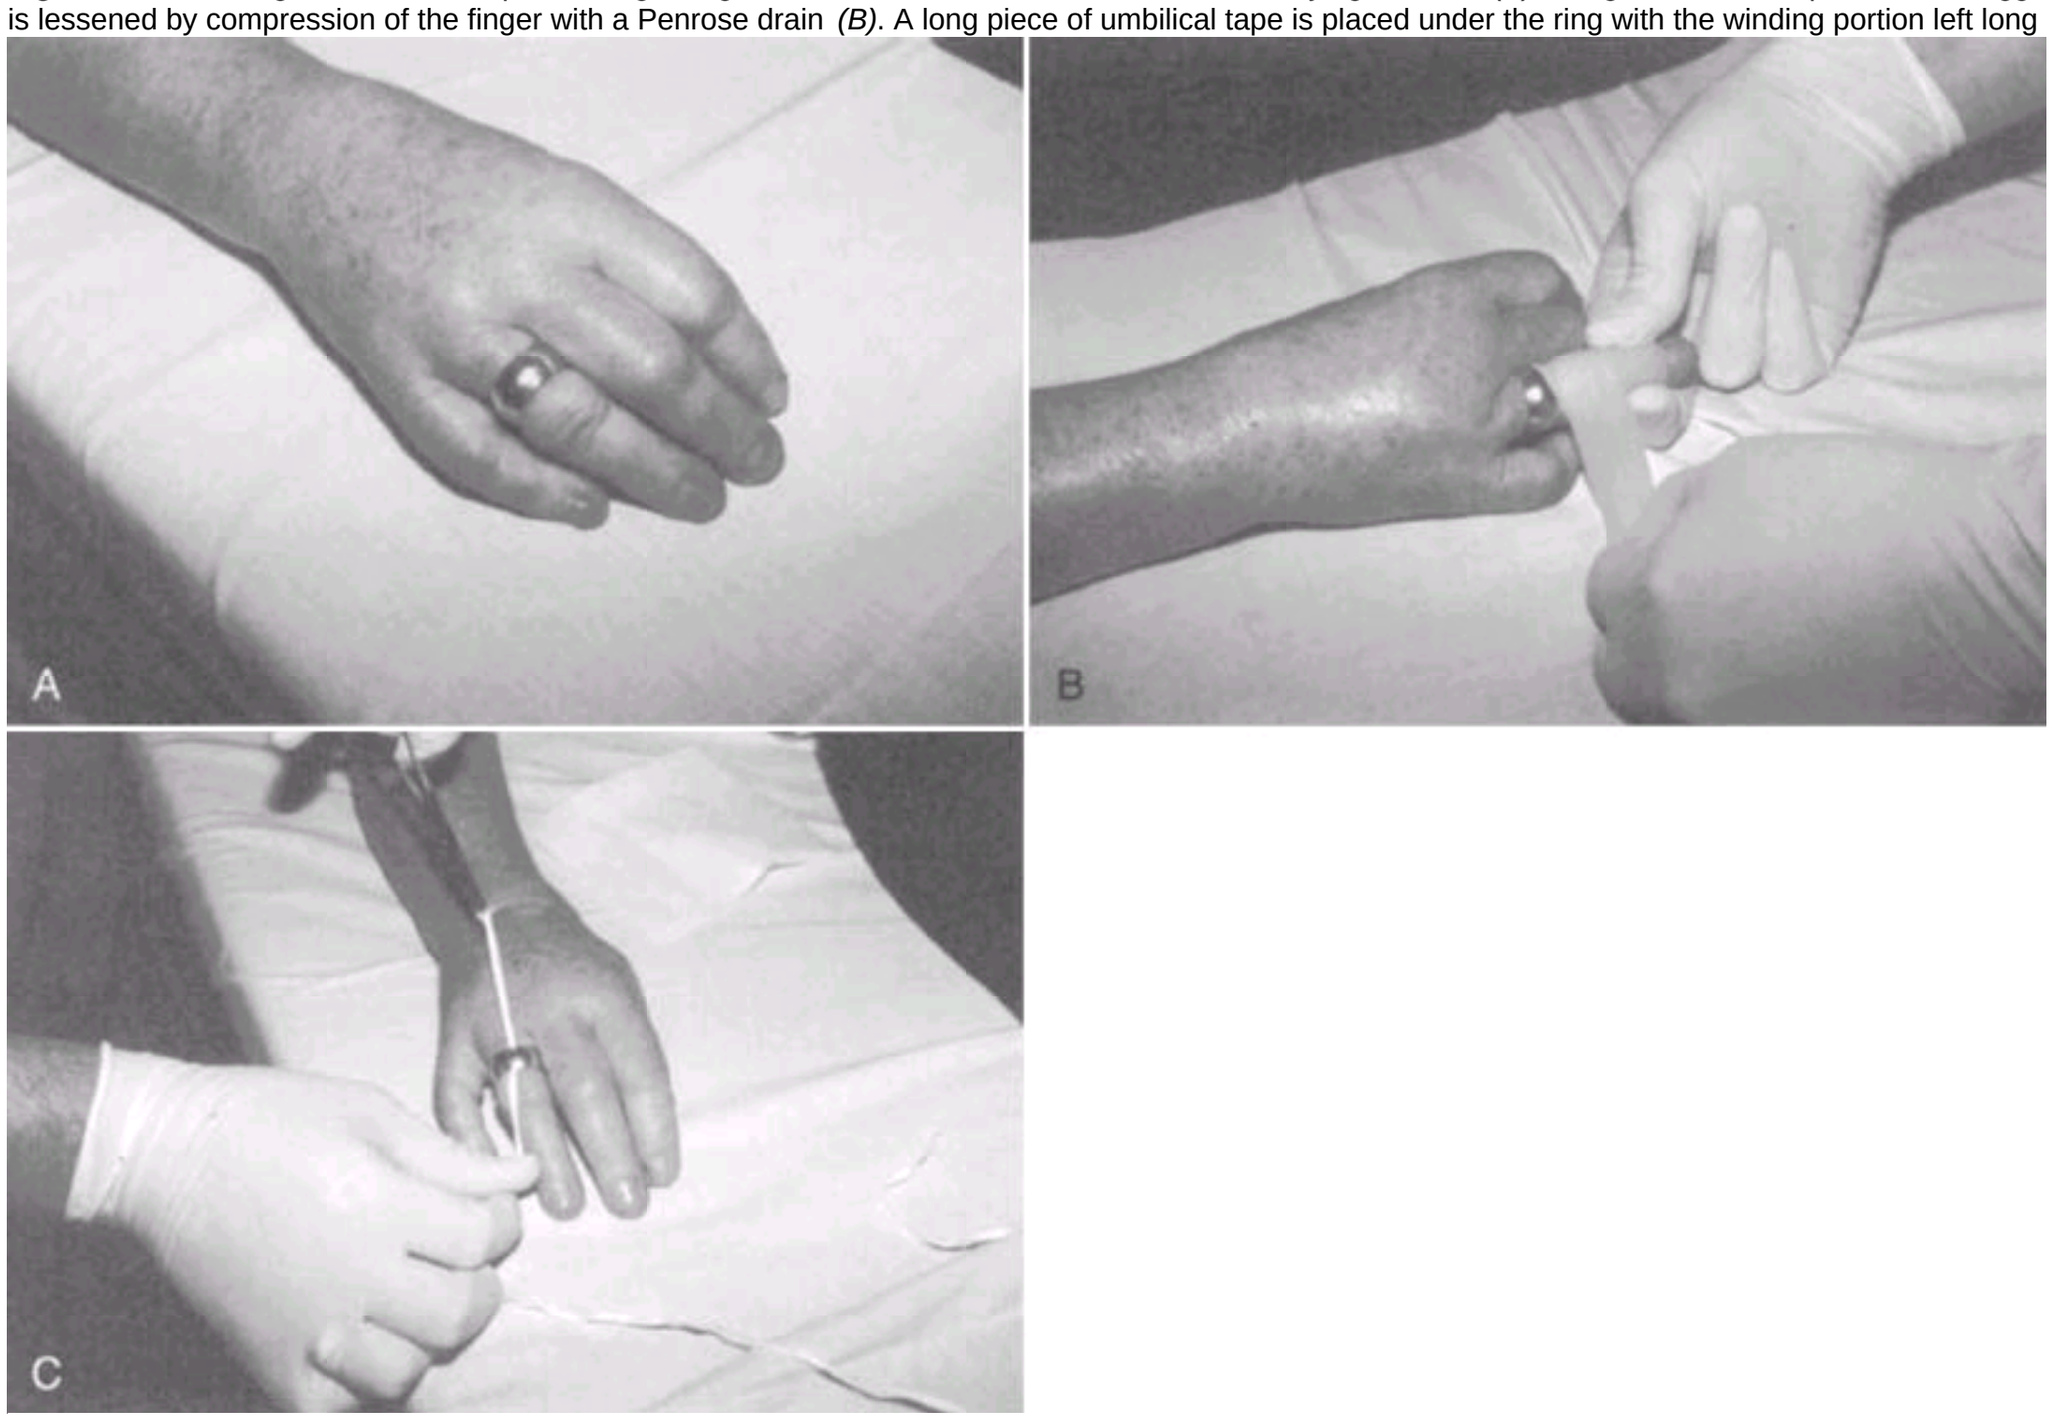

Figure 37-22b Begin winding either clockwise (*inset*) or counterclockwise (*photograph*) to compress the skin *(D) (see details in inset)*. The ring is removed by unwrapping the tape proximally and in the same direction it was wrapped *(E* and *F)*. The most difficult area to negotiate is the proximal interphalangeal joint. Note abrasion of skin after removal.

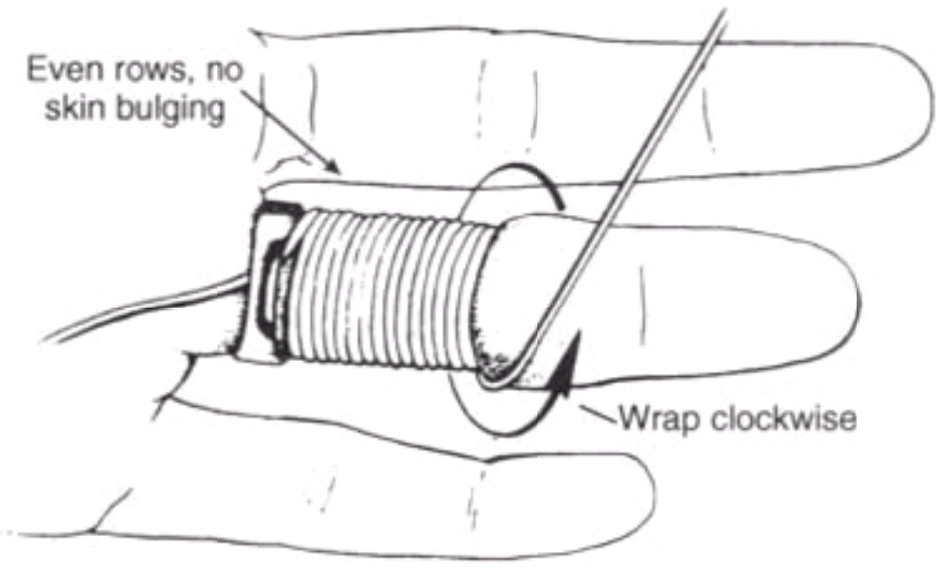

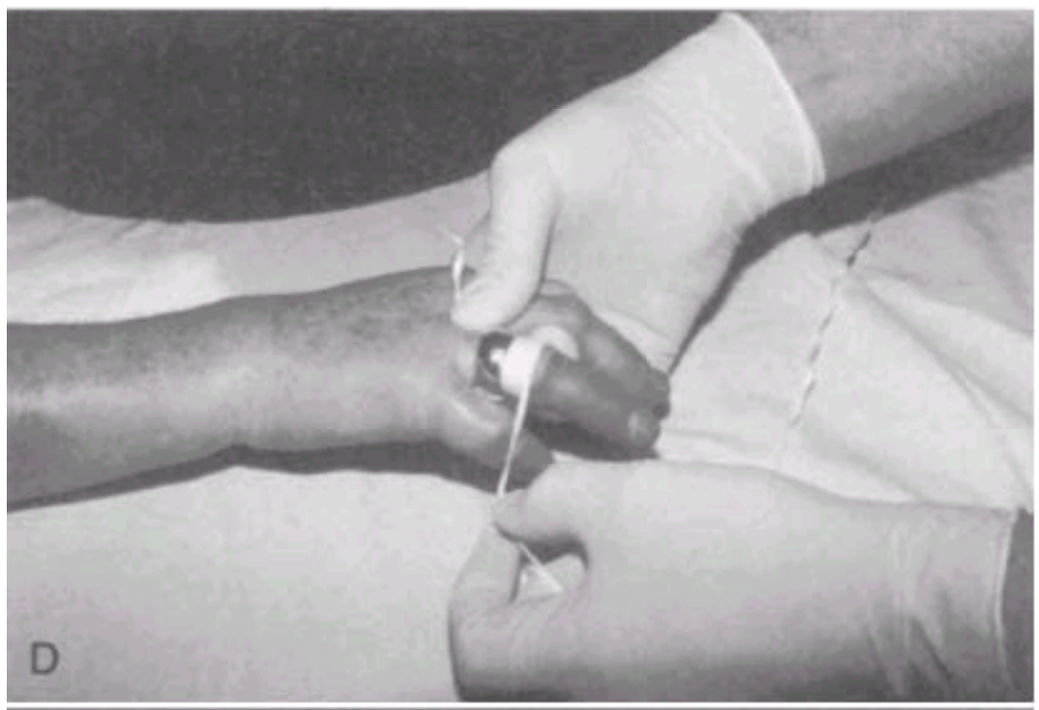

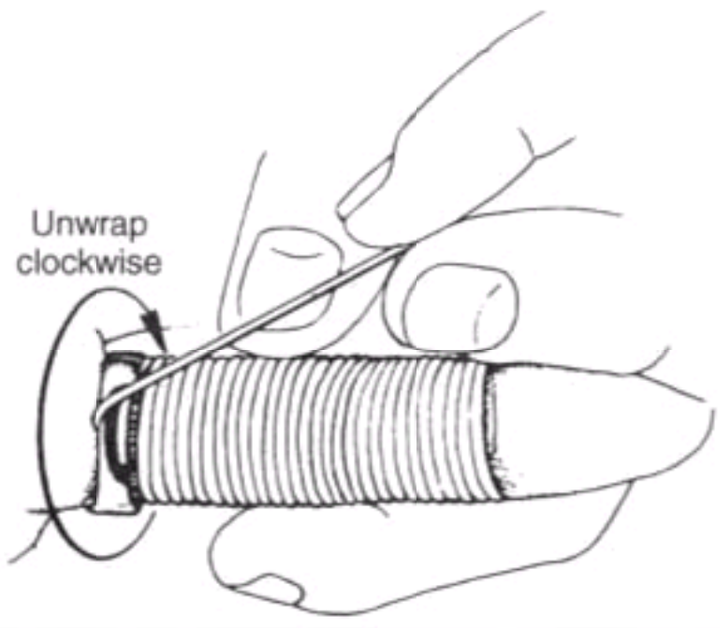

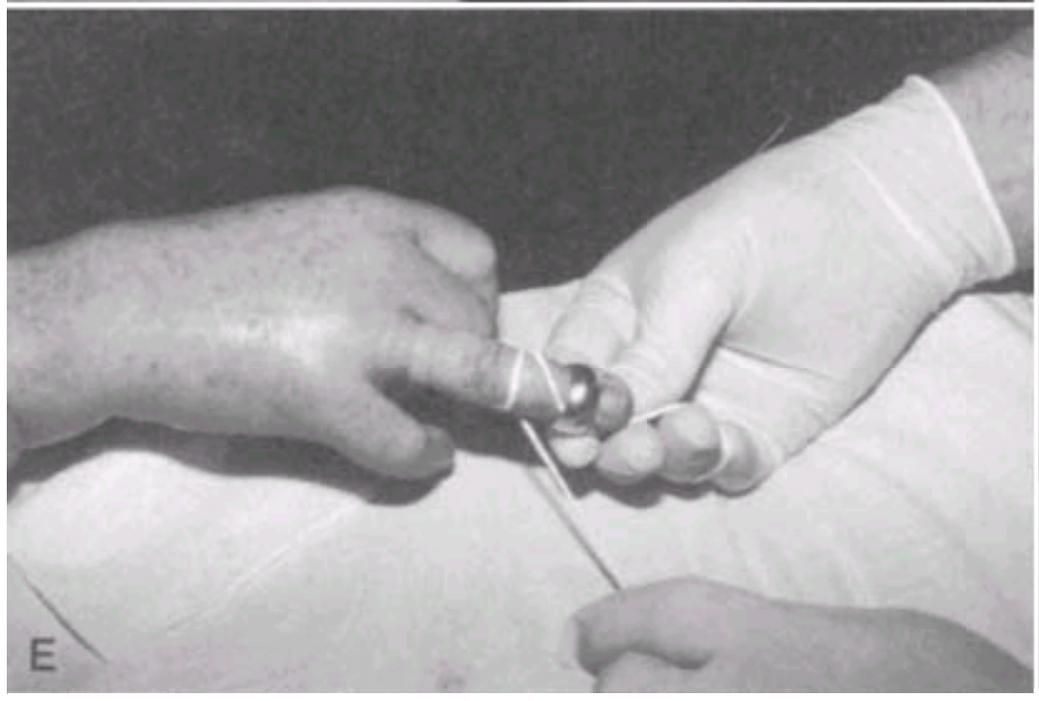

Figure 37-23 Ticks should be removed as soon as possible to minimize the transmission of tick-borne pathogens and to limit their fixation to the skin by a secreted cement compound. This engorged tick has been attached for about a day *(A)* and has burrowed under the skin. Most home remedies are worthless. A recommended approach is to grasp the tick with forceps near its head *(B)* where it enters the skin (avoid the soft body) and gently pull it out. Some advise twisting the head counterclockwise, but this has not objectively been found to be more effective. If pieces of the tick remain, they should be dug out.

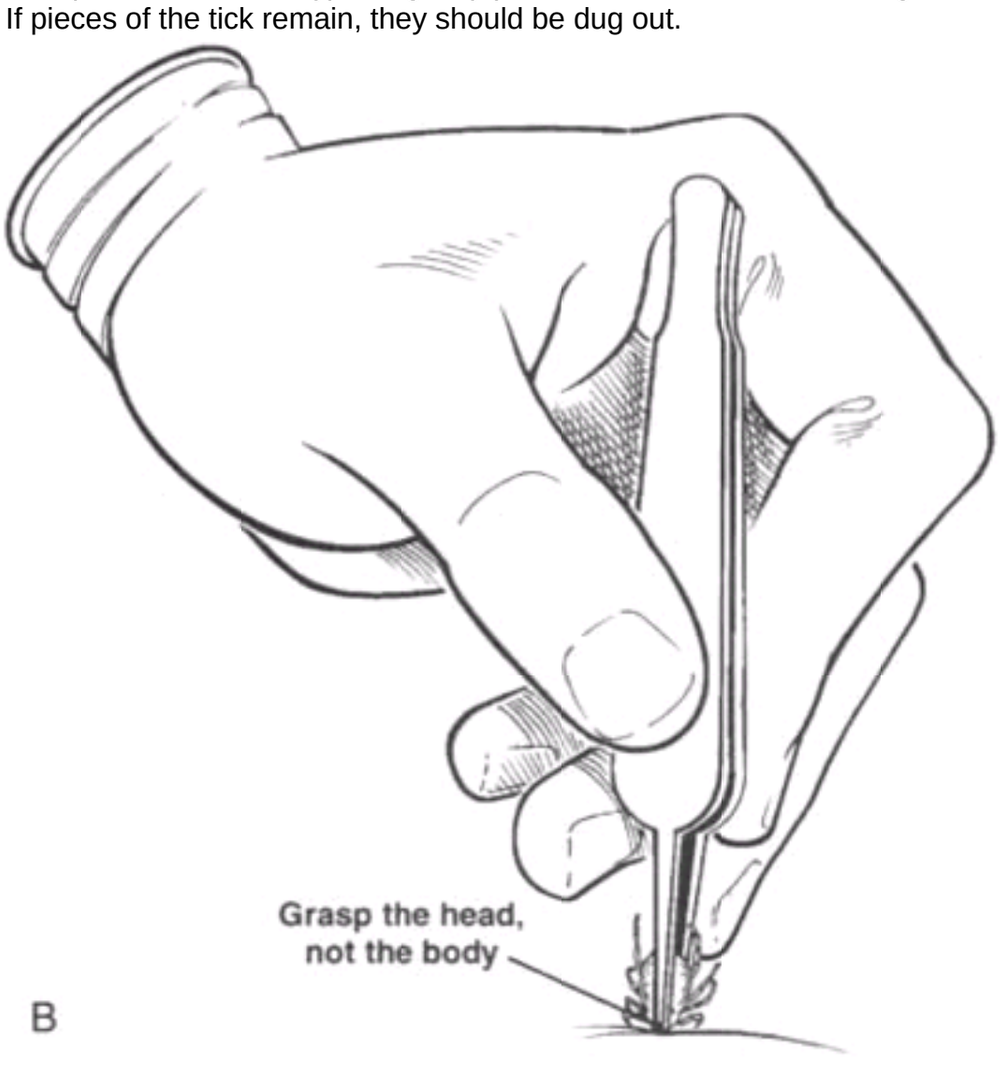

Figure 37-25 This child has multiple hairs compromising the circulation to two toes. The hairs are deeply embedded in the skin creases and cannot be visualized. The only way to ensure removal of the constriction is to cut the depth of the folds with a scalpel blade (using a dorsal incision to avoid the neurovascular bundle) and attempt to extricate individual fibers. Return of circulation should be obvious by temperature and color change in the affected digit(s), before it is assumed that all of the fibers have been cut.

Figure 38-1 An abscess that appears in an atypical place or recurs after initial treatment is successful should raise the possibility of rare or underlying conditions. *A*, This IV drug user had an "abscess" of the chest wall drained in various EDs several times over a 2-month period, and it seemed to initially respond to drainage and antibiotics. He still manifested an area of cellulitis, minor fluctuance, and continued drainage near the center of the chest. This is an atypical place for a simple cutaneous abscess. Magnetic resonance imaging demonstrated an abscess of the sternolclavicular joint that was draining to the skin, simulating a recurrent cutaneous abscess. He required extensive surgical debridement and prolonged antibiotics. The etiologic organism was never ascertained, but pseudomonas is often present. *B*, This patient has a large "abscess" of the lateral chest wall that initially drained unusual gelatinous material, not frank pus. *C*, At follow-up 3 days later the abscess was much improved. The contents of the abscess had been sent for pathologic analysis since it had an unusual consistency, and it demonstrated a highly undifferentiated malignancy. The fluid was sterile. Normally, analyzing or culturing the contents of an abscess will not yield helpful information, but in this case the unusual consistency of the collection prompted further analysis. *D*, This patient had a sternotomy for bypass surgery a few months ago. She had been sporadically treated for a minor wound infection but then presented with a draining fluctuant mass at the inferior border of the sternum. This is the external manifestation of an extensive sternal osteomyelitis.

Figure 38-2 This patient presented with a large abscess of the deltoid area (arrow) and could offer no explanation for it *(A)*. This is a typical scenario for a drug user who injects directly into the skin, and the characteristic circular skin lesion from "skin popping" found on the legs *(B)* confirmed the clinical suspicion. Even though a drug screen was positive for opioids, the patient still denied drug use and attributed the leg lesions to frequent trauma on the job.

Figure 38-3 *A,* To anesthetize an abscess, hold the syringe parallel to the skin and insert a 25-ga needle into the middle of the dome of the abscess, so the needle is just slightly under the skin. The anesthetic will spread over the entire abscess without moving the needle position. *B*, Note the blanching of the skin that spreads to cover the entire abscess without repositioning the needle. *C,* The skin over the abscess is incised the full length of the abscess. A small stab incision does not allow for proper drainage. *D,* An instrument is inserted into the abscess cavity to spread the skin, drain the pus, and break up loculations. *E*, One way to break up loculations is to wrap a hemostat with gauze and, *F*, swirl it around the margins of the wound. *Do not use a gloved finger to break up loculations in an abscess that may contain a sharp or jagged foreign body.*

Figure 38-4 The relation of the elective lines of tension in the face to the underlying mimetic musculature. Only in the lower eyelid are these lines not perpendicular to the muscles. The left side of the drawing shows the use of this principle when common facial lesions are excised or a facial abscess is drained. *(From Schwartz SI, Lillehei RC: Principles of Surgery, 2nd ed. New York, McGraw-Hill, 1974. Reproduced with permission.)*

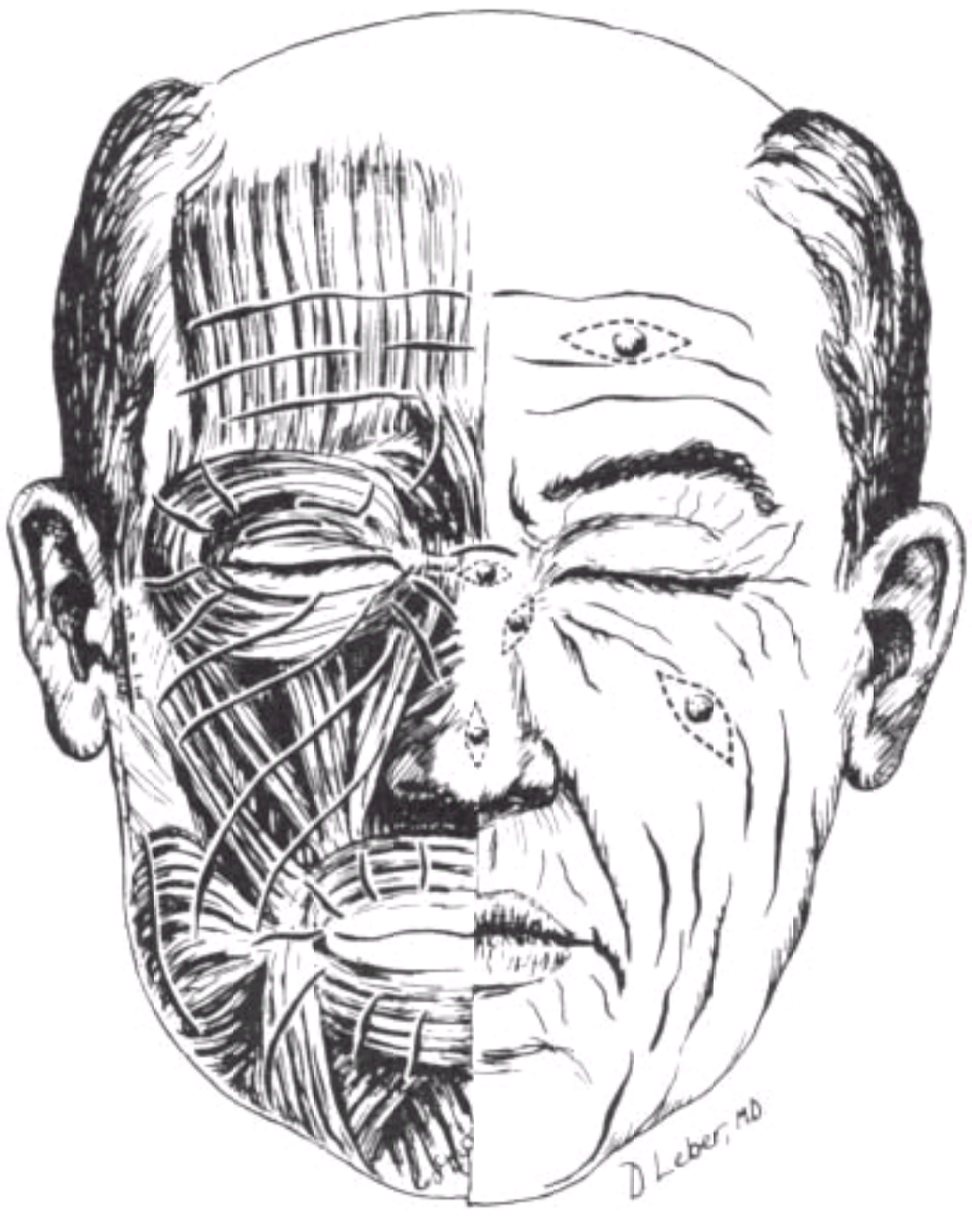

Figure 38-5 A simple linear incision is preferred over an "X" or crosshatched incision. In this case, a cutaneous post-surgical scalp abscess was drained by an "X" incision and the tips of the flap necrosed, leaving a slowly healing full thickness wound.

Figure 38-6 *A,* This intravenous drug user presented with an abscess *(arrow)* of the antecubital fossa. Following incision, the clinician attempted to break up the loculations with his finger. When a radiograph was obtained, three needle fragments (arrows) were found embedded in the wound *(B)*. The patient was HIV-positive and claimed no knowledge of the presence of the needles. Instead of using a finger, loculations should be broken up with an instrument.

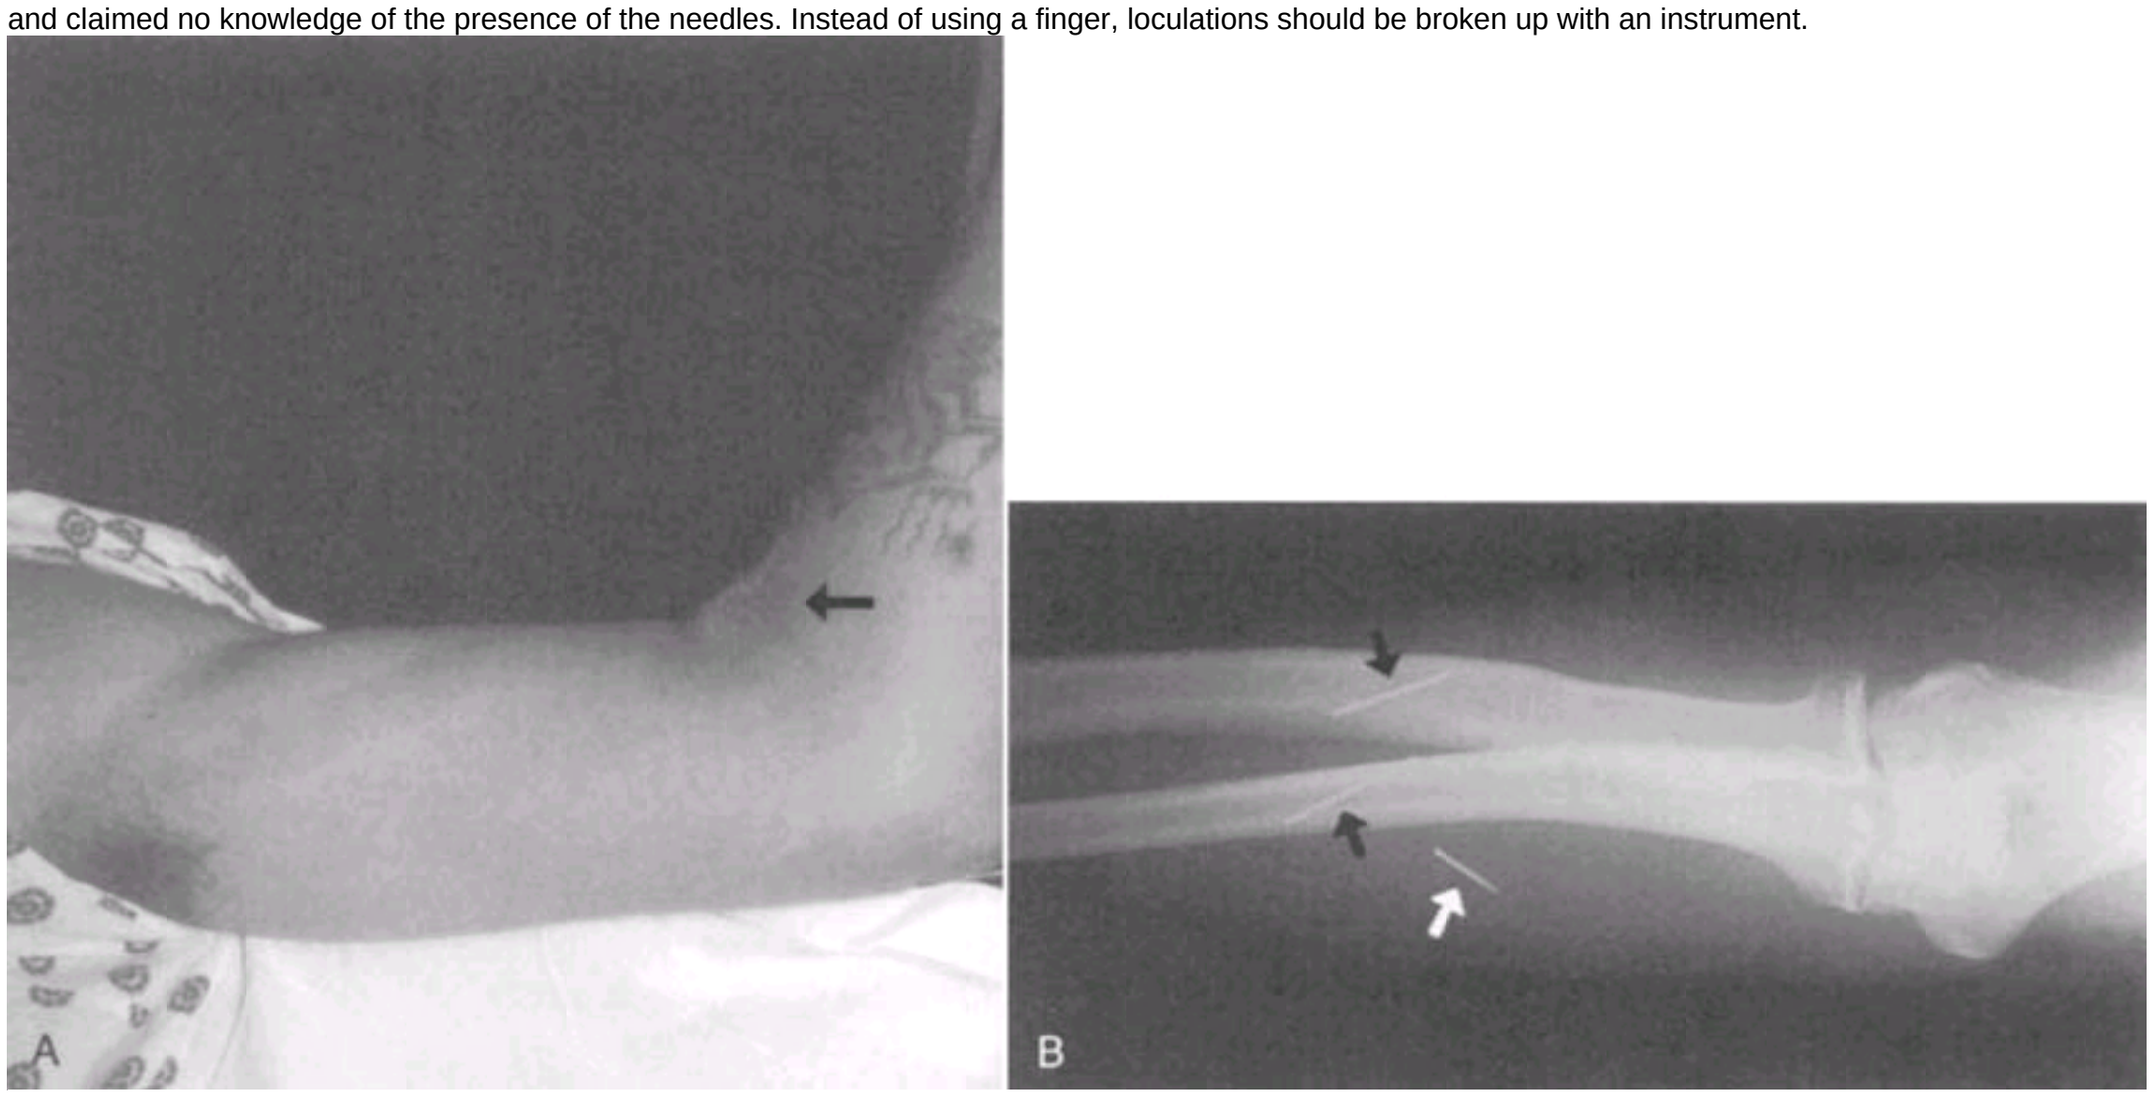

Figure 38-7 Packing change is usually performed by a health care professional. In the compliant and motivated patient, home care may replace frequent visits. Cotton-tipped applicators dipped in peroxide are used to swirl around the cavity to remove debris and the cavity is held open for tap water irrigation.

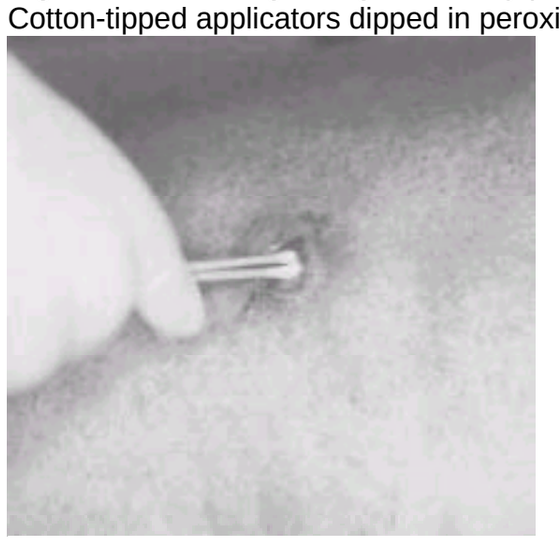

Figure 38-8 A carbuncle is a complicated abscess on the nape of the neck. It is very common in diabetics *(A)*. Because of many crypts and loculations, simple incision and drainage are often not readily curative. This patient had multiple incisions yet was not cured *(B)*. Antibiotics may augment healing of this abscess, but wide surgical excision may be required.

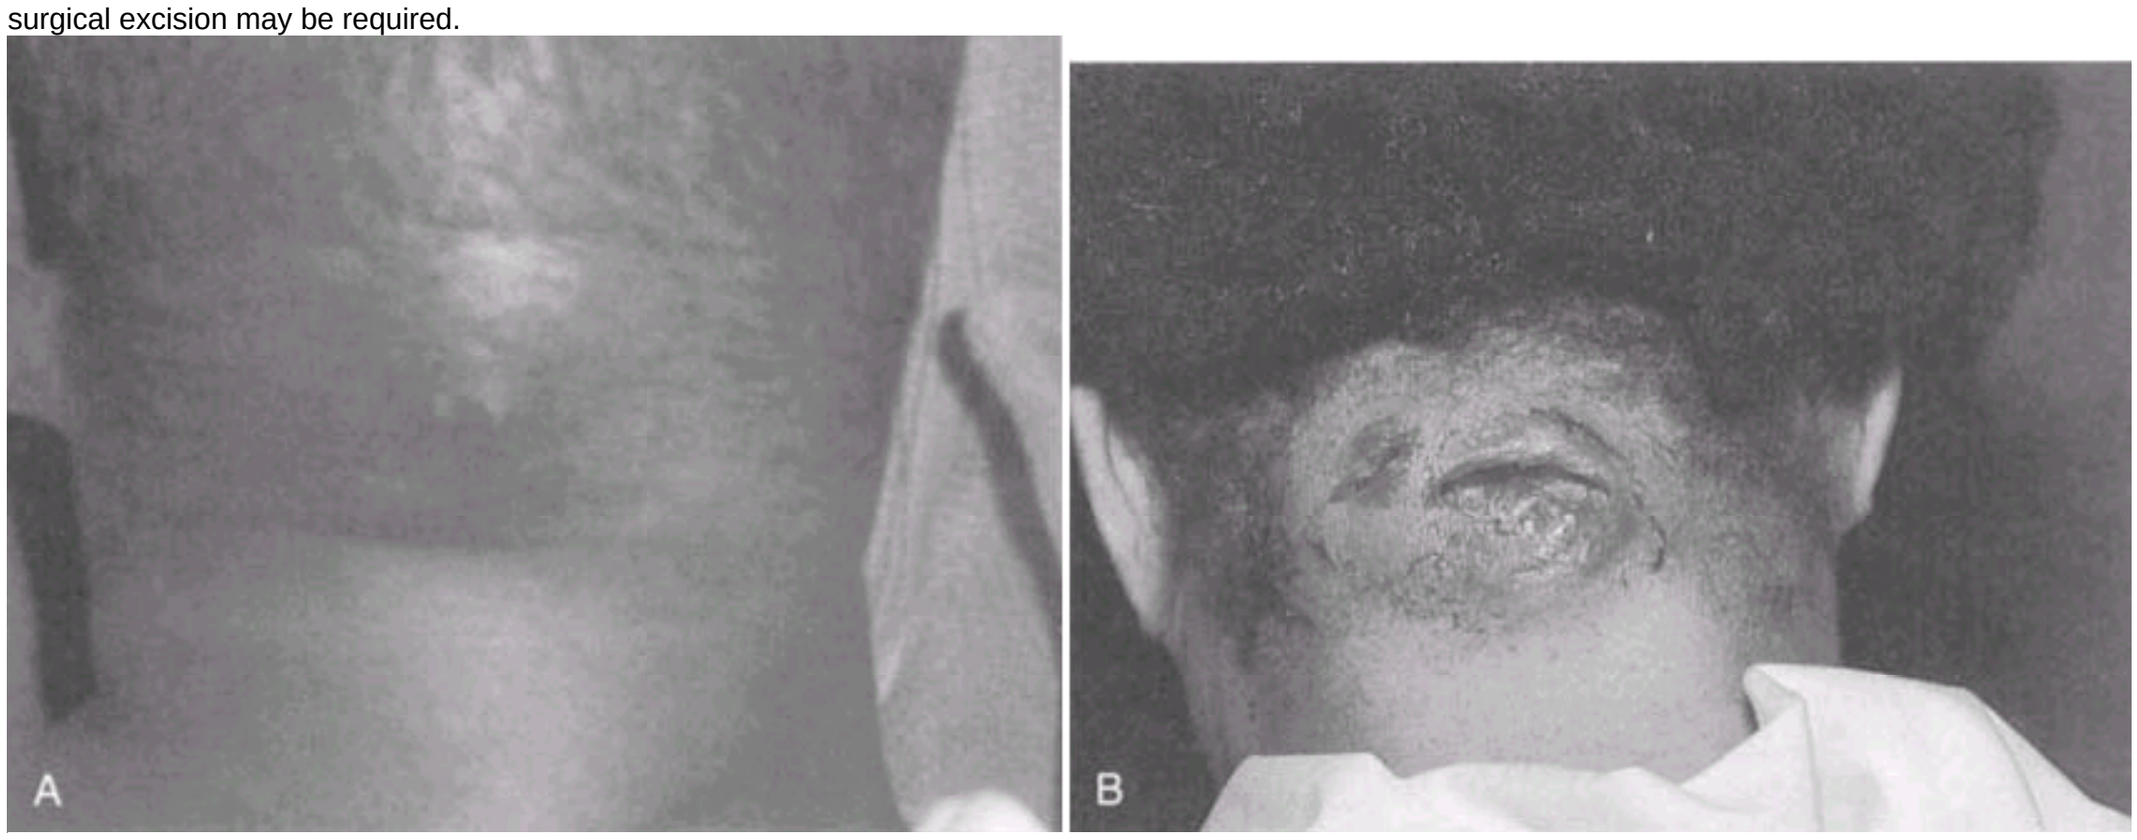

Figure 38-9 Hidradenitis suppurativa of the groin or axilla is a complicated series of abscesses that may not be amenable to simple incision and drainage. In the case of involvement with the groin, extensive surgery was required to excise recurrent infection.

Figure 38-10 *A,* A superficial breast abscess may be drained with a linear incision that radiates from the nipple. *B* and *C,* Diagrams of intramammary abscess *(B)* and retromammary abscess *(C)*. Both require drainage under general anesthesia. The abscess itself may not be fully appreciated if it is deep-seated, and the mistaken diagnosis of cellulitis may be made. *(Redrawn from Wolcott MW: Ferguson's Surgery of the Ambulatory Patient, 5th ed. Philadelphia, JB Lippincott, 1974. Reprinted with permission.)*

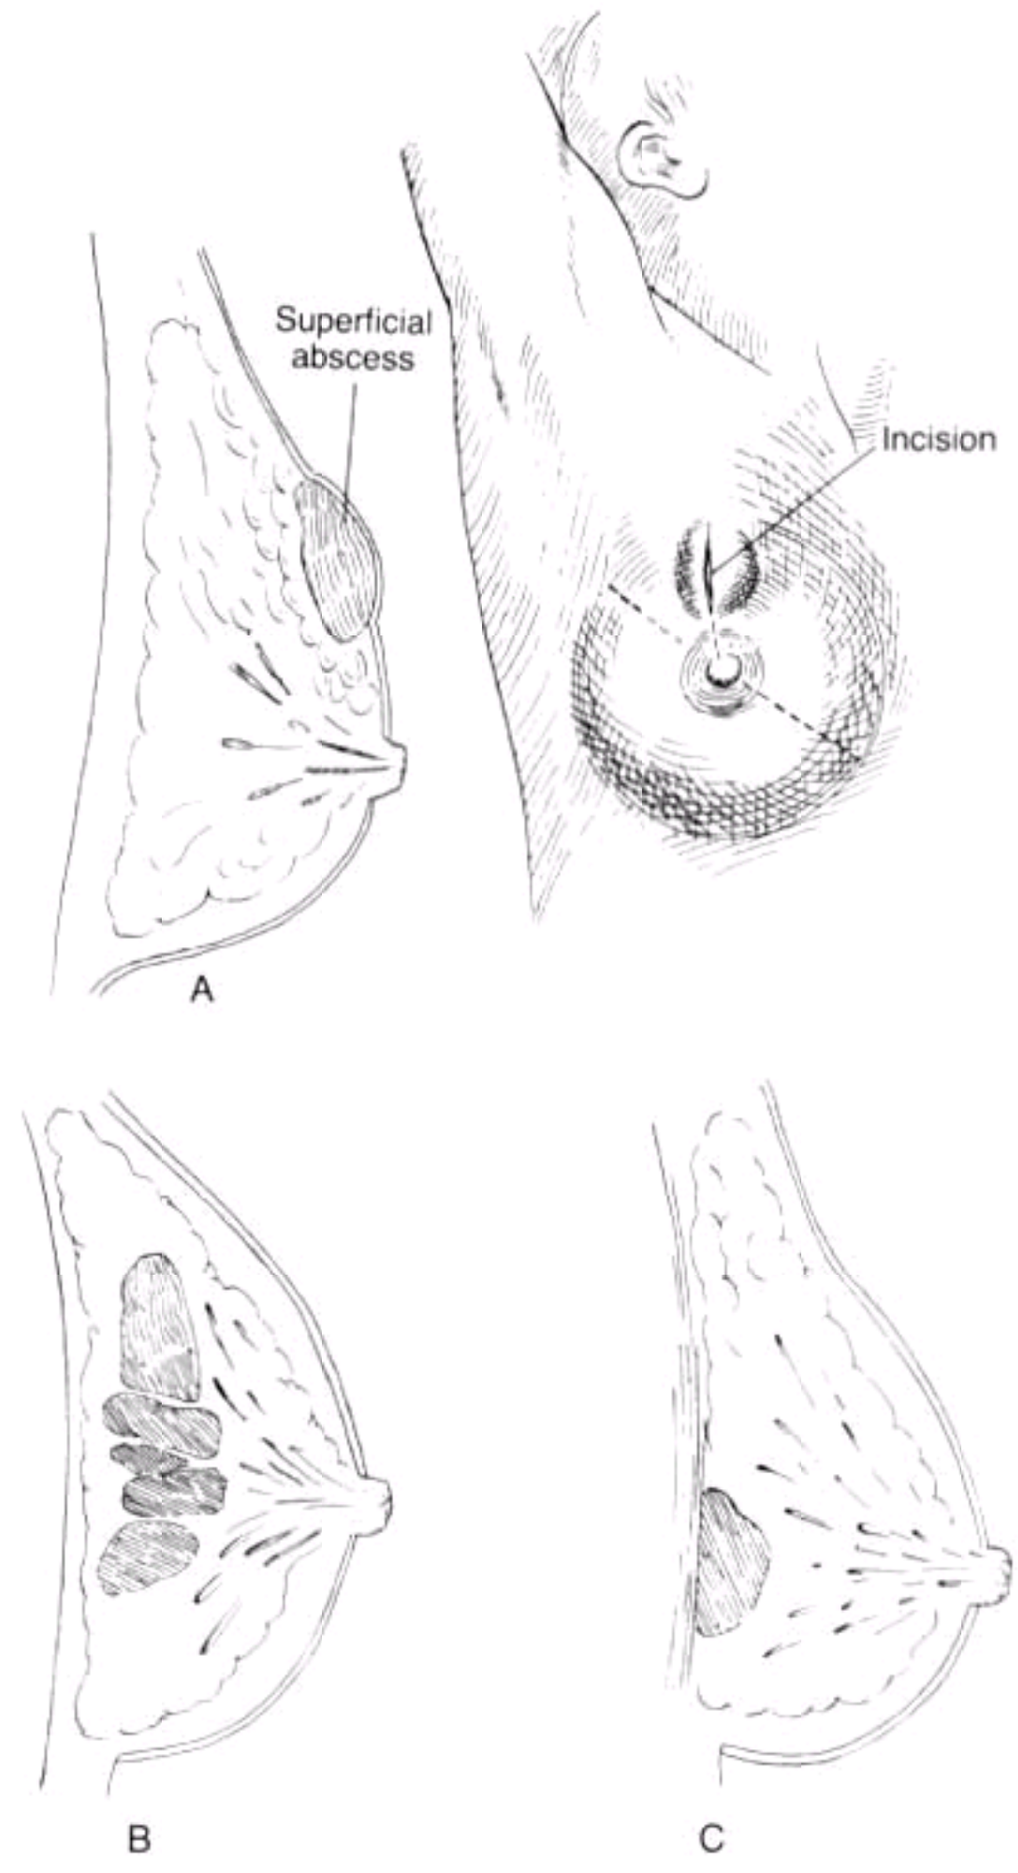

Figure 38-11 Use of the Word catheter for outpatient drainage of a Bartholin gland abscess. This is a fistulization procedure rather than a standard incision and drainage. A stab incision is made on the mucosal surface *(A)*. A catheter is inserted into the cyst cavity *(B)* and filled with 3 to 4 mL of water *(C)*. *D,* Inflatable bulb-tipped catheter. *Left,* Uninflated. *Right,* Inflated with 4 mL water. *(A through C from Word B: Office treatment of cyst and abscess of Bartholin gland. JAMA 190:777, 1964. D from Word B: Office treatment of cyst and abscess of Bartholin gland duct. South Med J 61:514, 1968. Reproduced with permission.)*

Figure 38-12a *A,* An alternative to formal incision, drainage, and packing for the treatment of this Bartholin abscess is to place a Word catheter. *B*, The abscess is stabilized with the thumb and index finger, and a local anesthetic is injected into the mucosal (not skin) surface. *C*, A stab incision is made with a scalpel. *D*, The abscess is punctured with a hemostat. Deep abscesses may be difficult to puncture.

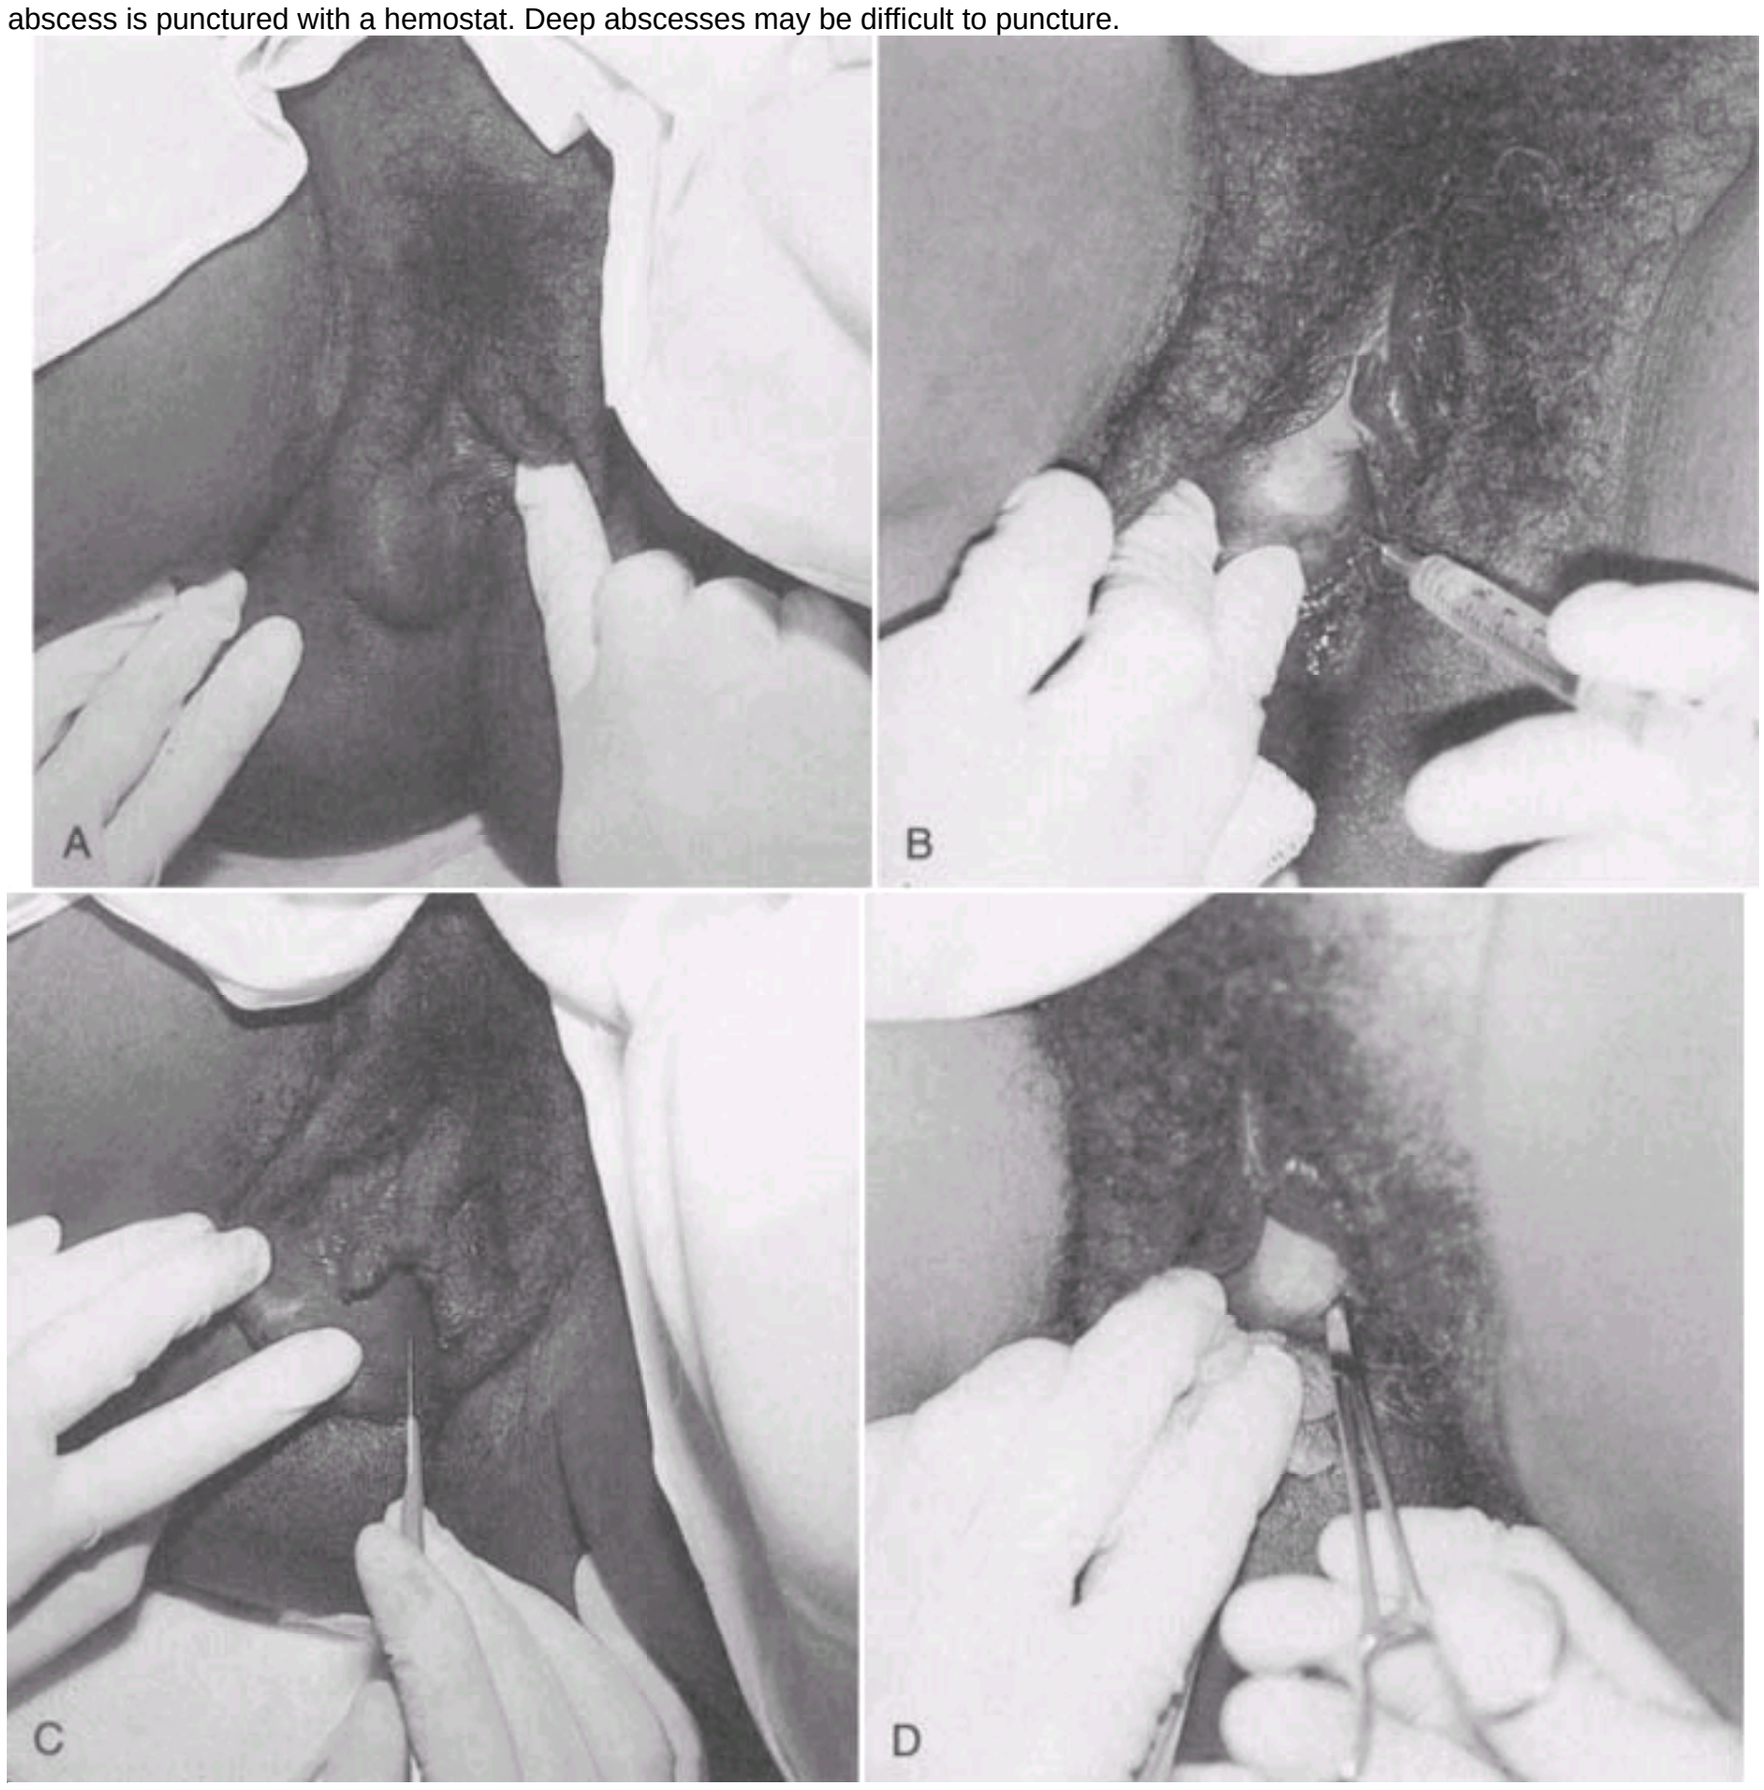

Figure 38-12b *E*, It is technically easier to enter the Bartholin gland abscess cavity if the hemostat is held steady and the abscess, held with the thumb and index finger, is skewered onto the hemostat. Attempting to puncture the deep immobilized abscess by stabbing with the hemostat may be more difficult. A palpable pop when entering the abscess or drainage of frank pus is expected. *F*, The catheter is placed to its hilt into the abscess cavity, and the balloon is filled with saline. Use a 25-ga needle to fill balloon. *G*, The catheter is left in place for 2 to 4 weeks to form a fistula.

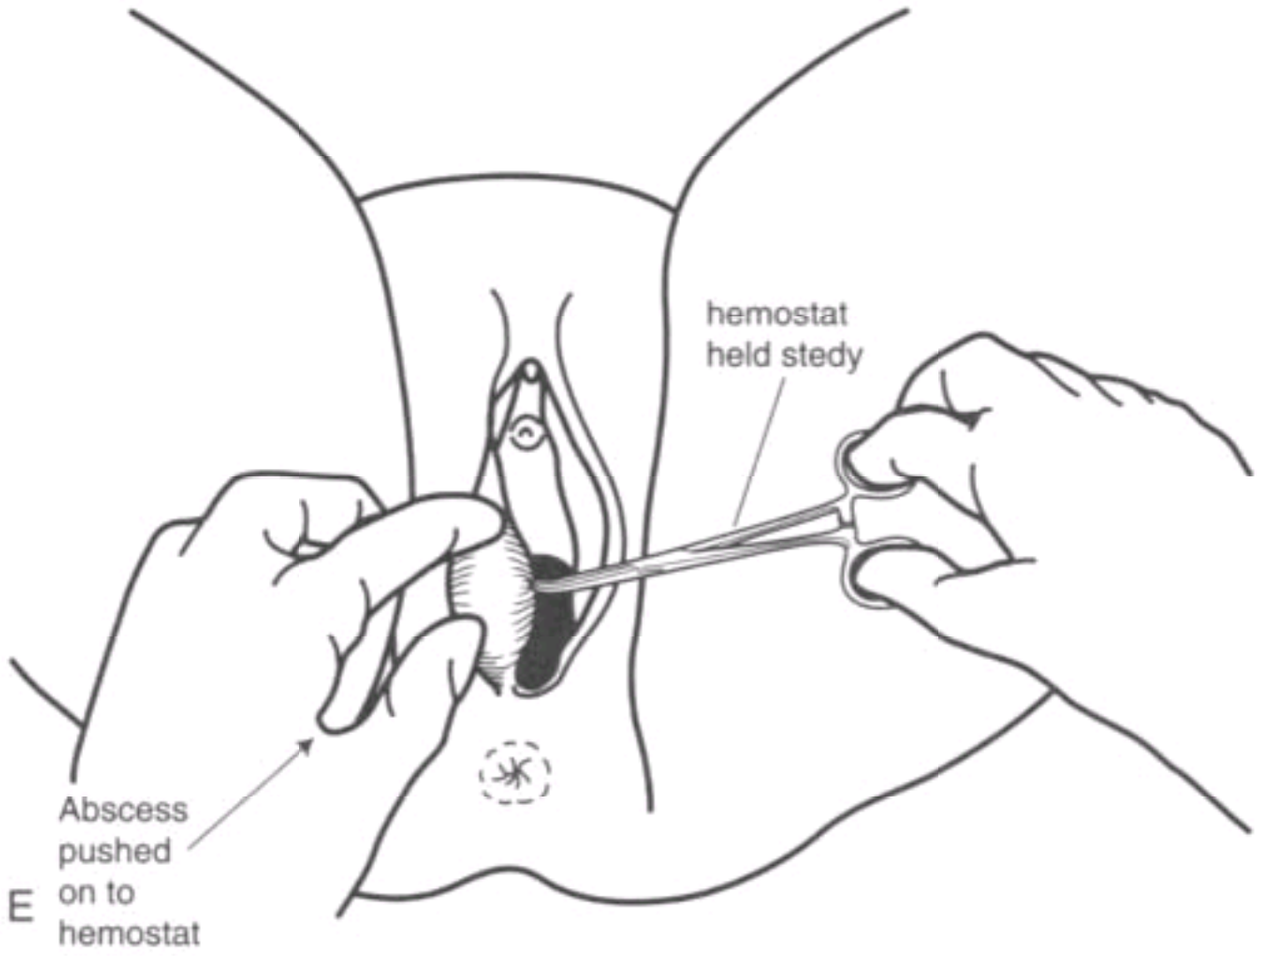

Figure 38-13 Pilonidal sinus. *A*, Sinuses occur in the midline some 5 cm above the anus in the natal cleft. *B*, Longitudinal section showing sinuses and pits. *(From Hill GJ II: Outpatient Surgery, 3rd ed. Philadelphia, WB Saunders, 1988. Reproduced with permission.)*

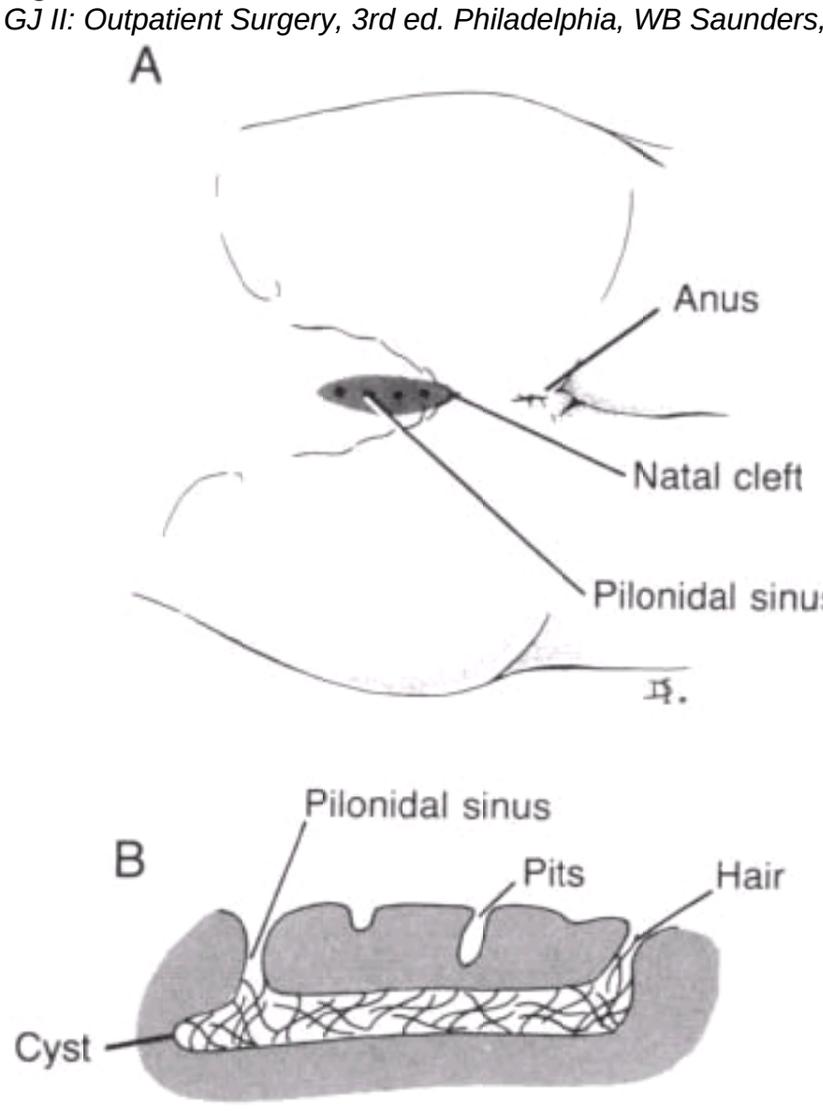

Figure 38-14 *A*, A pilonidal abscess can be quite extensive (*induration outlined by marker*) but it may be difficult to feel fluctuance because of the depth of the infection. *B*, Local anesthesia and conscious sedation make the initial ED incision and drainage successful. *C*, A deep incision yields copious pus, and occasionally other debris, such as hair. *D*, The abscess cavity is packed open. *Not shown*: When infection and inflammation have subsided, definitive treatment may include wide excision of the sinus and its lateral tracks.

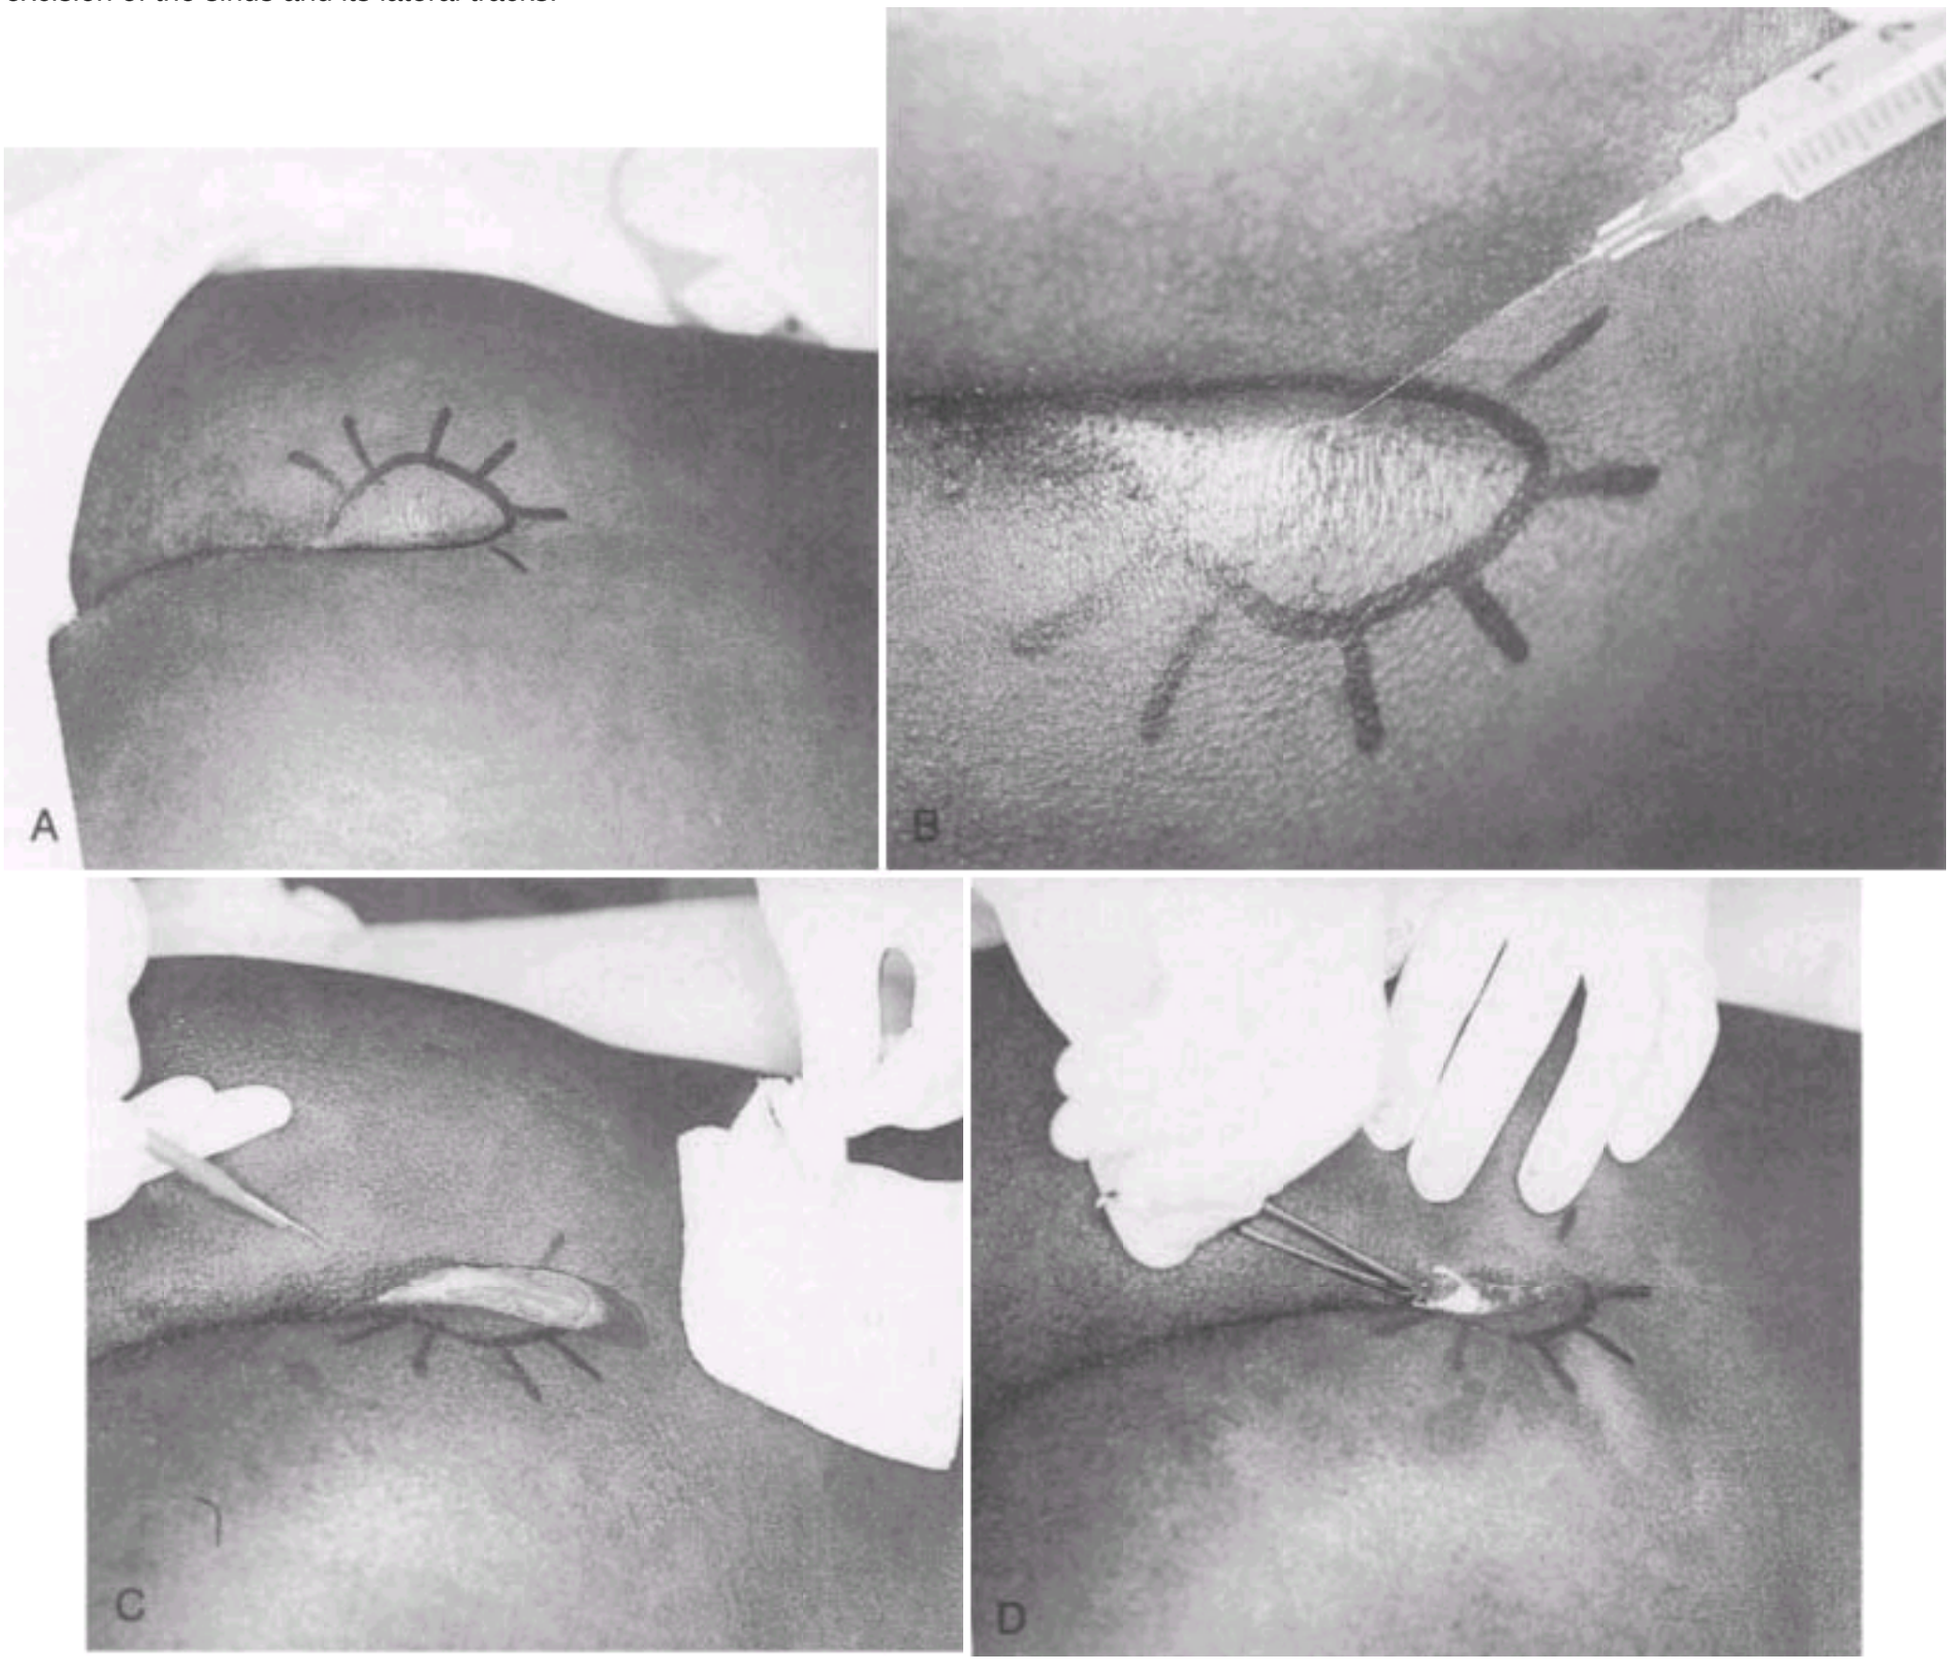

Figure 38-15 A method of prolonged drainage of a pilonidal abscess with a flared-end de Pezzer catheter. Following a stab incision, a stretched catheter (probe inside lumen) is inserted into the abscess cavity *(A)*. When the probe is removed, the head of the catheter expands and remains in the abscess cavity *(B)*. Drainage is continuous through the lumen of the catheter. *(From Phillip RS: A simplified method for the incision and drainage of abscesses. Am J Surg 135:721, 1978. Reproduced with permission.)*

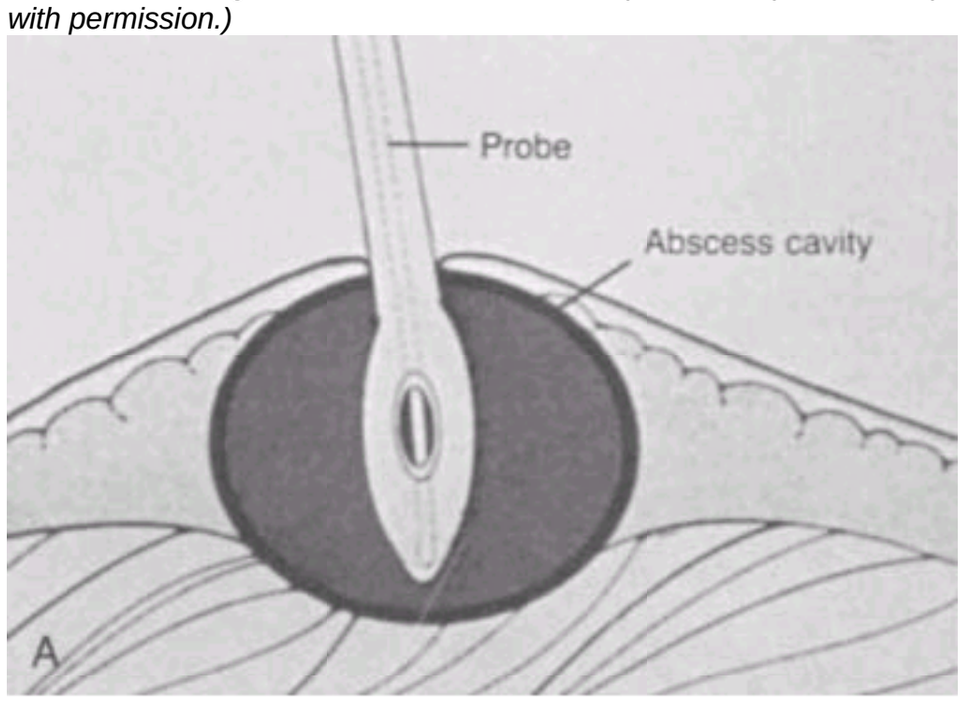

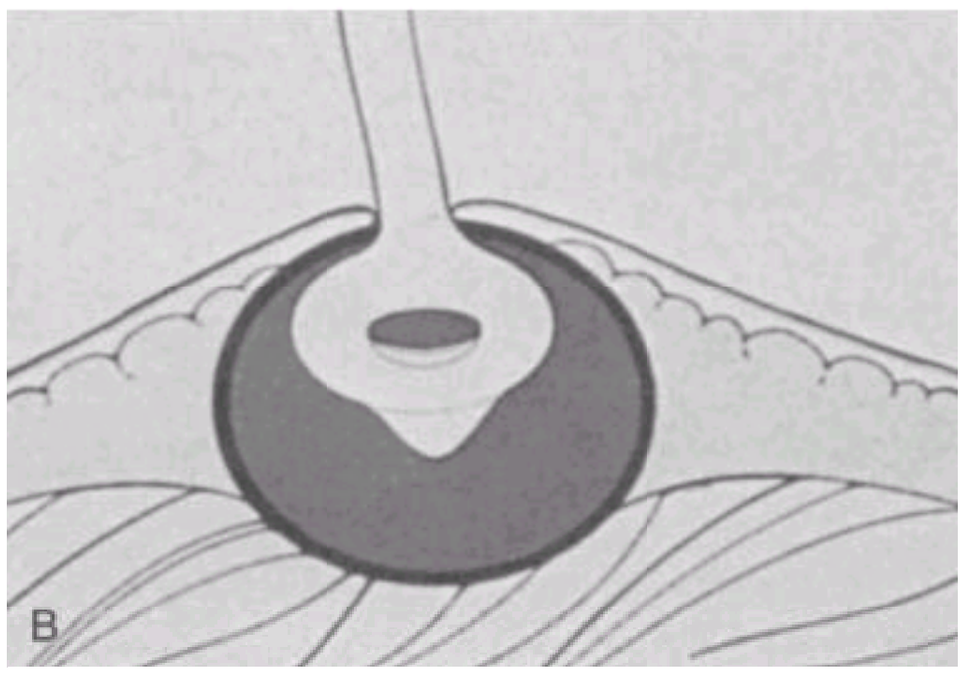

Figure 38-16 *A*, If a perirectal abscess spontaneously ruptures and drains, a formal incision, drainage, and packing should still be performed. *B*, A deep, poorly localized perirectal abscess of this size simply cannot be adequately drained in the ED. Arrows outline the area of induration. This patient requires extensive drainage under general anesthesia. A computed tomography scan may further evaluate the location of this abscess.

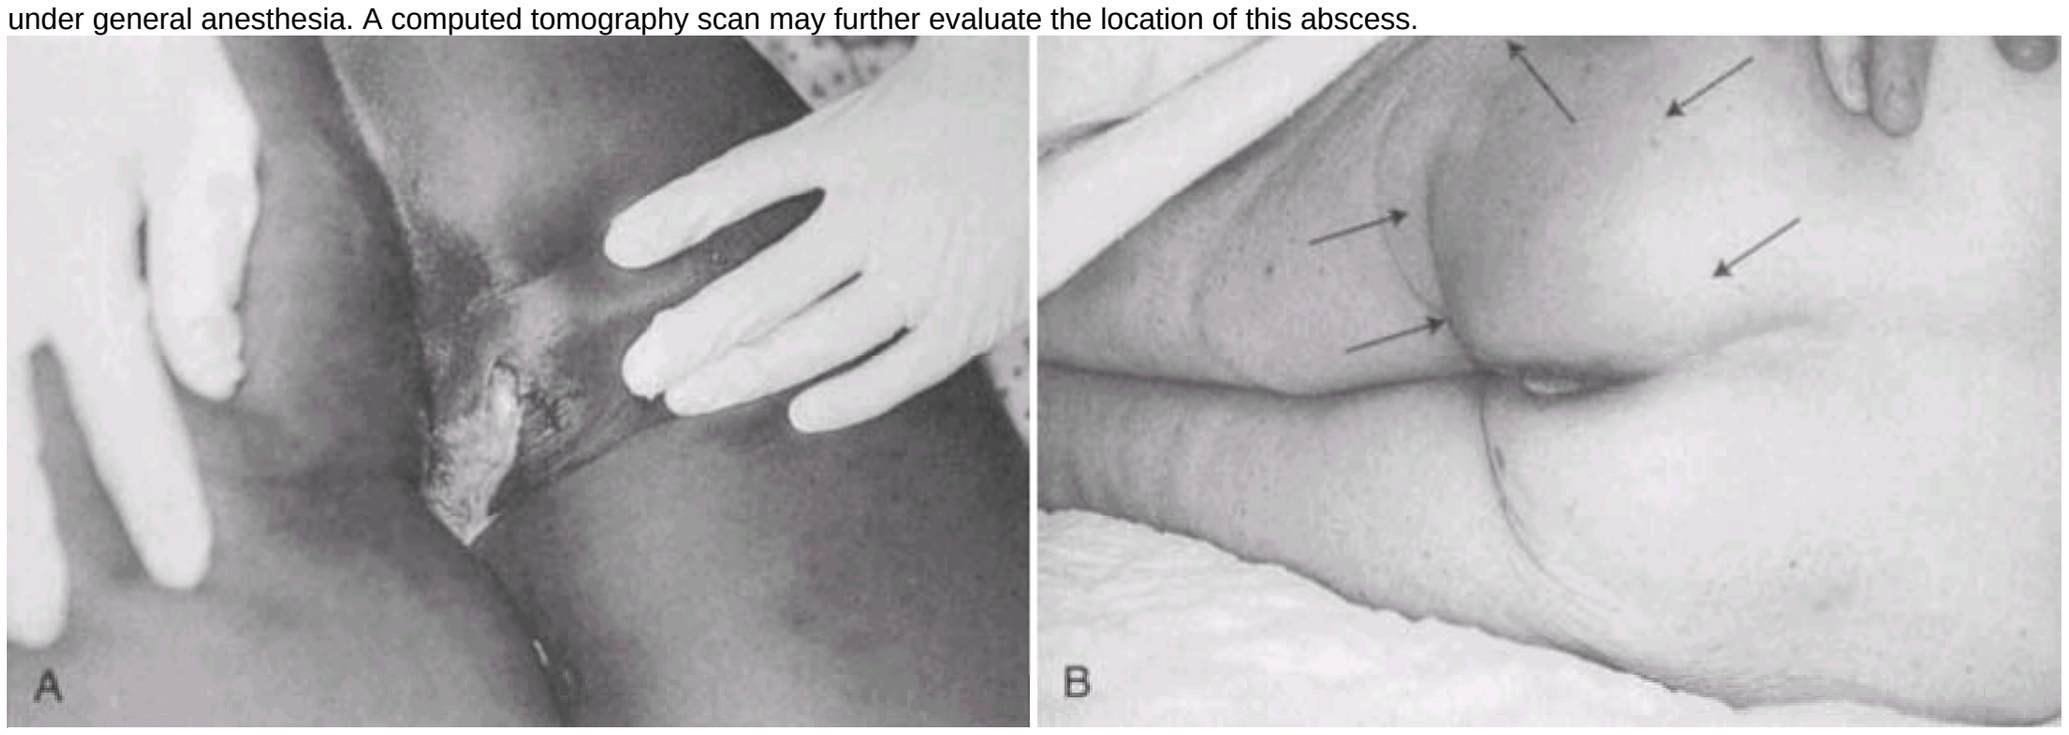

Figure 38-17 Schematic coronal section of the anal canal and the rectum. *(From Schwartz SI, Lillehei RC: Principles of Surgery, 2nd ed. New York, McGraw-Hill, 1974. Reproduced with permission.)*

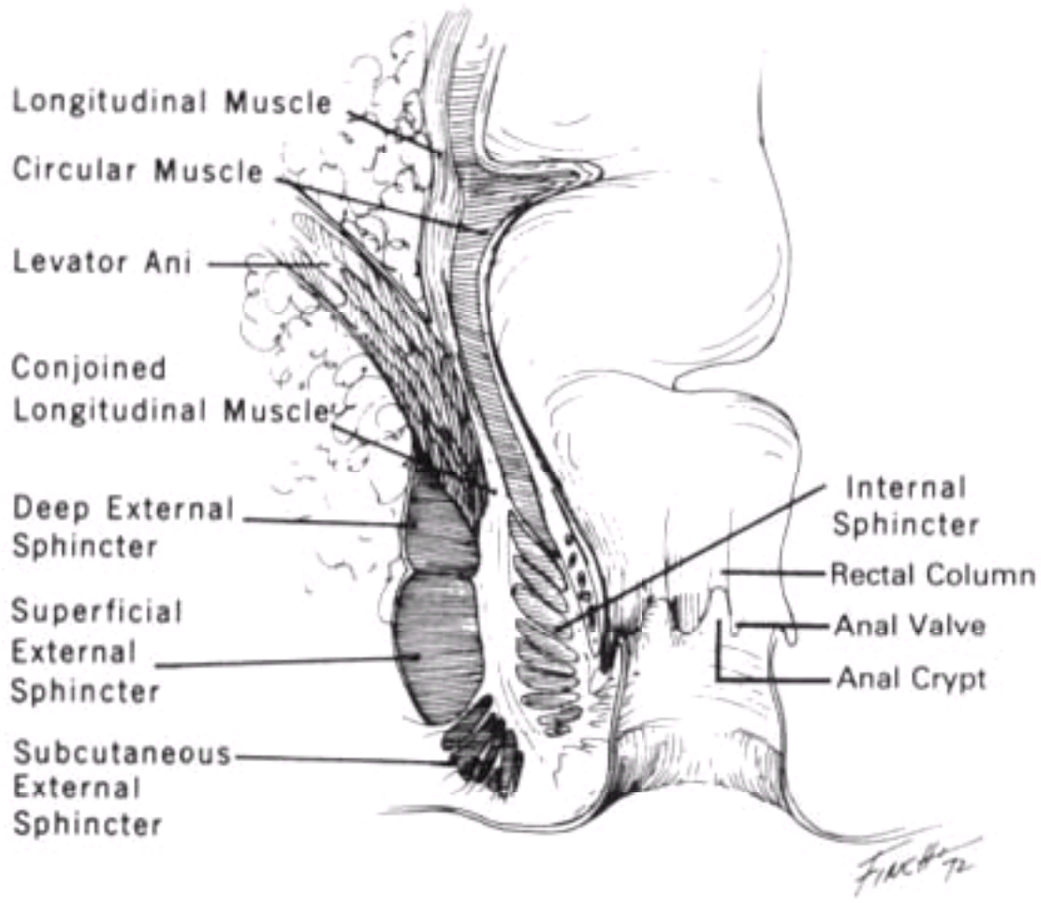

Figure 38-18 Classification of perirectal abscesses: 1, Perianal. 2, Ischiorectal. 3, Intersphincteric. 4, High intramuscular. 5, Pelvirectal. *(From Hill GJ II: Outpatient Surgery, 3rd ed. Philadelphia, WB Saunders, 1988. Reproduced by permission.)*

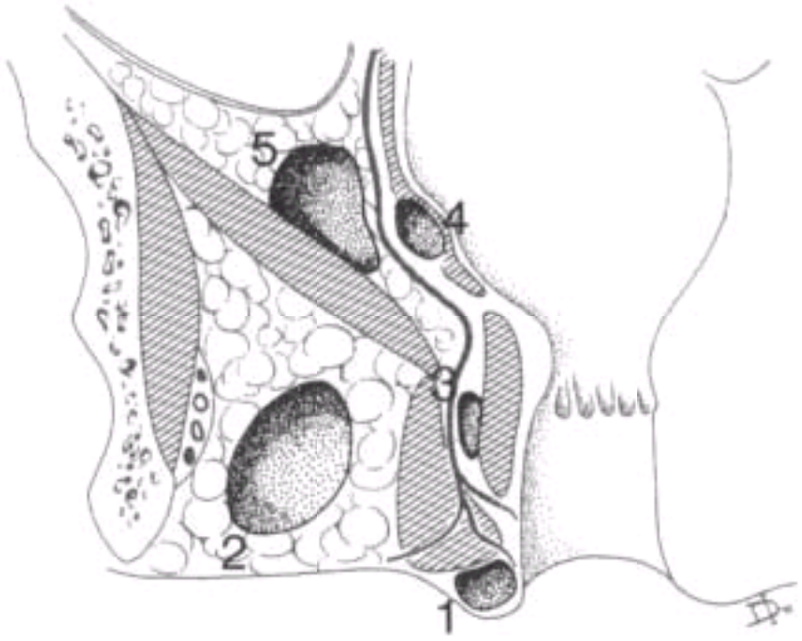

Figure 38-19 The thick, cheesy sebaceous material of a sebaceous cyst must be expressed after incision *(A)*. The shiny capsule of this infected sebaceous cyst is easily visible *(B)* and was removed in its entirety on the initial visit *(C)*.

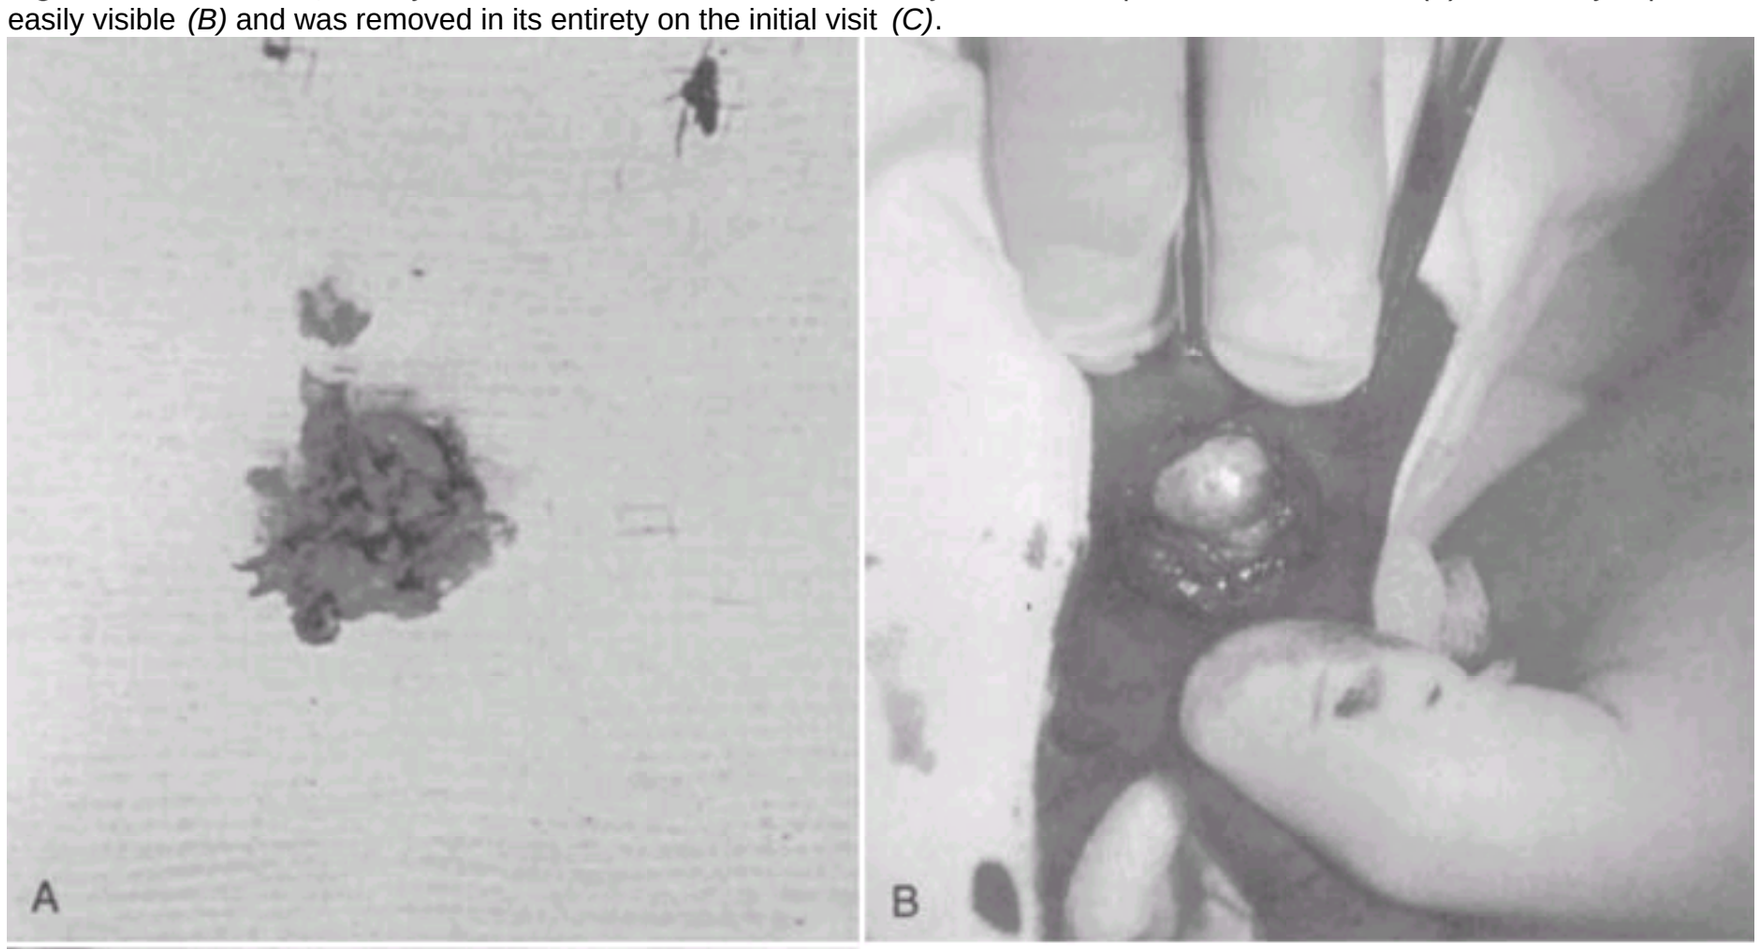

Figure 38-20 Paronychia. *1*, The site of the abscess at the side of the nail. *2*, The infection has extended around the base of the nail. It has raised the eponychium but has not penetrated under the nail. *3*, End stage of paronychia with a subeponychial and subungual abscess. *(From Wolcott MW: Ferguson's Surgery of the Ambulatory Patient, 5th ed. Philadelphia, JB Lippincott, 1974. Reproduced with permission.)*

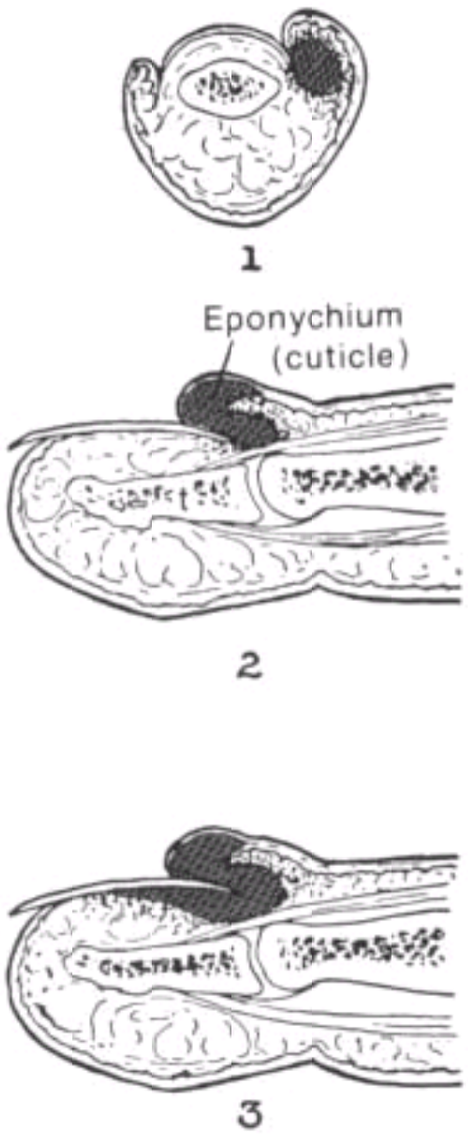

Figure 38-21 A paronychia may occur with obvious pus localization between the eponychium (cuticle) and the nail. *A*, Actual pus may be seen or, *B*, the area is swollen and tender. *C*, A paronychia can also occur in the toe. This is not a true cutaneous abscess but rather a collection of pus in a potential space. Actual skin incision is not required if eponychial elevation results in adequate drainage.

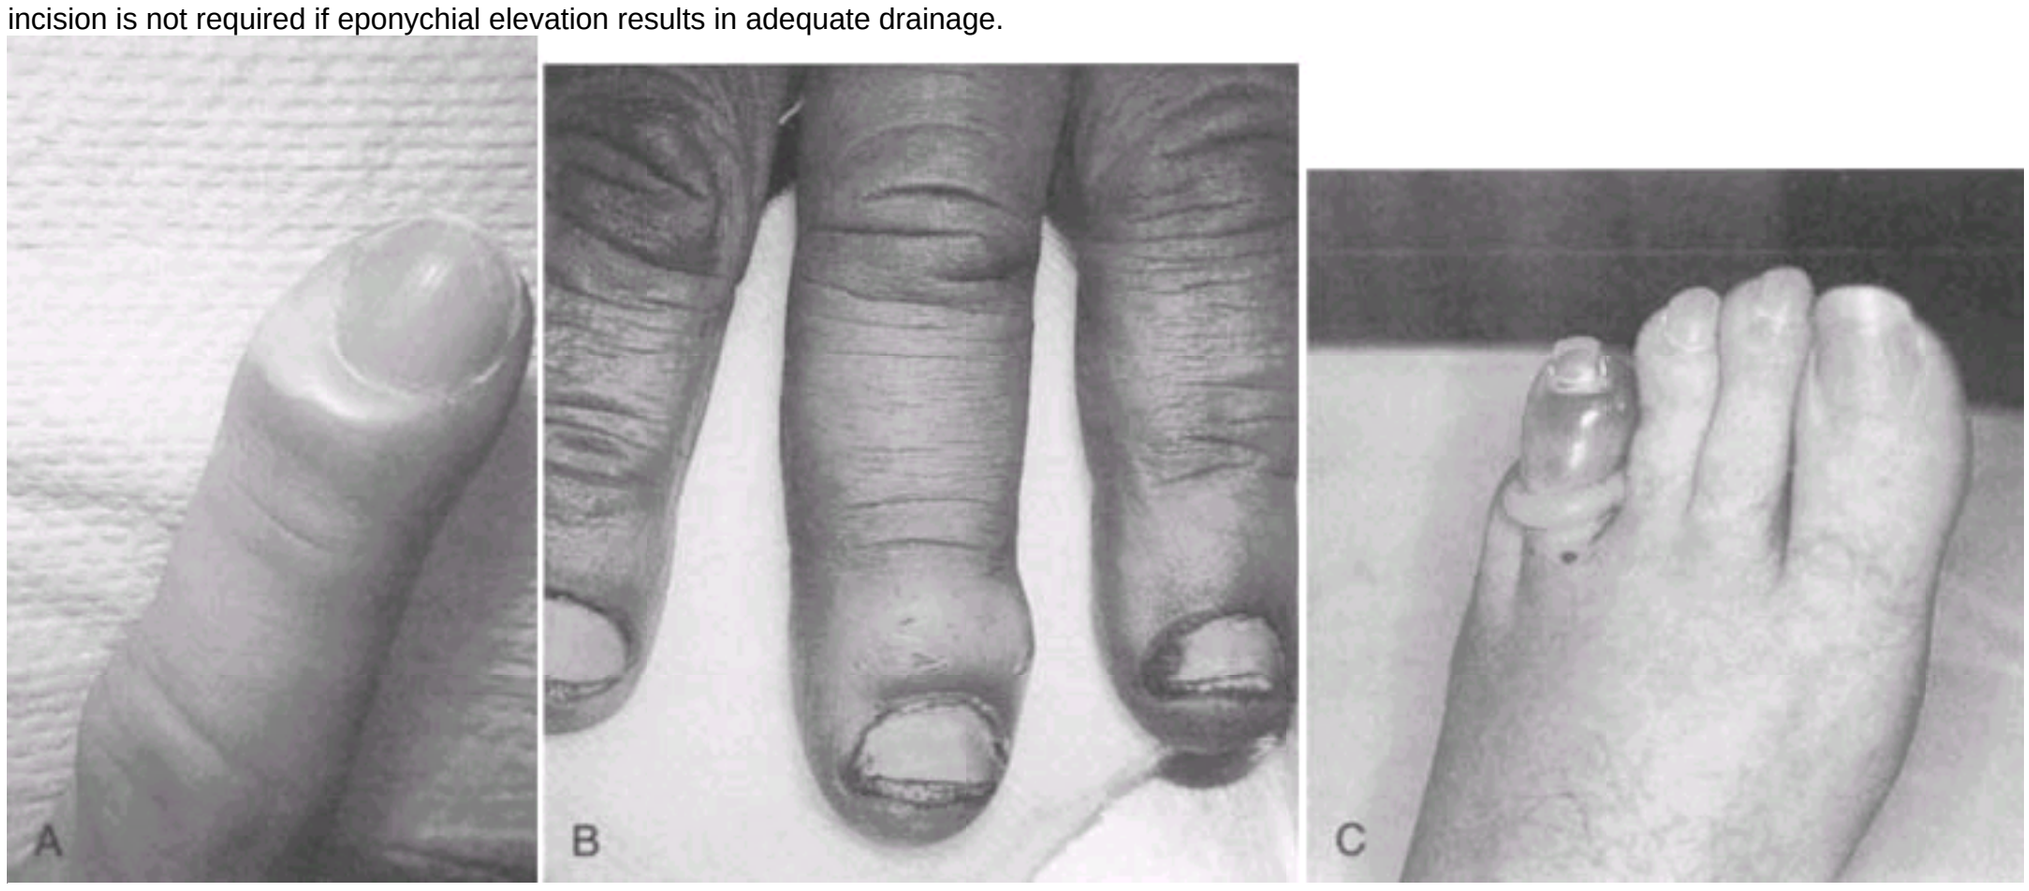

Figure 38-22 An initial treatment method for a well-localized paronychia. Following a digital nerve block, the eponychium (cuticle) is elevated at the area of greatest fluctuance, and no actual skin incision is made. A tourniquet can be used to limit bleeding and facilitate drainage. *A* and *B*, A sharp instrument (scissors or a No. 11 blade) is held parallel to the nail and advanced until pus is drained. *C* and *D*, A hemostat or scissors is placed into the base and all margins of the pus collection and spread in a fan-like fashion to open up the abscess. The entire pocket is opened to break up loculations and create a cavity. *E*, A small packing is placed for 2 days. At recheck a new pack may be placed or the cavity left open to heal. *Actual incision of tissue or removal of the nail is reserved for complicated or resistant infections and is not first-line therapy.*

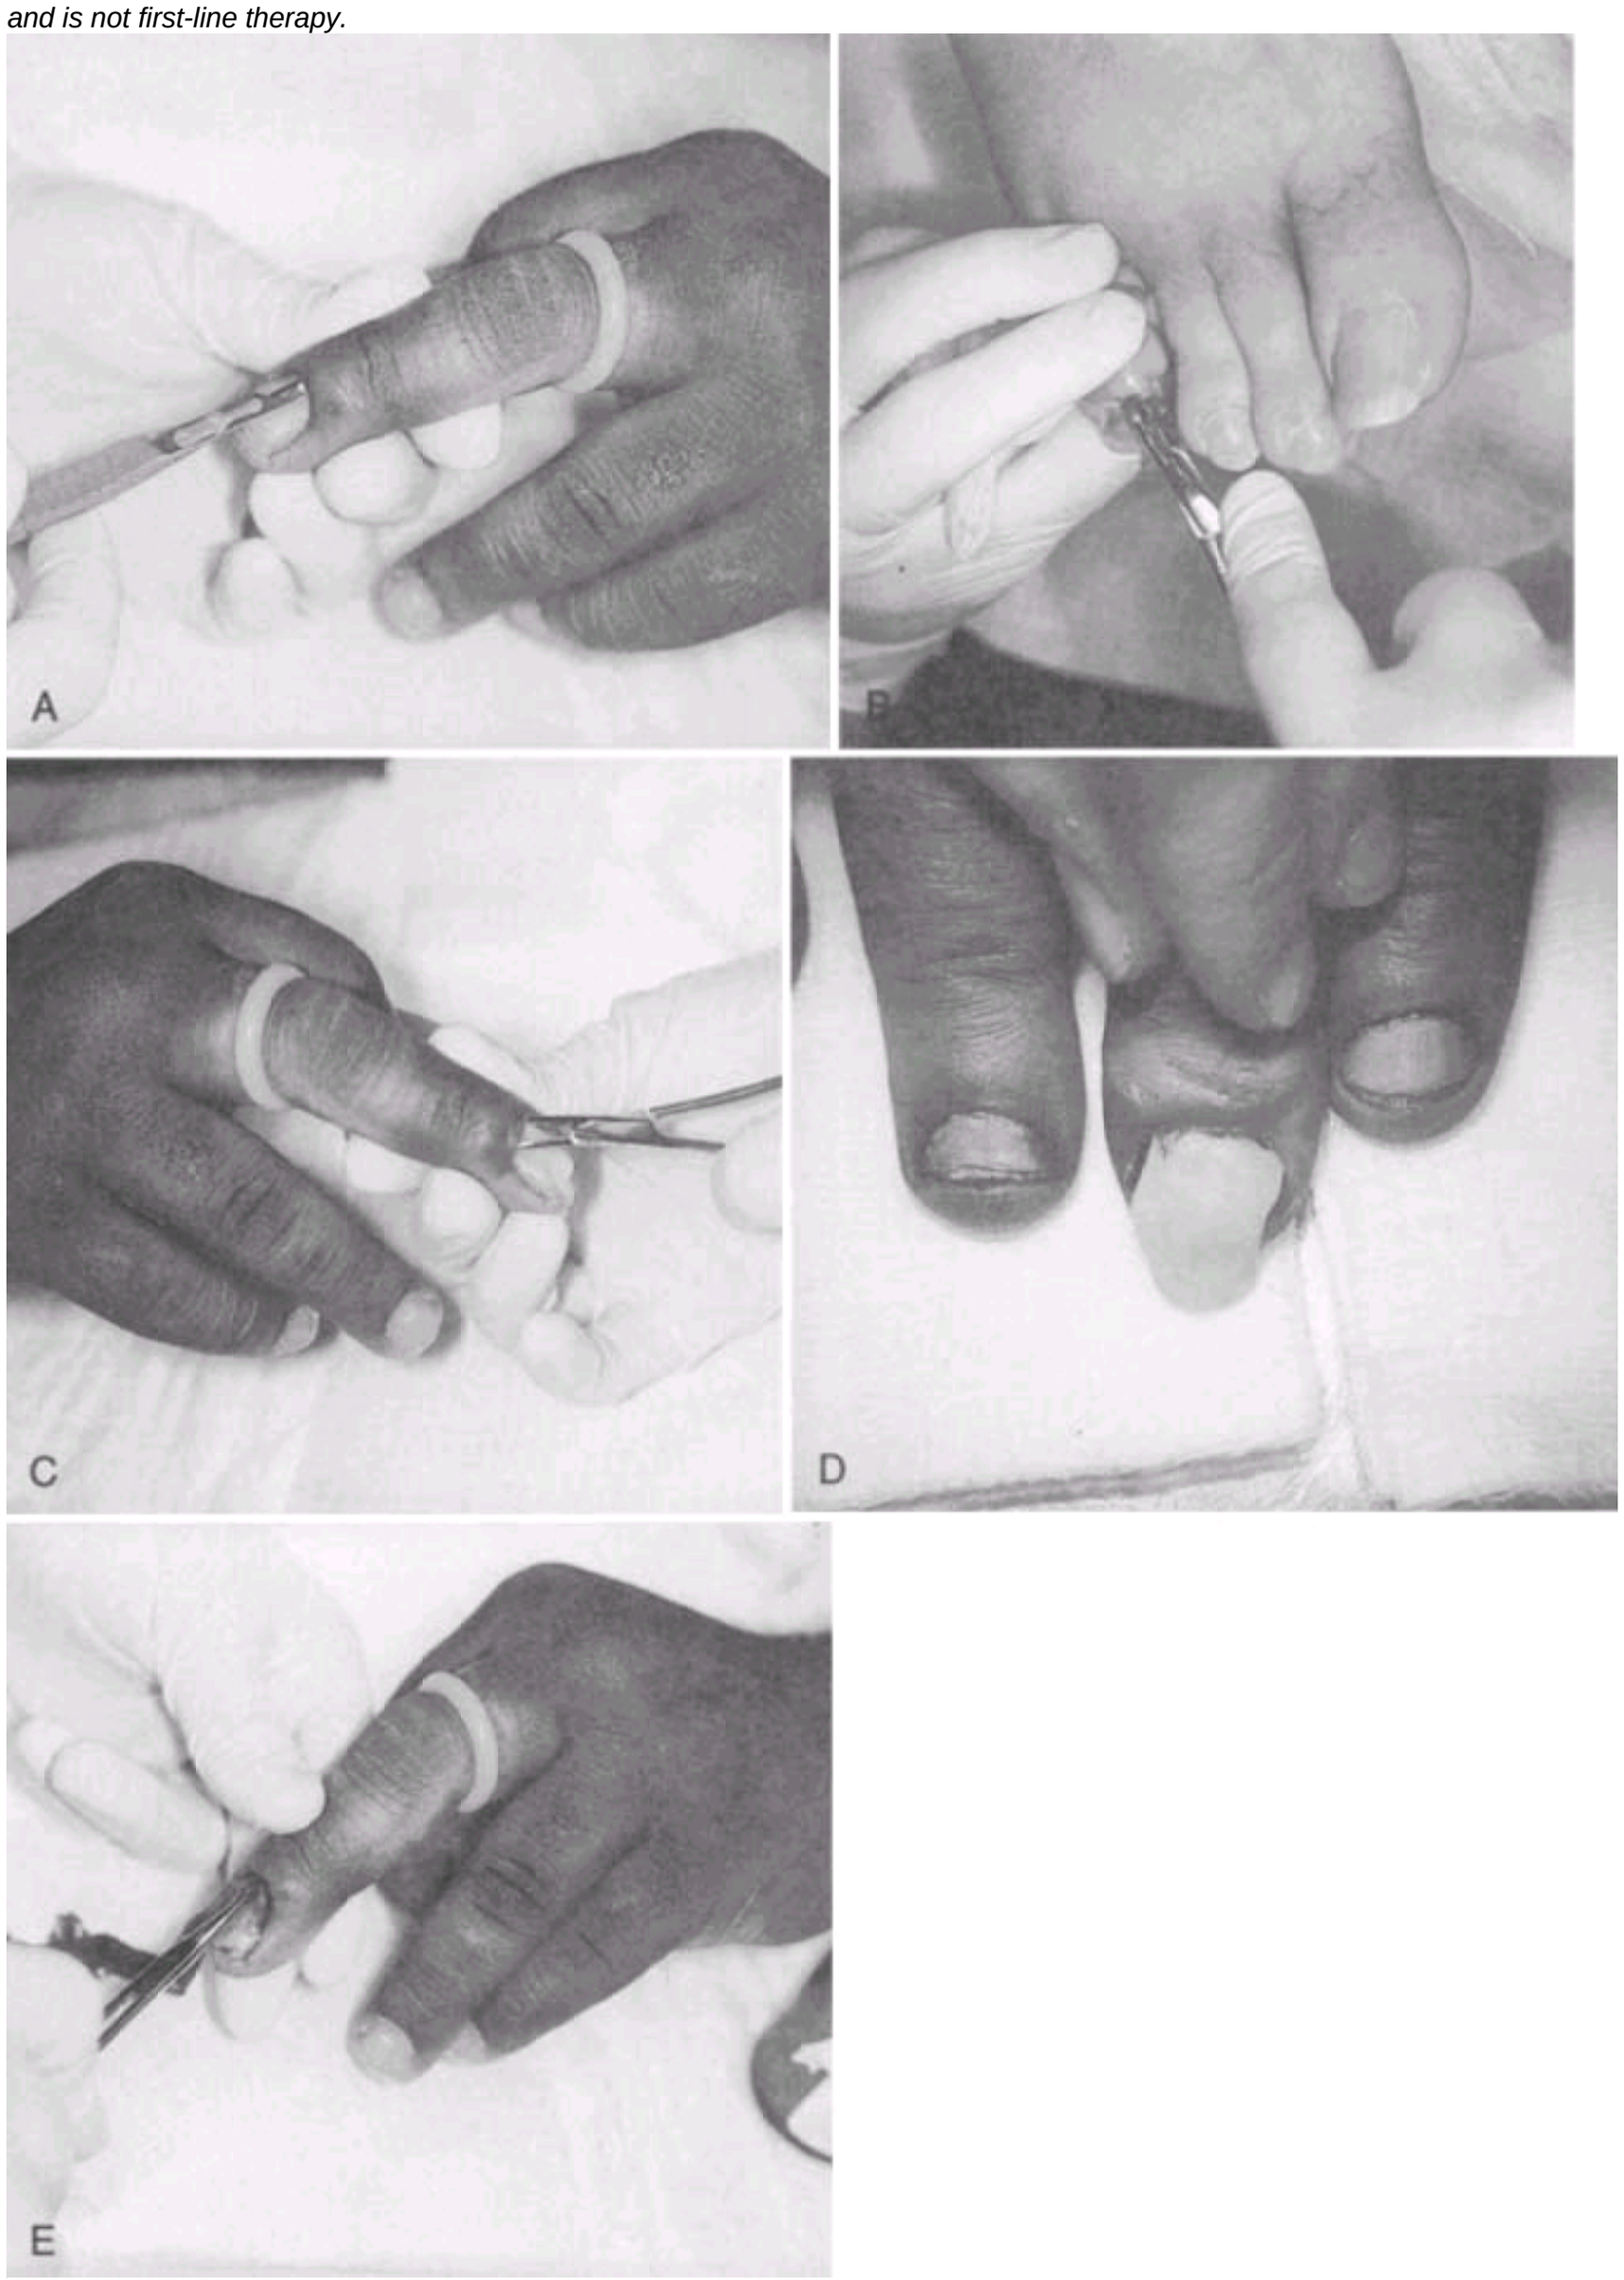

Figure 38-23 *A–C*, Aggressive treatment of recurrent paronychia or subungual abscess includes removal of a portion of the proximal nail and incision of the eponychium. *D,* Some physicians prefer to use a semilunar incision proximal to the eponychium rather than directly incising and potentially injuring the cuticle permanently. *These aggressive therapies are seldom required.*

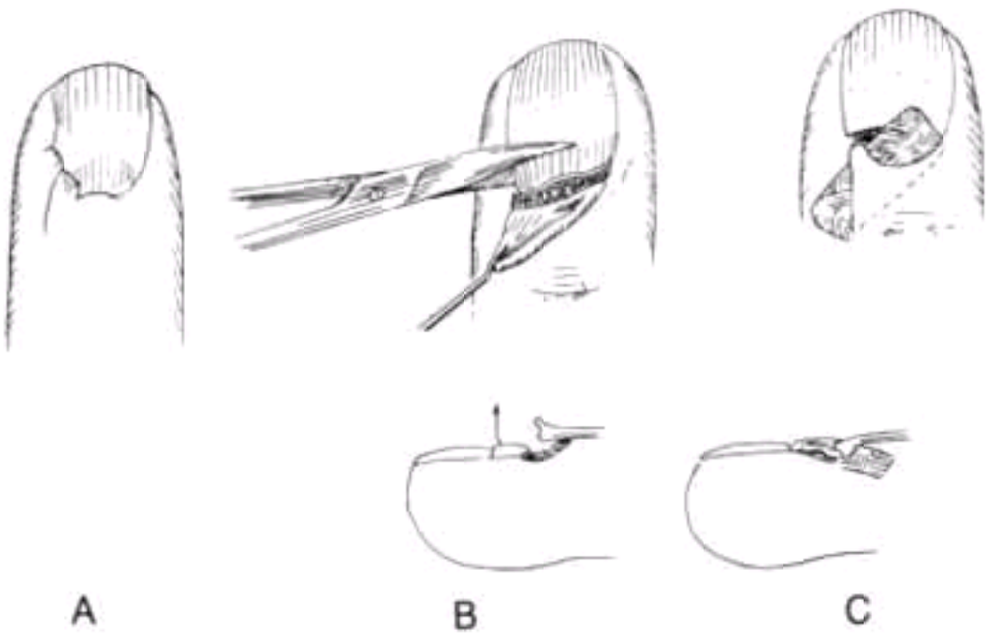

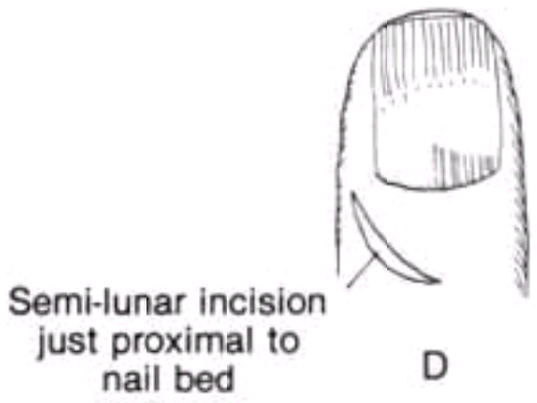

Figure 38-24 A well-developed felon. In this advanced case, the patient had little pain at the time of presentation, and the distal phalanx was almost completely resorbed owing to the extensive pressure and inflammation. This infection is extensive and warrants consultation with a hand specialist.

Figure 38-25 The preferred initial incision for draining a felon is one made directly into the area of most fluctuance. More aggressive incisions should be reserved for complicated cases, since they have a greater morbidity and require more complicated wound care. The unilateral longitudinal approach is a good first choice *(A)*. Fat pad incisions are acceptable but may be associated with a painful scar in an area that is often traumatized. The transverse fat pad incision should not injure digital nerves *(B),* and the longitudinal fat pad incision should avoid the flexor tendon *(C)*.

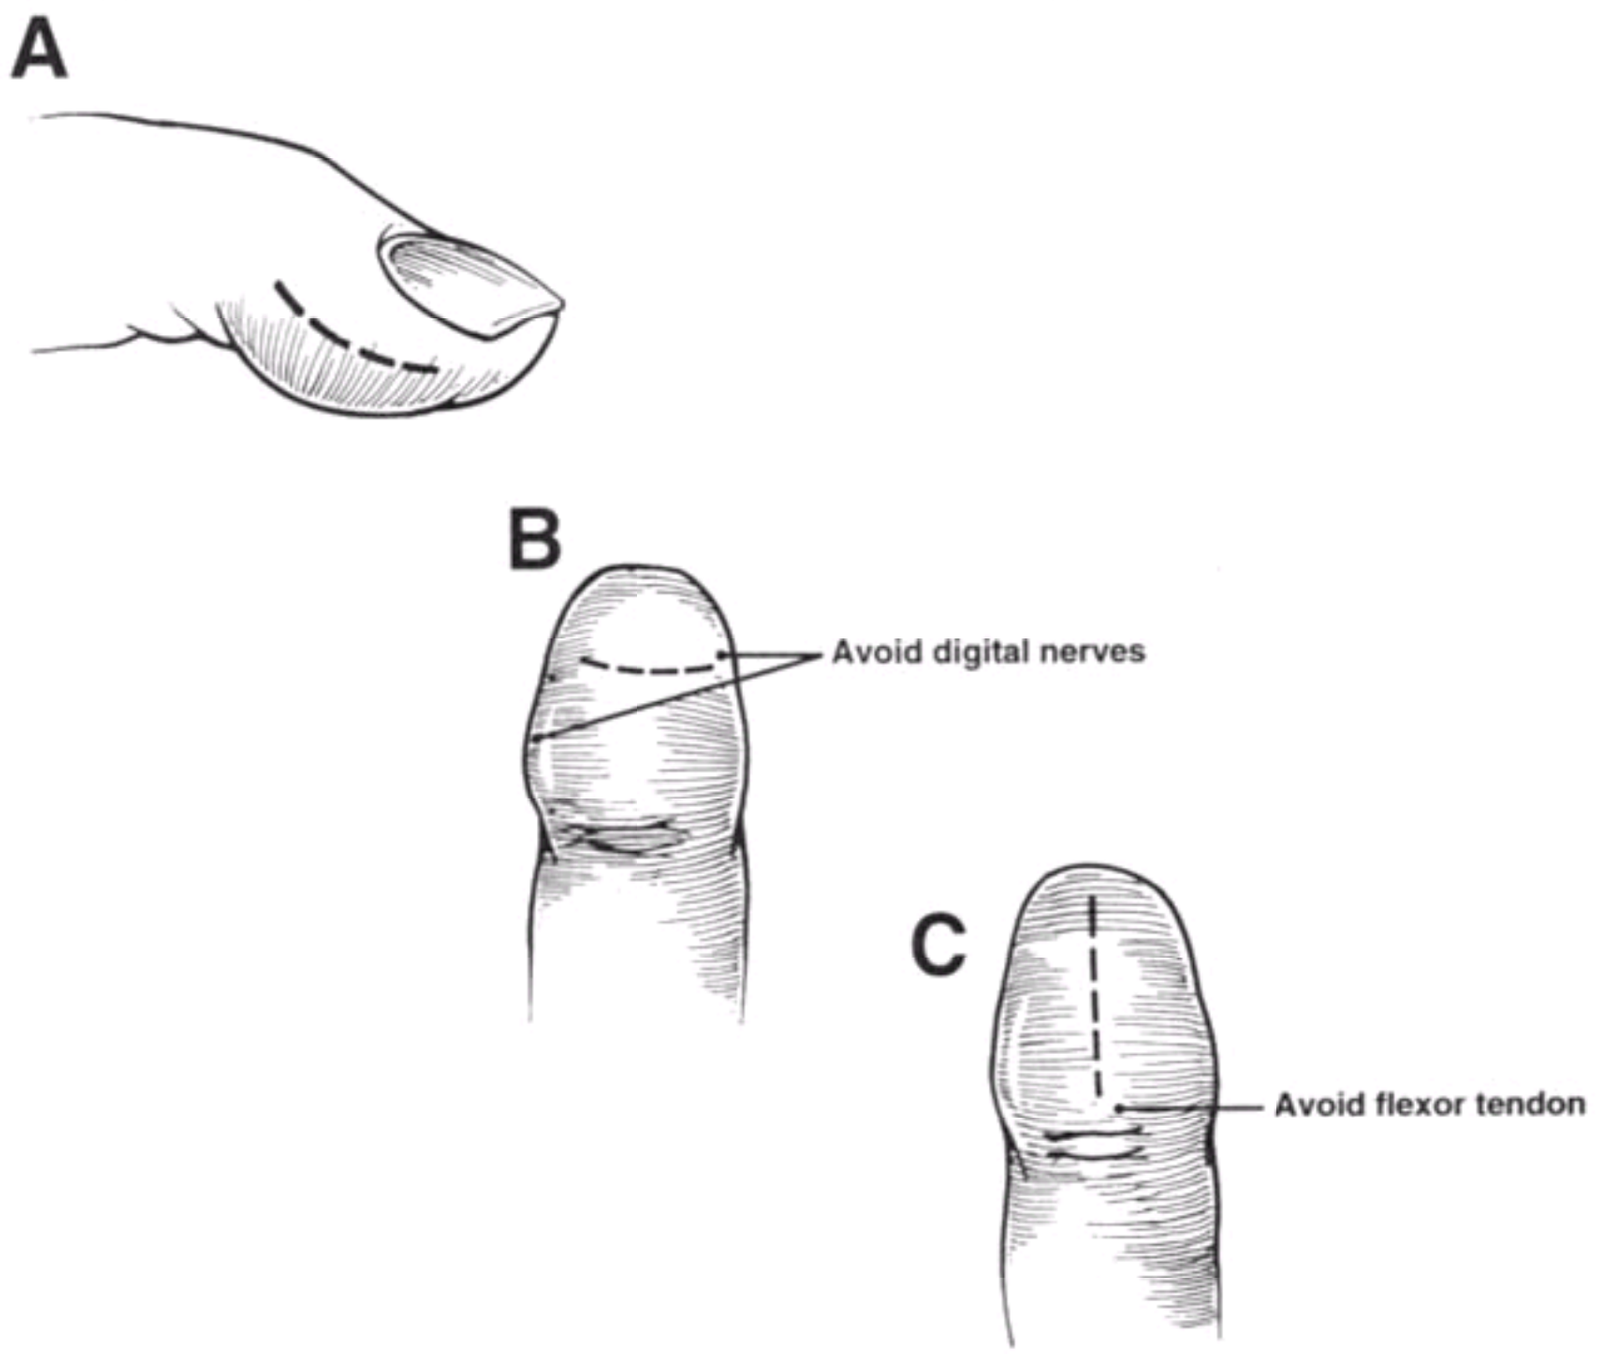

Figure 38-26 Hockey-stick incision for the drainage of a felon. *Note:* An incision on the ulnar side of the index, middle, and ring fingers is appropriate. The little finger is best incised on the radial side. The site of the incision on the thumb is also preferably on the radial side, but this may depend on the occupation of the patient. *(From Chase RA: Atlas of Hand Surgery. Philadelphia, WB Saunders, 1973. Reproduced with permission.)*

Figure 38-27 Through-and-through incision for a felon. A Penrose drain is placed for a few days to promote the withdrawal of fluid. This is an alternative to the hockey-stick incision.

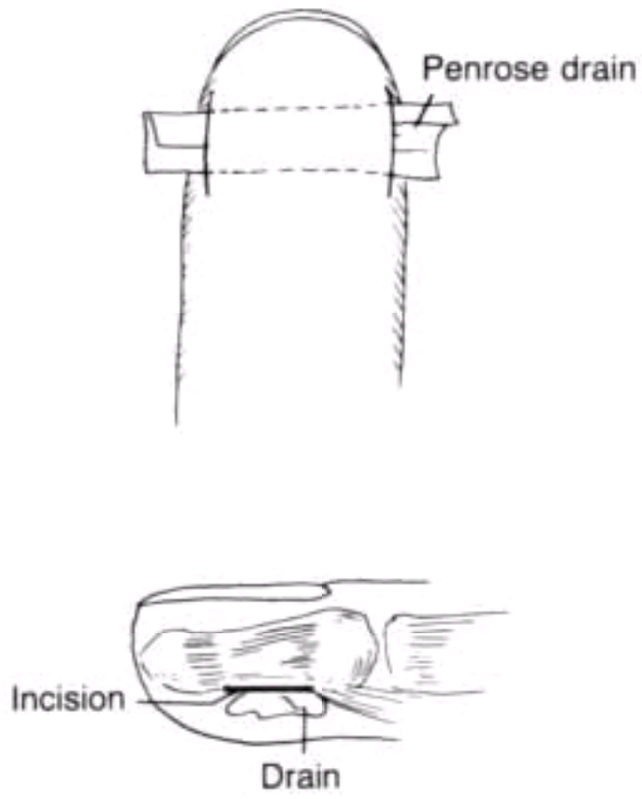

Figure 38-28 *A–C,* Fishmouth incision. This is a rather radical incision that is best reserved for resistant cases. Its advantage is that it allows for complete drainage and visualization of the infection in complicated cases. This incision takes longer to heal than others and may leave a large and sensitive scar. The fingertip may also be left unstable as a result of the lysis of all septa. The incision is seldom used on an outpatient basis for these reasons.

A

B

C

Figure 38-29 *A*, This patient slammed his finger in a car door, sustaining an acute flexion of the distal phalynx and a crush injury. It appears to be a simple subungual hematoma, but note the blood in the paronychial space. There is a communication between the nail bed laceration and the eponychium. *B*, All of the blood did not drain when the nail was trephinated. *C*, Blood accumulated in this area because the base of the fingernail has been avulsed, and lies between the eponychial fold and the skin of the cuticle. This is appreciated when the skin is debrided. The closed nature of the injury causes the confusion. With the nail removed, the nail bed laceration can be appreciated and repaired. *D*, The old trephined nail can now be replaced to its original position to keep open the eponychial space, or that space is packed with gauze for a few weeks to discourage scar formation and a subsequent nail deformity.

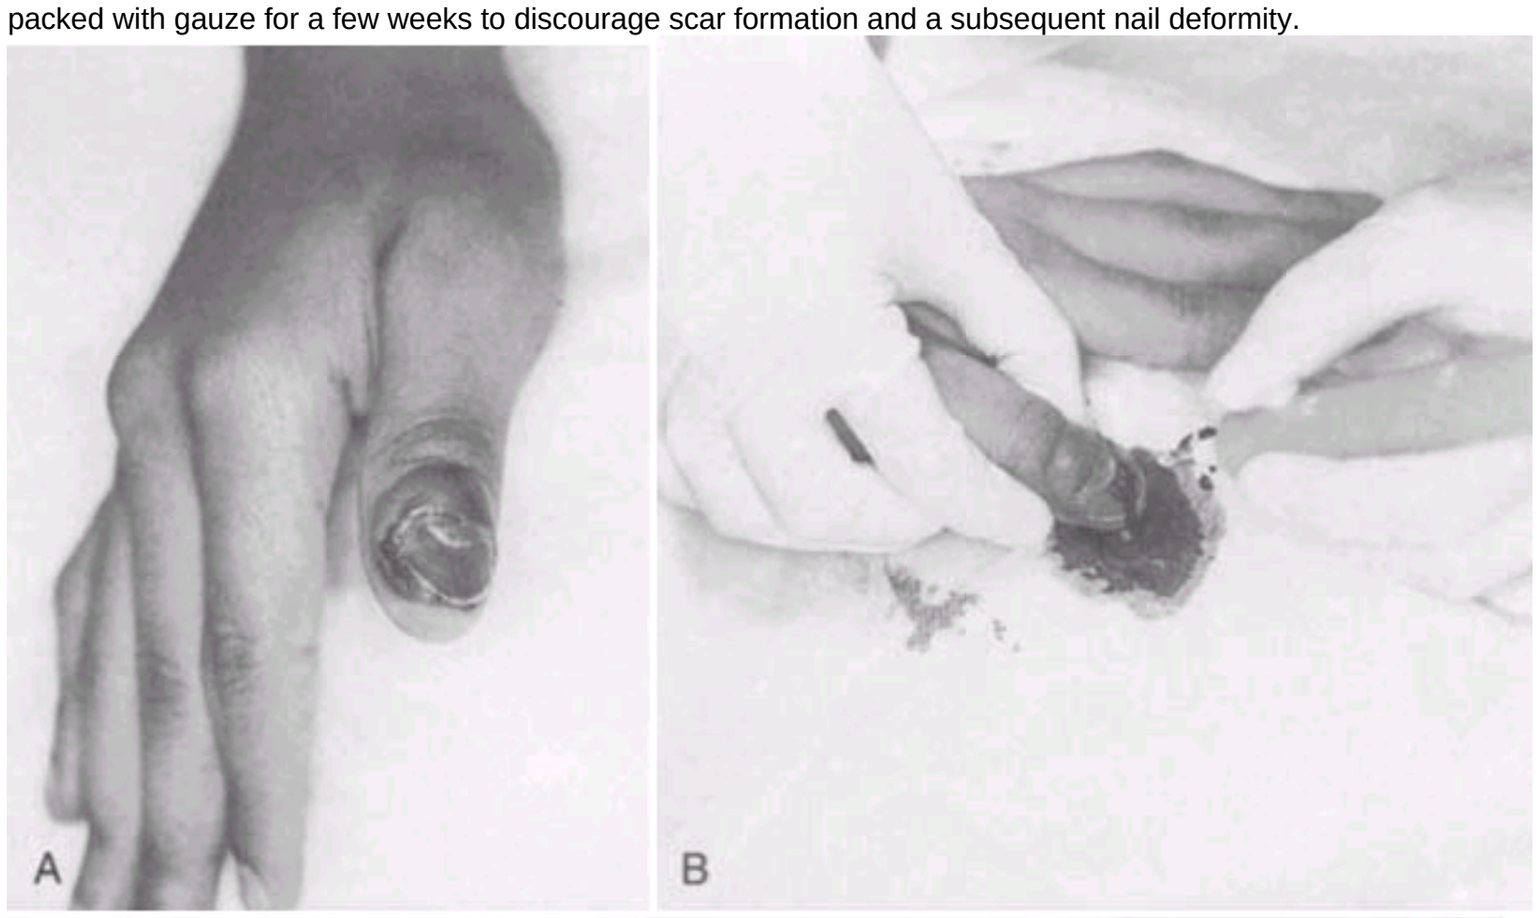

Figure 38-30 *A,* Subungual hematoma with a blackened nailbed. *B,* Following trephination, blood flows freely from the puncture site. An adequately sized drainage hole may be placed in the nail with a heated paper clip. Small holes, which tend to clog and inhibit drainage, should not be made. The hole should be large enough to allow continued drainage of blood. Note that in this example, the blood only accumulates under the nail, not in any paronychial areas.

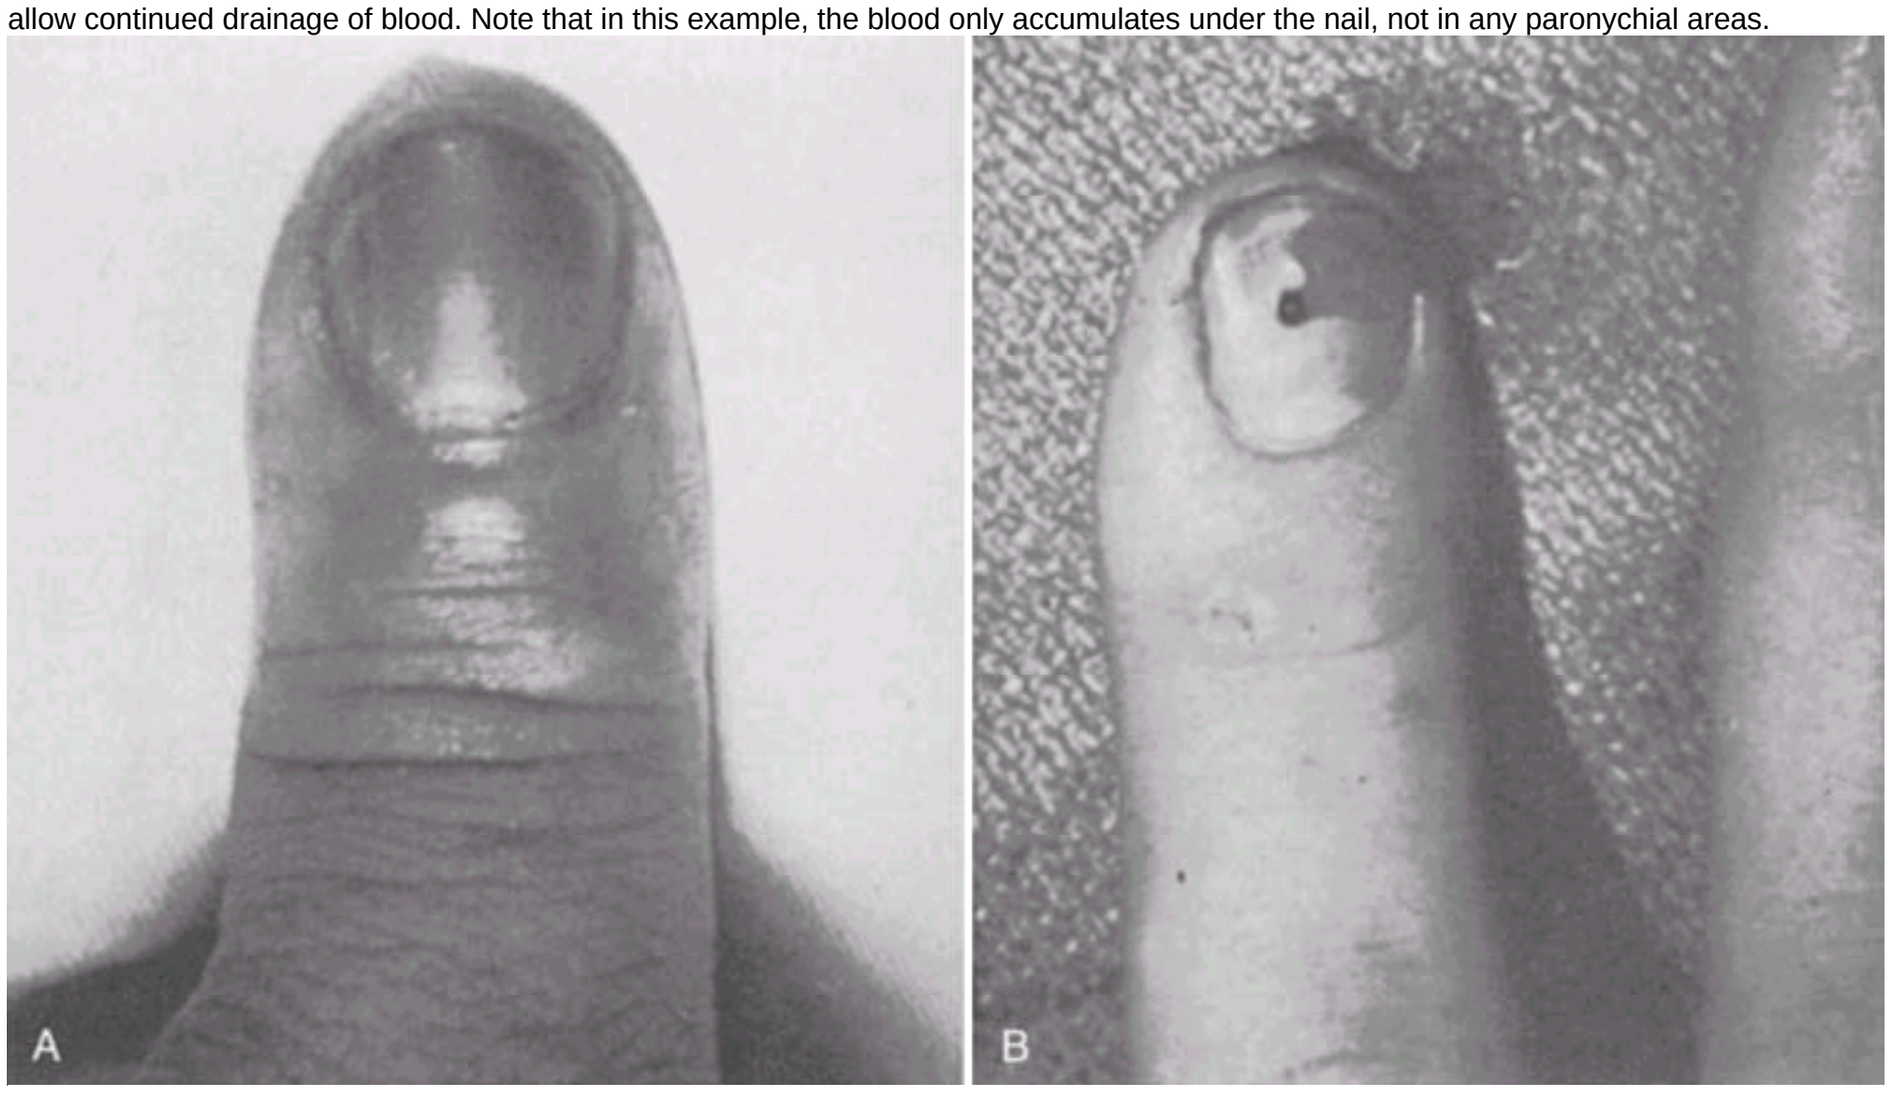

Figure 39-1 The "rule of nines" for estimating percentage of area burned. (As a rough guide, the area covered by the individual's palm is approximately 1.25% the total body surface area [TBSA].) The rule of nines is a rough estimate of the TBSA burned. Note that adults and children are different. This formula frequently *overestimates* the extent of a burn in clinical practice. See Figure 39-2 for a more accurate method of determining the TBSA burned for children.

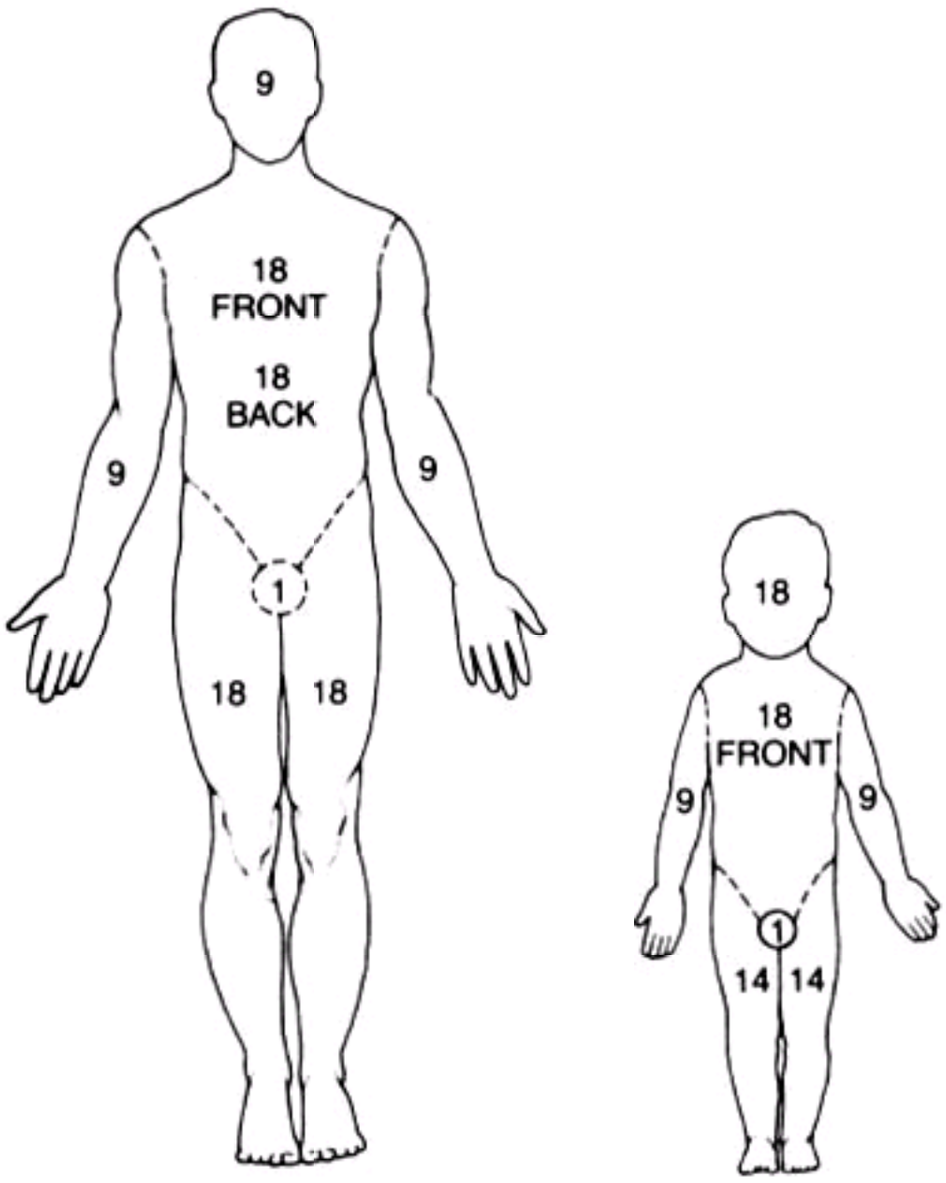

Figure 39-2 *A,* The Lund and Browder charts are somewhat more accurate than the rule of nines in estimating the TBSA burned. *B,* The proportion of TBSA of individual areas, according to age. Compared with adults, children have larger heads and smaller legs. Other areas are relatively equivalent throughout life. The rule of nines is not accurate in determining the percentage of TBSA burned in children.

B BODY AREA

Figure 39-3 It may be difficult to accurately assess the depth or severity of a burn on the first visit. *A*, This is a full-thickness burn that will not heal without a skin graft. *B*, This blistered hot water burn is likely second degree, but full-thickness burns can develop under blisters.

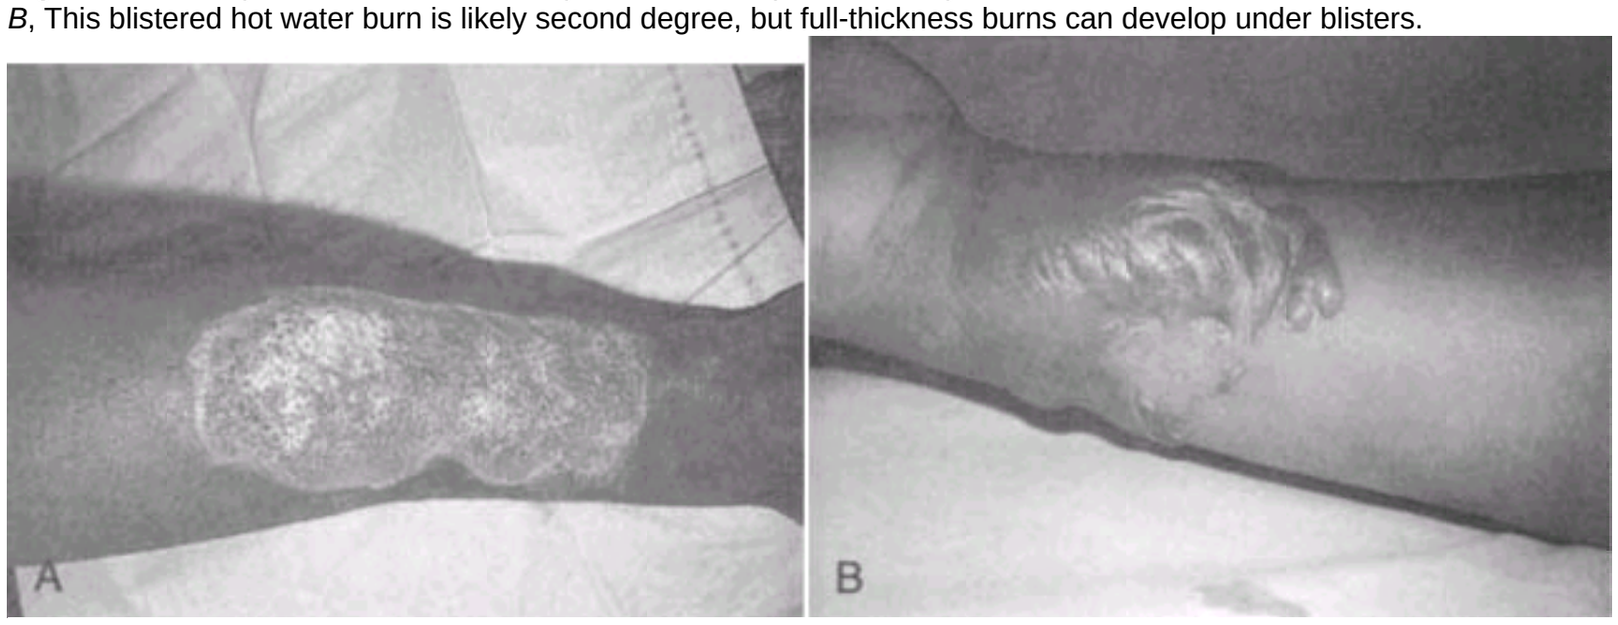

Figure 39-4 To cool a burn that cannot be easily immersed in water, cover the area with unfolded gauze pads that have been soaked in room-temperature saline. Continue to frequently soak the gauze with cool saline or tap water drawn up in a syringe. Adding a few ice chips to the liquid is helpful, but do not cover the burn with ice. Towels are generally too bulky for this procedure.

Figure 39-5 Outpatient burn dressing of the hand. Persons with serious hand burns should be admitted to the hospital, but persons with minor burns can be treated in the outpatient setting. Following application of an antibiotic ointment or a dry, nonadherent dressing, the fingers are separated with fluffs in the web spaces *(A),* and the entire hand is enclosed in a position of function *(B)* (here with the help of a roll of Kerlix). If the wrist is involved, a removable plaster splint may be applied over the dressing *(C)*. *D,* The result of a minor burn to the hand when the fingers were not wrapped individually. Initially there were only a few blisters, but this patient now has second-degree skin loss due to an improper burn dressing that caused maceration of normal skin. Not only were the fingers *incorrectly* wrapped together in one gauze wrap, but the first wound check was *incorrectly* scheduled in 6 days, too long for the first wound check in a hand burn.

Figure 39-6 It is difficult to do anything wrong with minor burn blisters, and many regimens are acceptable. Eventually, however, blisters will have to be debrided. An expeditious and relatively painless way to debride a burn is to use a dry gauze pad to grasp the dead skin *(A)* and peel it off *(B)*. Meticulous instrument debridement is often time consuming and stressful to the patient. Be aware that pain occurs when air comes in contact with the debrided skin and prophylactic analgesia should be provided.

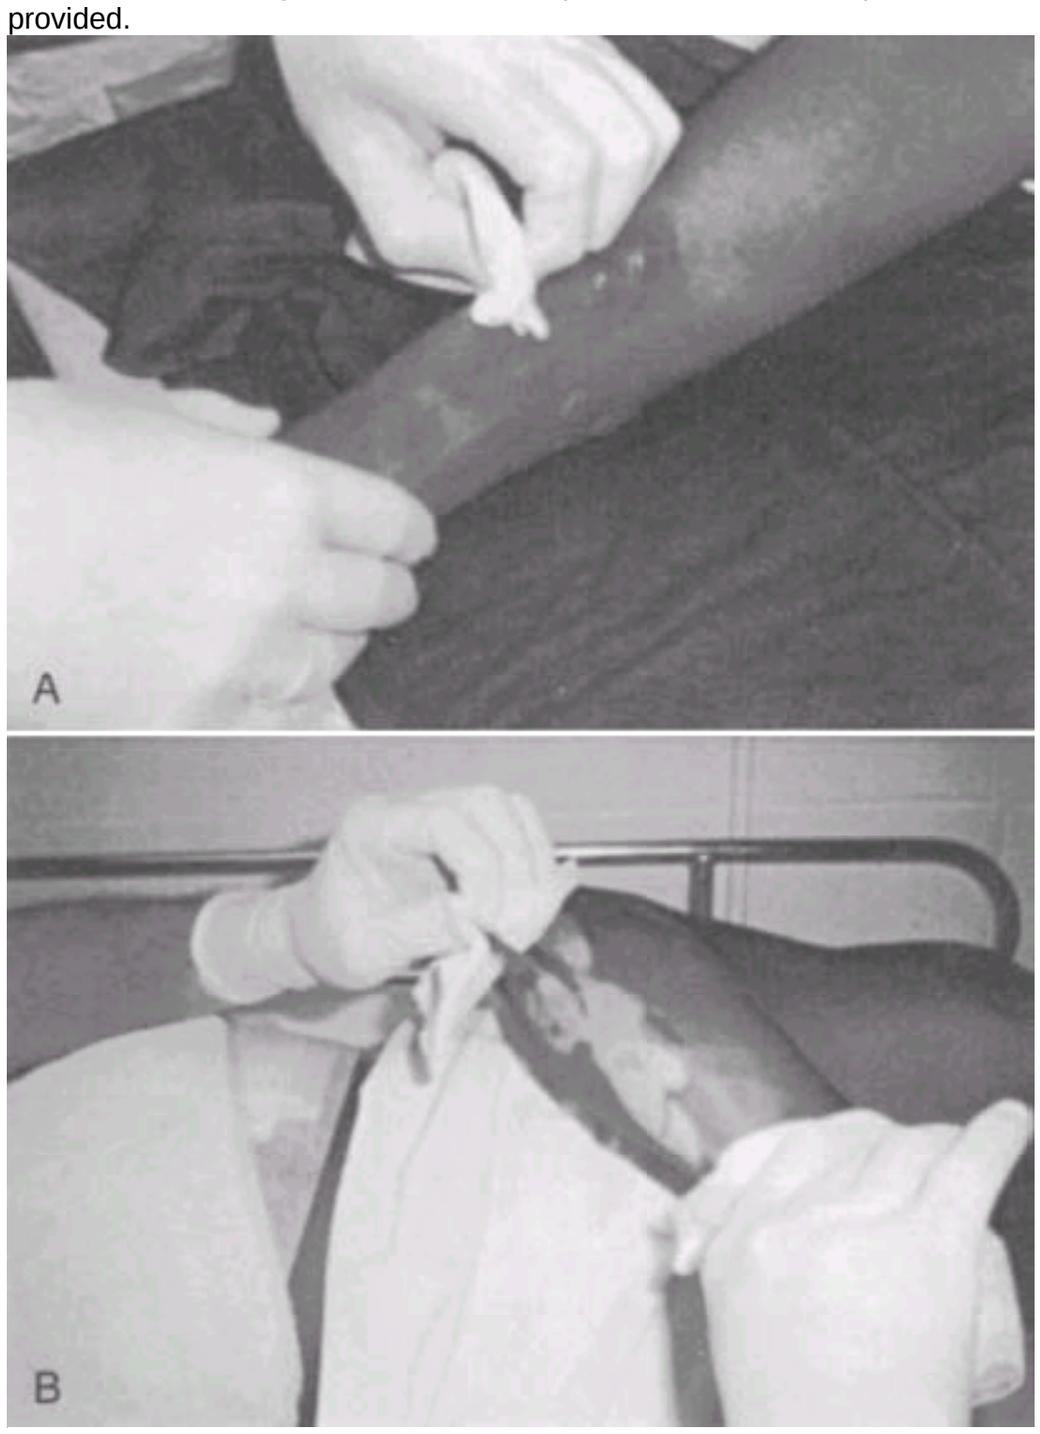

Figure 39-7 Elevation of a burned hand should begin in the ED. After a properly applied hand dressing is applied, the arm is suspended from an IV pole with stockinette.

Figure 39-8 *A*, The most popular topical burn preparation is Silvadene cream. While commonly used on minor burns, it likely has little beneficial effect on healing, and minor burns rarely become infected. Nonetheless, Silvadene is a standard intervention that at least causes the patient to look at the burn and become involved in dressing changes. *B*, Many burn specialists suggest inexpensive topical antibiotic ointments (such as bacitracin and neosporin) for all outpatient burns. They are commonly used on face and neck burns. Bacitracin is preferred since a contact dermatitis, such as noted in this abrasion, can occur from the neomycin portion of some topicals.

Figure 39-9 Burns of the feet are specialized burns that require a careful evaluation and an individualized treatment plan, even if the burn surface area is relatively small. It is difficult for most patients to provide ideal burn care at home when the feet are involved. *A*, It is tempting to initially treat this seemingly minor superficial second-degree foot burn in an outpatient setting, but the patient's compliance and social situation must be ideal for a successful outcome. Hospitalization until home health care can be established is prudent. *B*, An example of a foot burn that is a potential disaster, in this case due to a late presentation in a diabetic.

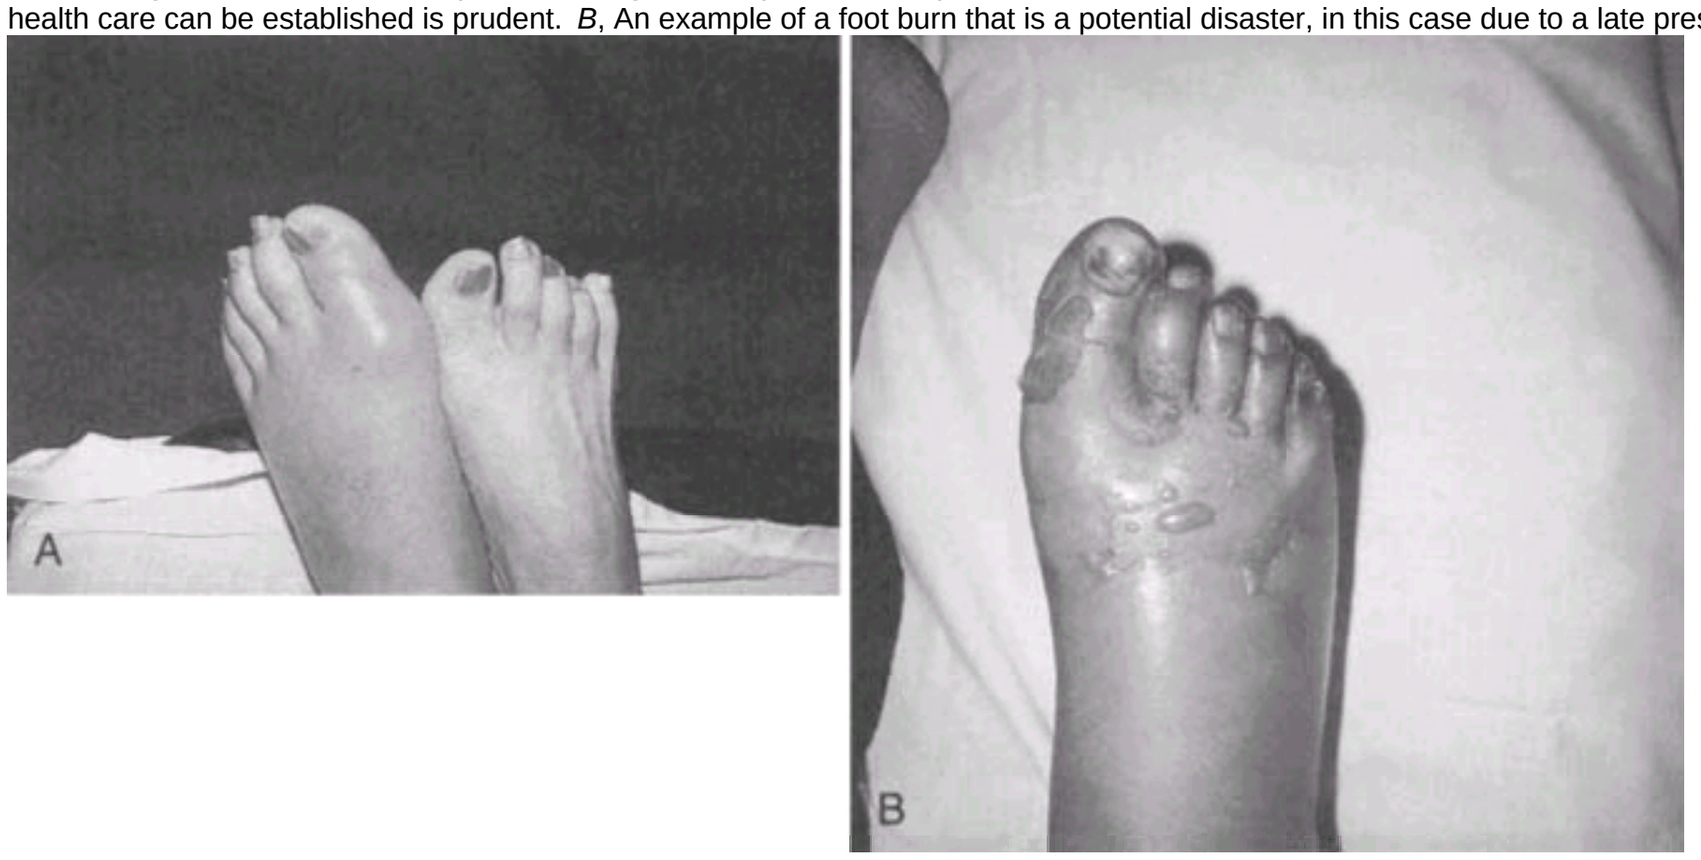

Figure 39-10 This badly burned hand requires referral to a burn center and should not be handled as an outpatient.

Figure 39-11 *A*, Flash burns to the face from lighting a gas stove. These burns are painful and may cause edema, but usually they do well. Note the singed facial hair. The eyes are usually protected by rapid reflex blinking and carbon monoxide poisoning and pulmonary burns are not an issue. Most can be handled in the outpatient setting with bacitracin ointment and no dressing. Pain control may be problematic unless opioids are prescribed. *B*, Facial and neck burns when a radiator cap was removed and the victim was sprayed with steam and hot antifreeze.

Figure 39-12 Burns can be a manifestation of child abuse, spouse abuse, or abuse of the elderly. *A*, Abuse burns from contact with a hot metal grate, from a child allegedly falling. *B*, This burn was the result of spouse abuse, caused by throwing hot soup during an argument. The delayed presentation to the hospital was a clue. *C*, Burns of the face and neck are common when a toddler pulls hot liquid from a stove. This case was never proven to be child abuse, but burns in young children often are due to abuse, especially if they are in atypical places. Although the body surface area of this burn is relatively small, the patient's age and the burn's location, coupled with the possibility of child abuse, require that this child be hospitalized.

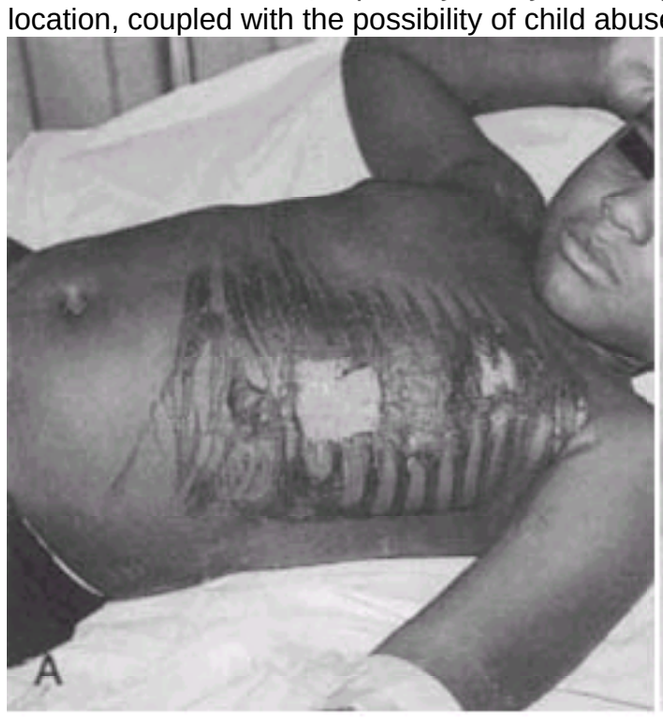

Figure 39-13 There is no compelling reason to remove all tar on the first visit. Physical removal of cooled tar usually results in avulsion of the underlying skin. Skin that is obviously loose should be debrided, but adherent tar is best liquefied with an emulsifying agent. Neomycin cream, not ointment, is a suggested emulsifier, but others are acceptable (see text). Final removal may be delayed for several days to permit loosening of the tar. Frequent dressing changes using an emulsifying agent can be performed by the patient, removing the tar over a few days.

Figure 39-14 Tar stuck to the face *(A)* can be emulsified with various agents and a lot of patience and persistence *(B)*. Fortunately, tar burns are usually not full-thickness burns.

Figure 39-15 There is no need to remove all the tar on the first visit *(A)*. This extremity was covered with an emulsifying agent and with gauze, and the residual tar was washed off easily 36 hours later *(B)*.

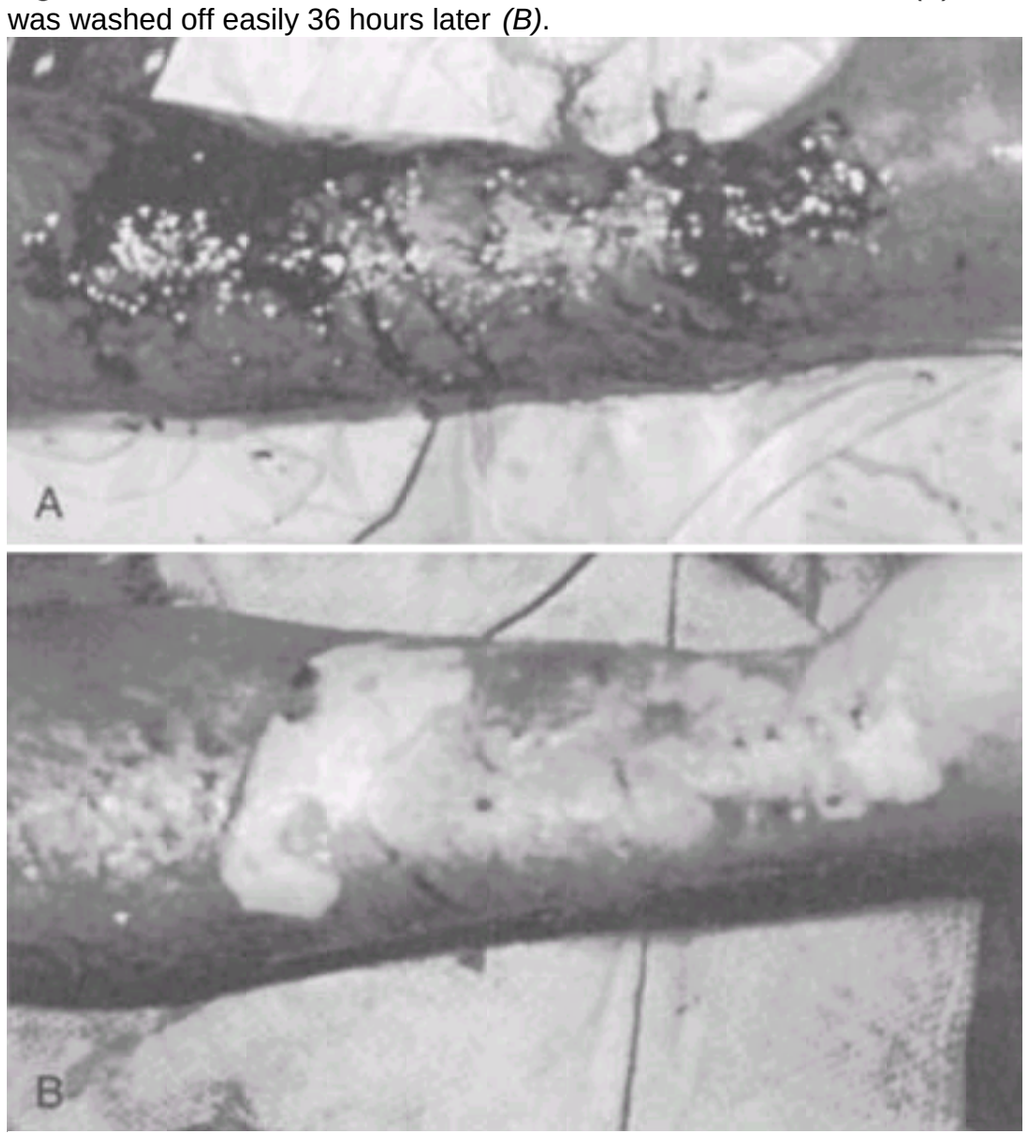

Figure 39-16 Alkali burns from wet cement develop insidiously, are extremely painful, and are frequently full-thickness injuries. They are most common on the feet when cement leaks over the top of the boots *(A)* or from kneeling in wet cement while working *(B)*. The alkali can penetrate clothing.

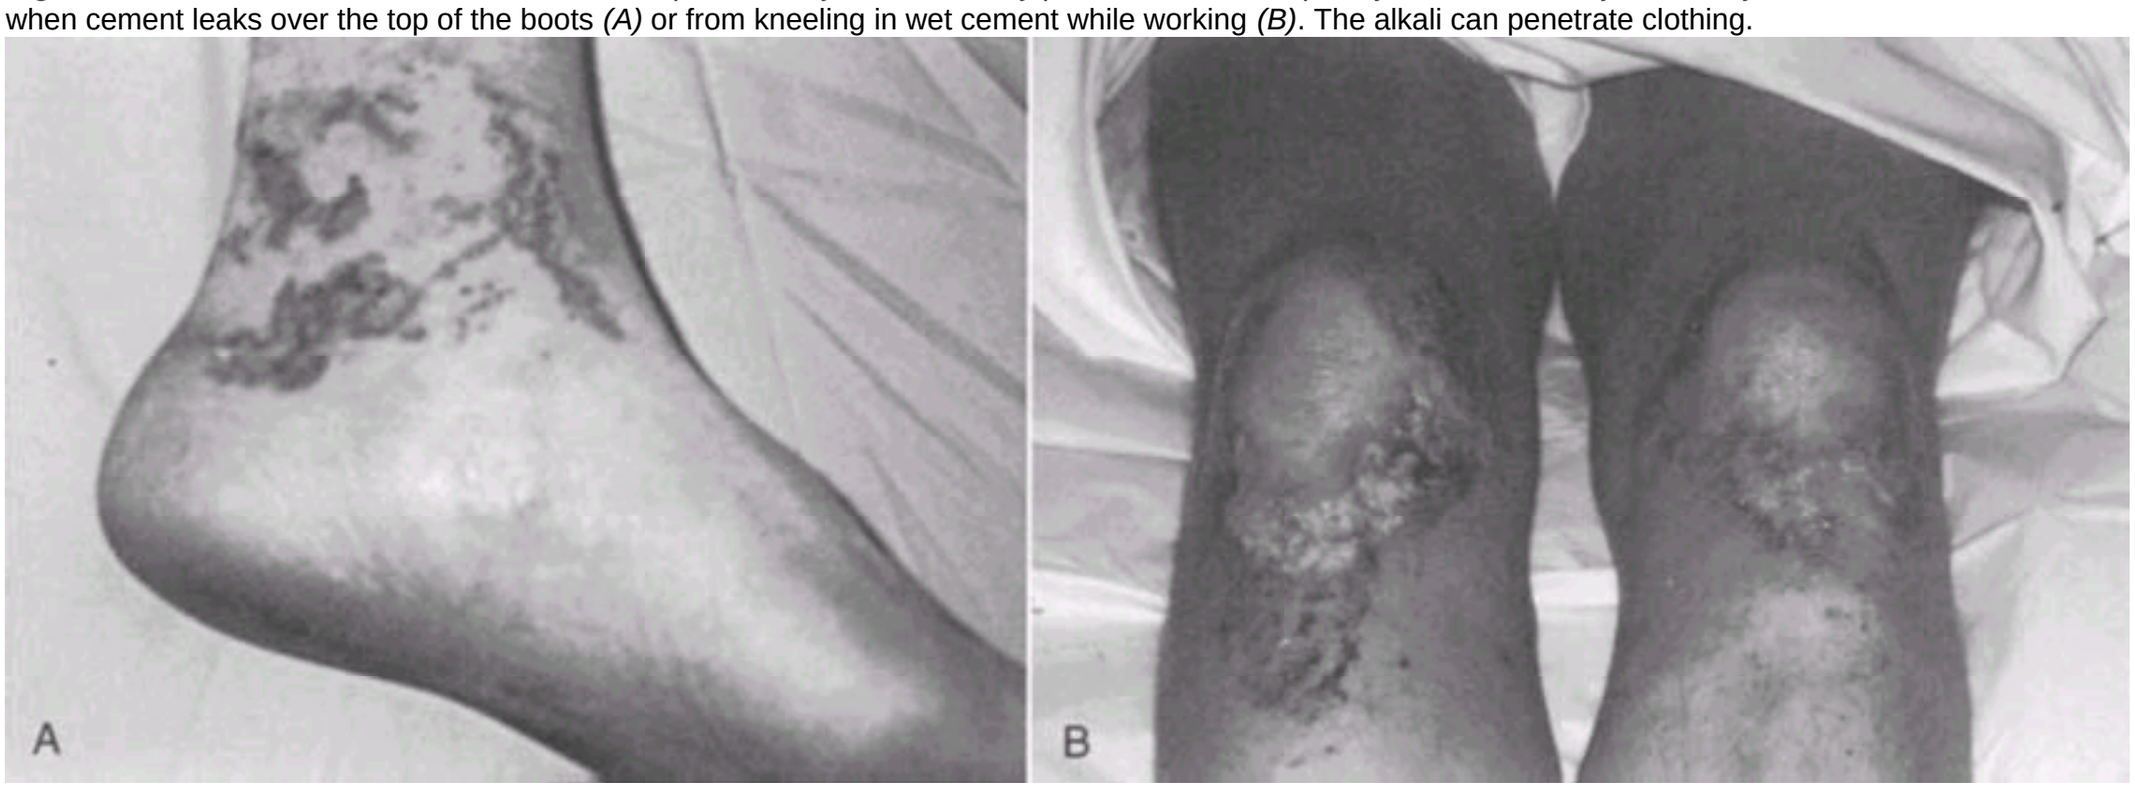

Figure 39-17 *A*, Initially this very painful hydrofluoric acid burn of the thenar and hypothenar emminence appeared minimal. *B*, Despite infiltration with calcium gluconate, a deep burn developed 3 days later.

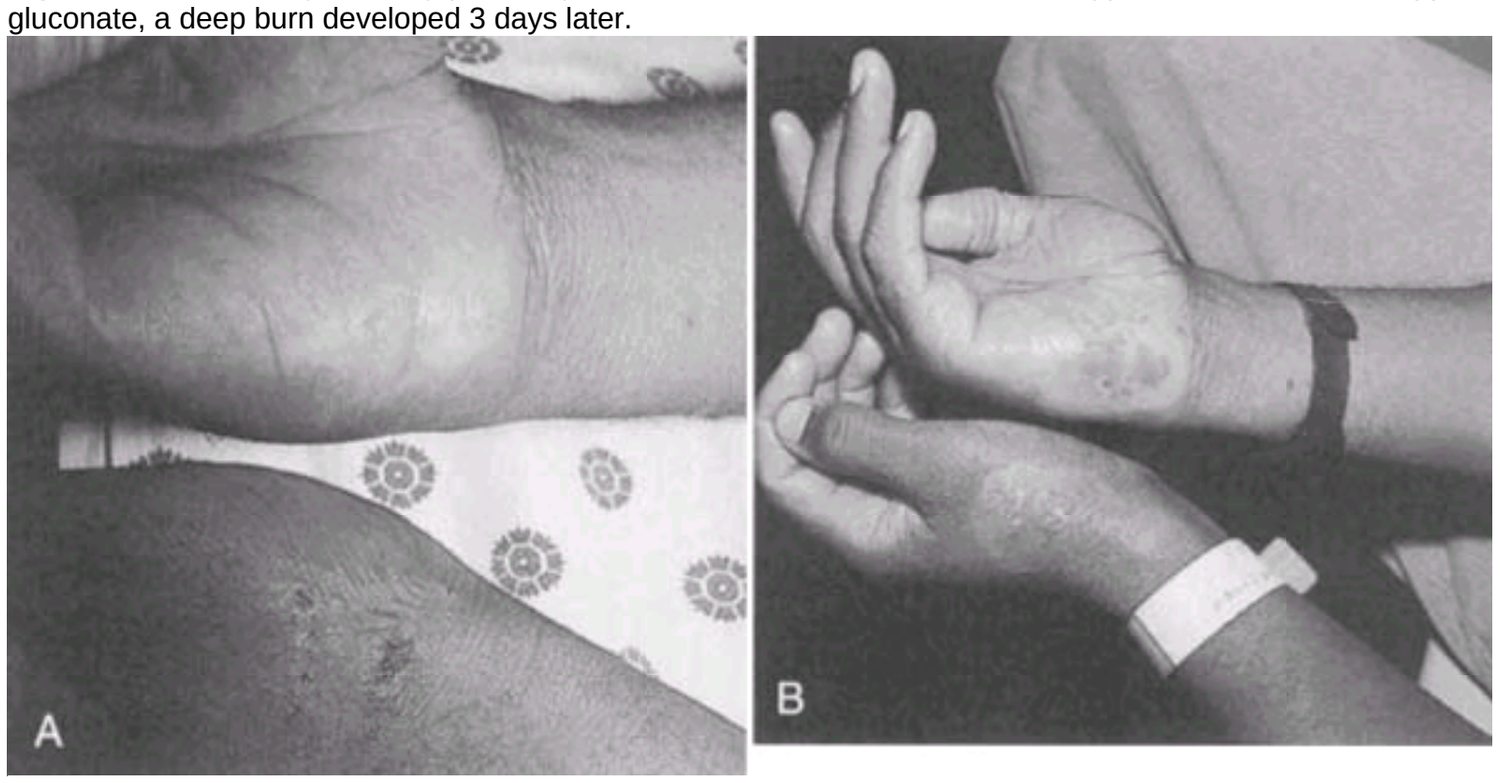

Figure 39-18 Hydrofluoric acid burns to the fingertips are extremely painful, despite minimal clinical findings. In this case the pain was excruciating, but the patient manifested only hyperemia and minor ecchymosis. *A,* Note that the acid has penetrated the intact fingernail, producing a significant injury to the nailbed. *B,* Prior to performing digital block anesthesia in order to painlessly infiltrate the fingertips with calcium gluconate, the patient outlines the painful areas with a felt-tip marker to ensure accurate placement of the antidote. *C,* In the treatment of hydrofluoric acid burns, topical therapy is often ineffective. Calcium gluconate may be injected subcutaneously with a 25- to 27-ga needle into the nailbed via the fat pad under a digital nerve block. *Fingernails should not be removed routinely* if burns are mild, such as those seen with household products containing <10% concentration of the acid. Intra-arterial calcium infusions are often quite successful in relieving pain and limiting necrosis.

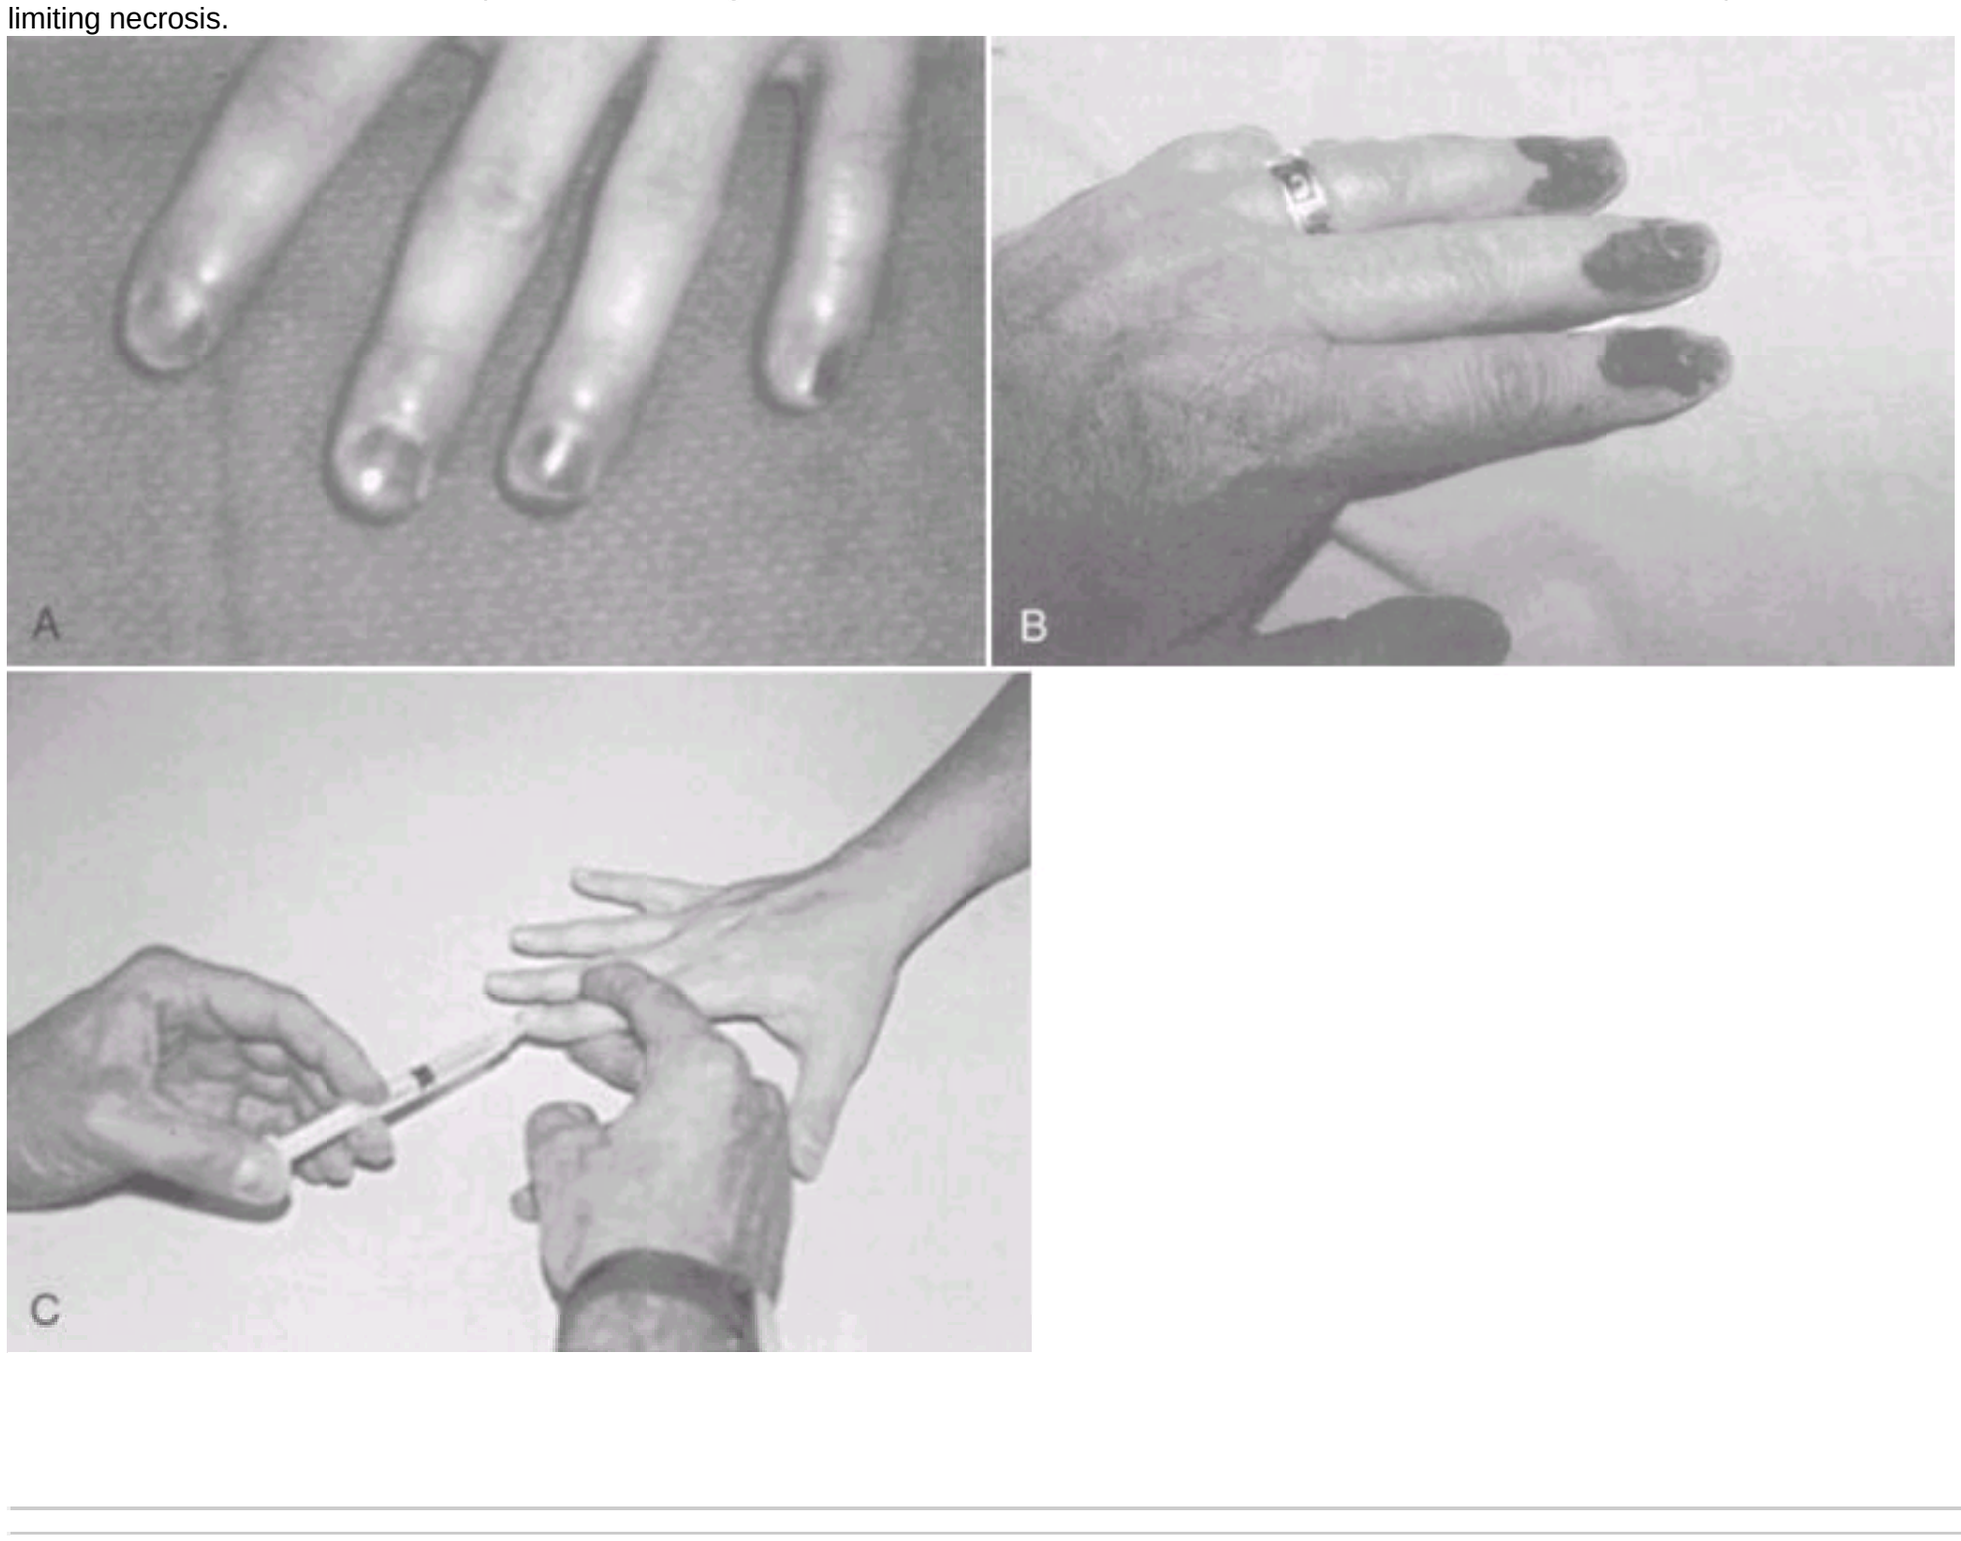

Figure 39-19 The circulatory embarrassment caused by edema beneath the encircling full-thickness burns of the legs of this patient was relieved by escharotomy incisions placed in the midmedial line of each limb. The restriction of the ventilatory excursion of the chest wall caused by the encircling full-thickness truncal burns was relieved by escharotomies placed in both anterior axillary lines and by a costal margin escharotomy. Compression of the abdominal contents and restriction of diaphragmatic excursion by the constricting deep abdominal wall burns were relieved by placement of escharotomy incisions in the lateral abdominal wall bilaterally. *(From Davis JH, Drucker WR, Foster RS, et al: Clinical Surgery. St. Louis, CV Mosby, 1987.)*

Figure 39-20 Diagram showing preferred sites for escharotomy incisions. *Dotted lines* indicate the escharotomy sites. *Bold lines* indicate areas where caution is required since vascular structures and nerves may be damaged by escharotomy incisions. *(From Davis JH, Drucker WR, Foster RS, et al: Clinical Surgery. St. Louis, CV Mosby, 1987.)*

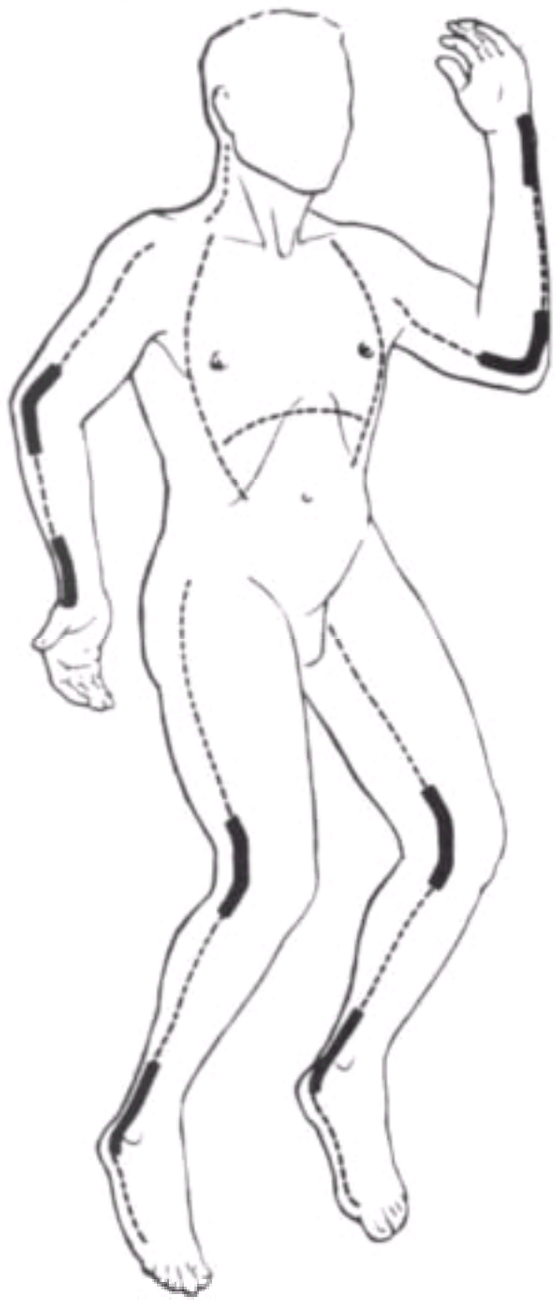

Figure 40-1 Blunt esophageal foreign bodies are most commonly lodged at one of three anatomical areas of narrowing: the cricopharyngeus muscle; the level of the aortic crossover; and the lower esophageal sphincter.

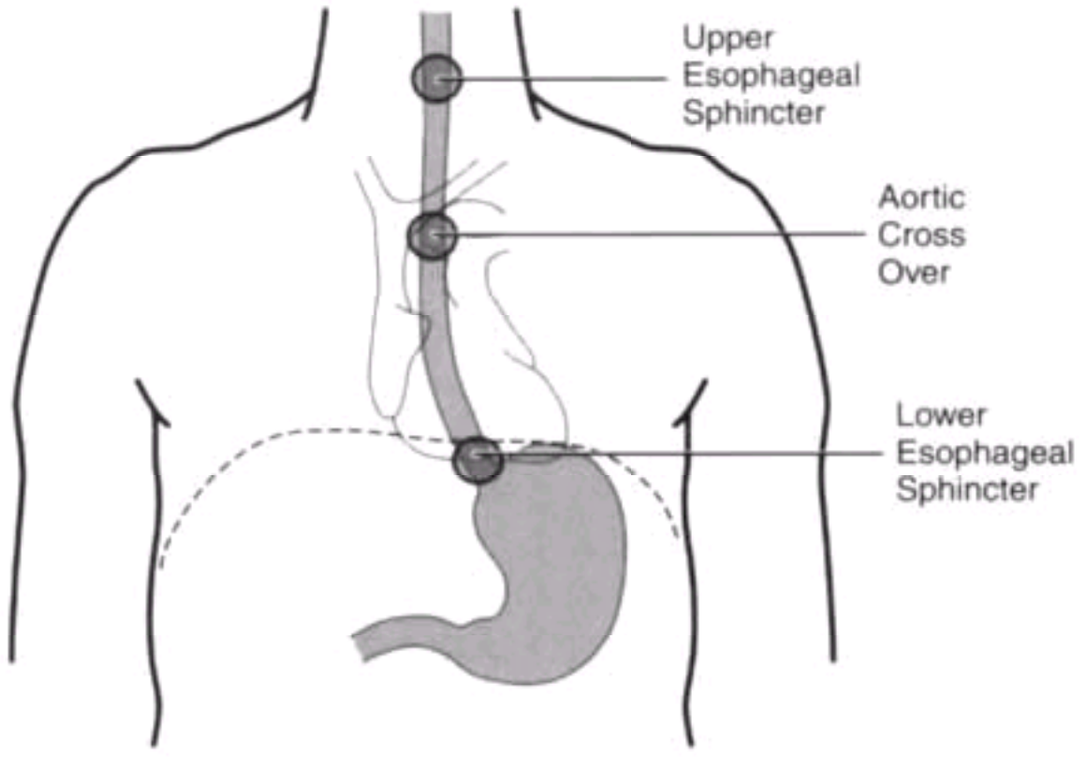

Figure 40-2 PA radiograph of an esophageal foreign body (coin) lodged at the level of the cricopharyngeus muscle. This is the most common area of the esophagus to harbor a coin in children.

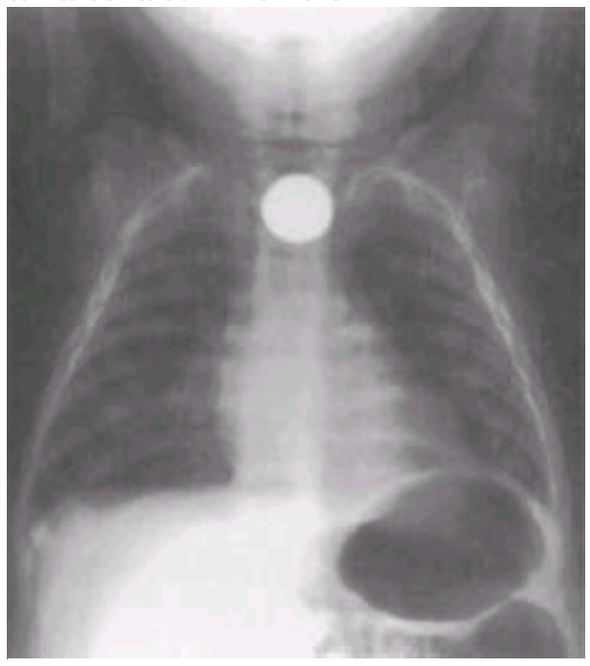

Figure 40-3 Posteroanterior radiograph of an esophageal foreign body (coin) lodged at the level of the aortic cross-over.

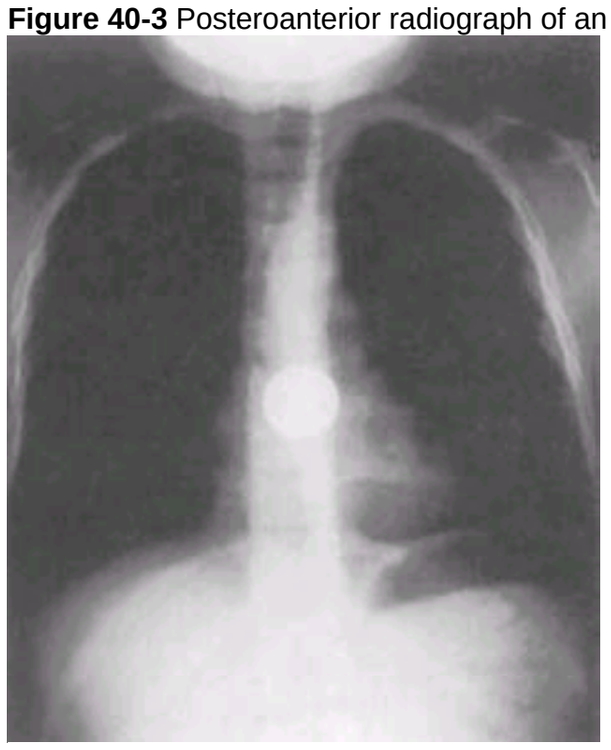

Figure 40-4 A posteroanterior radiograph of an esophageal foreign body (coin) lodged at the level of the lower esophageal sphincter (LES).

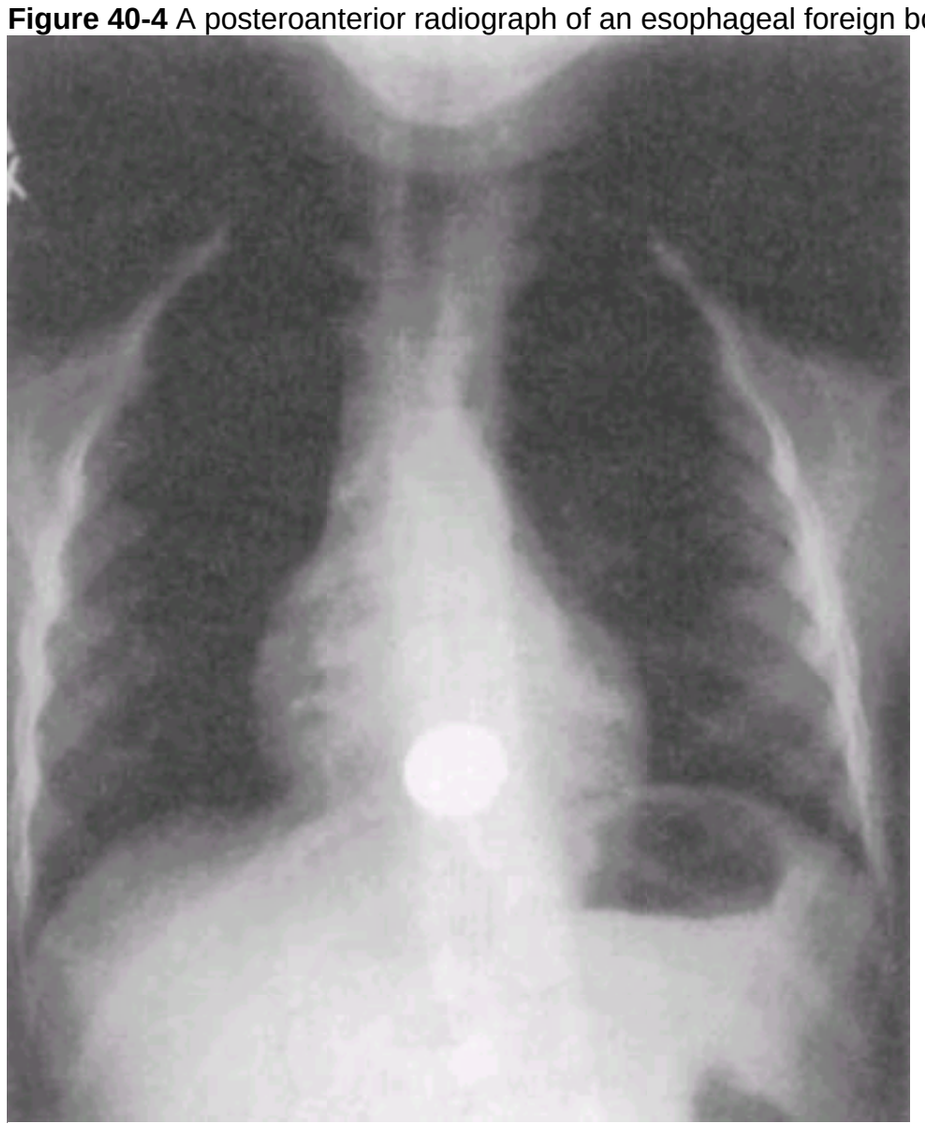

Figure 40-5 A lateral neck radiograph showing a chicken bone lodged in the pharynx with associated soft tissue swelling. The arrow points to the bone. Plain radiographs have poor diagnostic accuracy for detecting bones in the esophagus and they are often eschewed in favor of a CT scan if radiographic evaluation is deemed necessary.

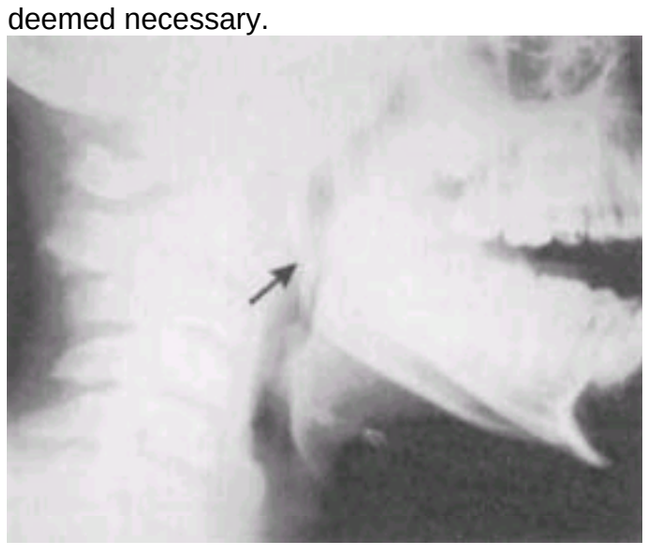

Figure 40-6 A barium swallow demonstrating a complete esophageal obstruction in the proximal to mid-esophagus.

Figure 40-7 Computed tomography demonstrating an esophageal foreign body.

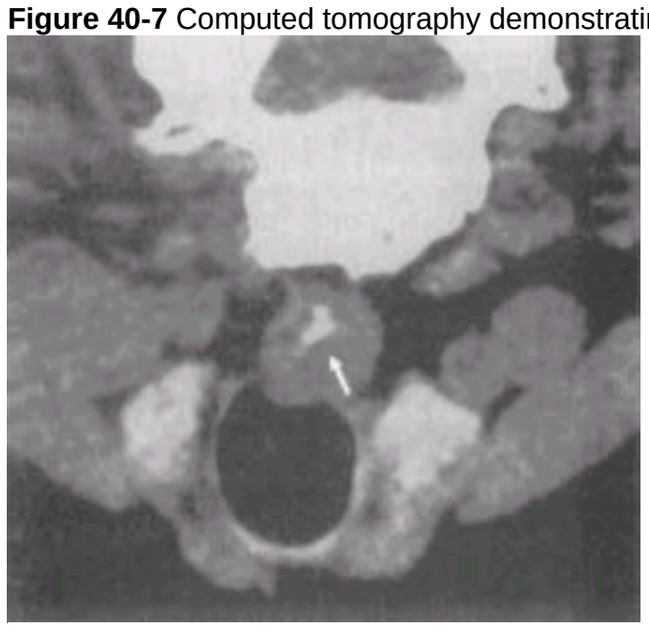

Figure 40-8 Esophageal foreign body seen on nasopharyngoscopy.

Figure 40-9 Technique of Foley catheter extraction. In children, this procedure is best done with the patient restrained on a papoose board, or consciously sedated, with the head lowered. Some operators place the patient in a prone position or roll the patient to the prone position after catheter insertion to enhance oral expulsion of the foreign body. *A,* A catheter is inserted orally into the esophagus distal to the coin. A bite block may be used to assist oral passage. *B,* The balloon is inflated. Gentle traction moves the coin proximally through the esophagus. *C,* The coin is moved steadily past the glottis. *D,* The coin is present in the mouth to be expectorated or grasped. *(Adapted from McSwain N: Esophageal foreign body. Emerg Med 21:85, 1989.)*

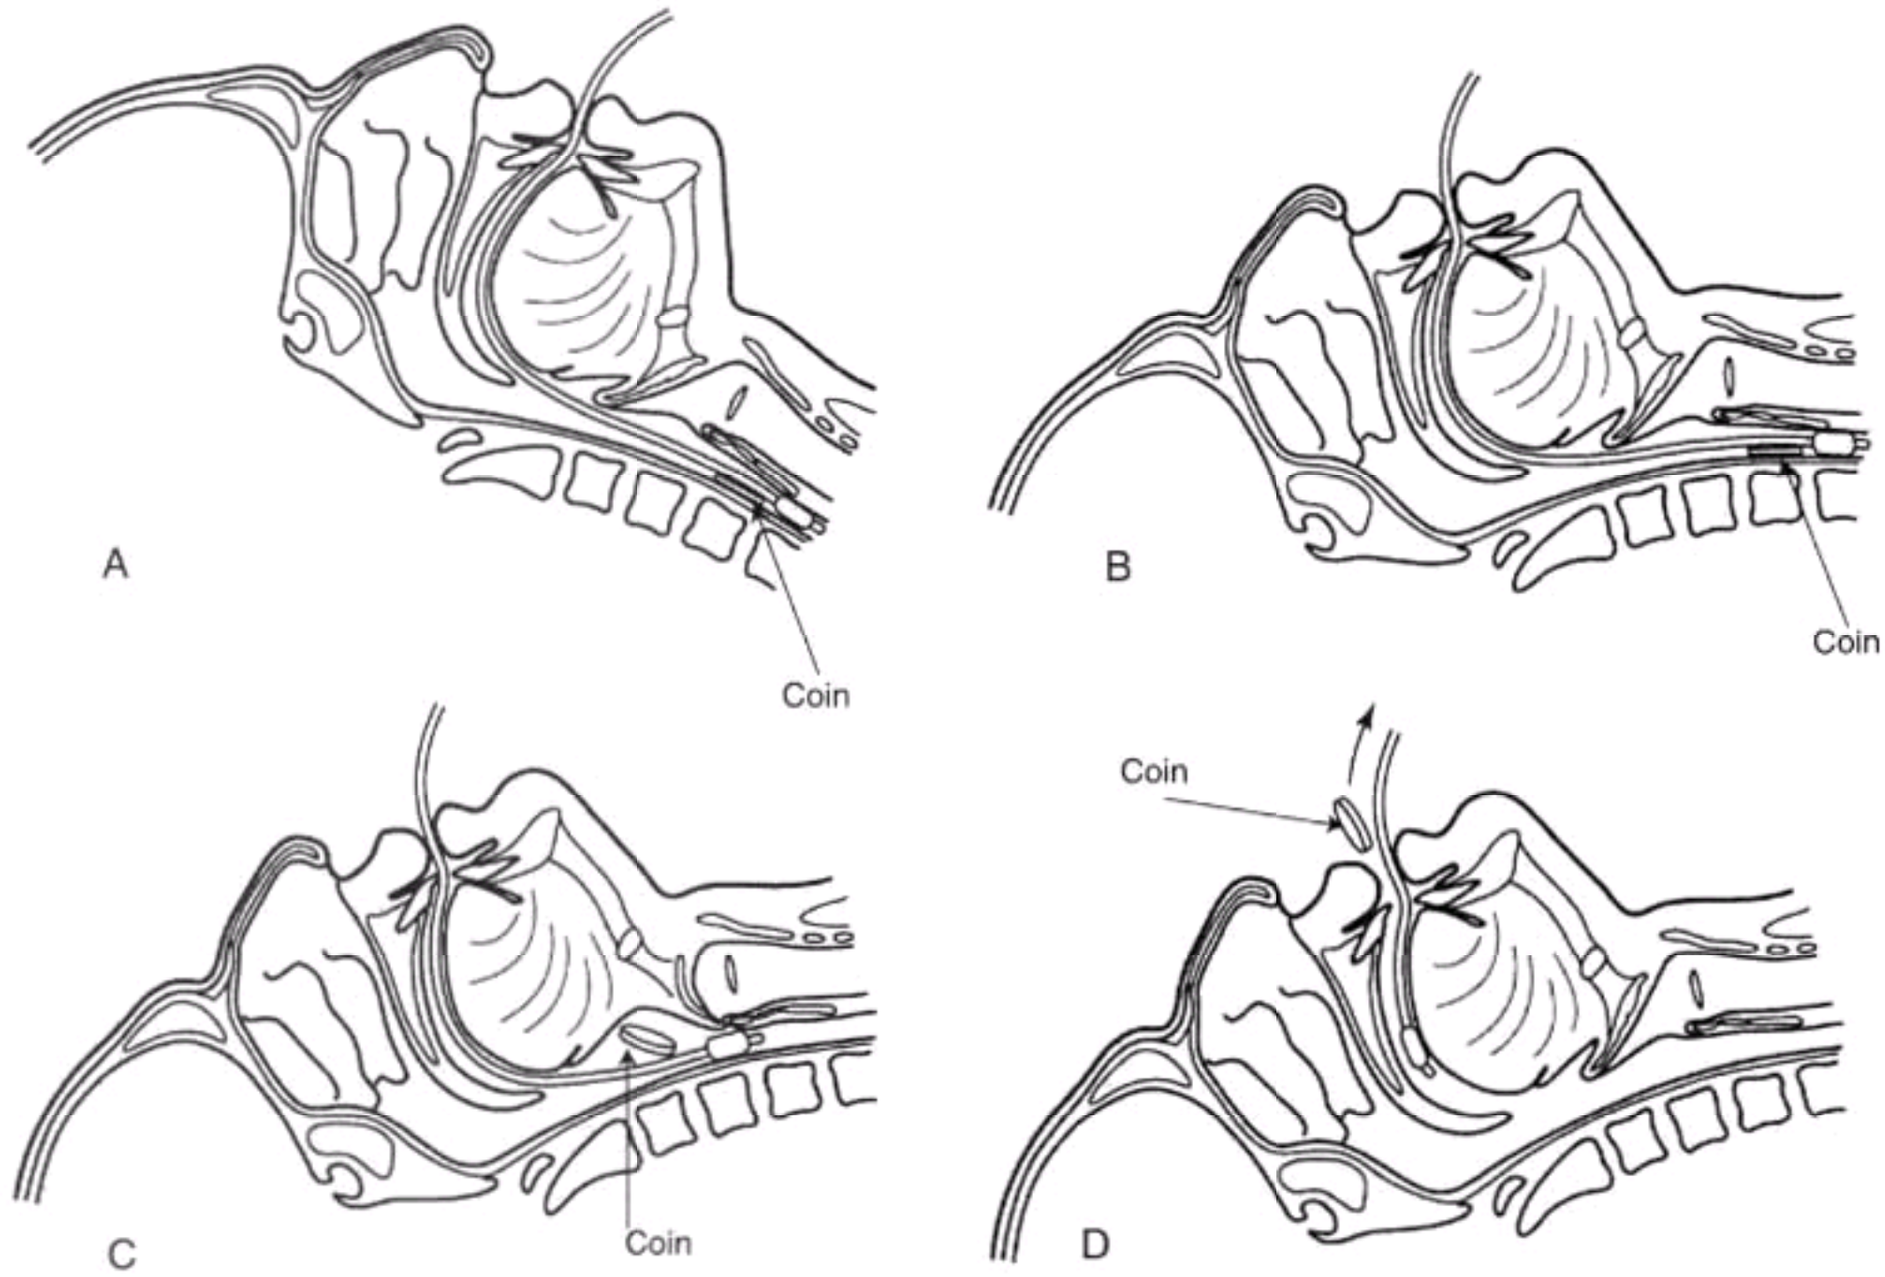

Figure 40-10 *A*, Lateral radiograph of the child shown in Figure 40-2 . This lateral view shows four coins at the same location. Multiple swallowed coins are common in children. It is important to obtain both posteroanterior and lateral films to ascertain the exact number and location of swallowed coins. *B*, A single coin was seen on the PA chest film, but this lateral film suggests three coins. However, they do not seem to be stacked directly on top of each other. This digital radiograph was accidentally exposed three times, and actually only one coin was swallowed.

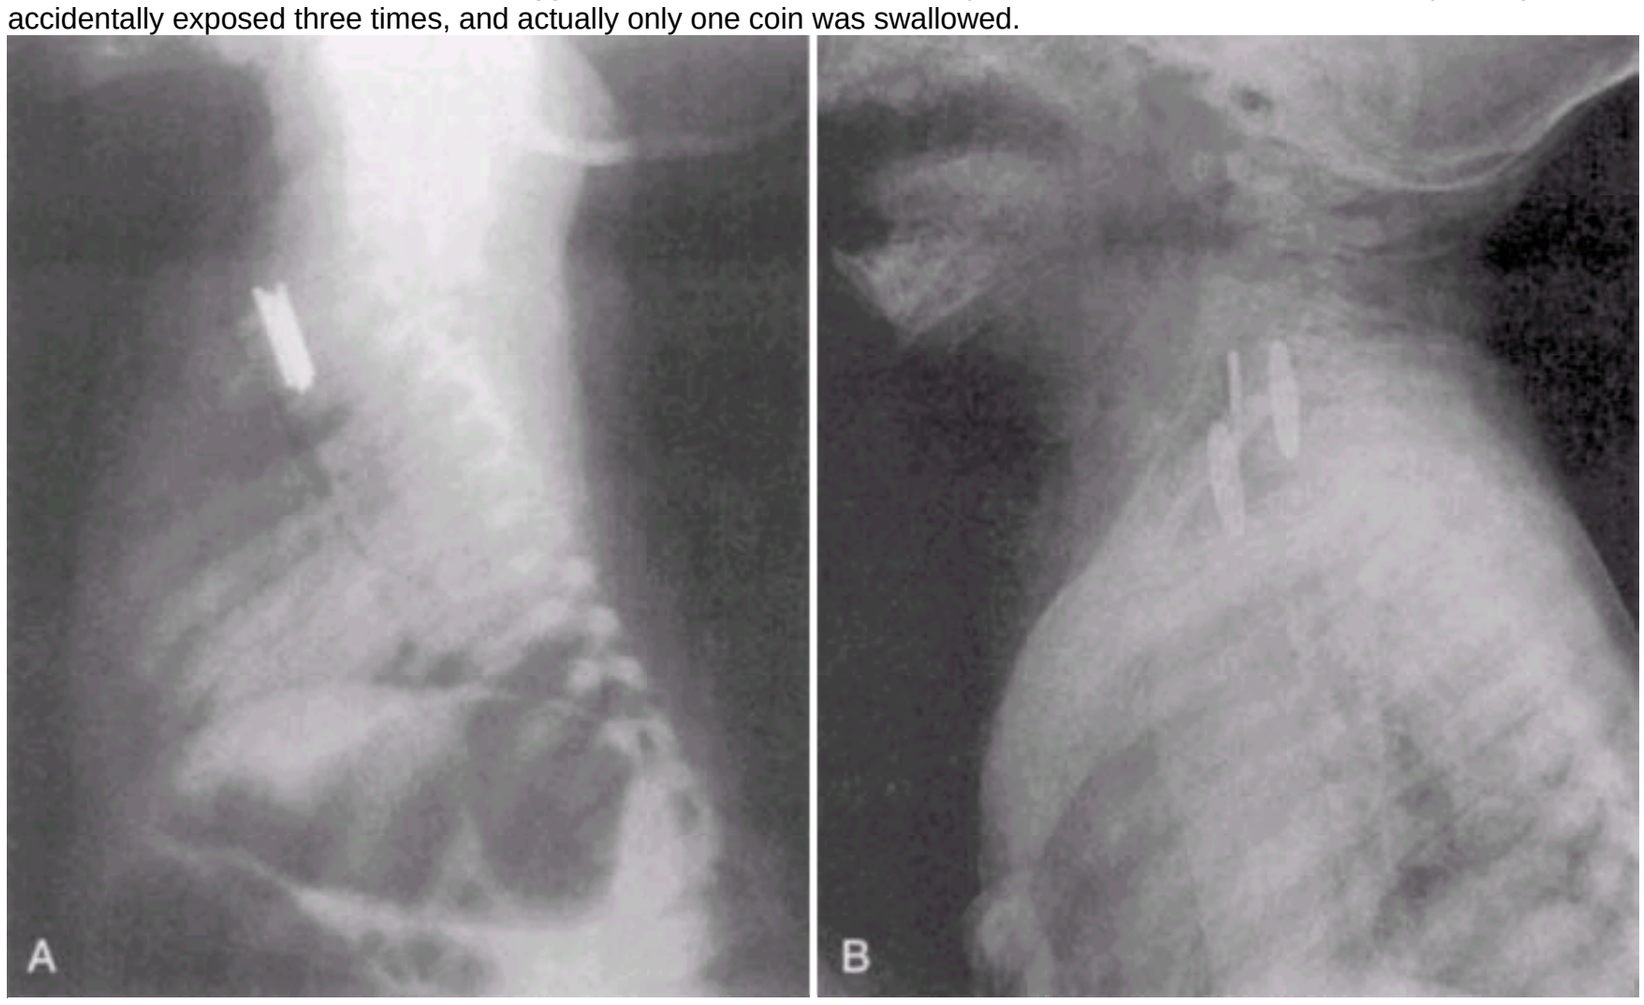

Figure 40-11 Flow diagram outlining an approach to the management of swallowed coins.

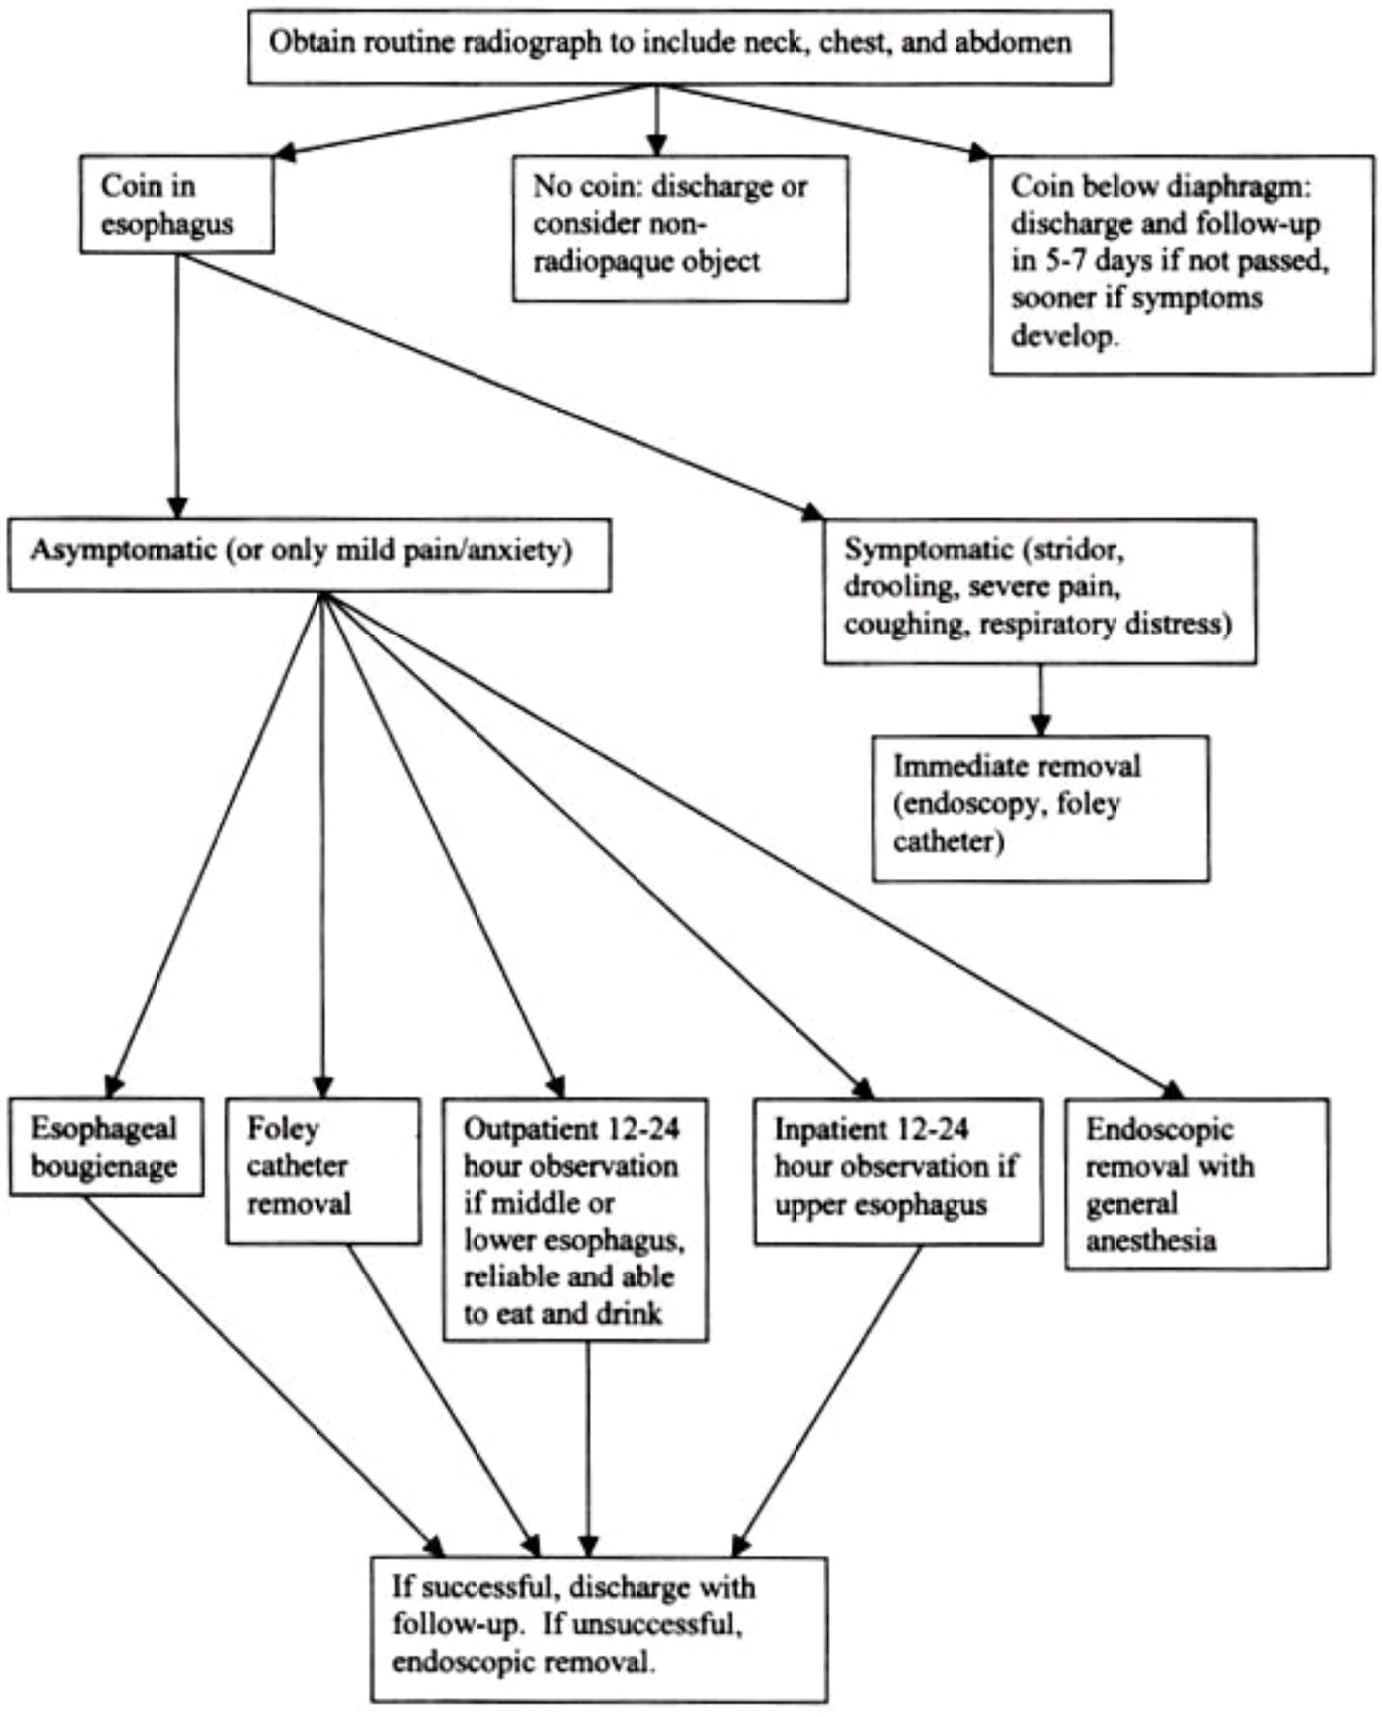

Figure 40-12 Many fish bones become impaled in the soft tissues of the upper digestive tract. This woman felt a bone catch in her throat while eating fish. As is often the case, she was able to consistently localize the FB to the submandibular area (*A*). With only a tongue blade, local anesthetic spray, and good lighting, a fish bone was found embedded in the tonsil and was easily removed with forceps (*B*). Strands of saliva can mimic a fish bone, so be careful when probing and grasping.

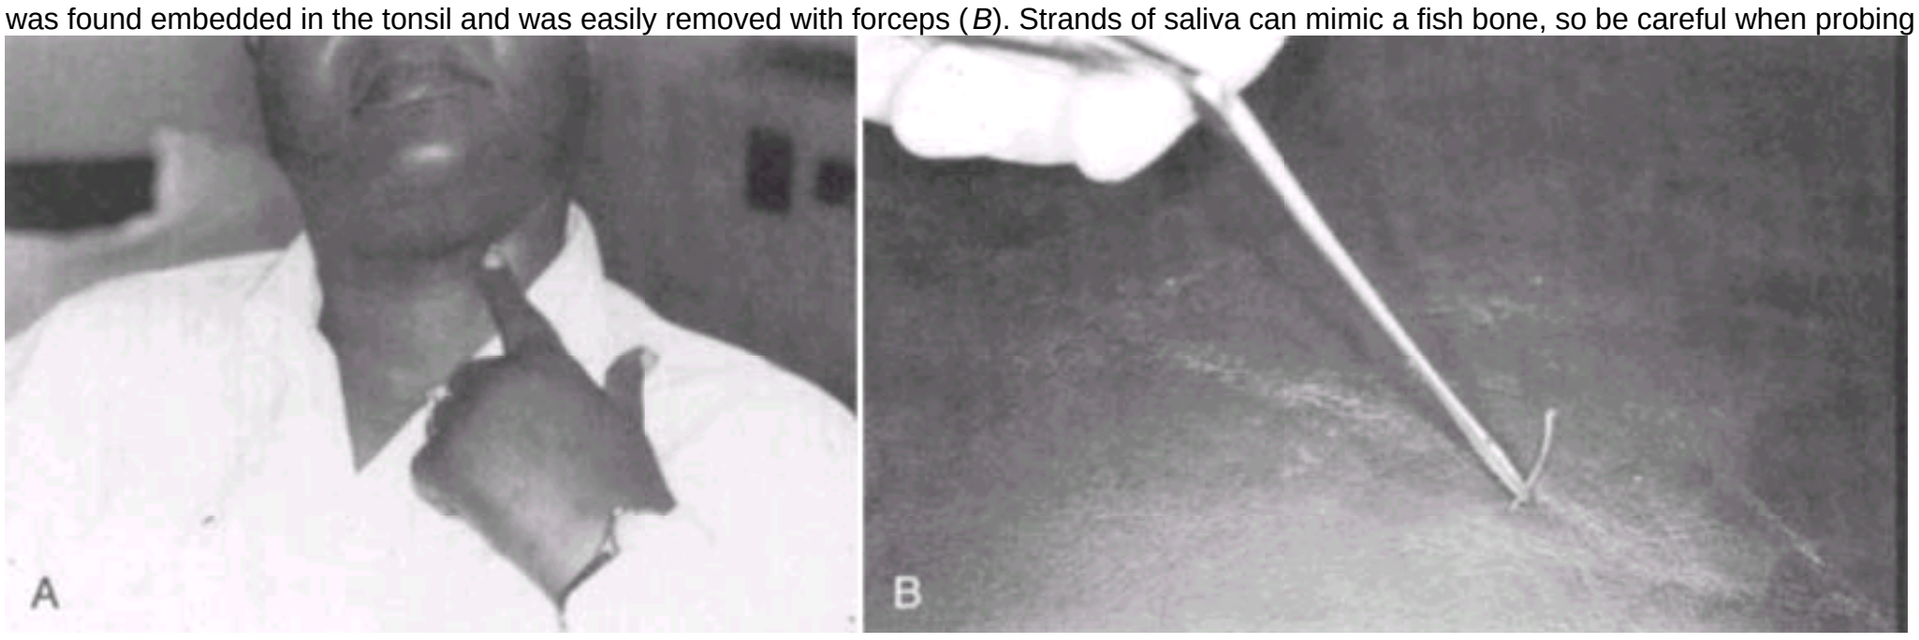

Figure 40-13 *A*, Posteroanterior radiograph of an open safety pin lodged in the upper esophagus. Sharp foreign bodies in the esophagus are best removed with endoscopic visualization. *B*, This 10-year-old child came to the ED with severe chest pain. No history of a foreign body was given. Even when the radiograph demonstrated this metallic object in the esophagus, it remained a mystery how it got there. Objects such as this are removed under anesthesia with an endoscope, and no ED intervention, except for pain relief, is indicated.

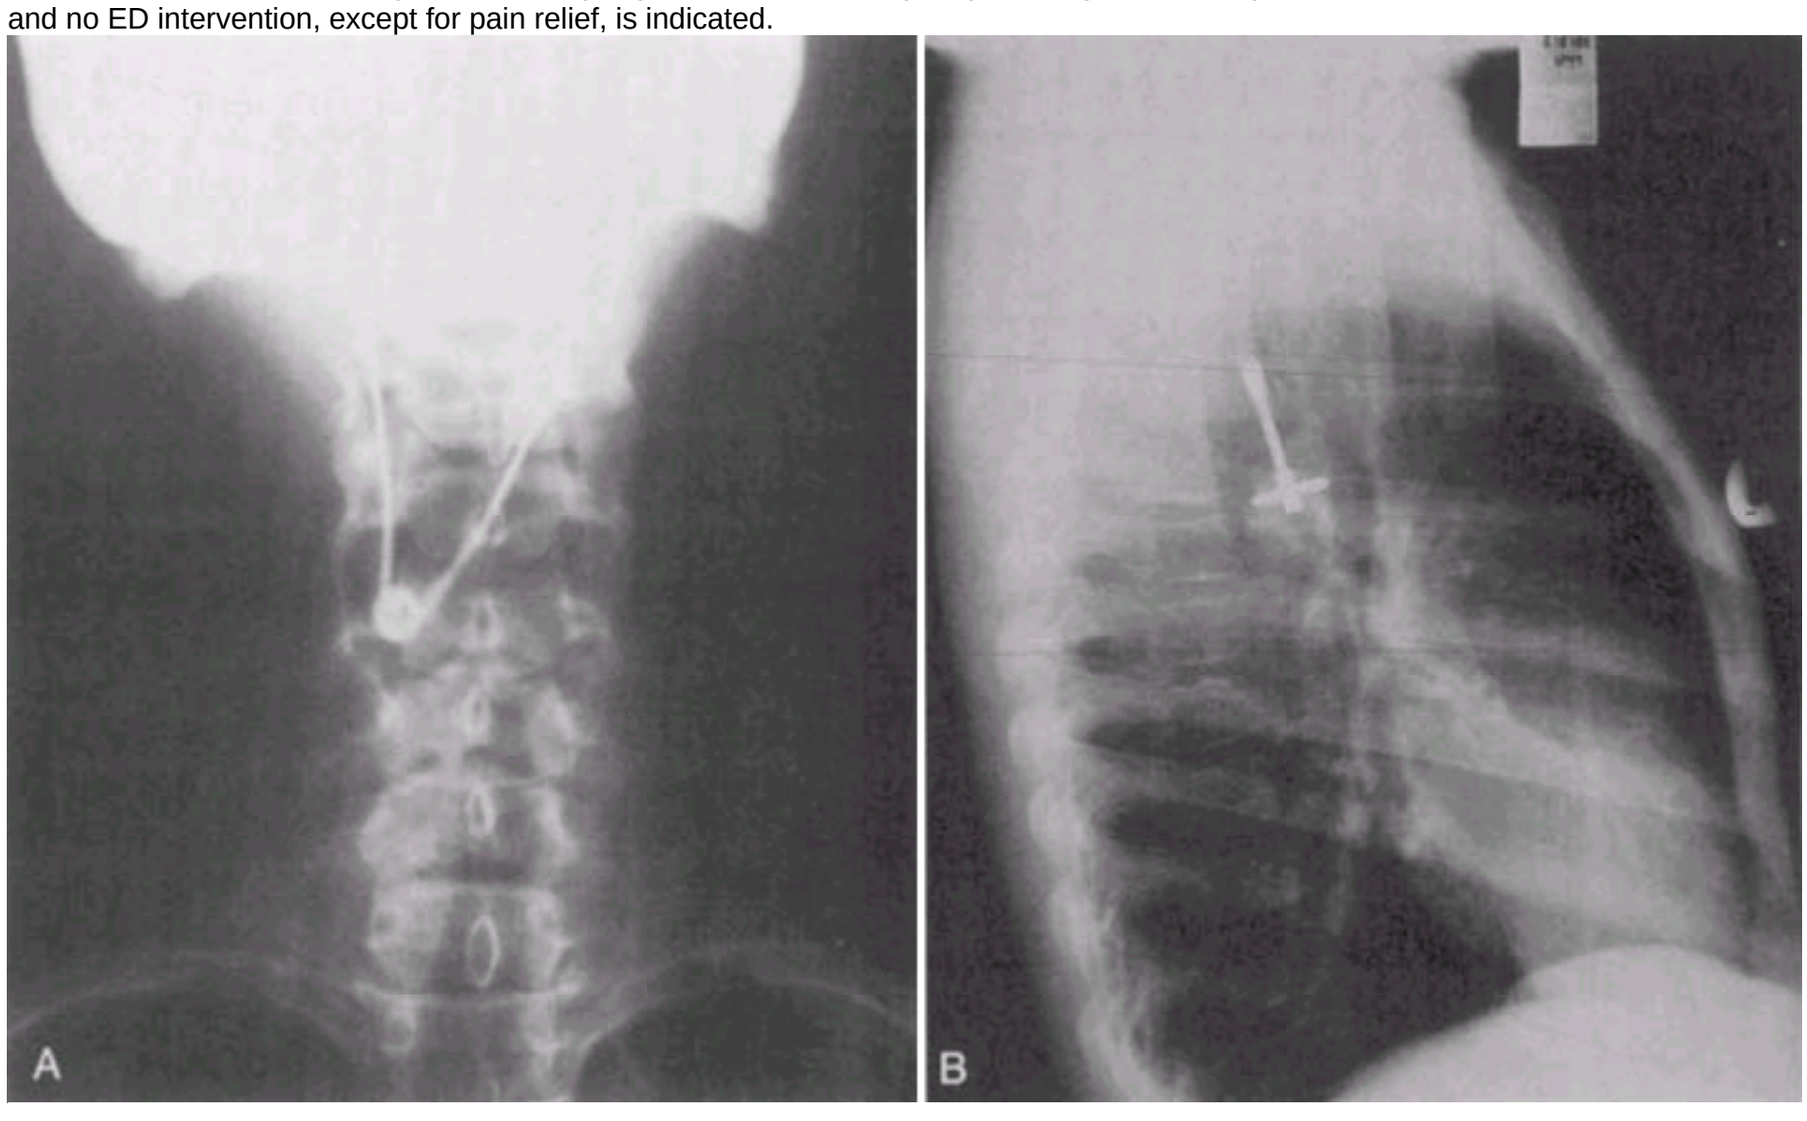

Figure 40-14 Button batteries. These batteries have a wide range of sizes and can mimic coins on radiographs.

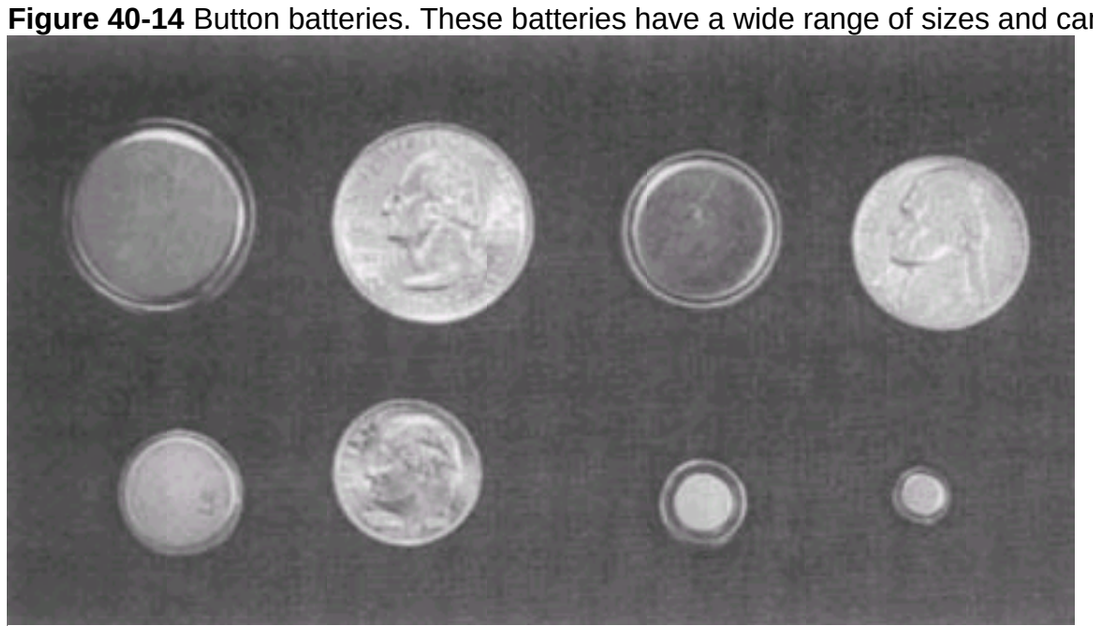

Figure 40-15 Posteroanterior radiograph of a button battery lodged in the esophagus, which can easily be confused with a coin. Button batteries can cause esophageal wall necrosis within 2 hours and must be removed expeditiously. *(From Kost KM, Shapior RS: Button battery ingestion: A case report and review of the literature. J Otolaryngol 16:4, 1987.)*

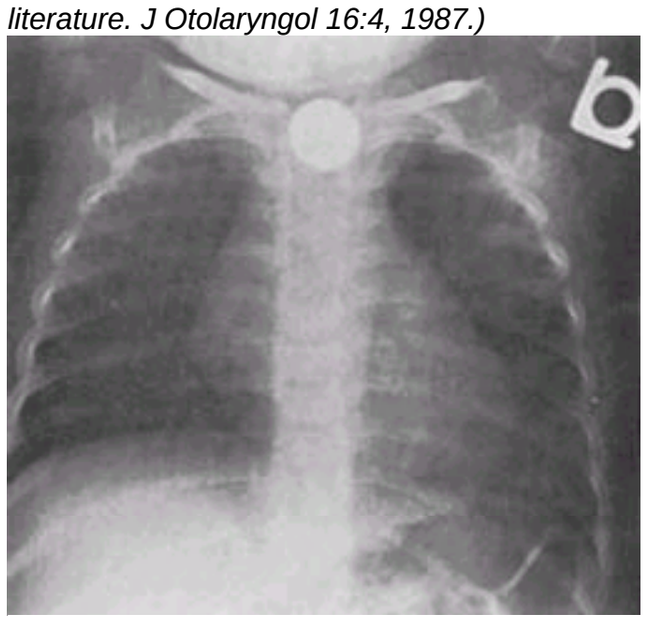

Figure 41-1 Standard nasogastric tubes. *A,* Standard Levin tube. This tube has a single lumen. It is sufficient for instilling material into the stomach or for diagnostic stomach aspiration. *B,* Salem sump tube. This tube contains a second lumen that allows venting during continuous suction. *1,* Gastric end with suction eyes. *2,* Pigtail extension (blue) of the air vent lumen. *3,* Connector for attachment of suction lumen to vacuum line.

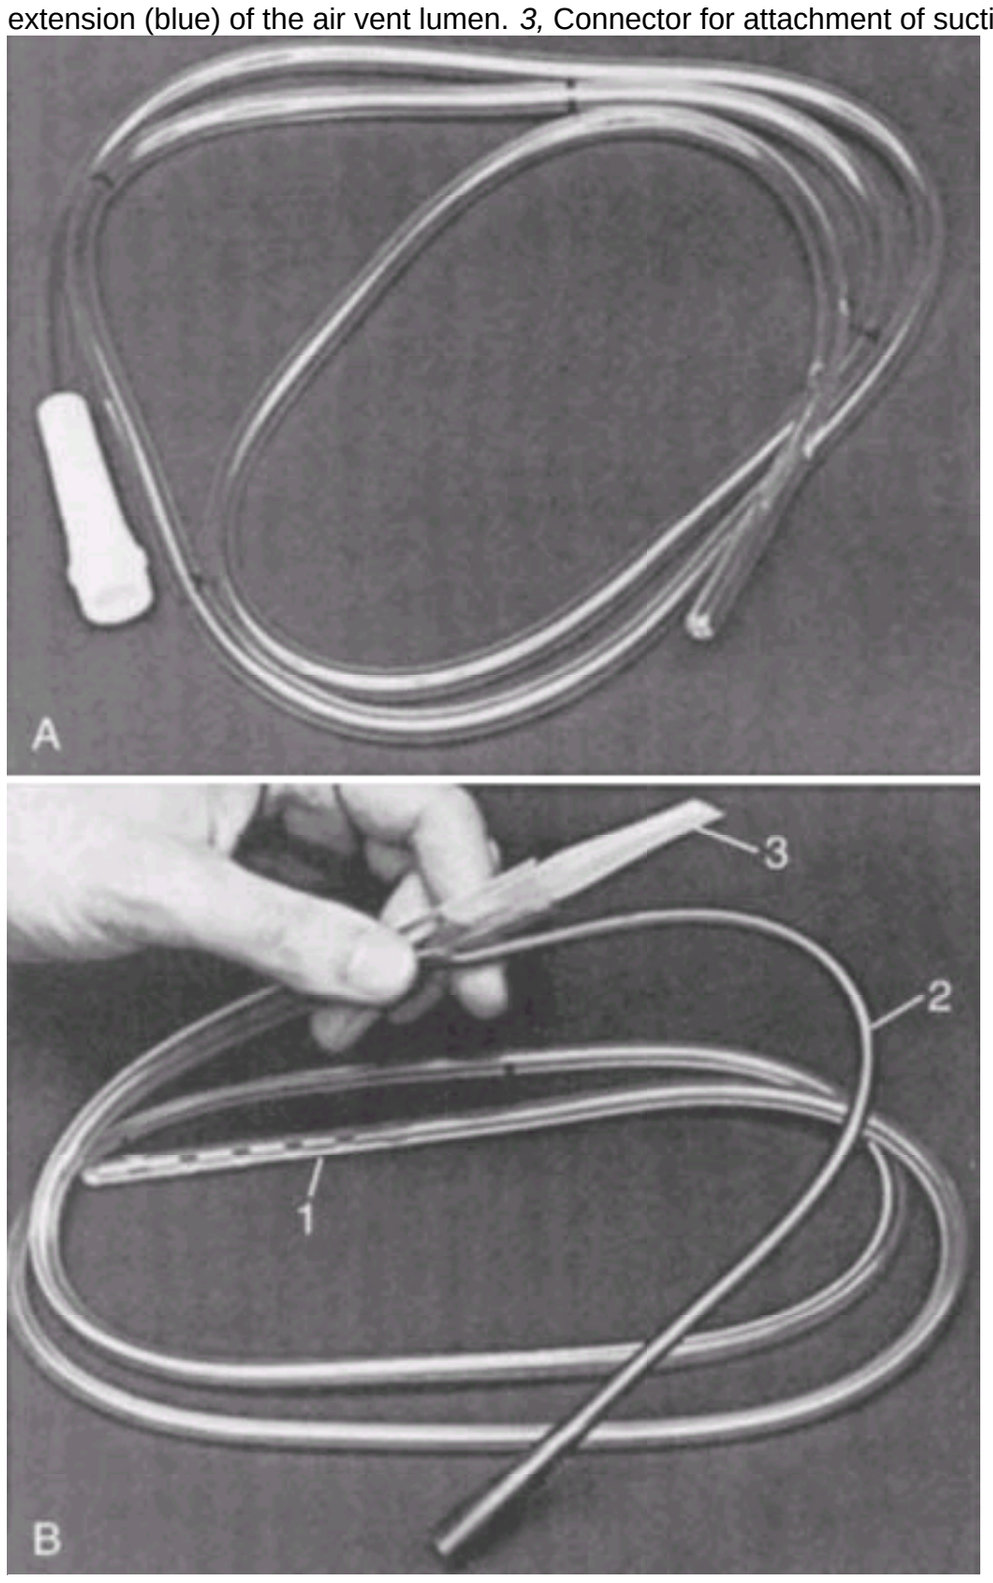

Figure 41-2 Diagram of the Salem sump tube. *A,* General design. *B,* Diagram of double-lumen principle for suction. *(Courtesy of the Argyle Division of Sherwood Medical, St. Louis, MO.)*

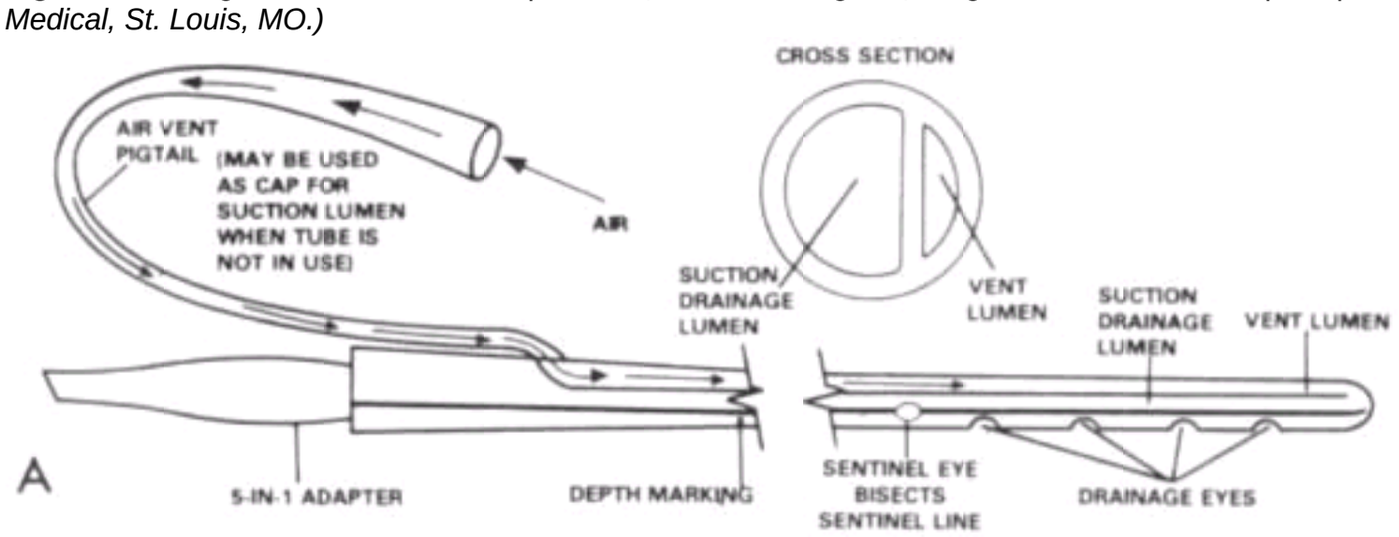

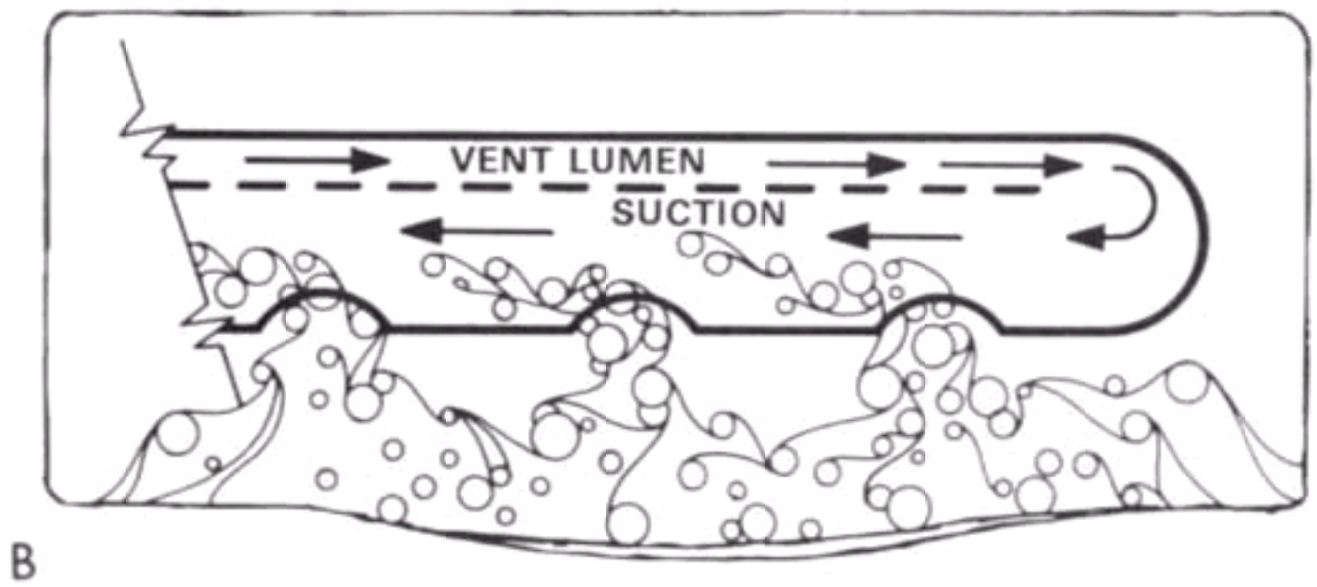

Figure 41-3 An NG tube may enter the cranium or facial soft tissues in patients with severe head or facial trauma. Those with a coagulopathy may experience significant bleeding from nasal or pharyngeal trauma during passage of an NG tube. In such cases, a standard NG tube inserted through the mouth may be a better alternative.

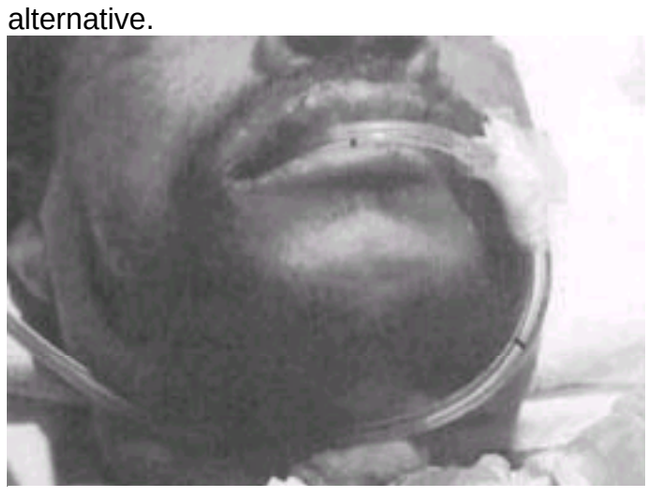

Figure 41-4 Estimation of tube insertion depth. Before inserting the nasogastric tube, the clinician should estimate the length of tubing that will be required to ensure intragastric positioning without excess coiling. Holding the tube against the patient's body, measure the distance from the tip of the xiphoid to the earlobe *(A)*. Add the distance from the earlobe to the tip of the nose *(B)*. Then add another 15 cm *(C)*. Note the total distance using markers on the tube, or attach a piece of tape to the tube.

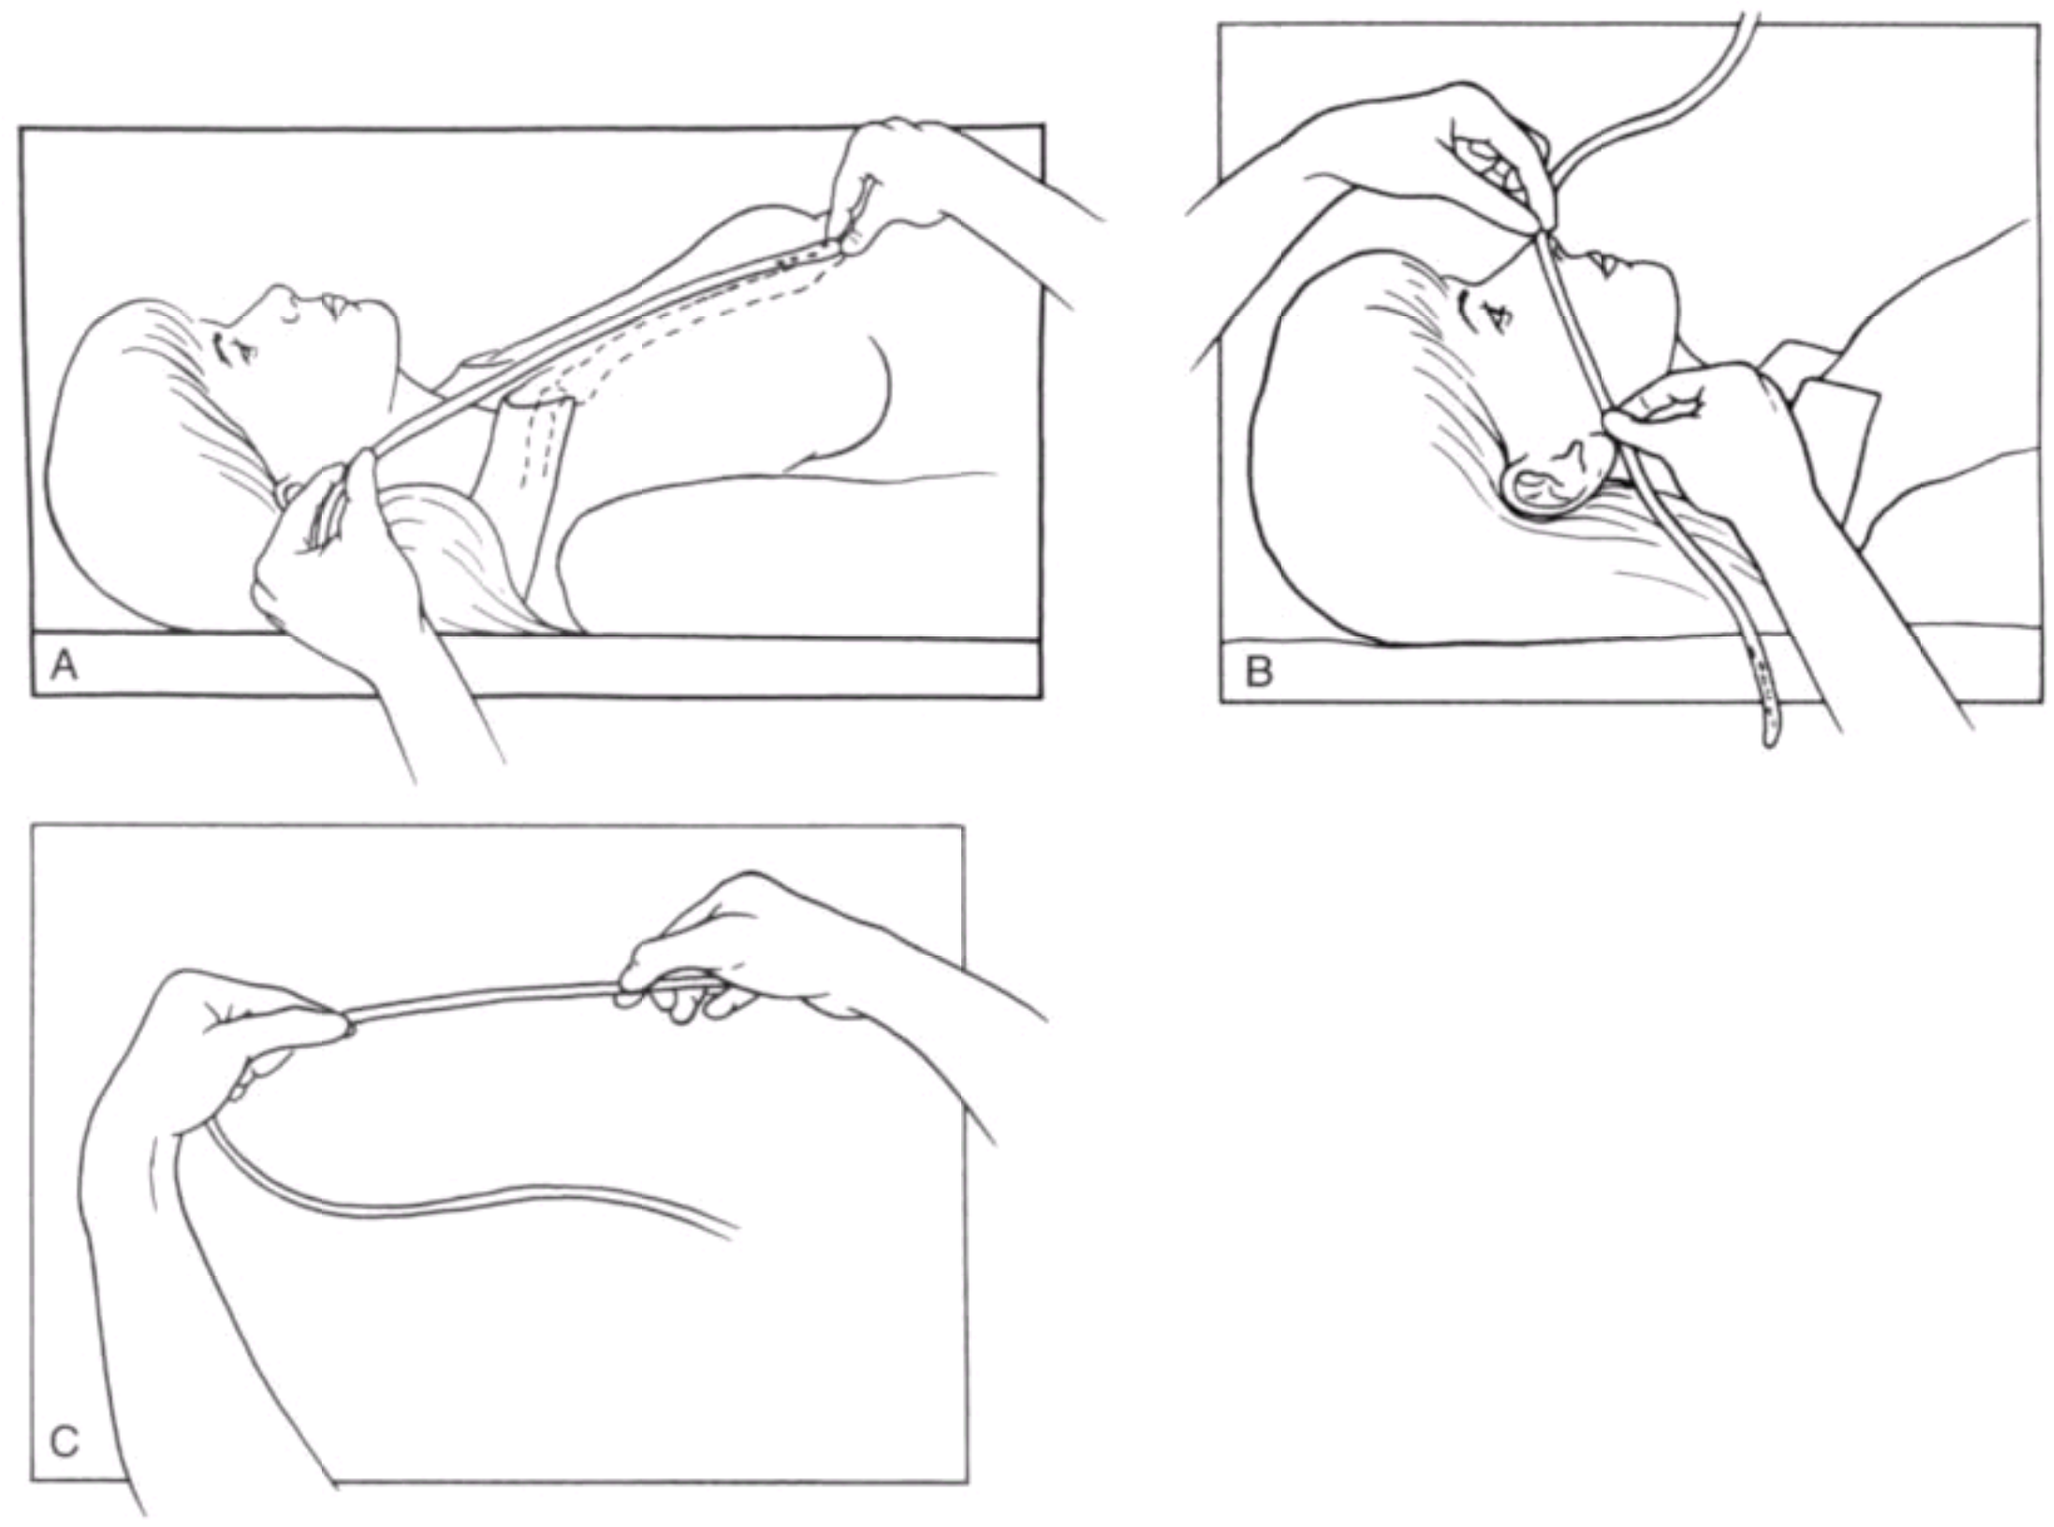

Figure 41-5 If time and situation permit, administration of nebulized lidocaine (2.5 mL of 4% solution) via a face mask and standard nebulizer used to deliver asthma medications, can decrease pain and gagging without increasing aberrant placement. The patient is instructed to breathe through the mouth and nose to anesthetize the nose and pharynx.

Figure 41-6 Whenever possible, some form of topical anesthesia should be used before passing a nasogastric tube. The method pictured can be used in addition to atomized anesthetic, and will be more effective than treating only the nasal opening. Fill a syringe barrel with 5 mL of 2% viscous lidocaine. Without using a needle, squirt the solution along the floor of the nose and allow it to drip into the nasopharynx and be swallowed. This method works best with the patient supine. Wait 5 minutes for the anesthetic to take effect.

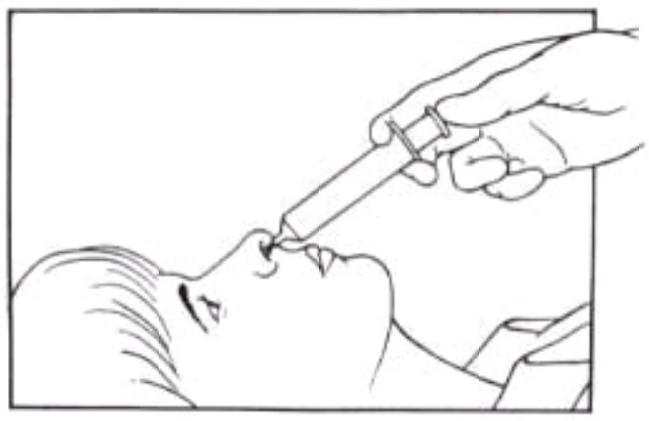

Figure 41-7 Tube location in the nostril. The nasogastric tube is directed along the *floor* of the nose, not toward the nasal bridge. The tube often slides through the tunnel beneath the inferior turbinate.

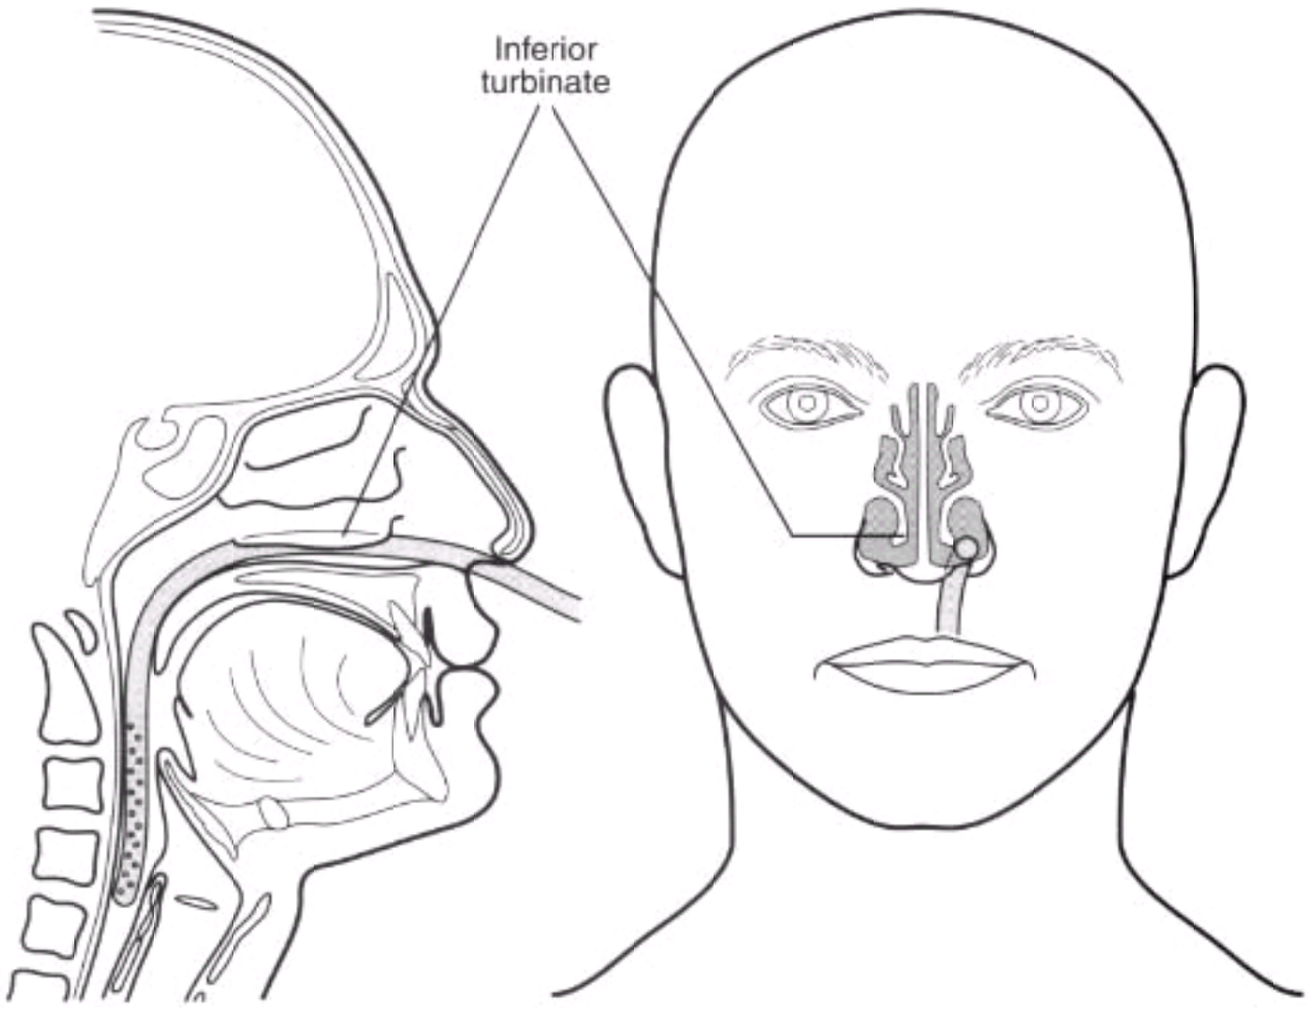

Figure 41-8 Attachment of tube to gown. *A,* Attach the nasogastric tube to the patient's gown using a rubber band and a safety pin as shown, so that the first tug on the tube pulls the gown and not the tape holding the tube in the patient's nose. *B,* Close-up view of attachment site.

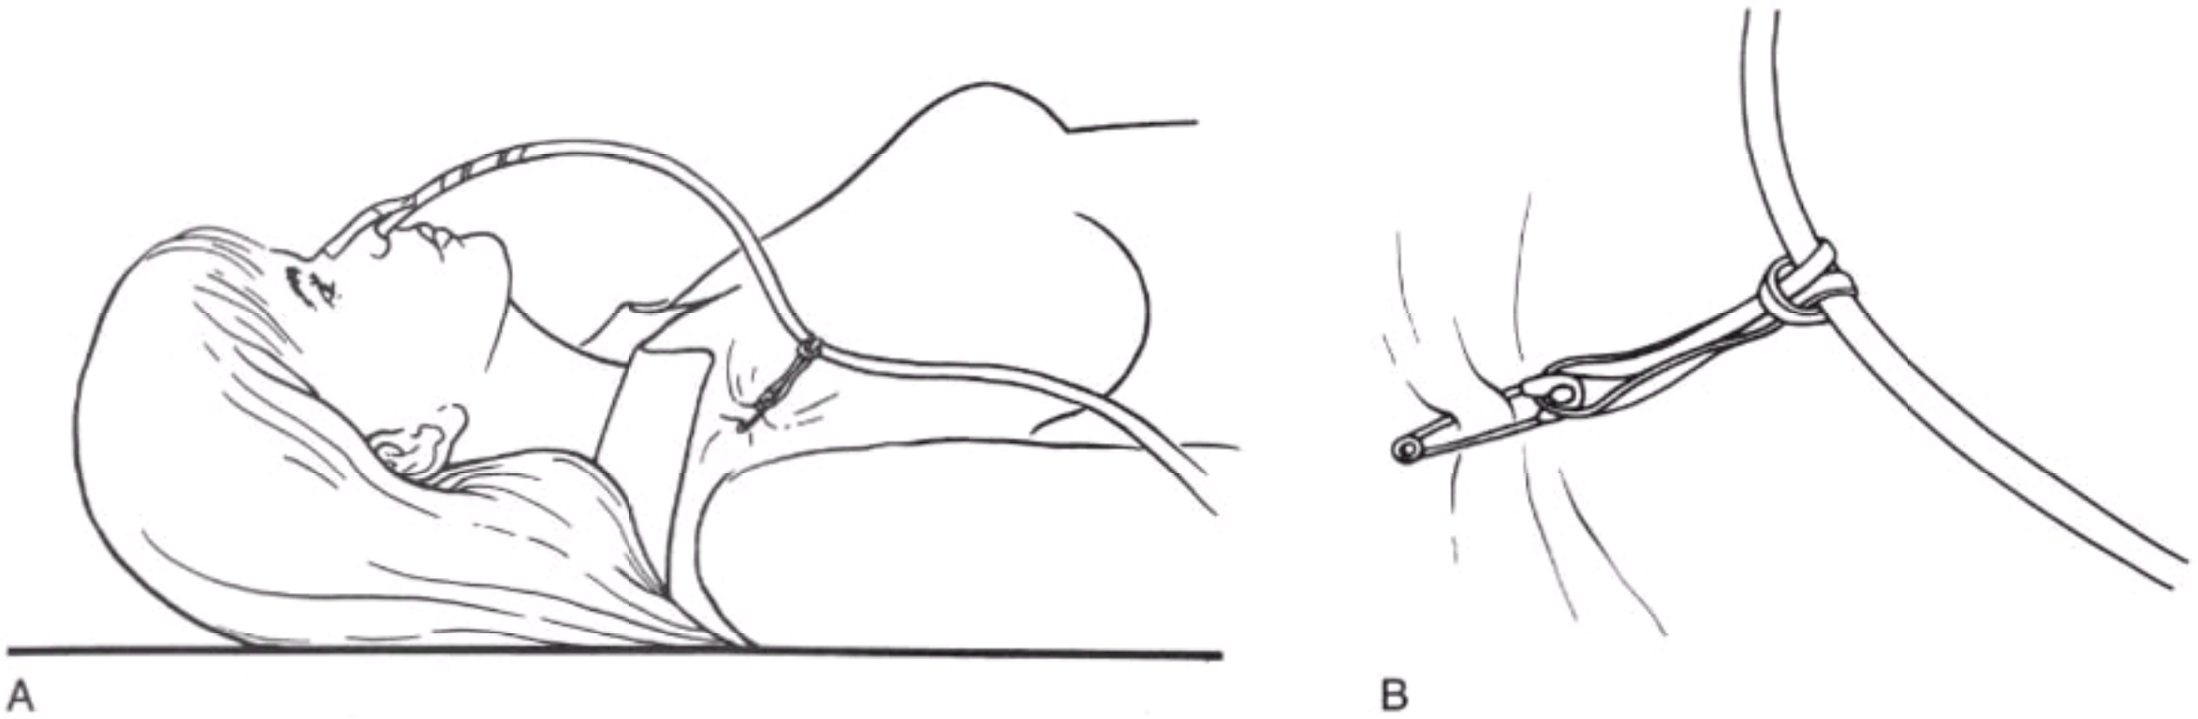

Figure 41-9 Diagrammatic representation of the separation of the nasogastric tube from the guiding endotracheal (ET) tube through the slit in the guiding ET tube. The nasogastric tube has first been passed through the nose and is pulled out through the mouth. The tip of the tube is then threaded into the guiding ET tube to ensure passage down the esophagus. The guiding ET tube is removed from the esophagus before separation from the nasogastric tube. Note the prior placement of another endotracheal tube in the trachea (partially shown) to avert passage of the guiding ET tube into the trachea. *(From Sprague DH, Carter SR: An alternate method for nasogastric tube insertion. Anesthesiology 53:436, 1980.)*

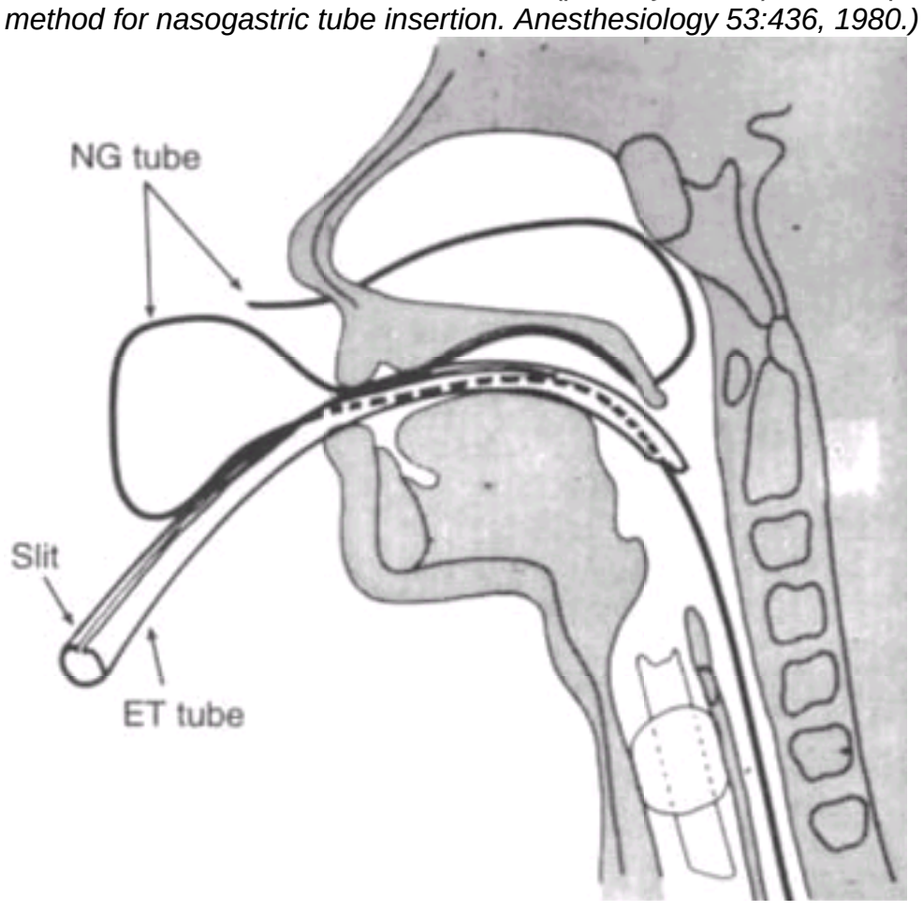

Figure 41-10 The passage of an nasogastric tube through the nose of an intubated patient. An endotracheal tube is in the tracheal via the mouth. The second and third fingers are placed into the posterior pharynx. Fingers depress the tongue. The nasogastric tube is guided down the esophagus by passing it through the second and third fingers that are in the posterior pharynx. The thumb is under the jaw and pulls the jaw forward.

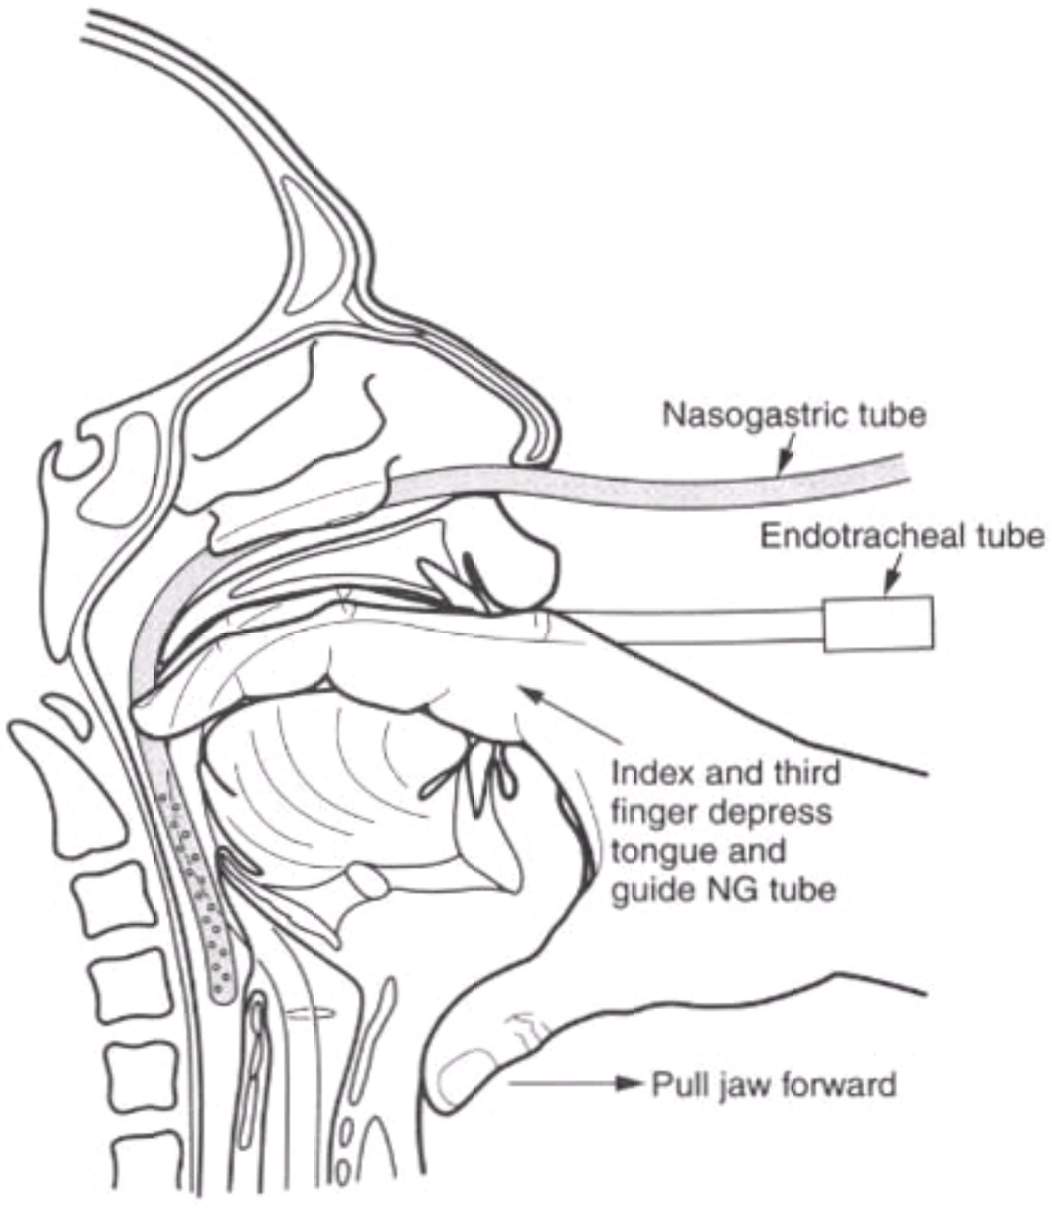

Figure 41-11 Levin tube inadvertently placed in the right main stem bronchus; an alveolar infiltrate consistent with early pneumonia is also shown. *(From Johnson JC: Letter to the editor: Back to basics for morbidity-free nasogastric intubation. JACEP 8:289, 1979.)*

Figure 41-12 Anteroposterior and lateral skull radiographs demonstrating intracranial insertion of a nasogastric tube in a patient with multiple skull fractures. *(From Johnson JC: Letter to the editor: Back to basics for morbidity-free nasogastric intubation. JACEP 8:289, 1979.)*

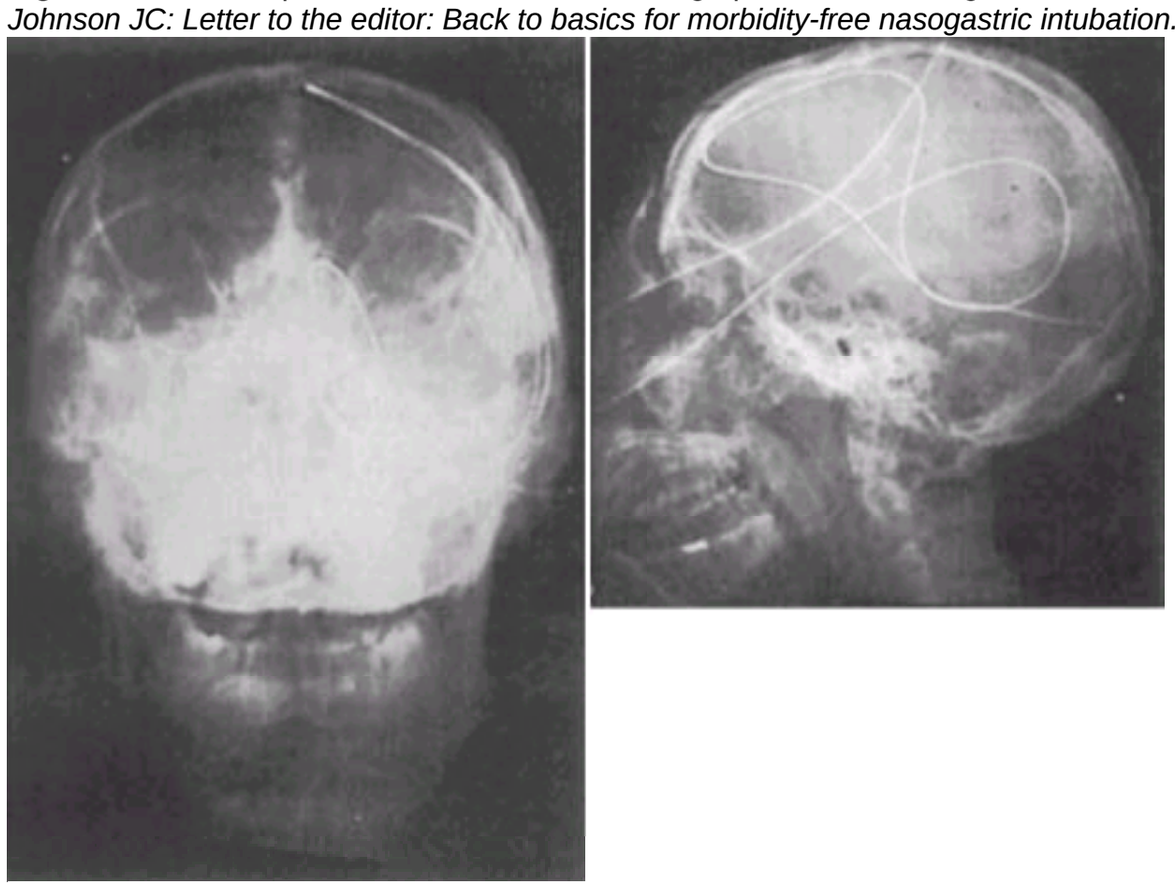

Figure 41-13 To facilitate the passage of a soft or very pliable plastic feeding tube, the tip of the feeding tube is joined to the tip of a stiffer nasogastric tube (such as a Salem sump) with the aid of a gelatin capsule. The capsule dissolves in the stomach in a few minutes, and the companion nasogastric tube separates and is withdrawn, leaving the feeding tube in place.

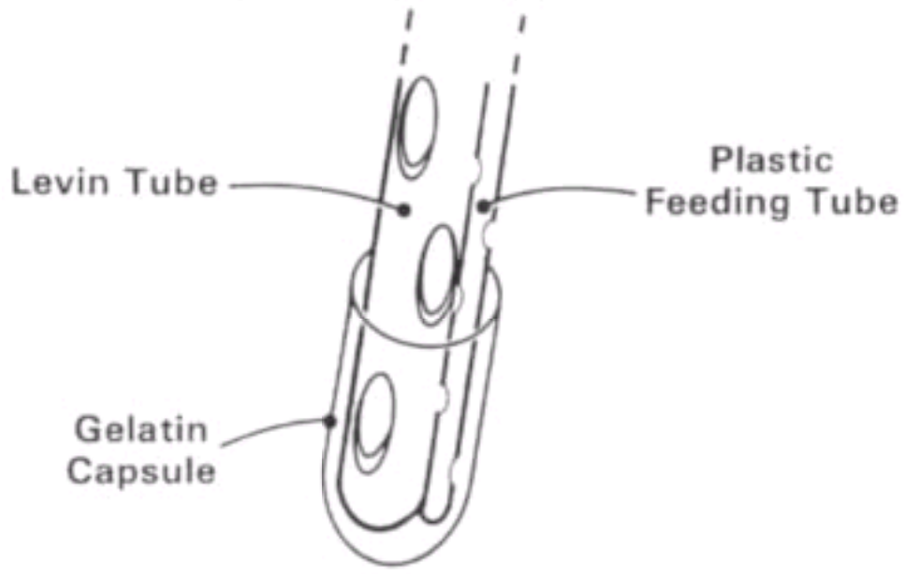

Figure 41-14 Placement of a nasogastric tube anchor to secure a companion nasogastric or feeding tube in an uncooperative patient who repeatedly pulls out the feeding tube. *A*, Forceps grasp the tube in the pharynx and pull it out through the mouth. This will serve as an anchor tube. *B*, The ends of the short anchor tube are tied together to form a loop, and the companion nasogastric or feeding tube is tied to the anchor loop.

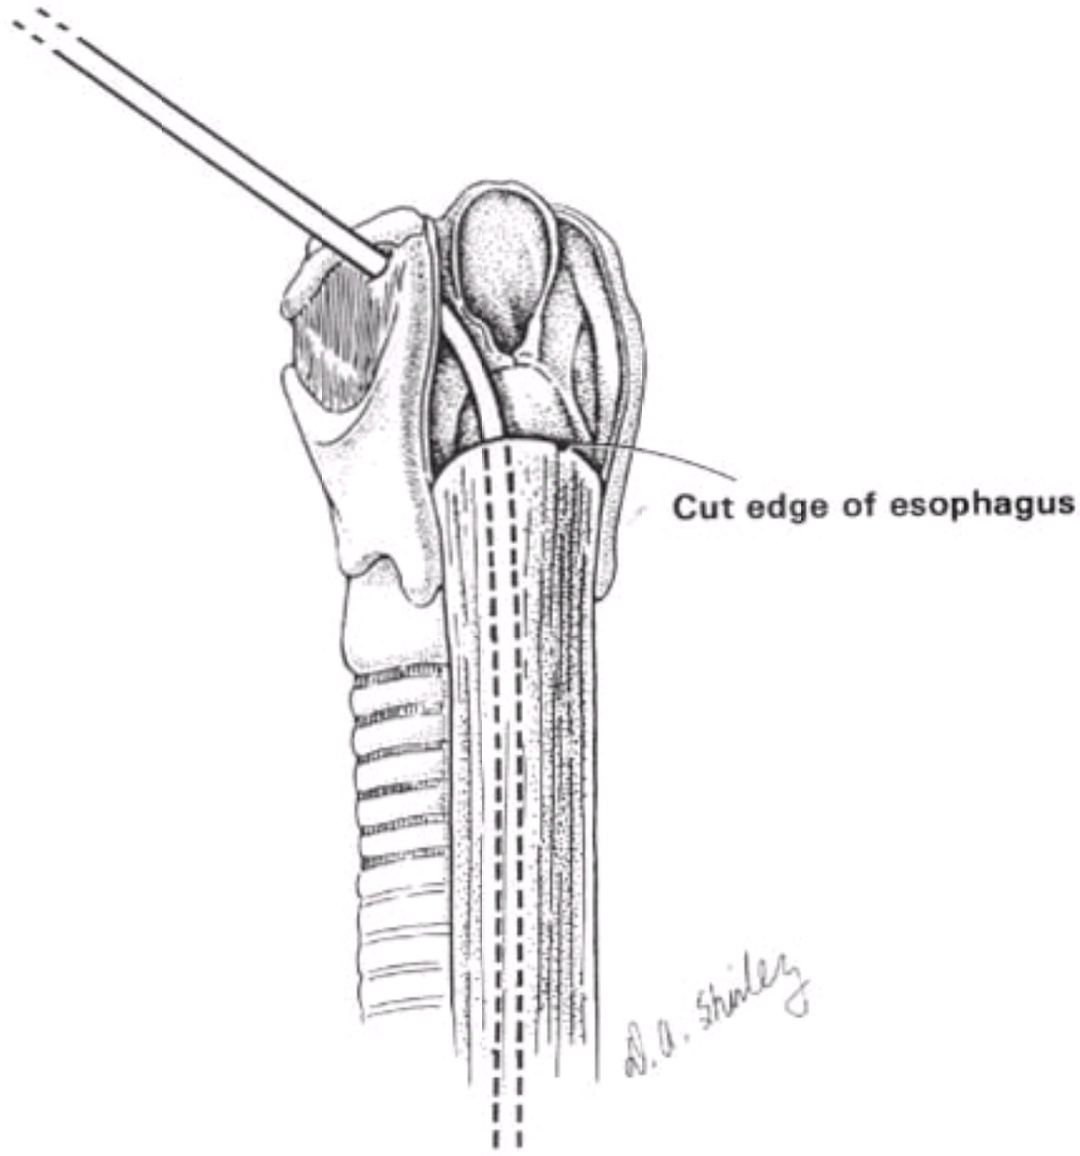

Figure 41-17 *A,* Formation of the Witzel tunnel. *B,* Final catheter placement. *(From Wiedeman JE, Smith VC: Use of the Hickman catheter for jejunal feedings in children. Surg Gynecol Obstet 162:69, 1986.)*

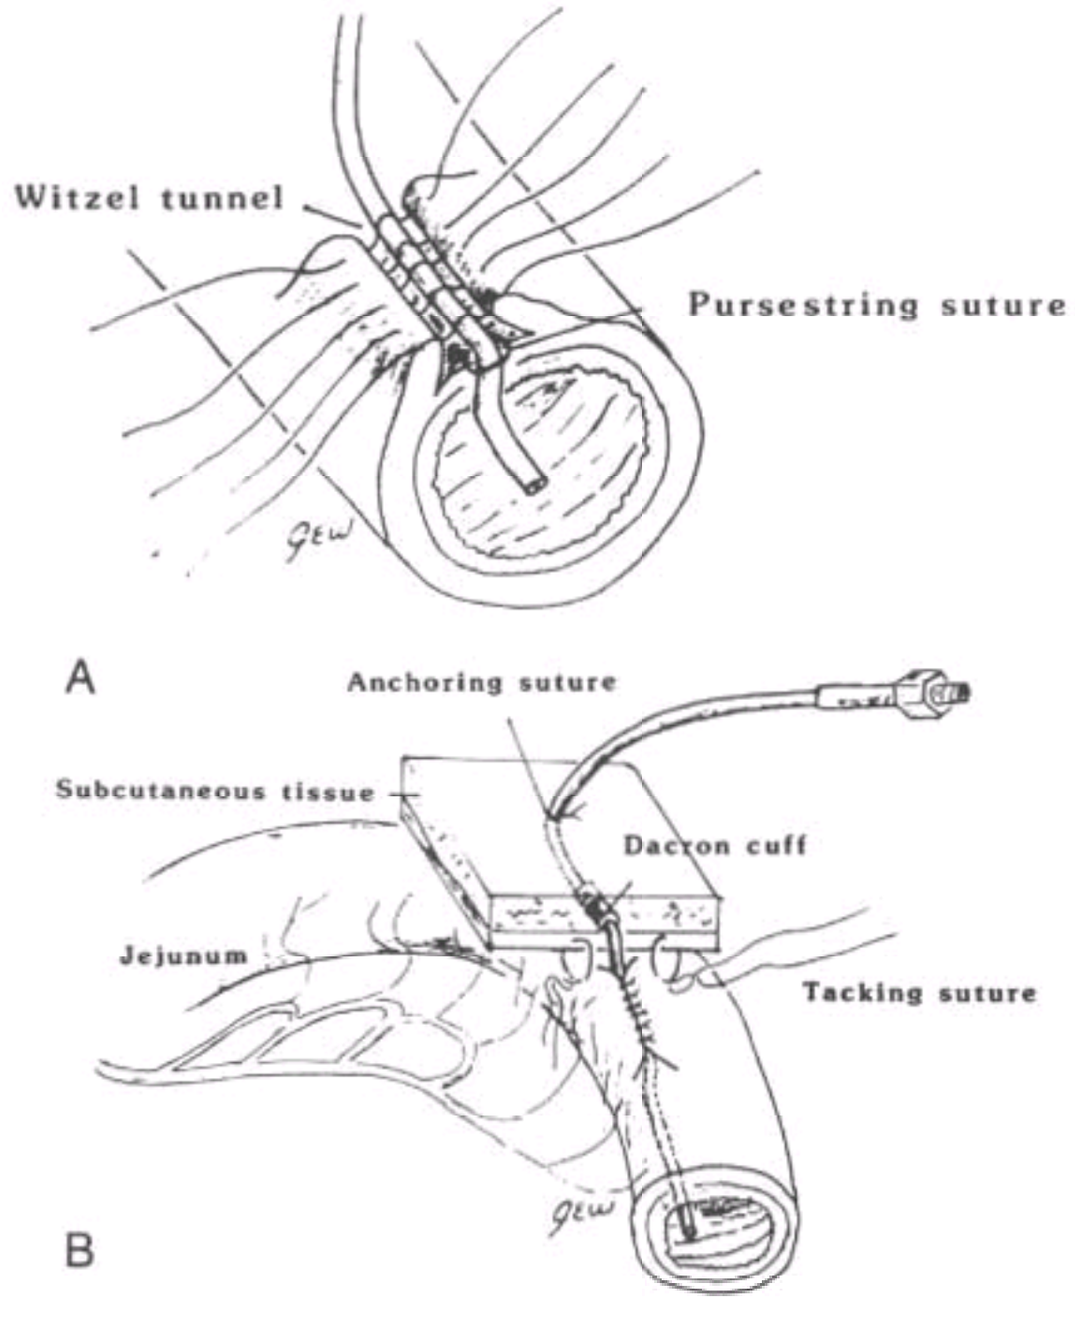

Figure 41-18 *A,* Various types of gastrostomy tubes. *1,* Polyurethane catheter with collapsible foam flange (CORPAK MedSystems of Kentec Medical Inc, Irvine, CA). *2,* Silicone catheter (American Endoscopy [Bard Interventional Products, Billerica, MA]). *3,* Latex catheter with a movable external bolster and an internal mushroom or de Pezzer-type flange on the end (American Endoscopy [Bard Interventional Products, Billerica, MA]). *4,* Balloon (Foley) catheter (Wilson-Cook Co., Winston-Salem, NC). *B,* A user-friendly gastrostomy tube is supplied by CORPAK MedSystems (Wheeling, IL). The tube is packaged with lubricant, a prefilled syringe for inflating the balloon, and an extension set. The color-coded inflation valve indicates tube size (12–24 Fr). The silicone tube uses a retention balloon and a movable bolster, similar in design to a Foley catheter. Note that the retention bolster is designed to prevent inward migration of the tube and is not to be an anchoring device sutured to the skin. *C,* Placement of the CORPACK feeding tube and inflation of the balloon. Note that the bolster on the external tube is advanced to the skin to secure the tube. *D,* A standard Foley catheter may serve as a more specialized feeding tube replacement. The latex balloon may deflate or be weakened by gastric acid; so, this catheter is not ideal for long-term use. In addition, unless the Foley catheter is secured to the skin, it may migrate and the balloon may cause a pseudo obstruction.

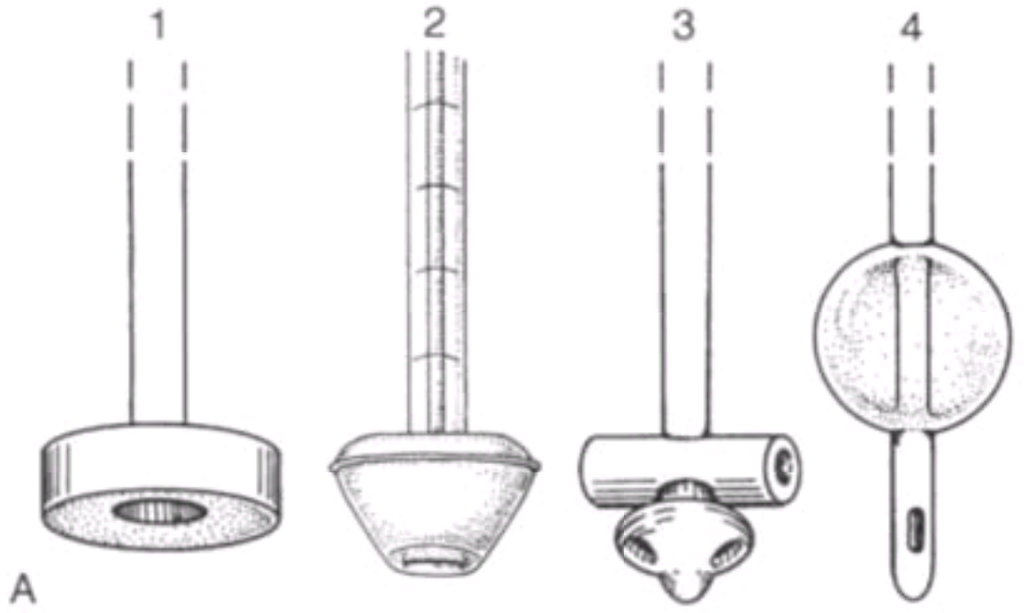

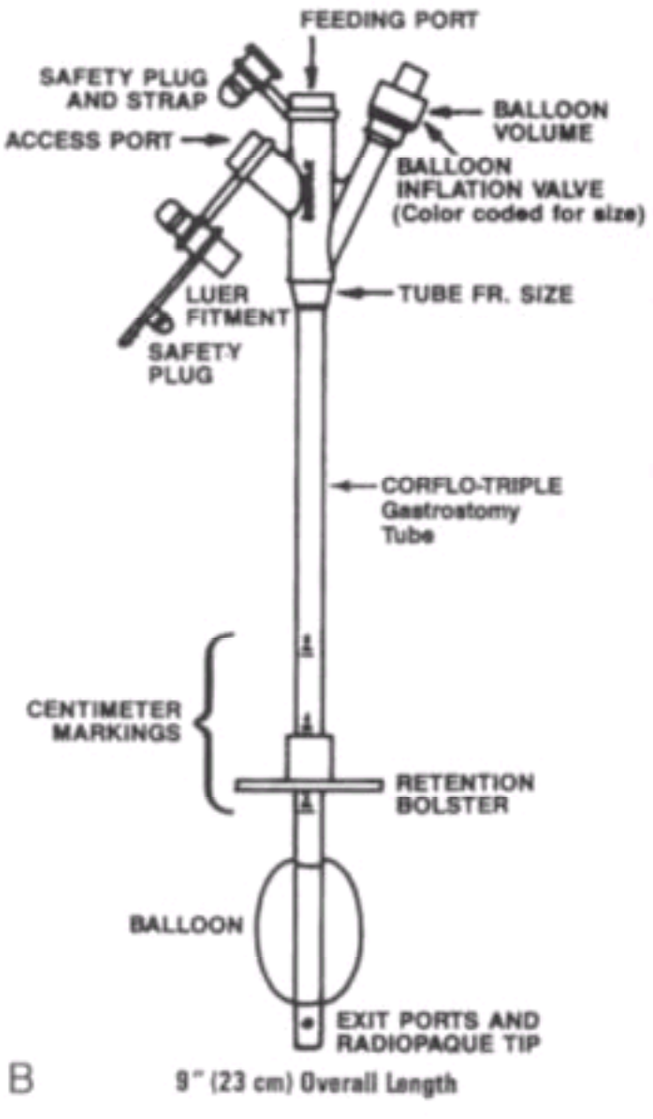

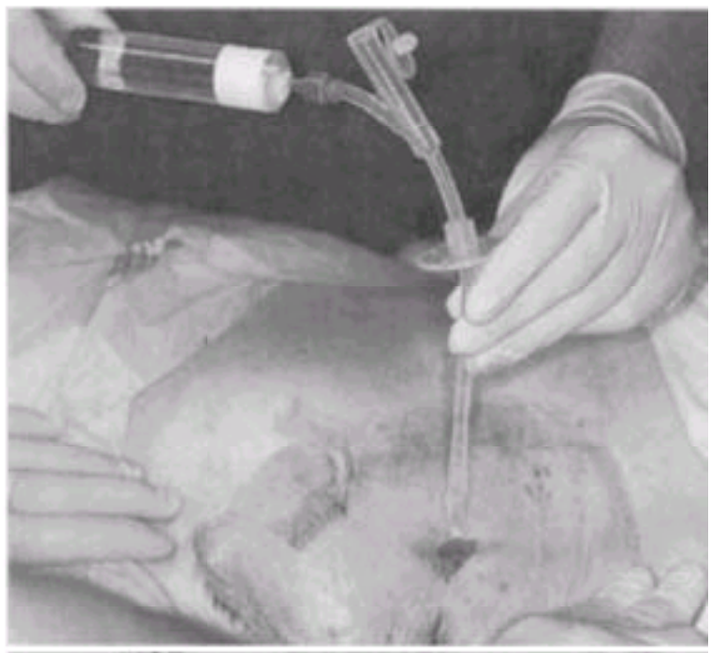

Figure 41-19 *A,* An endotracheal tube stylet used to distend the flange of the de Pezzer catheter. *B,* A lubricated wooden cotton-tipped swab can also be used as a makeshift stylet.

Figure 41-20 A modified pediatric chest tube inserter used to distend the flange of the de Pezzer catheter. The sharpened end of the inserter (trocar) has been rounded.

Figure 41-21 Gentle, firm traction *(A),* using the flat part of the opposite hand for countertraction, may remove most percutaneous endoscopic gastrostomy tubes, even those with internal mushroom bumpers *(B)*.

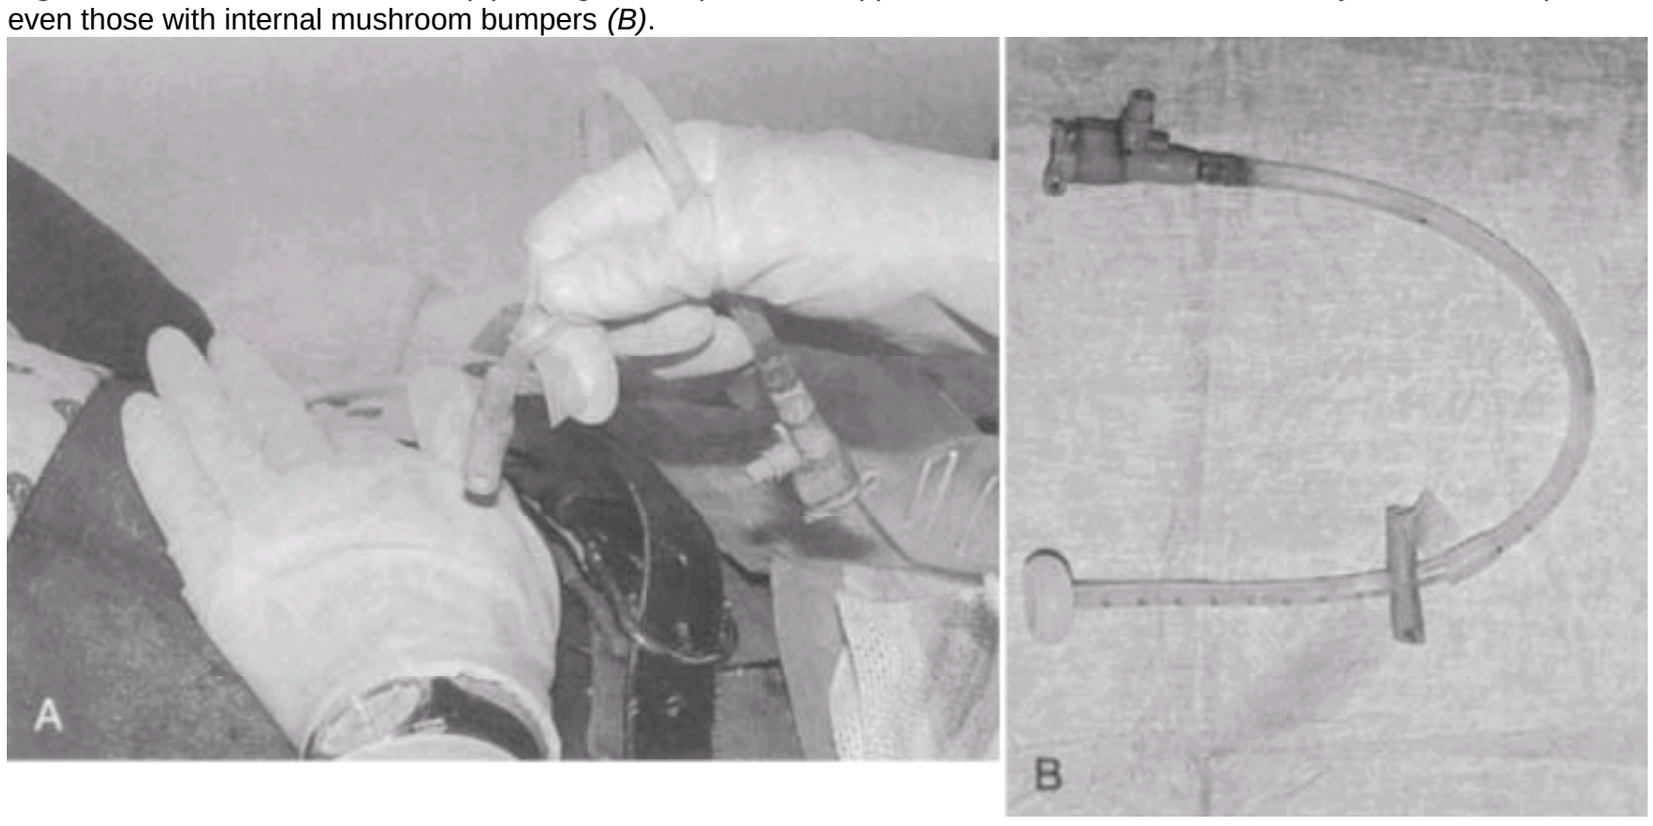

Figure 41-22 The tract of a feeding tube may close or become narrowed within a few hours after removal. When replacing a tube that has been removed, gentle probing of the tract of the previously placed feeding tube gives the clinician an idea of the patency and direction of the tract. In this case, a sterile cotton swab is gently advanced, being careful not to produce a false tract.

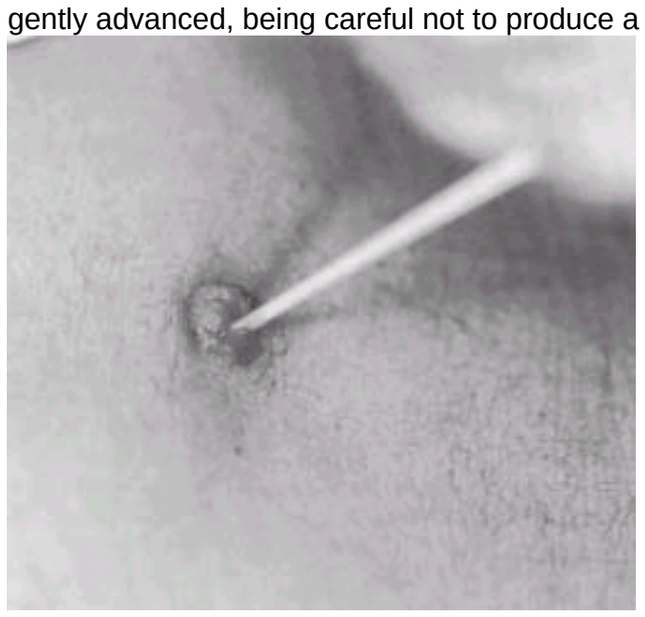

Figure 41-23 *A,* A 3-cm segment of thick latex tubing is cut from the proximal segment of a catheter. This segment is used to make an external bolster for a feeding tube and anchors the feeding tube, preventing unwanted ingress of the tube into the patient. *B,* A 3-cm segment of latex tubing is bent in half and cut to create a hole on each side of the segment.

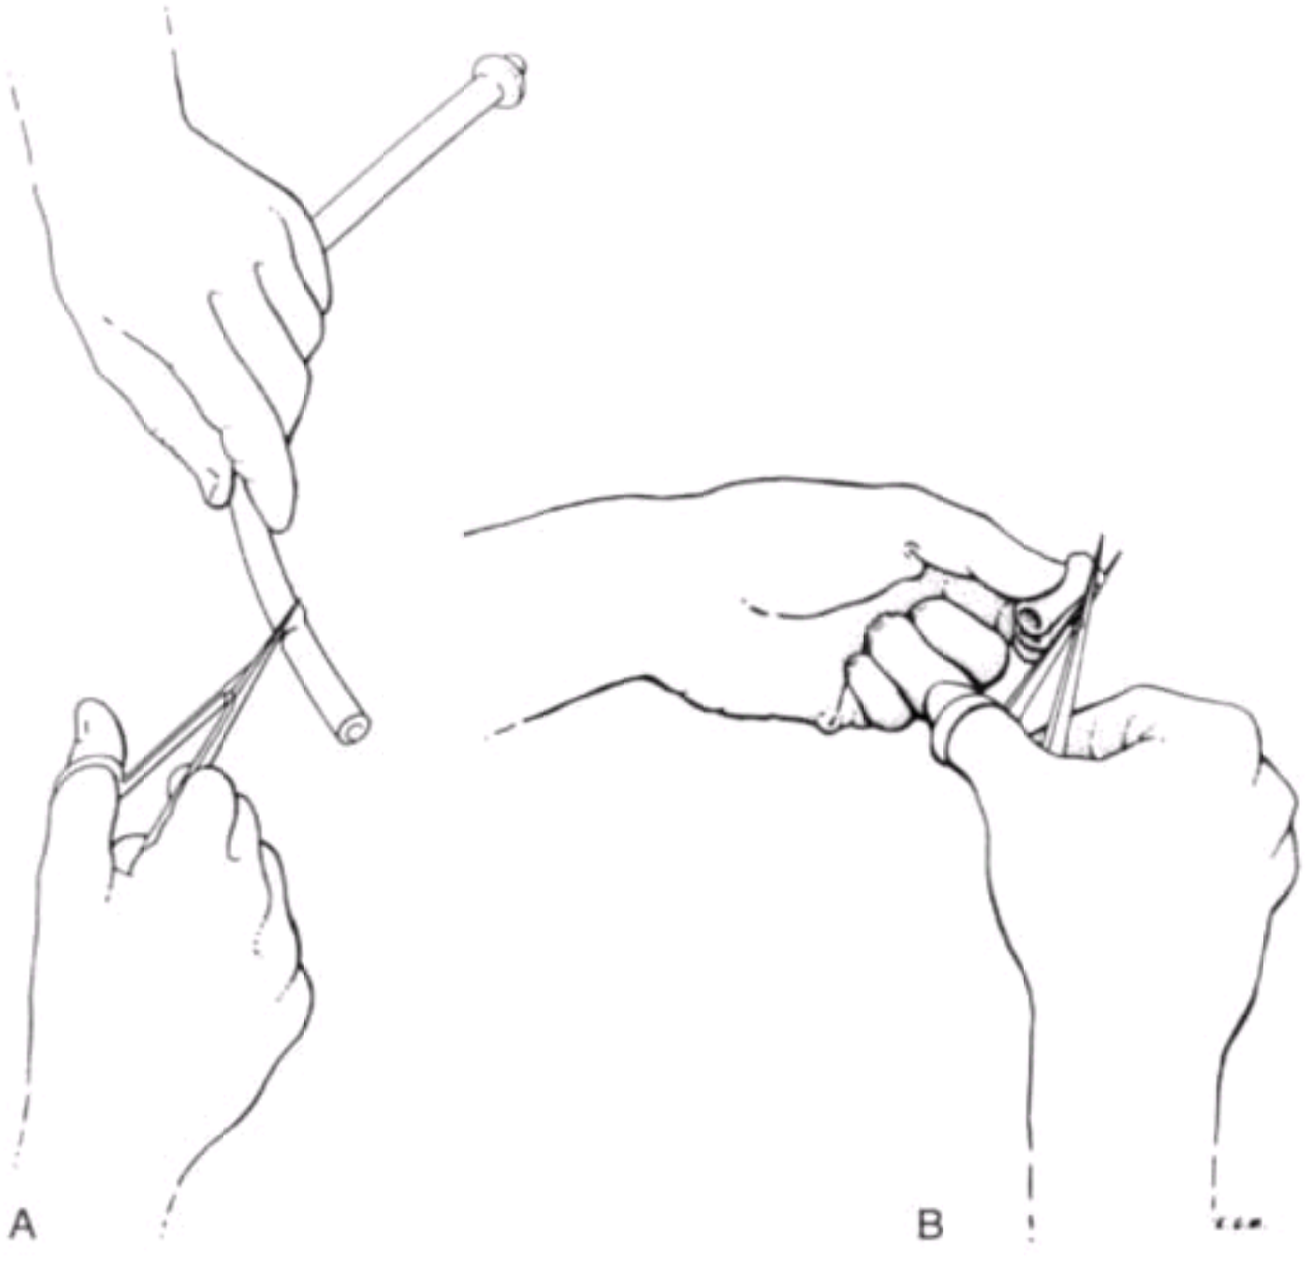

Figure 41-24 A hemostat is inserted through the holes in the completed bolster and grasps the feeding tube. The end of the feeding tube has been folded to reduce its external diameter.

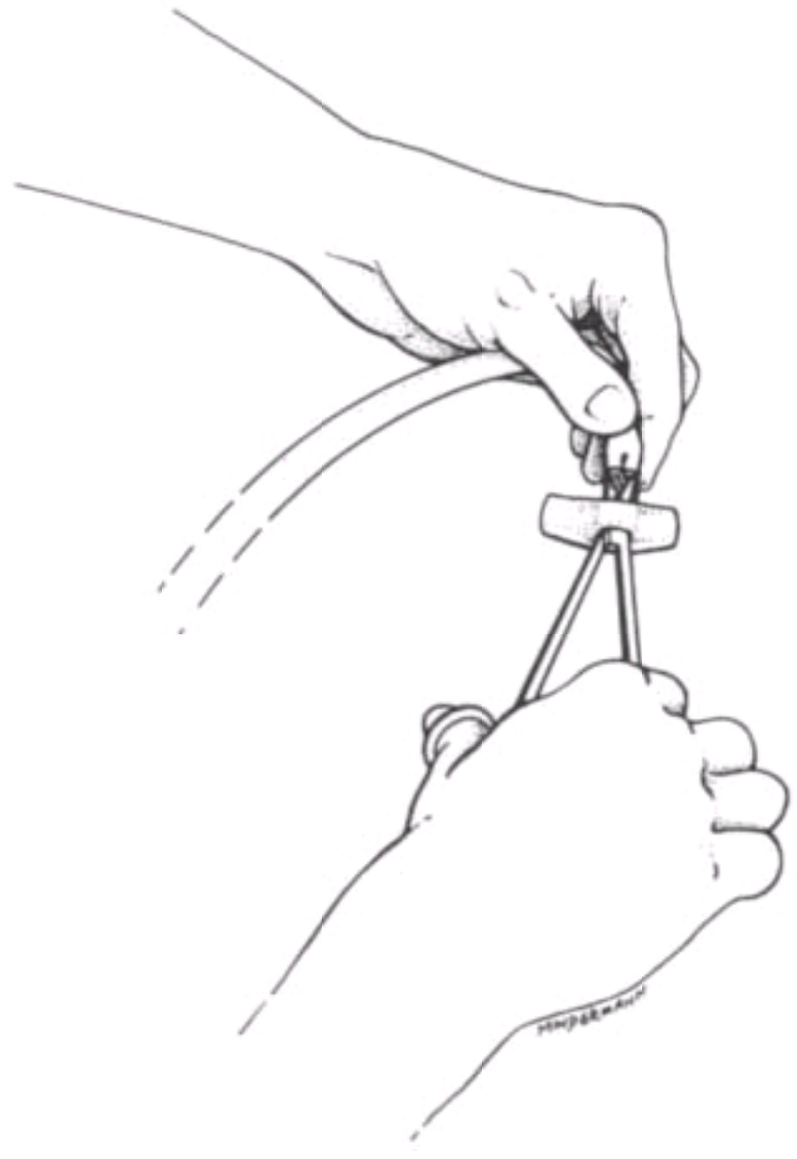

Figure 41-25 The feeding tube is pulled through the bolster. The bolster is advanced to 1 cm above the skin of the external abdomen.

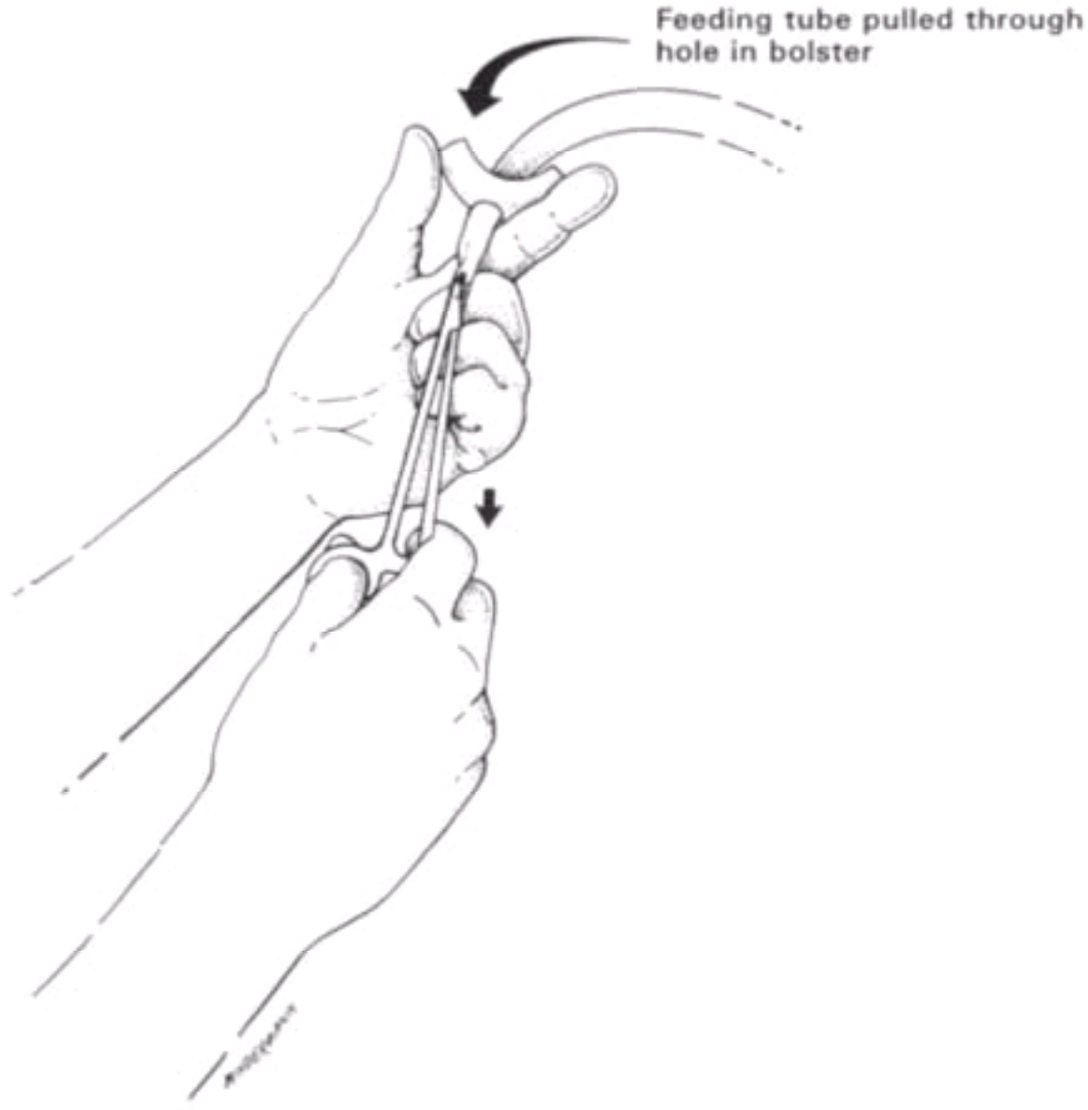

Figure 41-26 A Foley catheter can always be used as a temporary feeding tube replacement *(A)*. The thin-walled Foley balloon usually only remains inflated for a month or so, and a specialized feeding tube, such as the CORPAK (see Fig. 41-18) is preferred for long-term use. A bolster can be made to prevent inward migration of the tube. In this case the previously removed Foley catheter was used to make the bolster for the new one *(B)*.

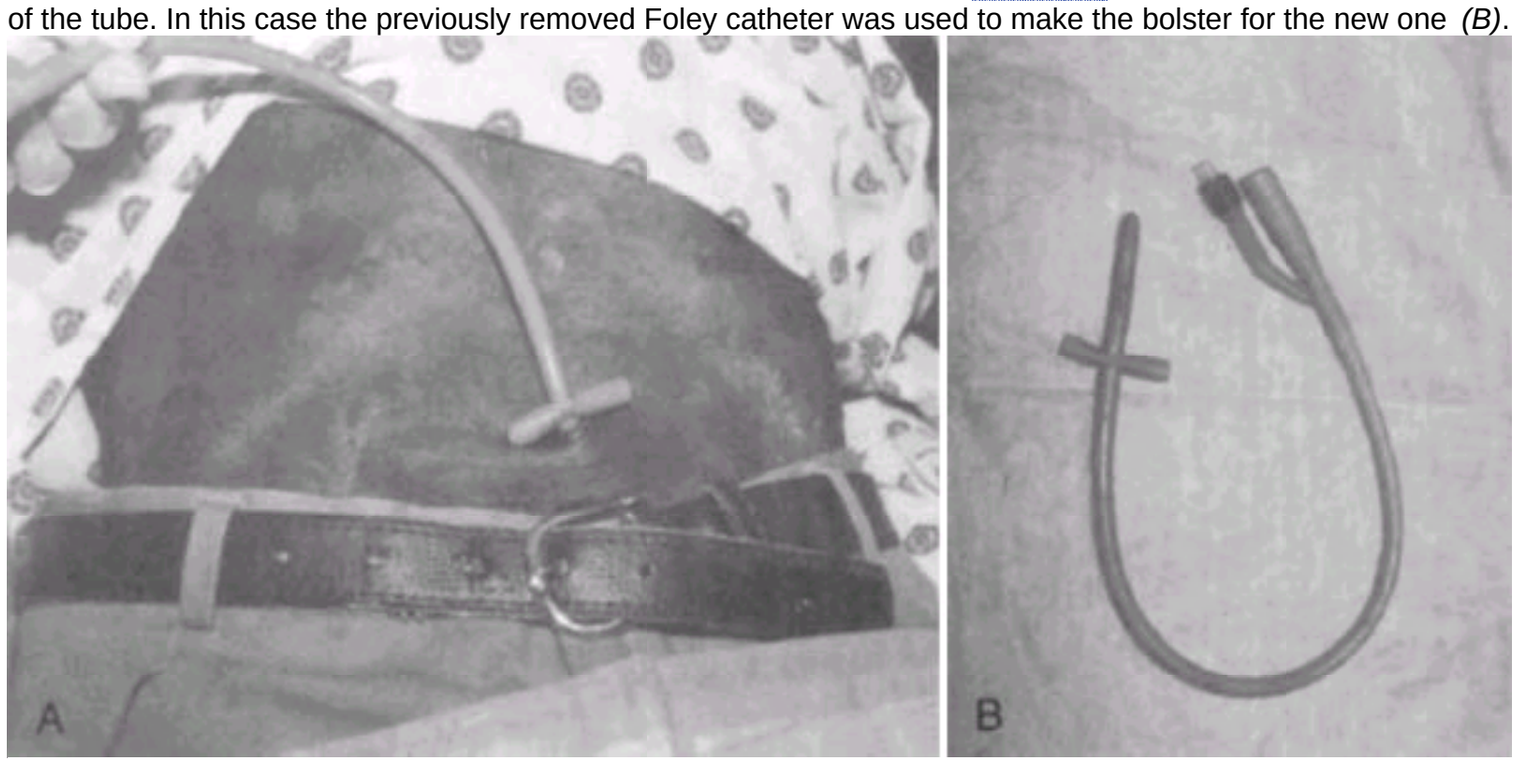

Figure 41-27 Contrast study demonstrating correct placement of a feeding tube. Note the outline of the gastric rugae and the characteristic mucosal folds of the small intestine.

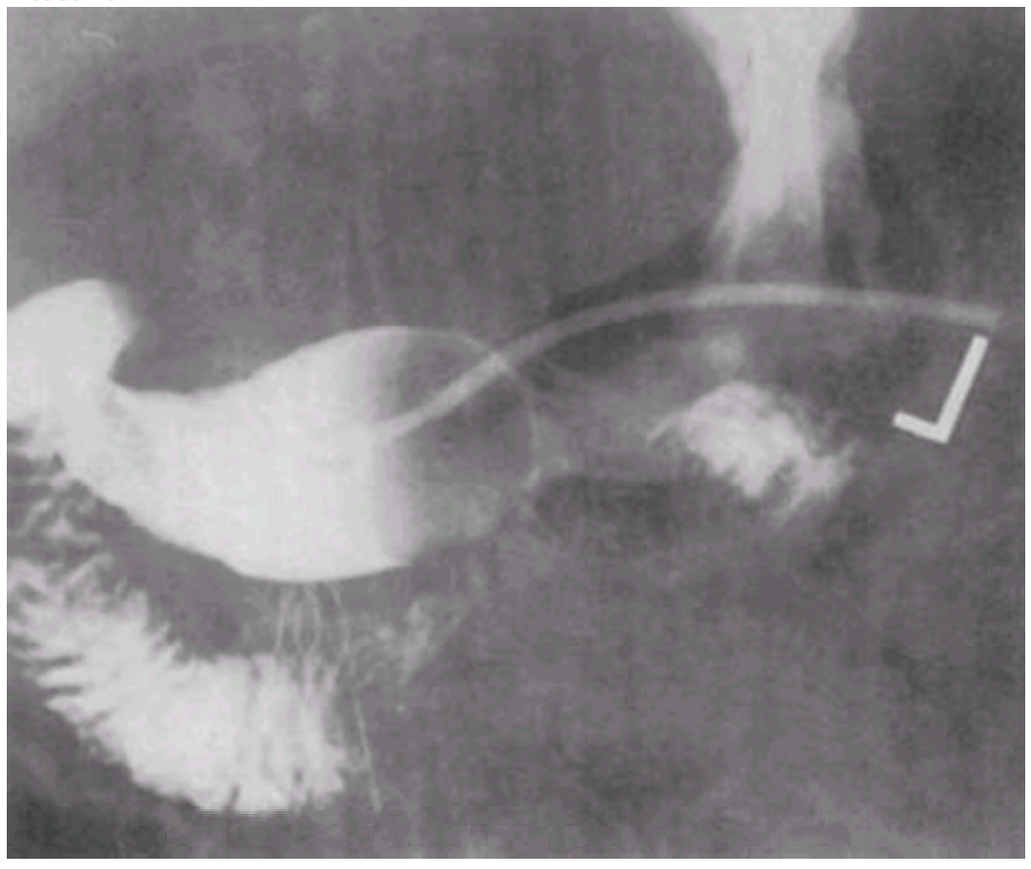

Figure 41-28 Although this feeding tube seemed to be easily replaced in an uncommunicative nursing home patient, gastric contents could not be aspirated; therefore, a contrast study was performed. Note the free flow of contrast material throughout the abdomen, especially outlining the liver *(arrows)*. This film indicates placement of the feeding tube into the peritoneum. Placing food through this tube could be disastrous.

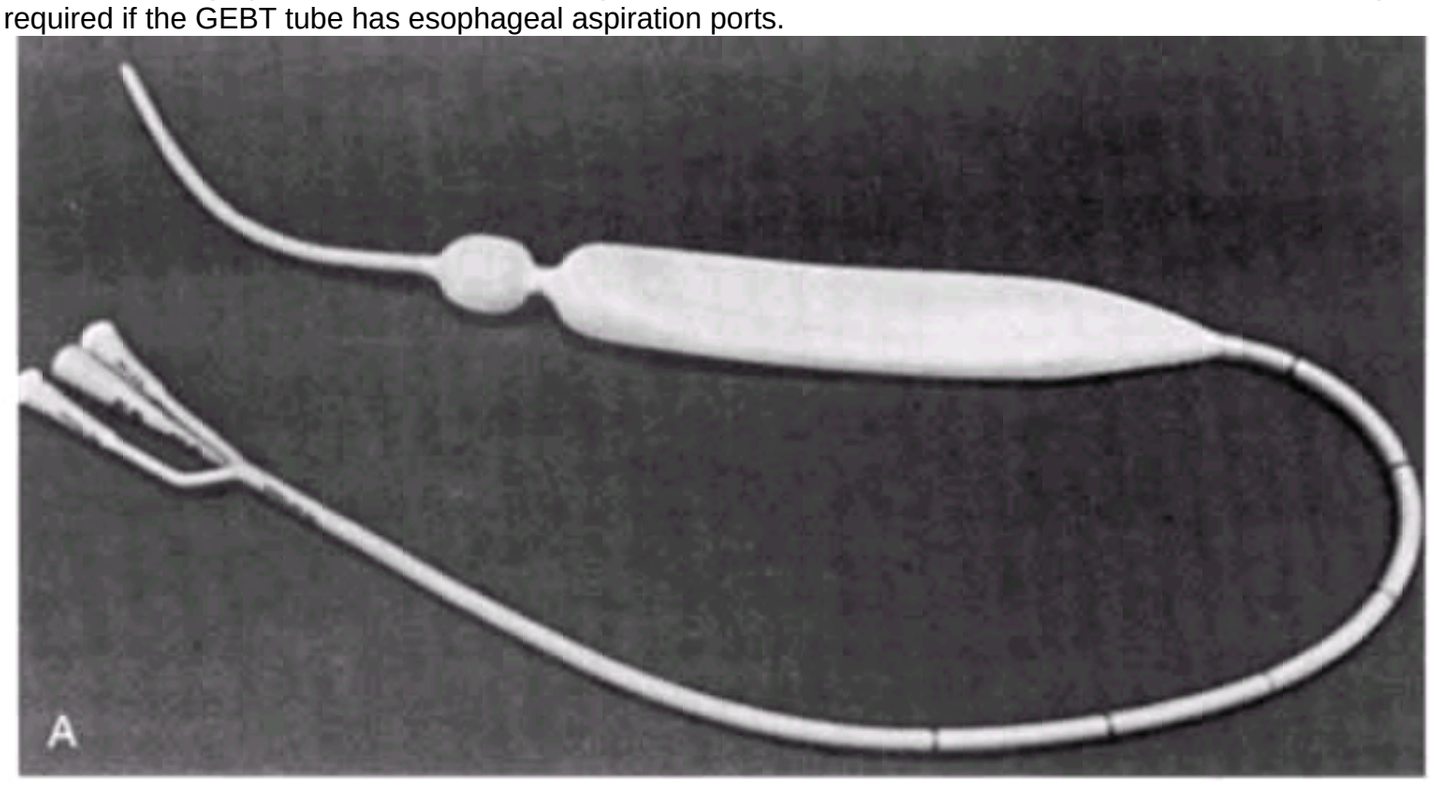
Figure 42-1 *A,* Photograph of the three-lumen Sengstaken-Blakemore tube with the balloons deflated. *B,* Diagram of GEBT tube with nasogastric tube attached. This is not required if the GEBT tube has esophageal aspiration ports.



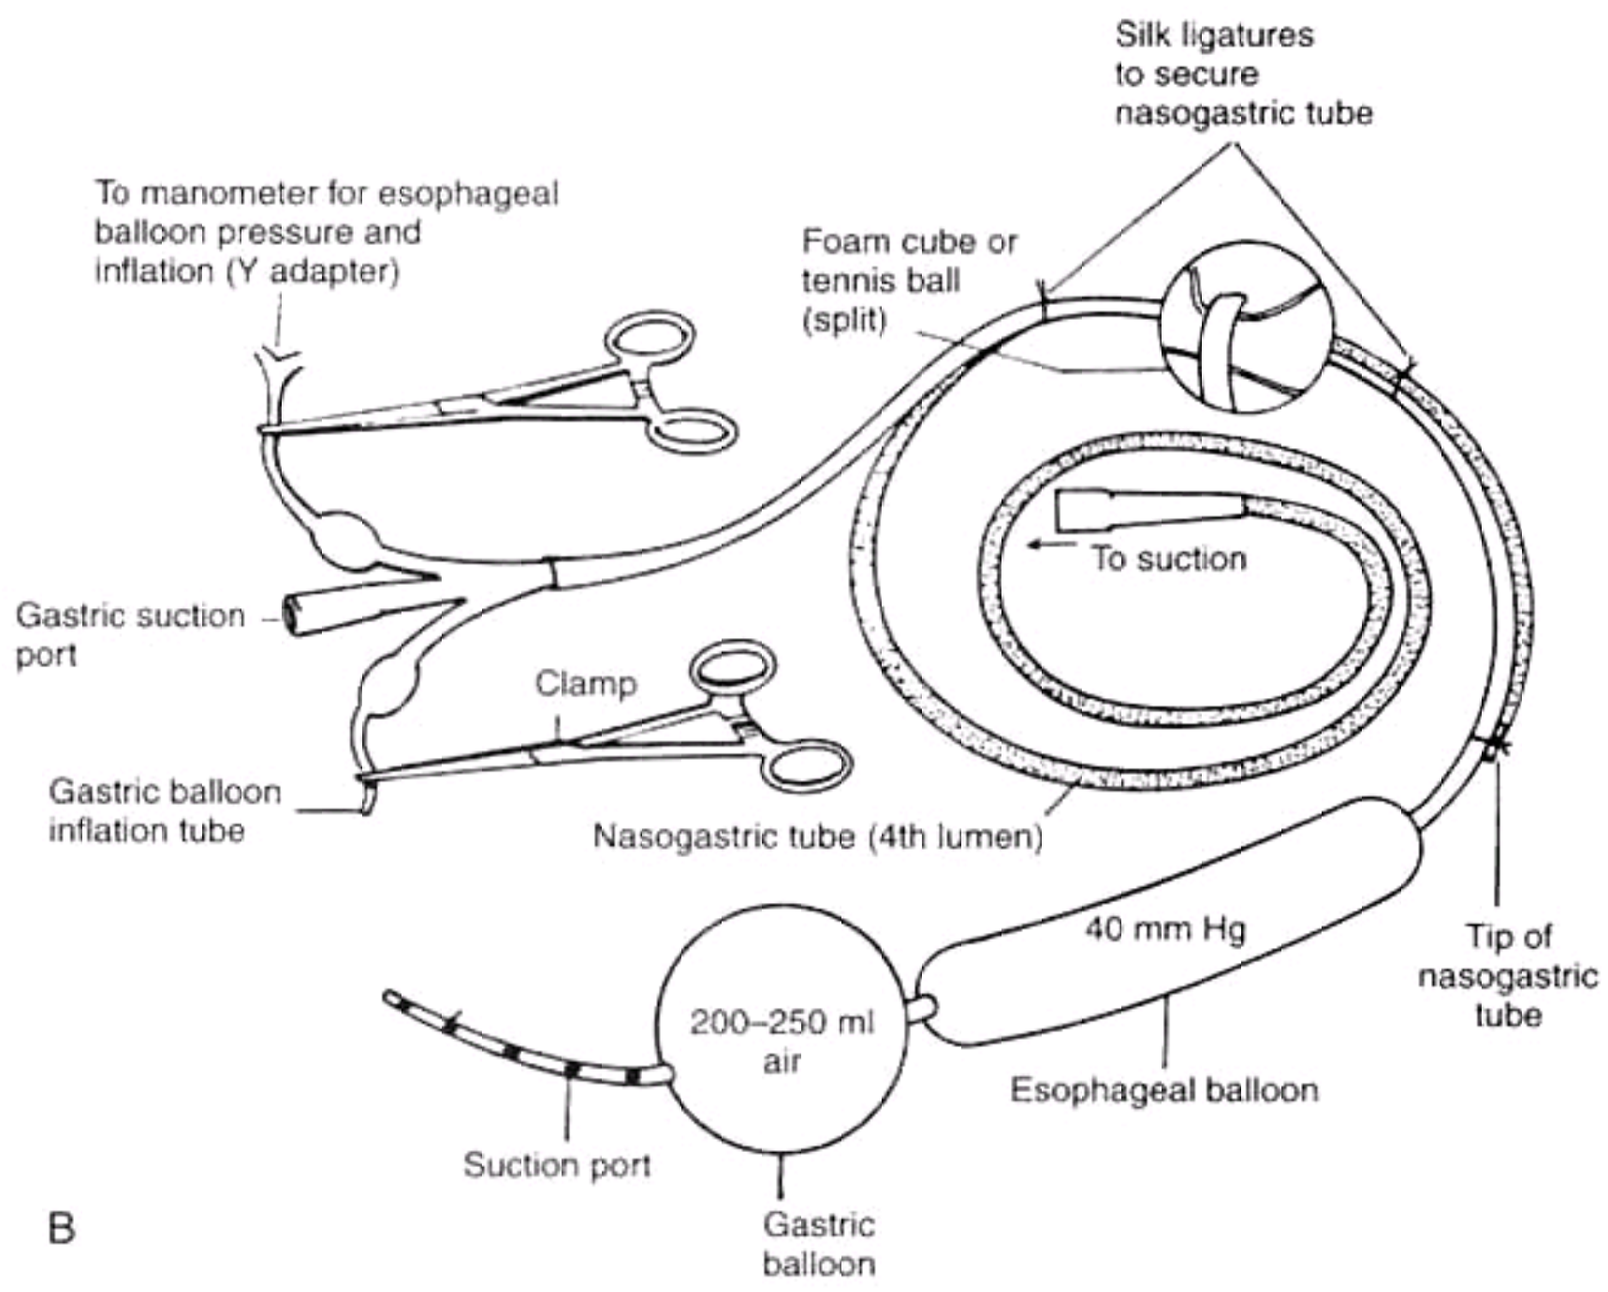


Figure 42-2 Diagrammatic representation of the four-lumen Minnesota tube with the balloons properly positioned and inflated. Note manometer attached to esophageal balloon port to measure pressures foam rubber cuff at nose as a fixation device, and the esophageal aspiration lumen.

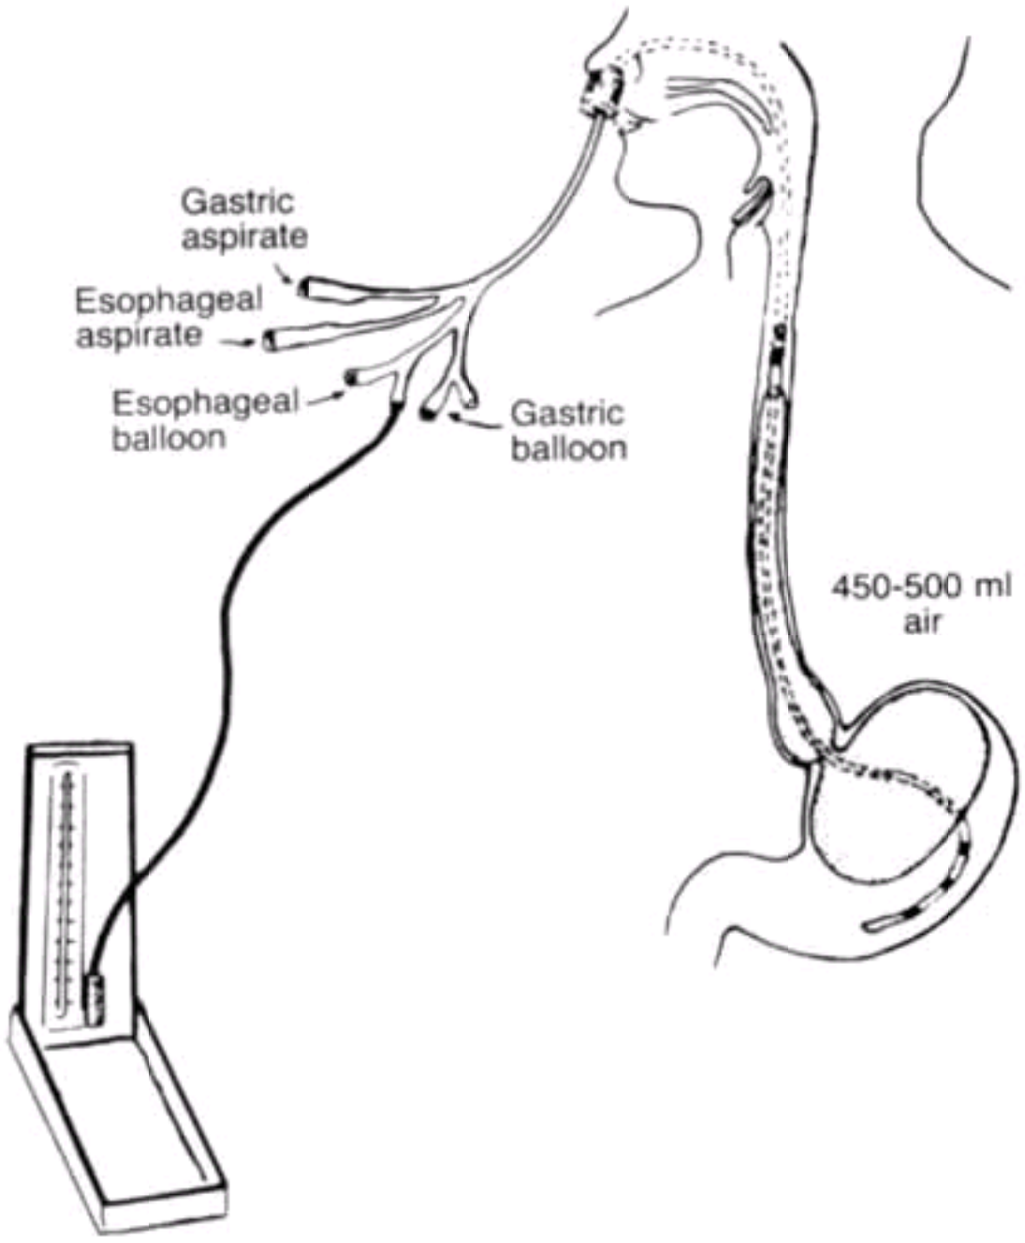

Figure 42-3 Algorithm for management of acute variceal hemorrhage, showing the role for balloon tamponade. After endoscopy banding and/or lauage have been used. Note that balloon tamponade can also be used after failed sclerotherapy as a temporizing measure pending emergency surgery, or between repeat attempts at sclerotherapy.

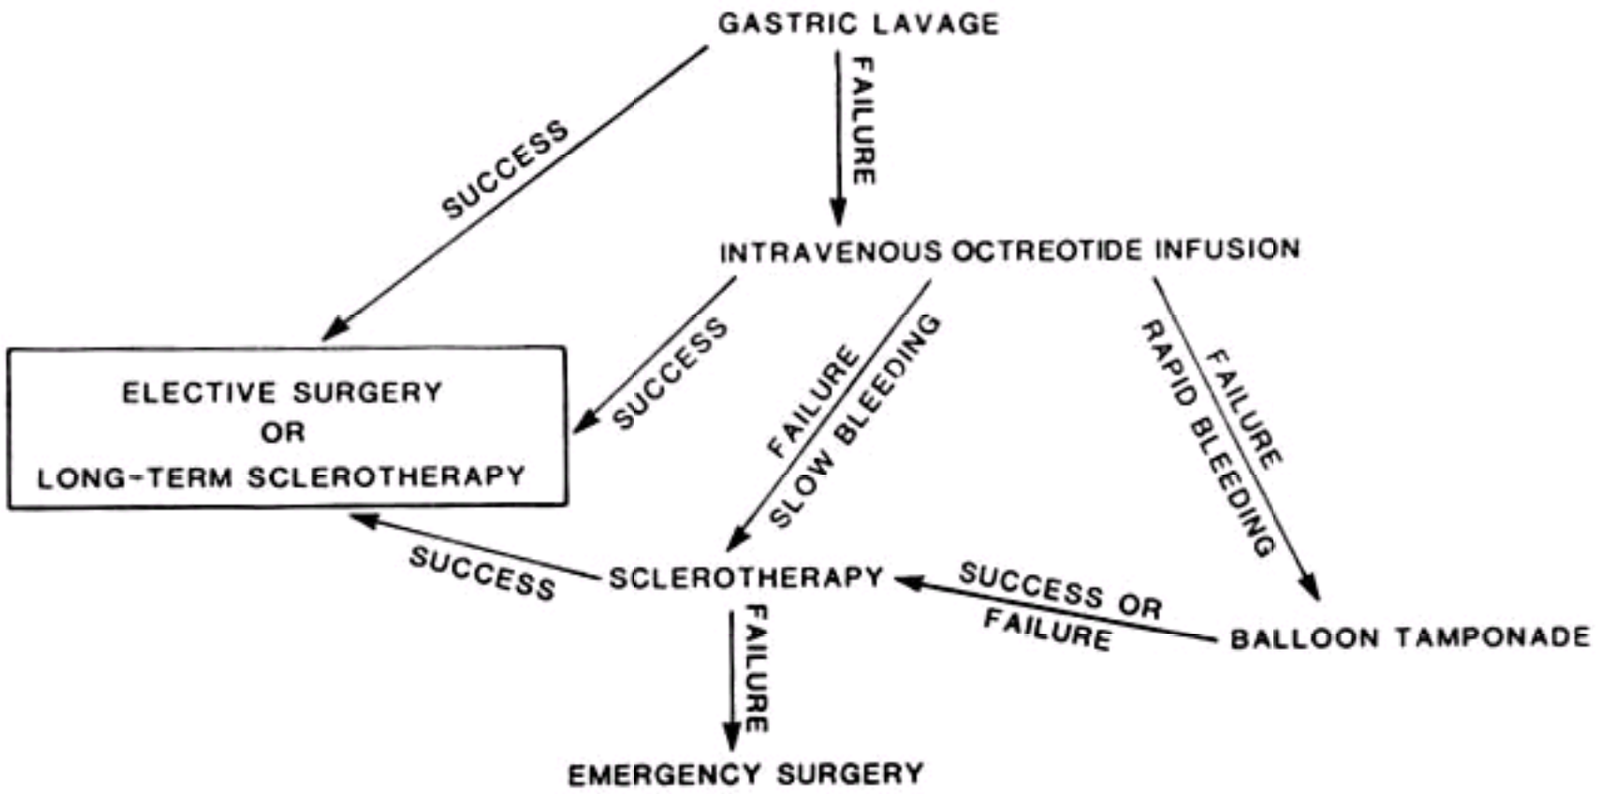

Figure 42-4 Esophageal balloon pressure measurement in the Sengstaken-Blakemore tube using a manometer. To inflate the esophageal balloon, the operator inserts one end of a Y connector to the esophageal balloon port, one end to a manometer, and one end to a bulb. At this point, no clamps are closed. The bulb is compressed until the manometer reads the desired pressure, and then the esophageal balloon port is clamped. Periodic readings to check the esophageal balloon pressure are subsequently taken by clamping the bulb port and unclamping the esophageal balloon port. The pressure in the esophageal balloon may vary with respirations and spasms, but the baseline pressure should not exceed 45 mm Hg. Most bleeding is controlled with pressures well below the maximum safe pressure. Note that standard toothed clamps are to be avoided (see text).

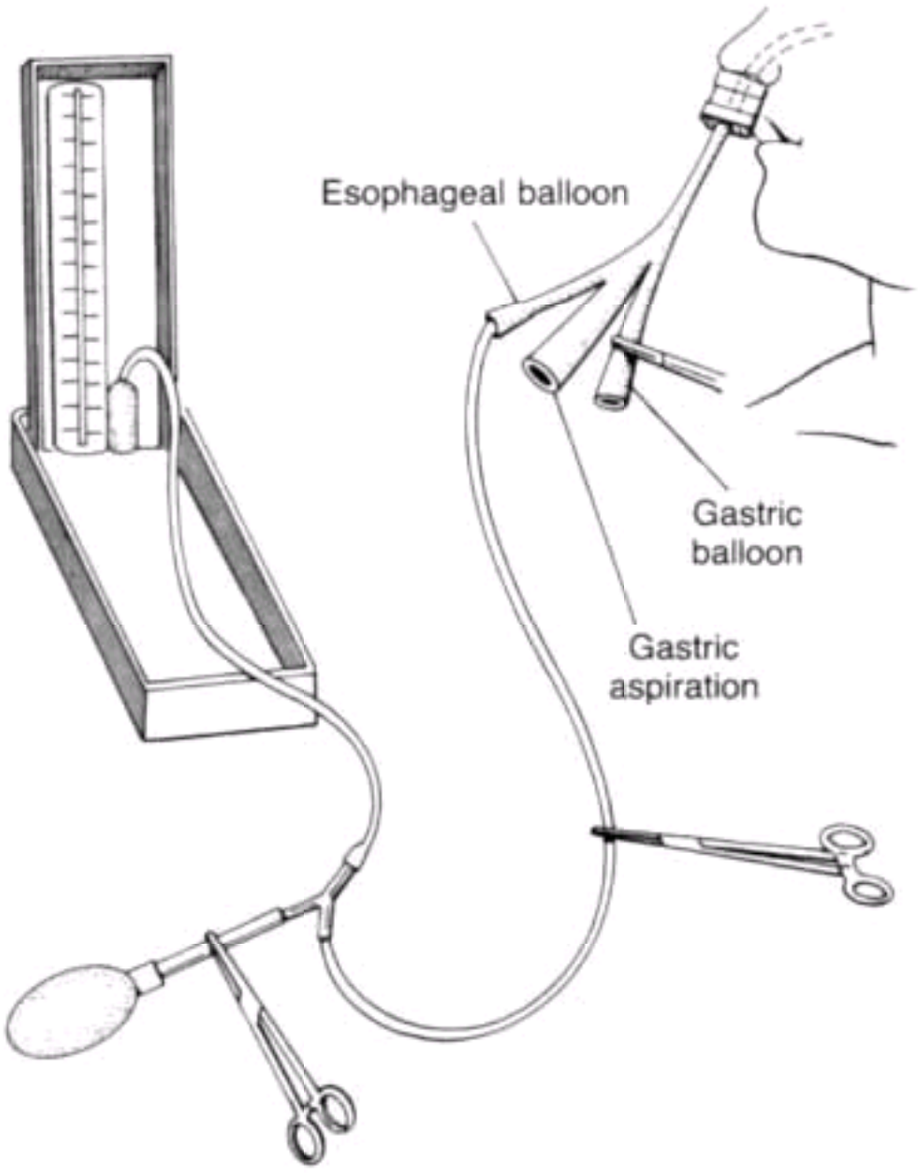

Figure 43-1 Position statement: ipecac syrup. *(From the American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists. Published in Clin Toxicol 35:699, 1997.)*

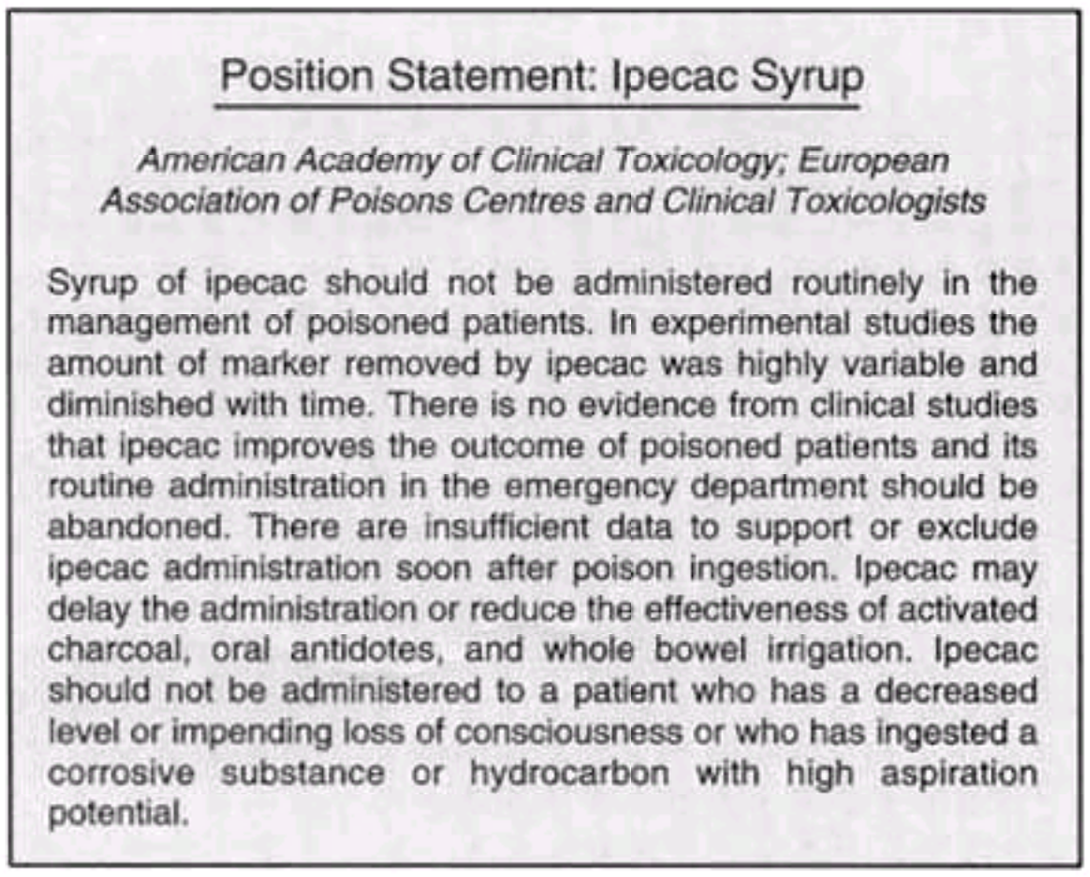
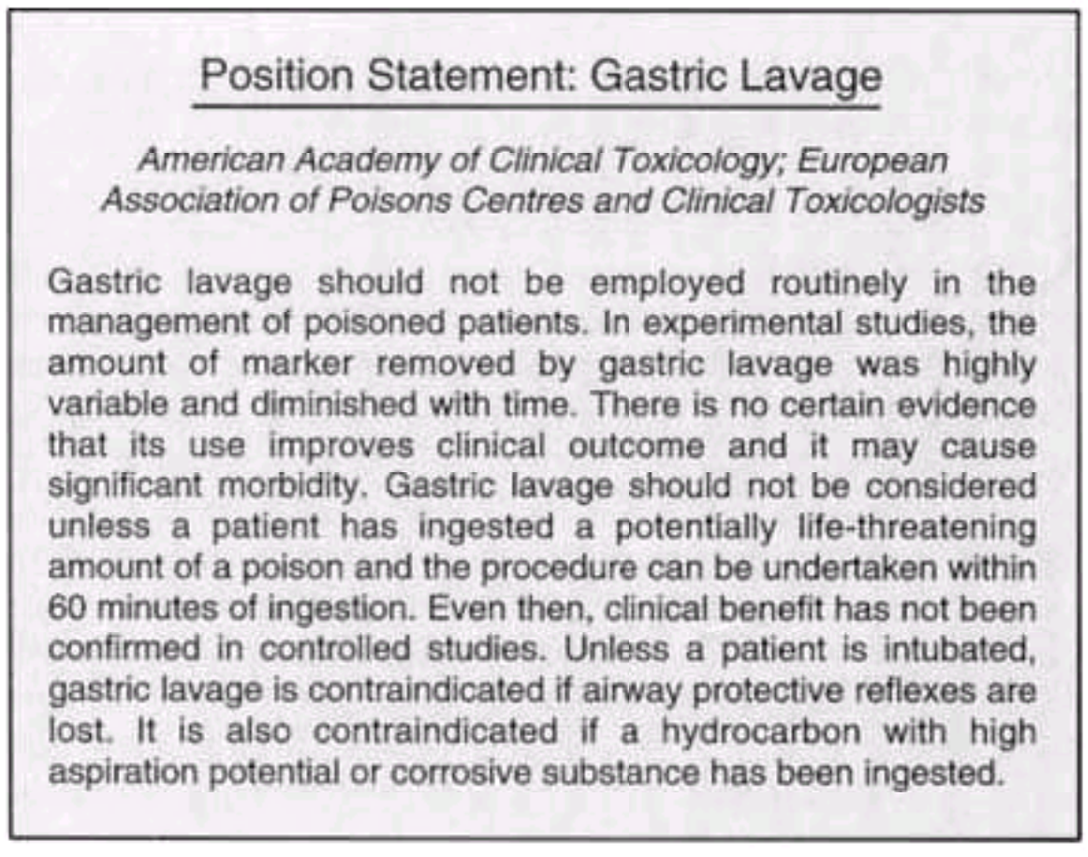


Position Statement: Ipecac Syrup

American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists

Syrup of ipecac should not be administered routinely in the management of poisoned patients. In experimental studies the amount of marker removed by ipecac was highly variable and diminished with time. There is no evidence from clinical studies that ipecac improves the outcome of poisoned patients and its routine administration in the emergency department should be abandoned. There are insufficient data to support or exclude ipecac administration soon after poison ingestion. Ipecac may delay the administration or reduce the effectiveness of activated charcoal, oral antidotes, and whole bowel irrigation. Ipecac should not be administered to a patient who has a decreased level or impending loss of consciousness or who has ingested a corrosive substance or hydrocarbon with high aspiration potential.

Figure 43-2 Position statement: gastric lavage. *(From the American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists. Published in Clin Toxicol 35:711, 1997.)*



Position Statement: Gastric Lavage

American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists

Gastric lavage should not be employed routinely in the management of poisoned patients. In experimental studies, the amount of marker removed by gastric lavage was highly variable and diminished with time. There is no certain evidence that its use improves clinical outcome and it may cause significant morbidity. Gastric lavage should not be considered unless a patient has ingested a potentially life-threatening amount of a poison and the procedure can be undertaken within 60 minutes of ingestion. Even then, clinical benefit has not been confirmed in controlled studies. Unless a patient is intubated, gastric lavage is contraindicated if airway protective reflexes are lost. It is also contraindicated if a hydrocarbon with high aspiration potential or corrosive substance has been ingested.

Figure 43-3 The effect of patient positioning on lavage. The left lateral decubitus position is preferred.

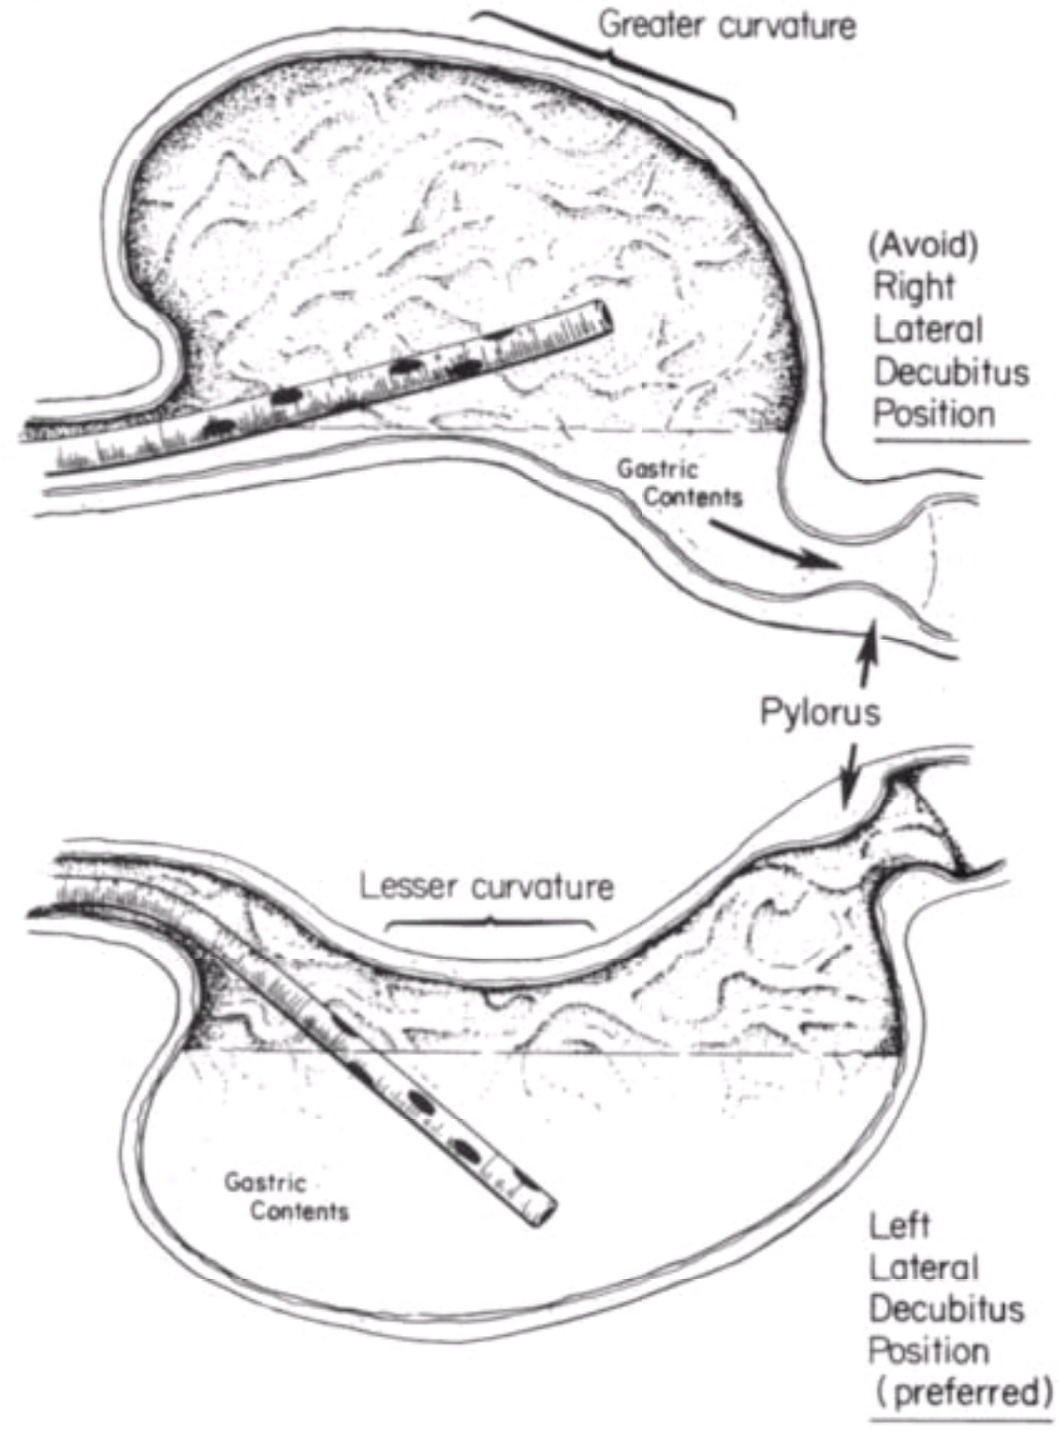


Figure 43-4 A large-diameter gastric tube. Note the extra side holes that have been cut near the tip. This is a theoretical advantage over a standard tube or a nasogastric tube. For small pill particles and liquids, a large-bore nasogastric tube may suffice.

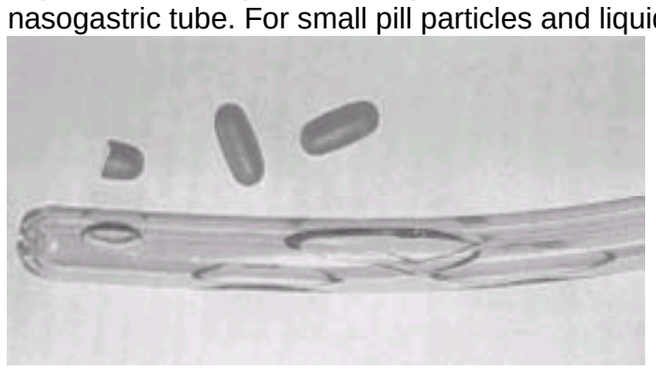

Figure 43-5 Gastric lavage in a child is always problematic. Obviously, an adult-sized large-bore oral gastric tube cannot be used, but a nasogastric (NG) tube may suffice. Some pediatric textbooks recommend a 24 Fr oral gastric tube for toddlers, and a 36 Fr tube for adolescents. In this case, a child was found with an open bottle of digoxin, and it could not be determined if ingestion had occurred. She would not drink charcoal. The 18 Fr NG tube was used to attempt to aspirate digoxin from the stomach (none was recovered) and to instill charcoal. Some would suggest the oral route for this tube, but it was passed rather easily through the nose. An NG tube is not ideal for some ingestants (iron, sustained-release products), but most pills quickly dissolve in the stomach and the small particles can easily be removed with an NG tube. Although lavage may have been reasonable in this scenario, a potent and safe antidote for digoxin does exist. The common routine practice of passing an NG tube in a child who is unwilling to drink charcoal is controversial and likely done far too often for benign ingestions. *(Reprinted with permission from Elsevier [The Lancet, vol 338 (8778), 1991, pp 1313–1315].)*

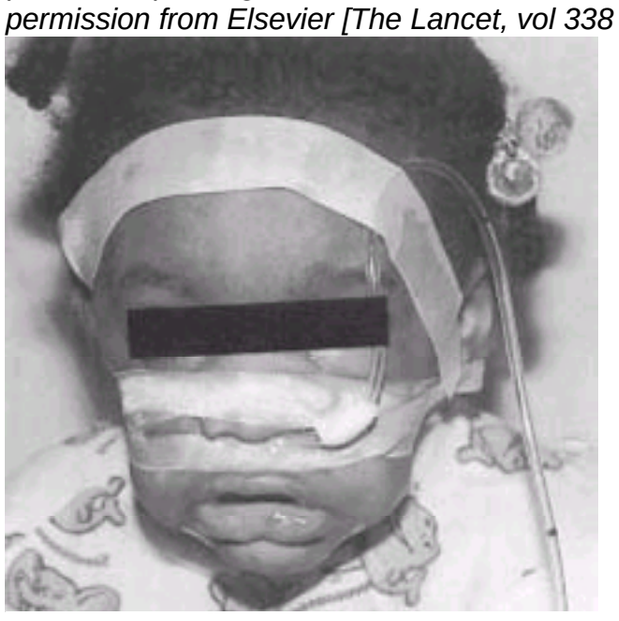

Figure 43-6 Failure to premeasure a lavage tube before passage is a common error. Here a piece of tape marks the depth of proper passage to ensure that the tip is in the stomach without excess tubing that may hinder fluid egress.

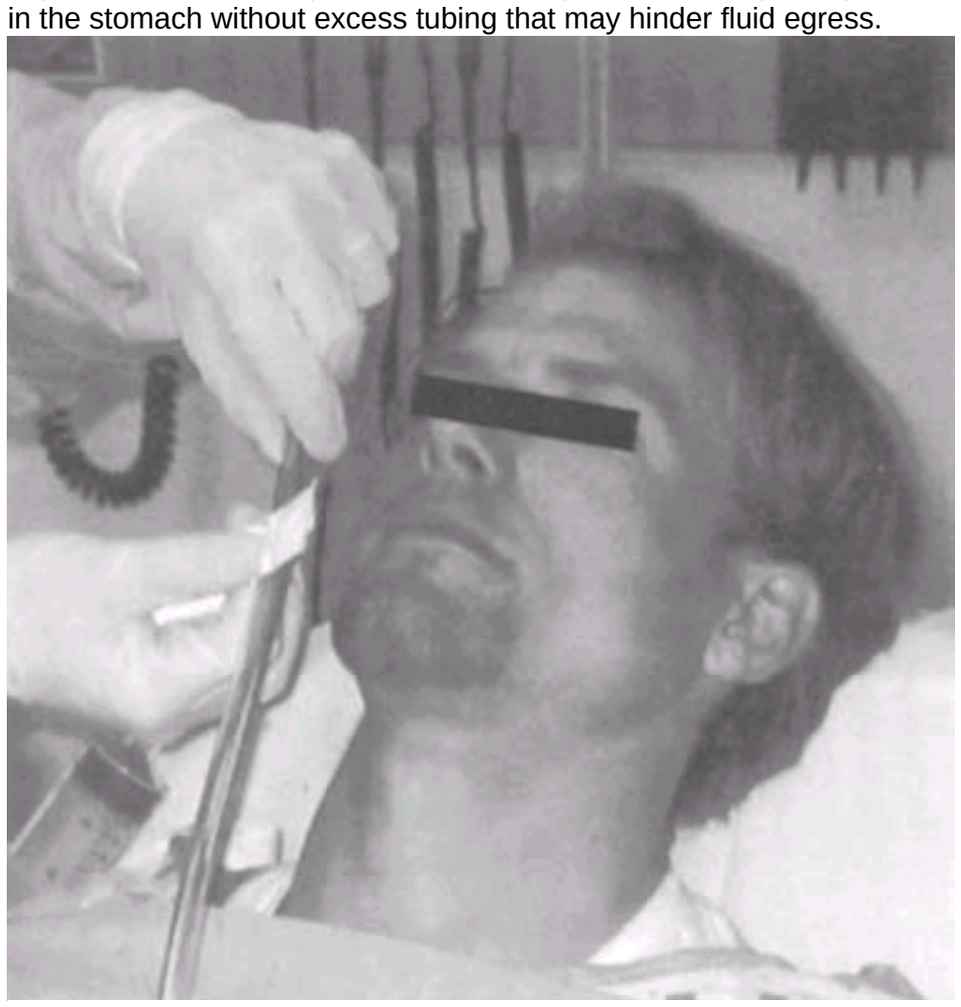

Figure 43-7 Positioning the patient's chin on the chest can facilitate passage of the tube into the esophagus once the pharynx has been entered. Once the tube is positioned, lavage is performed in the left lateral decubitus position. If the patient begins to vomit, the tube is immediately withdrawn.

Figure 43-8 An example of the Y connector closed system with the patient in a left lateral decubitus position. Patients on a ventilator, or those who are intubated may be lavaged in the supine position due to logistic issues, but an awake nonintubated patient is never lavaged in the restrained supine position.

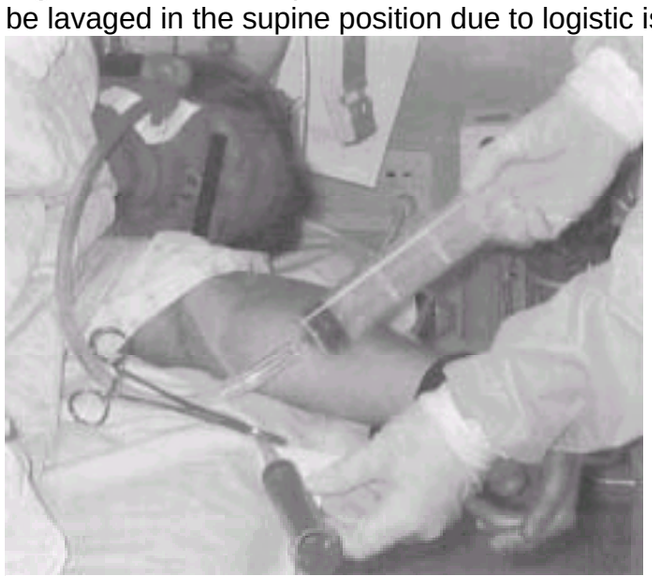

Figure 43-9 Position statement: single-dose activated charcoal. *(From the American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists. Published in Clin Toxicol 35:721, 1997.)*

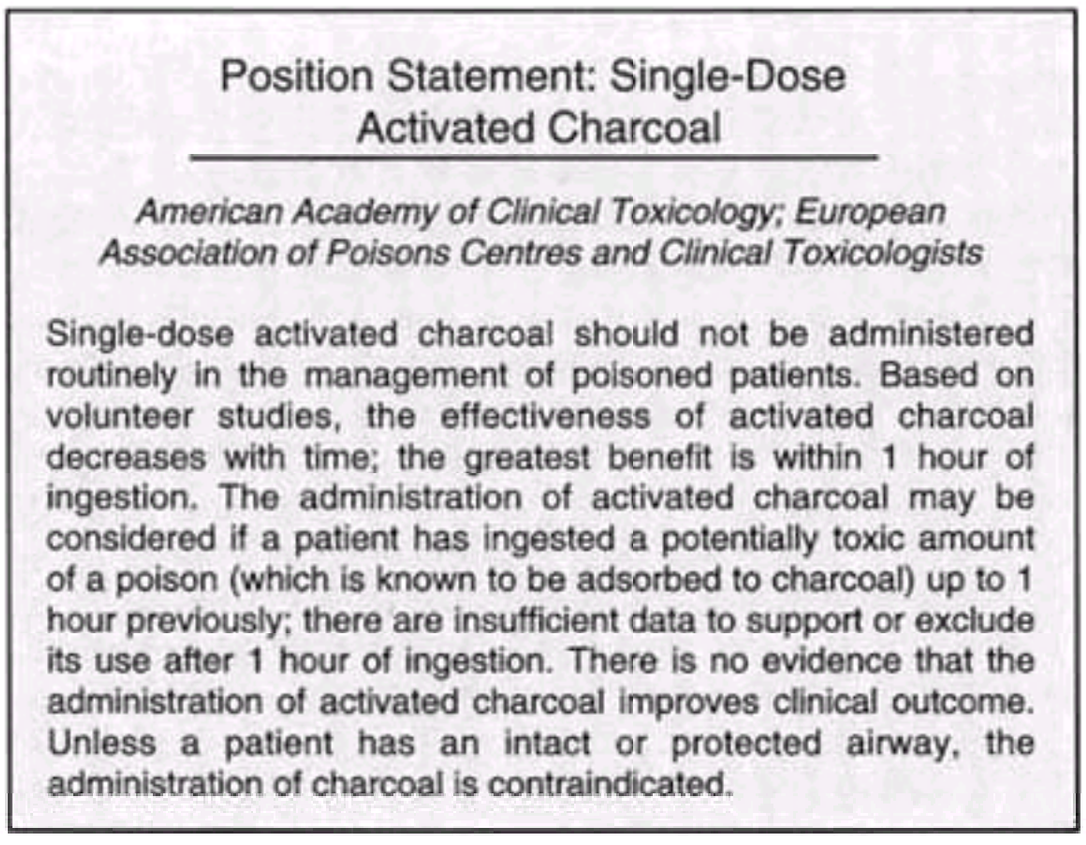

Position Statement: Single-Dose Activated Charcoal

American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists

Single-dose activated charcoal should not be administered routinely in the management of poisoned patients. Based on volunteer studies, the effectiveness of activated charcoal decreases with time; the greatest benefit is within 1 hour of ingestion. The administration of activated charcoal may be considered if a patient has ingested a potentially toxic amount of a poison (which is known to be adsorbed to charcoal) up to 1 hour previously; there are insufficient data to support or exclude its use after 1 hour of ingestion. There is no evidence that the administration of activated charcoal improves clinical outcome. Unless a patient has an intact or protected airway, the administration of charcoal is contraindicated.

Figure 43-10 Radiographic confirmation of nasogastric tube placement before lavage or instillation of charcoal. Tracheal placement of a lavage tube is usually readily evident. Vomiting during lavage suggests that the tube has curved back into the esophagus. A confirmatory radiograph is suggested in the obtunded patient if gastric placement is questioned. Tracheal intubation precludes passage of a tube into the lungs, but it does not ensure proper gastric placement.

Figure 43-11 If the overdose patient will voluntarily drink charcoal, there are few reasons to withhold it, even though a definite clinical benefit in the routine case cannot be proved. If a patient will not drink charcoal, patient management becomes controversial. Passing a nasogastric tube in a struggling patient or in a recalcitrant child merely to instill the unproven, but theoretically useful, antidote is not supported by scientific data. Nonetheless, it remains a common procedure. Although not always easy or pleasant, such an intervention is usually safe. Pulmonary aspiration, even in the awake patient, is the major downside. *Restrained supine patients are at greatest risk for aspiration, and that position should be avoided, even in the initially awake patient.*

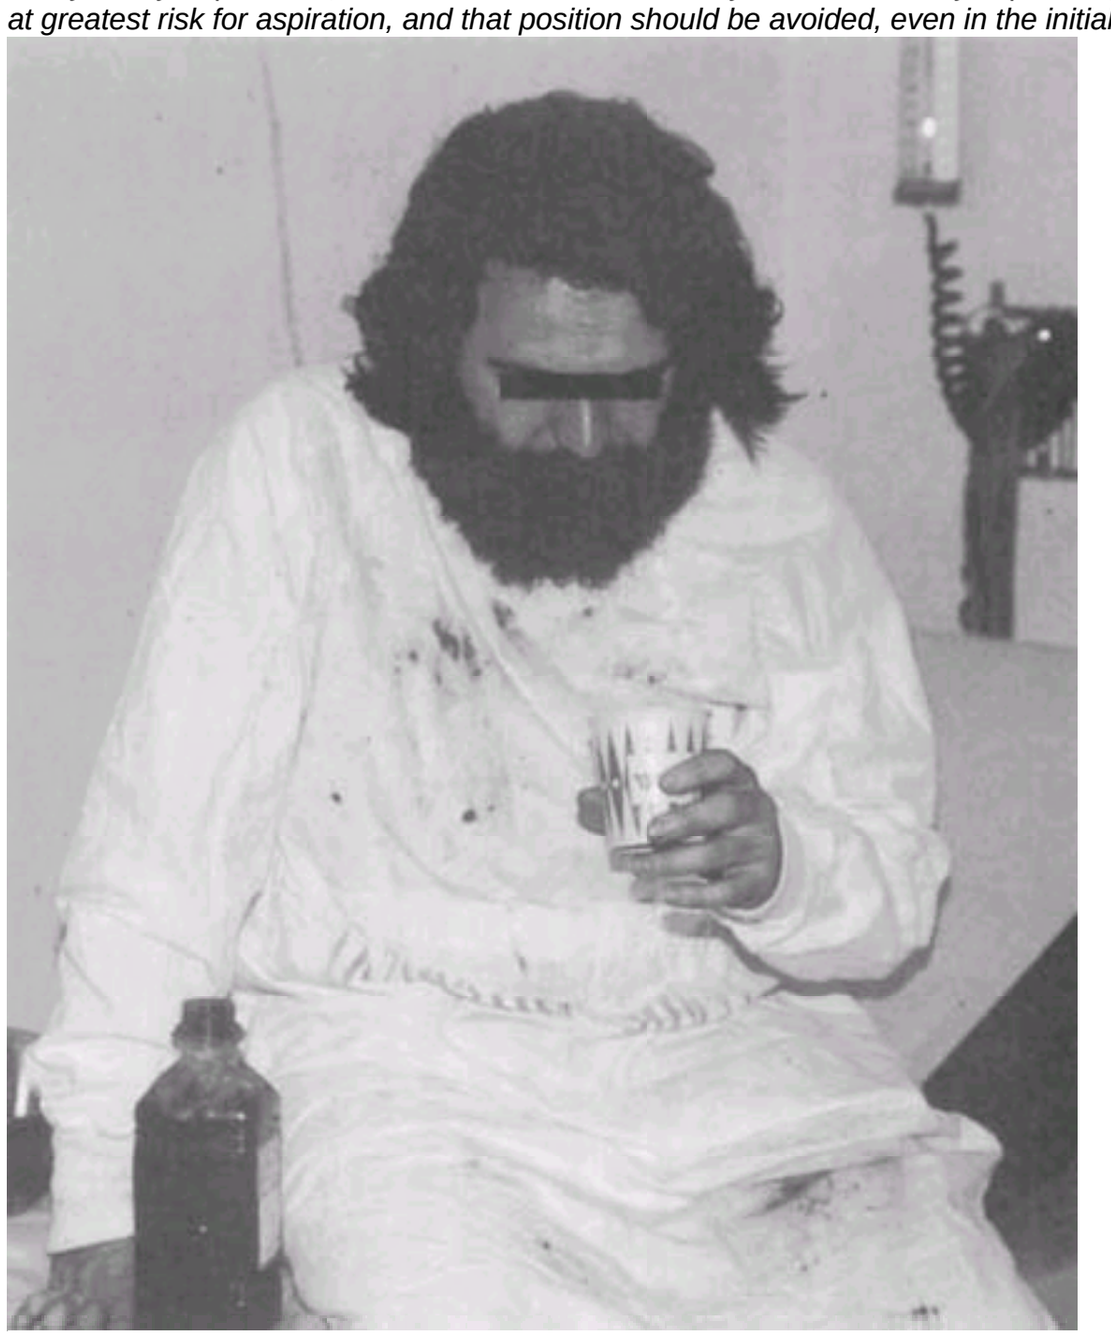

Figure 43-12 Charcoal that is voluntarily swallowed or instilled via an oral-gastric lavage tube or nasogastric tube can induce emesis. This occurs in both the obtunded and awake patient. In this instance, the patient was unconscious from the overdose and the airway was protected with prior tracheal intubation. Although the intubation procedure does not totally exclude pulmonary aspiration, and it carries some morbidity in its own right, it is recommended prior to charcoal use in the patient who is not able to fully protect the airway. Patients who initially are asymptomatic or minimally affected but have ingested drugs that have the potential to produce rapid deterioration, seizures, or loss of airway protection make decisions on the use of charcoal difficult for the clinician. In borderline cases, some experienced clinicians avoid the use of charcoal altogether.

Figure 43-13 Position statement and practice guidelines on the use of multi-dose activated charcoal in the treatment of acute poisoning. *(From the American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists. Published in Clin Toxicol 37:731, 1999.)*

Position Statement: Position Statement and Practice Guidelines on the Use of Multi-Dose Activated Charcoal in the Treatment of Acute Poisoning

American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists

Although many studies in animals and volunteers have demonstrated that multiple-dose activated charcoal increases drug elimination significantly, this therapy has not yet been shown in a controlled study in poisoned patients to reduce morbidity and mortality. Further studies are required to establish its role and the optimal dosage regimen of charcoal to be administered.

Based on experimental and clinical studies, multiple-dose activated charcoal should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, Phenobarbital, quinine, or theophylline. With all of these drugs there are data to confirm enhanced elimination, though no controlled studies have demonstrated clinical benefit.

Although volunteer studies have demonstrated that multiple-dose activated charcoal increases the elimination of amitriptyline, dextropropoxyphene, digitoxin, digoxin, disopyramide, nadolol, phenylbutazone, phenytoin, piroxicam, and sotalol, there are insufficient clinical data to support or exclude the use of this therapy.

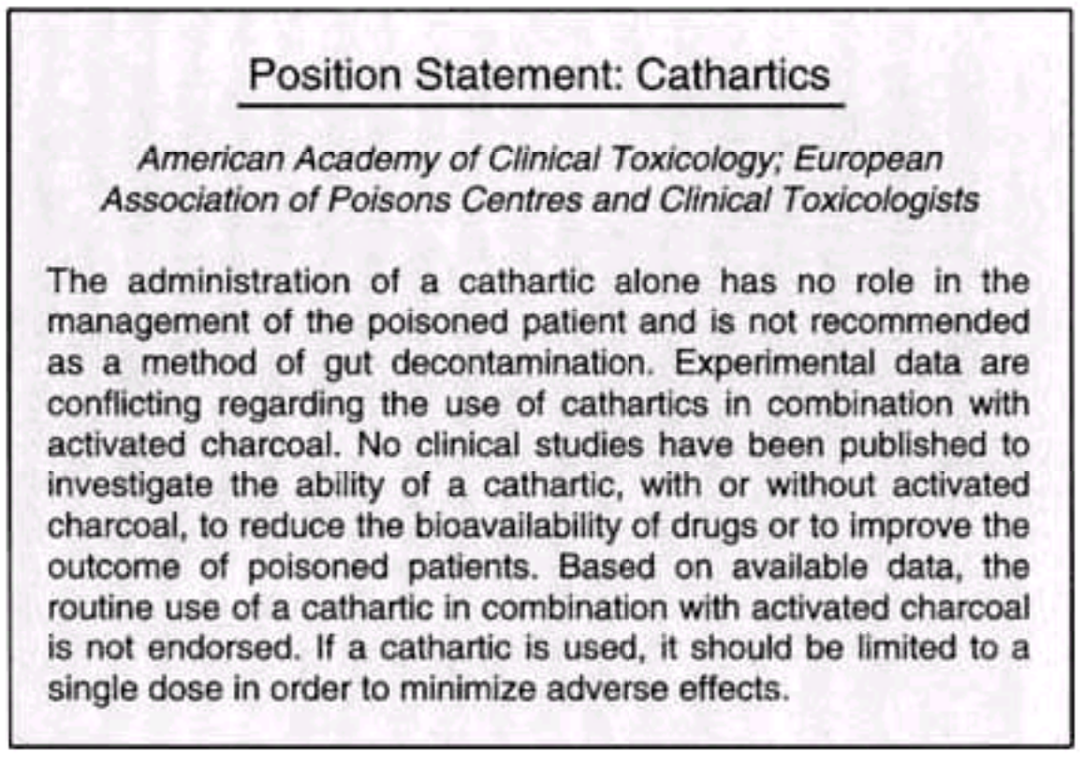
The use of multiple-dose charcoal in salicylate poisoning is controversial. One animal study and 2 of 4 volunteer studies did not demonstrate increased salicylate clearance with multiple-dose charcoal therapy. Data in poisoned patients are insufficient presently to recommend the use of multiple-dose charcoal therapy for salicylate poisoning.

Multiple-dose activated charcoal did not increase the elimination of astemizole, chlorpropamide, doxepin, imipramine, meprobamate, methotrexate, phenytoin, sodium valproate, tobramycin, and vancomycin in experimental and/or clinical studies.

Unless a patient has an intact or protected airway, the administration of multiple-dose activated charcoal is contraindicated. It should not be used in the presence of an intestinal obstruction. The need for concurrent administration of cathartics remains unproven and is not recommended. In particular, cathartics should not be administered to young children because of the propensity of laxatives to cause fluid and electrolyte imbalance.

In conclusion, based on experimental and clinical studies, multiple-dose activated charcoal should be considered only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, Phenobarbital, quinine, or theophylline.

Figure 43-14 Position statement: cathartics. *(From the American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists. Published in Clin Toxicol 35:743, 1999.)*



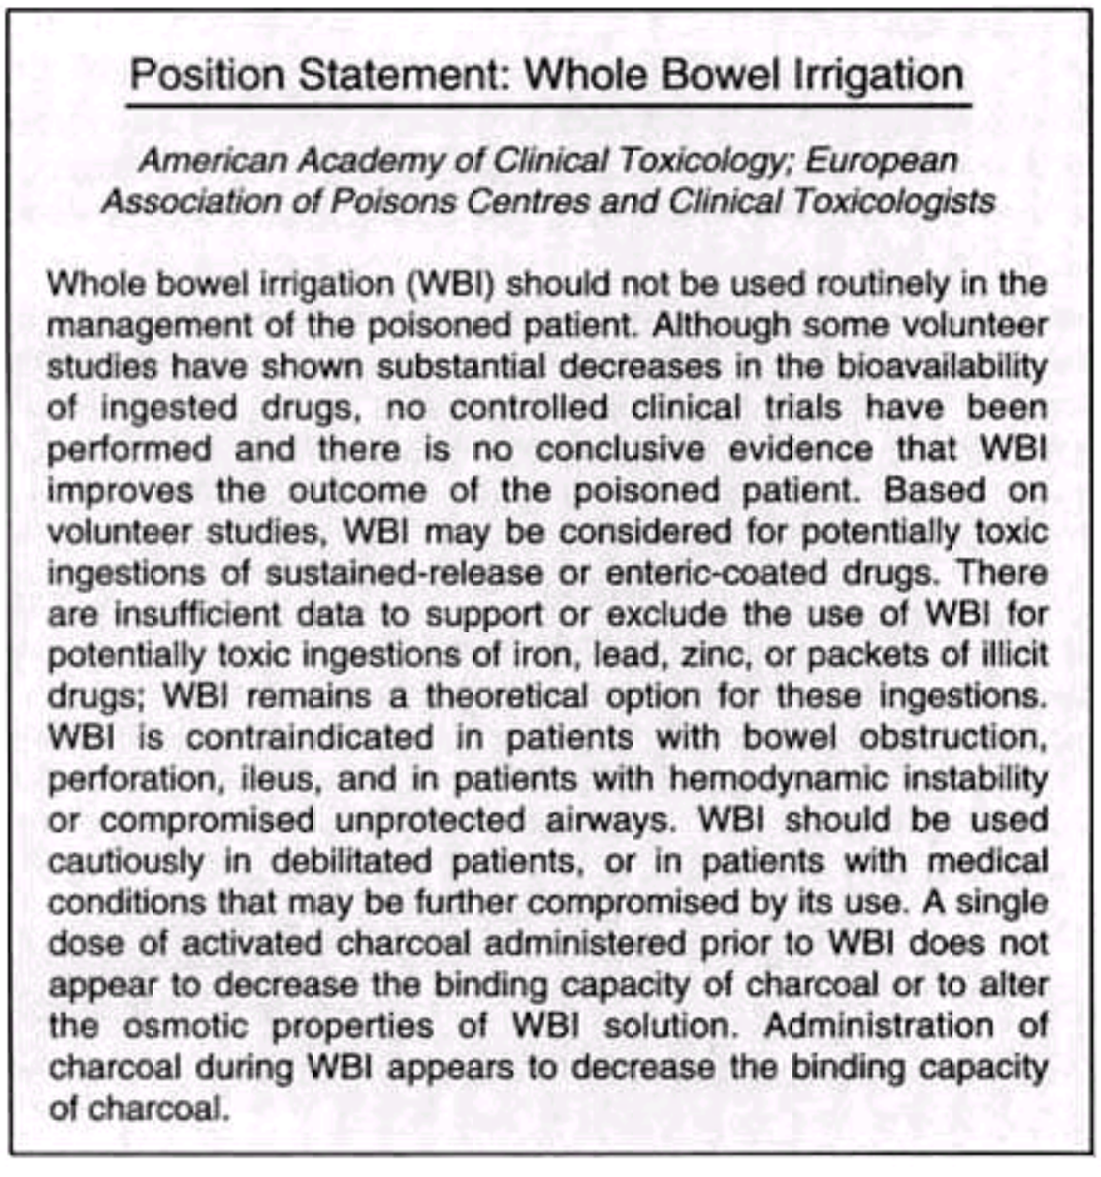
Position Statement: Cathartics

American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists

The administration of a cathartic alone has no role in the management of the poisoned patient and is not recommended as a method of gut decontamination. Experimental data are conflicting regarding the use of cathartics in combination with activated charcoal. No clinical studies have been published to investigate the ability of a cathartic, with or without activated charcoal, to reduce the bioavailability of drugs or to improve the outcome of poisoned patients. Based on available data, the routine use of a cathartic in combination with activated charcoal is not endorsed. If a cathartic is used, it should be limited to a single dose in order to minimize adverse effects.

Figure 43-15 This "body packer" *(A)* attempted to smuggle more than 50 packets of heroin. All packets were passed intact after 12 hours of whole-bowel irrigation. Note the integrity of the carefully wrapped packets that were passed *(B)*.

Figure 43-16 Position statement: whole-bowel irrigation. *(From the American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists. Published in Clin Toxicol 35:753, 1997.)*



Position Statement: Whole Bowel Irrigation

American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists

Whole bowel irrigation (WBI) should not be used routinely in the management of the poisoned patient. Although some volunteer studies have shown substantial decreases in the bioavailability of ingested drugs, no controlled clinical trials have been performed and there is no conclusive evidence that WBI improves the outcome of the poisoned patient. Based on volunteer studies, WBI may be considered for potentially toxic ingestions of sustained-release or enteric-coated drugs. There are insufficient data to support or exclude the use of WBI for potentially toxic ingestions of iron, lead, zinc, or packets of illicit drugs; WBI remains a theoretical option for these ingestions. WBI is contraindicated in patients with bowel obstruction, perforation, ileus, and in patients with hemodynamic instability or compromised unprotected airways. WBI should be used cautiously in debilitated patients, or in patients with medical conditions that may be further compromised by its use. A single dose of activated charcoal administered prior to WBI does not appear to decrease the binding capacity of charcoal or to alter the osmotic properties of WBI solution. Administration of charcoal during WBI appears to decrease the binding capacity of charcoal.

Figure 43-17 Whole-bowel irrigation is commonly recommended for the treatment of iron ingestion. These radiographs depict the effect of 5 hours of whole-bowel irrigation. Note the marked decrease of radiopaque pills in the gastrointestinal tract. Intact pills were recovered in the rectal effluent.

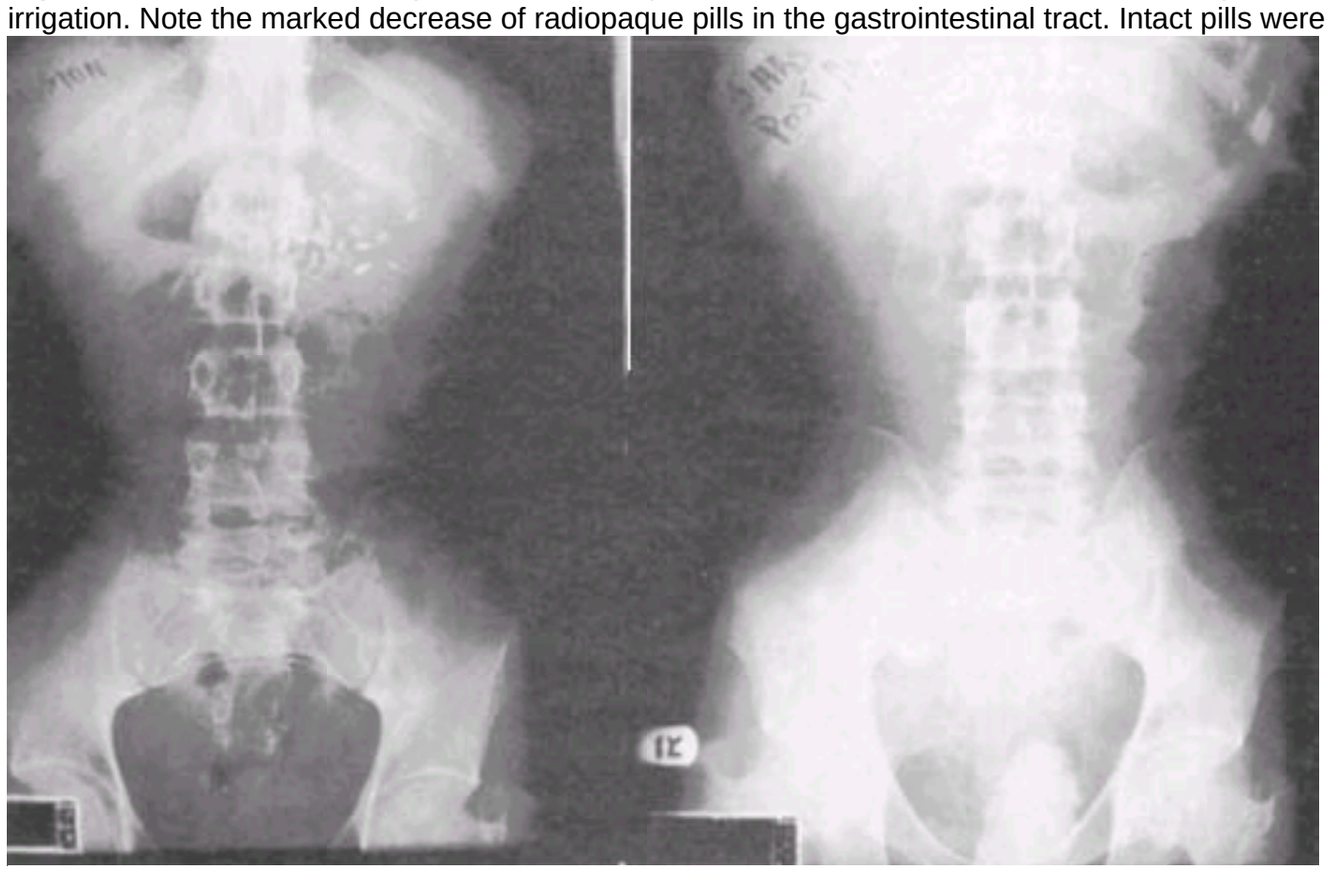


Figure 43-18 It is very difficult for even the most motivated patient to drink an effective volume of whole-bowel irrigation solution. To enhance compliance and to decrease vomiting, PEG-ES may be slowly and continuously administered via a nasogastric tube. An empty bag of saline is hung on an IV pole, the corner of the bag is removed, and the PEG-ES is poured into the bag. Standard IV tubing is connected to the proximal end of a nasogastric tube and the solution is infused continuously. In this picture, charcoal has been added to the whole-bowel irrigation solution. Metoclopramide was coadministered to reduce nausea.

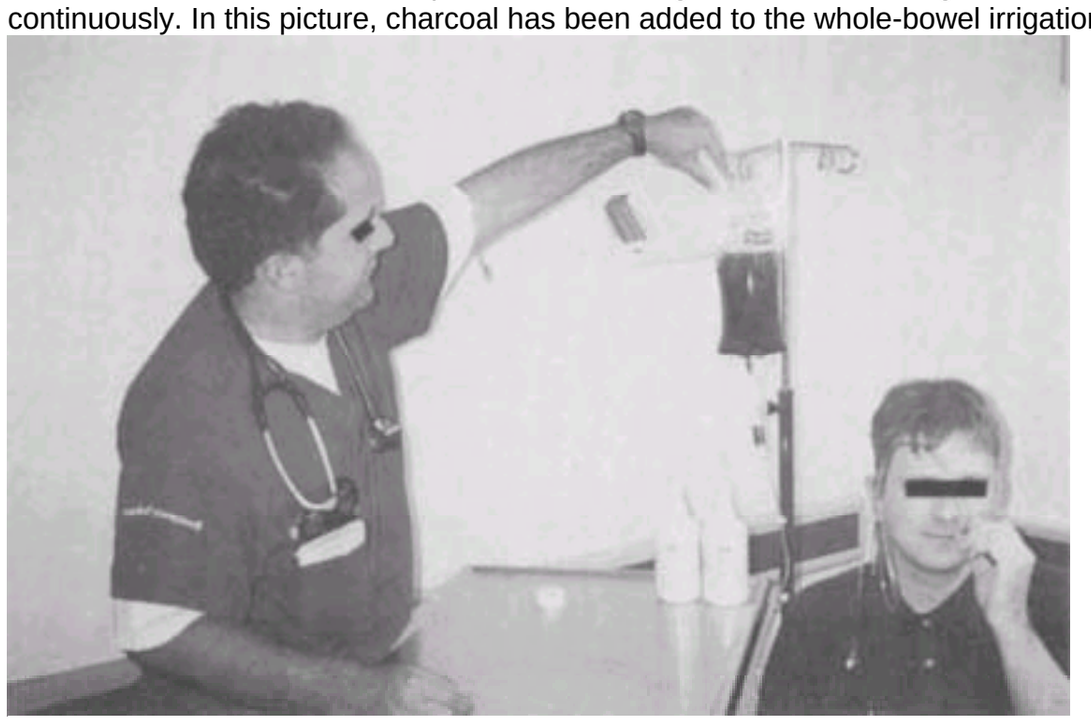

Figure 43-19 Decontamination of personnel using copious water irrigation.

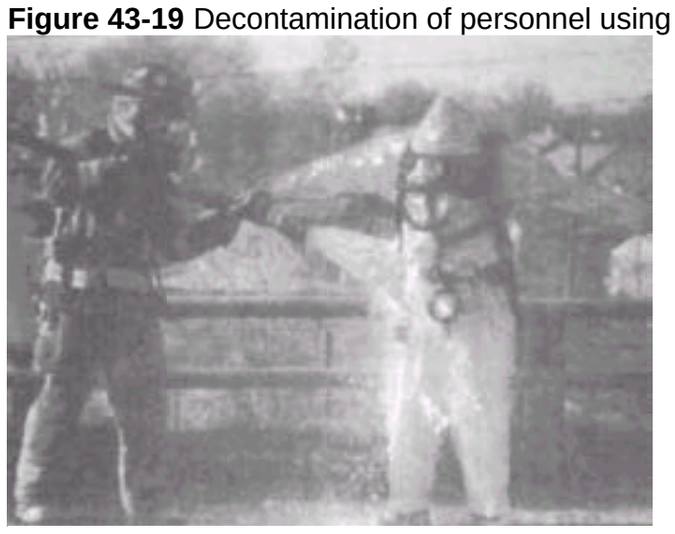

Figure 44-1 Blunt abdominal trauma algorithm. BAT, blunt abdominal trauma; CT, computed tomography; D/C, discharge; DPA, diagnostic peritoneal aspiration; DPL, diagnostic peritoneal lavage; IP, intraperitoneal; IPH, intraperitoneal hemorrhage; LAP, laparotomy; SPE, serial physical examinations; US, ultrasound. *Determined by unequivocal free intraperitoneal fluid on ultrasound or positive peritoneal aspiration on diagnostic peritoneal lavage. †Can be unreliable because of closed head injury, intoxicants, distracting injury, or spinal cord injury. ‡One or more studies may be indicated. §Need for laparotomy is based on clinical scenario, diagnostic studies, and institutional resources. *(From Marx J: Abdominal Trauma. In Marx JA, Hockberger RS, Walls RM, et al. [eds]: Rosen's Emergency Medicine Concepts and Clinical Practice, 5th ed. St. Louis, CV Mosby, 2002, p 432.)*

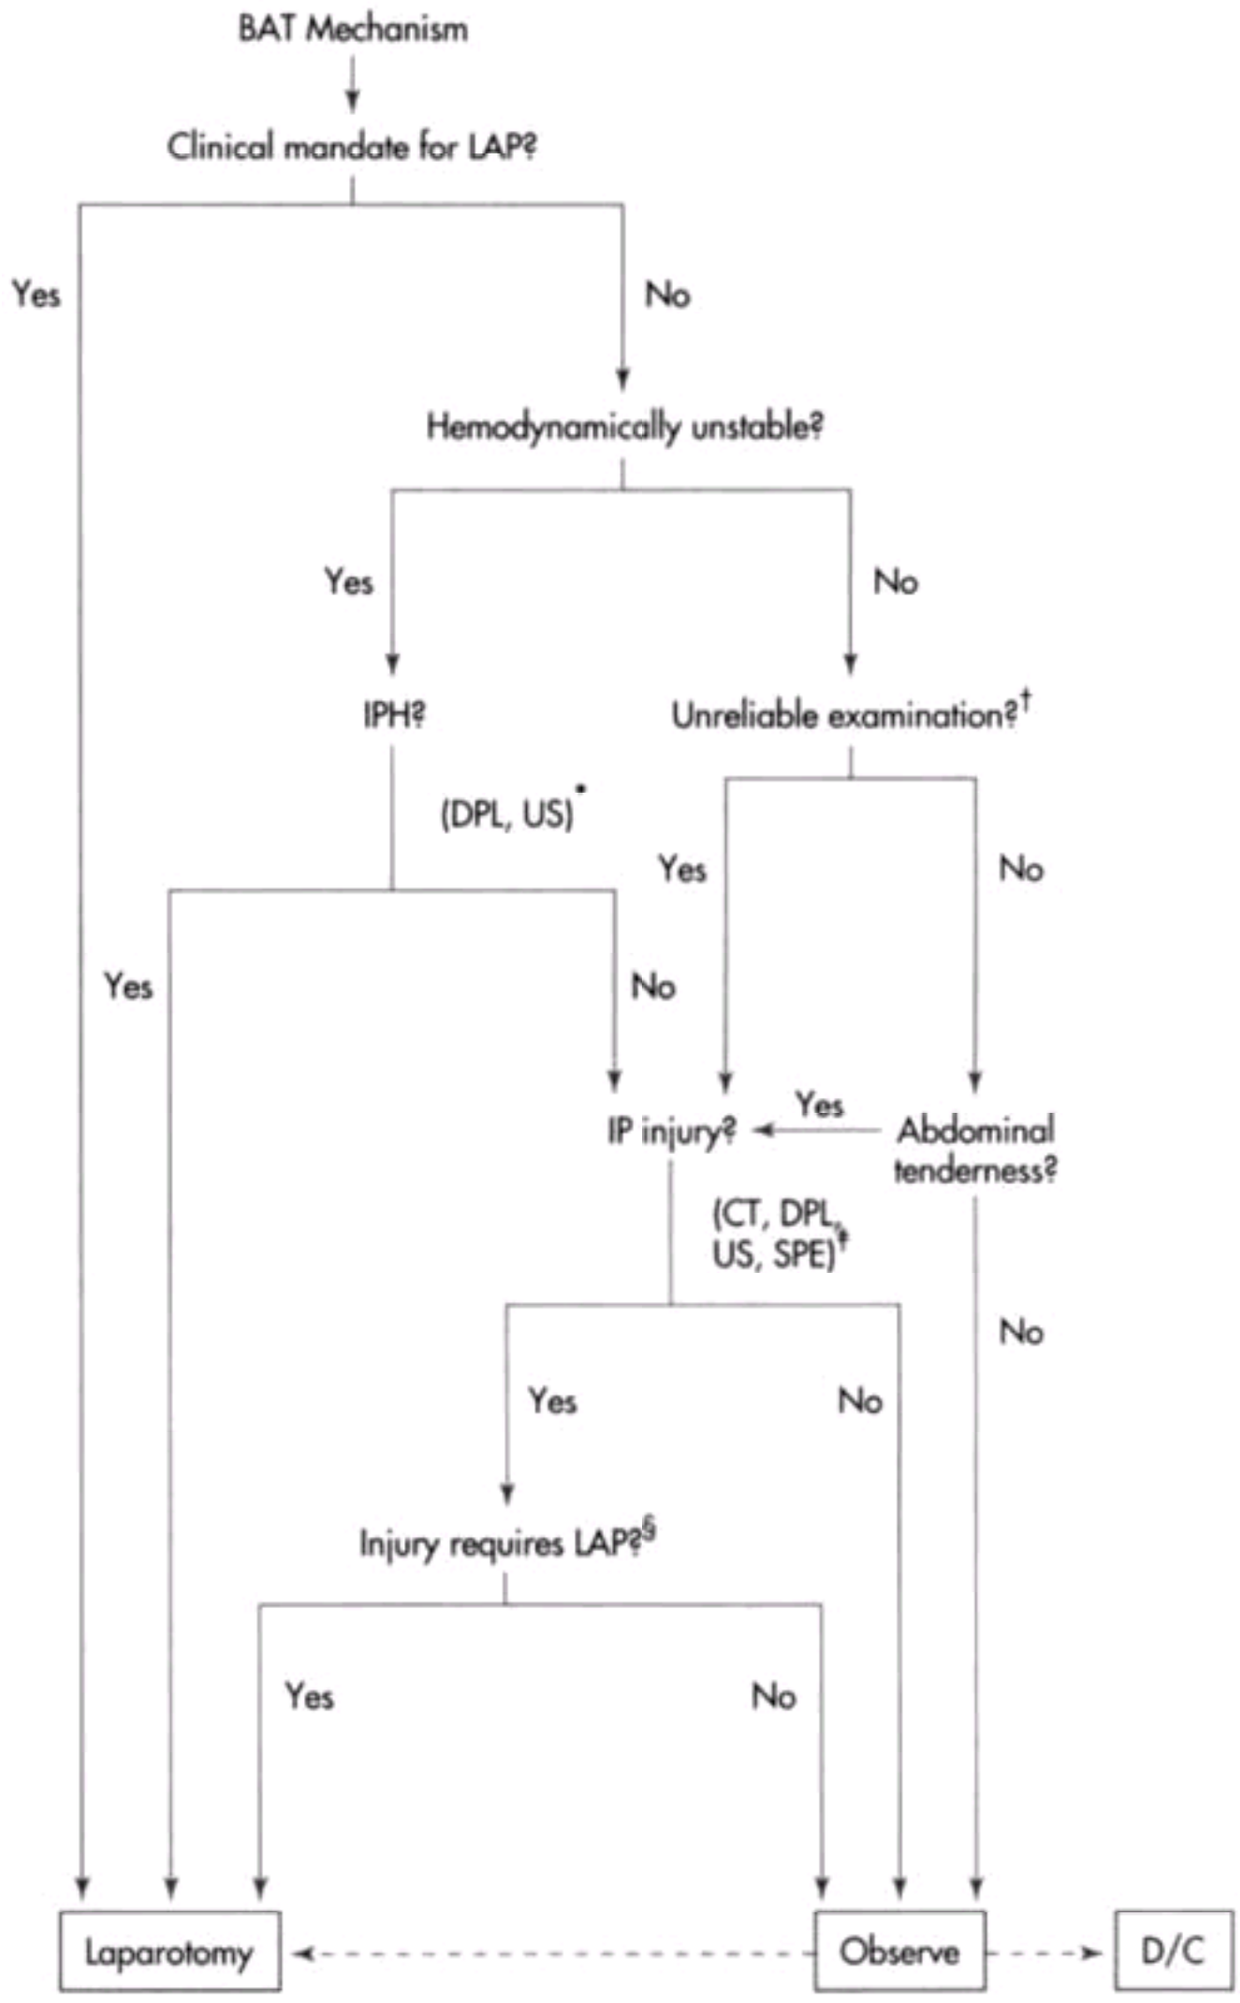

Figure 44-2 Anterior abdomen stab wound algorithm. *Plain films, ultrasound, laparoscopy, and computed tomography (CT) can assess peritoneal entry. †Laparoscopy or CT can complement or replace diagnostic peritoneal lavage. ‡Expectant management of injuries is infrequently attempted. D/C, discharge; DPL, diagnostic peritoneal lavage; LAP, laparotomy; LWE, local wound exploration; PEx, physical examination. *(From Marx J: Abdominal Trauma. Figure 44-3 Gunshot wound algorithm. D/C, discharge; DPL, diagnostic peritoneal lavage; LAP, laparotomy. *Can be assessed by missile path, plain films, local wound exploration, ultrasound, and laparoscopy. †Most centers proceed to laparotomy if peritoneal entry is suspected. ‡Patients with documented superficial and low-velocity injuries can be discharged; unknown depth or high-velocity injuries require further tests or observation. §Serial examinations, laparoscopy, or a computed tomography scan can complement or replace diagnostic peritoneal lavage. ¶Expectant management of injuries caused by gunshot wounds is rarely attempted. *(From Marx J: Abdominal Trauma. In Marx JA, Hockberger RS, Walls RM, et al. [eds]: Rosen's Emergency Medicine Concepts and Clinical Practice, 5th ed. St. Louis, CV Mosby, 2002, p 430.)*

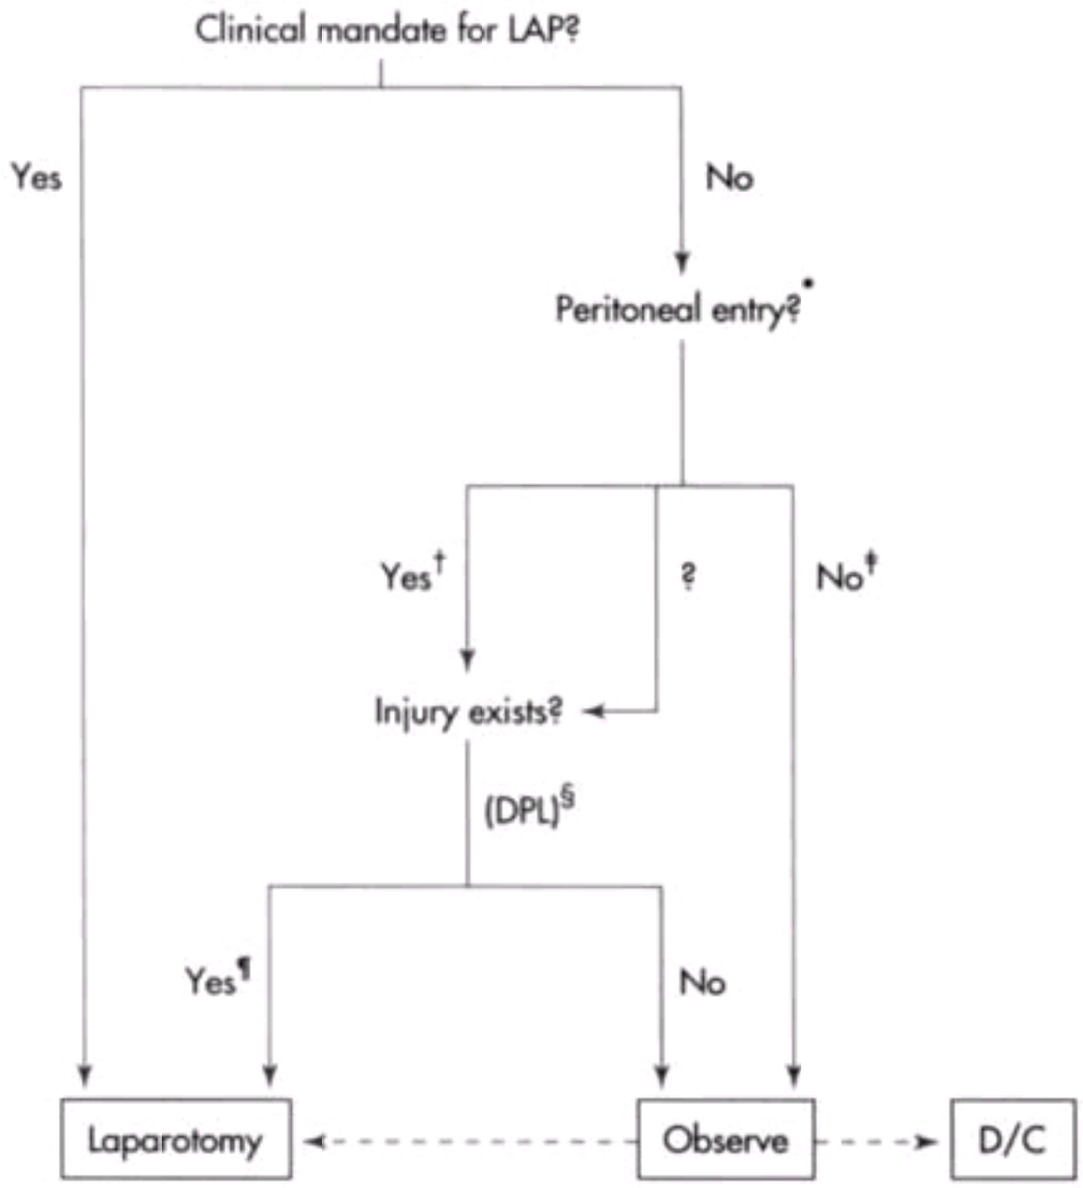

Figure 44-4 Local anesthesia is introduced at incision or puncture site. The patient is supine with the head of the bed elevated slightly.

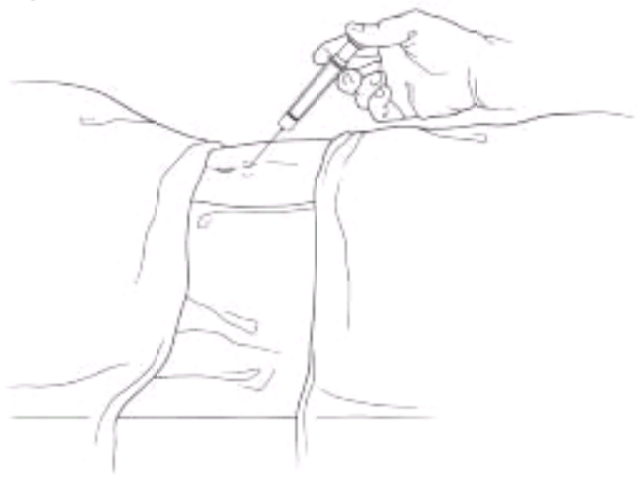

Figure 44-5 Standard equipment used for open lavage technique.

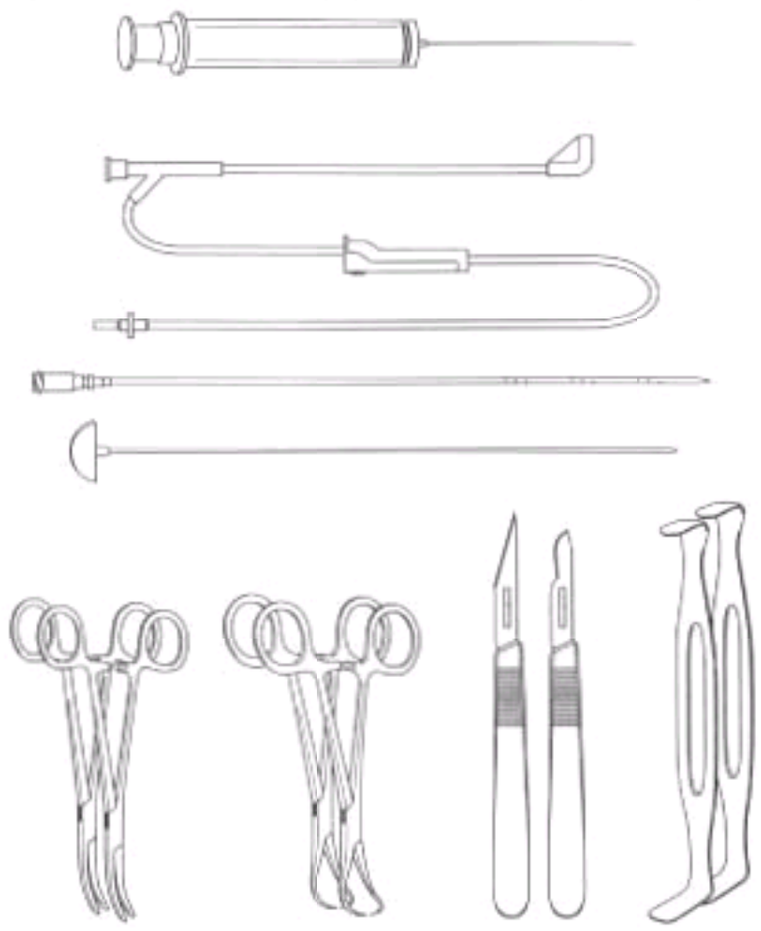

Figure 44-6 *A,* After bladder decompression (generally by Foley catheter placement), a 4- to 6-cm long vertical infraumbilical incision is made with a No. 11 scalpel. *B,* Blunt dissection using Army-Navy retractors is carried down to the *rectus fascia*. Crossing bands of crural fibers may be seen. *C,* A 2- to 3-mm incision is made through the *rectus fascia* in the midline (*linea alba*) with a No. 15 scalpel. *D,* Towel clips grasp each side of the *rectus fascia*, which is lifted prior to insertion of the trocar and diagnostic peritoneal lavage (DPL) catheter. *E,* The trocar with DPL catheter is passed at a 45° caudad angle into the fascial opening and through the peritoneum. Note that in the fully open method, the incision in the *rectus fascia* is extended, the peritoneum is directly visualized and incised, and the catheter alone is placed into the peritoneal cavity. *F,* As soon as the peritoneum has been entered, only the catheter is gently advanced into the peritoneal cavity while the trocar is withdrawn. It is often helpful to advance the catheter with a slight twisting motion and to direct it toward either the right or left pelvic gutter.

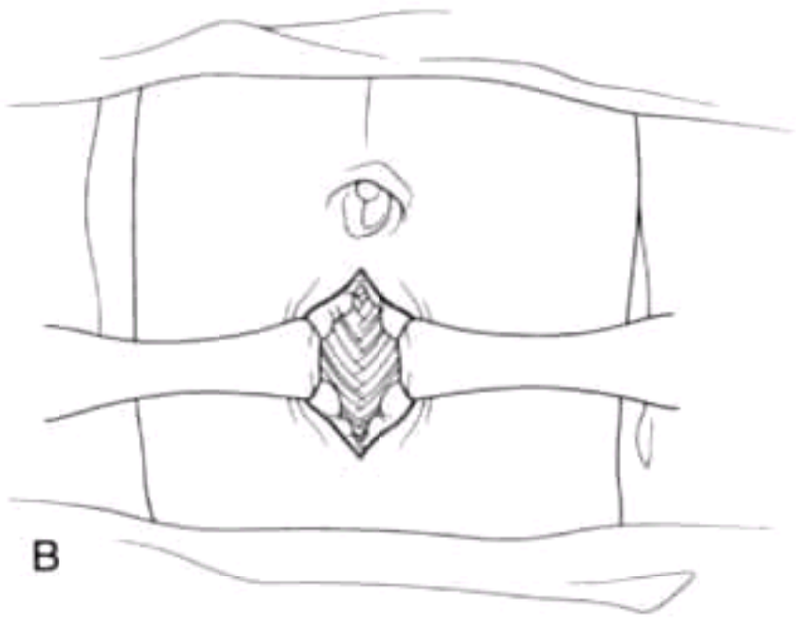
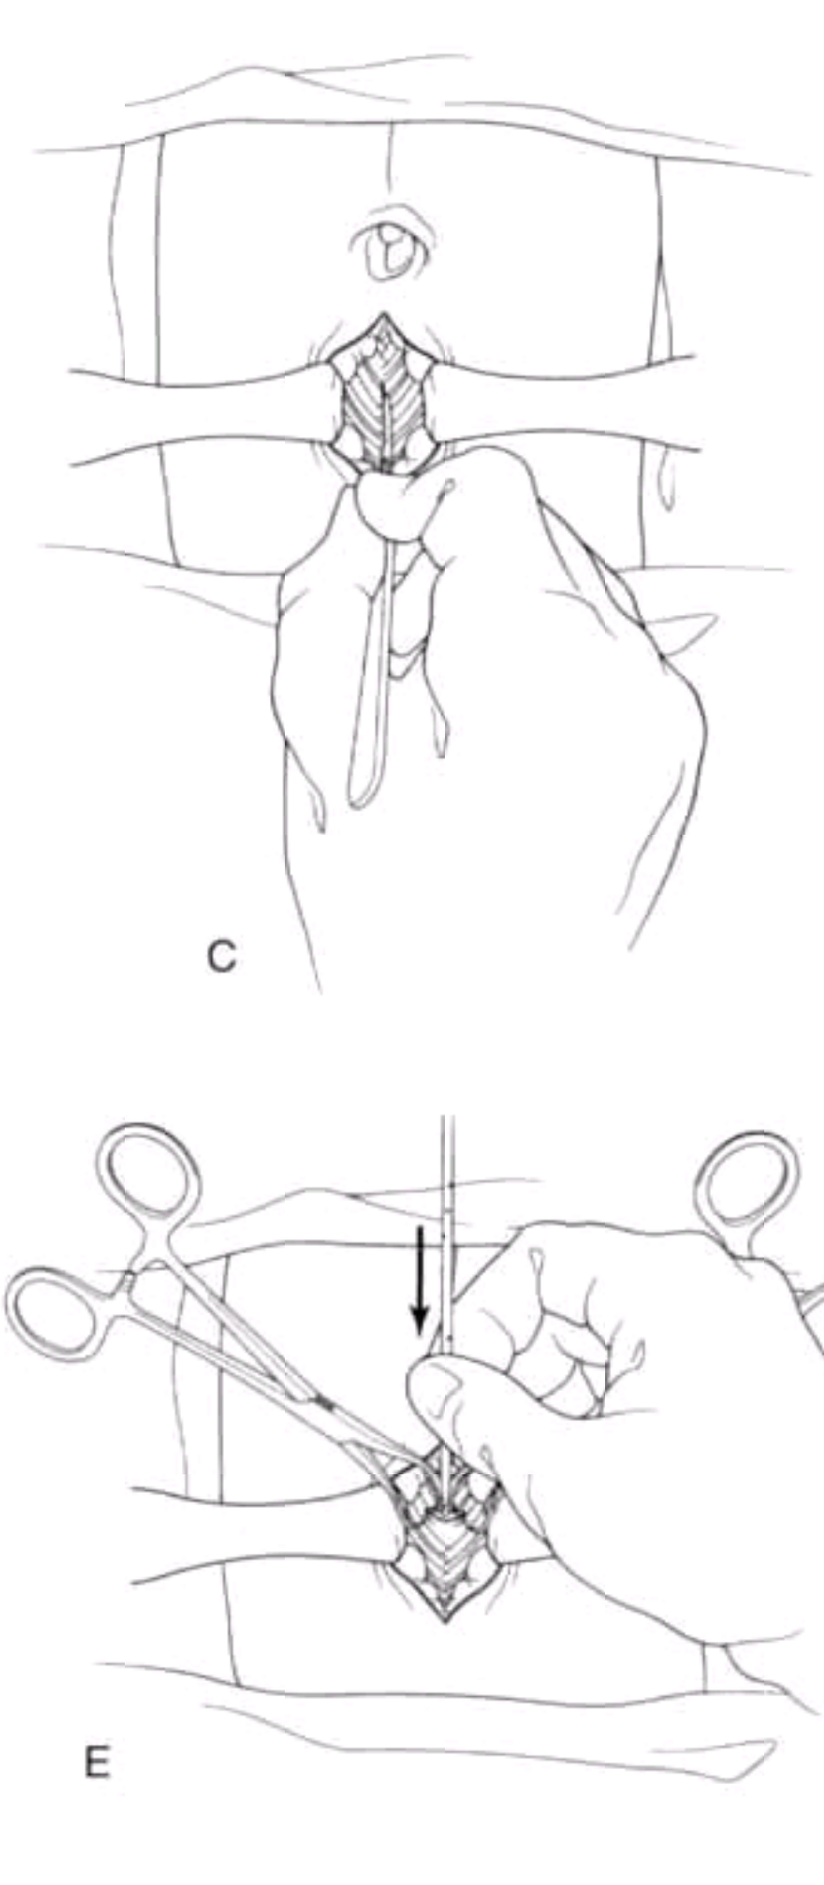
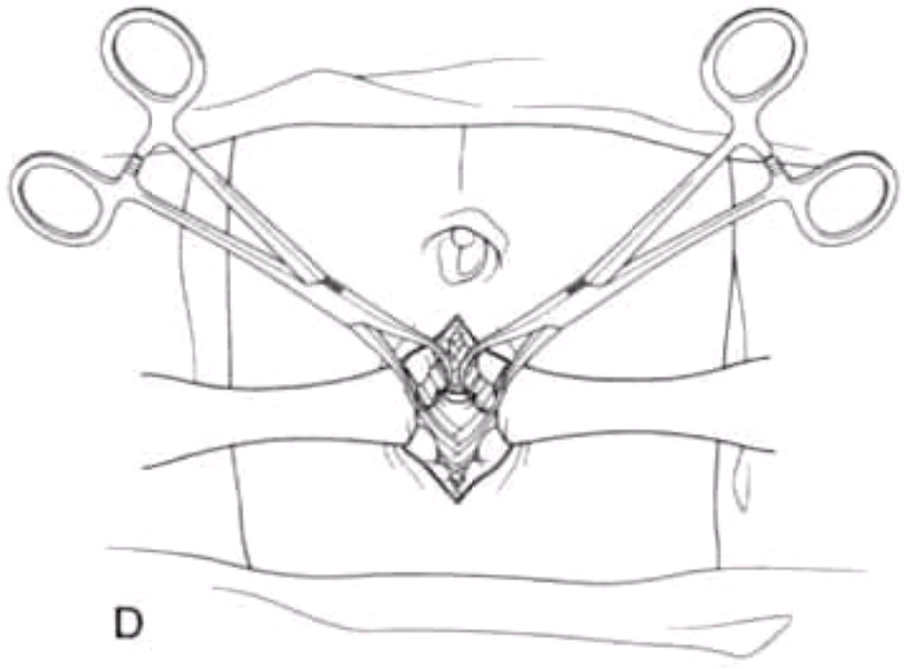
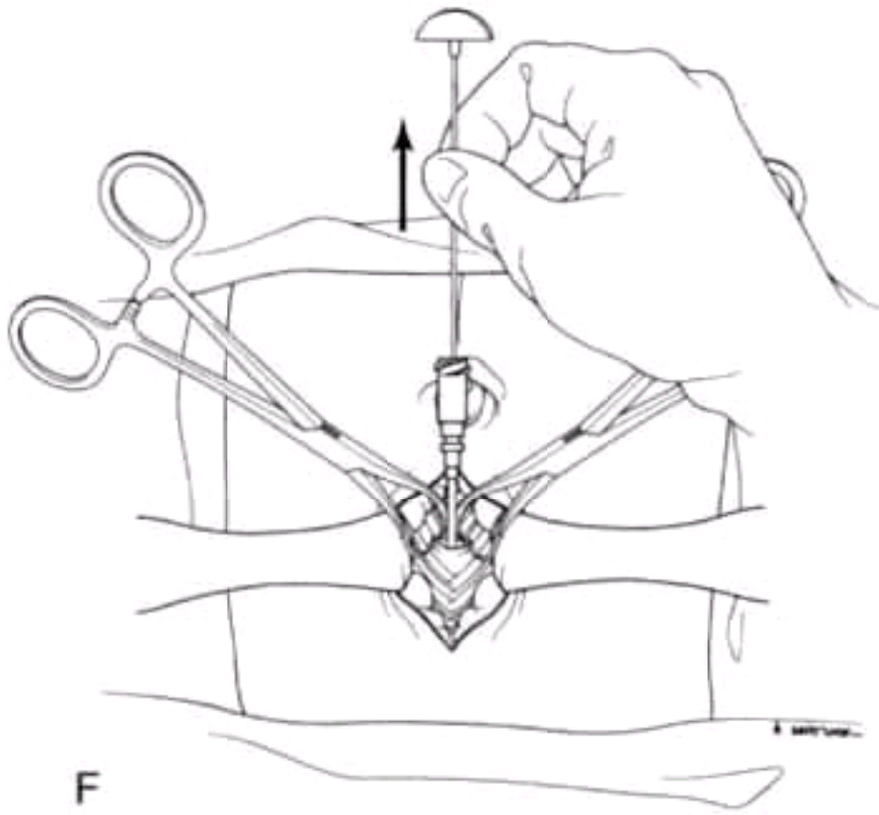








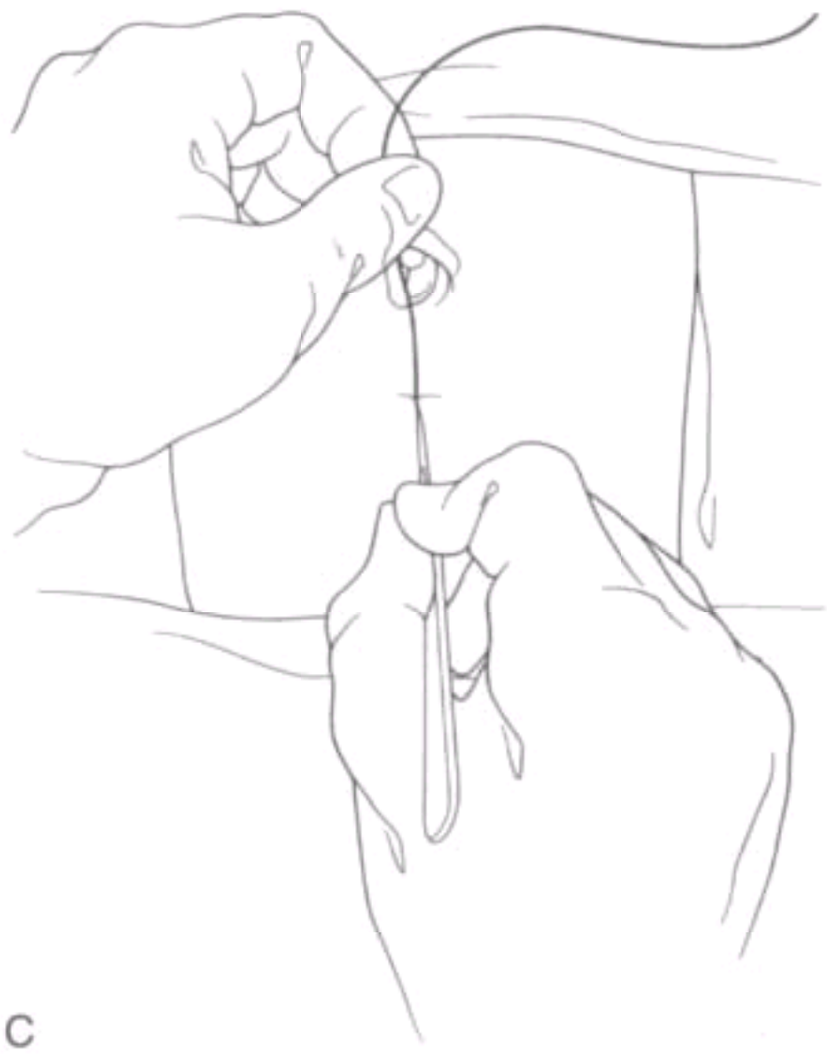
E

F

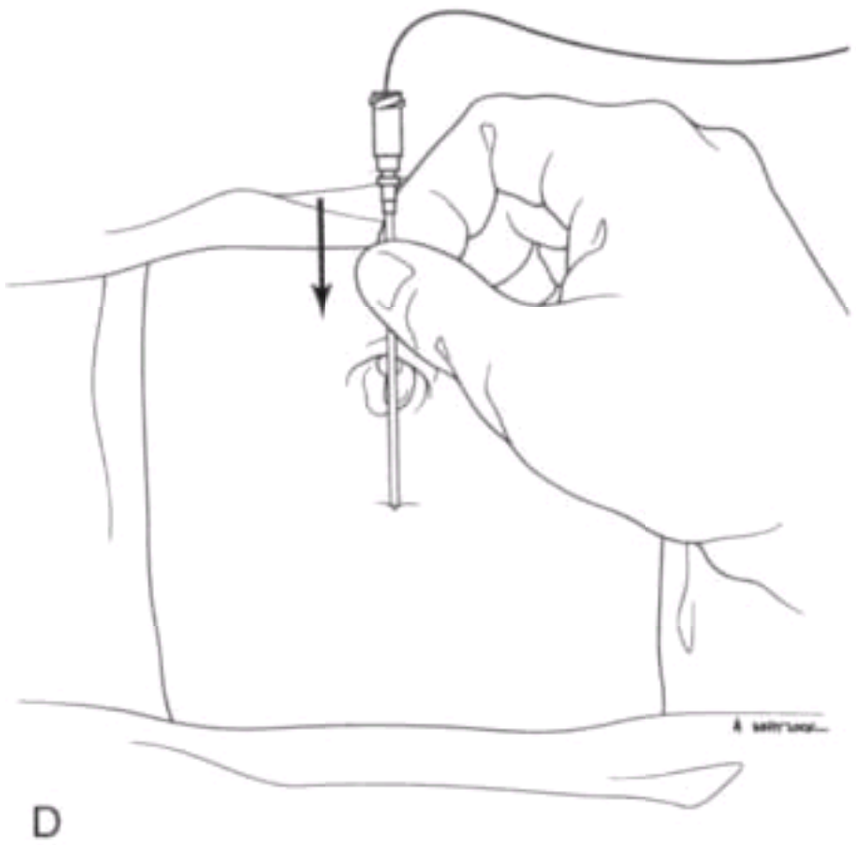
Figure 44-7 *A,* For the closed diagnostic peritoneal lavage (DPL) method using a guide wire (Seldinger technique), the needle is inserted into the peritoneal cavity in the midline just below the umbilicus and aimed slightly caudad. *B,* The flexible guide wire is passed through the needle and into the peritoneal cavity. Ideally, the wire should be directed toward the right or left pelvic gutter. The needle is withdrawn while the wire is stabilized with the operator's free hand at all times. *C,* A stab incision is made with a No. 11 scalpel immediately below the wire to permit easier passage of the DPL catheter. *D,* The DPL catheter is directed over the wire and into the peritoneal cavity using a slight twisting motion. The wire is stabilized by the operator at all times and removed after catheter placement. The catheter should be directed toward the right or left pelvic gutter when advanced.

A

B



C



D

Figure 44-8 After attachment of the right angle connector and extension tubing, aspiration of the peritoneum is attempted.

Figure 44-9 If the aspiration is negative, normal saline or Ringer's lactate solution is instilled through the catheter. *The IV tubing should have no valves in place.* After infusion, the fluid bag is placed on the floor and allowed to fill with peritoneal effluent via gravity.

Figure 44-10 Pelvic fracture algorithm. CT, computed tomography; D/C, discharge; DPA, diagnostic peritoneal aspiration; DPL, diagnostic peritoneal lavage; IP, intraperitoneal; IPH, intraperitoneal hemorrhage; LAP, laparotomy; Pelvic Fx, pelvic fracture; US, ultrasound. *Determined by unequivocal free intraperitoneal fluid on ultrasound or positive peritoneal aspiration on diagnostic peritoneal lavage. †One or more studies may be indicated. ‡Need for laparotomy is based on clinical scenario, diagnostic studies, and institutional resources. *(From Marx J: Abdominal Trauma. In Marx JA, Hockberger RS, Walls RM, et al [eds]: Rosen's Emergency Medicine Concepts and Clinical Practice, 5th ed. St. Louis, CV Mosby, 2002, p 434.*

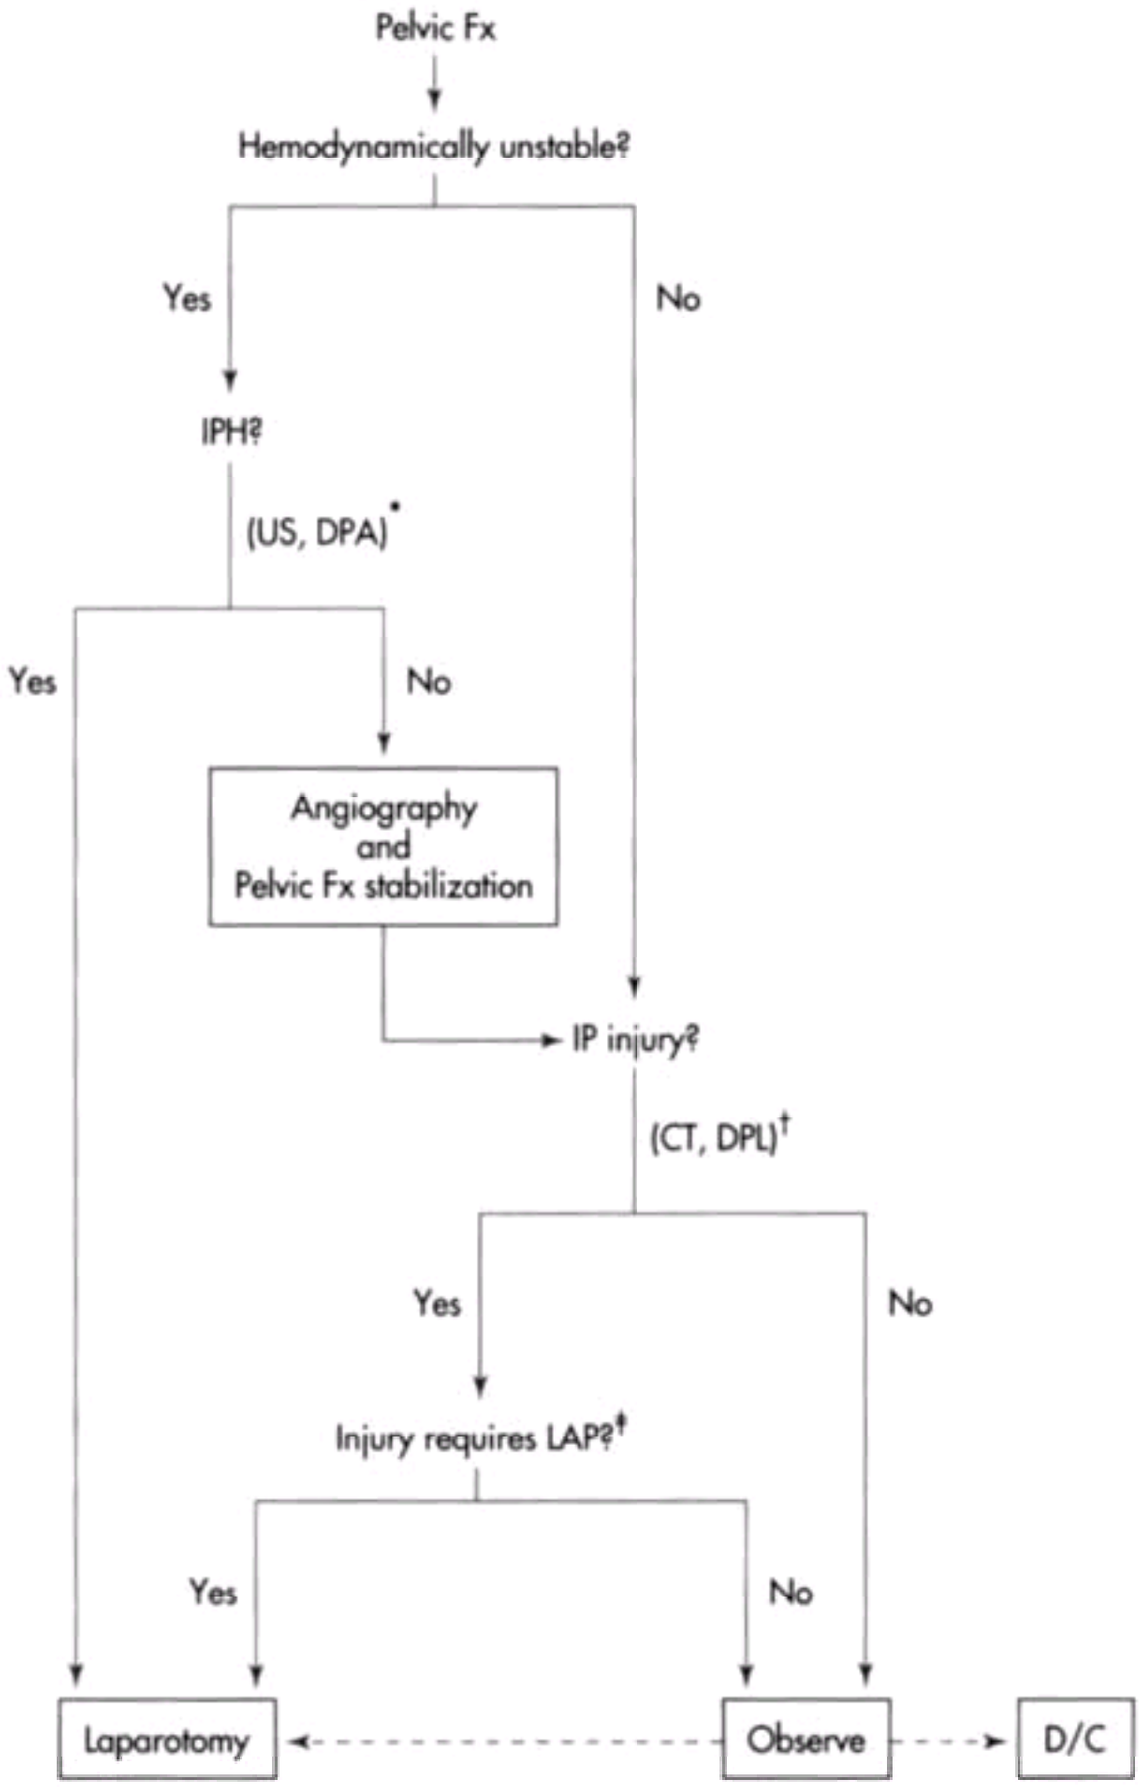


Figure 44-11 Preferred sites for paracentesis: *1,* Primary site is infraumbilical in midline through *linea alba*. *2,* Preferred alternate (lateral rectus) site is in either lower quadrant, approximately 4 to 5 cm cephalad and medial to the anterior superior iliac spine.

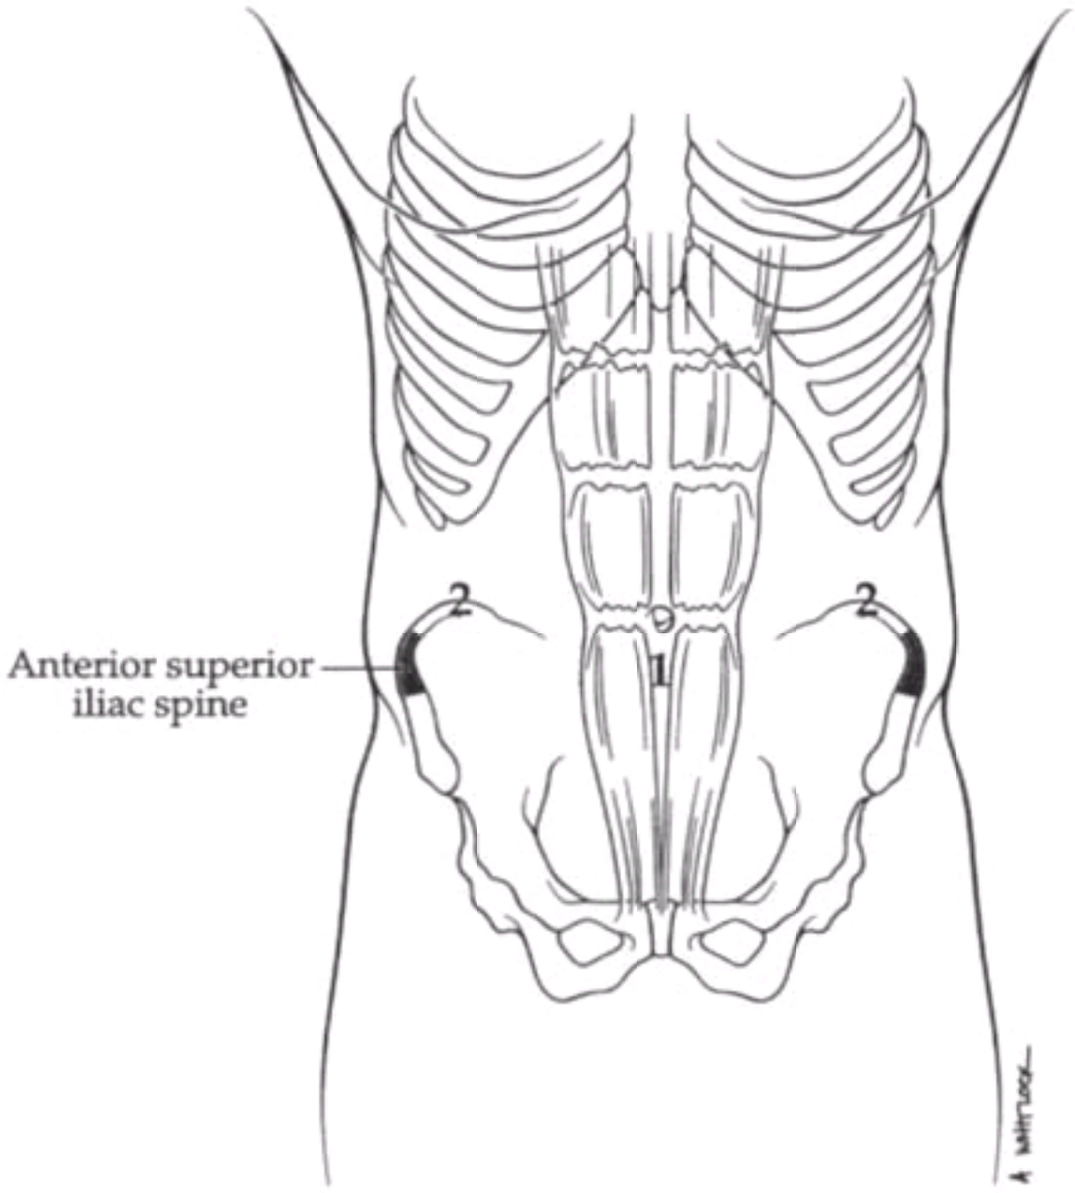

Figure 44-12 An alternative to the sitting or supine position for needle paracentesis is to place the patient in the lateral decubitus position. In this example the midline is aspirated, although the lateral rectus sites may also be used. Some prefer the lateral decubitus position routinely, because the bowel tends to float upward and out of the path of the needle.

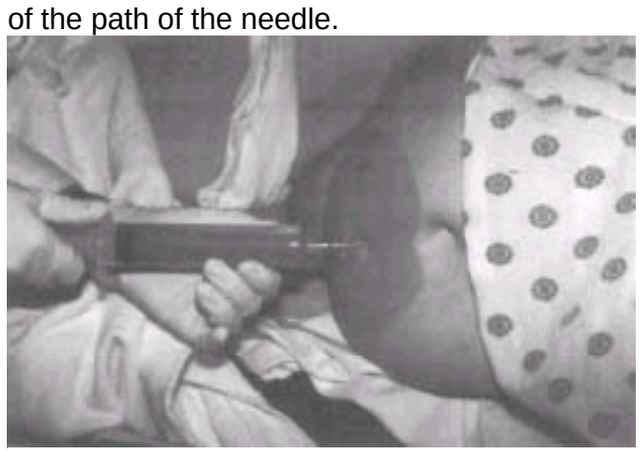

Figure 44-13 *A,* Z-tract method of paracentesis. The skin is pulled approximately 2 cm caudad in relation to the deep abdominal wall by the non-needle-bearing hand while the paracentesis needle is slowly being inserted directly perpendicular to the skin. *B,* After penetrating the peritoneum and obtaining fluid return, the skin is released. Note that the needle is now angulated caudally.

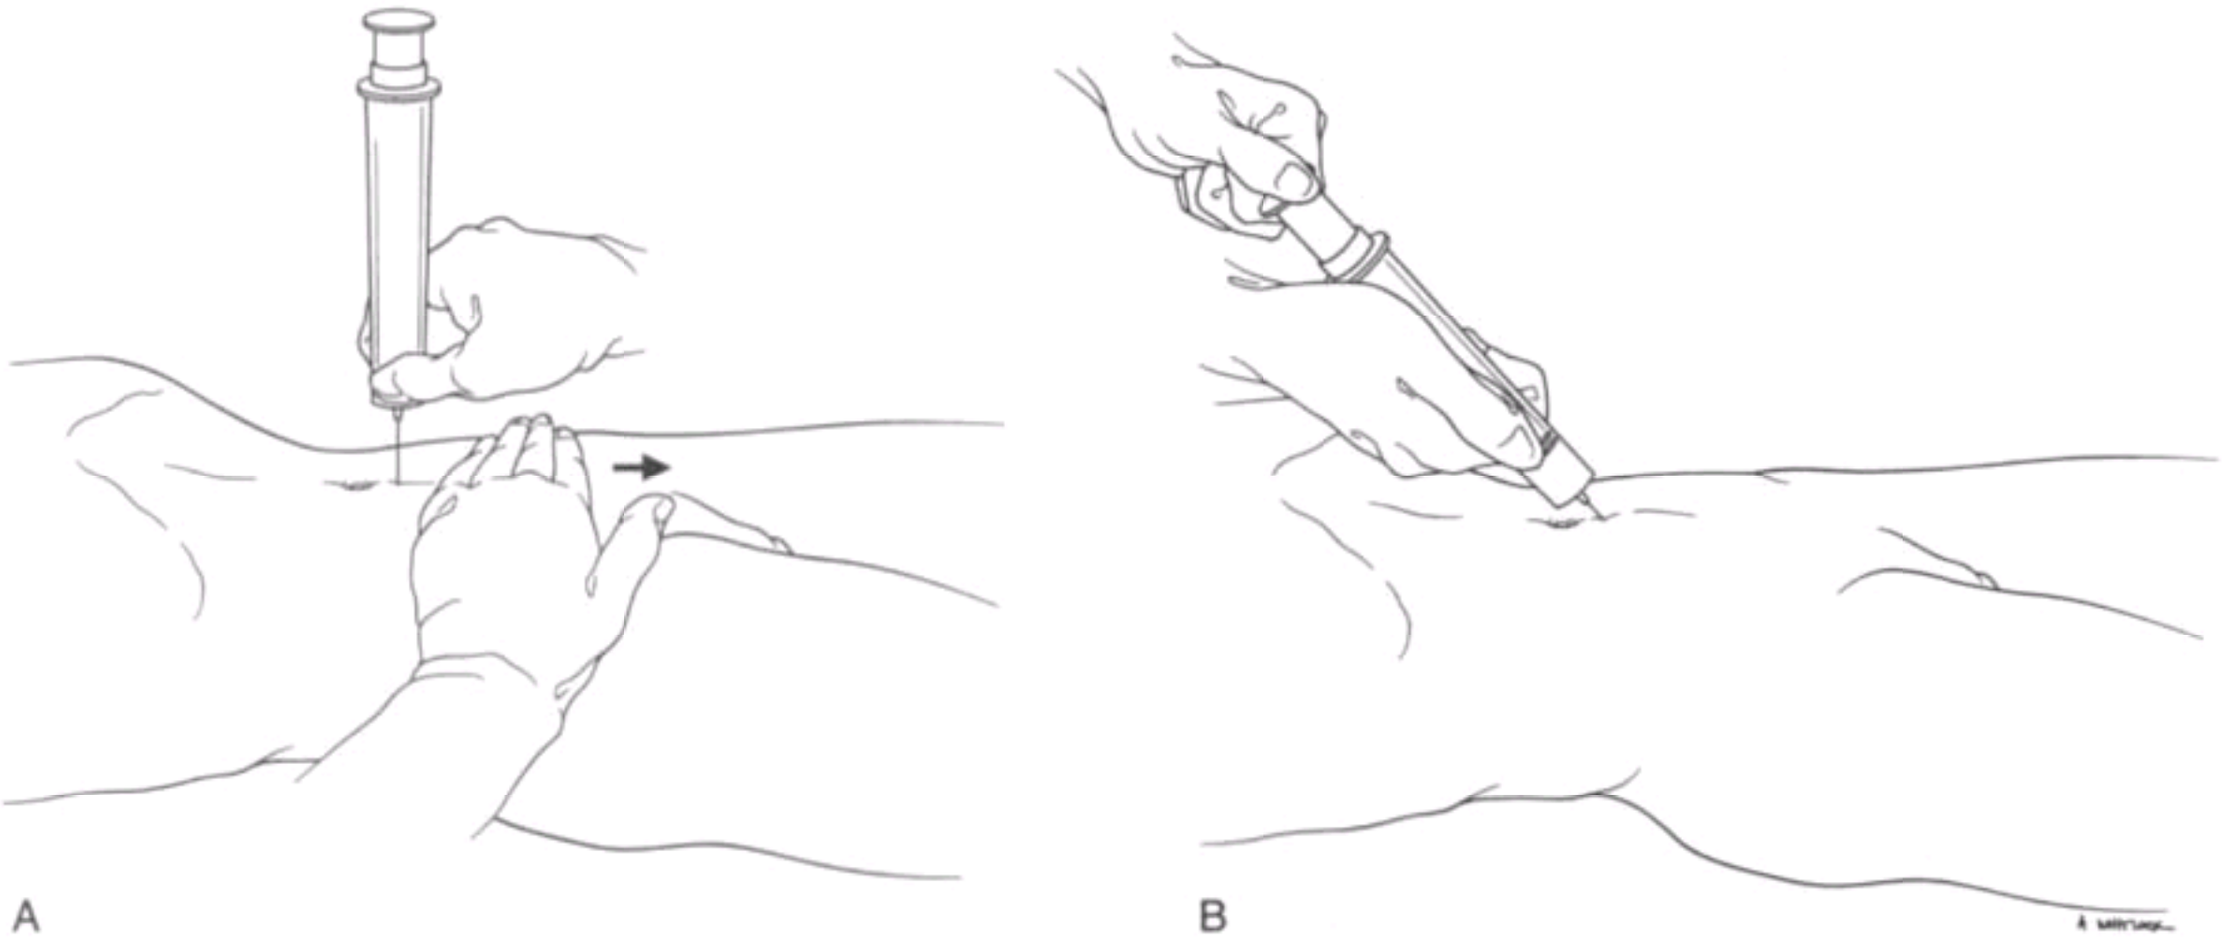

Figure 45-1 Indirect inguinal hernia.

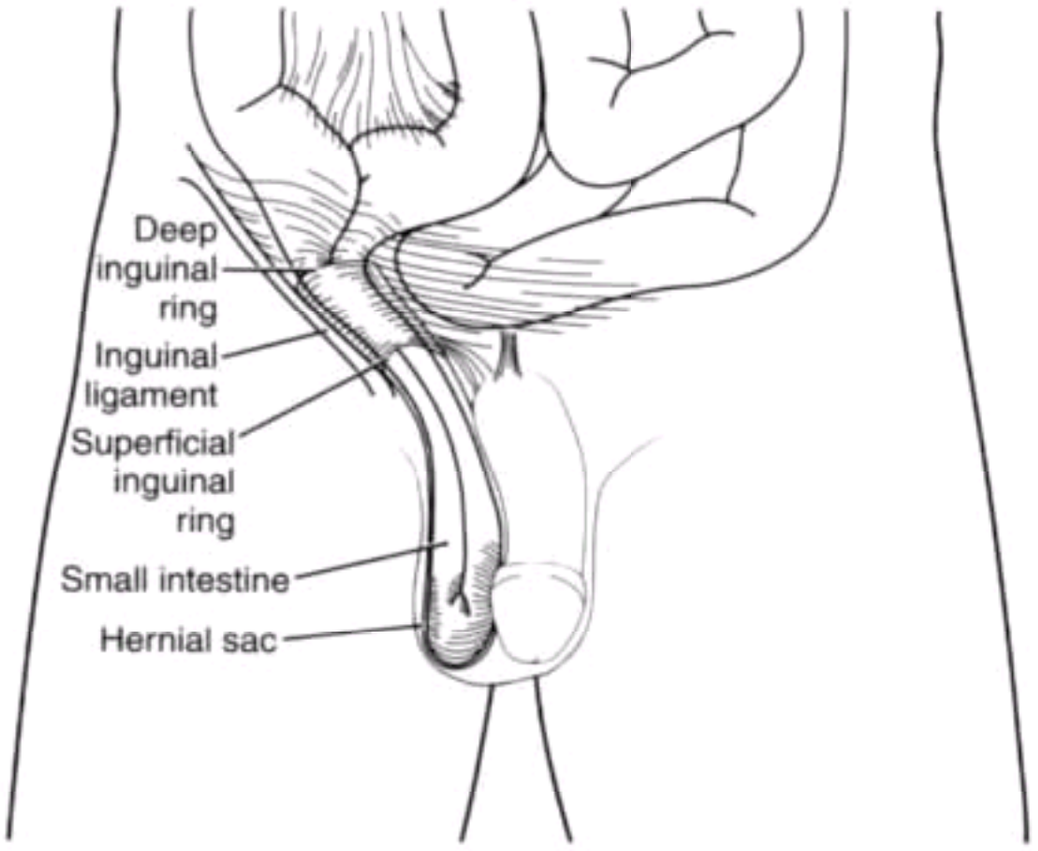

Figure 45-2 Direct inguinal hernia.

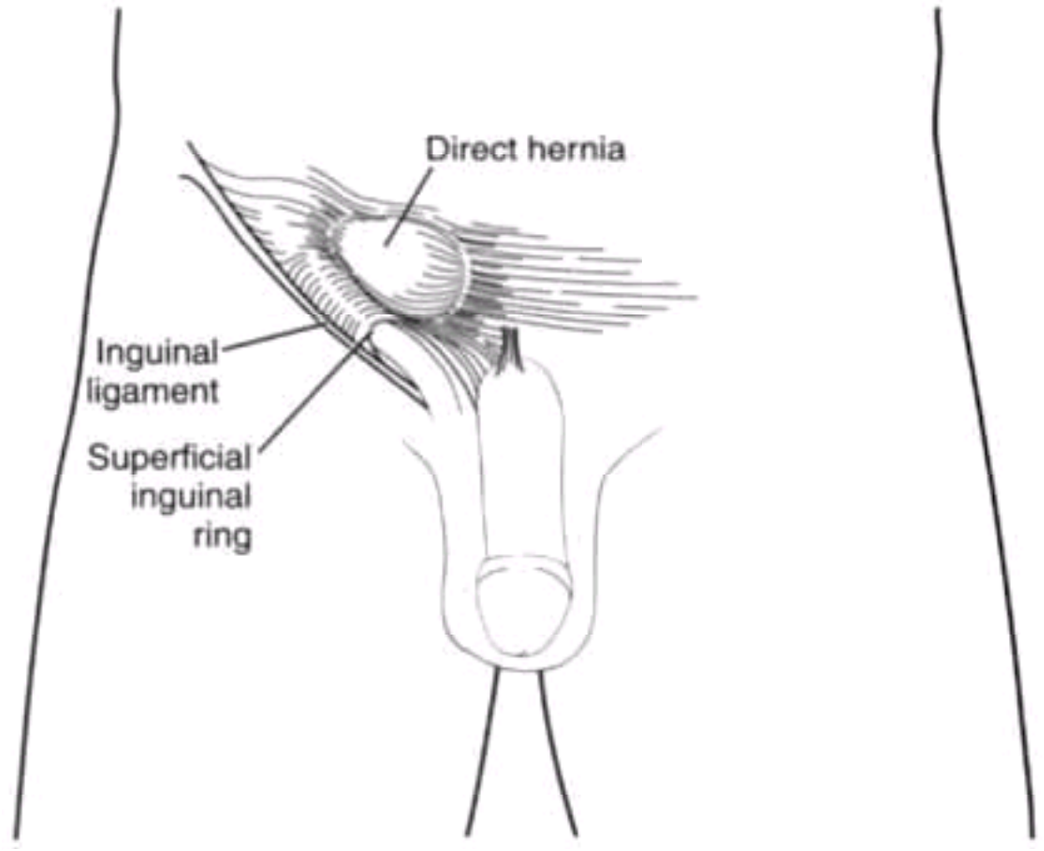

Figure 45-3 Femoral hernia.

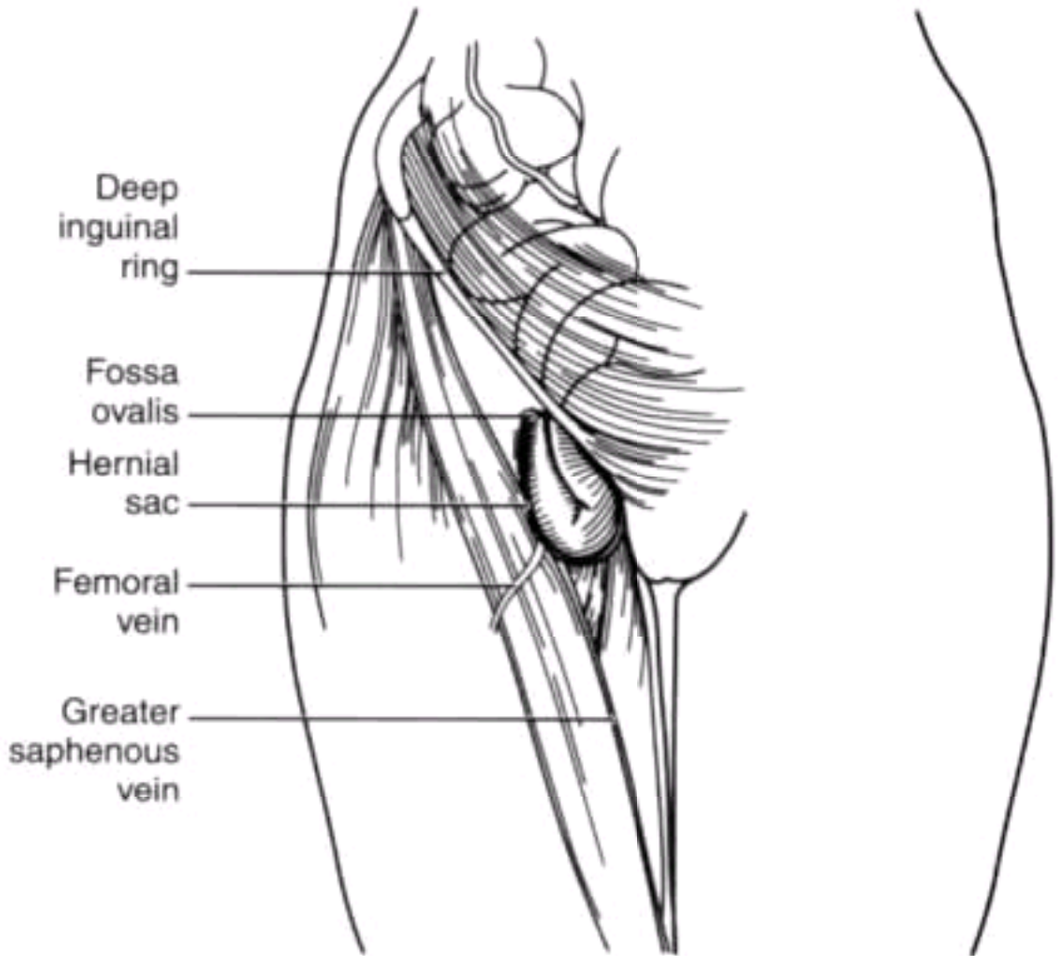

Figure 45-4 Ventral hernias. *A,* Incisional hernia. *B,* Umbilical hernia. *C,* Epigastric hernia. *D,* Spigelian hernia.

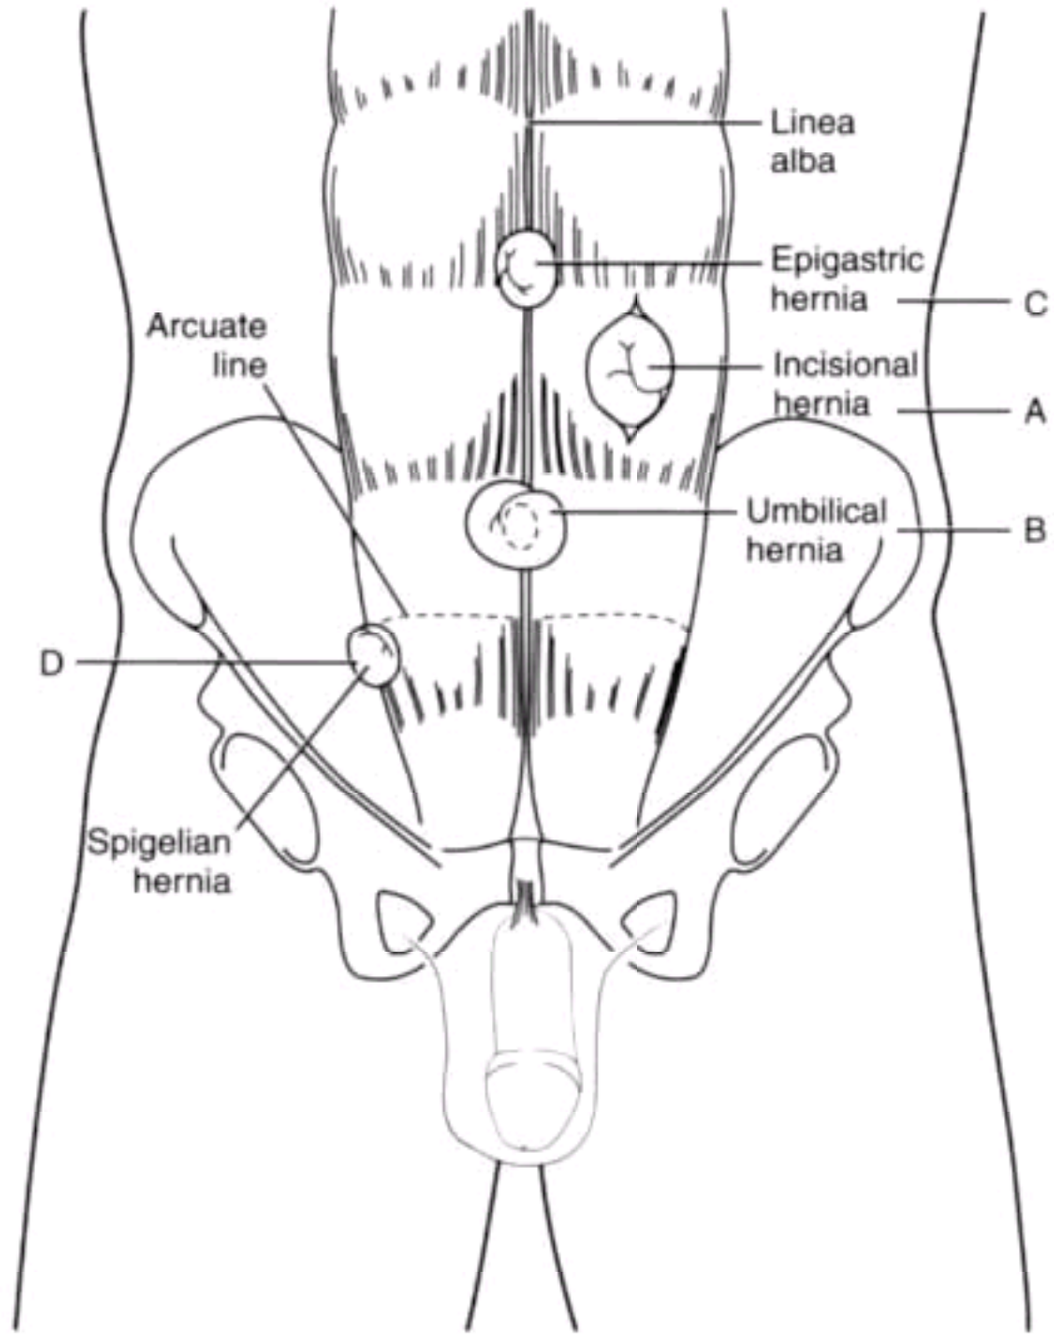

Figure 45-5 En masse reduction. *A,* When a hernia forms, it projects from the fascia into the subcutaneous fat. The object of reduction is to replace the hernia into the peritoneal cavity. *B,* If the hernia sac is partially reduced into the subcutaneous fat of an obese patient, it may appear reduced and may not be palpable owing to the patient's body habitus. However, the hernia is still susceptible to incarceration or ischemia, as it has not been returned to the peritoneal sac.

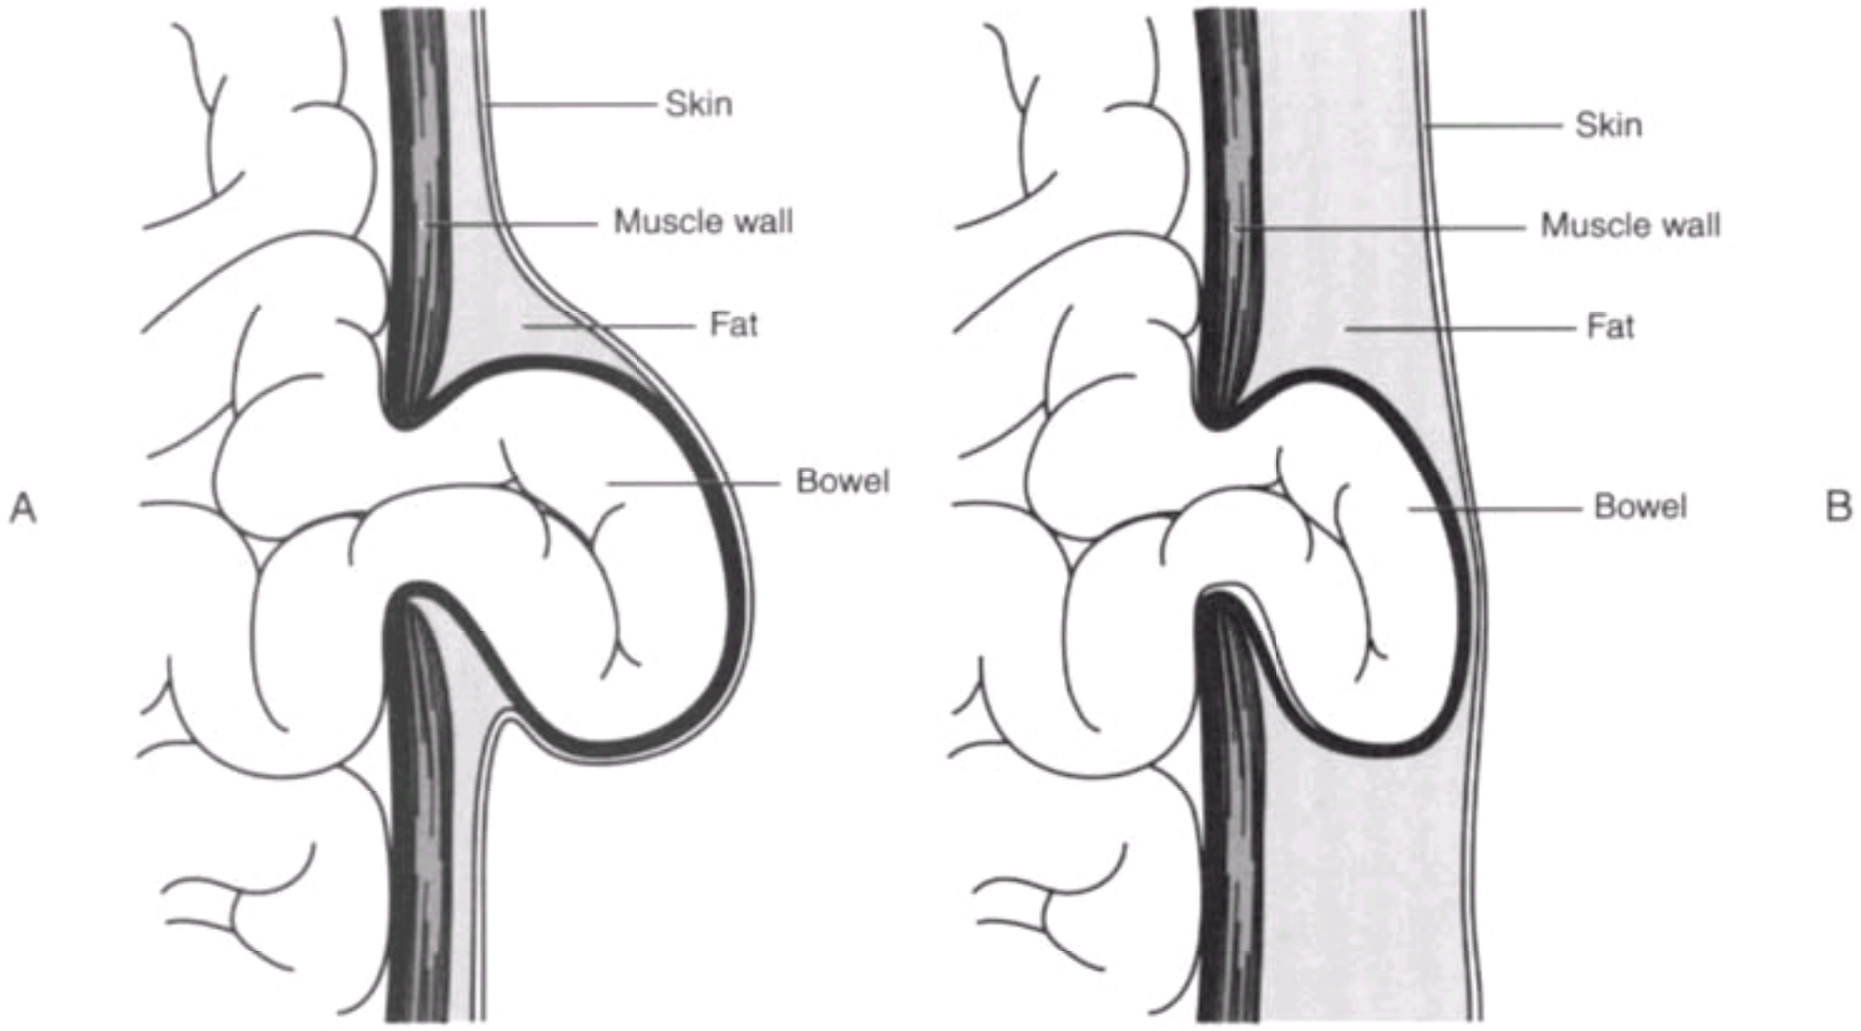

Figure 45-6 Hydrocele versus hernia. *A,* normal anatomy; *B,* noncommunicating hydrocele that may be confused with hernia; *C,* indirect hernia that can be palpated from inguinal ring to testicle.

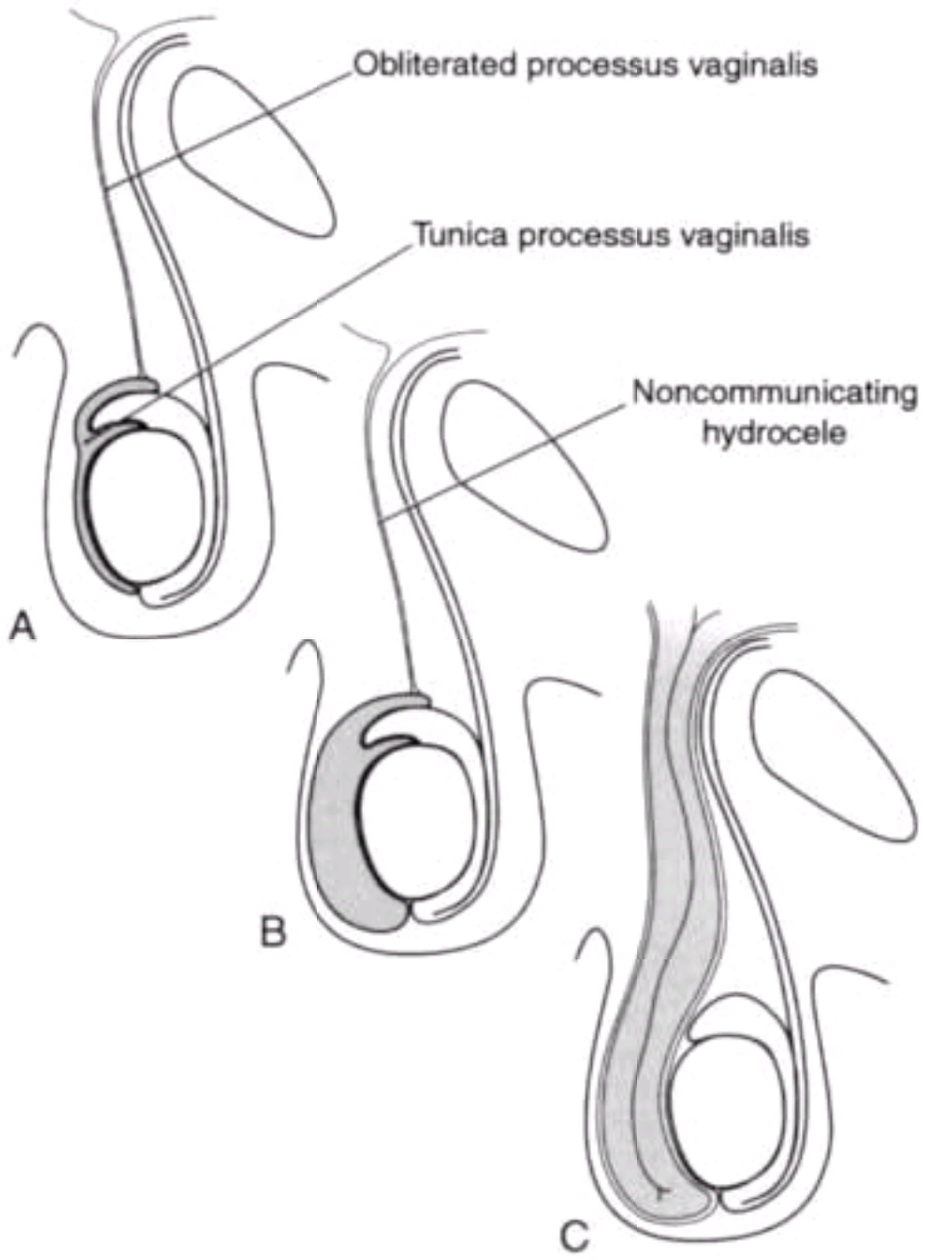

Figure 45-7 Ballooning of contents. *A,* When reducing a hernia, the contents may ride up over the edge of the fascial defect. This leads to ballooning of the contents around the neck of the hernia, which hinders the reduction. *B,* By placing fingers along the edge of the hernia neck, one can direct the contents into instead of over the fascial defect.

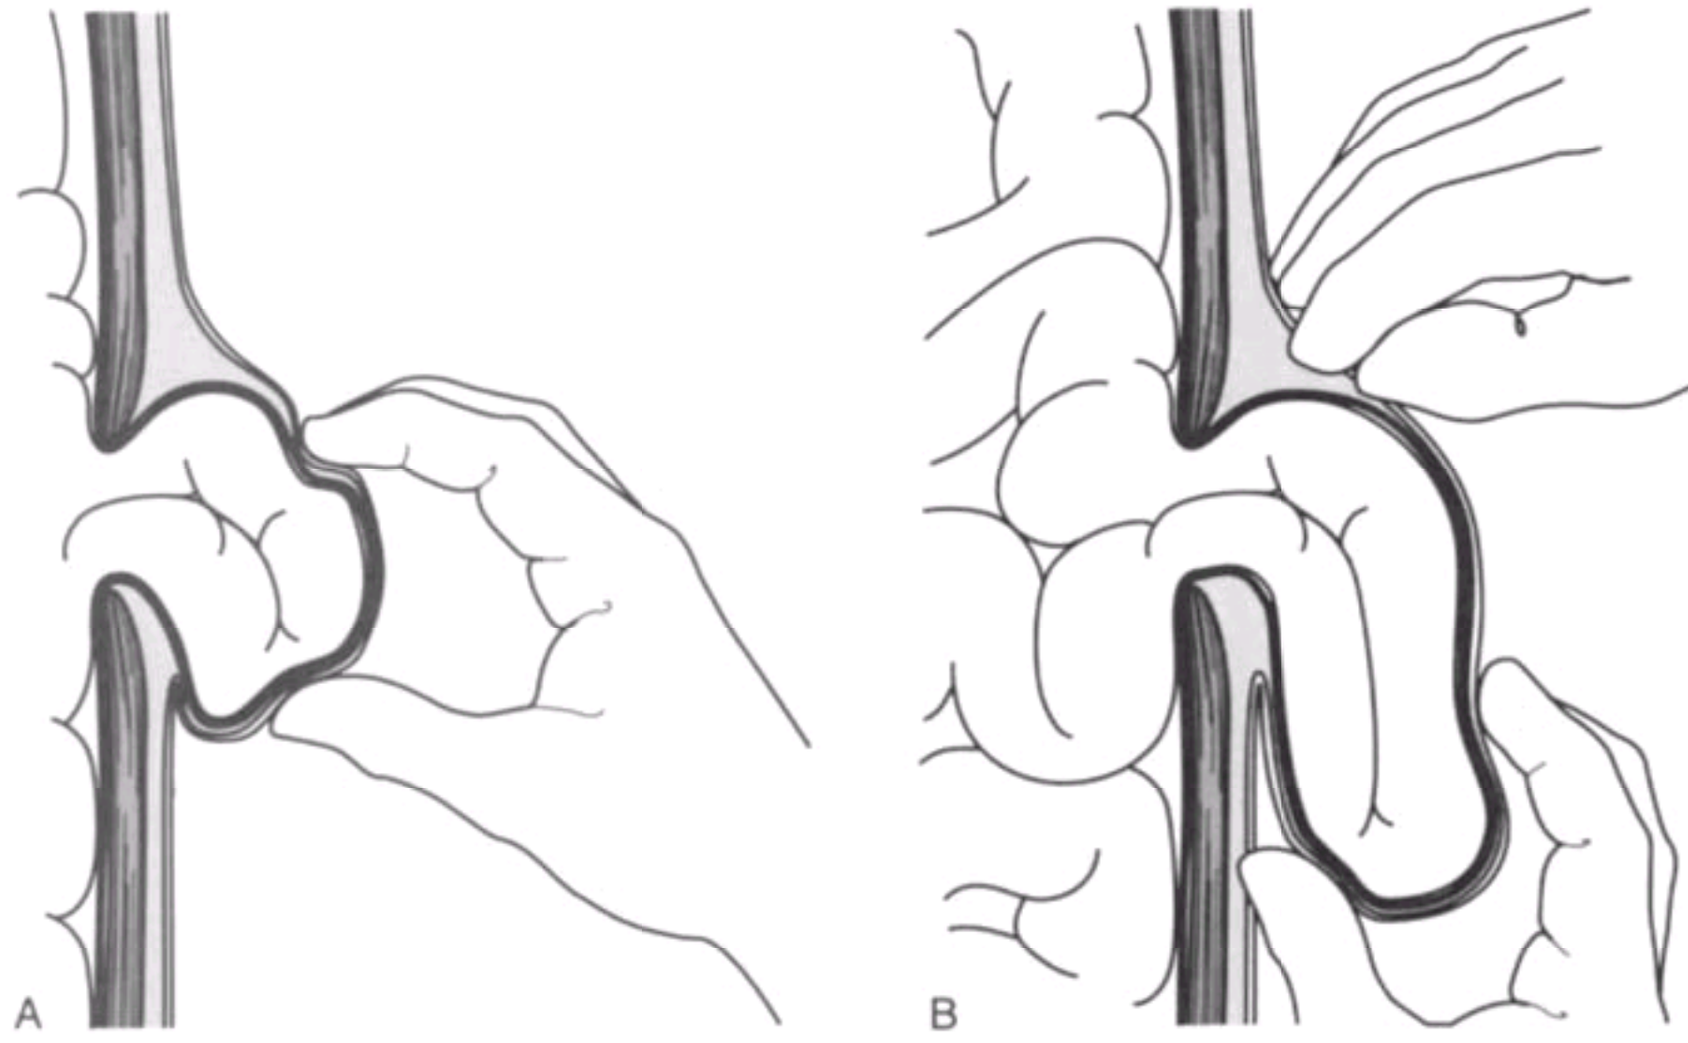

Figure 45-8 Guiding hernia into place. A, The hernia can be divided into several sections. The proximal portion is closest to the neck or fascial defect, through which the hernia protrudes. The distal portion is farthest from the neck. B, When attempting to reduce the hernia, be careful not to invaginate the distal portion first or the proximal portion may obstruct the opening as it is pushed over the sides. C, The last portion of the bowel that exits into the hernia sac should be the first returned to the peritoneal cavity.

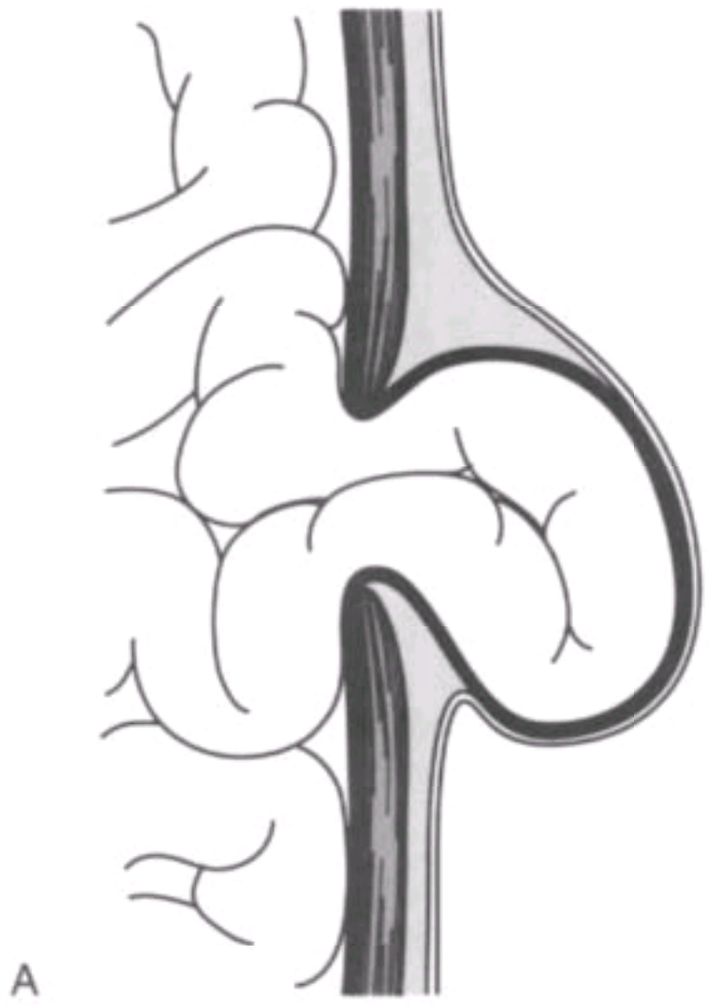
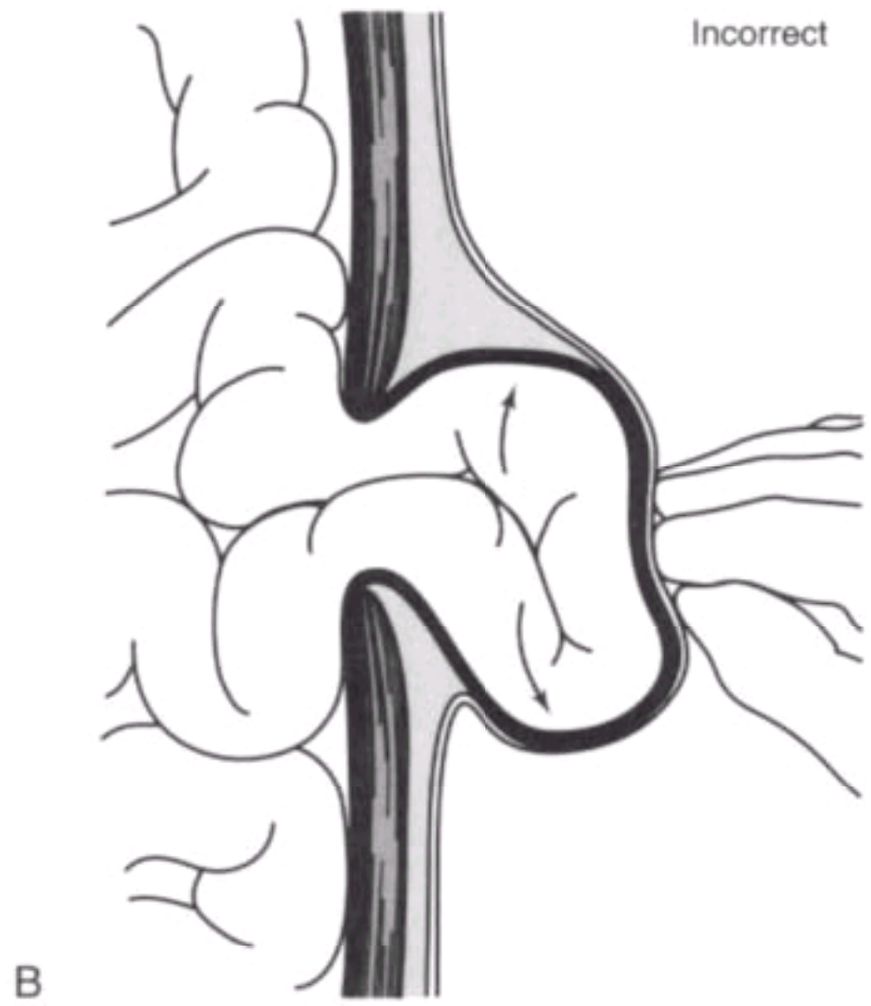
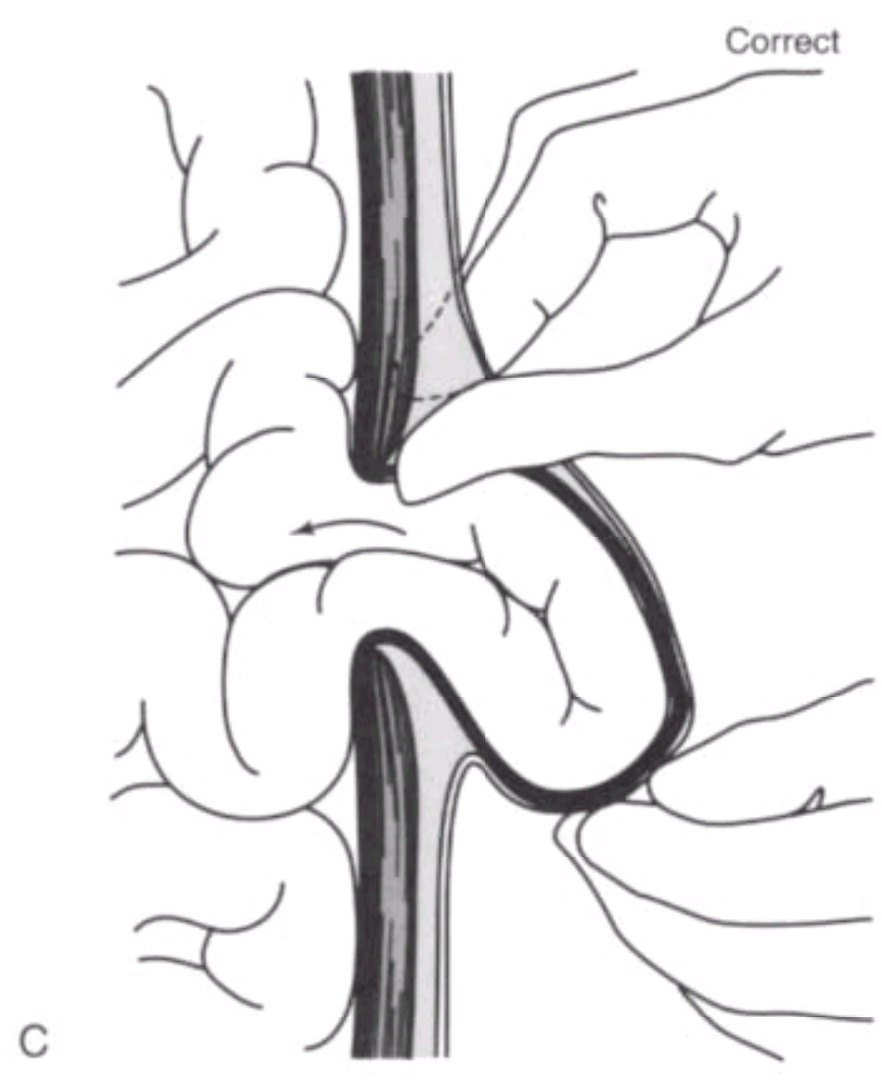


A



B



C

Figure 45-9 *A,* This patient presented with signs and symptoms of a bowel obstruction. It was not until the surgery consultant removed the patient's pants that an inguinal hernia was found to be the cause of the obstruction. *B,* After intravenous analgesia/sedation, the inguinal ring is stabilized with the left hand. *C,* Slow gentle, yet persistent pressure is applied to reduce the hernia. It required 5 minutes. The hernia was reduced. Although this was a reducible hernia, because of the bowel obstruction this patient should be admitted to the hospital for observation and next day surgery.

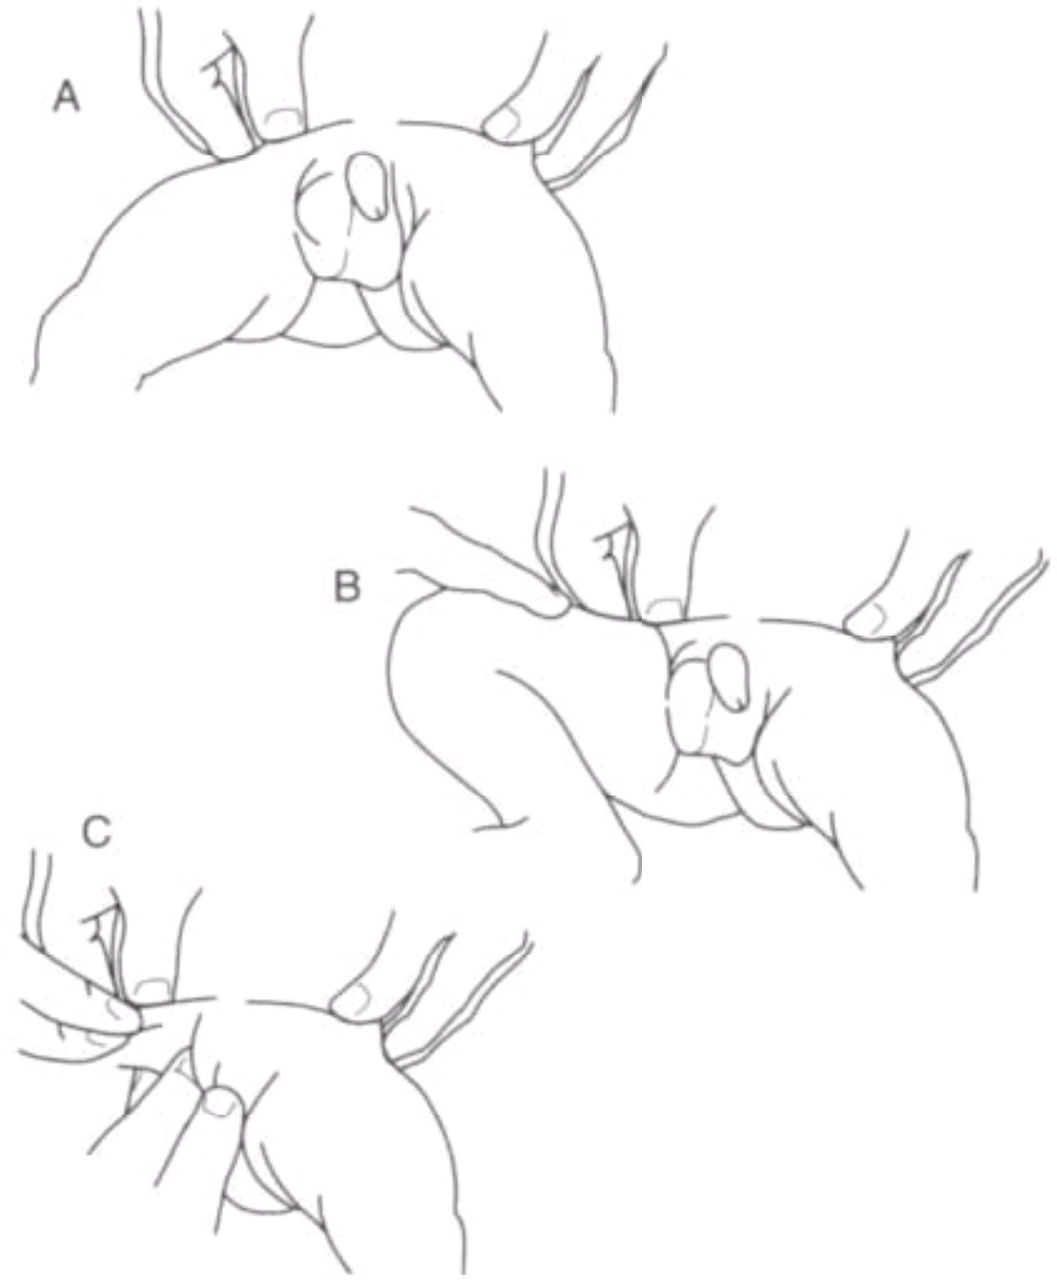

Figure 46-1 Anatomy of the terminal gastrointestinal tract. *(Redrawn from Abrahams PH, Webb PJ: Clinical Anatomy of Practical Procedures. London, Pitman, 1975.)*

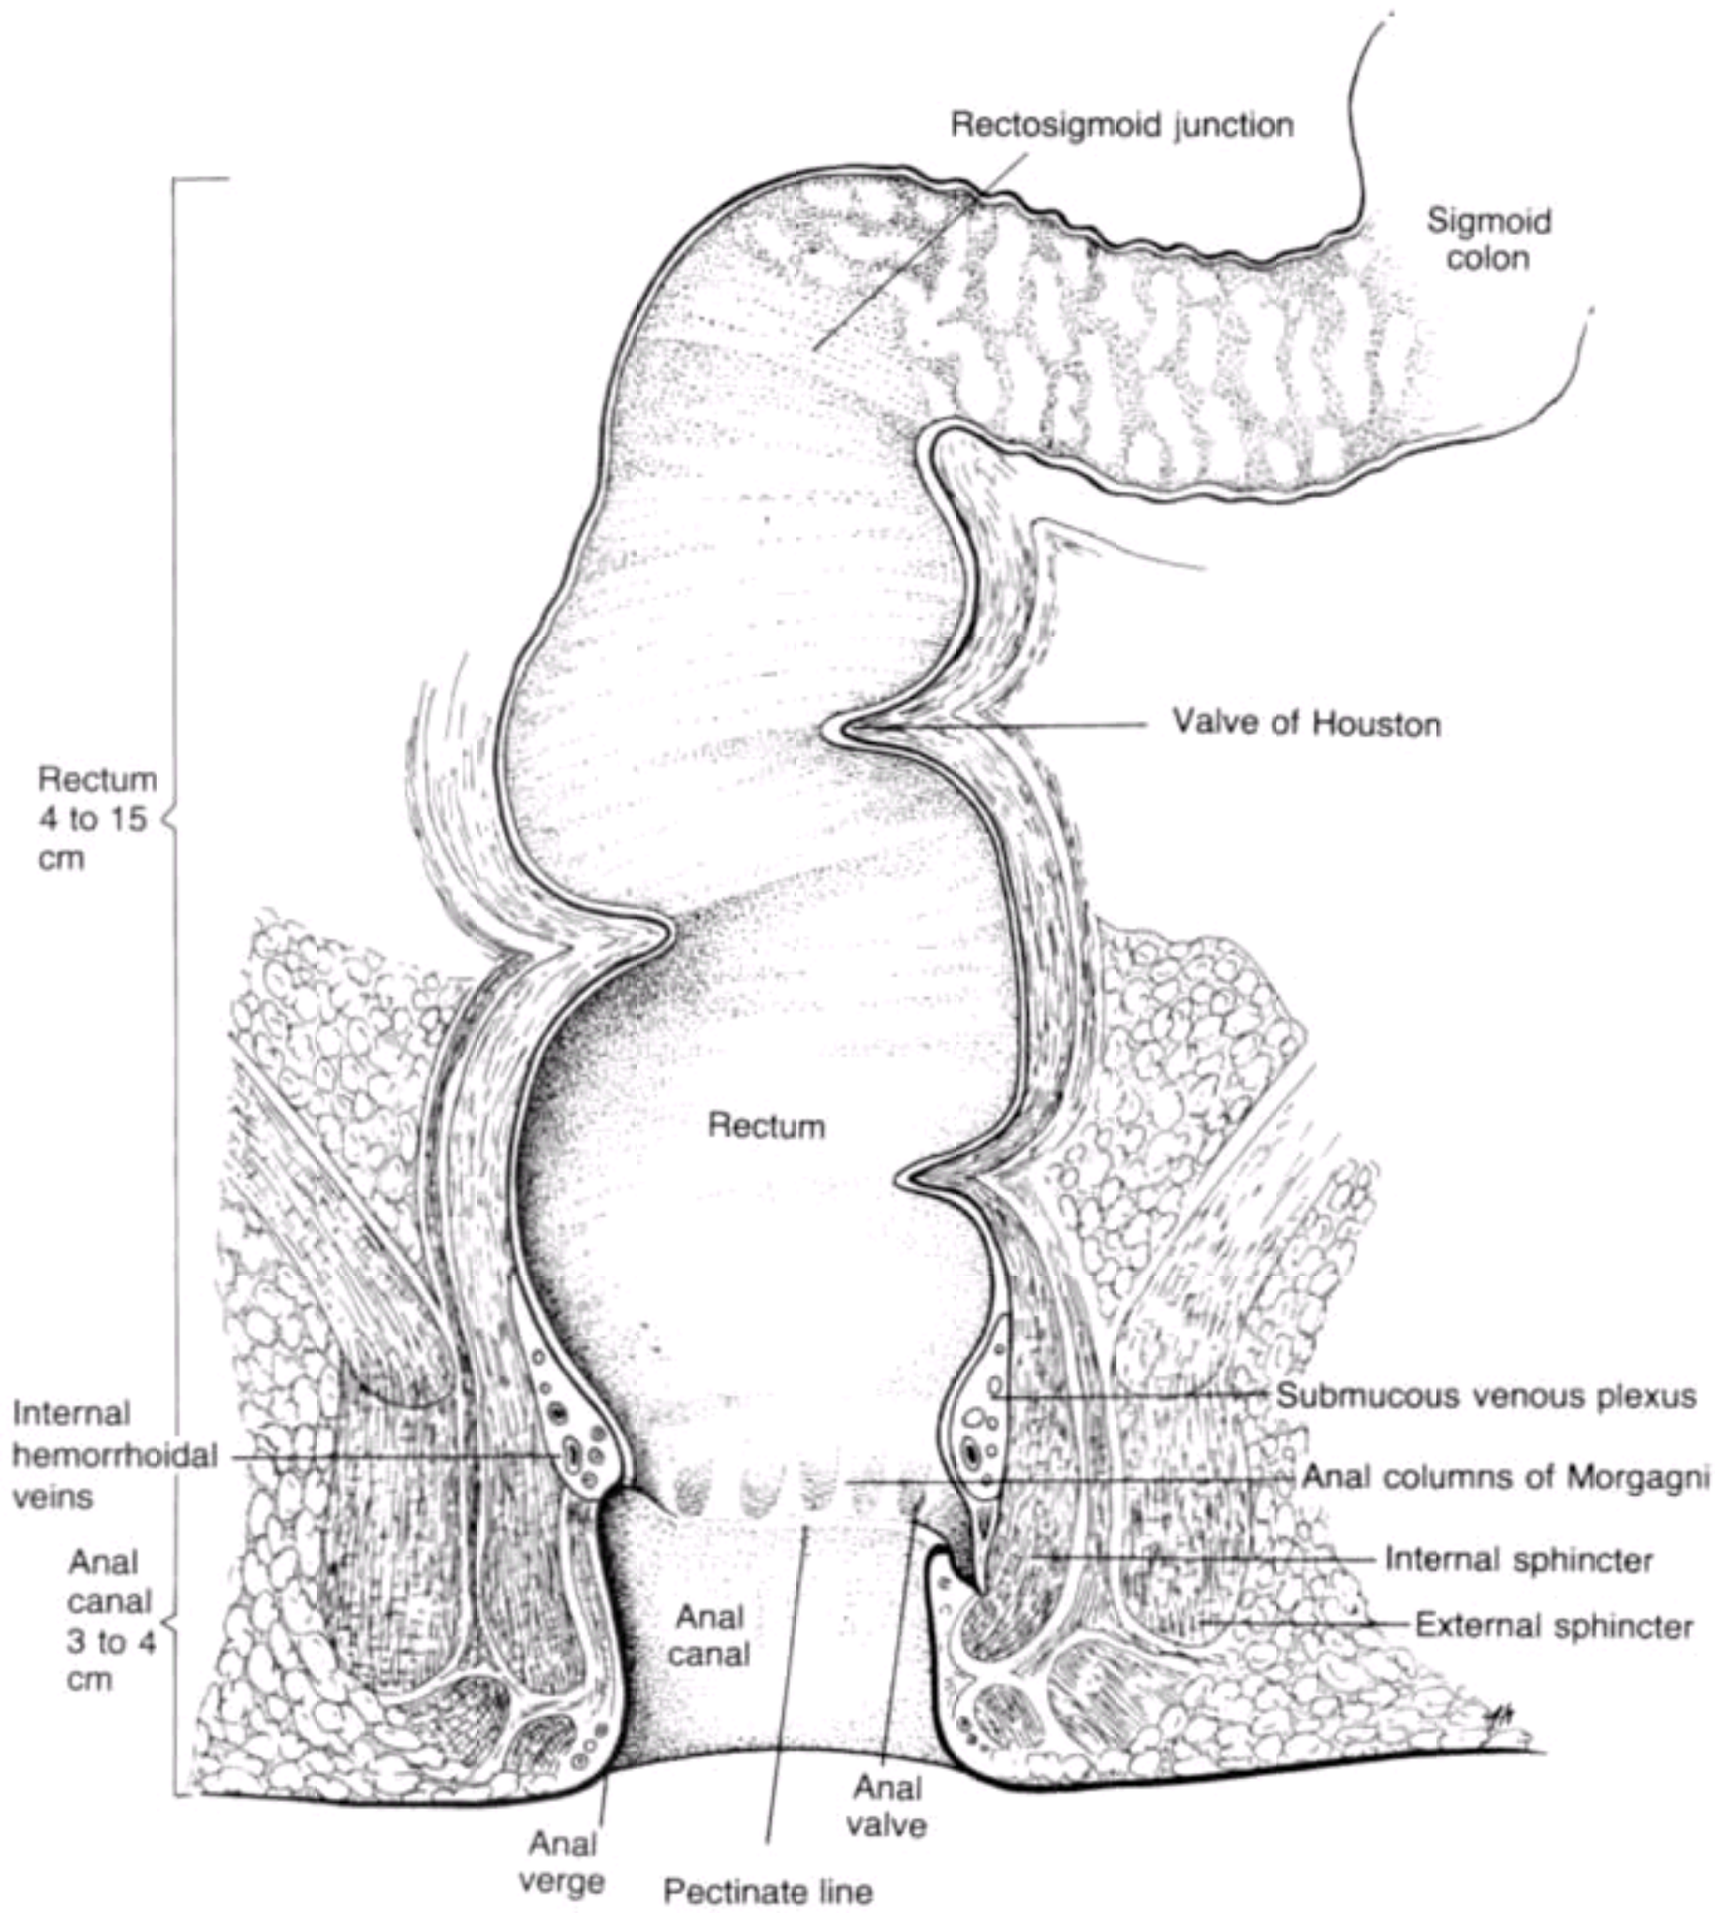

Figure 46-2 Stainless steel anoscope. *A,* Anoscope with obturator. *B,* Anoscope prepared for insertion.

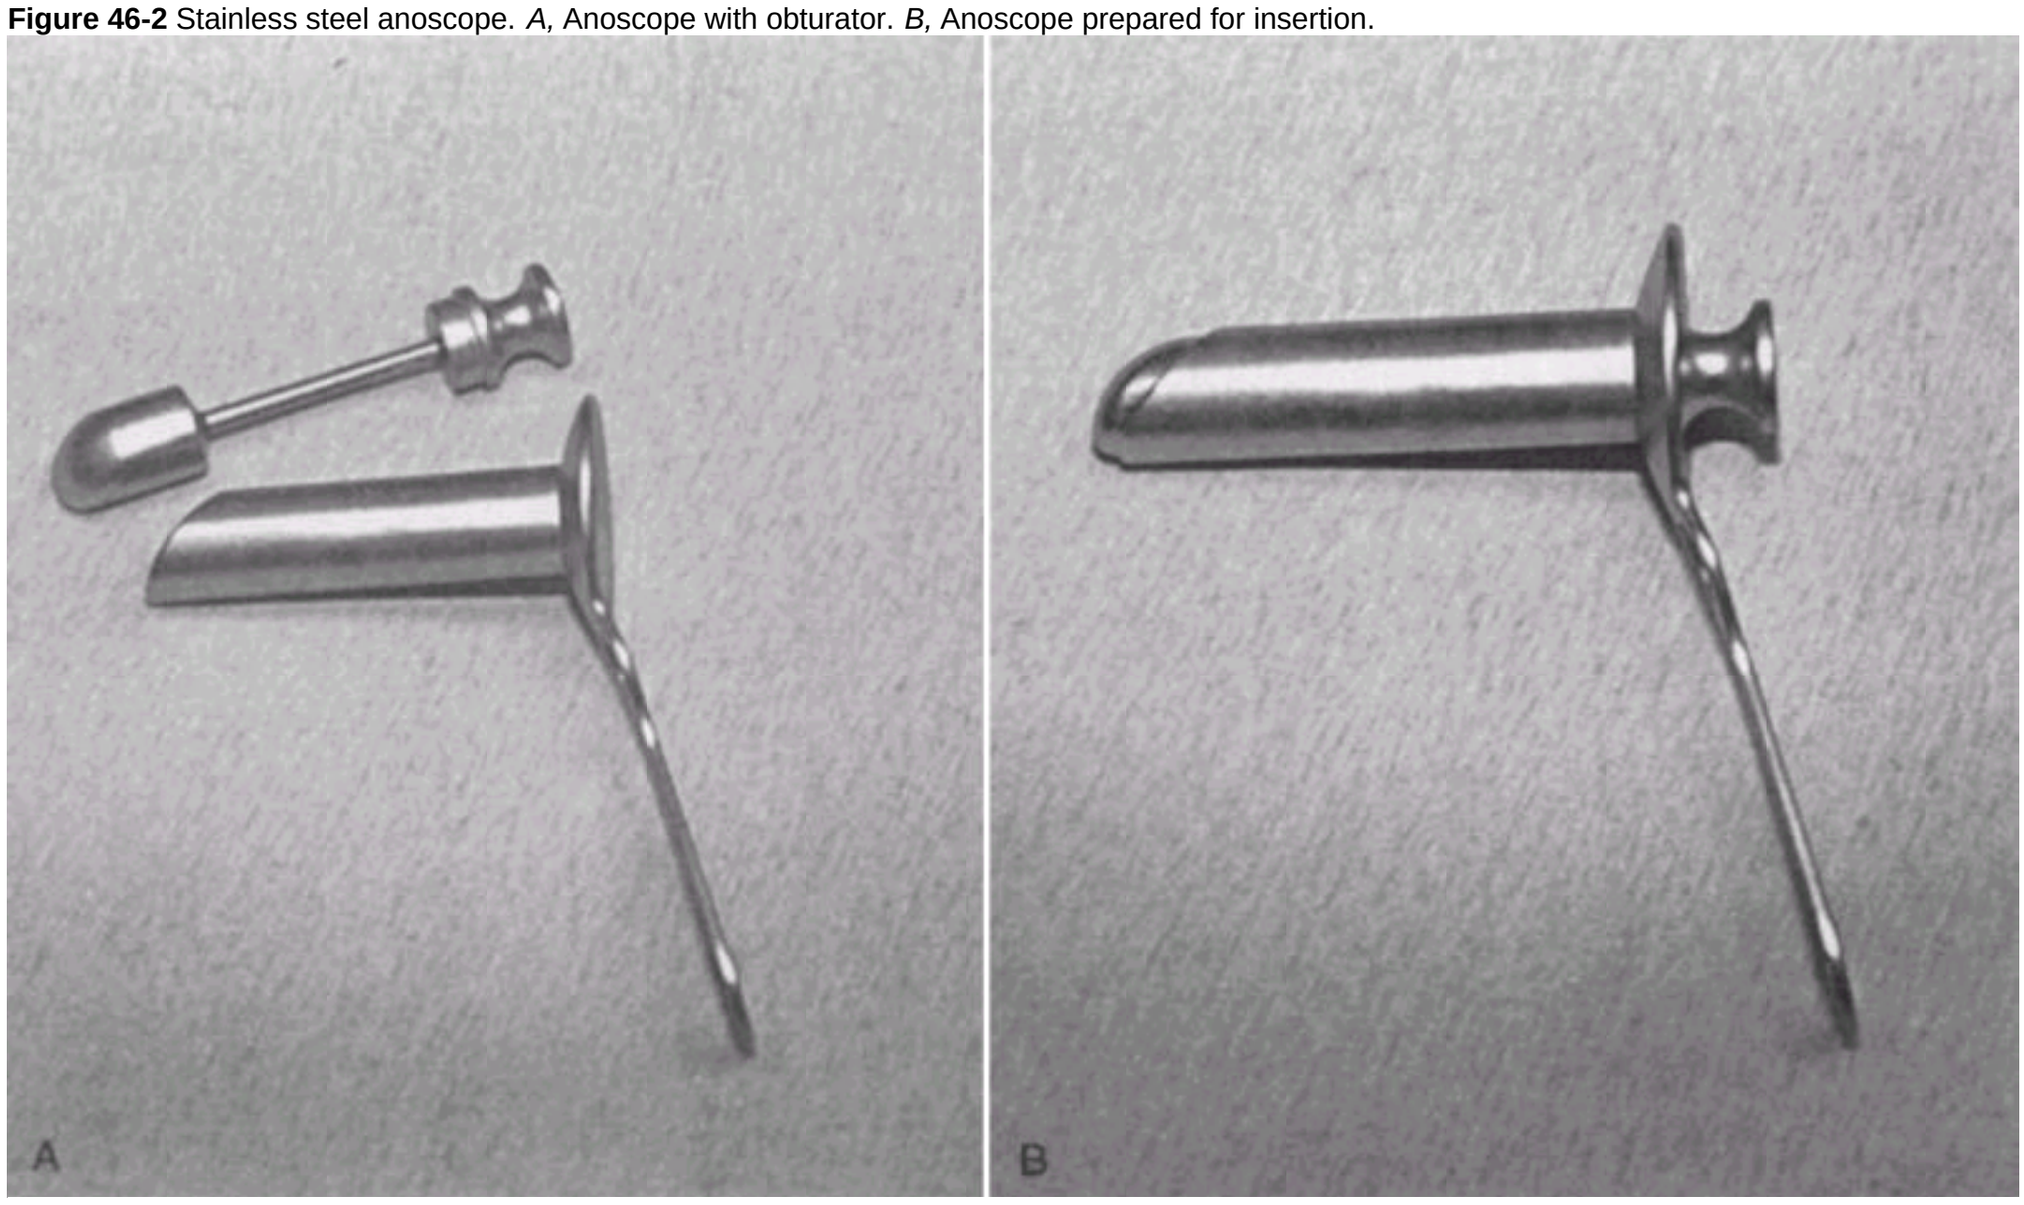

Figure 46-3 Anoscope with integrated light source. *A,* Scope with obturator in place for insertion. *B,* Scope attached to light source, also with obturator in place. Generally the scope is inserted before attaching it to the light source.

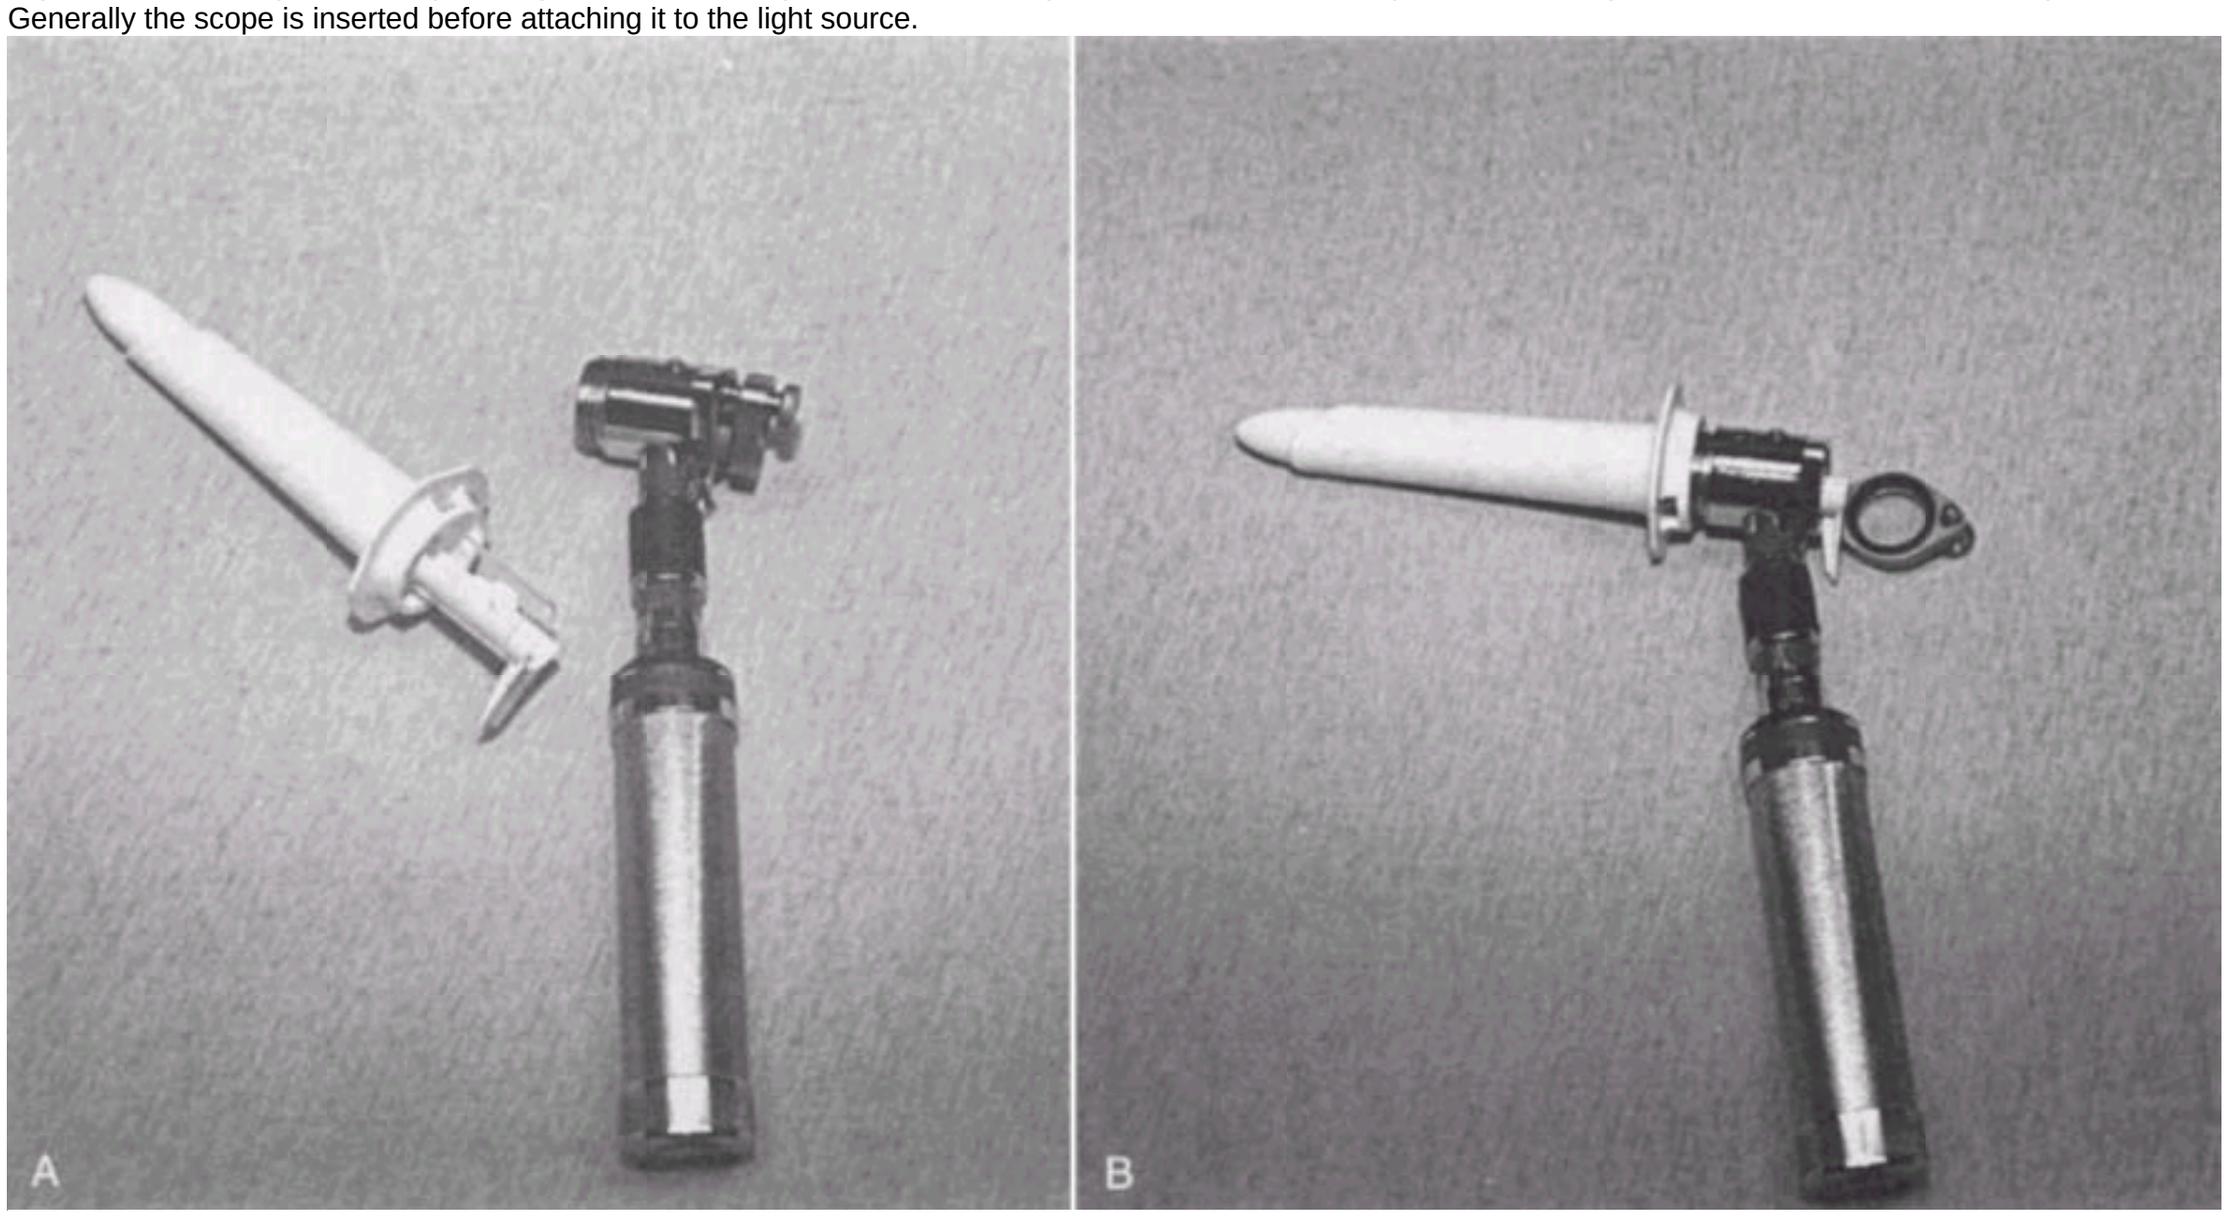

Figure 46-4 Positions for performing sigmoidoscopy or anoscopy. *(From Hill GJ II: Outpatient Surgery, 3rd ed. Philadelphia, WB Saunders, 1988.)*

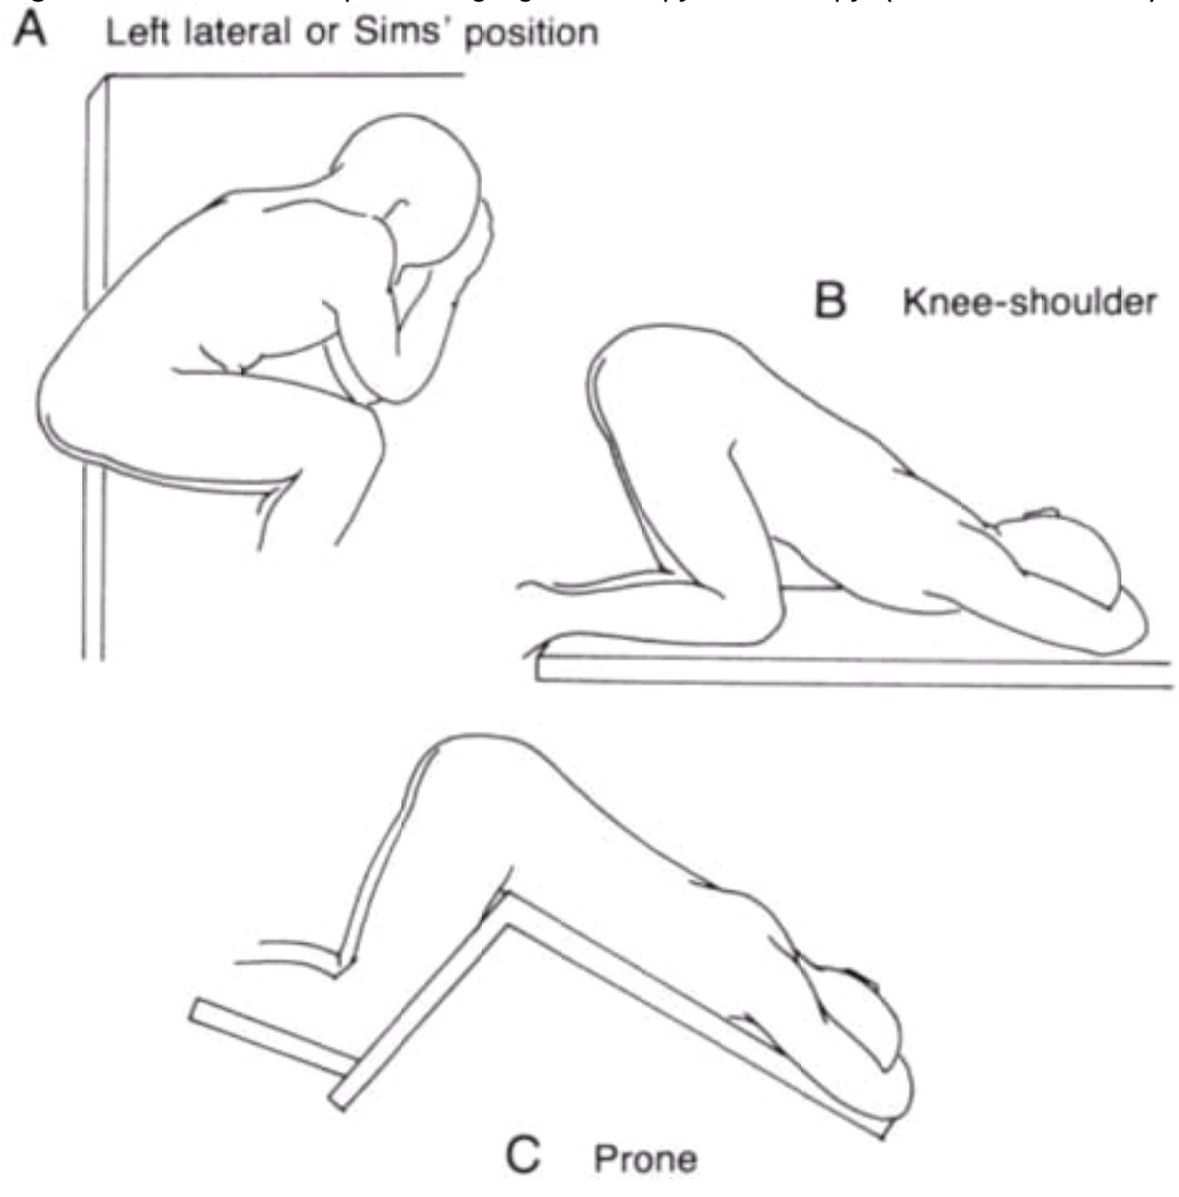

Figure 46-5 Anoscopy. Initially, with the thumb used to keep the obturator fully inserted during passage of the instruments, the anoscope is directed toward the umbilicus, and the obturator is not withdrawn until the scope has been passed to the hilt. Detailed examination is performed on withdrawal of the instrument. A penlight is used in this illustration for illumination of the deep anus.

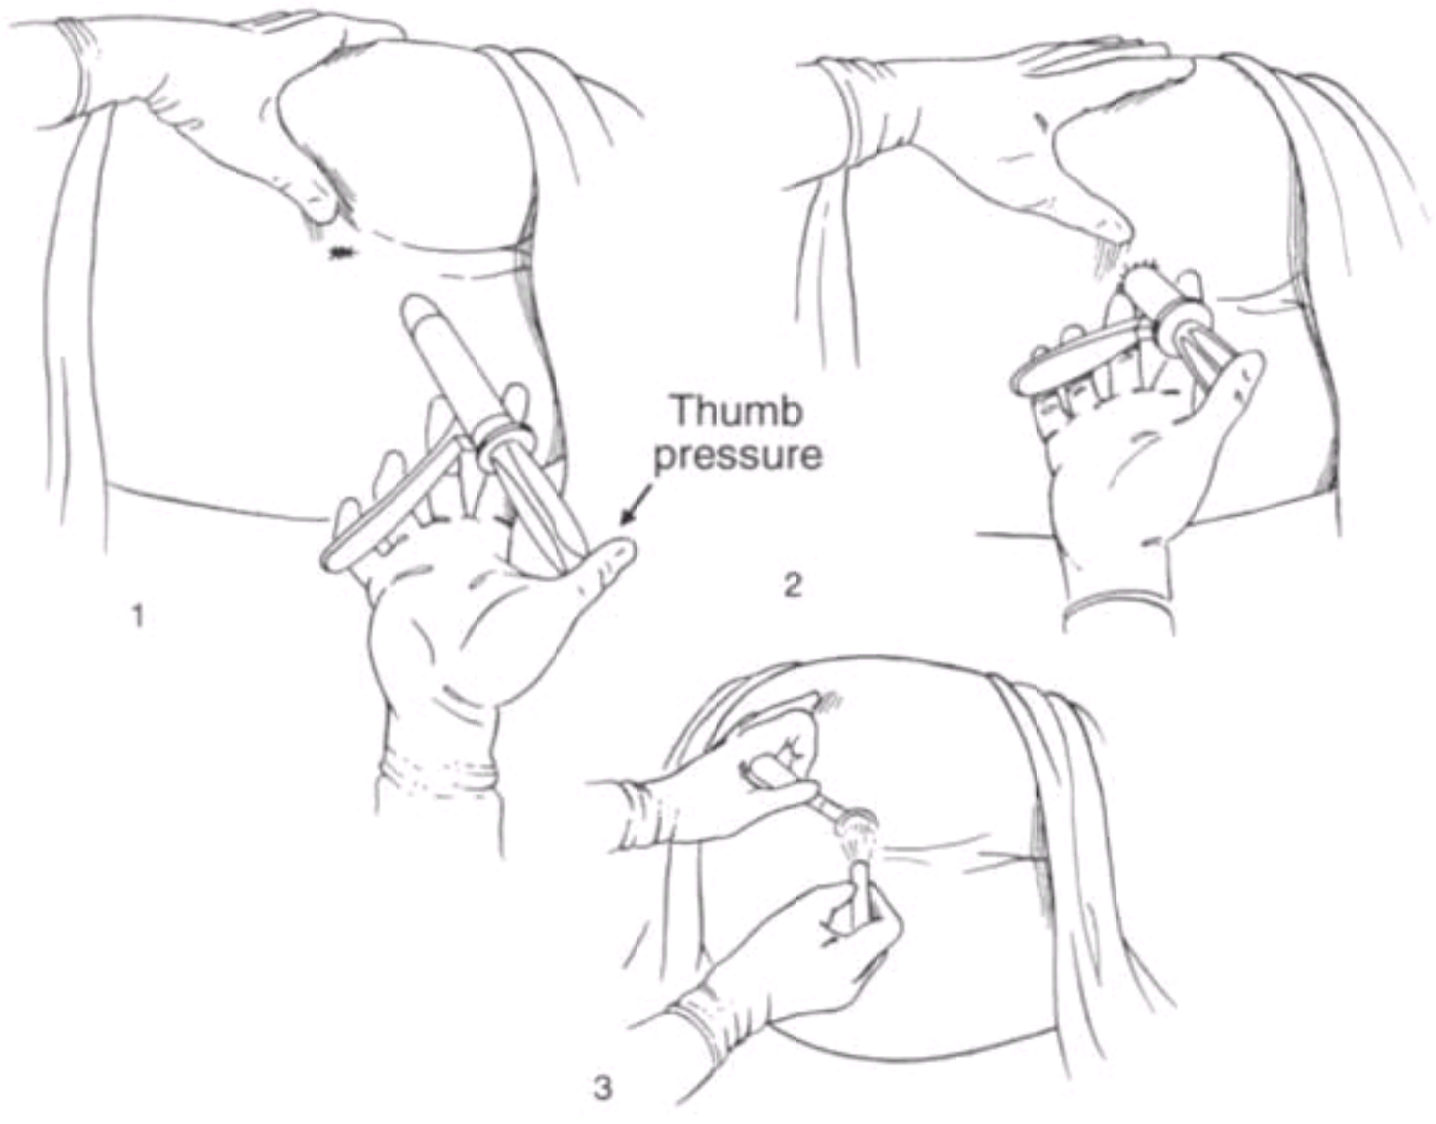

Figure 46-6 *A*, Anatomic location of internal and external hemorrhoids. *B*, Large thrombosed external hemorrhoid. *C*, This thrombosed external hemorrhoid spontaneously ruptured. This demonstrates the concept that a thrombosed hemorrhoid is actually a hematoma into soft tissues. *D*, Thrombosed prolapsed internal hemorrhoids. These hemorrhoids cannot be reduced and are quite painful. They should not be incised in the ED, a formal hemorrhoidectomy is required if conservative measures are not successful. They are often mistaken for a partial "rectal prolapse". *(A from Hill GJ II: Outpatient Surgery. 2nd ed. Philadelphia, WB Saunders, 1980. Reproduced by permission.)*

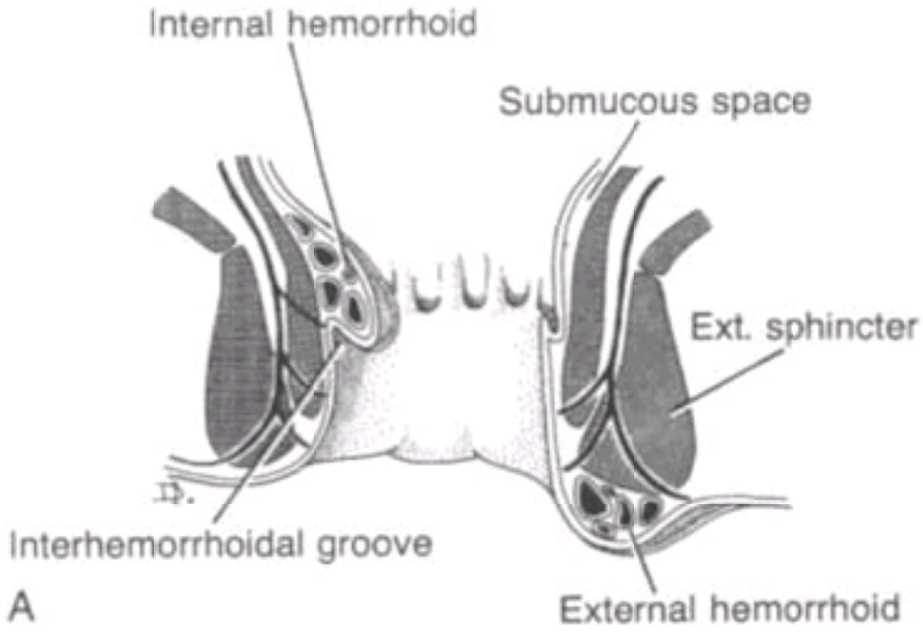

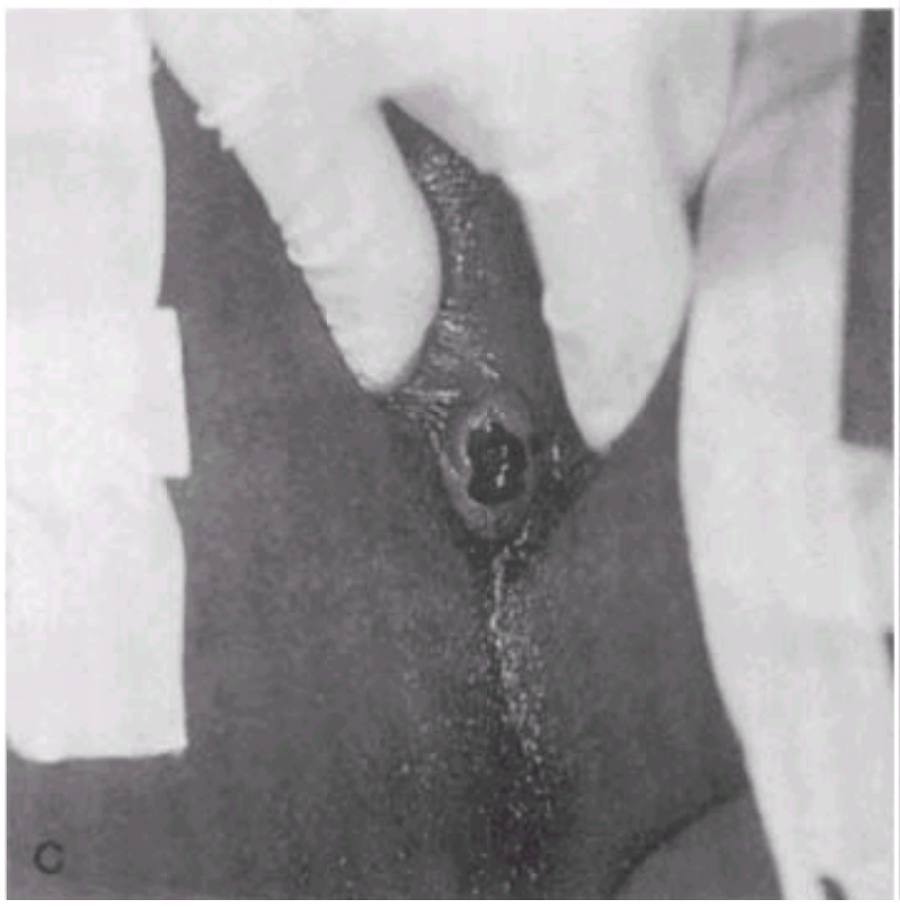

Figure 46-7 Taping the buttocks to gain exposure.

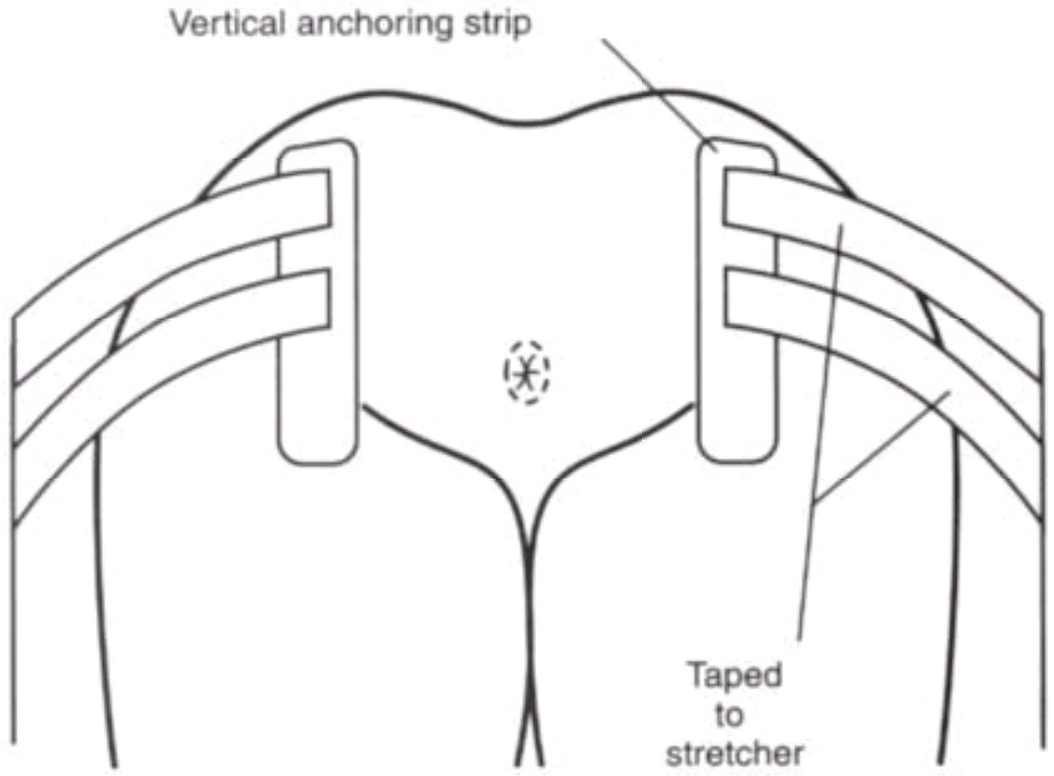

Figure 46-8 Very adequate anesthesia often can be obtained by a single injection of long-acting bupivacaine. *A,* A 25-ga needle is inserted in the middle of the swollen hemorrhoid, just below the skin surface. *B,* With the injection, the anesthetic spreads over the surface of the dome and into the surrounding tissue. A field block about the hemorrhoid can also be used, but it is much more painful, usually not required, and not advised as a first attempt at anesthesia.

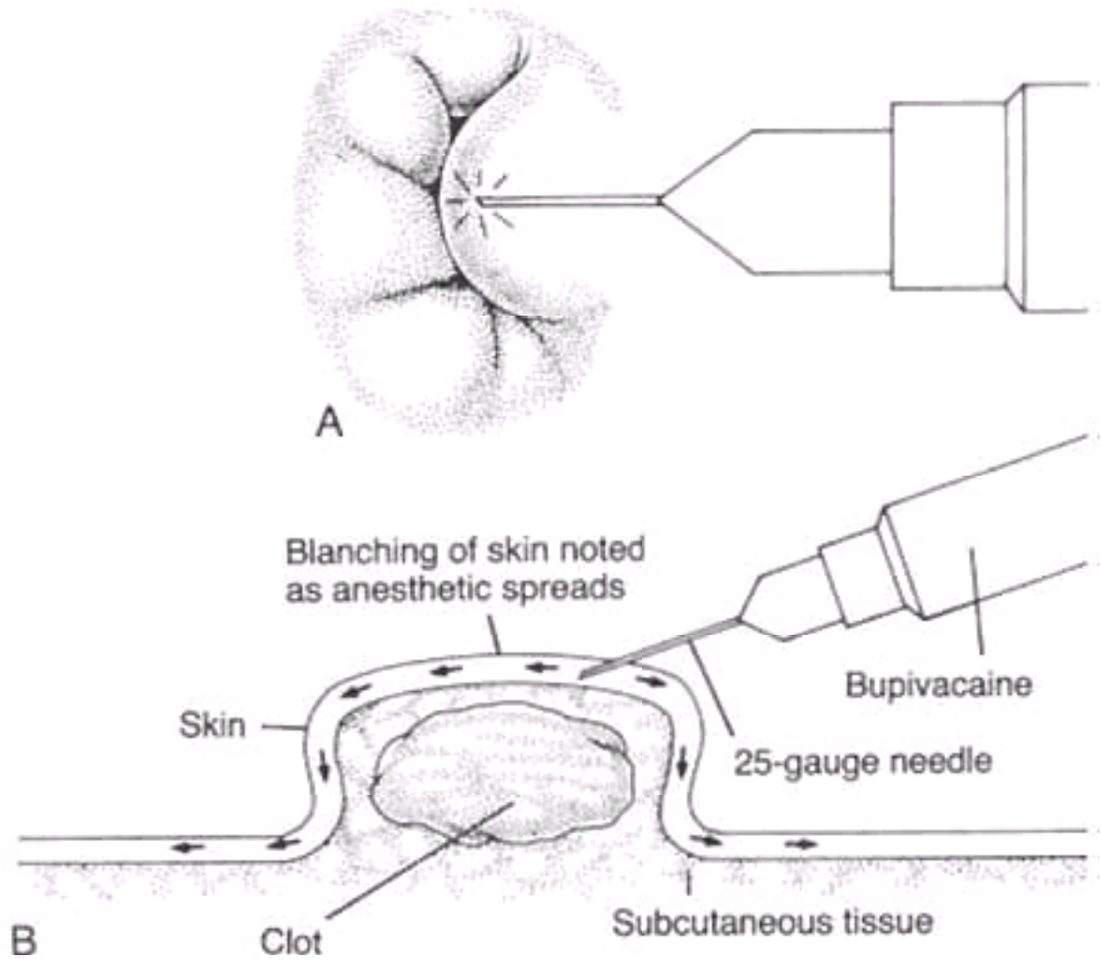

Figure 46-9 Subcutaneous injection of a long-acting local anesthetic using a field block will provide complete anesthesia during a procedure, but is rarely required.

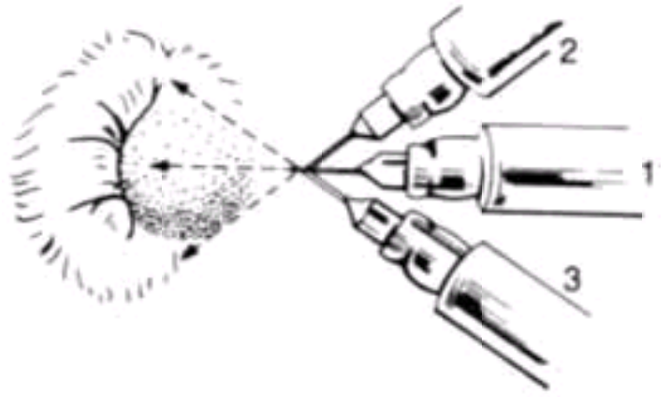

Figure 46-10 An unroofing technique uses an elliptic or triangular incision that removes a piece of the overlying skin. A simple linear incision should not be used.

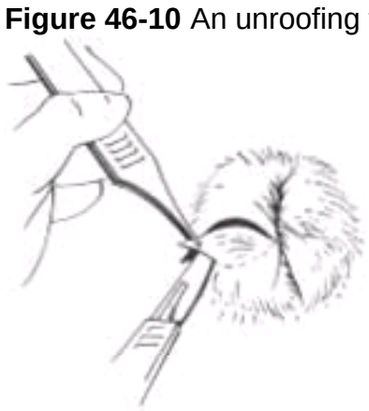

Figure 46-11 Blood clots are removed with forceps *(A)* or expressed with the fingers *(B)*. Often multiple clots are present, and all should be removed. *C,* After the initial clot is removed, an assistant spreads the incision to expose the base of the hemorrhoid and allow other smaller clots to be removed individually with forceps or with a small hemostat.

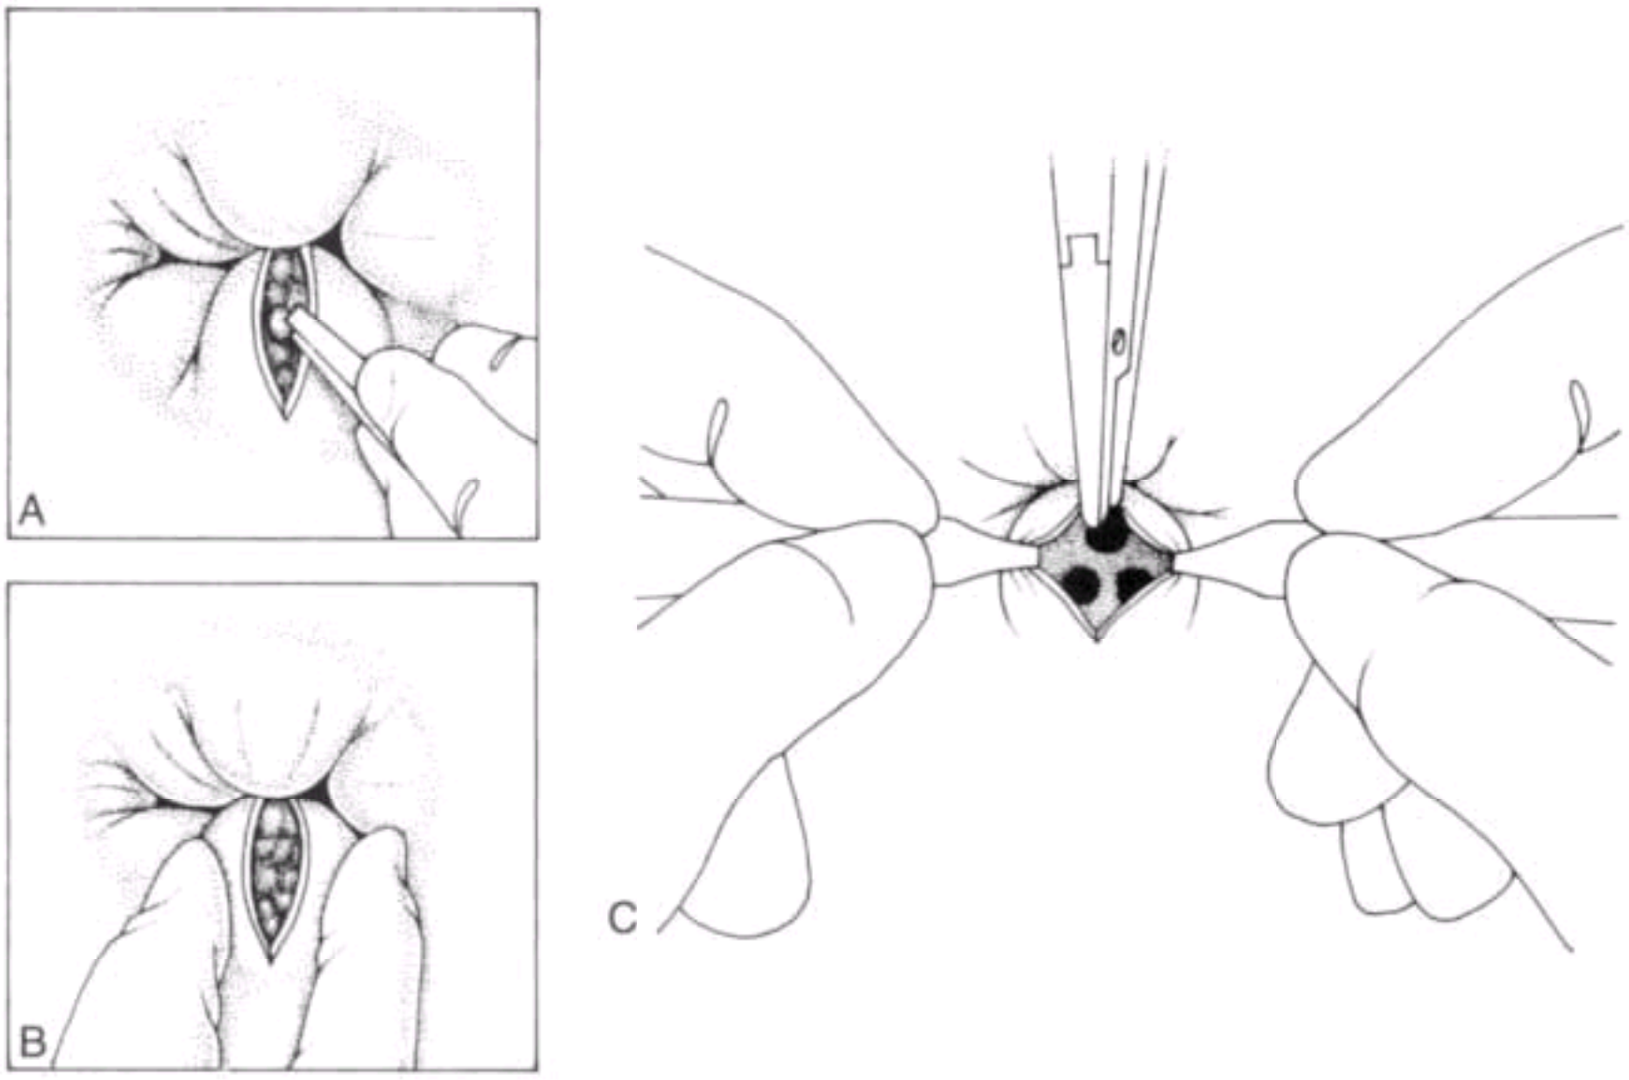

Figure 46-12 Emergency approach to the removal of rectal foreign bodies. Foreign bodies that are fragile or are associated with rectal spasm are generally managed with regional or general anesthesia. The use of supplemental analgesic, anxiolytic, and local anesthetic medications is highly recommended.

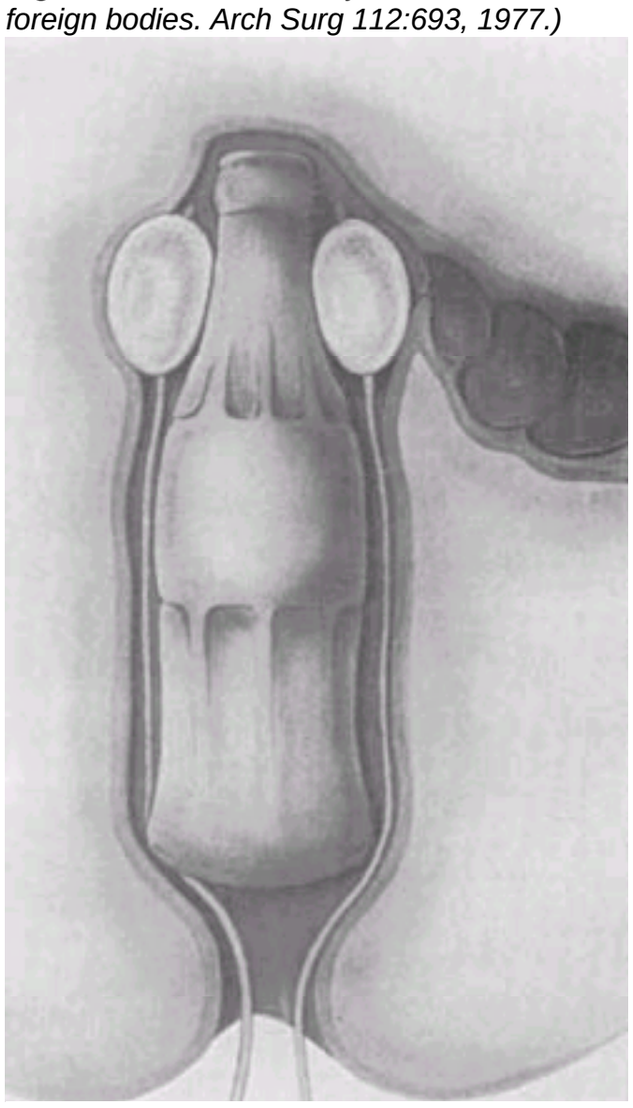

Figure 46-16 *A,* Type I procidentia (rectal prolapse). *B,* Intussusception of sigmoid colon beyond the anus. *(From Kratzer GL, Demarest RJ: Office Management of Colon and Rectal Disease. Philadelphia, WB Saunders, 1985, pp 221–333.)*

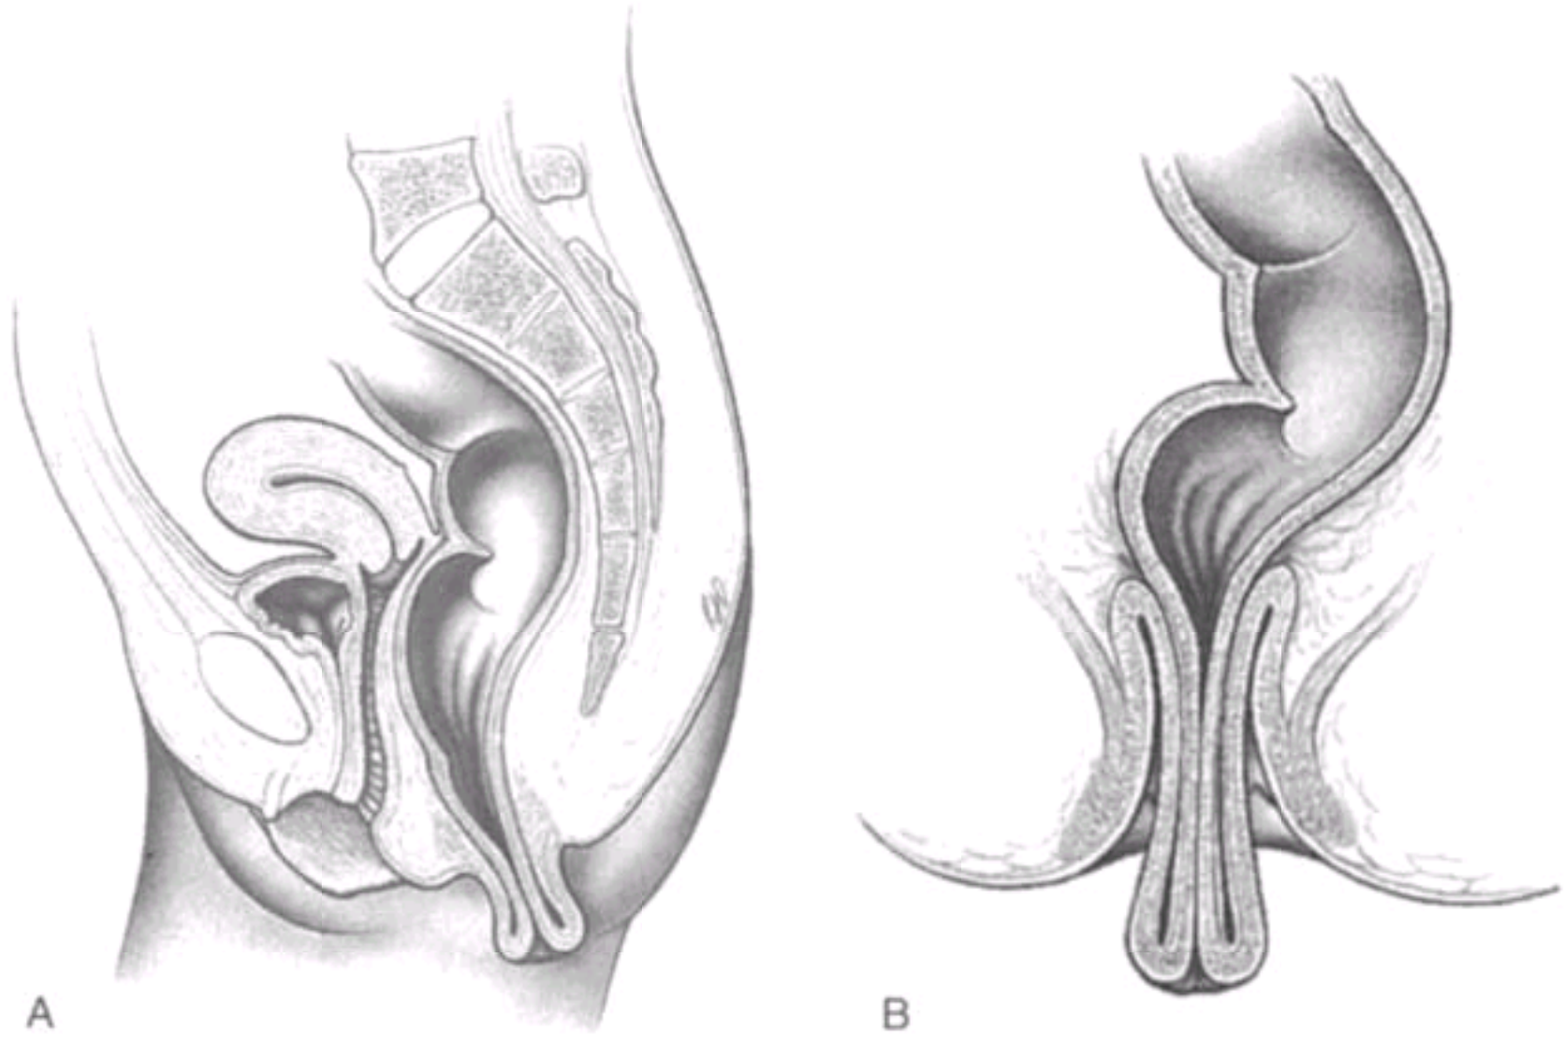

Figure 46-17 *A,* Complete (recurrent) rectal prolapse in a nursing home patient. This can be very distressful and painful, or relatively asymptomatic. *B and C,* To reduce the prolapse, an assistant spreads the buttocks and the clinician's hands encircle the prolapse. The key to success is adequate sedation/analgesia and a slow steady gentle pressure. *D,* Successful reduction.

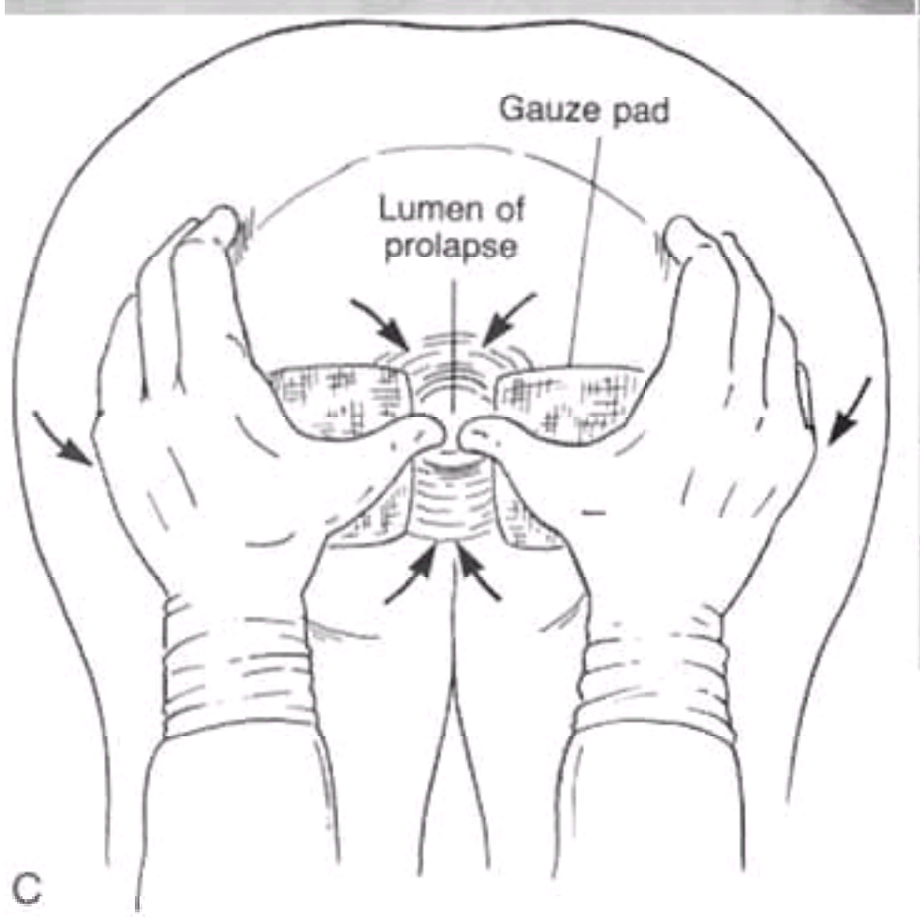

Figure 47-1 Philadelphia collar. This is a two-piece, high-type collar that comes in four sizes. The collar supports the head in a dish-shaped contour that is formed when the front and rear halves are joined by Velcro fasteners. When properly sized for a patient, this collar provides excellent support. When applied too tightly, it tends to force the mandible backward and can cause thyroid compression in some patients. It is extremely comfortable. *(Courtesy of Philadelphia Cervical Collar Company, Westville, NJ.)*

Figure 47-2 Stifneck collar. This collar is made of high-density polyethylene (a hard material) and padded with semiflexible foam margins. Note the low-reaching anterior panel, which contacts the sternum for additional support. *(Courtesy of Laerdal Medical Corporation, Wappingers Falls, NY.)*

Figure 47-3 *A,* Young child immobilized on a standard backboard; note how the large head forces the neck into flexion. Backboards can be modified by an occiput cutout (*B*) or a double mattress pad (*C*) to raise the chest. *(Adapted from Herzenberg JE, Hensinger RN, Dedrick DK, et al: Emergency transport and positioning of young children who have an injury of the cervical spine. J Bone Joint Surg Am 71:15, 1989.)*

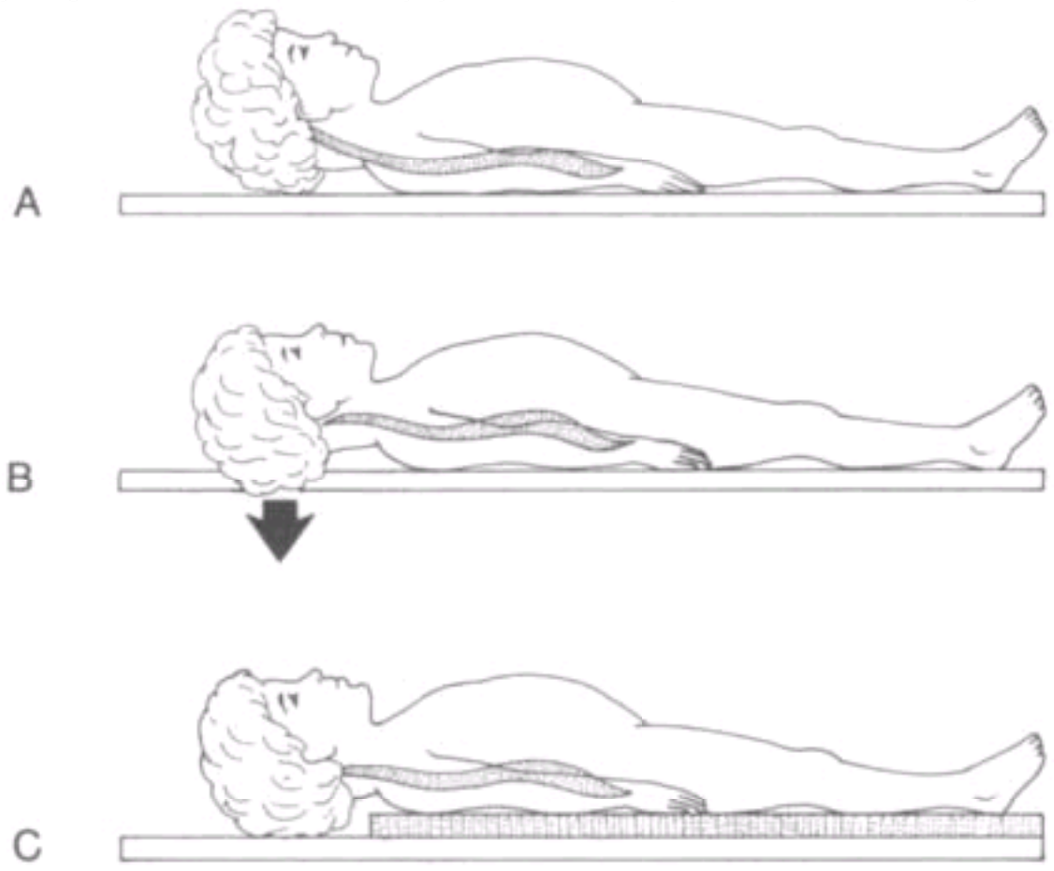

Figure 47-4 Pediatric high-cut extrication collar. *(Courtesy of Laerdal Medical Corporation, Wappingers Falls, NY.)*

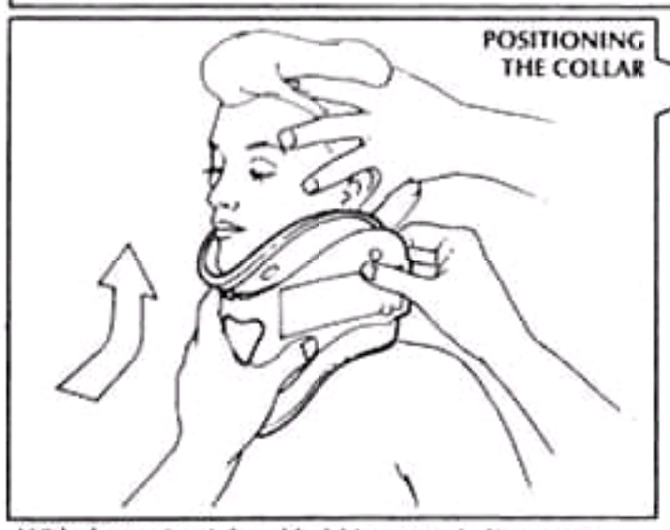
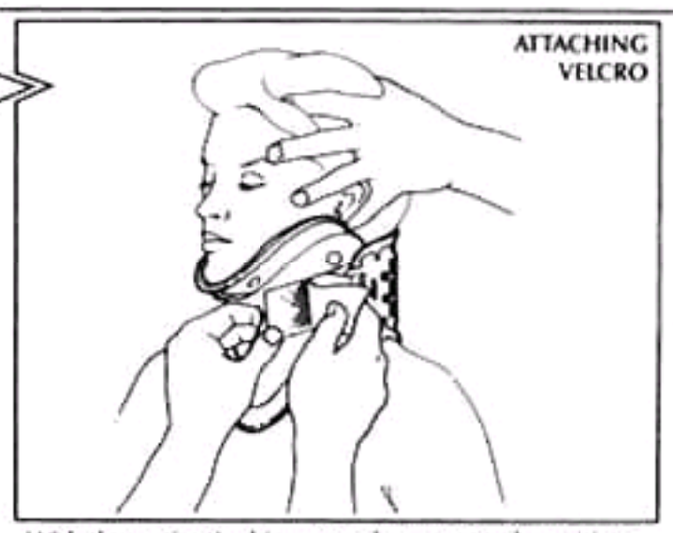
Figure 47-5 LSP pediatric immobilization board with cervical collar. *(Courtesy of Allmed, St. Louis.)*

Figure 47-6 Technique for the application of an extrication collar. *(Courtesy of Laerdal Medical Corporation, Wappingers Falls, NY.)*

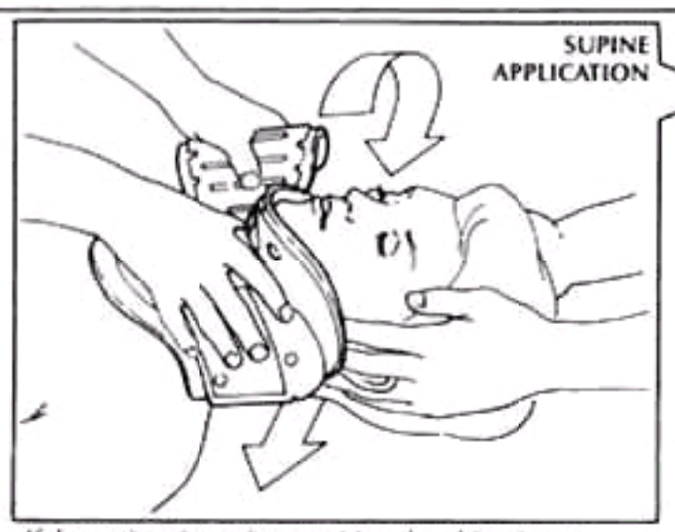
APPLICATION



With the patient's head held in neutral alignment, position the chin piece by sliding the collar up the chest wall. Be sure that the chin is well supported by the chin piece and that the chin extends far enough onto the chin piece to at least cover the central fastener. Difficulty in positioning the chin piece may indicate the need for a shorter collar.



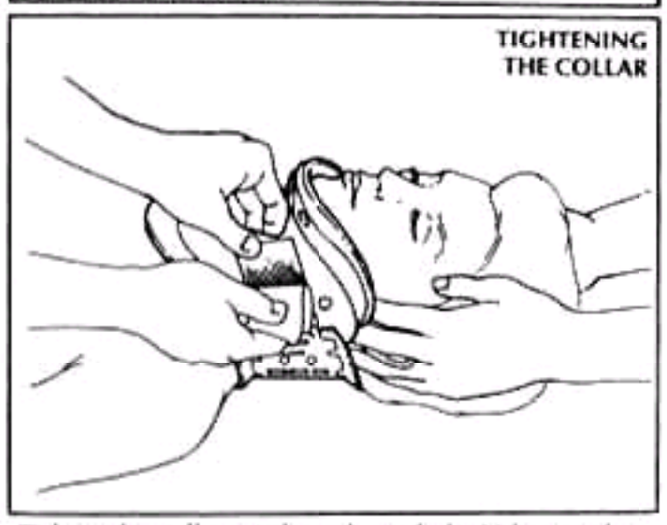
With the patient's chin properly supported, position the back of the collar around the neck and attach the loop velcro so that it mates with, and is parallel to, the hook velcro. Use the trach hole to keep the collar in proper position as you tighten the velcro. BE SURE TO MAINTAIN NEUTRAL ALIGNMENT THROUGHOUT THIS PROCEDURE.



If the patient is supine, position the chin piece as previously described and slide the back portion of the collar behind the patient's neck. Be sure to fold the loop velcro inward on top of the foam padding to prevent it from collecting debris which could limit its gripping ability.

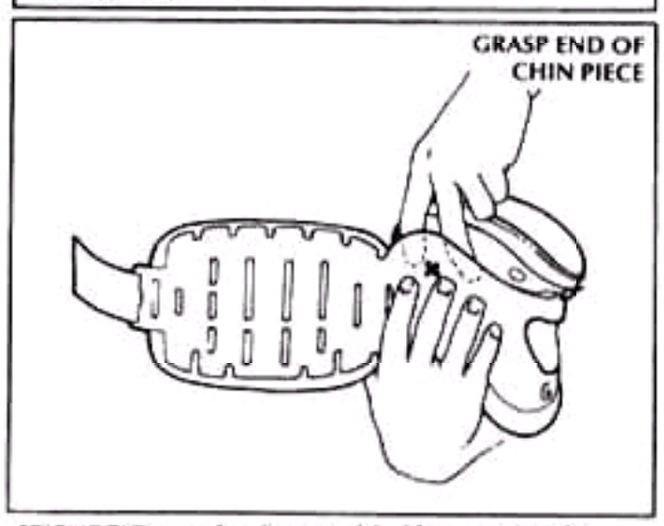
An alternative is to begi
of the collar behind the
velcro is again visible,
positioning the chin pie
described.

APPLICATION



Tighten the collar gently and attach the Velcro so that the two pieces are parallel. Re-check the position of the patient's head and collar for proper alignment. Tighten the collar further until proper support is obtained.

DISASSEMBLY



STIFNECK™ may be disassembled by grasping the end of the chin piece, as shown, with the black fastener between the fingers and working this fastener out of its hole. Do not try to pull the white fastener apart.

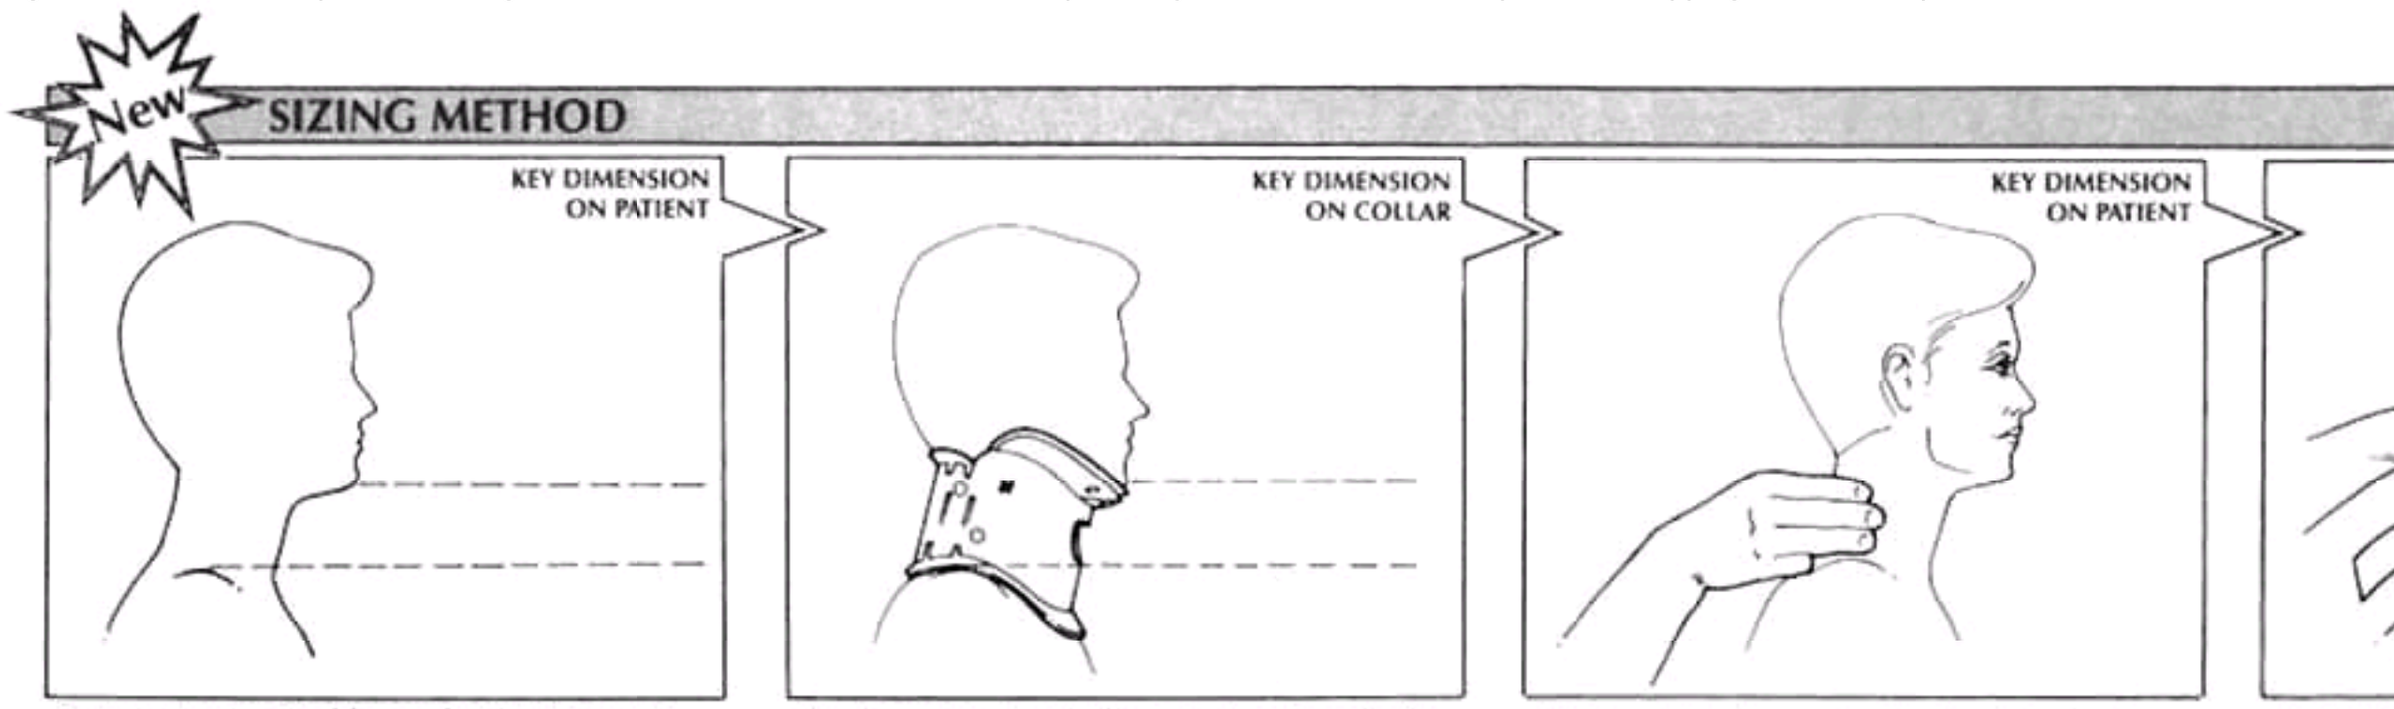
DO'S

1. DO follow the directions of your local EMS authorities for the approved use of extrication collars.
2. DO use all appropriate cervical spine immobilization techniques.
3. DO refer to your EMT paramedic training manual regarding the use of extrication collars and spinal immobilization techniques.

DON'TS

1. DO NOT rely on any cervical collar to adequately immobilize a patient's cervical spine. Collars are tools to aid in immobilization, but no collar by itself provides sufficient immobilization.
2. DO NOT use an improperly sized collar. Too large a collar may hyperextend a patient's cervical spine; too small a collar may not provide appropriate stability.
3. DO NOT hesitate to contact your local EMS dealer or local EMS authority with questions regarding the use of extrication collars.

Figure 47-7 Method for predetermining the correct size for an extrication collar. *(Courtesy of Laerdal Medical Corporation, Wappingers Falls, NY.)*



Proper sizing is critical for good patient care. Too short a collar may not provide enough support. Too tall a collar may hyperextend. Use the tallest collar that does not hyperextend. The key dimension is the distance between an imaginary line drawn across the top of the shoulders, where the collar will sit, and the bottom of the patient's chin.

This dimension is easily determined on the collar by measuring the distance between this black fastener and the lower edge of the rigid plastic encircling band (not the foam padding).

Use your fingers to visualize the shoulder to chin distance on the patient.

Figure 47-8 No-Neck extrication collar. Designed for individuals with extremely short necks. *(Courtesy of Laerdal Medical Corporation, Wappingers Falls, NY.)*

Figure 47-9 Horse collar. Most extrication collars are available in three to five factory sizes. If a collar is not sized properly to fit a particular patient, it performs no function. Patients with extremely long necks or especially short ones can be immobilized by means of a horse collar fashioned from a bulky rescue blanket. The blanket is rolled to the thickness desired and slid under the patient's neck while a bystander applies manual stabilization; the ends of the blanket are then brought across the patient's anterior chest. The patient's forearms are fastened as shown to stabilize the "tails" of the collar. *(From Dick T: Tricks of the trade: Horse sense, immobilizing necks that don't fit collars. J Emerg Med Serv 7:23, 1982. Reproduced with permission.)*

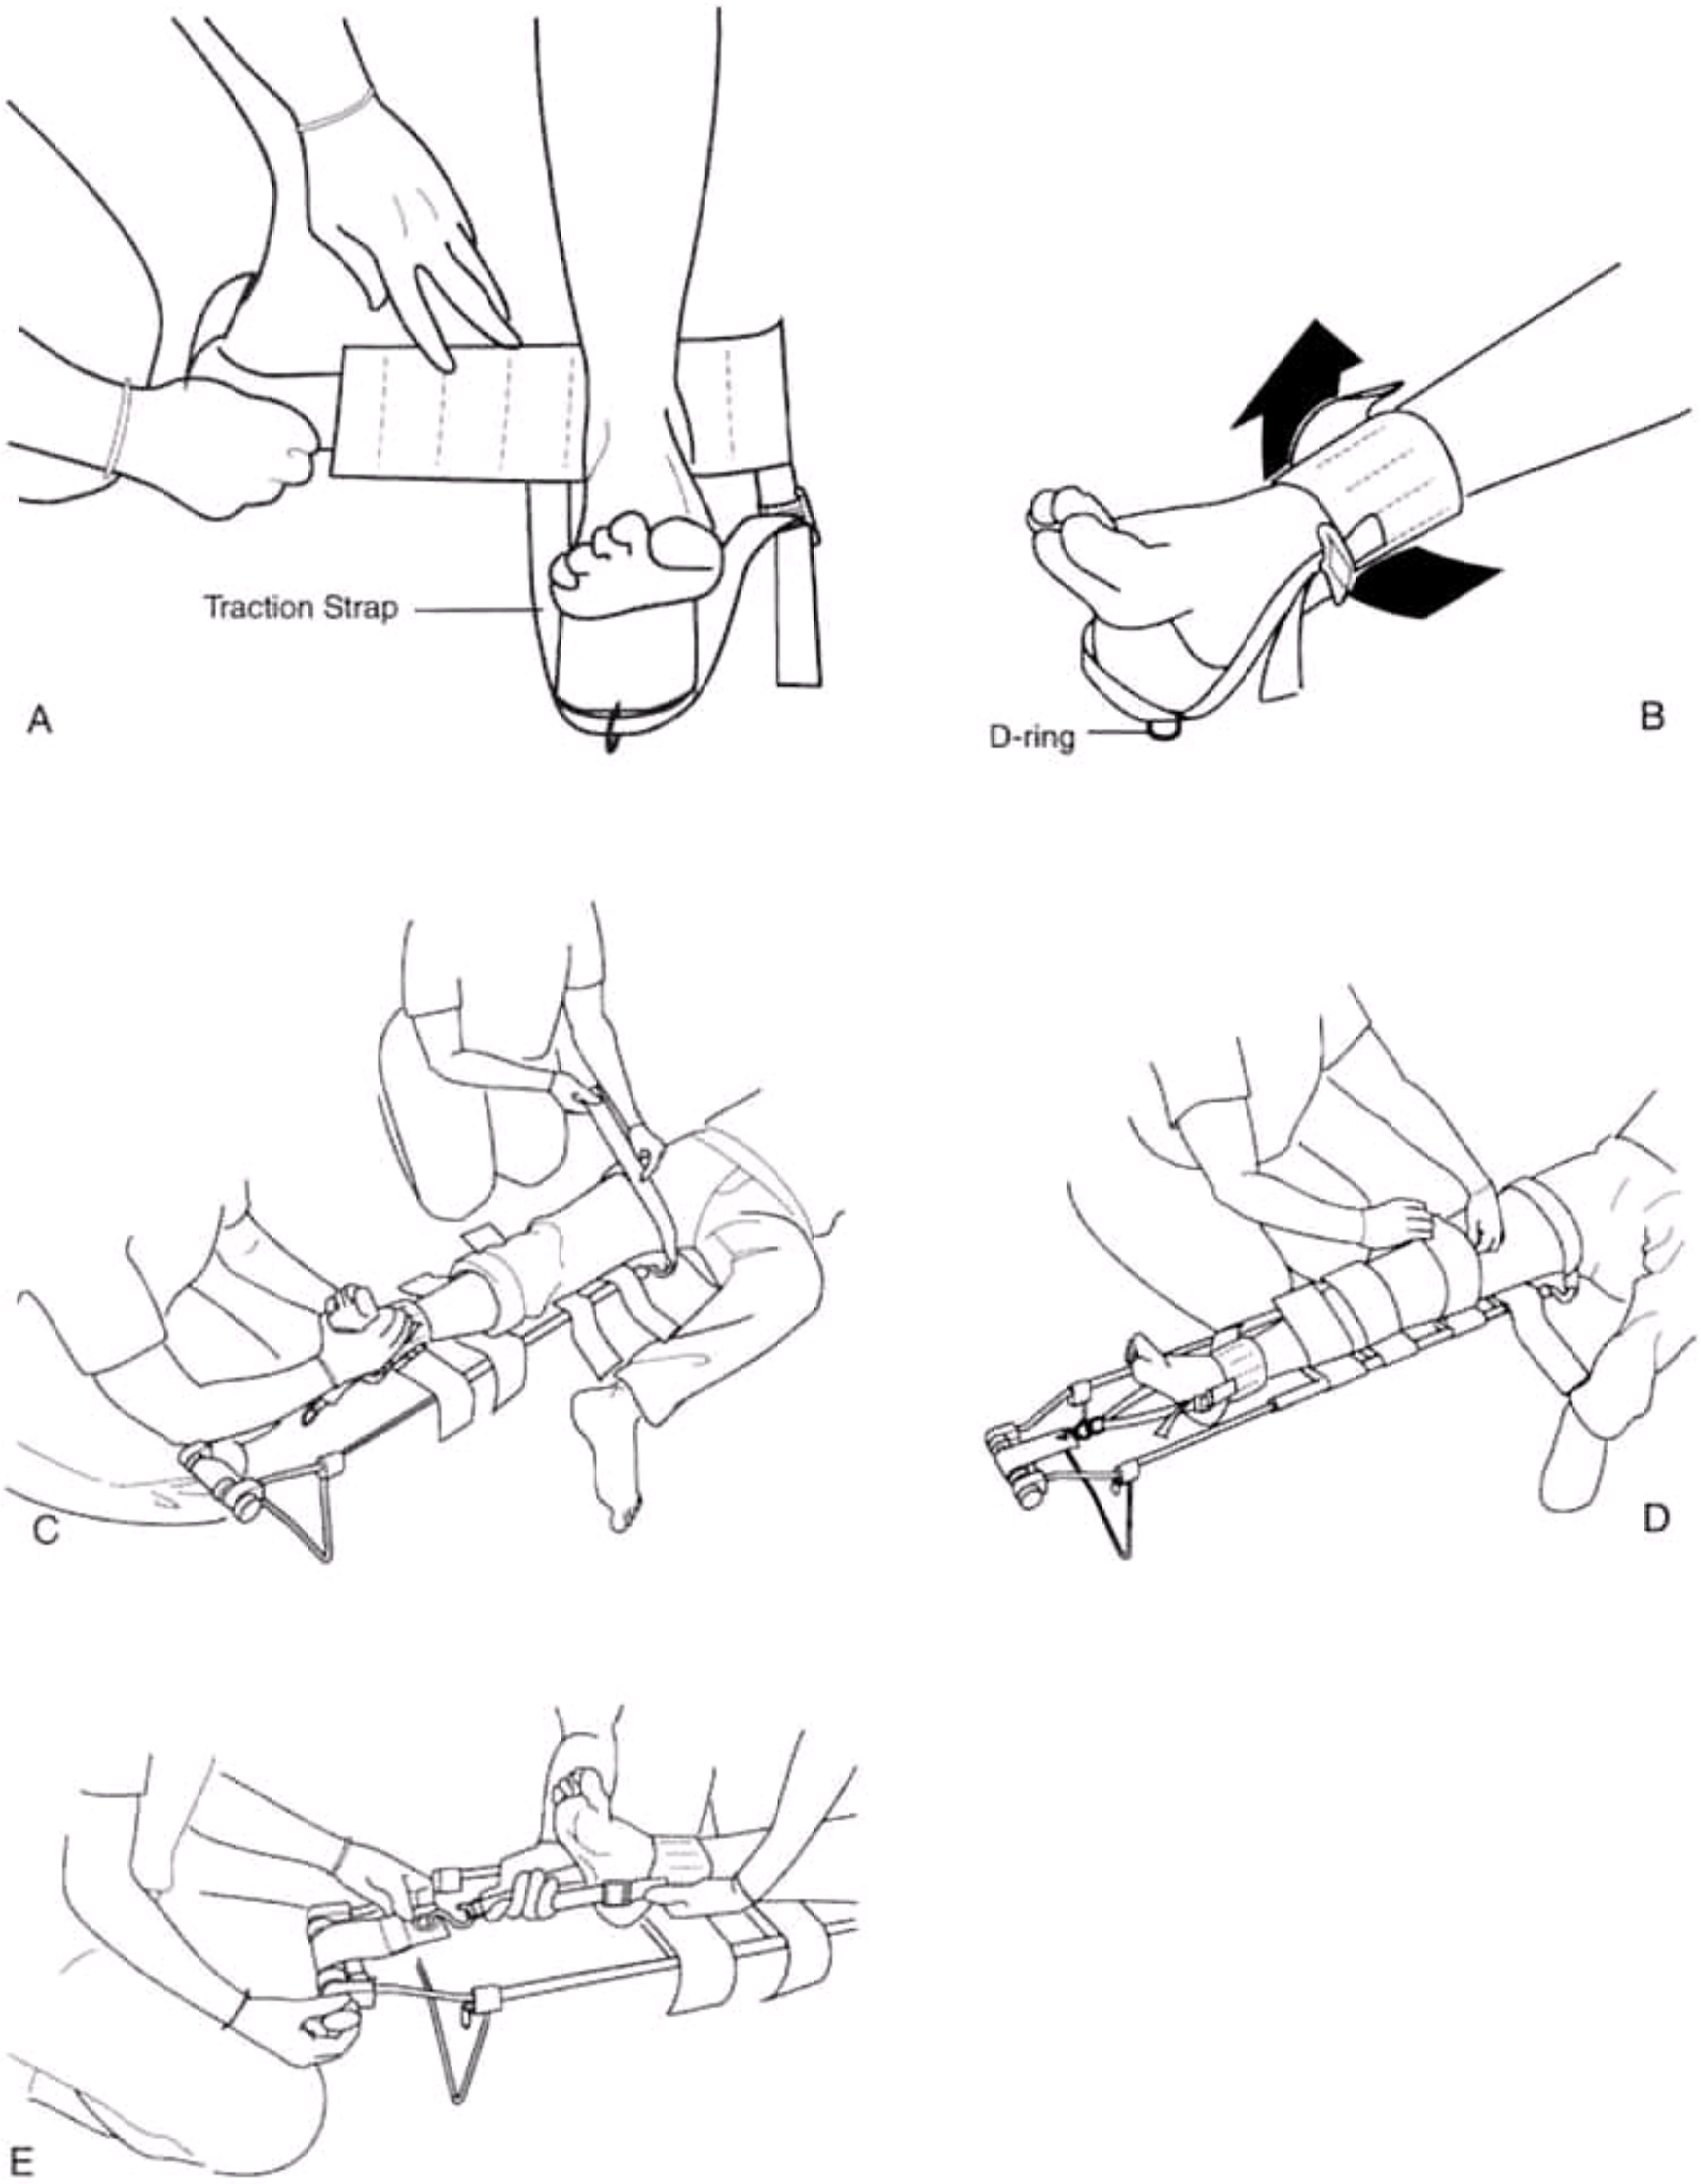

Figure 47-32a Application of the Sager emergency traction splint. *A–J*, Standard application.

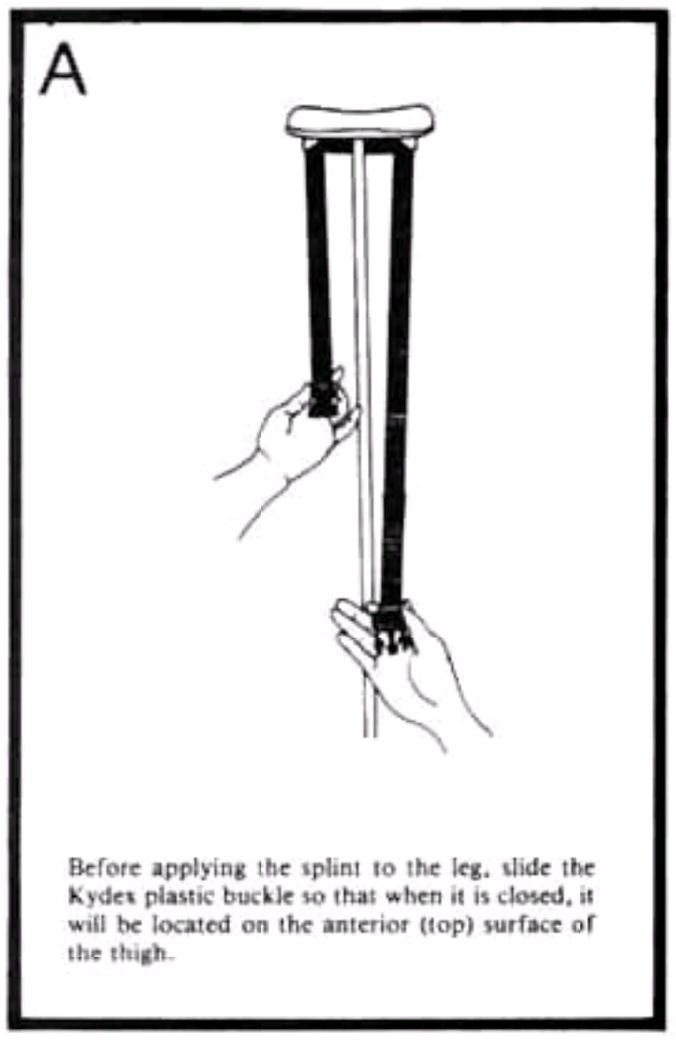
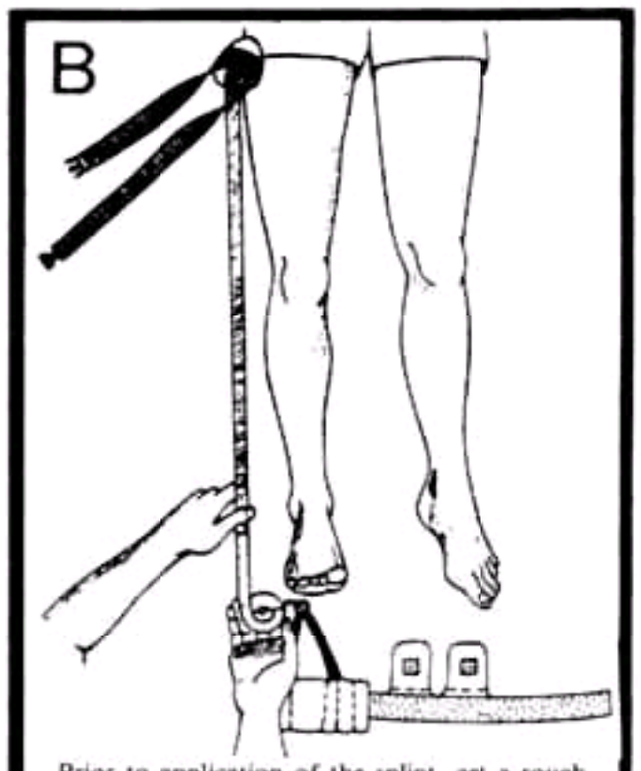
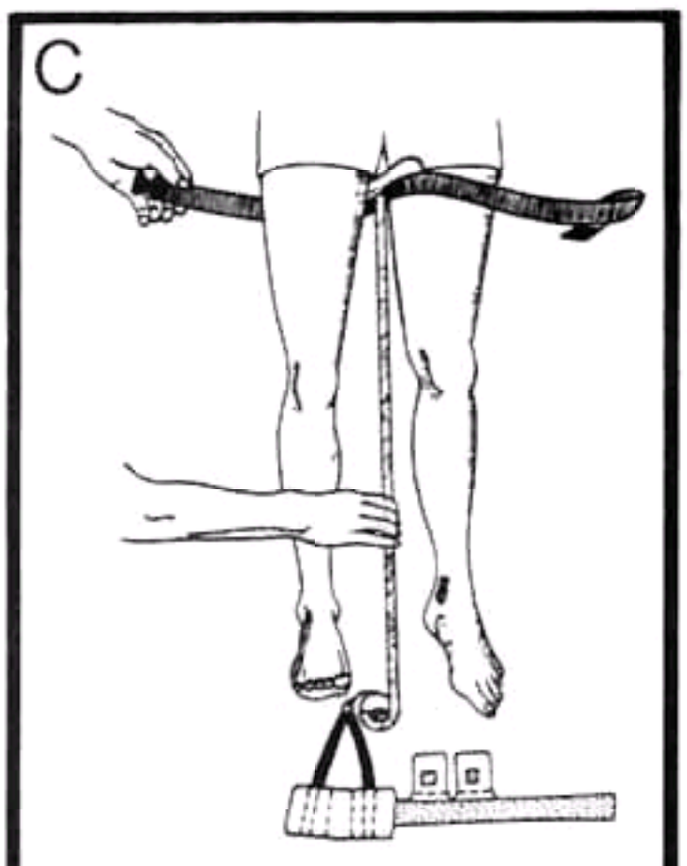


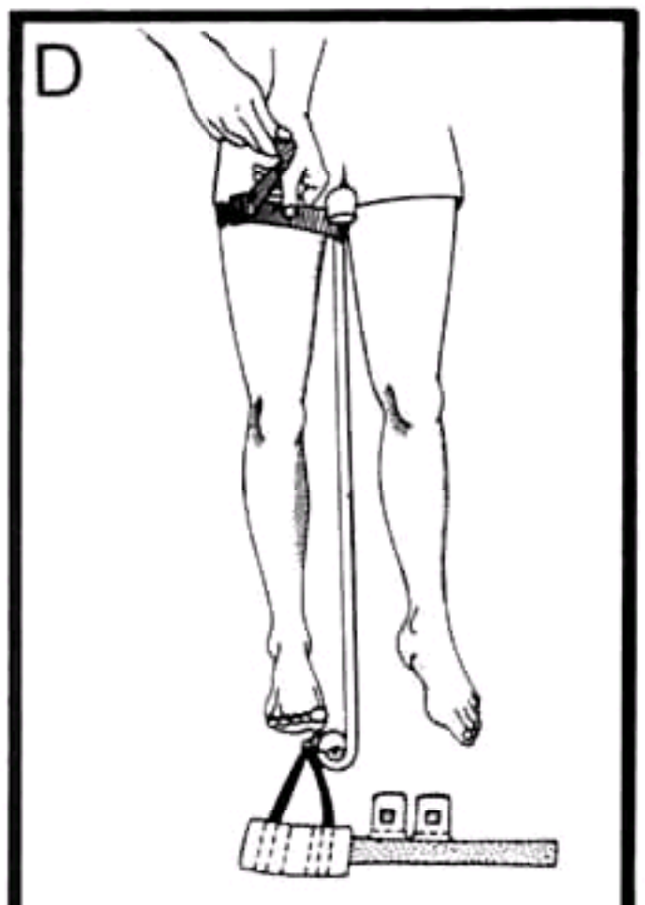
Before applying the splint to the leg, slide the Kydex plastic buckle so that when it is closed, it will be located on the anterior (top) surface of the thigh.



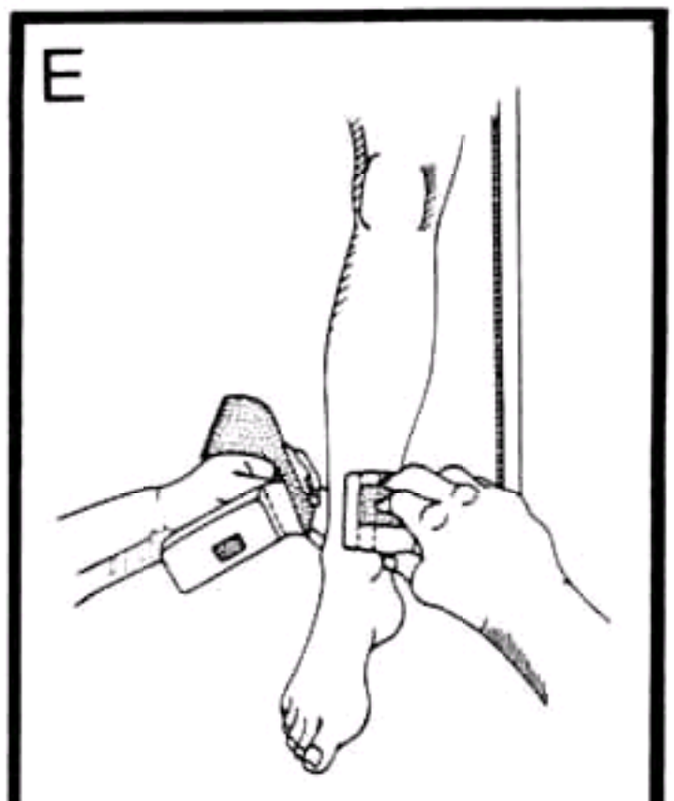
Prior to application of the splint, get a rough measure of length of splint needed. Extend the splint so that the wheel is at the heel. NOTE: Patients wearing tight jeans or underclothing, especially males, will find the splint uncomfortable to wear unless clothing is removed or cut open, which, of course, should be done as part of patient secondary evaluation prior to application of splint.



Grasp the Kydex buckle and slide the thigh strap up under the leg so that the perineal cushion is snug against the perineum and ischial tuberosity.

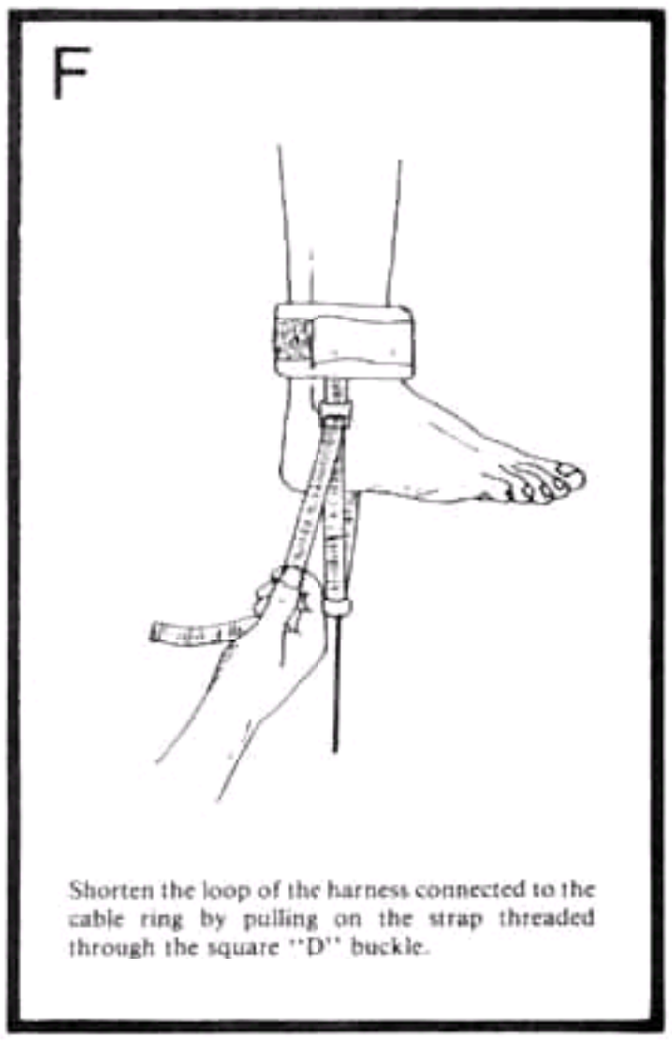


Tighten the Kydex buckle thigh strap, drawing the perineal-ischial pad to the lateral portion of the crotch.

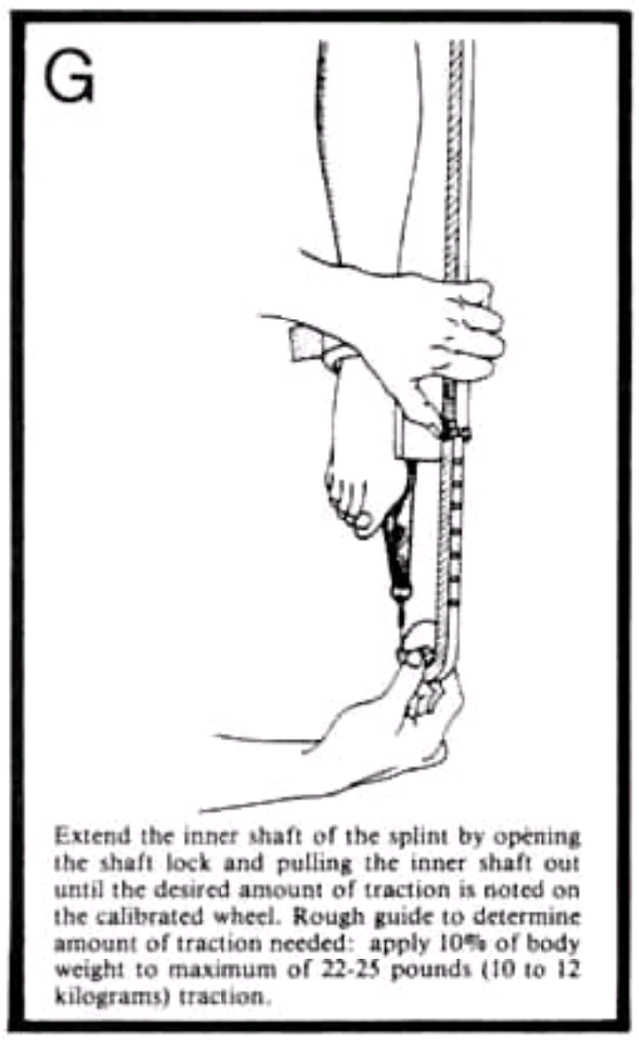


Apply the ankle harness tightly around the ankle above the medial and lateral malleoli of the ankle. Check posterior tibial and dorsalis pedis pulses before hitch application and after traction is established.

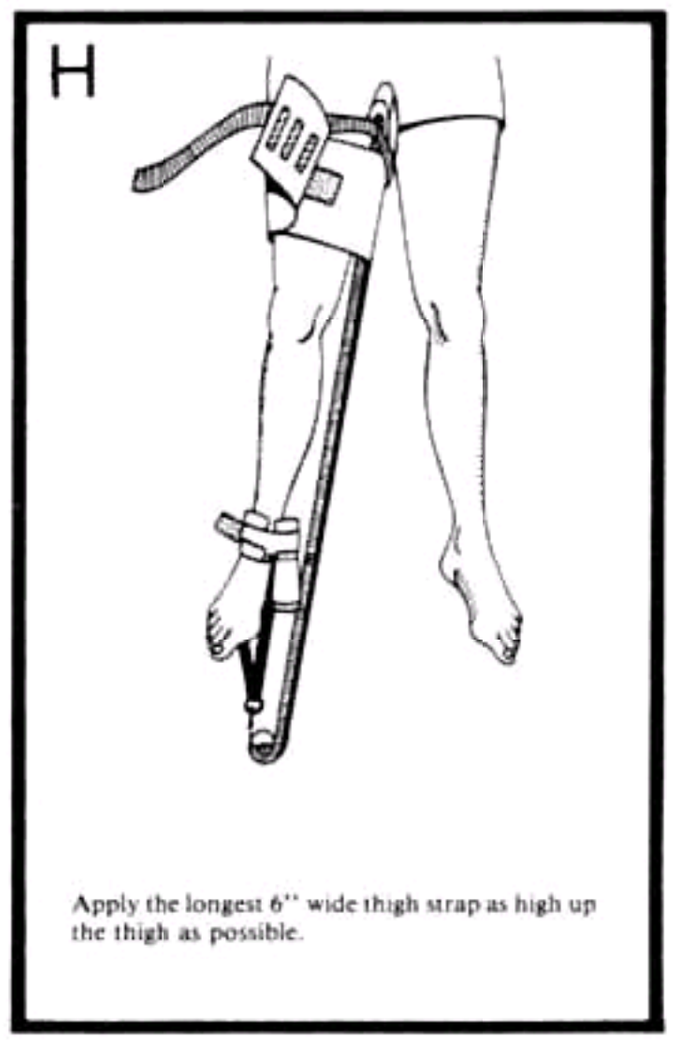
Figure 47-32b



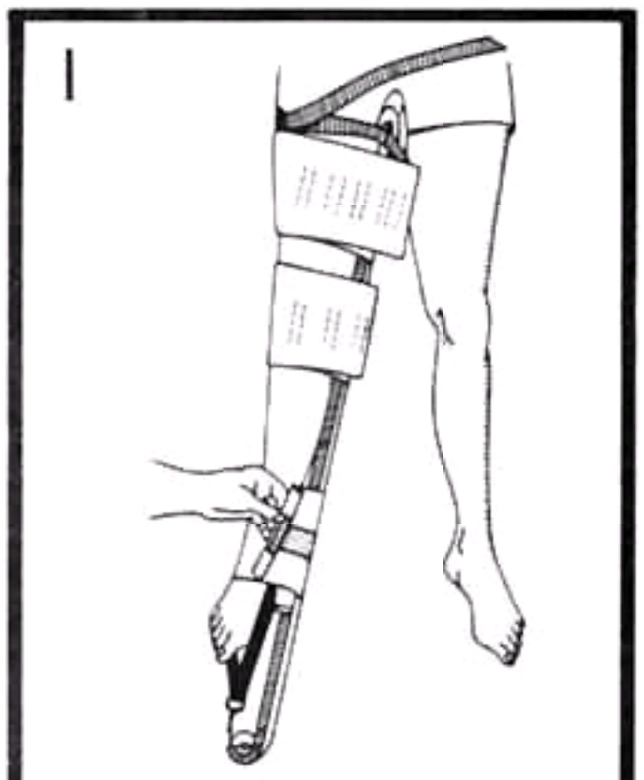
Shorten the loop of the harness connected to the cable ring by pulling on the strap threaded through the square "D" buckle.



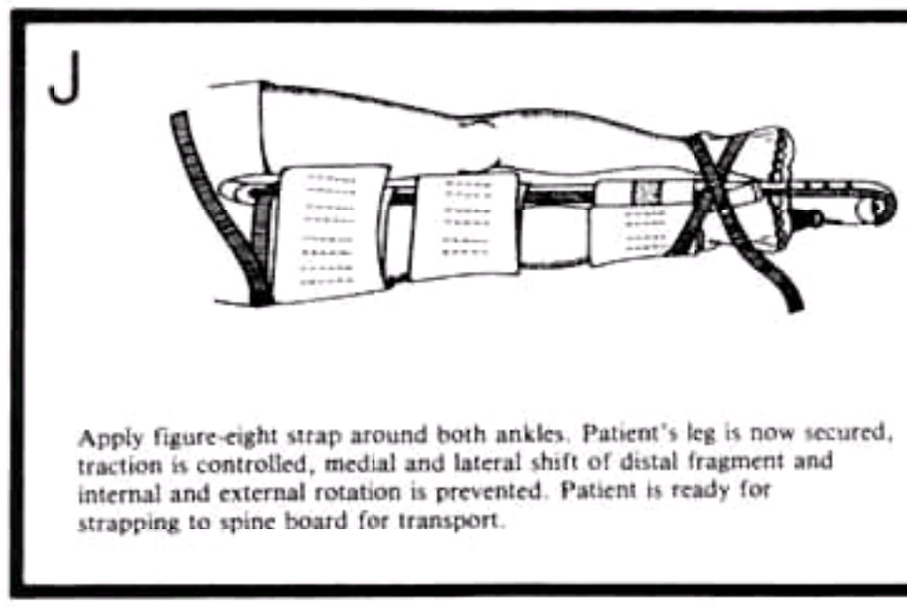
Extend the inner shaft of the splint by opening the shaft lock and pulling the inner shaft out until the desired amount of traction is noted on the calibrated wheel. Rough guide to determine amount of traction needed: apply 10% of body weight to maximum of 22-25 pounds (10 to 12 kilograms) traction.



Apply the longest 6" wide thigh strap as high up the thigh as possible.



Apply the second longest thigh strap around the knee. Use padding as needed. Next, apply the shortest 6-inch wide strap over the ankle harness and lower the leg.



Apply figure-eight strap around both ankles. Patient's leg is now secured, traction is controlled, medial and lateral shift of distal fragment and internal and external rotation is prevented. Patient is ready for strapping to spine board for transport.

Figure 47-32c *K–N*, Application on the outside of the leg. *O–Q*, Application of the bilateral splint.

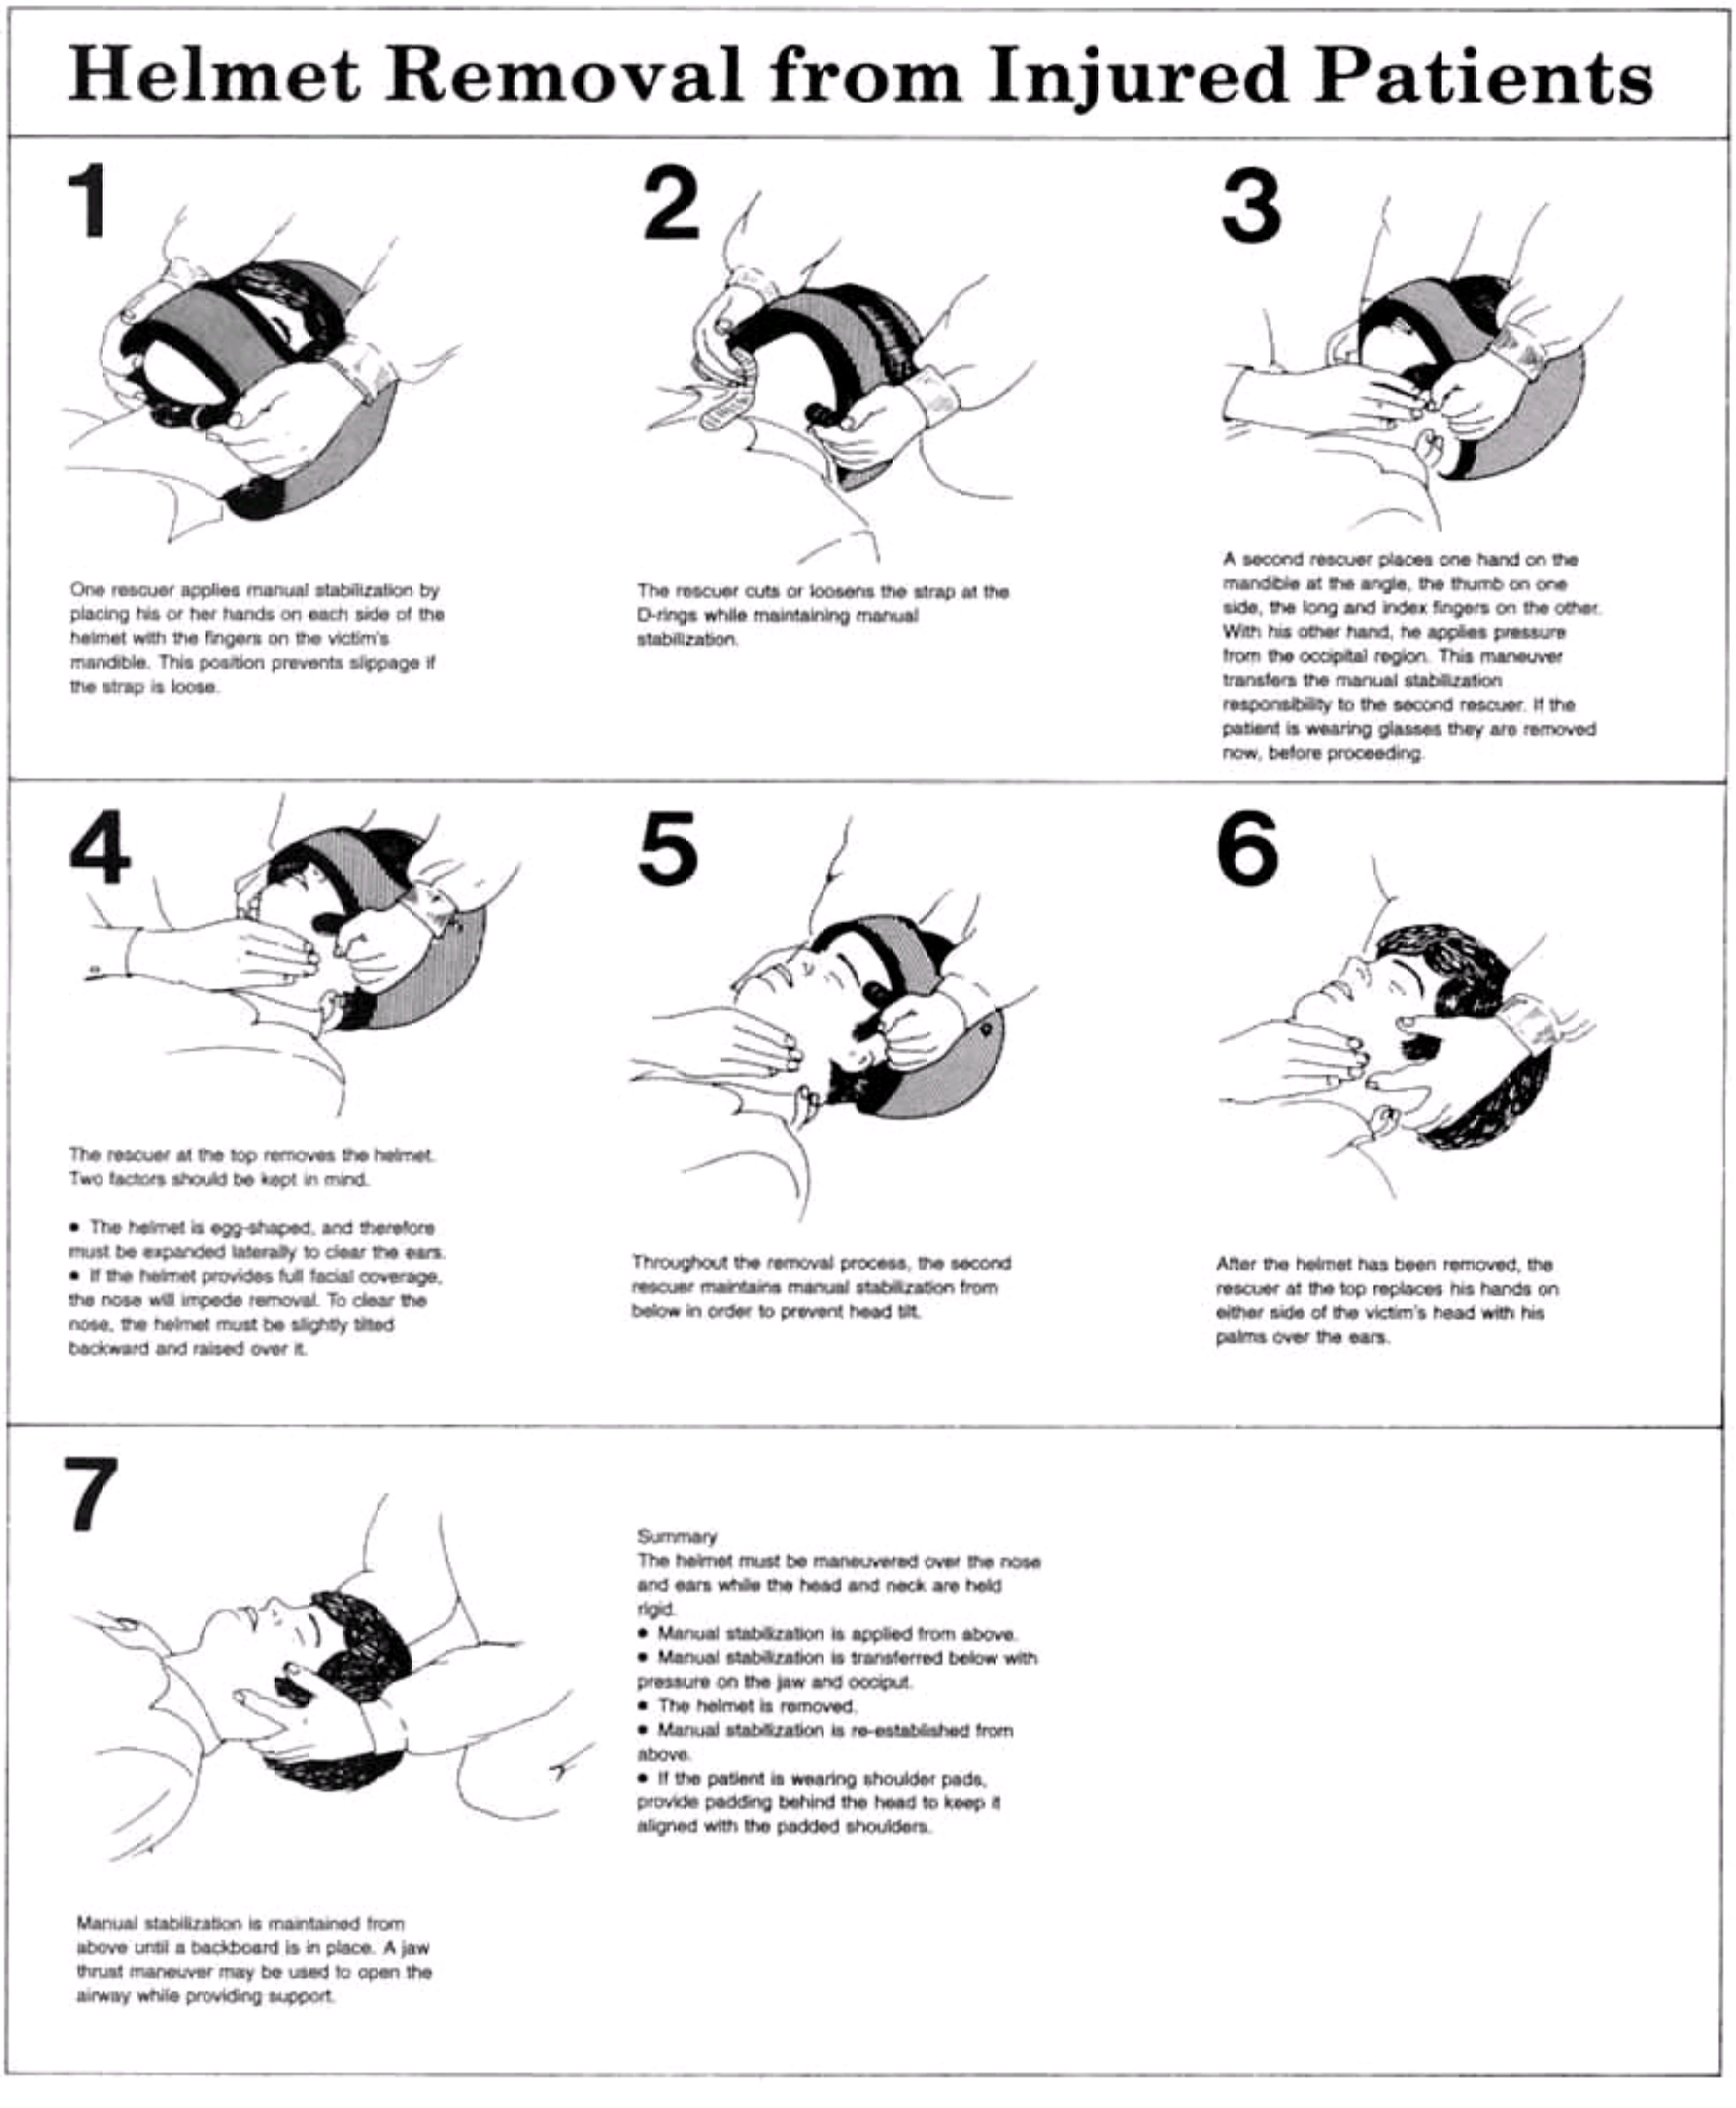

Figure 48-1 Evaluate the patient's condition to ensure that resuscitation is not necessary before transfer. *A,* The wound should be rinsed with saline solution. *Do not scrub or apply antiseptic solution to the wound.* Apply saline moistened sterile dressing, wrap in Kling or Kerlix for pressure, and elevate. *B,* The amputated part should be rinsed with saline. *Do not scrub or apply antiseptic solution to the amputated part.* Wrap it in moist sterile gauze or a towel, depending on its size, and place it in a plastic bag or plastic container. *Do not place the amputated part directly in saline. C,* The part is then put in a container, preferably Styrofoam, and cooled by separate plastic bags containing ice or in a container of ice water. Do not pack the bagged, injured part in ice, but it can be immersed in half water, half ice. *(From Hand Trauma: Emergency Care. Baltimore, MD, Emergency Services.)*

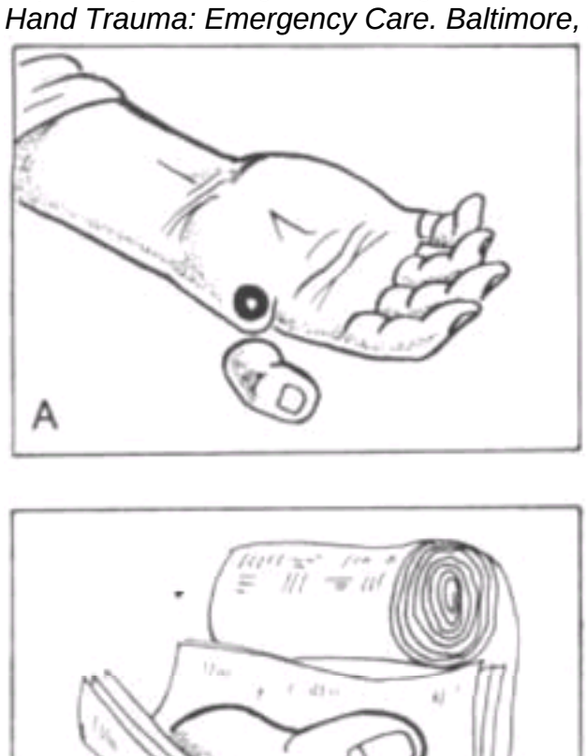

Figure 48-2 For a *partial amputation*, rinse with saline (*A*); then place part(s) in a functional position, apply a saline moistened sterile dressing, and splint and elevate *(B)*. Apply coolant bags to the *outside* of the dressing *(C)*. *Do not scrub or apply antiseptic solution to the wound.* Control any bleeding with pressure. If a tourniquet is necessary, place it close to the amputation site. *(From Hand Trauma: Emergency Care. Baltimore, MD, Emergency Services.)*

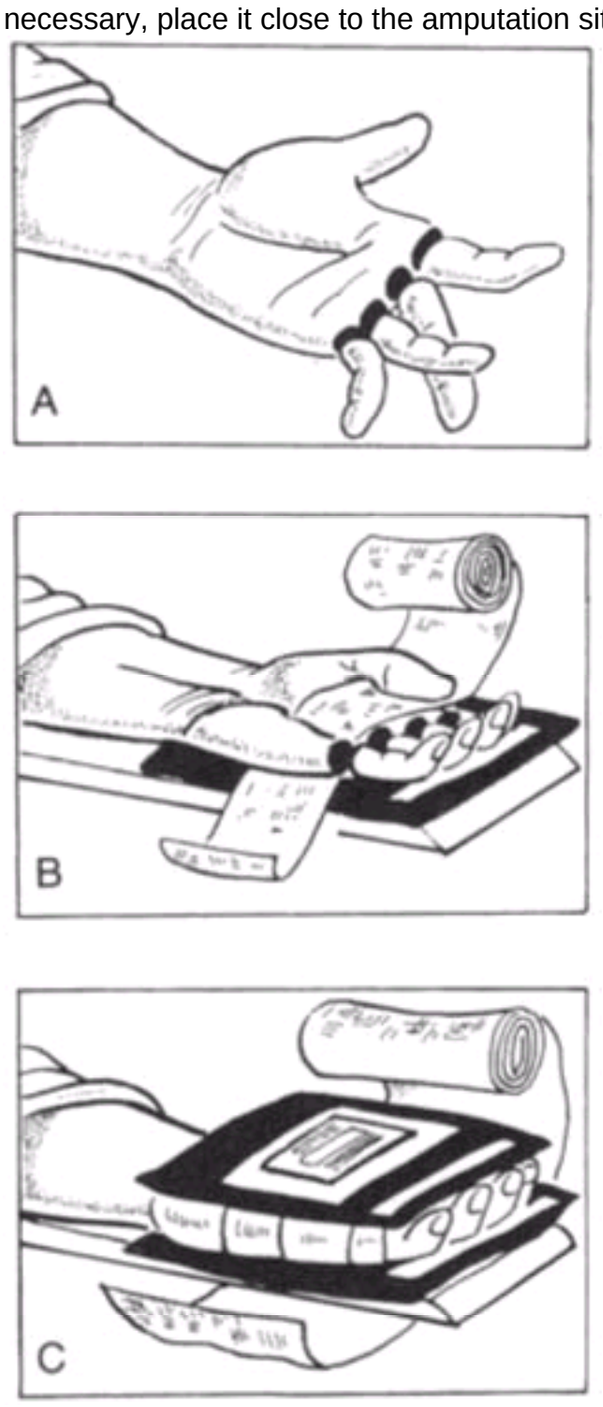

Figure 49-1 Extensor muscles and tendons of the RIGHT forearm and wrist. *A,* superficial layer. *B,* deep layer *(Modified from Pansky B: Upper extremity. In Review of Gross Anatomy, 4th ed. New York, Macmillan Publishing, 1979, pp 219 and 243.)*

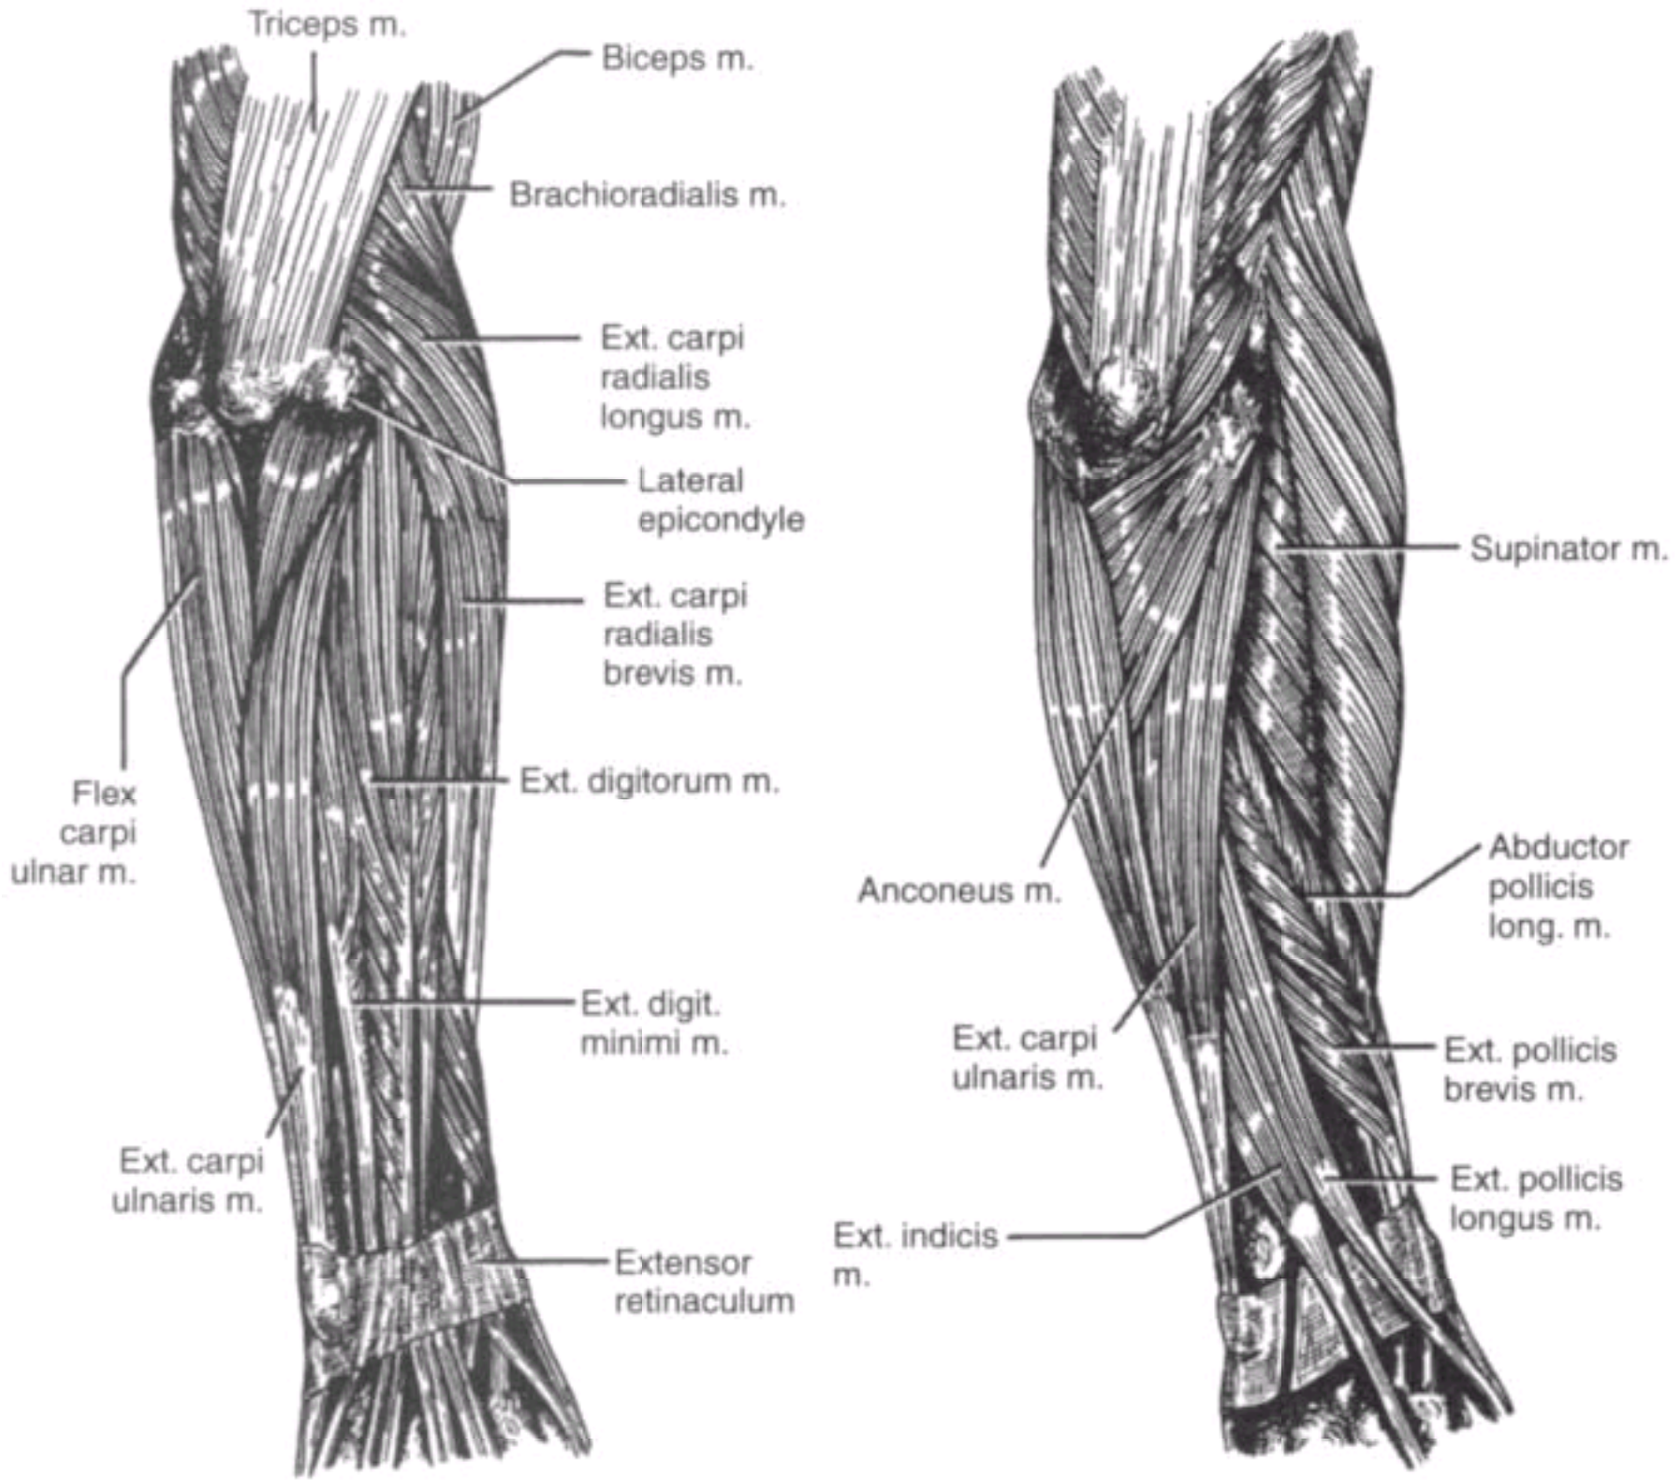

Figure 49-2 *A,* The extensor mechanism at the wrist and dorsum of the right hand. The six extensor compartments at the wrist contain *(1)* the abductor pollicis longus (APL) and extensor pollicis brevis (EPB); *(2)* the extensor carpi radialis longus (ECRL) and brevis (ECRB); *(3)* the extensor pollicis longus (EPL); *(4)* the extensor digitorum communis (EDC) II–V and extensor indicis proprius (EIP); *(5)* the extensor digiti quinti (EDQ); and *(6)* the extensor carpi ulnaris (ECU). An important anatomic detail is the presence of a synovial sheath around each tendon unit within each fibro-osseous canal. *(From Thomas JS, Peimer CA: Extensor tendon injuries: Acute repair and late reconstruction. In Chapman MW [ed]: Operative Orthopaedics, 3rd ed. Philadelphia, JB Lippincott, 2001, p 1497.) B,* Cadaver model demonstrating the dorsal retinaculum of the left wrist with a probe passing through the fourth dorsal compartment. Note that the EDQ is also called the extensor digiti minimi (EDM) by some authors.

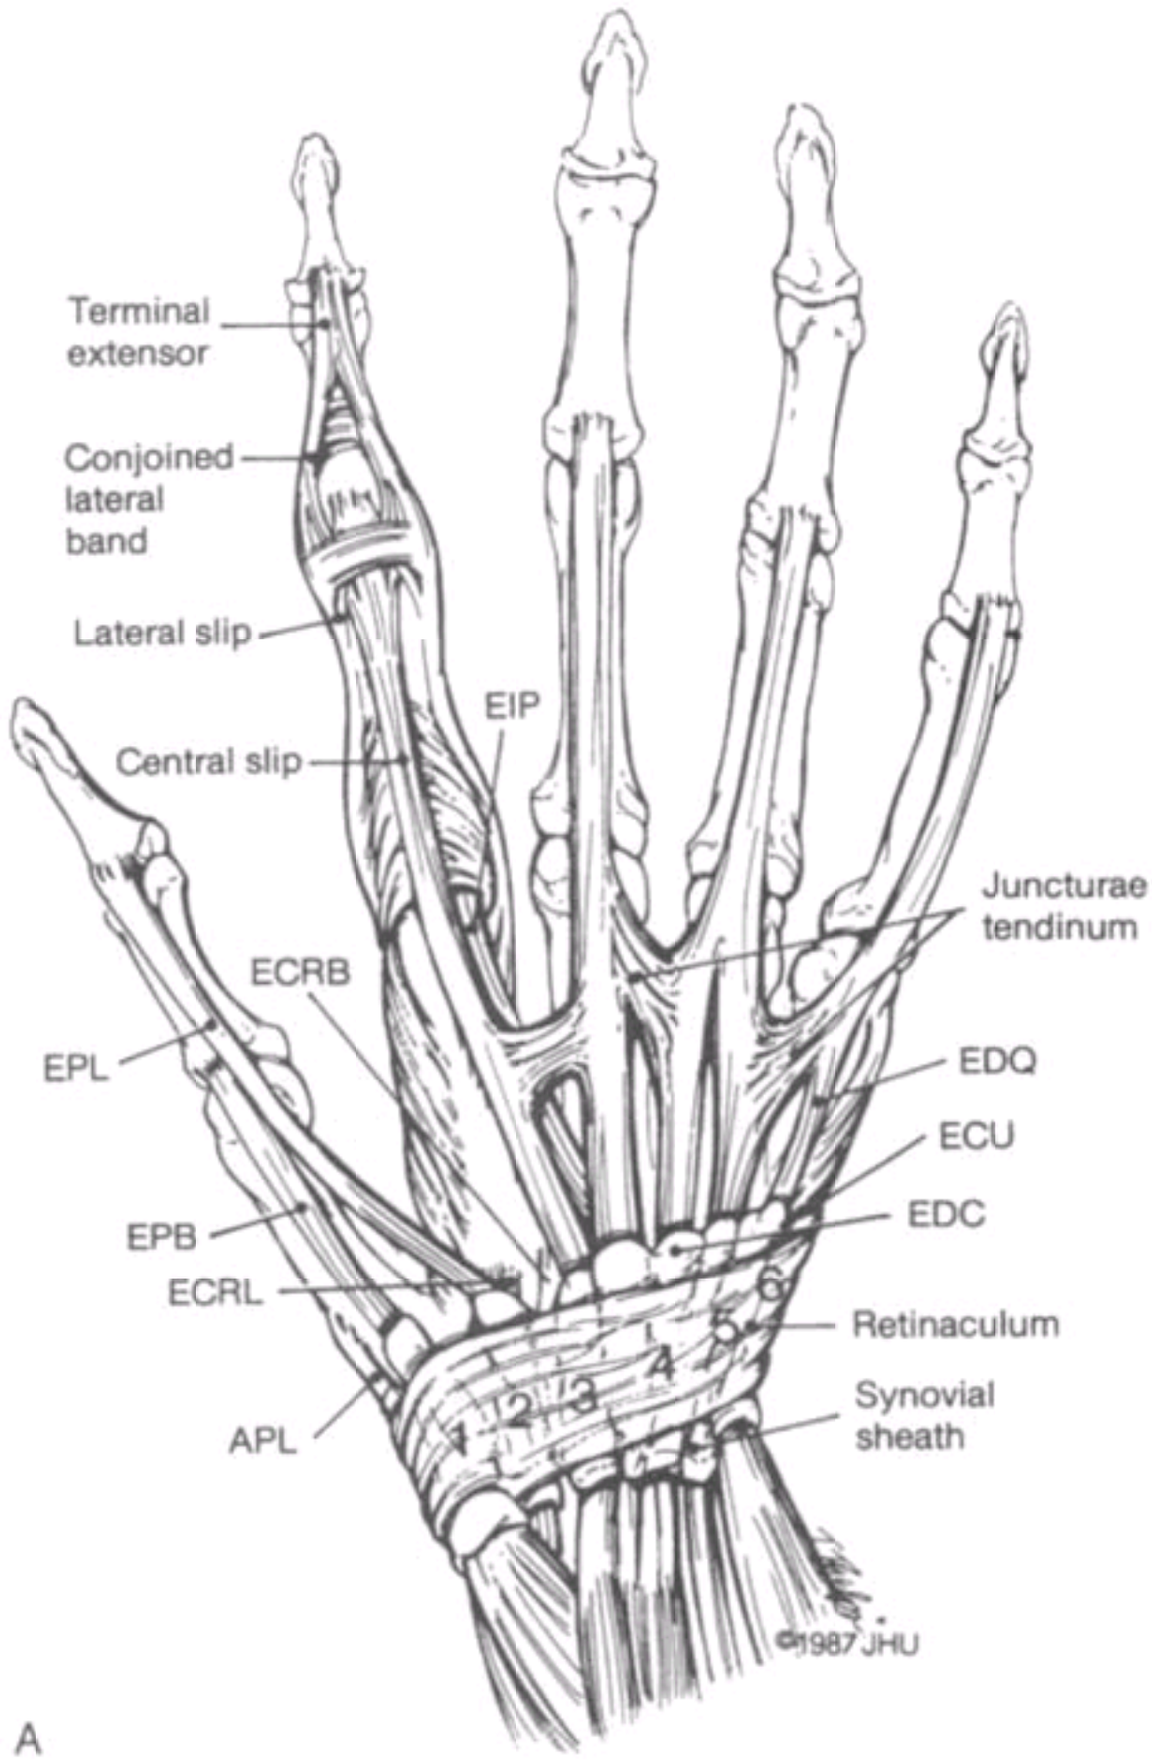

Figure 49-3 Digital extensor mechanism. *A,* Dorsal view. *B,* Lateral view. ORL, oblique retinacular ligament. See text and Figure 49-1 legend for other abbreviations. *(From Thomas JS, Peimer CA: Extensor tendon injuries: Acute repair and late reconstruction. In Chapman MW [ed]: Operative Orthopaedics, 3rd ed. Philadelphia, JB Lippincott, 2001, p 1498.)*

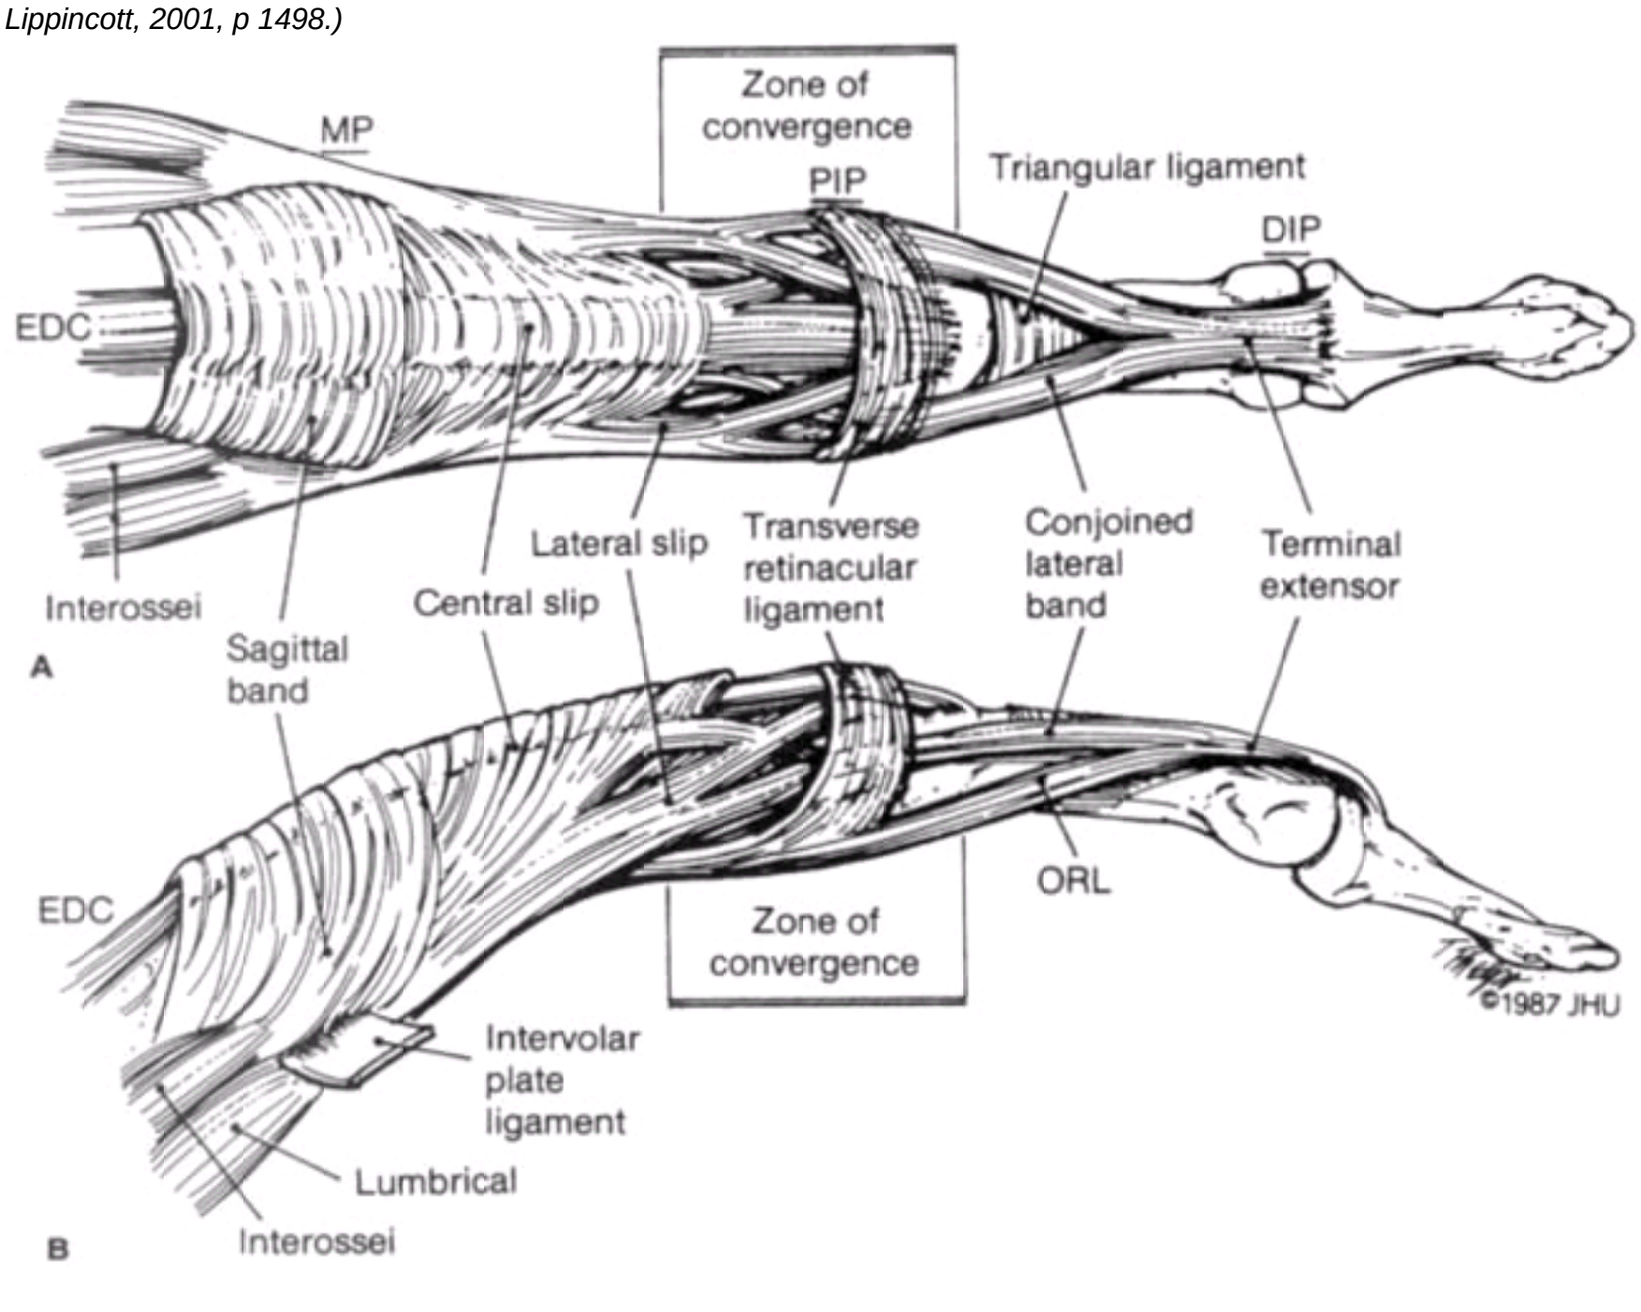

Figure 49-4 The zone of convergence of the digital extensor mechanism, which begins at about the midportion of the proximal phalanx and ends at the level of the central slip insertion into the dorsal base of the middle phalanx. Proximal to the zone of convergence, the extrinsic and intrinsic components of the extensor mechanism are separate: the central slip is extrinsic, whereas the lateral slips are intrinsic. Within the zone of convergence there is complete reciprocal crossover of fibers from the central slip and lateral slips. The products of the completed convergence are the central slip insertion and the conjoined lateral bands, both of which have dual muscular activity. PIP, proximal interphalangeal joint; TRL, transverse retinacular ligament; ORL, oblique retinacular ligament; E, extrinsic contribution to conjoined lateral bands; I, intrinsic contribution to central slip insertion. *(From Thomas JS, Peimer CA: Extensor tendon injuries: Acute repair and late reconstruction. In Chapman MW [ed]: Operative Orthopaedics, 3rd ed. Philadelphia, JB Lippincott, 2001, p 1500.)*

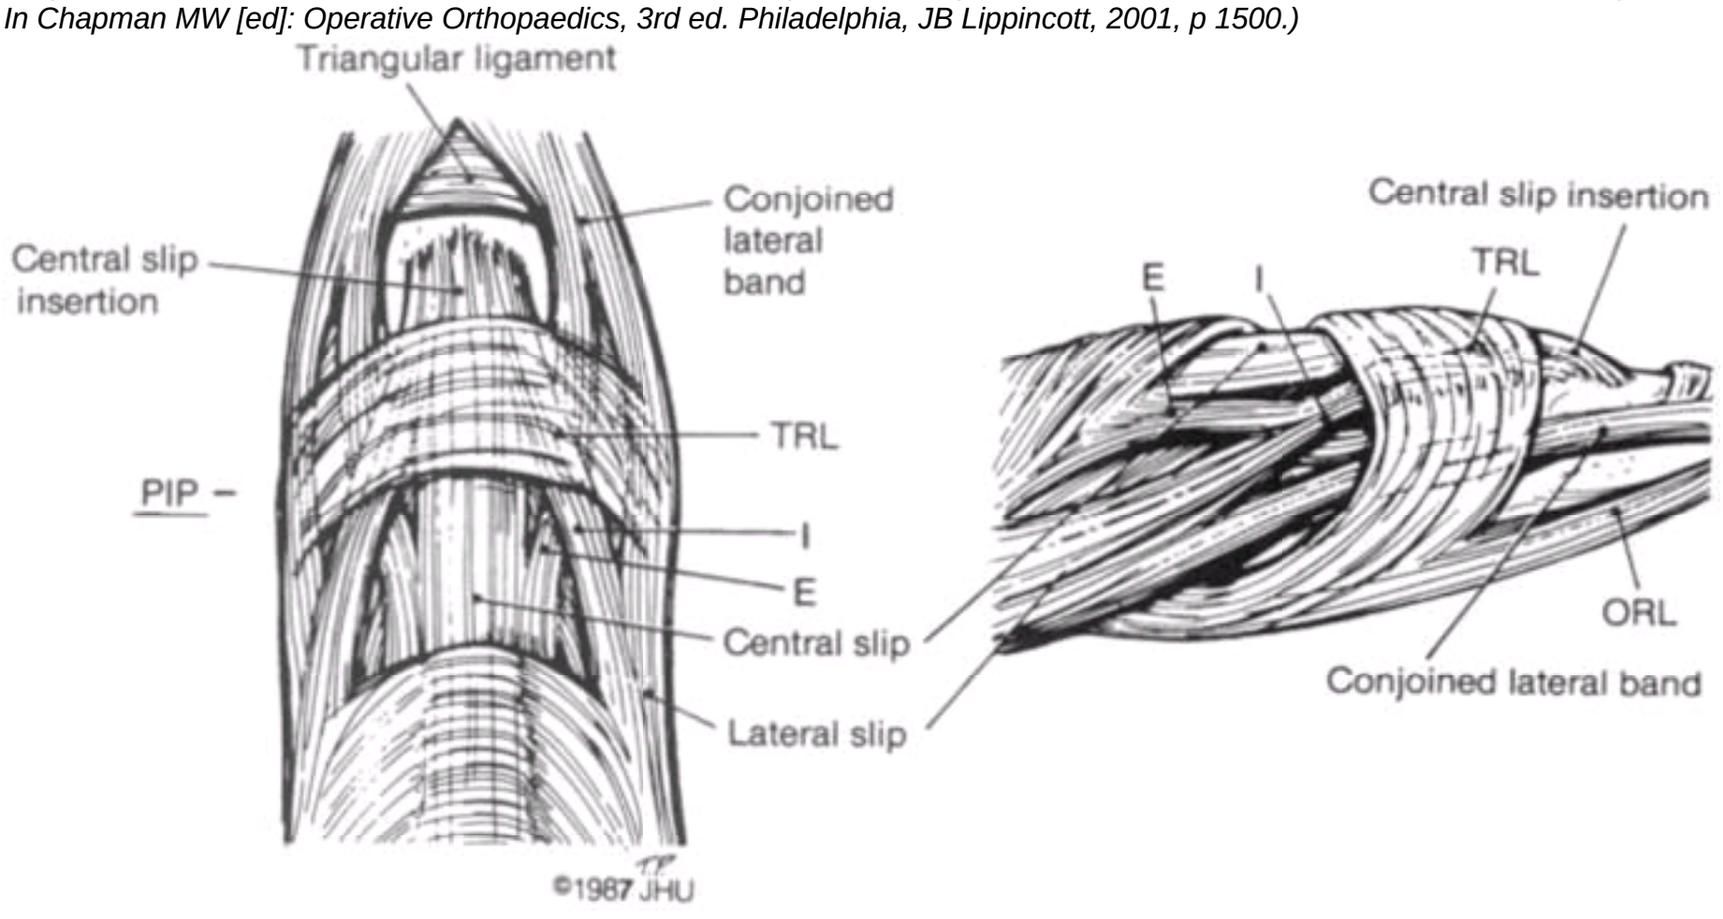

Figure 49-5 The extensor mechanism on the dorsum of a finger. *Arrows* point to the radial and ulnar lateral band portions of the extensor mechanism, and the probe lifts the entire structure up off the phalanx.

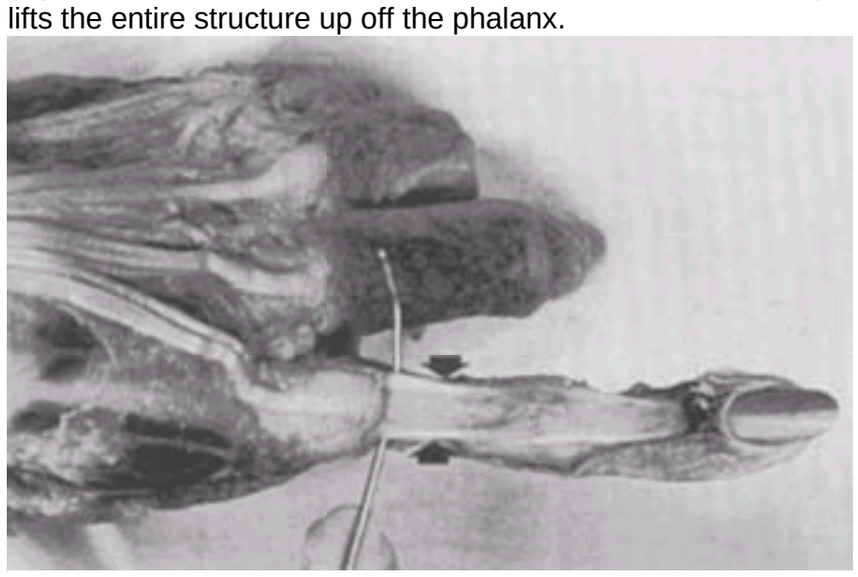

Figure 49-6 The terminal extensor mechanism.

Figure 49-7 Because of their superficial location, it is difficult to avoid at least partial injury to extensor tendons in even superficial lacerations of the dorsum of the wrist, hand, or fingers. In some cases *(A)* the injury is obvious. In other cases, a partial tendon laceration is not appreciated, but becomes obvious when complete rupture occurs *(B)*. In this case the patient seemingly had full tendon function during the initial ED evaluation, but the entire tendon could not be visualized due to an uncooperative patient. An unappreciated partial laceration progressed to complete rupture by the time of suture removal. The injury was diagnosed and an expeditious delayed primary repair resulted in a good outcome. Note: Inability to extend index finger is evident in both photos.

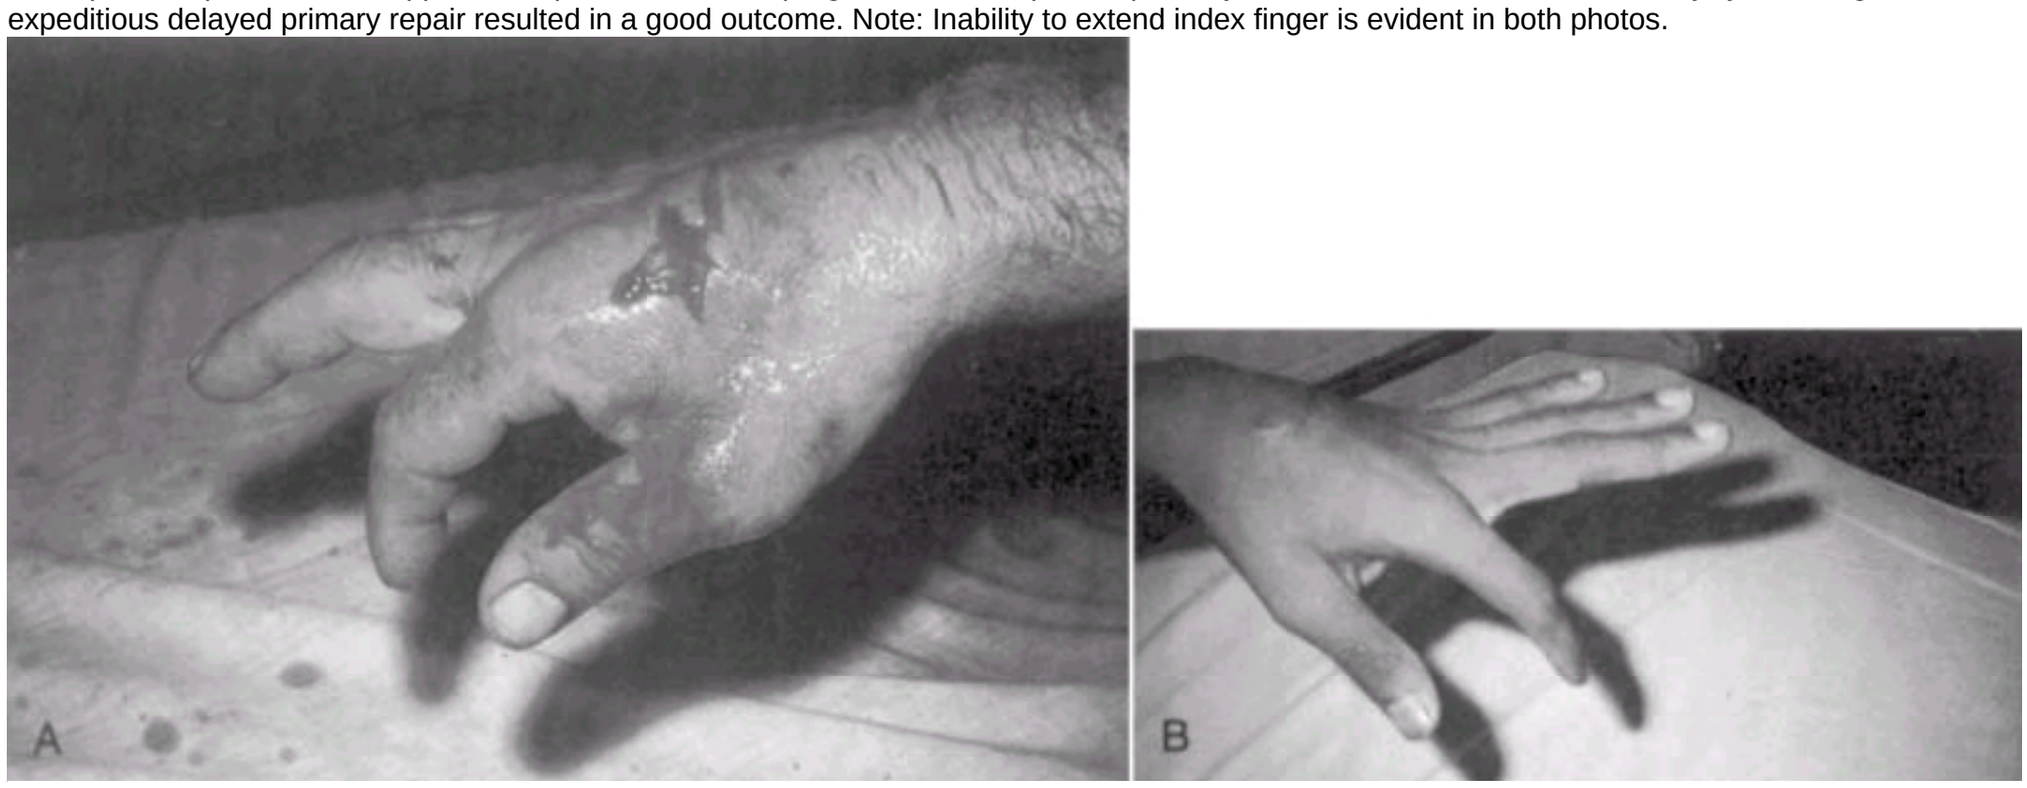

Figure 49-8 The location and depth of this laceration suggests an extensor tendon injury. On examination, the patient had full extension. Note that an intact tendon is visualized when the laceration is examined with the fingers in extension *(A)*. The injury occurred with a closed fist, and when the fingers were fully flexed, an 80% laceration of the extensor tendon could be viewed in the depths of the wound *(B)*. Note: Contrary to this figure, gloves should be worn by the examiner.

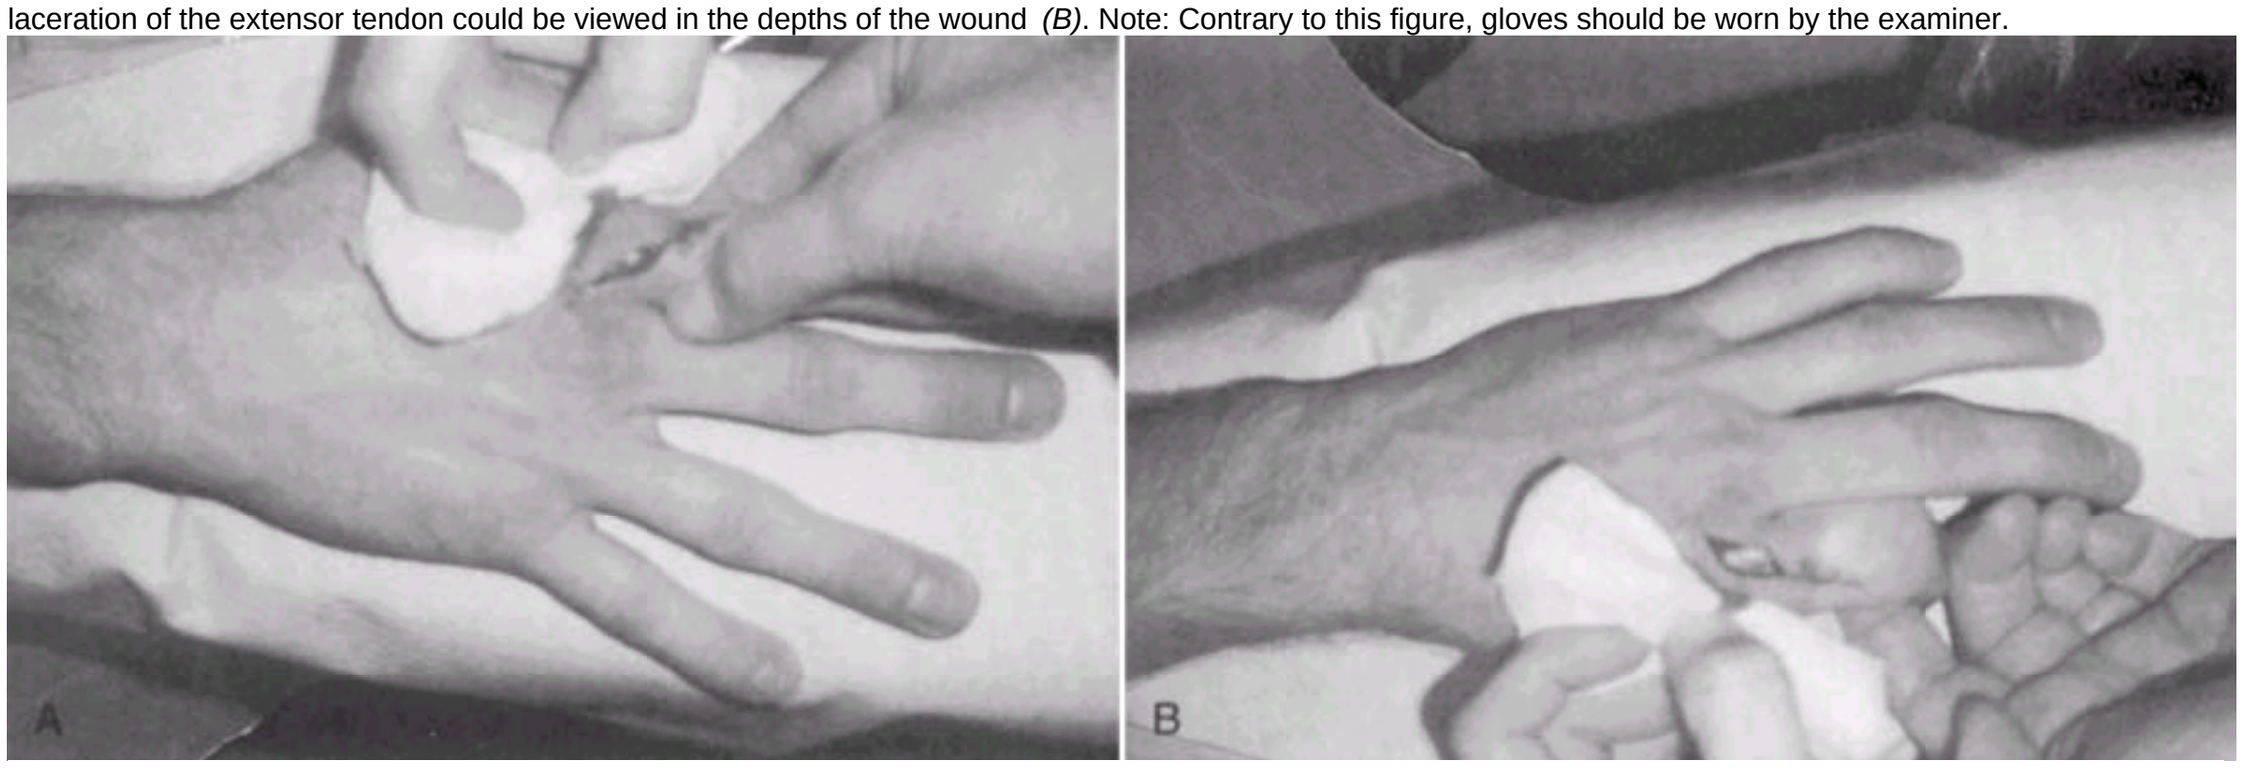

Figure 49-9 With this injury on the dorsum of the hand, the clinician should expect to find an extensor tendon injury. The proper way to examine this wound includes a bloodless field (often with the use of a blood pressure cuff tourniquet), good light, a cooperative patient, excellent anesthesia, and extending the skin laceration to visualize the depths of the laceration. Note that the tendon is visualized with the fingers manipulated from full extension to full flexion.

Figure 49-10 Dorsum of left hand. The injury classification system recommended by Verdan includes eight anatomically based zones. *(From Blair WF, Steyers CM: Extensor tendon injuries. Orthop Clin North Am 23:142, 1992.)*

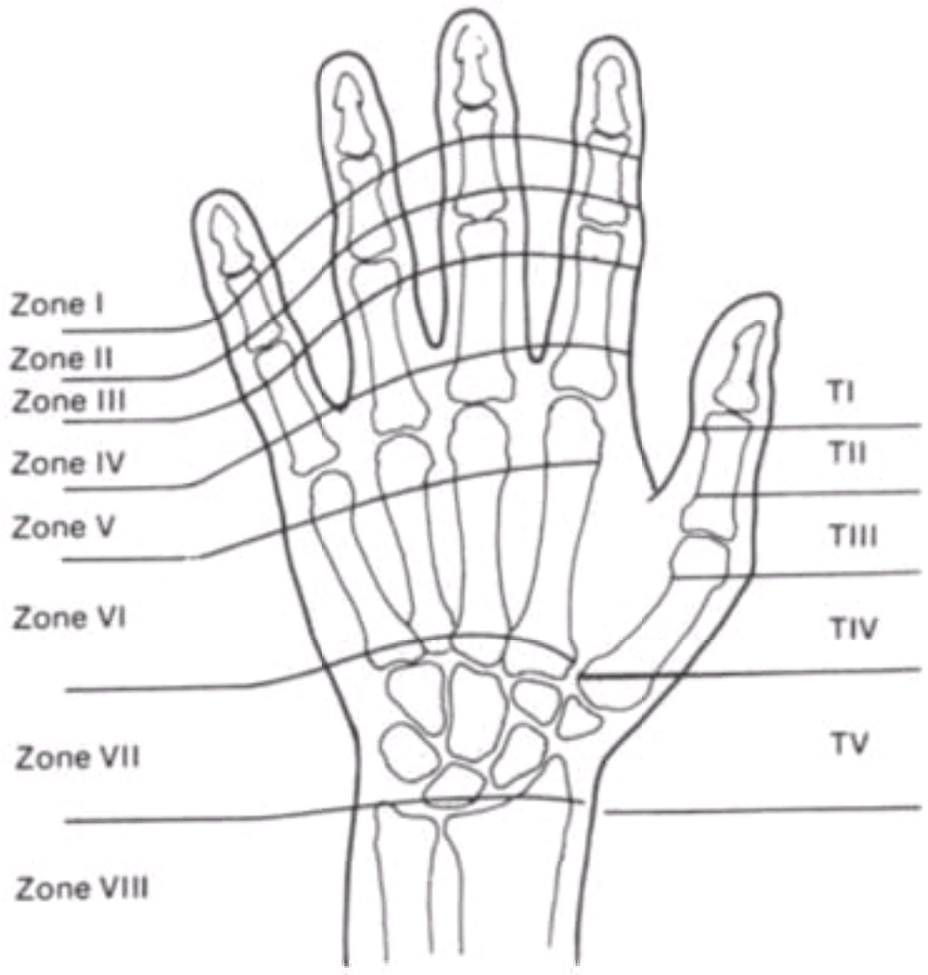

Figure 49-11 An effective way to fully immobilize a finger with a tendon laceration is to incorporate an aluminum foam splint into the middle of a standard dorsal plaster/fiberglass splint.

Figure 49-12 Suture techniques used in extensor tendon repair. *(From Newport ML, Williams CD: Biomechanical characteristics of extensor tendon suture techniques. J Hand Surg 17:1117, 1992.)*

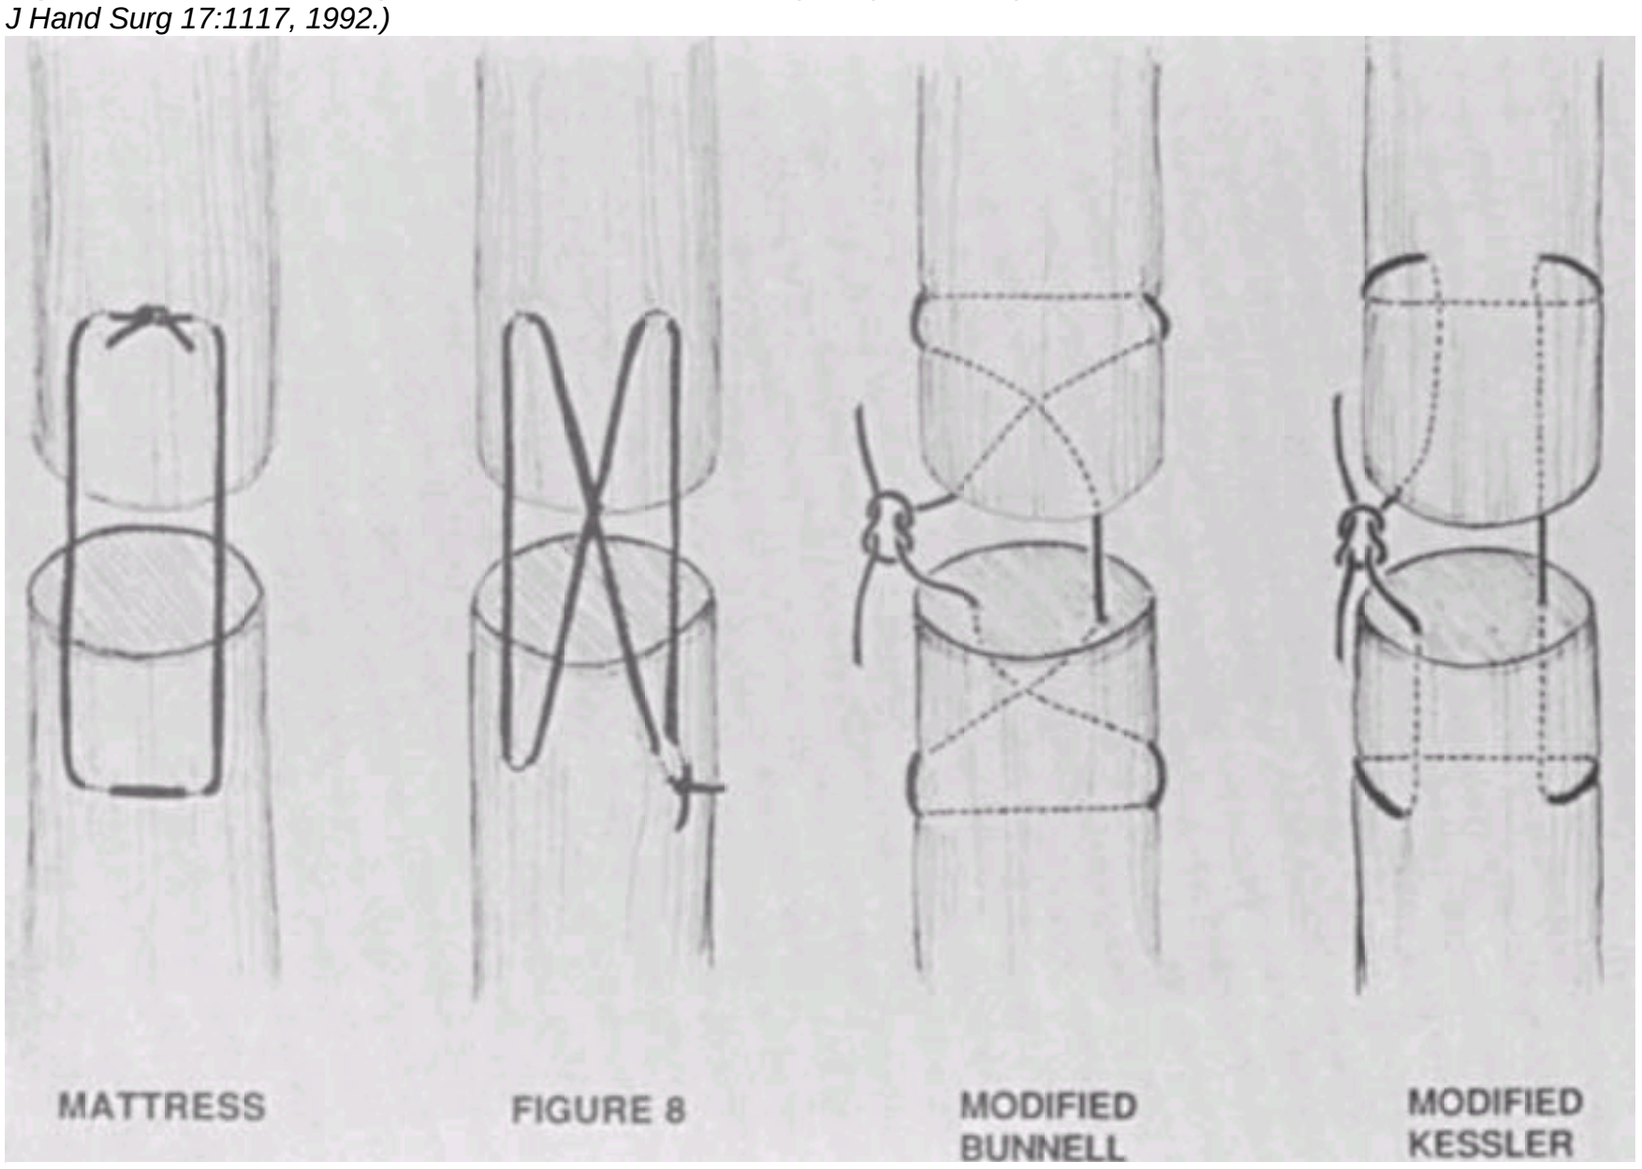

Figure 49-13 Four-strand suture techniques used in extensor tendon repair. *(Adapted from Howard RF, Ondrovic L, Greenwald DP: Biomechanical analysis of four-strand extensor tendon repair techniques. J Hand Surg 22:839, 1997.)*

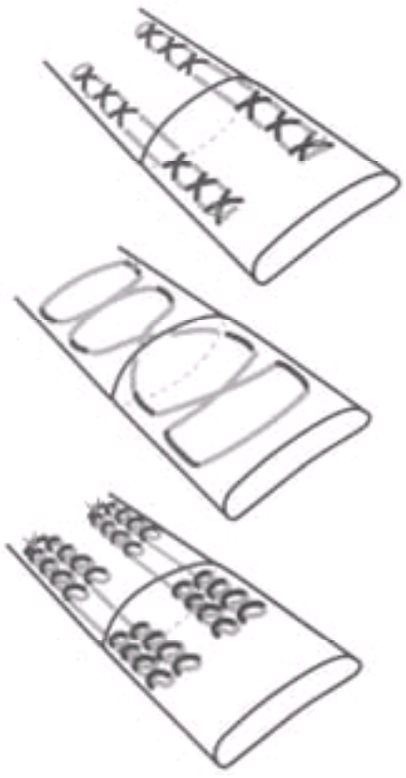

Figure 49-14 *A,* Regardless of this patient's history, this wound is highly suggestive of a human bite injury. Human bites cause extensor tendon injuries, fractures, and joint capsule injuries, and can harbor foreign bodies. *B,* This patient stated that he cut his hand on a piece of metal at work (expecting a Workers Compensation claim), but was unable to explain the piece of tooth that was found in the wound on exploration.

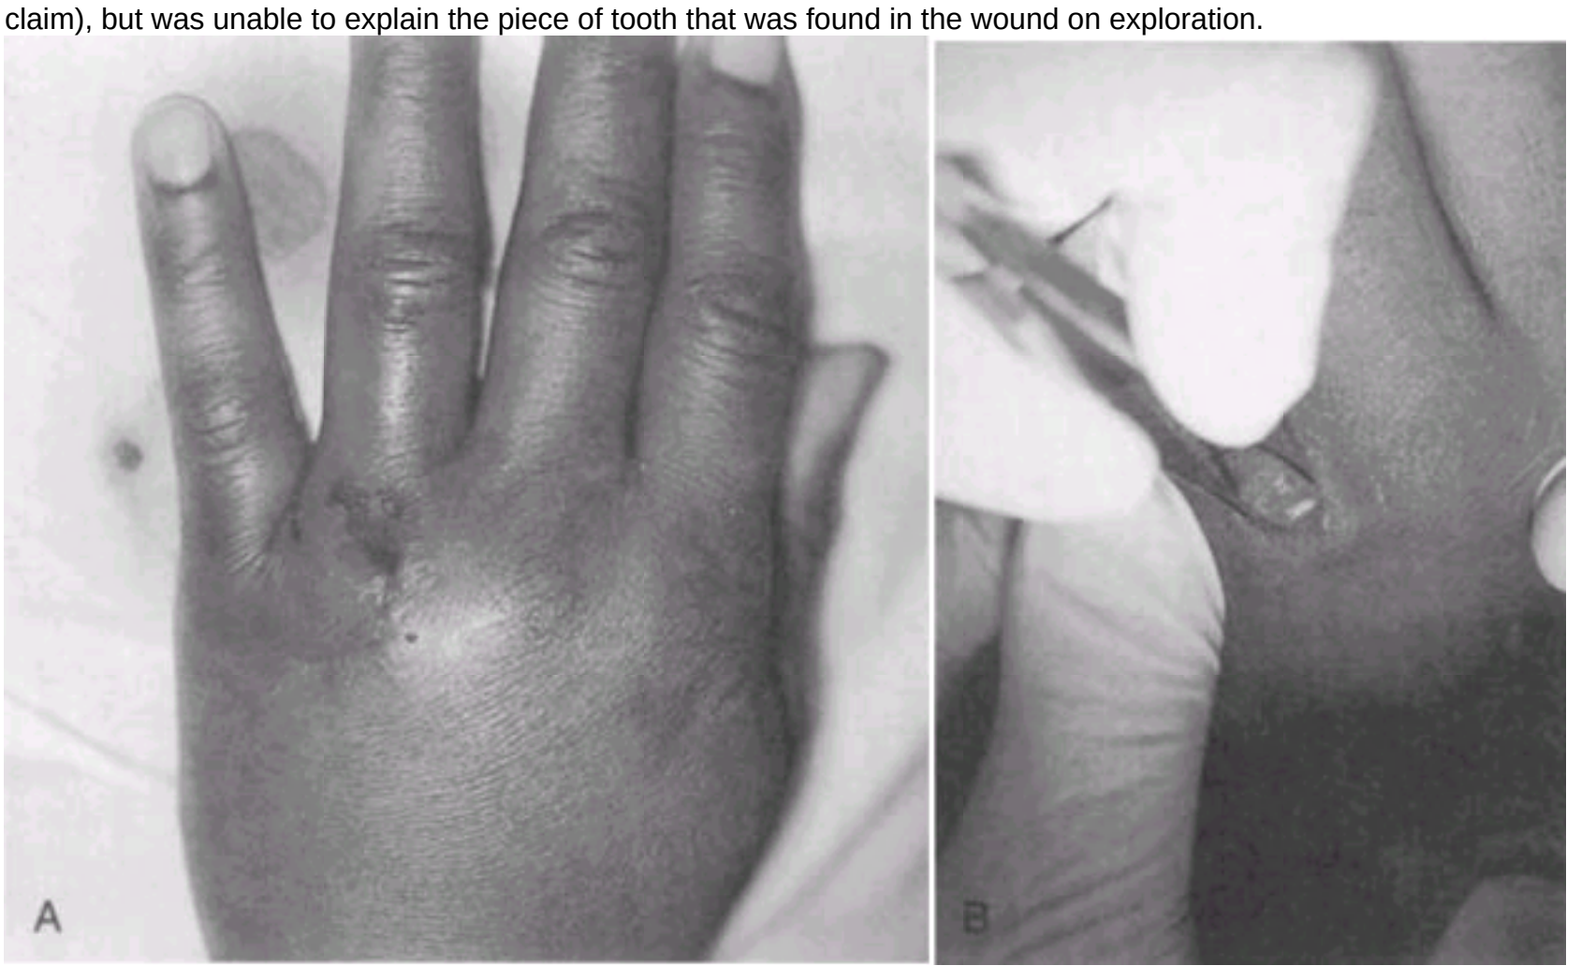

Figure 49-15 Ulnar dislocation of the extensor tendon of metacarpophalangeal joint of the middle finger. *(From Leddy JP, Dennis TR: Tendon injuries. In Strickland JW, Rettic AC [eds]: Hand Injuries in Athletes. Philadelphia, WB Saunders, 1992, p 196.)*

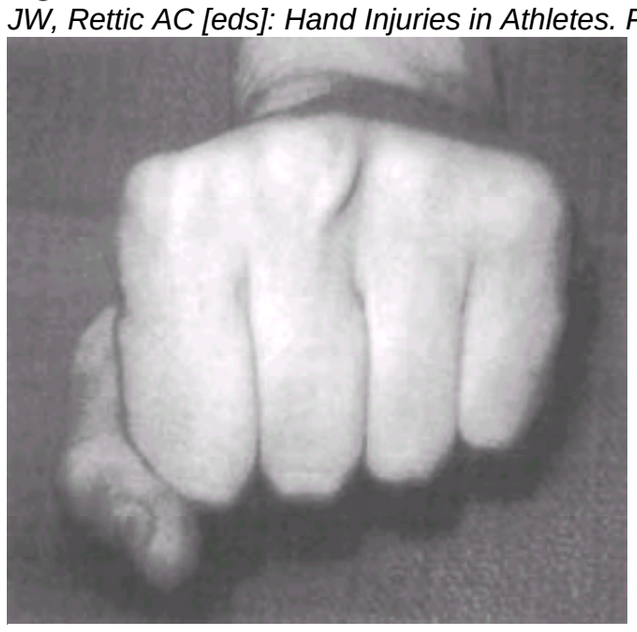

Figure 49-16 Boutonnière deformity. This can be an open or closed injury. Note flexion of the PIP joint and extension of the DIP joint, from a laceration of the central slip mechanism.

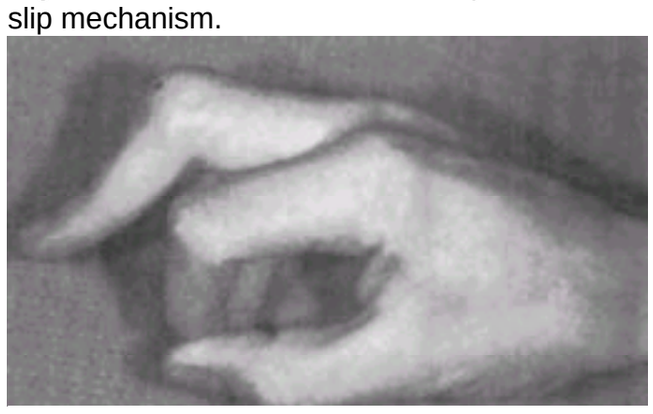

Figure 49-18 *A,* Boutonnière splint. *B,* This splint allows active flexion at the metacarpophalangeal and distal interphalangeal joints.

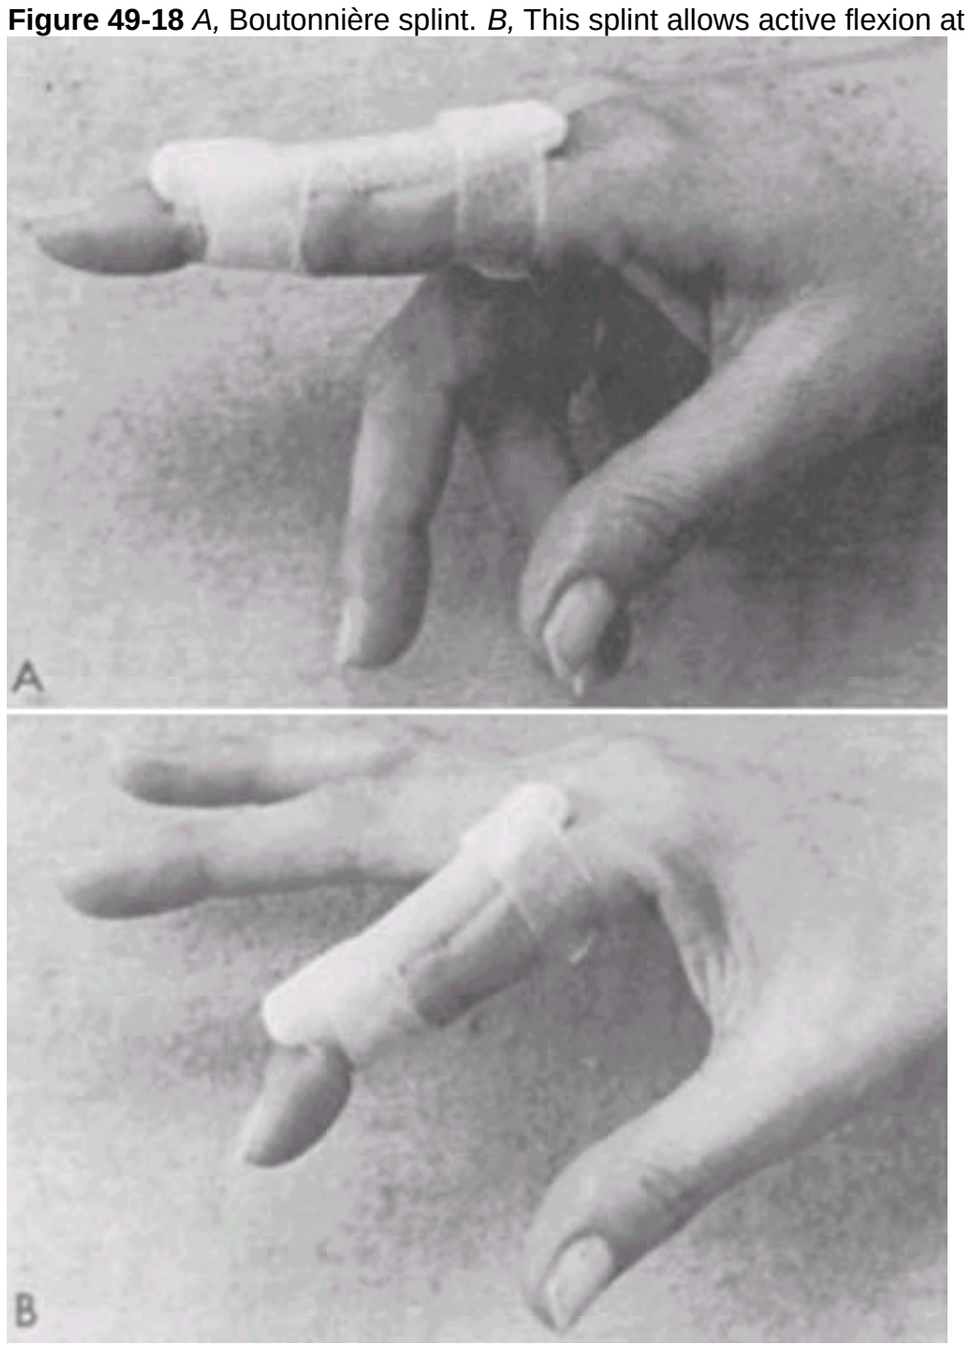

Figure 49-19 Mallet finger deformity. *(From Leddy JP, Dennis TR: Tendon injuries. In Strickland JW, Rettic AC [eds]: Hand Injuries in Athletes. Philadelphia, WB Saunders, 1992, p 180.)*

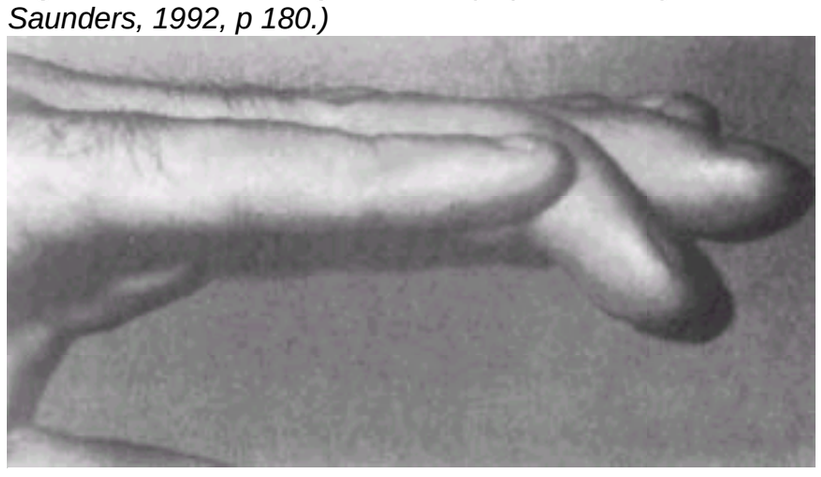

Figure 49-20 Dermatotenodesis technique for zone I extensor tendon repair. *A,* Fresh lacerations of the extensor mechanism over the distal joint with mallet finger deformity are repaired by a running-type suture, which simultaneously approximates the skin and tendon *(B and C)*. A small dressing is applied along with a splint, which maintains the joint in full extension. The sutures are removed at 10 to 12 days, but the splint is continued for a total of 6 weeks. *(Adapted from Doyle JR: Extensor tendons: Acute injuries. In Green DP [ed]: Operative Hand Surgery, 4th ed. New York, Churchill Livingstone, 1999, p 1968.)*

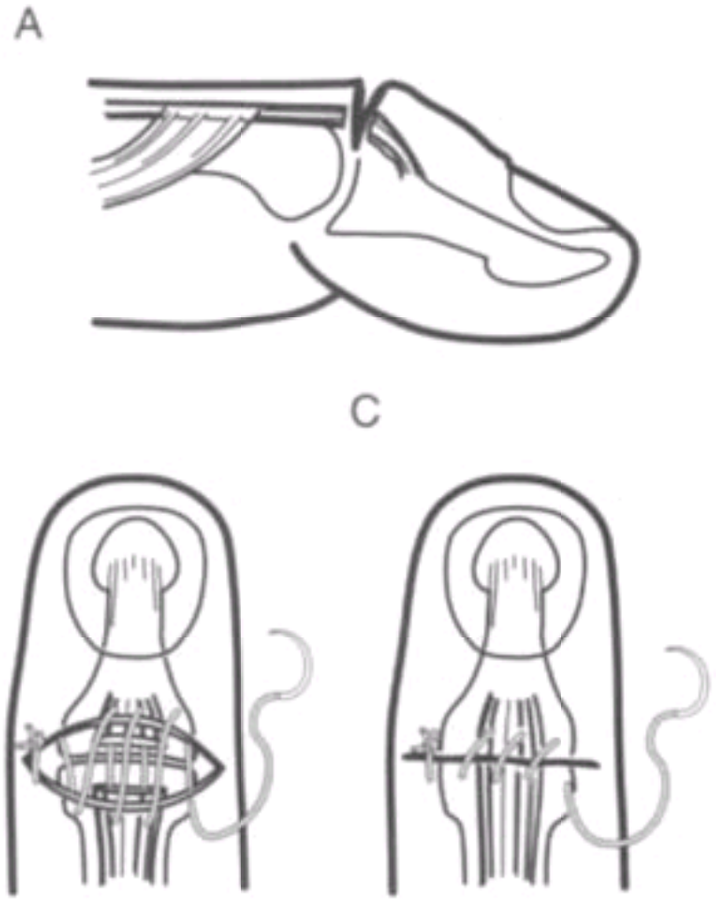

Figure 49-21 Repair of zone II extensor tendon lacerations *(A)*. Zone II lacerations may be repaired with a running stitch *(B)* near the edge of the laceration, followed by the cross-stitch *(C)*. The extensor tendon in this zone is comparatively thin, and this dual-suture technique has sufficient grasping capability to restore and maintain the normal length of the extensor. The repair is protected by 6 weeks of DIP joint splinting, as for zone I injuries. *(Adapted from Doyle JR: Extensor tendons—Acute injuries. In Green DP [ed]: Operative Hand Surgery, 4th ed. New York, Churchill Livingstone, 1999, p 1971.)*

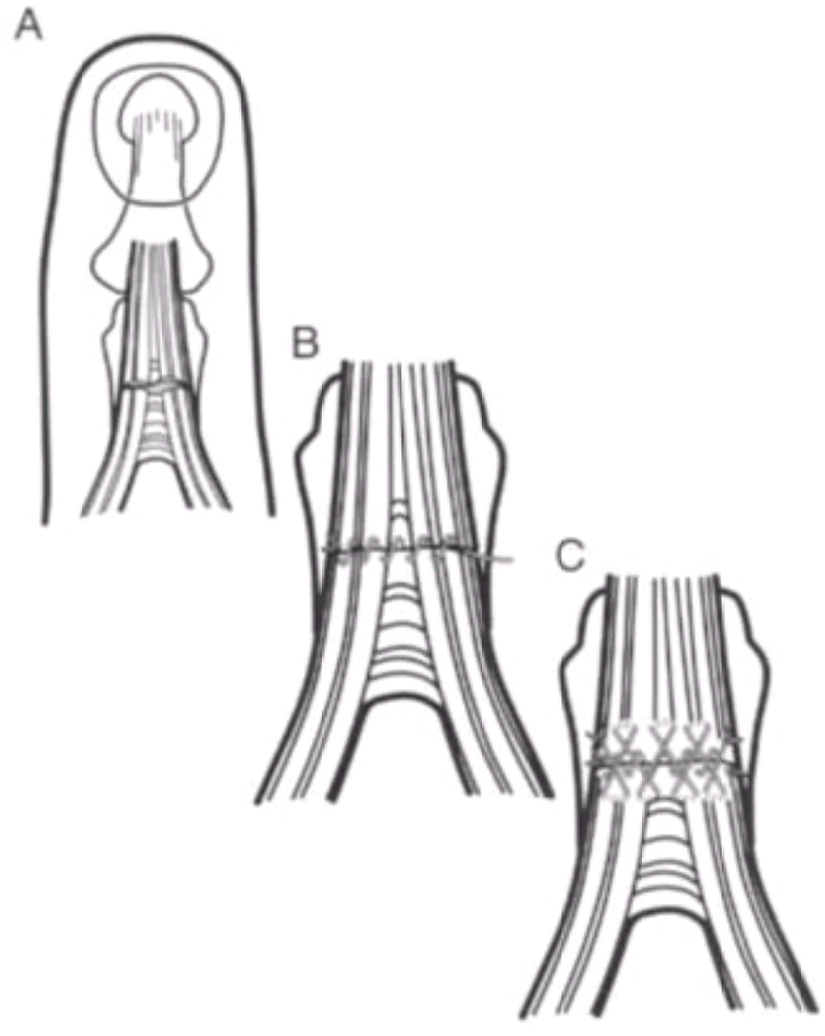

Figure 49-22 A proper mallet finger splint. Either a commercially available volar plastic splint (Stack mallet finger splint) *(A–C),* or a volar or dorsal aluminum foam splint may be used *(D and E)*. The splint should allow easy motion of the proximal interphalangeal joint. *(Adapted from Doyle JR: Extensor tendons—Acute injuries. In Green DP [ed]: Operative Hand Surgery, 4th ed. New York, Churchill Livingstone, 1999, p 1967.)*

Figure 49-24 Swan neck deformity. *(Courtesy of Raymond G. Hart and Joseph E. Kutz.)*

Figure 49-25 A dynamic extension splint allows for early motion following extensor tendon repair. Elastic retraction maintains the fingers in extension. Excursion of the repaired tendon is achieved by active flexion. *(Adapted from Doyle JR: Extensor tendons—Acute injuries. In Green DP [ed]: Operative Hand Surgery, 4th ed. New York, Churchill Livingstone, 1999, p 1957.)*

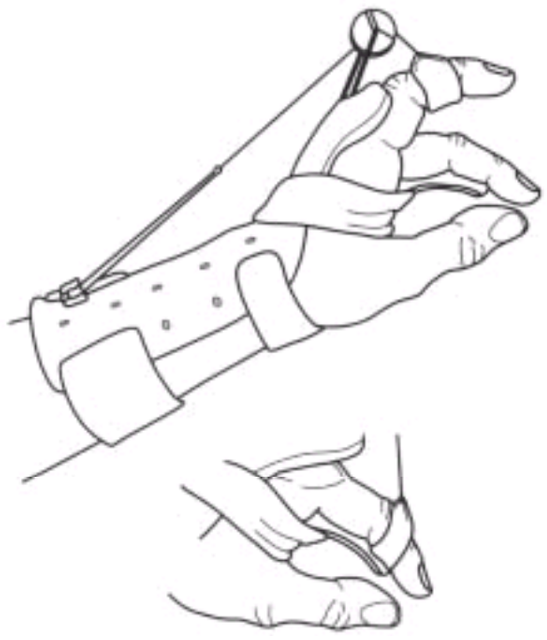

Figure 49-26 First layer of the dorsum of the foot and ankle. *1,* anterior tibial artery; *2,* anterior medial malleolar artery; *3,* anterior lateral malleolar artery; *4,* dorsalis pedis artery; *5,* first dorsal metatarsal artery; *6,* arcuate artery; *7,* dorsal metatarsal arteries; *8,* medial tarsal artery; *9, 10,* deep peroneal nerve; *11,* motor nerve branch to extensor digitorum brevis; *12,* inferior extensor retinaculum; *13,* superomedial band of inferior extensor retinaculum; *14,* inferomedial band of inferior extensor retinaculum; *15,* superolateral band of inferior extensor retinaculum; *16,* superior extensor retinaculum; *17,* tibialis anterior tendon; *18,* extensor hallucis longus tendon; *19,* extensor digitorum longus tendon; *20,* extensor digitorum brevis muscle to toes; *21,* extensor hallucis brevis muscle. *(From Sarrafian SK: Functional Anatomy of the Foot and Ankle: Descriptive, Topographic, Functional, 2nd ed. Philadelphia, JB Lippincott, p 423.)*

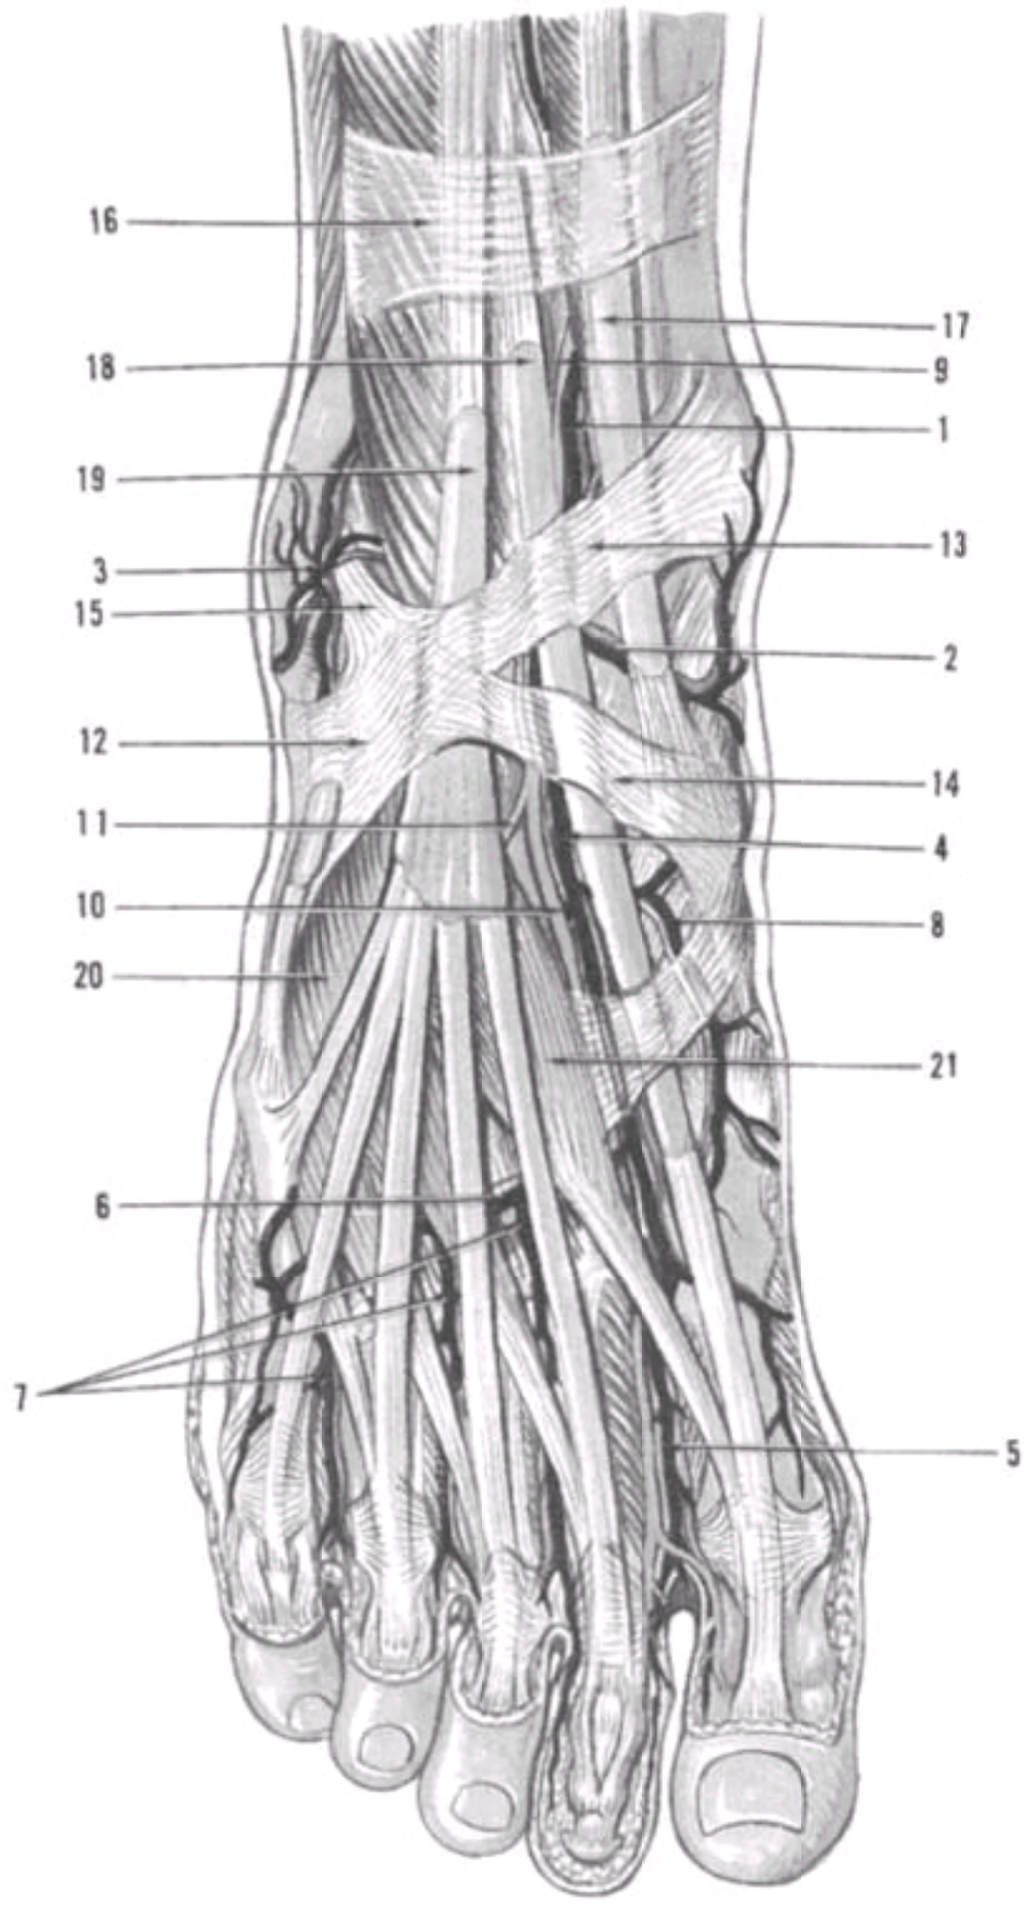

Figure 49-27 Flexor tendons of the right forearm, wrist, and hand. *A,* Superficial forearm layer. *B,* Deep forearm layer. *C,* Left wrist and palm. Proper function of the flexor tendons requires defect-free tendons and smooth tendon sheaths for easy gliding, and an intact pulley system; hence, flexor tendon lacerations are seldom repaired in the ED. *(Modified from Pansky B: Upper extremity. In Pansky B [ed]: Review of Gross Anatomy, 4th ed. New York, Macmillan Publishing, 1979, pp 219, 243.)*

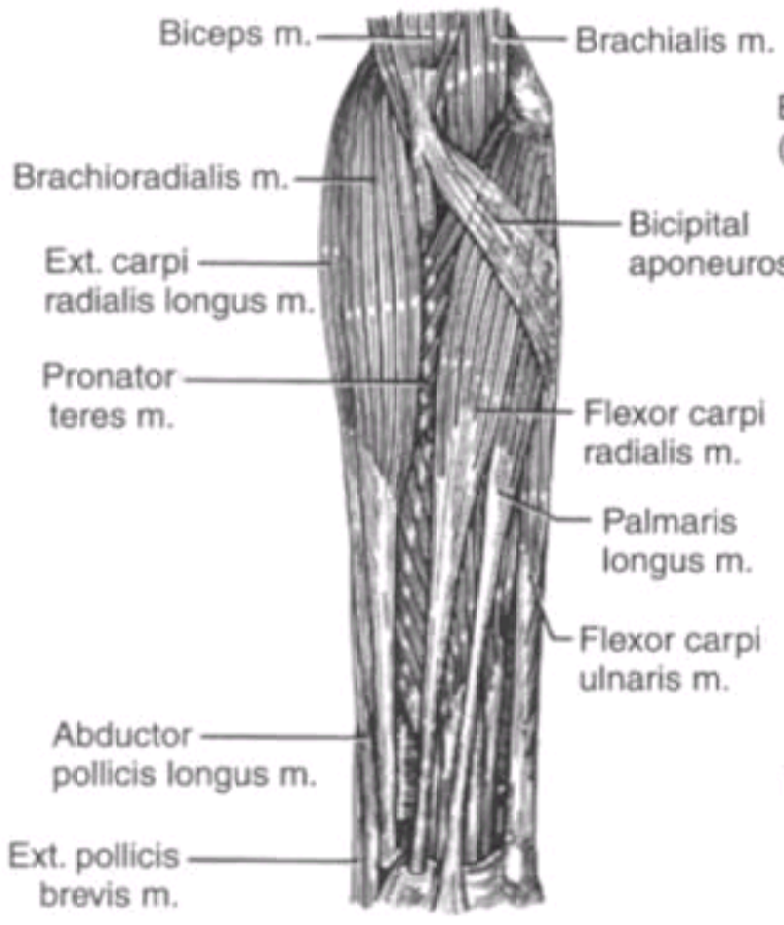
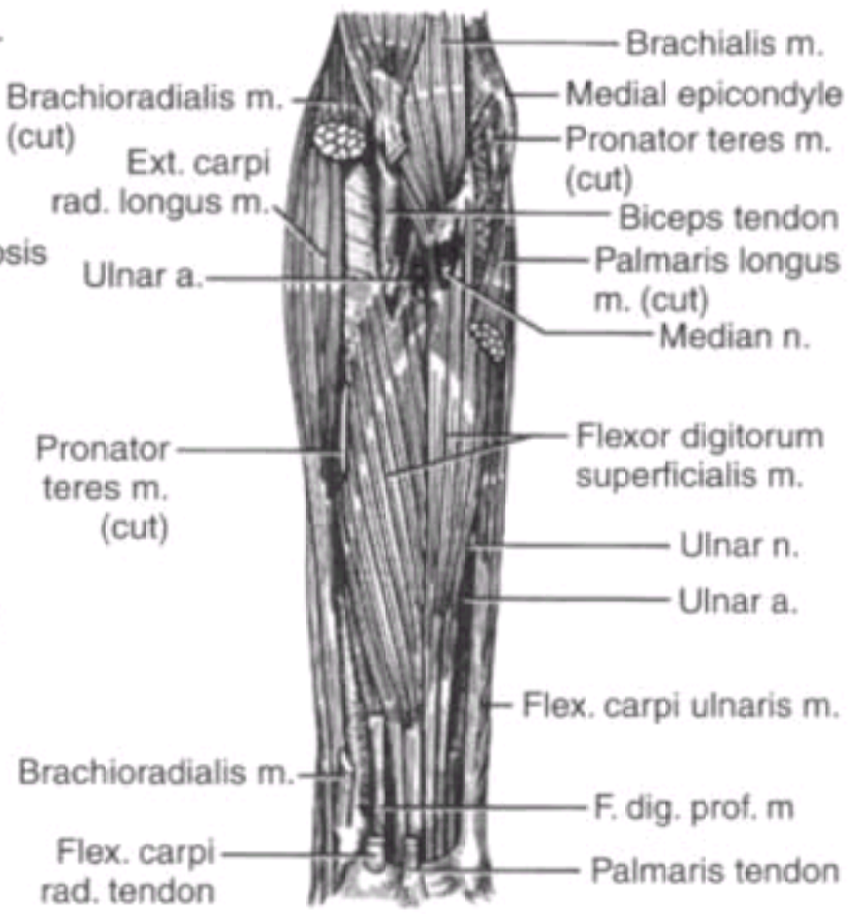
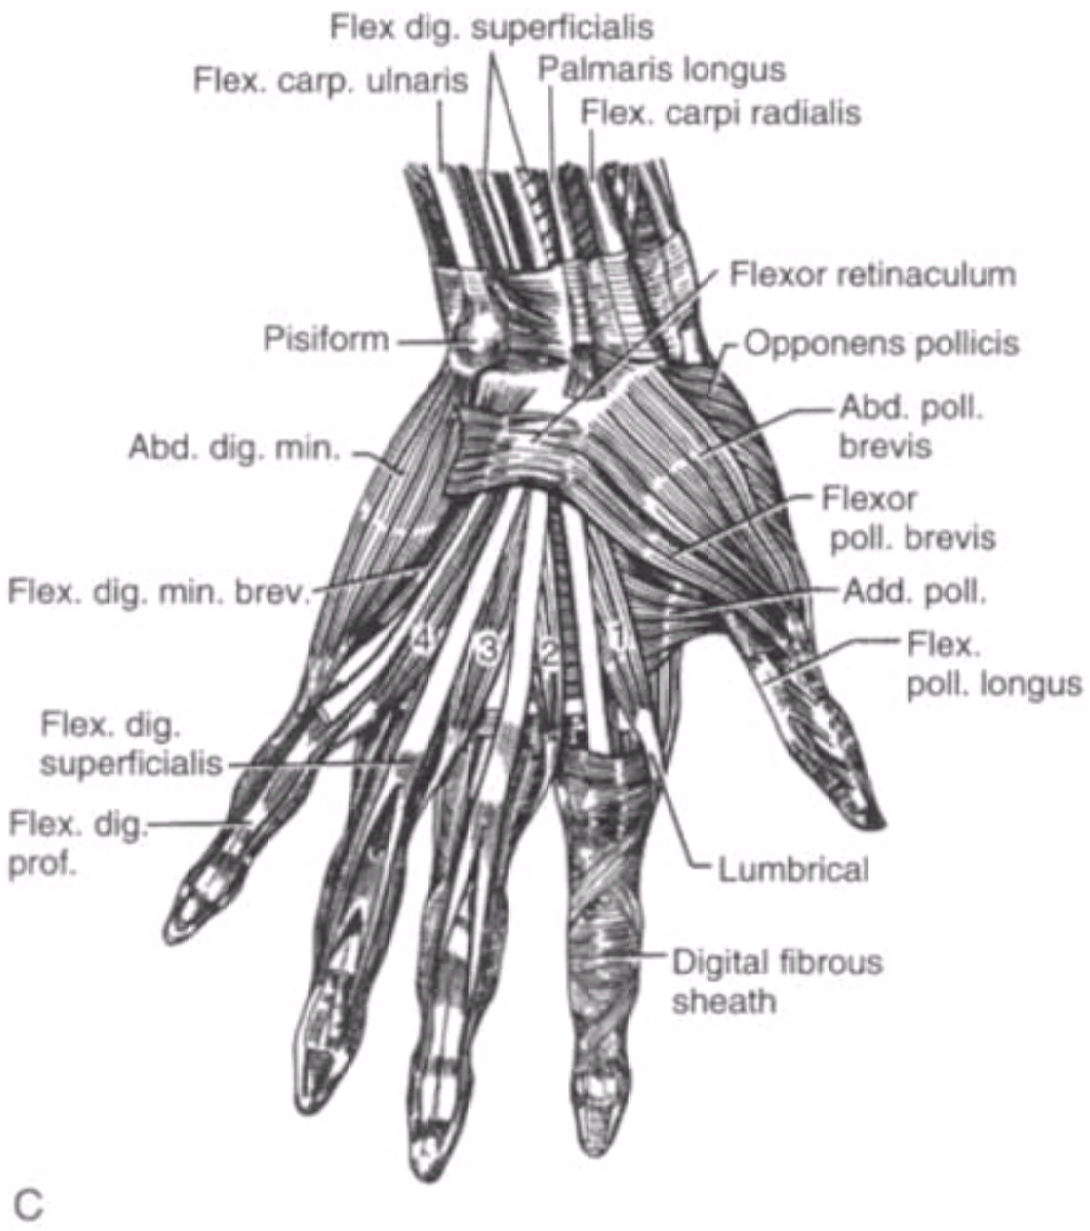


A



B



C

Figure 49-28 Deep puncture wounds of the palm may injure flexor tendons. The depth of this wound precludes extensive exploration to visualize the tendon. Partial tendon lacerations may still initially allow full function. Clues to a partial tendon laceration include weakness of flexion or pain with attempts at flexion against resistance, but many partial lacerations are clinically silent. Despite full function this wound's location and depth suggest the possibility of at least a partial tendon injury. The prudent course would include meticulous wound care, splinting, skin closure, and contact with a hand specialist to arrange re-examination in a few days, while cautioning the patient that further care may be required.

Figure 49-29 *A,* The flexor digitorum profundus tendon is examined by immobilizing the digit in question and asking the patient to flex the distal interphalangeal joint against resistance. *B,* The flexor digitorum superficialis tendon is examined by immobilizing the digits not being tested and asking the patient to flex the proximal interphalangeal joint against resistance. Pain and weakness associated with flexion against resistance may suggest a partial tendon laceration, but this is often a very subtle or inaccurate evaluation that must be repeated when pain and swelling have subsided.

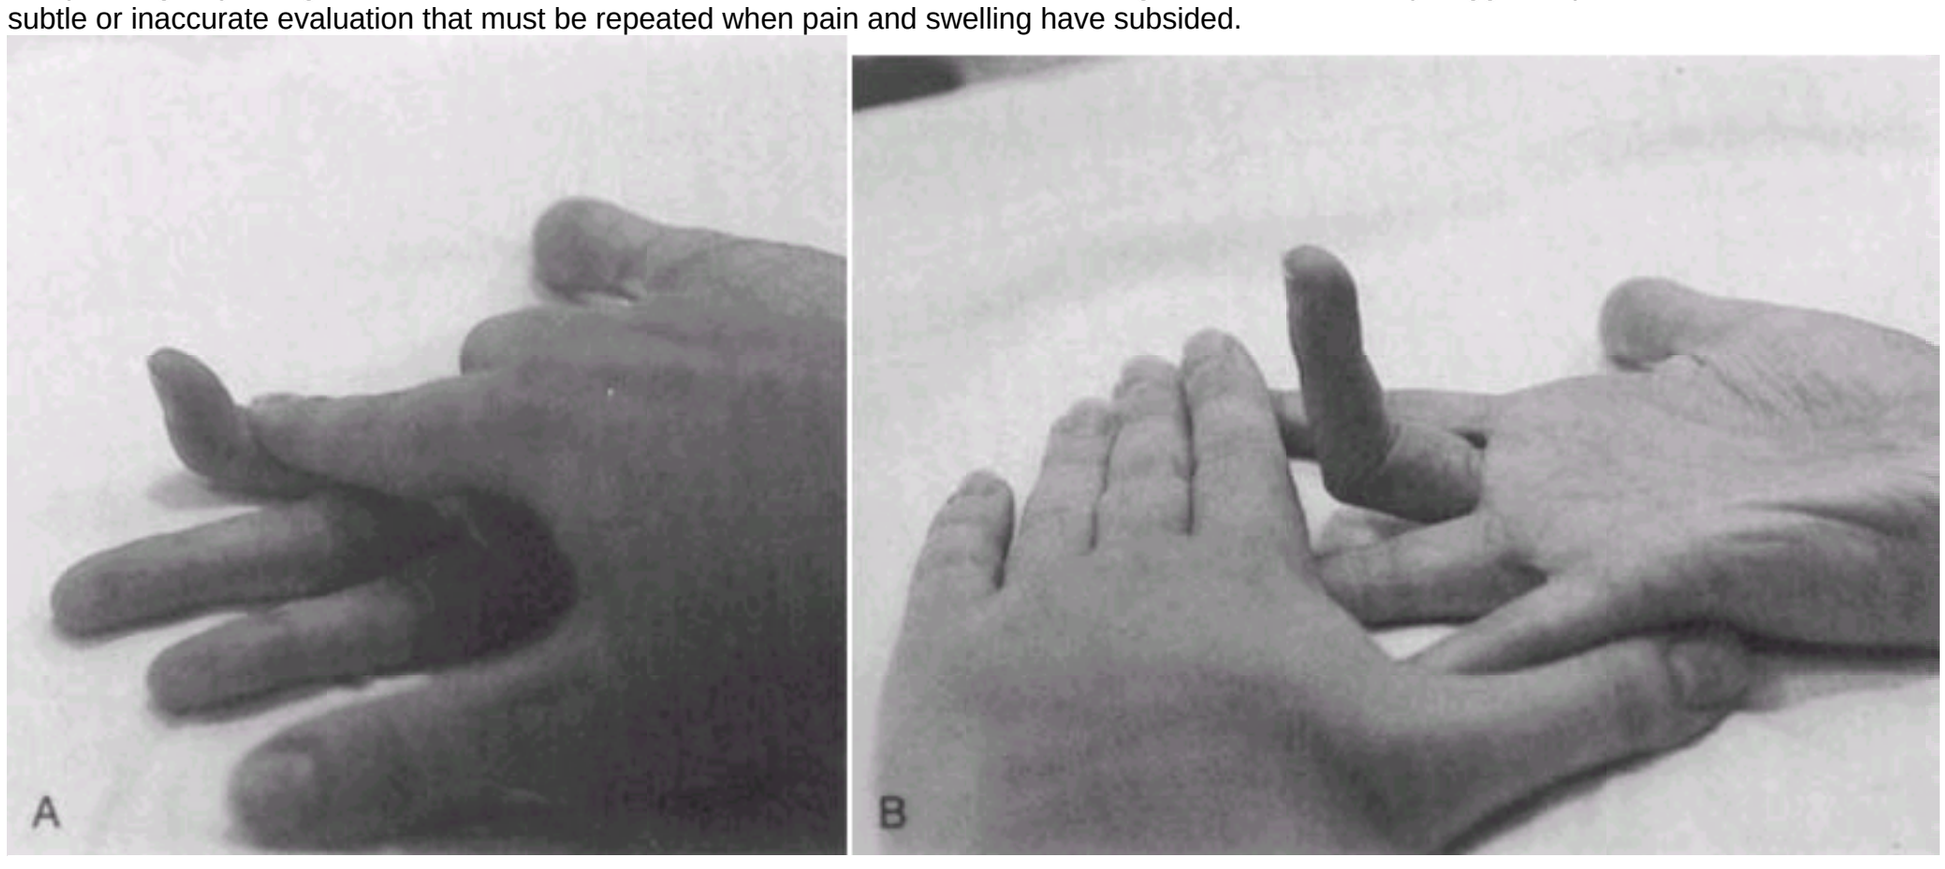


Figure 50-1 Significant vascular injuries from dislocations, such as the knee, are usually obvious, but some reduction in distal circulation may be subtle due to partial vascular compromise that heralds subsequent ischemia. The standard techniques to assess vascular injury are assessing the strength of the pulse and capillary refill, but other techniques may be helpful. While these procedures are neither well studied nor quantified, taking the blood pressure distal to the injury with a cuff and Doppler (shown here) or applying a pulse oximeter distal to the injury and comparing the results to the uninjured extremity may give some helpful clues to underlying vascular injuries. Calculating a brachial/ankle blood pressure index (see Chapter 1) is also more accurate than simple palpation.

Figure 50-2 *A* and *B*, Because the distal pulse is weak and the toes are numb, it may be tempting to immediately reduce these obvious dislocations while the patient is still on the ambulance stretcher. Some clinicians prefer to first obtain proper analgesia/sedation to allow a less traumatic reduction. *C*, Prereduction radiographs (even limited-view portable films are acceptable) can be helpful since once the reduction is accomplished, the specific initial injury may be impossible to reconstruct from the physical examination alone. The few minutes required to properly prepare the patient for reduction and to document the initial injury should not result in a more adverse outcome than has been prognosticated by the initial injury. However, when the patient has sustained multiple trauma and extremity films are a low priority, early reduction without radiographs may be warranted.

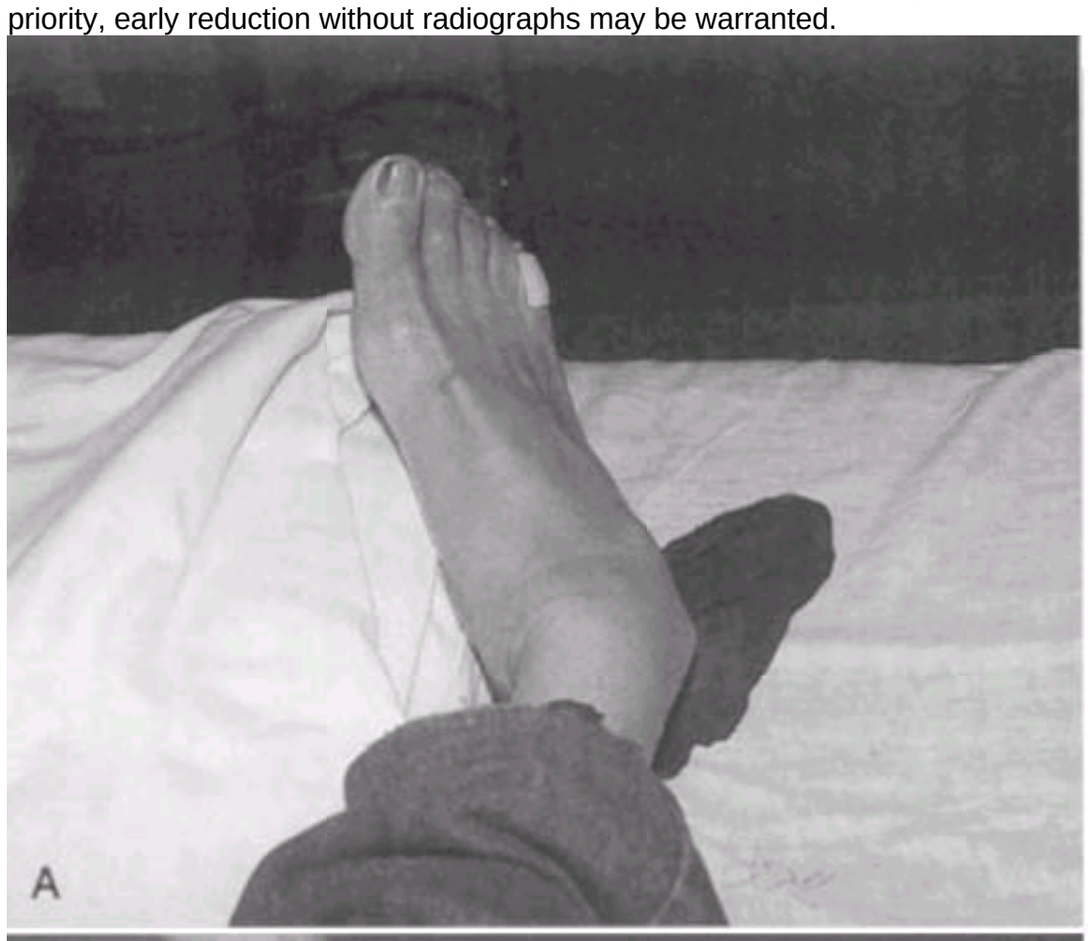

Figure 50-3 Types of anterior dislocations. These types of anterior dislocations should receive the same treatment. *A,* Subglenoid dislocation (rare type). *B,* Subcoracoid dislocation (most common type). *C,* Subclavicular dislocation (rare type). *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, p 617. Reproduced by permission.)*

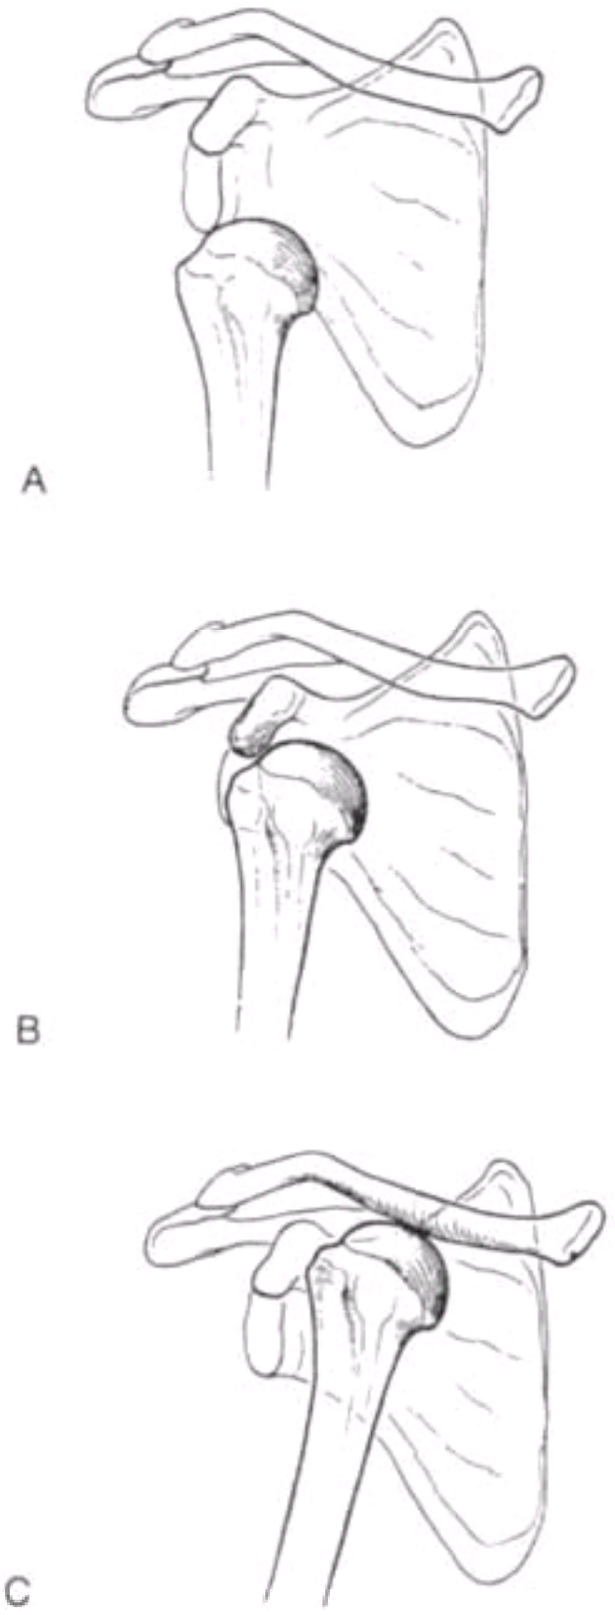

Figure 50-4 *A*, Typical presentation of an anterior right shoulder dislocation. The shoulder is very painful; thus, the patient resists movement. The outer round contour of the shoulder is flattened, and the displaced humeral head may be appreciated in the subcoracoid area. Often the patient abducts the arm slightly, bends the torso toward the injured side, and supports the flexed elbow on the injured side with the other hand. *B*, Another example of an obvious left shoulder dislocation. This chronic dislocation occurred frequently with minimal trauma, in this case from rolling over in bed.

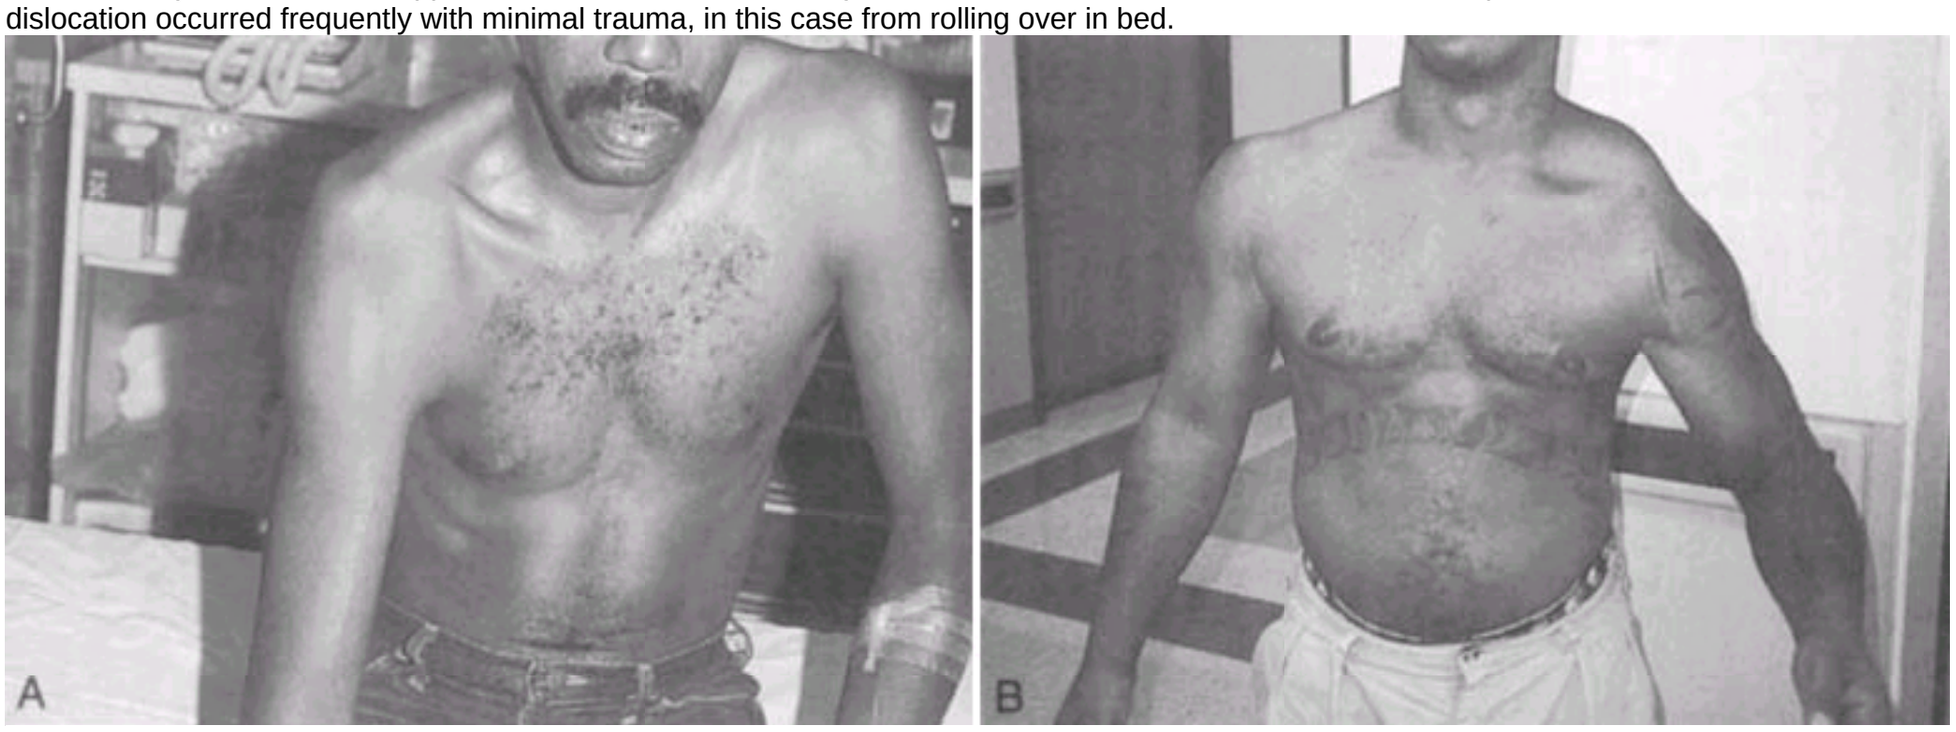

Figure 50-5 Evaluation of the upper extremity with a shoulder dislocation. Axillary (circumflex) nerve palsy is the most common neurologic complication. The axillary nerve has a sensory and motor function. Test the integrity of the nerve by assessing sensation to pin prick (*1)* in its distribution over the "regimental badge" area. (The shoulder is usually too painful to allow assessment of deltoid activity with certainty.) Look for other (rare) involvement of the radial portion of the posterior cord (*2)* and involvement of the axillary artery (*3)*. *(From McRae R: Practical Fracture Treatment. Edinburgh, Churchill Livingstone, 1981, p 84. Reproduced by permission.)*

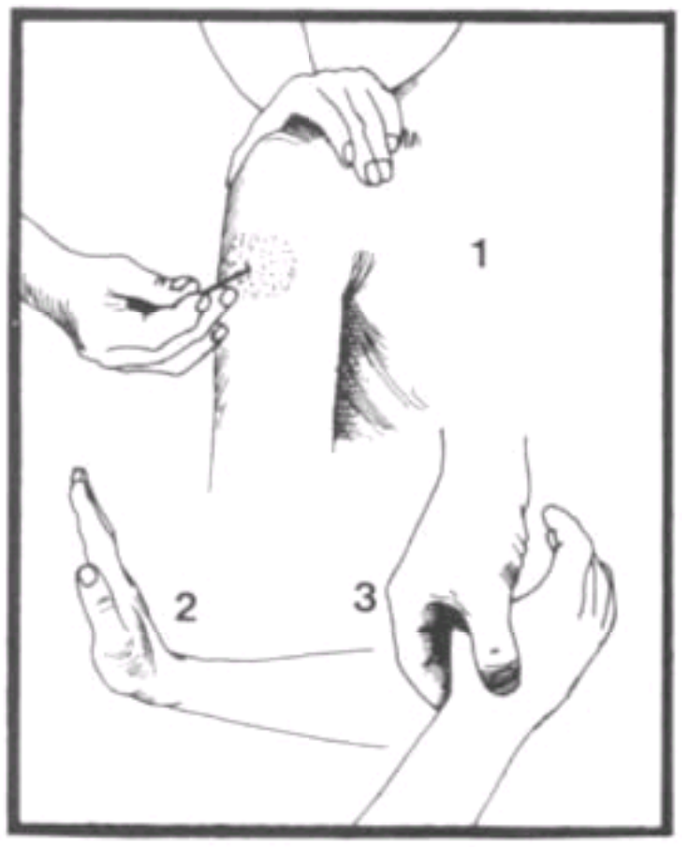

Figure 50-6 With repeated anterior shoulder dislocations, a Hill-Sachs lesion may form. During the dislocation the humeral head is damaged by the sharp anterior rim of the glenoid *(2)*. With repeated dislocation the lesion, called the "hatchet sign" develops *(3)*. On the reduction film the lesion is apparent *(4)*.

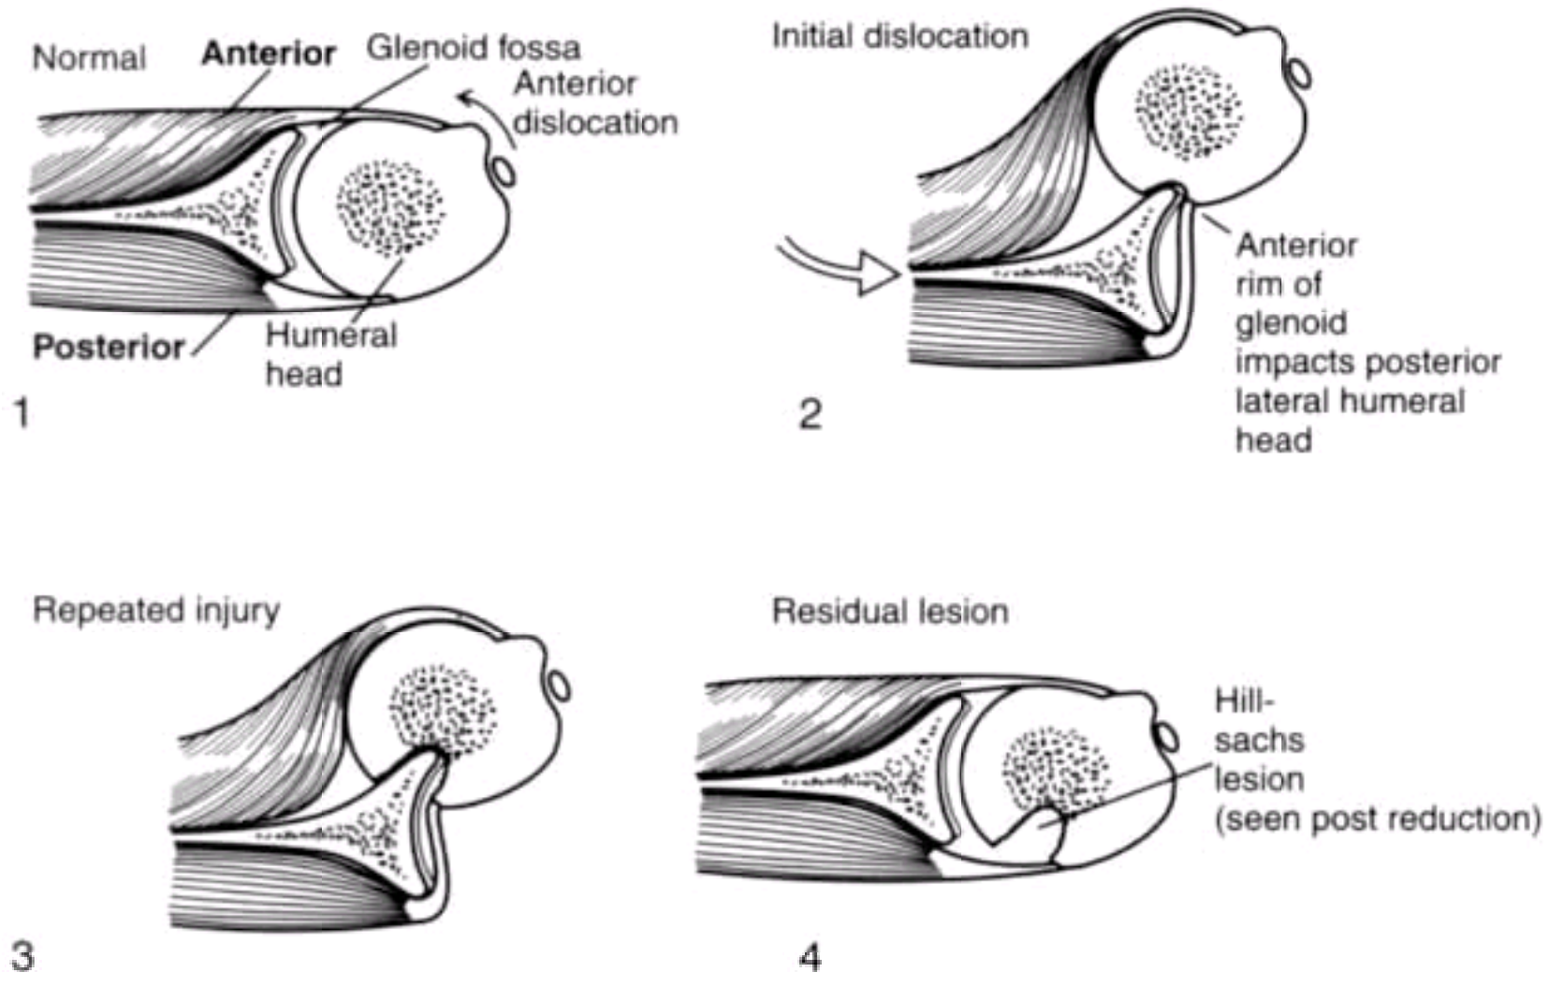

Figure 50-7 Trauma series includes two views of the shoulder made perpendicular and parallel to the scapular plane. This provides an anteroposterior (*A*) and a scapular Y (*B*) view. The advantage is that roentgenograms may be obtained without moving the patient or removing the arm from the sling. *(From Heppenstall RB: Fracture Treatment and Healing. Philadelphia, WB Saunders, 1980, p 374. Reproduced by permission.)*

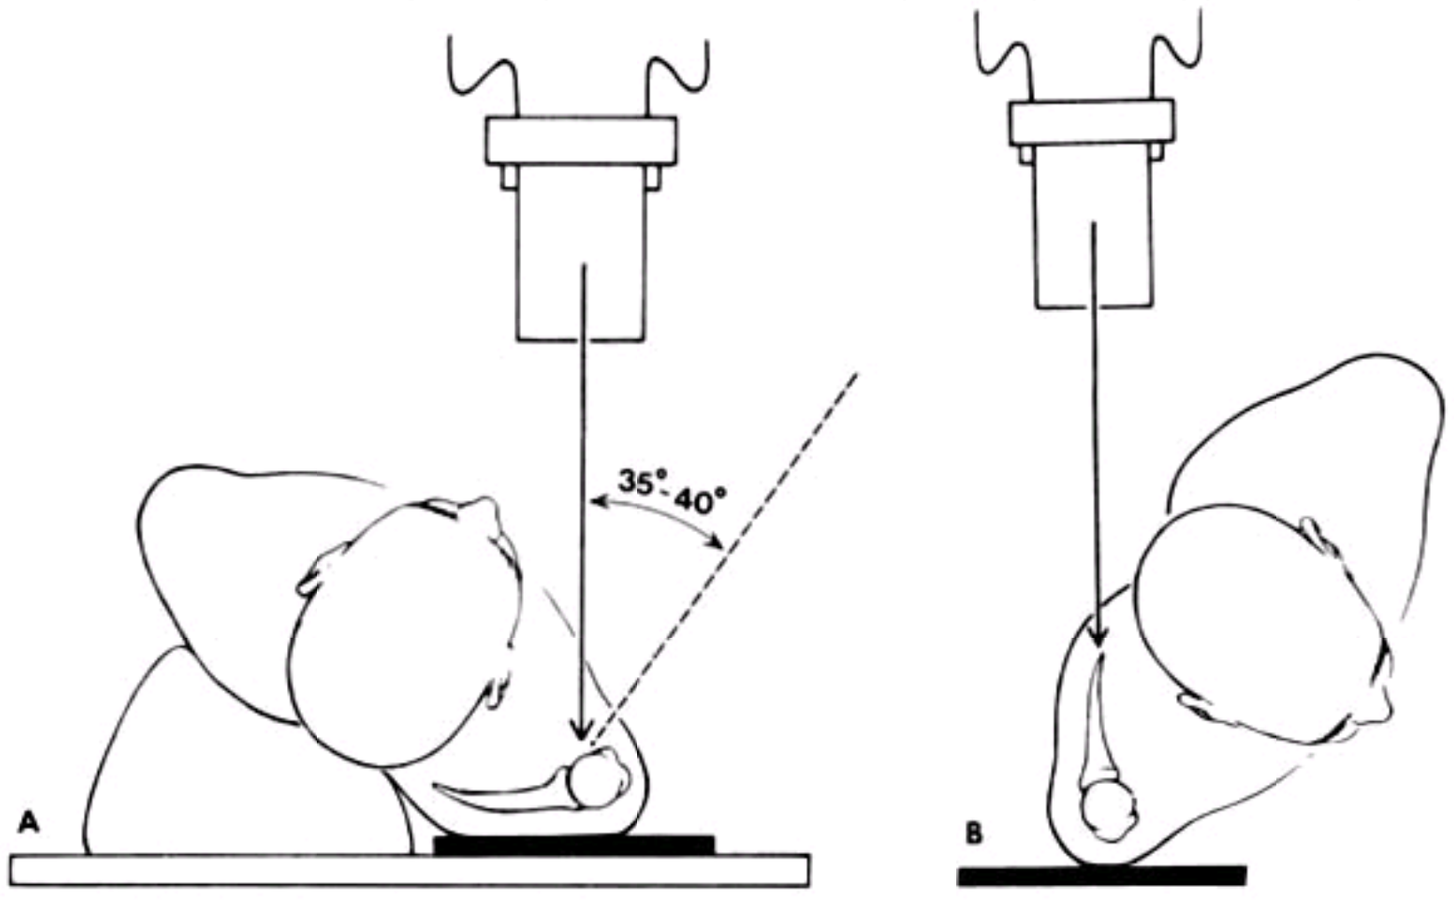

Figure 50-8 In the trauma series, a lateral view of the scapula (also called scapular Y view) demonstrates the head of the humerus displaced inferiorly and medially, the most common position for an anterior dislocation *(A)*. An anterior dislocation is shown on the anteroposterior projection *(B)*. A posterior dislocation: Transscapular projection showing the dislocated humeral head, posterior in relationship to the intersecting limbs of the Y *(C)*. *(A and B from Heppenstall RB: Fracture Treatment and Healing. Philadelphia, WB Saunders, 1980, p 392; C from Greenbaum E (ed): Radiology of the Emergency Patient. New York, John Wiley & Sons, 1982, p 512.)*

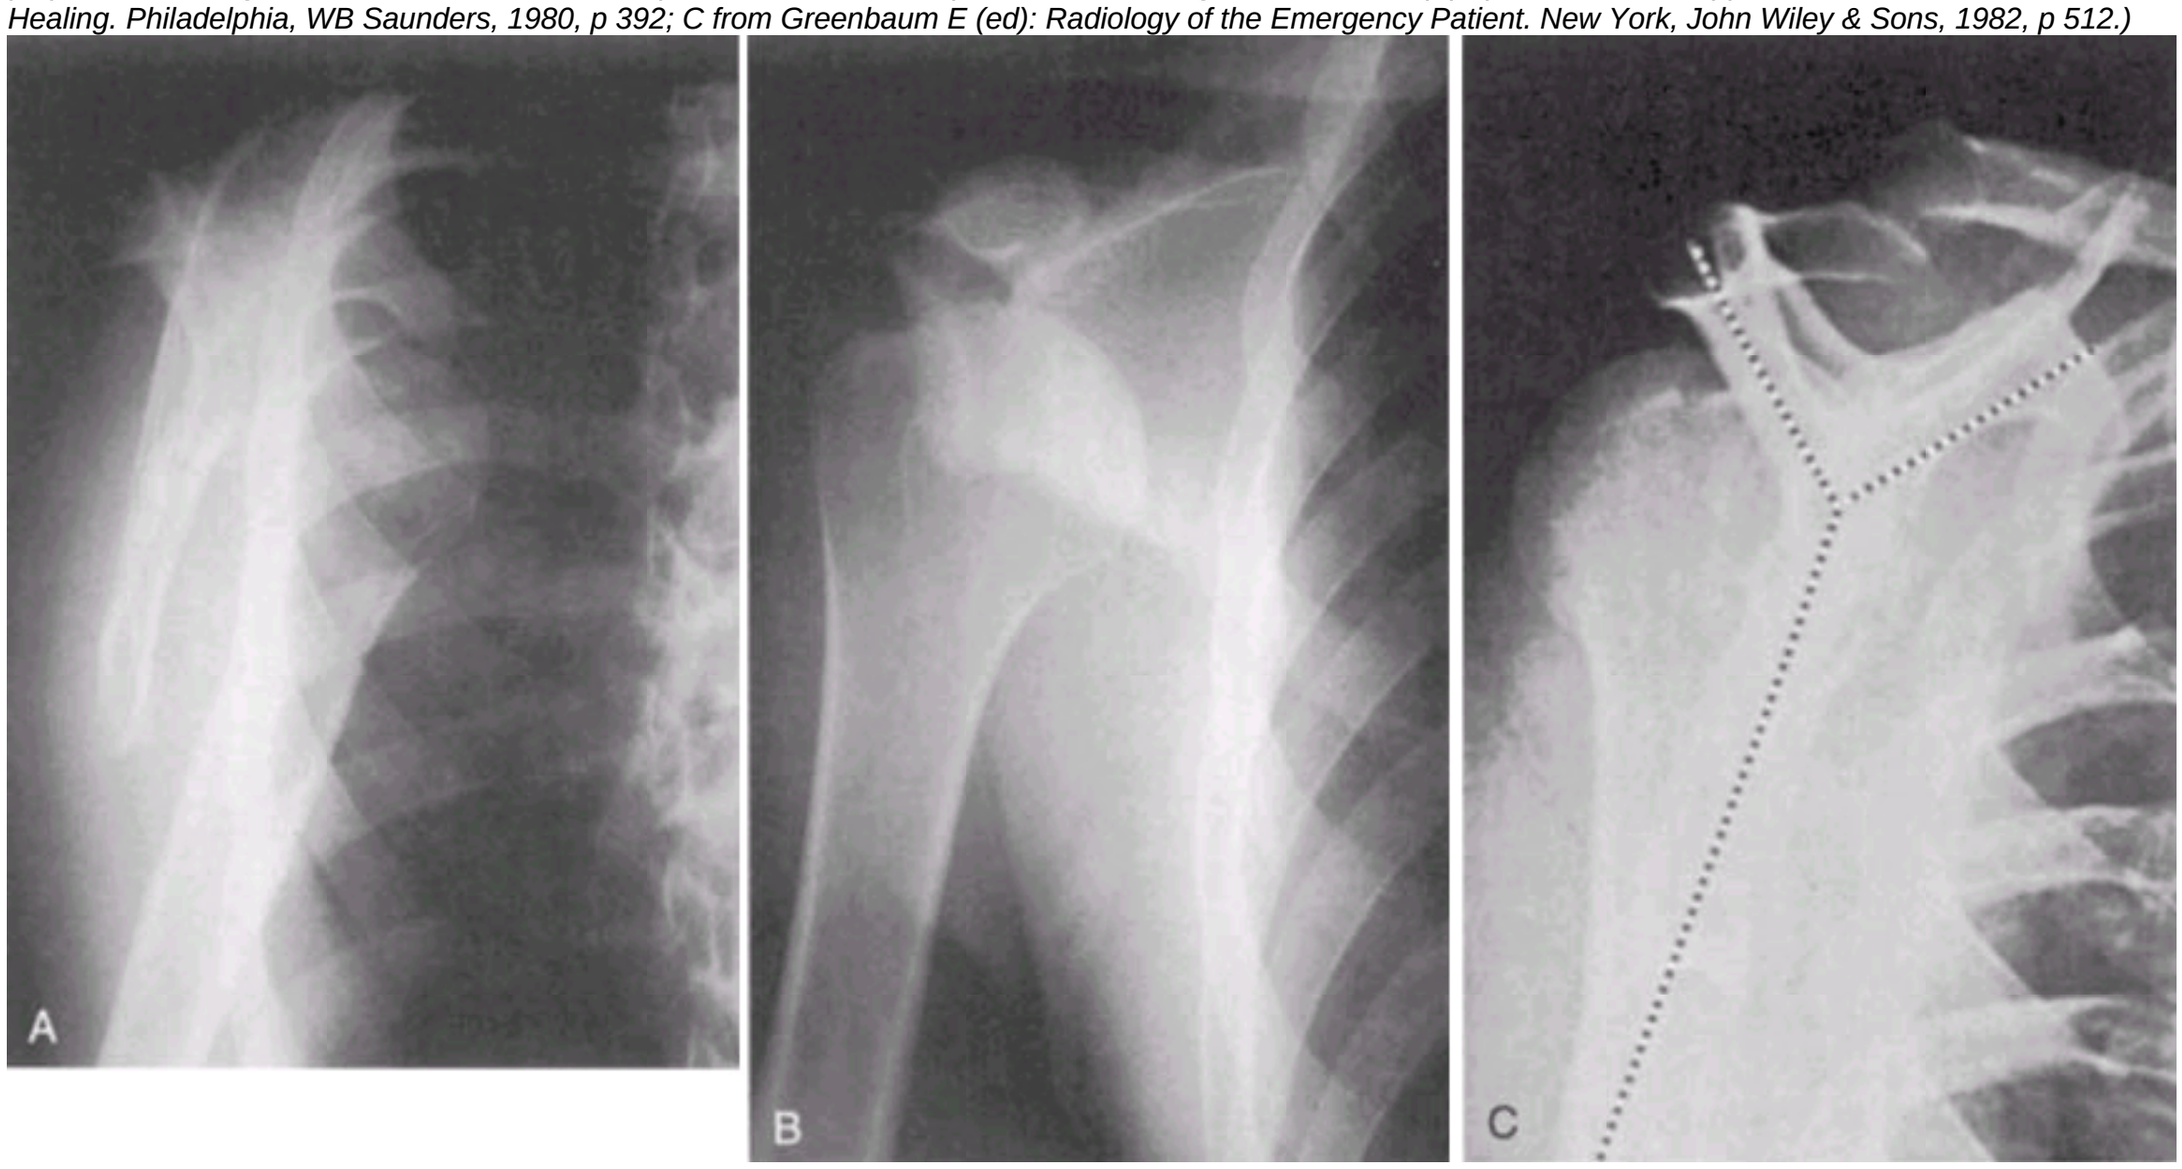

Figure 50-9 *A,* Positioning for apical oblique view. The affected shoulder is placed at a 45° oblique position and the central ray is angled 45° caudad. The affected arm is adducted. *B,* Normal apical oblique view. *(A and B from Heppenstall RB: Fracture Treatment and Healing. Philadelphia, WB Saunders, 1980, p 392. Reproduced by permission.)*

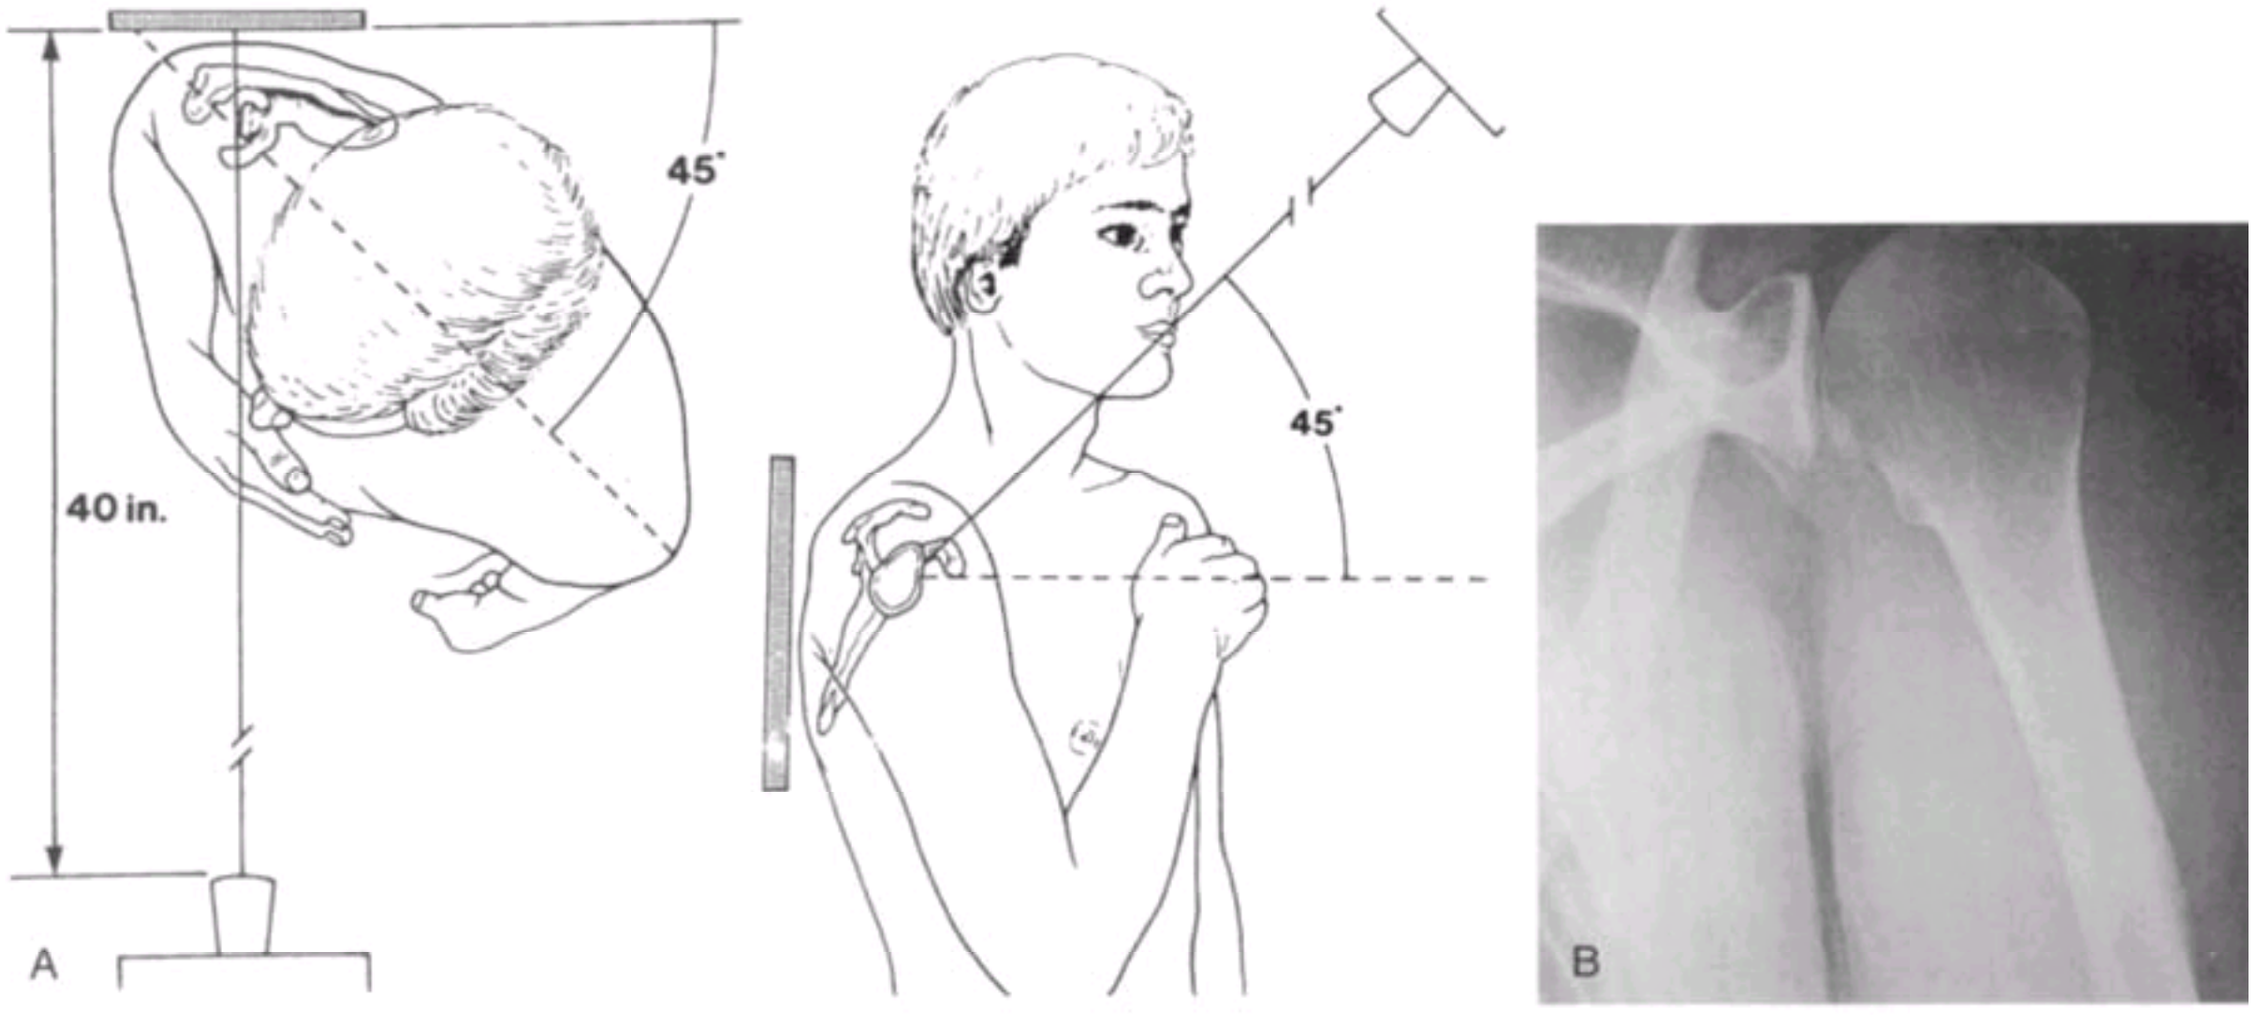

Figure 50-10 Intra-articular injection for the reduction of an acute anterior shoulder reduction. *A,* After aspirating blood from the joint, 10 to 20 mL of 1% plain lidocaine is slowly injected through the lateral sulcus, aiming slightly caudad. *B,* Anterior view. Allow 15 to 20 minutes for the lidocaine to take effect. *(From Matthews DE, Roberts T: Intraarticular lidocaine versus intravenous analgesic for reduction of acute anterior shoulder dislocations. Am J Sports Med 23:54, 1995. Reproduced by permission).*

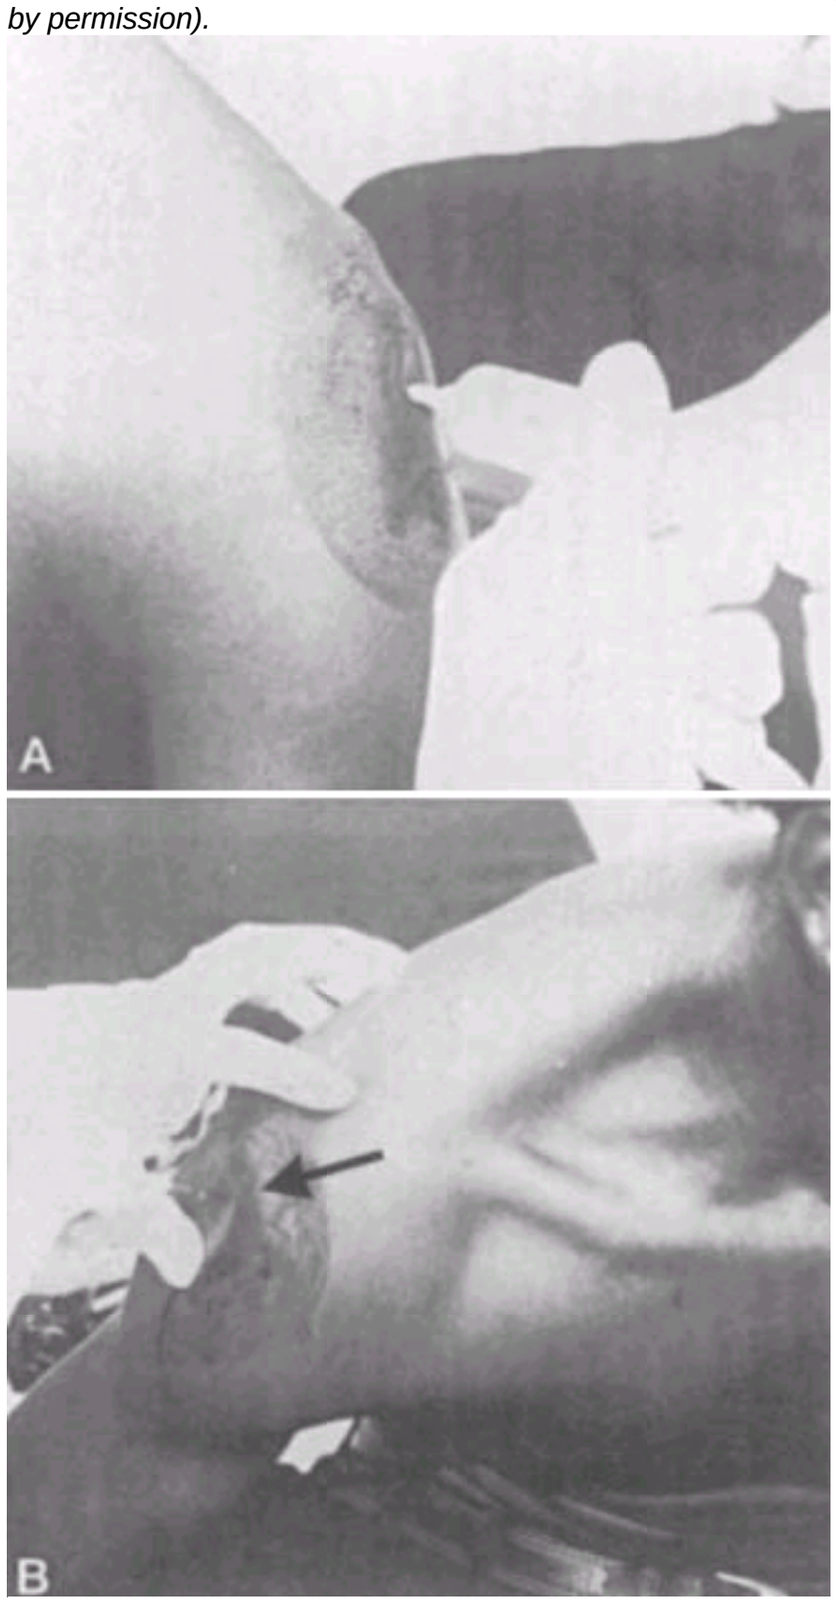

Figure 50-11 Stimson technique. This technique is often tried first, because it is the least traumatic if the patient can relax the shoulder muscles. *1,* The patient is lying prone on the edge of the table. One must be careful that the sedated or intoxicated patient does not fall off the table. Belts or sheets can be used to secure the patient to the stretcher. *2,* 5-kg weights are attached to the arm, and the patient maintains this position for 20 to 30 minutes, if necessary. *3,* Occasionally, gentle external and internal rotation of the shoulder with manual traction aids reduction. *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, p 618. Reproduced by permission.)*

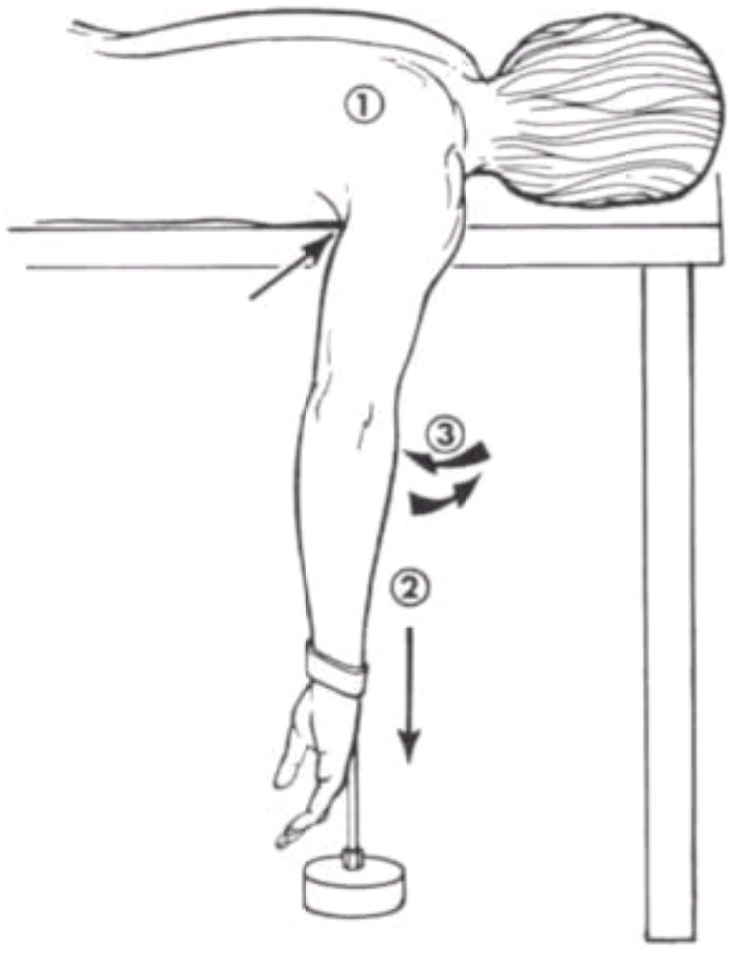

Figure 50-12 Scapular manipulation technique. *A,* The inferior tip of the scapula is pushed medially and dorsally with the thumbs while the superior aspect of the scapula is stabilized with the fingers of the superior hand. Weights may be attached to the hand to apply hanging traction. *B,* While the patient is seated, the operator applies traction with one hand and countertraction with the other, while an assistant rotates the scapula in the same manner as in *A*. *(From McNamara RM: Reduction of anterior shoulder dislocations by scapular manipulation. Ann Emerg Med 22:1140, 1995. Reproduced by permission.)*

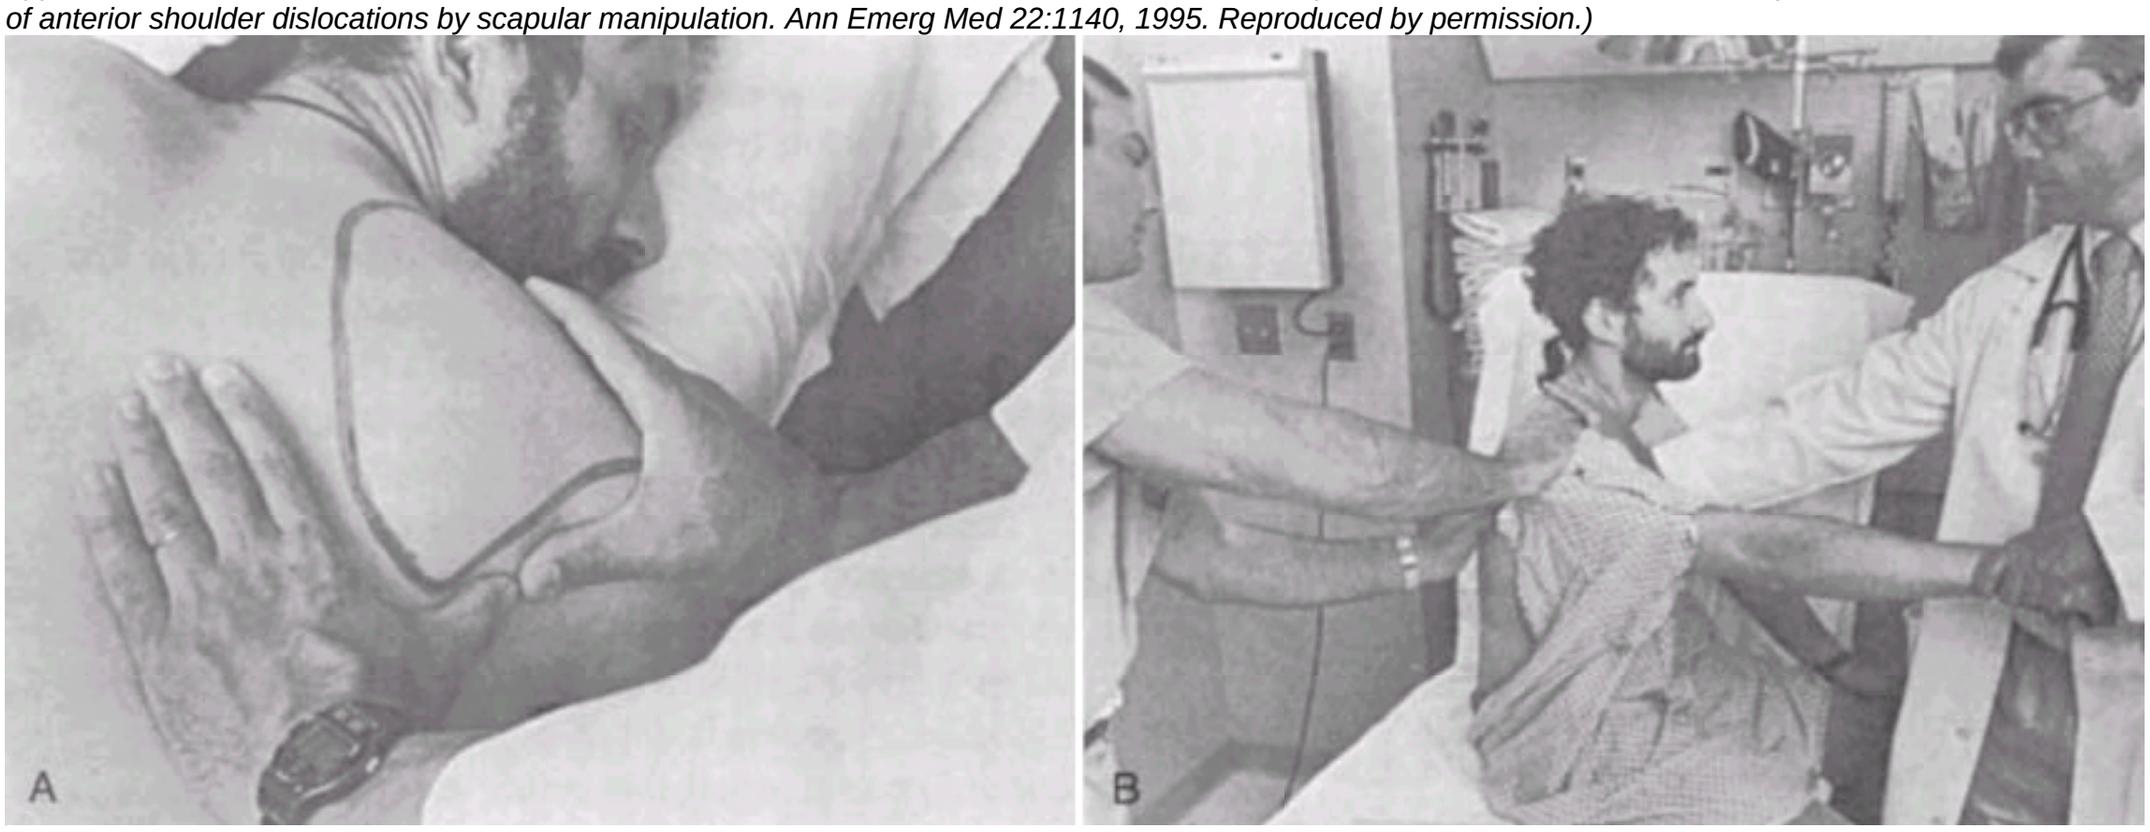

Figure 50-13 External rotation method. No traction is applied and a slow, gentle approach is essential. *A,* Arm is adducted to the patient's side. In one hand, the elbow is held flexed at 90° while the other hand grasps the wrist. *B,* Slowly and gently, the forearm is used as a lever to rotate the arm externally. *C,* Usually by the time the forearm has reached the coronal plane, the shoulder will have been reduced. *(From Mirick MJ, Clinton J, Ruiz E: External rotation method of shoulder dislocation reduction. JACEP 8:529, 1979. Reproduced by permission.)*

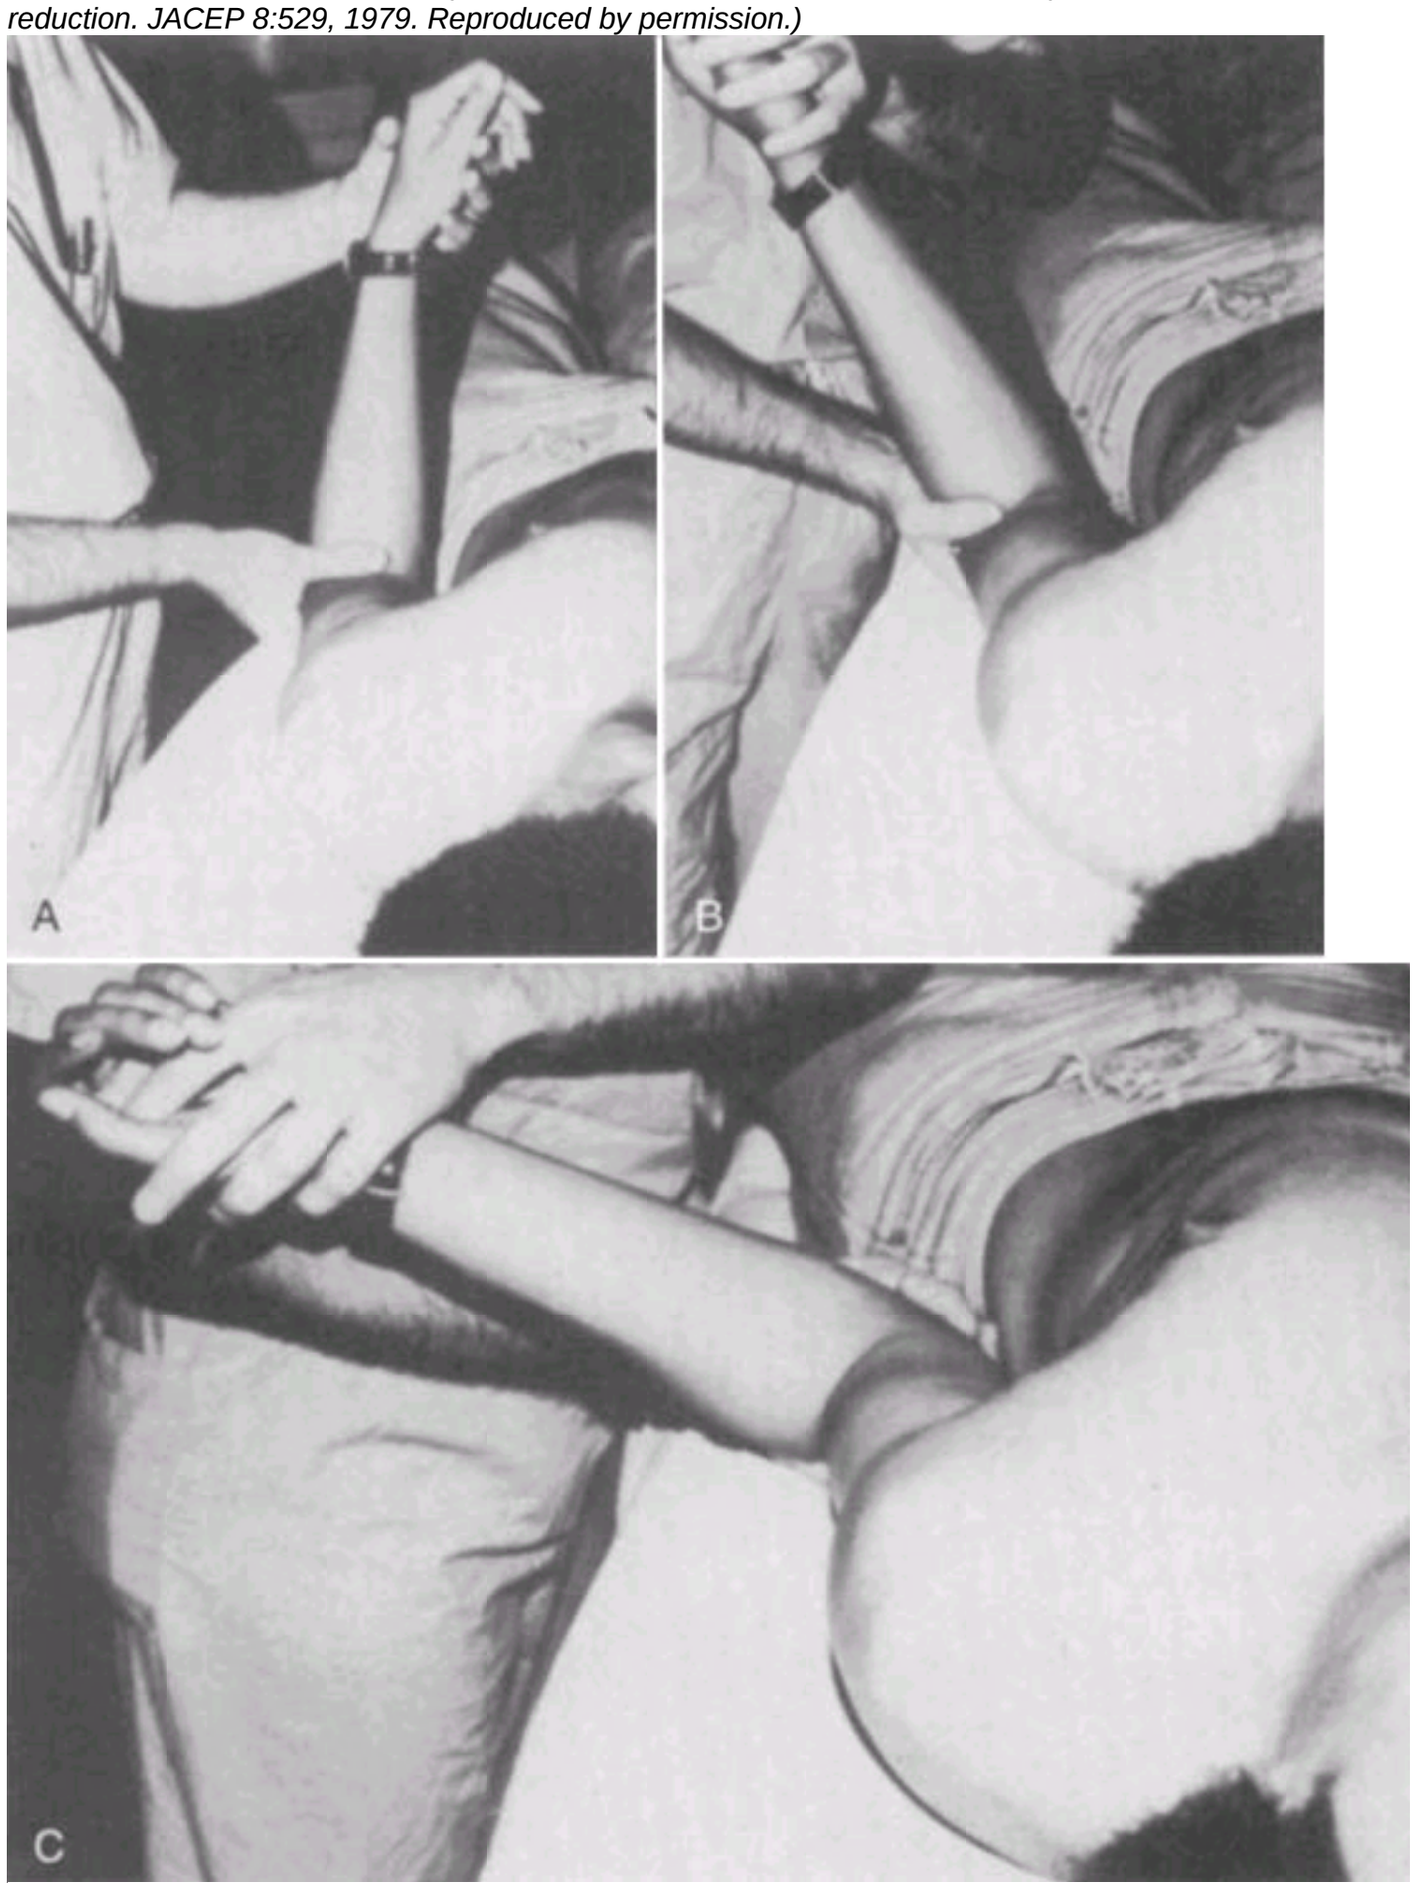

Figure 50-14 *A*, Milch technique. Slow, steady abduction with overhead-traction, external rotation (not shown), and direct pressure over the humeral head are the steps of the Milch technique. The procedure may take 3 to 4 minutes to complete, and the operator should avoid sudden, jerky manipulations. It may help to ask the patient to make a motion as if he or she is reaching up and picking an apple from a tree. *B*, The Milch method diagrammed: reduction of an anterior shoulder dislocation includes *(1)* abduction and external rotation, and *(2)* slow and steady gentle traction. When reduced, the arm is adducted *(3)*. Pressure to the humeral head with the operator's hand during traction *(4)* may aid the reduction.

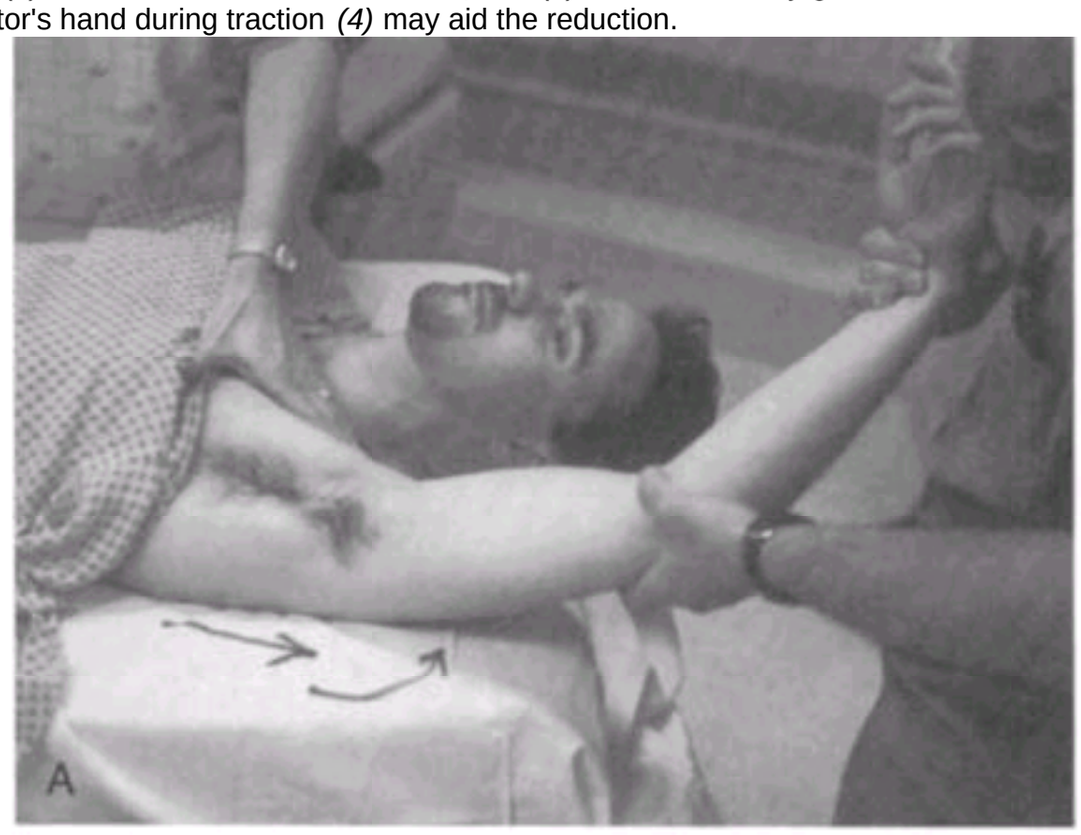

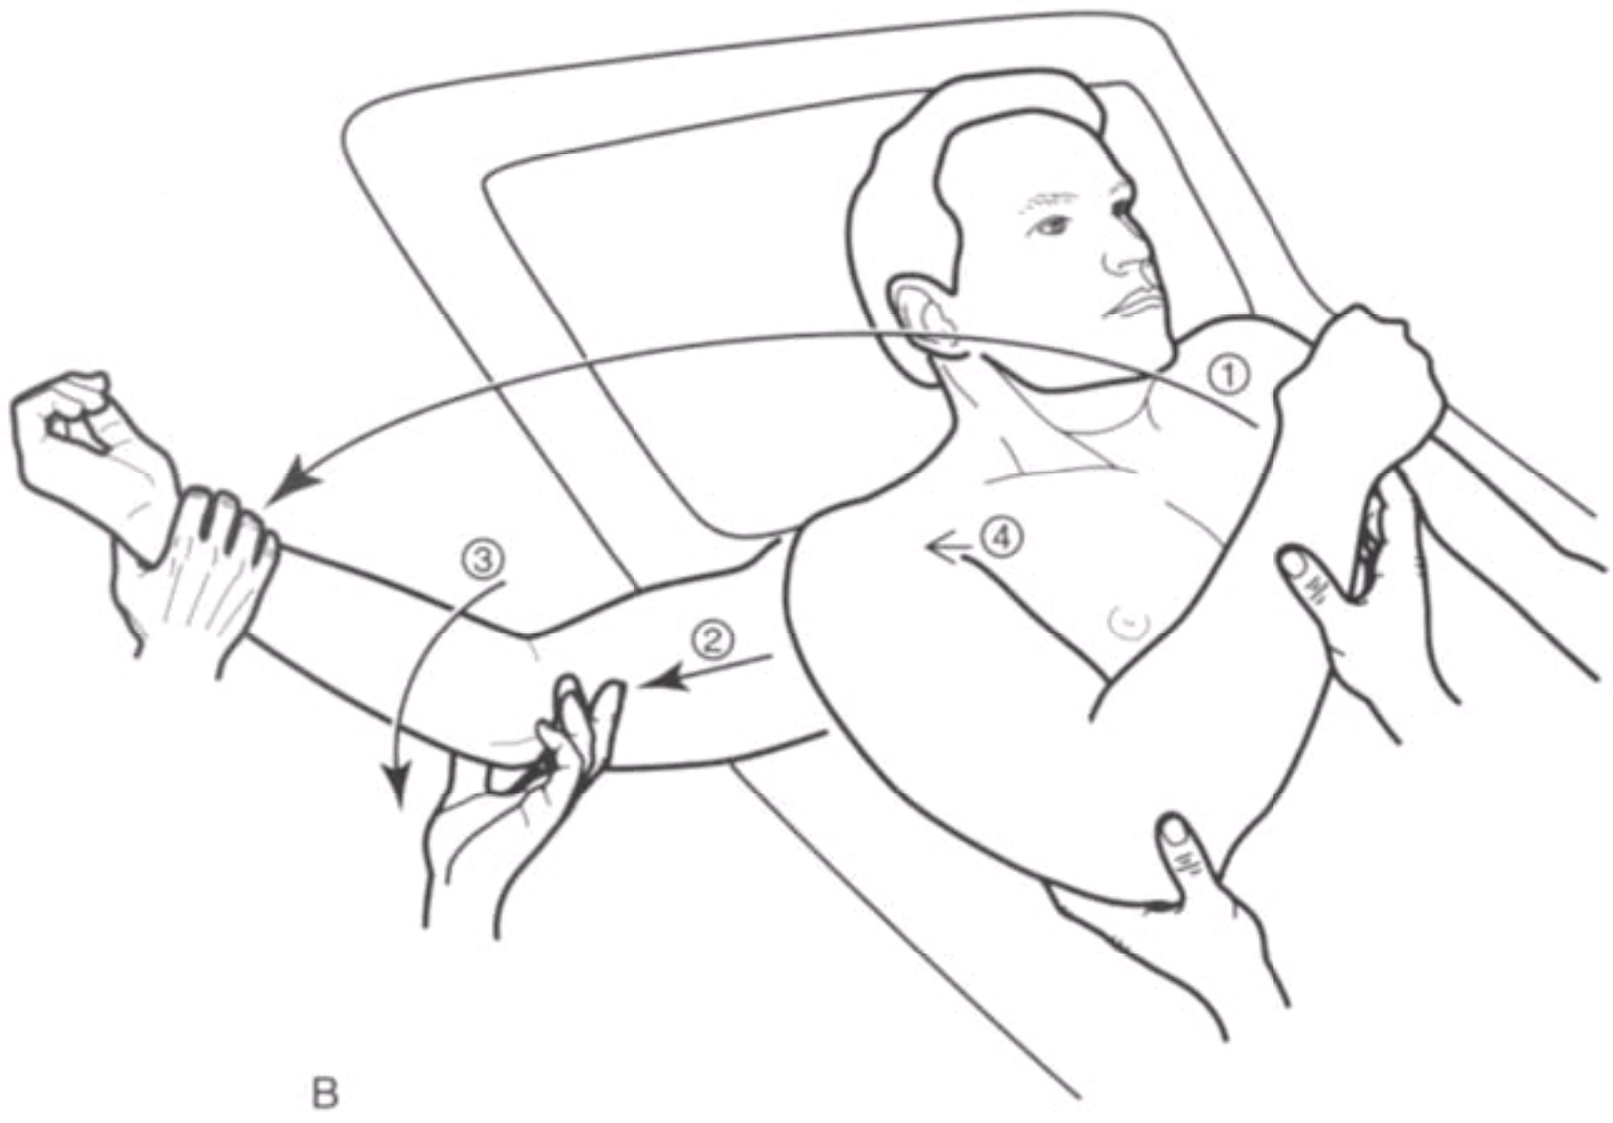

Figure 50-15 Traction-countertraction method. This simple technique for reducing the dislocated shoulder applies gradual and steady traction along the axis of the dislocated limb. A bedsheet, wrapped around the supine patient's upper chest wall and over the unaffected shoulder, is either tied or held by an assistant and acts as a fixed counterforce. A second bedsheet is placed around the patient's flexed forearm, just distal to the flexed elbow, and securely tied behind the operator's back. Note that a significant skin avulsion or friction burn may occur if there is excessive motion of the sheets, especially in the elderly patient with thin, delicate skin. With the patient's forearm held in a neutral rotation and the hand in a vertical position, the operator applies traction by leaning back, rather than using the biceps to apply traction. *(From Respet PB: A practical technique for reducing shoulder dislocations. J Musculoskel Med 5:29, 1988.)*

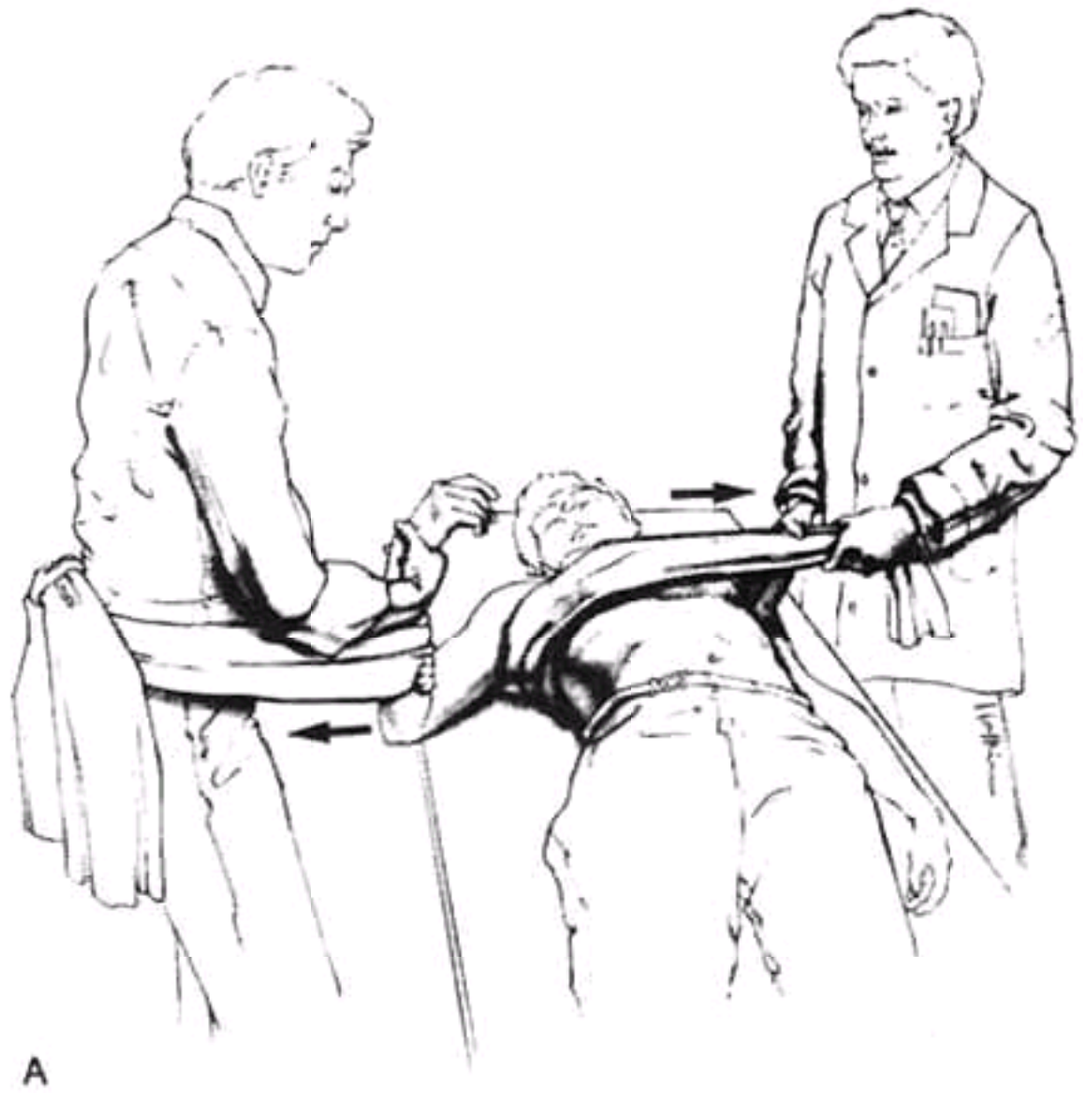
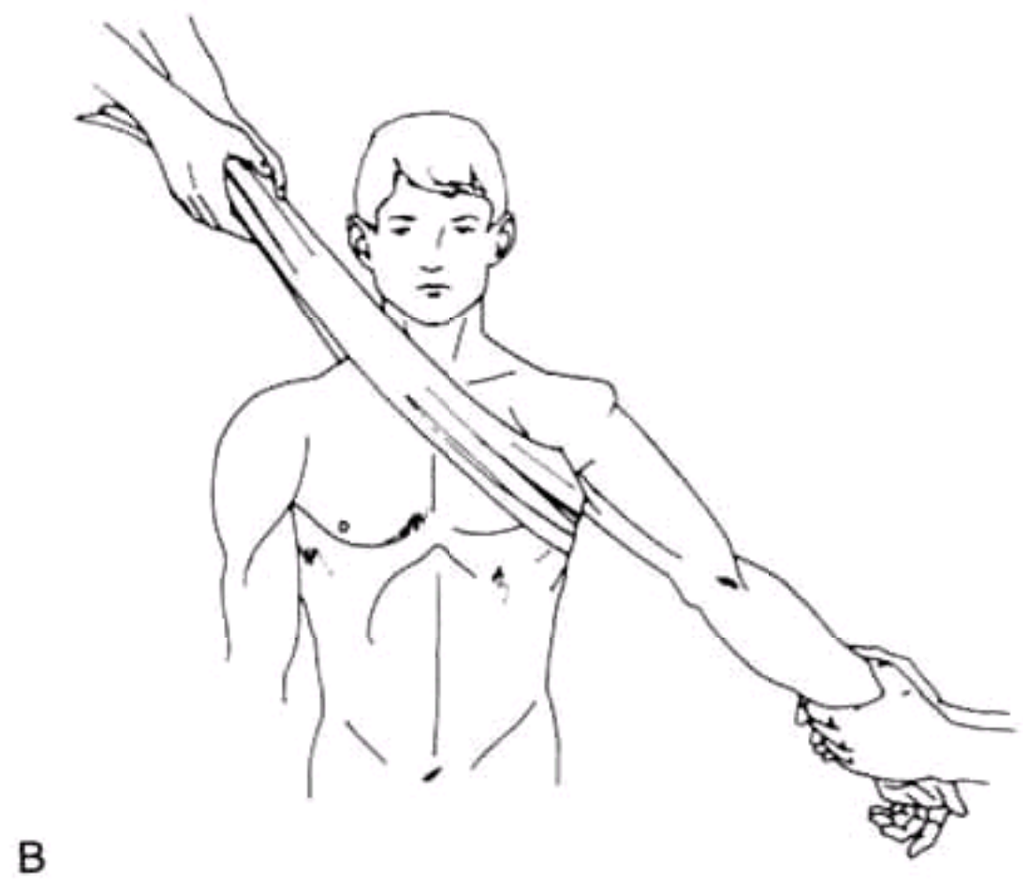
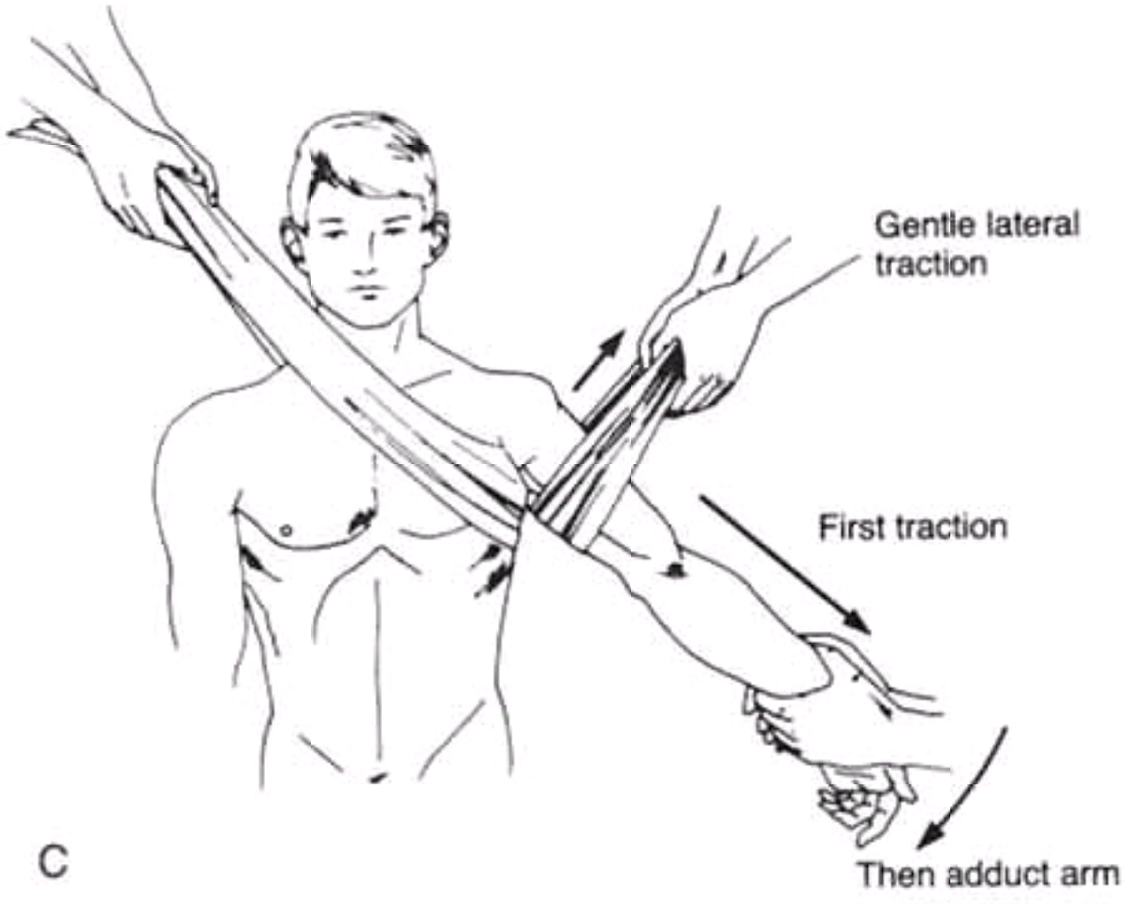


A



B



C

Figure 50-16 Spaso technique. While maintaining gentle vertical traction, the affected arm is externally rotated by grasping the wrist or forearm. Reduction may be subtle.

Figure 50-17 If a patient with a shoulder injury can place the palm of the injured arm on top of the contralateral shoulder, it is unlikely that a shoulder dislocation is present. Alternatively, completion of this maneuver after a reduction attempt provides strong evidence that the reduction was successful.

Figure 50-18 *A,* A clue to a posterior shoulder dislocation is the arm locked in adduction and internal rotation, with patient's inability to rotate the shoulder externally with the elbow flexed at 90°. *B,* Note that extension of the elbow with supination of the forearm may obscure loss of the external rotation.

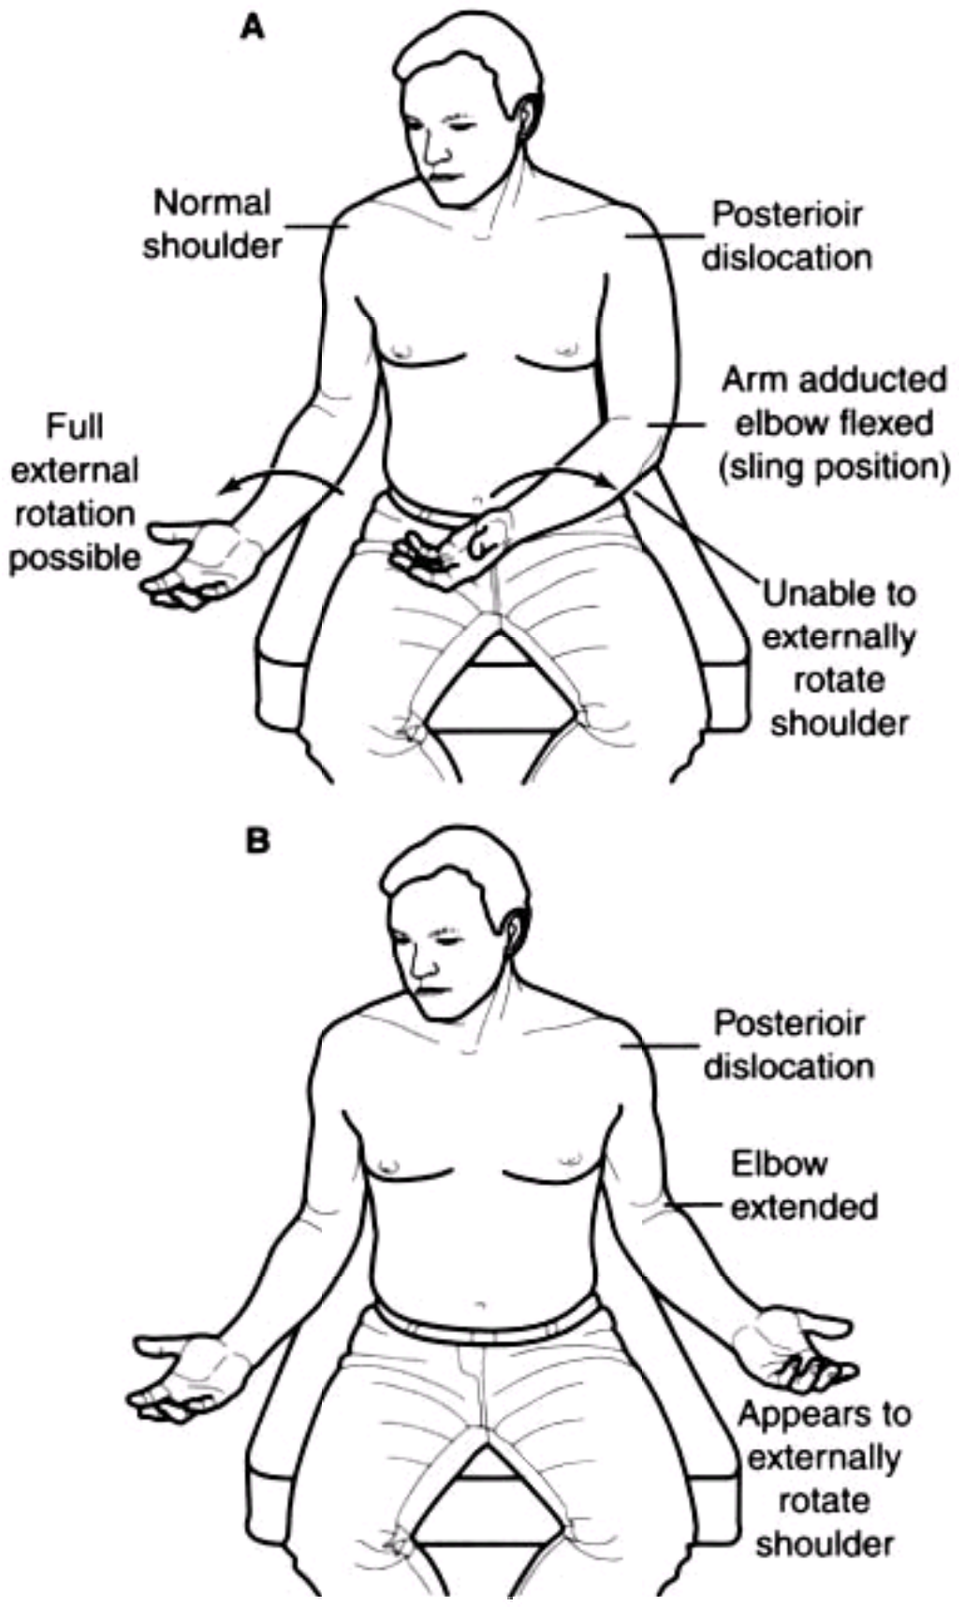


Figure 50-19 *A,* This patient has a posterior dislocation of the humerus. Because the dislocation is directly posterior, there is no superior or inferior displacement of the humeral head. On superficial observation, the head of the humerus appears to maintain a normal relationship with the glenoid fossa and the acromion process. However, definite abnormalities exist in this film. The space between the humeral head and the glenoid fossa is abnormally wide, and because of the extreme internal rotation of the humerus, the head and neck are seen end on. In this projection, the humeral head resembles a light bulb. Compare this film with the same patient's normal opposite shoulder (note that the film is reversed for illustrative purposes) *(B)*. *C,* The normal axillary view of the shoulder. The *asterisk* indicates the glenoid process. The *open arrow* indicates the coracoid process of the scapula and the *closed arrow* indicates the acromion process of the scapula. *D,* Axillary view of a posterior shoulder dislocation with an impression fracture of the humeral head. *(From Harris JH, Harris WH (eds): The Radiology of Emergency Medicine. Baltimore, Williams & Wilkins, 1971.)*

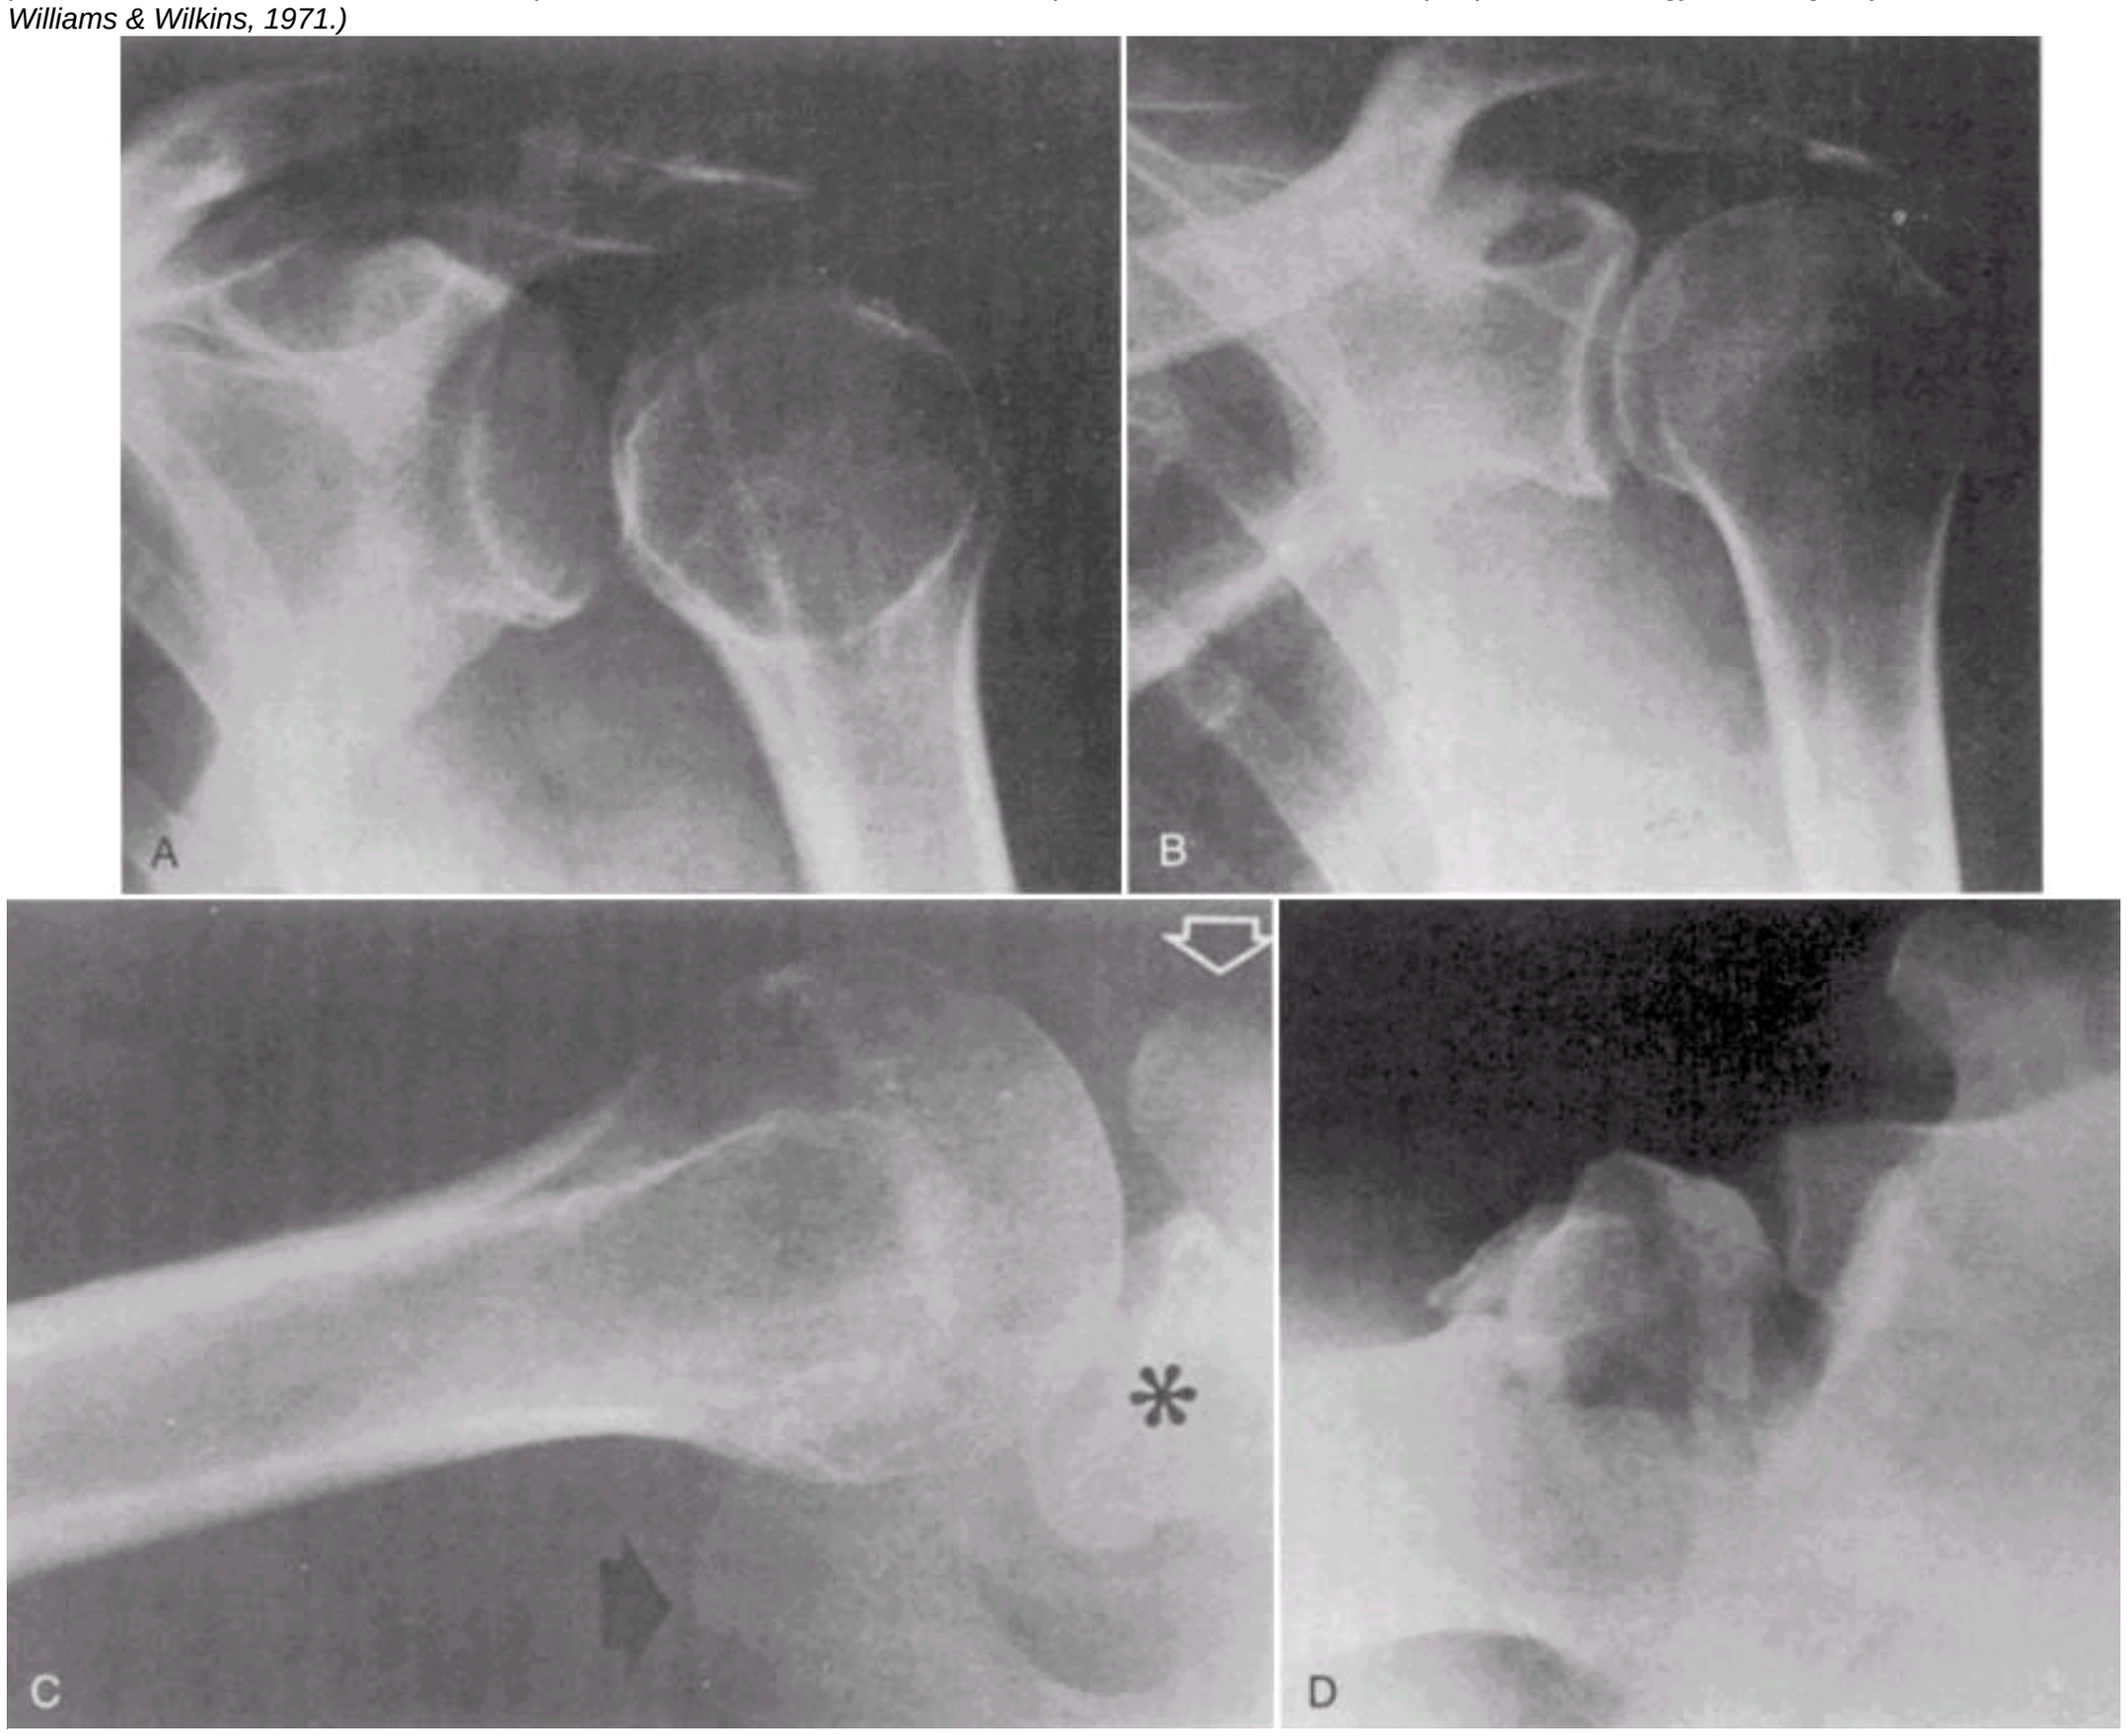

Figure 50-20 *A,* Note the normal elliptical pattern of overlap produced by the head of the humerus and the glenoid fossa. *B,* In the patient with a posterior dislocation, this pattern is lost, and internal rotation of the greater tuberosity is also noted. *(From Simon R, Koenigsknecht S: Orthopedics in Emergency Medicine. New York, Appleton-Century-Crofts, 1982, p 344. Reproduced by permission.)*

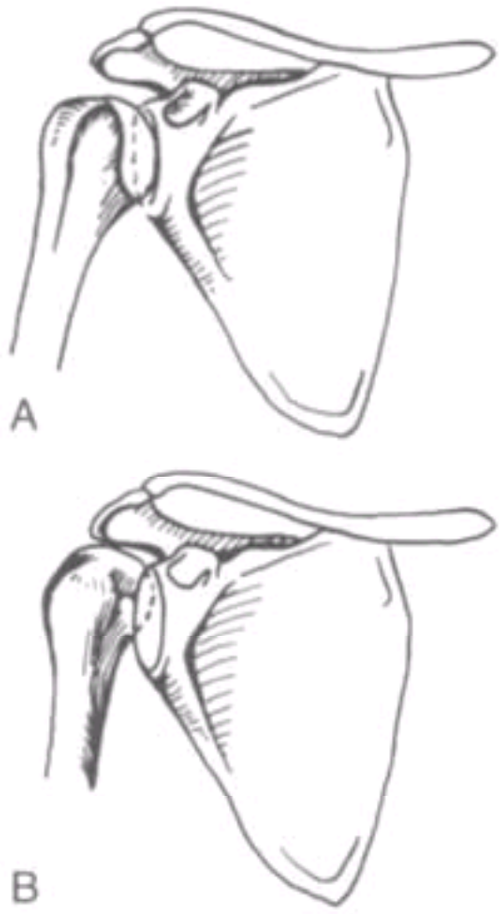

Figure 50-21 Posterior dislocation of the humeral head is a subtle, easily missed finding on the anteroposterior view. A key finding is an abnormal overlap of the humeral head with the glenoid fossa, but additional views are usually needed to confirm the dislocation. Comparison with the normal shoulder may also help. *A,* This AP film showing a posterior dislocation was initially read as normal, but the dislocation was obvious on an axillary view (see Fig. 50-19). *B,* "Light-bulb" appearance of the humeral head in a posterior dislocation. Posterior dislocation should be suspected in patients with significant pain and dysfunction after trauma, especially following seizures and electrical shock injuries. Occasionally the dislocations are bilateral. *(From Riddervold HO: Easily Missed Fractures and Corner Signs in Radiology. Mt Kisco, NY, Futura, 1991.)*

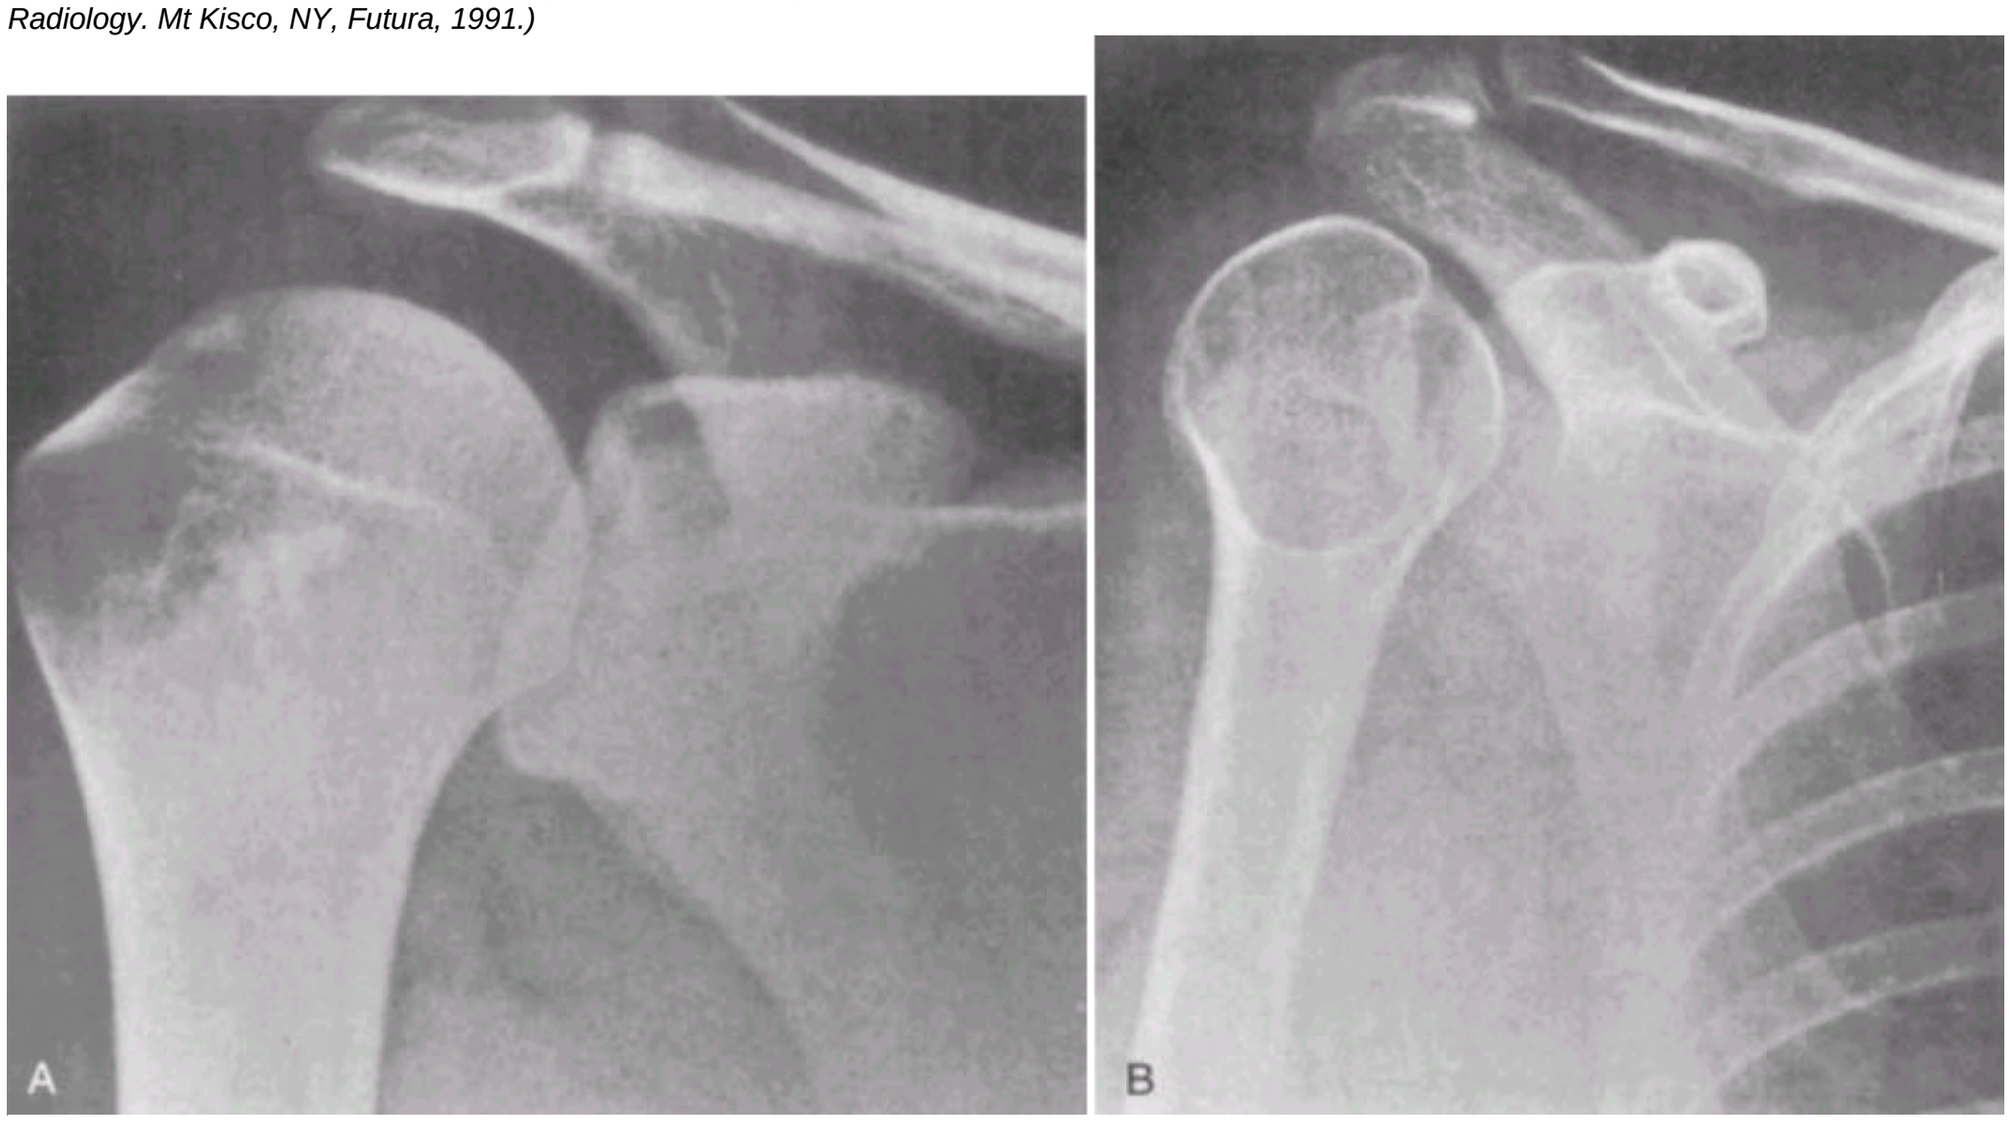

Figure 50-22 Reduction of posterior shoulder dislocation—with countertraction being applied, traction on the internally rotated and adducted arm is combined with posterior pressure on the humeral head to effect reduction.

Figure 50-23 Handshake cast—after successful reduction of an acute posterior shoulder dislocation, this cast is applied in neutral rotation, slight extension, and 15 to 20 degrees of abduction. *(From Rockwood CA, Wirth MA: Subluxations and Dislocations about the Glenohumeral Joint. In Rockwood CA, Green DP, Bucholz RW, et al (eds): Rockwood and Green's Fractures in Adults, vol 2, 4th ed. Philadelphia, Lippincott-Raven, 1996, p 1291. Reproduced by permission.)*

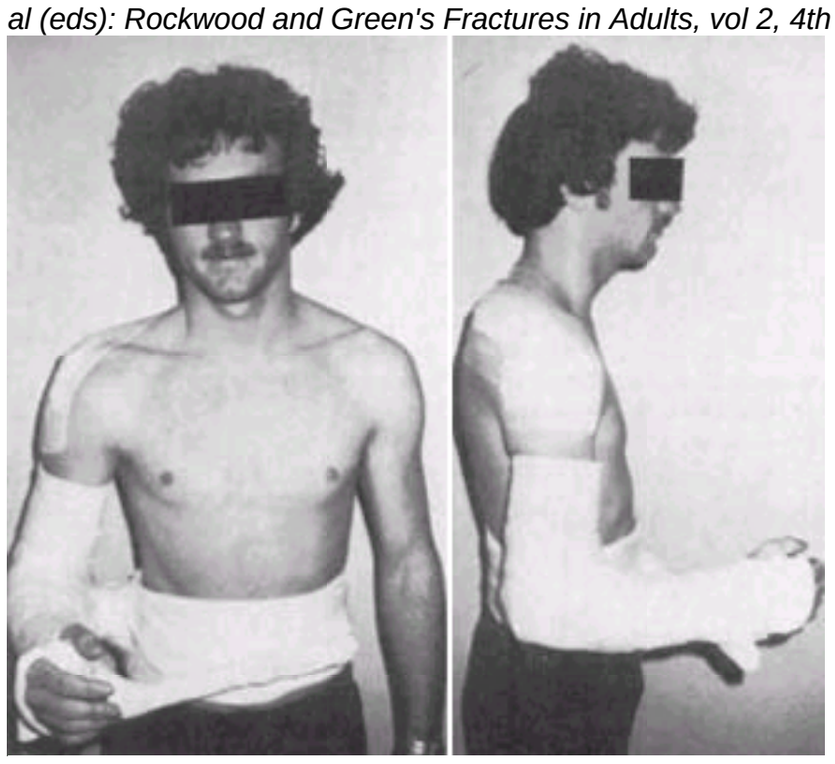

Figure 50-24 Grades I to III of acromioclavicular separation. (See text for description.) *(From Heppenstall RB: Fractures and dislocations of the distal clavicle. Orthop Clin North Am 6:480, 1975.)*

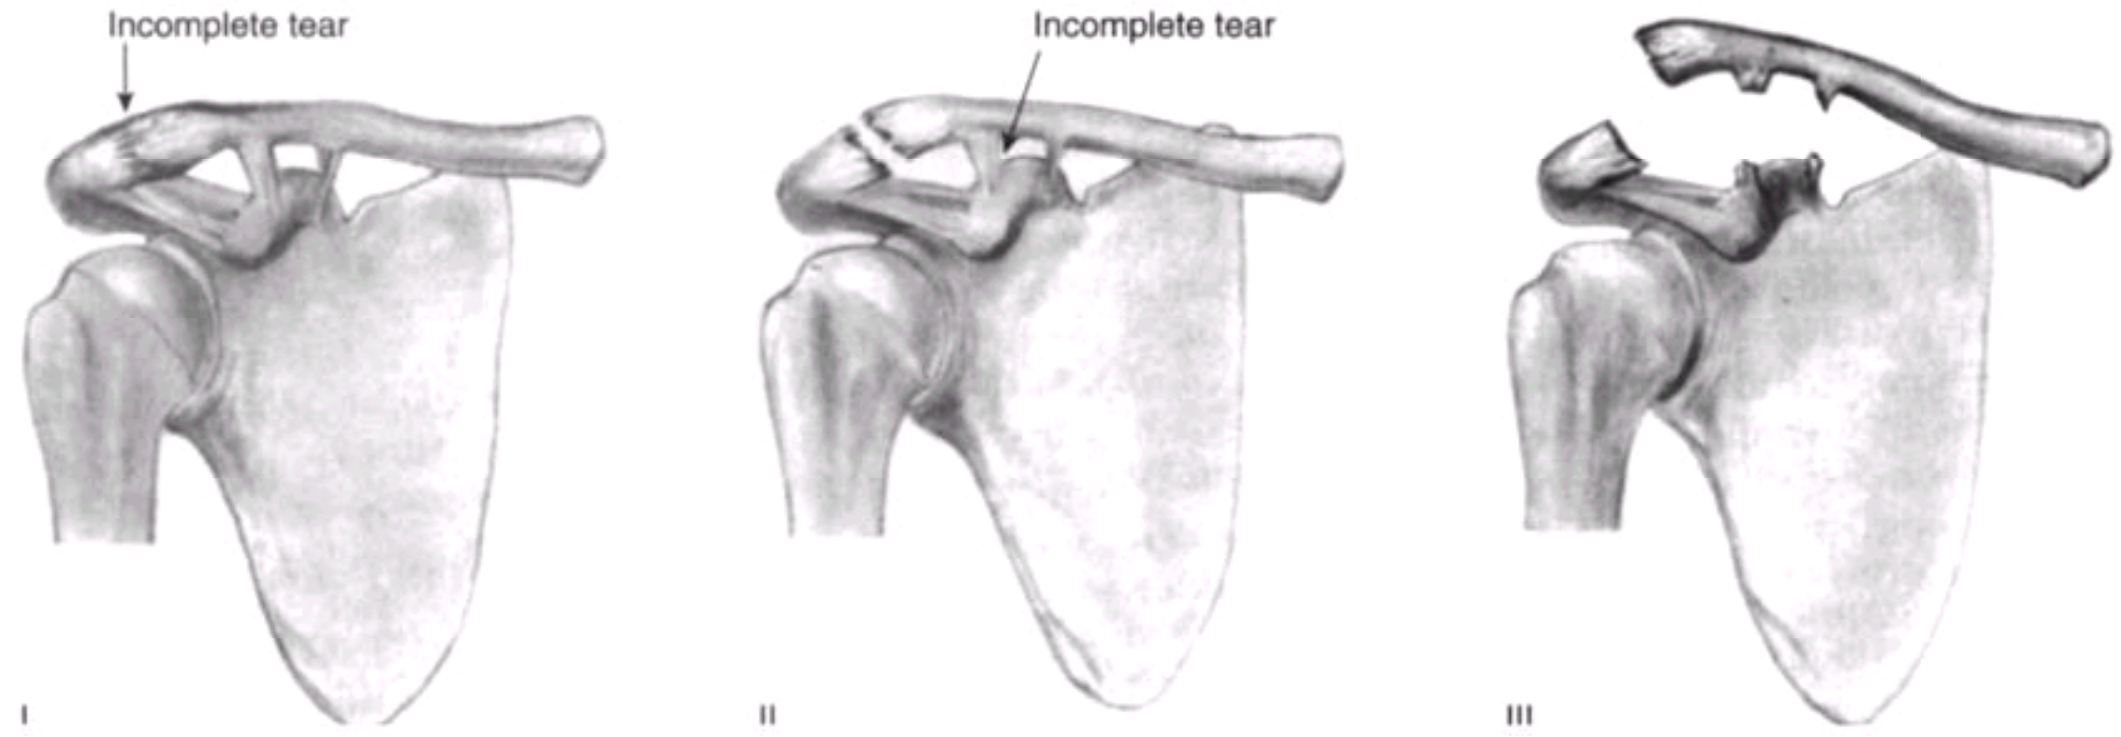

Figure 50-25 Classification of elbow dislocations. *(From Simon R, Koenigsknecht S: Orthopedics in Emergency Medicine. New York, Appleton-Century-Crofts, 1982, p 333. Reproduced by permission.)*

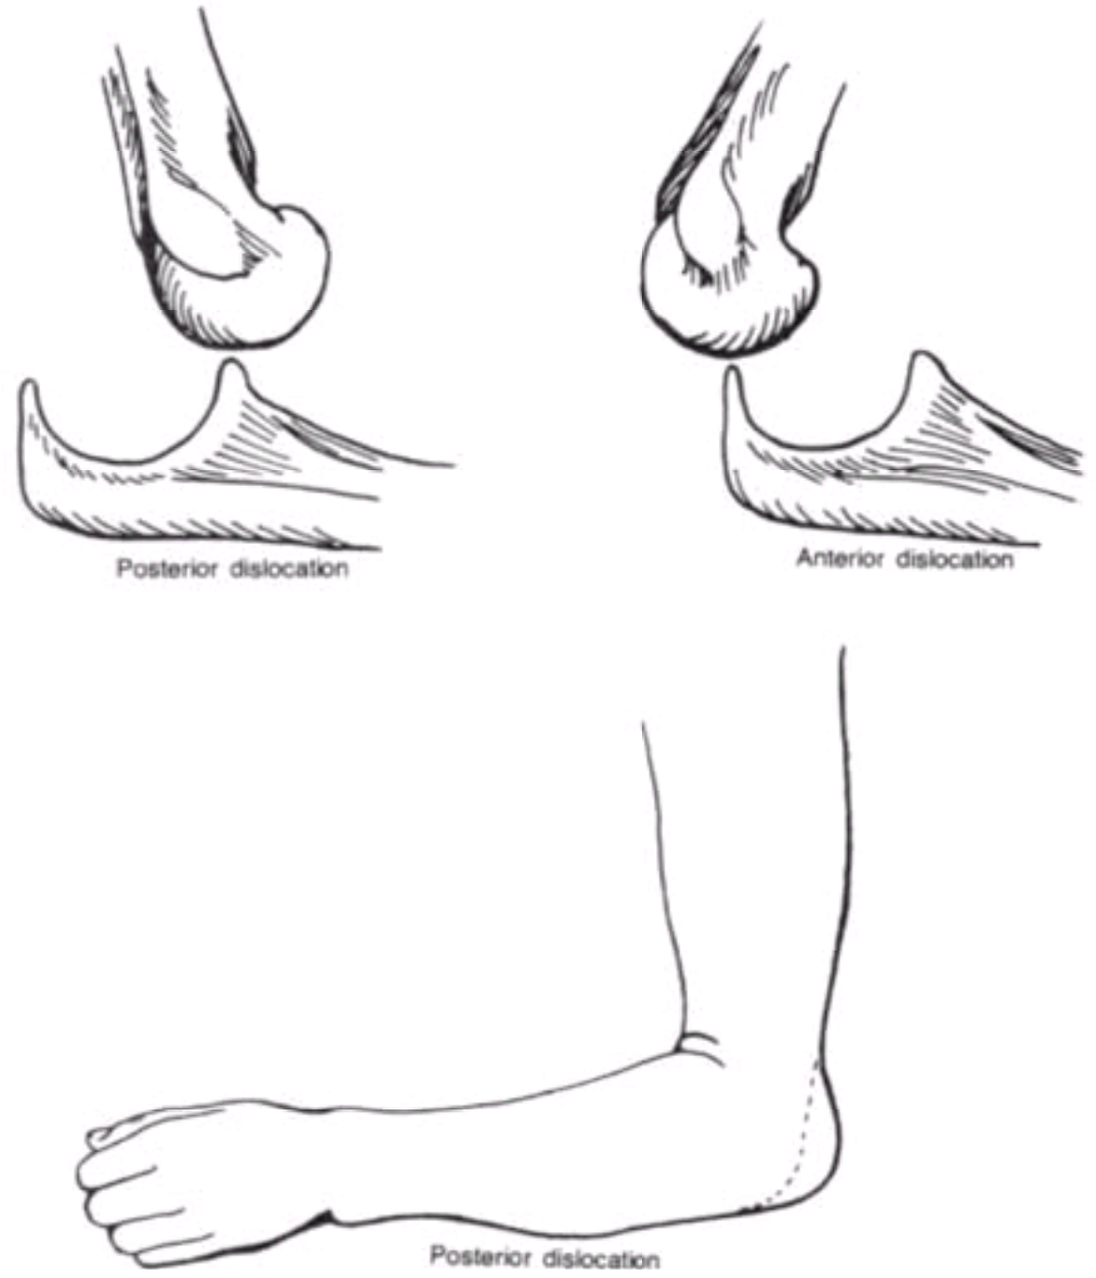

Figure 50-26 Manipulative reduction of posterior elbow dislocation. While an assistant holds the arm and makes steady countertraction *(1),* grasp the wrist with one hand and apply steady traction on the forearm in the position in which it lies *(2)*. While traction is maintained, correct any lateral displacement with the other hand *(3)*. While traction is maintained *(4),* gently flex the forearm *(5)*. Note that with reduction, a clunk is usually felt and heard as the olecranon engages the articular surface of the humerus. *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, pp 793 and 794. Reproduced by permission.)*

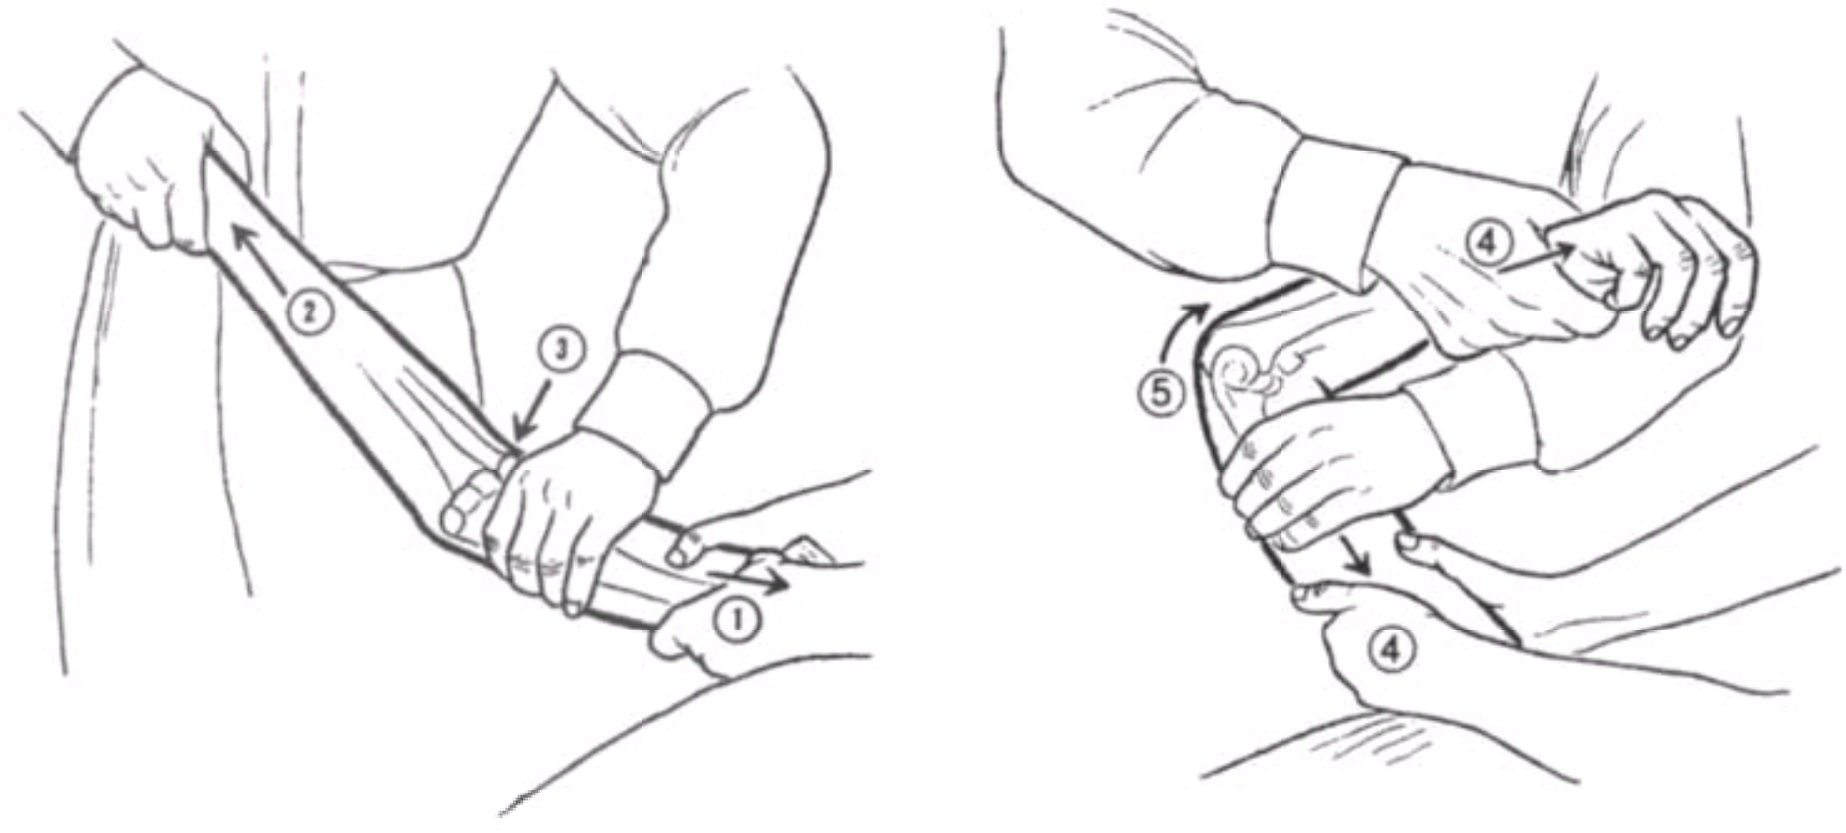

Figure 50-27 *A,* Hanging method of elbow dislocation reduction. Downward traction is applied to the hand while the olecranon is guided into place. *(From Lavine LS: A simple method of reducing dislocations of the elbow joint. J Bone Joint Surg Am 35:785, 1953.) B,* Reduction of posterior elbow dislocation. An assistant encircles the distal humerus and applies pressure to the olecranon. Traction is applied with the elbow in slight flexion to relax the triceps. The reduction can be performed with the patient reclining *supine* as shown. Having the patient recline *prone* with the upper arm supported by the stretcher can often enhance muscle relaxation.

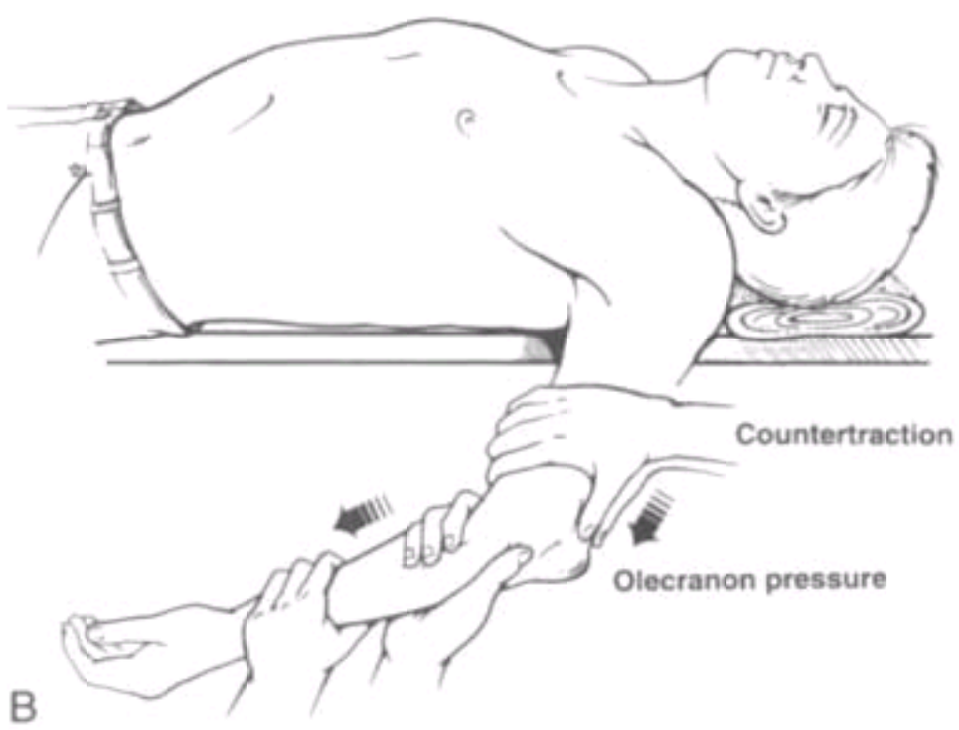

Figure 50-28 Manipulative reduction of anterior elbow dislocation. Reduction is performed with the patient under local or general anesthesia. *1*, An assistant grasps the arm and provides countertraction. *2*, The operator grasps the wrist with one hand and applies traction in the line of the arm, and with the other hand applies firm, steady pressure downward and backward on the upper end of the forearm *(3)*. A clunk usually indicates that reduction is achieved. *4*, The arm is flexed to 45° beyond a right angle. *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, p 796. Reproduced by permission.)*

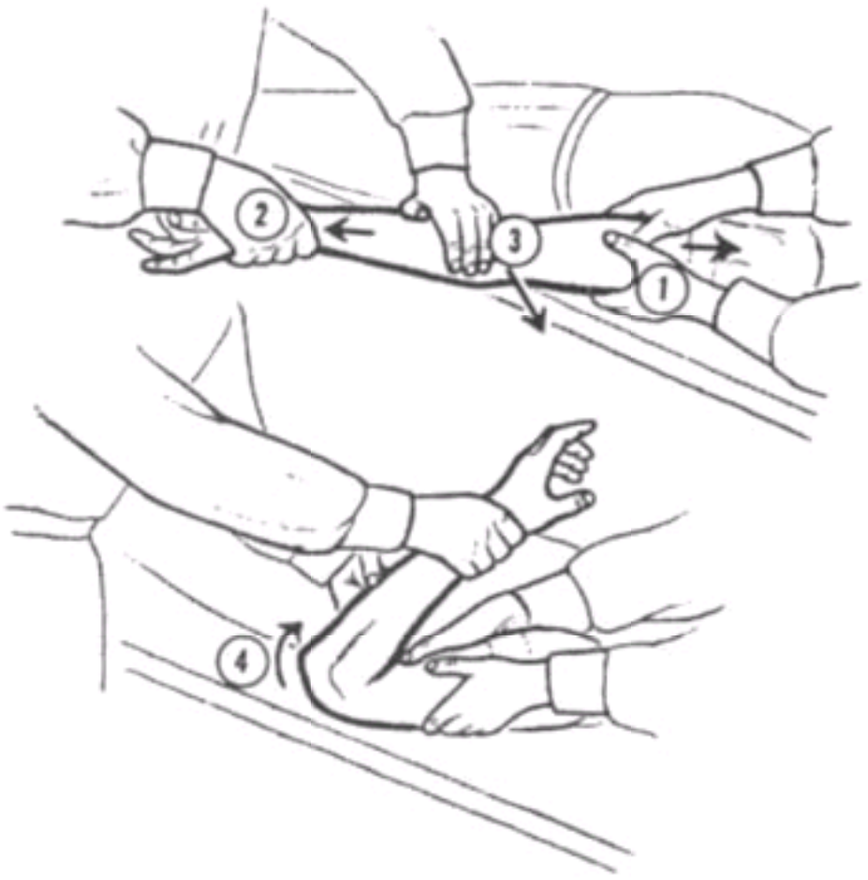

Figure 50-29 Typical presentation of a child with a subluxation of the radial head (nursemaid's elbow). It may be difficult to determine exactly where the pathology exists, and often the wrist is thought to be the culprit. This child will not use the injured arm but has minimal discomfort as long as the elbow is not manipulated. *A*, The affected arm hangs down at the side, slightly flexed and pronated. *B*, Once reduced, full activity is generally regained in a matter of minutes.

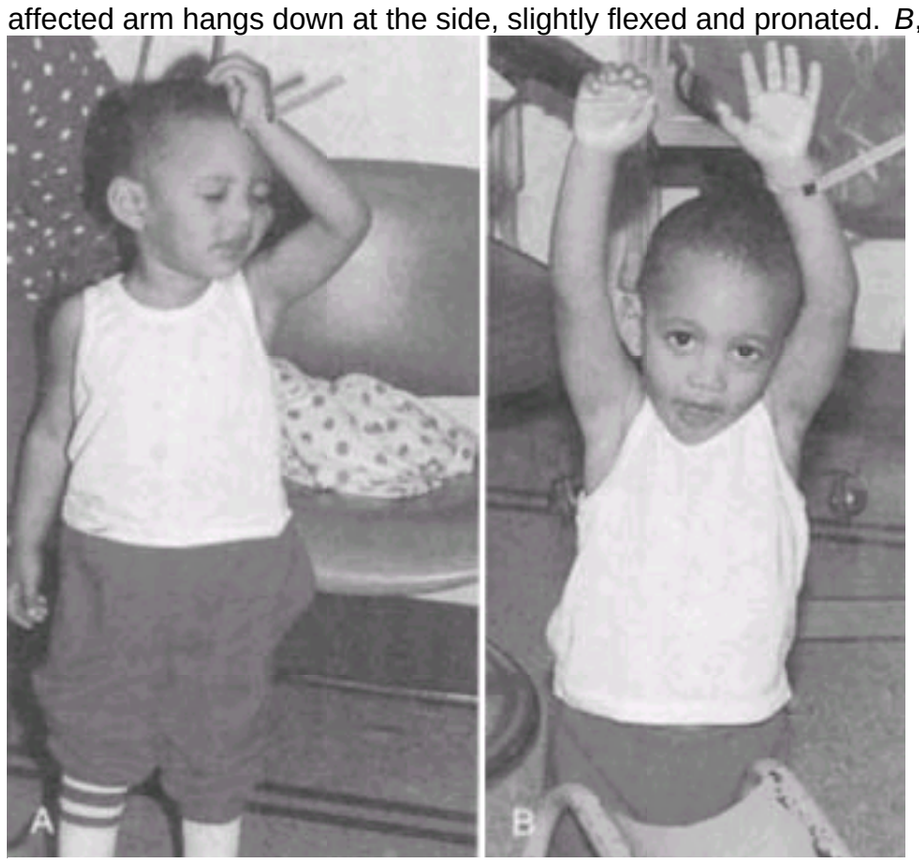

Figure 50-30 Radial head subluxation. *A*, Anatomically, this injury represents interposition of the torn annular ligament between the radial head and the capitellum. *B*, The supination method of reduction is performed by grasping the arm about the wrist and placing the other hand about the elbow with the thumb over the radial head. The forearm is then supinated *(C)* and then the arm is flexed *(D)* in one continuous motion. *(From Fleisher GR, Ludwig S: Textbook of Pediatric Emergency Medicine. Baltimore, Williams & Wilkins, 1988, p 1322. Reproduced by permission).*

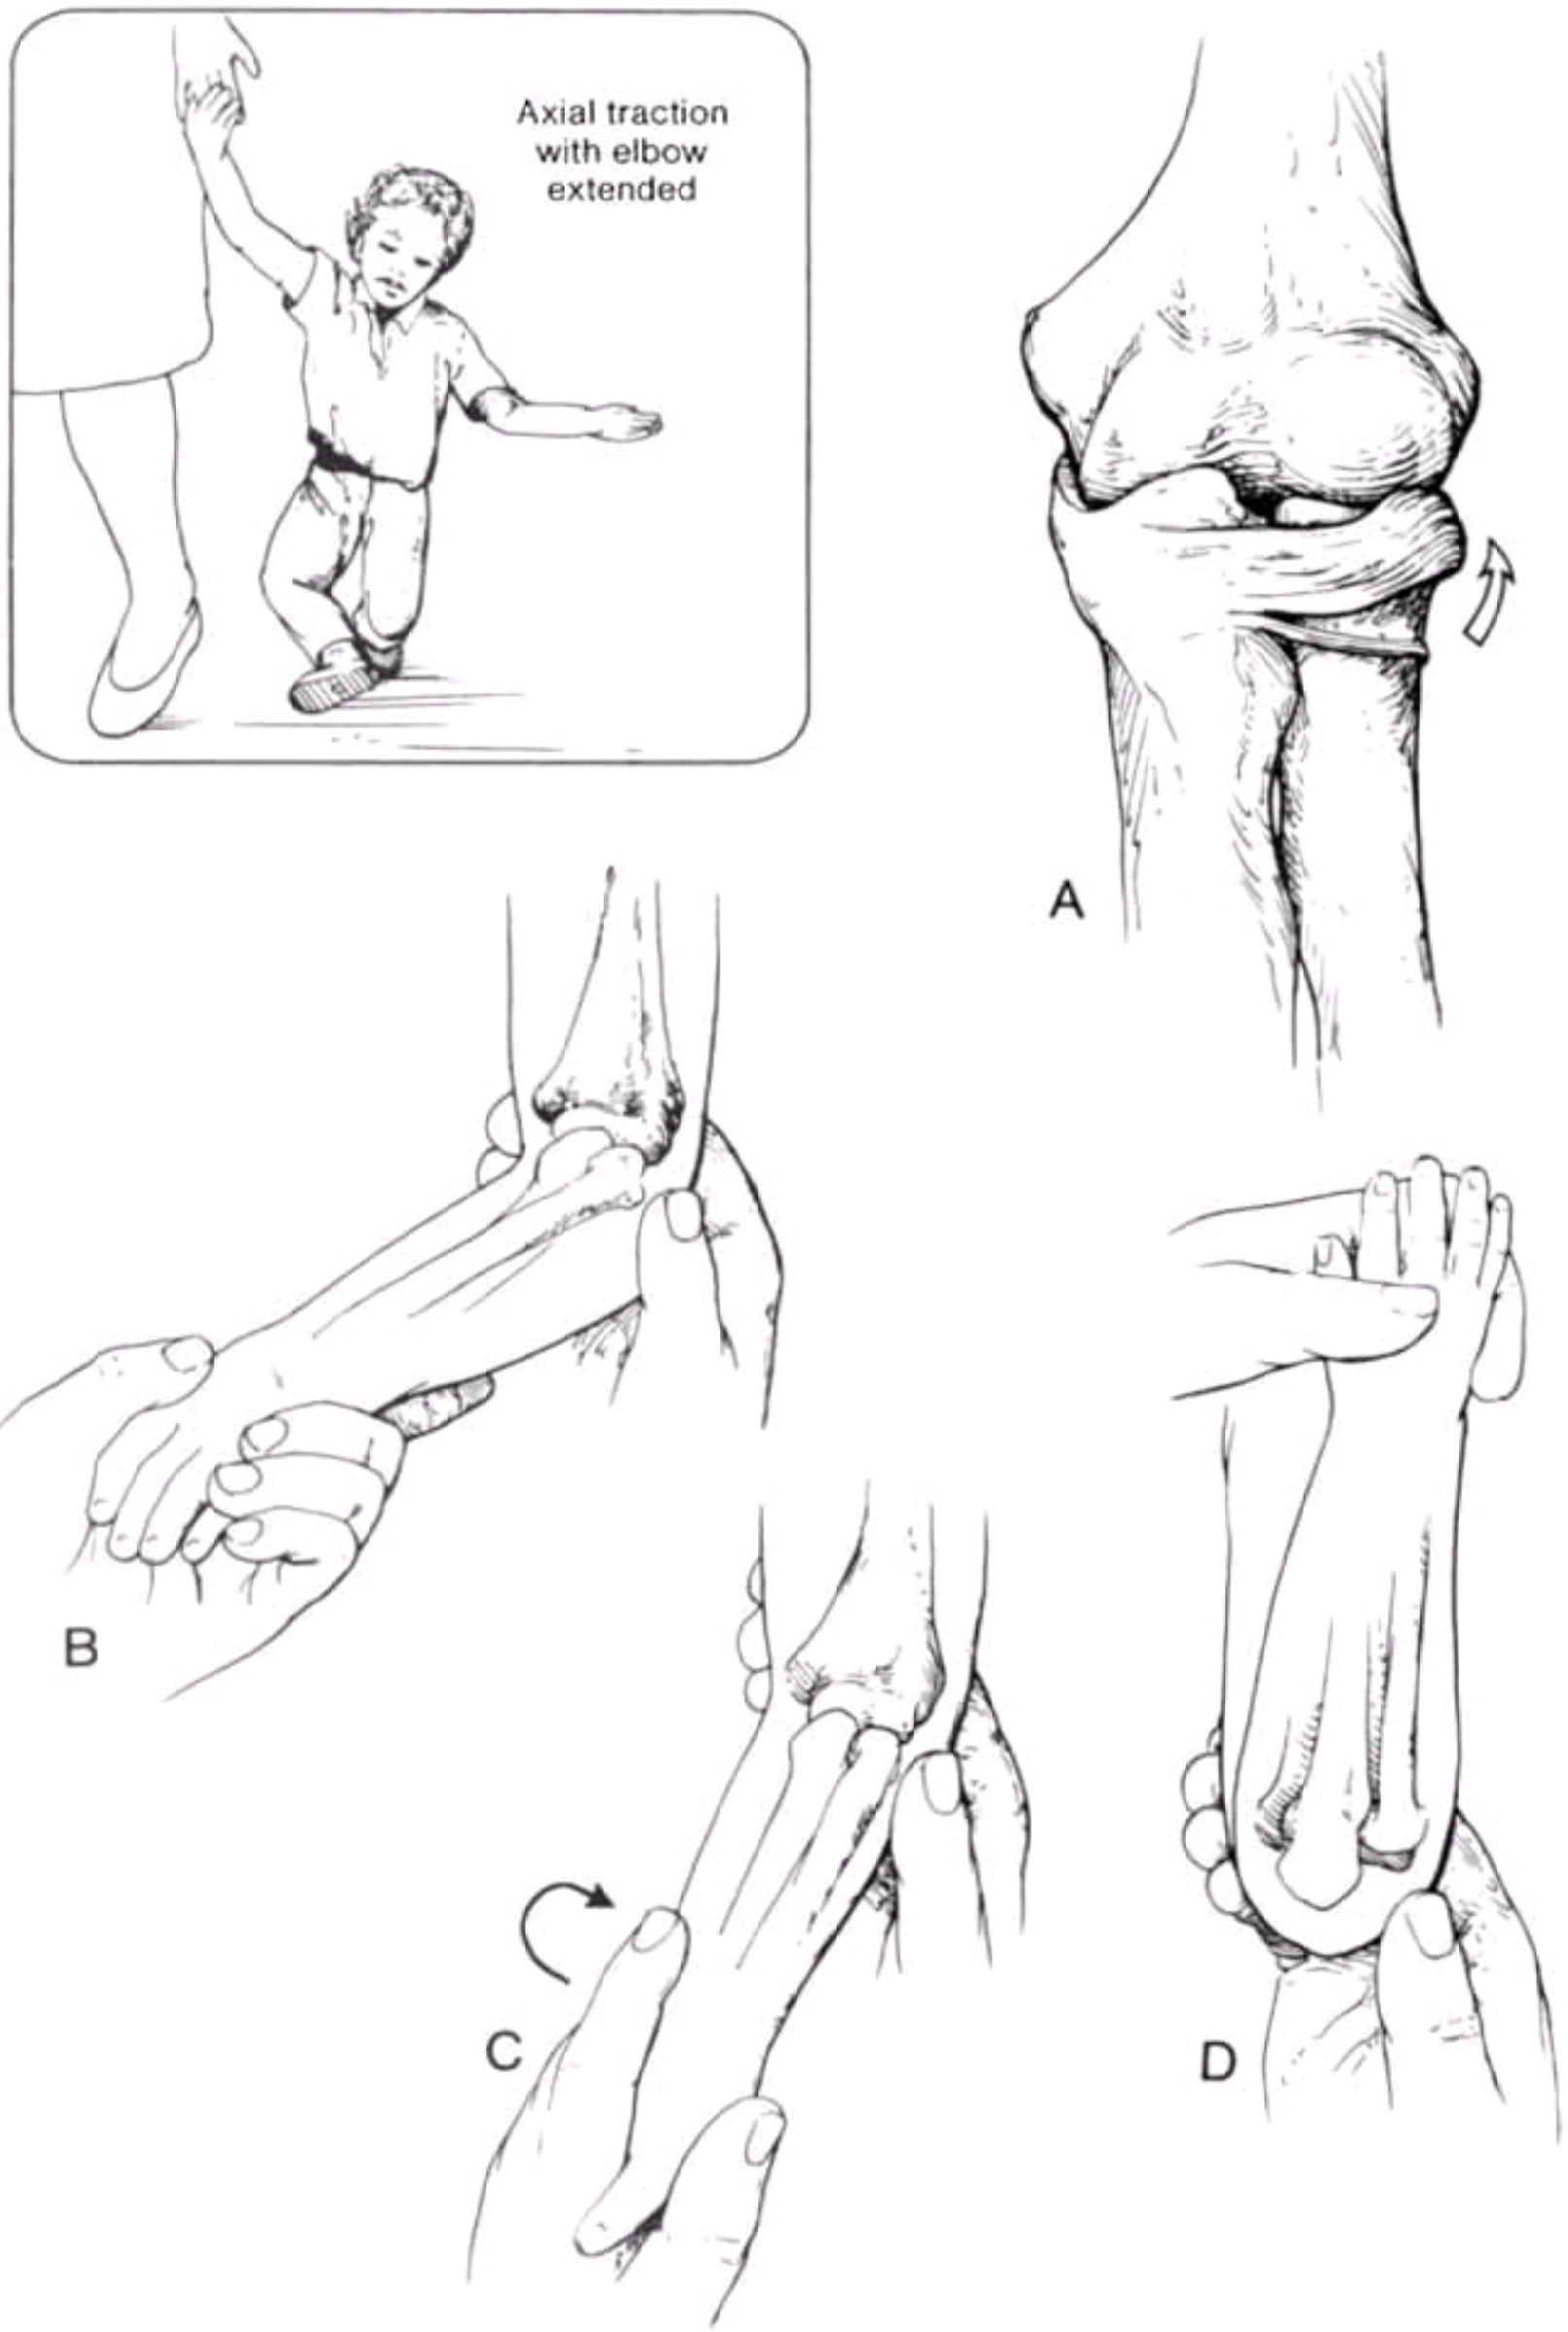

Figure 50-31 *A* and *B,* The collateral ligament-volar plate relationship. The metacarpophalangeal (MCP) and interphalangeal (IP) joints derive their strength from a combination of the two collateral ligaments and the volar plate. Dislocations of these joints require tearing of at least two parts of this three-part structure. *(From Carter P [ed]: Common Hand Injuries and Infections. Philadelphia, WB Saunders, 1983, p 114. Reproduced by permission.) C,* Lateral view demonstrating collateral ligament-volar plate relationship. *(Redrawn from Eaton RG: Joint Injuries of the Hand. Springfield, IL, Charles C Thomas, 1972.)*

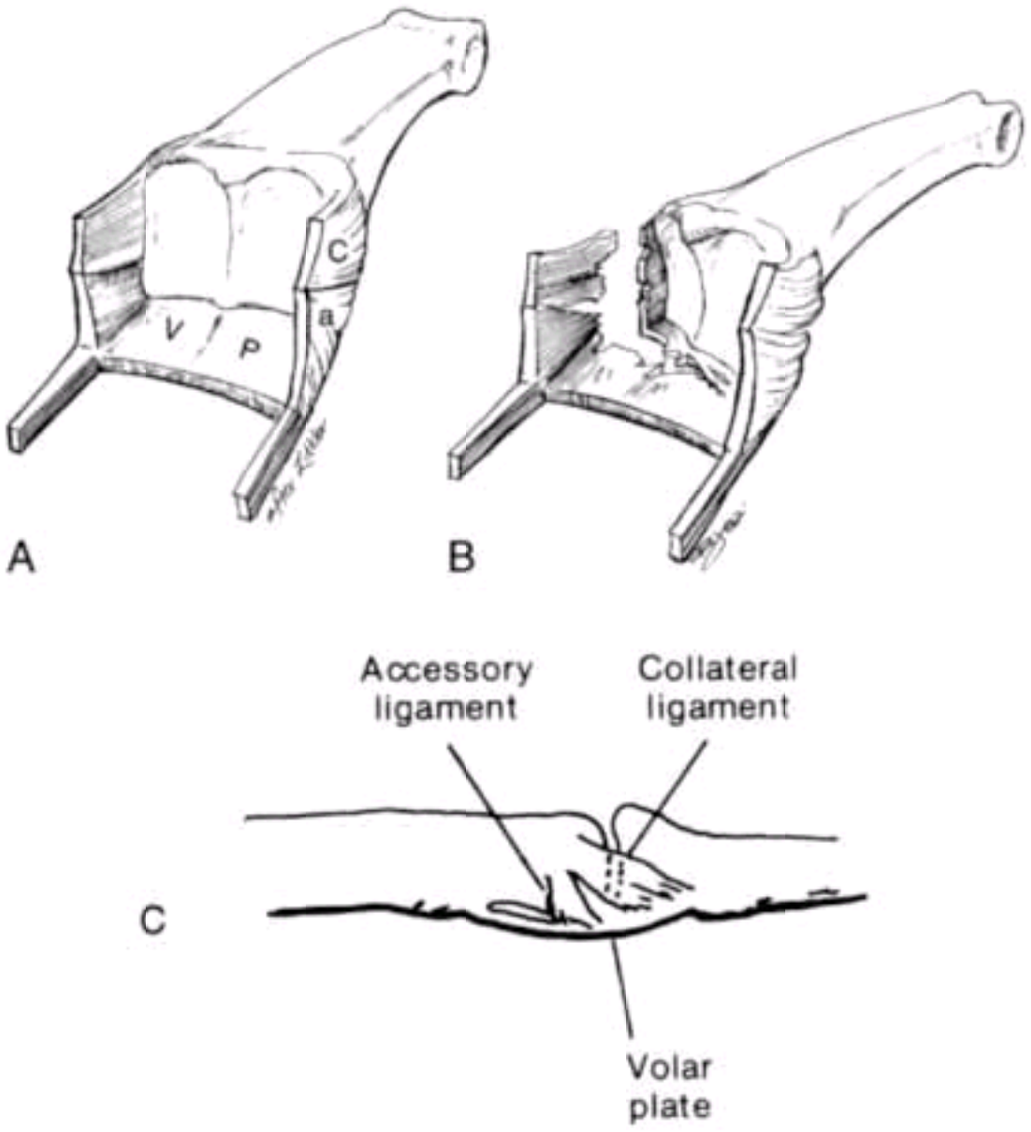

Figure 50-32 *A–D,* Traction method of joint reduction. Complete anesthesia using a regional block should precede reduction attempts. *E–H,* Exaggeration of existing deformity method. First, exaggerate the deformity that is present. Then, in addition to steady traction, push the joint back into position. *(From Carter P [ed]: Common Hand Injuries and Infections. Philadelphia, WB Saunders, 1983, pp 109 and 110. Reproduced by permission.)*

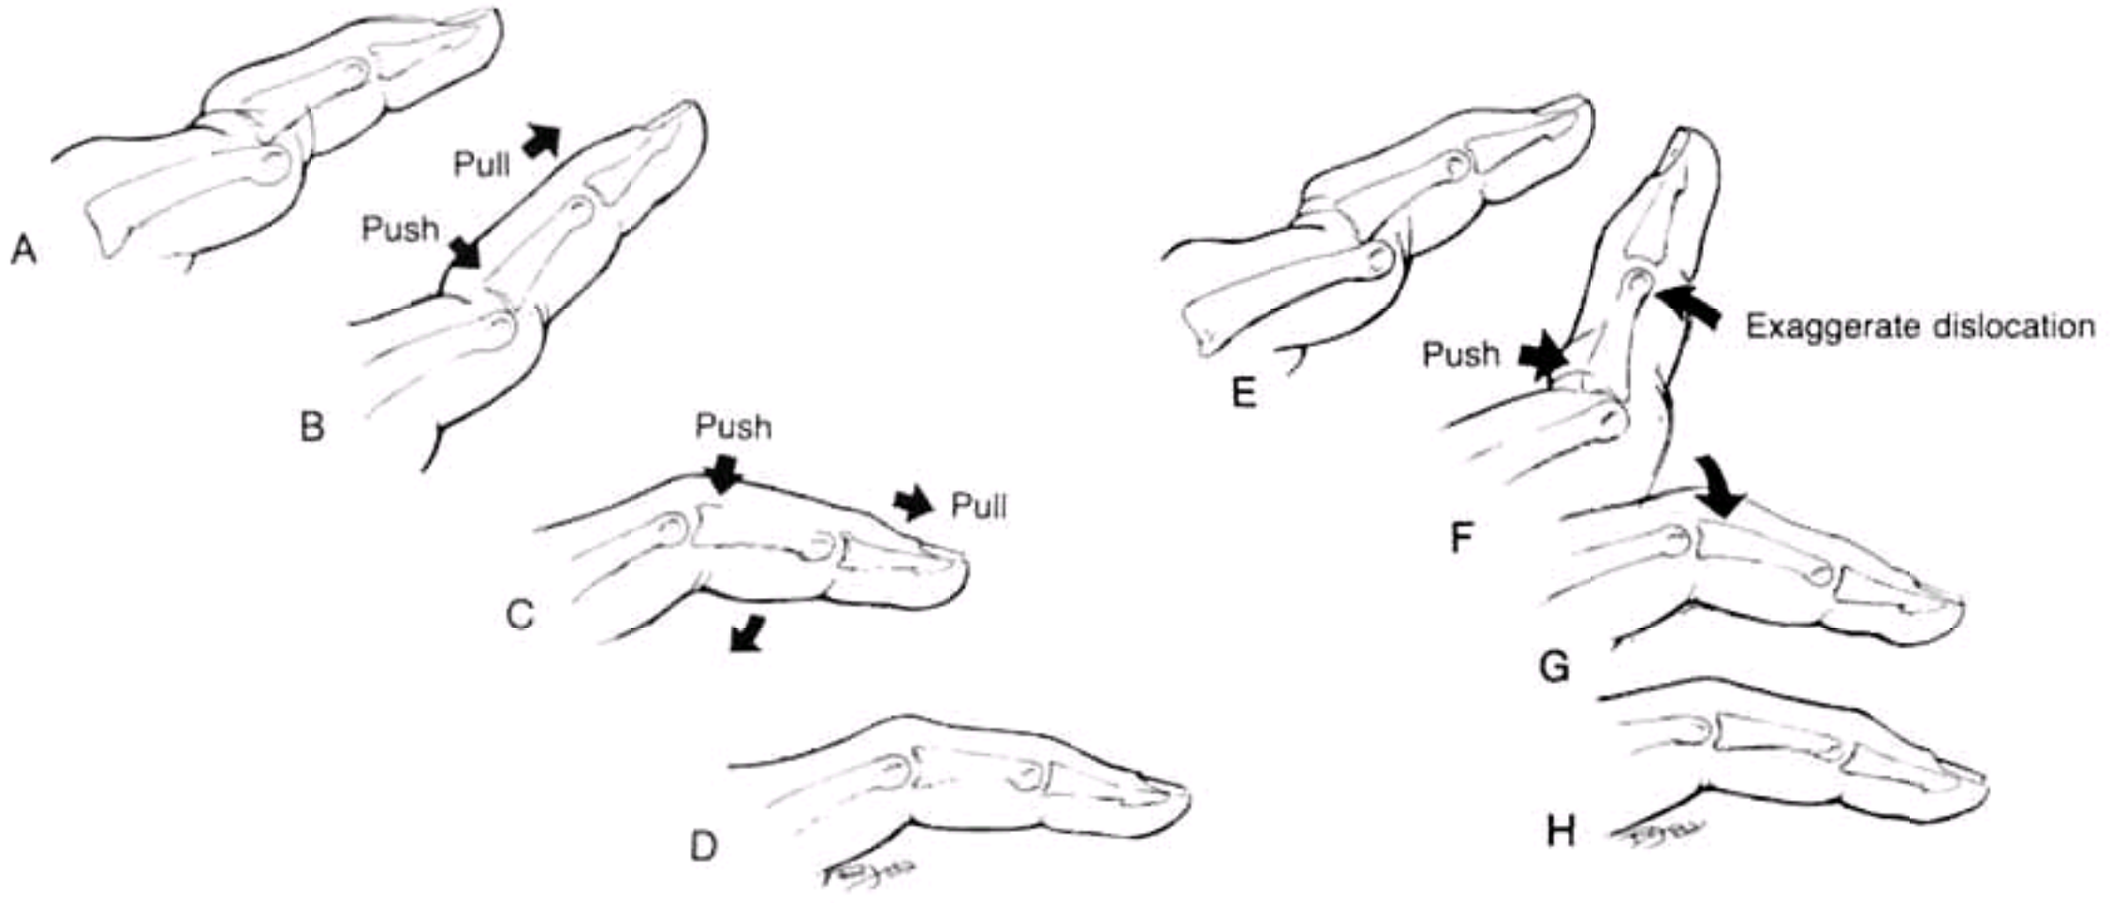

Figure 50-33 Complete dorsal dislocation at the metacarpophalangeal (MCP) joint of the thumb. There is neither associated fracture nor epiphyseal separation. *(From Harris JH Jr, Harris WH: Radiology of Emergency Medicine. 2nd ed. Baltimore, Williams & Wilkins, 1981, p 239. Reproduced by permission.)*

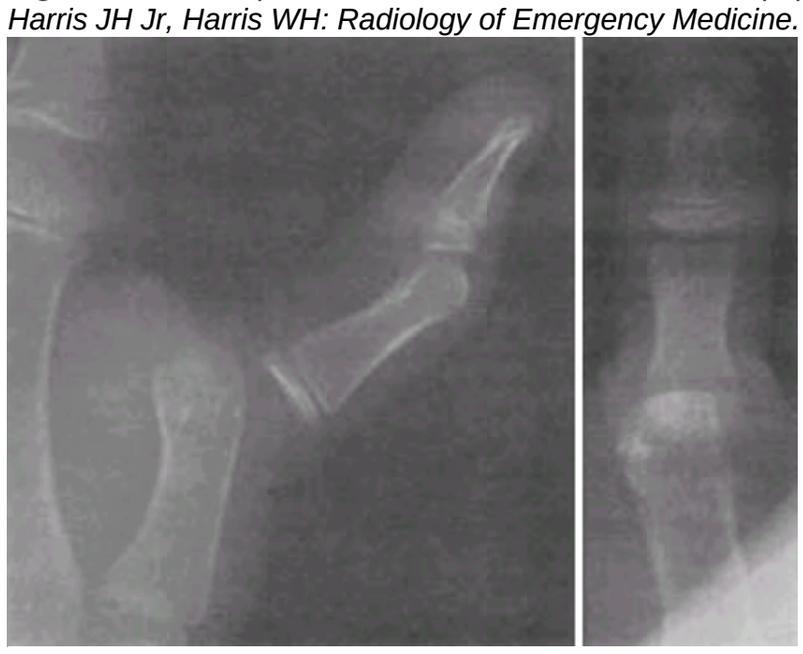

Figure 50-34 *A,* In a simple dorsal metacarpophalangeal (MCP) joint dislocation (note right angle between phalanx and metacarpal), the volar plate remains in front of the metacarpal head, although it is detached from its weaker metacarpal insertion. *B,* In a complex dislocation (note more parallel alignment between phalanx and metacarpal), the volar plate becomes entrapped in the joint and results in an irreducible reduction by closed methods. *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, p 1177. Reproduced by permission.)*

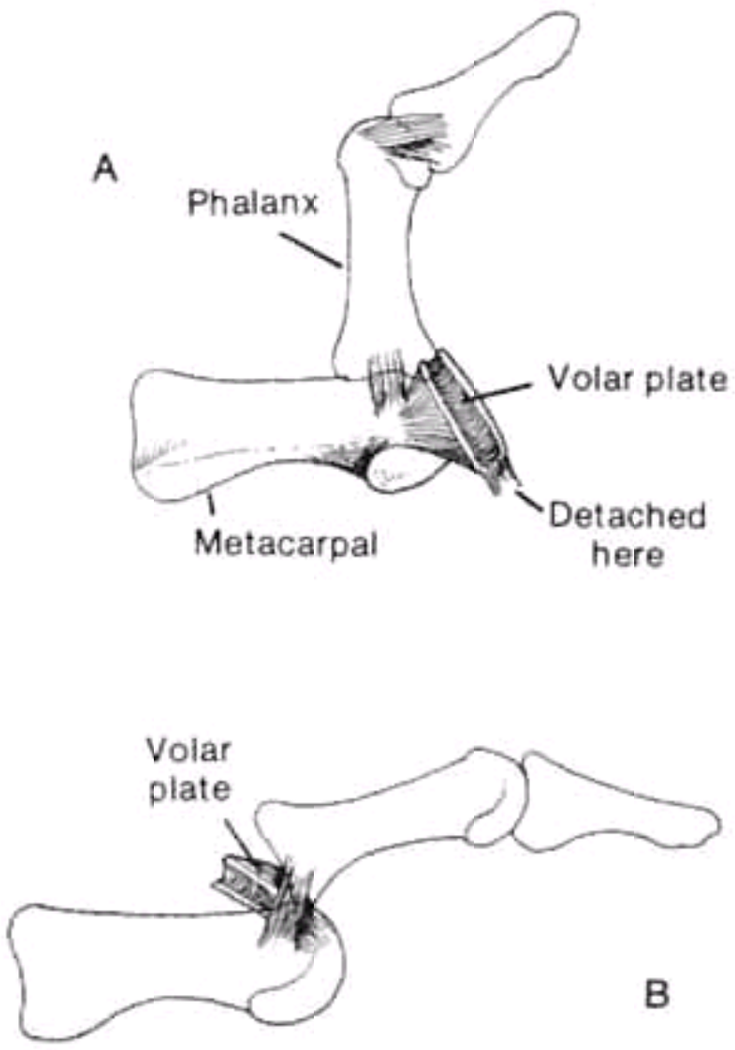

Figure 50-35 Irreducible metacarpophalangeal (MCP) joint dislocation of the thumb. Note the sesamoid bone *(arrow)*, indicating volar plate interposition between the two bone ends, which may prevent closed reduction. *(From Carter P [ed]: Common Hand Injuries and Infections. Philadelphia, WB Saunders, 1983, p 115. Reproduced by permission.)*

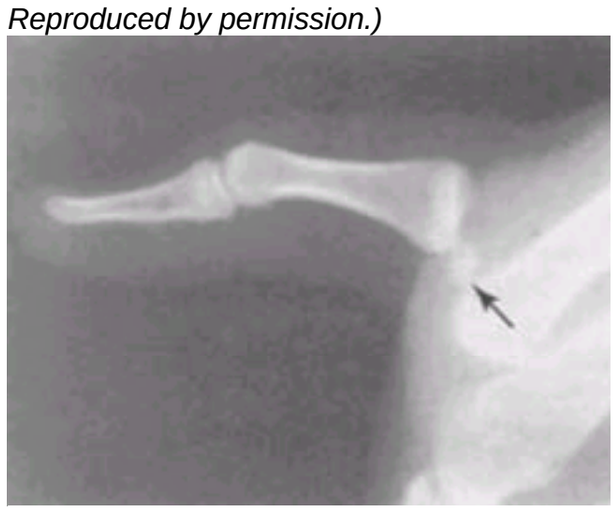

Figure 50-36 If a simple thumb metacarpophalangeal (MCP) dislocation is treated with traction alone, the forces will often interpose the volar plate and result in an irreducible complex dislocation. The proper technique for reduction includes *(1)* a good hold on the patient's distal thumb; *(2)* initial hyperextension of the dislocated phalanx; *(3)* pushing the base of the dislocated phalanx, rather than using traction alone; and *(4)* flexing the thumb. *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, p 1178. Reproduced by permission.)*

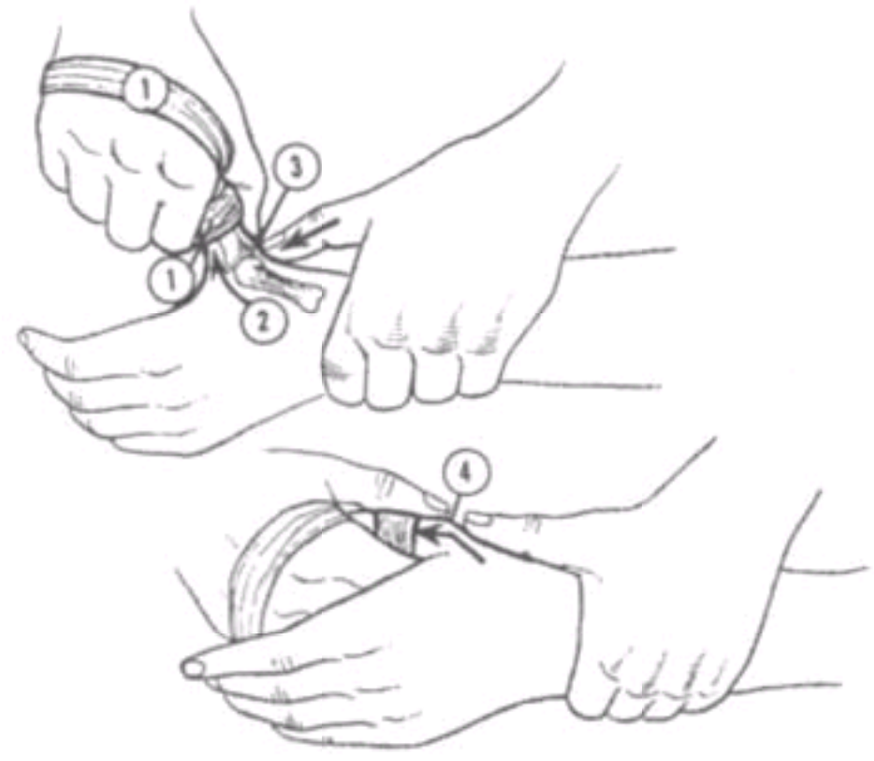

Figure 50-37 Rupture of the ulnar collateral ligament (gamekeeper's thumb). *1,* This injury is caused by forcible abduction. If unrecognized and untreated, progressive metacarpophalangeal (MCP) subluxation may occur *(2)* with interference during grasp, causing significant permanent disability. Suspect this injury when there is a complaint of pain in this region. Look for tenderness on the medial side of the MCP joint. *(From McRae R: Practical Fracture Treatment. Edinburgh, Churchill Livingstone, 1981, p 162. Reproduced by permission.)*

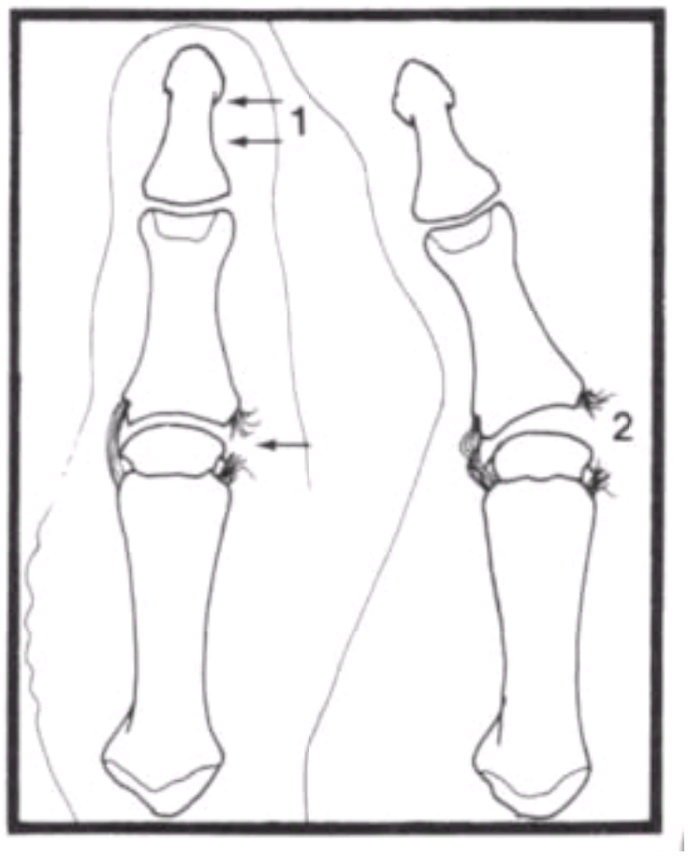

Figure 50-38 Stress testing of the ulnar collateral ligament of the thumb. This is done both clinically and with an anteroposterior radiograph. *A*, A line is drawn on the skin with a pen. The line is along the long axis of the metacarpal and the proximal phalanx. *B*, Deviation of the straight line during stress indicates instability. The metacarpal is fixed with the operator's other hand.

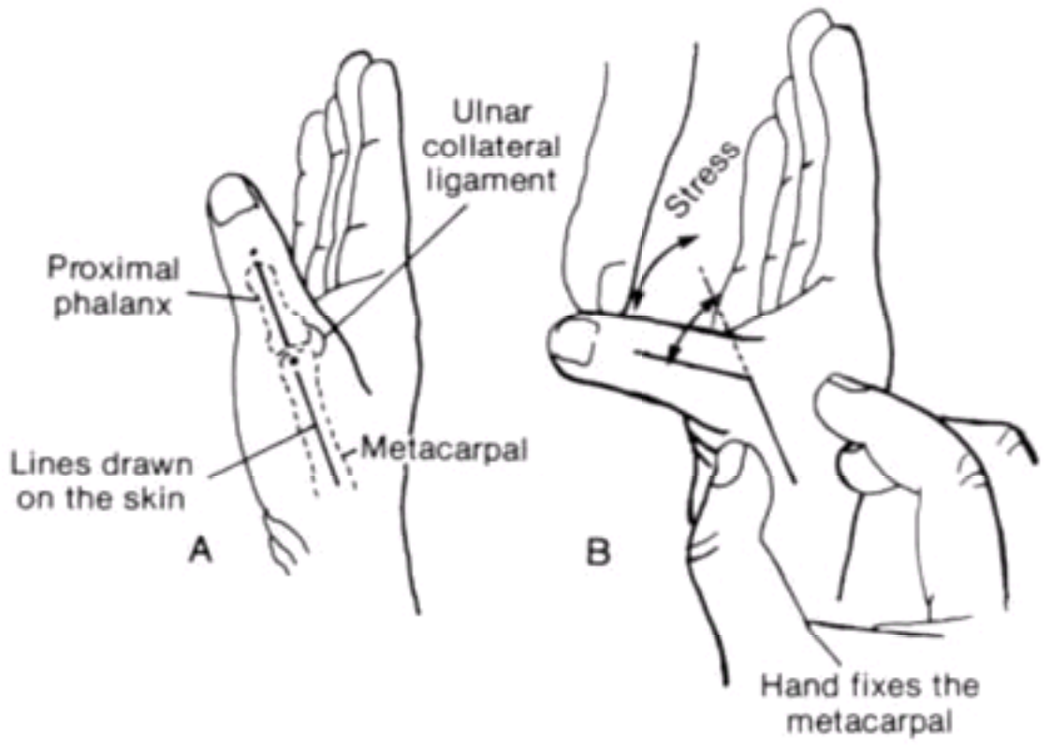

Figure 50-39 *A*, This fracture-dislocation is only fully appreciated on the true lateral film. *B*, A small fragment of bone was avulsed with the volar plate. This frequently is appreciated only with the postreduction film in a true lateral projection. *(From Carter P [ed]: Common Hand Injuries and Infections. Philadelphia, WB Saunders, 1983, p 113. Reproduced by permission.)*

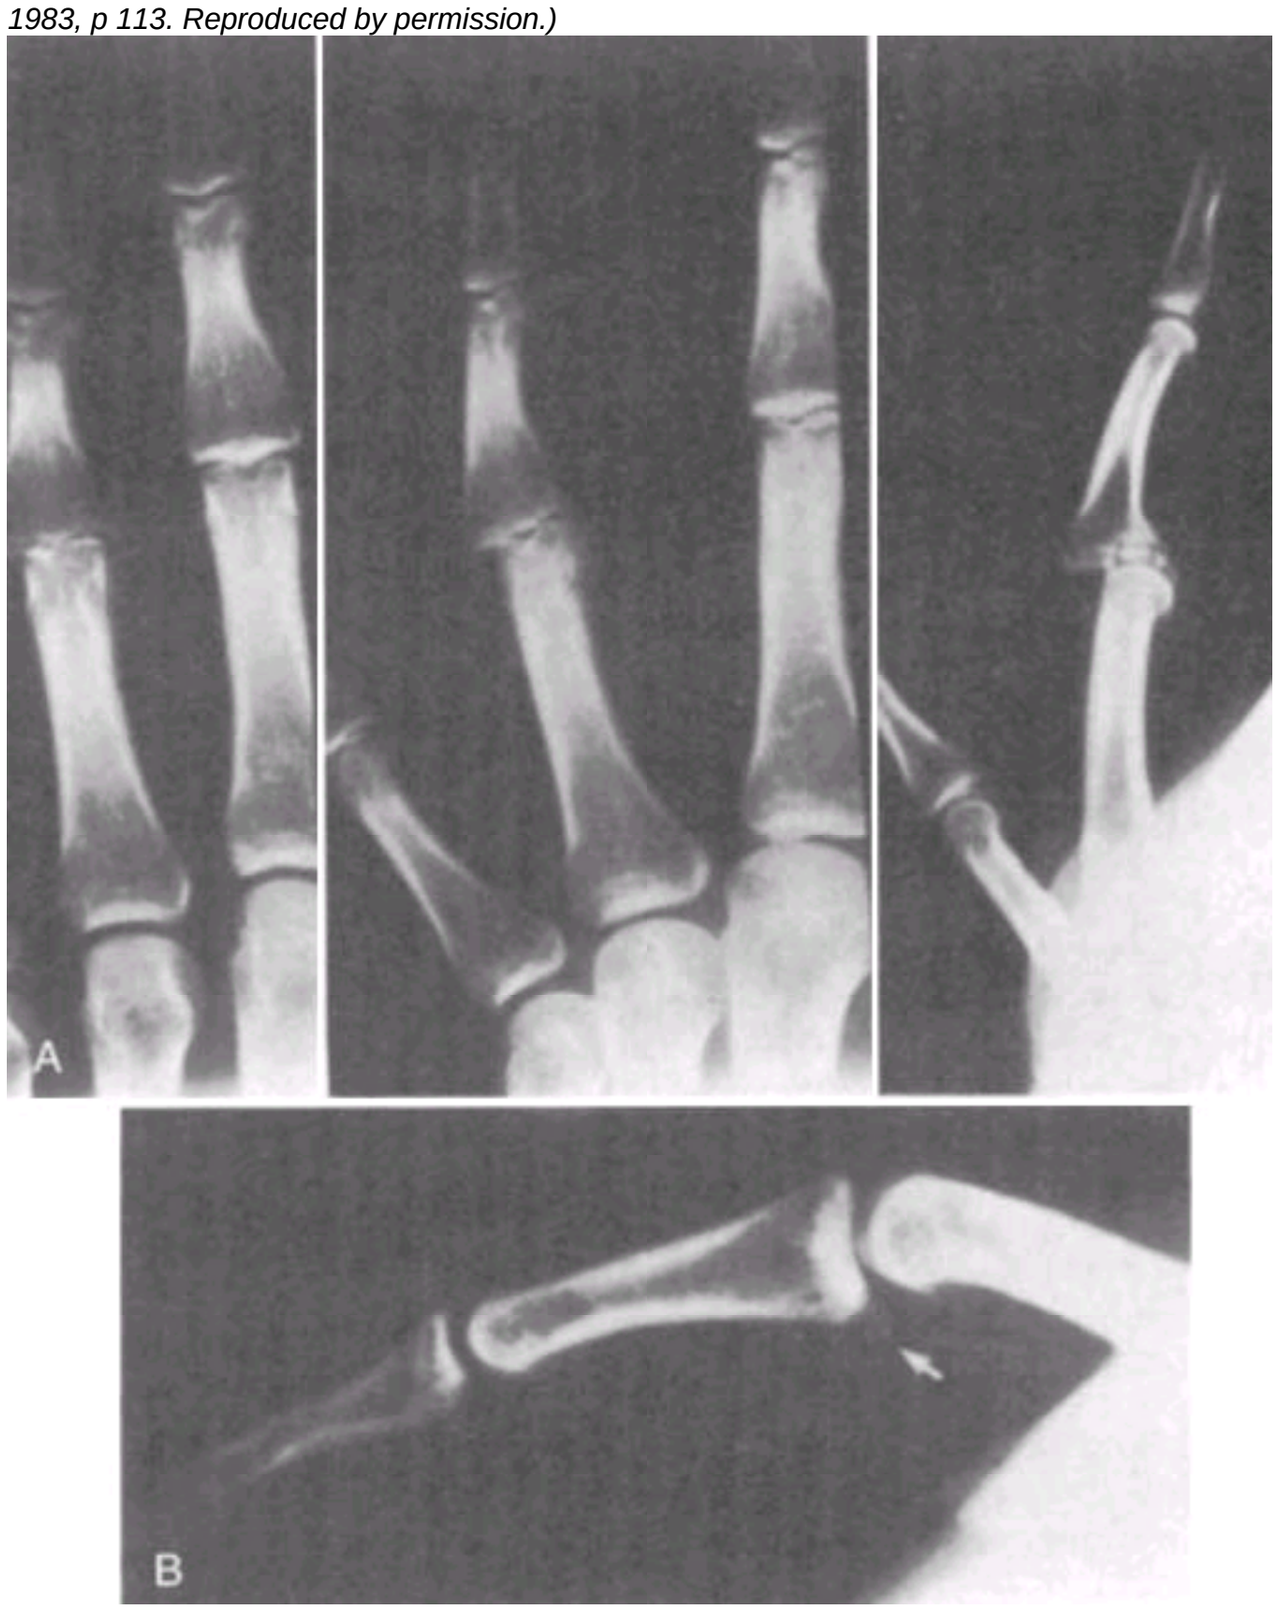

Figure 50-40 Postreduction stress of proximal interphalangeal dislocation. *A,* If the volar plate has been completely disrupted, the proximal interphalangeal joint will hyperextend with both passive and active motion. *B,* An inability to actively extend the proximal interphalangeal joint indicates a rupture of the central slip of the extensor tendon. *C,* Passive lateral stress is performed to check integrity of collateral ligaments. *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders 1970, pp 1203 and 1204. Reproduced by permission.)*

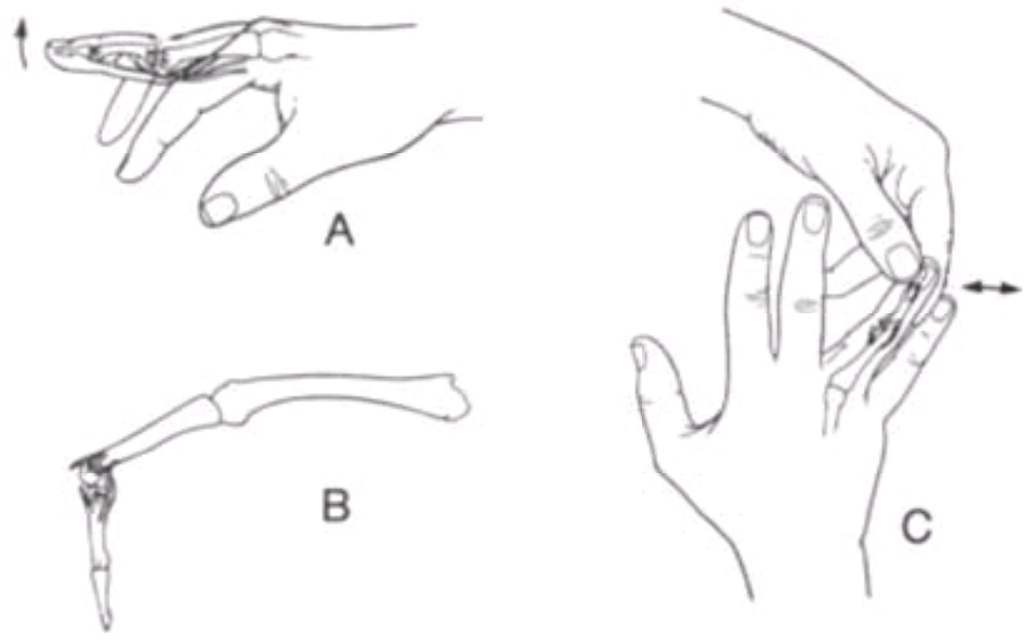

Figure 50-41 A dorsal proximal interphalangeal joint dislocation may involve rupture of the volar plate itself *(A)* or may involve an avulsion of varying amounts of bone from the middle phalanx *(B)*. If a large fragment of bone is avulsed from the base of the phalanx, the dislocation is unstable after reduction. The collateral ligaments will tear in varying degrees and should be assessed with stress testing following reduction.

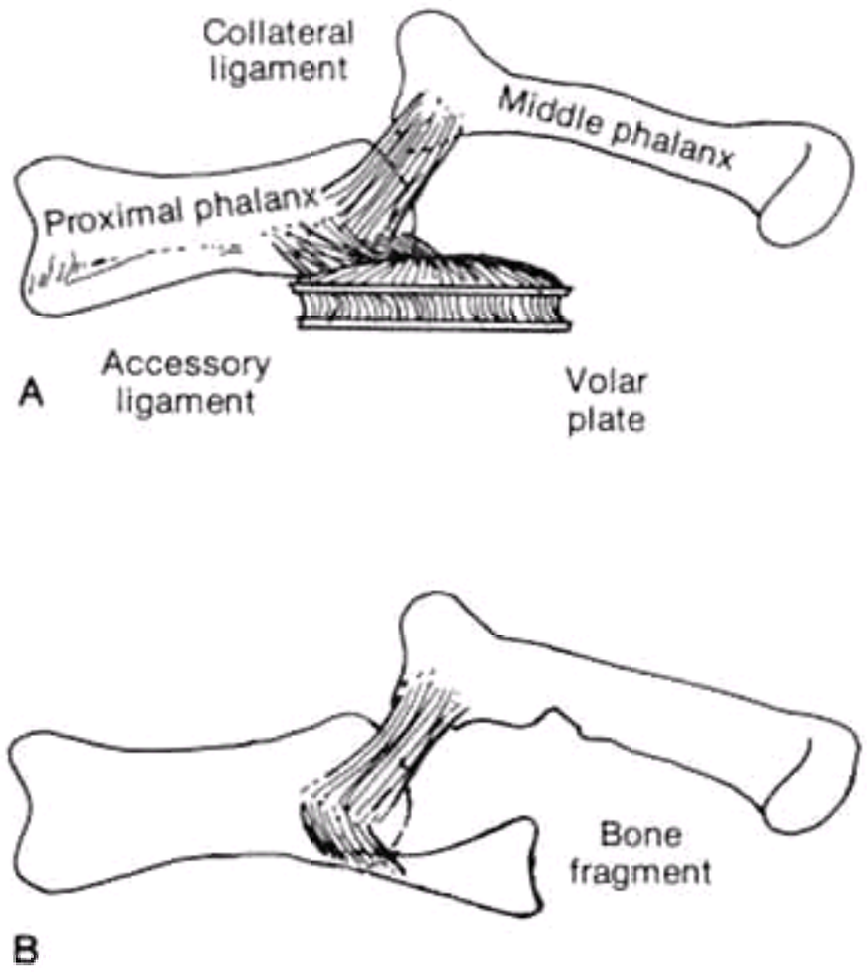

Figure 50-42 *A*, The mallet finger injury is not a dislocation; it is a rupture of the extensor tendon to the distal phalanx. *B*, This mallet deformity was caused by a baseball striking the fingertip end on, producing acute flexion of the joint.

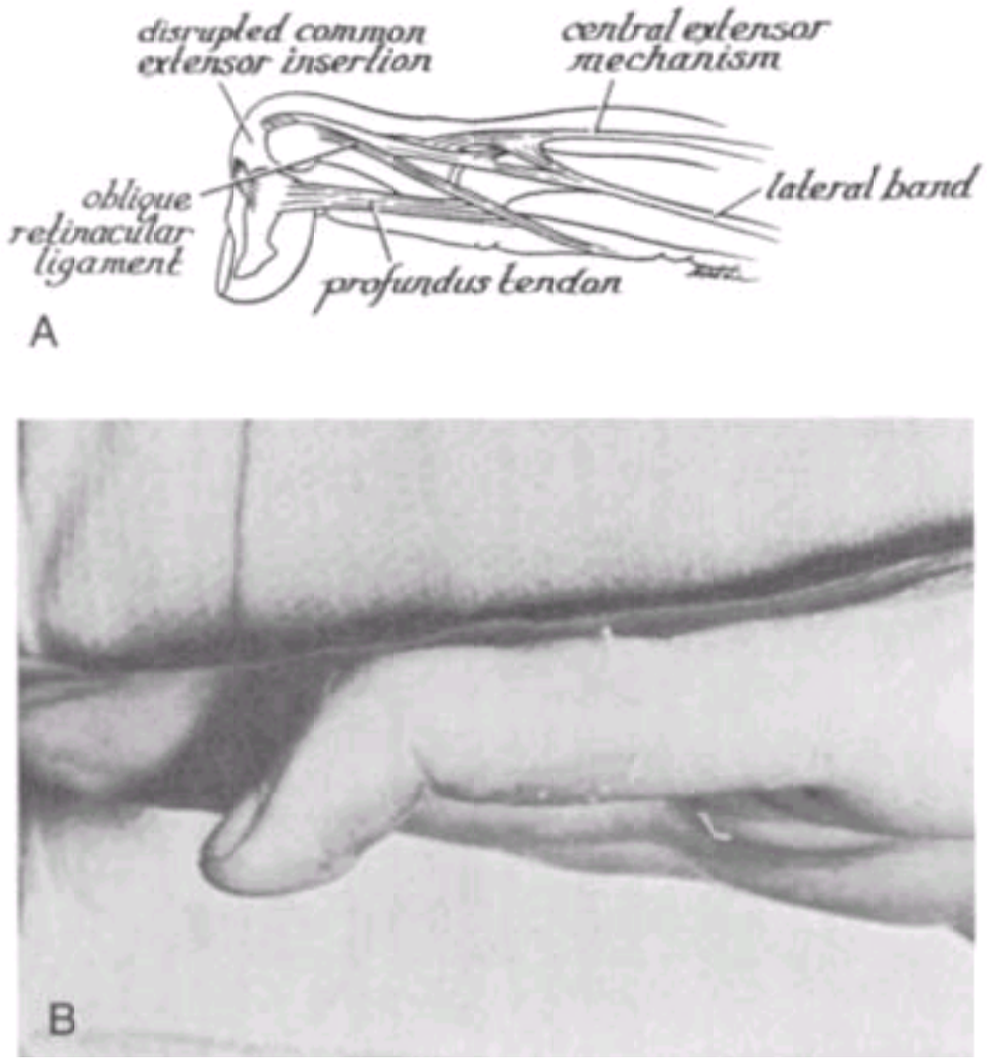

Figure 50-43 *A*, Posterior dislocation of the hip. *B,* In a severely injured patient, a hip dislocation may be initially missed while more pressing or obvious injuries are managed. In this posterior dislocation, the femur is adducted, internally rotated, and superiorly displaced, and an associated posterior acetabular fracture is present. A Malgaigne fracture of the pelvis is also present, with diastasis of the public symphysis and left sacroiliac joint. *(A from Simon R, Koenigsknecht S: Orthopedics in Emergency Medicine. New York, Appleton-Century-Crofts, 1982, p 366. B from Greenbaum E: Radiology of the Emergency Patient. New York, John Wiley & Sons, 1982, p 563. Reproduced by permission.)*

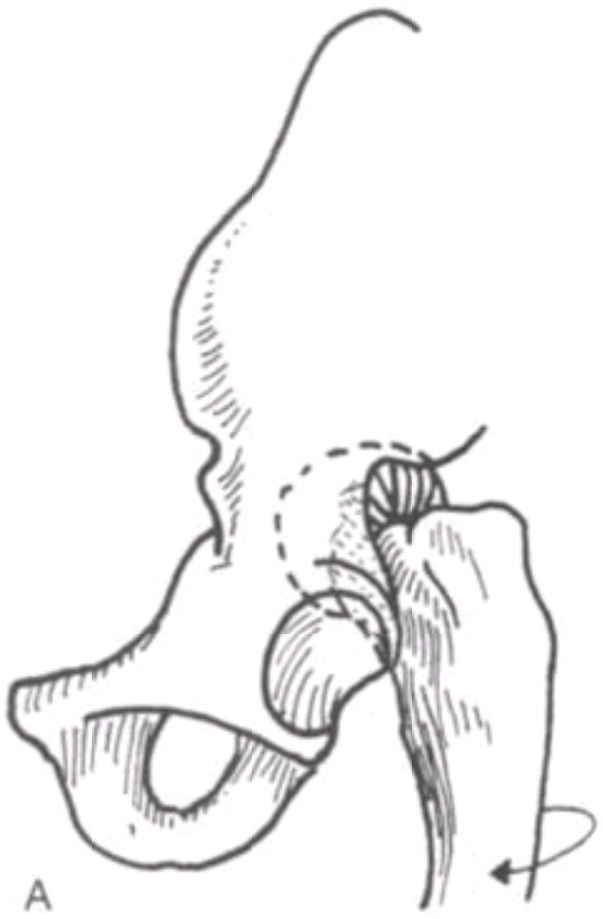

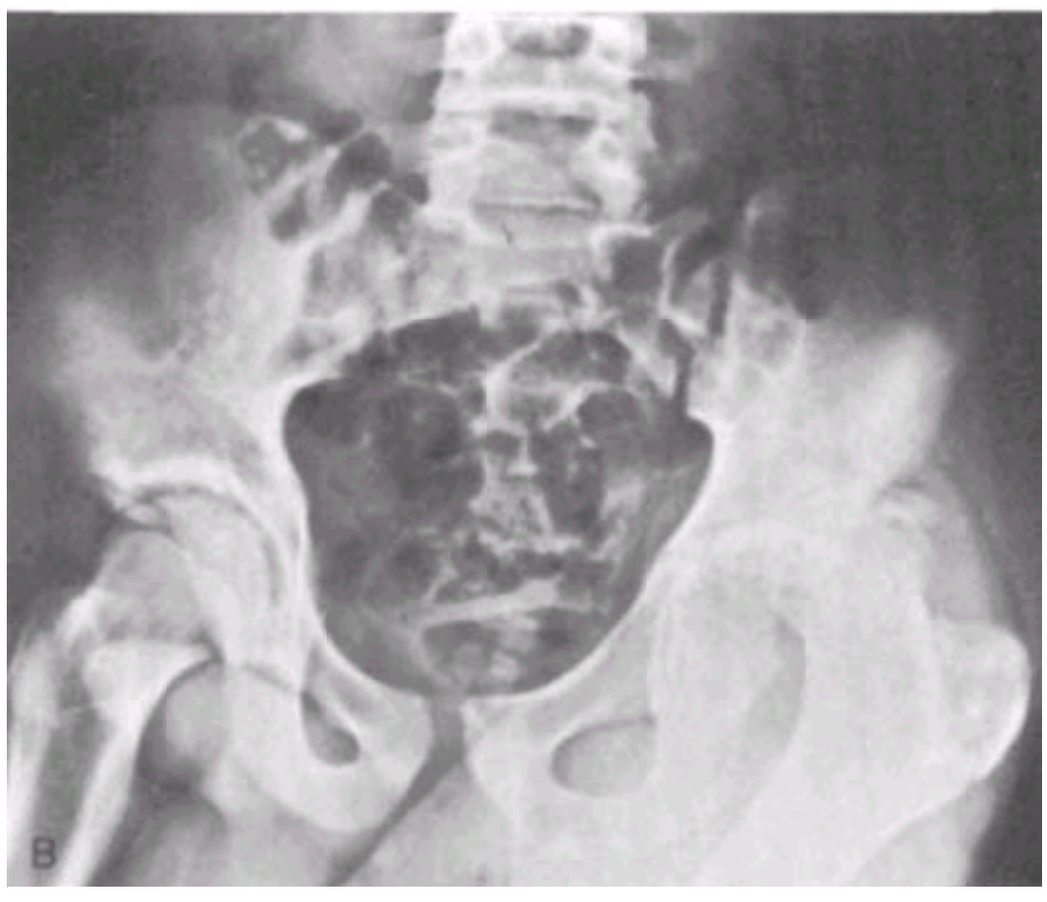

Figure 50-44 Stimson method of reduction for posterior dislocation of the hip (see text for description). *(From DeLee JC: Fractures and dislocations of the hip. In Rockwood CA, Green DP [eds]: Fractures in Adults, vol 2. Philadelphia, JB Lippincott, 1991, p 1588. Reproduced by permission.)*

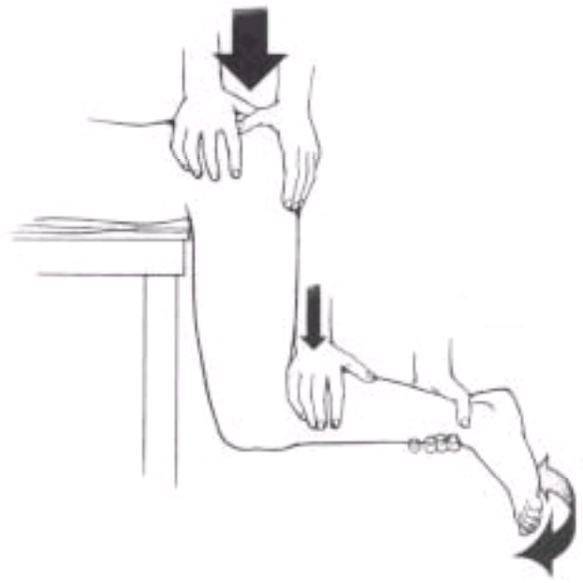

Figure 50-45 Usually a hip dislocation is the result of significant trauma. *A*, An anterior dislocation of the hip occurred in this elderly patient with a hip prosthesis from minimal trauma (rolling over in bed). *B*, Note the position of the left leg, with the hip abducted, externally rotated, and extended. This is the same position assumed by a patient with an intertrochanteric hip fracture. The more common posterior dislocation positions the hip as adducted and internally rotated. *C* and *D*, Some clinicians prefer to climb on the bed to effect reduction. The assistant may lie over the pelvis or hold the pelvis for countertraction. Care must be taken not to disrupt the prosthesis by using excessive force. Also note that osteoporotic bones can fracture during a forceful reduction. *E*, Following relocation, a knee immobilizer usually prevents the motions required to produce a recurrent dislocation.

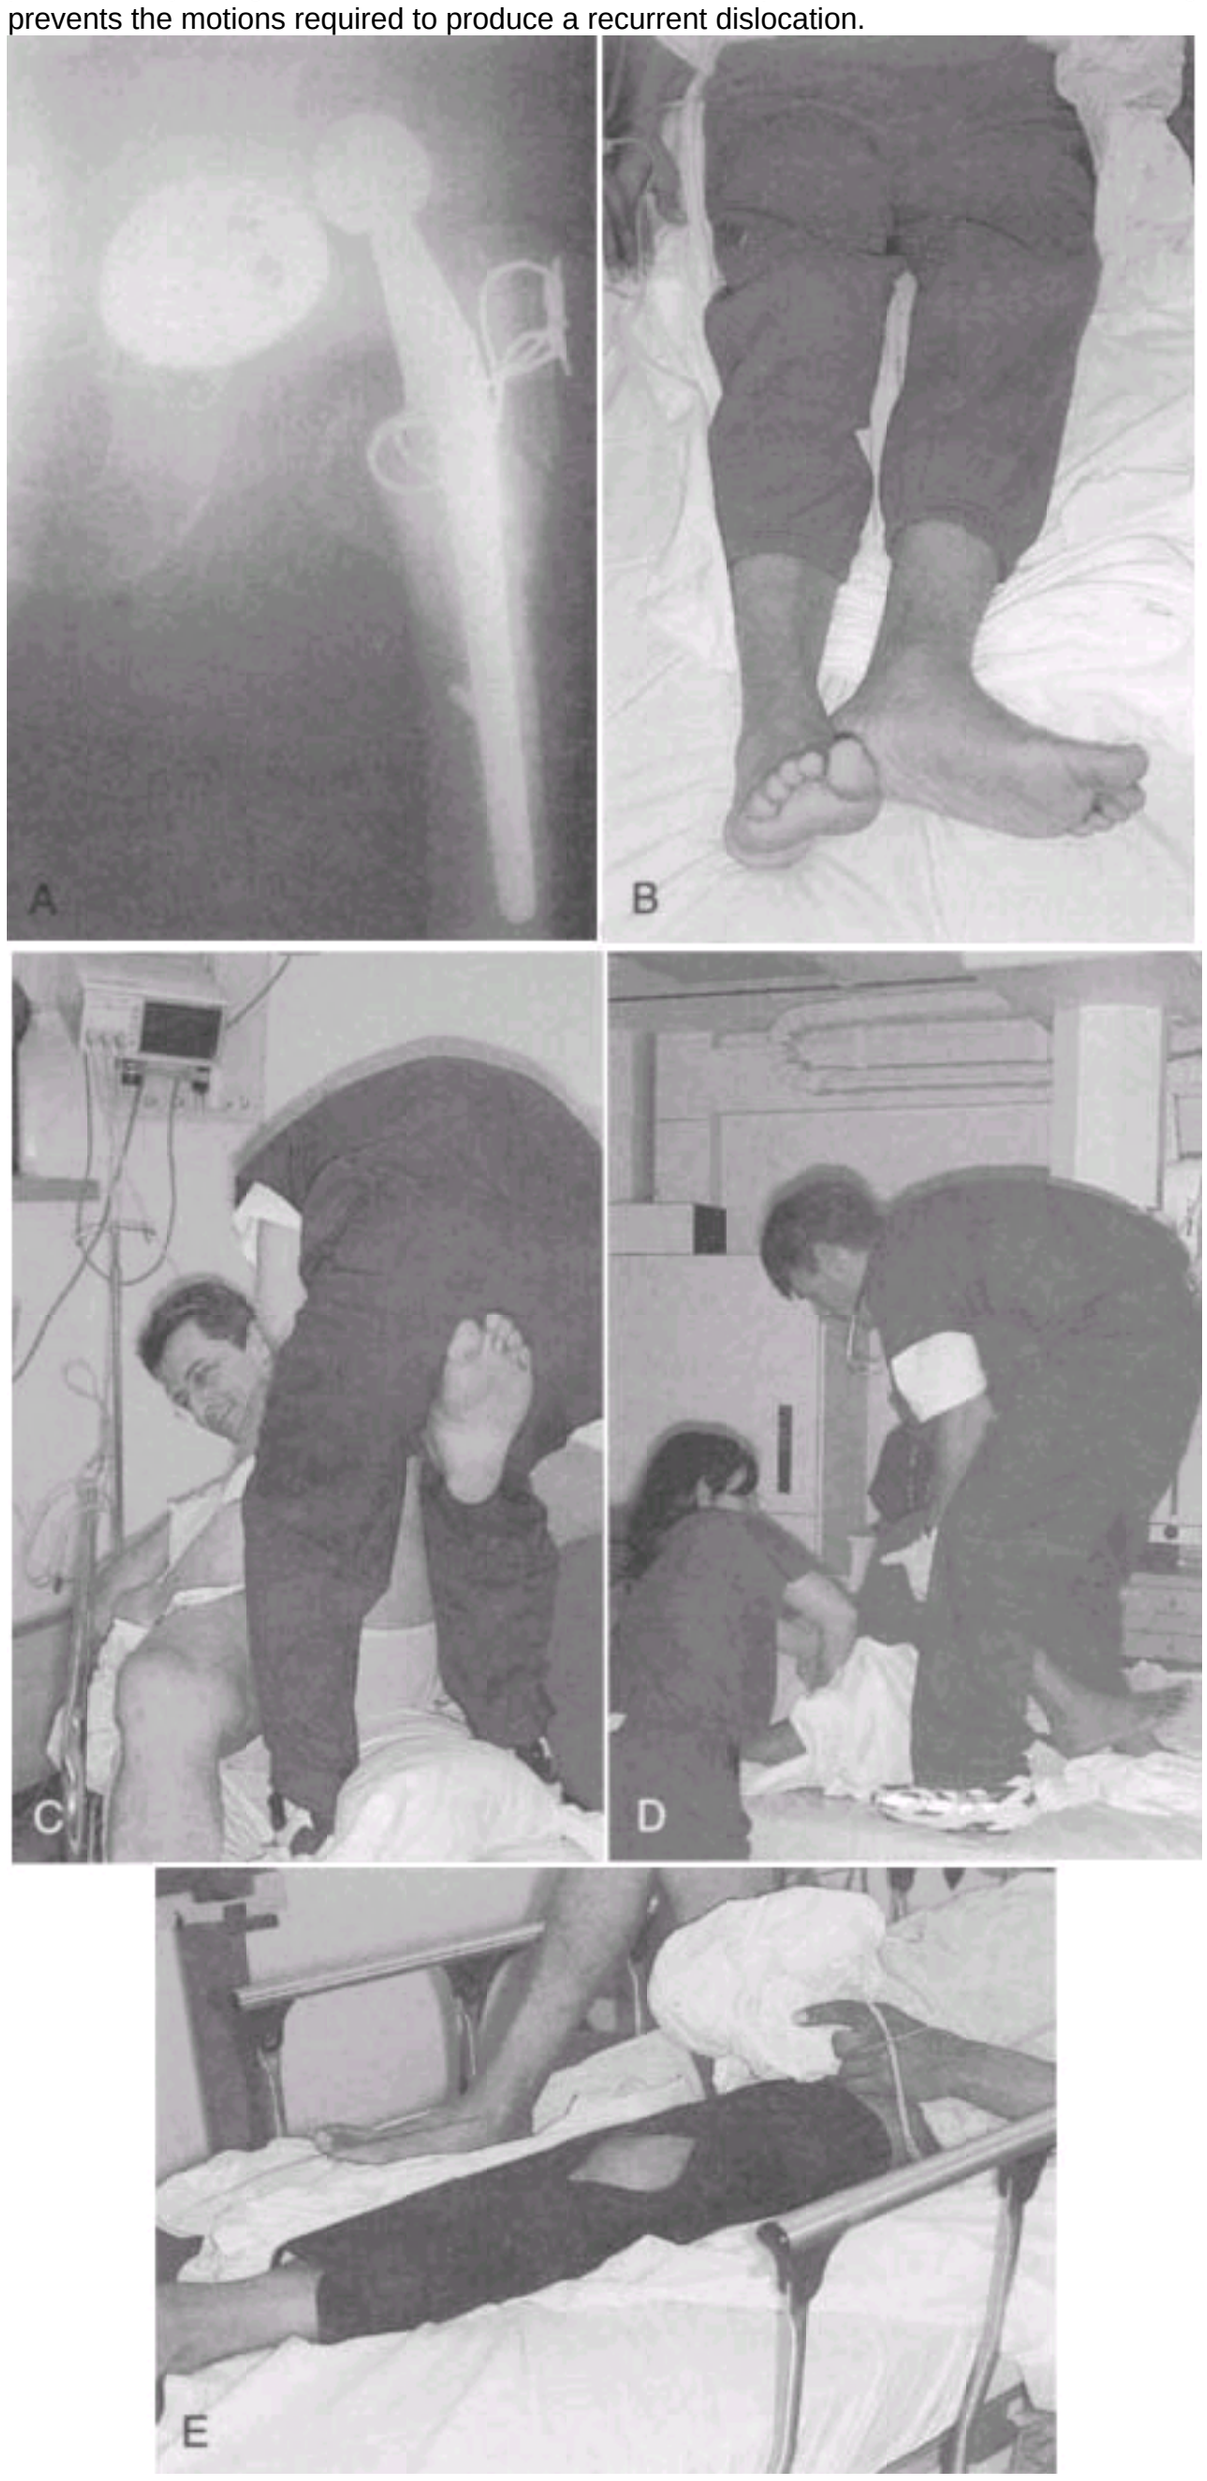

Figure 50-46 Allis method of reducing posterior dislocation of the hip (see text for description). *(From DeLee JC: Fractures and dislocations of the hip. In Rockwood CA, Green DP [eds]: Fractures in Adults, vol 2. Philadelphia, JB Lippincott, 1991, p 1594. Reproduced by permission.)*

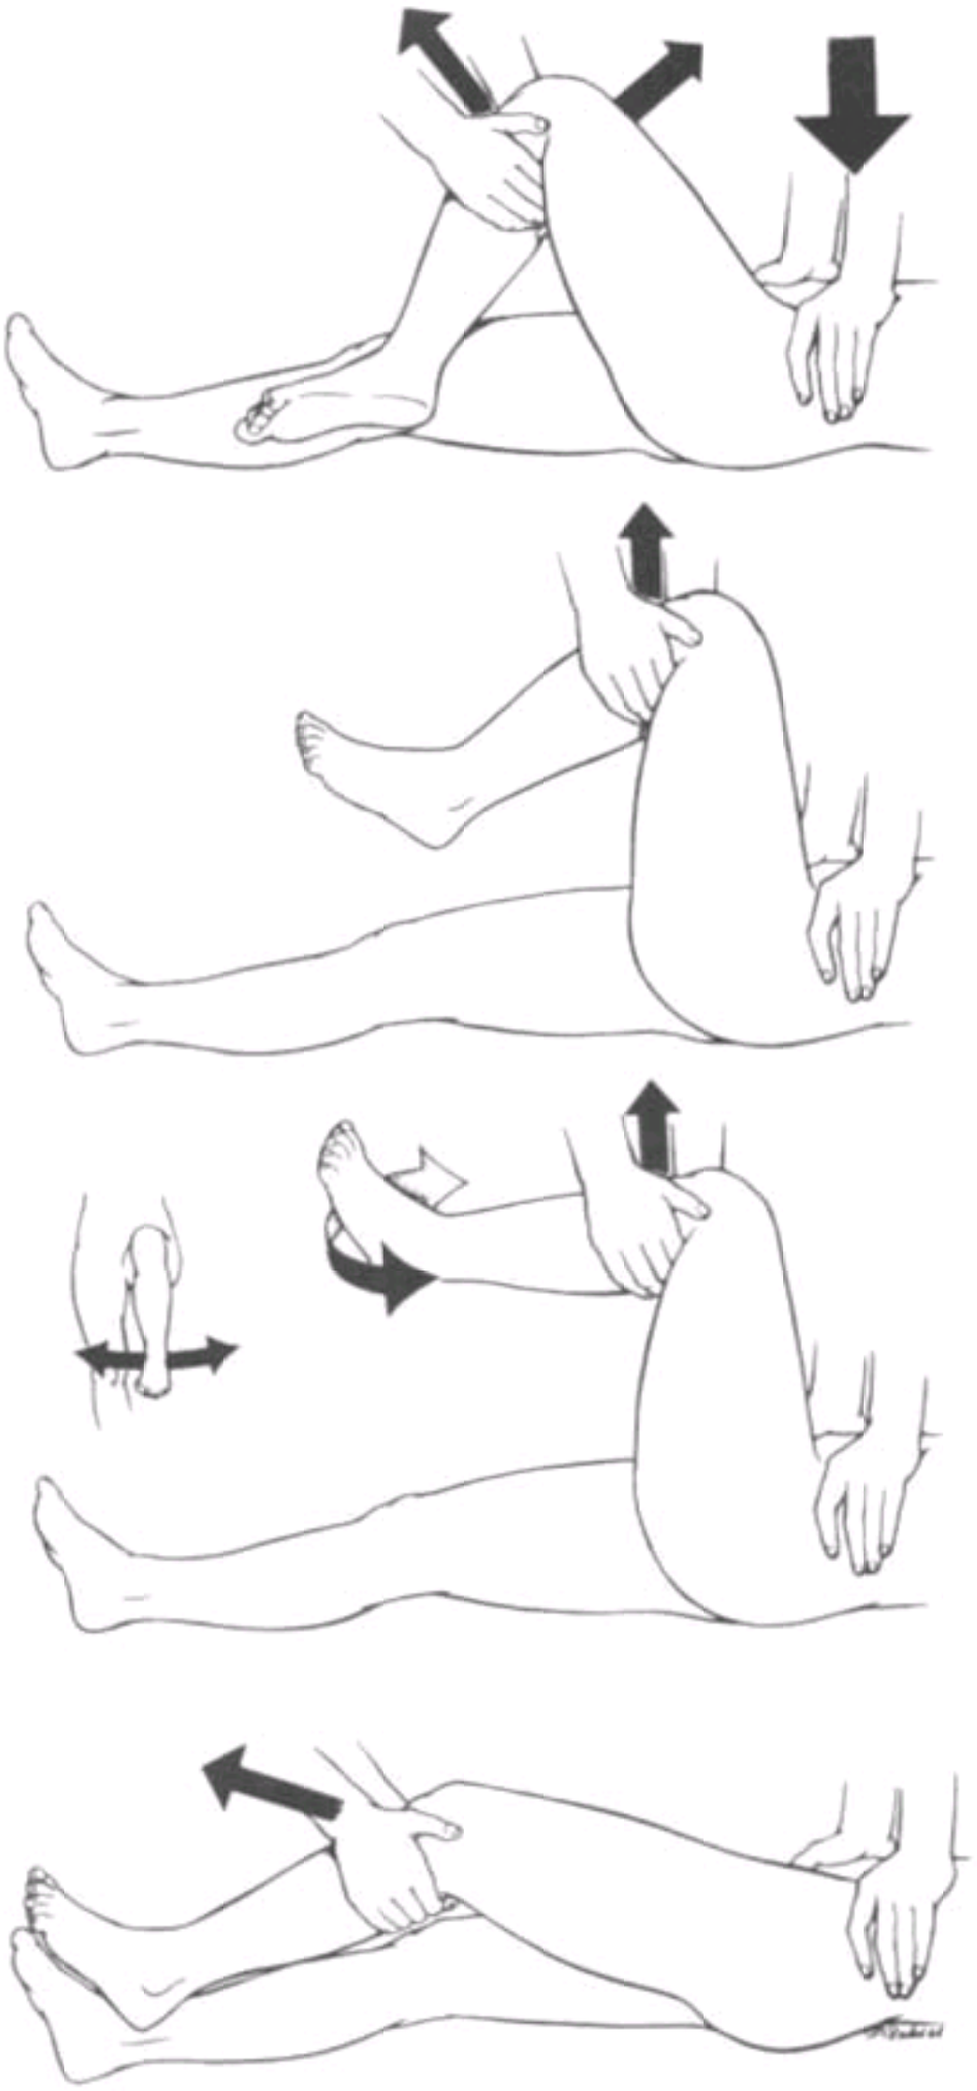

Figure 50-47 Whistler technique of reducing posterior hip dislocation. The operator stabilizes the affected ankle with one hand while placing the other arm under the affected knee to grasp the unaffected knee. While an assistant stabilizes the pelvis, the operator raises the shoulder, elevating the knee to reduce the dislocation.

Figure 50-48 Anterior dislocations of the hip: obturator, pubic, and iliac. *(From Simon R, Koenigsknecht S: Orthopedics in Emergency Medicine. New York, Appleton-Century-Crofts, 1982, p 367. Reproduced by permission.)*

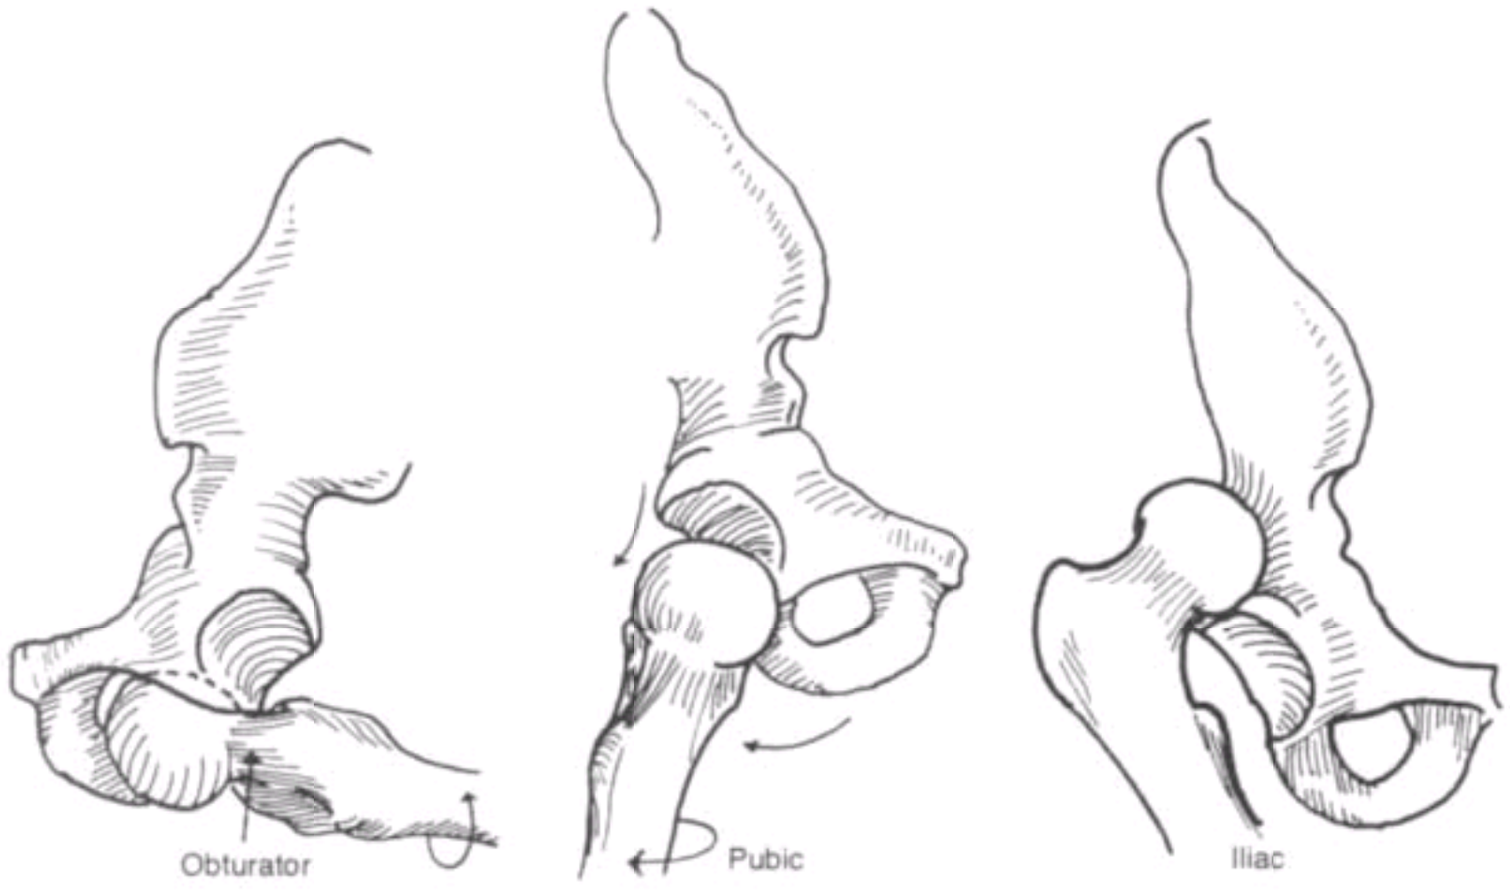

Figure 50-49 Modified Allis maneuver for reduction of anterior hip dislocation (see text for description). *(From DeLee JC: Fractures and dislocations of the hip. In Rockwood CA, Green DP (eds): Fractures in Adults, vol 2. Philadelphia, JB Lippincott, 1991, p 1588. Reproduced by permission.)*

Figure 50-50 *A*, In an obese patient a dislocated knee may not be obvious on initial inspection. This patient stated that she stepped into a hole and twisted the knee (a classic mechanism for dislocation), causing the clinician to suspect only a sprain. *B*, An x-ray demonstrated the seriousness of this seemingly benign injury. *If a spontaneous reduction occurs prior to ED evaluation, this diagnosis may not even be considered. C*, The dislocation is usually readily reduced by traction-countertraction. Tibial manipulation concurrent with traction-countertraction is often helpful.

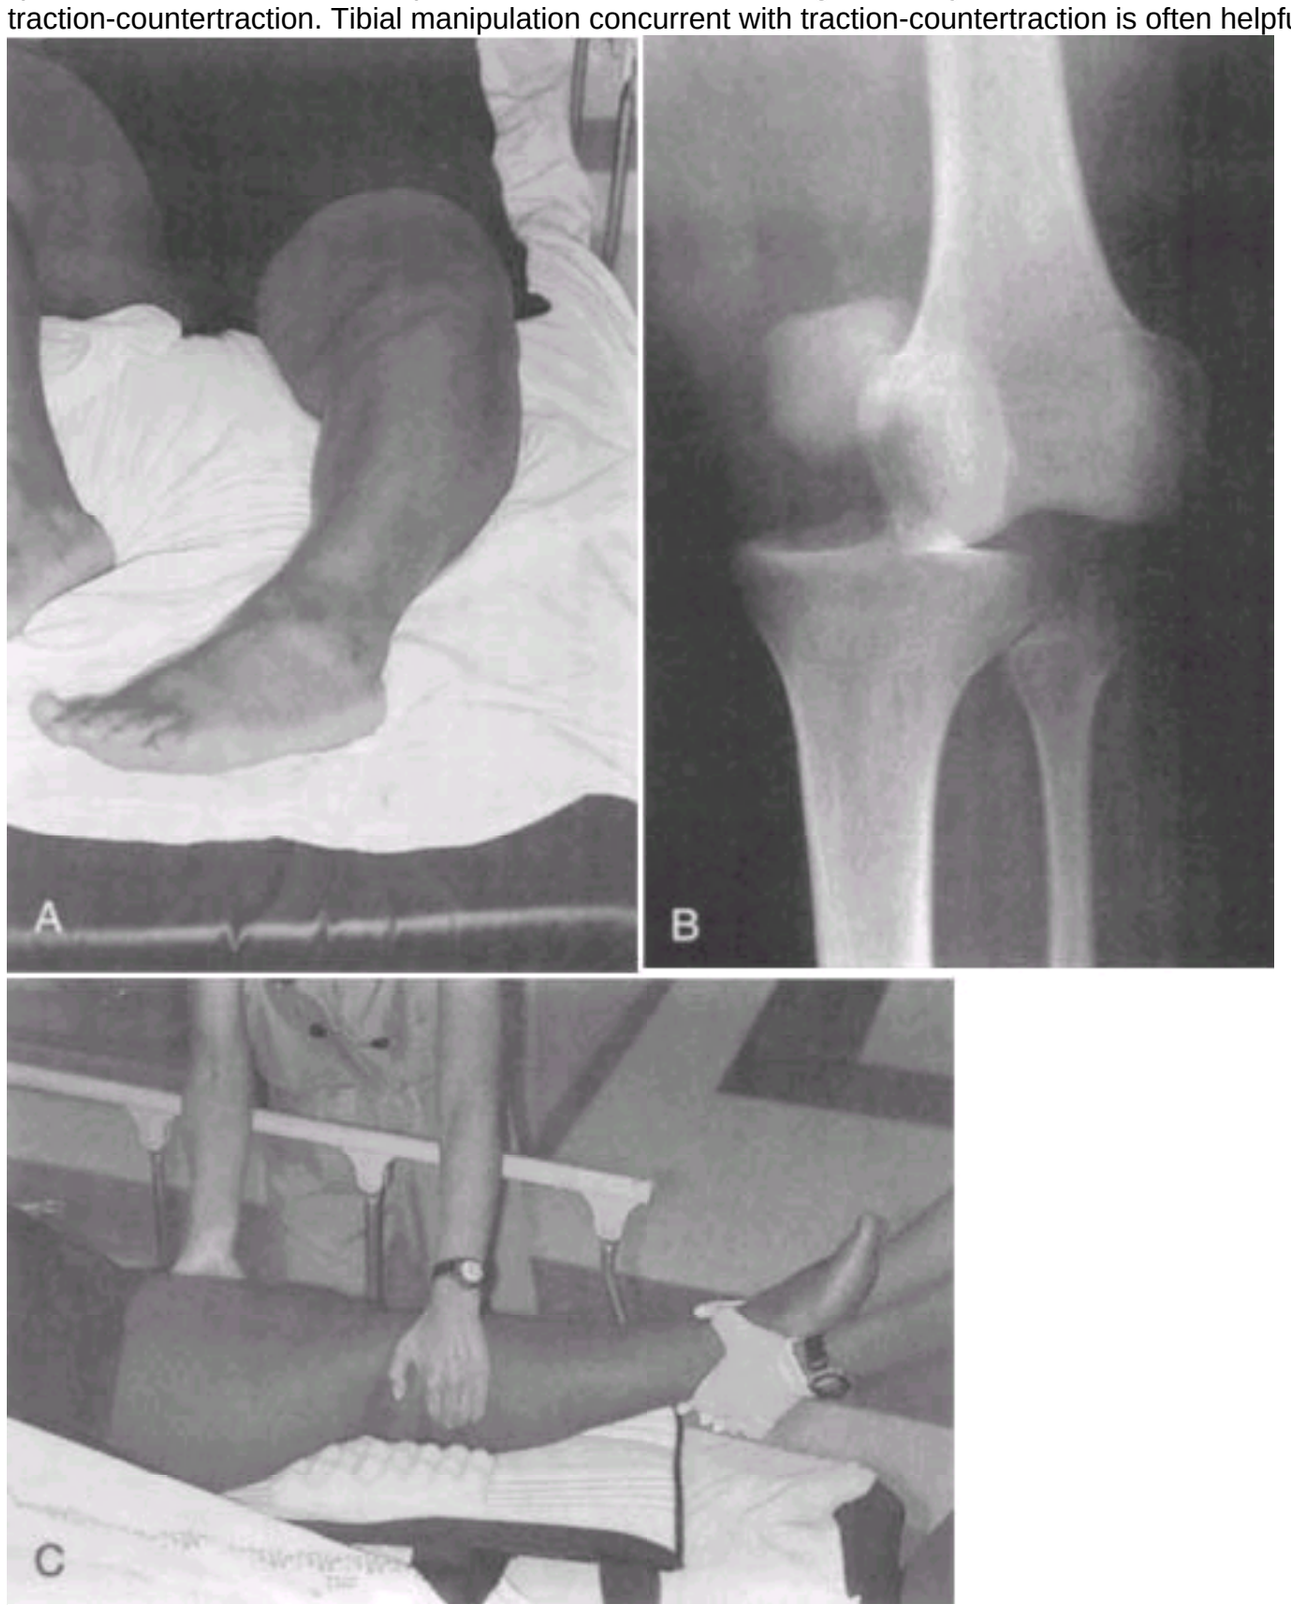

Figure 50-51 Types of knee dislocations. Anterior (*1*), posterior (*2*), and lateral (*3*). *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, p 1621. Reproduced by permission.)*

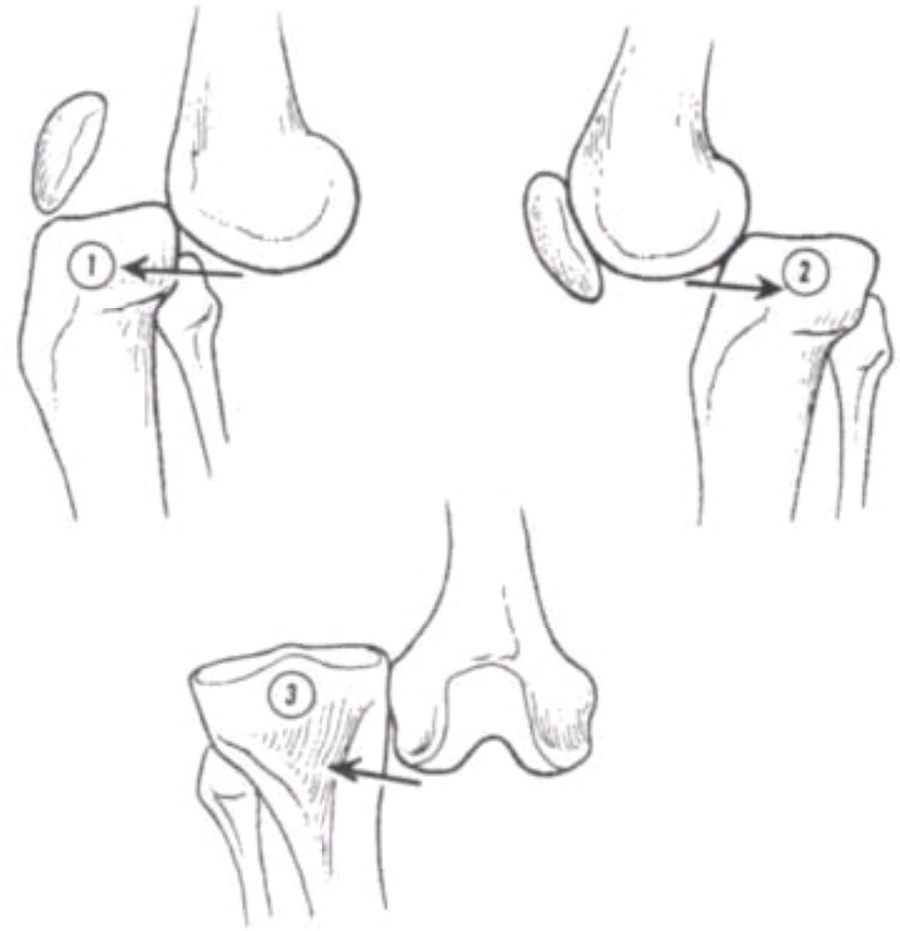

Figure 50-52 Manipulative reduction of a knee dislocation. *1,* An assistant fixes and provides countertraction on the thigh. *2,* Another assistant provides straight traction on the leg (this usually reduces the dislocation). *3,* The operator puts direct pressure over the displaced bones. *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, p 1623. Reproduced by permission.)*

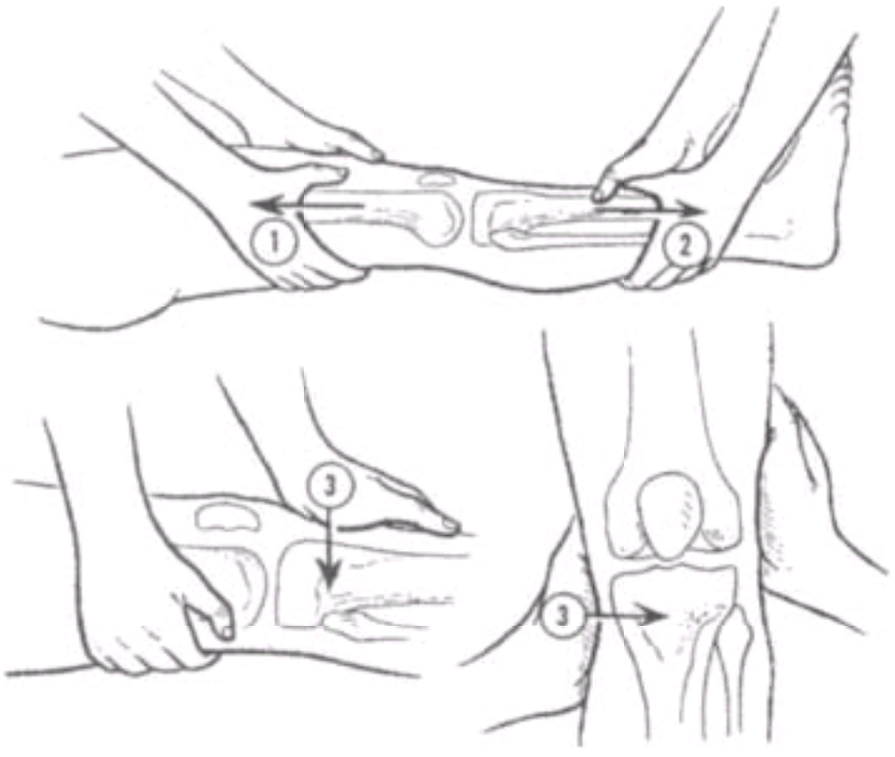

Figure 50-53 Anterolateral fibular head dislocation compared to the normal knee. The interosseous distance is widened and the proximal fibula is displaced laterally. *A*, normal anteroposterior projection of knee. *B*, lateral displacement of proximal fibula. *C*, use of bilateral comparison views to highlight fibular displacement.

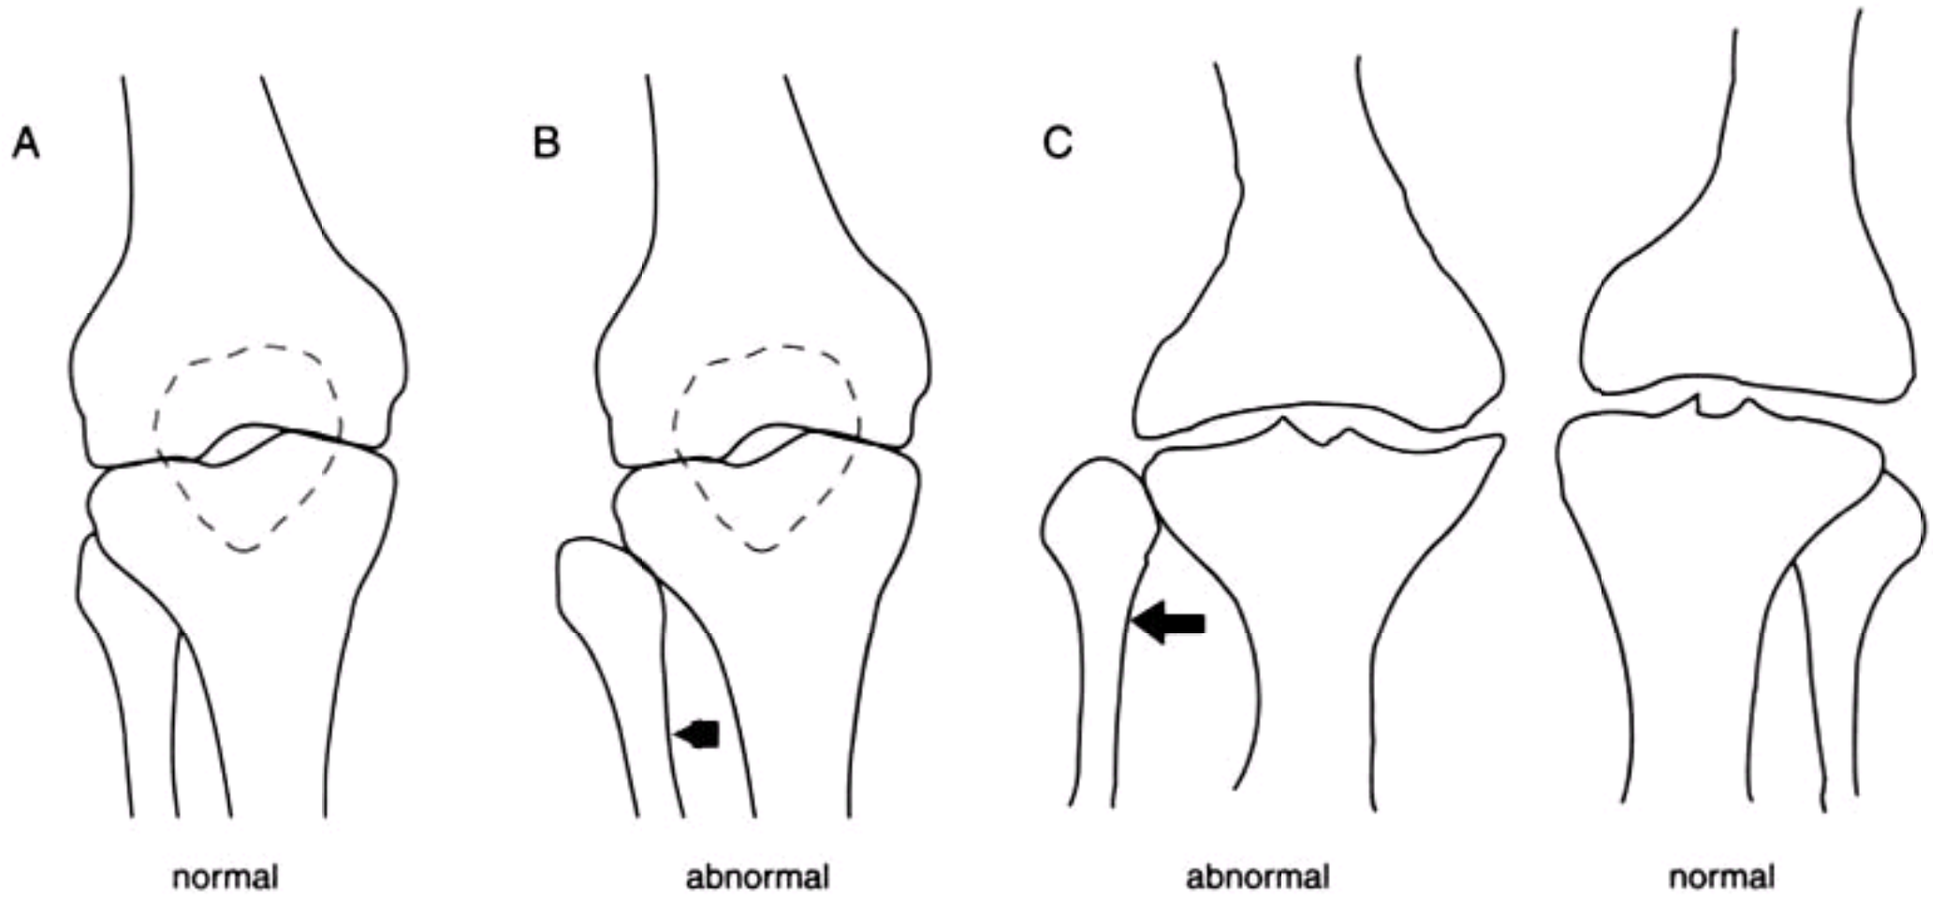

Figure 50-54 Various types of patellar dislocation. The lateral dislocation is the most common.

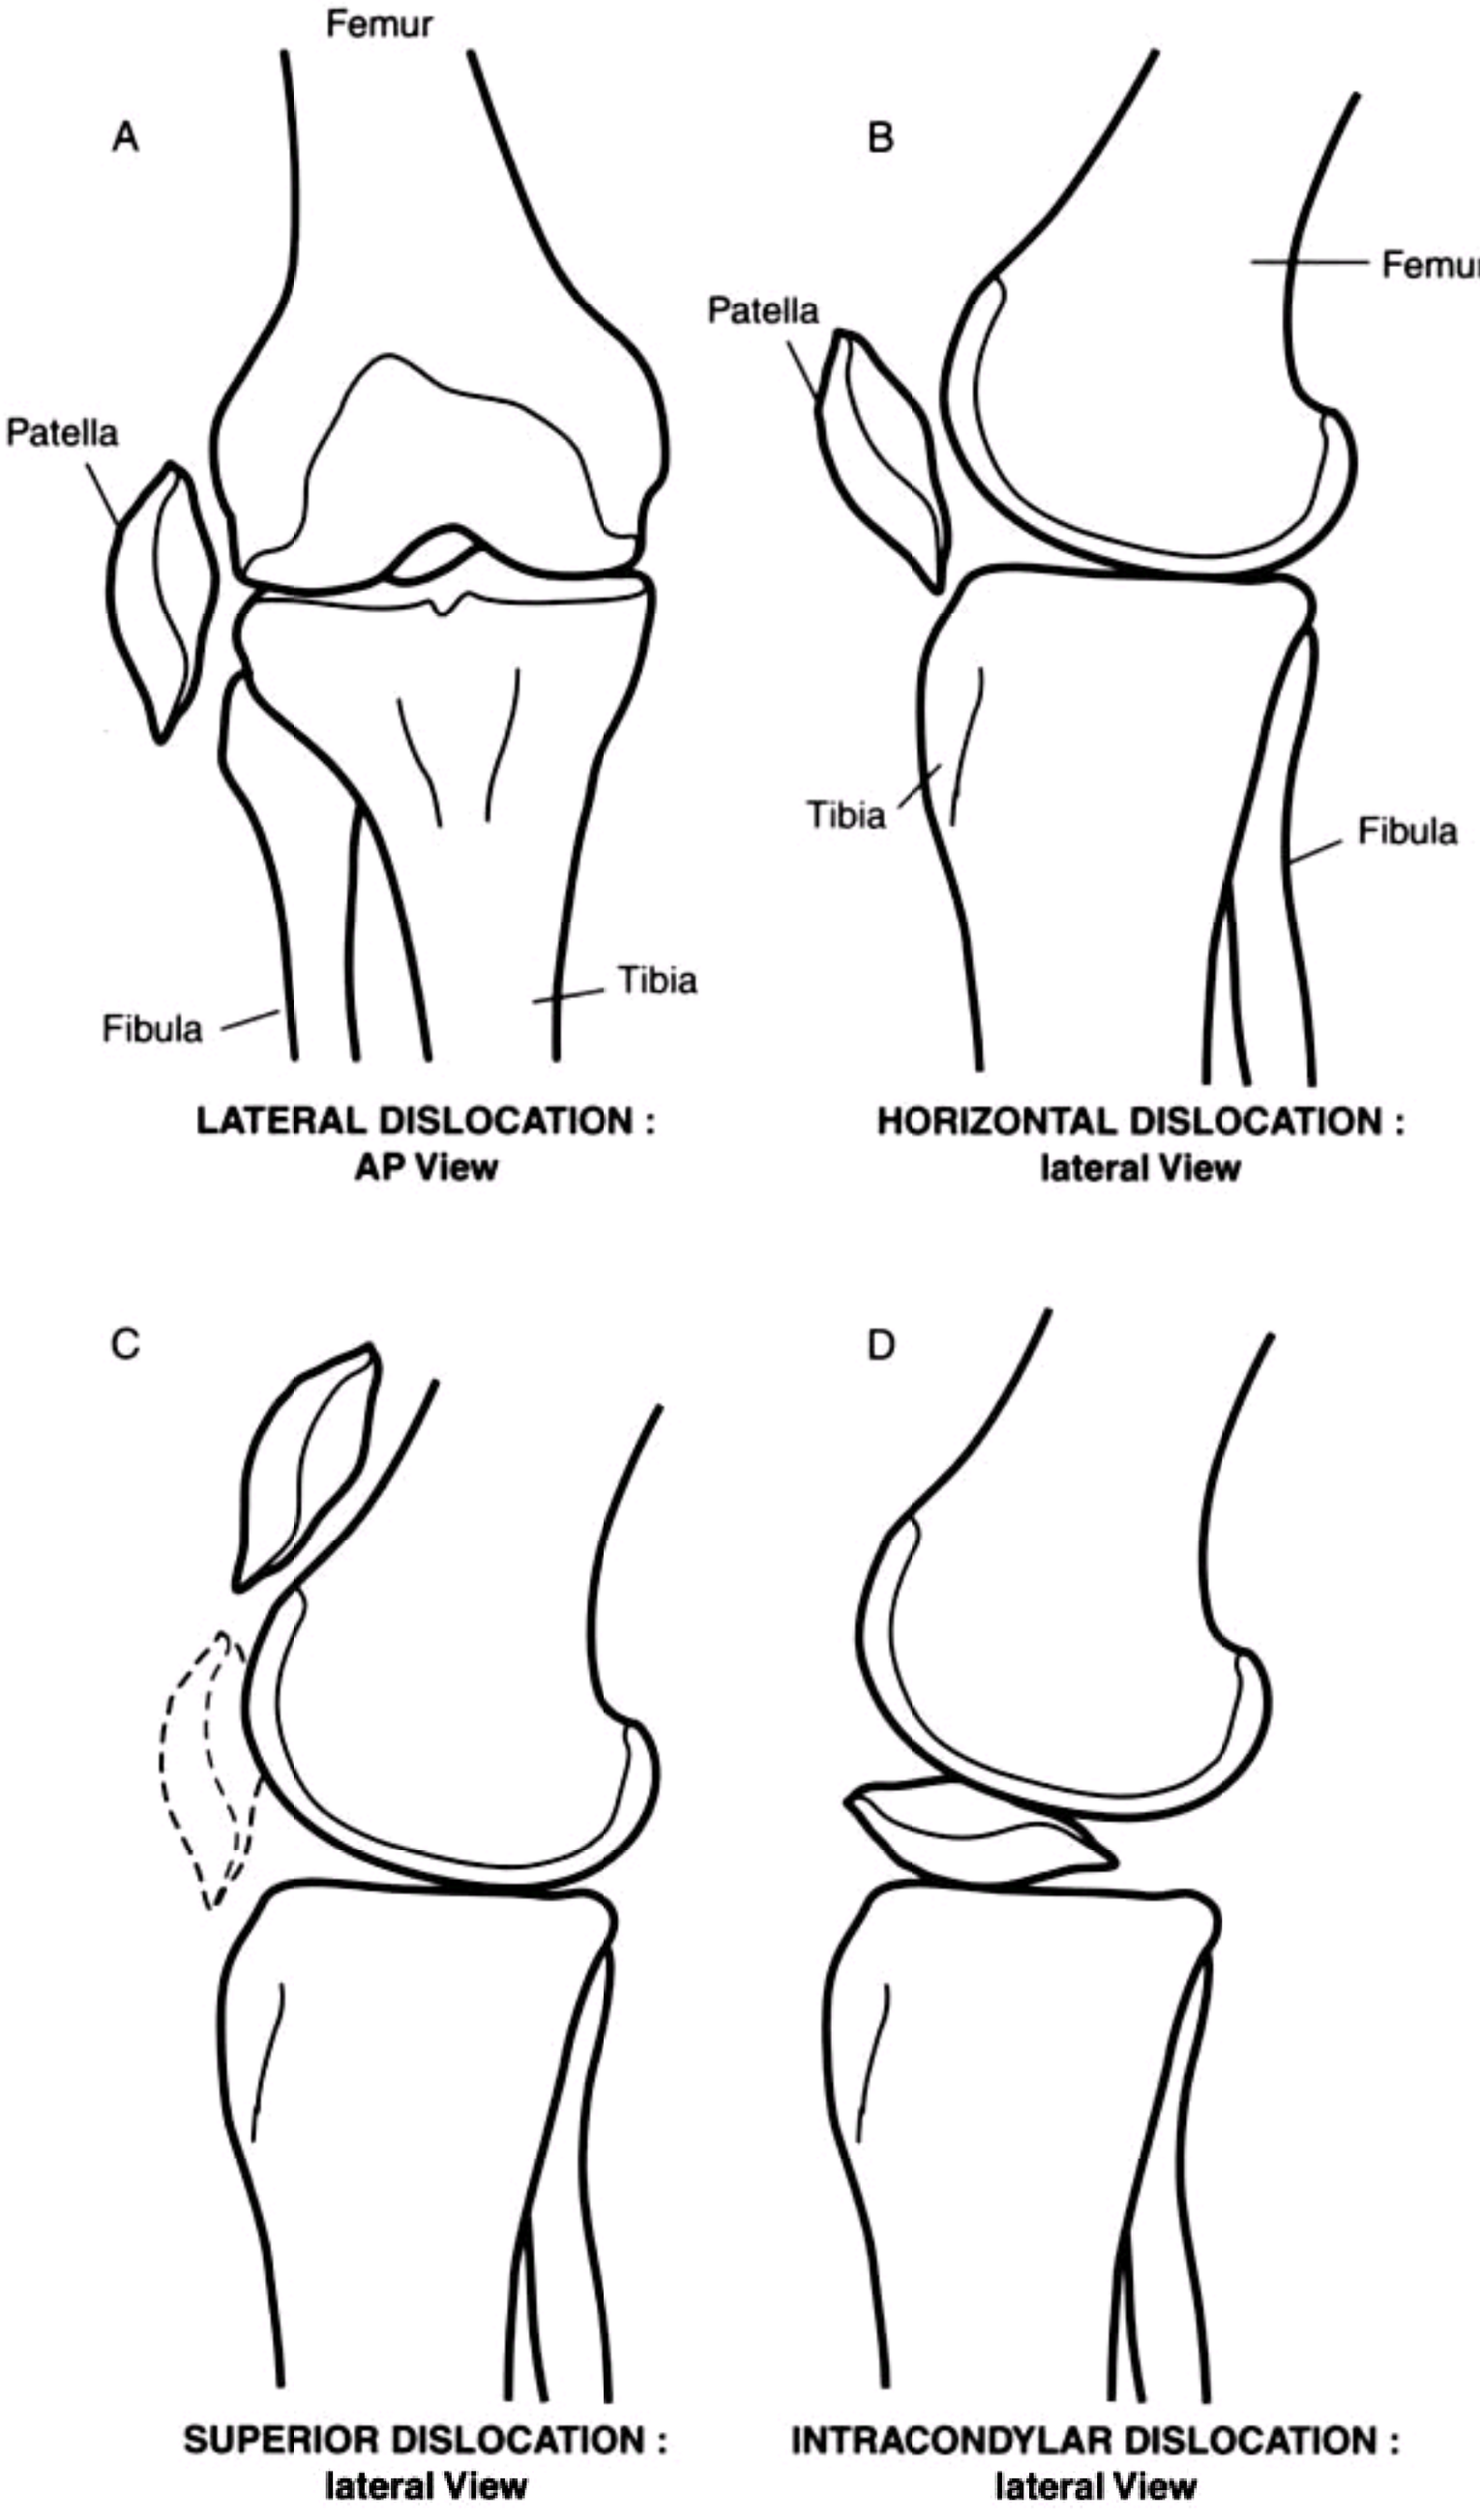

Figure 50-55 *A*, Lateral dislocation of the patella. *B*, To reduce a lateral dislocation, the knee is extended while the patella is directed medially using slight anteriorly directed elevation.

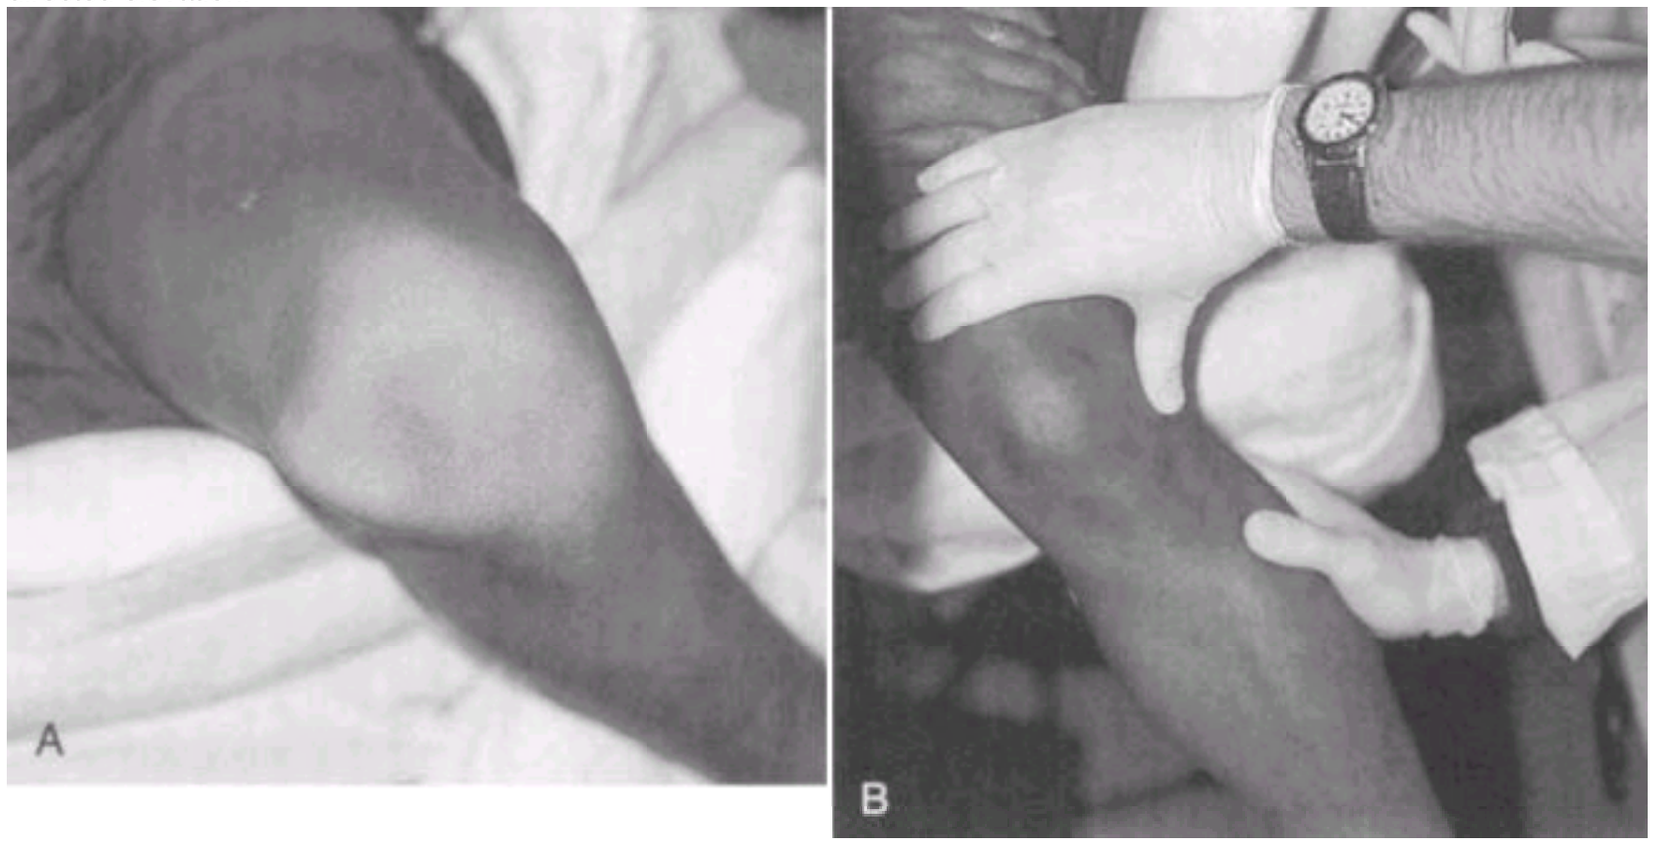

Figure 50-56 Manipulative reduction of a lateral patellar dislocation. Extend the knee gradually (*1*) while applying medially directed pressure on the patella *(2)*, pushing it over the lateral femoral condyle. *(From DePalma AF: Management of Fractures and Dislocations. Philadelphia, WB Saunders, 1970, p 1665. Reproduced by permission.)*

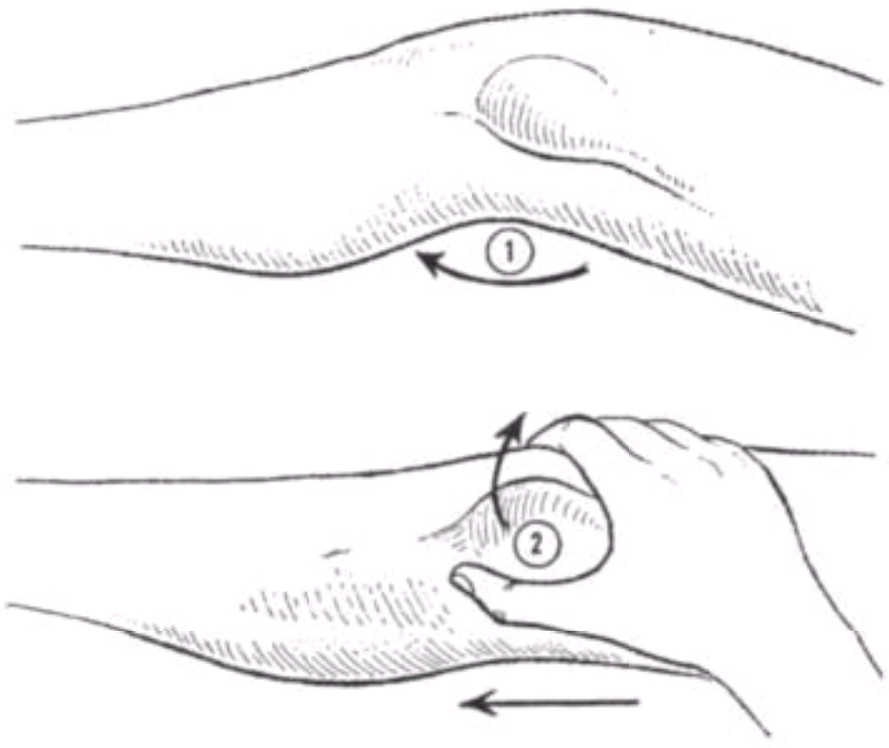

Figure 50-57 The types of dislocations of the ankle. *(From Simon R, Koenigsknecht S: Orthopedics in Emergency Medicine. New York, Appleton-Century-Crofts, 1982, p 419. Reproduced by permission.)*

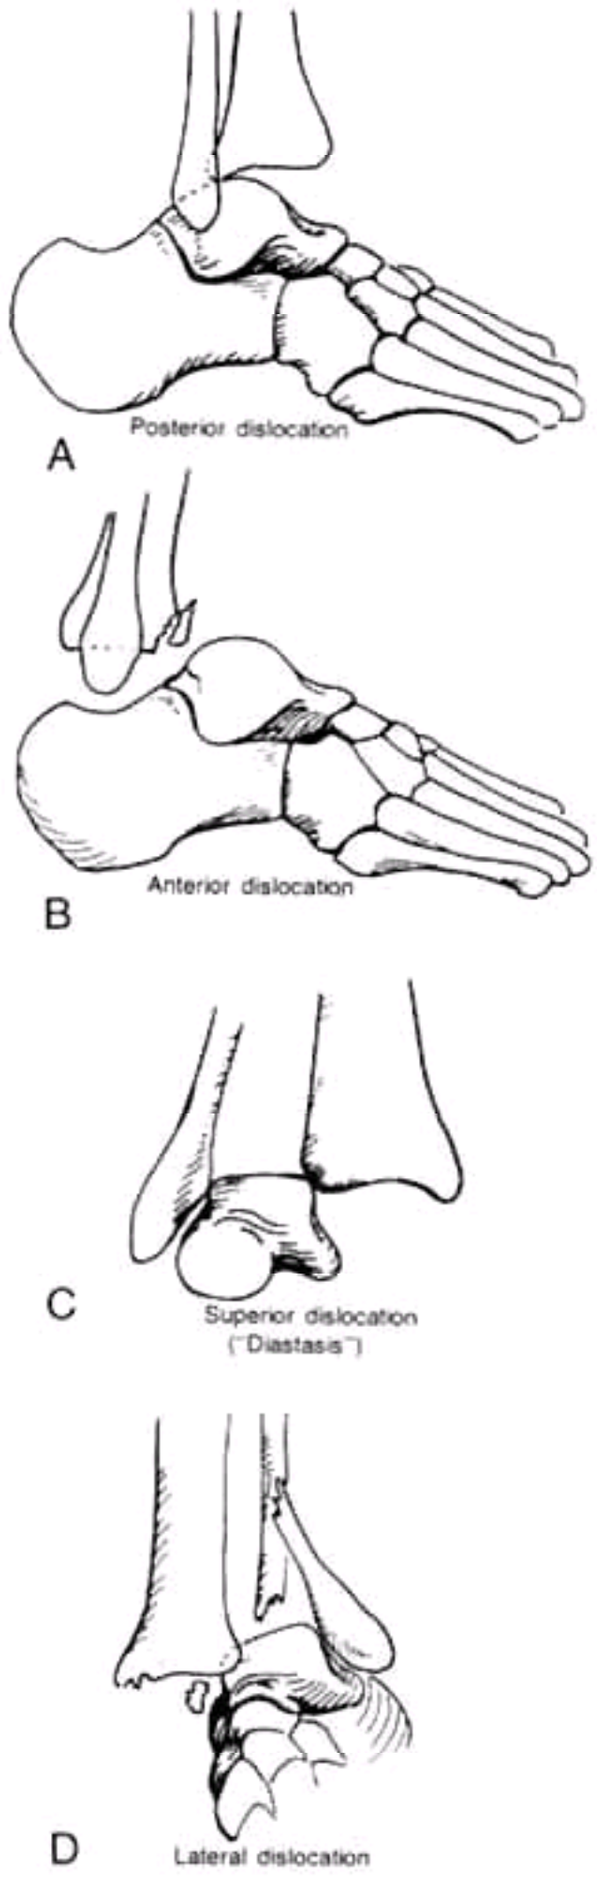

Figure 50-58 Isolated posterior tibial lip fracture *(open arrow),* seen after reduction of posterior ankle dislocation. *(From Harris JH Jr, Harris WH: Radiology of Emergency Medicine, 2nd ed. Baltimore, Williams & Wilkins, 1981, p 629. Reproduced by permission.)*

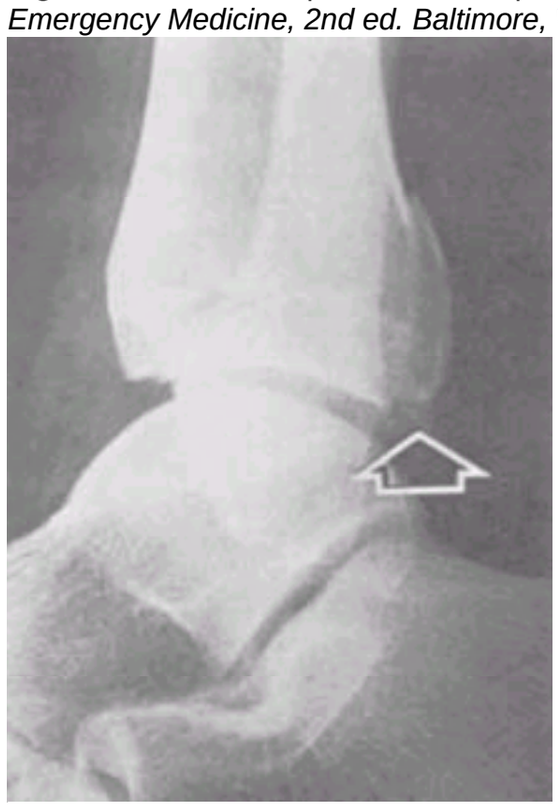

Figure 50-59 Manipulative reduction of a posterior ankle dislocation. *1,* The knee is flexed. *2,* The assistant provides countertraction on the leg. *3,* The forefoot is grasped with one hand and the heel with the other hand. *4,* The foot is slightly plantar flexed. *5,* Apply straight downward traction on the plantar flexed foot, then pull the foot forward *(6)* while a second assistant provides counterpressure on the front of the lower leg *(7)*. *(From DePalma AF: Management of Fractures and Dislocations. Philadelphia, WB Saunders, 1970, pp 1916 and 1917. Reproduced by permission.)*

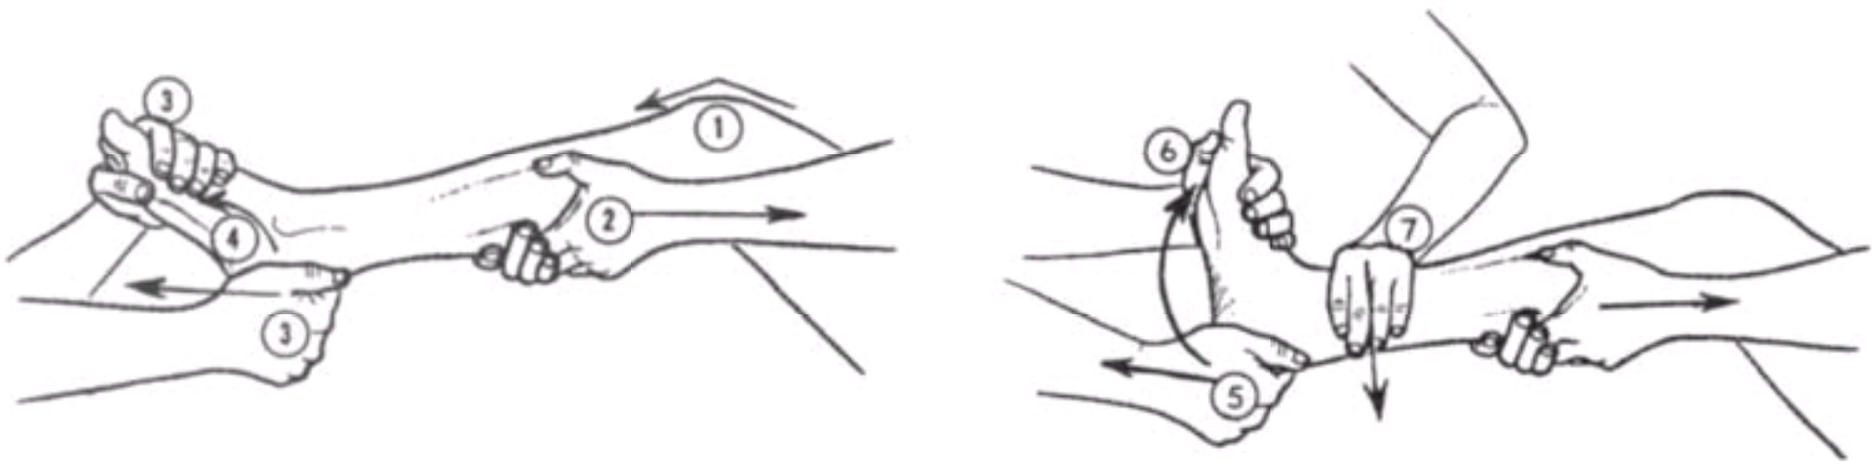

Figure 50-60 Manipulative reduction of anterior ankle dislocation. *1,* The knee is flexed. *2,* The operator grasps the forefoot with one hand and the heel with the other hand. *3,* Dorsiflexion of the foot is slightly increased (to disengage the talus). *4,* An assistant provides countertraction on the leg. *5,* Straight longitudinal traction is applied, then the foot is pushed directly backward *(6)* while a second assistant provides countertraction on the back of the lower leg *(7)*. *(From DePalma AF: Management of Fractures and Dislocations. Philadelphia, WB Saunders, 1970, pp 1918 and 1919. Reproduced by permission.)*

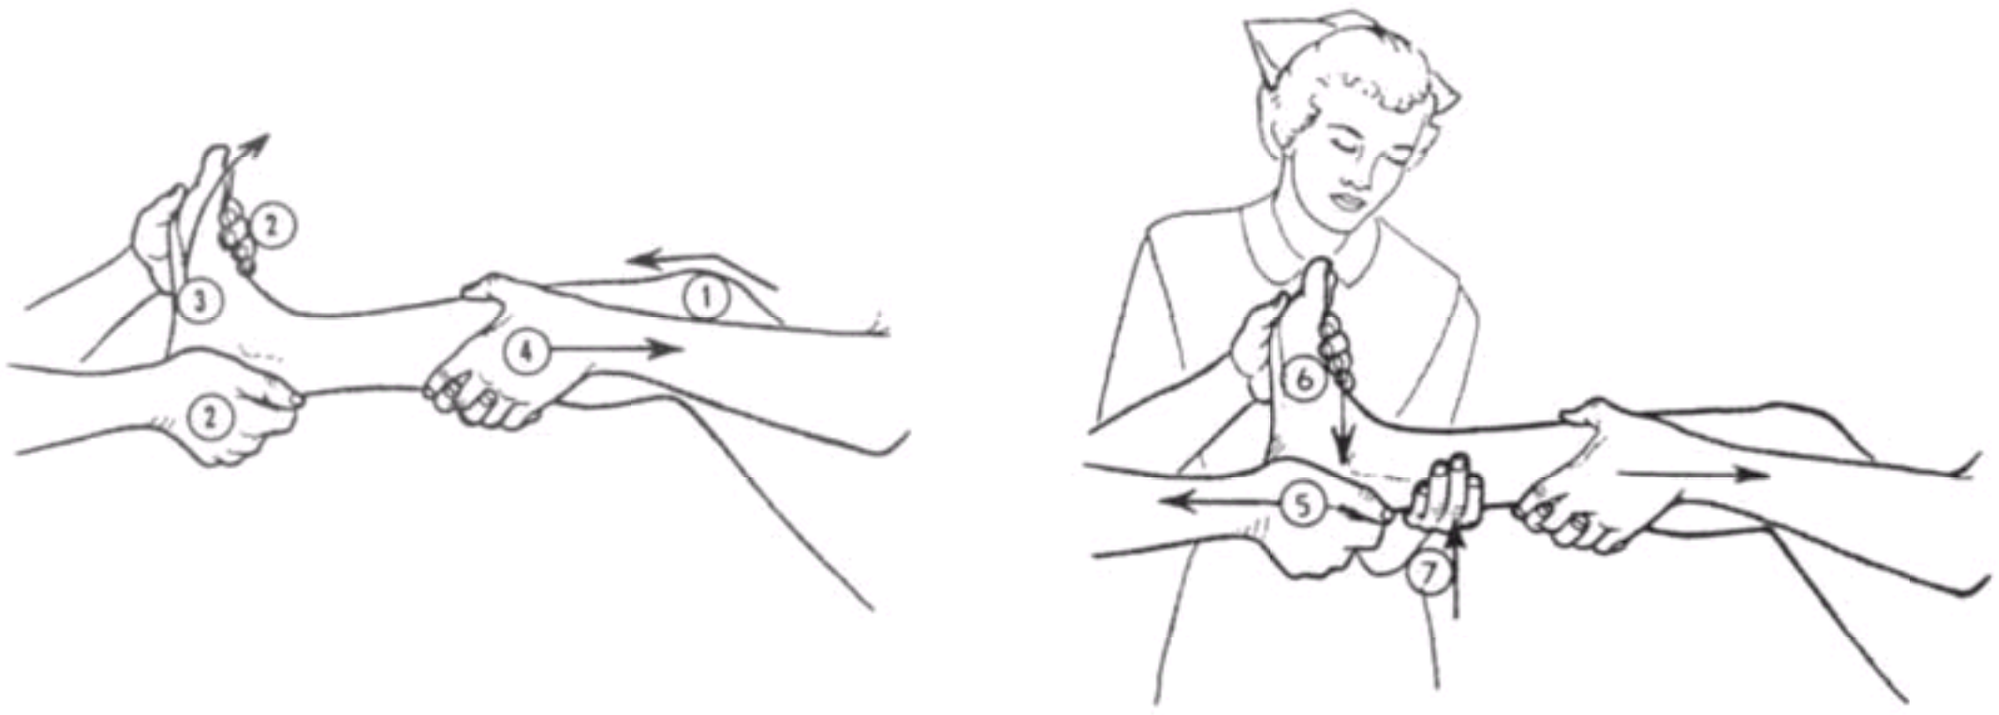

Figure 51-1 Some clinicians prefer to use premade plaster splints for temporary immobilization (e.g., OCL, J-Splint). There is less latitude for custom fitting with these products compared with the technique demonstrated in Figure 51-3 . *A,* Measure the appropriate length. (Note that plain plaster slabs shrink several centimeters when wet. Cut the material slightly long, since the excess may be folded back on itself if necessary). *B,* Submerge the plaster until bubbling stops (do not oversoak). *C,* Roll and squeeze excess water from the premade splint. *Inset,* If using plain plaster slabs, allow the water to drip off. *D,* Smooth the sheets to remove wrinkles and mix the plaster throughout the layers. *E,* Apply the splint and secure it with an elastic bandage. *F,* Mold the splint to fit the contour of the extremity—an important step. *(Courtesy of Johnson & Johnson Products, Inc., New Brunswick, NJ.)*

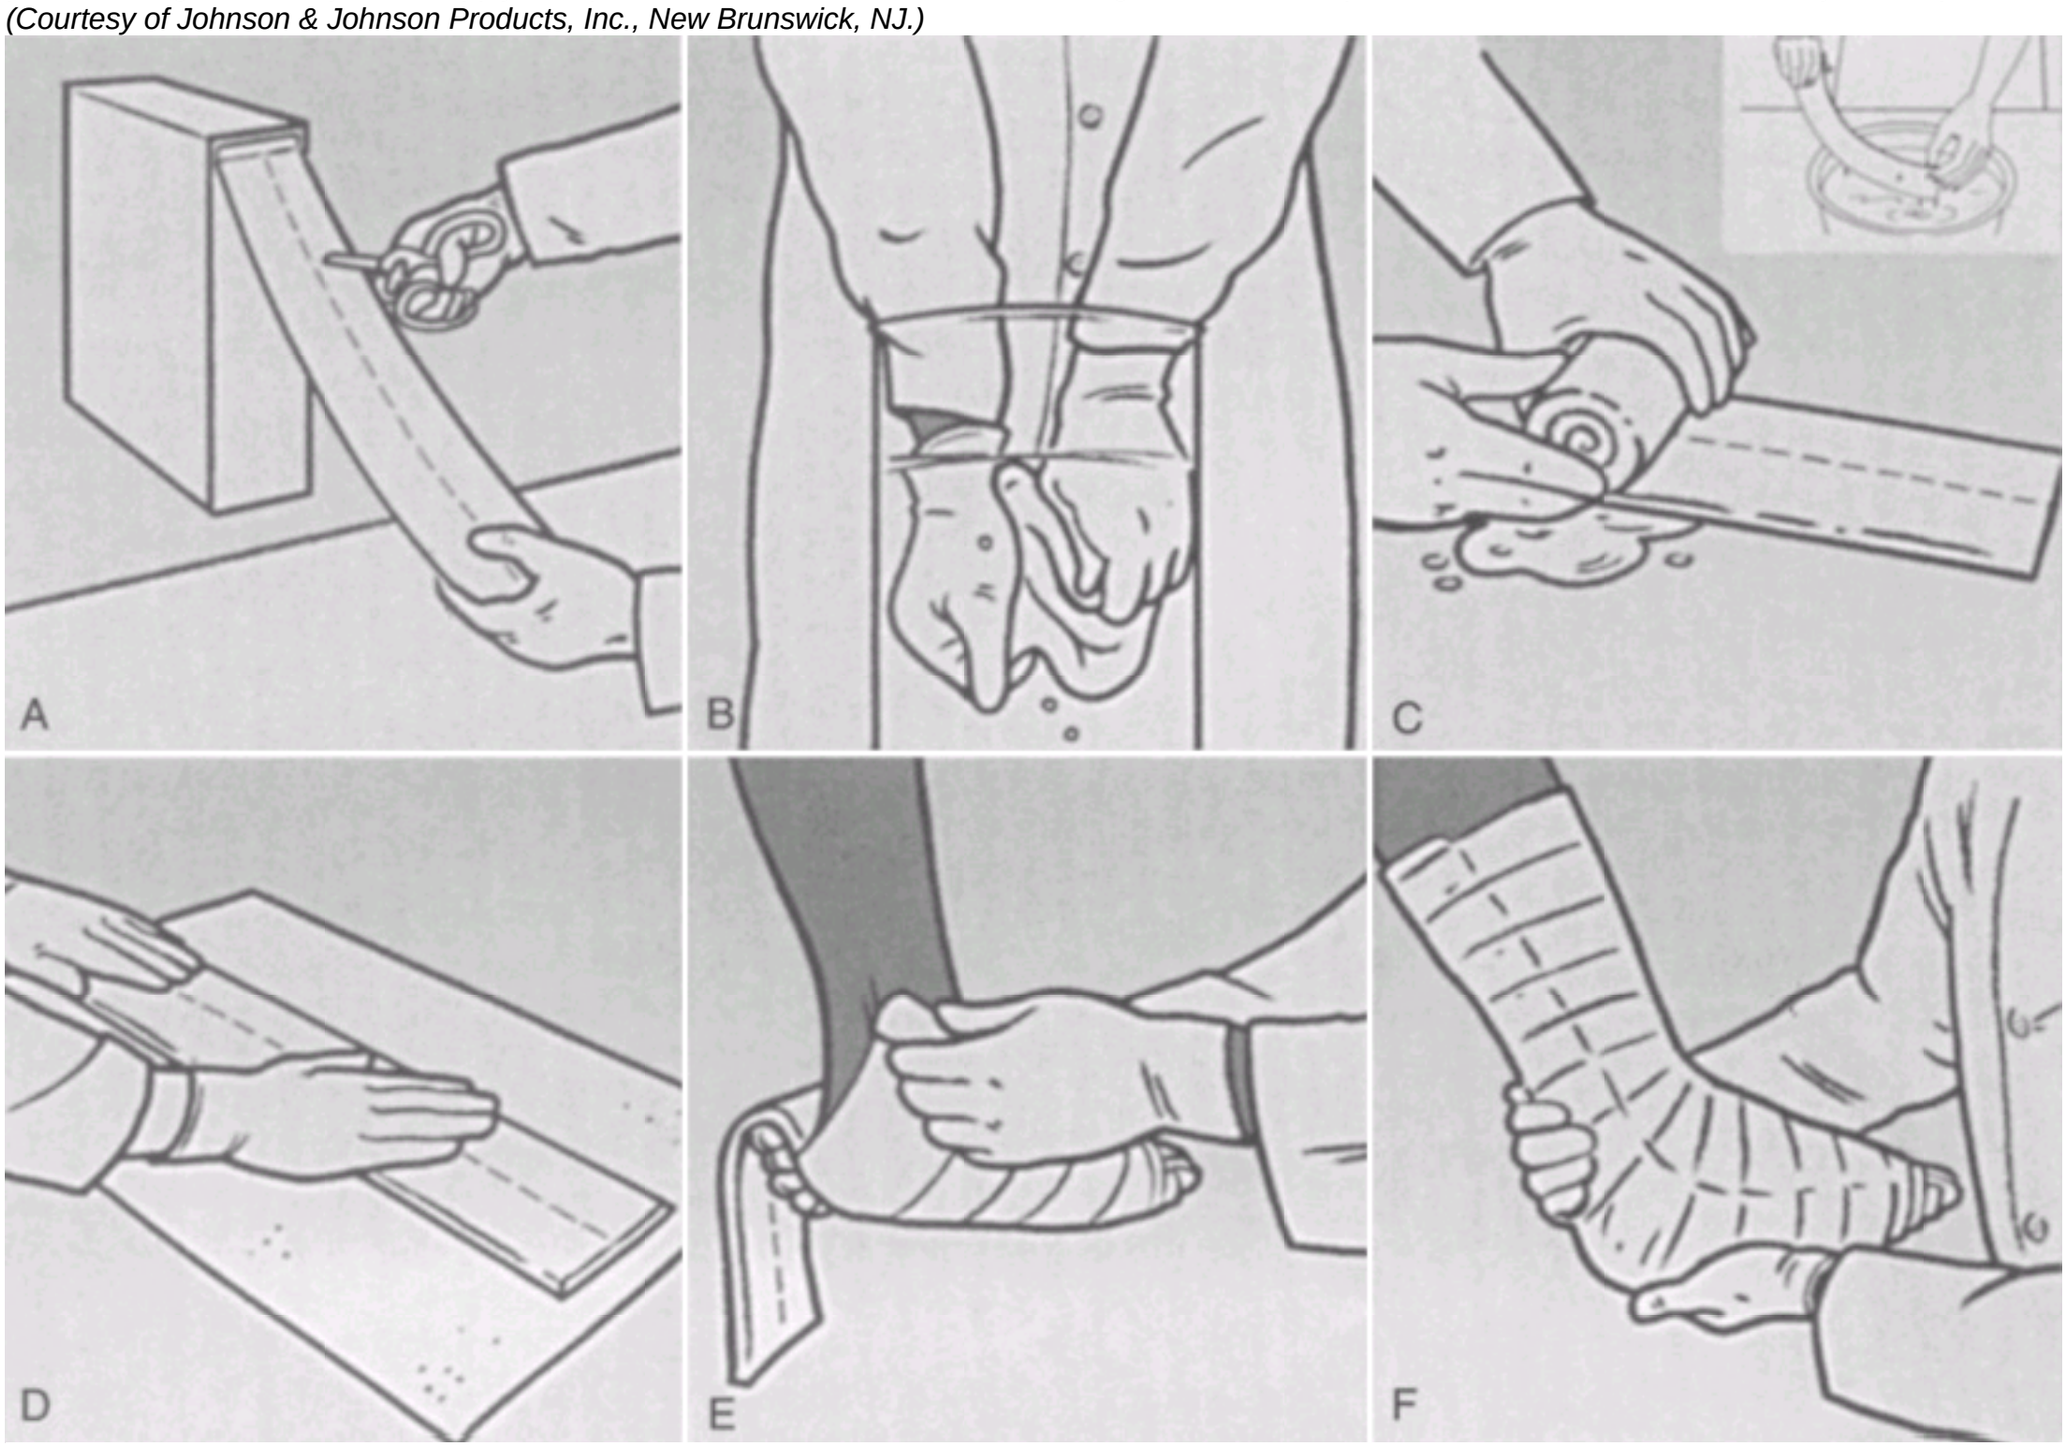

Figure 51-2 Premade fiberglass splints are also popular for temporary immobilization. Fiberglass splints set and cure more rapidly, have no messy residue (i.e., can be hydrated in a conventional sink without a special trap), can be washed and reapplied, and are lighter and stronger than plaster splints. *A*, Open the pouch and cut the splint to the desired length, stretching the padding to cover the exposed edge. Dip into cool water and squeeze three or four times (Note: Prefabricated fiberglass splints that do not contain water-repellant felt are hydrated in a different manner—Always follow the manufacturer's instructions). Remove the splint from the bucket and squeeze to remove any excess water (this allows a curing time of 3 to 4 minutes). *B*, Place the splint on an absorbent towel to remove excess water. *C,* Apply the splint and secure it with an elastic bandage. When applying the splint at a right angle (e.g., posterior ankle splint), pinch and fold over any extra splinting material). *(Adapted, courtesy of 3M Medical Division, 3M Health Care Markets, St. Paul, MN.)*

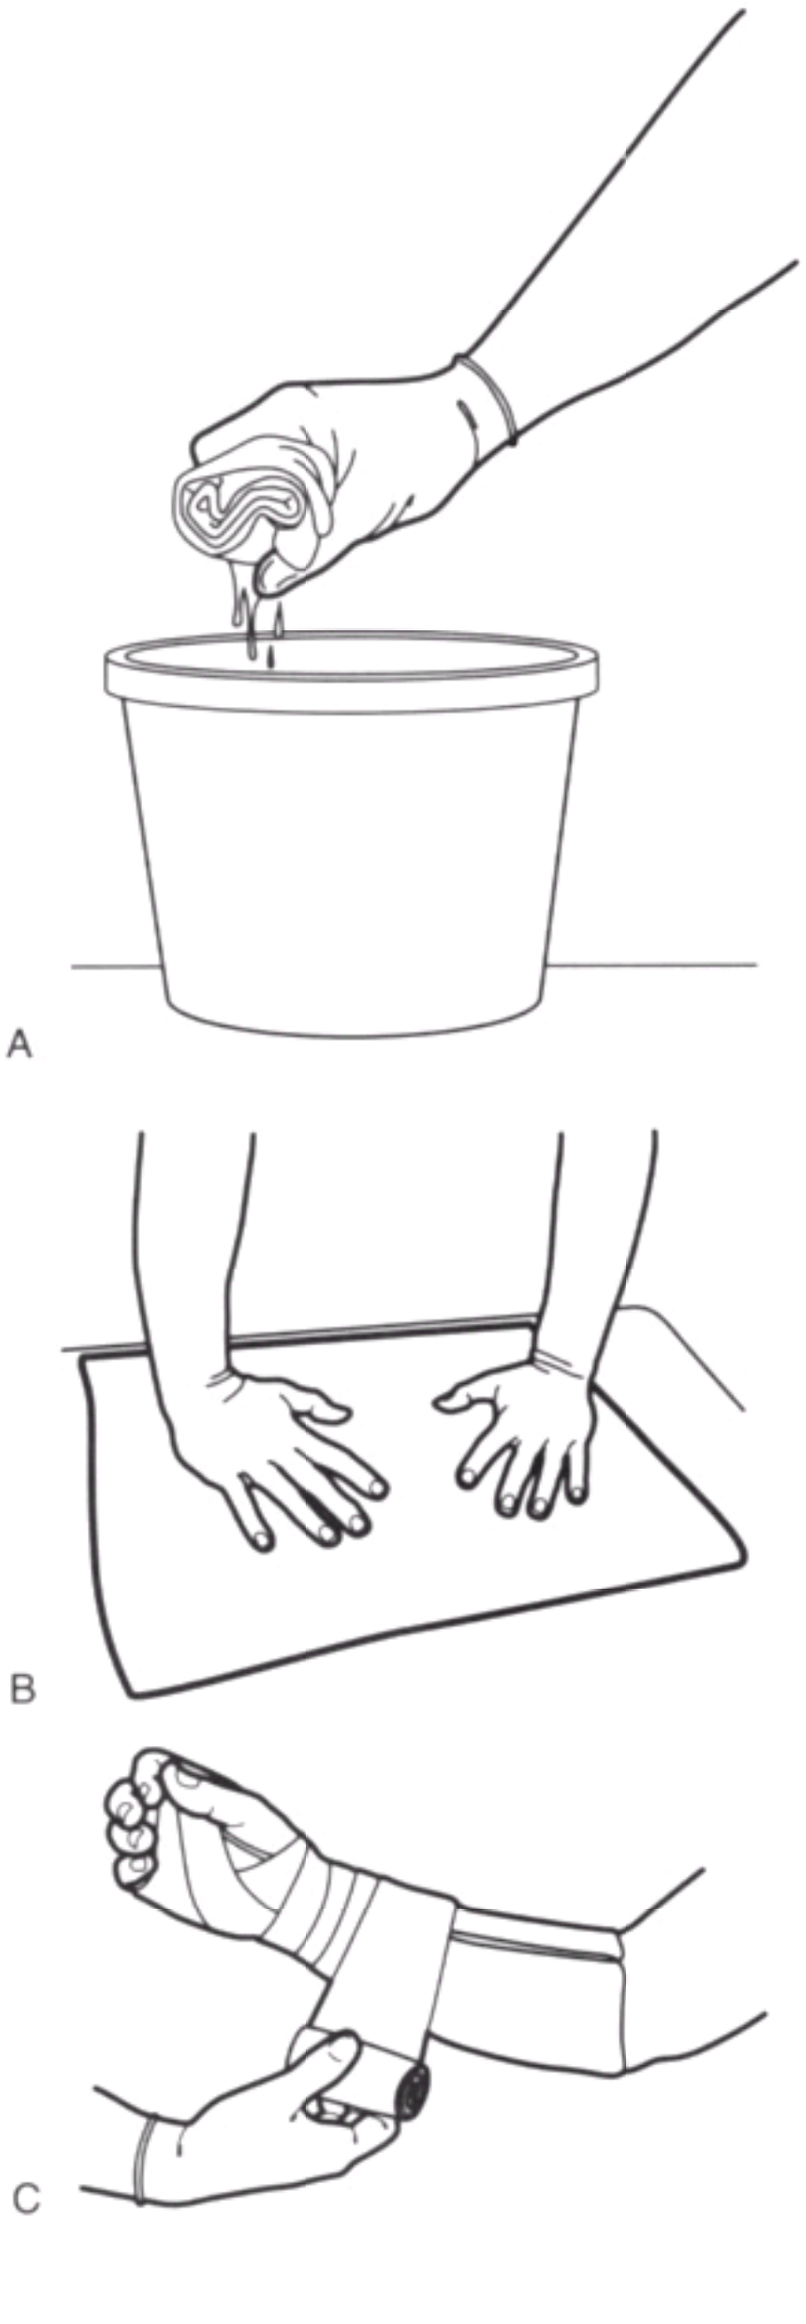

Figure 51-3 Principles of custom splint application. *A*, Stockinette is applied to extend 2 or 3 in beyond the plaster. *B*, Two to three layers of Webril are evenly and smoothly applied over the area to be splinted. *C*, The plaster slab is positioned over the area to be immobilized and the stockinette and Webril are folded back to help secure the slab in place and to form smooth, rounded ends. *D*, The elastic bandage is applied to secure the splint. *E*, While still wet, the plaster is molded to conform to the shape of the extremity. This is an important step that is often overlooked.

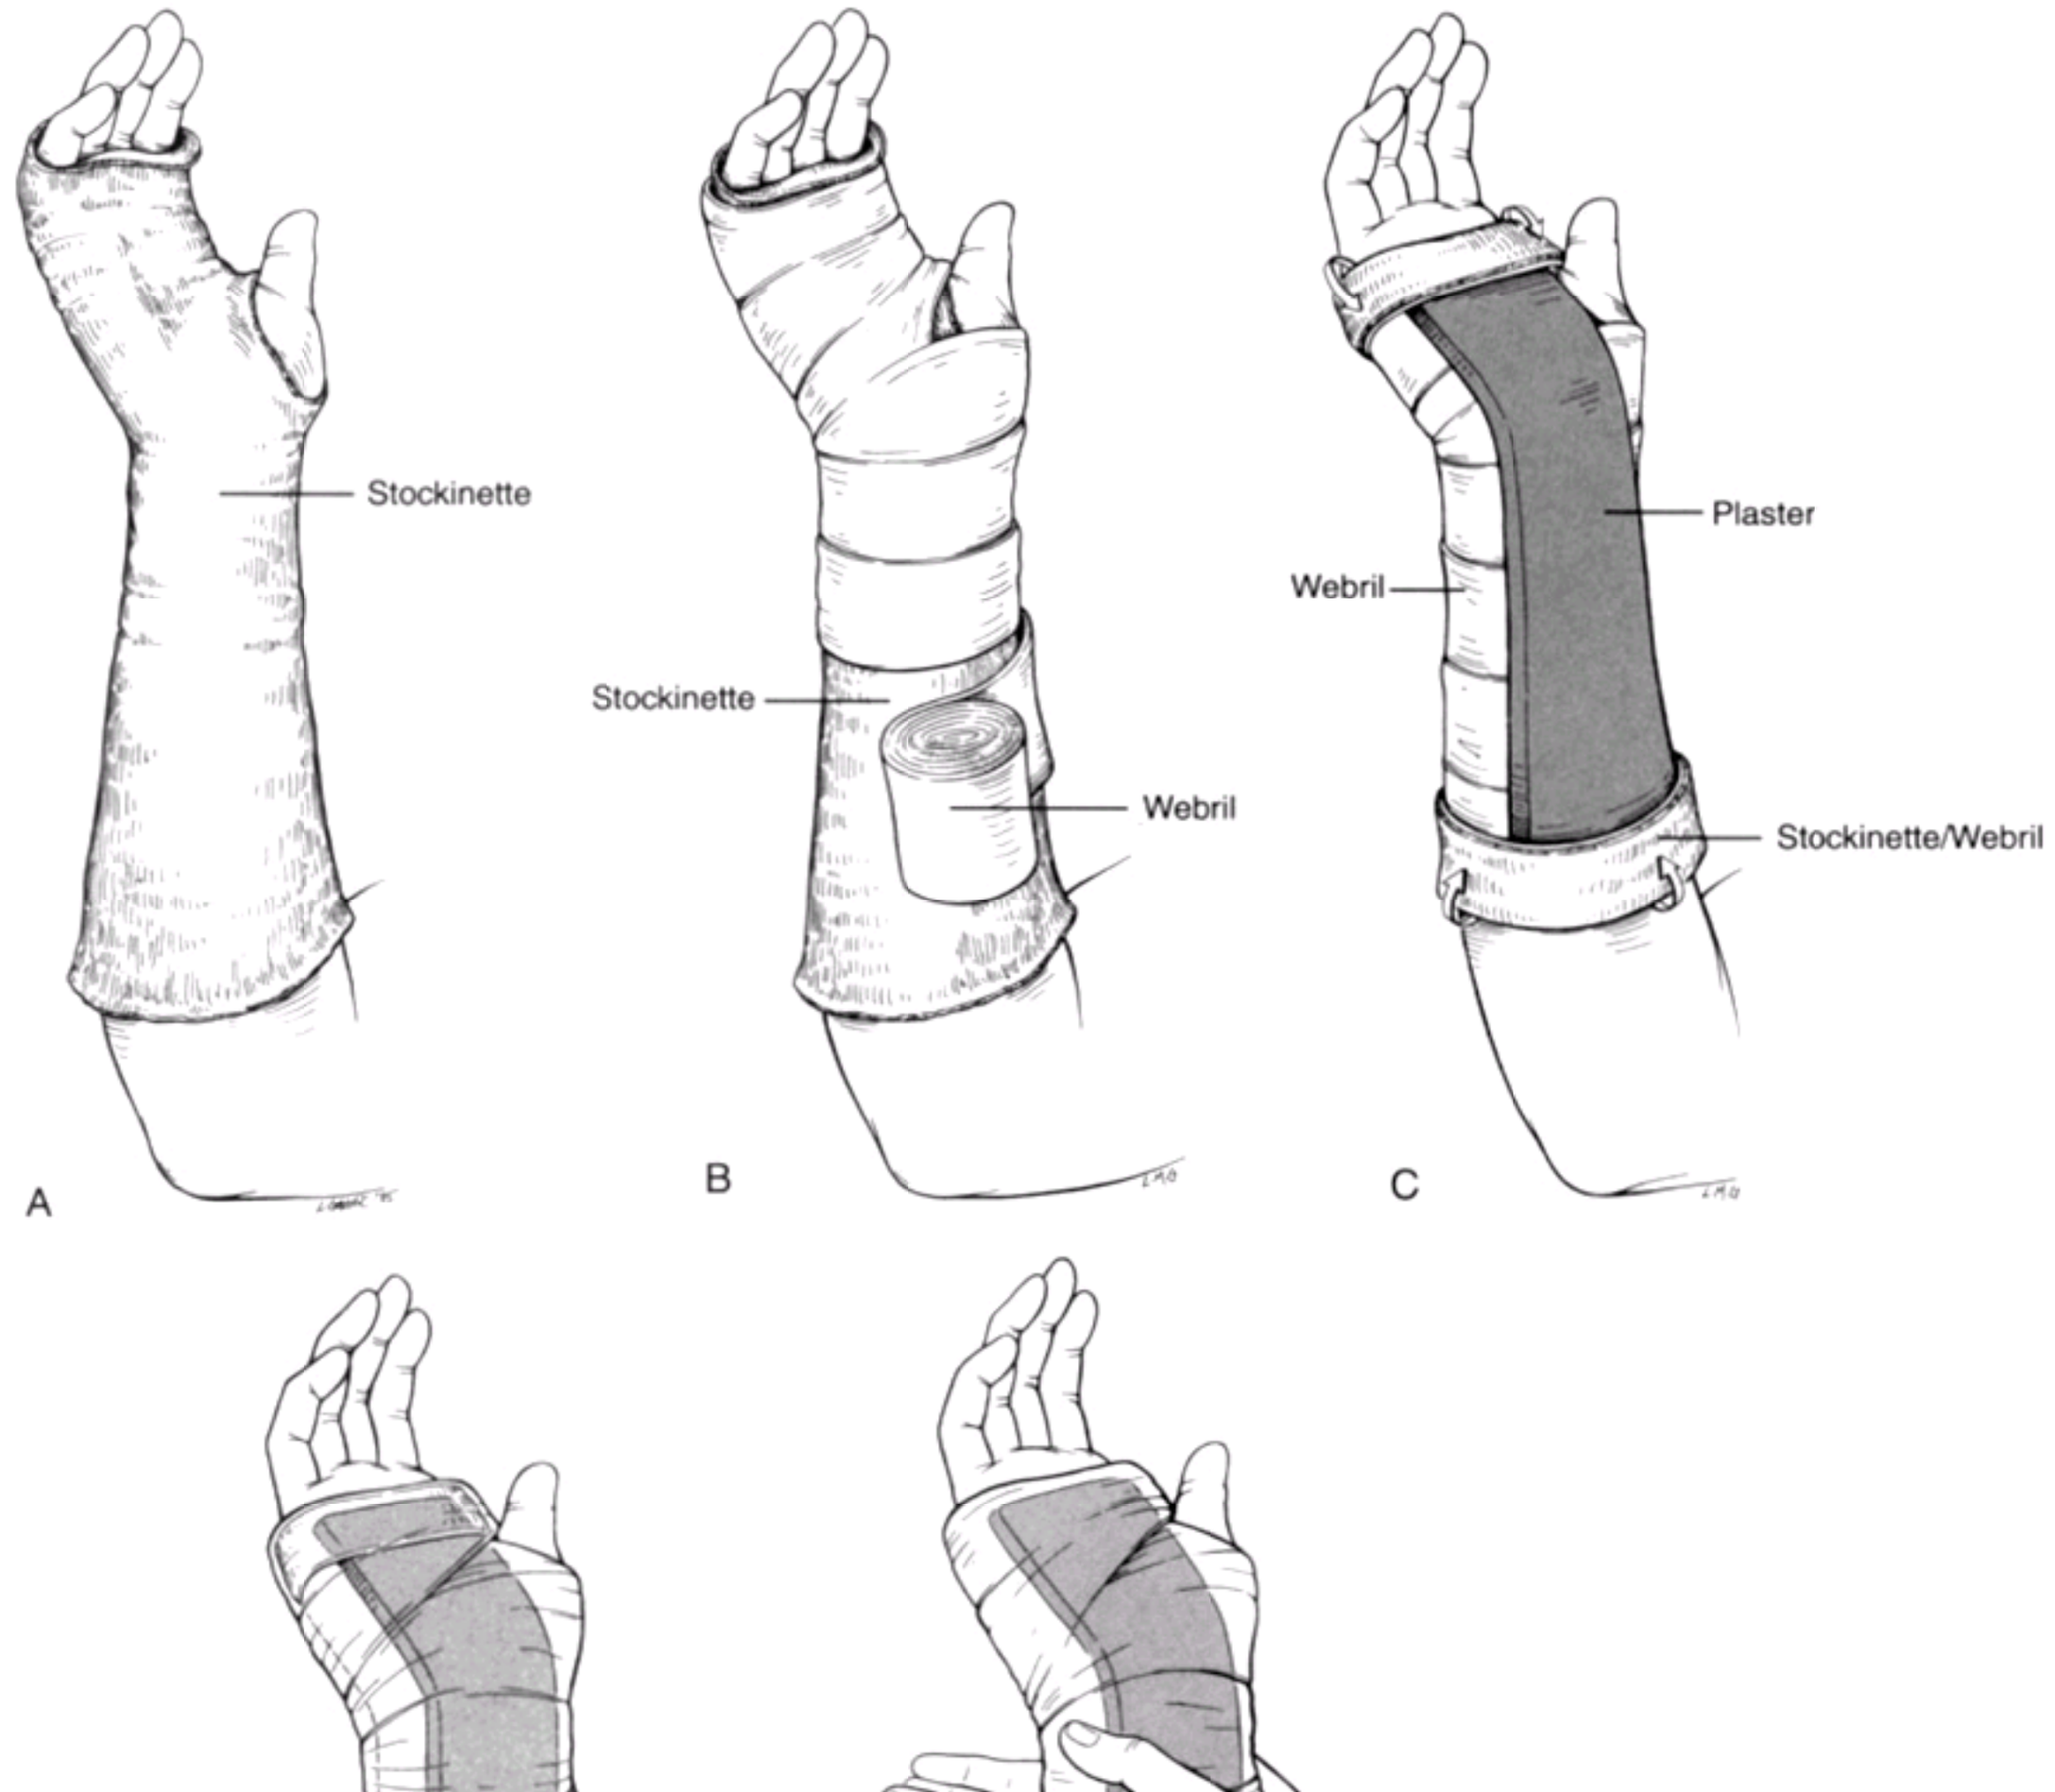

Figure 51-4 Alternative method of Webril application. If significant swelling is anticipated, Webril (the same diameter as the plaster) may be placed directly over the wet plaster, rather than wrapping it around the extremity. The Webril-lined splint is then positioned over the area to be immobilized and secured with an elastic bandage. Sandwiching the plaster strips with Webril will also minimize rigid adherence of the plaster to the elastic wrap.

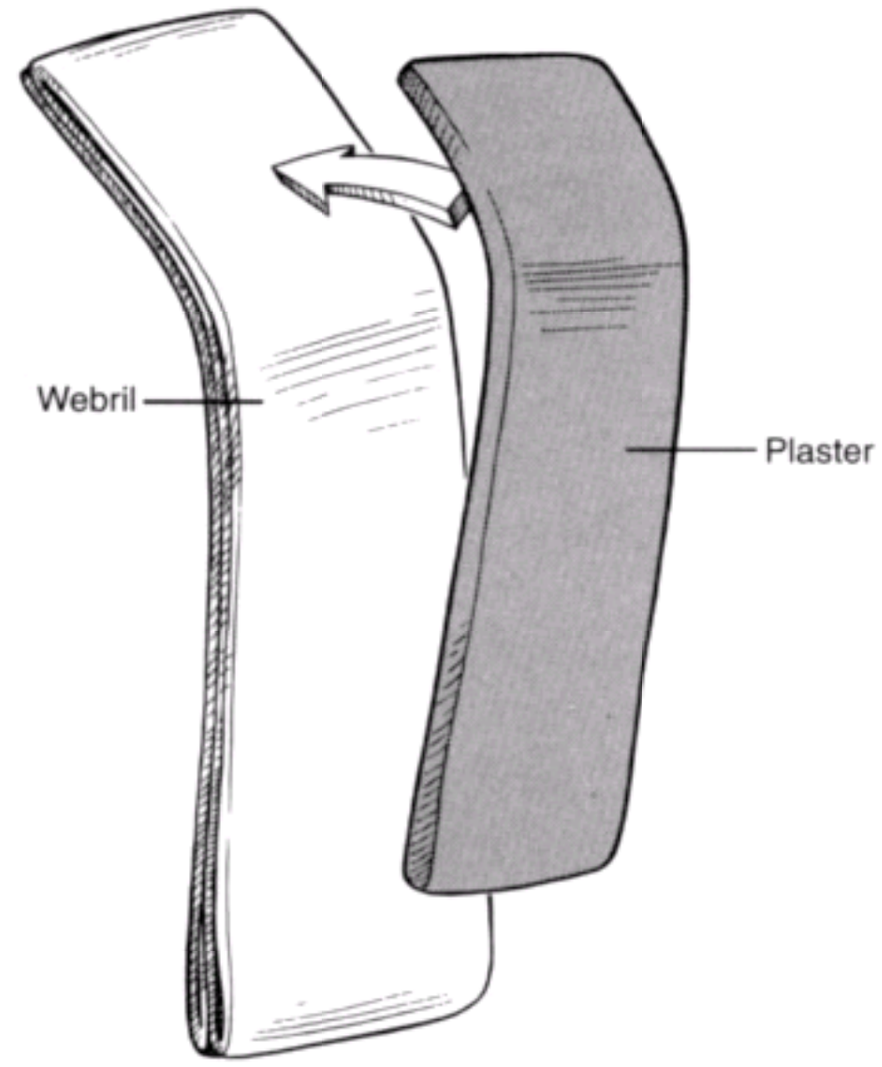

Figure 51-5 Application of a long arm posterior splint. *A*, The posterior portion of the splint begins on the posterior aspect of the proximal humerus. It runs down the arm to the elbow and then continues along the ulnar aspect of the forearm and hand to the distal metacarpals. The elbow is flexed at a 90° angle, the forearm is in the neutral (thumb up) position, and the wrist is in a neutral position or slightly (10°–20°) extended. *B*, Adding an anterior splint. The anterior splint mirrors the posterior splint by running down the anterior aspect of the arm to the antecubital fossa, where it continues along the radial aspect of the forearm and hand to the distal radius. The anterior splint is never used alone, but rather as an adjunct to the long arm posterior splint. It improves immobilization by increasing stability and preventing pronation and supination of the forearm.

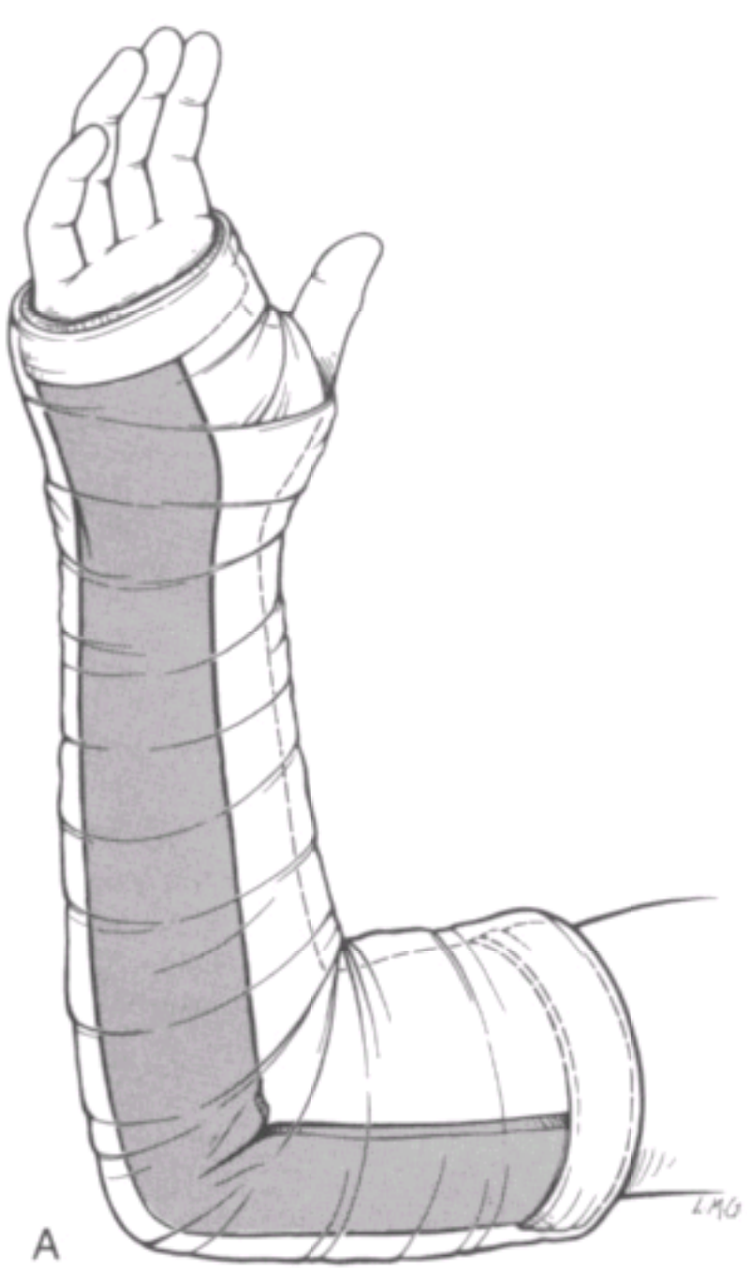

Figure 51-6 An alternative to the long arm posterior splint is a double sugar-tong splint. This splint immobilizes the elbow and prevents pronation and supination of the forearm. The splint consists of two separate pieces of 4-in plaster, a forearm splint, and an arm splint. The elbow is flexed at a 90° angle, the forearm is in the neutral (thumb up) position, and the wrist is in a neutral position or slightly (10°–20°) extended. The forearm portion of the splint is applied first. It runs from the metacarpal heads on the dorsum of the hand, along the dorsal surface of the forearm, and around the elbow. It continues along the volar surface of the forearm, stopping at the level of the metacarpophalangeal joints. The arm portion of this splint begins on the anterior aspect of the proximal arm. It runs down the arm over the forearm splint and around the elbow. It then continues up the posterior aspect of the arm, once again going over the forearm splint until it reaches the starting point. The fingers and thumb should remain free to avoid stiffness.

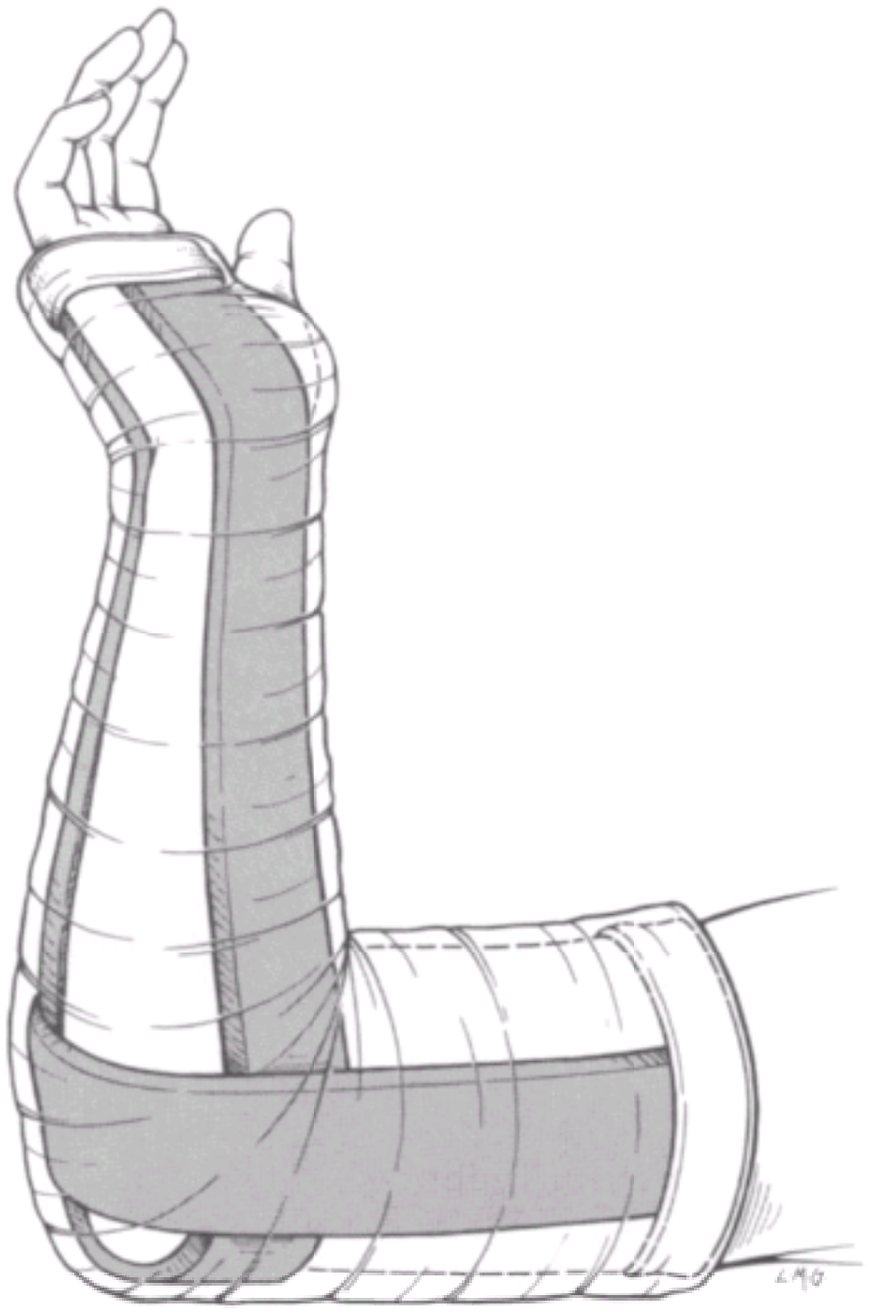

Figure 51-7 Application of a volar splint. *A*, The splint begins in the palm at the metacarpal heads and extends along the volar surface of the forearm to a point just proximal to the elbow. If any of the fingers are injured, the splint may be extended to incorporate the involved digits. The forearm is placed in the neutral position (thumb upward) with the wrist slightly (10°–20°) extended. Wrist flexion should be avoided. *B*, For more serious injuries, an additional dorsal slab may be used to create a bivalve splint.

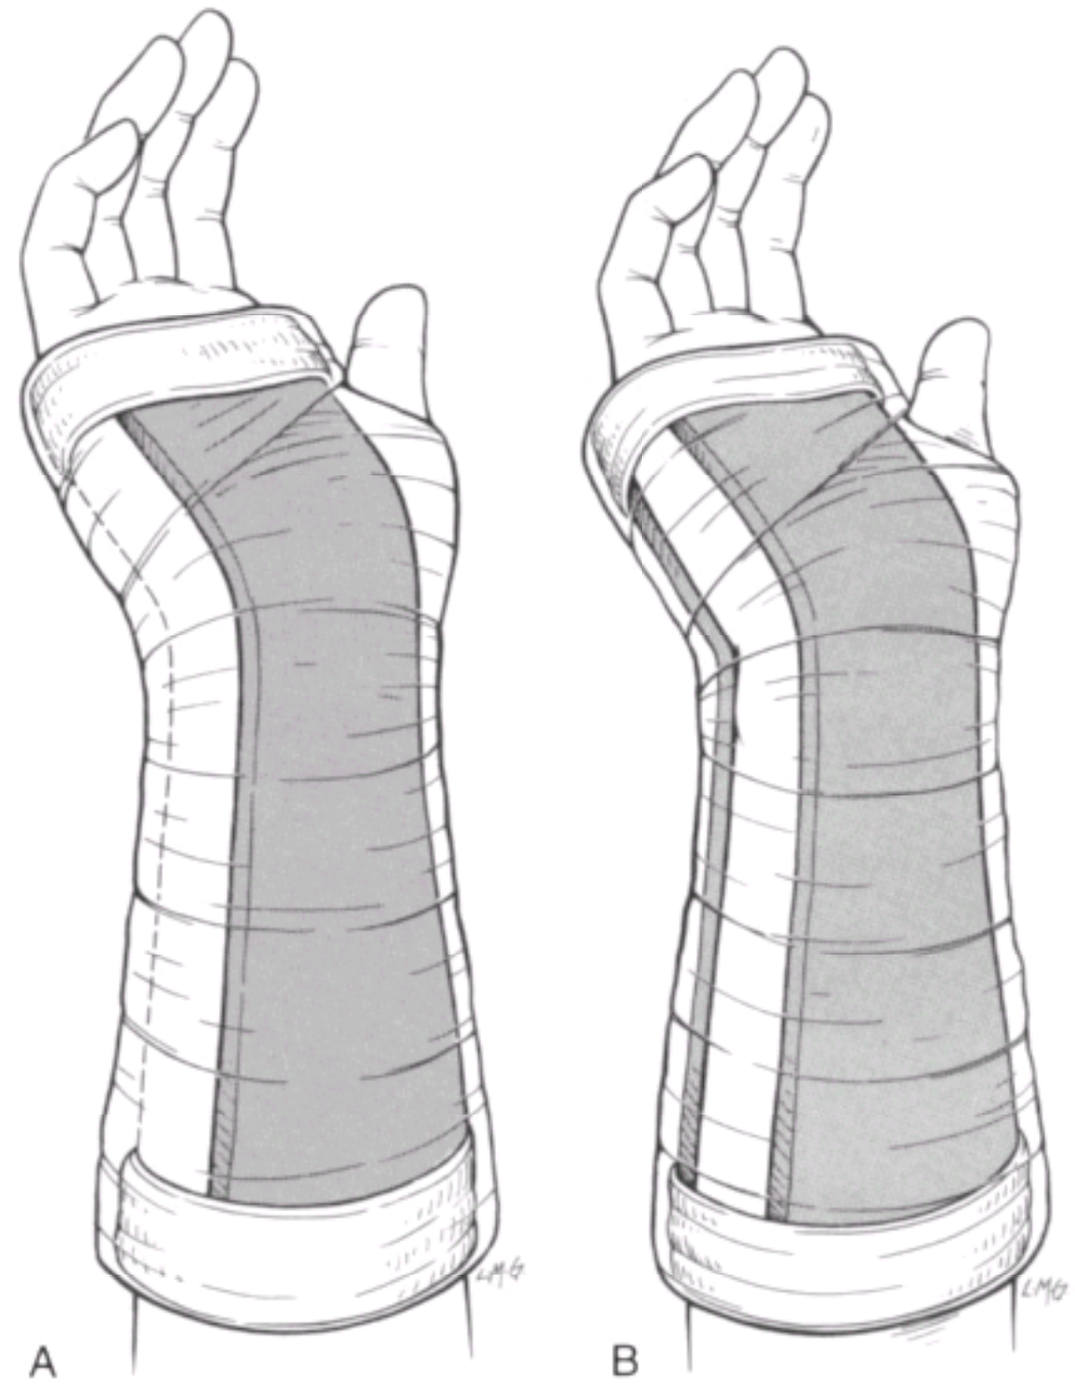

Figure 51-8 Application of a forearm sugar-tong splint. The splint runs from the metacarpal heads on the dorsum of the hand, along the dorsal surface of the forearm, and around the elbow. It continues along the volar surface of the forearm stopping at the level of the metacarpophalangeal joints. The elbow is flexed at a 90° angle, the forearm is in the neutral (thumb up) position, and the wrist is in a neutral position or slightly (10°–20°) extended. The advantage of this splint over the volar splint is immobilization of the elbow and prevention of pronation and supination of the forearm.

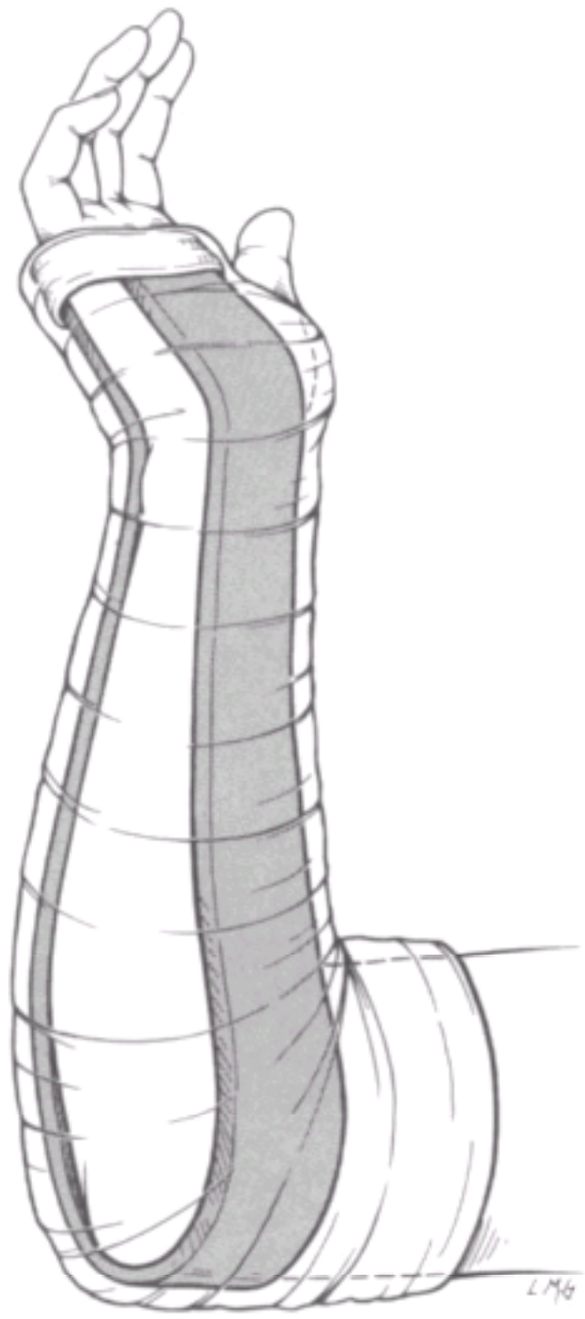

Figure 51-9 Application of a thumb spica splint. The splint extends from just distal to the interphalangeal joint of the thumb to the mid-forearm. The forearm is placed in the neutral position with the wrist extended 25° and the thumb in the wine glass position (see Fig. 51-10). *Inset, A* small (1- to 2-cm) perpendicular cut is made 1 cm distal to the first metacarpophalangeal joint on each edge of the plaster to allow molding of the splint around the thumb without creating a buckle in the plaster.

Figure 51-10 The wine glass position, which is a safe splint position for the hand. The wrist should allow alignment of the thumb with the forearm, the metacarpophalangeal joint should be moderately flexed, and the interphalangeal joints should be only slightly flexed. The thumb should be abducted away from the palm.

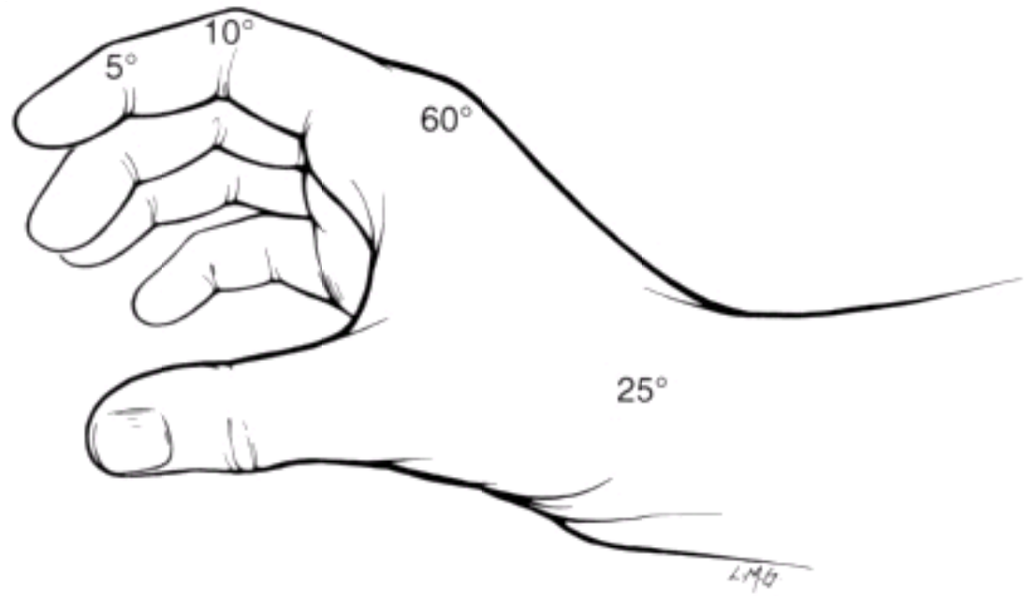

Figure 51-11 Application of an ulnar gutter splint. The ulnar gutter splint incorporates both the little and ring fingers. Webril or gauze should be placed between the digits to prevent maceration of the skin. The splint runs along the ulnar aspect of the forearm from just beyond the distal interphalangeal joint of the little finger to the mid-forearm. The forearm is in the neutral position with the wrist in slight extension (10°–20°), the metacarpophalangeal joint in 50° of flexion, and the proximal and distal interphalangeal joint in slight (10°–15°) flexion. When immobilizing a metacarpal neck fracture, the metacarpophalangeal joint should be flexed to 90°.

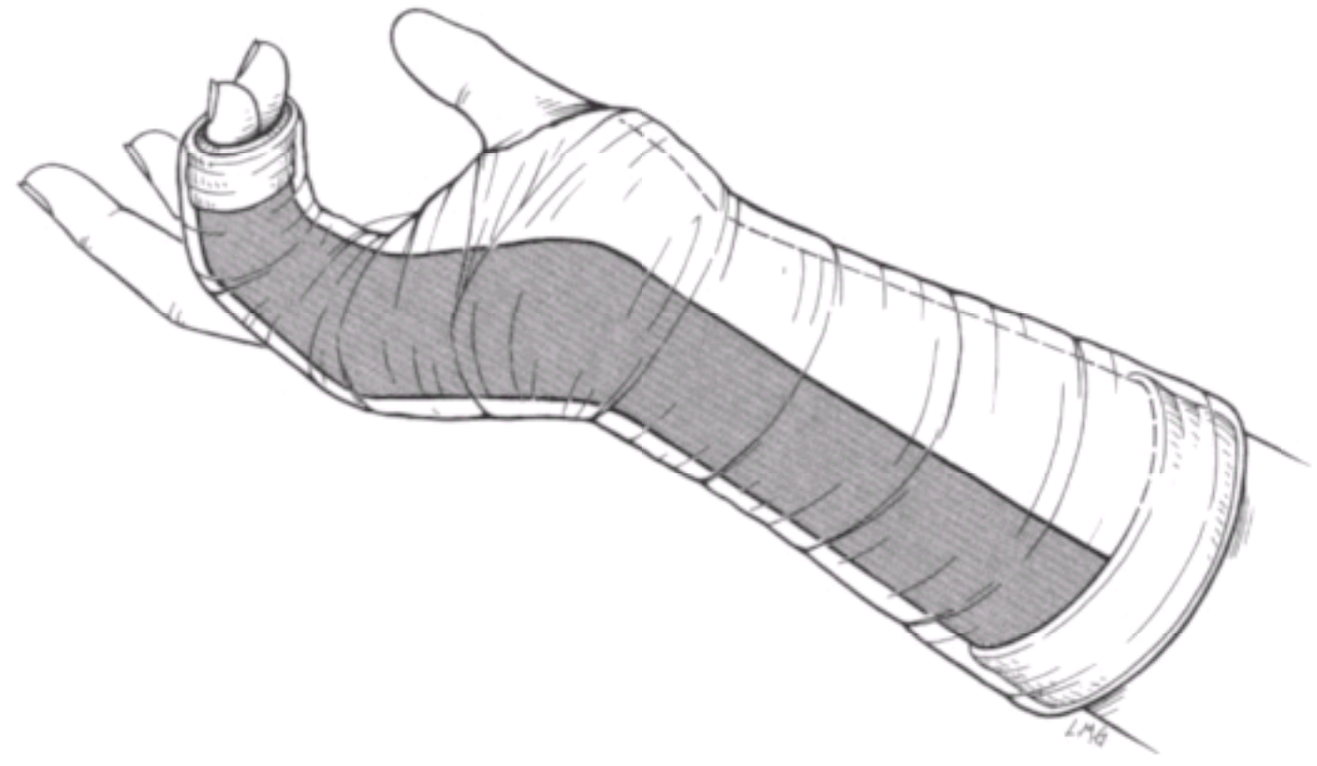

Figure 51-12 Application of a radial gutter splint. The radial gutter splint incorporates both the index and long fingers. Webril or gauze should be placed between the digits to prevent maceration of the skin. The splint runs along the radial aspect of the forearm from just beyond the distal interphalangeal joint of the index finger to the mid-forearm. The forearm is in the neutral position with the wrist in slight extension (10°–20°), the metacarpophalangeal joint in 50° of flexion, and the proximal and distal interphalangeal joint in slight (10°–15°) flexion. When immobilizing a metacarpal neck fracture, the metacarpophalangeal joint should be flexed to 90°.

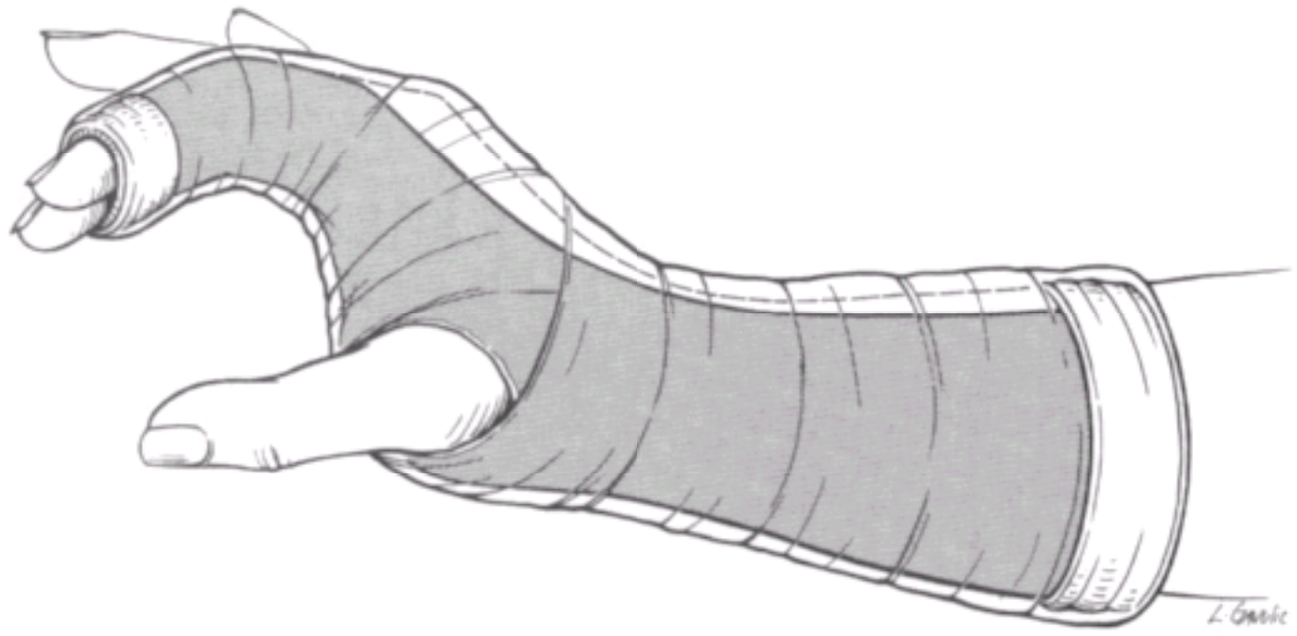

Figure 51-13 "Buddy tape" technique. Taping between the digital joints allows the normal adjacent finger to protect the collateral ligament of its injured neighbor. Webril should be placed between the digits to prevent maceration of the skin.

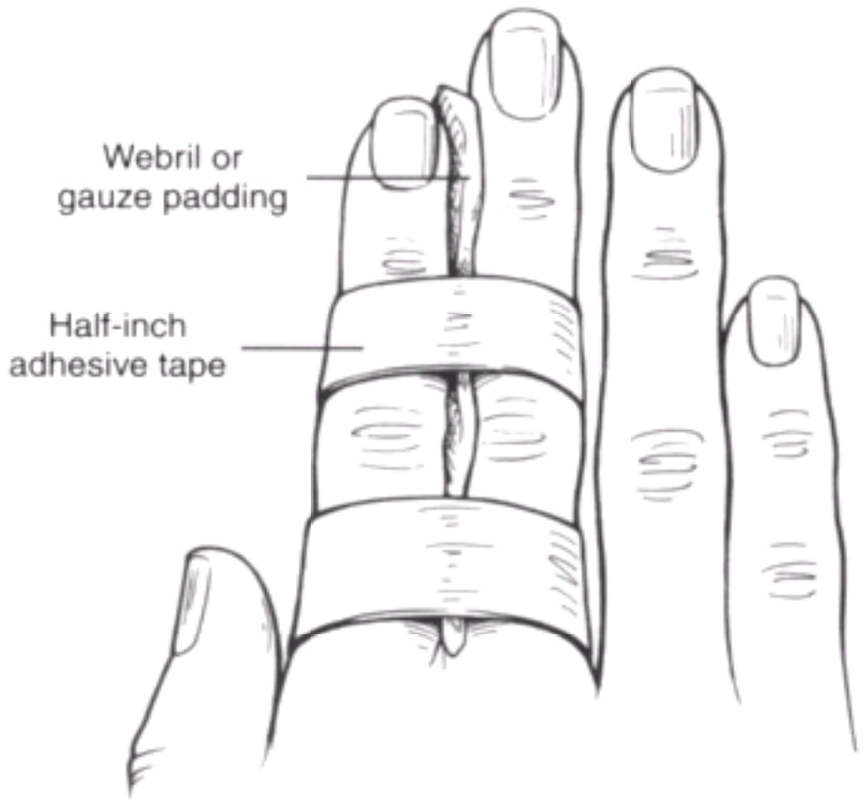

Figure 51-14 Dorsal aluminum foam splint. The bone is subcutaneous dorsally, and splints here afford better immobilization of the digit. The dorsal splint also allows preservation and use of tactile sense, which encourages function and better splint acceptance on the part of the patient.

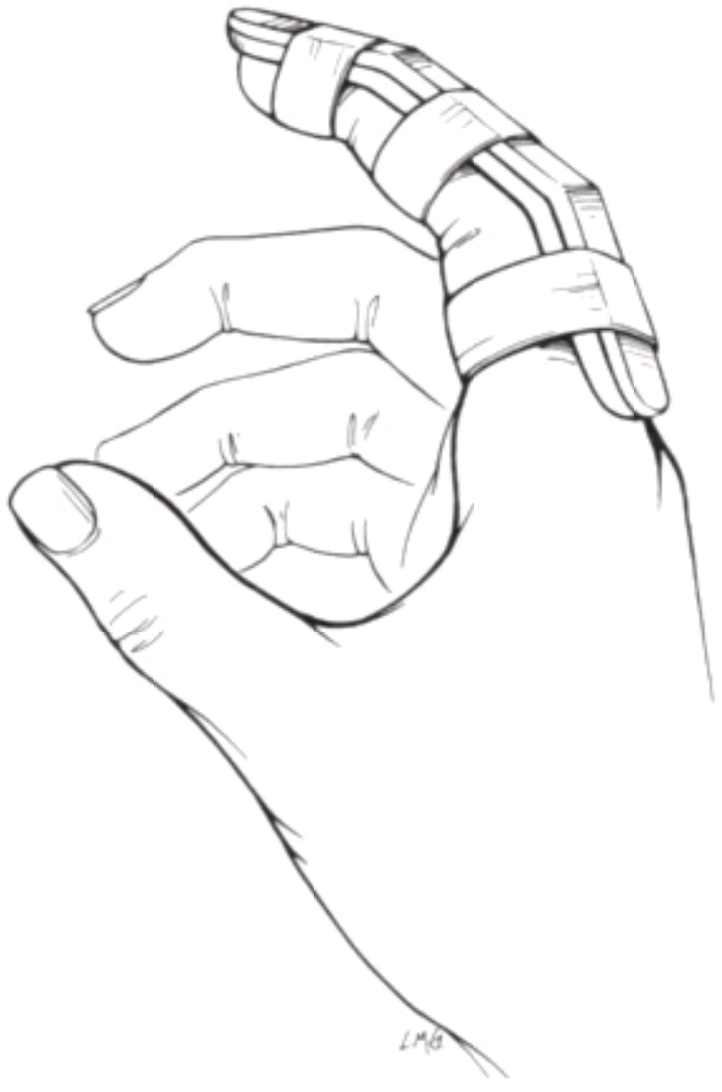

Figure 51-15 Splinting a mallet finger. The dorsal splint immobilizes only the distal interphalangeal joint. This allows use of the finger. Hyperextension of this joint predisposes to skin sloughing and should be avoided. The patient should be advised not to flex the joint during splint changes.

Figure 51-16 "Outrigger" finger splint for complete immobilization of the finger. A padded aluminum splint is incorporated into the middle of a plaster splint, forming an outrigger configuration. The plaster splint is applied to the dorsum of the hand and wrist with an elastic bandage; the finger is then taped to the aluminum splint.

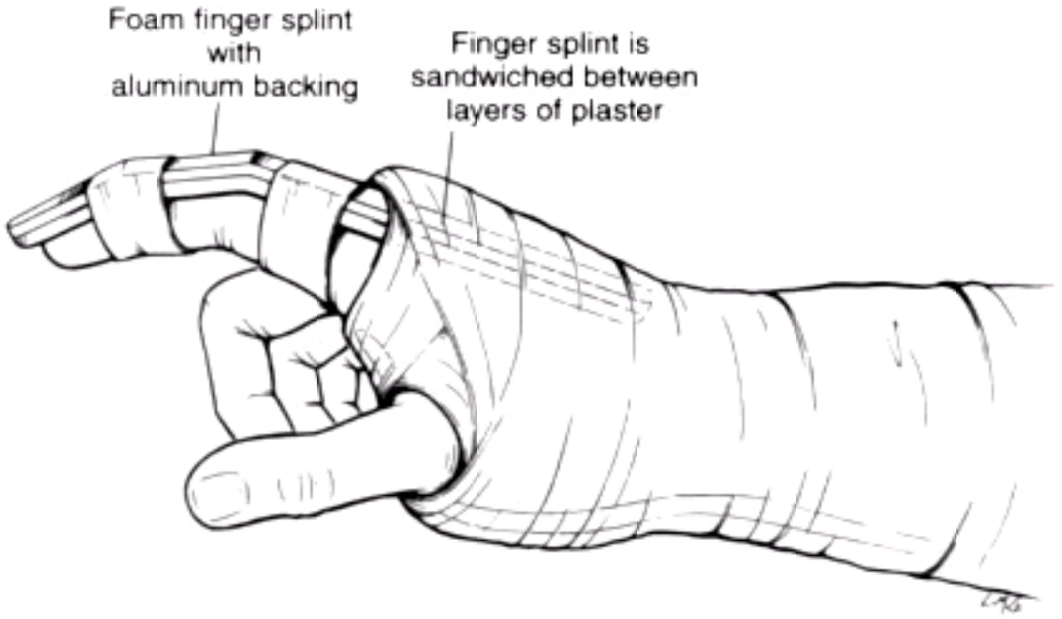

Figure 51-17 *A*, Step-wise application of a triangular muslin sling. (1) Place tip X over the uninjured shoulder. (2) Bring tip Y over the injured shoulder to enclose the arm. (3) Draw tip Z around the front and pin. *B*, Completed triangular muslin sling (Note: When applying a sling, it is important to have adequate support of the wrist and hand. A sling that is too short will allow the wrist and hand to hang down [ulnar deviate] and can result in ulnar nerve injury).

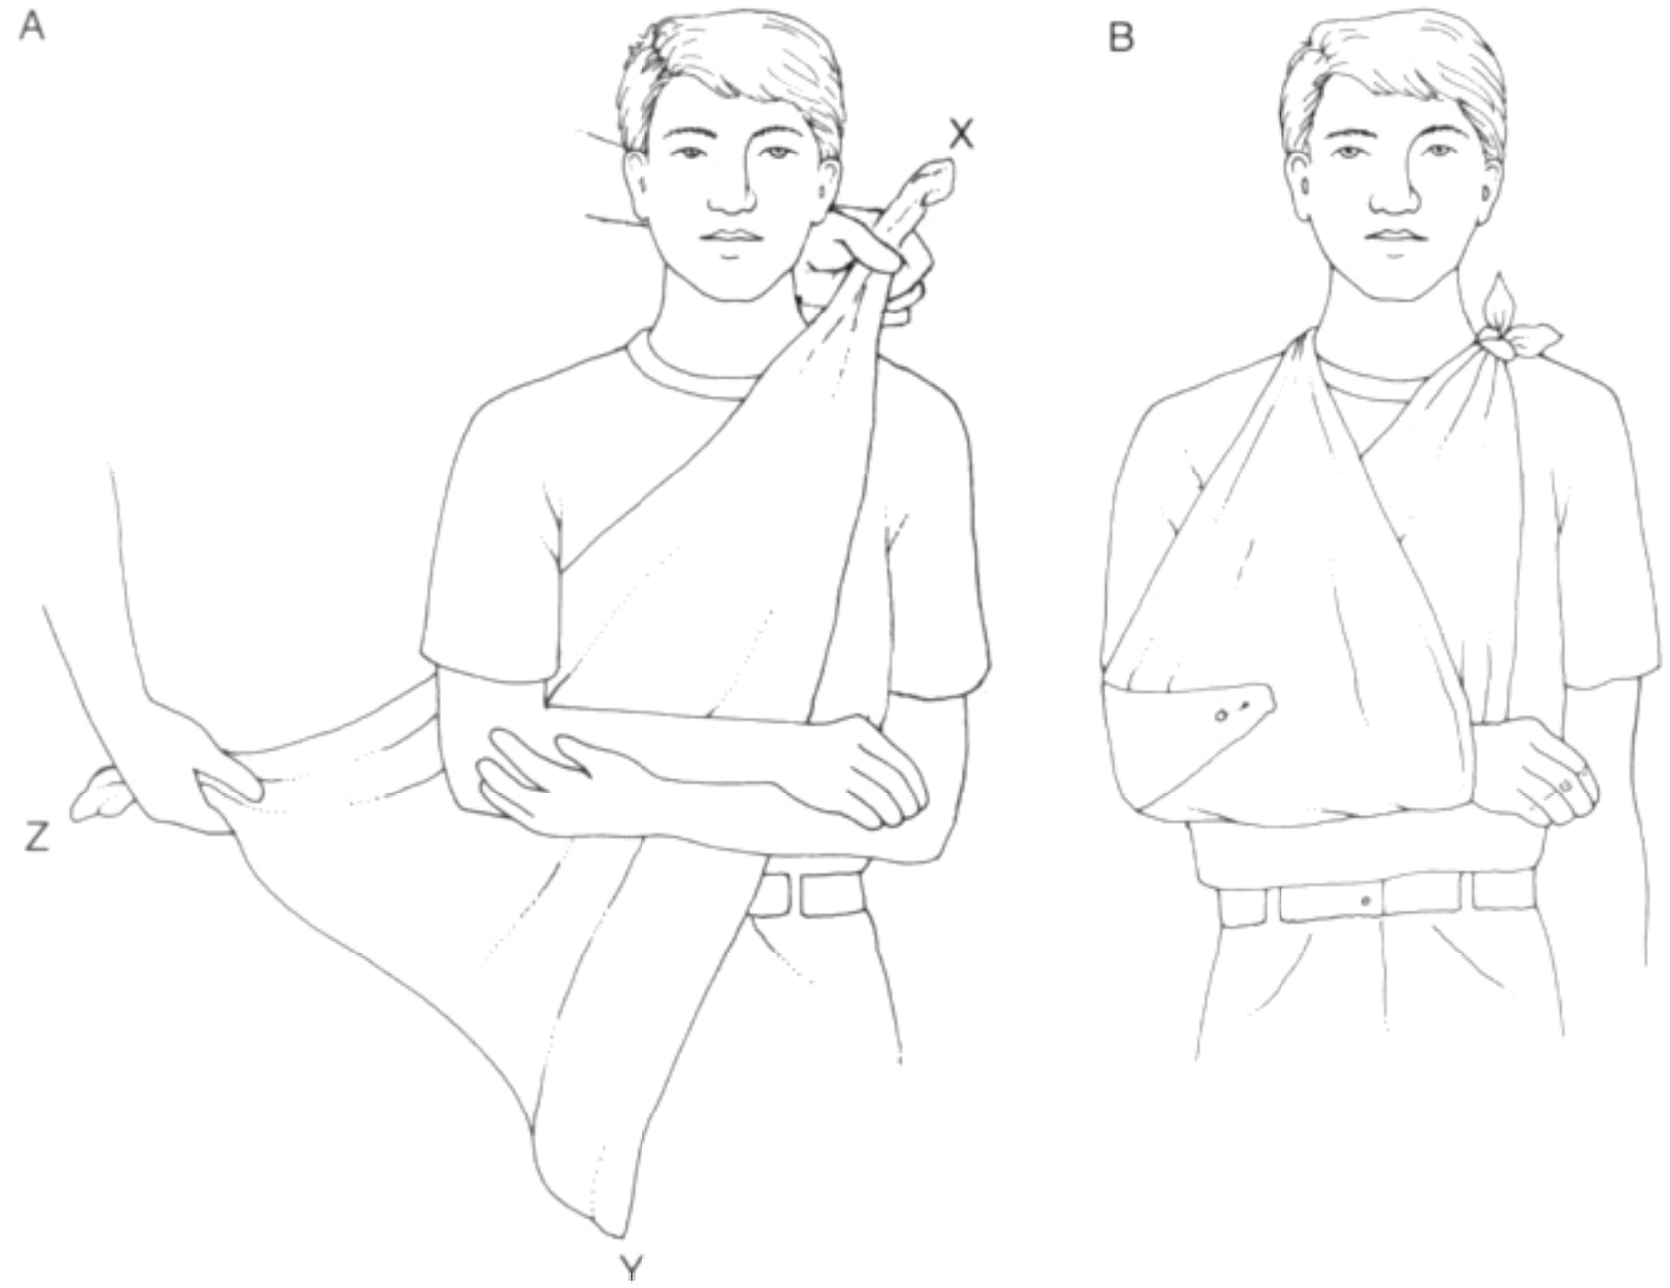

Figure 51-18 The shoulder immobilizer is used for most proximal humerus fractures and shoulder injuries. It may be removed for showering and range-of-motion exercises and is easily reapplied by the patient.

Figure 51-19 The Velcro strap bulky knee immobilizer is easily removed and readily applied by the patient. It can be worn over clothes.

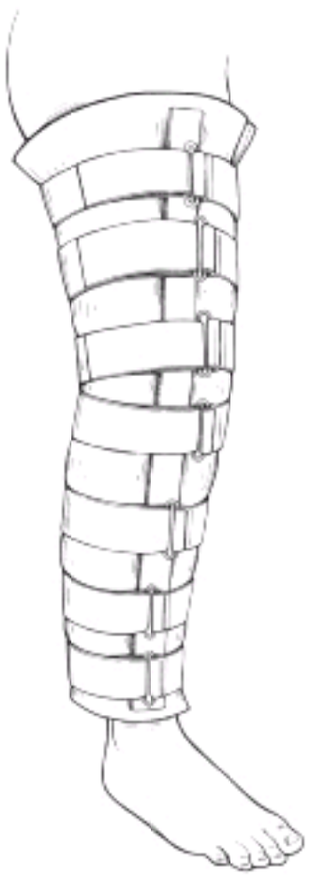

Figure 51-20 Application of a posterior knee splint. *A*, The posterior knee splint runs from just below the buttocks crease to approximately 2 to 3 cm above the malleoli. *B*, Alternatively, two parallel splints can be placed along each side of the leg and foreleg, creating a bivalve effect.

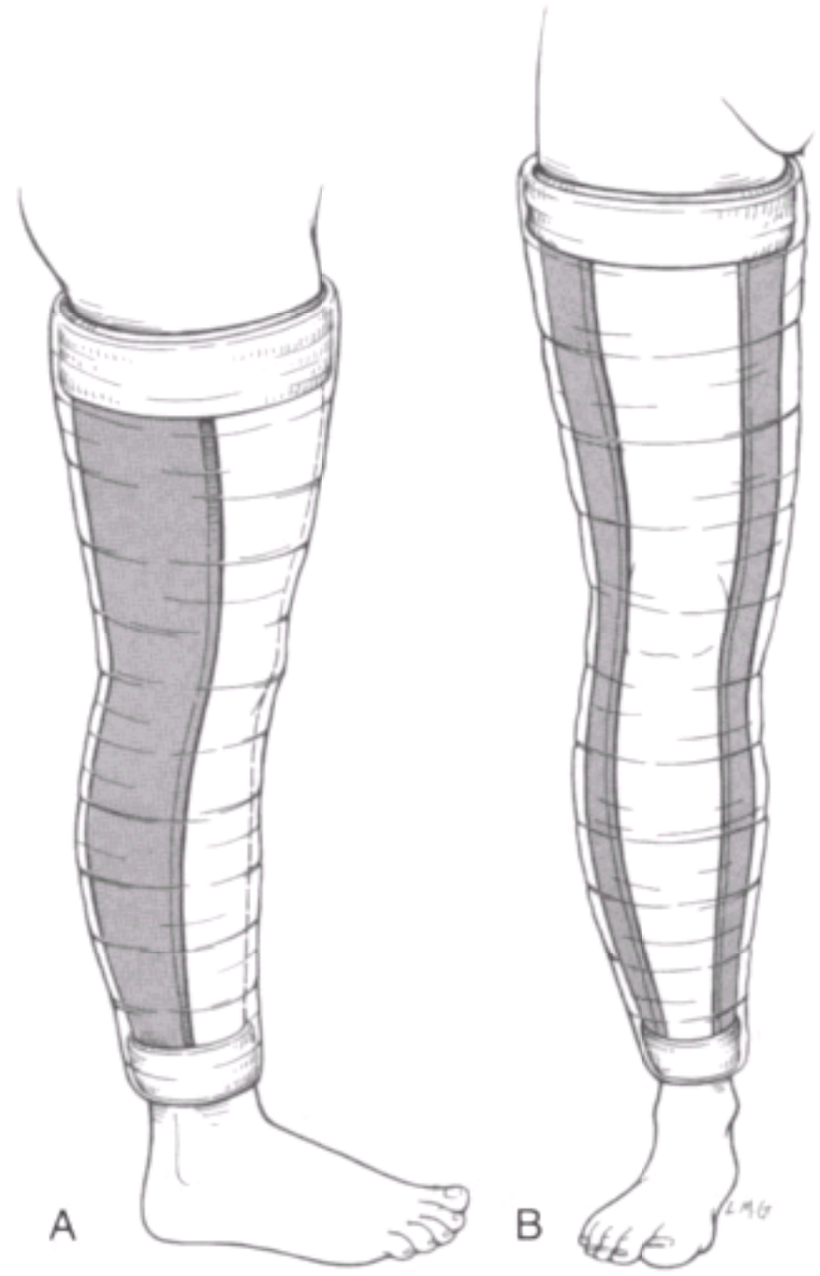

Figure 51-21 Posterior ankle pitfalls. *A*, Proper application of a posterior ankle splint. This splint extends from the plantar surface of the great toe (or metatarsal heads) along the posterior surface of the foreleg to the level of the fibular head. The ankle should be at a 90° angle. *B,* The most convenient way to apply an ankle splint is to have the patient lie prone and bend the knee to a 90° angle, thereby relaxing the calf muscles. The ankle should be at a 90° angle so that the foot is flat for partial weight bearing. *C, Incorrect splint application.* There are three things wrong with this posterior ankle splint: (1) It does not extend distally enough to support the entire foot. (2) The ankle is not maintained at a 90° angle. (3) The edges and ankle area are not molded. Overall the splint is sloppy and ineffective. *D*, The problem with this splint is that it was intended to be used for only a few days, but the patient wore it for 3 weeks. Note the resultant full-thickness skin loss. No padding was used under the premade splint. Skin grafting was eventually required.

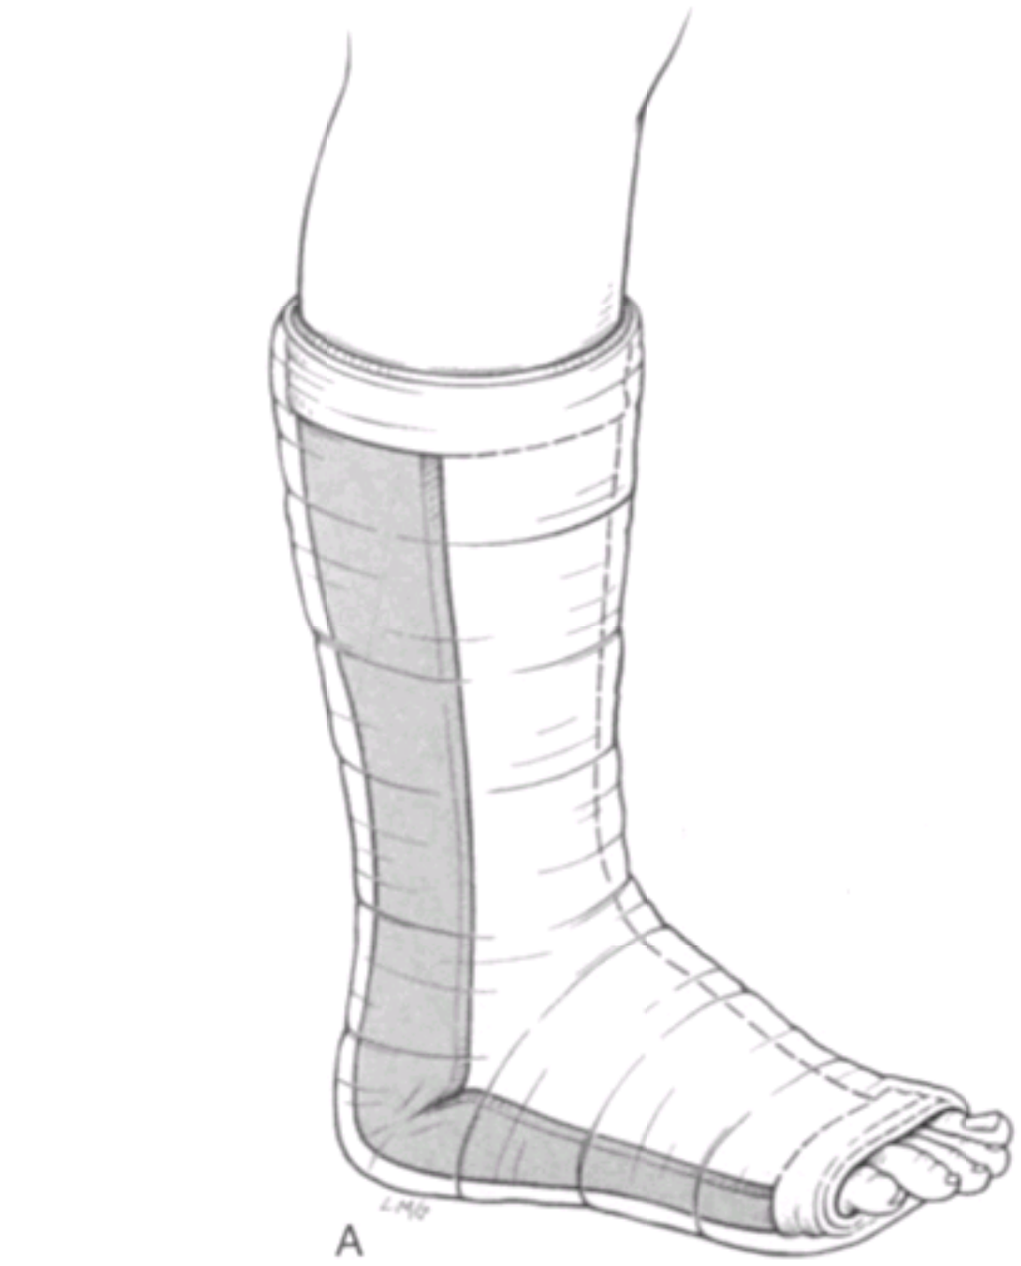

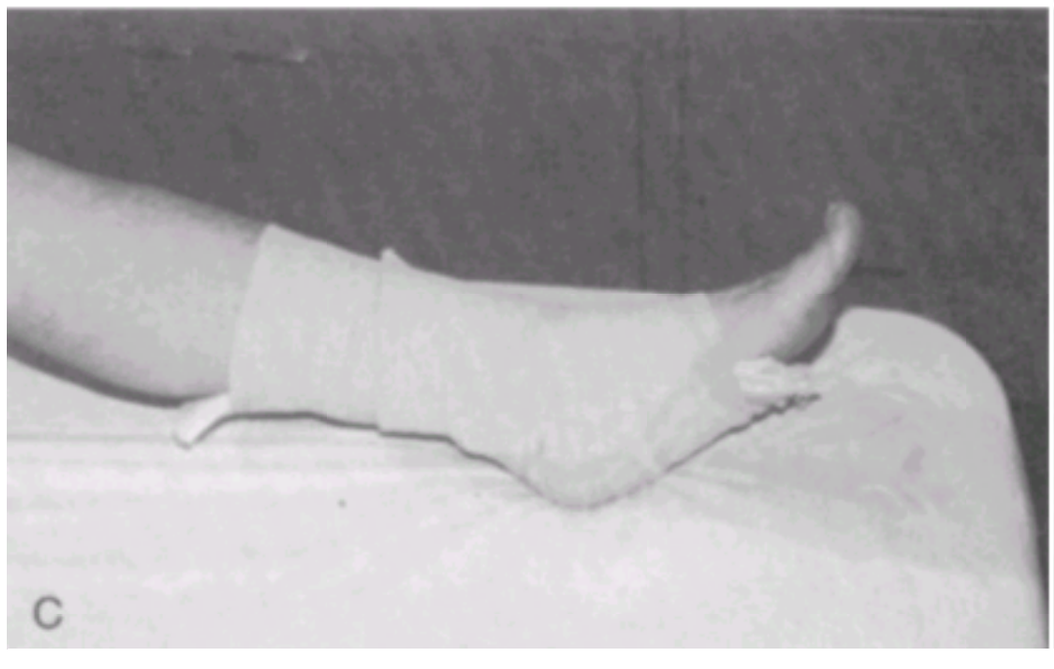

Figure 51-22 Application of an anterior-posterior ankle splint. In particularly severe or unstable injuries, an anterior splint may be added to a posterior ankle splint to provide extra immobilization resembling that of a formal cast. The anterior splint is never used by itself, but it can augment a posterior splint, creating a bivalve effect. The ankle should be at a 90° angle.

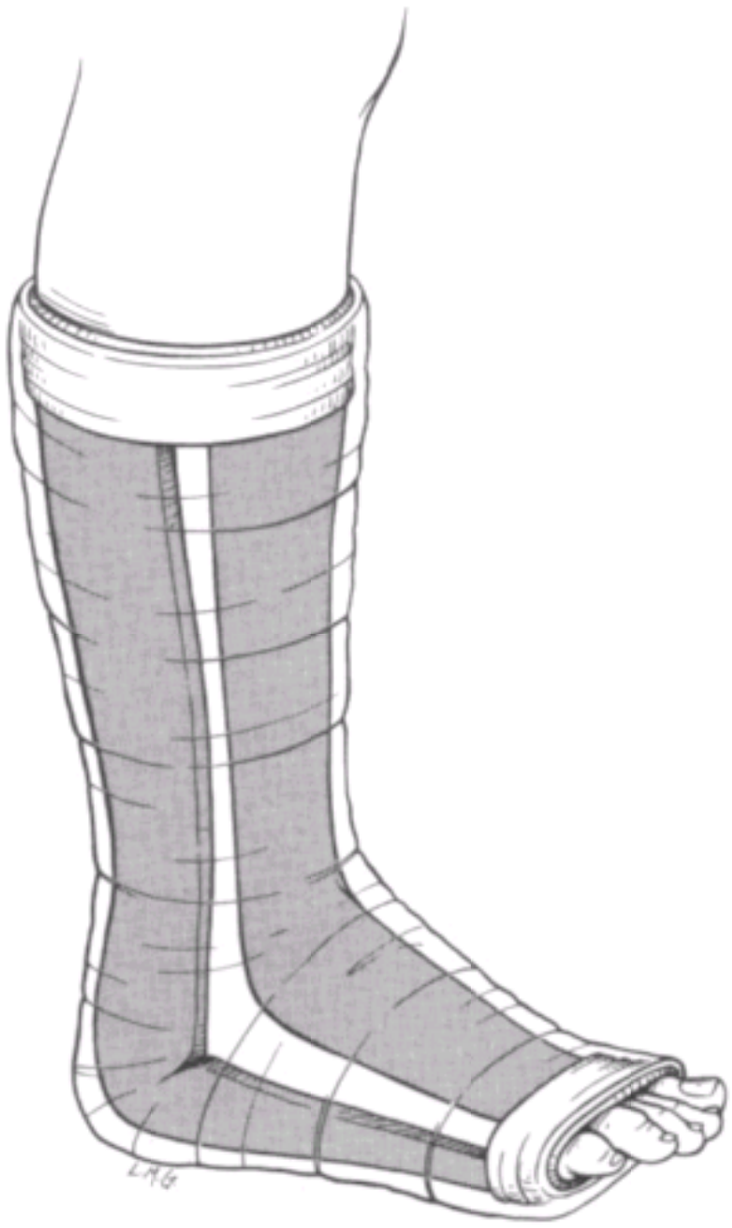

Figure 51-23 The U-splint (AKA sugar-tong or stirrup splint) is also used primarily for injuries to the ankle. The splint passes under the plantar surface of the foot, extending up the medial and lateral sides of the foreleg to just below the level of the fibular head. The ankle should be at a 90° angle. For immobilization of the knee, the sides of the splint may be extended proximally to the groin, creating a long leg splint.

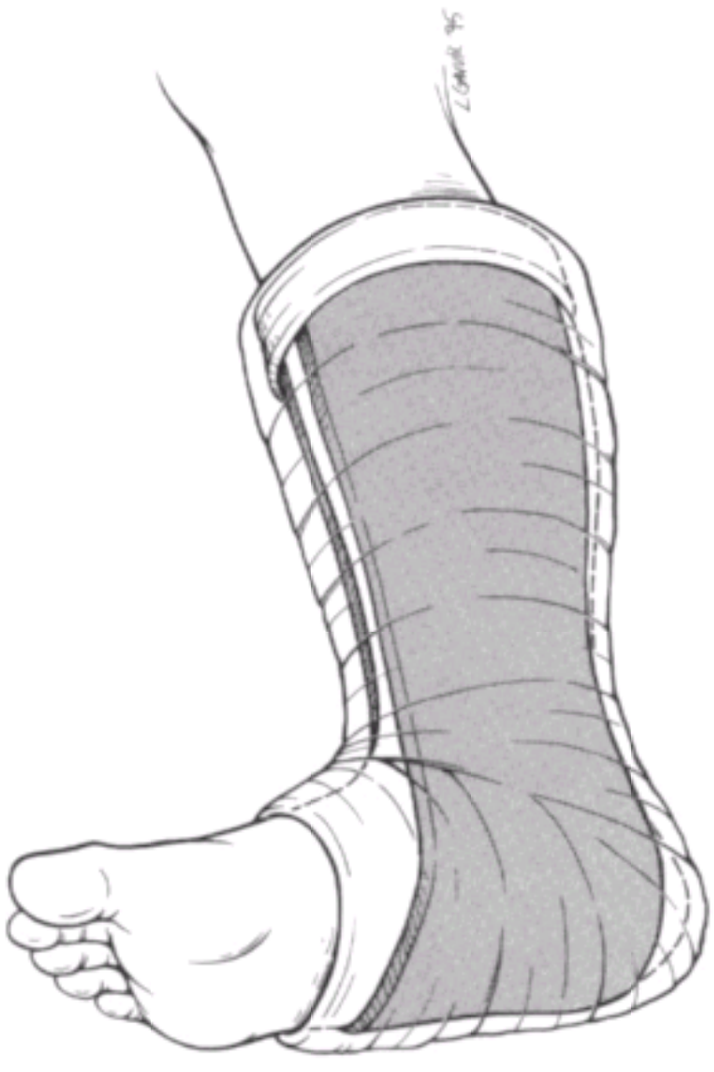

Figure 51-24 The Unna boot provides effective immobilization of an ankle soft tissue injury. It is applied from a semisolid paste roll. The wrap is then covered with gauze or an elastic bandage. The entire dressing can be cut off by the patient at home. For similar short-term immobilization without plaster, a modified Jones dressing can be used. Webril is wrapped around the ankle and it is covered with an elastic bandage.

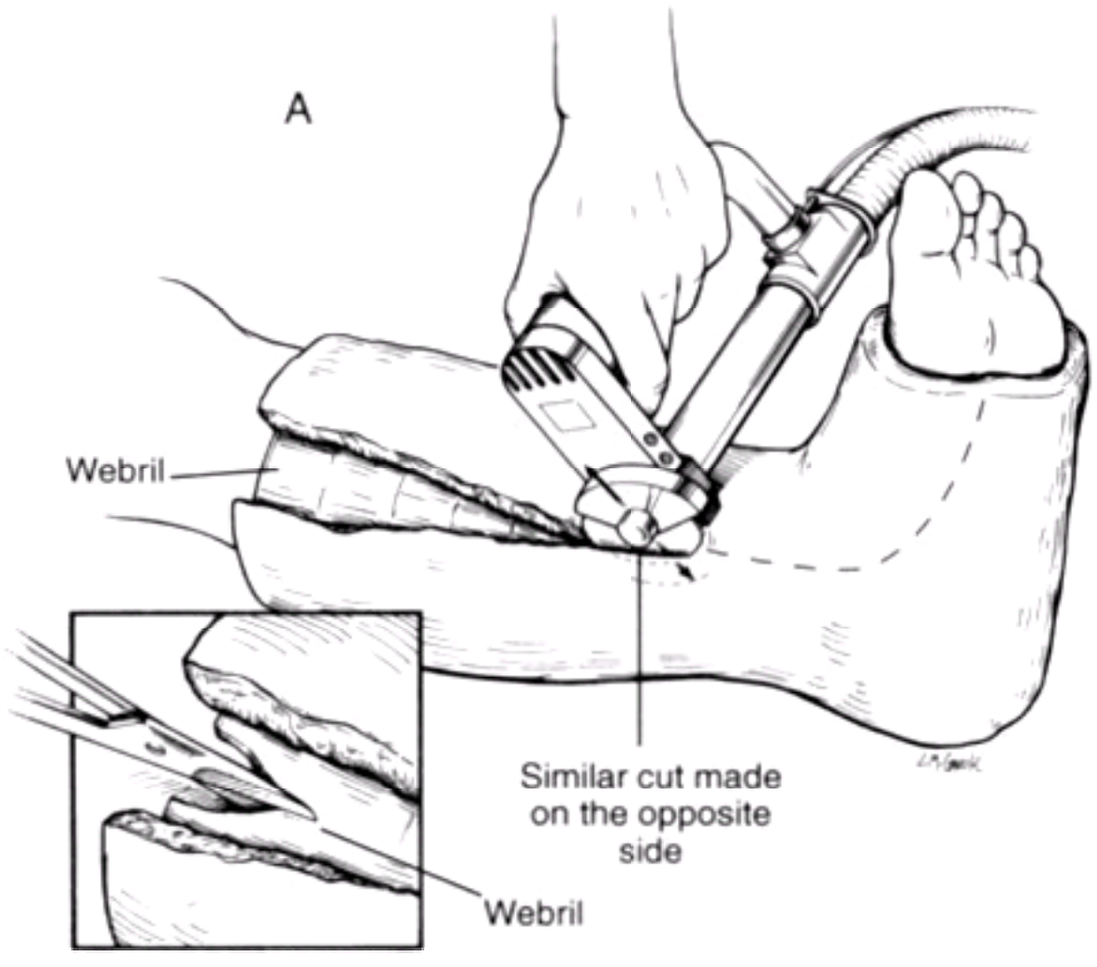
Figure 51-25 *A,* The cast saw vibrates; it does not rotate. The blade is controlled by placing the thumb on the splint and lowering the saw to the plaster. The blade is raised and lowered for each cut; it is *not* drawn across the plaster like a knife. *B,* This cast was too tight, and it was therefore bivalved from cast to forefoot with a cast saw. After separation of the edges of the cut cast, the anterior and posterior components were secured in place with an elastic bandage. Note that the underlying Webril padding was cut to relieve pressure but was not removed *(inset).* A bivalved cast provides temporary immobilization equal to that of an intact cast.



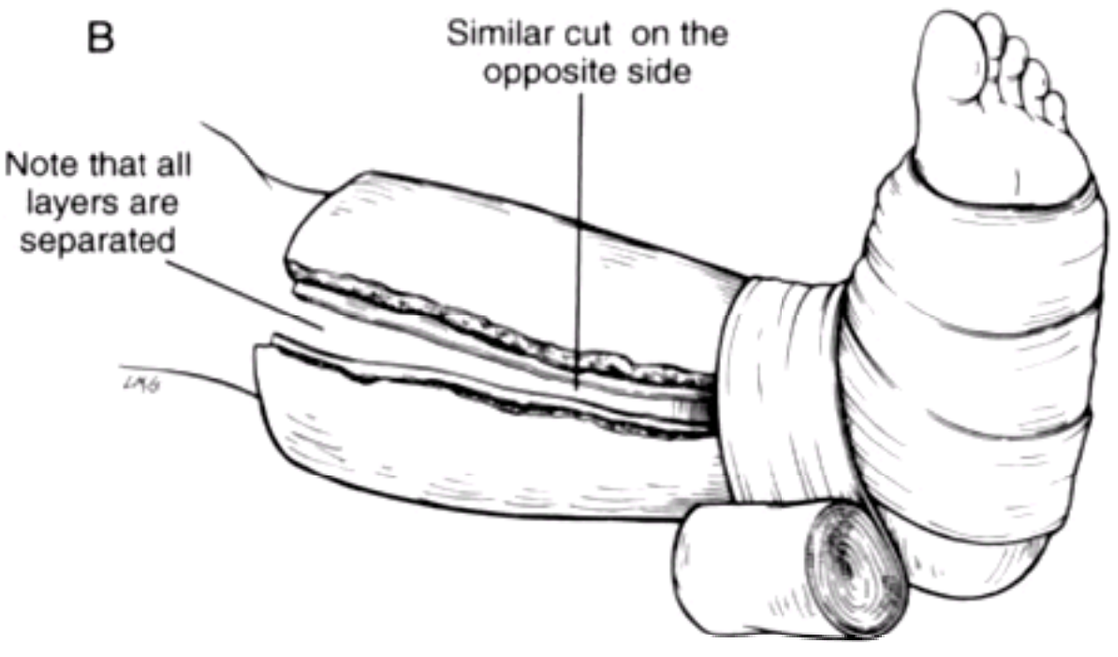


Figure 52-1 Use of aperture pads to redistribute pressure from painful areas to surrounding structures. *(Courtesy of Kenneth R. Walker, DPM.)*

Figure 52-2 Use of a self-adherent bunion pad. *(Courtesy of Kenneth R. Walker, DPM.)*

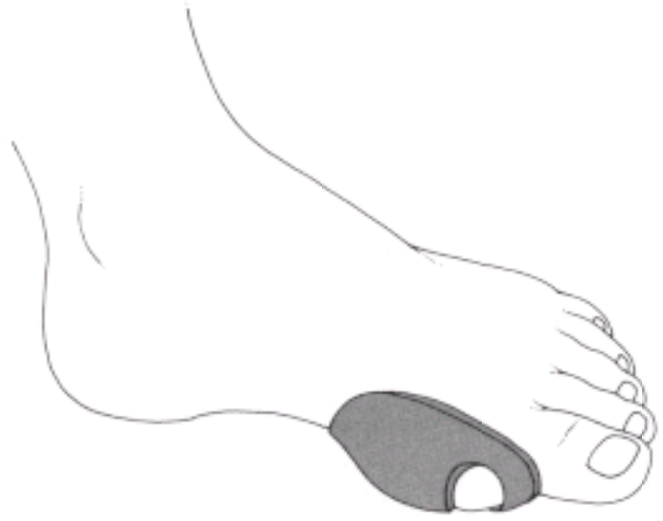

Figure 52-3 "Buddy taping" of a fractured lesser toe. *A,* a pad is placed between the injured toe and an adjacent toe. *B,* the toes are secured together with tape or self-adherent wrap. *(Courtesy of Kenneth R. Walker, DPM.)*

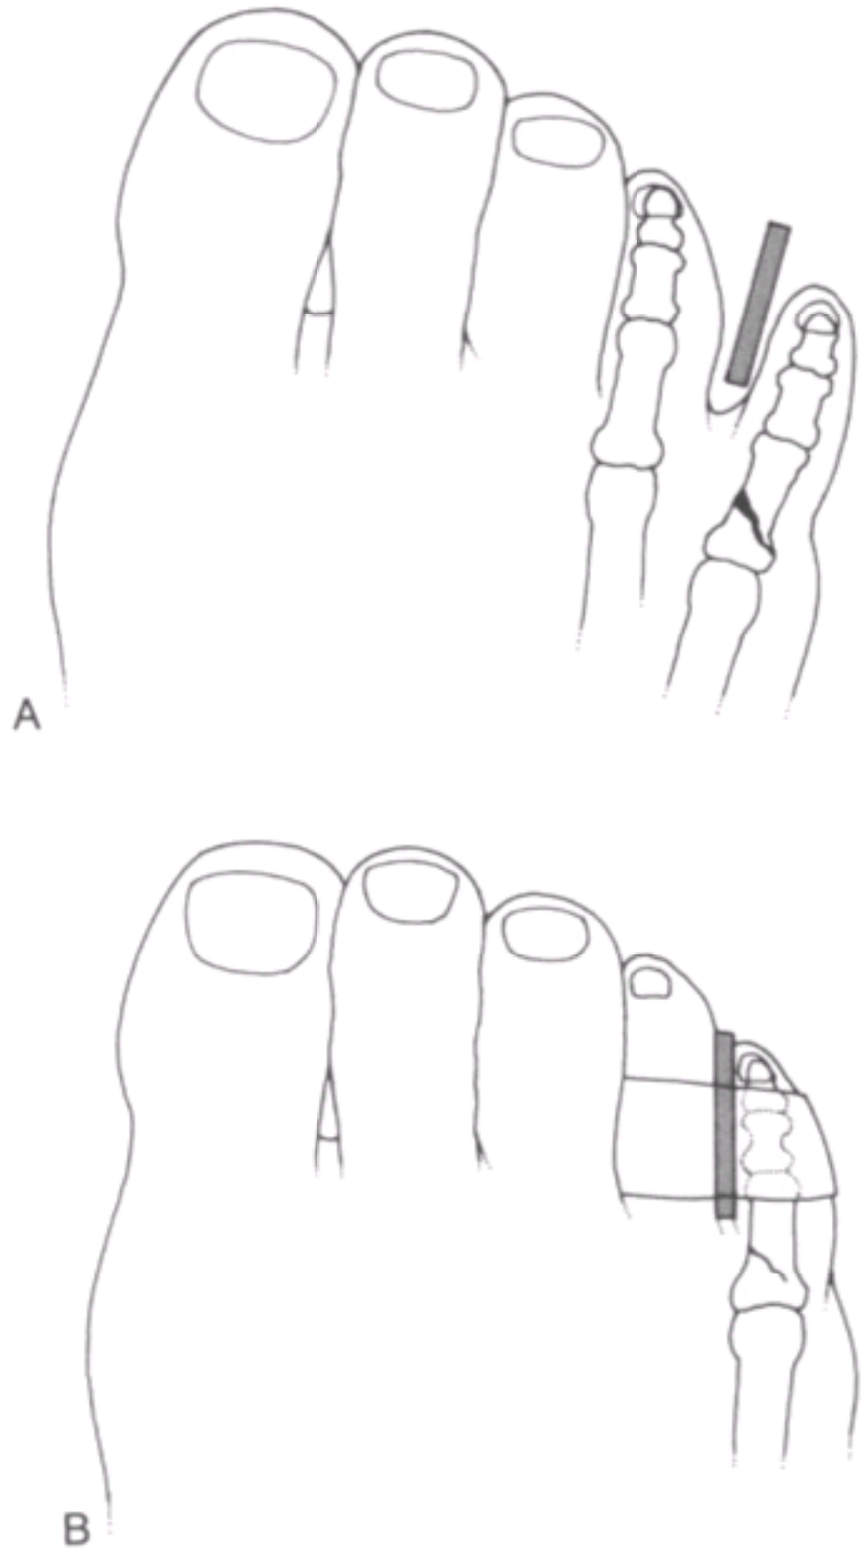

Figure 52-4 Bunion shields redistribute pressure away from fractured sesamoid bones. *(Courtesy of Kenneth R. Walker, DPM.)*

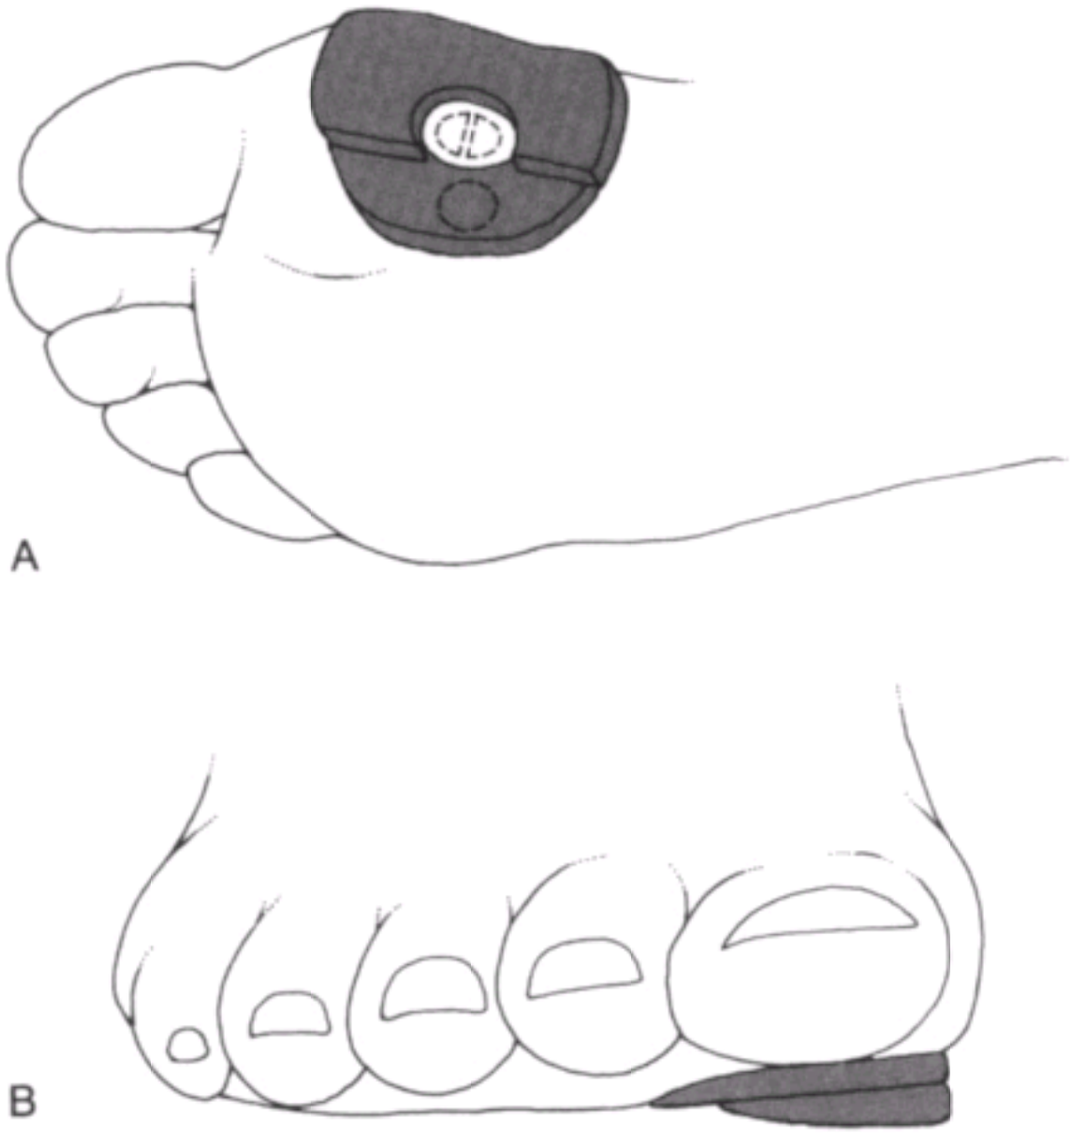

Figure 52-5 *A,* An ingrown toenail of this degree requires removal of a portion of the nail and debridement of inflamed tissue. *B,* Two days later, there is marked improvement. *C,* To remove a toenail, small scissors are held parallel to the nail bed, advanced, and spread. This will produce the least damage to the nail bed.

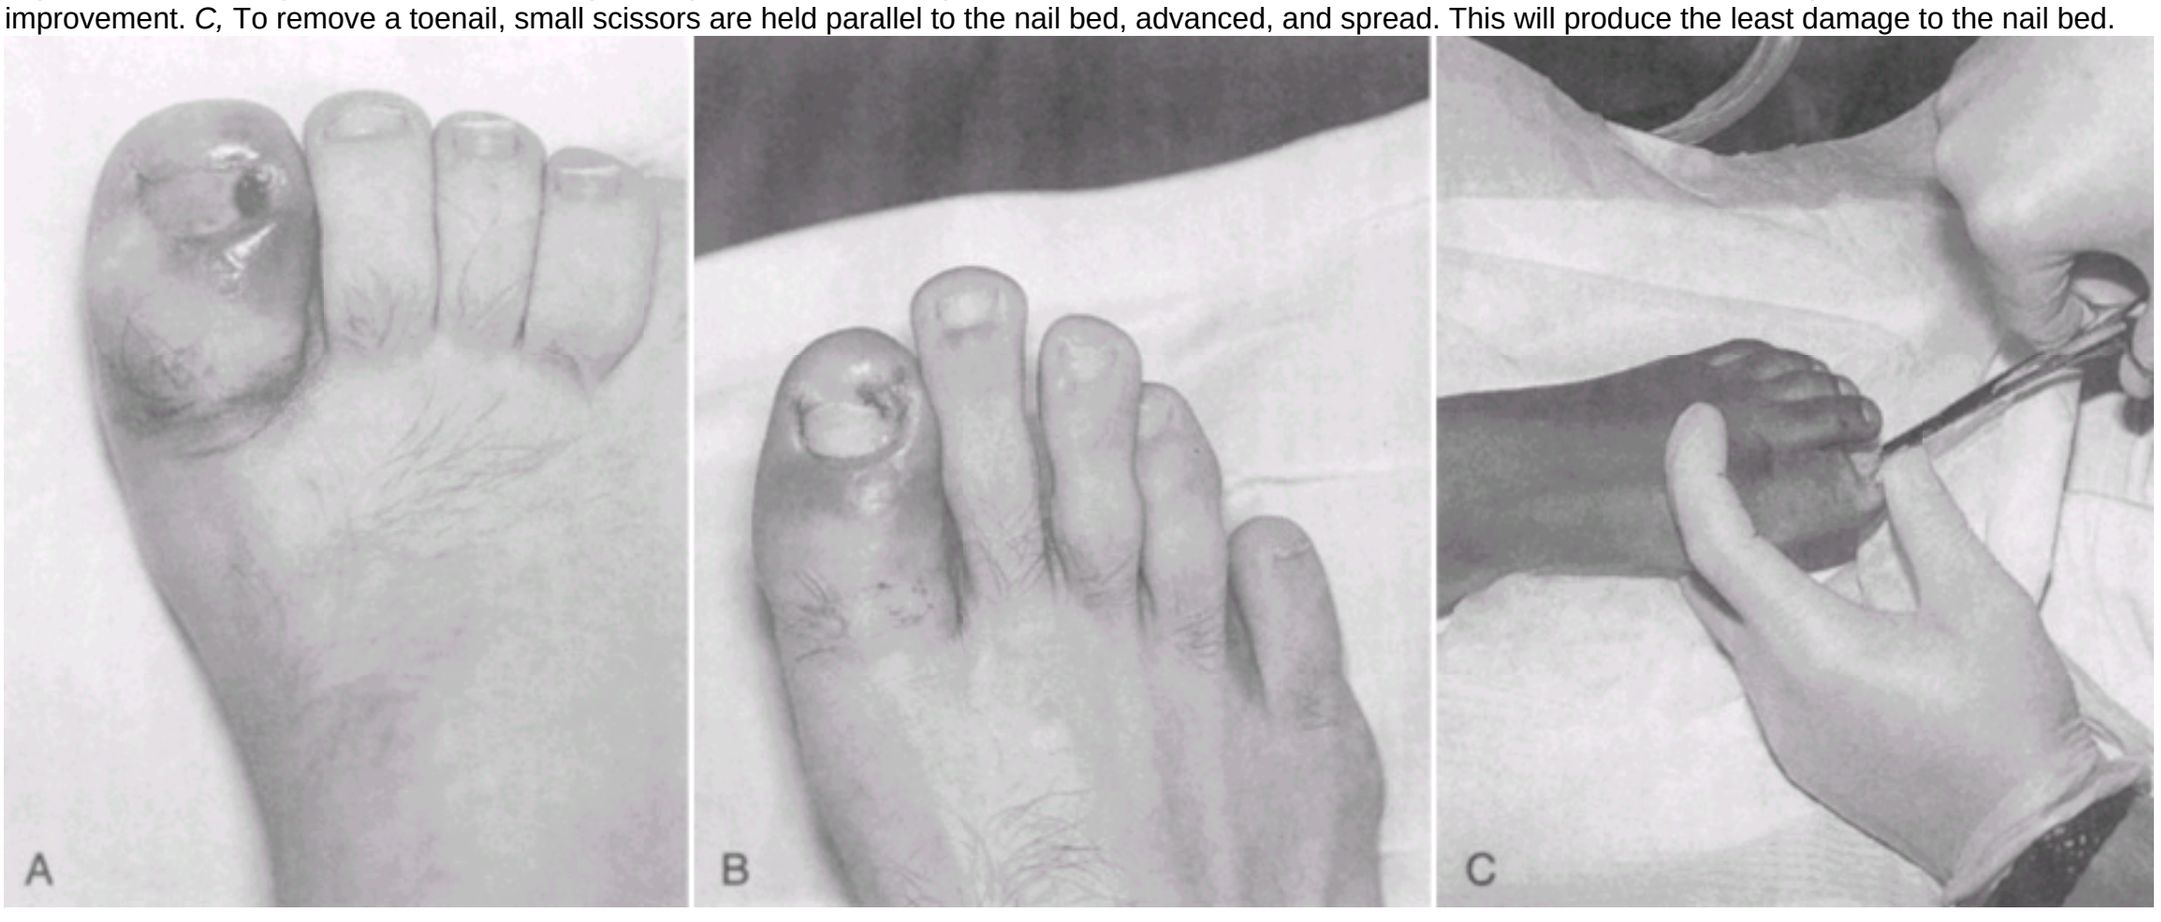

Figure 52-6 *A,* The best way to examine a puncture wound of the foot is to place the patient prone on a stretcher and obtain good lighting and a bloodless field (in this case, a blood pressure cuff was applied to the lower leg). *B,* When the overlying skin was unroofed, a small piece of rubber from the patient's sneaker was found imbedded in the wound. It was removed by a coring technique and packed.

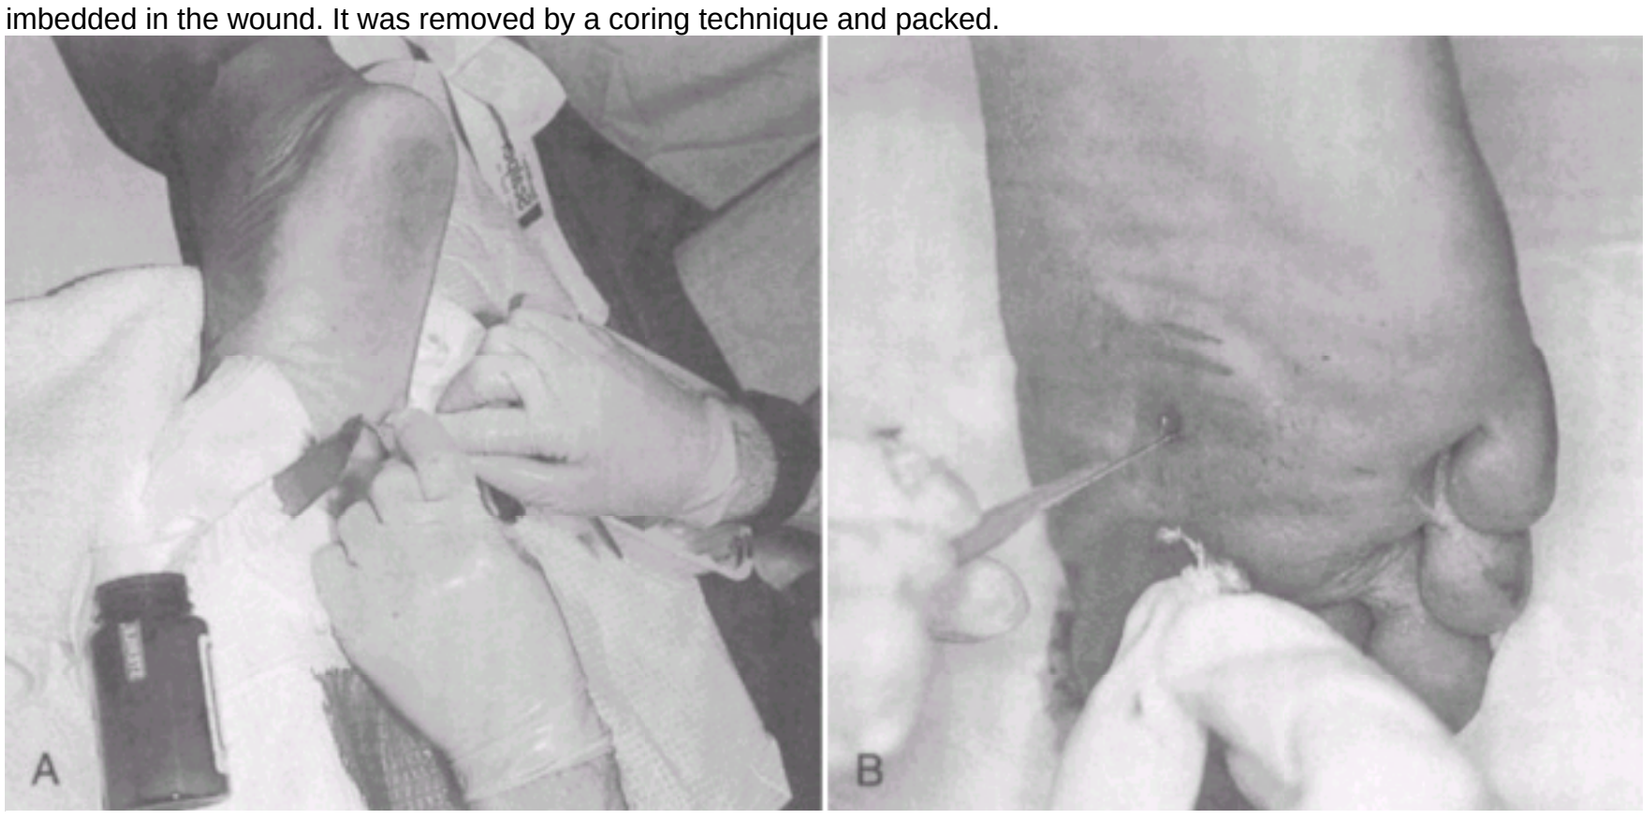

Figure 52-7 *A,* Patients who present with lymphangitis, obvious cellulitis, or both within a few days of stepping on a nail usually have a gram-positive soft tissue infection. *B,* In this case, the puncture wound was excised by a coring technique, yielding a few bits of foreign material. A pack was placed in the wound, oral antibiotics were given, and the patient did well.

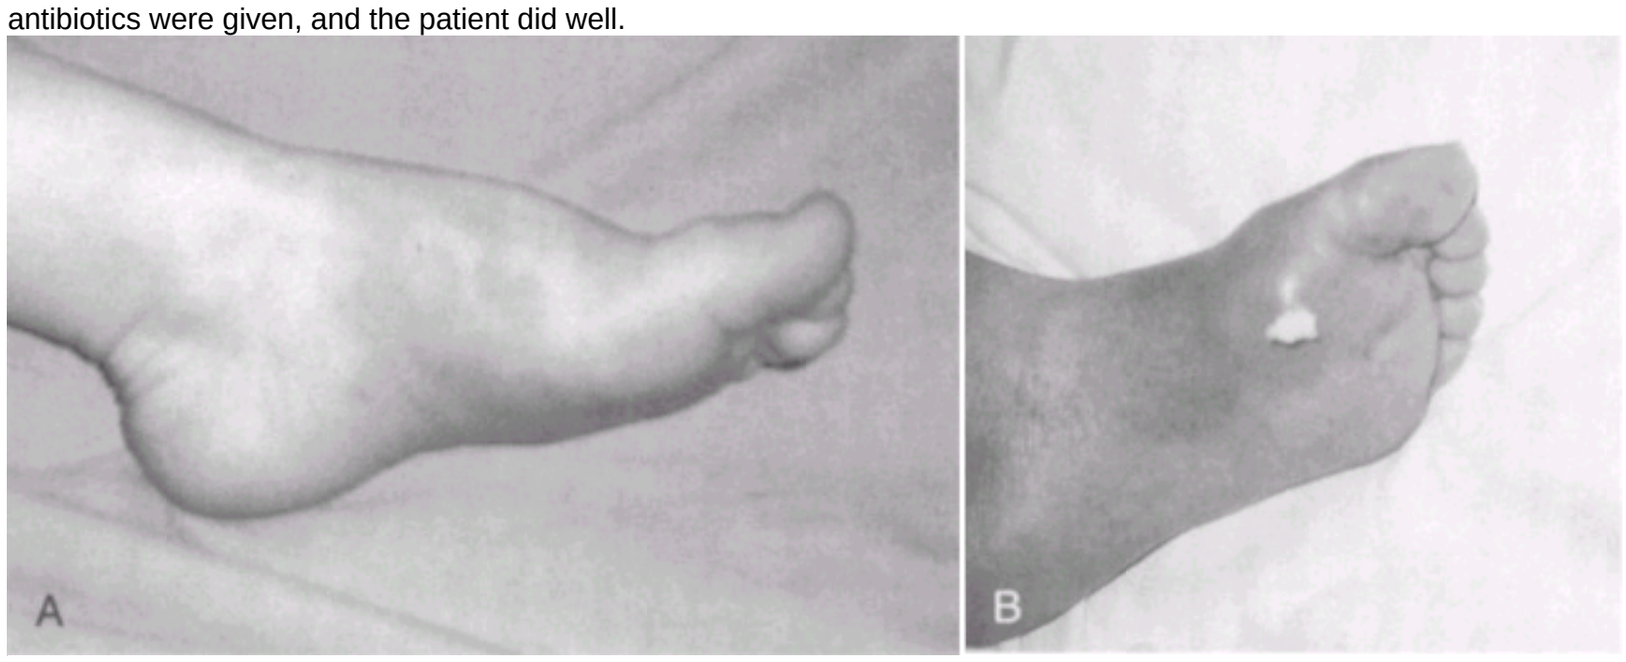

Figure 52-8 This 4-day-old inflamed puncture wound tract likely harbors a foreign body. Excision of a core of the tract found a few pieces of the patient's sock embedded in the wound.

Figure 52-9 A patient stepped on a nail while wearing this shoe. An initial ED evaluation 3 weeks previous found no foreign body or infection. A week previous, the patient began taking antibiotics, but did not improve. The physical examination was quite benign, but the continued aching pain and minimal swelling suggested a deep infection. The complete blood count, sedimentation rate, and plain film were negative. A magnetic resonance imaging scan demonstrated osteomyelitis. *Pseudomonas* is often the offending organism in this scenario.

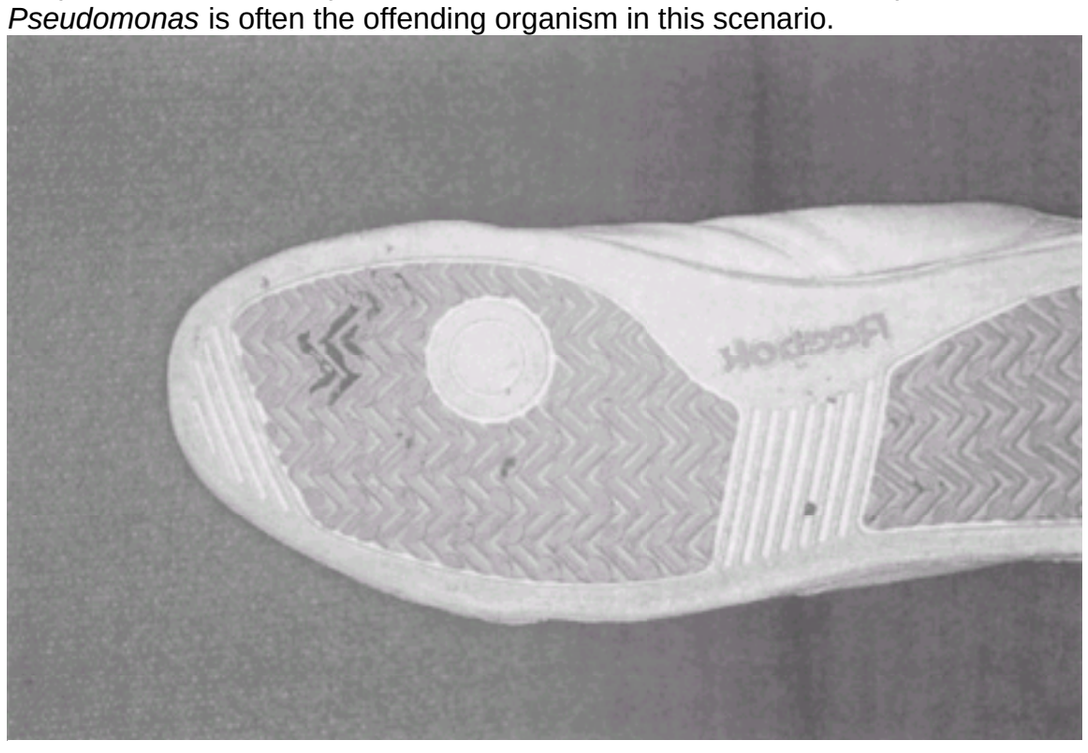

Figure 52-10 Plantar puncture wound management. *A,* Management within 24 hours of wounding. *B,* Management after 72 hours. *(From Chisolm CD, Schlesser JF: Plantar puncture wounds: Controversies and treatment recommendations. Ann Emerg Med 18:1352, 1989.)*

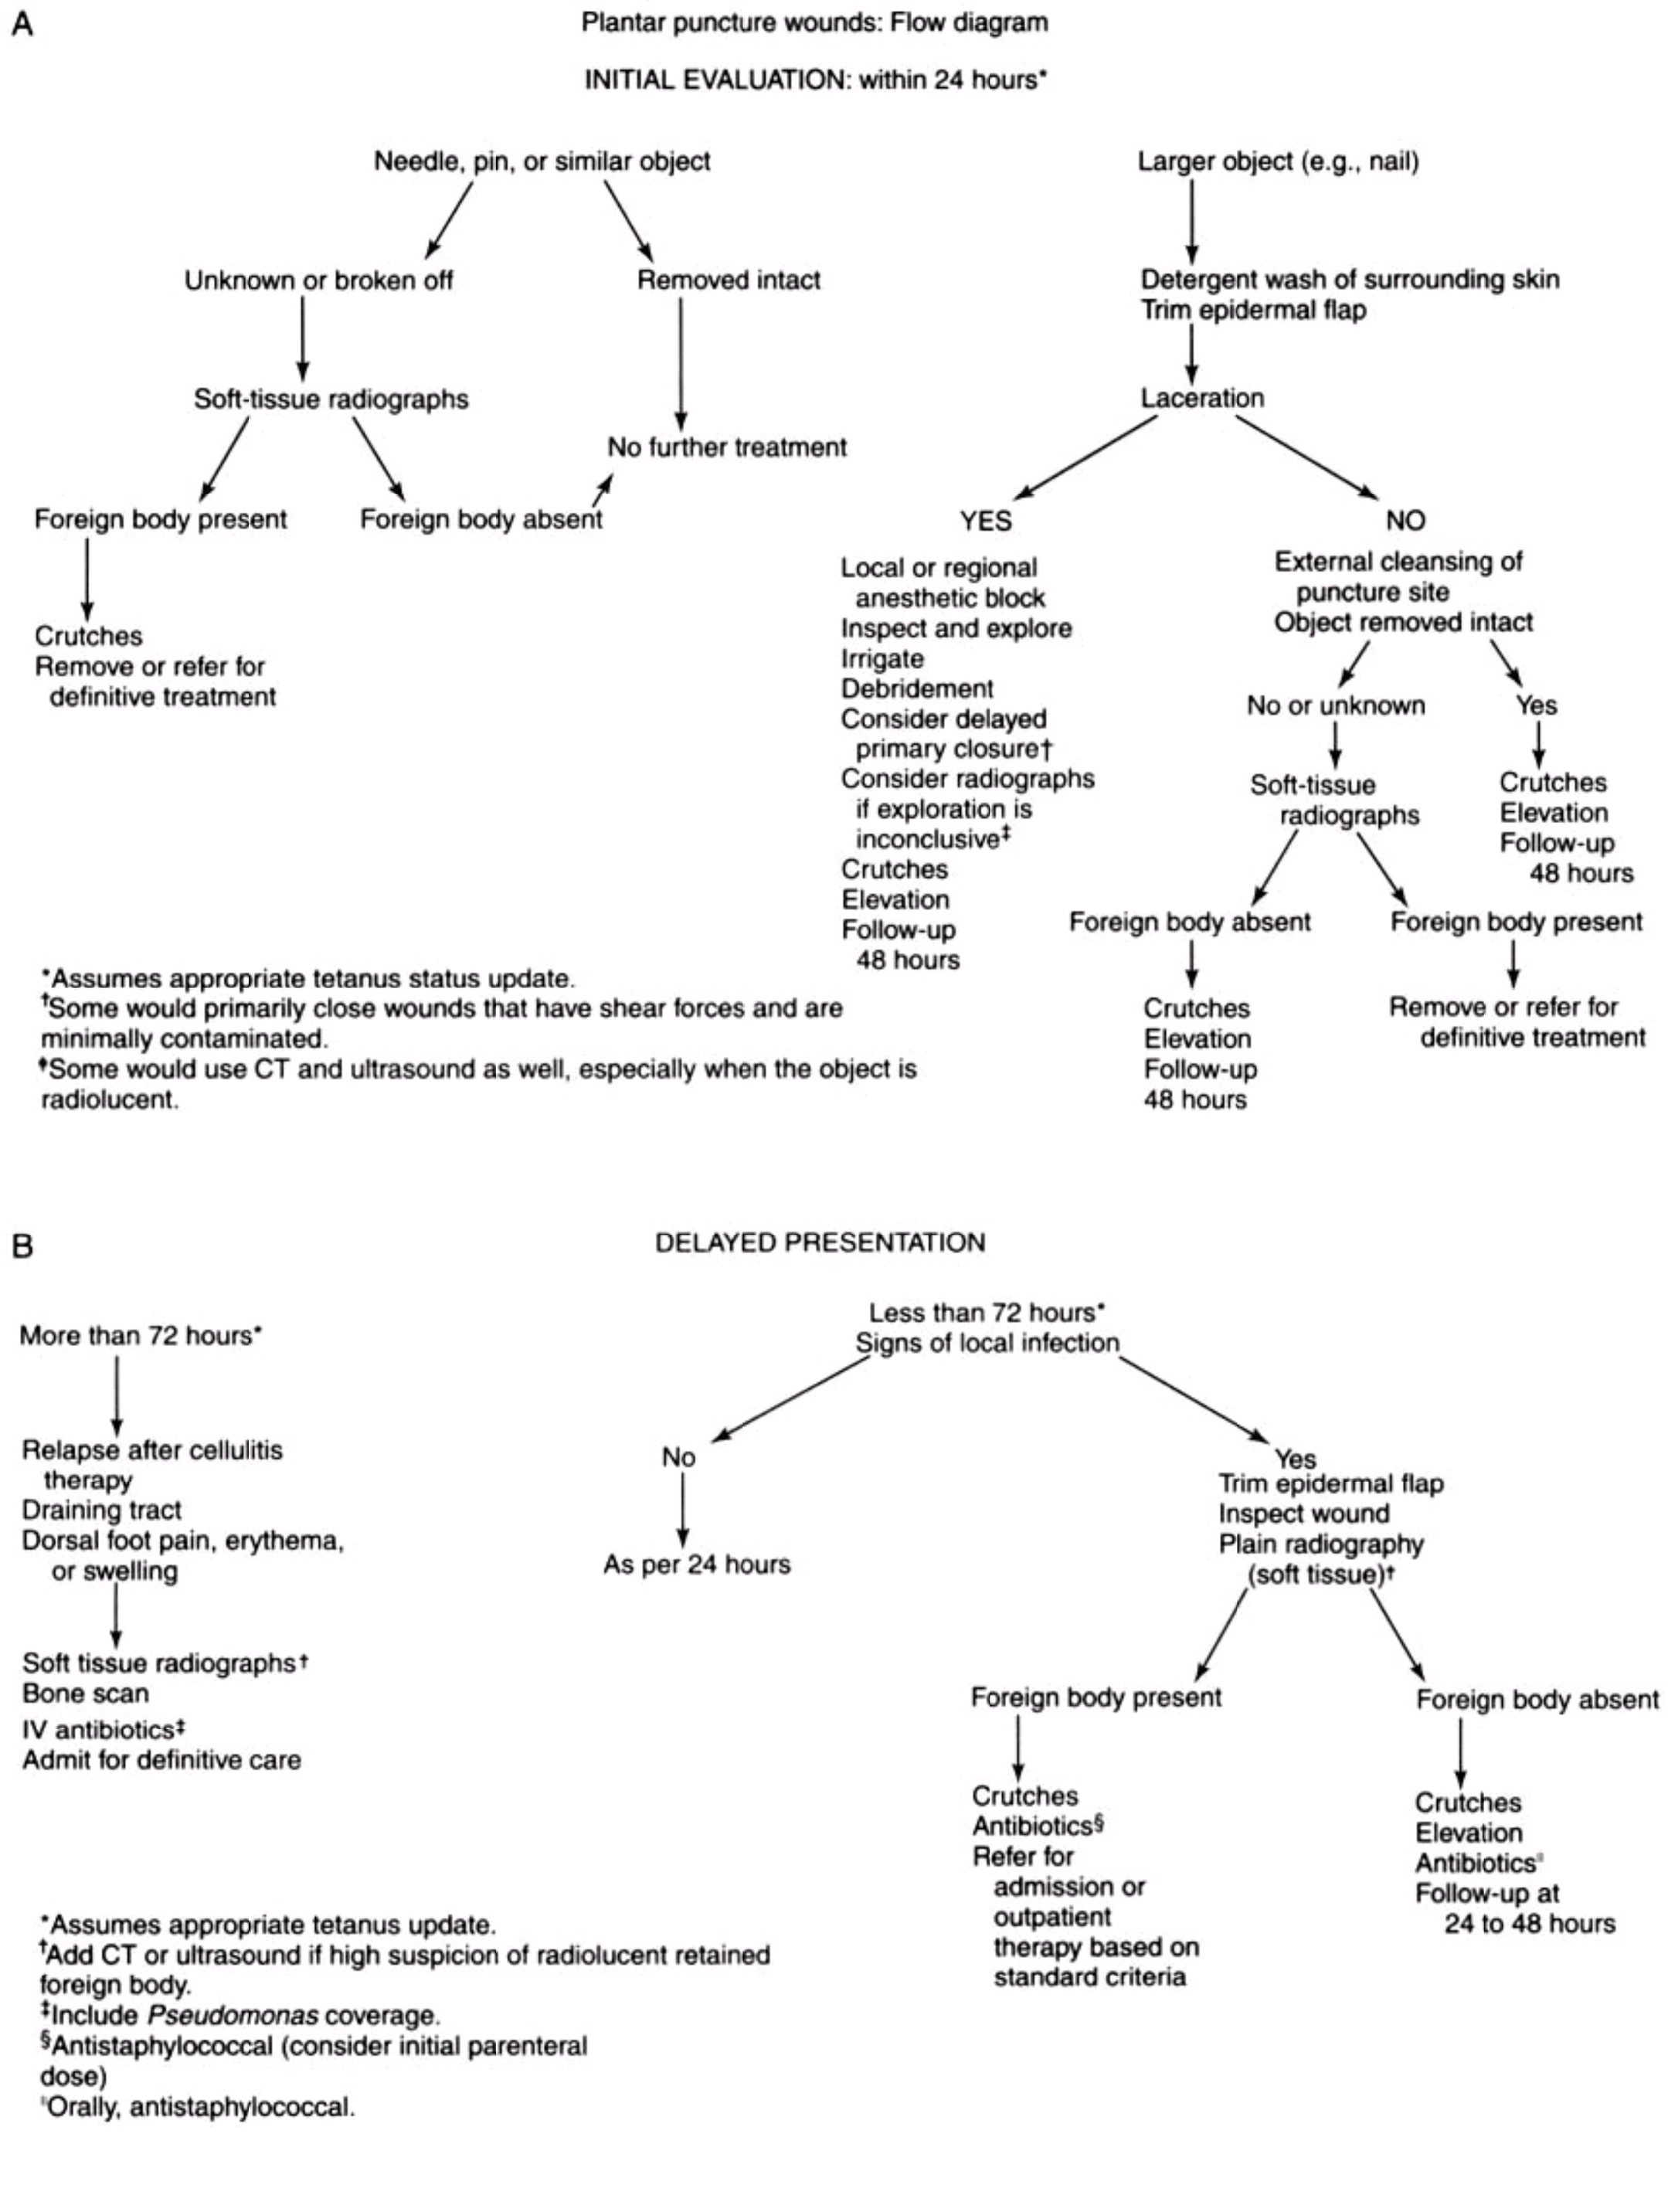

Figure 52-11 Pathology of an ingrown toenail. The normal free space at the nail margin is obliterated by inflammation and granulation tissue, which is caused by improper nail trimming, trauma to the matrix, and faulty footwear. *(From Hill GL II: Outpatient Surgery, 3rd ed. Philadelphia, WB Saunders, 1988. Reproduced by permission.)*

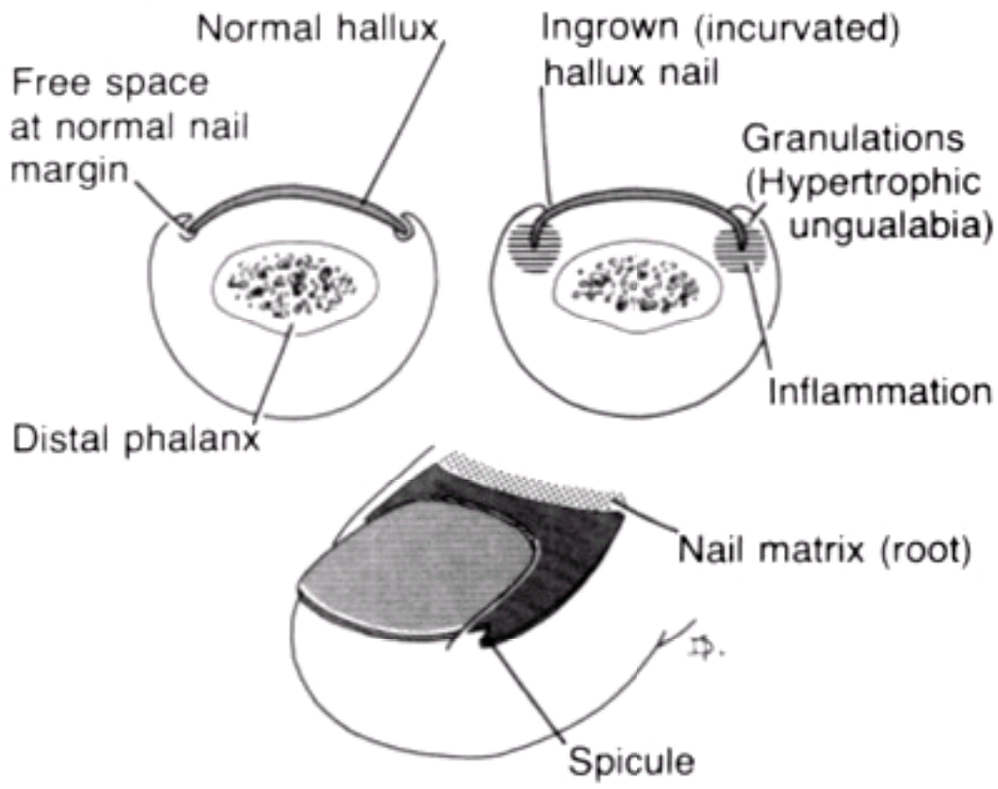

Figure 52-12 An oblique wedge of nail is trimmed from the lateral margin of the nail to free it from the hyperkeratotic area. *(Courtesy of Kenneth R. Walker, DPM.)*

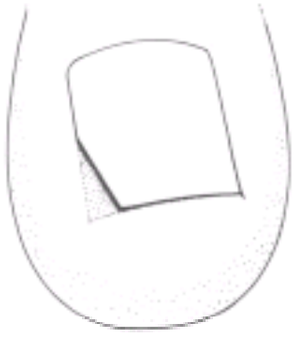

Figure 52-13 English nail anvil used to divide the nail. *(Courtesy of Gill Podiatry Supply Company, Middleburg Heights, OH.)*

Figure 52-14 The nail ablation technique for treatment of an ingrown toenail. The lateral portion of the nail is cut and removed (*A*), exposing the nailbed. Granulation tissue is curetted (*B* and *C*) and the nail matrix is cauterized with absolute phenol (*D*) (see text).

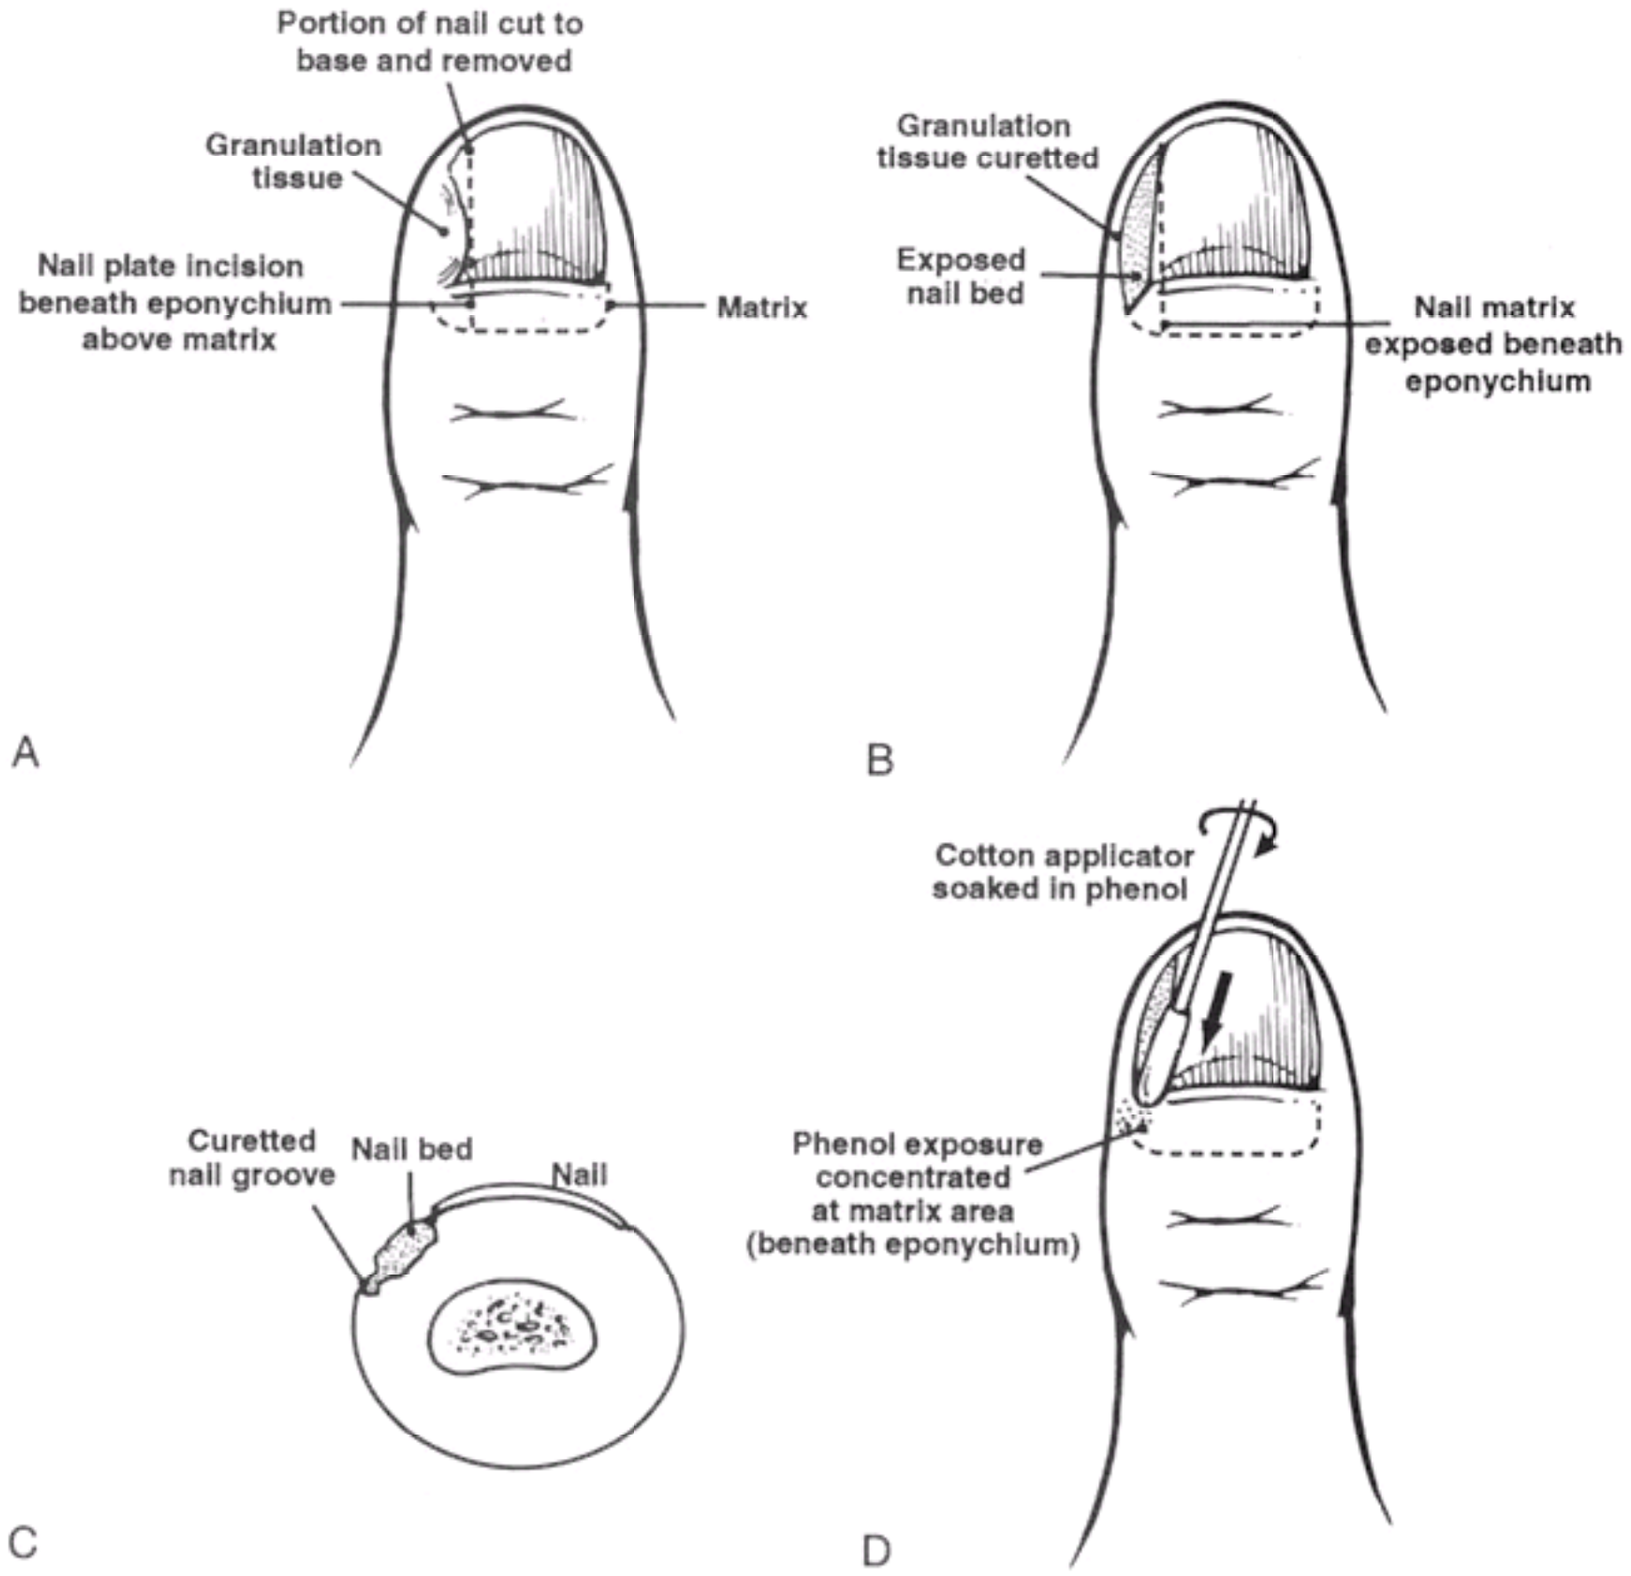

Figure 53-4 *A,* Anatomic site for injection into the bicipital groove for treating bicipital tendinitis. The anesthetic is infiltrated around the biceps tendon sheath in a fan-wise distribution, avoiding intratendinous injection. *B,* Actual peritendon injection of bicipital tendinitis: The patient is seated with the forearm and hand resting in the lap and externally rotated.

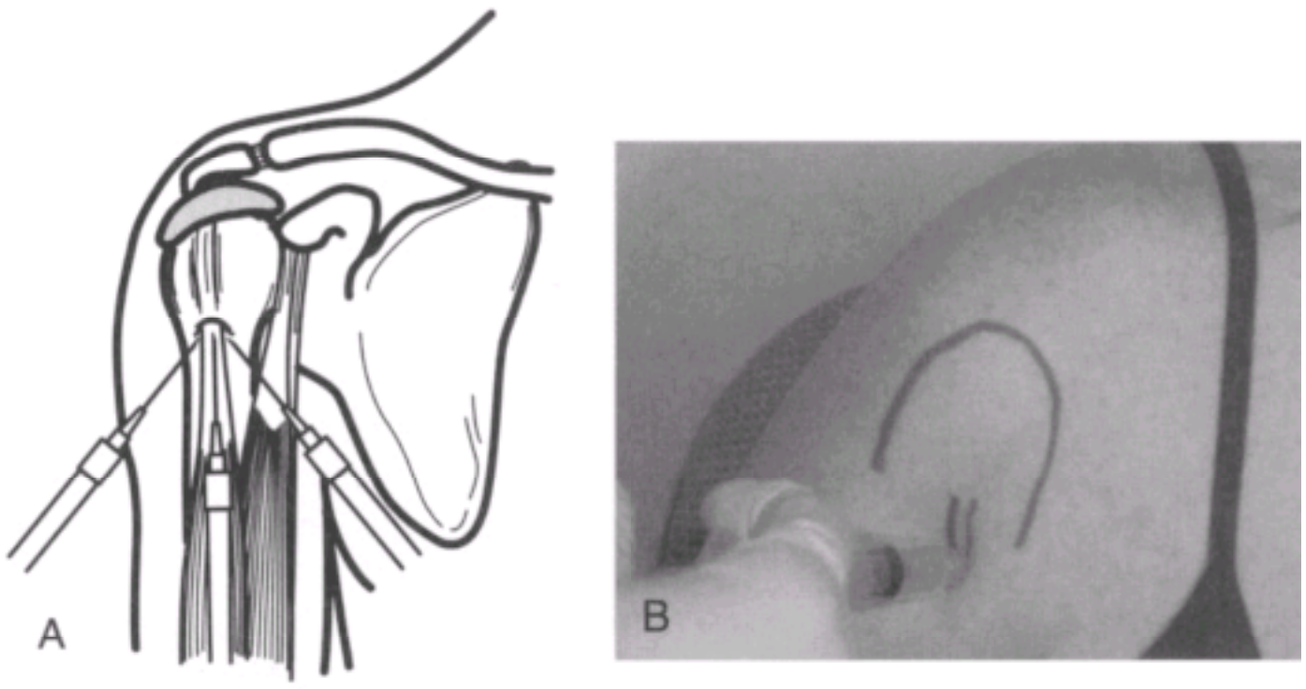

Figure 53-5 The "critical zone." Note the close relationship of the supraspinatus tendon and subacromial bursa to the humeral head and acromion.

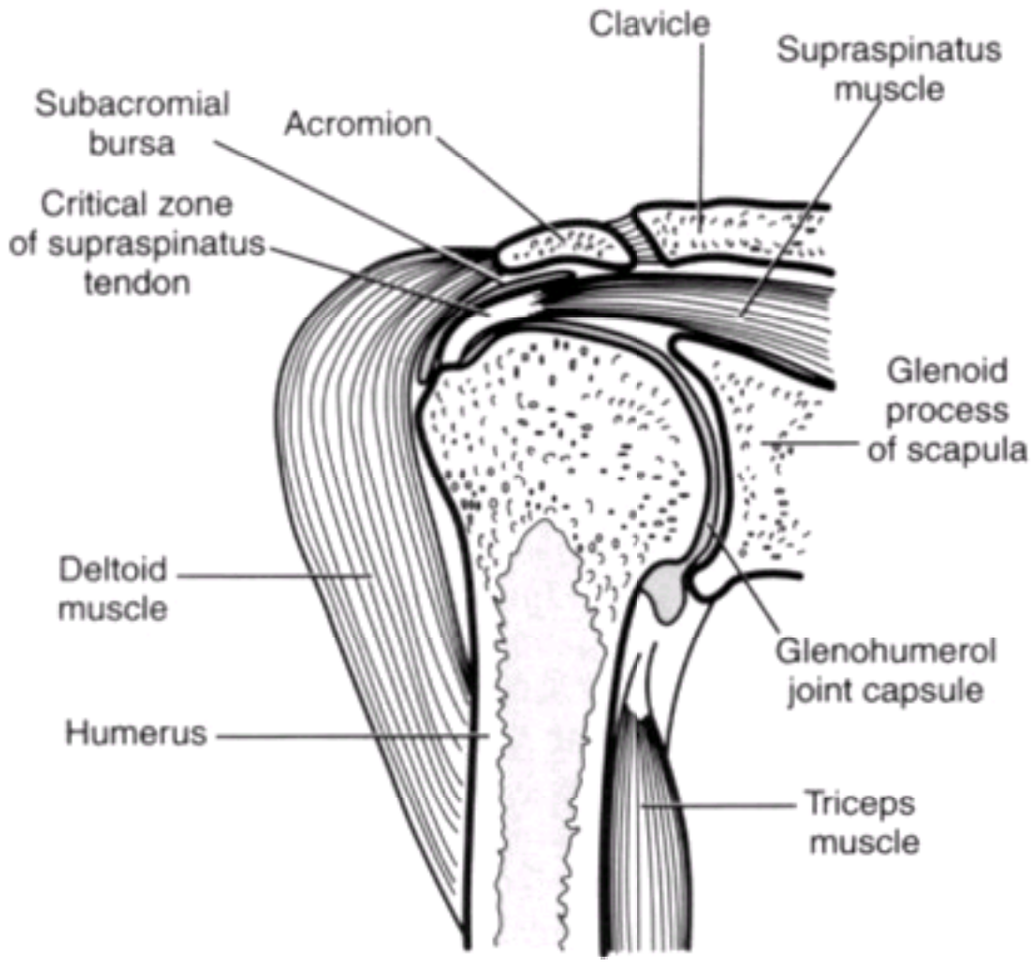

Figure 53-6 Abnormal calcific deposits in calcareous tendinitis of the shoulder are usually demonstrated roentgenographically in the suprahumeral region or adjacent to the greater tuberosity. When bursal calcifications appear dense (as in this x-ray film), they are frequently asymptomatic, whereas lightening at the margins of the calcium deposit is compatible with the presence of inflammatory edema in the rotator cuff, which produces pain and tenderness in the shoulder region. The location of the calcific deposit in the radiograph may be a useful guide for the point of entry of aspiration and injection. The needle is directed to the calcareous deposit, aspiration is carried out, and a portion of the steroid medication is deposited there. The calcium may subsequently disappear. Not infrequently, it does so spontaneously, without a needling procedure.

Figure 53-7 *A,* Anterior approach to the subacromial bursa or supraspinatus tendon. The needle is inserted into the depression located inferolateral to the coracoid process and medial to the humeral head.

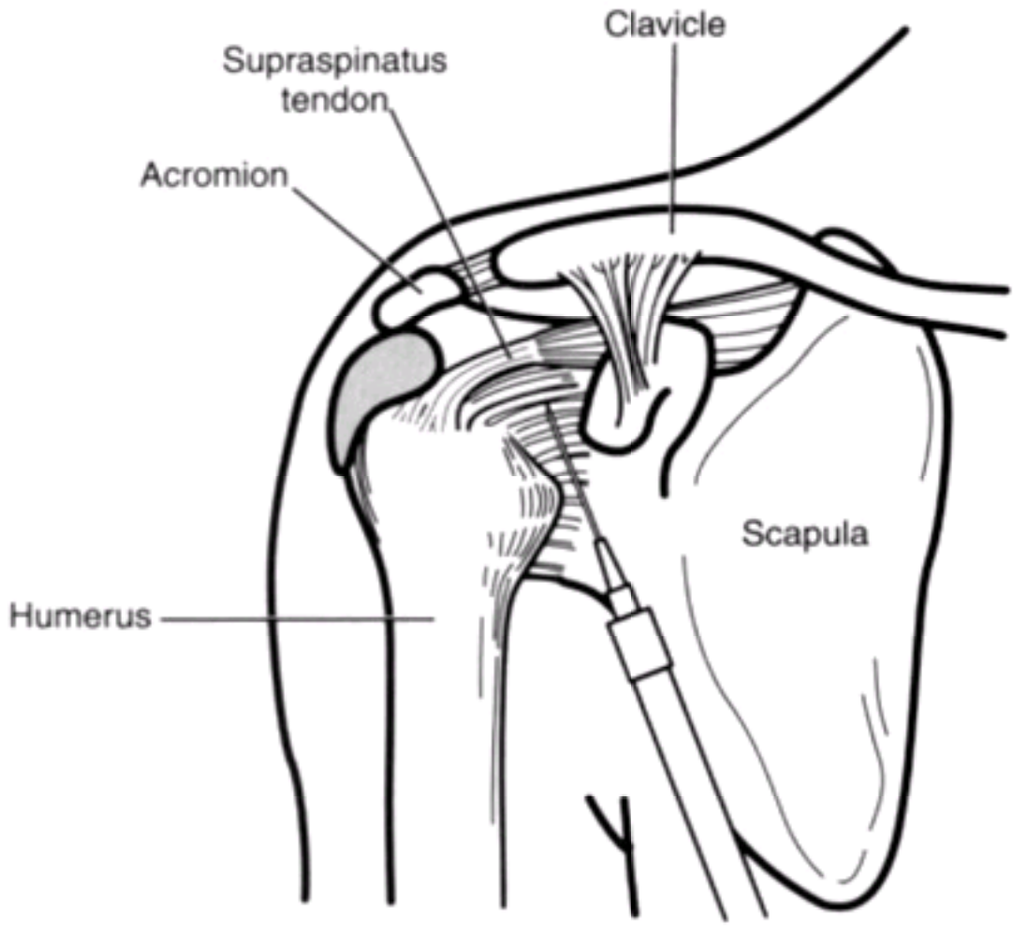

Figure 53-8 Posterolateral approach. *A,* The needle is inserted in the depression just inferior to the posterolateral tip of the acromion and superior to the head of the humerus. *B,* Injection using the posterolateral approach. The angle of entry should be approximately 15°.

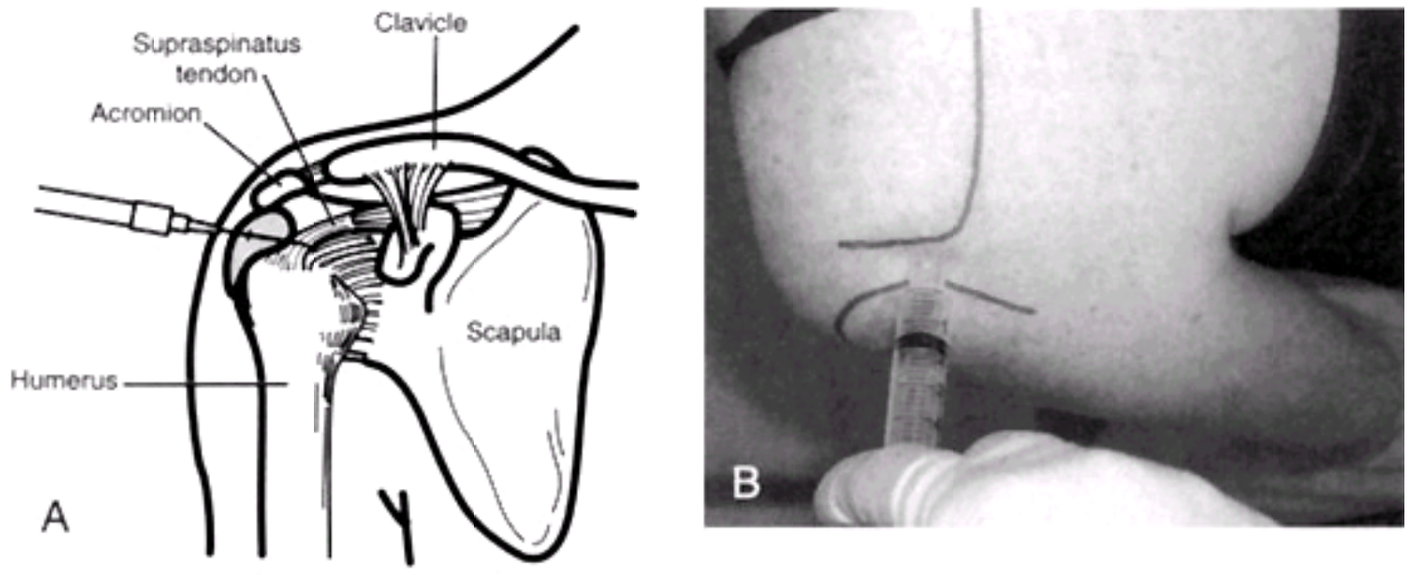

Figure 53-9 Injection of the acromioclavicular joint. Entry is made at the "V"-shaped depression at the most lateral aspect of the clavicle.

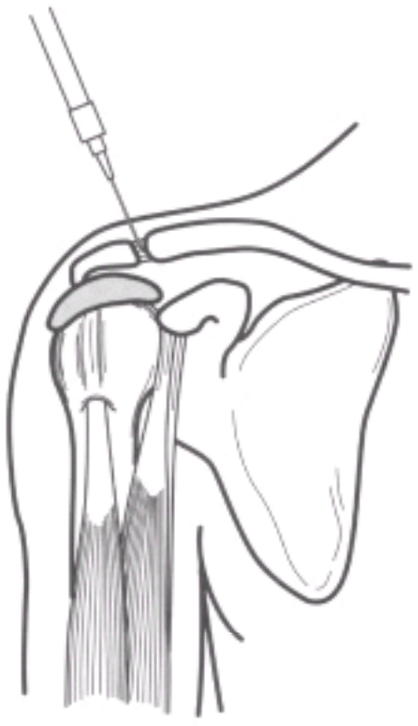

Figure 53-11 Clinical test for lateral epicondylitis. The patient extends the wrist against resistance, while the examiner localizes the site of maximal tenderness at the lateral epicondyle.

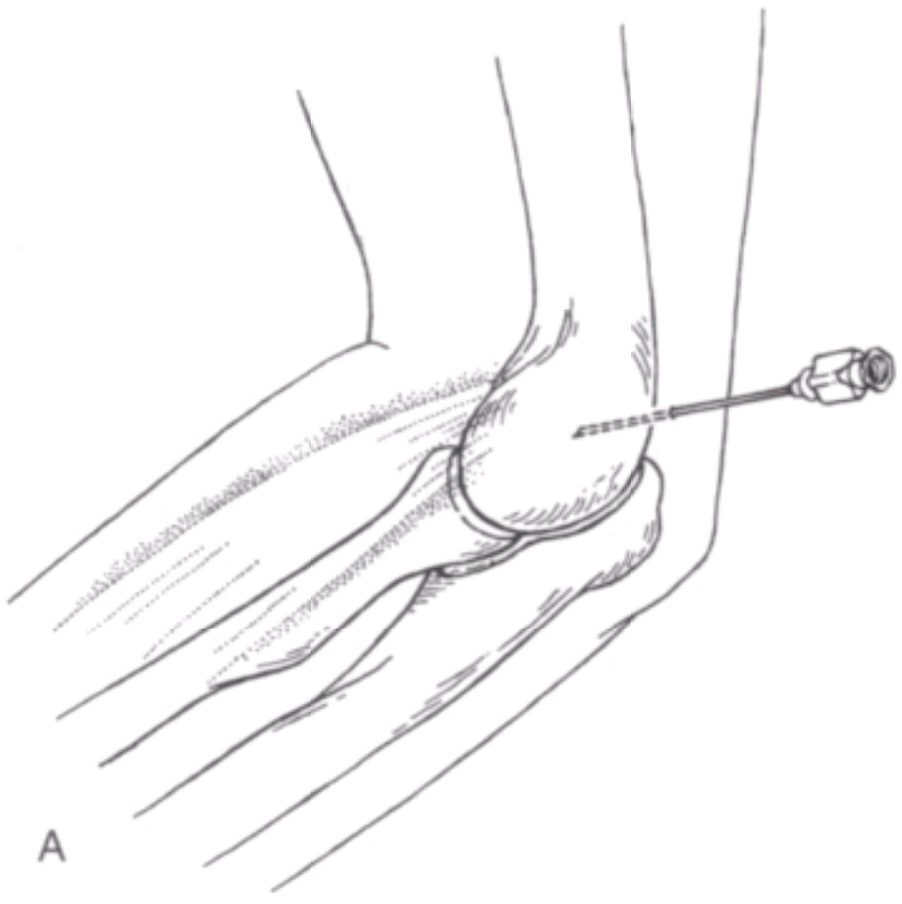
Figure 53-12 *A,* Injection at lateral epicondyle for treatment of "tennis elbow." *(Redrawn from steinbrocker O, Neustadt DH: Aspiration and Injection Therapy in rthritis and Musculoskeletal Disorders: A Handbook on Technique and Management. Hagerstown, MD, Harper & Row, 1972. Reproduced with permission.) B,* The needle is inserted in the area of maximal tenderness, avoiding injection directly into the tendon.



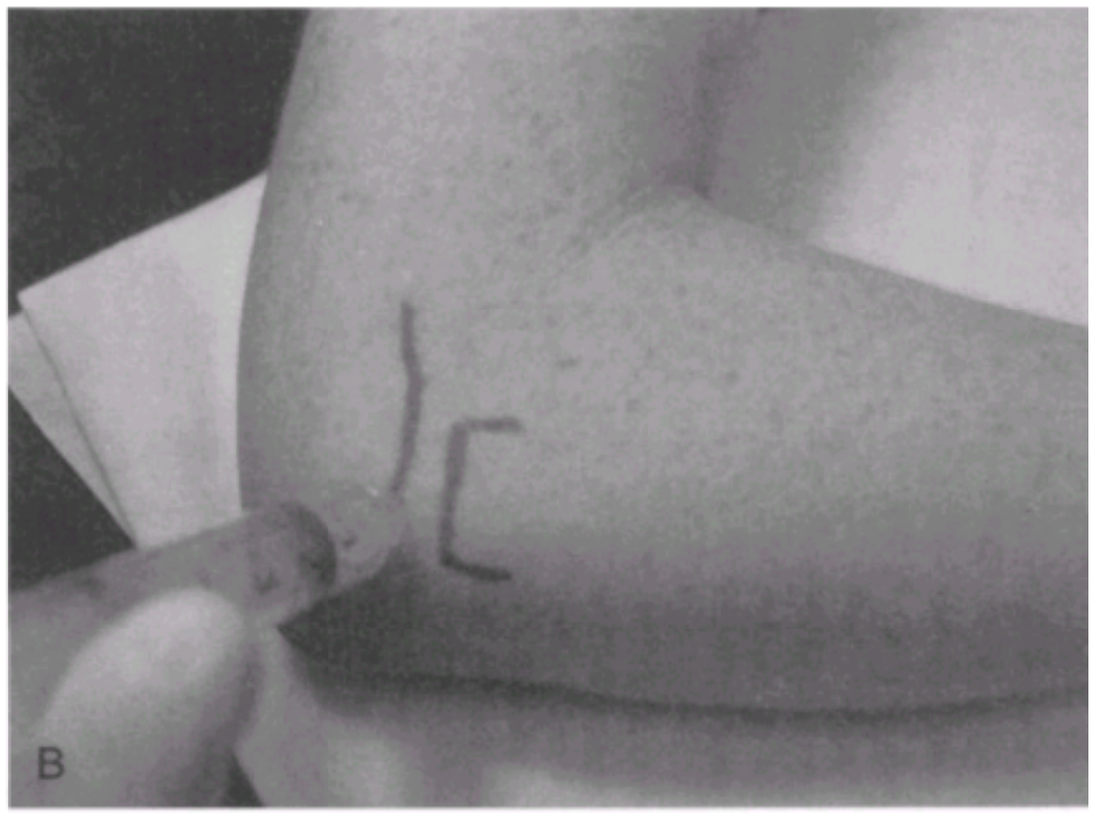


Figure 53-13 *A,* Anatomy showing location of the olecranon bursa superficial to the ulnar olecranon. *B,* traumatic painless swelling over the posterior elbow is characteristic of nonseptic olecranon bursitis. The mass is soft, movable, and fluctuant and is usually filled with serosanguineous fluid. *C,* Using sterile preparation, a 20-ga needle on a 10-mL syringe is advanced parallel to the forearm, and the bursal fluid is completely aspirated. *D,* The aspirating syringe is changed while the needle remains in the bursal sac, and a long-acting steroid preparation (such as 40 mg of methylprednisolone) is injected. An elastic bandage provides compression for 12 hours. *E,* An alternative posterior approach to the bursa. *F,* An extreme case of tophaceous gout involving the olecranon bursa. Most cases of acute gout bursitis resemble septic bursitis.

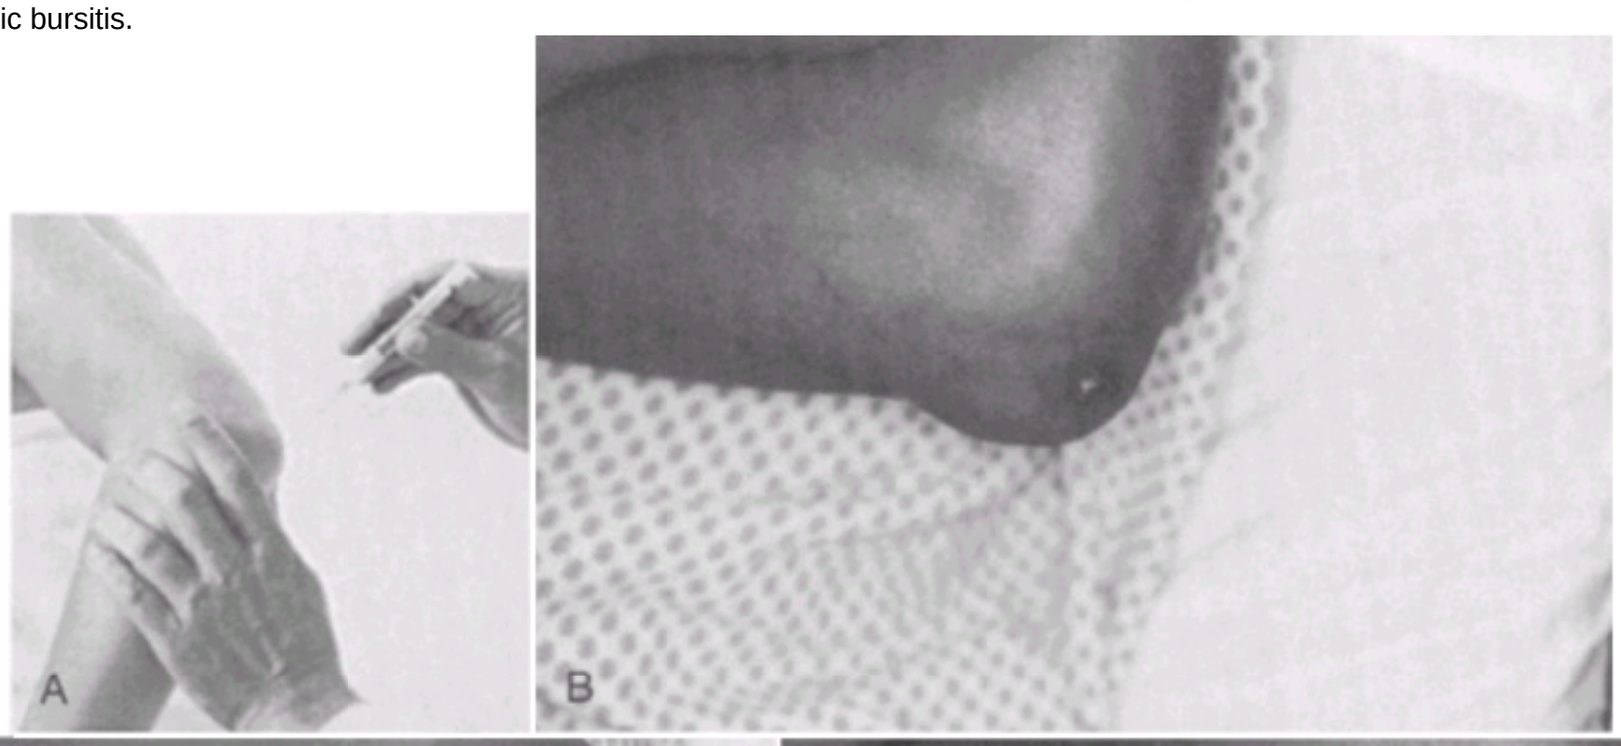

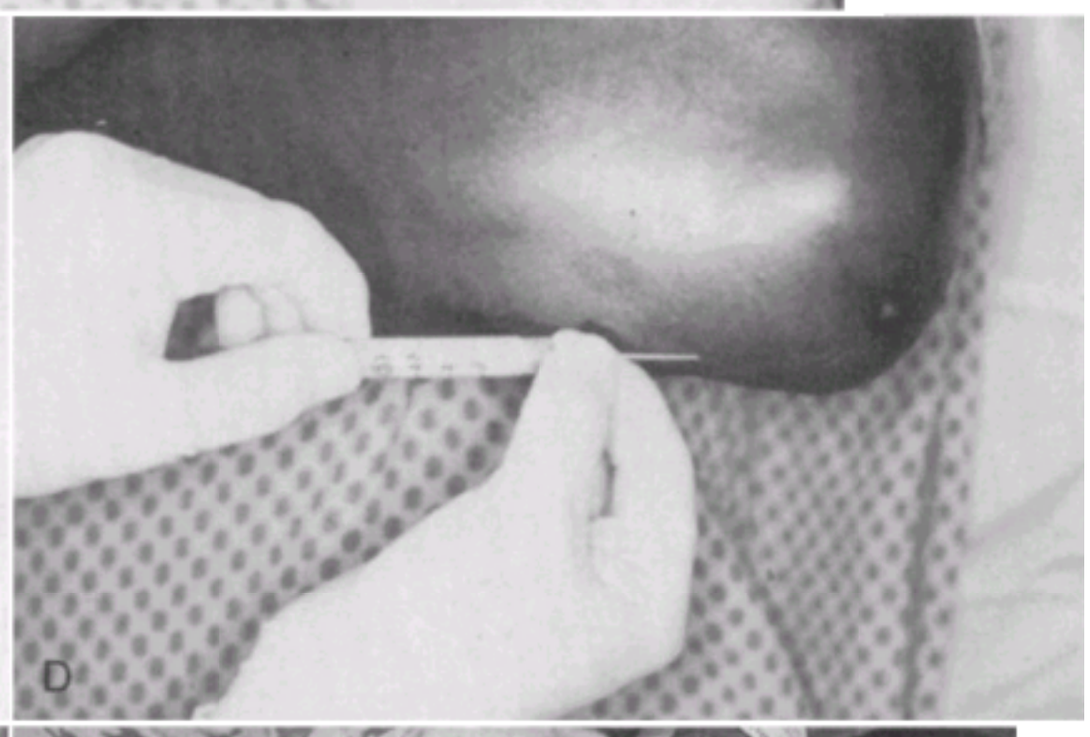

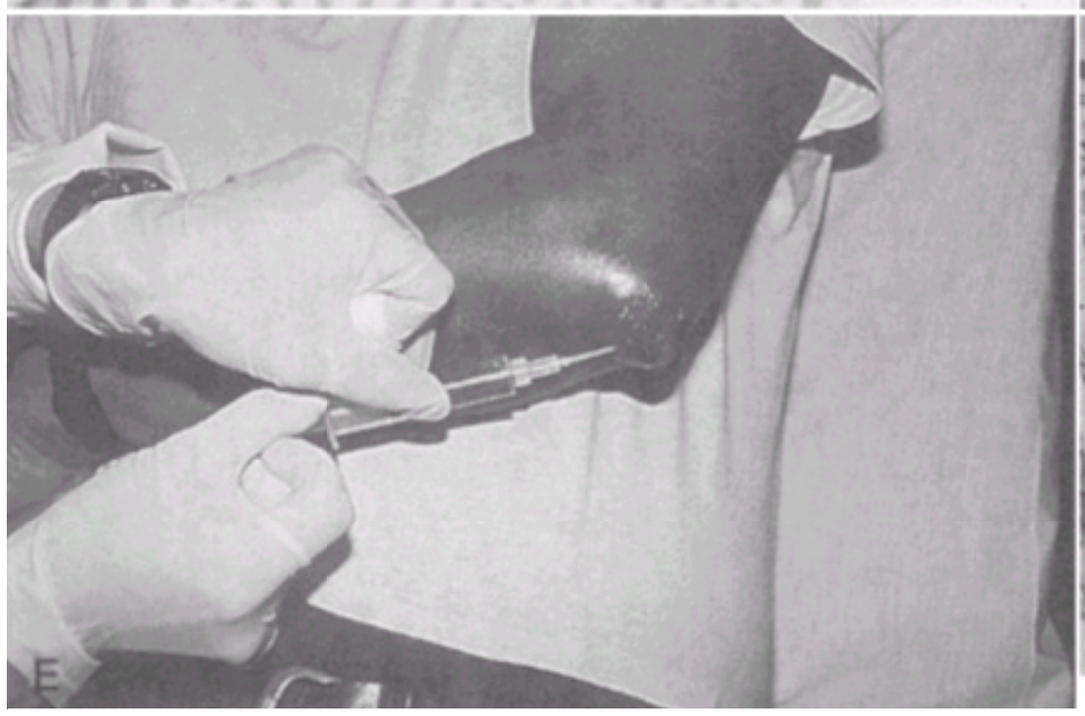

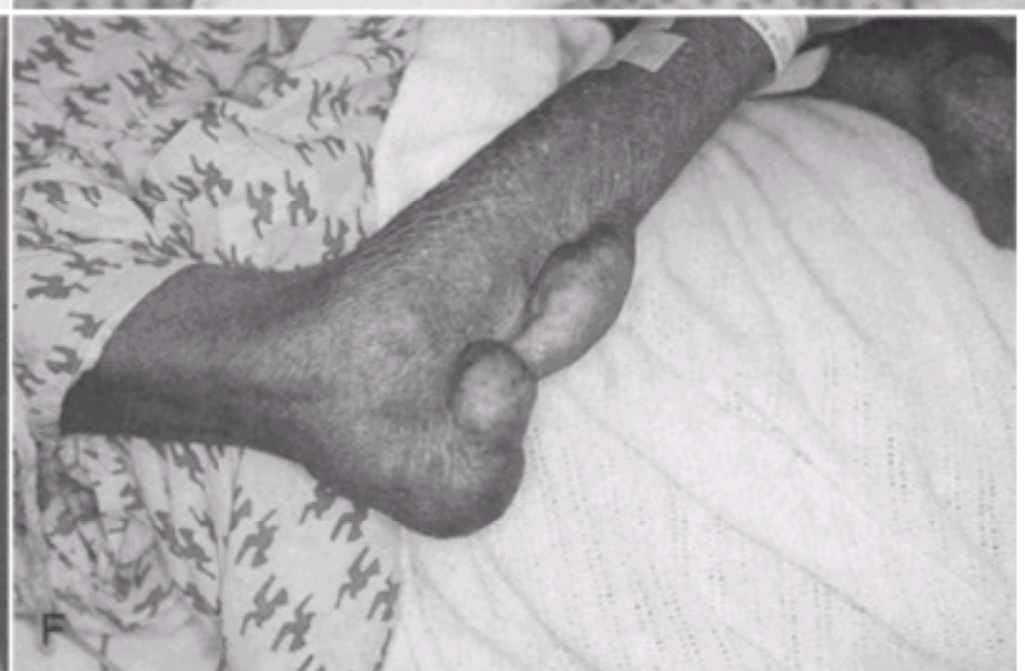

Figure 53-14 Fully developed septic olecranon bursitis is easily distinguished from nonseptic bursitis by clinical parameters. In the septic variety, there is diffuse swelling, as opposed to a discrete mass; the area is red, warm, and quite tender. In addition, bursal fluid leukocytosis is present.

Figure 53-15 A typical volar ganglion cyst of the wrist (*A*) and dorsum of the foot (*B*).

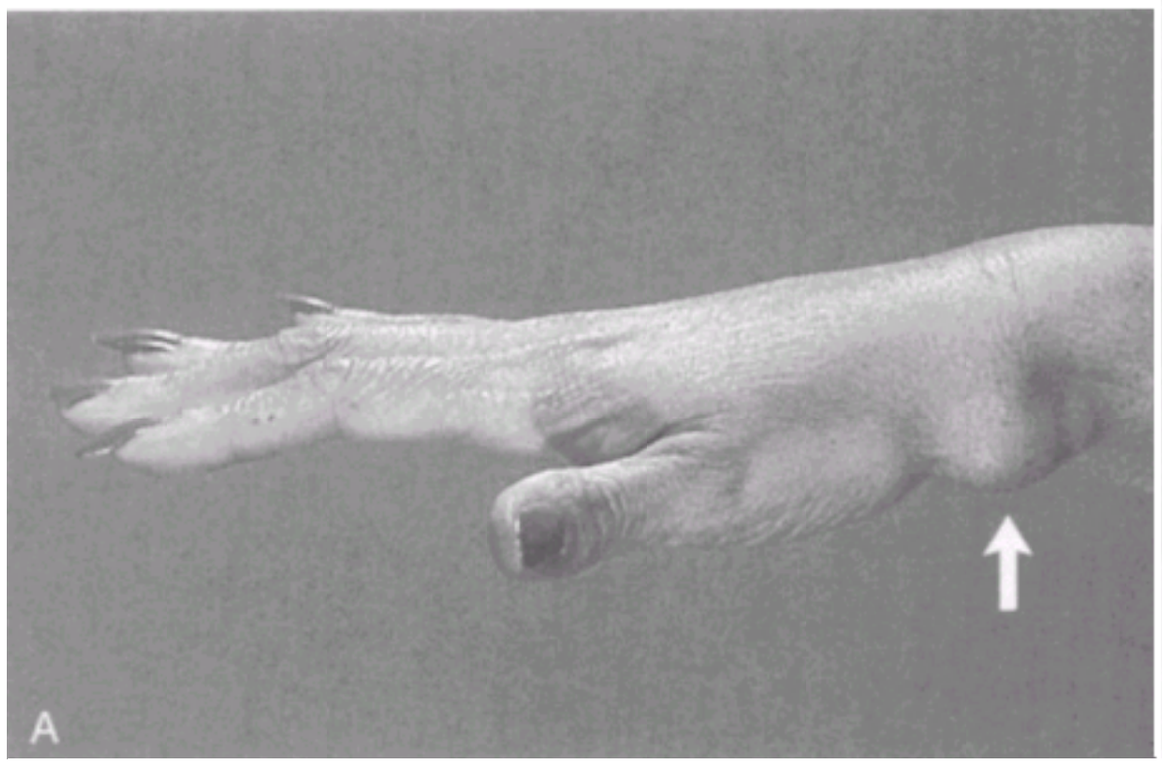

Figure 53-17 *A,* Site of de Quervain disease at the *extensor pollicis brevis* (EPB) and *abductor pollicus longus* (APL) tendons. *B,* Site of intersection syndrome at the *extensor carpi radialis longus* (ECRL) and *extensor carpi radialis brevis* (ECRB) tendons.

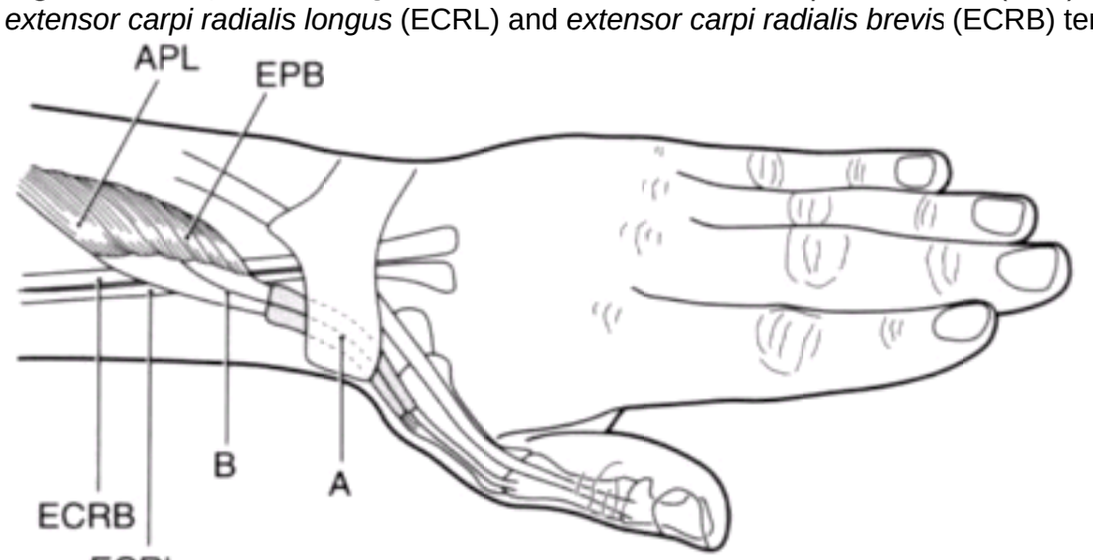

Figure 53-18 Photograph of a patient's wrist with intersection syndrome. Note that the swelling (arrow) is several centimeters *proximal* to the radial styloid, overlying the compartment of the common wrist extensors (*extensor carpi radialis longus* and *extensor carpi radialis brevis*). *(From Hanlon DP, Luellen JR: Intersection Syndrome: A case report and review of the literature. J Emerg Med 17:970, 1999. Reproduced with permission.)*

Figure 53-19 Injection of abductor tendon sheath (de Quervain disease). When giving an injection for de Quervain disease, it is desirable to avoid direct tendon injection and to instead aim for a peritendinous infiltration (*A*). If 3 to 4 mL of a local anesthetic is added to the steroid, generous infiltration over a diffuse area can compensate for a less than perfect localization (*B*). *(A from Steinbrocker O, Neustadt DH: Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders: A Handbook on Technique and Management. Hagerstown, MD, Harper & Row, 1972. B from Zingas C, Failla JM, Holsbeeck MV: Injection accuracy and clinical relief of de Quervain tendinitis. J Hand Surg 23a:89, 1998. Reproduced with permission.)*

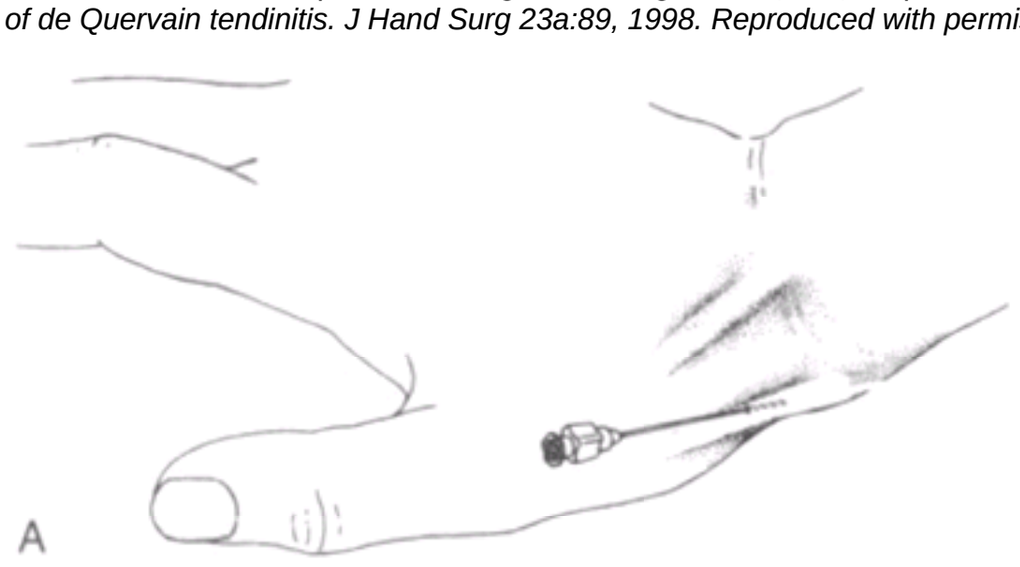

Figure 53-20 *A,* Injection of the median carpal tunnel with the wrist dorsiflexed over a rolled towel. To avoid direct injection of the median nerve, the needle is introduced just medial (ulnar) to the *palmaris longus* tendon. *B,* A palpable bulge at the distal edge of this ligament indicates correct placement of the injection. Direct injection into the median or ulnar nerve is to be avoided. *(A redrawn from Steinbrocker O, Neustadt DH: Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders: A Handbook on Technique and Management. Hagerstown, MD, Harper & Row, 1972. B from Dehaan MR, Wilson RL: Diagnosis and management of carpal tunnel syndrome. J Musculoskel Med 6:47, 1989. Reproduced with permission.)*

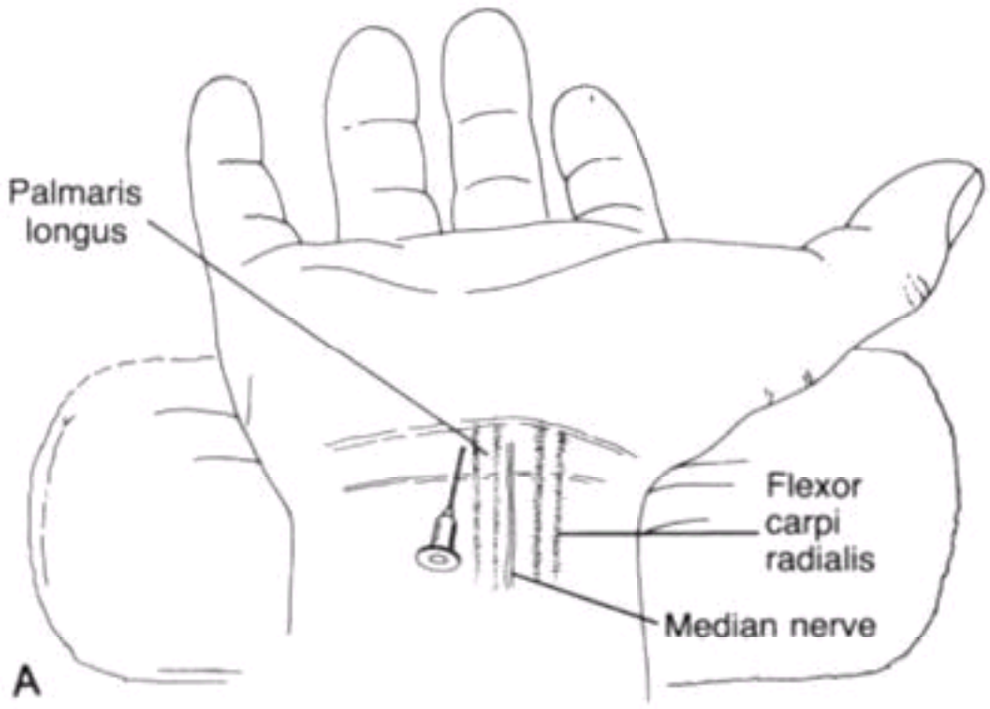

Figure 53-22 Injection of flexor tendon sheath in digital tenosynovitis.

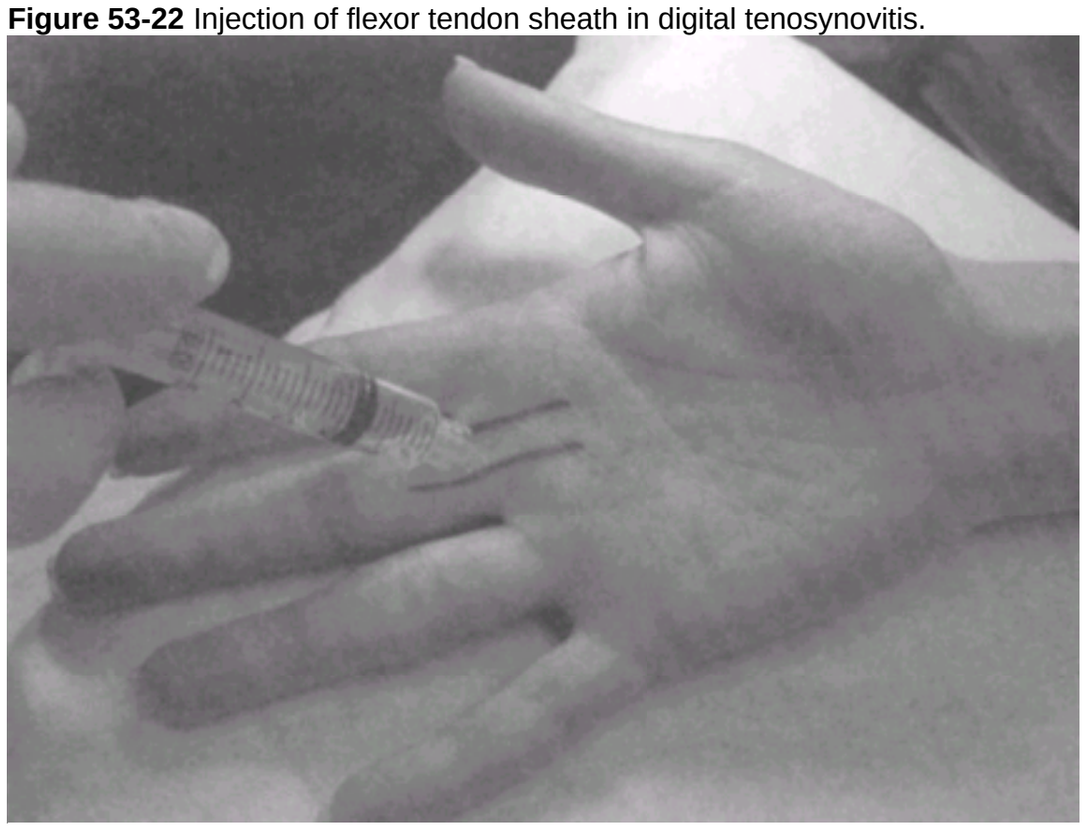

Figure 53-23 Trochanteric bursitis. The principal bursa lies between the gluteus maximus and the greater trochanter, although other bursae may also be involved.

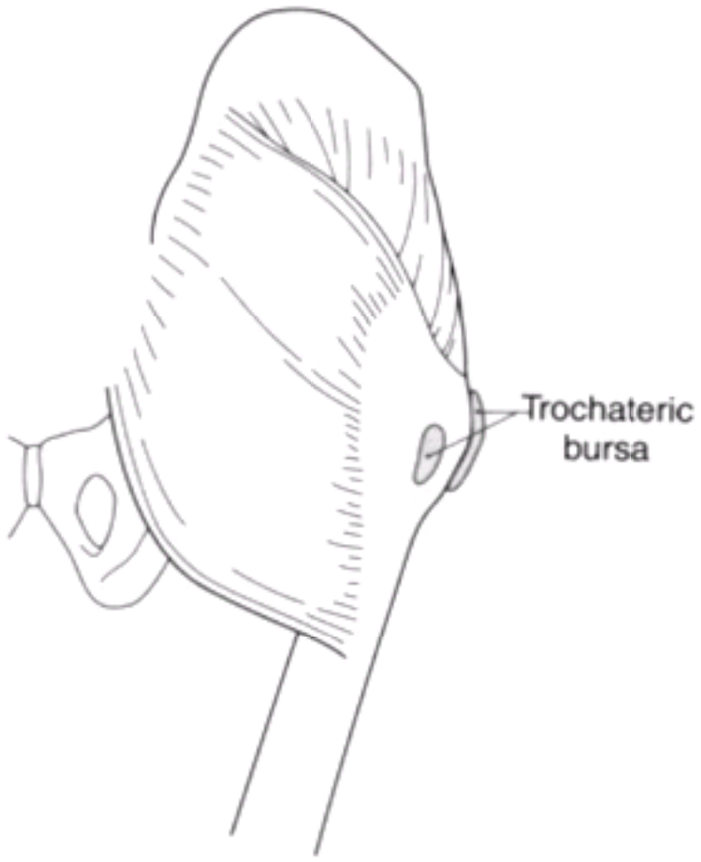

Figure 53-24 Prepatellar bursitis and *pes anserine* bursitis. The prepatellar bursa lies superior to the patella, while the *pes anserine* bursa lies deep to the insertion of the sartorius, gracilis, and semitendinosus tendons.

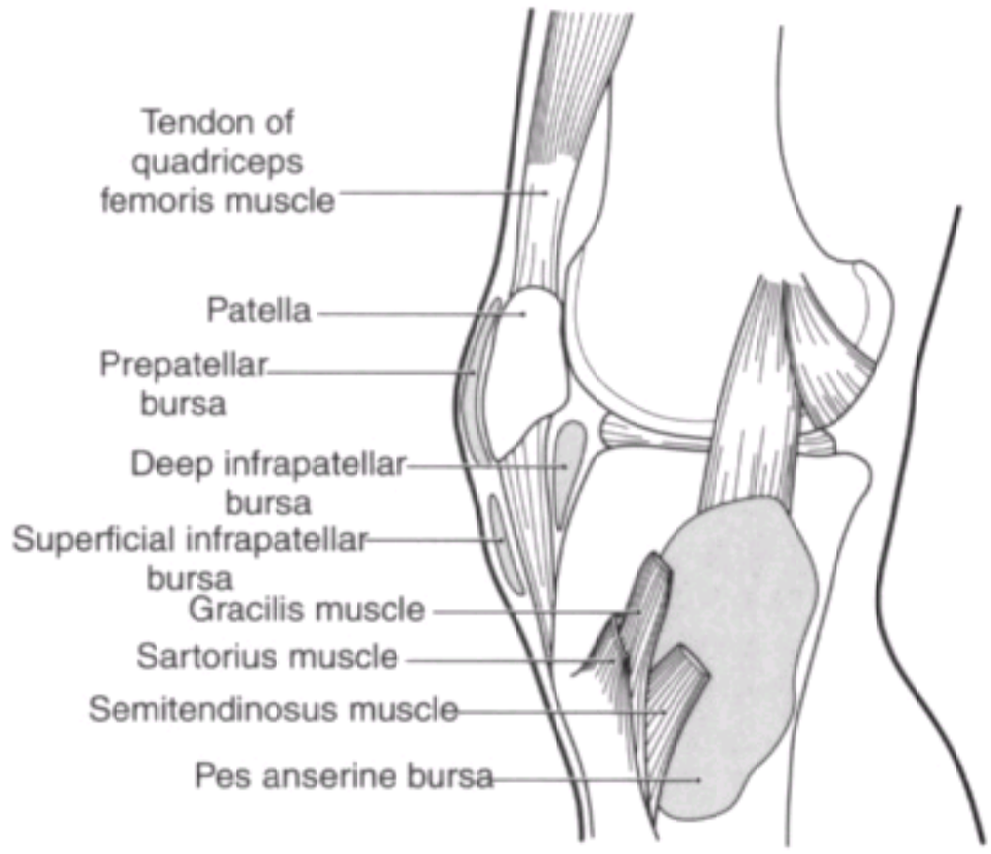

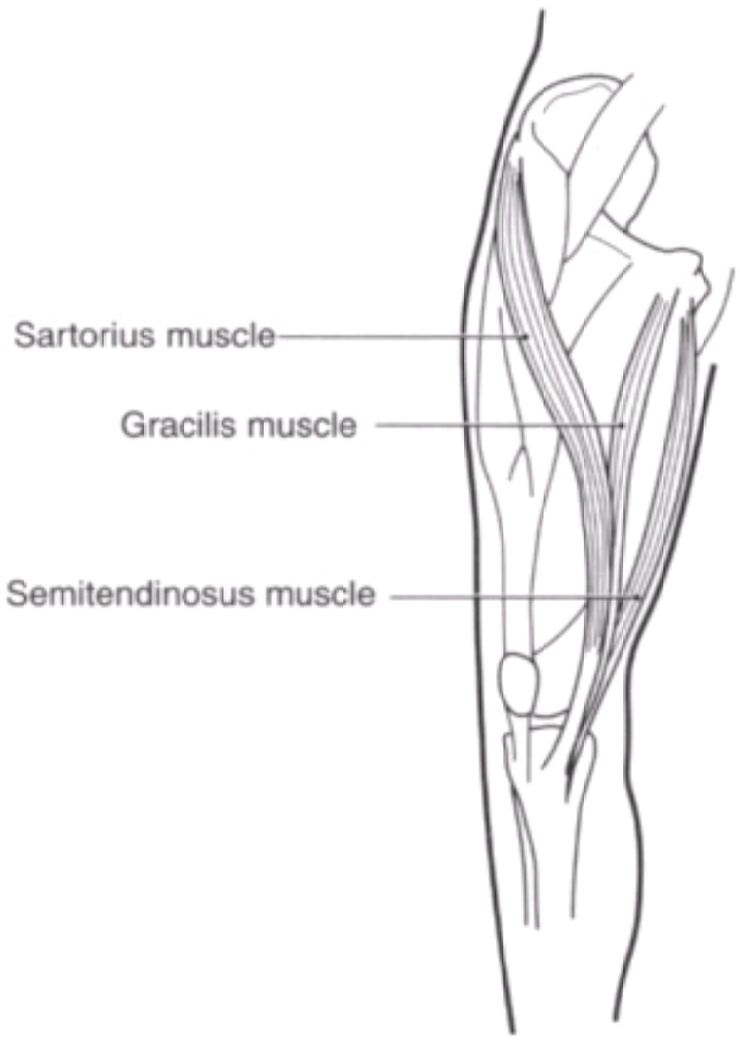

Figure 53-25 Injection of the anserine bursa of the knee. Note that the point of entry, which is the point of maximal tenderness, is inferior to the patella and medial to the tibial tuberosity.

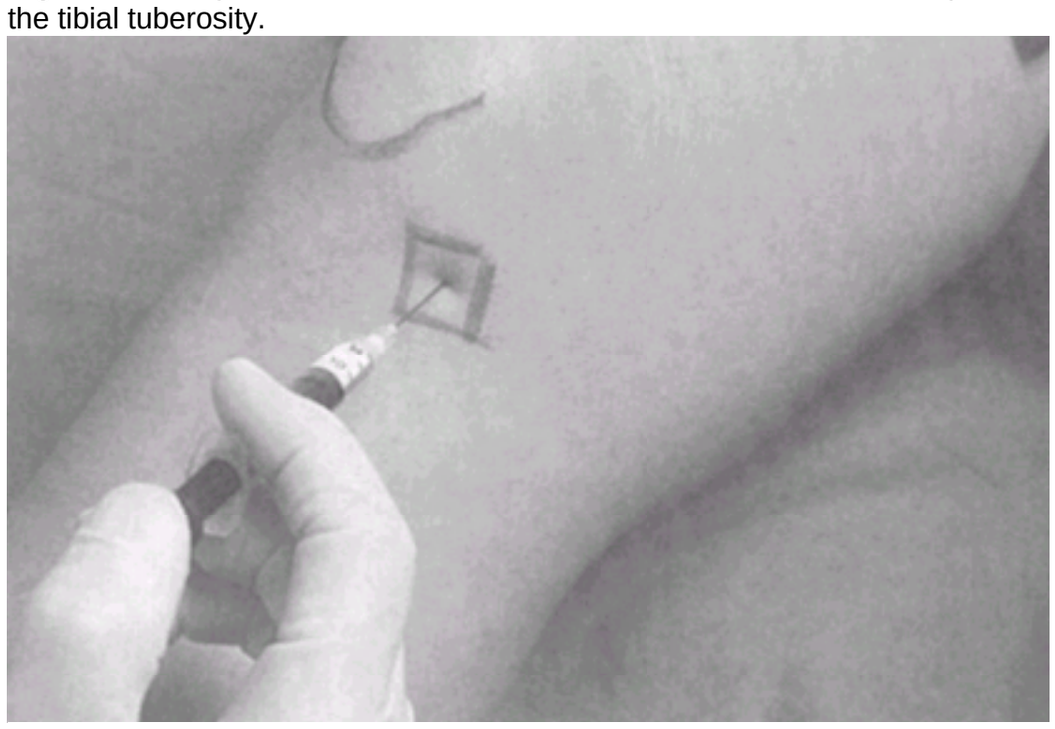

Figure 53-26 Heel pain. Talalgia may involve the tendons, bursa, or fascia around the heel.

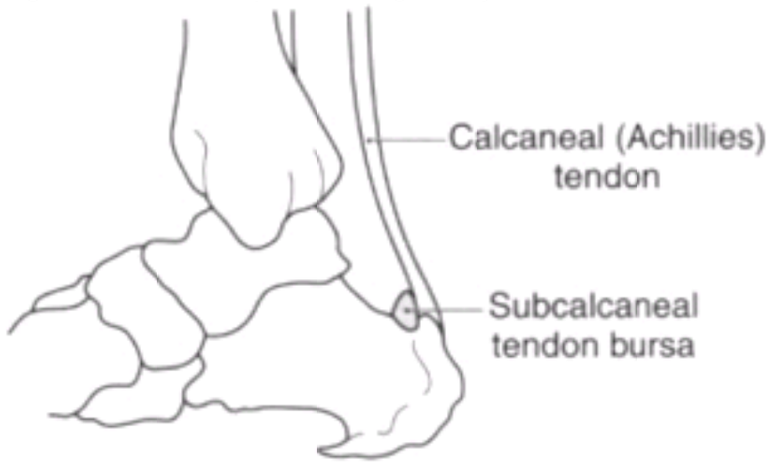

Figure 53-27 Injection of calcaneal bursitis with heel spur. *(Redrawn from Steinbrocker O, Neustadt DH: Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders: A Handbook on Technique and Management. Hagerstown, MD, Harper & Row, 1972.)*

Figure 54-1 Periarticular problems may mimic an intra-articular process. *A*, This patient had trauma to the knee and presented with anterior soft tissue swelling and fluctuance, representing a hematoma of the prepatellar bursa. *B*, While an assistant (gloves should be worn) compresses the fluid, the bursa is aspirated of all blood.

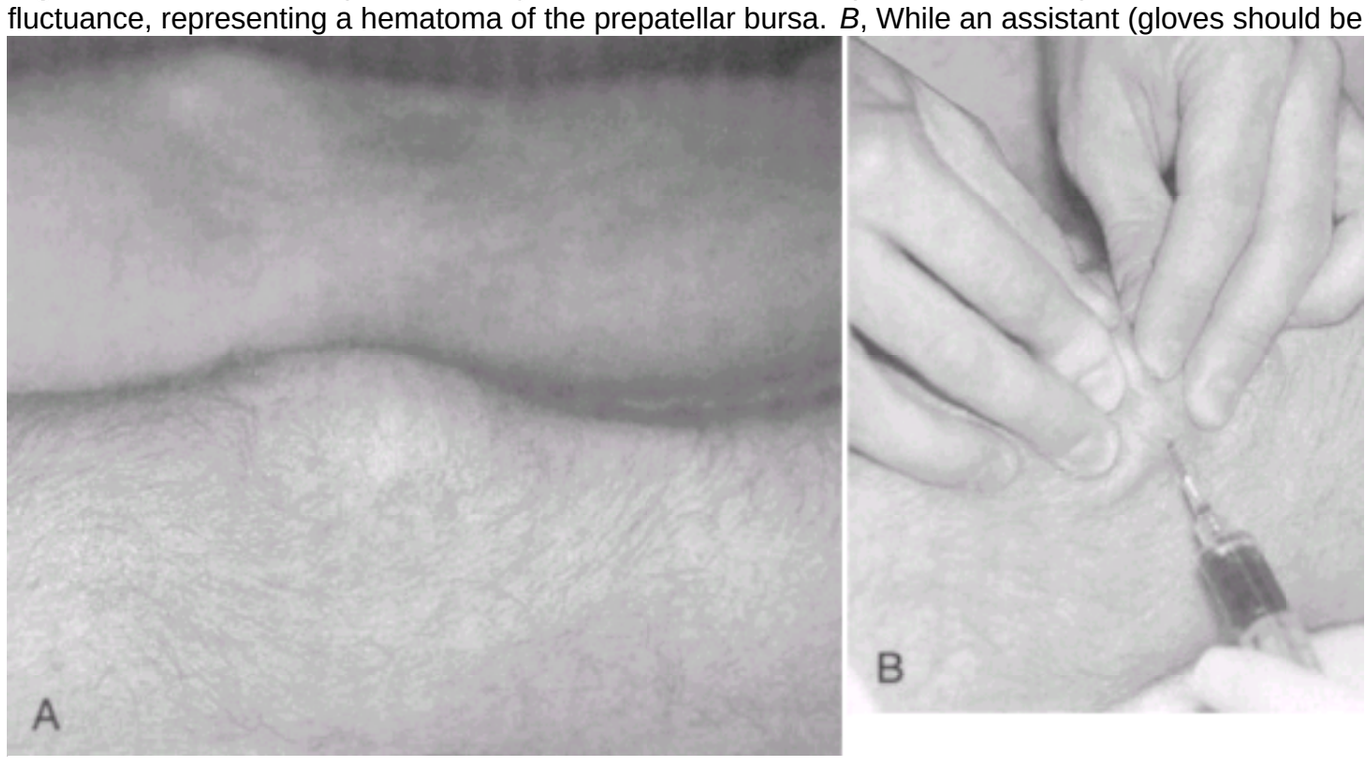

Figure 54-2 *A*, *B*, and *C*, Dramatic representation of tophaceous gout. These nodules are painless and full of uric acid crystals. An acutely swollen and painful joint in this patient is most likely acute gouty arthritis. *D*, This markedly swollen wrist is secondary to acute gouty arthritis. The patient had a fever and leukocytosis, and arthrocentesis with joint fluid analysis was the only way to differentiate gout from a septic joint.

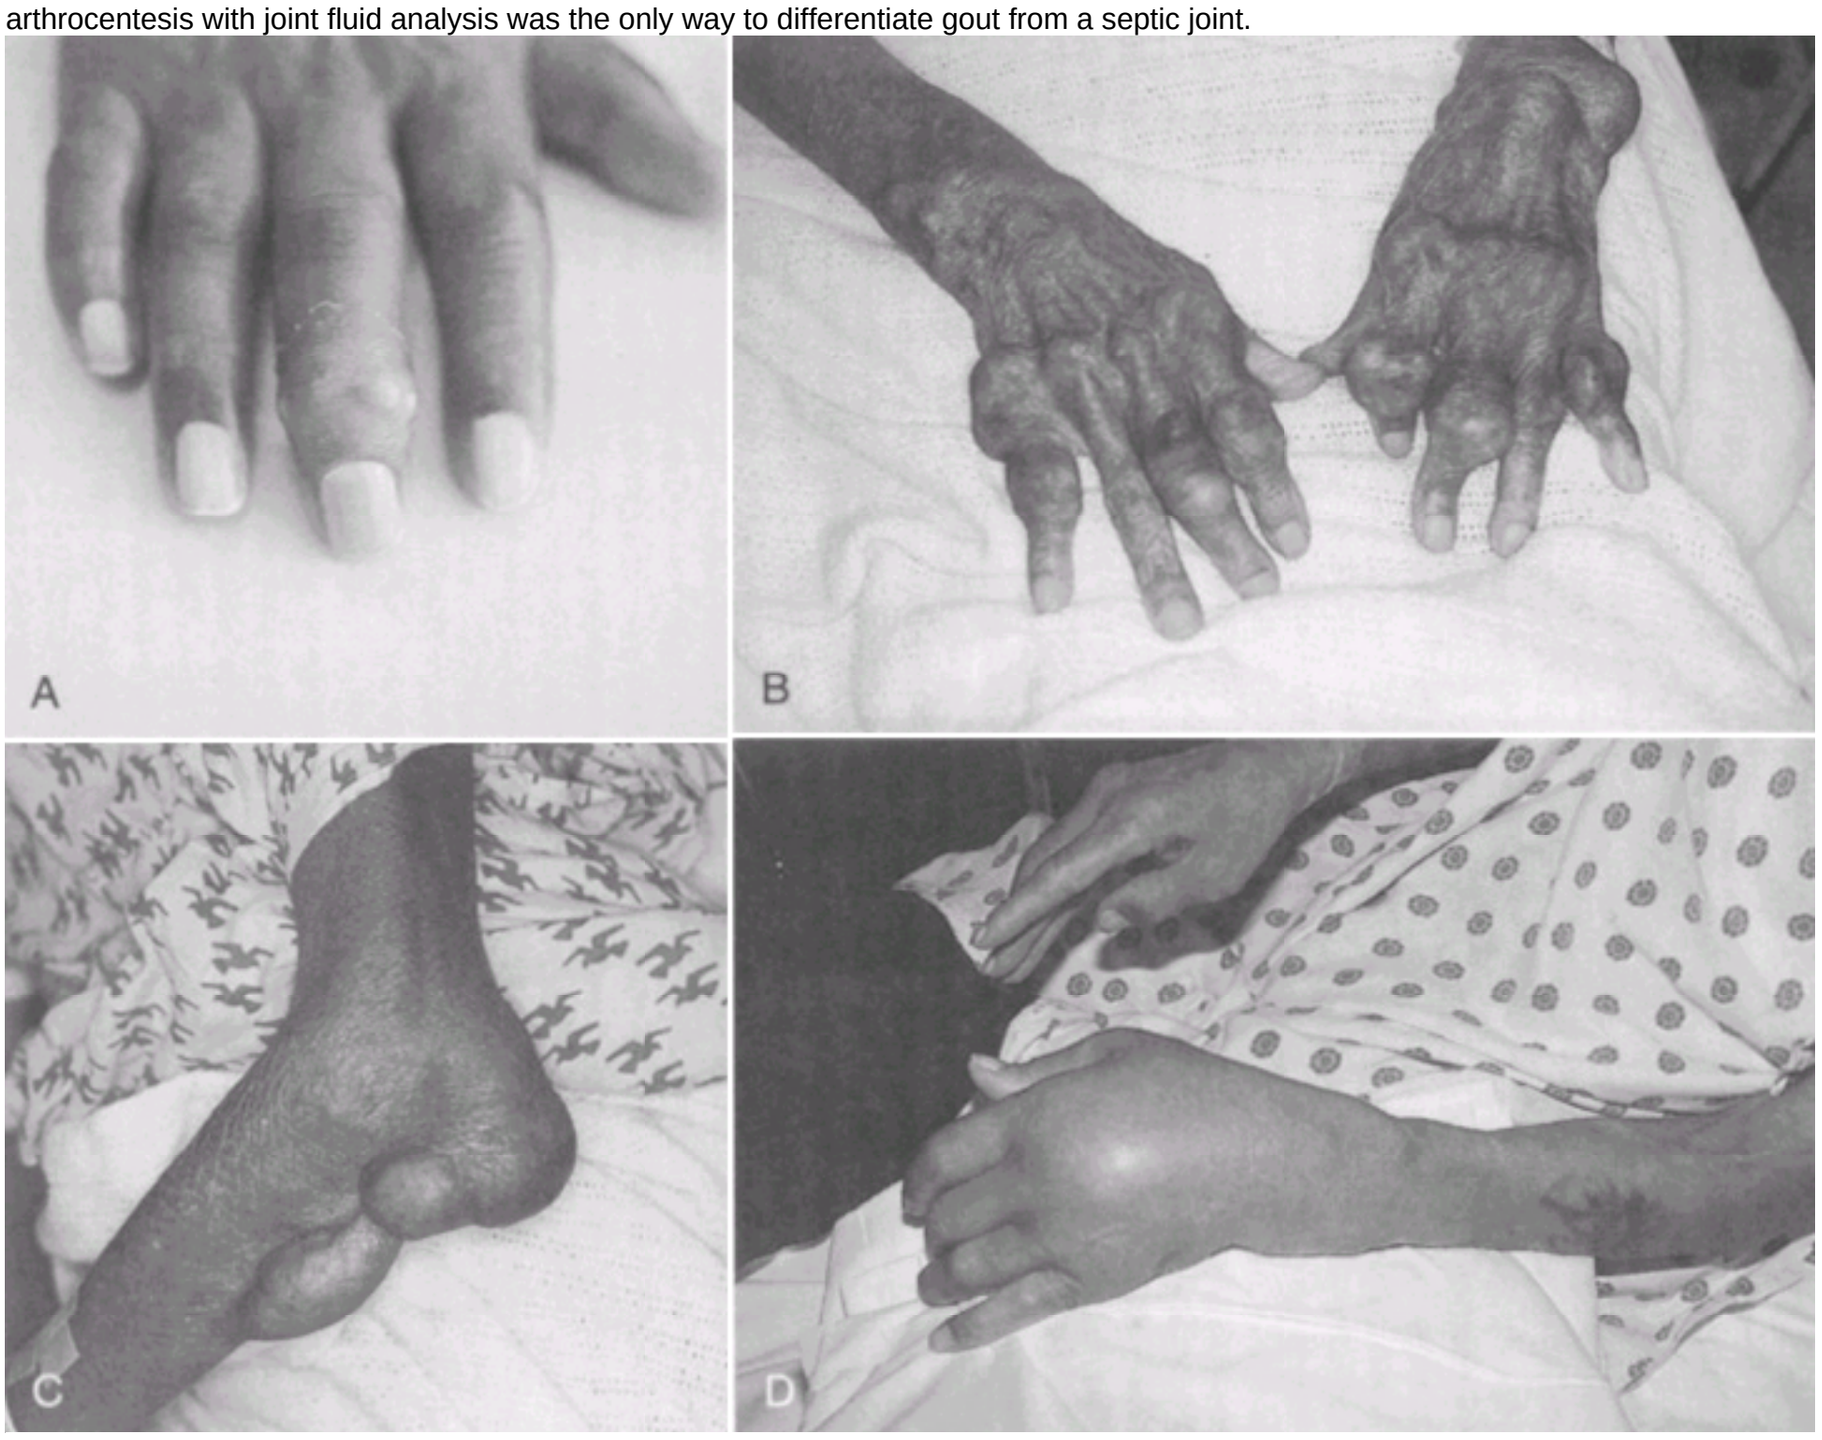

Figure 54-3 *A*, Skin lesions, ranging single or multiple petechiae to pustules may be seen in patients with acutely swollen joints infected with *Neisseria gonorrhoeae*. Skin lesions are usually found on the extremities, especially the feet and hands, and may be present before a large joint effusion accumulates, or with gonococcal tenosynovitis.

Figure 54-4 *A*, A chronic miniscus tear can produce a large effusion of clear yellow fluid. The miniscus has no blood supply, and a hemarthrosis suggests another or additional diagnosis. *B*, If the syringe is too small to accommodate all of the fluid, grasp the needle hub with a hemostat and remove the syringe without disturbing the correct position of the needle. A stopcock will negate the need to change the syringe. *C*, With the needle still held in place, use another syringe to instill a steroid when the aspirate is a clear yellow. *D*, Cloudy fluid such as this is from an inflammatory source, such as gout or a septic joint. Intra-articular steroids should not be administered in the setting of a cloudy aspirate.

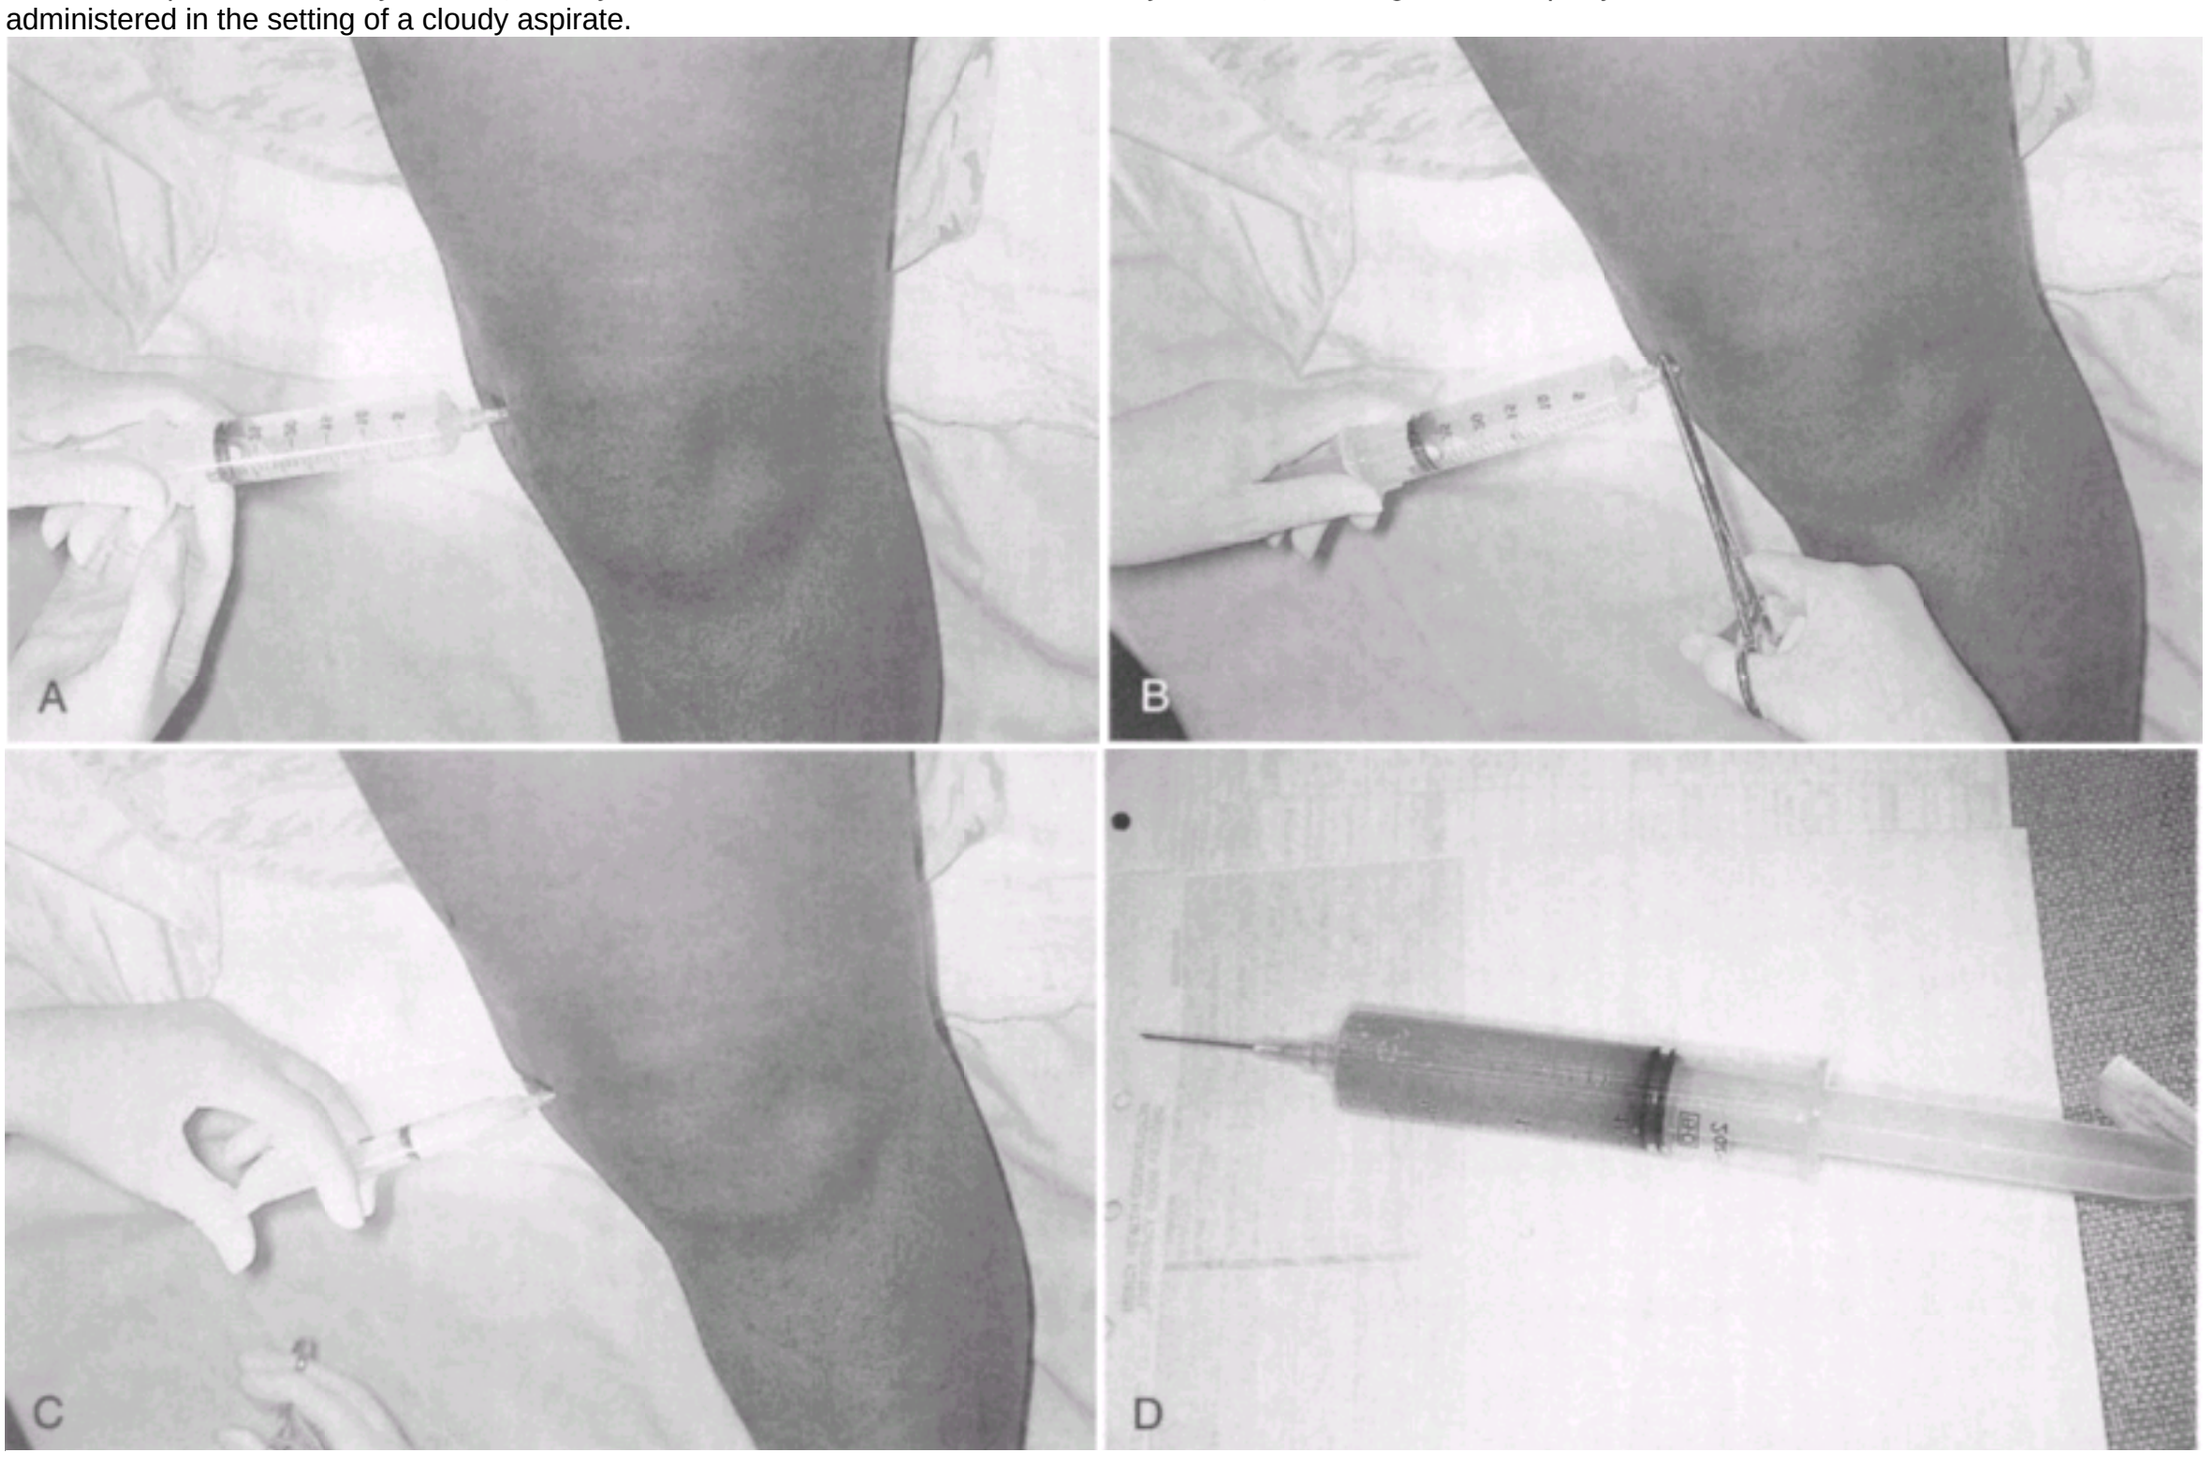

Figure 54-5 Landmarks for arthrocentesis of first carpometacarpal joint (see text). *(From Akins CM: Aspiration and injection of joints, bursae, and tendons. In Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

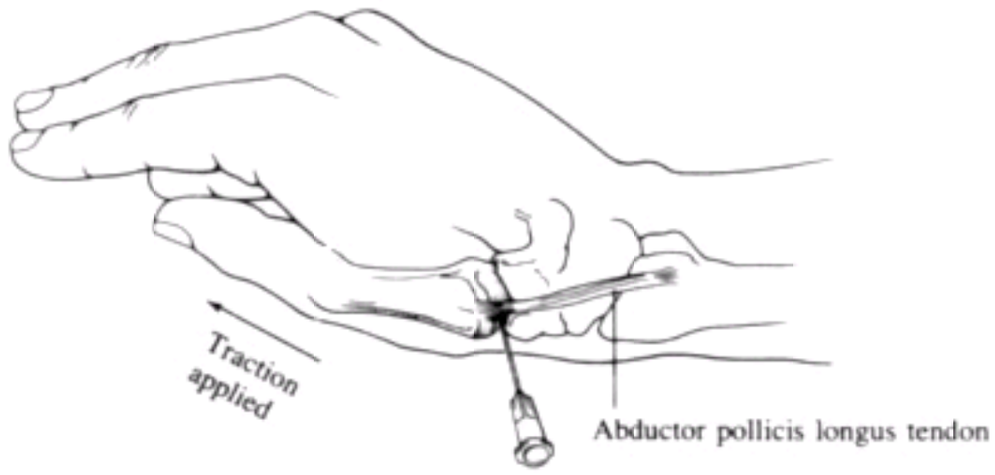

Figure 54-6 Landmarks for arthrocentesis of interphalangeal and metacarpophalangeal joints (see text). *(From Akins CM: Aspiration and injection of joints, bursae, and tendons. In Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

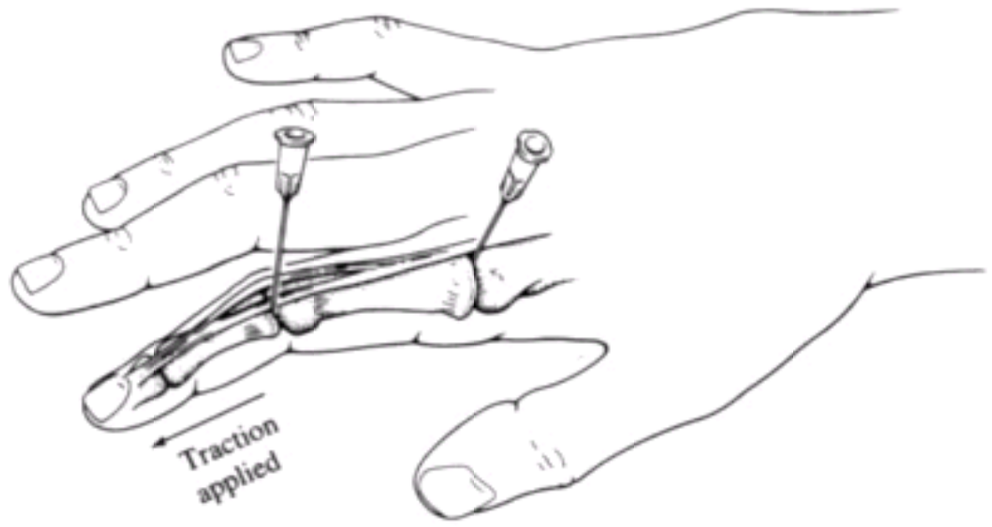

Figure 54-7 Landmarks for arthrocentesis of the radiocarpal joint (see text). Traction is applied with slight flexion. Contrary to the figure, *no* radial deviation is applied. *(From Akins CM: Aspiration and injection of joints, bursae, and tendons. In Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

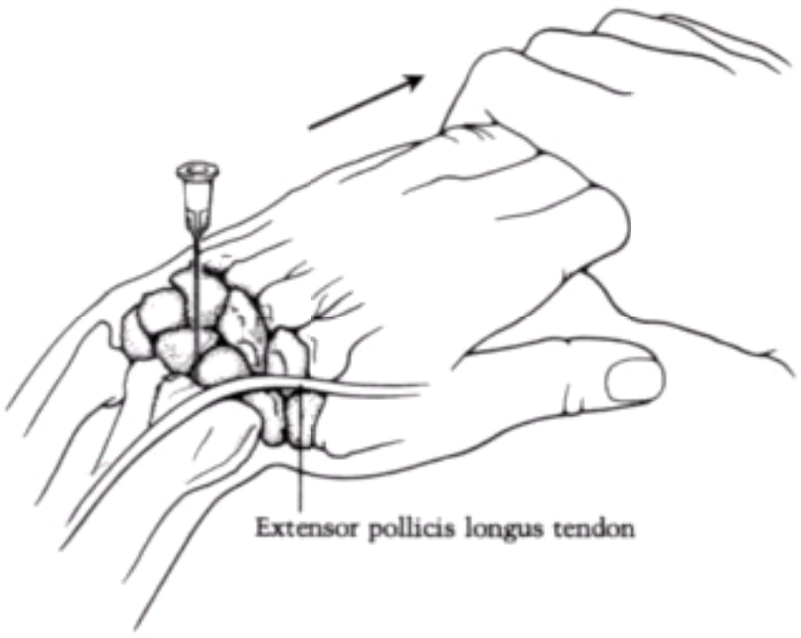

Figure 54-8 *A*, On a lateral elbow radiograph, displacement of the anterior fat pad (arrows) or the presence of a posterior fat pad (arrows) indicate blood, pus, or fluid in the joint. *B*, Landmarks for arthrocentesis of the radiohumeral joint (see text). *(From Akins CM: Aspiration and injection of joints, bursae, and tendons. In Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.) C*, An effusion in the elbow joint can usually be readily palpated. The index finger is placed over the lateral epicondyle and slid posteriorly toward the olecranon. Usually a depression is felt as the finger leaves the epicondyle, but a bulge is appreciated if there is a joint effusion. *D*, Removal of only a few milliliters of blood will reduce pain and hasten recovery of the range of motion. The most common pathology following trauma with an x-ray negative for fracture, but positive for a hemarthosis, is a nondisplaced radial head fracture.

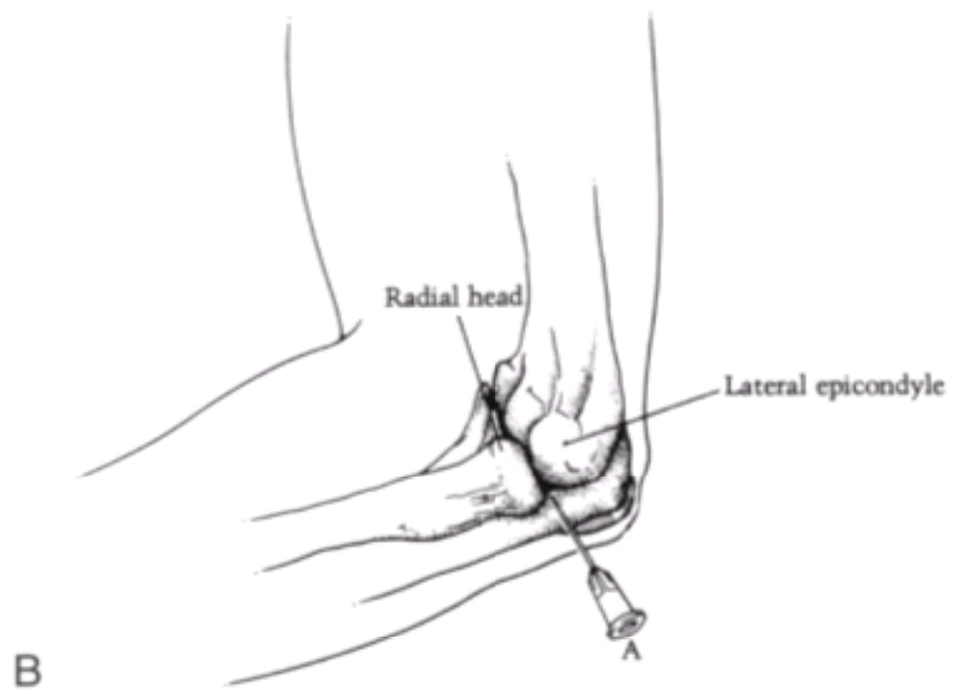

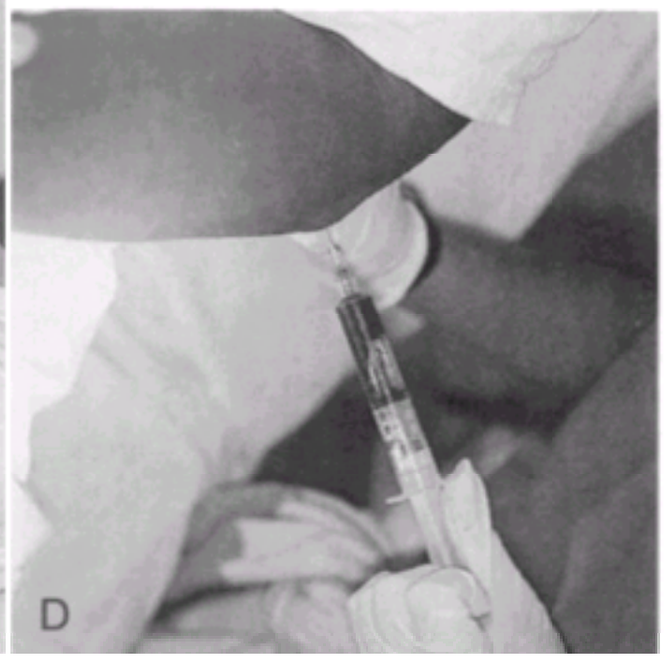

Figure 54-9 Landmarks for arthrocentesis of glenohumeral joint (see text). *(From Akins CM: Aspiration and injection of joints, bursae, and tendons. In Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

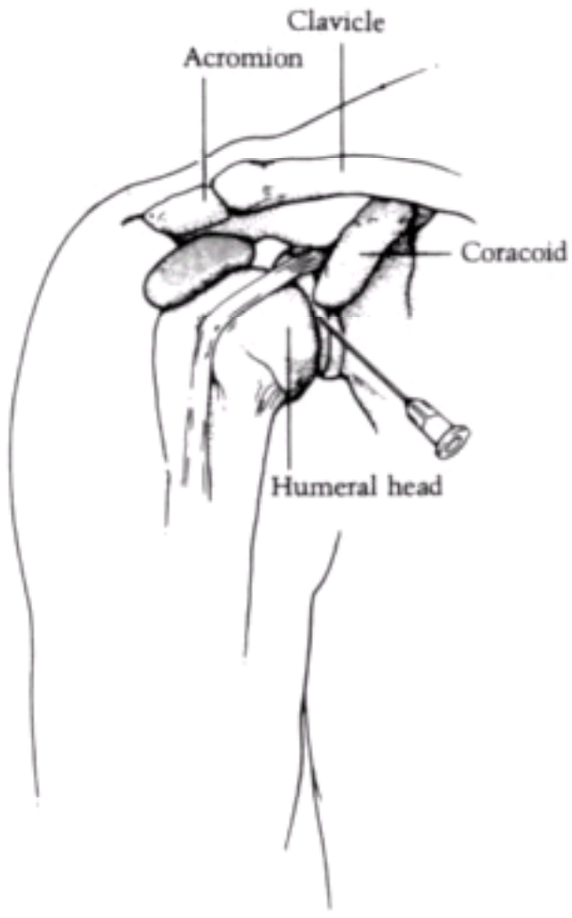

Figure 54-10 *A*, Landmarks for arthrocentesis of the knee joint, medial approach (see text). *B*, Note the use of a stopcock on the syringe to allow complete drainage without repositioning the needle. Compression of the suprapatellar region by the operator or an assistant will facilitate complete aspiration. For the knee, a 60 mL syringe should be used to drain large effusions. *(From Akins CM: Aspiration and injection of joints, bursae, and tendons. In Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

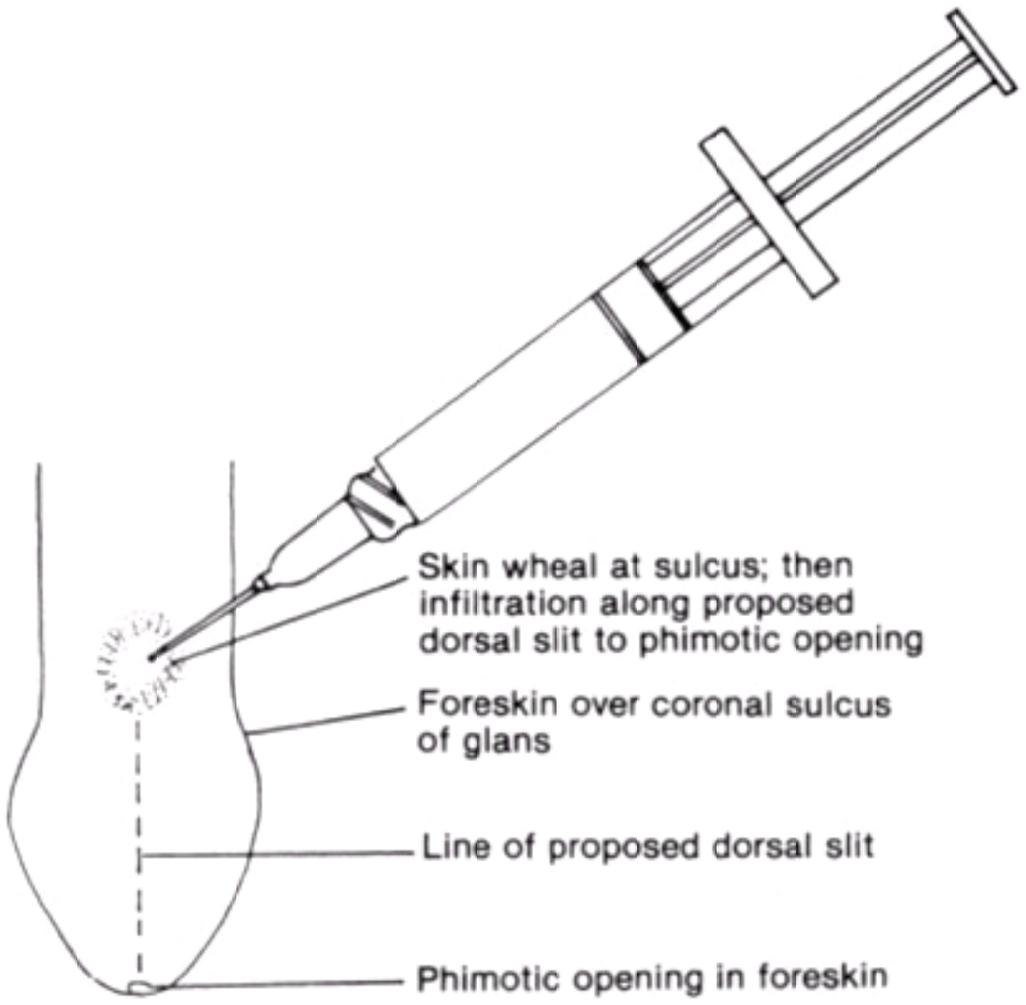

Figure 56-2 *A*, Dorsal nerve block at the base of the penis will provide anesthesia of only the dorsum of the penis. *B,* Circumferential subcutaneous lidocaine infiltration for a ("ring") field block at the base of the penis can provide anesthesia to the entire distal penis. *(A from Soliman MG, Tremblay NA: Nerve block of the penis for postoperative pain relief in children. Anesth Analg 57:495, 1978. Reproduced by permission.)*

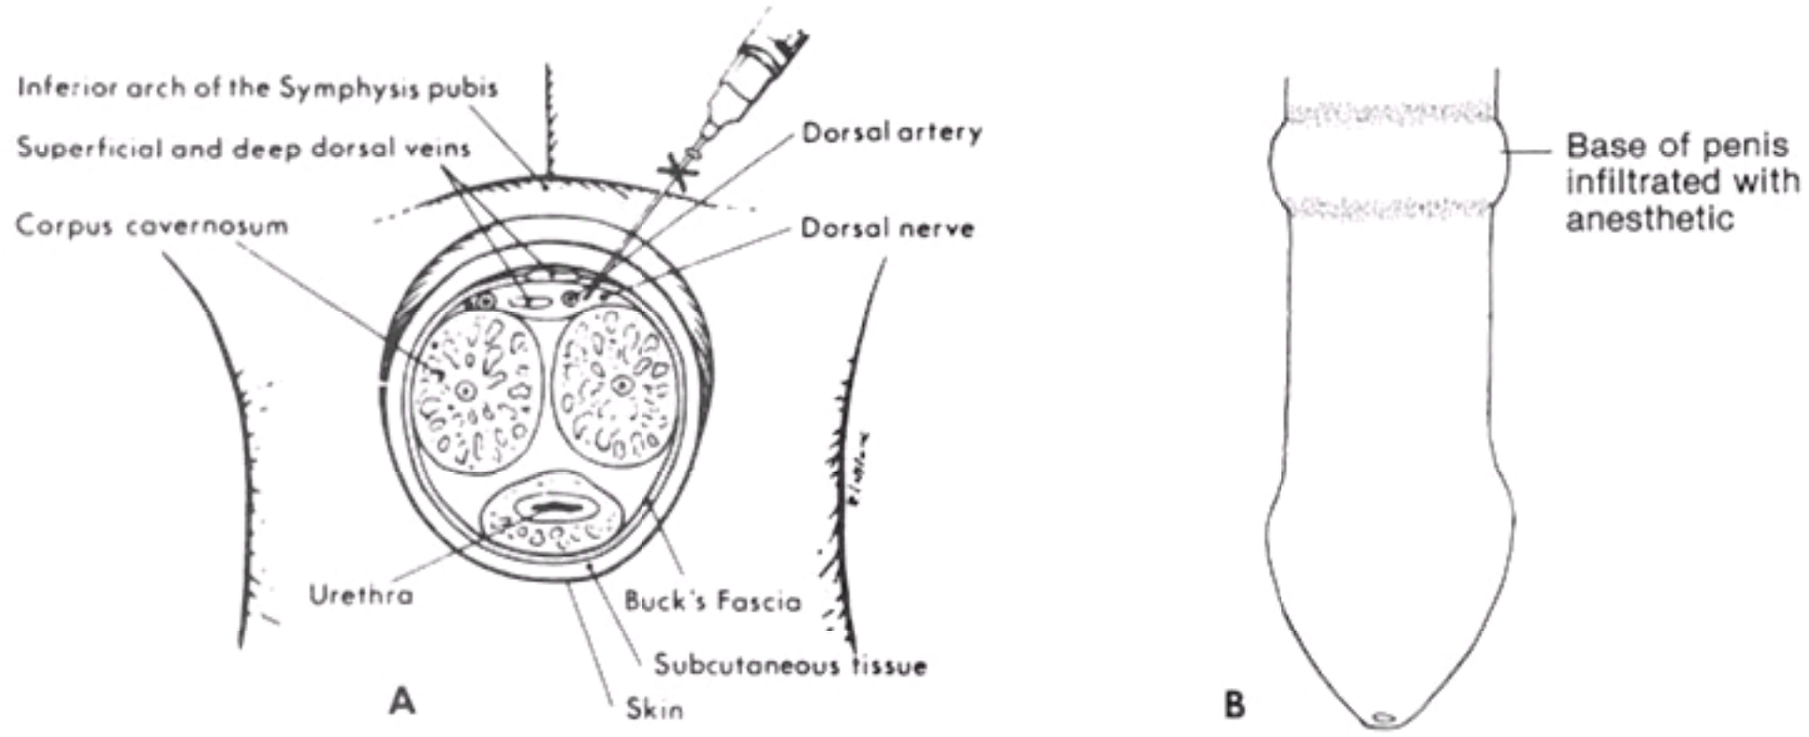

Figure 56-3 Placement of hemostat for treatment of phimosis. The "tenting up" of the foreskin in this manner proves that the tip of the hemostat is *not* in the urethra or under the glans. Once properly placed between the glans and overlying foreskin, the instrument is closed to crush the area of the foreskin to be cut.

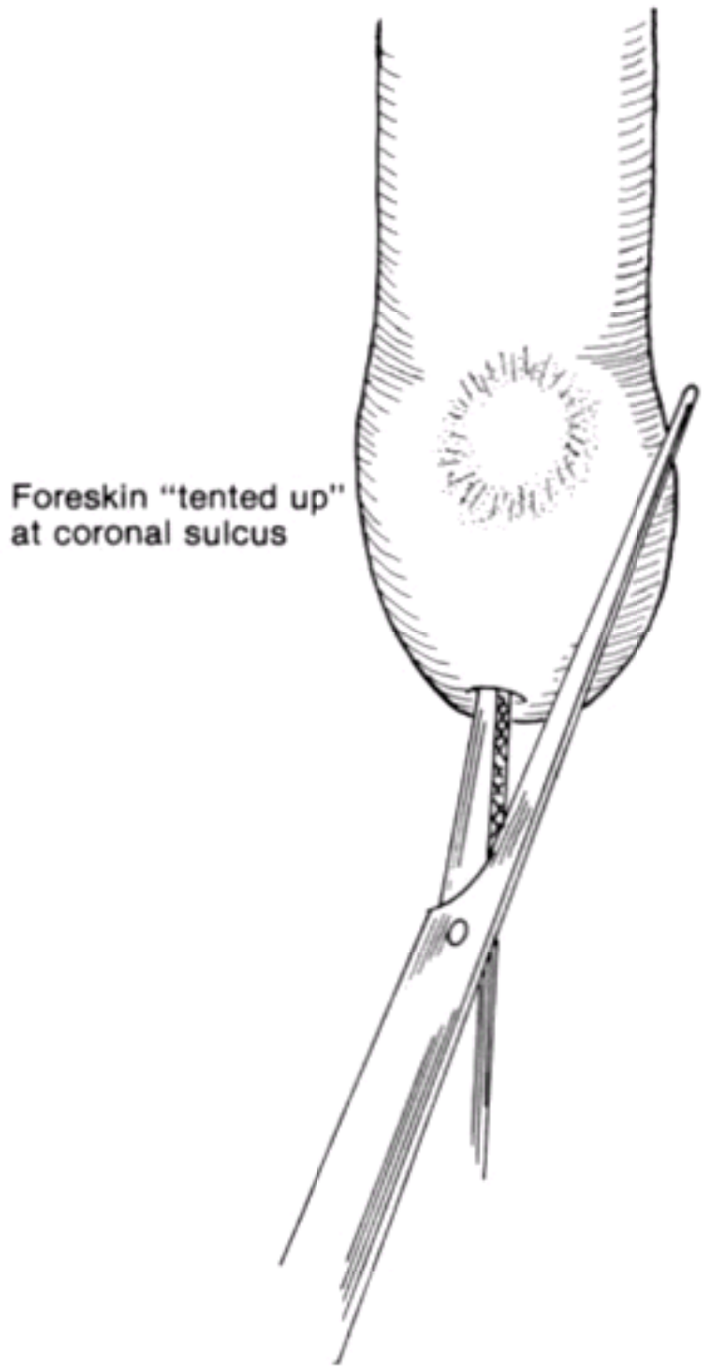

Figure 56-4 Treatment of phimosis. *A,* Dorsal slit in phimotic foreskin. Exposed glans is shaded. A single (dorsal) lengthwise incision has been made through crushed tissue (a^1, outer layer of foreskin; *a,* inner layer of foreskin). *B*, Cut edges of foreskin drawn back around glans penis. First, a^1 is sutured to *a*, then the remainder of the cut edges are sewn together for hemostasis. *C,* Final "beagle-ear" deformity of ventral transposed foreskin after the dorsal slit procedure has been completed. *D*, Postoperative appearance of dorsal slit.

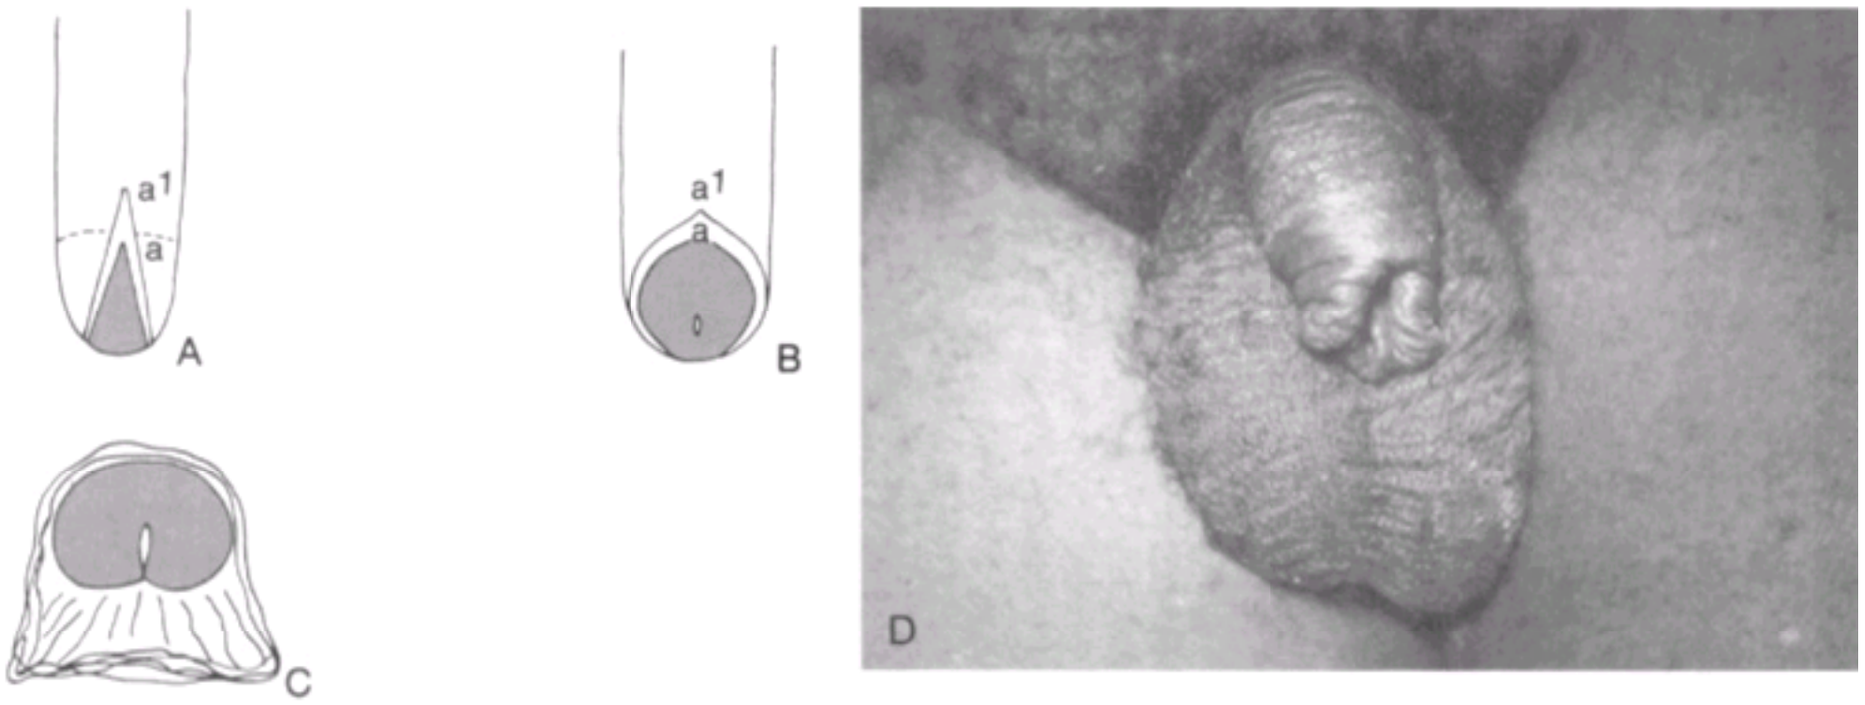

Figure 56-5 *A,* Paraphimosis, pictured here, may be mistaken for penile trauma, angioedema, or infection. The cause of paraphimosis in this case was failure to replace the foreskin following a catheter change in a demented nursing home patient. Prior to reduction, the catheter is usually removed. When the edema is minimal, the catheter may be left in place during reduction. *B,* Manual compression of the foreskin, or wrapping the penis with an elastic bandage for a few minutes, may reduce edema before a reduction of the paraphimosis is attempted. *C,* Technique for reduction of paraphimosis. Gentle, steady pressure is placed on the glans with the tips of the thumbs while gentle traction is applied to the foreskin. In this line drawing, the catheter is left in place during reduction. *D,* In a manner reminiscent of removing a rubber glove, the thumb forces the glans through the foreskin that is encircled by the entire palm to achieve final reduction *(E)*. *(C from Neuwirth H, et al: Genitourinary imaging and procedures by the emergency clinician. Emerg Med Clin North Am 7:1, 1989.)*

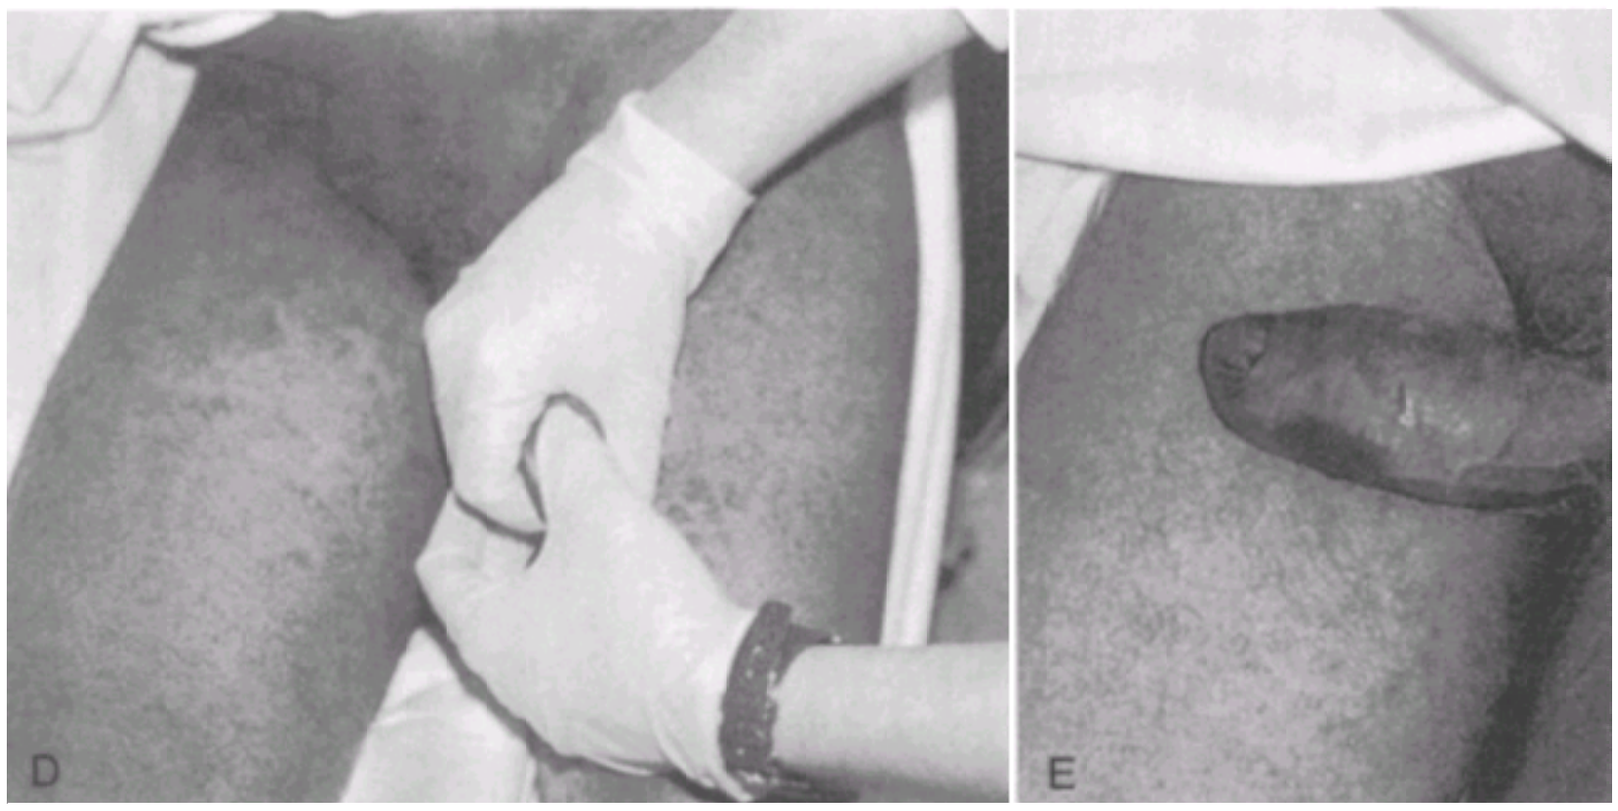

Figure 56-6 *A,* Application of Babcock clamps to reduce paraphimosis. *B,* Foreskin reduced. *(From Skoglund RW, Chapman WH: Reduction of paraphimosis. J Urol 104:137, 1970. Reproduced by permission. © Williams & Wilkins, 1970.)*

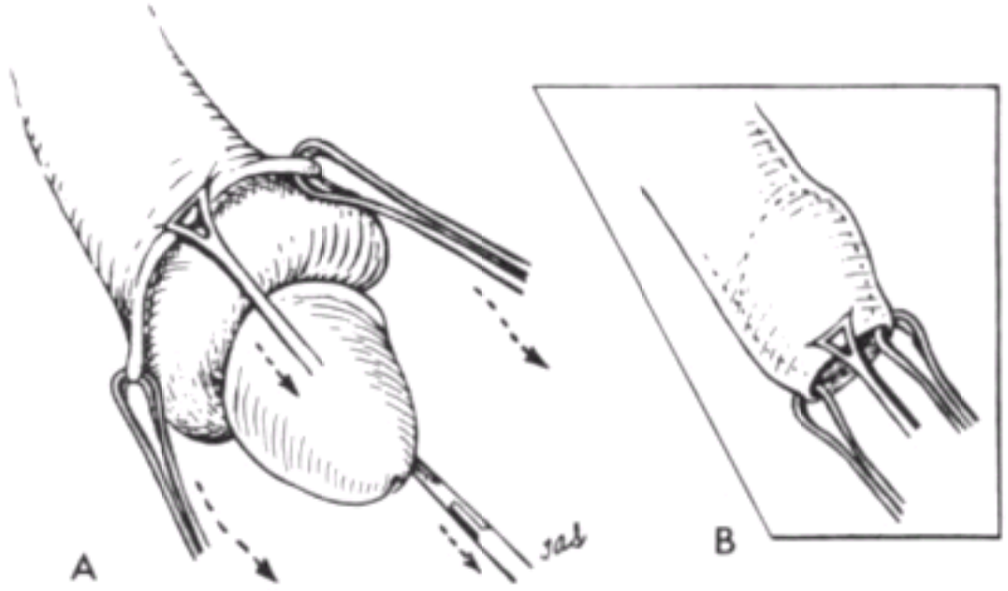

Figure 56-7 *A,* Anesthetizing the penis for surgical treatment of paraphimosis. Line of infiltration of local anesthesia used before performing dorsal slit. *B,* Incision for paraphimosis. Diamond-shaped defect resulting from incision of foreskin. The two apices of the dorsal slit *(a* and *b)* are approximated after the foreskin is reduced.

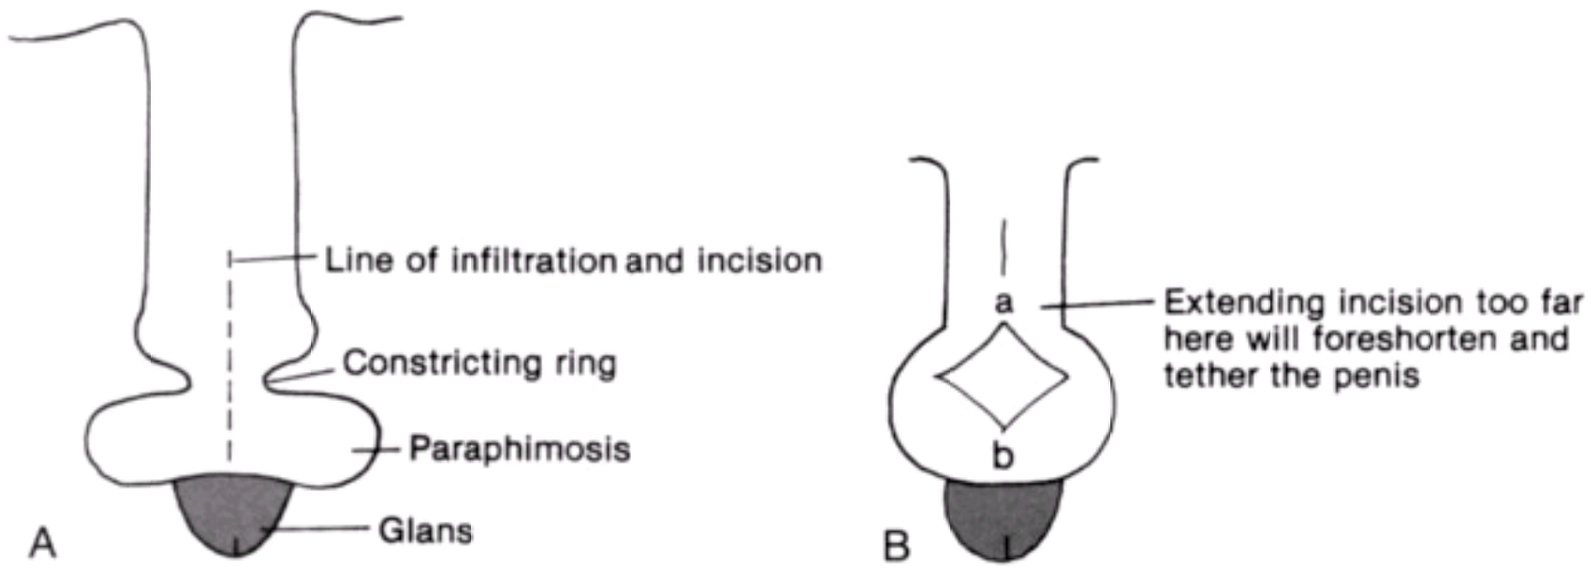

Figure 56-8 As an initial approach to priapism, and as an alternative to aspiration/irrigation, the intracorporeal injection of vasoactive drugs such as phenylephrine may be used. A small gauge needle is used to inject the corpus at 10 o'clock or 2 o'clock, at the base of the penis. Repeat injection may be required.

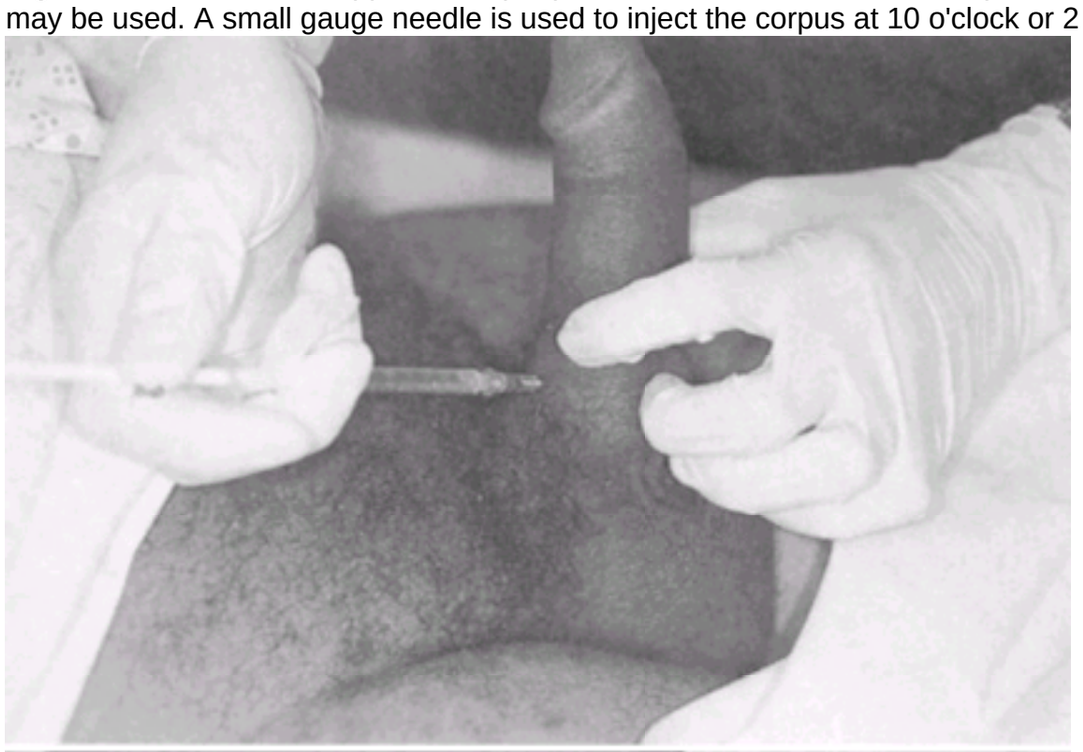

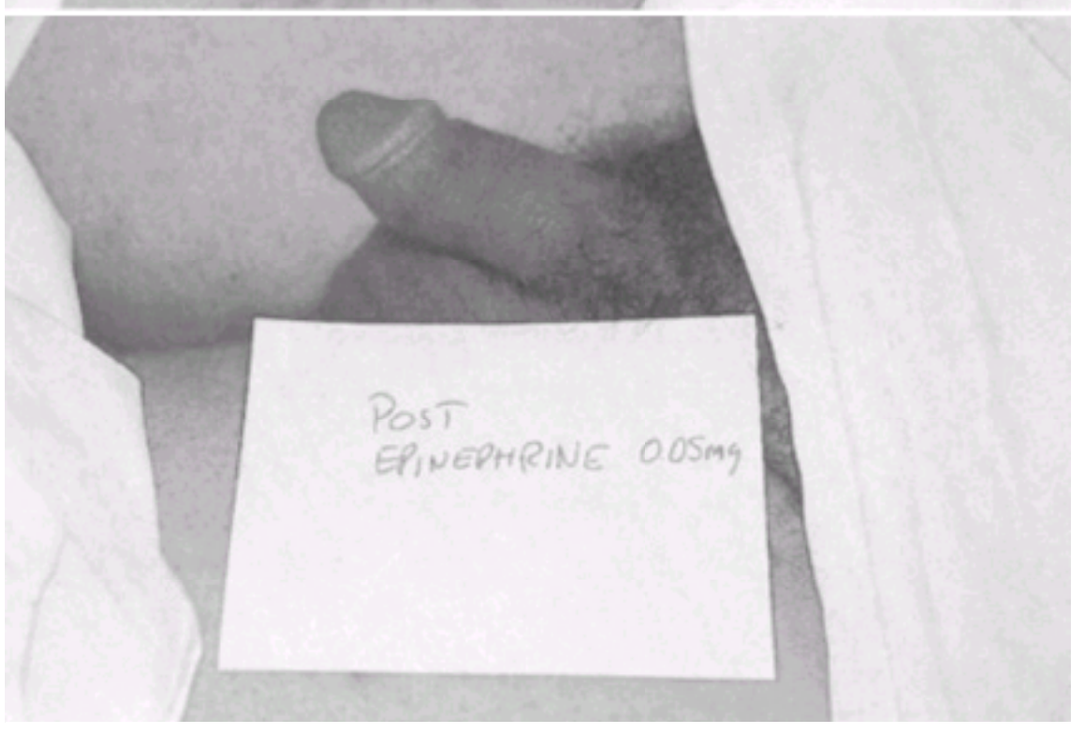

Figure 56-9 *A,* This patient experienced 18 hours of priapism after penile self-injection of papaverine as therapy for impotence. *B,* A penile dorsal nerve block is performed. *C,* A 19-ga butterfly needle is inserted into the corpus via the penile shaft at either the 2 o'clock or 10 o'clock position, and aspiration is performed. Slow steady suction will be most successful, while excessive suction may halt the aspiration. Do not puncture the corpus via the glans (see text). *D,* After detumescence with aspiration or with irrigation and injection of a vasoactive medication (see text), the penis is wrapped with an elastic bandage to discourage re-engorgement and to compress the puncture site.

Figure 56-10 Proper position of the Doppler probe in the examination of the acute scrotum. Note caudal orientation of the probe (drawing is a lateral projection).

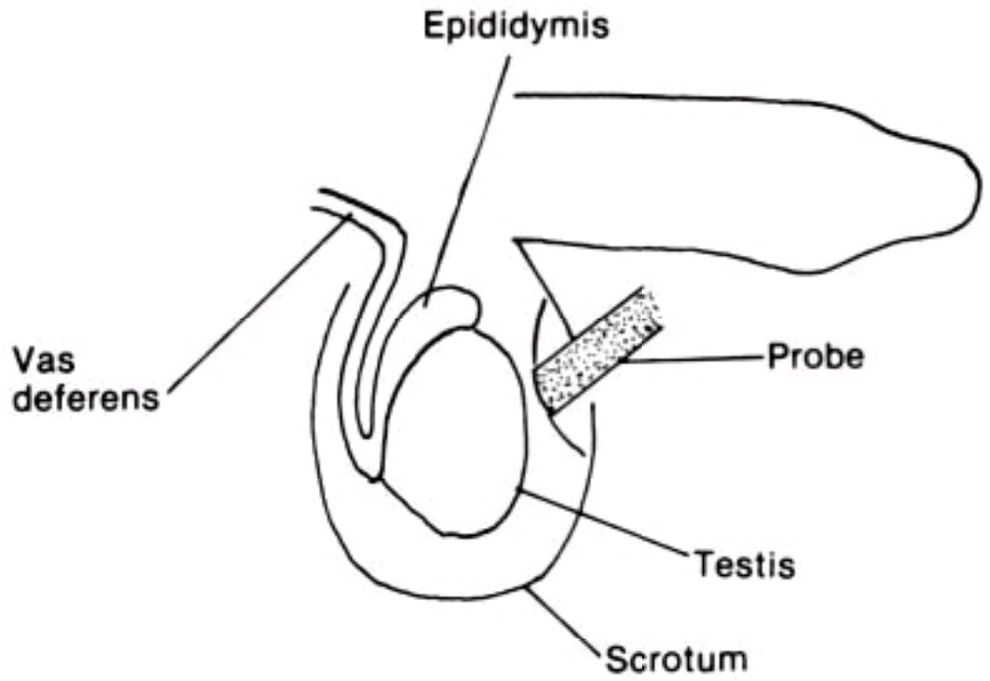

Figure 56-11 *A,* Testicular torsion usually occurs in a medial direction. Detorsion should be attempted initially by rotating the testis outward toward the thigh. This is most successful if attempted within the first few hours of torsion, before the onset of significant scrotal swelling. Intravenous narcotics (such as fentanyl) or a cord block can be administered before attempting detorsion. *B,* Detorsion of the testicle may require testicular rotation through two planes. To release the cremasteric muscle, the testis is rotated in a caudal to cranial direction simultaneously with medial to lateral rotation. The right testis is shown. *(B from Freeman S, et al: Urologic procedures. Emerg Med Clin North Am 4:543, 1986.)*

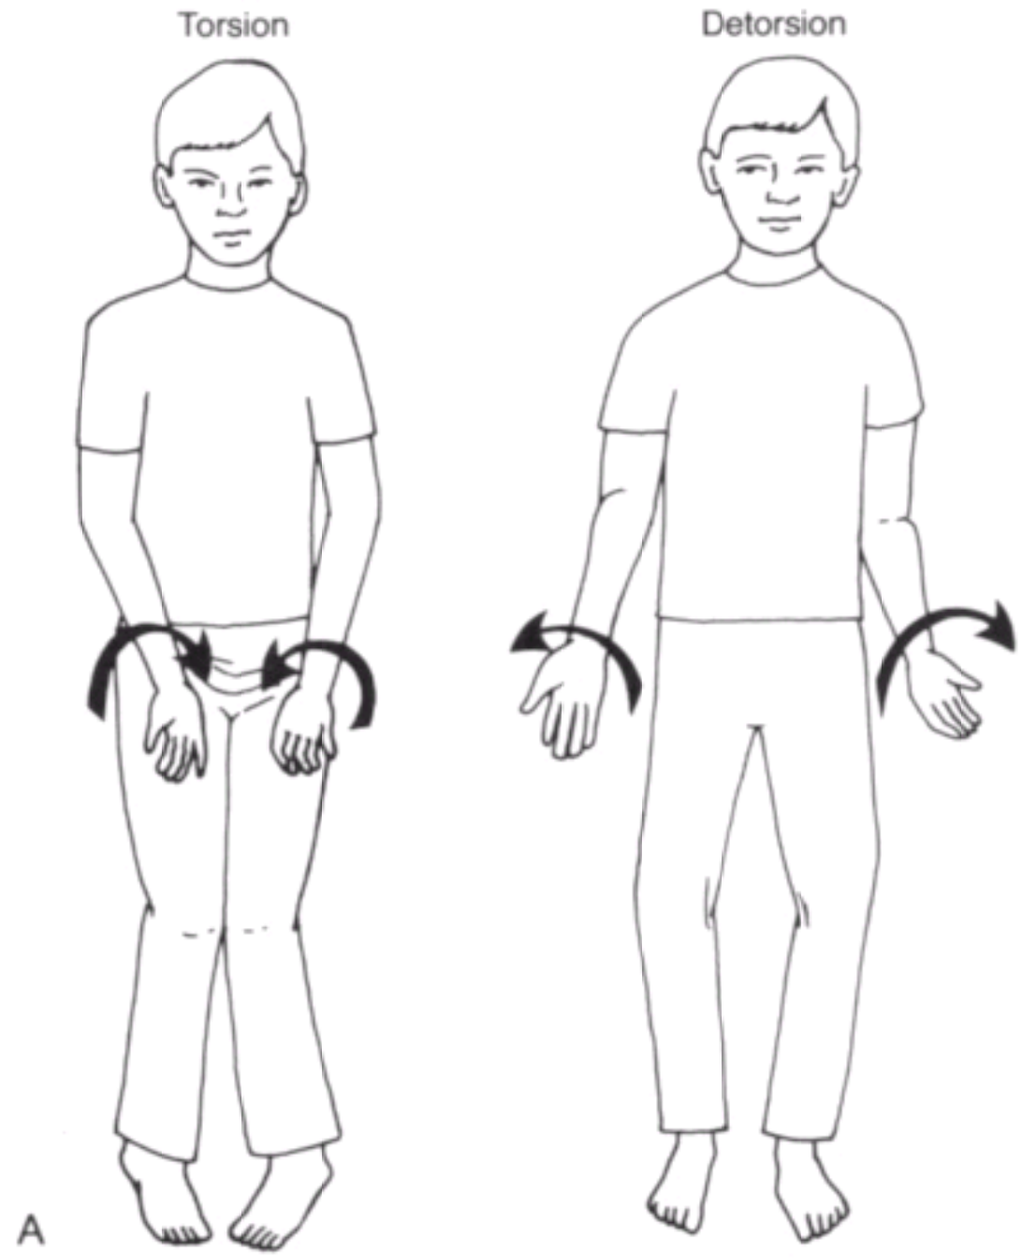

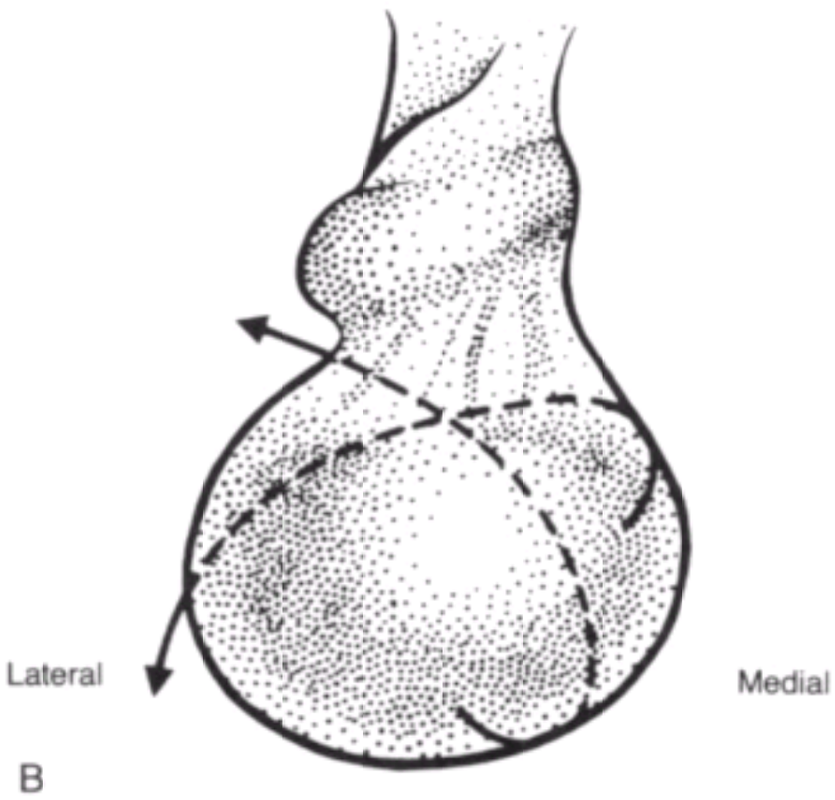

Figure 56-12 *A,* Anatomy of the female external genitalia. *B,* Uncomplicated catheterization in the female. *(A from Flocks RH, Culp DA: Surgical Urology: A Handbook of Operative Surgery, 4th ed. Chicago, Year Book Medical Publishers, 1975, p 357. B from Brunner LS, Suddarth DS: Lippincott Manual of Nursing Practice. Philadelphia, JB Lippincott, 1974, p 465. Reproduced by permission.)*

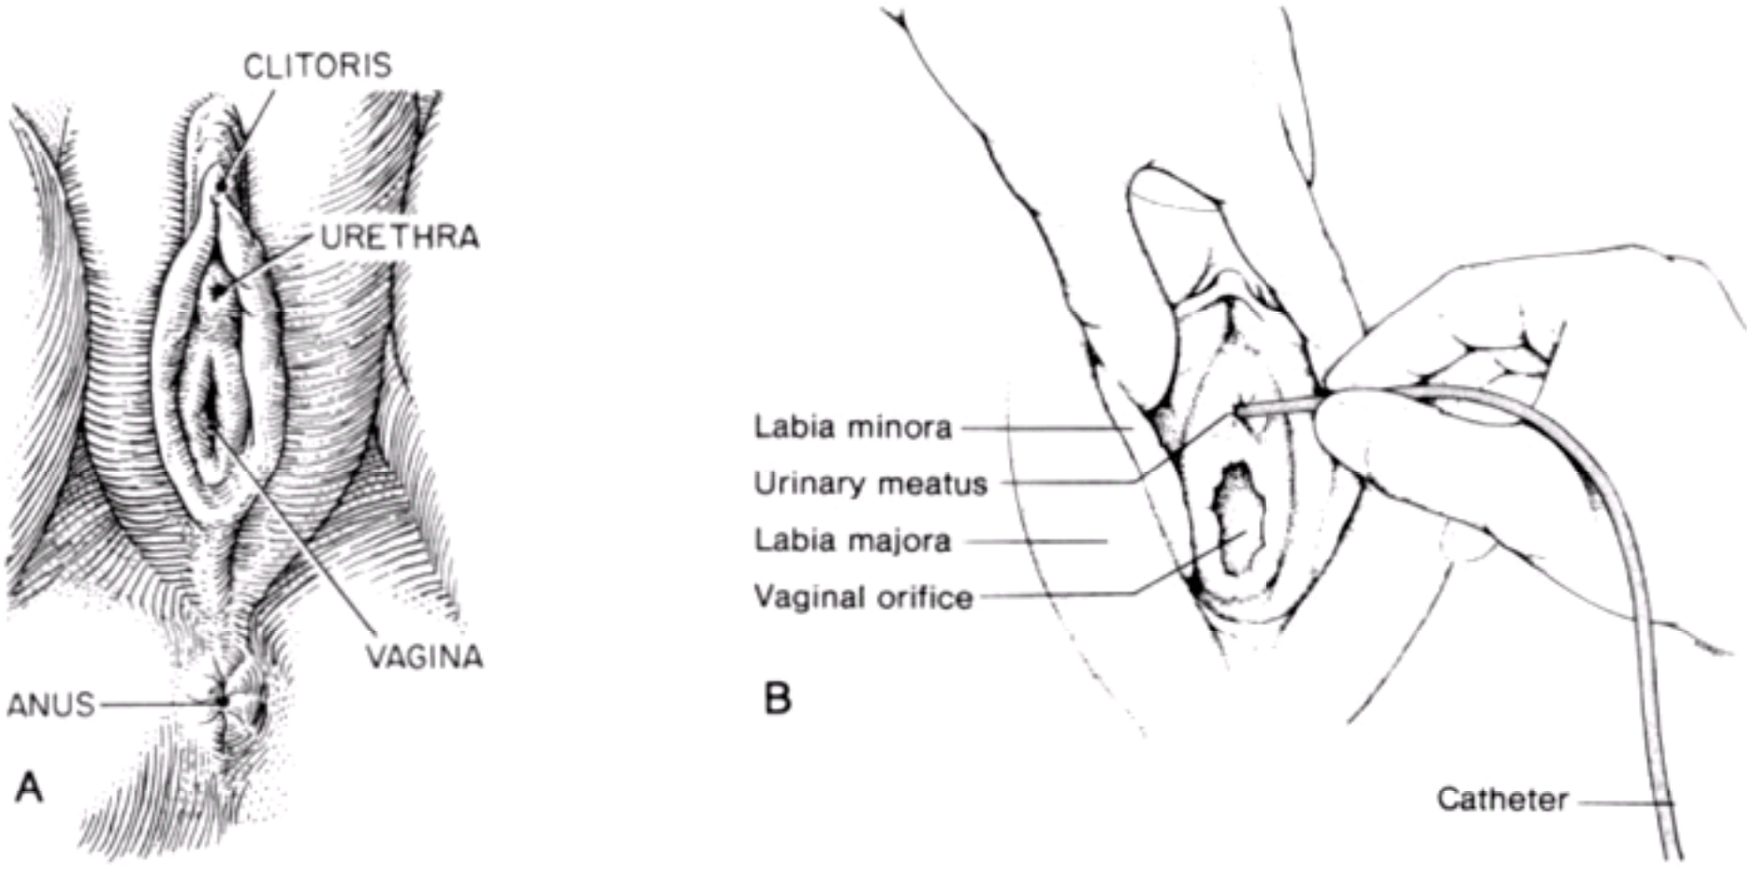

Figure 56-13 Female urethra. *A,* Sagittal view showing normal urethral course into the bladder. *B* and *C,* Cystourethrocele with loss of anterior support (frontal and sagittal views). *D* and *E,* Intravaginal re-creation of normal anatomic relationships with nondominant index and long fingers (frontal and sagittal views).

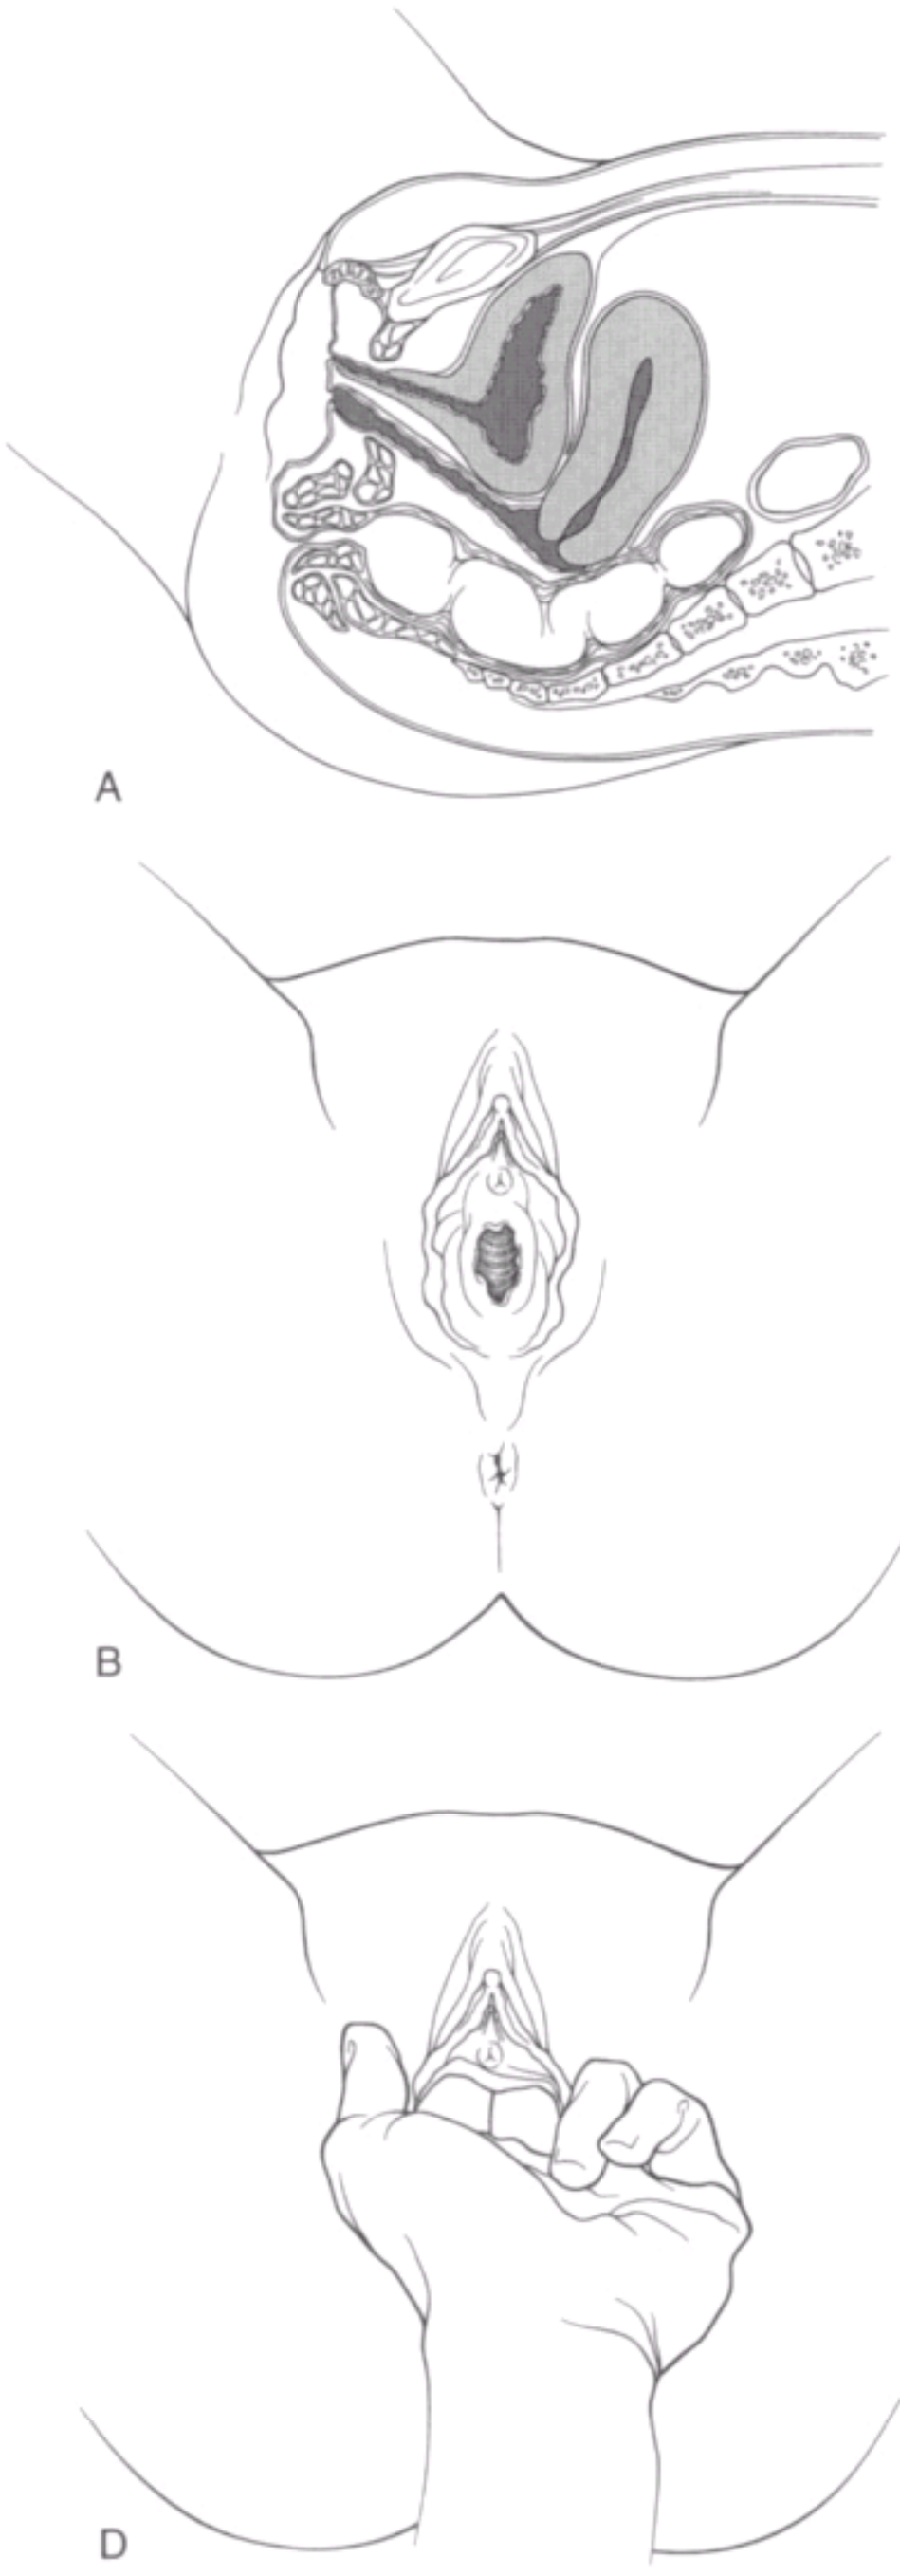

Figure 56-14 Anatomy of the male urethra. *(From Flocks RH, Culp DA: Surgical Urology: A Handbook of Operative Surgery, 4th ed. Chicago, Year Book Medical Publishers, 1975, p 359. Reproduced by permission.)*

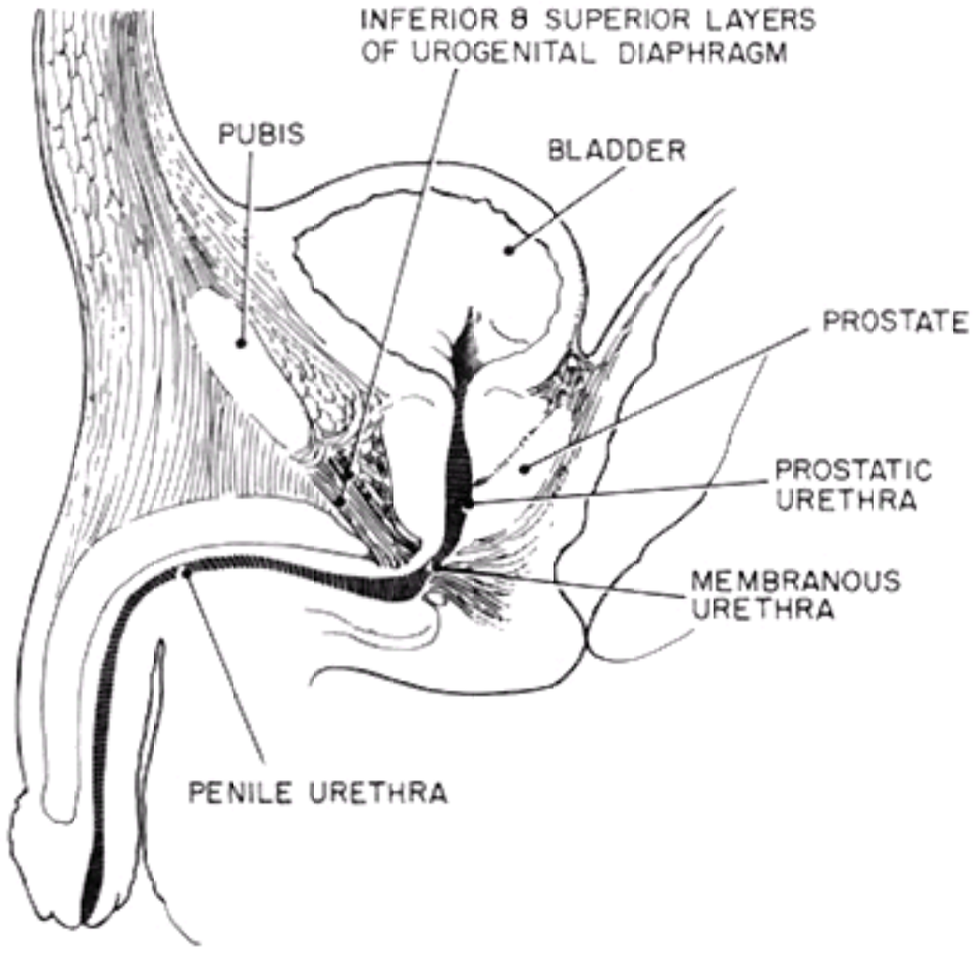

Figure 56-15 Foley catheter placement. Foley catheter is inserted fully (i.e., to the balloon port) before air or water is injected to inflate the balloon.

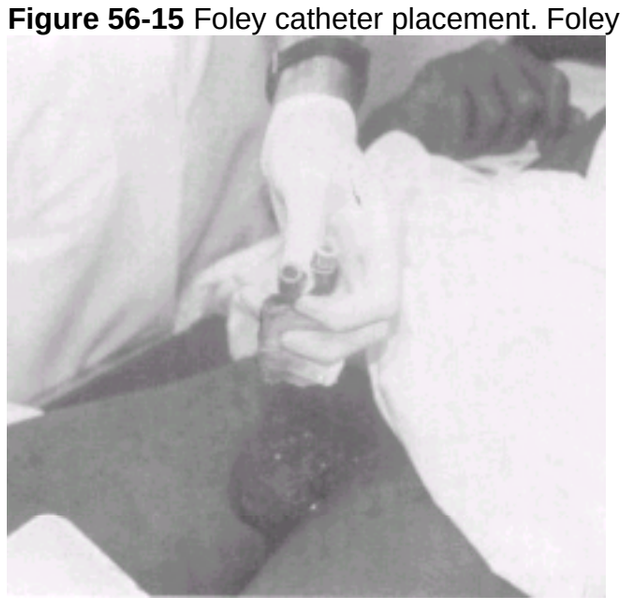

Figure 56-16 Foley catheter placement. *A,* Holding penis taut and upright prevents urethral folding, lessens external sphincter spasm, and promotes unobstructed catheterization. *B,* Proper uncomplicated male catheterization with upward traction on the penis. *(From Brunner LS, Suddarth DS: Lippincott Manual of Nursing Practice. Philadelphia, JB Lippincott, 1974, p 465. Reproduced by permission.)*

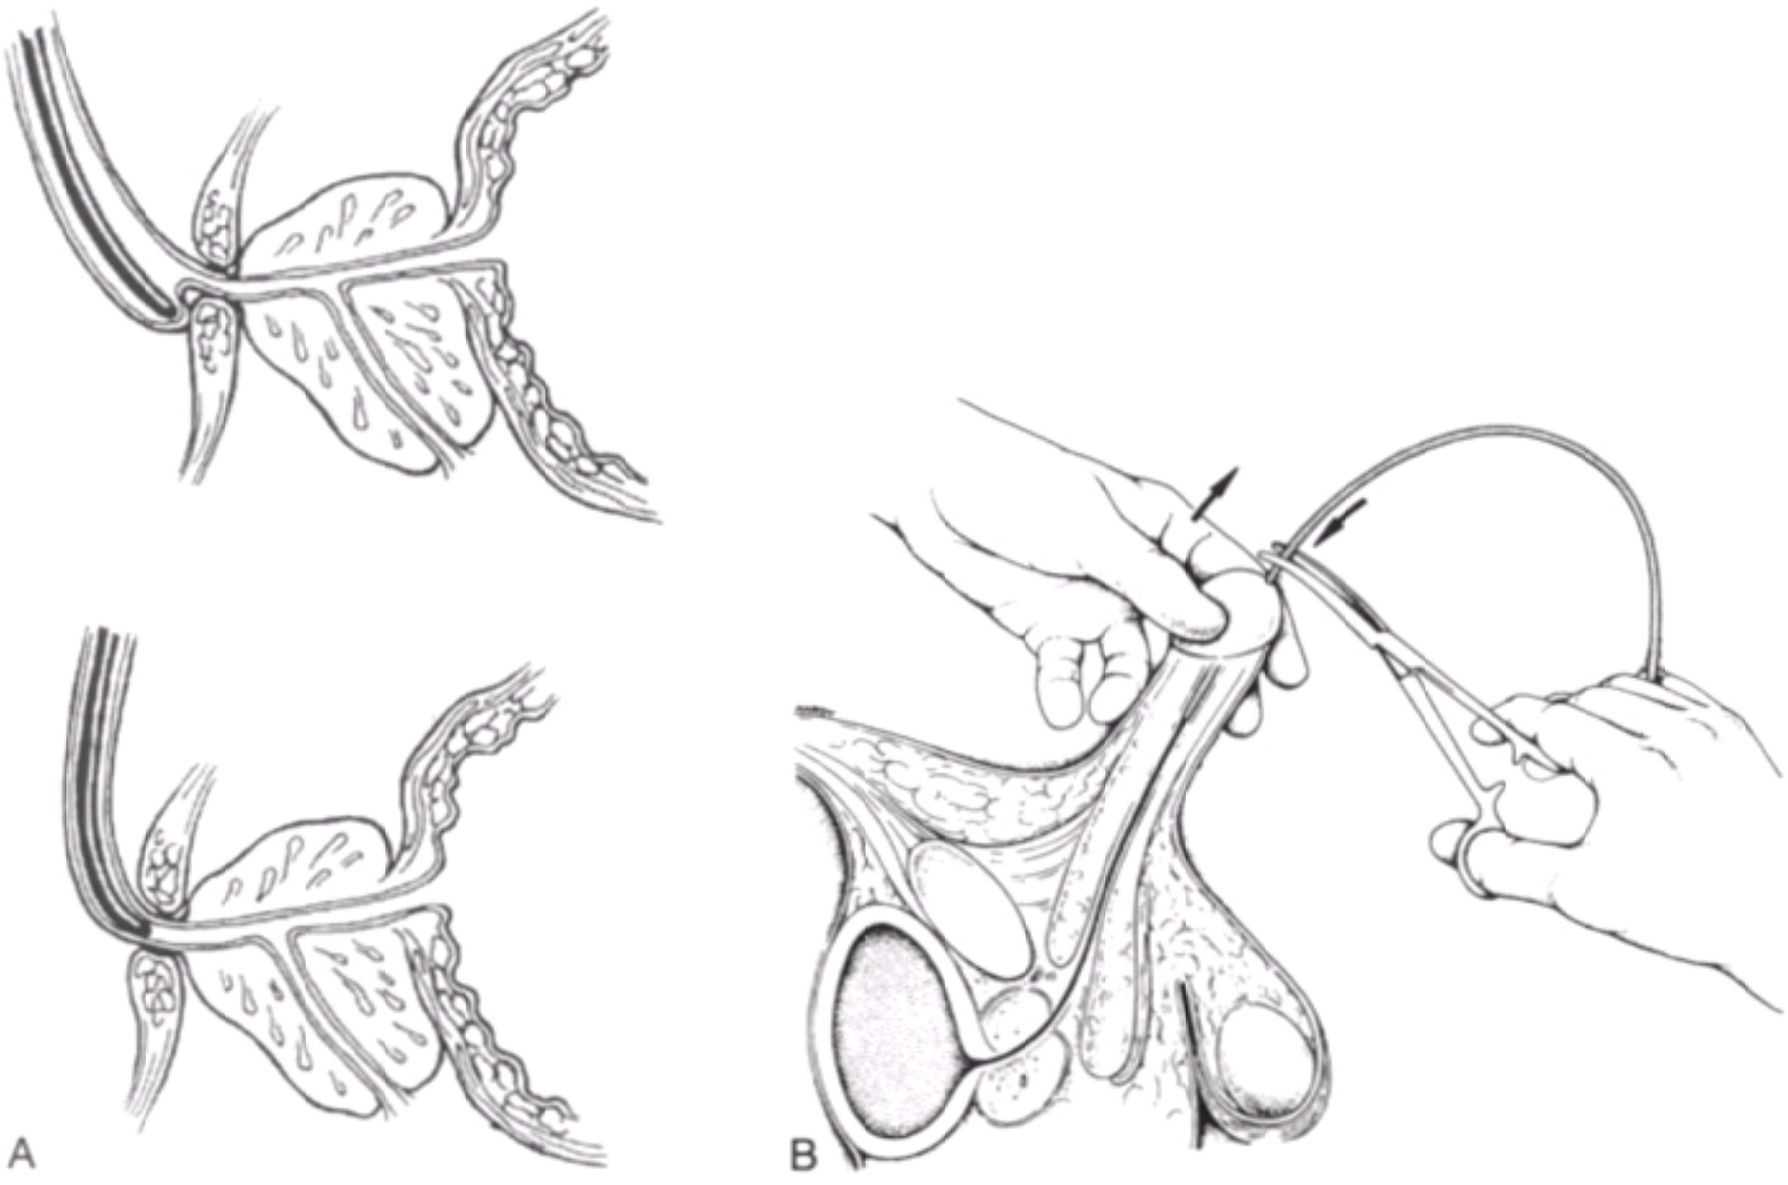

Figure 56-17 Foley catheter placement. It is important to fully retract the foreskin *(A),* especially in the uncircumcised male, so that a folded 4 × 4 gauze sponge can be wrapped around the coronal sulcus *(B)* and prevent foreskin reduction during the procedure. Once the procedure is terminated, the foreskin must be reduced to its normal anatomic position.

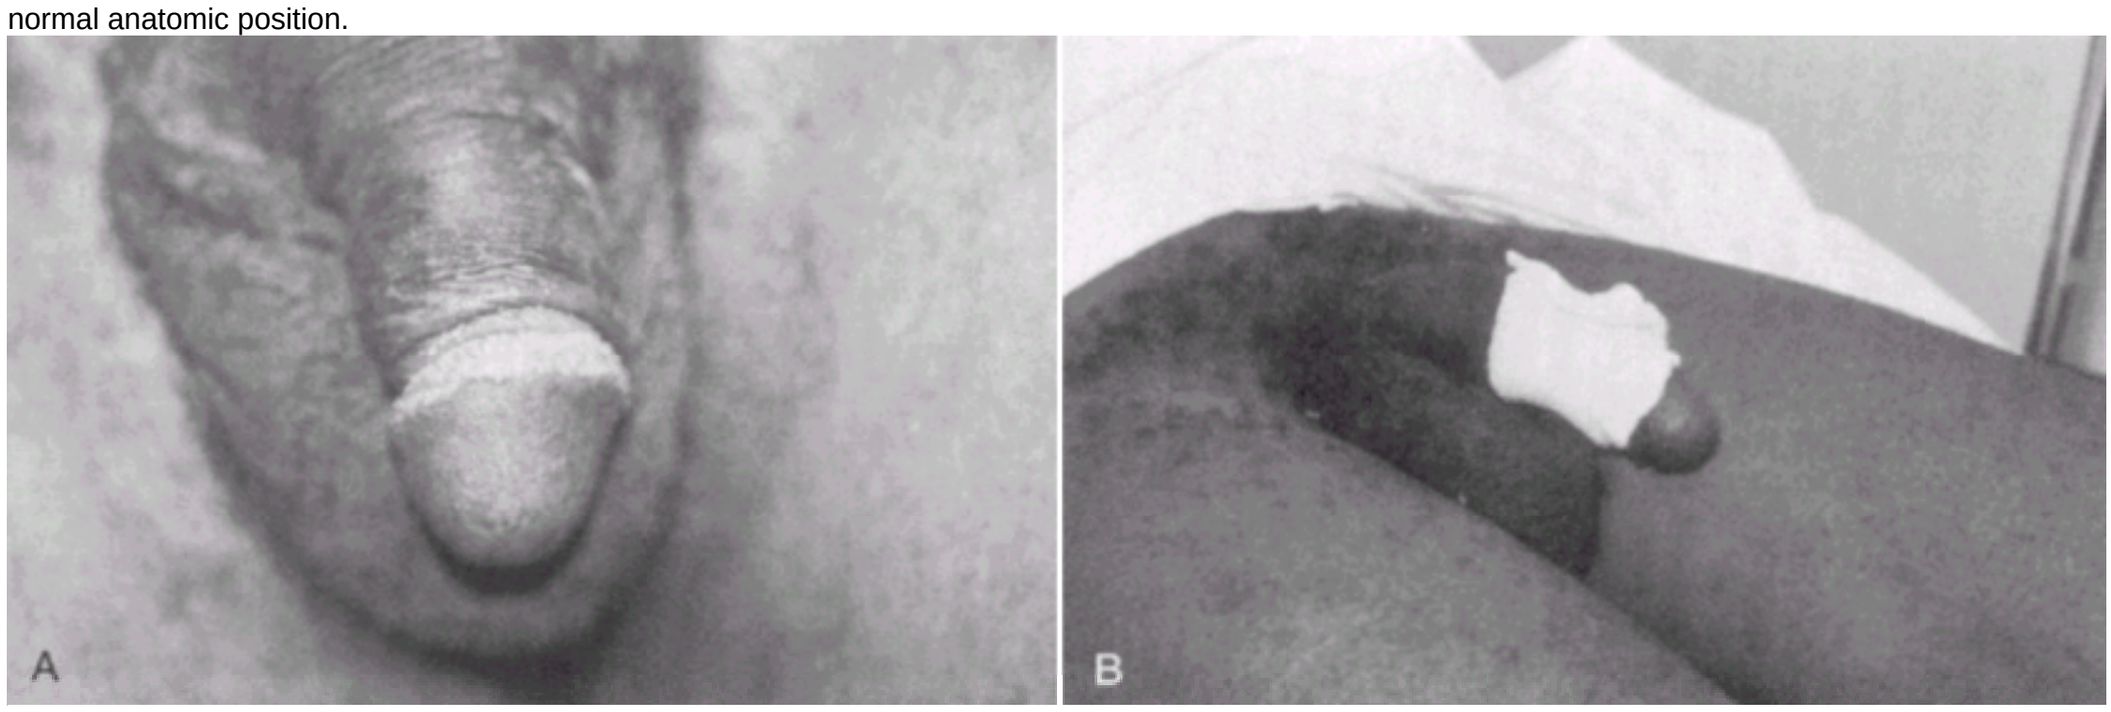

Figure 56-18 Penile stabilization. To optimize manual dexterity during urethral instrumentation, the prepared penis should be grasped between the nondominant long and ring fingers. This leaves the index finger and thumb available to stabilize the catheter or glans.

Figure 56-19 Paraphimosis. Tremendous foreskin edema from paraphimosis can make this diagnosis difficult unless the examiner searches diligently for the constricting band.

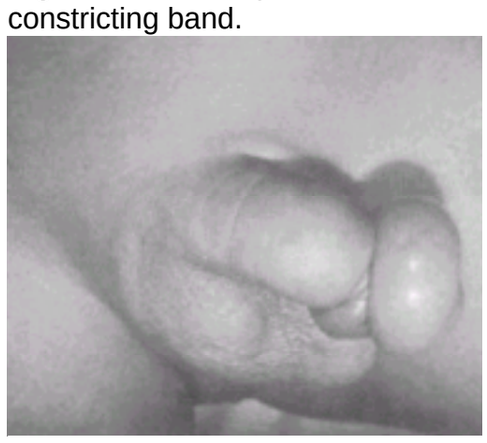

Figure 56-20 Paraphimosis. The appearance of this penis *(A)* could easily be mistaken as being normal. Proximal foreskin retraction reveals a normal coronal sulcus *(B)*. Distal foreskin manipulation *(C)* reveals a phimotic band causing paraphimosis.

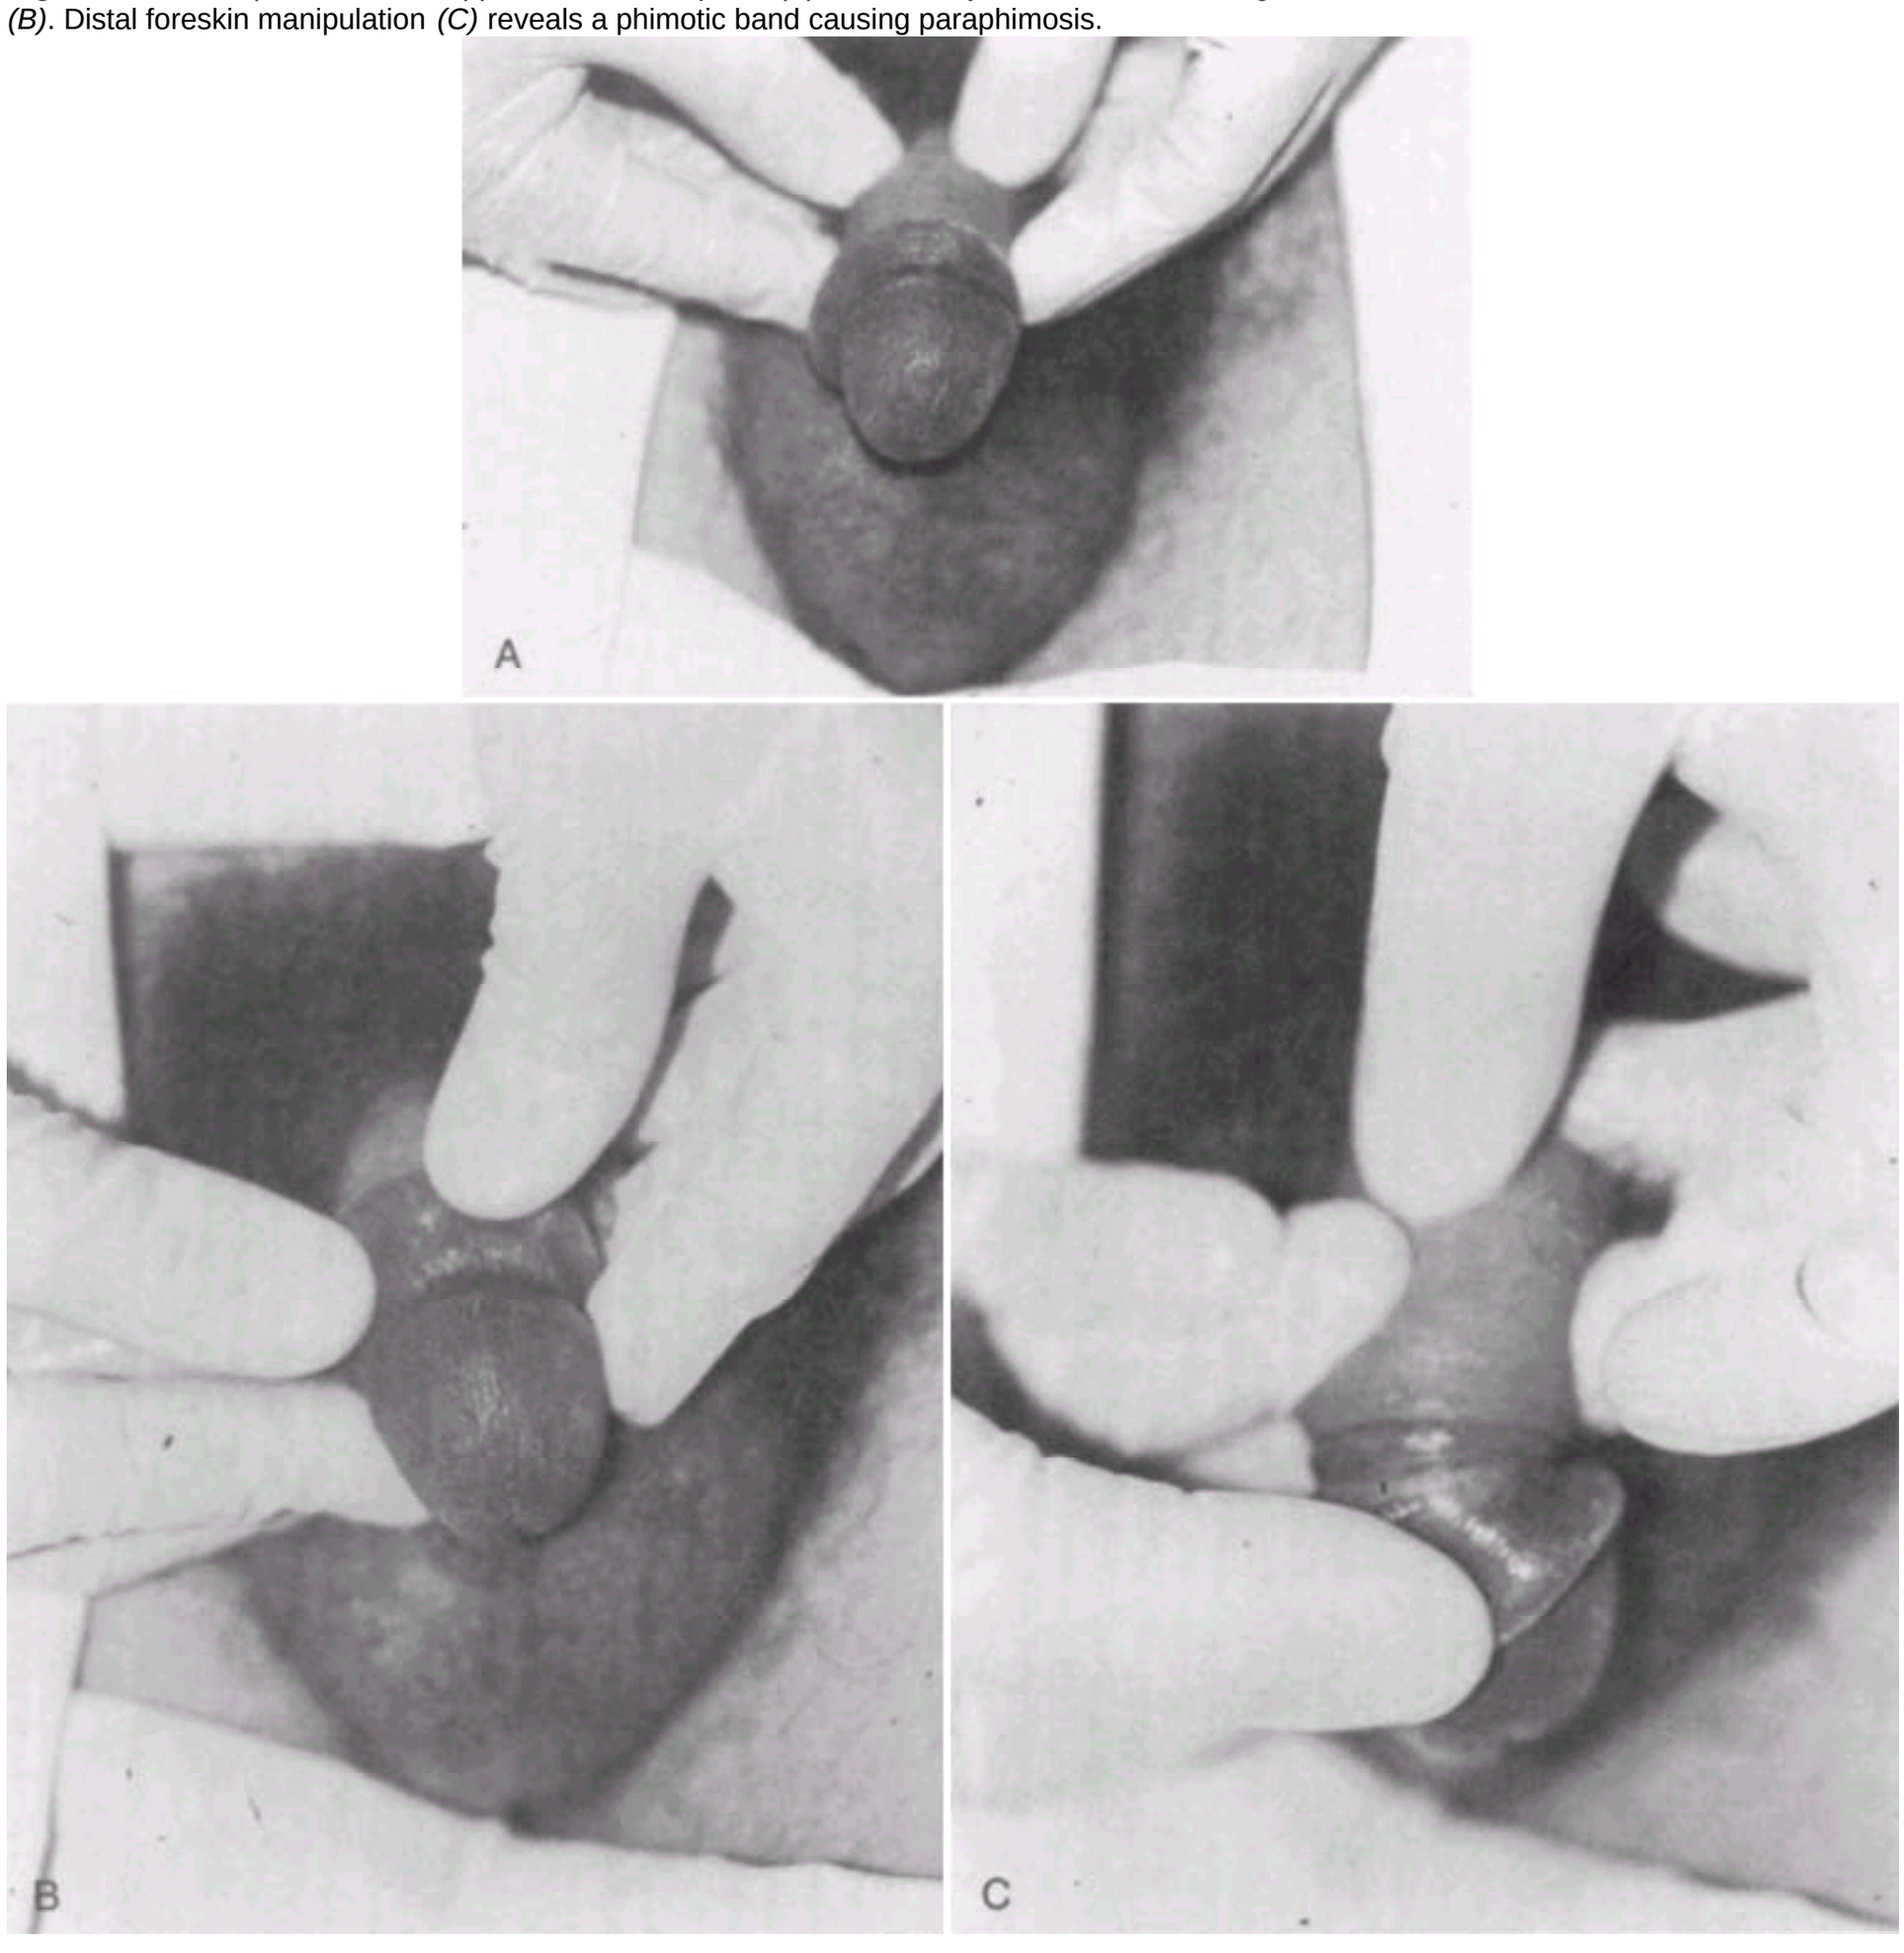

Figure 56-21 *A,* Passage of the filiform past the urethral stricture. *B,* Sequential passage of filiforms, with entry of the first catheter into the false passage. *C,* Advancement of the second filiform to the stricture site. *D,* Passage of the third filiform past the stricture. Following passage of the filiform into the bladder, redundant catheters are removed. *E,* Pigtail filiform passing through the stricture. *F,* Attachment of a follower to the filiform. *G,* Dilation of the stricture with a follower. *(E from Blandy J: Operative Urology. Oxford, Blackwell Scientific Publications, 1978, p 204. B, C, and D from Hill GJ: Outpatient Surgery. Philadelphia, WB Saunders, 1973. Reproduced by permission.)*

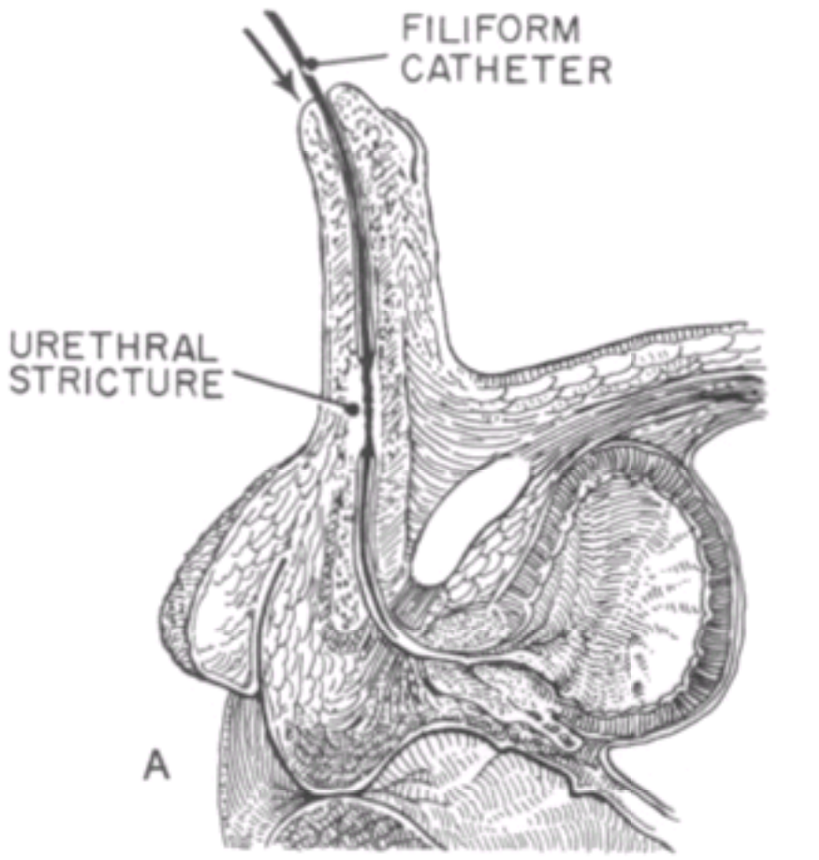

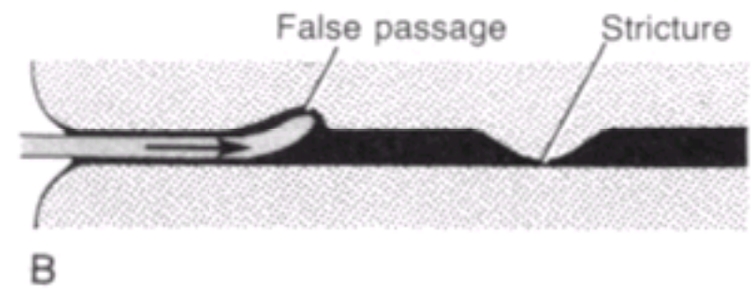

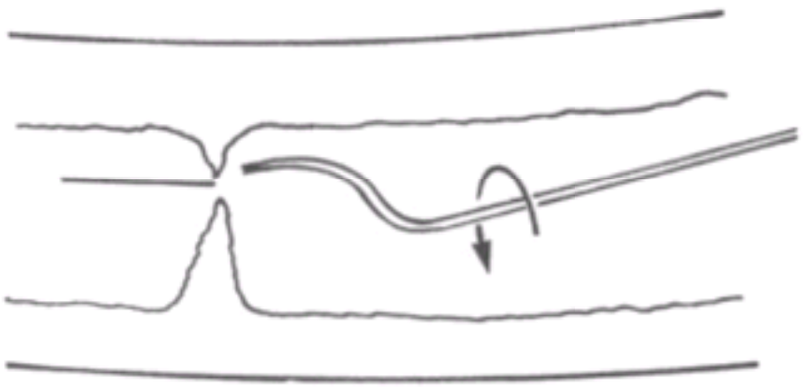

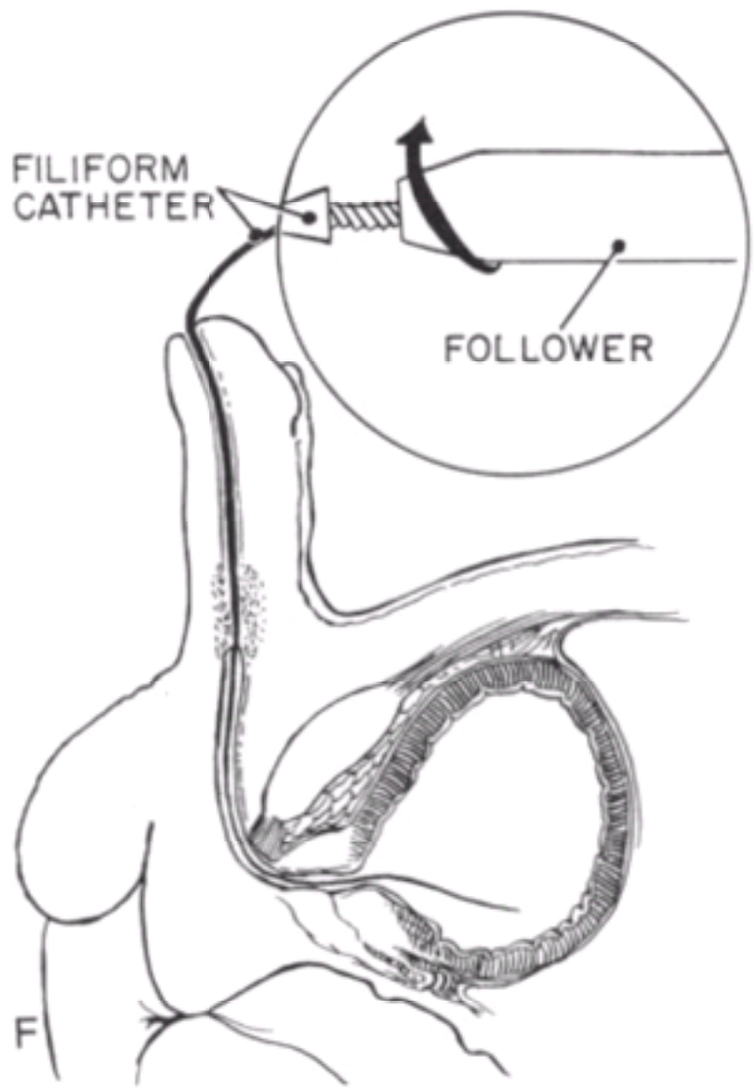

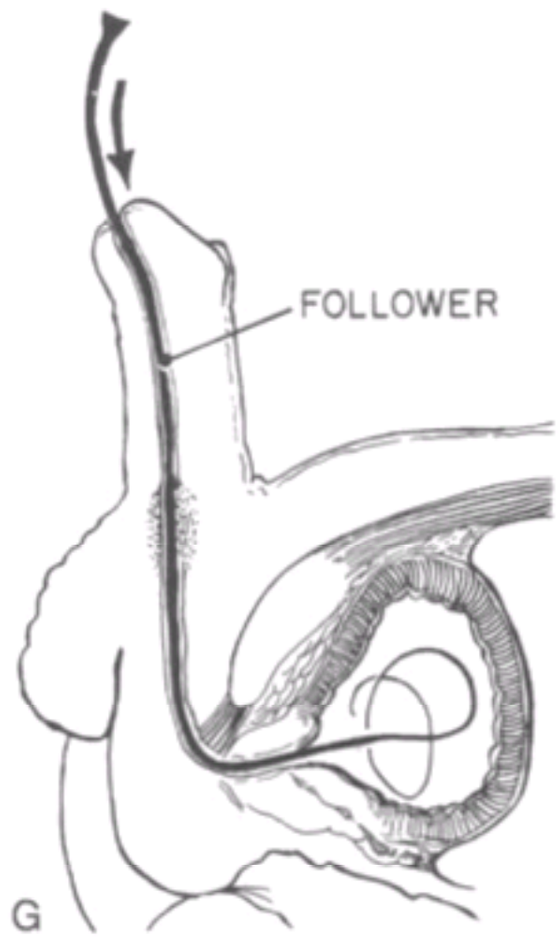

Figure 56-22 *A,* Self-retaining Foley-type catheter. *B,* Coudé catheter (also available in a non-self-retaining model). *C,* Superior pressure on the prostate may facilitate catheter passage. *D*, Catheter guide or stylet should be used only by a urologist.

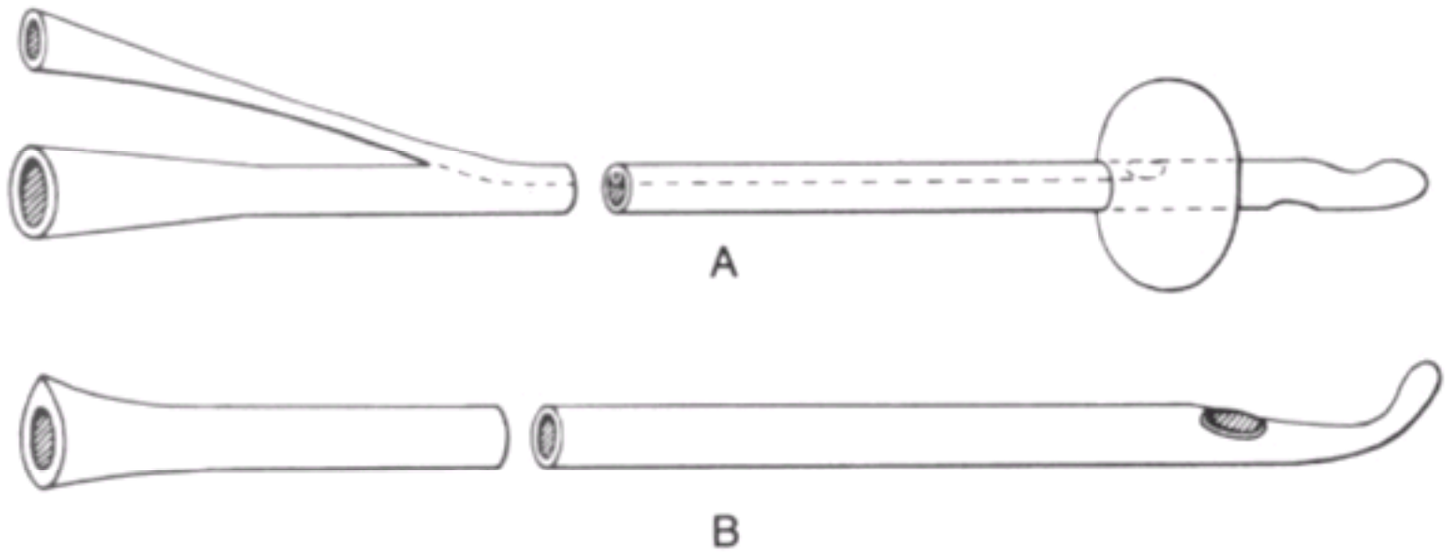

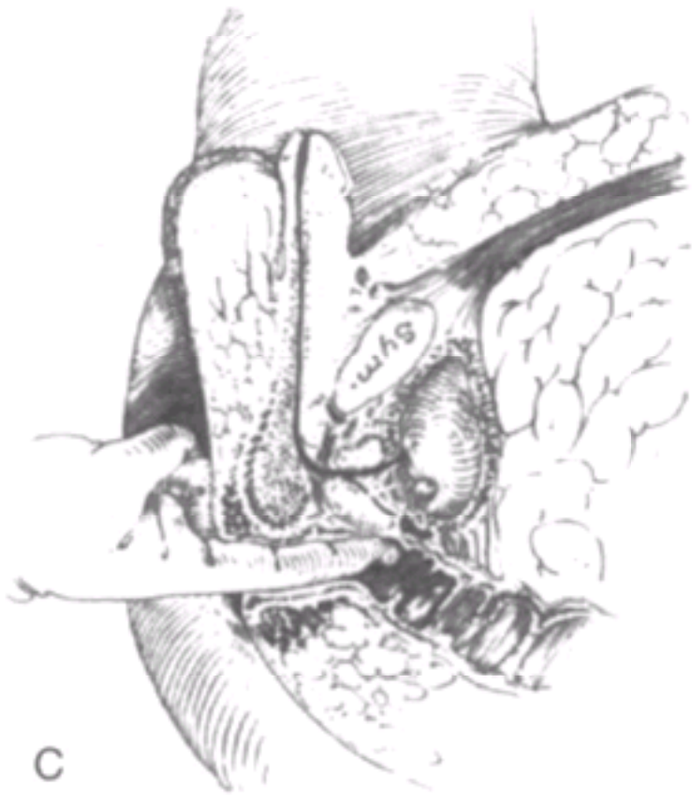

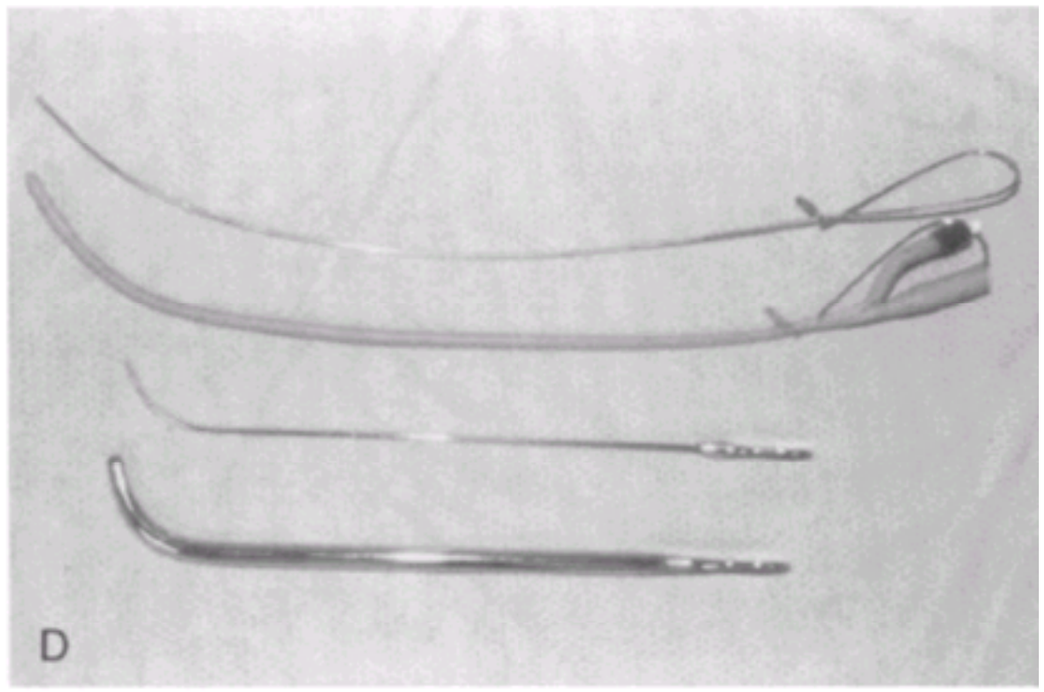

Figure 56-23 A flap-like defect in the inflating channel of a balloon catheter that is being raised by a wire stylet passed down the inflating channel to deflate the balloon. *(From Eichenberg HA, Amin M, Clark J: Nondeflating Foley catheters. Int Urol Nephrol 8:171, 1976. Reproduced by permission.)*

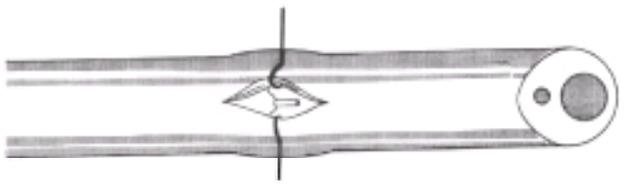

Figure 56-24 *A,* For a suprapubic bladder tap, the infant is restrained and placed in a frog-legged position. *B,* A 22-ga needle punctures the abdominal wall in the midline approximately 1 to 2 cm cephalad to the superior border of the pubic bone. The syringe is perpendicular to the plane of the abdominal wall (usually 10°–20° from the true vertical). The bladder is an abdominal organ in infants, and placing the needle too close to the pubic bone or angling toward the feet may cause the needle to miss the bladder. Localizing the bladder with bedside ultrasound facilitates this procedure.

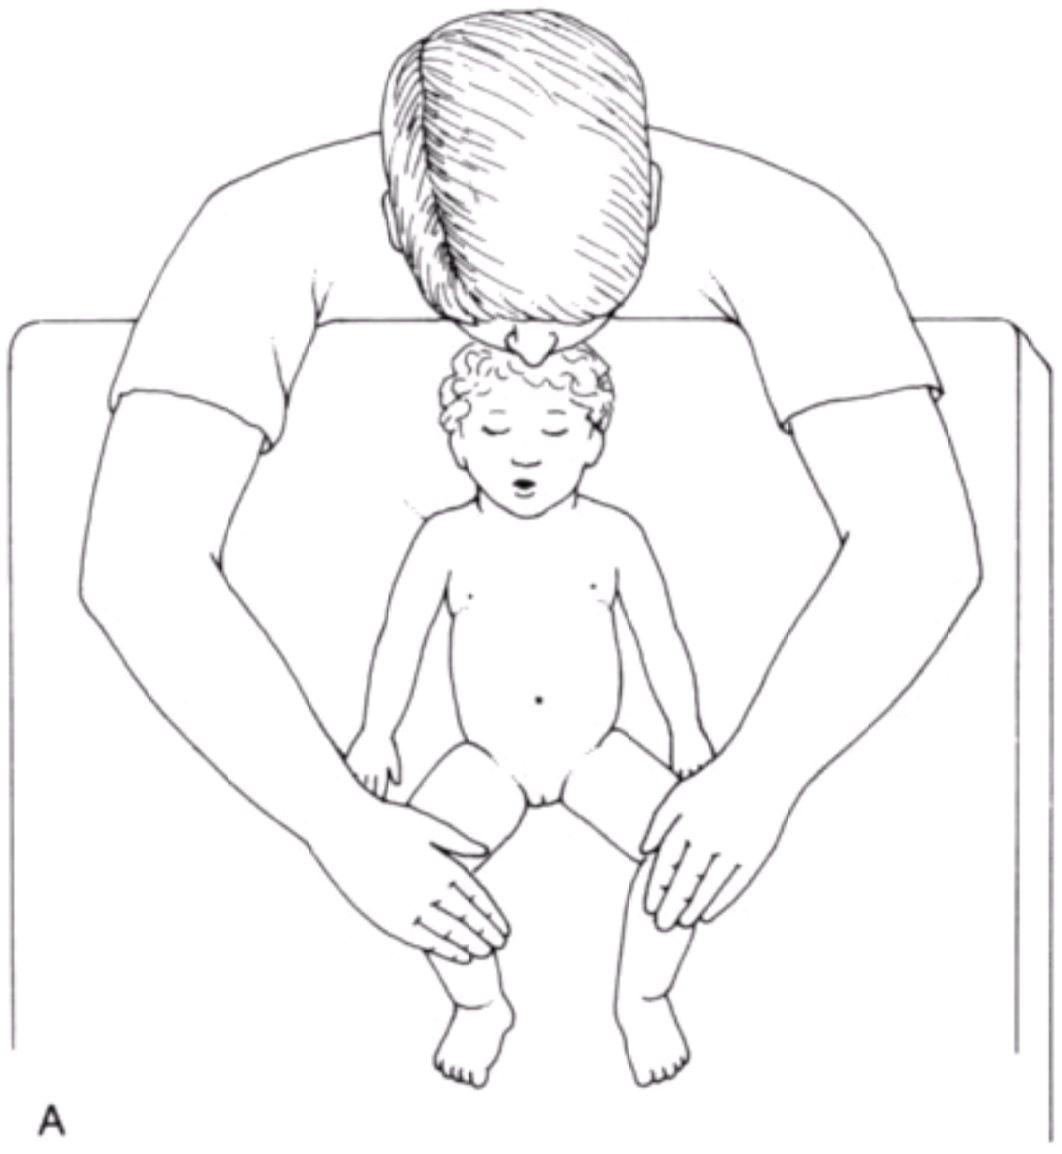

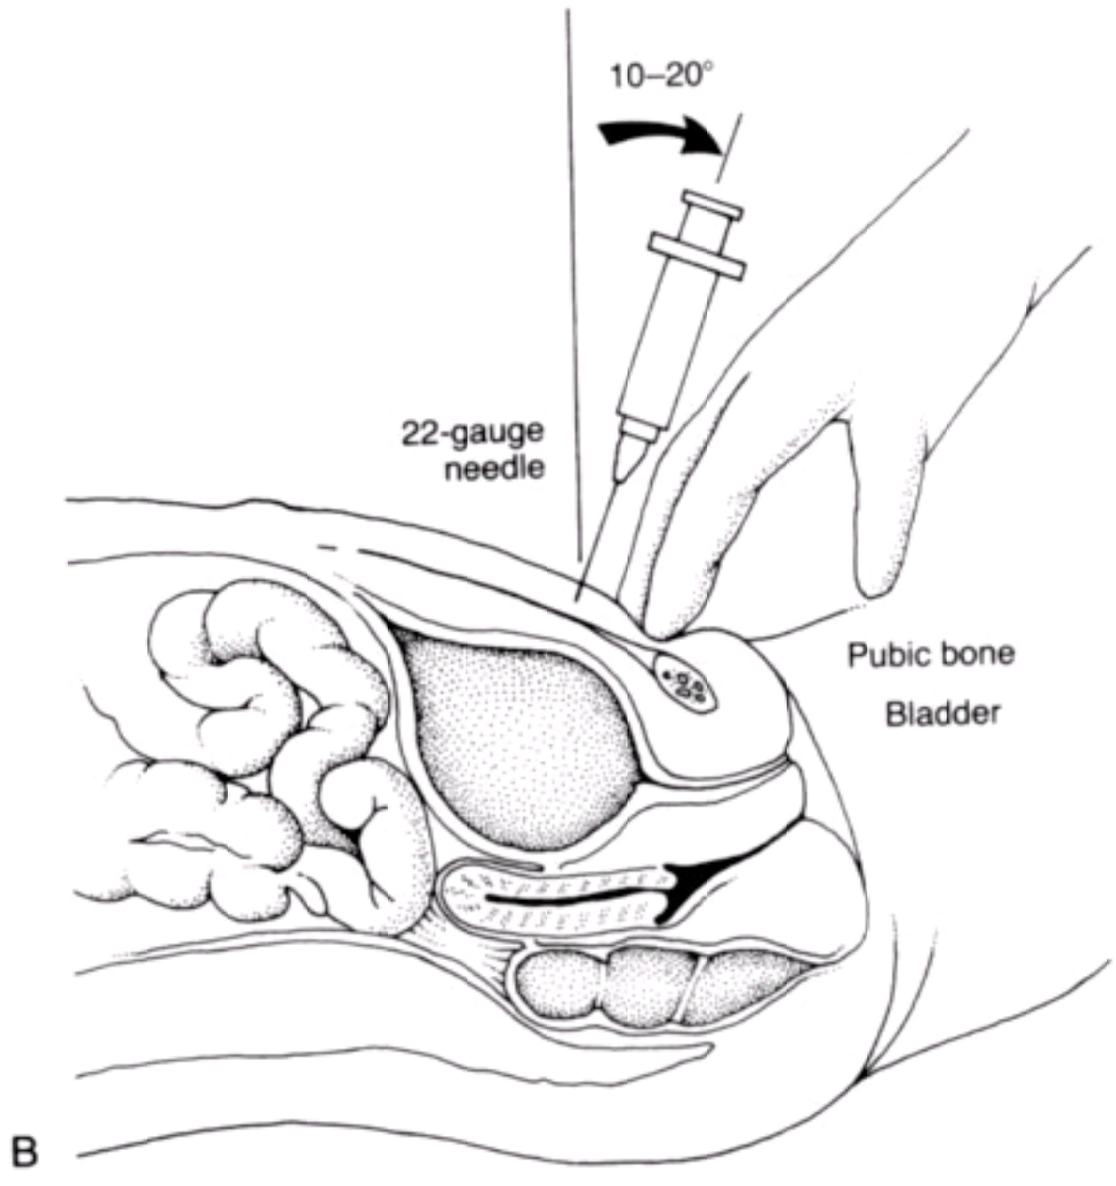

Figure 56-25 The peritoneum is pushed cephalad by the filled bladder during suprapubic aspiration in an adult. The needle is directed slightly caudad.

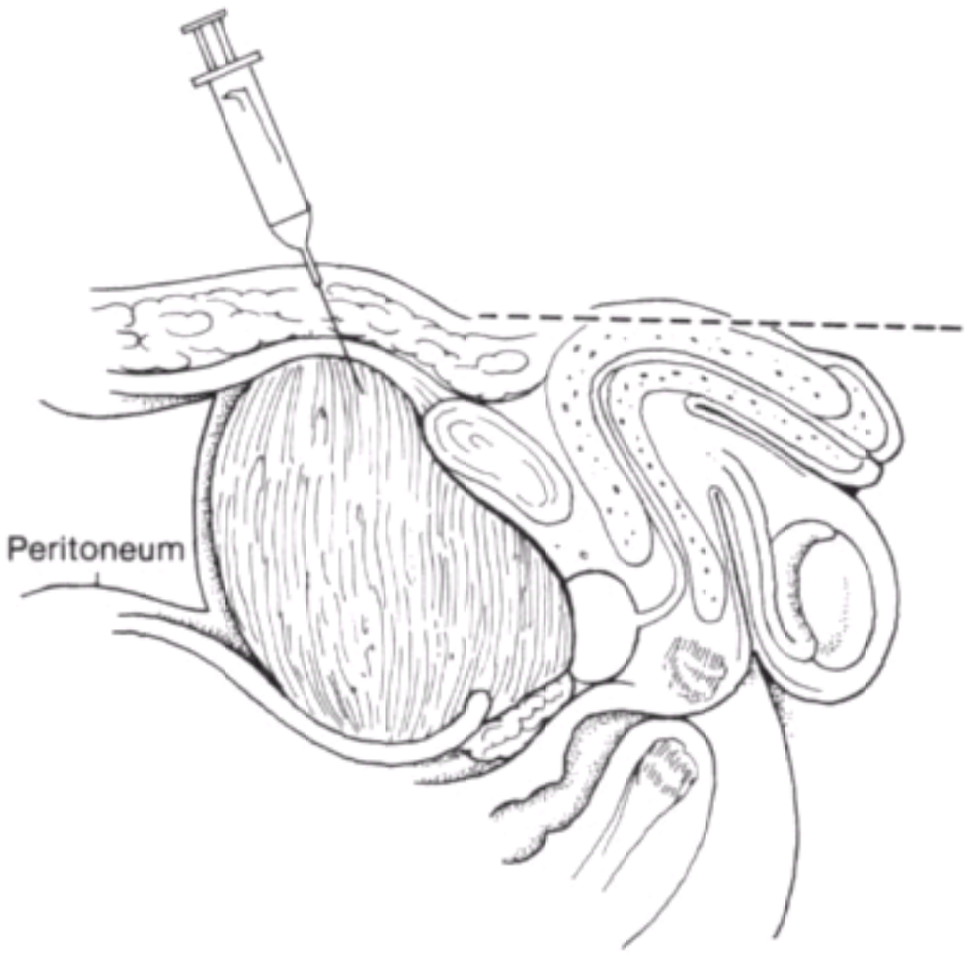

Figure 56-26 Suprapubic cystostomy with the Cook peel-away sheath introducer. *A,* Bladder is entered with a syringe and needle. Location is confirmed by the aspiration of urine. *B,* Syringe is removed and the guide wire is passed through the needle into the bladder. *C,* The needle is removed, then the dilator and peel-away sheath are passed over the wire into the bladder. A small stab wound in the anterior abdominal fascia may be required to accommodate the dilator and sheath. *D,* The dilator and wire are removed, leaving only the sheath inside the bladder. *E,* The preselected Foley balloon catheter is passed through the sheath into the bladder. Urine is aspirated to confirm location. *F,* The balloon is inflated with a minimum of 10 mL of air, saline, or water. A 5-mL balloon will accommodate 10 mL easily and make accidental catheter distraction less likely. *G,* The sheath is removed from the bladder, anterior abdominal wall, and cutaneous entry site, and is then literally peeled away from the indwelling catheter. *H,* The catheter is withdrawn until a snug fit is ensured at the cystostomy site.

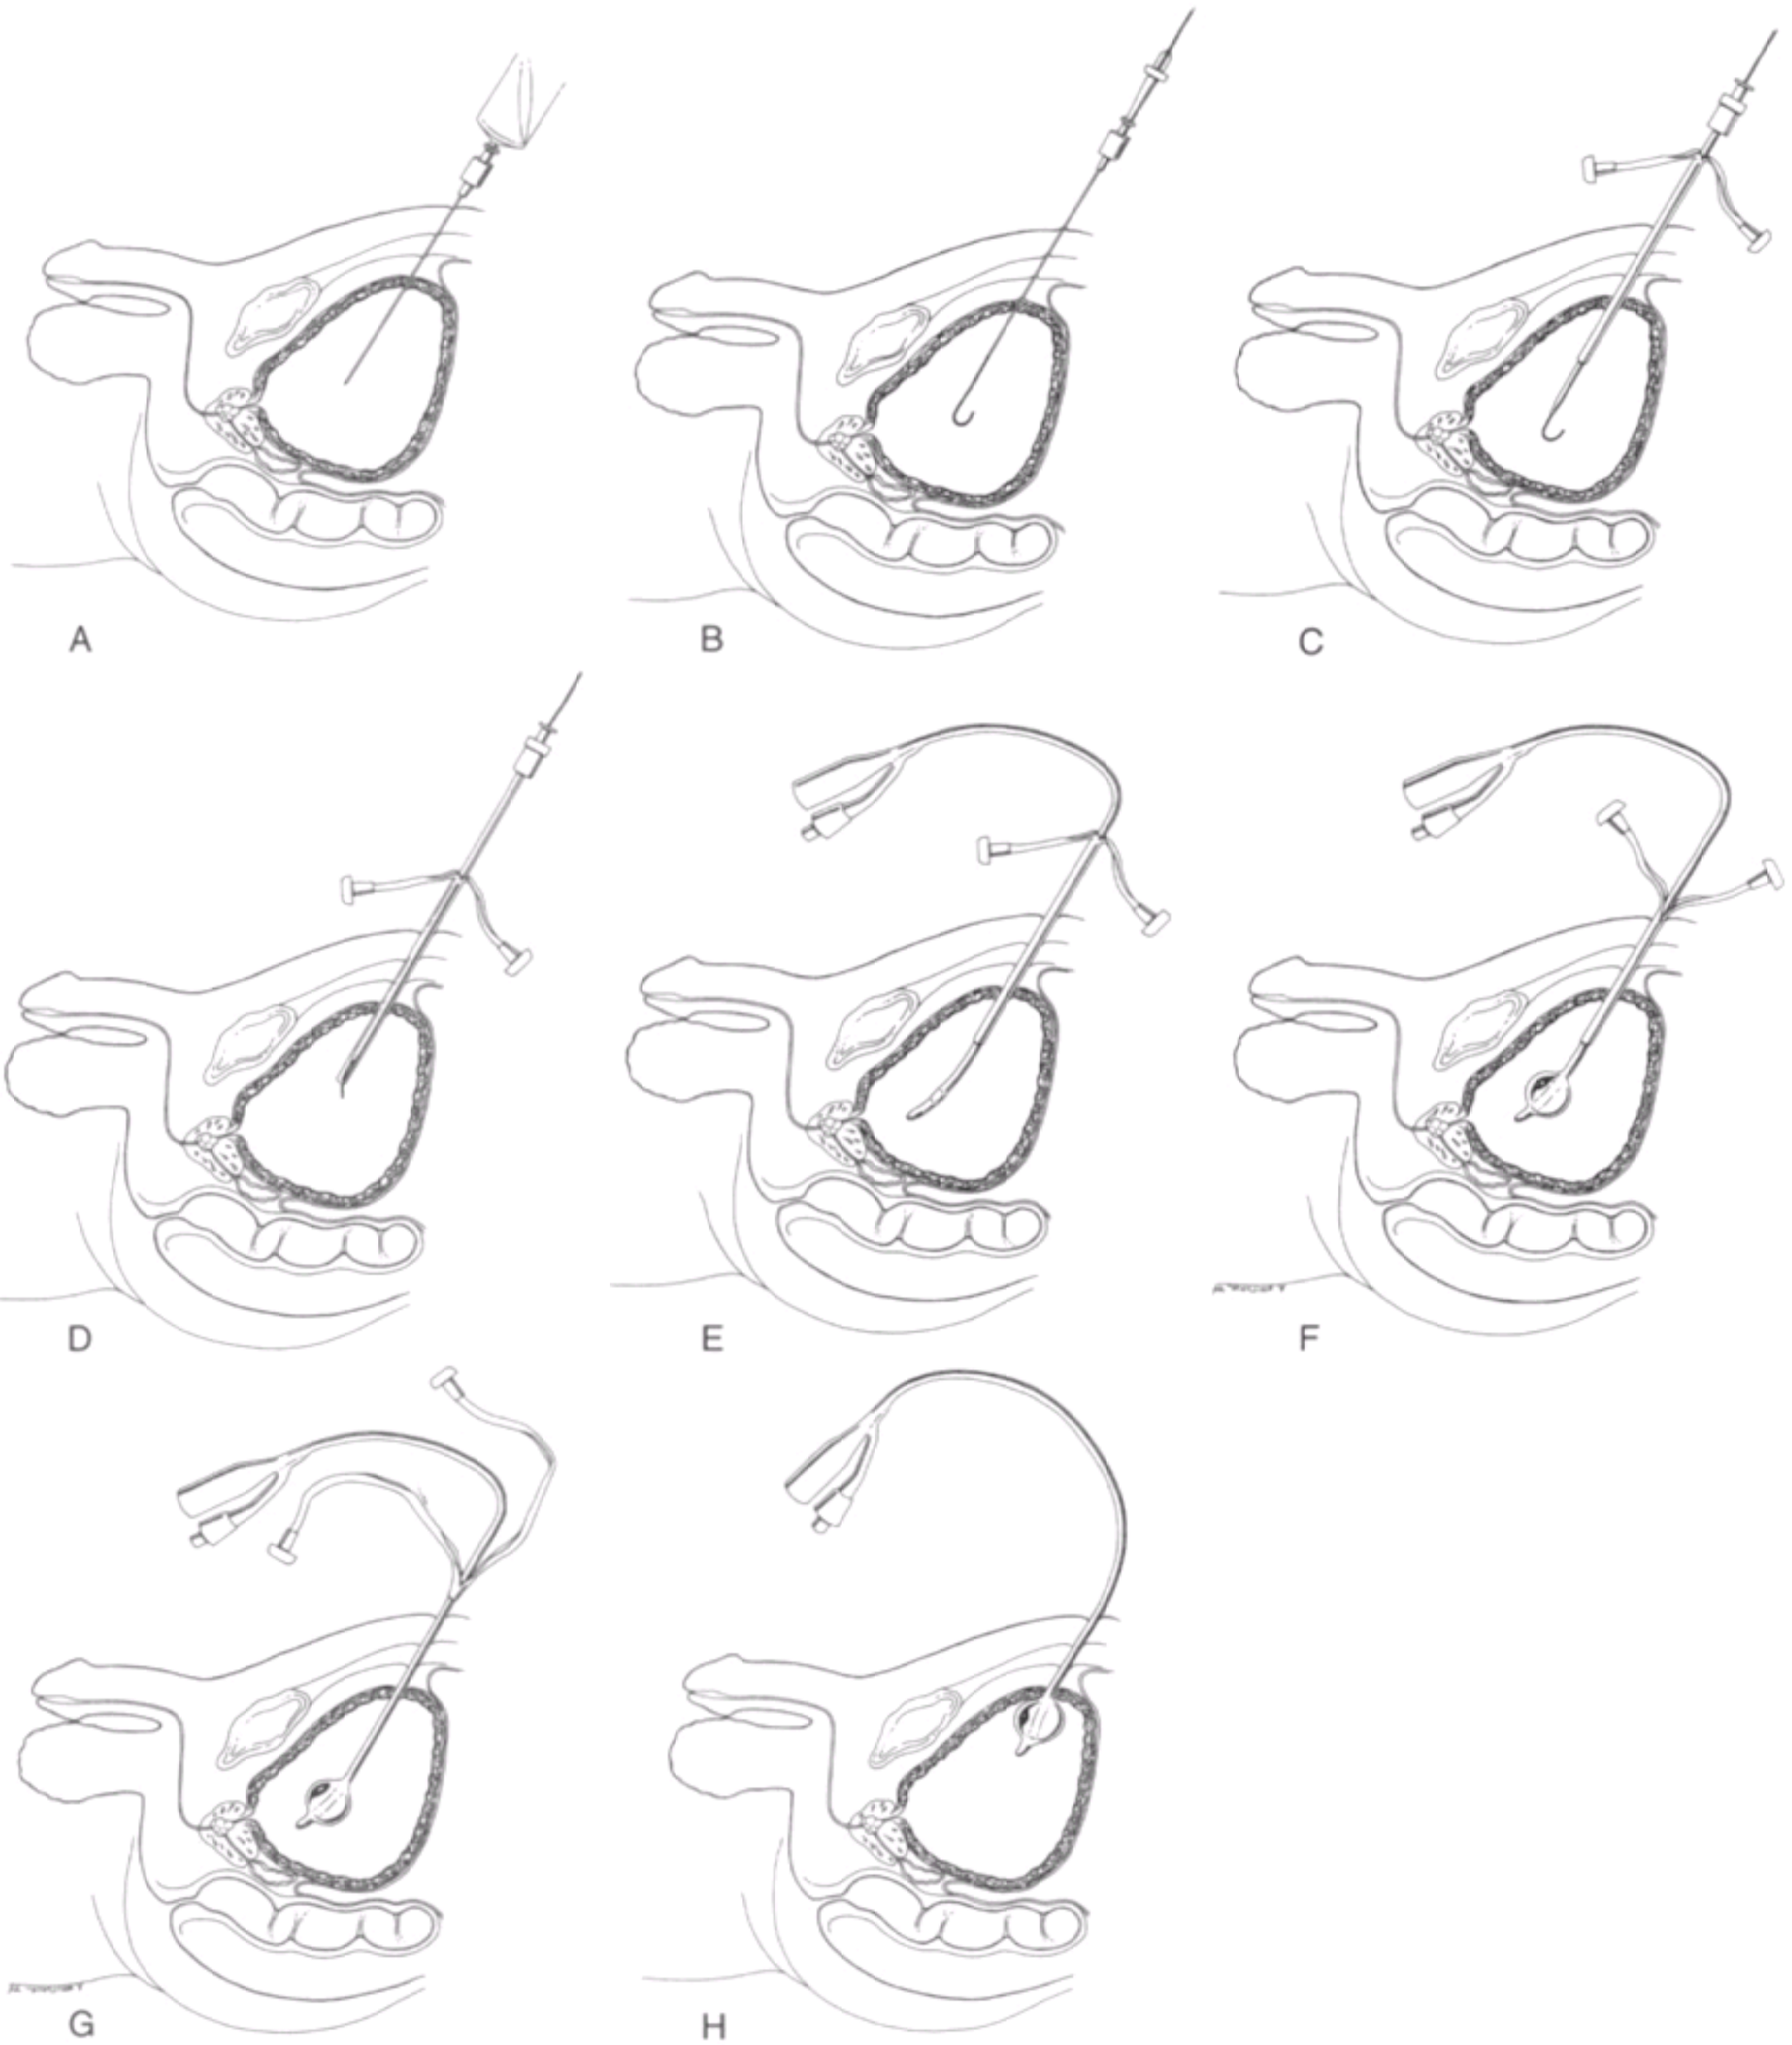

Figure 56-27 A common posterior urethral injury is a disruption of the membranous urethra. In this case, a distended bladder and attached prostate gland are sheared from the fixed membranous urethra. Note the development of a perivesical hematoma and the presence of a "high-riding" prostate gland.

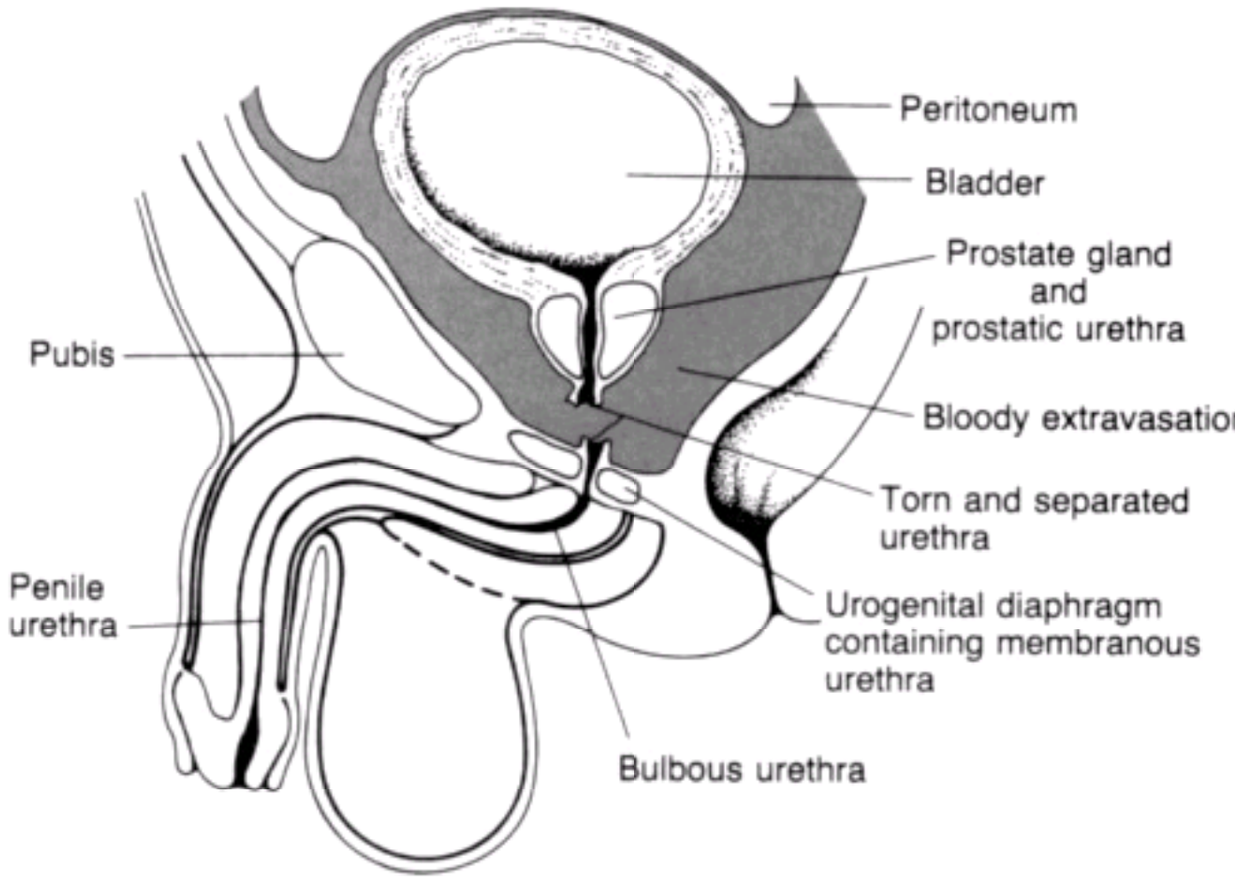

Figure 56-28 *A,* Disruption of the anterior urethra (bulbous urethra) occurs with straddle-type injuries in the male. Extravasation of urine and blood may occur in the perineum or scrotum, or along the anterior abdominal wall. Note that in this diagram, Buck fascia has been penetrated. *B,* Anterior urethral injury in which Buck fascia remains intact. In this situation, extravasation is confirmed and results in a swollen and ecchymotic penis. Such an injury usually results from instrumentation of the anterior urethra.

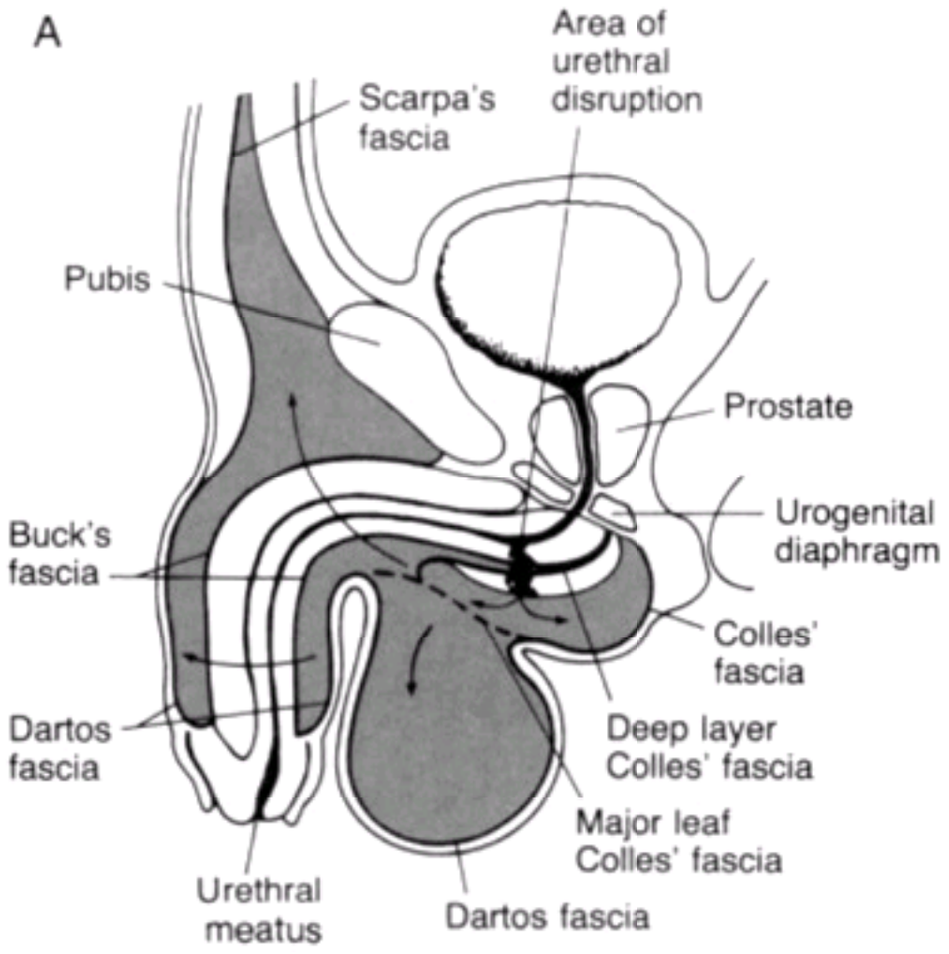

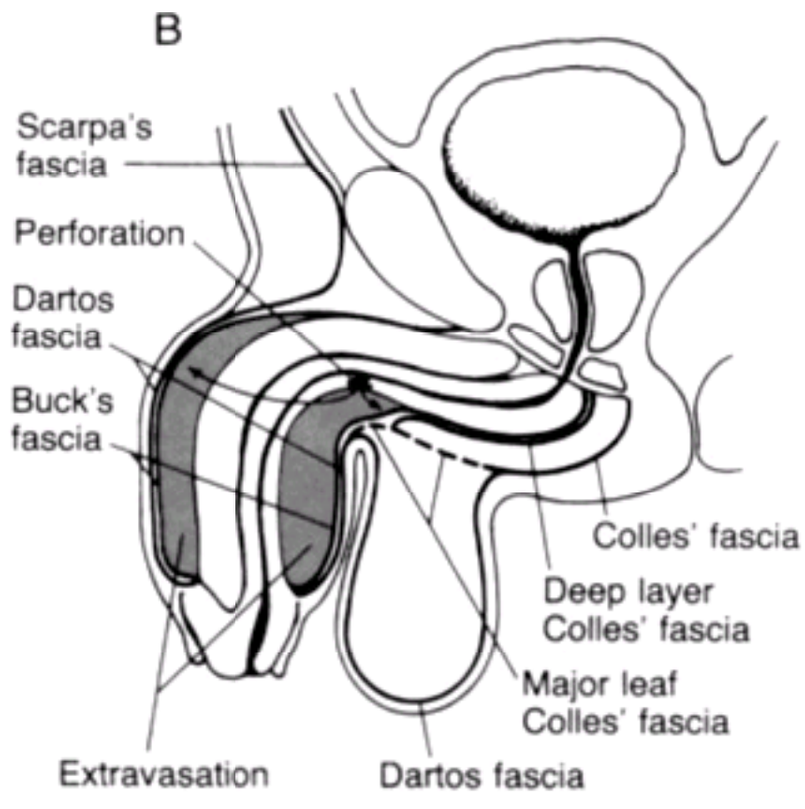

Figure 56-29 Retrograde urethrogram. The foreskin is fully retracted and an unwrapped 4 × 4 gauze sponge is folded in half longitudinally and wrapped around the penis proximal to the coronal sulcus, to prevent foreskin reduction. *A,* The penis is held between the long and ring fingers of the nondominant hand. The thumb and index finger ensure a snug fit of the syringe in the urethra. *B,* Equipment needed for retrograde urethrography and cystography. *C,* Alternative technique for securing the "irrigation-tip" syringe in the urethra.

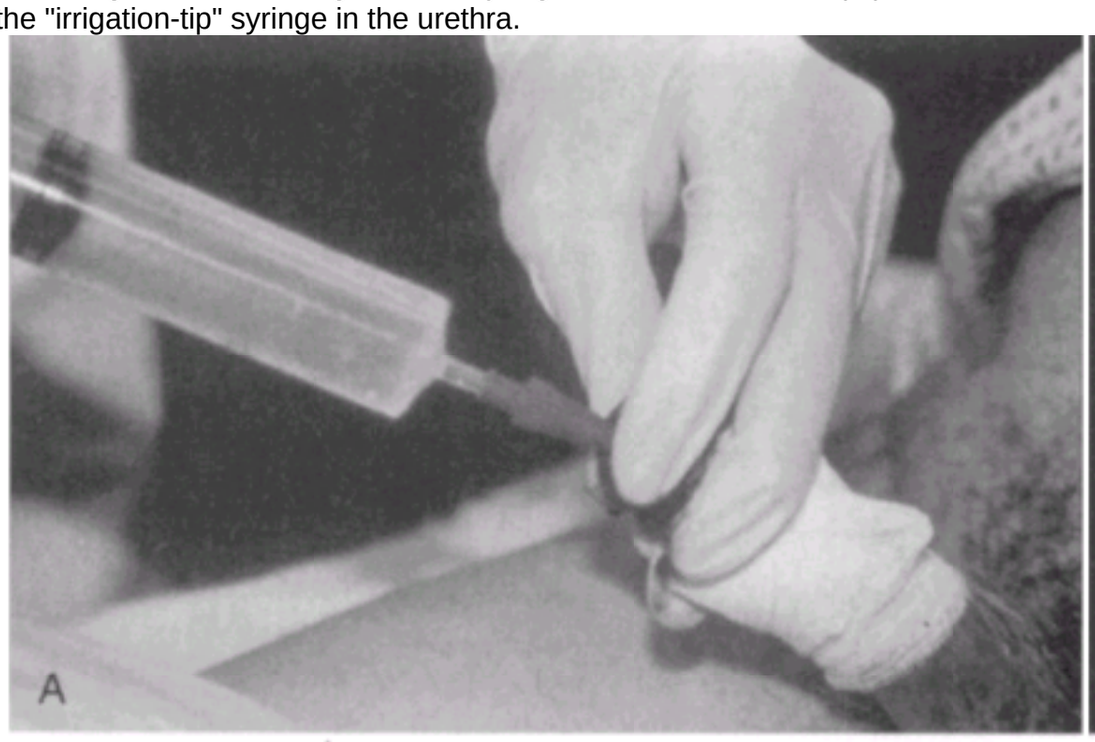

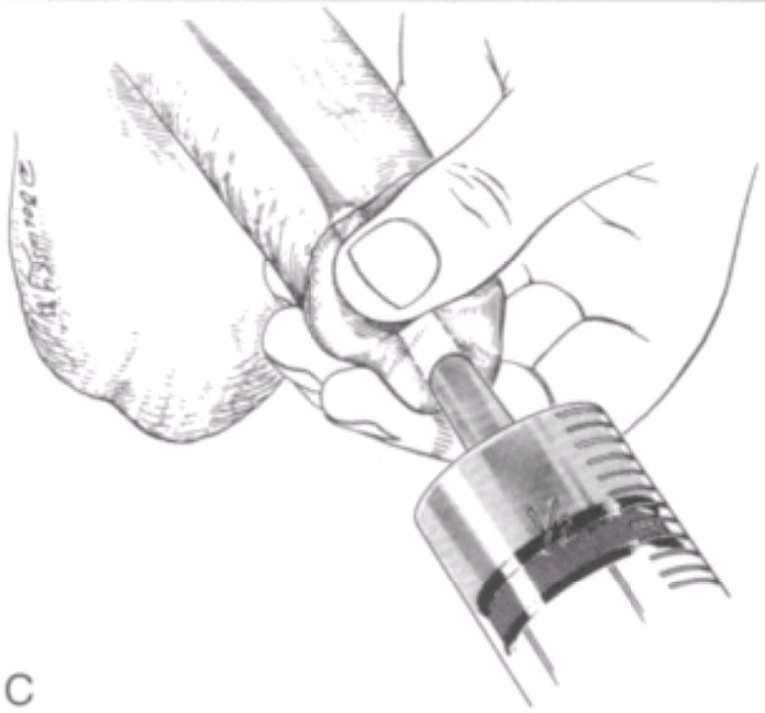

Figure 56-30 Normal retrograde urethrogram. The patient is supine on the examination table. The penis is stretched perpendicularly across the patient's right thigh to allow urethral unfolding and complete urethral visualization.

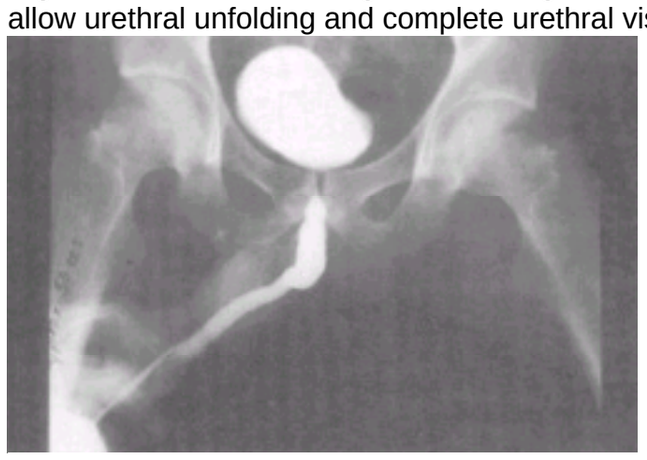

Figure 56-31 Venous intravasation (*arrows*) during a forceful retrograde urethrogram. This may mimic urethral extravasation, but it clears immediately, as opposed to actual extravasation, which remains indefinitely. The presence of intravasation is benign. *(From Richter MW, Lytton B, Myerson D, Grnja V: Radiology of genitourinary trauma. Radiol Clin North Am 11(3):626, 1973.)*

Figure 56-32 Retrograde urethrogram using a Foley catheter (8 Fr). Slowly inflate the balloon with 2 mL of air, tap water, or sterile saline to create a snug fit; then slowly inject 60 mL of a 10% solution of contrast material through the catheter lumen (see text).

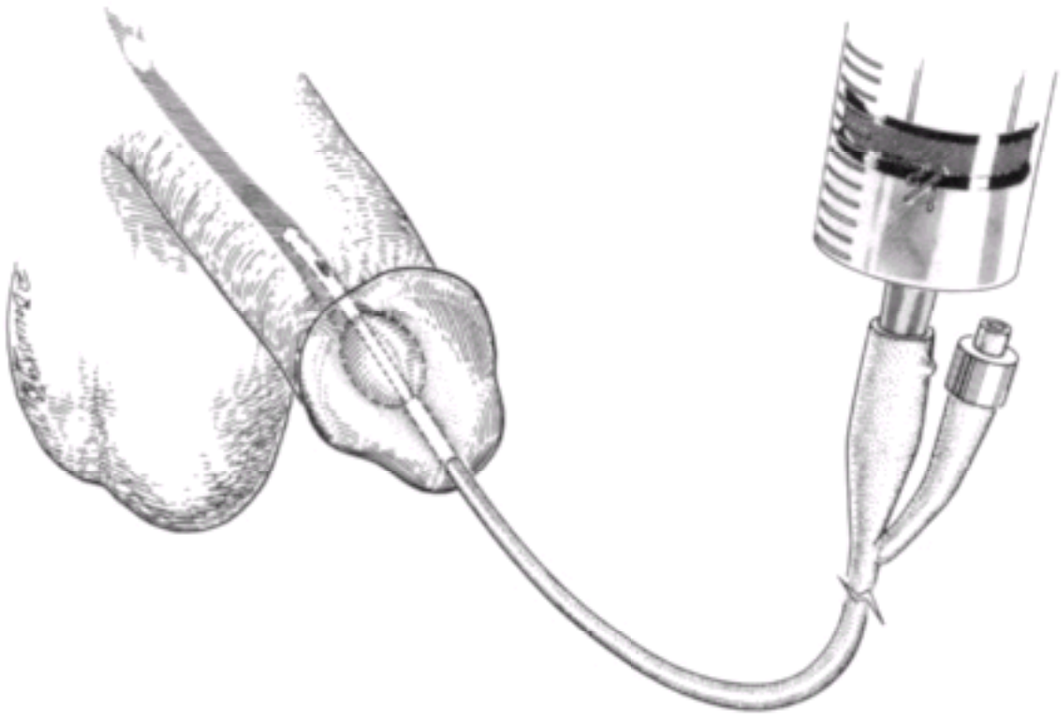

Figure 56-33 *A,* Retrograde urethrogram. Urethrogram in case of supramembranous urethral rupture. Contrast extravasation is typical of that seen with this type of injury. *B,* A rupture at the proximal bulbous urethra into the scrotum (*arrows*). *C,* Residual contrast material within perineum and scrotum. *(A from Morehouse DD, MacKinnon KJ: Posterior urethral injury: Etiology, diagnosis, initial management. Urol Clin North Am 4:74, 1977. C from Richter MW, Lytton B, Myerson D, Grnja V: Radiology of genitourinary trauma. Radiol Clin North Am 11:627, 1973.)*

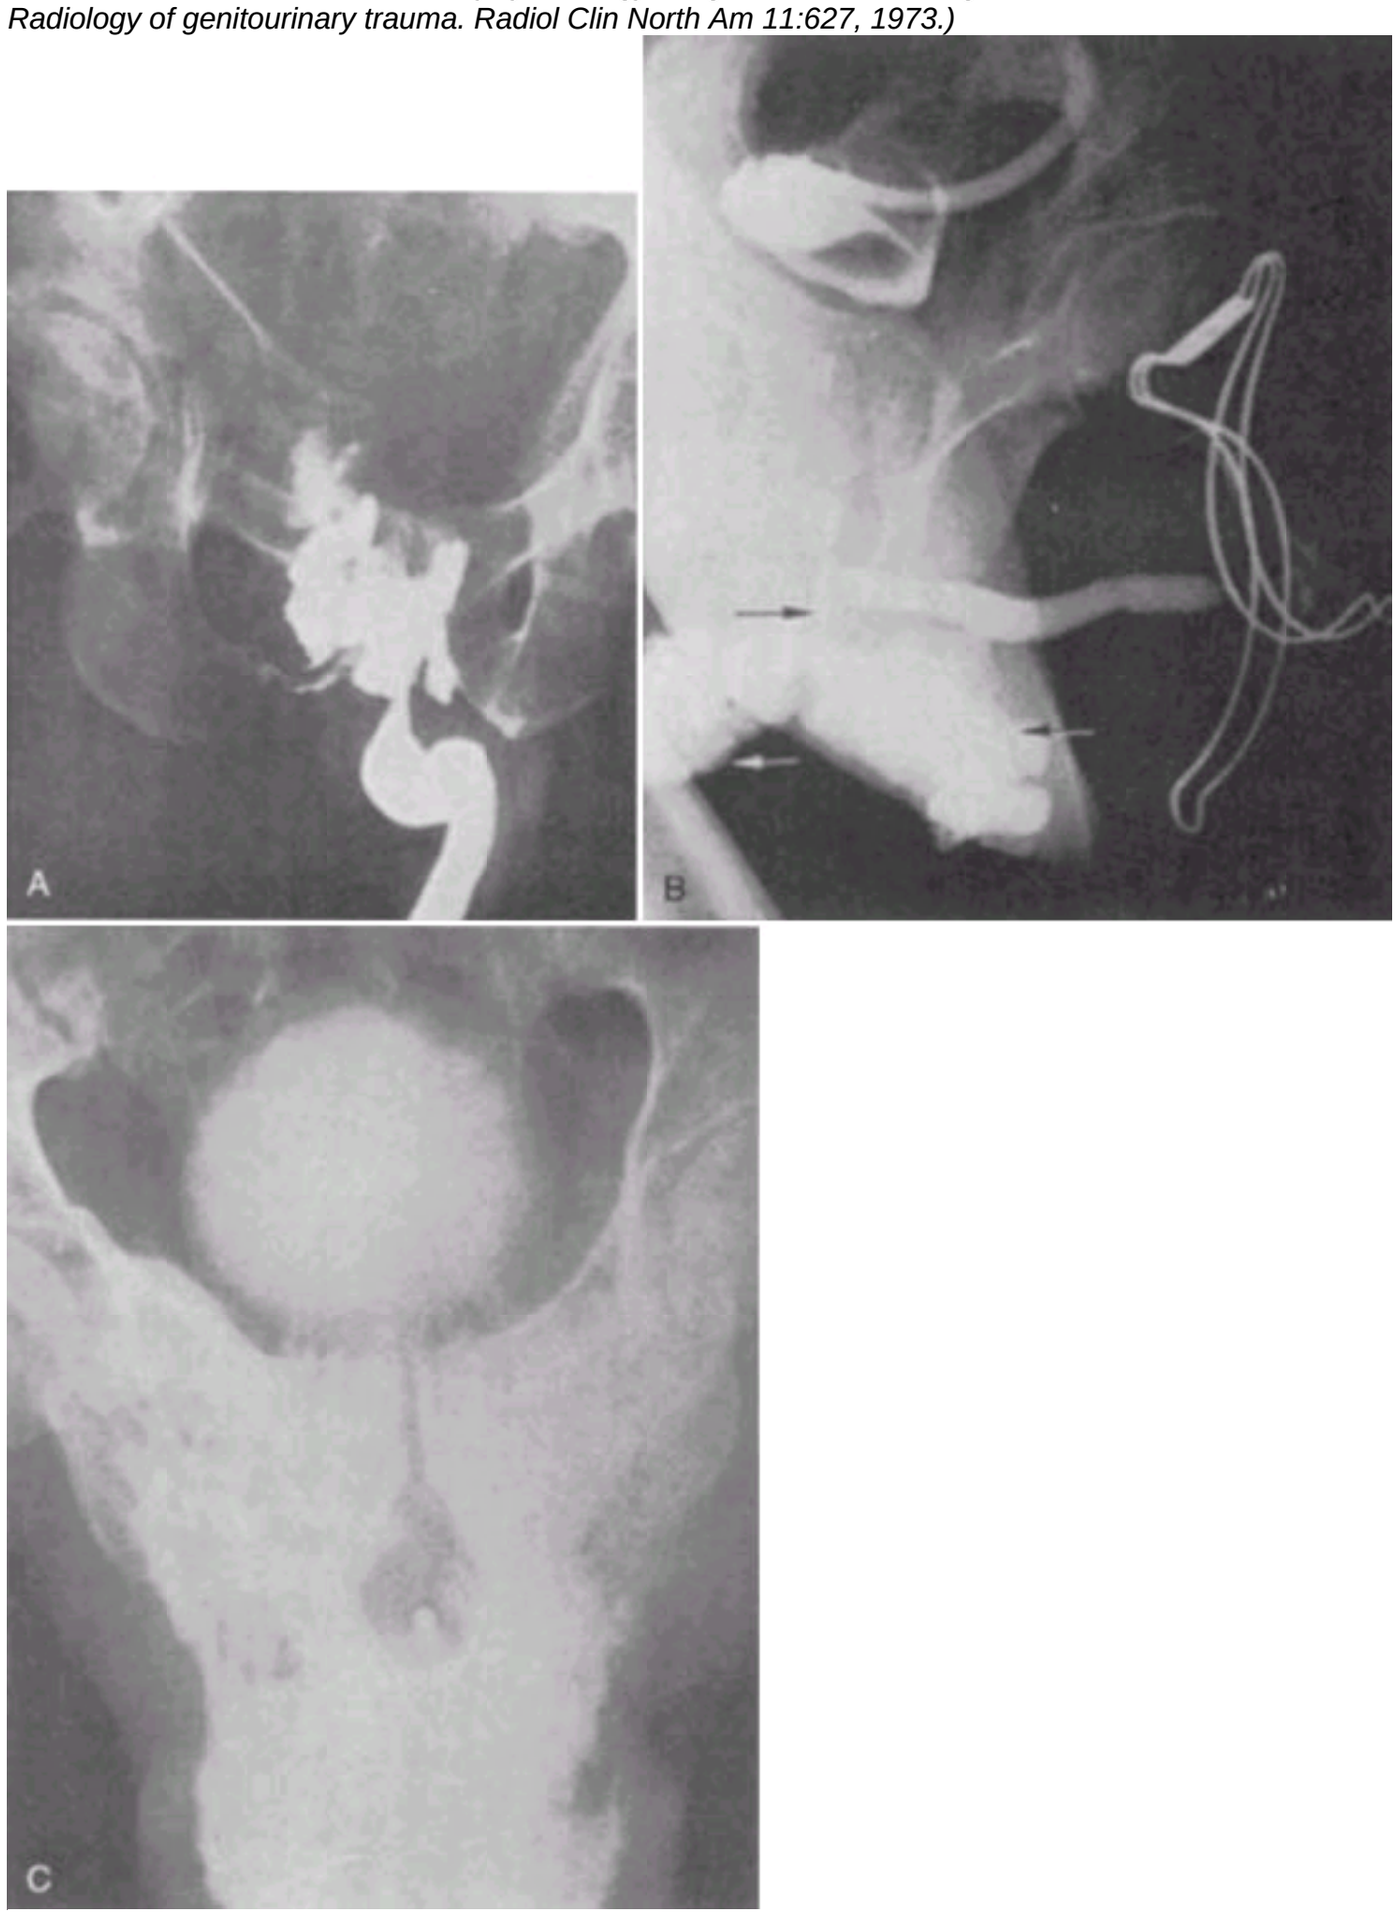

Figure 56-34 Evaluation of a urethral injury with a Foley catheter in place. A lubricated pediatric feeding tube has been advanced into the urethra beside the indwelling Foley catheter.

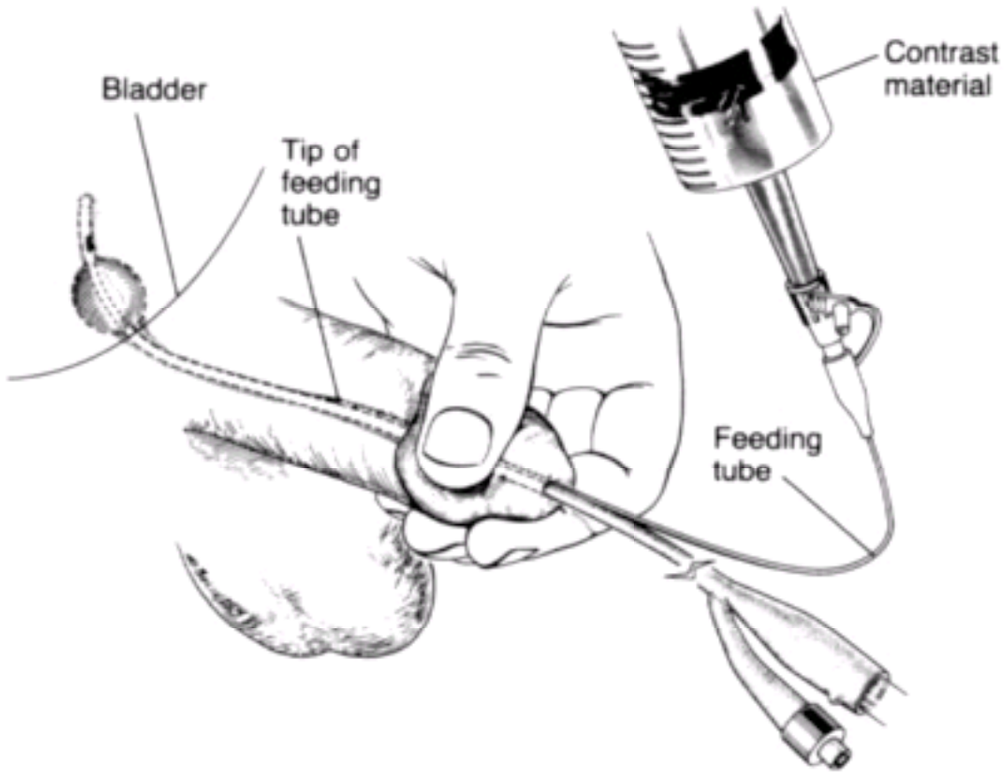

Figure 56-35 Retrograde cystogram. *A,* In patients with pelvic fracture, retrograde cystography should be done with the patient supine throughout the examination. Here, gross extravasation is evident, but its superior extent is not well defined. *B,* A lateral film may help define the extent of any extravasation. This film shows no intraperitoneal extension, so the extravasation must be totally extraperitoneal.

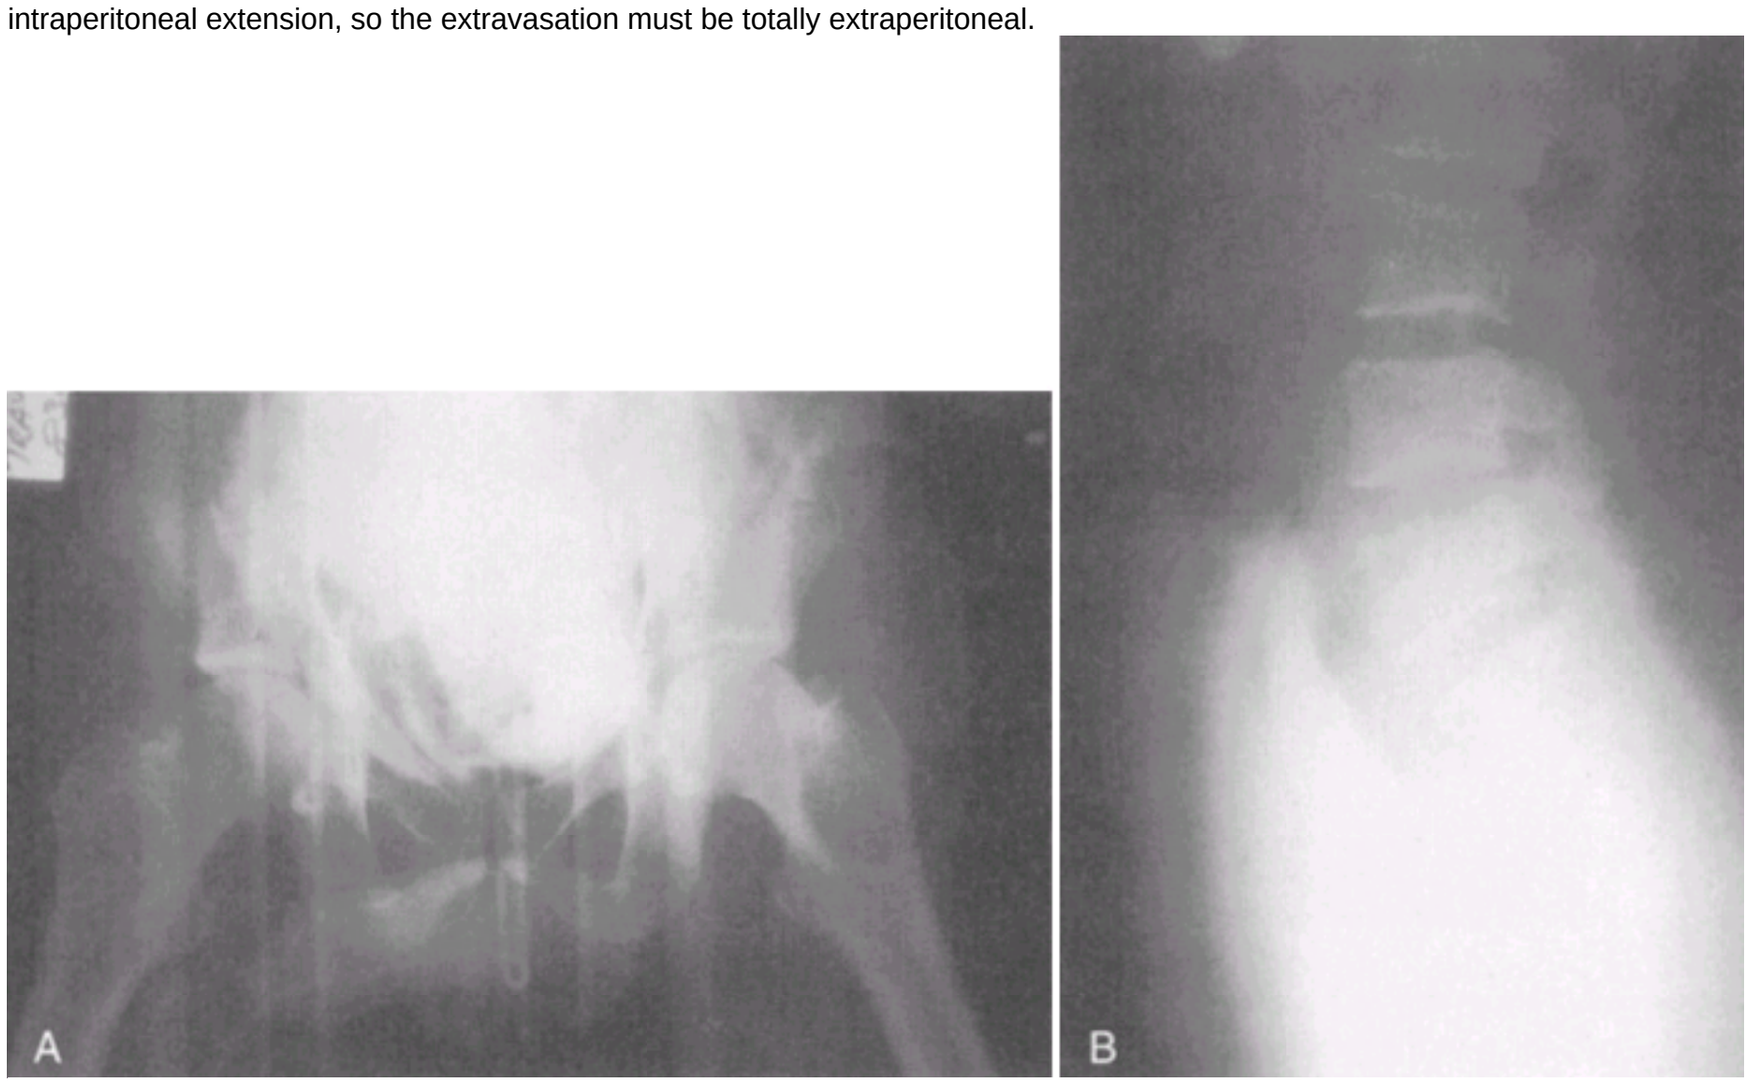

Figure 56-36 Retrograde cystogram. *A,* Anteroposterior (AP) filled-bladder film. *B,* AP postevacuation film of same patient showing extensive extravasation not seen on the AP filled-bladder film. Balloon of catheter is identified by *arrows*. *C,* "KUB" (kidneys, ureters, and bladder) showing bullet in the area of pelvis. *D,* AP filled-bladder film of same patient showing bladder displacement to right, presumably from a pelvic hematoma. No extravasation is visible with the bladder full of contrast. *E,* AP postevacuation film of same patient, showing subtle contrast extravasation in area of bullet that could easily be missed without a high-quality preliminary KUB and post-evacuation film.

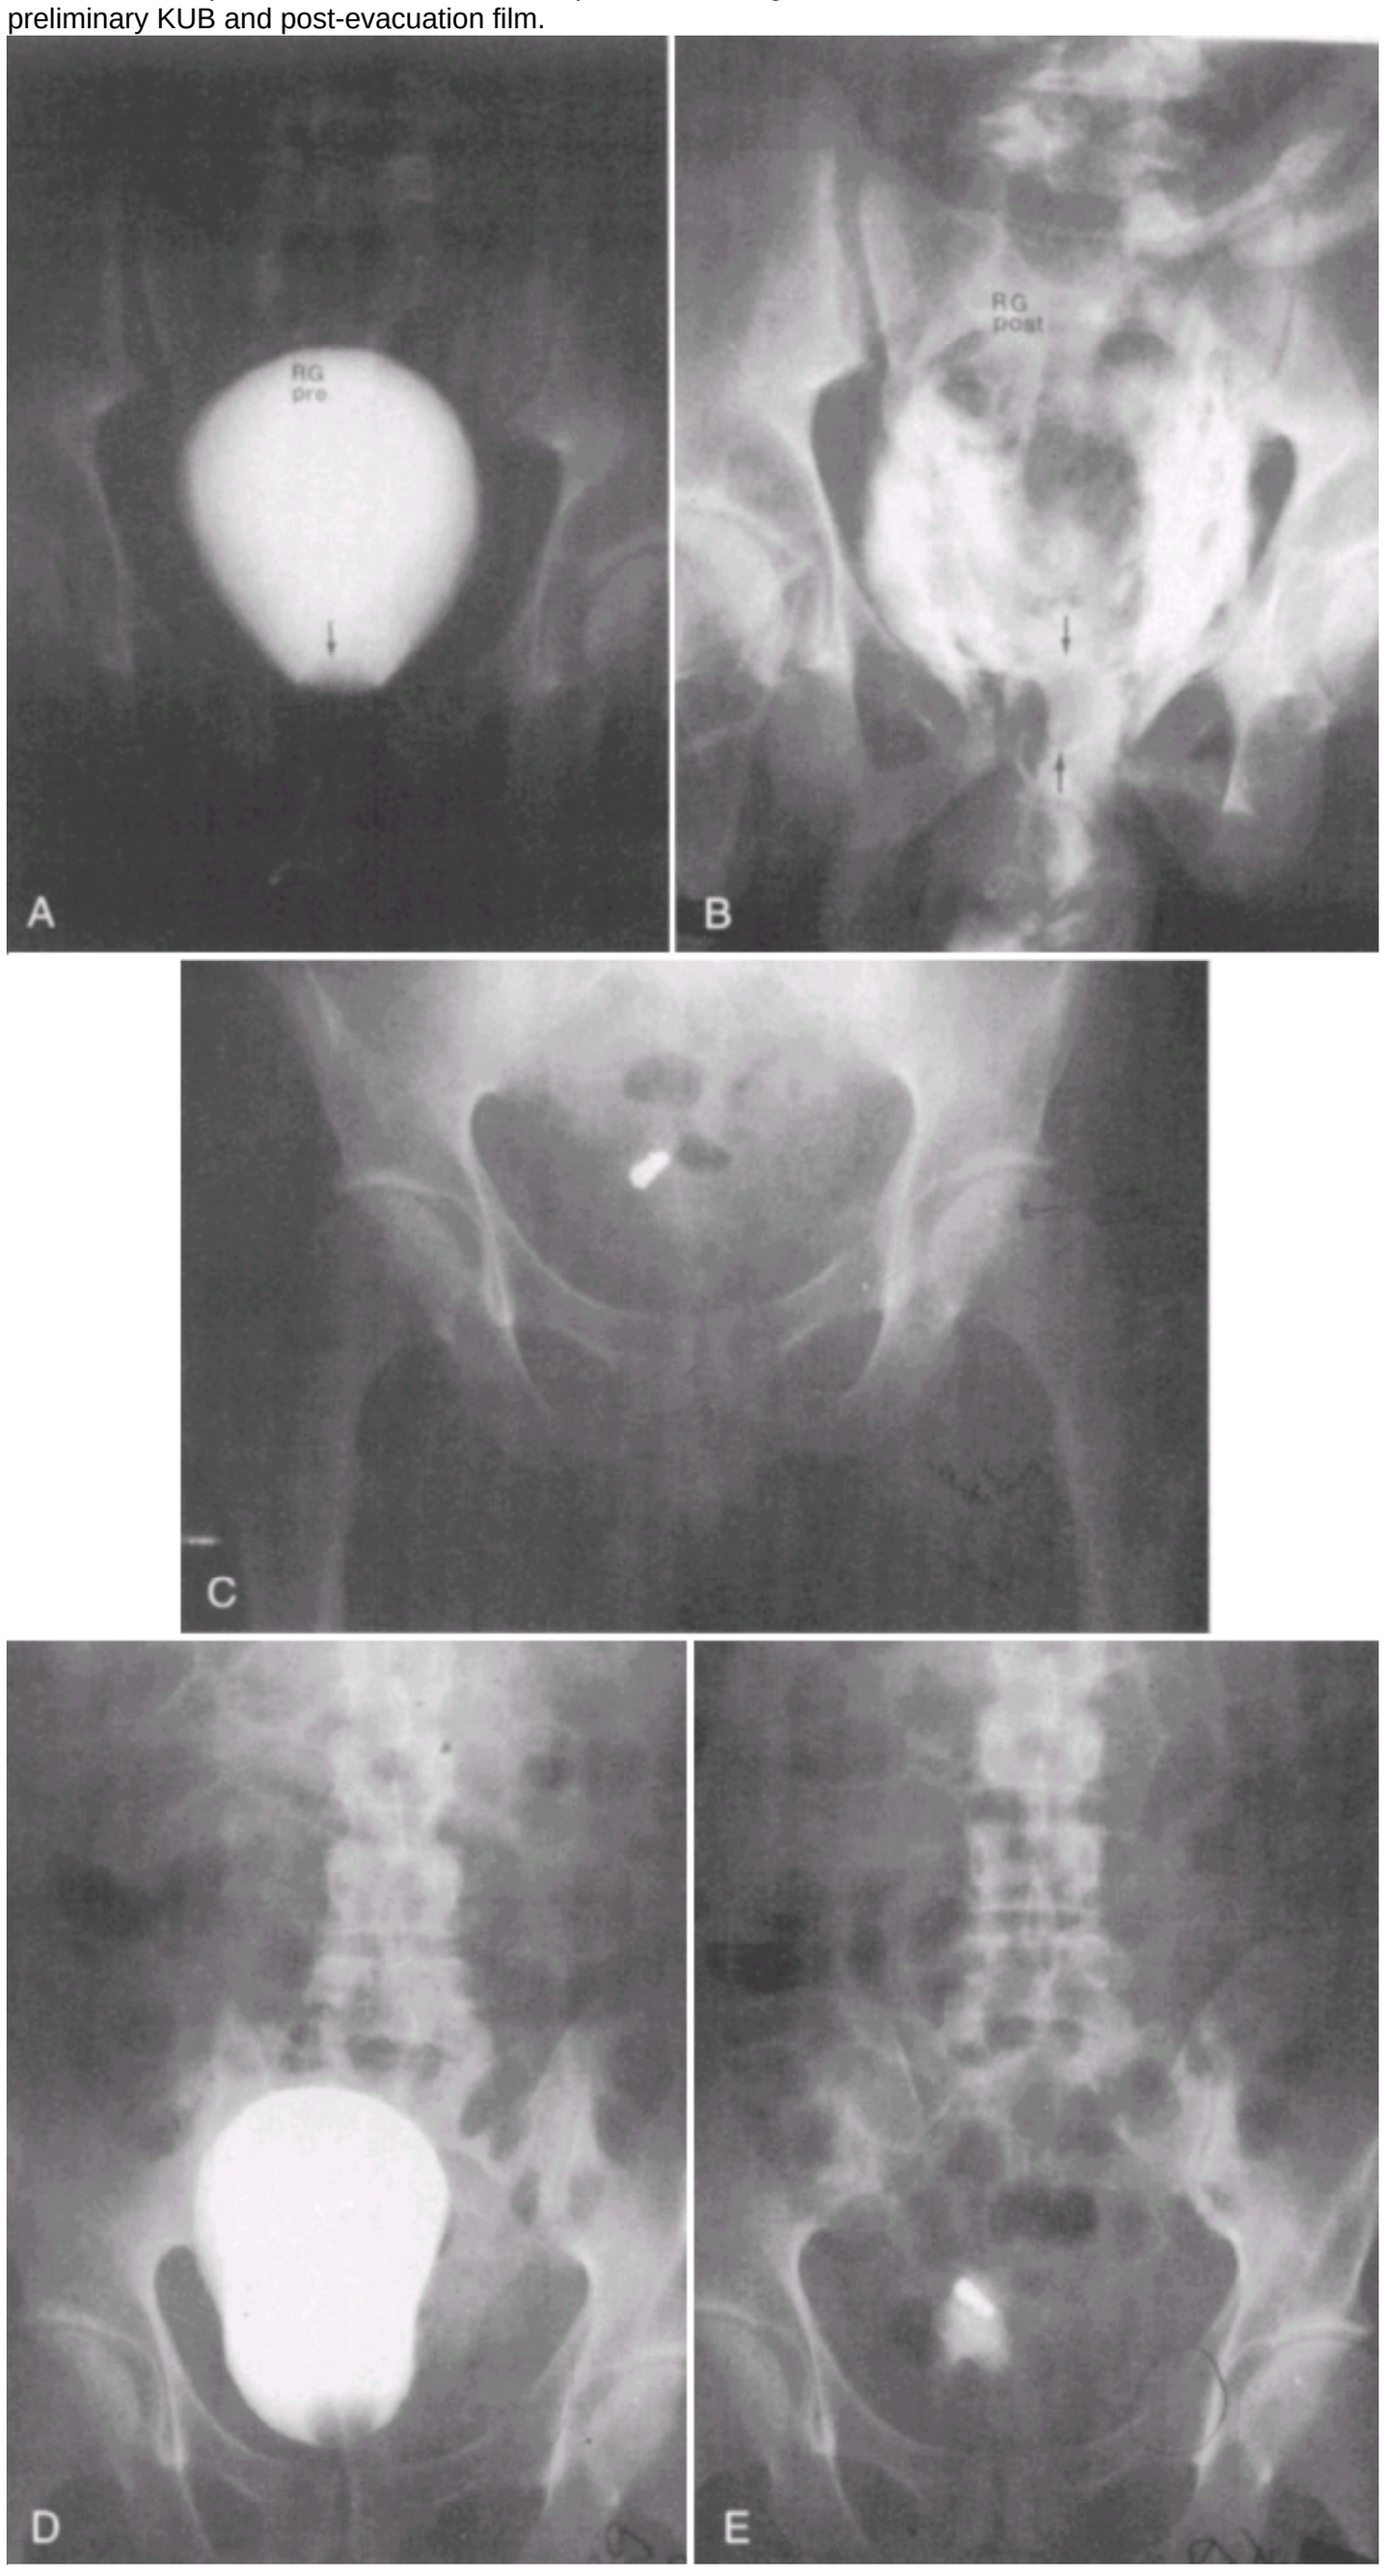

Figure 56-37 Examples of extraperitoneal bladder rupture. *A,* Note the amorphous extravasation of contrast material within the perivesical space (*arrows*) in a patient with a right pelvic fracture (*arrowheads*). *B,* A second patient with a pelvic fracture (*arrowhead*) and perivesical hematoma shows the teardrop shape of a deformed bladder and extraperitoneal extravasation (*arrows*). *(From Richter MW, Lytton B, Myerson D, Grnja V: Radiology of genitourinary trauma. Radiol Clin North Am 11:623, 1973.)*

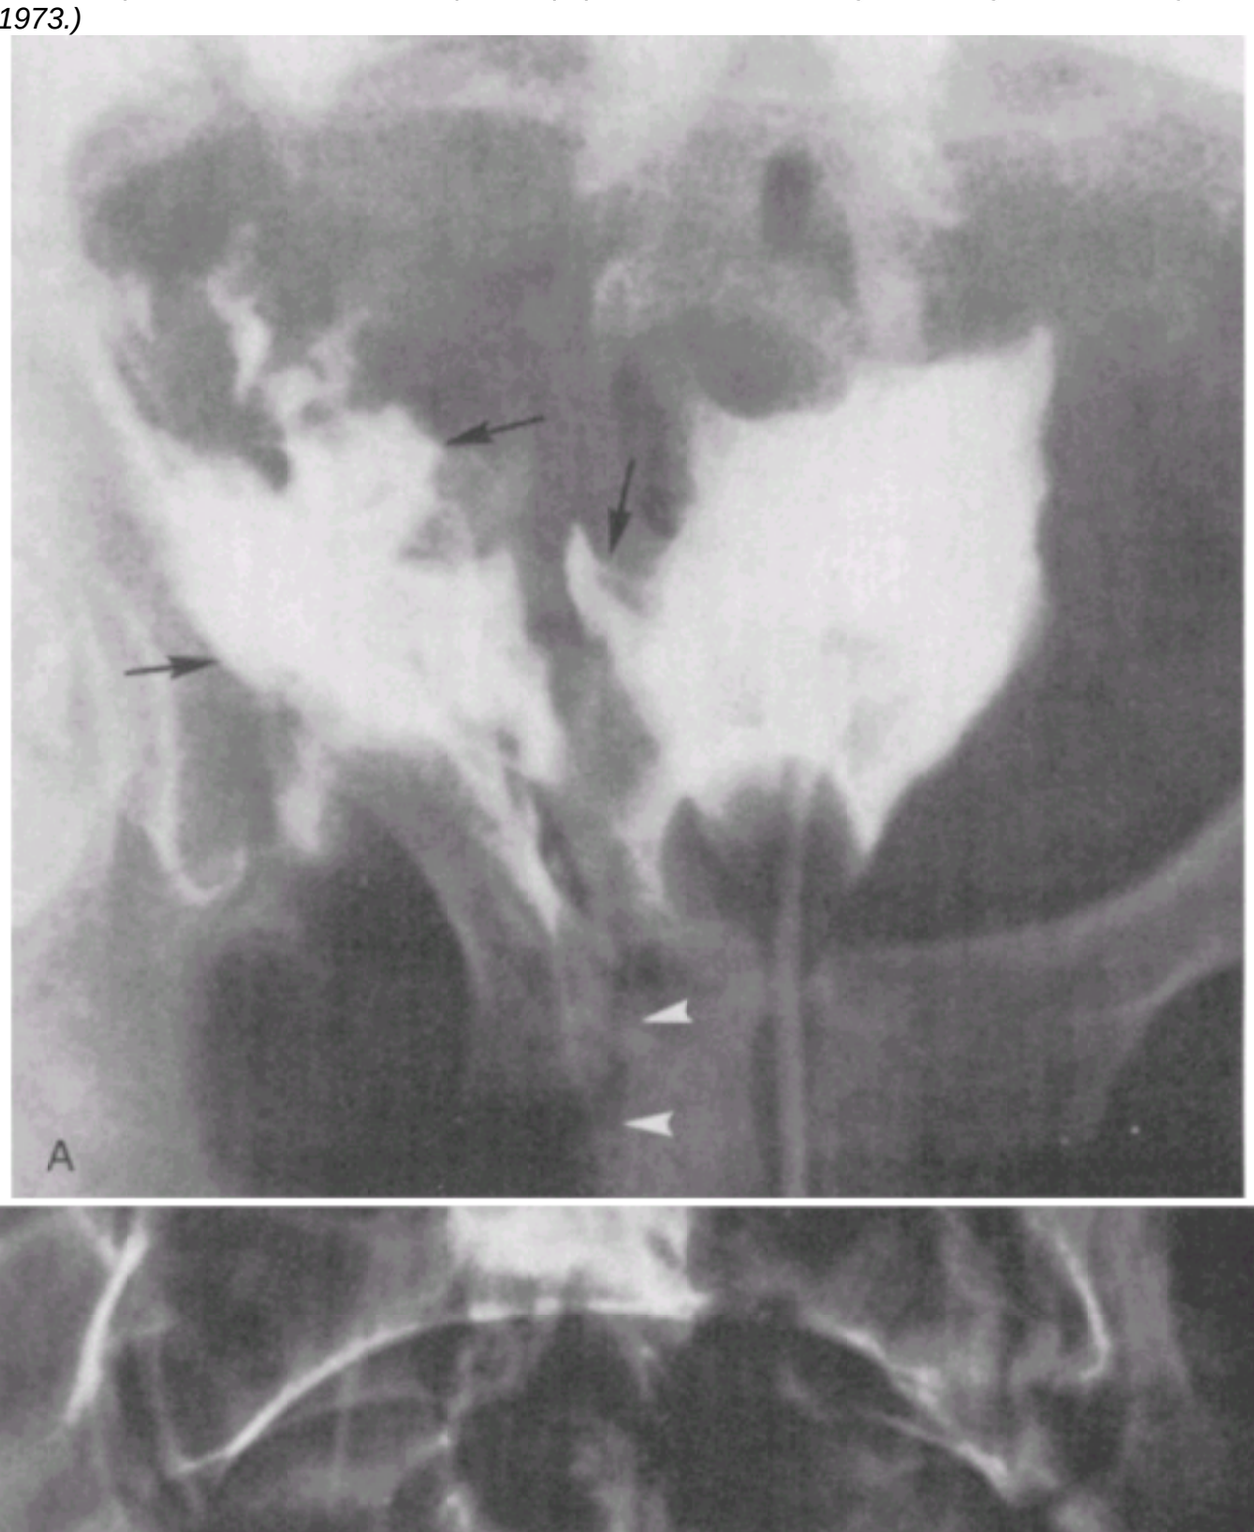

Figure 56-38 Intraperitoneal bladder rupture. *A,* A 22-year-old pedestrian hit by an automobile. Note extravasation of contrast material beginning at the dome and tracking up the left paracolic gutter (*arrows*). *B,* This 57-year-old man had fulguration of a bladder tumor at the bladder dome and sustained perforation. A cystogram dramatically demonstrates the extravasation of contrast material that outlines the bowel loops (*arrows*) and the paracolic gutters. *(Courtesy of Morton A, Bosniak MD, New York.) (From Richter MW, Lytton B, Myerson D, Grnja V: Radiology of genitourinary trauma. Radiol Clin North Am 11:623, 1973.)*

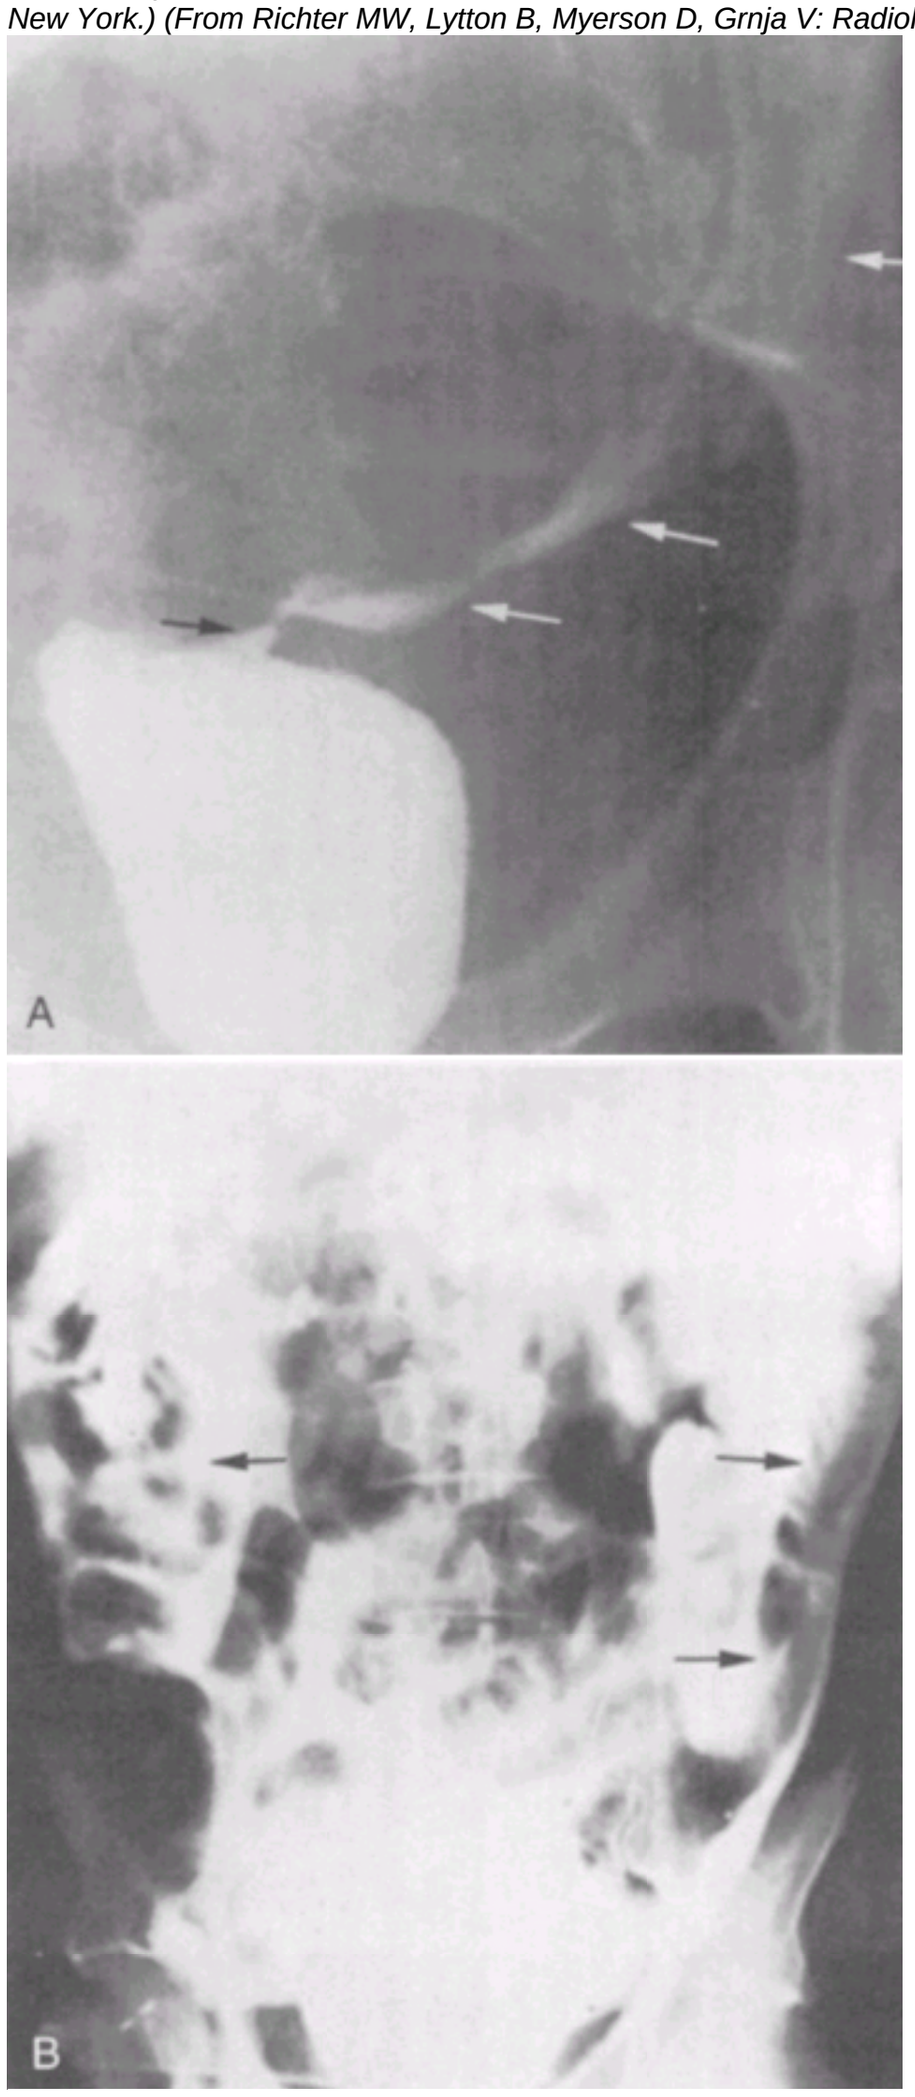

Figure 56-39 Retrograde cystogram and abdominal computed tomography (CT) scan. These two procedures can be done concomitantly. The bladder is filled in the standard retrograde fashion and the catheter is clamped. Intravenous and oral contrast can then be administered and CT scanning performed. This film demonstrates contrast ascites, which is consistent with intraperitoneal bladder rupture and extravasation.

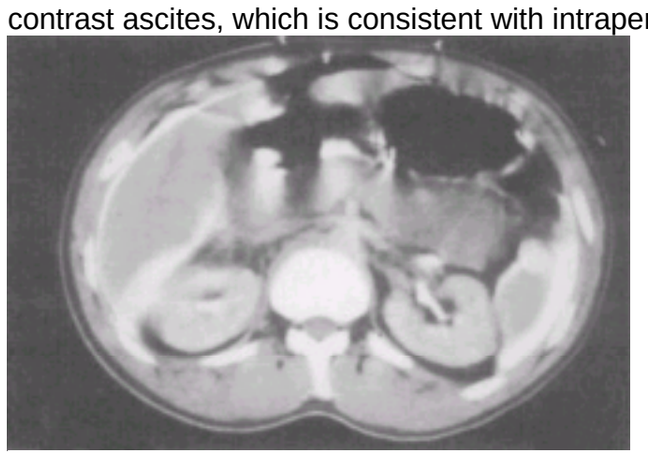

Figure 57-6 Station of the fetal head. As a reference point, the level of the ischial spines is zero station. *(From Benson RC [ed]: Current Obstetric and Gynecologic Diagnosis and Treatment, 3rd ed. Los Altos, Calif., Lange Medical Publications, 1980.)*

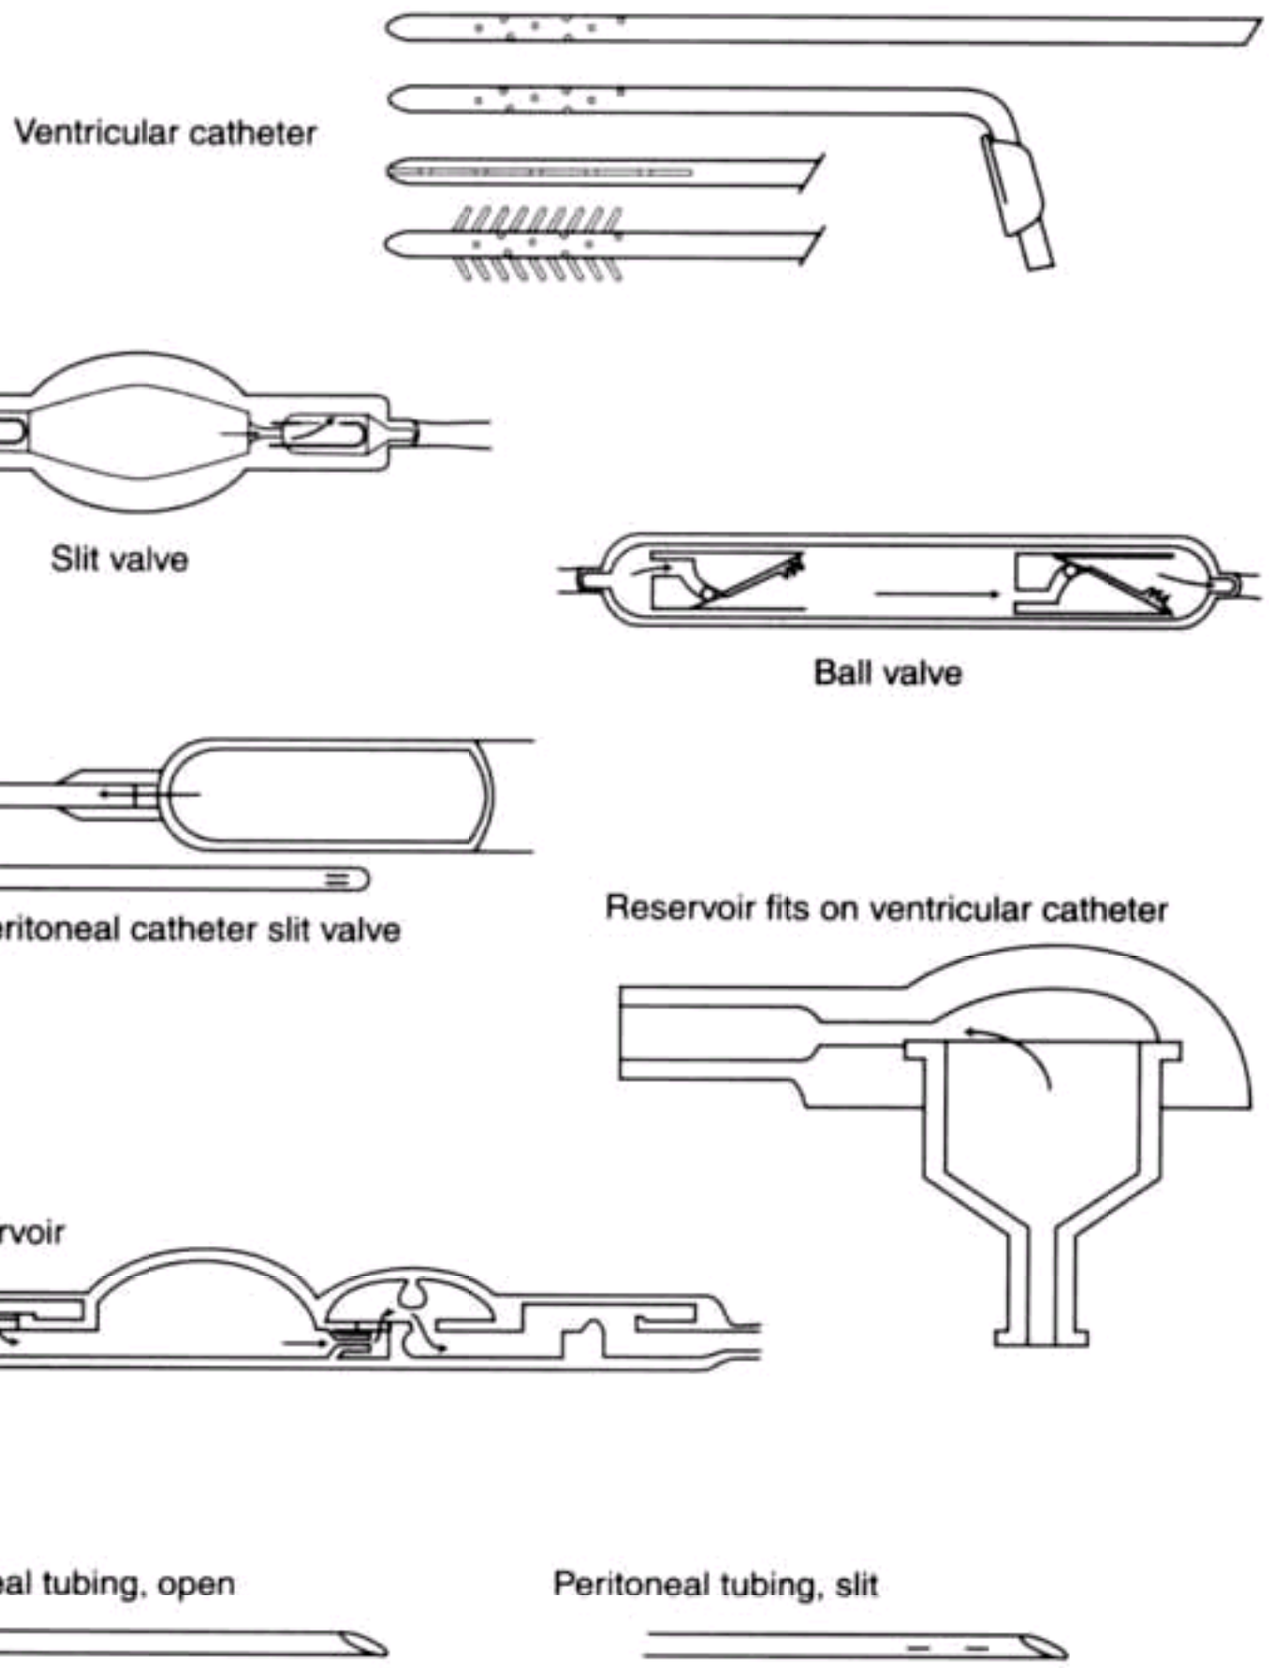

Figure 61-8 Cross section of a Pudenz flushing valve (American Heyer-Schulte, Santa Barbara, CA) illustrating the diaphragm valve. The proximal inlet tube and silicone base are placed in the burr hole so that only the reservoir (silicon dome) protrudes above the skull *(Courtesy of PS Medical, Goleta, CA).*

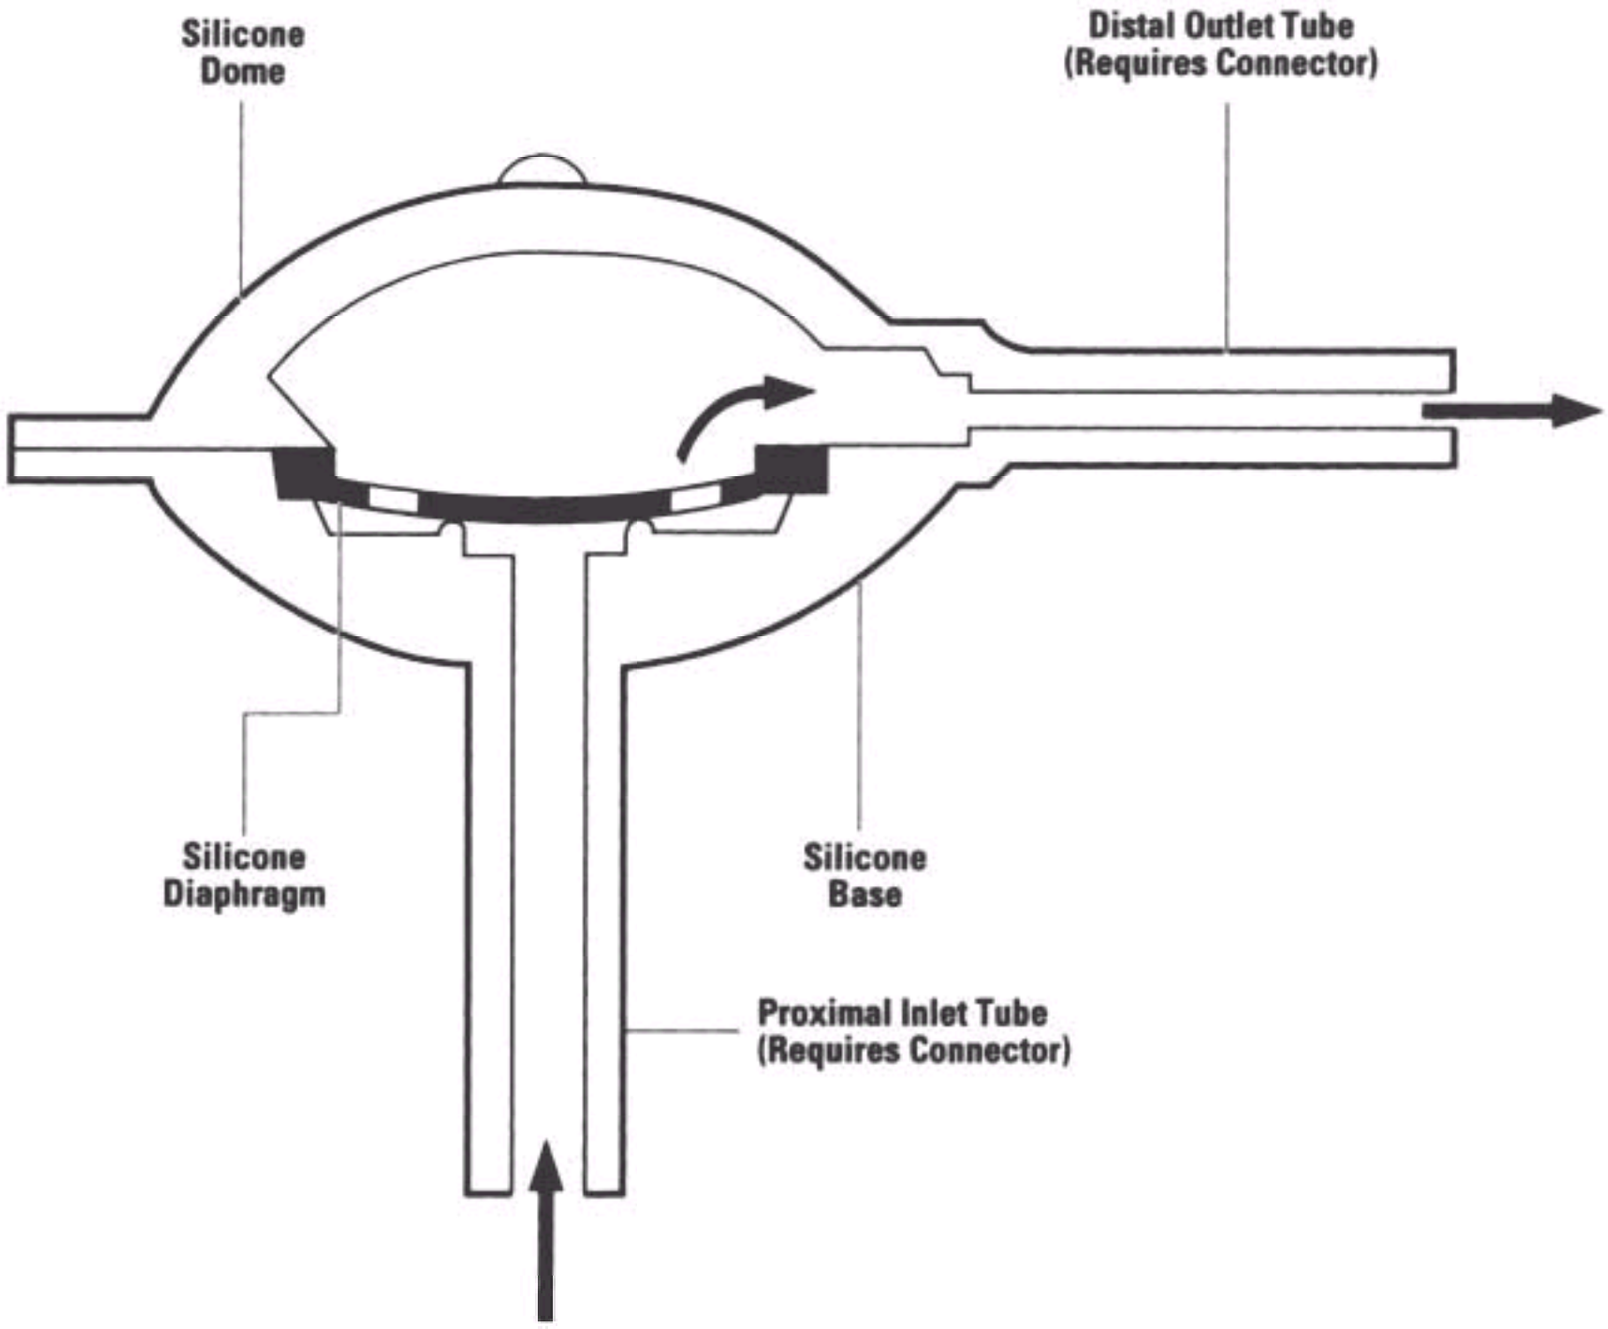

Figure 61-9 Ventriculoperitoneal shunt and alternative occipital placement *(From Rengachary and Wilkins: Principles of Neurosurgery. Philadelphia, Mosby, 1994, Fig. 7-6).*

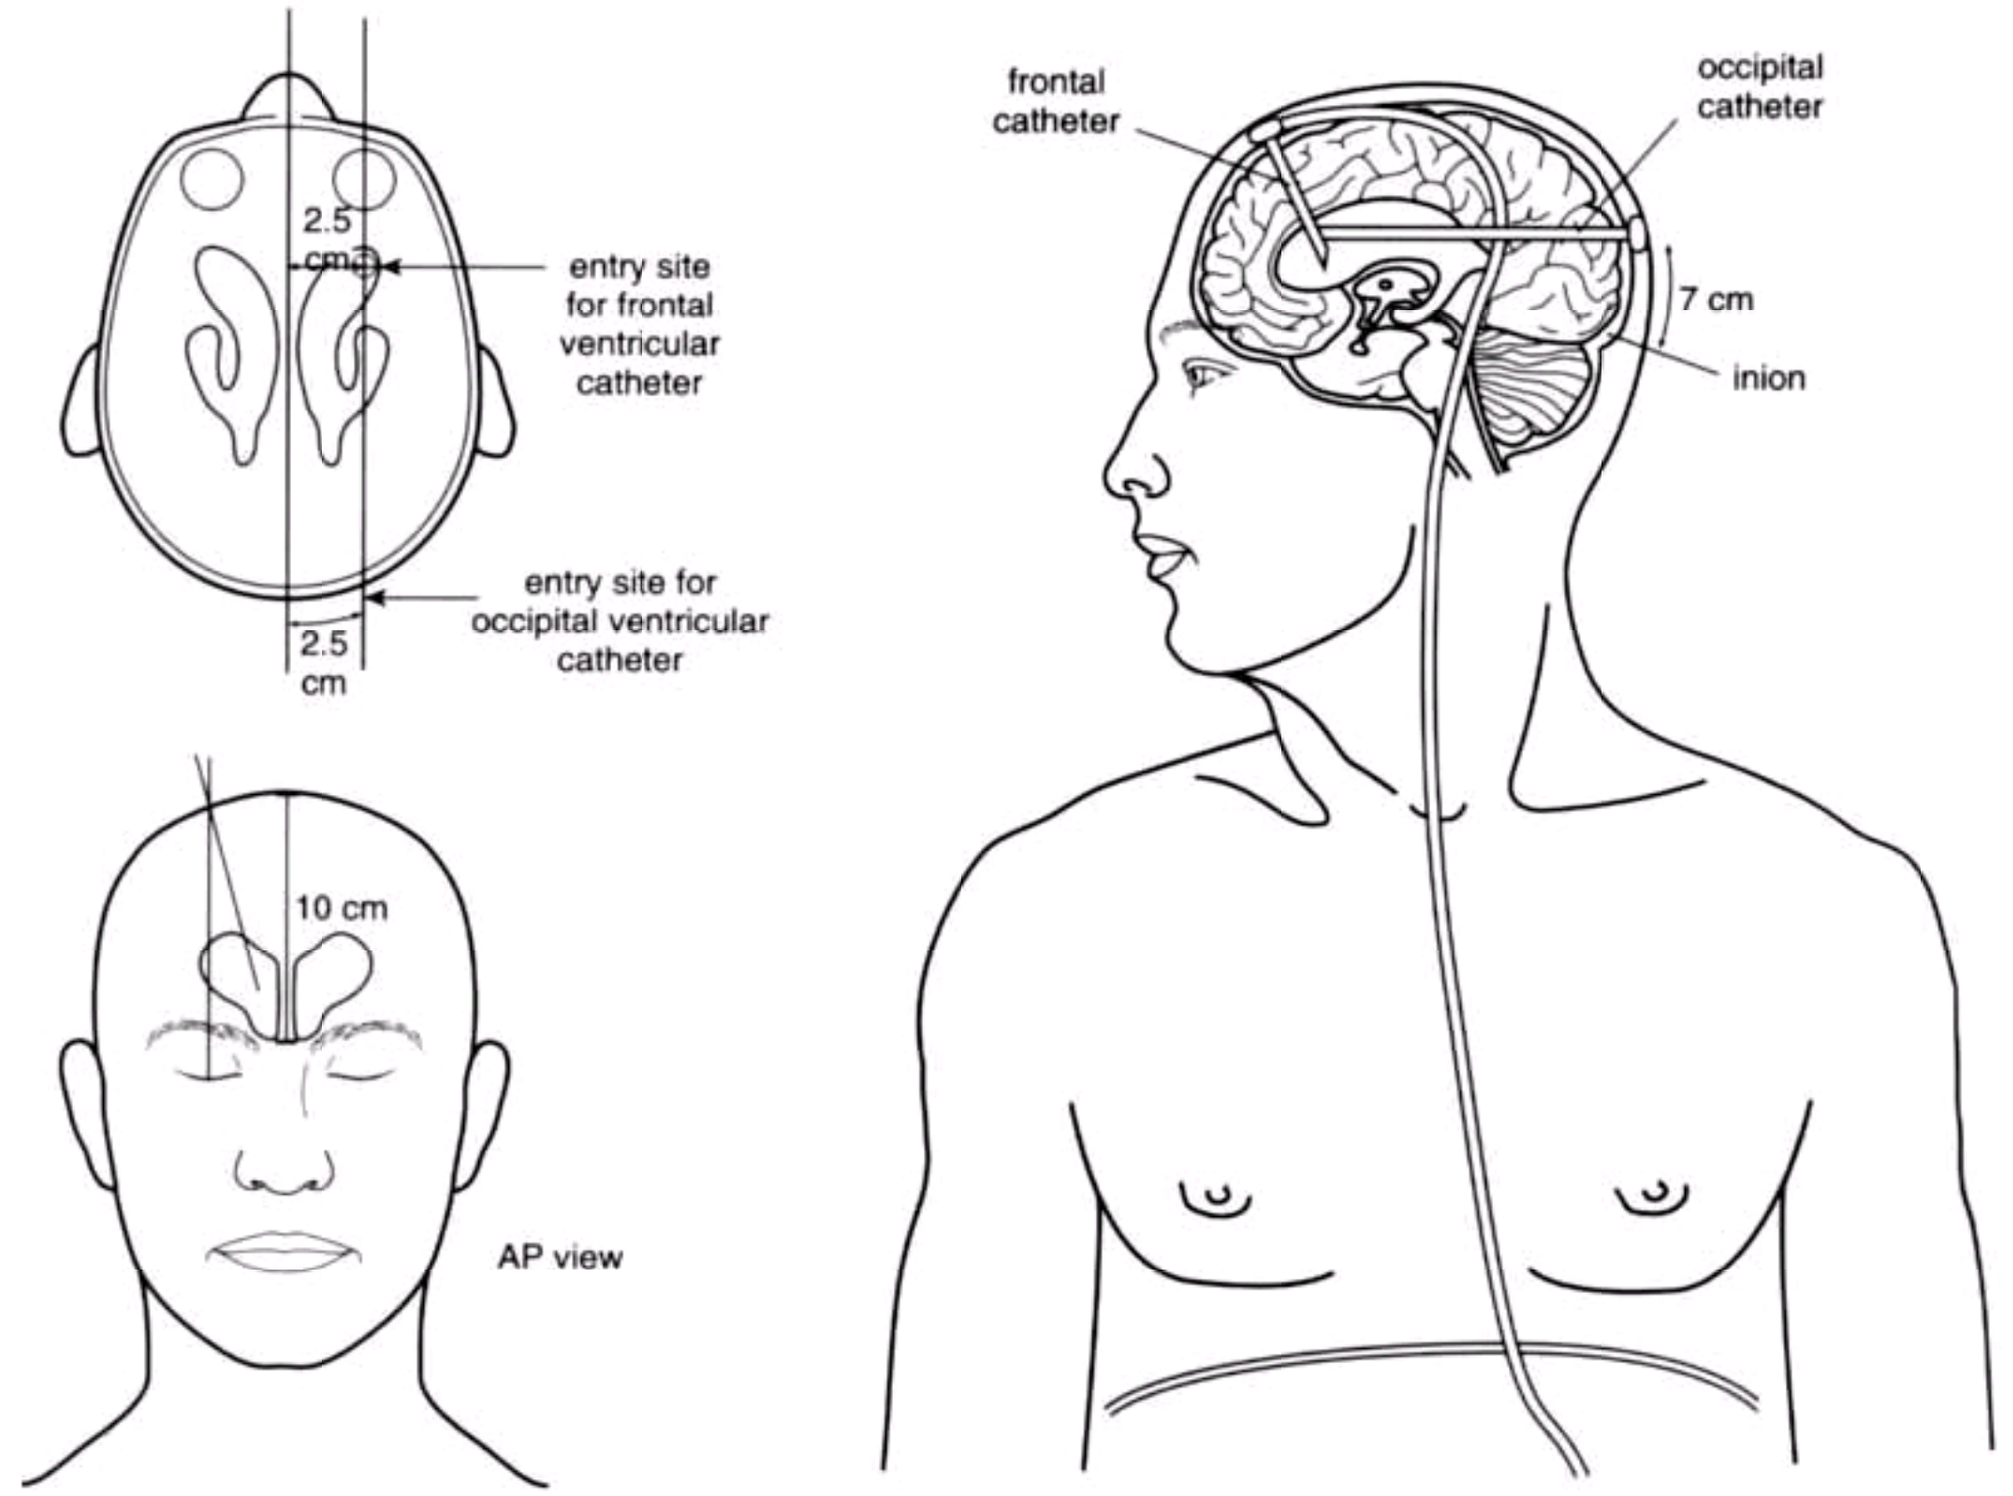

Figure 61-10 A standard shunt series includes an anteroposterior (AP) skull, lateral skull, and chest radiograph and kidney, ureters, bladder (KUB) series. This intact shunt is a Rickham reservoir over the burr hole, with a cylindrical Holter valve a few centimeters distal. This AP skull radiograph reveals the proximal intracranial portion of the shunt and a Rickham reservoir over the burr hole.

Figure 61-11 Lateral skull radiograph of patient in Figure 61-10 . This view better reveals a cylindrical Holter valve situated a few centimeters distal to the Rickham reservoir.

Figure 61-12 Anteroposterior chest and abdominal radiograph of patient in Figure 61-10 . This radiograph reveals the distal portion of the shunt. Note the length of the catheter to allow for patient growth.

Figure 61-13 Lateral chest and radiograph of the patient in Figure 61-10 .

Figure 61-14 Connector discontinuity of a ventricular peritoneal shunt, at the level of the clavicle, is illustrated in this chest radiograph from a shunt series.

Figure 61-15 Normal lateral skull radiograph demonstrating an intact ventricular peritoneal shunt in a young patient with a Holter valve. This shunt later became disconnected (see Fig. 61-17 and Fig. 61-18).

Figure 61-16 Normal anteroposterior chest and abdominal radiograph demonstrating an intact ventricular peritoneal shunt in the patient in Figure 61-15 .

Figure 61-17 Repeat films from the patient in Figure 61-15 and Figure 61-16 illustrating shunt disconnection at the level of the valve and subsequent migration of the distal catheter into the pelvis. This lateral skull radiograph demonstrates the disconnection from the valve.

Figure 61-18 Abdominal radiograph of patient in Figure 61-17 demonstrating migration of the catheter into the pelvis.

Figure 61-19 Cranial computed tomography scan of the patient with shunt disconnection shown in Figure 61-17 . This CT scan at presentation reveals ventriculomegaly. After revision, the ventricles returned to normal size (see Fig. 61-20).

Figure 61-20 Cranial computed tomography scan of patient in Figure 61-19 after shunt revision. The ventricles have returned to normal size.

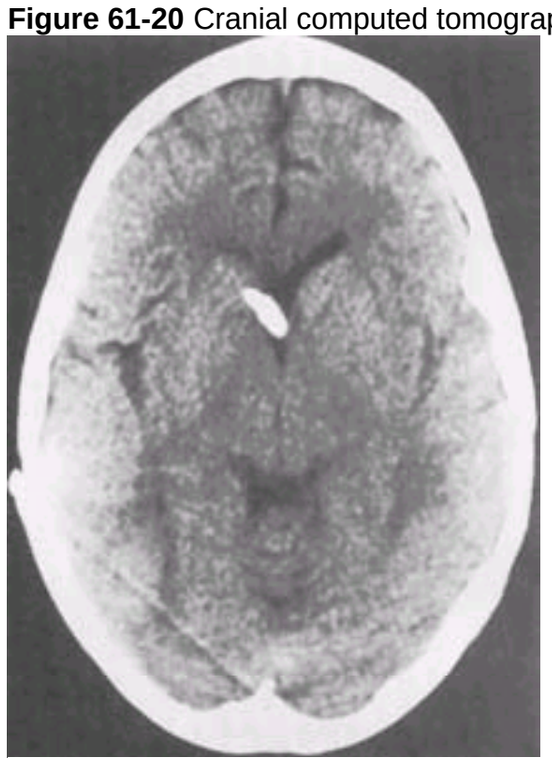

Figure 61-21 A 25-ga butterfly needle puncture of a reservoir. To avoid damage to the reservoir, the angle should be approximately 20° to 30°. Note that the dome reservoir is under the skin. Prior to passage of the butterfly needle, the skin is anesthetized, sterilized with povidone-iodine, and nicked with a number 11 scalpal or larger needle. Fluid is not aspirated but is allowed to drain passively.

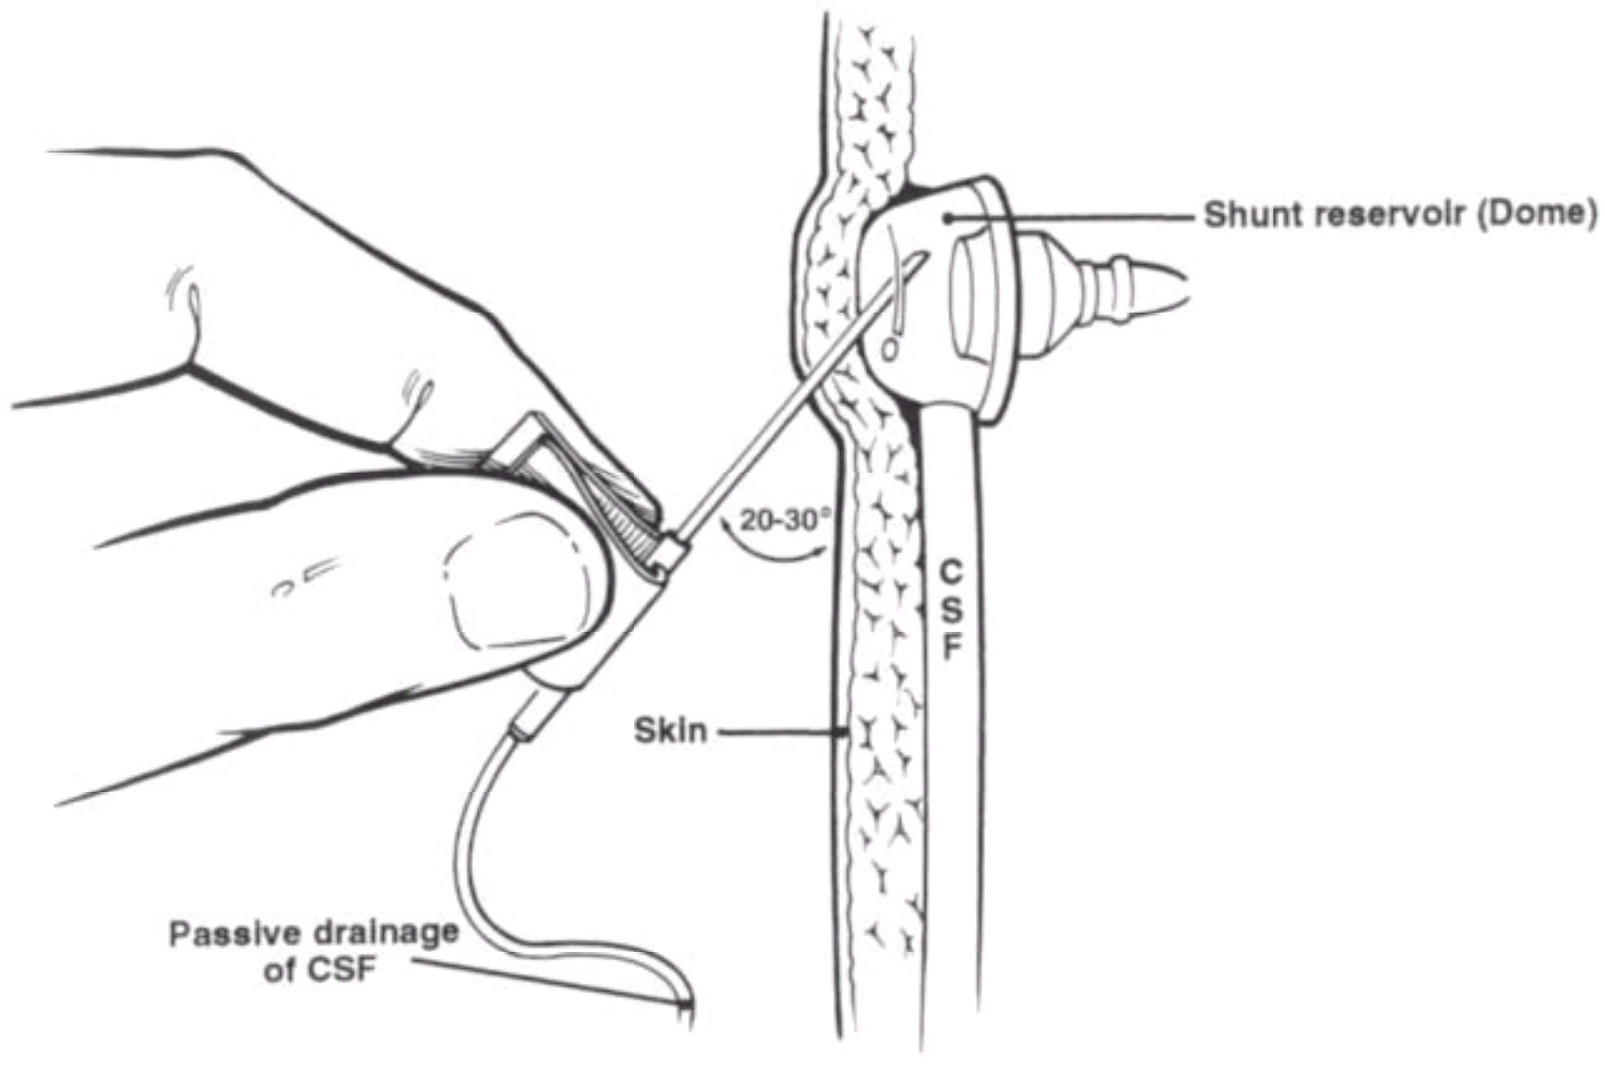

Figure 62-1 Standard lumbar puncture tray. Separate equipment is available for infants, children, and adults. *(Image courtesy of the American Pharmaseal Company, Glendale, CA.)*

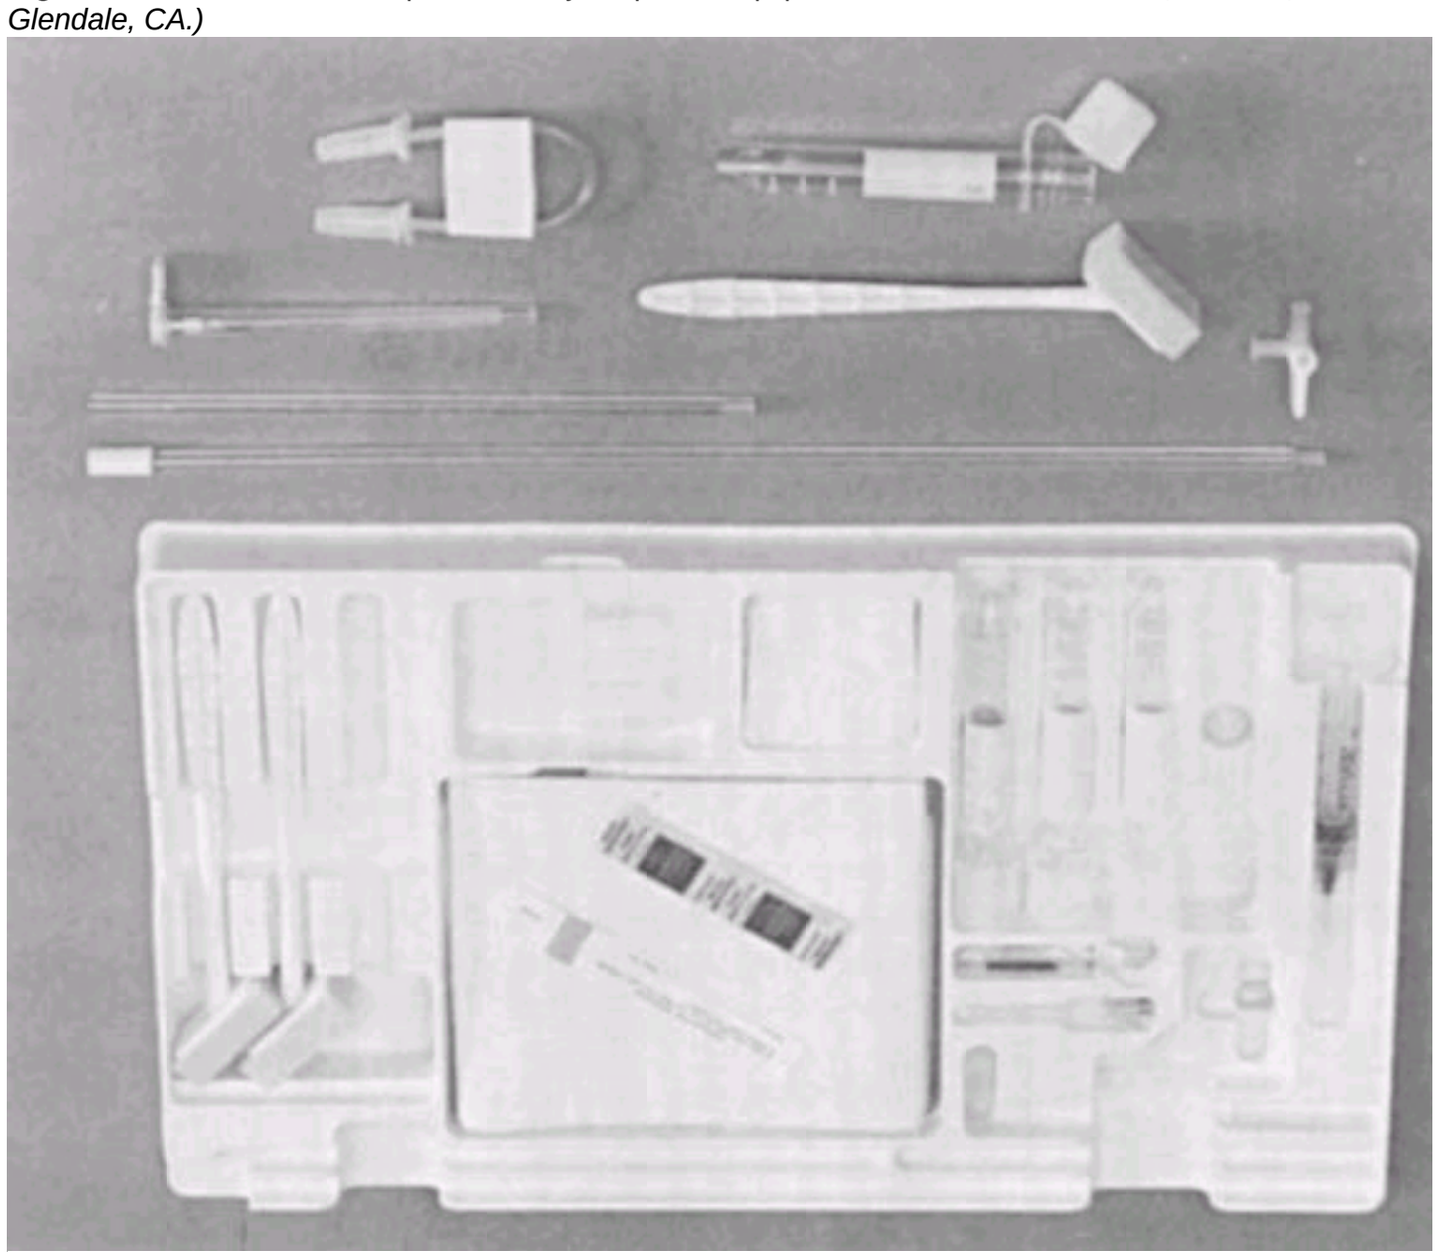

Figure 62-4 The spinal needle is usually advanced ½ to ¾ of its length before the spinal canal is reached. In this obese patient the needle was advanced all the way to the hub of the needle before spinal fluid was returned.

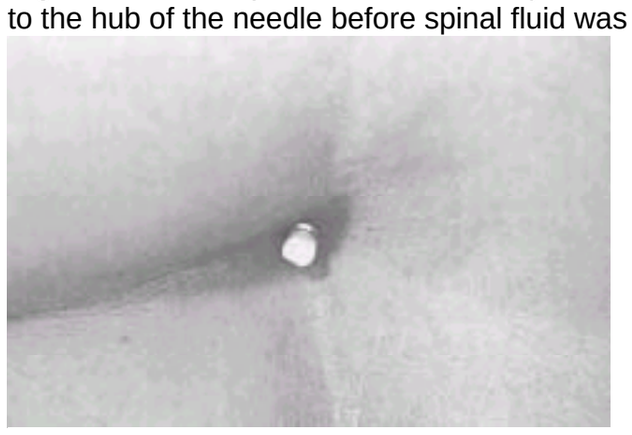

Figure 63-1 Schematic drawing of the brainstem, showing the major elements of the vestibulo-ocular reflex (VOR) pathway. The *solid line* indicates the direct projection between the vestibular nuclei and the third and sixth nuclei. The *stippled area* represents the indirect projections between the nuclei. *(Modified from Barr ML, Kiernan JA: The Human Nervous System—An Anatomical Viewpoint, 5th ed. Philadelphia, JB Lippincott, 1988, p 330.)*

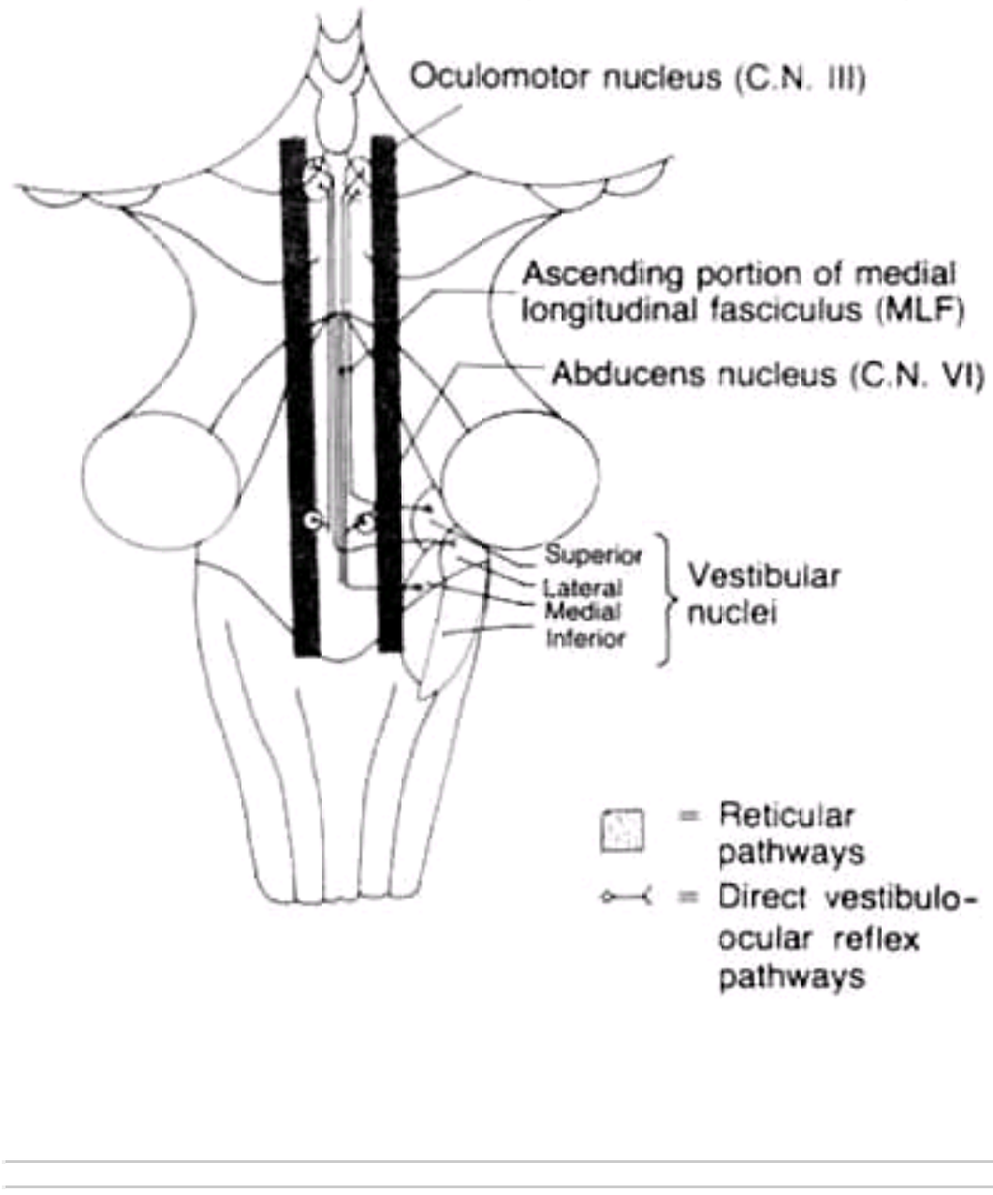

Figure 63-7 Neurotransmitter action at a neuromuscular junction. Acetylcholine *(Ach)* is formed and stored in the nerve terminal. It is released by nerve terminal depolarization in the presence of calcium and binds with receptors on the postsynaptic membrane. After producing an ionic conductance charge, it is hydrolyzed by acetylcholinesterase. *(From Daube JR, Reagen TJ, Sandok BA, Westmoreland BF: Medical Neurosciences: An Approach to Anatomy, Pathology and Physiology, and Physiology by Systems and Levels. Boston, Little, Brown, 1986, p 278.)*

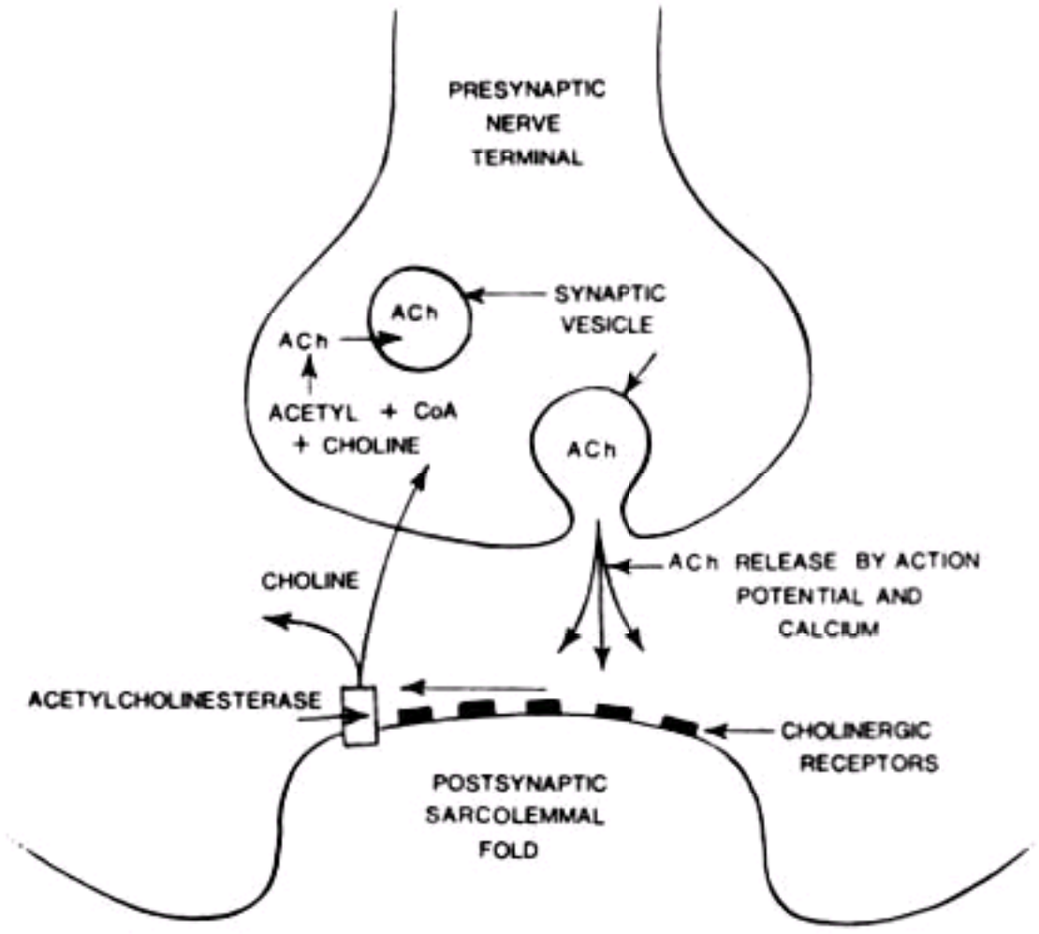

Figure 63-8 *A,* Before ice pack placement. *B,* After ice pack placement, improvement is noted in ptosis of the right eye. *(From Sethi KD, Rivner MH, Swift TR: Ice pack test for myasthenia gravis. Neurology 37:1383, 1987.)*

Figure 64-1 The "routine" progression of visual acuity assessment is reversed in the emergent presentation. Assessing an intact visual pathway begins with quickly discerning if the patient has light perception (LP), can see hand motion (HM), and count fingers at 3 feet (CF). Subsequent progression to assess vision at 10, then 20, feet from a standard eye chart ensues.

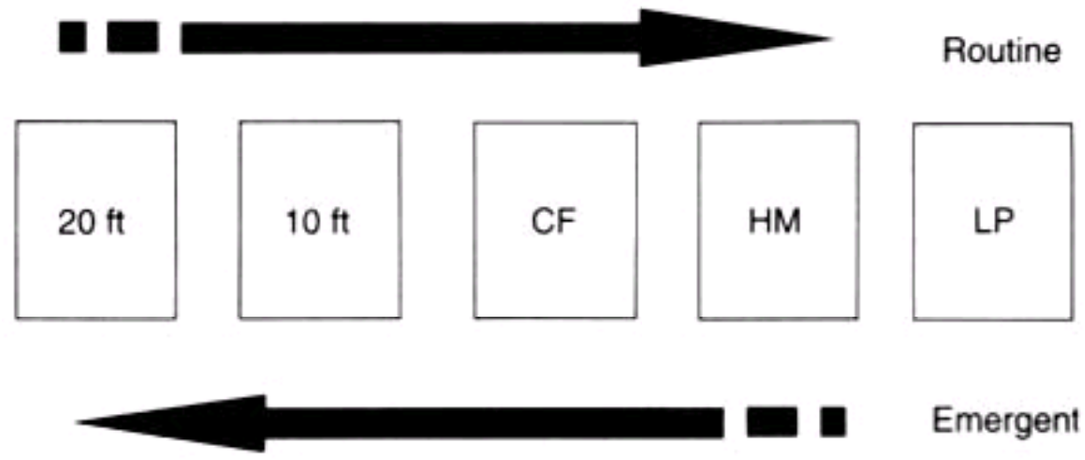

Figure 64-2 A commercial pinhole device reveals refractive error caused by corneal aberration (excess tearing or nearsightedness). *A*, First measure visual acuity without the device. *B*, Then measure with the pinhole cover lowered. Acuity with and without the pinhole device should be documented. *C*, If the patient cannot stand or a formal eye chart is not available, ask the patient to read this "distance equivalent" chart by holding this figure 14 inches away from the patient.

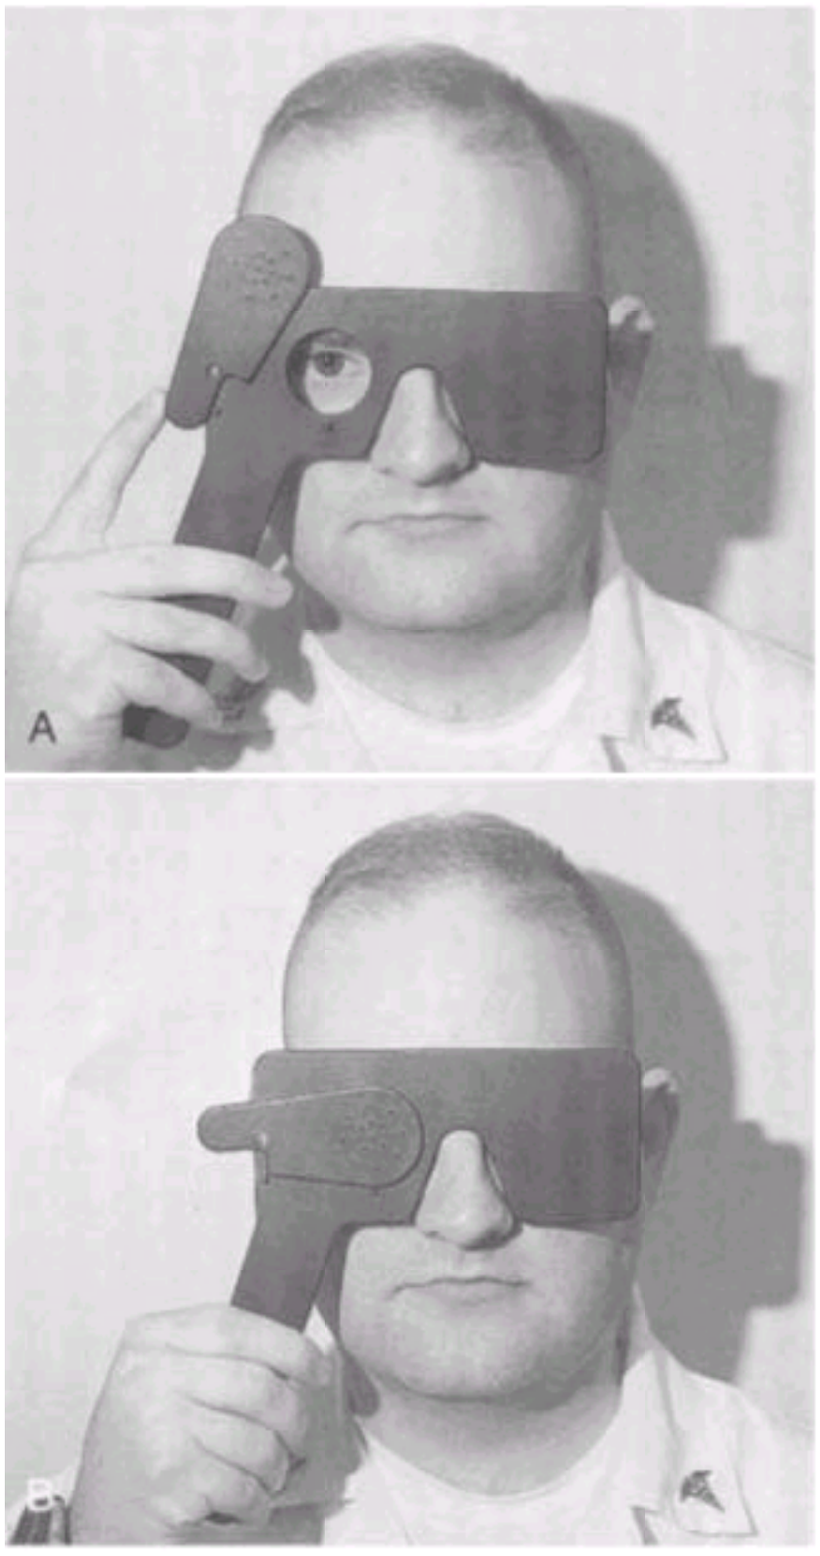

Figure 64-3 Optokinetic Nystagmus (OKN) testing will determine if there is an intact visual pathway. OKN is induced by the passage of a regularly sequenced pattern in front of the eye such as this commercially available drum. The patient is directed to look at the drum that is held in front of the patient and rotated slowly. Alternatively, a tape measure can be drawn across the line of sight while asking the patient to look directly at it as it passes.

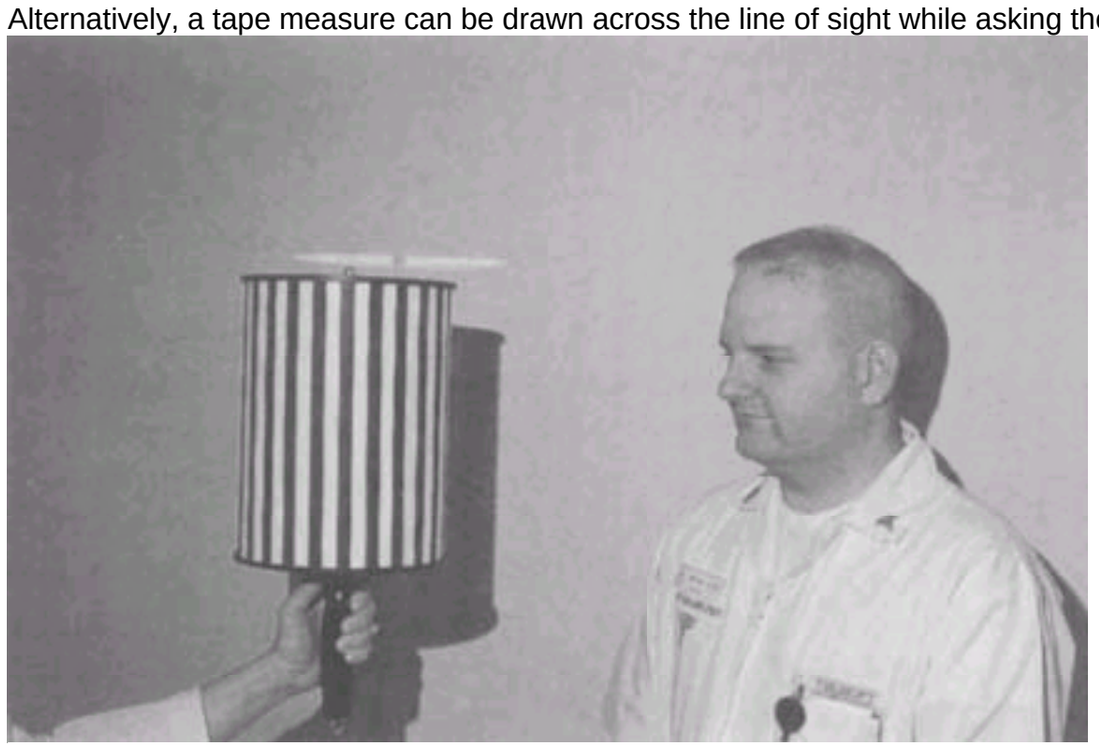

Figure 64-4 Anterior chamber depth and transillumination test. *A,* Normal anterior chamber with negative transillumination test. Note that the entire iris is illuminated. *B,* Shallow anterior chamber with positive transillumination test. Note the shadow on the outer half of the iris. *C,* Shallow anterior chamber with correctly placed light source yielding a true-positive test result in the presence of a shallow anterior chamber. *D,* Shallow anterior chamber with incorrectly placed light source giving a false-negative test result. *E,* Clinical use of the penlight examination to assess the depth of the anterior chamber. The examiner sits face-to-face with the patient to ensure that the light source is perfectly perpendicular to the line of vision. *F*, Note the shadow cast on the nasal portion of the iris, indicating a very narrow anterior chamber in this patient with acute angle closure glaucoma. *(A–D from Bresler MJ, Hoffman RS: Prevention of iatrogenic acute narrow-angle glaucoma. Ann Emerg Med 10:535, 1981. Reproduced by permission.)*

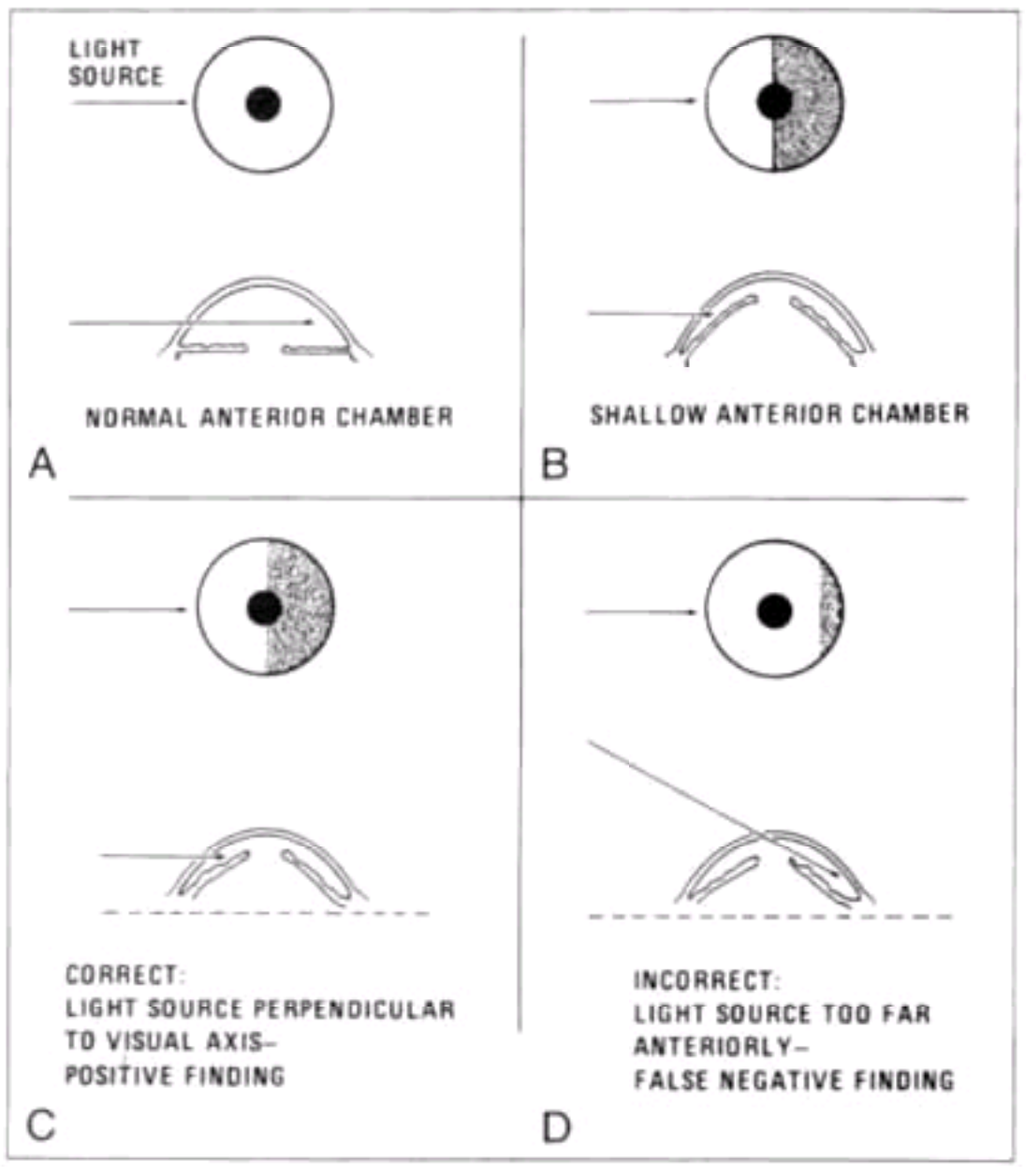

Figure 64-5 *A*, After neosynephrine drops were instilled in the nose to facilitate tube passage, this comatose patient was nasotracheally intubated for his drug overdose. *B*, On a subsequent examination a unilateral fixed and dilated pupil was noted. The pupil dilation was from neosynephrine nose drops that were snorted from the nose into the eye during intubation, simulating cerebral herniation. Other unusual causes of a fixed and dilated pupil are endotracheal epinephrine expelled from the lungs and splashed in the eye during cardiopulmonary resuscitation and inadvertant contamination of the eye following application of a scopolamine patch behind the ear.

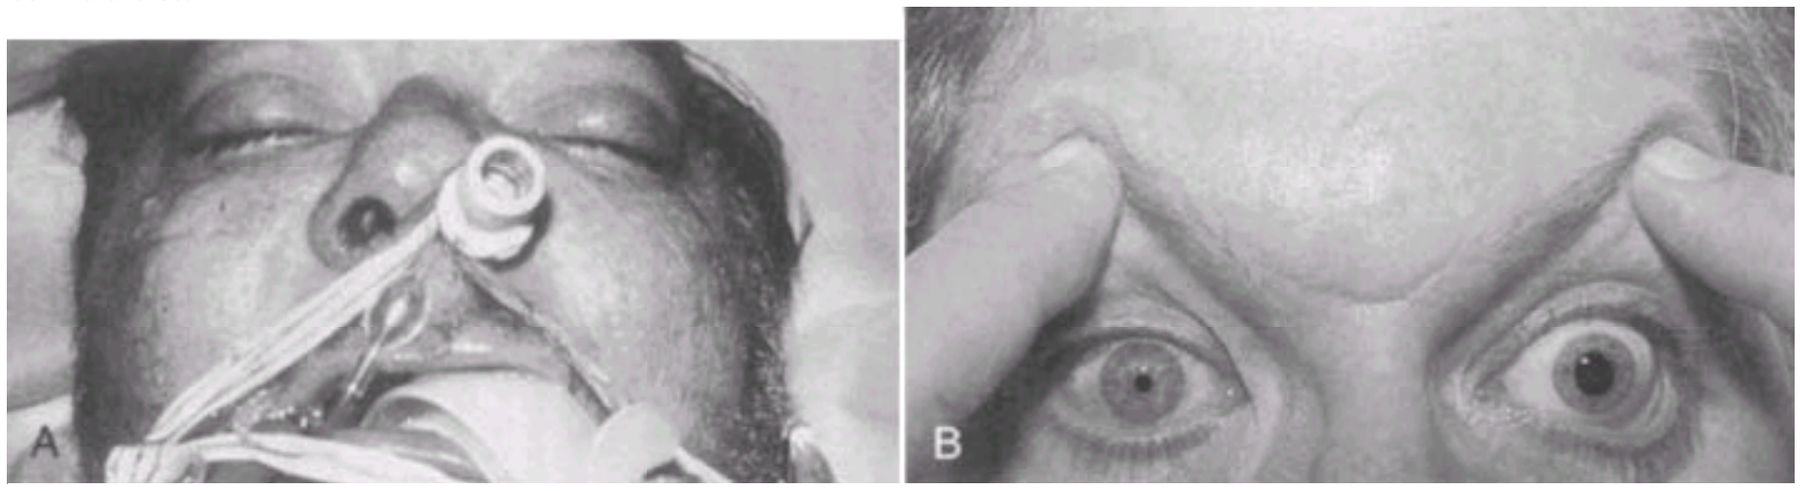

Figure 64-6 *A*, Administration of eyedrops. The patient should lie in a supine position or with the head tilted back. The patient's gaze should be directed upward. The lower lid is pulled downward and a single drop of medicine is instilled in the lower conjunctival fornix. The patient should be instructed to close the eyelids for 1 minute to increase the contact of the medicine with the globe and to decrease the medication outflow down the tear duct and over the lid margin. *B*, If one is administering large amounts of eye drops that have systemic effects, such as beta blocker drops, the operator's index finger is placed under the inferior eyelid along the nasal borders of the eye, firmly compressing the nasolacrimal duct against the globe for a few minutes, thereby preventing migration of the drops into the nose and reducing systemic absorption.

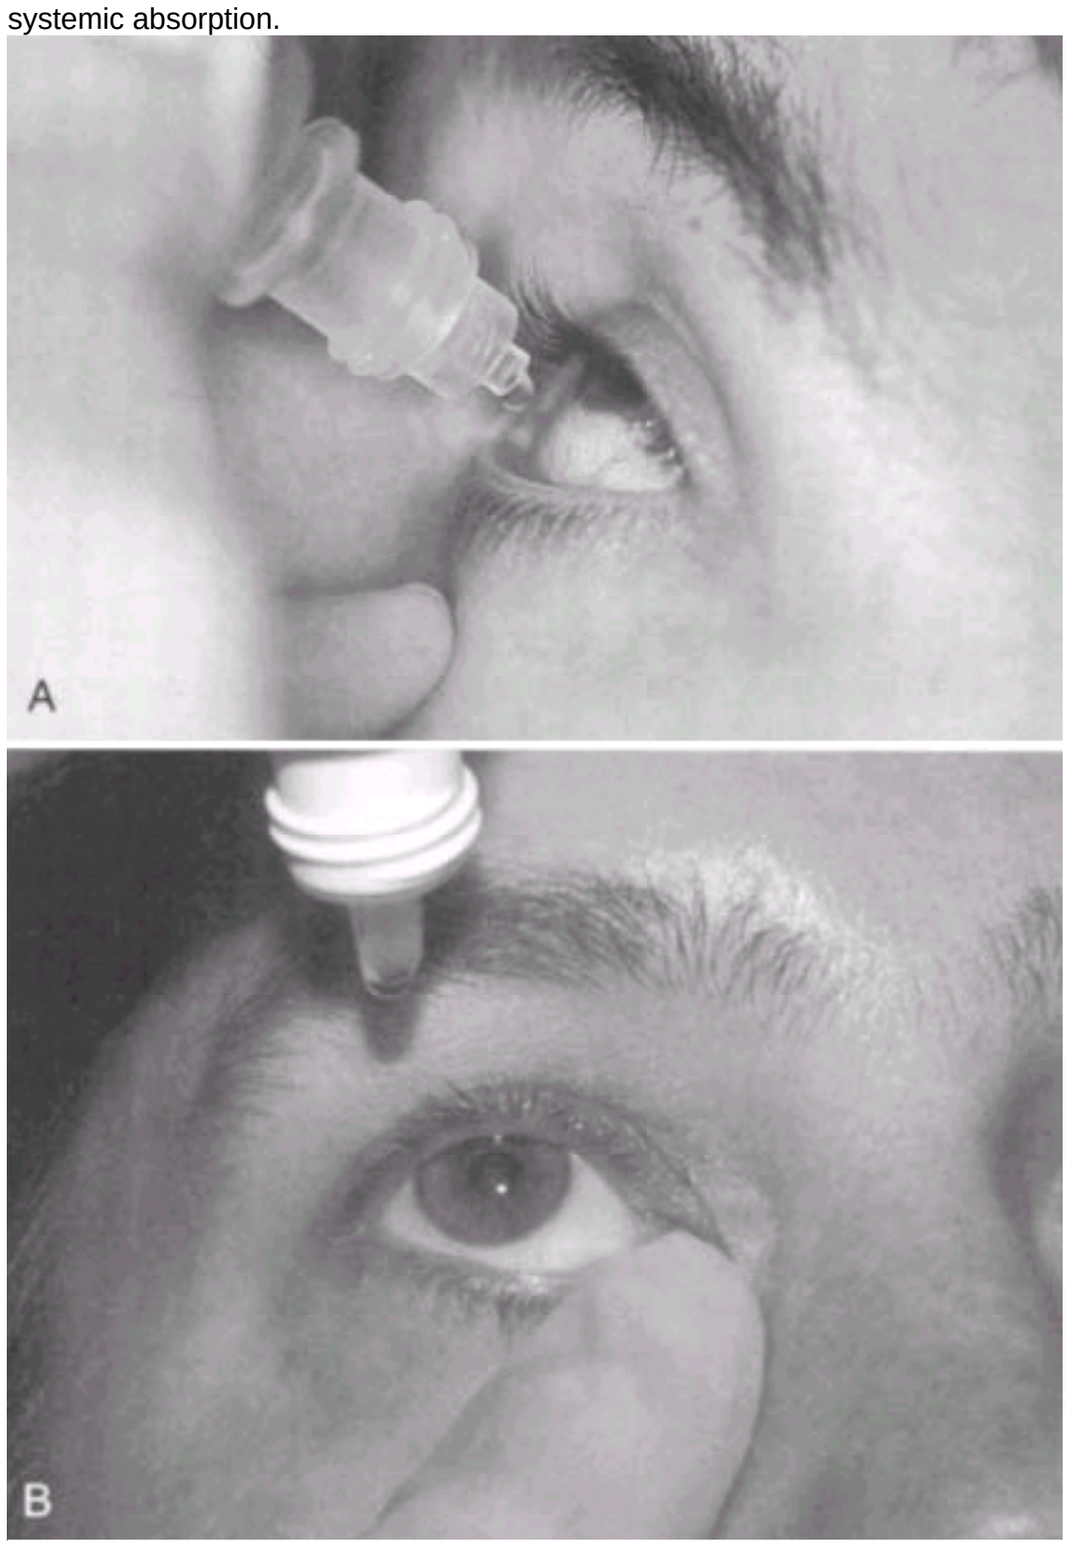

Figure 64-7 *A*, Sodium fluorescein absorbs light in the blue wavelengths and emits the energy in the longer green wavelengths. *B*, This large corneal abrasion is readily seen without the slit lamp when fluorescein is instilled into the eye. Smaller abrasions, or corneal injuries produced by keratitis or welder's arc flash injuries, require slit lamp evaluation to identify minor corneal defects. Even minor traumatic abrasions will escape detection with only a blue light examination by the naked eye.

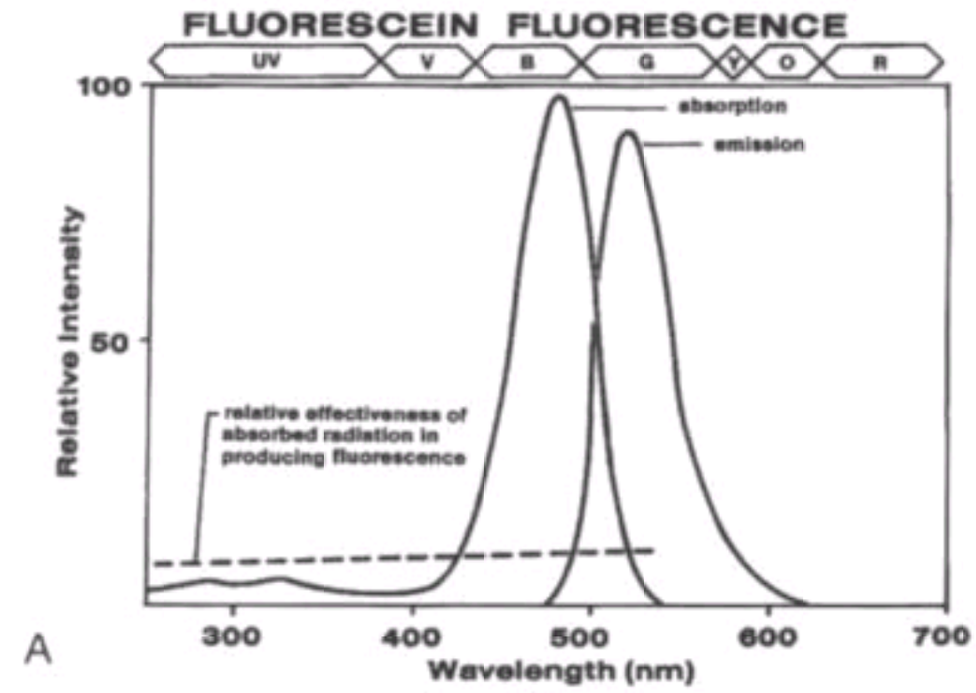

Figure 64-8 The fluorescein strip has been moistened with 1 drop of saline or tap water. The lower lid is depressed and a wetted strip is then placed gently onto the inside of the patient's lower lid so that only the smallest amount is instilled. Excess fluorescein may obscure subtle findings and thus should be avoided. Fluorescein will permanently stain contact lenses not removed (as seen in this model).

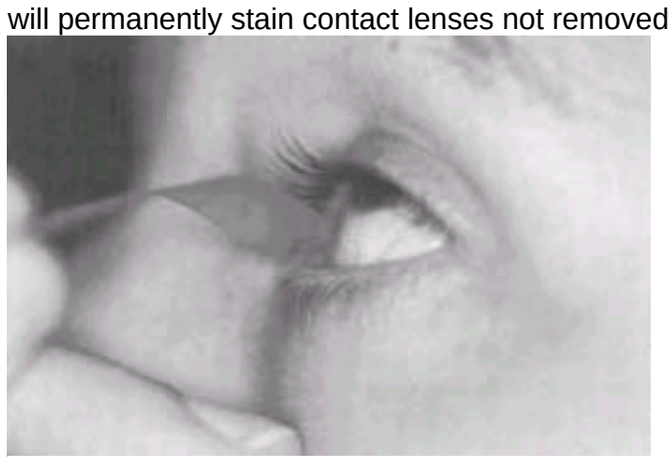

Figure 64-10 Patterns of acute corneal injury.

1. Traumatic abrasion: usually with linear features and sharp borders when seen early (< 24 hours). Occurs more in the central cornea.
2. Abrasion from foreign body (FB): vertical abrasions on the upper cornea seen when an FB is embedded in the upper lid. Also shown is a rust ring with a metallic FB.
3. Exposure pattern: seen with prolonged exposure to ultraviolet (e.g., welding flash, sunlamp exposure); produces bandlike keratitis over lower half of the cornea. Squinting in the setting of the bright light protected the upper corneal surface.
4. Herpes simplex keratitis: classic dendritic pattern.
5. Adenovirus keratitis: Diffuse minute corneal staining seen in epidemic keratoconjunctivitis about 7 days after symptoms.
6. Contact lens overuse: Central punctate staining.

(From Knopp, K, Trott A: Ophthalmologic procedures in the emergency department—Part III: Slit lamp use and foreign bodies. Acad Emerg Med 2:227, 1995. Reproduced by permission.)

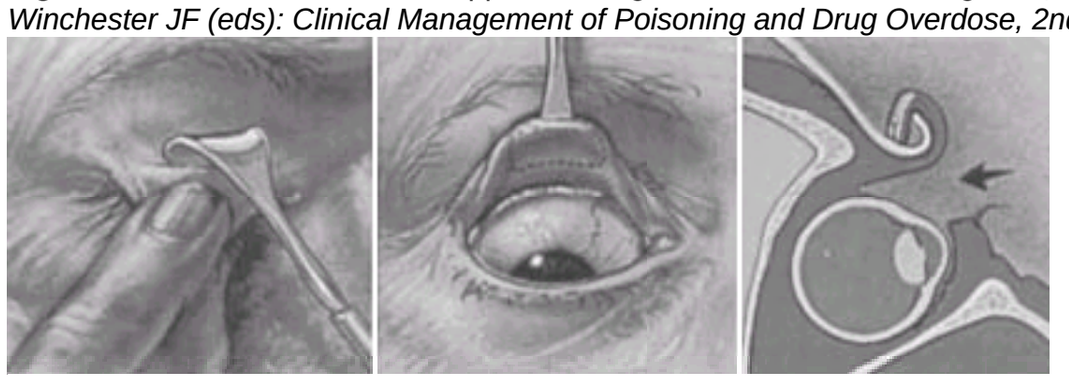

Figure 64-12 Devices for separating eyelids. A Desmarres retractor and a retractor improvised from a paper clip allow active manipulation of lids. Freestanding specula may require a seventh nerve block to reduce blepharospasm. *(From Fogle JA, Spyker DA: Management of chemical and drug injury to the eye. In Haddad LM, Winchester JF (eds): Clinical Management of Poisoning and Drug Overdose, 2nd ed. Philadelphia, WB Saunders, 1990. Reproduced by permission.)*

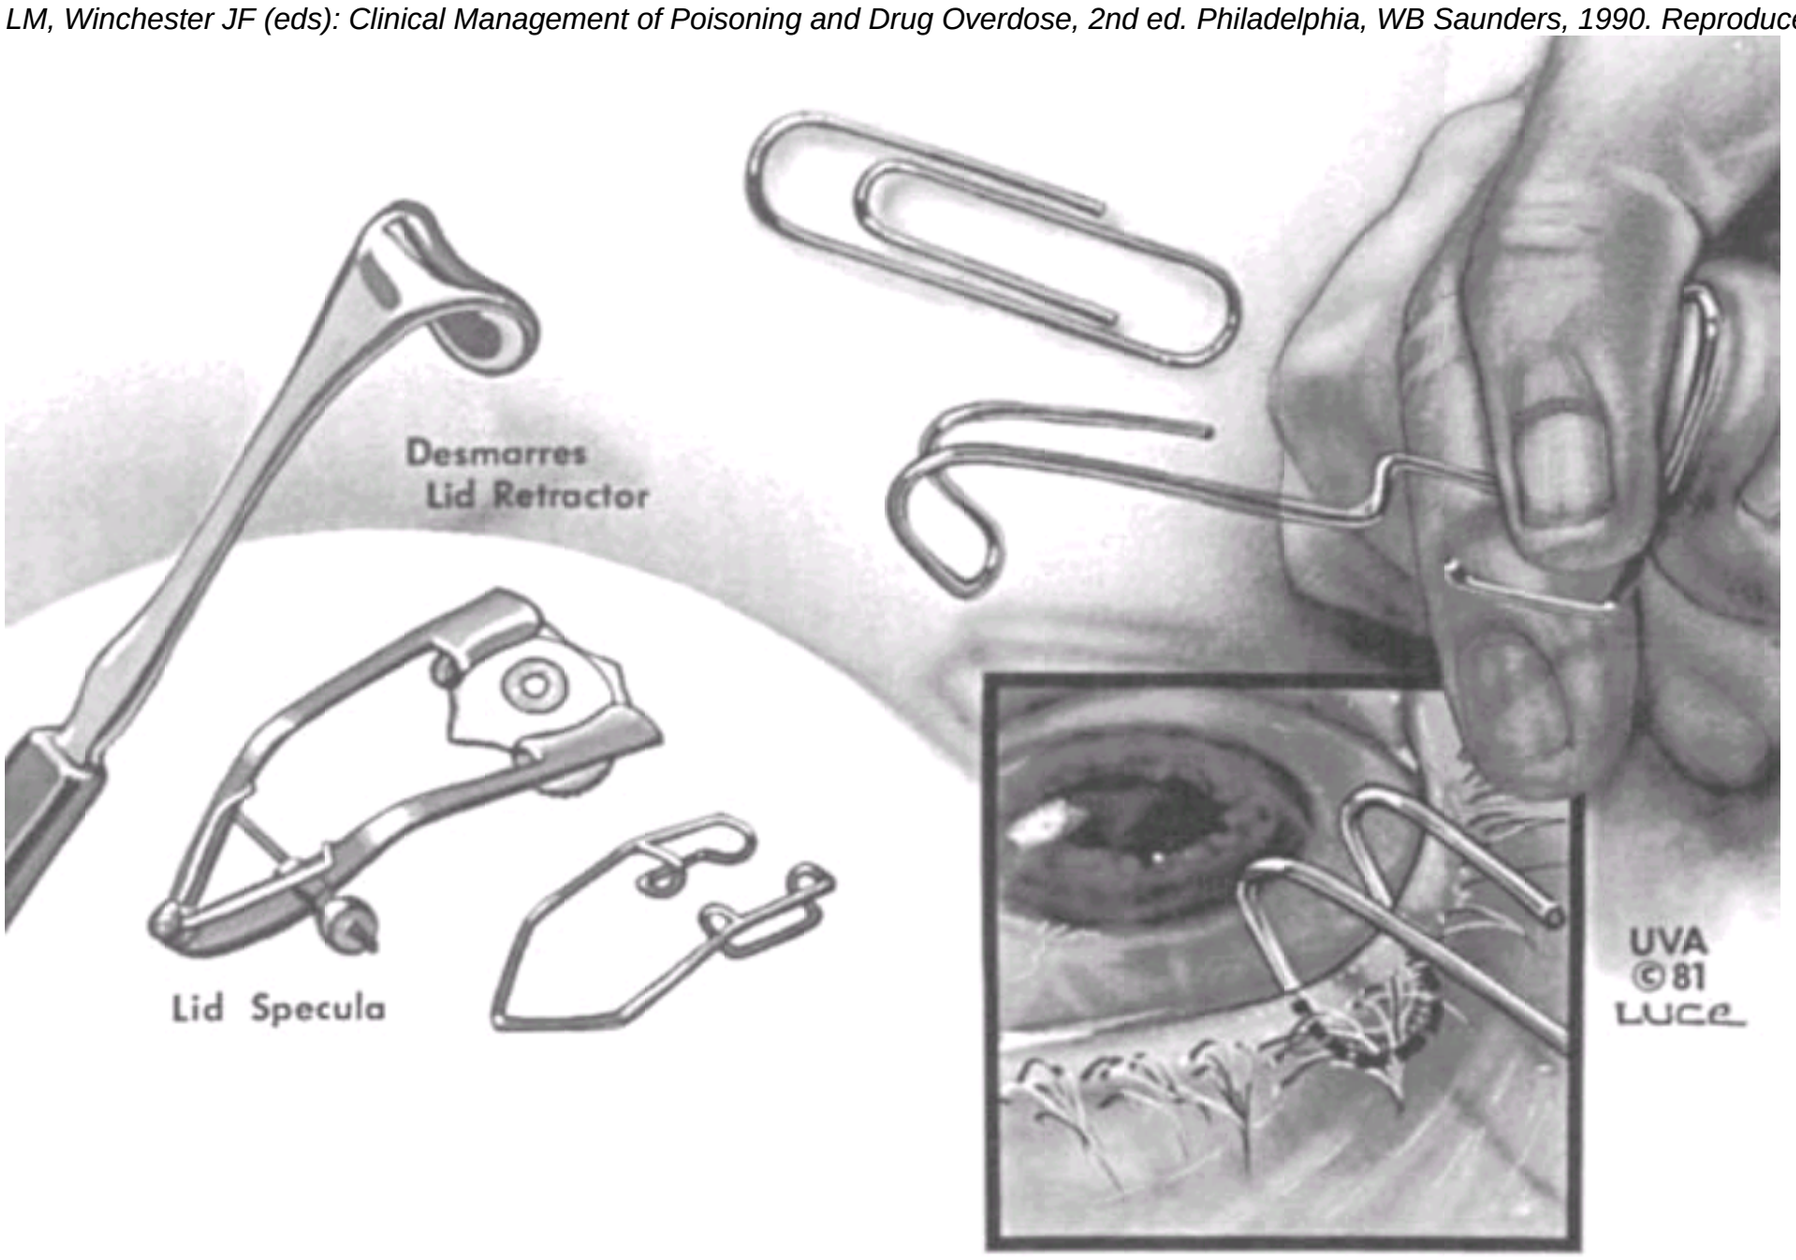

Figure 64-13 Irrigation technique using a Desmarres retractor for lid separation Irrigation is performed with saline or lactated Ringer's solution. For alkaline injuries the pH of the eye should be checked with pH paper to assess the adequacy of irrigation (normal pH = 7.4). Since a rebound may occur with alkaline products, the pH should be rechecked 20 to 30 minutes *after irrigation* to assure complete removal. *(From Fogle JA, Spyker DA: Management of chemical and drug injury to the eye. In Haddad LM, Winchester JF: Clinical Management of Poisoning and Drug Overdose, 2nd ed. Philadelphia, WB Saunders, 1990. Reproduced by permission.)*

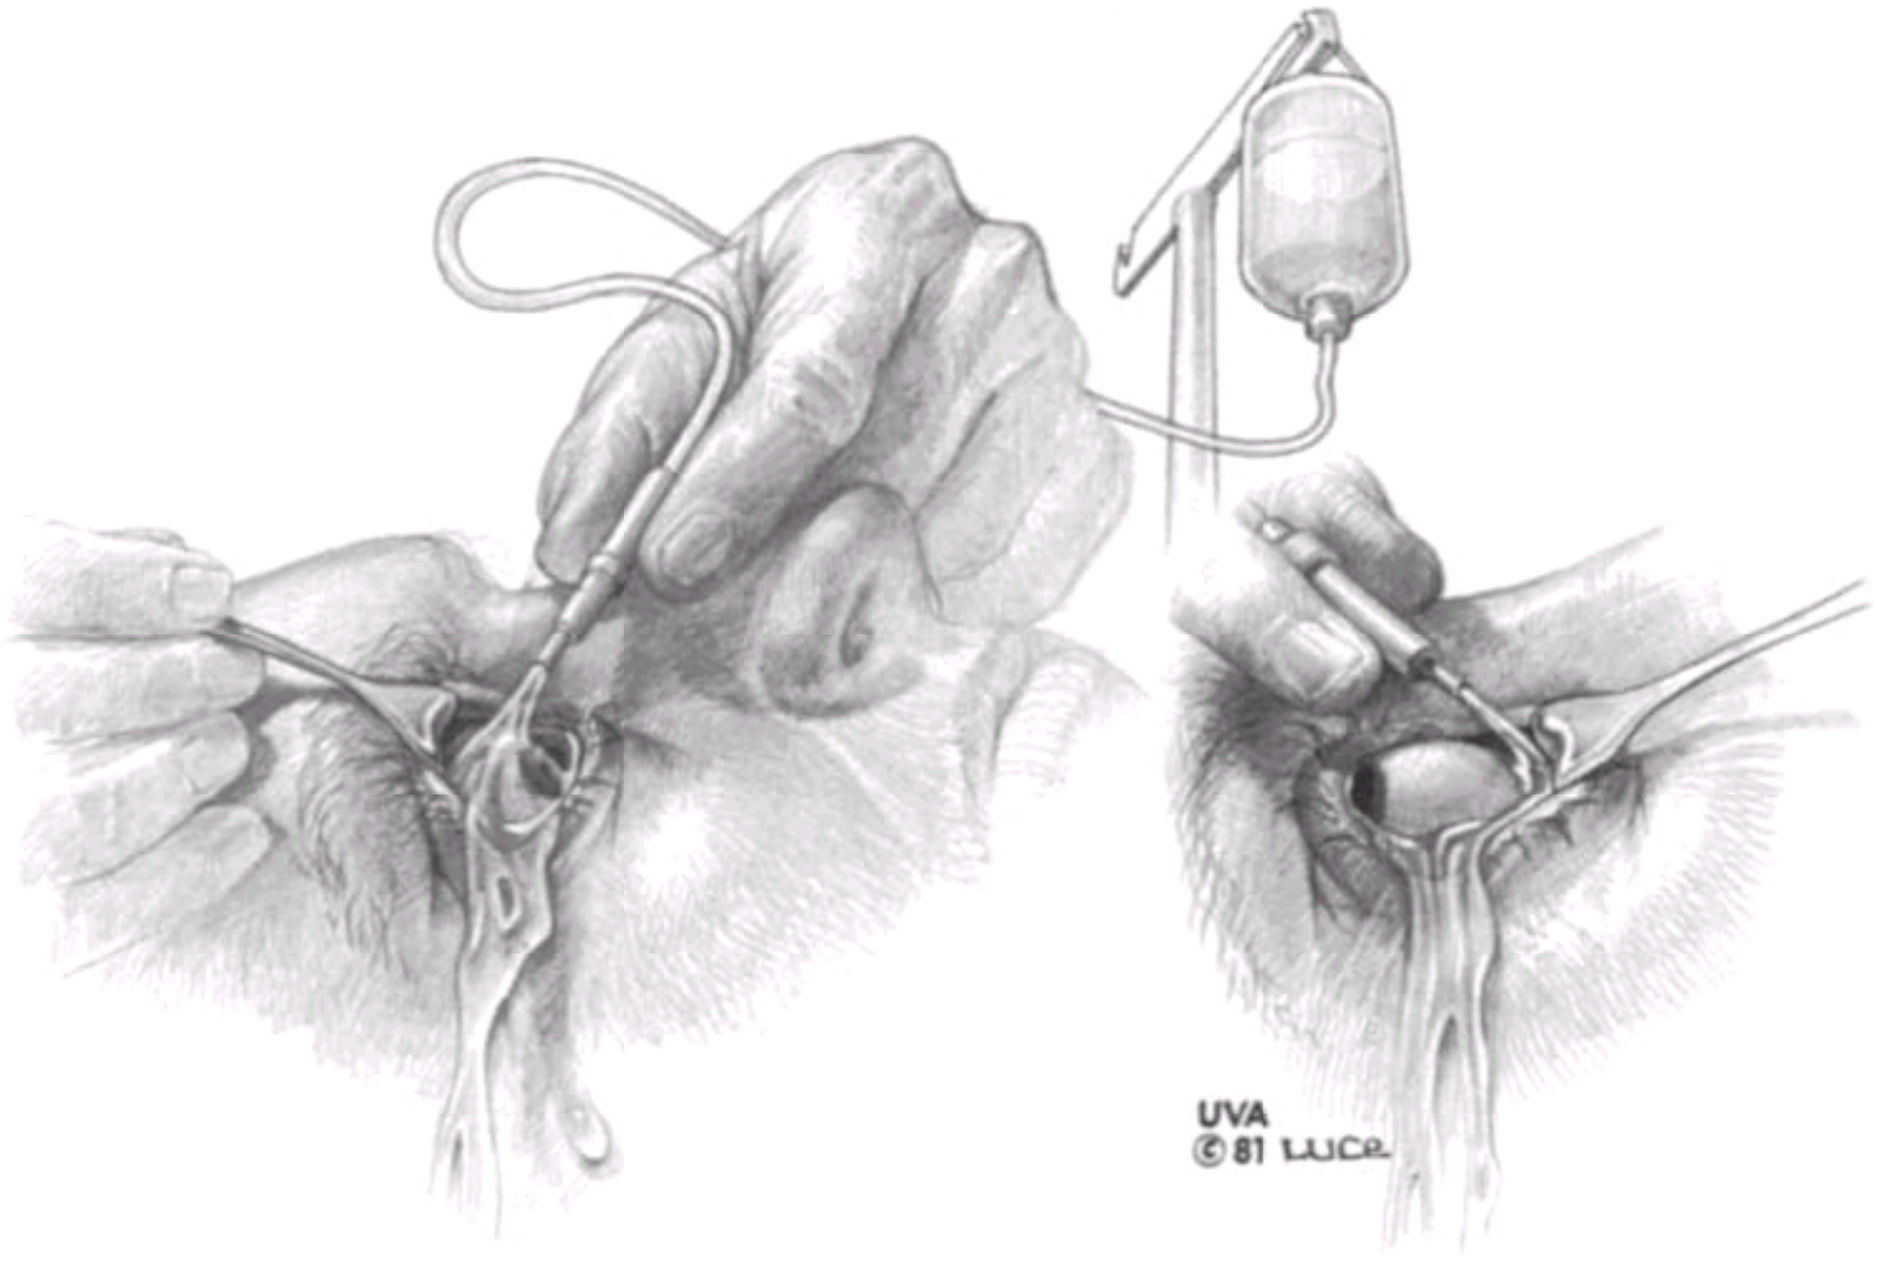

Figure 64-14 Injection points for facial and orbital anesthesia and akinesia. *A,* Van Lint technique of orbicularis infiltration. *B,* Retrobulbar injection site. *C,* O'Brien facial nerve block. *C',* Alternative facial nerve block by tympanomastoid fissure injection. *D,* Infraorbital sensory block. *E,* Supraorbital sensory block. Injection of orbicularis *(A)* or facial nerve *(C* or *C')* permits examination and treatment of the eye in the setting of severe blepharospasm. Anesthesia is placed within several mm of the nerves. *(From Deutsch TA, Feller DB: Paton and Goldberg's Management of Ocular Injuries, 2nd ed. Philadelphia, WB Saunders, 1985, p 17.)*

Figure 64-15 *A,* The Morgan therapeutic lens attached to intravenous tubing. *B,* Placement of the device into the anesthetized eye for irrigation. *(Courtesy of MorTan, Inc, Missoula, MT.)*

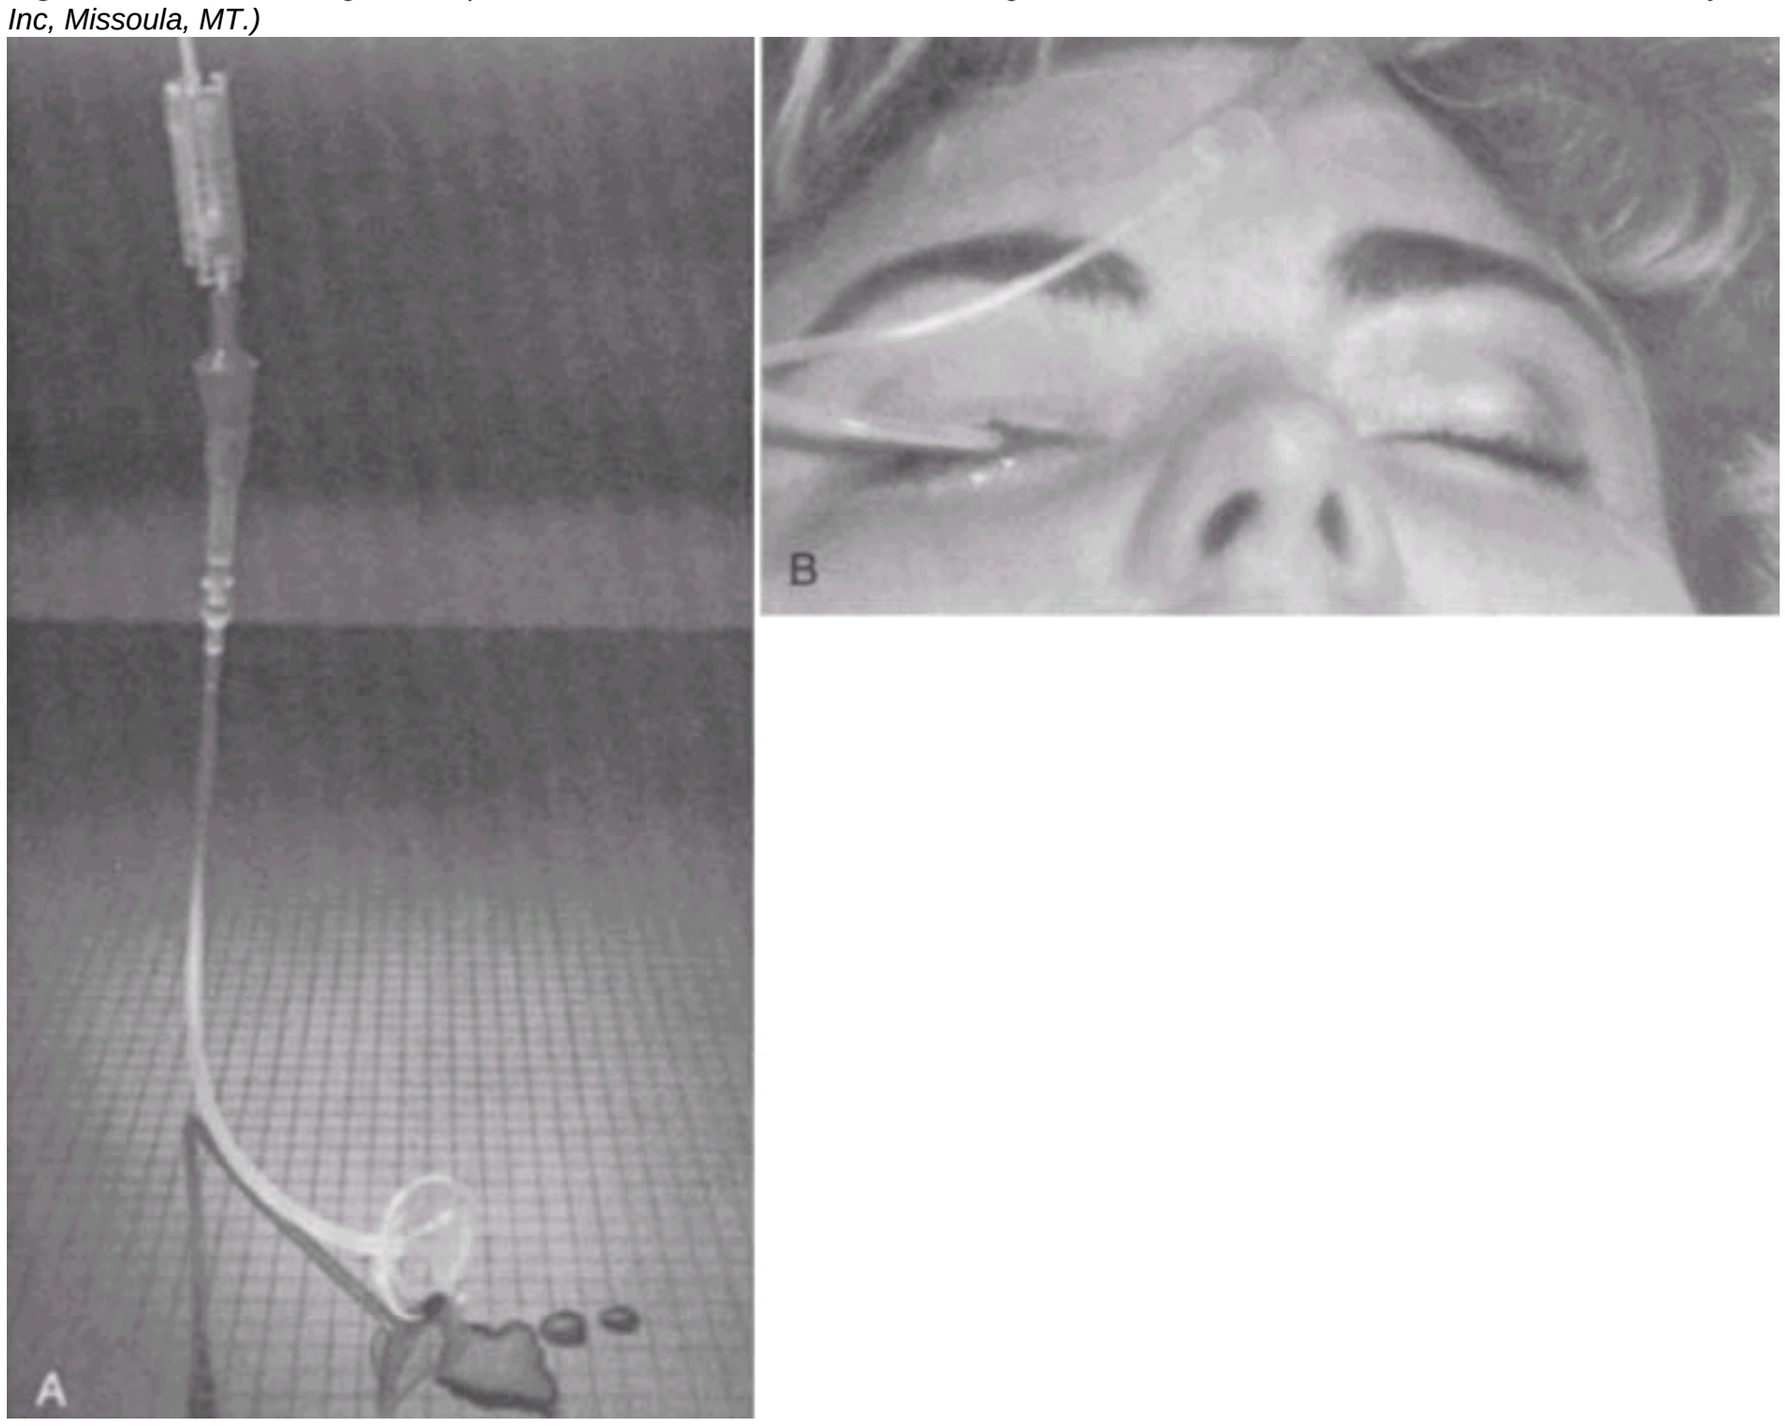

Figure 64-16 Continuous irrigation device. A central venous catheter (after perforation by the clinician) is looped in the fornices of the anesthetized eye, beginning from the temporal border of the eyelids. The eye is lightly patched after catheter placement.

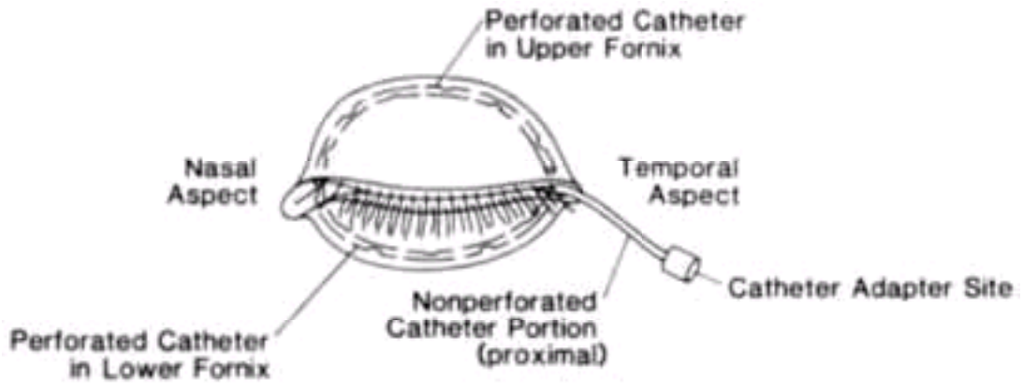

Figure 64-17 The Eye Irrigator is designed to slide up under the upper lid as shown. Irrigation is accomplished by connecting the device to an intravenous bag containing the desired irrigation fluid. It is used primarily at the injury site to supplement flushing at the eyewash station. *(Courtesy of the Eye Irrigator, American Health and Safety, Inc.)*

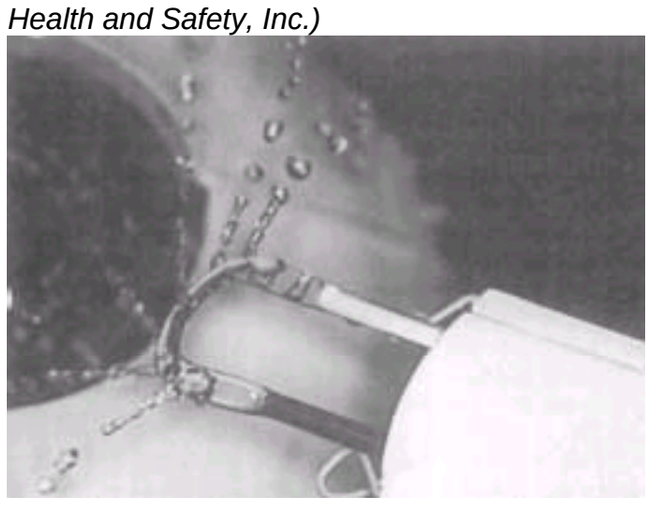

Figure 64-18 *A*, Corneal laceration with prolapse of the iris. The extruded iris is dark, mimicking a corneal foreign body. Often the only clue is an abnormal pupil and the extruded iris may not be appreciated as intraocular tissue. The pupil is irregular (often pear- or teardrop-shaped), pointing toward the laceration (photo courtesy of Lawrence B. Stack, MD). *B*, A pear-shaped pupil without protrusion of the lens is a more subtle, yet characteristic, indication of a perforated globe. *C*, Another indication of a penetrating globe injury is periorbital fat protruding from an upper eyelid laceration. This patient was stabbed by a knife. *D*, This patient has an obviously cloudy lens soon after trauma. A projectile entered the temporal portion of the globe and produced a seemingly minor scleral hemorrhage. Patients with penetrating injuries to the globe should be treated with systemic antibiotics (such as cefazolin/gentamycin combination), tetanus toxoid if indicated, and antiemetics to control vomiting (which raises intraocular pressure).

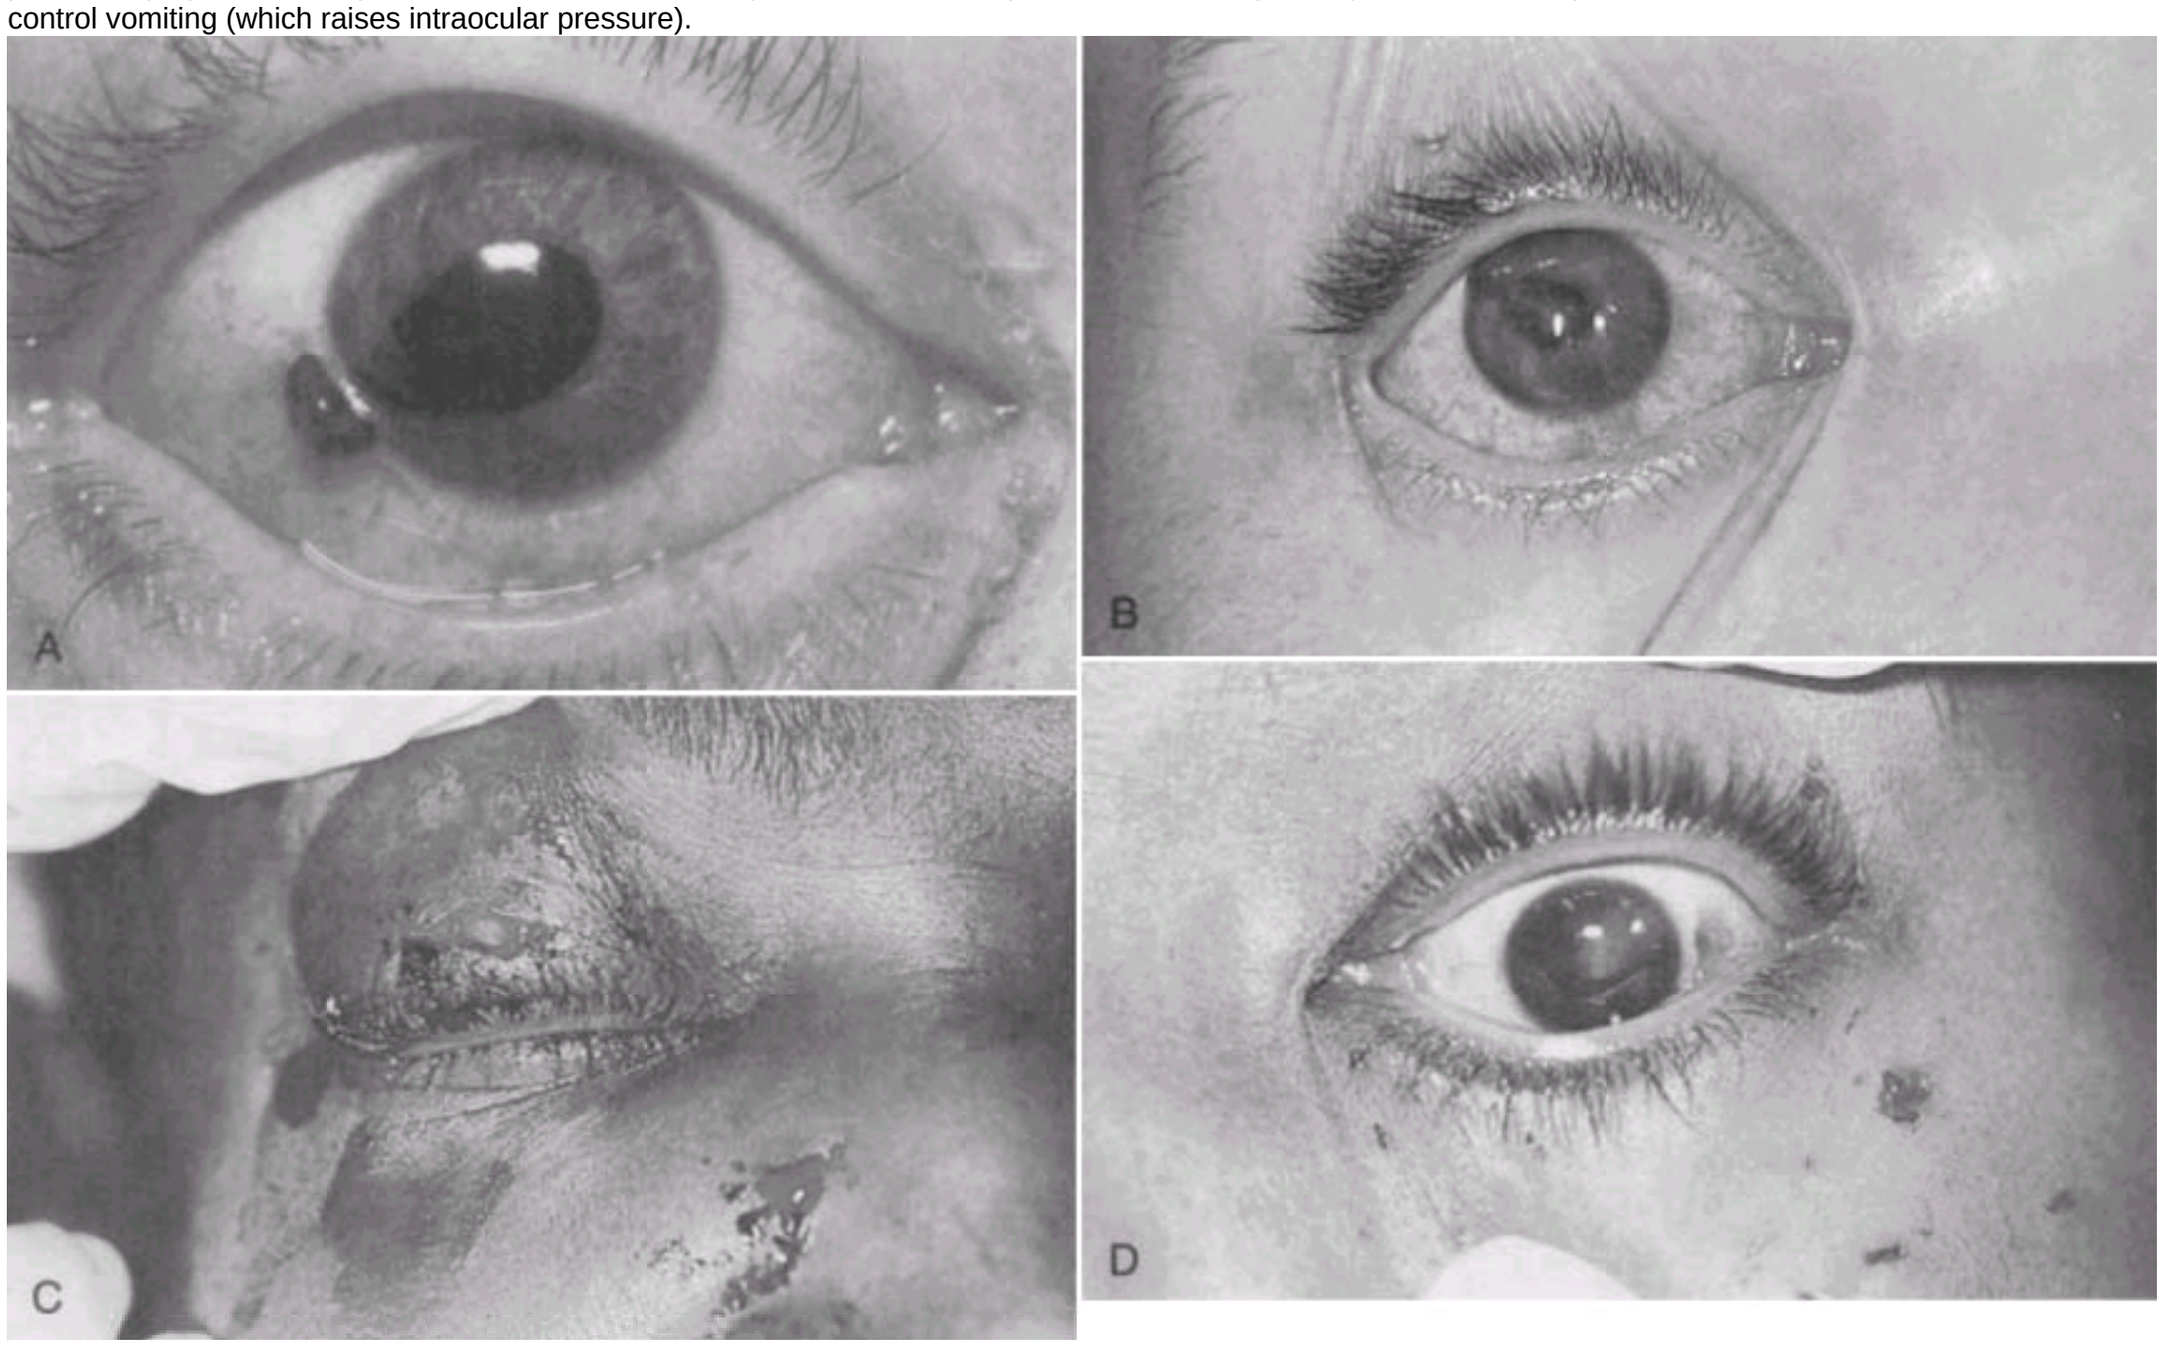

Figure 64-19 When a penetrating globe injury is suspected and a metal shield is not available in the emergency department or prehospital setting, a makeshift shield can be fashioned with available materials. A paper cup was used to fashion this shield.

Figure 64-20 Single upper lid eversion. *A,* The patient is instructed to look downward, and the end of a cotton-tipped applicator is placed above the tarsal plate while the lashes and the lid margin are pulled down, out and up. *B,* One everts the lid and holds it by pressing the lashes against the superior orbital rim. If the foreign body is seen on the lid, it can usually be removed by touching it with a moistened cotton-tipped applicator. *(From Pavan-Langston D: Manual of Ocular Diagnosis and Therapy, 3rd ed. Boston, Little, Brown & Co, 1991. Reproduced by permission.) C*, This patient presented with a swollen and tender upper eyelid thought to be secondary to a stye. *D*, With lid eversion a small pustule was found under the upper eyelid. *E*, With a 27-gauge needle the pustule was incised and a drop of pus was expressed, and she made a rapid and uneventful recovery.

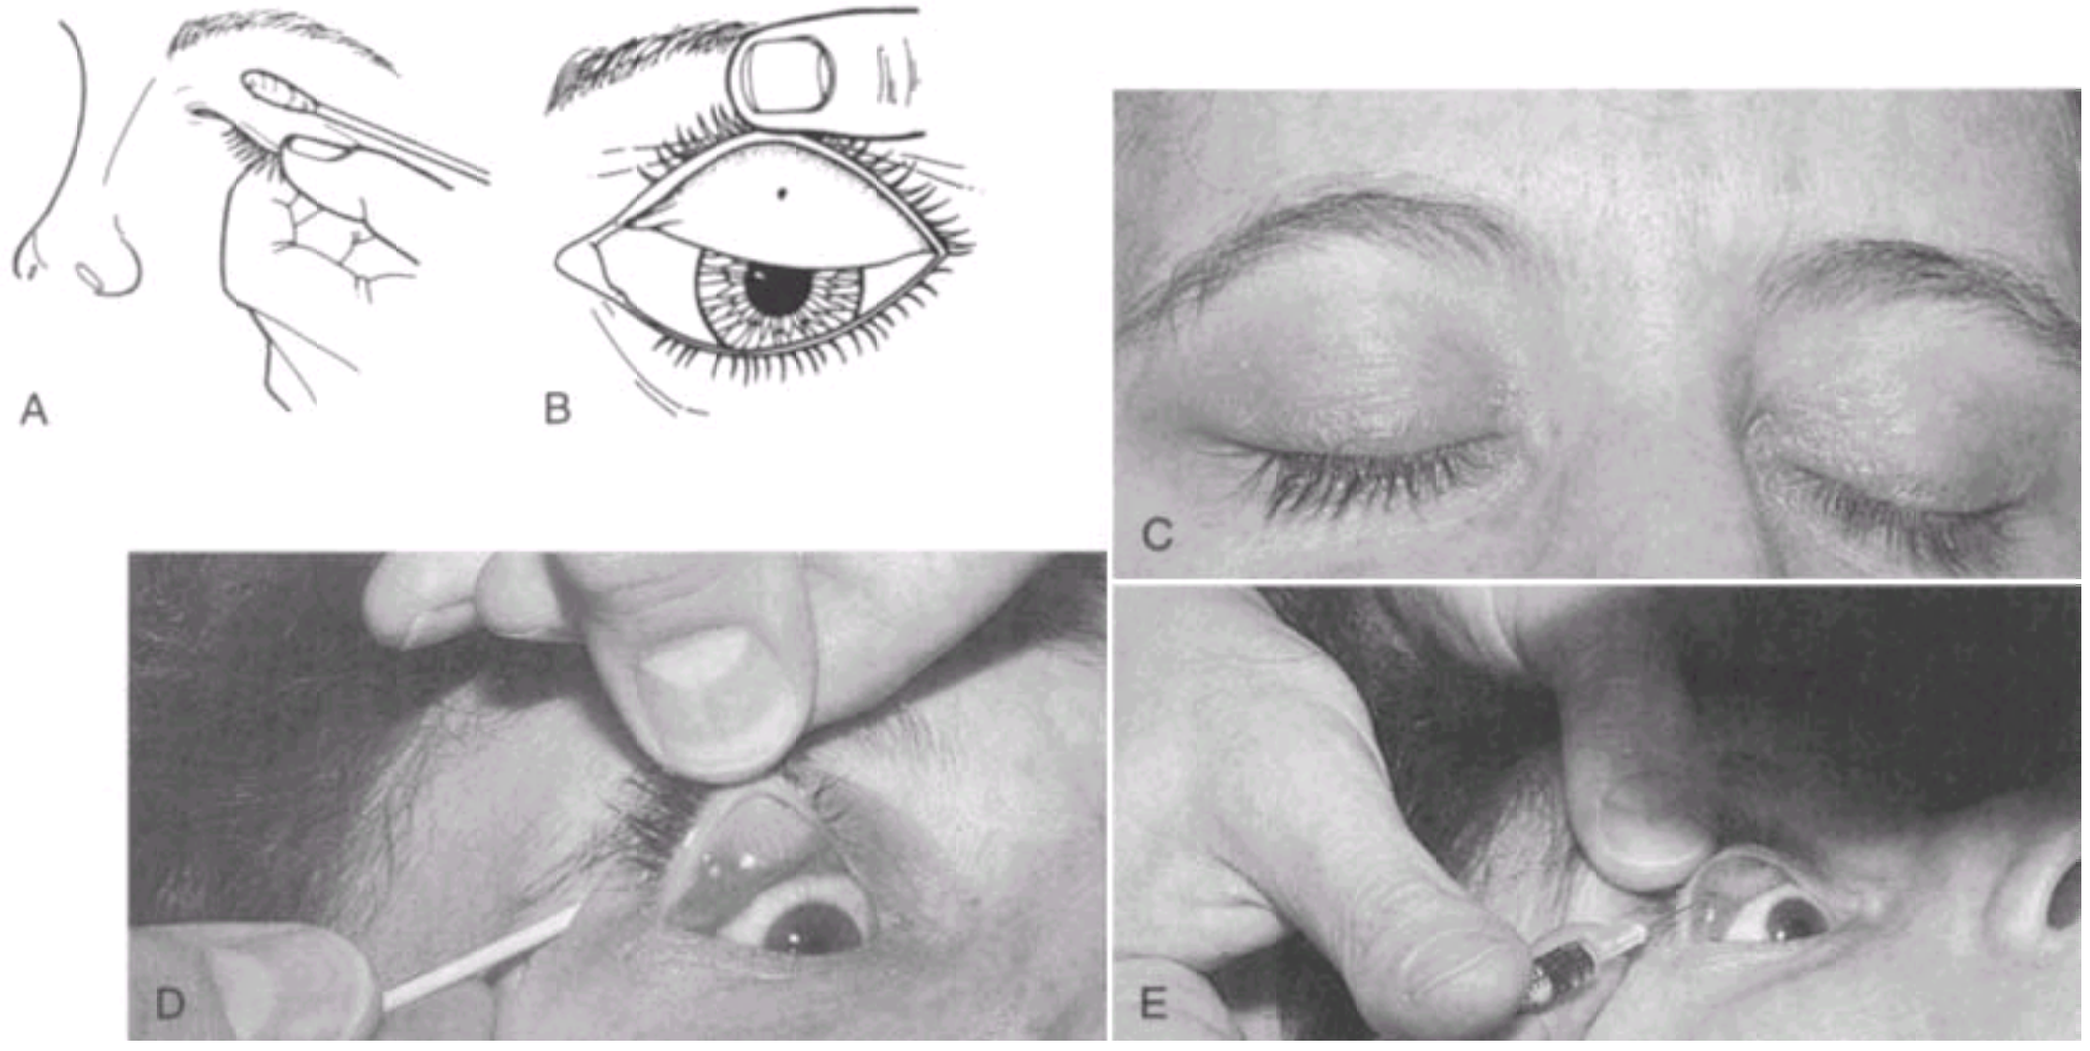

Figure 64-21 An "invisible" corneal abrasion casts an obvious shadow on the iris. The relative positions of *(a)* the corneal abrasion and *(b)* the iris shadow depend on the direction of the incident light (as in *A* and *B*). *(From Paton D, Goldberg MF: Management of Ocular Injuries. Philadelphia, WB Saunders, 1976. Reproduced by permission.)*

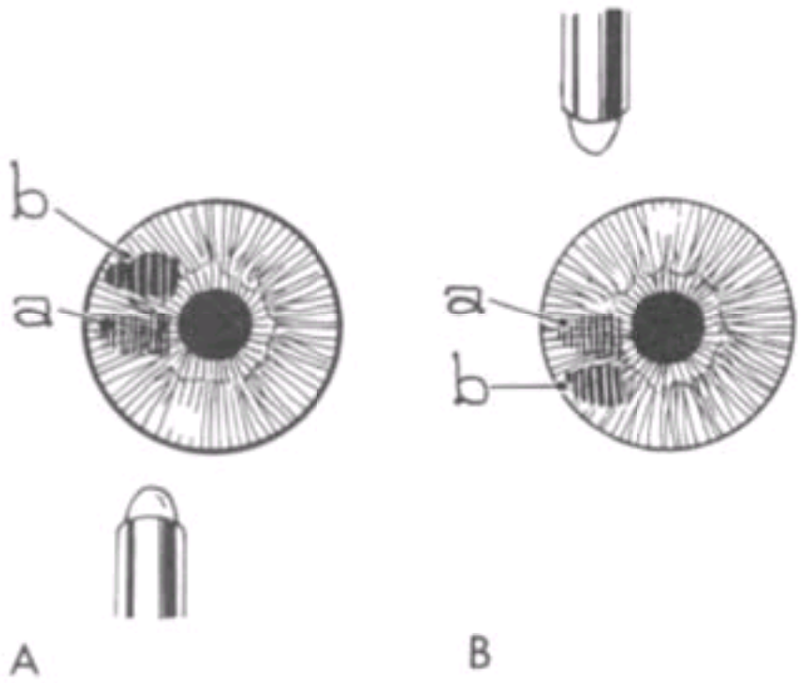

Figure 64-22 This embedded corneal foreign body is readily seen under slit lamp examination. A removal device (needle, spud, or burr drill) should be used for careful removal.

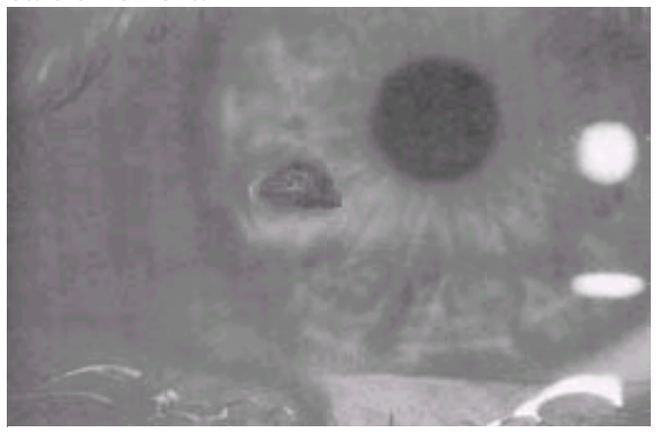

Figure 64-23 It is preferable to remove the corneal foreign body (FB) under the slit lamp. A topical anesthetic is applied and the operator uses a small syringe with a short 25- to 27-ga needle (such as a tuberculin syringe). Be certain that the needle is firmly attached to the syringe. *A*, *Under direct vision*, the syringe is brought close to the eye and the operator rests the hand on the patient's cheek. Be sure that the patient's forehead maintains continual contact with the cross bar on the slit lamp. *B,* While looking through the slit lamp, the needle is brought to the cornea and the FB is removed. *C,* The side of the instrument (drill bit or beveled edge of the needle) should be held tangential to the cornea. Arrows indicate the direction of device in order to remove the FB. *(From Knoop K, Trott A: Ophthalmologic procedures in the emergency department—Part III: Slit lamp use and foreign bodies. Acad Emerg Med 2:224, 1995. Reproduced by permission.)*

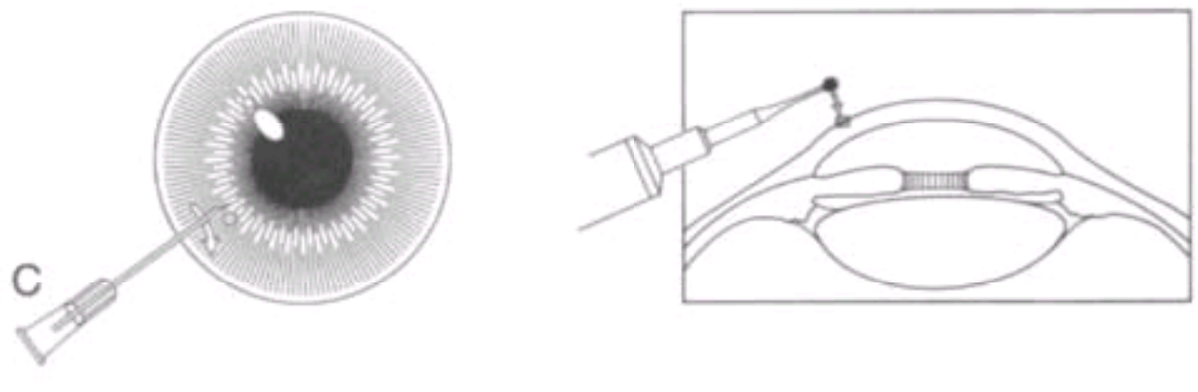

Figure 64-24 A typical rust ring is seen at 8 o'clock on the cornea. A burr drill can be used for attempted removal, which if unsuccessful, can be reattempted in 24 hours. *(From Knoop KJ, Stack LB, Storrow AB (eds). Atlas of Emergency Medicine, 2nd ed. New York, McGraw-Hill, 2002. Reproduced by permission.)*

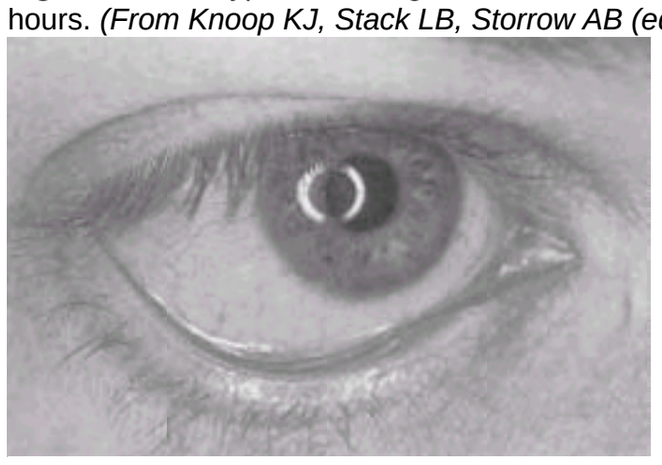

Figure 64-25 Application of eye patch. *A,* Vertically folded first patch in orbital recess. *B,* Horizontally oriented second patch with forehead to cheek taping. The contralateral eye should be kept closed throughout patching.

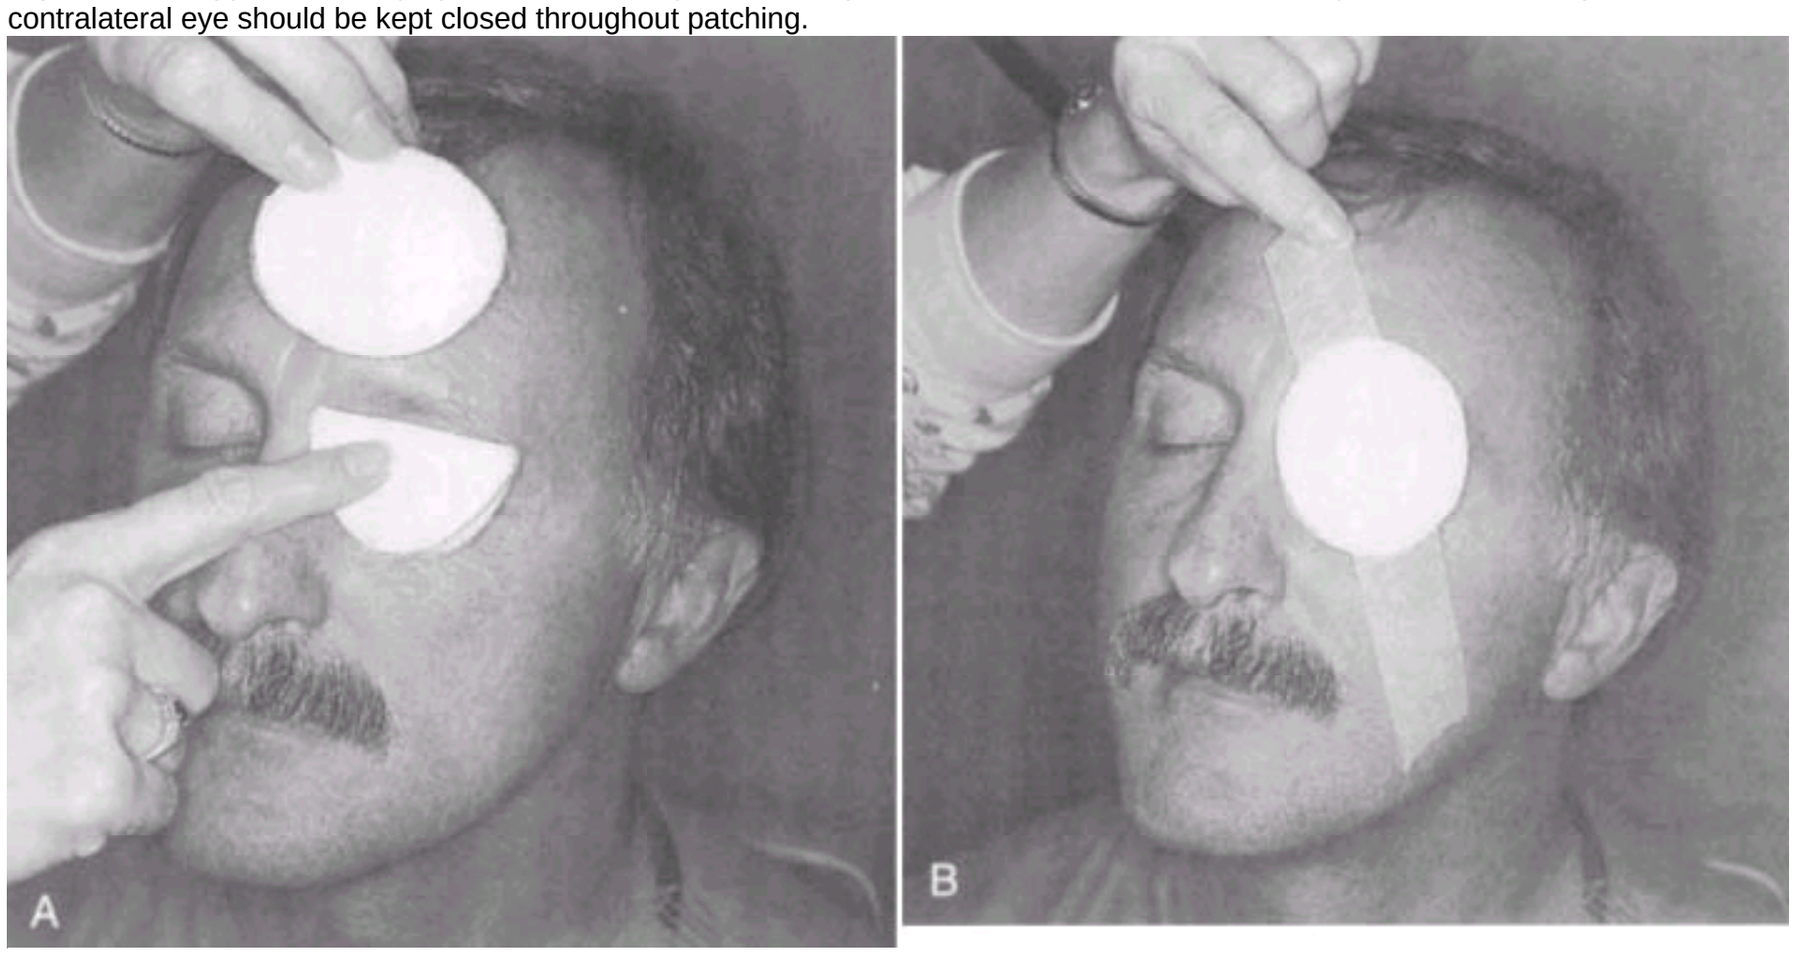

Figure 64-26 Final appearance of pressure eye patch.

Figure 64-27 Use of the adjustable elastic strap pressure patch, Presspatch II. The clinician should ensure that the elastic straps for the patch are adjusted to avoid excessive globe pressure. *(Courtesy of Precision Therapeutics, Inc, Las Vegas, NV.)*

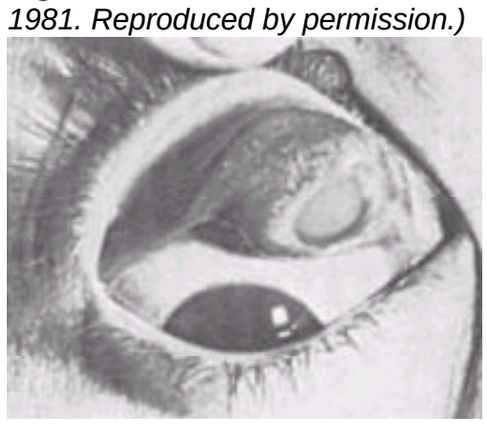

Figure 64-34 Principle of tonometry. At equilibrium: $P_t = F/A$. *(From Draeger J, Jessen K: Tonometry and tonography. In Bellows JG (ed): Glaucoma: Contemporary International Concepts. New York, Masson Publishing USA, 1979. Reproduced by permission.)*

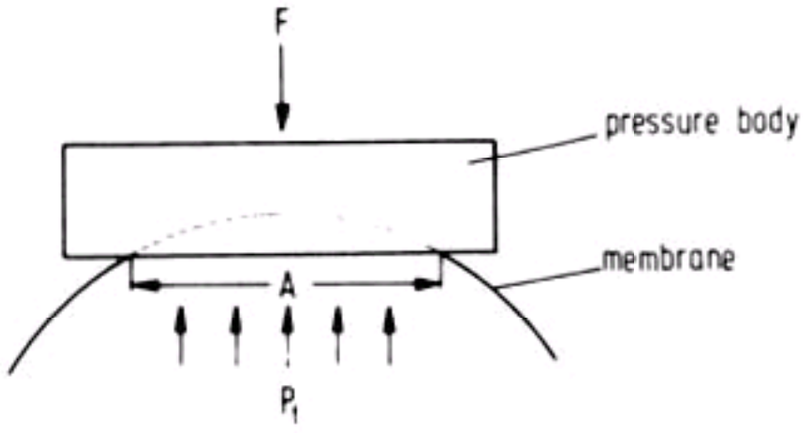

Figure 64-35 Principle of impression tonometry. In reality, P_t is increased slightly by the weight of the instrument. *(From Draeger J, Jessen K: Tonometry and tonography. In Bellows JG (ed): Glaucoma: Contemporary International Concepts. New York, Masson Publishing USA, 1979. Reproduced by permission.)*

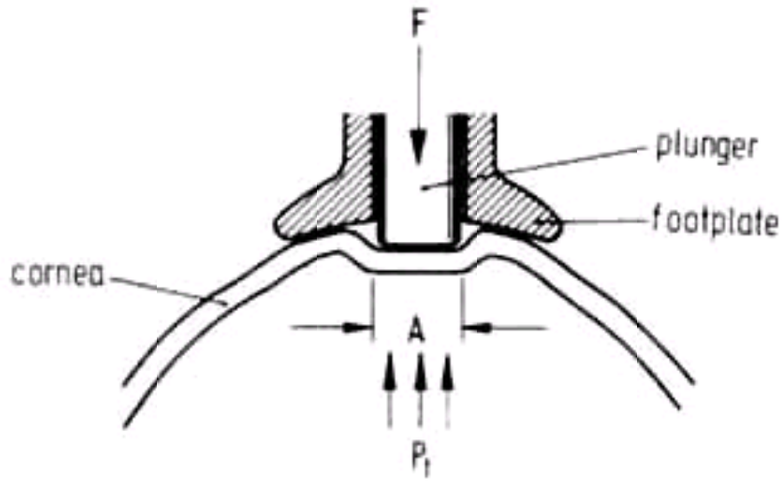

Figure 64-36 Principle of applanation tonometry. The effect of surface tension counters the pressure rise produced by application of the instrument. *(From Draeger J, Jessen K: Tonometry and tonography. In Bellows JG (ed): Glaucoma: Contemporary International Concepts. New York, Masson Publishing USA, 1979. Reproduced by permission.)*

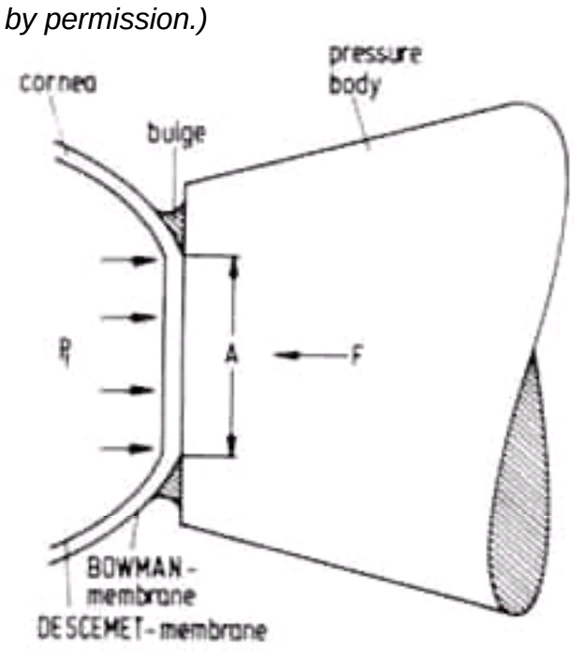

Figure 64-37 The relatively unskilled examiner can detect very high intraocular pressure of acute angle closure glaucoma with tactile tonometry. The examiner rests both hands upon the patient's forehead and alternately applies just enough digital pressure on the globe to indent it slightly with one index finger while feeling the compliance of the globe with the other.

Figure 64-38 One technique of lid separation and Schiotz tonometer placement. Lid separation pressure is applied to the bony orbital rims. An assistant may separate the lids while the operator concentrates on proper placement of the tonometer. The tonometer is held vertically during use, and the clinician's hand is established against the patient's facial bones. After instillation of anesthetic drops, the patient will not experience any pain from this procedure. It is important to have a relaxed patient, since squinting and blepharospasm may interfere with the reading. *(From Keeney AH: Ocular Examination, 2nd ed. St Louis, CV Mosby, 1976. Reproduced by permission.)*

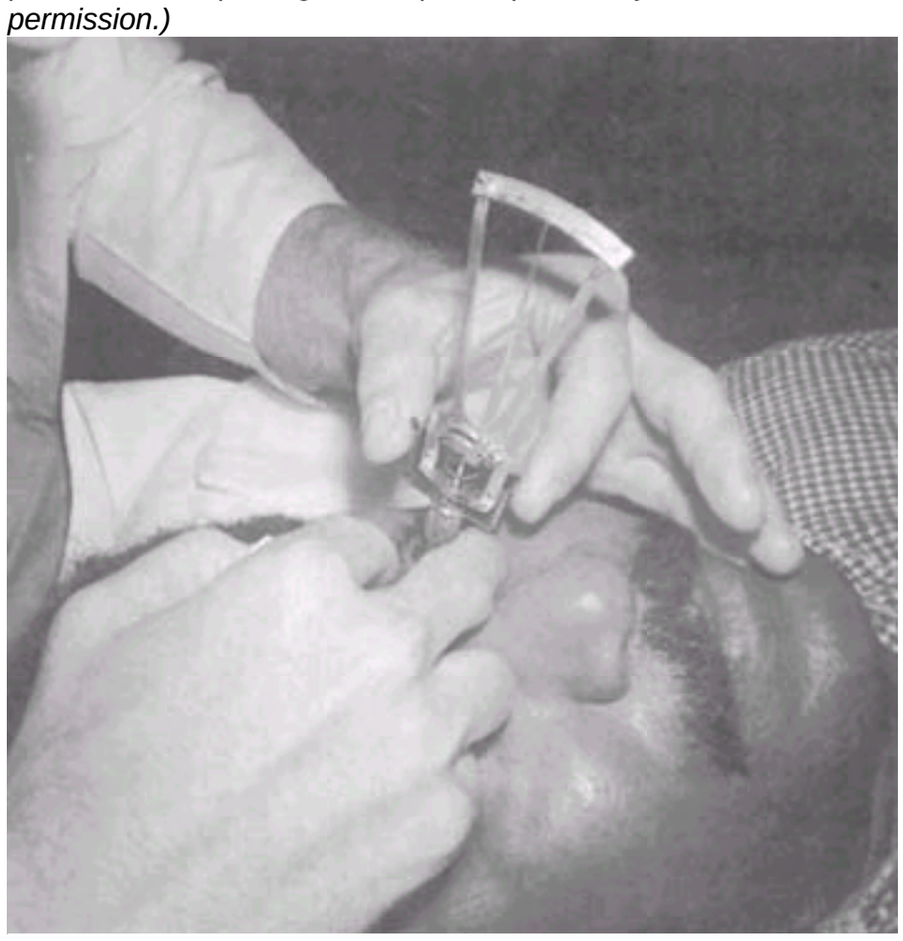

Figure 64-39 Bedside tonometry is easily accomplished with the Tono-Pen XL. The battery-powered device averages four consecutive readings and reports statistical reliability.

Figure 64-40 After topical anesthesia, the Tono-Pen XL is touched lightly and briefly to the cornea with a tapping motion, then withdrawn. Disposable tip covers are used to minimize any cross contamination.

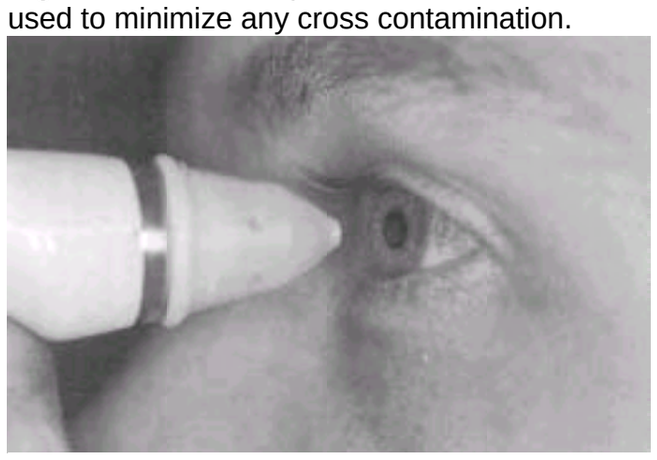

Figure 64-41 Goldmann applanation tonometer with the biprism aligned with the patient's right cornea.

Figure 64-42 Schematic representation of semicircles seen through the contact applanation prism of the Goldmann tonometer. *A,* Semicircles are too wide, suggesting excessive moistening of the prism or cornea. The prism must be withdrawn and dried. *B,* Semicircles are too narrow, suggesting that the lacrimal fluid has dried out, as during a prolonged measurement. The prism must be withdrawn so that the patient may blink a few times. The measurement is then repeated. *C,* Semicircles are of appropriate width, and their inner borders just touch. Cardiac pulsations transmitted through the globe cause rhythmic or pulsating movement of the semicircles over each other through a small amplitude. *D,* Semicircles are slightly separated, indicating applied pressure below that of the eye. The measuring drum must be turned to increase applanation pressure until the end point is reached. *(From Keeney AH: Ocular Examination, 2nd ed. St Louis, CV Mosby, 1976. Reproduced by permission.)*

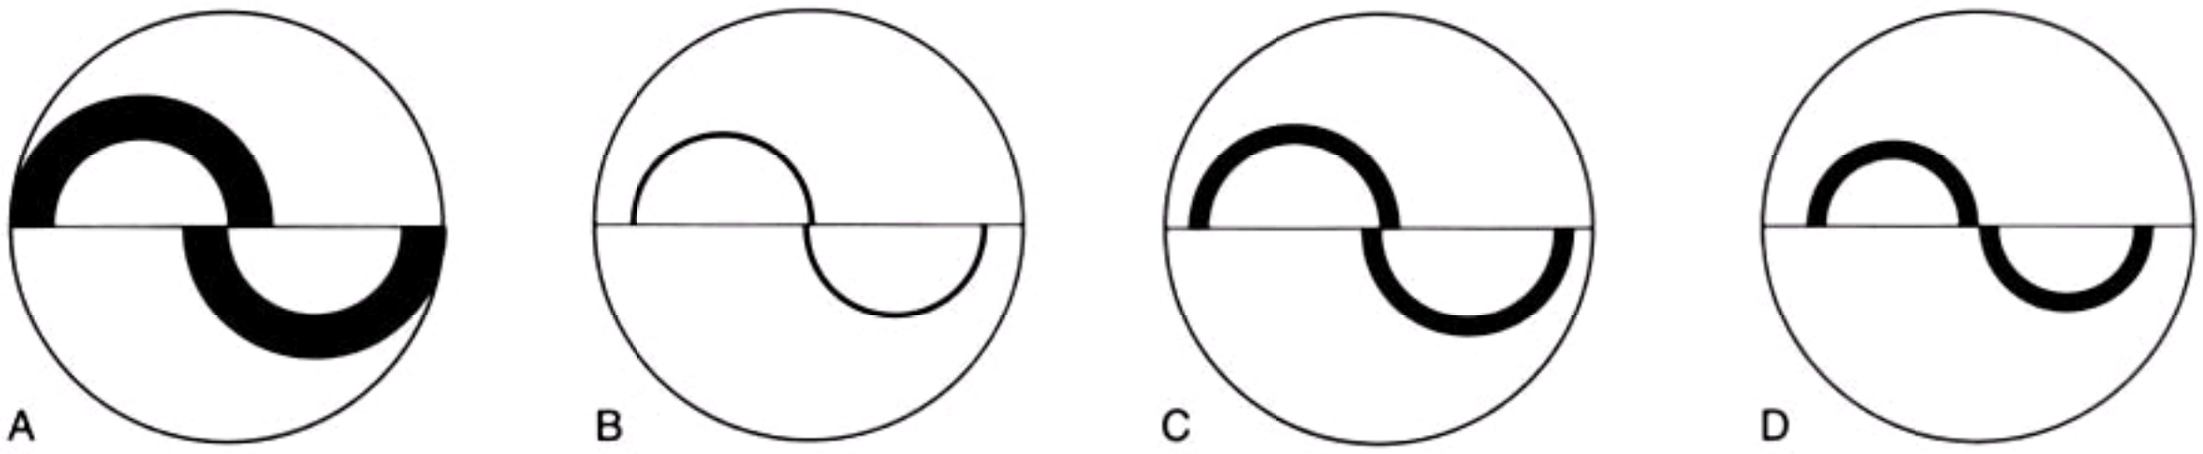

Figure 64-43 Appearance of the semicircles in applanation tonometry. Rotate the pressure knob to align the innermost concave margins of the two semicircles. IOP = intraocular pressure. (1) Pressure on the tonometer head is too high—rotate the knob to decrease reading. (2) Pressure on the tonometer head is too low—rotate the knob to increase reading. (3) Pressure on the tonometer head is equal to IOP—the dial reading equals IOP. *(From Knoop K, Trott A: Ophthalmologic procedures in the emergency department—Part III: Slit lamp use and foreign bodies. Acad Emerg Med 2:224, 1995. Reproduced by permission.)*

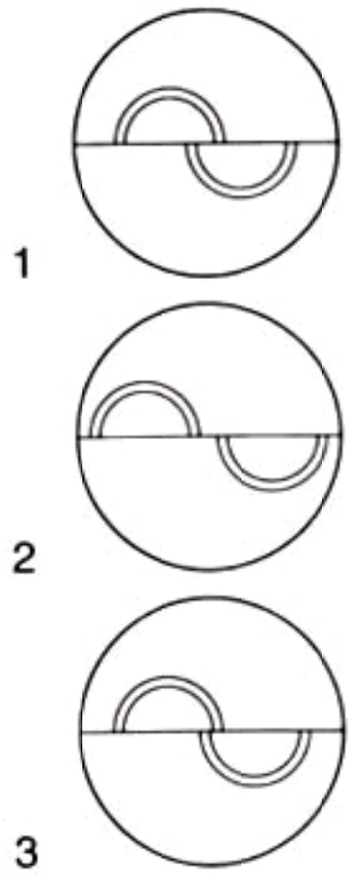

Figure 64-44 Slit lamp controls. *(From Operating Instructions for Slit Lamp Microscopes. Marco Equipment, Inc., Jacksonville, FL.)*

Figure 64-45 Slit lamp photograph of a normal right eye under low power. The curved slit of light on the left is reflected off the cornea while the slit on the right is reflected off the iris. The depth of the anterior chamber can easily be appreciated under this low magnification setup. *(Courtesy of D. Price.)*

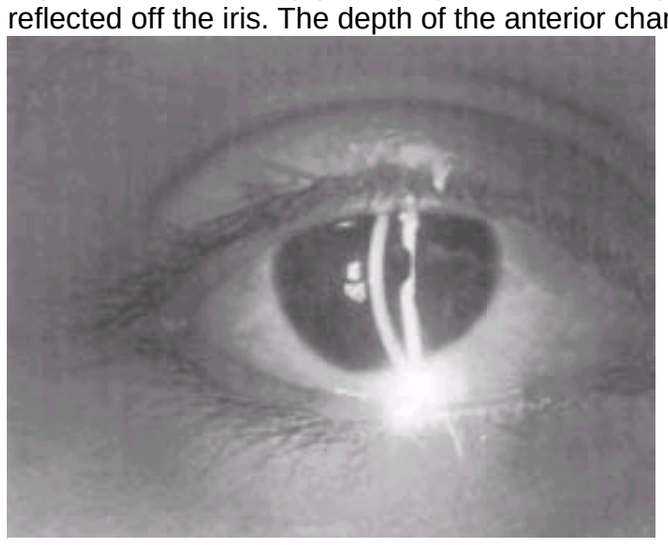

Figure 64-46 Appearance of the left eye during anterior chamber examination under low power: *a,* corneal epithelium; *b,* corneal stroma; *c,* corneal endothelium; *d,* anterior chamber (potential location of cells or flare); *e,* iris; *f,* lens reflection. The slit of light shines in the temporal to nasal direction at 45° to the anterior surface of the cornea. The depth of the cornea and anterior chamber examination are best done under high power in a dark room.

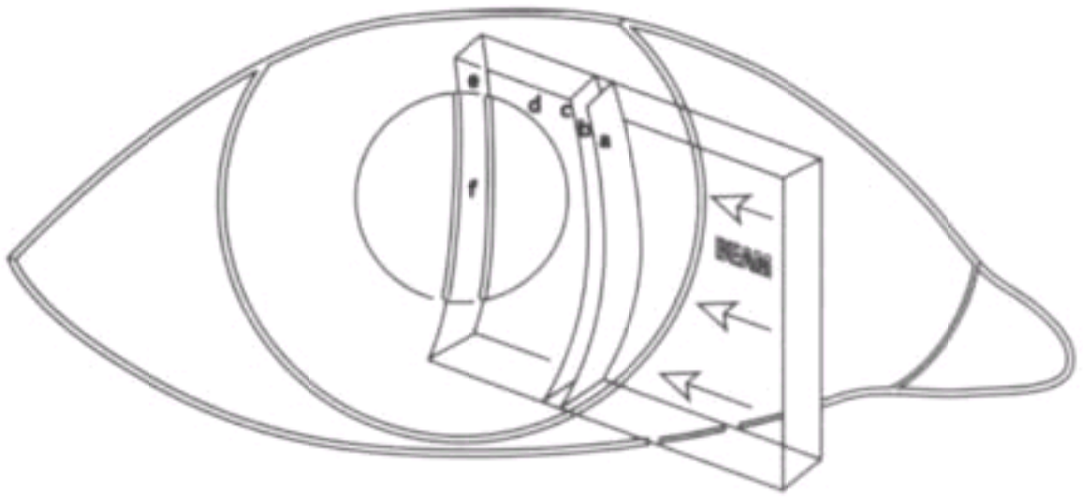

Figure 64-47 Digital globe massage is performed by applying firm steady pressure on the globe with the examiner's thumb for approximately 5 seconds, followed by abruptly releasing the pressure for 5 to 10 seconds. The process is repeated for up to 20 minutes or until improvement of vision is observed.

Figure 64-48 Anterior chamber paracentesis. After topical and subconjunctival anesthesia (see text), a 30-ga needle is directed obliquely from the 4:30 or 7:30 o'clock position toward the 6 o'clock position to avoid the lens. An assistant stabilizes the globe with forceps, grasping the conjunctiva (see text). *Top*, Anteroposterior projection. *Bottom*, Tangential projection. *(From Knoop K, Trott A: Ophthalmologic procedures in the emergency department: I. Immediate sight-saving procedures. Acad Emerg Med 1:408, 1994.)*

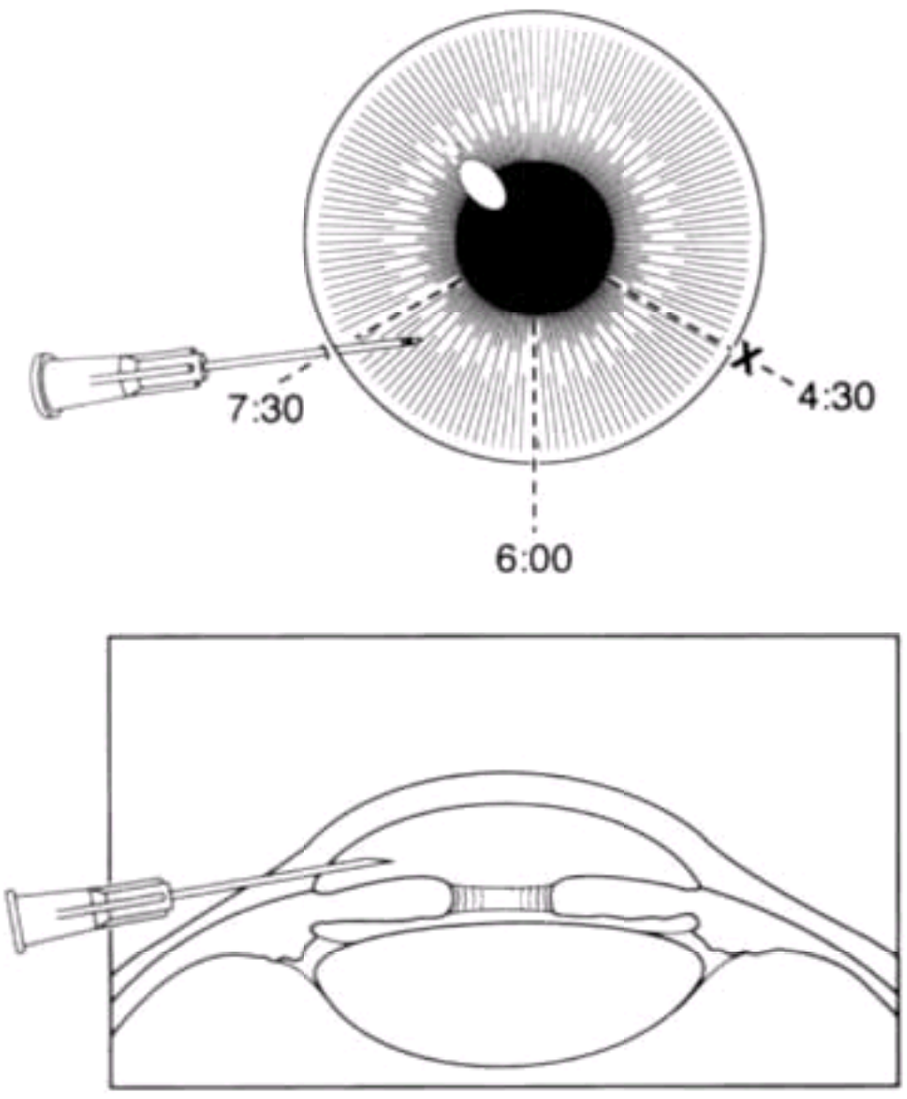

Figure 64-49 *A,* Severe proptosis secondary to acute traumatic retrobulbar hemorrhage. *B,* Anatomy of orbital structures demonstrating the inferior and superior crura of the lateral canthal tendon beneath the lateral canthus. The crura join and as a common tendon are attached to the inner aspect of the lateral orbital wall, forming Whitnall's tubercle. The lateral canthus, formed by the upper and lower eyelid, has been removed. *C, D,* A clamp crushes the lateral canthus to reduce bleeding when it is incised. The canthotomy allows the inferior crus to be exposed and cut to decompress the eyeball. *E,* A 1 centimeter horizontal incision is made in the lateral canthus, through the tissue that was compressed. *F,* The lower lid is pulled down and away from the lateral orbital rim, separating the skin and conjunctiva. If bleeding hinders identification of the inferior crus, it may be palpated. *G,* Only the inferior crus need be lysed initially. If intraocular pressure is not reduced, the superior crus is lysed. *(From S. Vassallo et al: Traumatic retrotubular hemorrhage: Emergent decompression by lateral canthotomy and cantholysis. J Emerg Med 22:21, 2002.)*

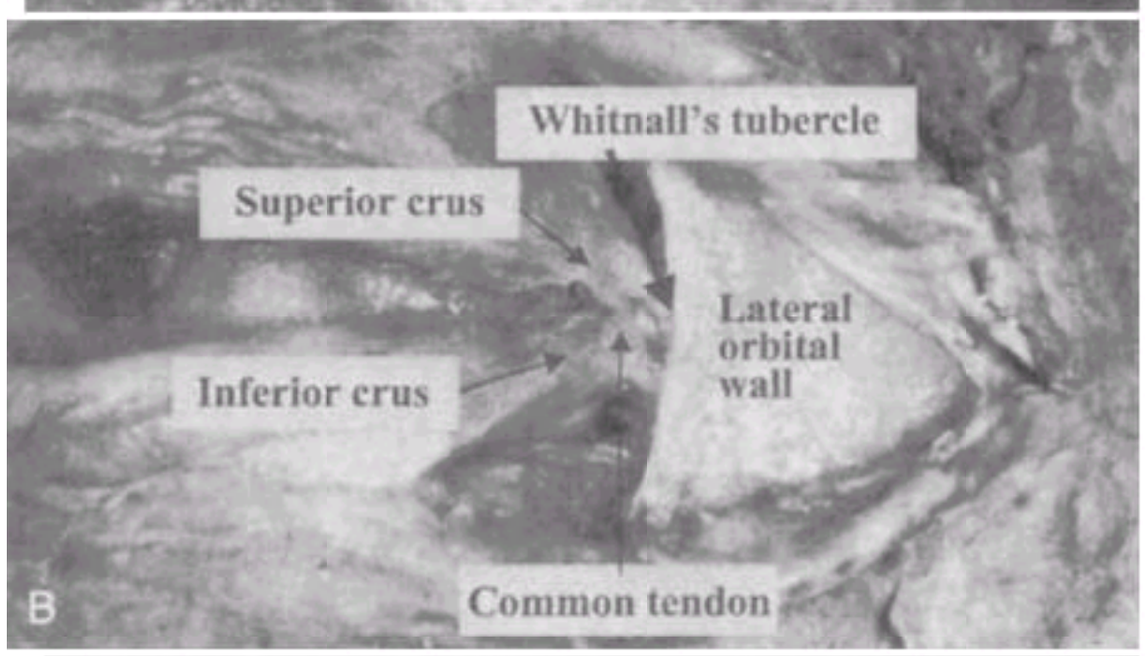

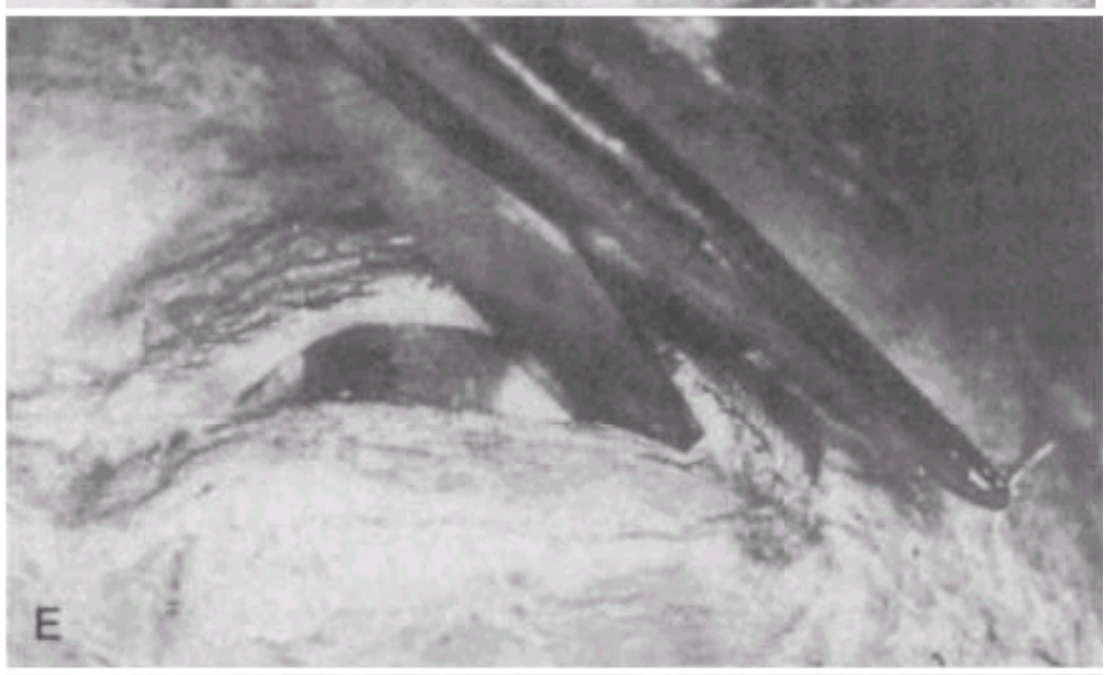

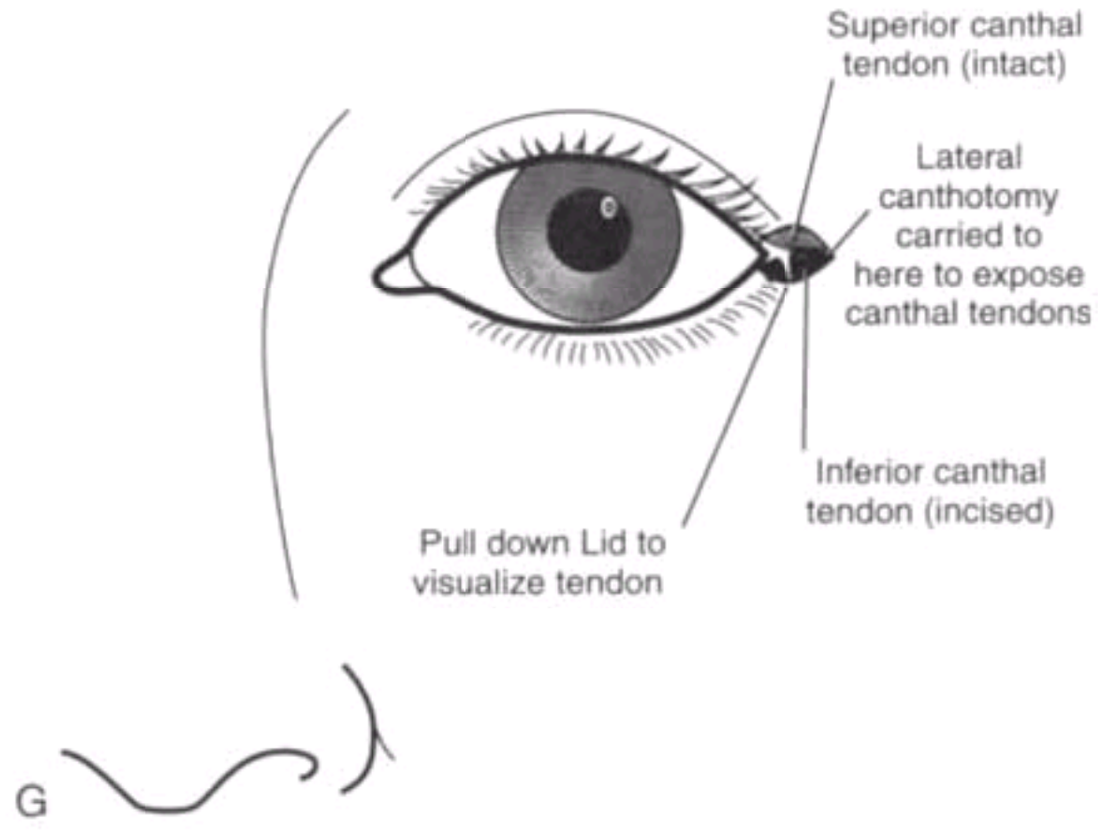

Figure 64-50 Appearance of bilateral luxated globe; superior (*top)* and lateral (*bottom*) projections. *(From Love JN, Bertram-Love JE: Luxation of the globe. Am J Emerg Med 11:61, 1993; original photographs courtesy of WR Green, MD, Wilmer Eye Institute, Baltimore.)*

Figure 65-1 Anatomy of the oropharynx. Sagittal section of the neck. Also depicted is the use of the nasopharyngeal scope through the nasopharynx and the oropharynx.

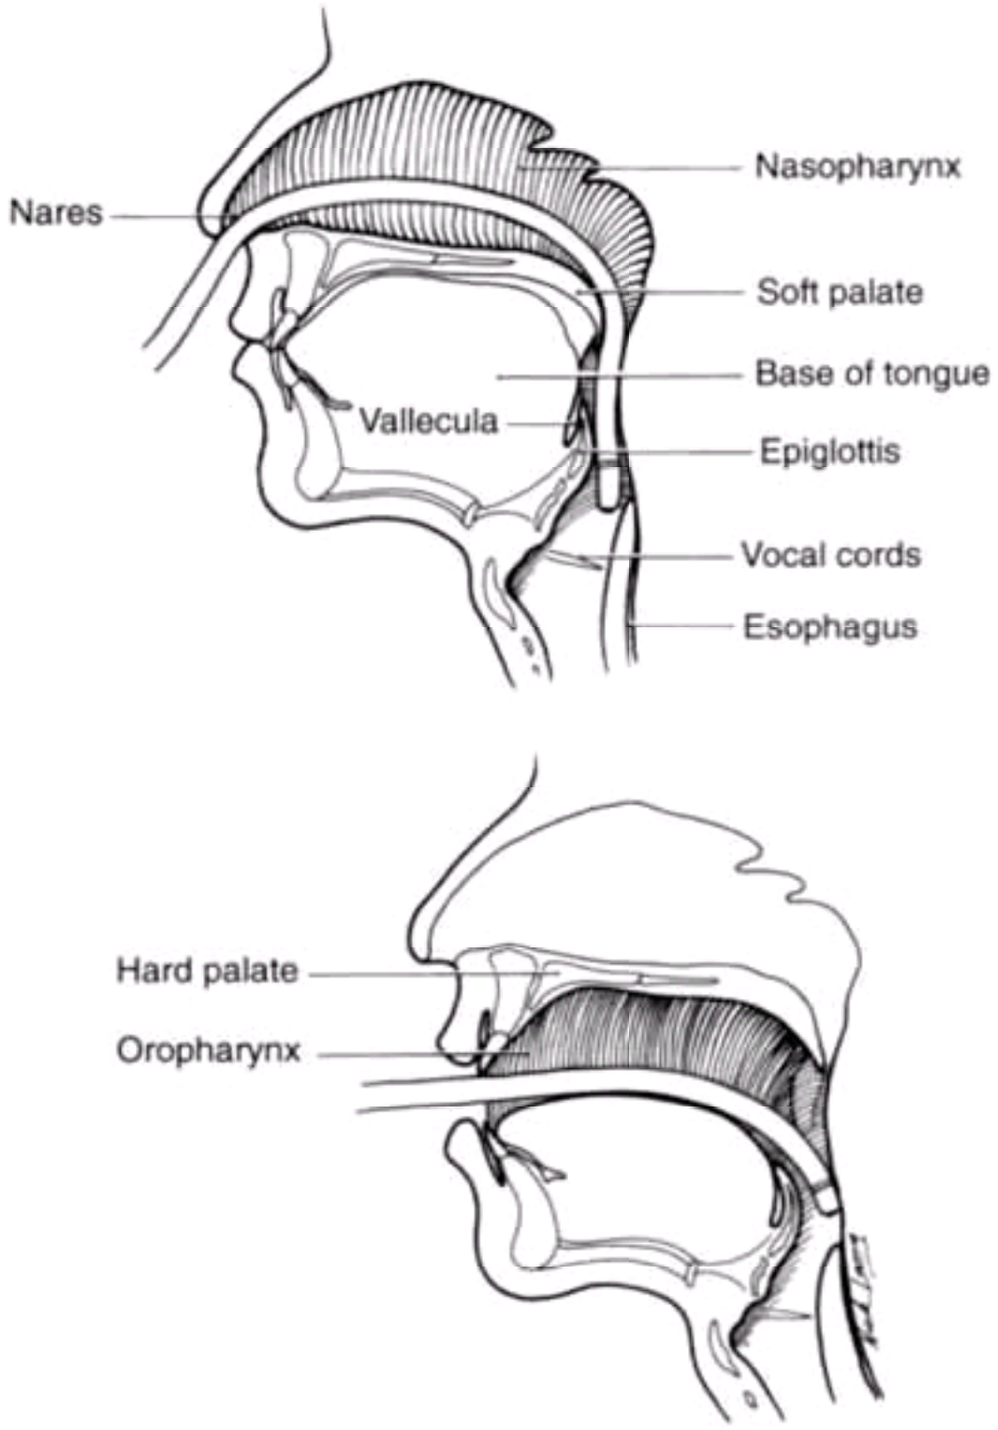

Figure 65-2 Indirect mirror evaluation of oropharynx. Grasp the patient's tongue between the thumb and first finger, using a gauze pad to provide traction. Elevate the upper lip with the middle finger. Advance the warmed laryngeal mirror into the posterior oropharynx, taking care not to stimulate the posterior tongue or pharynx. Remember that the structures in the mirror will be reversed. Always use universal precautions.

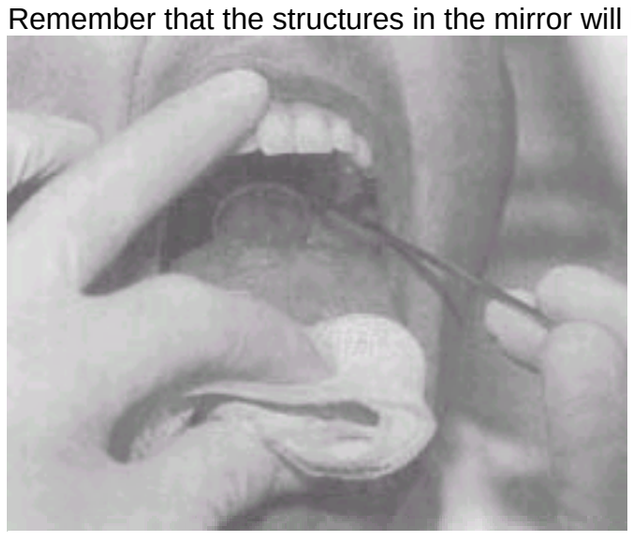

Figure 65-3 View of the larynx from above. The true and false vocal cords are sketched, with the arytenoid eminences behind them on each side. The epiglottis, piriform fossae, and valleculae are also labeled.

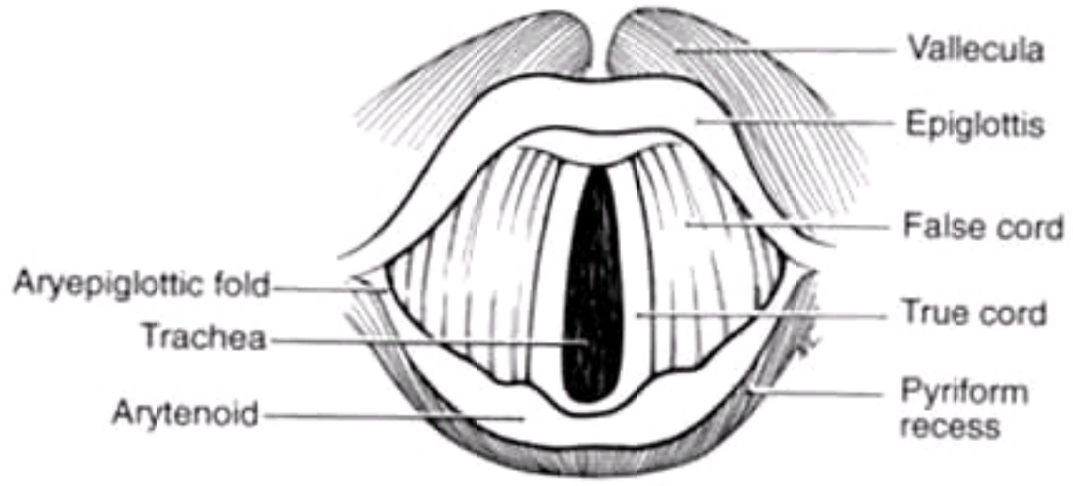

Figure 65-4 Fiberoptic scope with light source.

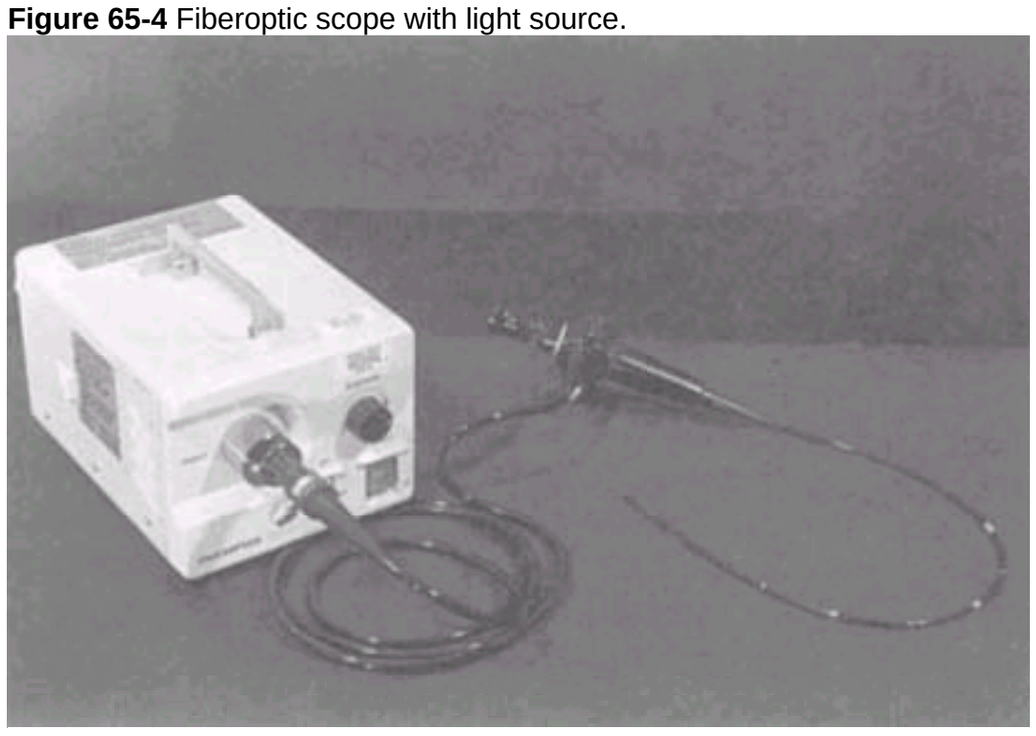

Figure 65-5 Fiberoptic nasopharyngoscope in use. Prepare the patient's throat and nares with topical anesthetic. Topical vasoconstrictors may also be used in the nares. The use of a nasal trumpet is optional. Advance the scope slowly into the naris with the hand stabilized on the patient's nose; guide the scope using the thumb and index finger. Visualize the passage of the scope through the naris into the posterior nasopharynx. Always use universal precautions.

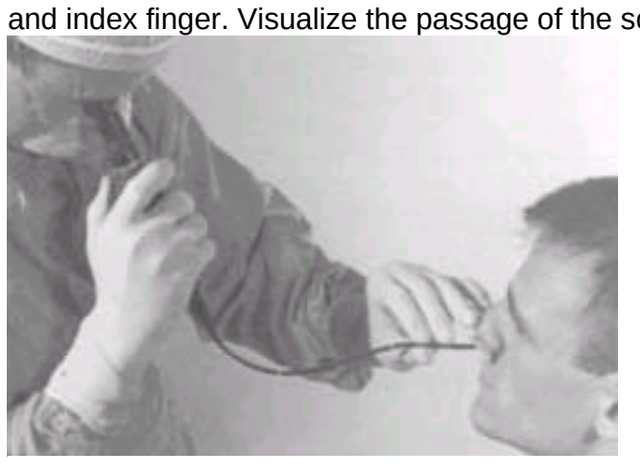

Figure 65-6 Anatomy of a peritonsillar abscess. The palatine tonsil and peritonsillar space are identified on the patient's right. A peritonsillar abscess is shown on the patient's left. Note that the abscess can extend medially, displacing the uvula. The carotid artery and jugular vein are posterior and lateral to the abscess. Avoid lateral angulation of the aspirating needle and use a needle guard to prevent injury.

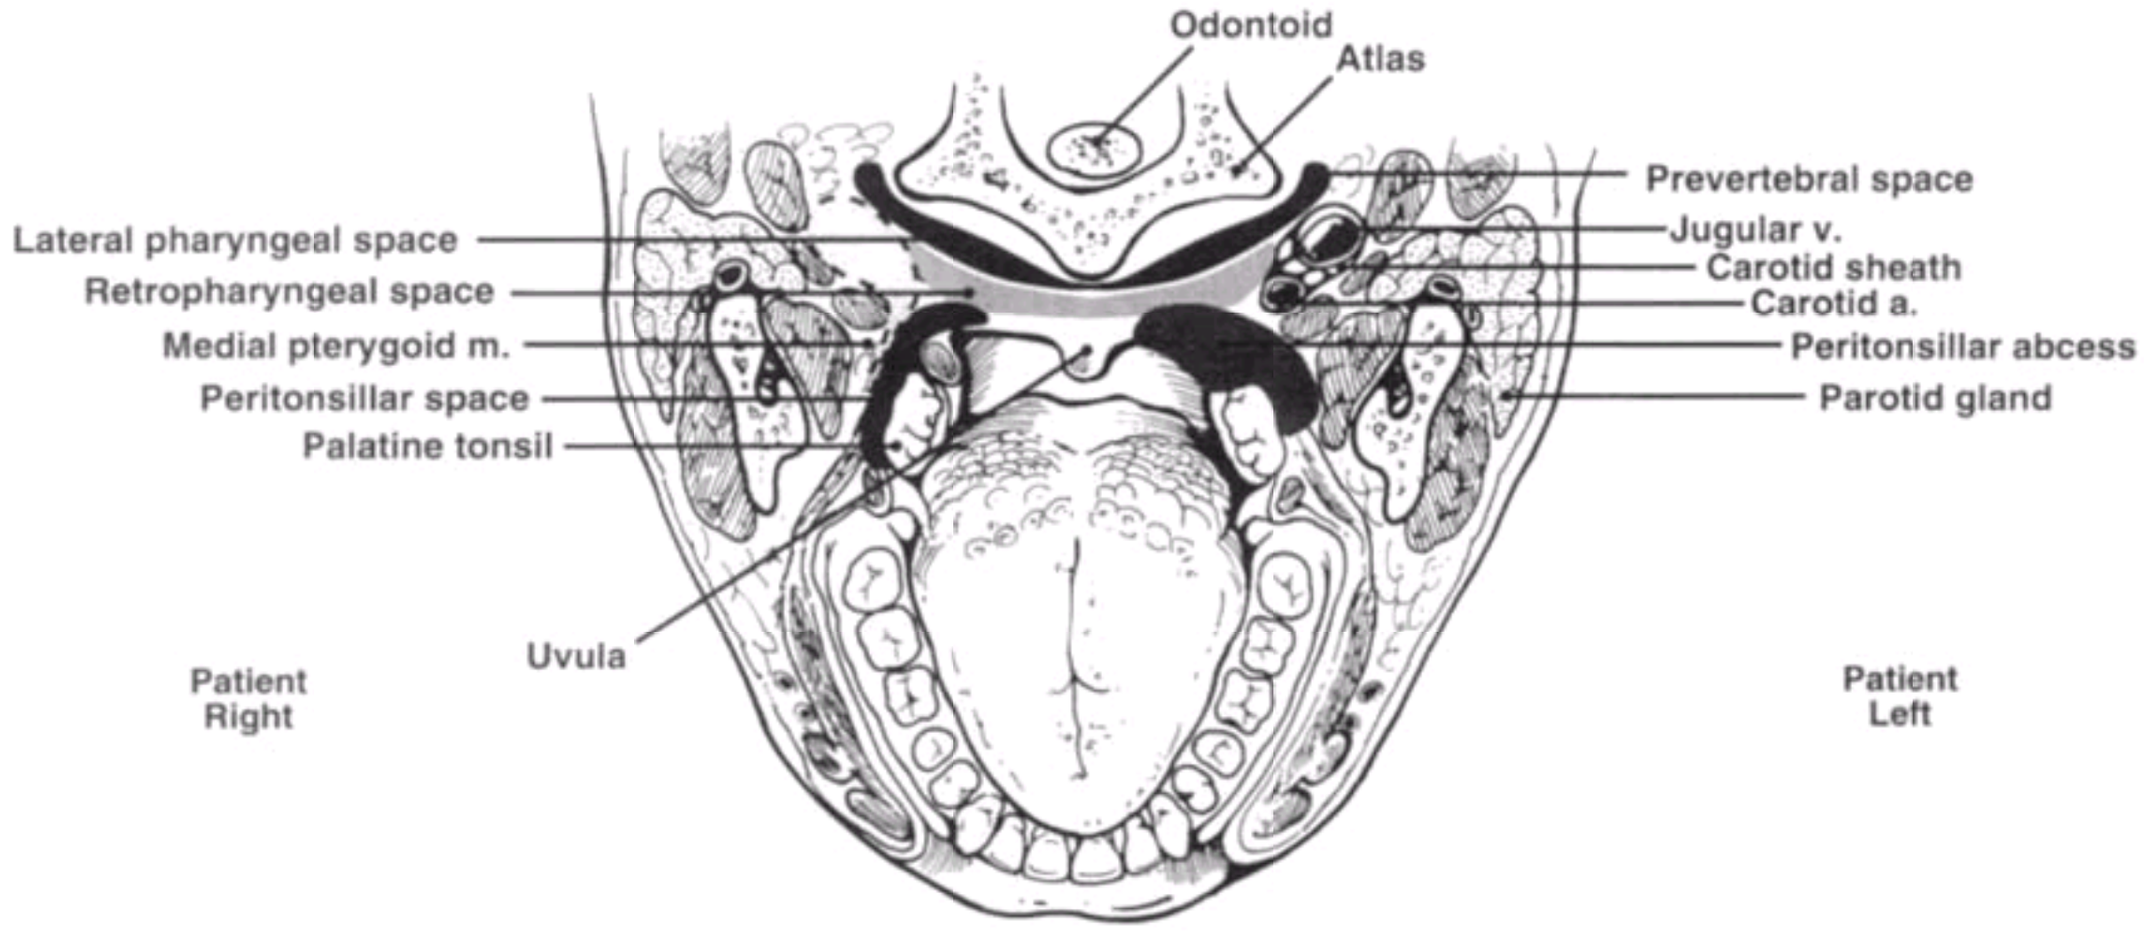

Figure 65-7 Clinical symptoms and visual inspection may not be sufficient to differentiate peritonsillar abscess from cellulitis. The clinician's gloved index finger is used to palpate the peritonsillar area to search for fluctuance and localized swelling.

Figure 65-8 Needle aspiration of a peritonsillar abscess. The patient sits upright with the head supported by the back of the stretcher (or a dental chair head rest). A head lamp provides light and an assistant retracts the cheek laterally to maximize visibility.

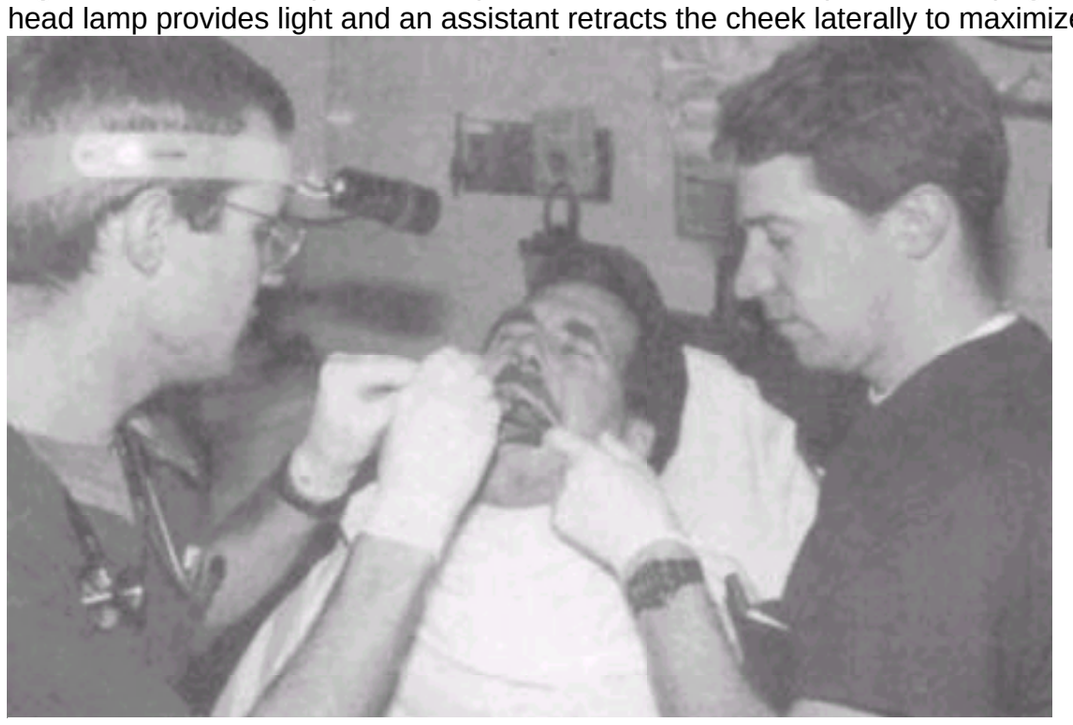

Figure 65-9 *A*, As a safeguard to prevent deep penetration of a needle used to drain a peritonsillar abscess, select a long 18- to 20-gauge needle. Remove the plastic needle guard and cut off the distal 1 cm. *B*, Replace the guard on the needle and tape it to the hub.

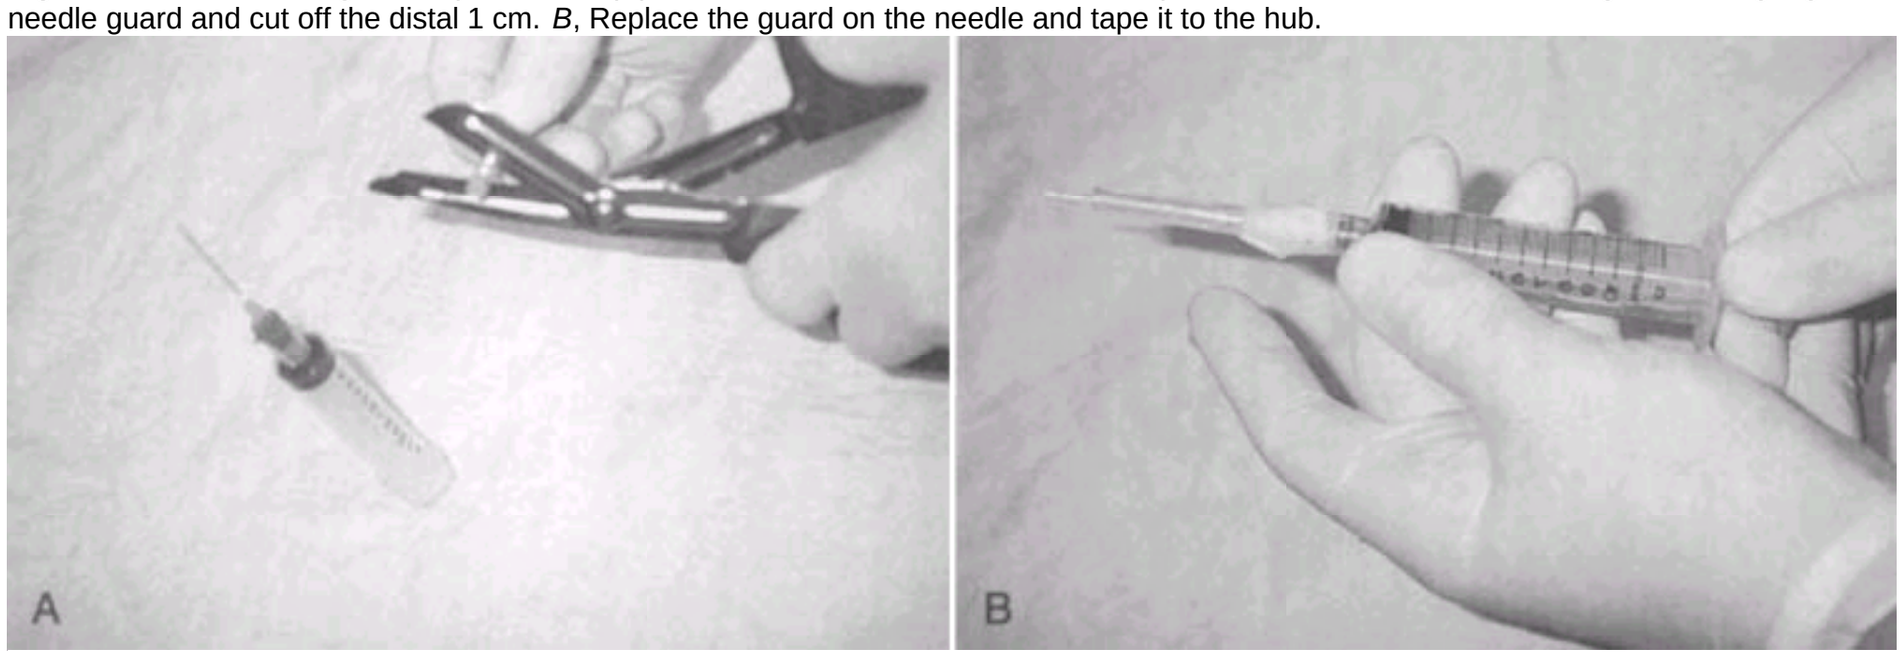

Figure 65-10 *A*, Needle aspiration of a peritonsillar abscess. Anesthetize the posterior pharynx with topical lidocaine spray. Blanch the mucosa with lidocaine/epinephrine with a 27-gauge (ga) needle on a long syringe (to allow visualization of the site) in the area to be aspirated. Advance an 18- or 20-ga needle with needle guard into the area of greatest fluctuance, usually the superior pole. Aspirate as you advance the needle. Advance the needle in the sagittal plane. Do *not* direct the needle laterally toward the carotid artery or jugular vein. *B,* The superior pole is aspirated first, but the middle and inferior poles should be aspirated if pus is not obtained initially. Note that the tonsil itself is not aspirated. The *peritonsillar space* contains the abscess.

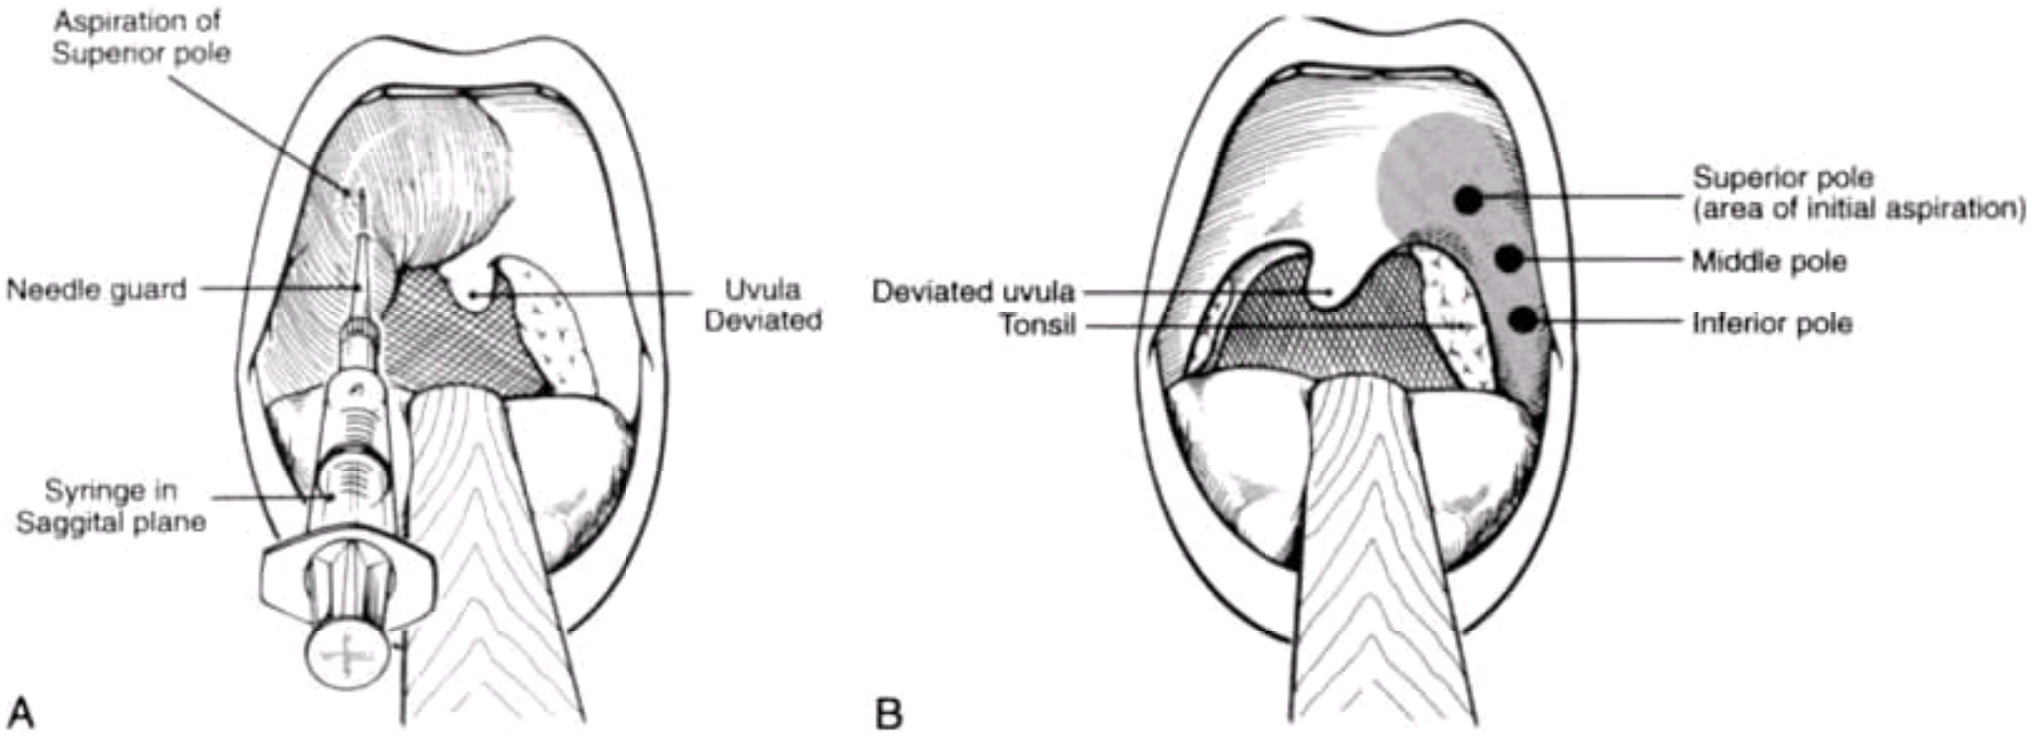

Figure 65-11 Needle aspiration usually yields 2 to 6 mL of thick pus. Greater volumes are unusual. Removing only a small amount will produce a marked reduction in symptoms.

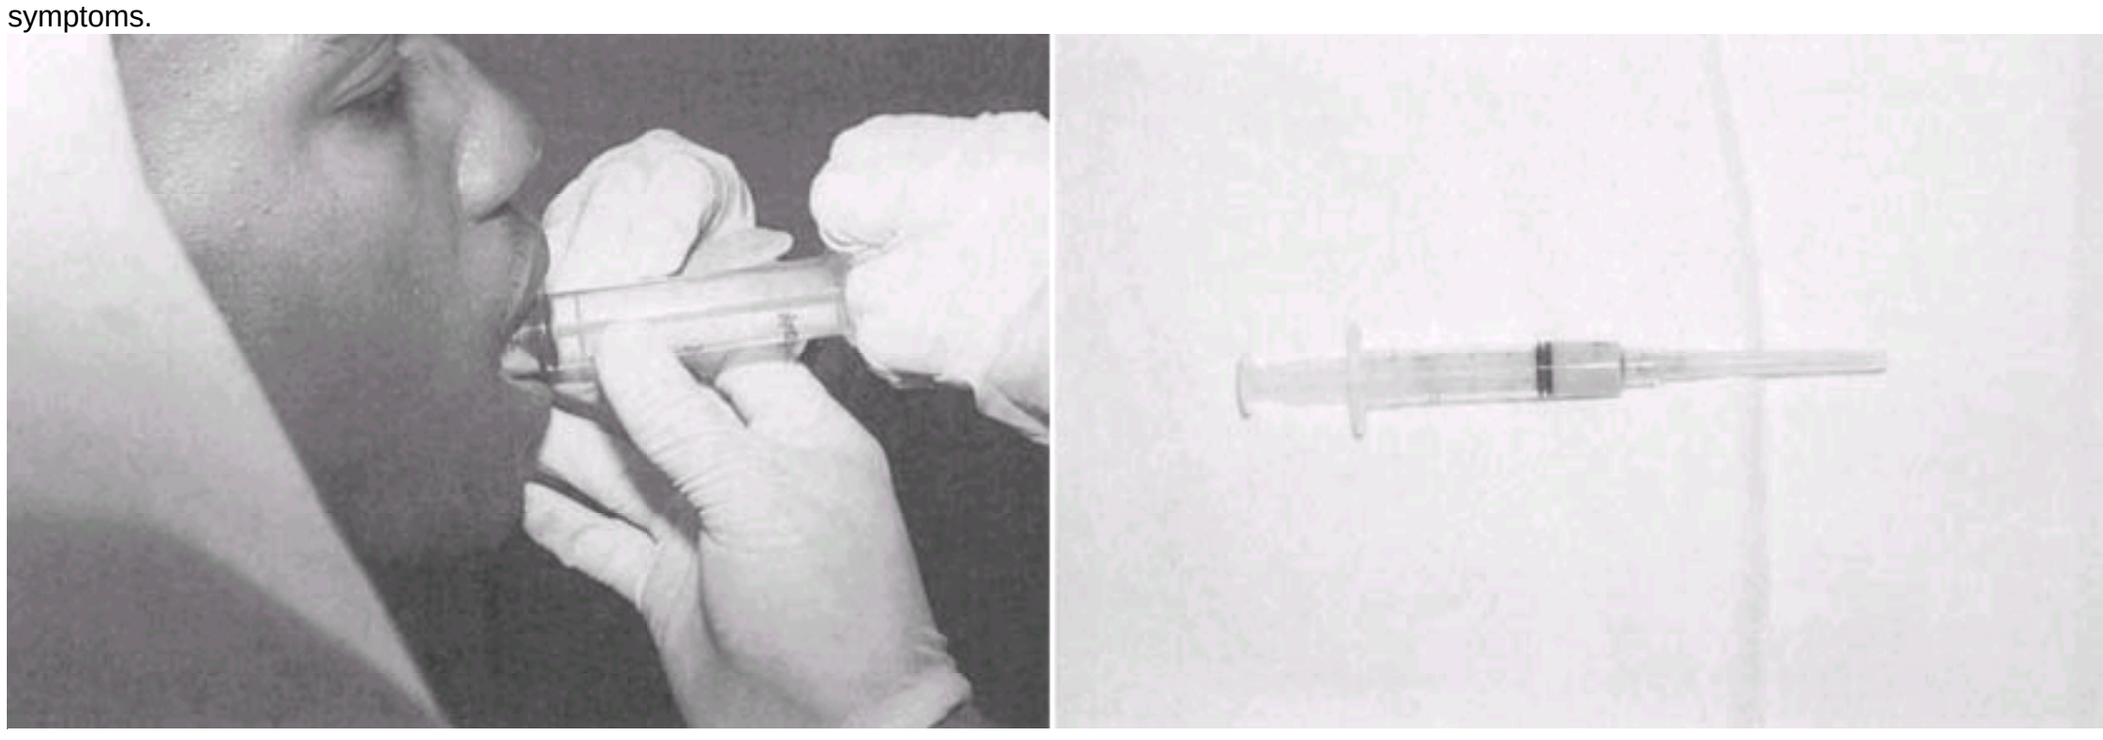

Figure 65-12 Aspiration is often the only procedure required to successfully treat a peritonsillar abscess, but it has a 10% failure rate. In some instances the clinician will opt for incision and drainage of a peritonsillar abscess. This procedure may used initially, or after aspiration if copious pus is aspirated, or if pus continues to drain or reaccumulates. *A,* Normal-appearing oropharynx. *B,* Peritonsillar abscess on the right side of the throat. *C,* Incision of the abscess at the area of greatest fluctuance. Notice that the scalpel is taped to prevent deep penetration. *D,* Loculations are removed by gentle probing with hemostats.

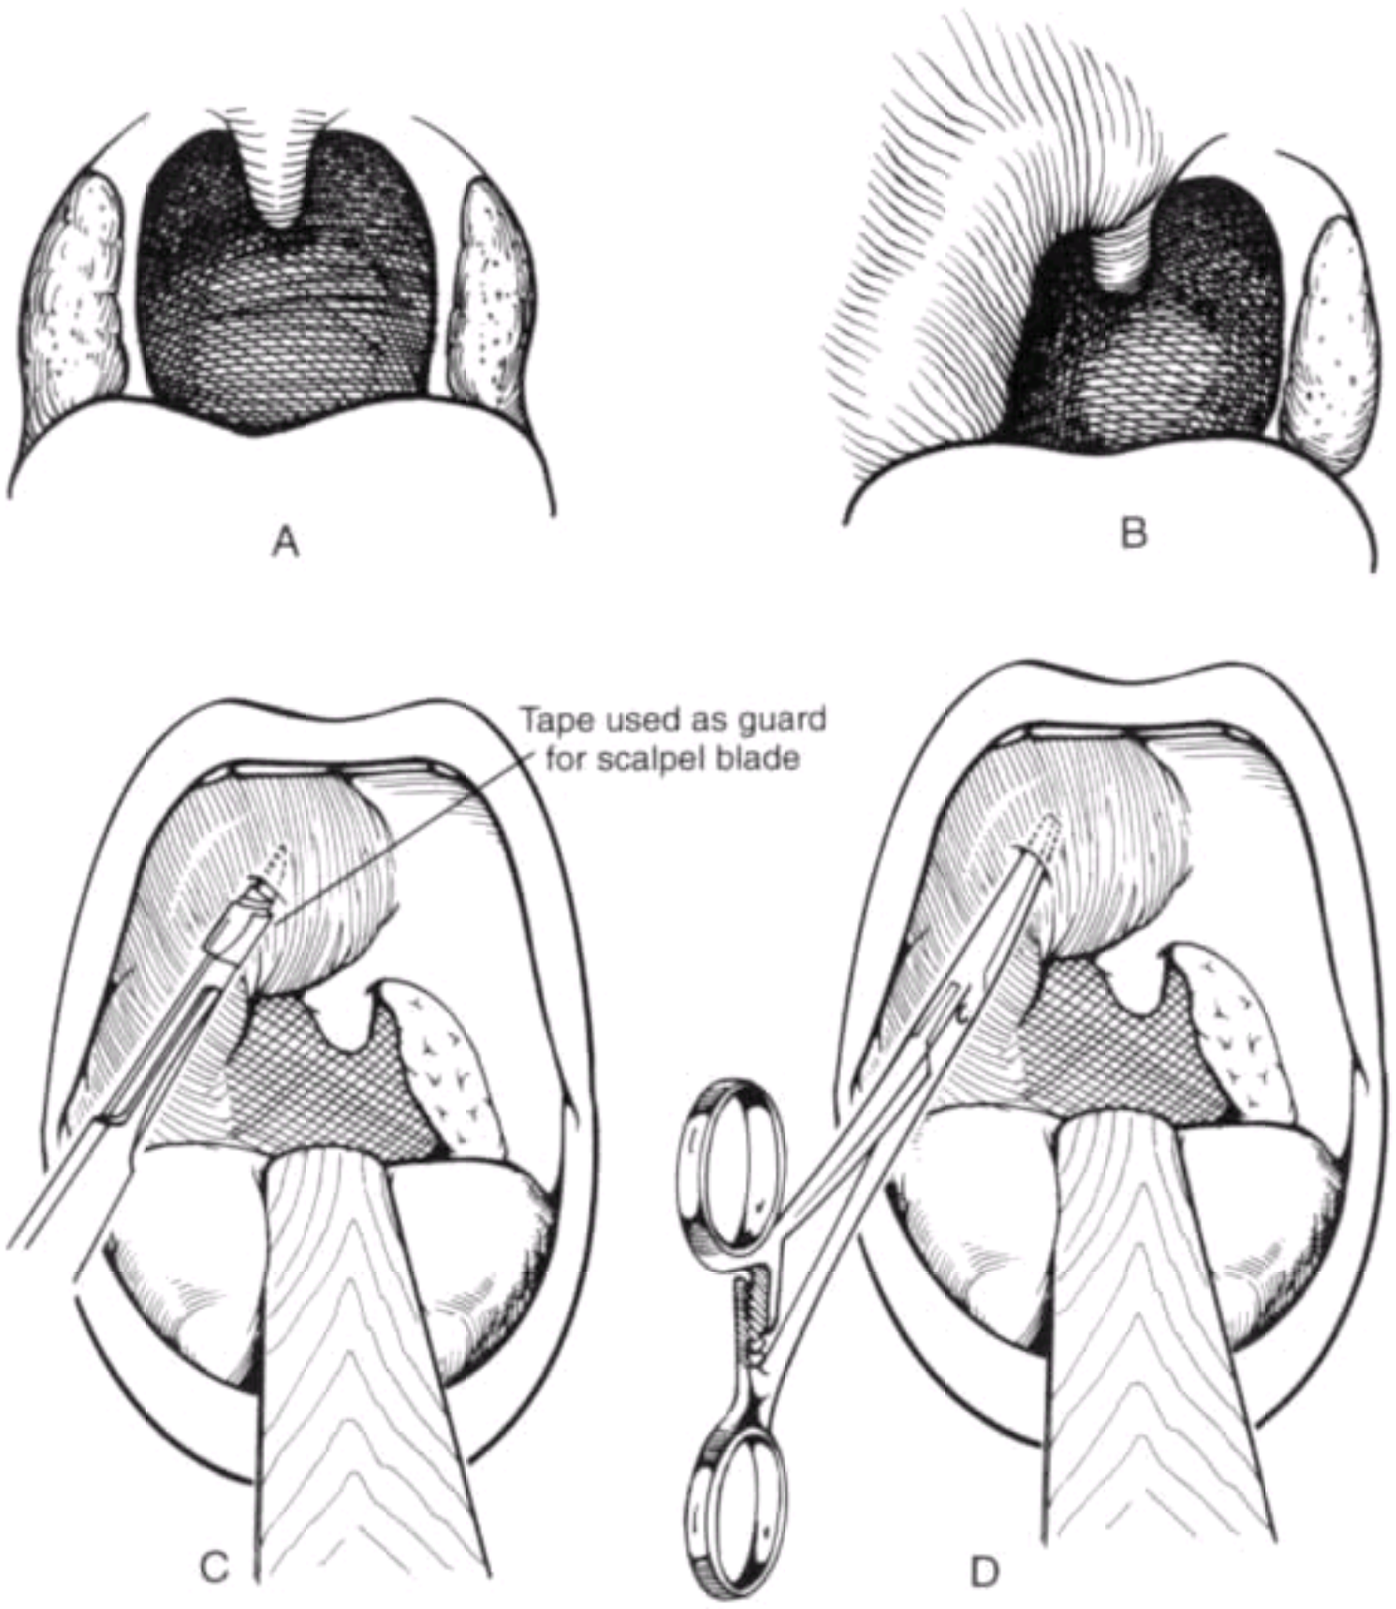

Figure 65-13 *A* and *B,* External anatomy of the ear and innervation of the auricle.

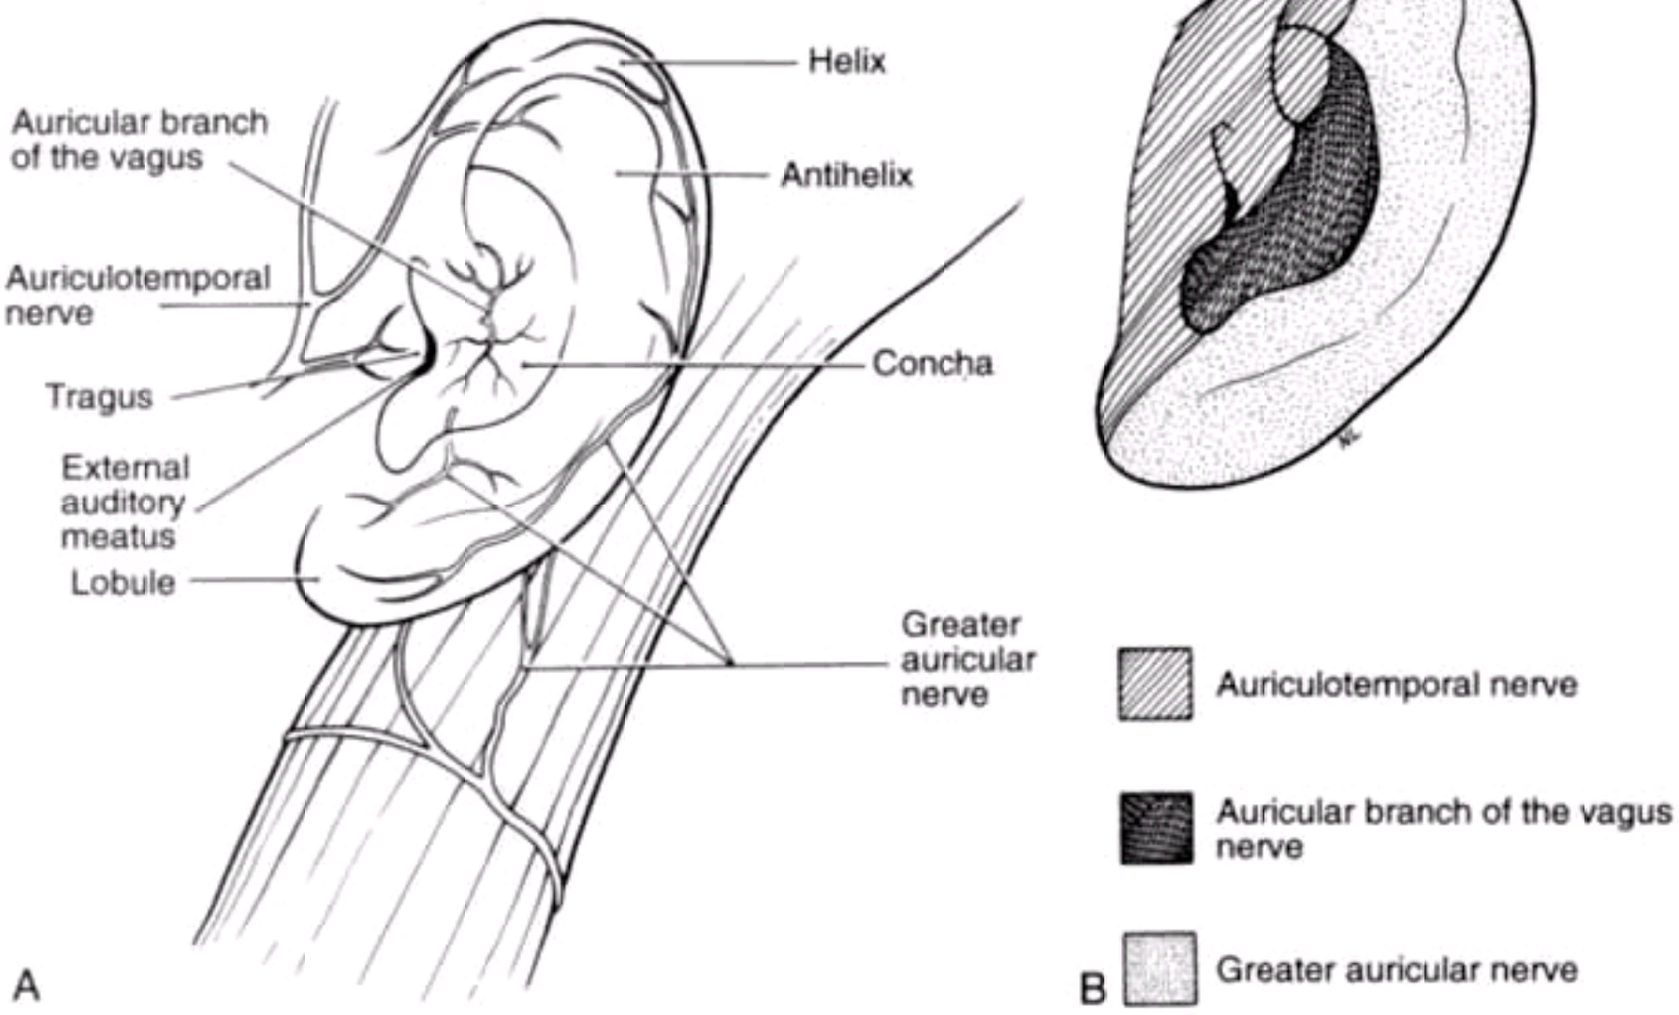

Figure 65-14 Field blocks of the auricle. *A,* One method uses approximately 3 to 4 mL of anesthetic, both in the posterior sulcus and at a point just anterior to the tragus. *B,* Alternative field block technique that deposits 2 to 3 mL of anesthetic for each needle pass. See text for more details.

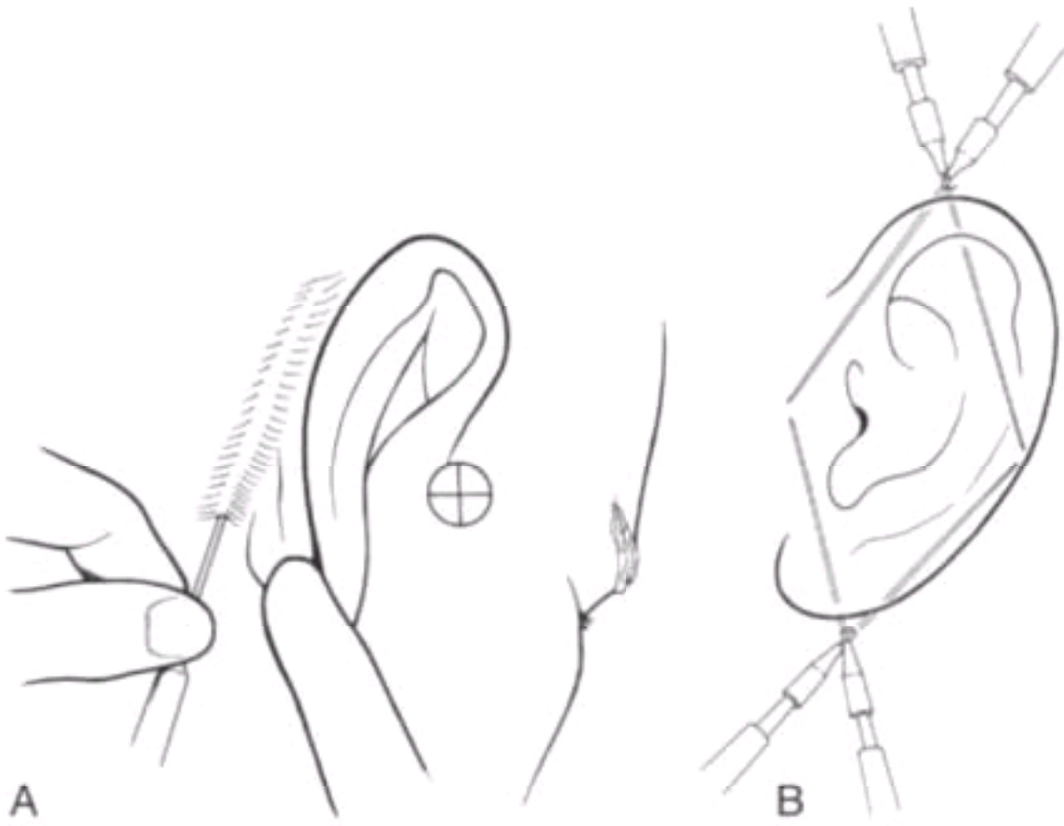

Figure 65-15 Four-quadrant field block anesthesia of the external auditory canal. Local anesthetic is injected subcutaneously in the four quadrants of the lateral portion of the ear canal. The largest speculum that will fit is used to guide the injections. The speculum is withdrawn slightly, tilted toward each of the four quadrants, and the needle is inserted subcutaneously *(x)*. A very small amount of anesthetic (0.25 to 0.50 mL) is injected to produce a slight bulge in the soft tissue. A total of 1.5 to 2.0 mL of anesthetic is usually sufficient to anesthetize the ear canal and permit painless removal of a foreign body.

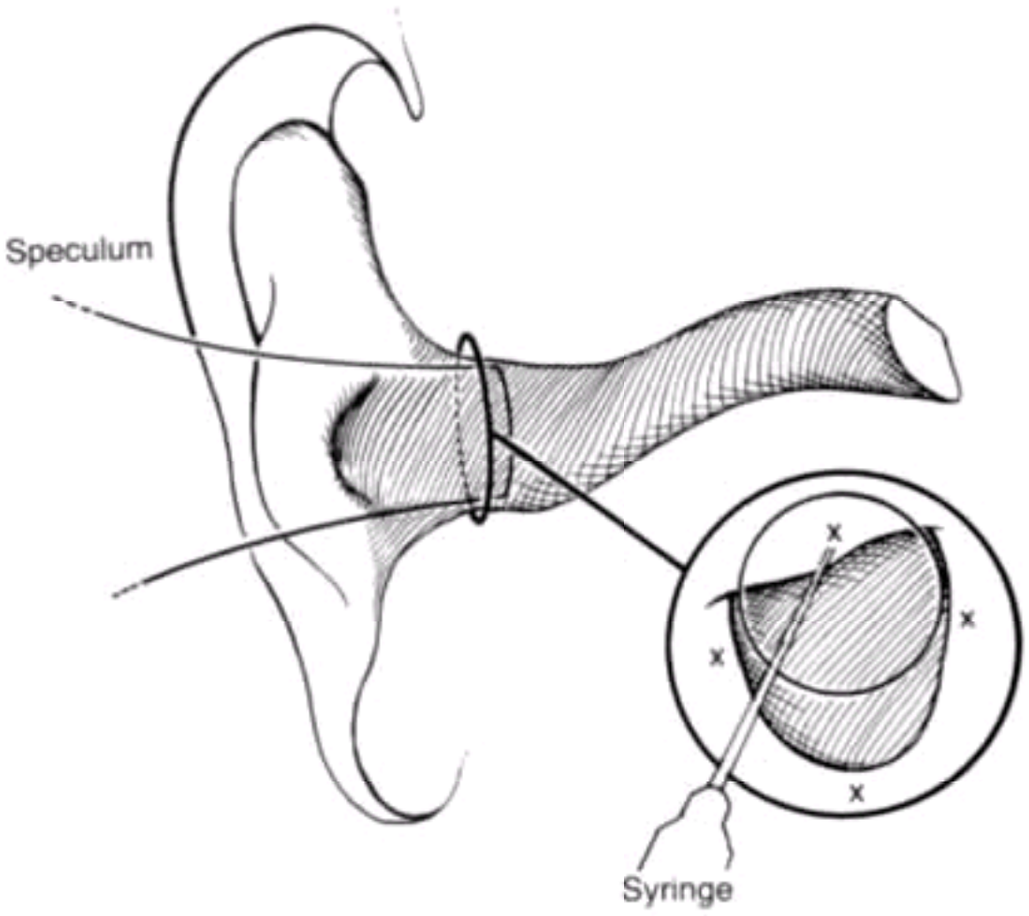

Figure 65-16 Diagram of injection sites for an alternative technique to anesthetize the ear canal and central concha. Each site should be injected with approximately 0.5 mL of 1% lidocaine. Do not inject if external signs of infection are present.

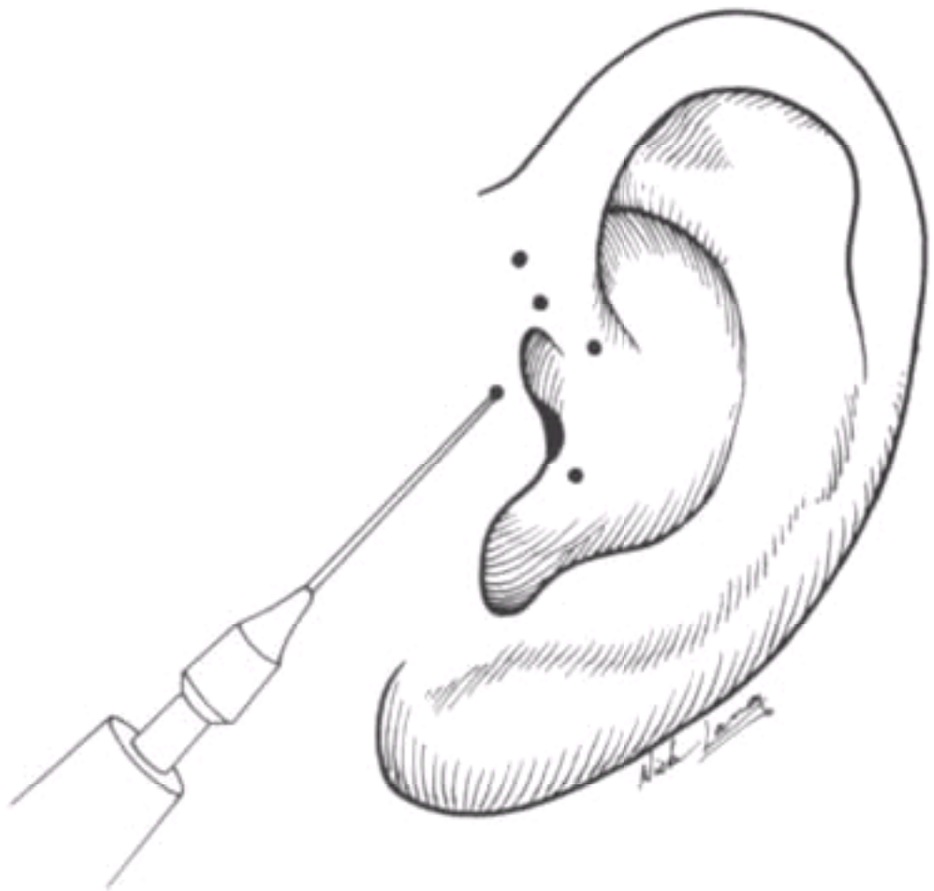

Figure 65-17 Examination of ear canal. The pinna is retracted in a superior and posterior direction to straighten out the ear canal. The scope is held in the other hand and stabilized against the patient's head. This prevents inadvertent injury if the patient moves unexpectedly.

Figure 65-18 Irrigation is a simple, painless, and usually successful way to remove cerumen. After a wax-softening agent has been instilled for 15 to 20 minutes, an assistant applies traction on the ear to straighten the canal, and the plastic tubing of a 19-ga butterfly device (needle and wings removed) is inserted 1 cm into the canal. A basin is held by the patient, and warm water is introduced with a 20-mL syringe. A number of irrigations may be required, and the procedure may be supplemented with careful removal of large cerumen pieces with a curette.

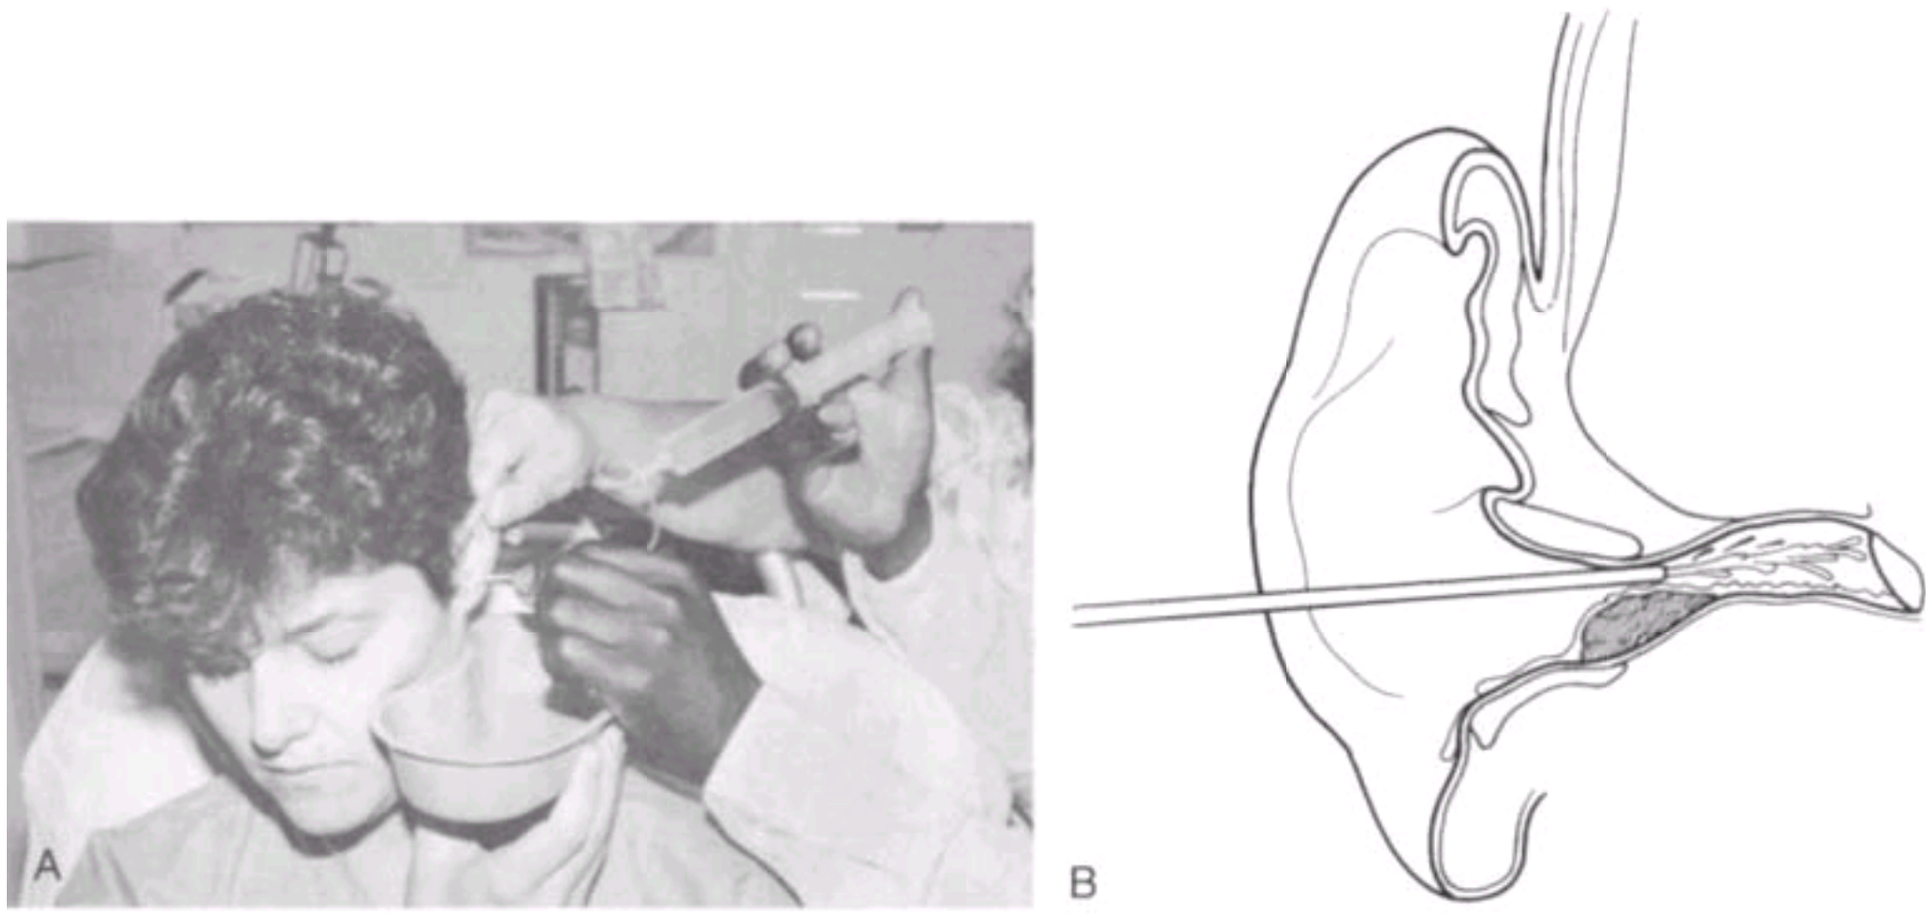

Figure 65-19 The most readily available device for ear irrigation is an 18-gauge flexible catheter attached to a 60-mL syringe. Since multiple irrigation may be required, small syringes are counterproductive.

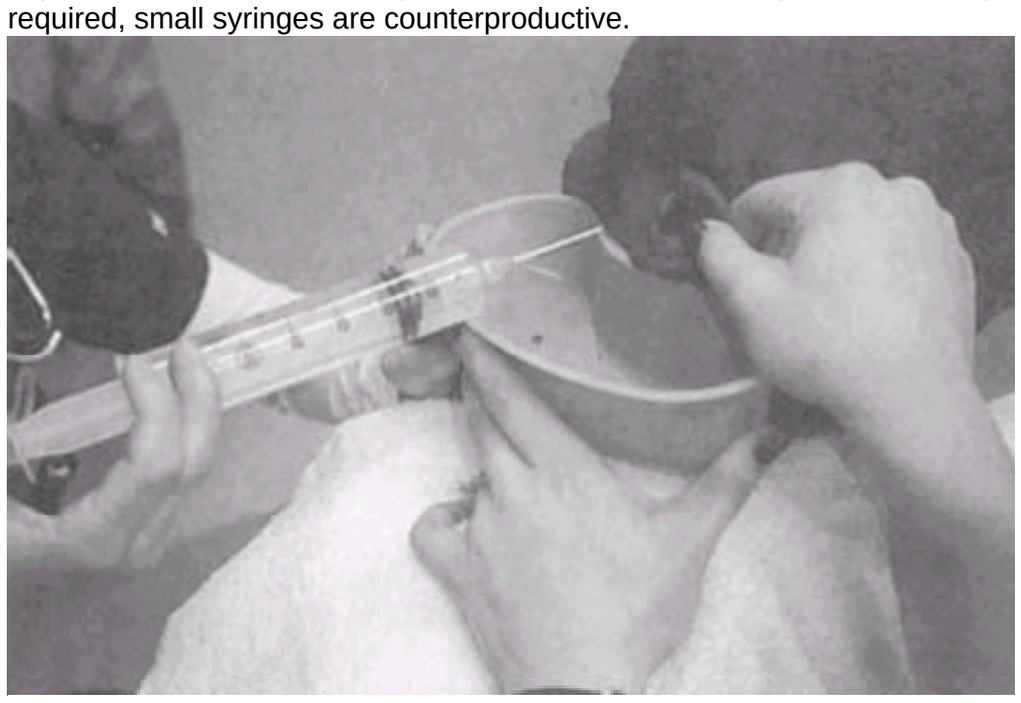

Figure 65-20 This DeVilbiss irrigator uses compressed air to eject the irrigating solution, which should be near body temperature to avoid caloric stimulation of the inner ear. The more conventional metal ear syringe can be equally effective and does not require a source of compressed air to function.

Figure 65-21 Technique for direct visualization and mechanical removal. Use of alligator forceps through a diagnostic otoscope. Note that the magnification device has been slid laterally and that no ear speculum has been attached. *Inset,* Use of ear curettage through operating otoscope. *(From Fritz S, Kelen GD, Sivertson KT: Foreign bodies of the external auditory canal. Emerg Med Clin North Am 5:184, 1987.)*

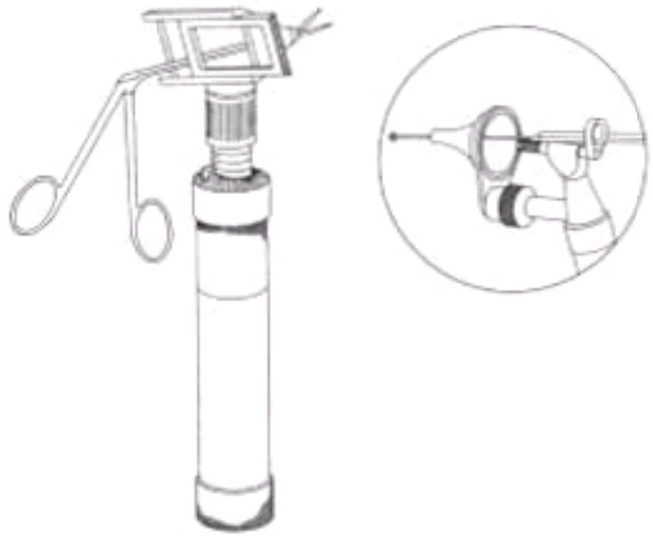

Figure 65-22 Instruments used for foreign body extraction. From left to right: alligator forceps, bayonet forceps, right-angle hook, wire loop, soft-tipped suction, Frazier suction.

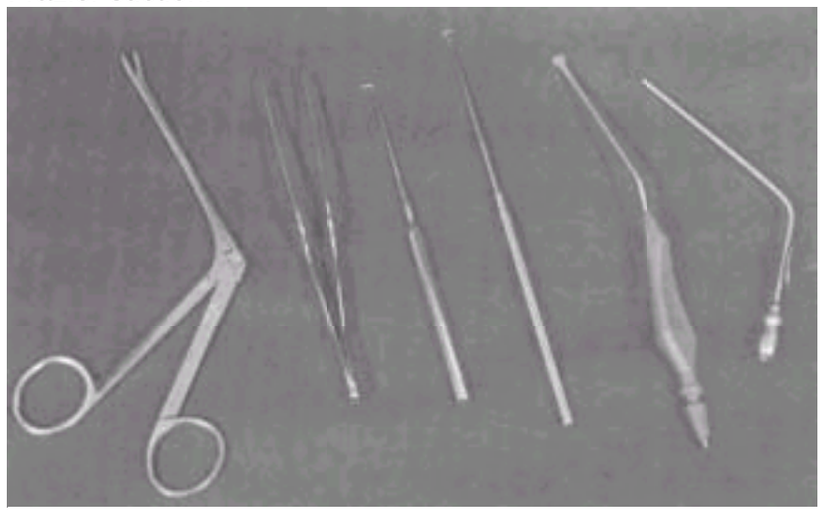

Figure 65-23 Removal of impacted cerumen. Pass the tip of the wire loop beyond the wax and gently tease the wax off the ear canal wall. Extract the wax slowly from the canal. Under direct visualization, avoid contact with the skin of the ear canal to prevent pain and excoriation.

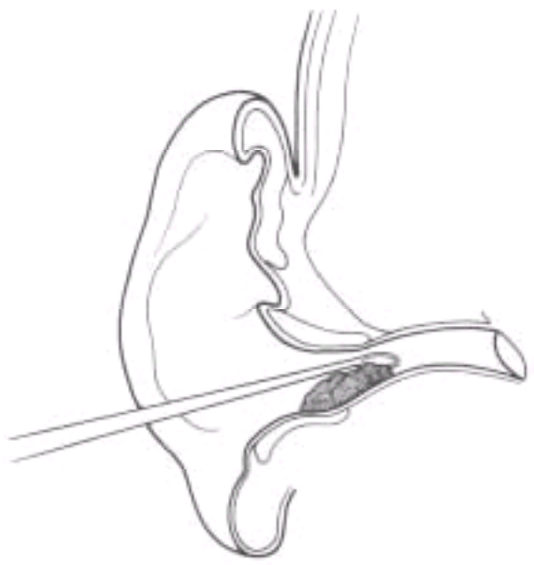

Figure 65-24 Debridement of external otitis. A cotton-tipped applicator is inserted into the canal and debris is gently removed from the canal. Irrigation of the ear may also be helpful if the tympanic membrane is not perforated. *Inset,* the edema has almost closed the canal and will not allow medication to be instilled into the inner canal. An ear wick will prove useful in this situation.

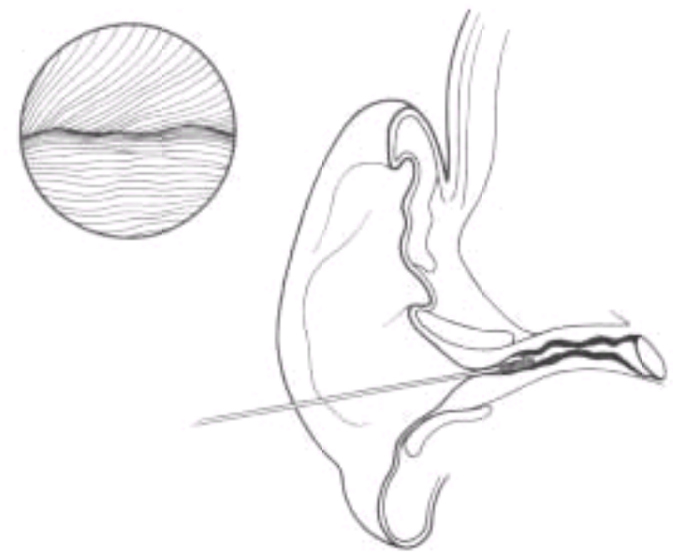

Figure 65-25 The Hognose device for foreign body removal. *A*, The Hognose attached to the otoscope and to wall suction. *B*, Occlusion of the open insufflation port to engage suction and remove the foreign body (attached).

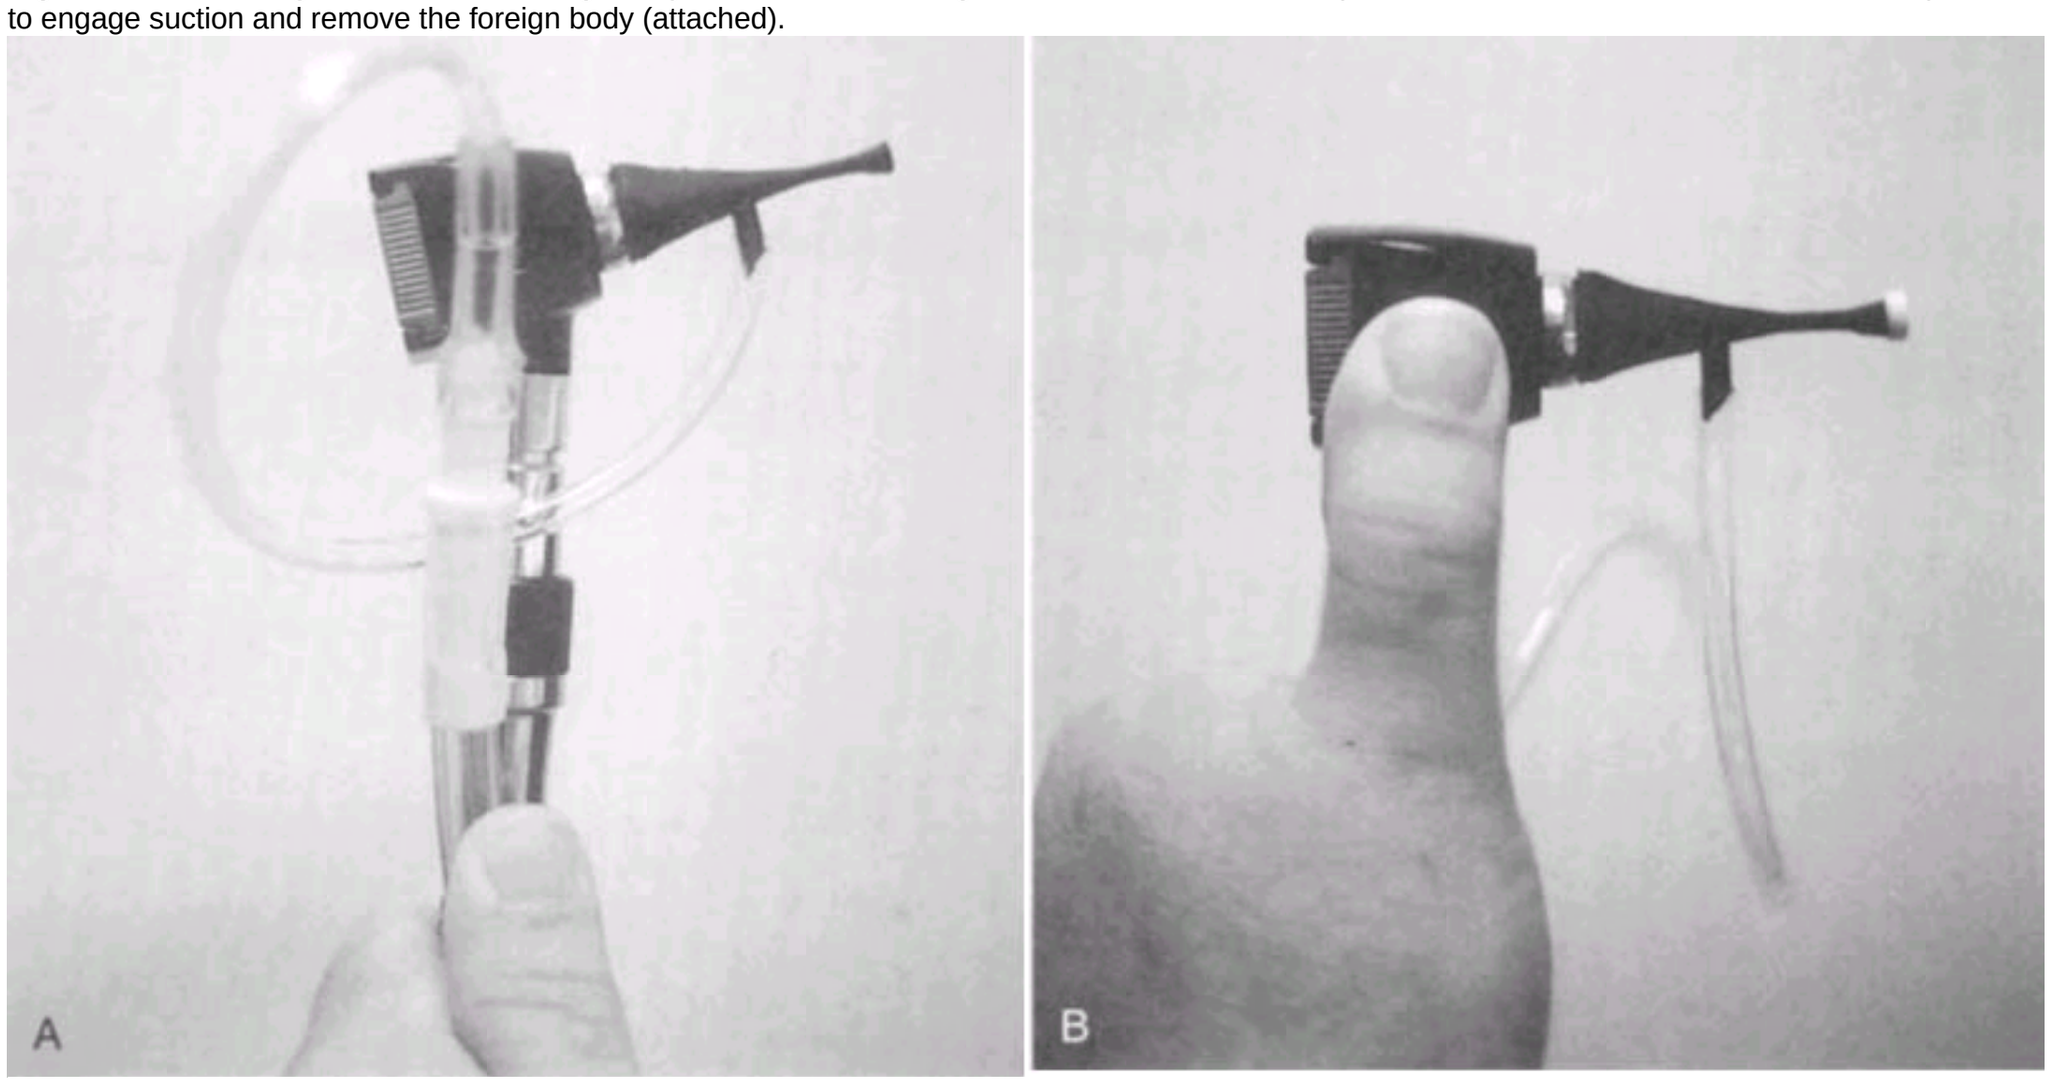

Figure 65-26 Application of various methods of foreign body removal from the ear canal. *A*, Right-angle hook. *B*, Irrigation. *C*, Alligator forceps. *D*, Soft-tipped suction.

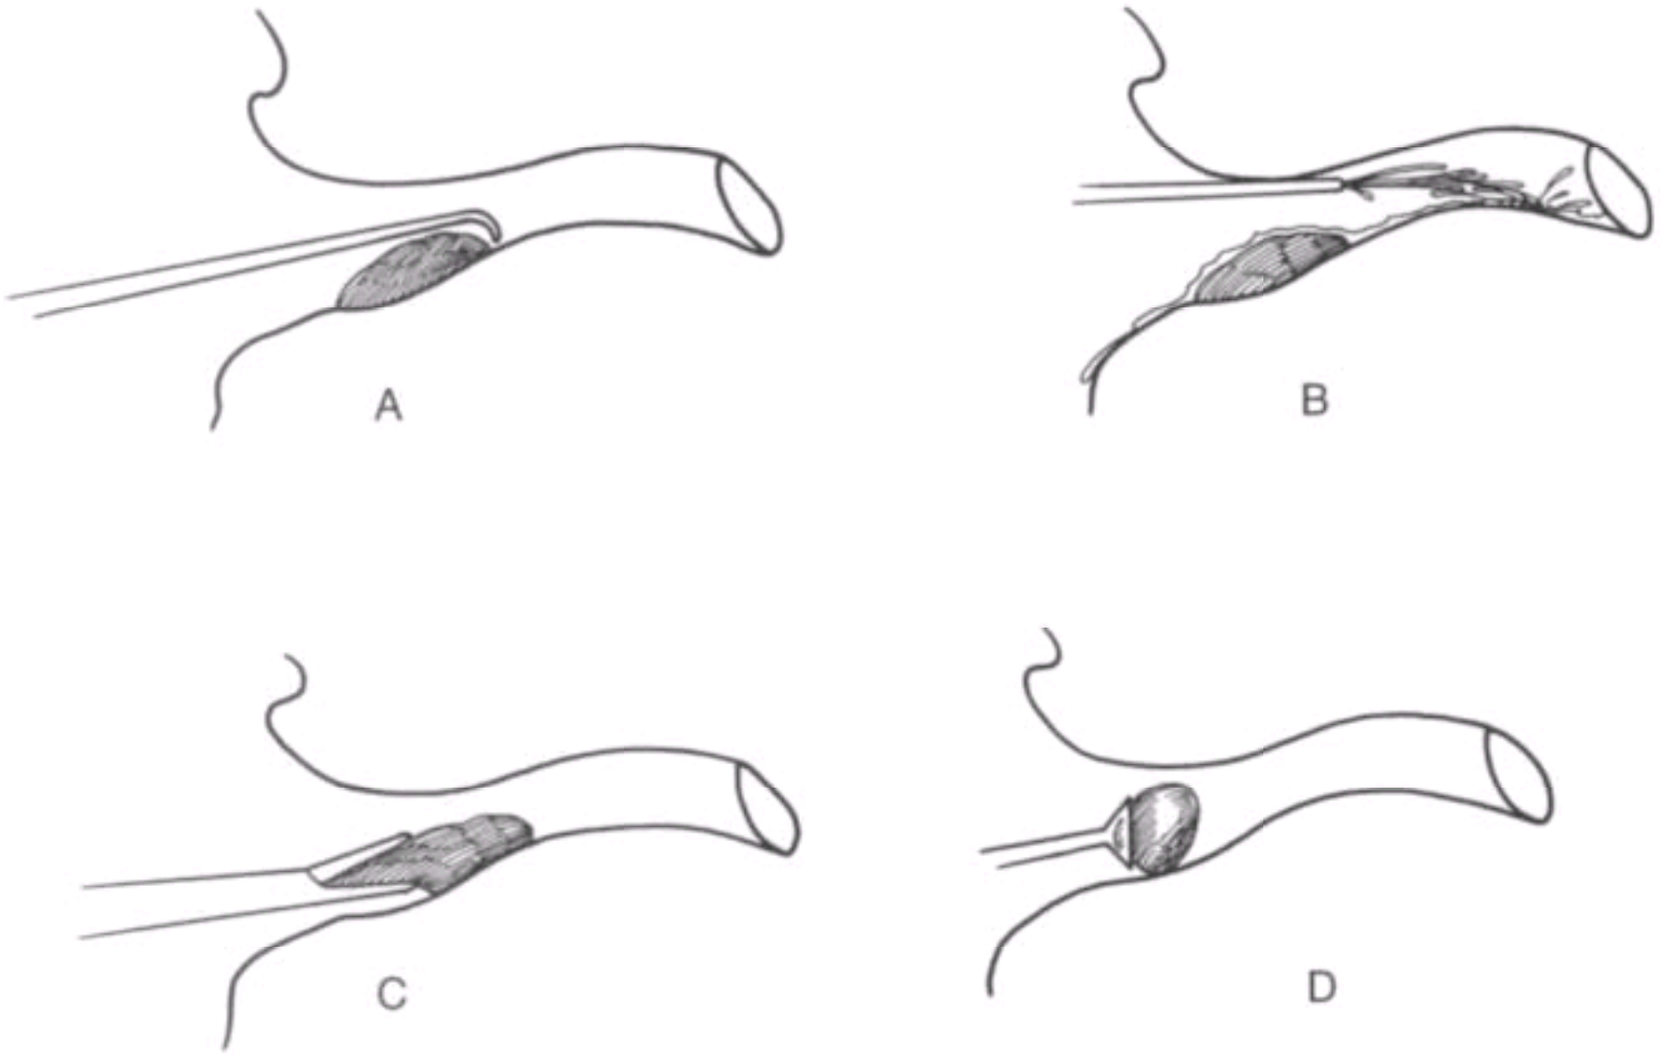

Figure 65-27 *A,* Subperichondrial hematoma within the concha of the ear. *B,* Needle aspiration of an auricular hematoma. A topical antiseptic is used to clean the ear, but local anesthesia is seldom required. While stabilizing the pinna with the thumb and fingers, the most fluctuant part of the hematoma is punctured with a 20-ga needle. The thumb "milks" the hematoma into the syringe until the entire hematoma has been evacuated. The thumb maintains continued pressure on the ear for 3 minutes after the needle has been withdrawn. A pressure dressing is then applied, and the ear is checked for reaccumulation of blood in 24 hours. Reaspiration may be required, and persistent accumulations require incision and drainage. *(B redrawn with permission from Fleisher GR, Ludwig S, Henretig FM, et al: Textbook of Pediatric Emergency Medicine. Baltimore, Williams & Wilkins, 1983.)*

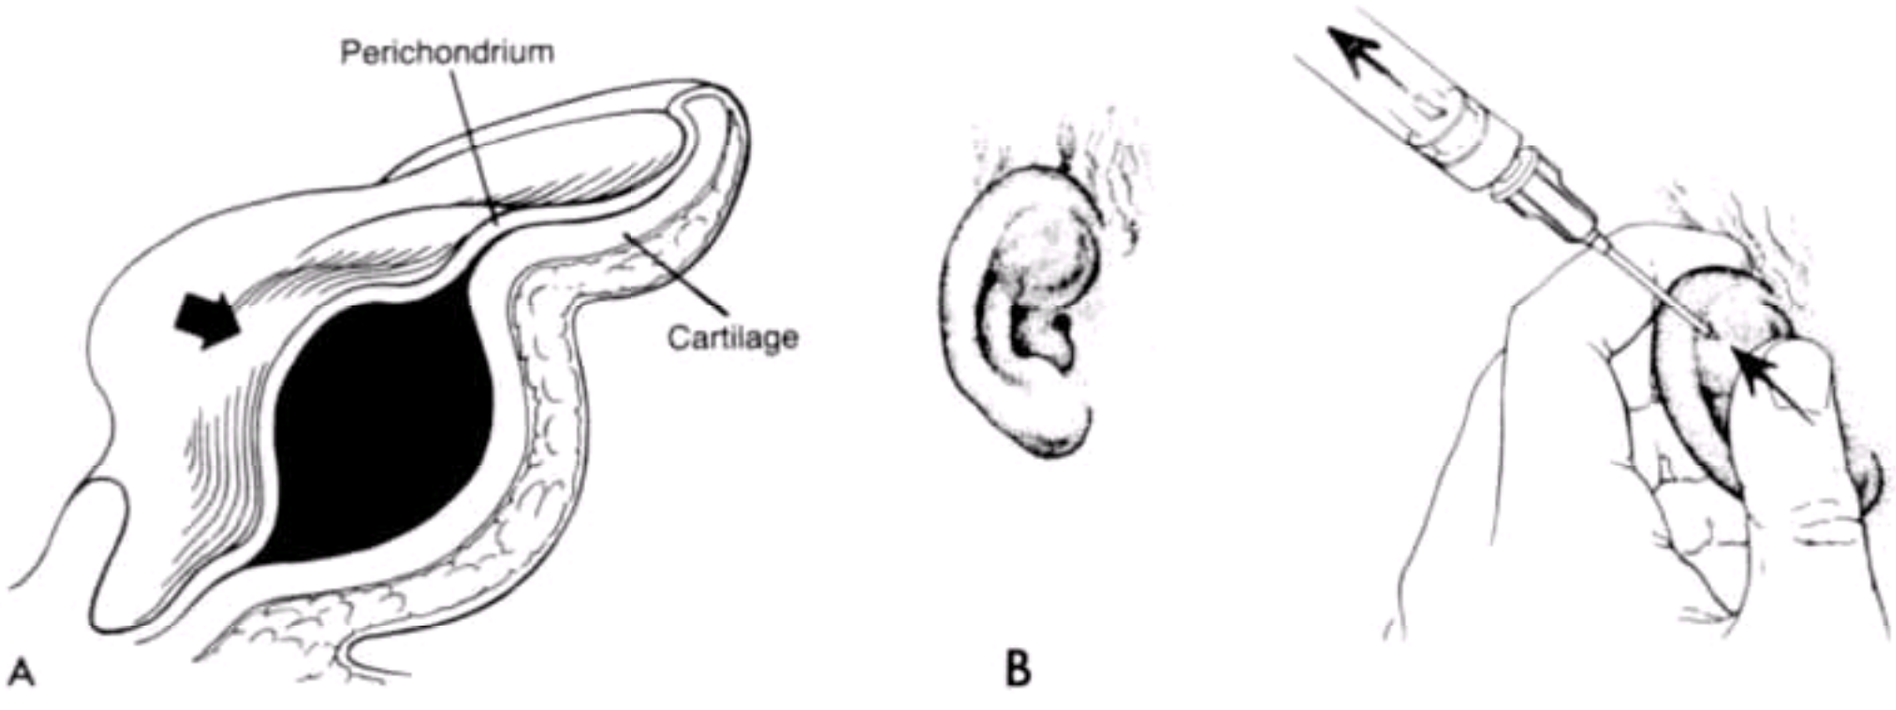

Figure 65-28 Auricular hematoma. *A*, Hematoma separating the perichondrium from the cartilage. *B*, Incision *(arrows)* made along the skin curvature at the posterior edge of the hematoma. Hematoma is evacuated and area irrigated. *C*, Two anterior dental rolls are secured with sutures to a posterior dental roll to maintain normal anatomy of the pinna. *D*, Side view illustrates position of sutures and dental rolls in relation to incision site. Note that the perichondrium is apposed to the cartilage. *(From Clemons JE, Seveneid LR: Otohematoma. In Cummings CW (ed): Otolaryngology—Head and Neck Surgery, 2nd ed. St Louis, Mosby-Year Book, 1993, p 2866.)*

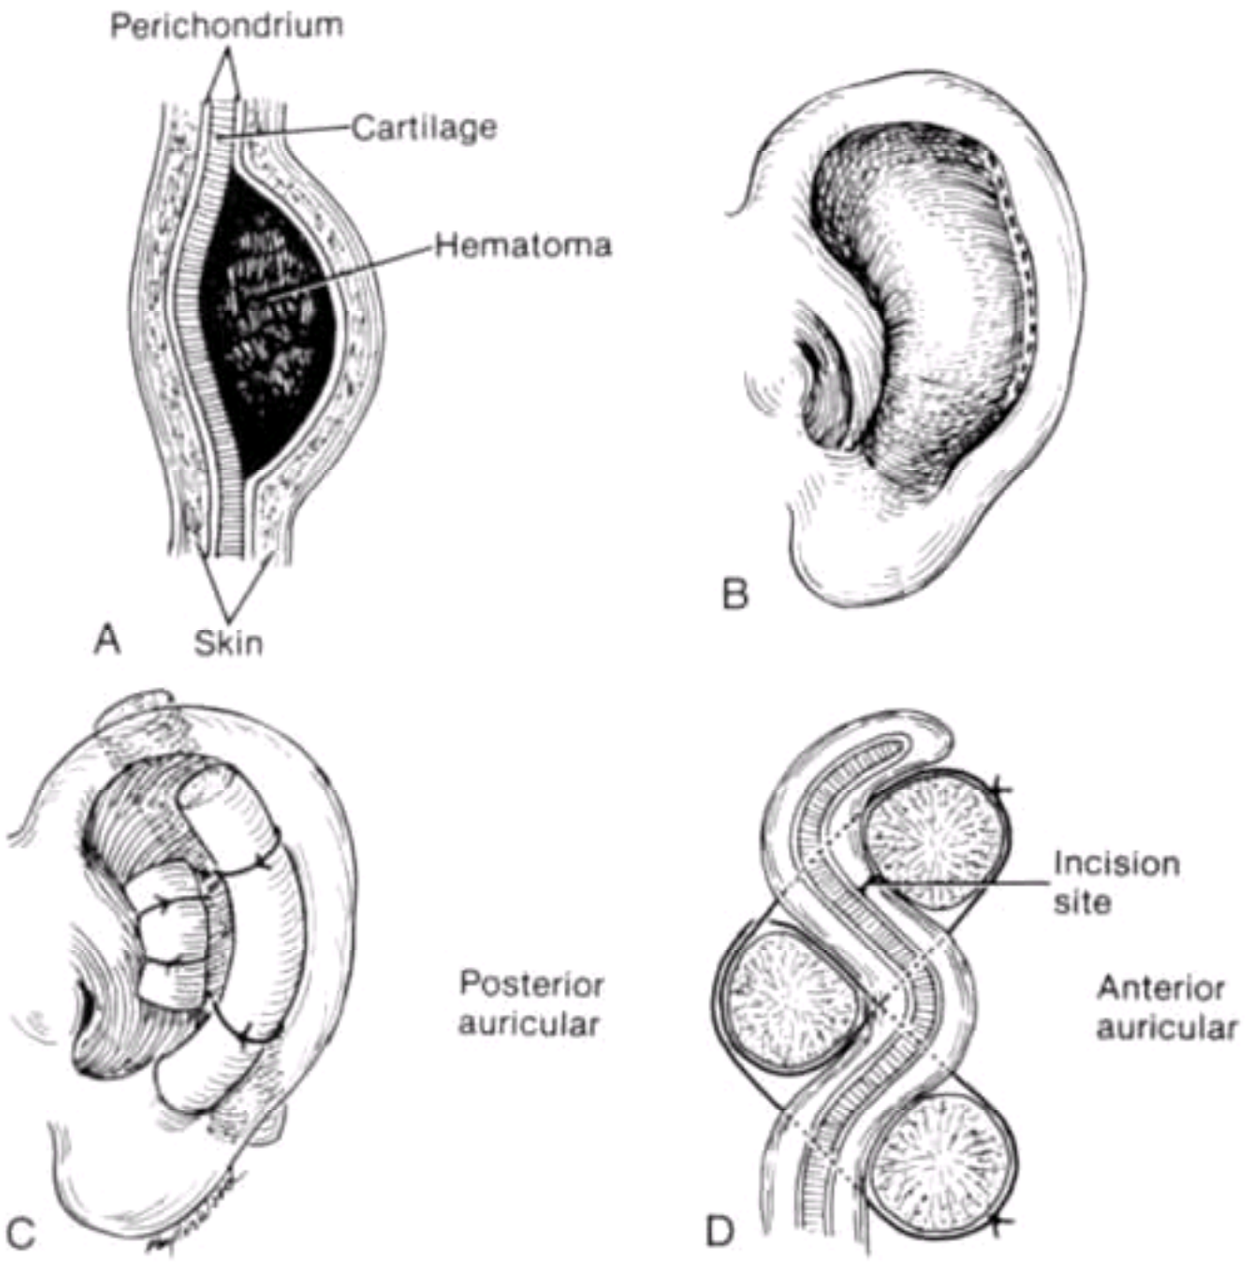

Figure 65-29 Compression dressing of the ear. Following successful aspiration of an auricular hematoma, a compression dressing is used to prevent reaccumulation of the hematoma or fluid. *A,* Dry cotton is first placed into the ear canal. A conforming material is then carefully molded into all the convolutions of the auricle. One may use Vaseline gauze or cotton soaked in mineral oil or saline. *B,* When the convolutions are fully packed, a posterior gauze pack is placed behind the ear. A V-shaped section has been cut from the gauze to allow it to fit easily behind the ear. *C,* Multiple layers of fluffed gauze are placed over the packed ear, and the entire dressing is held in place with Kling gauze or an elastic gauze roll. *D,* The ear is thus compressed between two layers of gauze, and the packing ensures even distribution of pressure to all parts of the auricle.

Figure 65-30 Vascular supply to the lateral wall. The most common site of posterior epistaxis is the sphenopalatine artery as it emerges posterior to the middle turbinate. *(From Maceri DR: Epistaxis and nasal trauma. In Cummings CW (ed): Otolaryngology—Head and Neck Surgery, 2nd ed. St Louis, Mosby-Year Book, 1993, p 728.)*

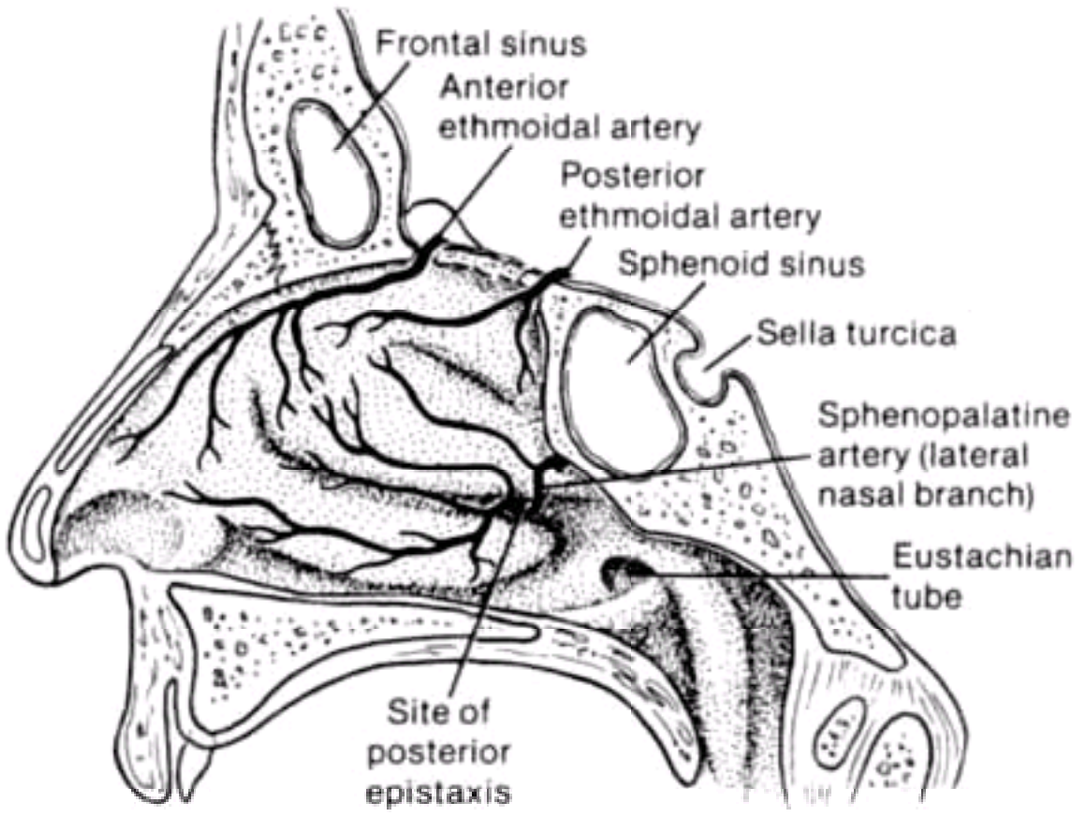

Figure 65-31 Vascular supply to the septum. The most common site of anterior epistaxis is within the area labeled Kiesselbach's plexus. *(From Maceri DR: Epistaxis and nasal trauma. In Cummings CW (ed): Otolaryngology—Head and Neck Surgery, 2nd ed. St Louis, Mosby-Year Book, 1993, p 728.)*

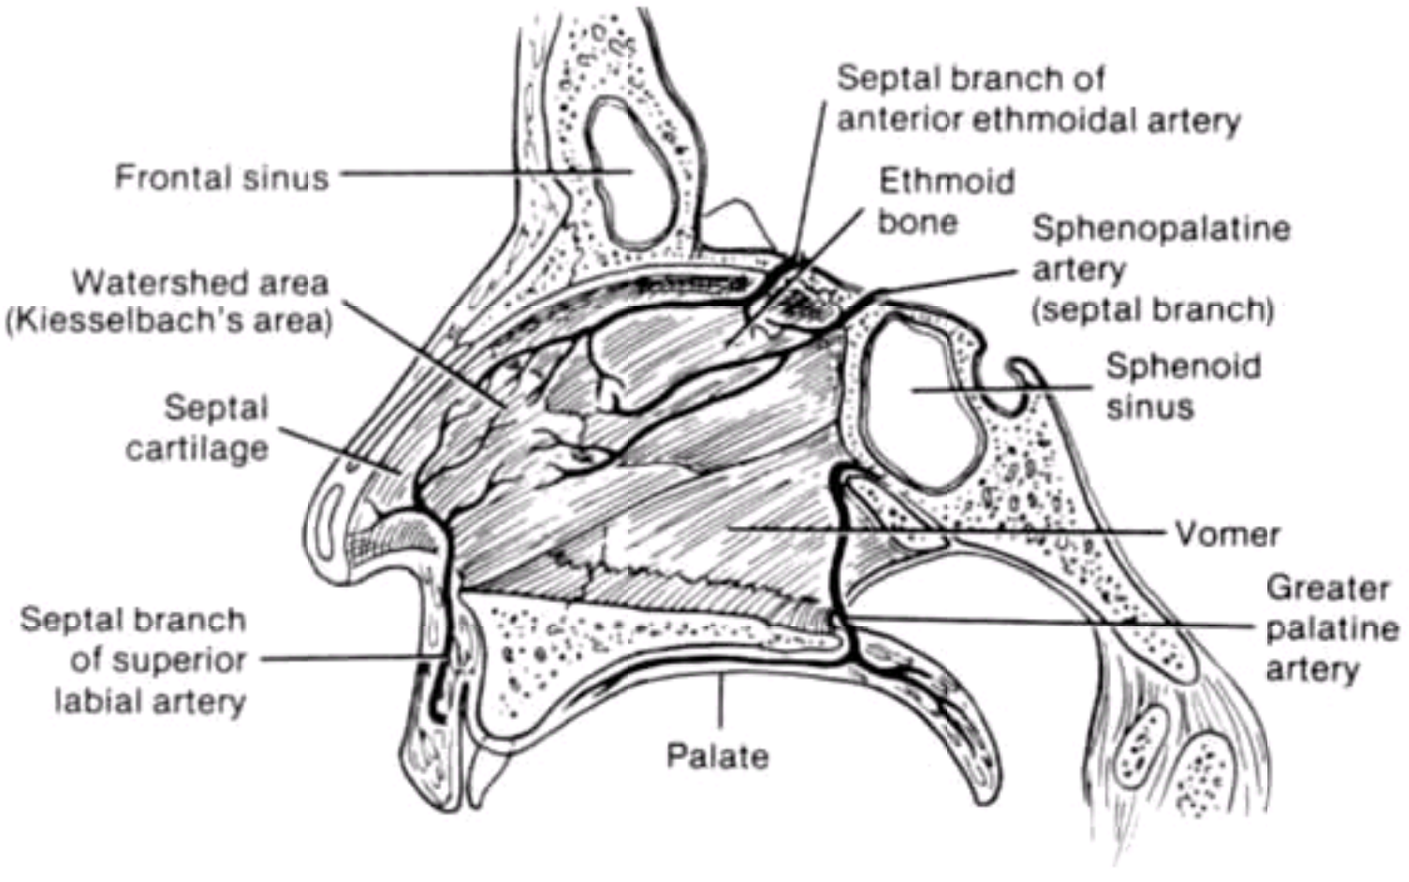

Figure 65-32 Placement of local anesthetic in the nose for anesthesia before reduction of nasal fracture by blockage of the anterior ethmoidal nerve superiorly and the sphenopalatine ganglion at the posterior end of the middle turbinate. *(From DeWeese DD, Saunders WH, Schuller DE, Schleuning AJ II (eds): Otolaryngology—Head and Neck Surgery, 7th ed. St Louis, CV Mosby, 1988.)*

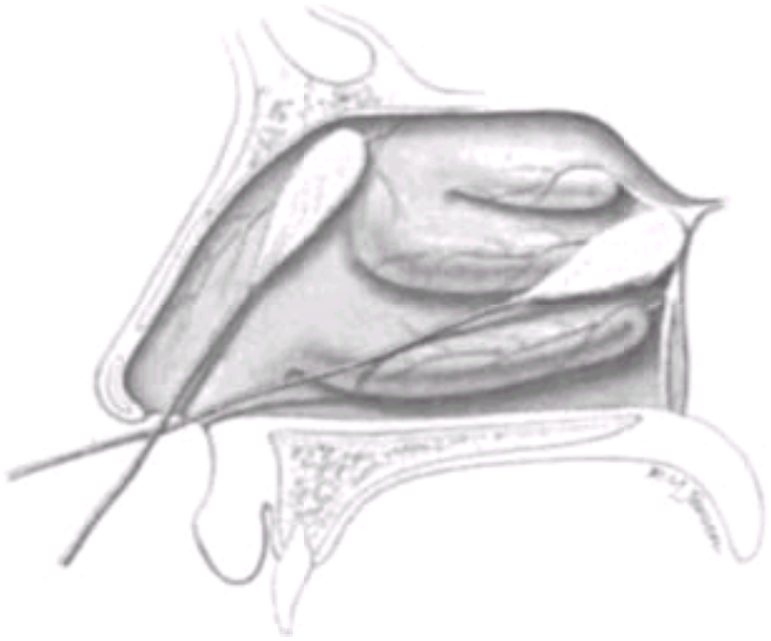

Figure 65-33 Topical anesthetic and vasoconstrictors are applied on individually made cotton pledgets. The size of the pledget may be changed according to the extent of the nasal cavity to be anesthetized and the size of the patient. *A,* An appropriately sized cotton pledget is grasped in a bayonet forceps. *B,* The cotton is then grasped with the opposite hand, and the forceps is rotated. *C,* The pledget is removed and is ready for insertion. *D,* To completely anesthetize the nasal cavity, three pledgets are necessary. The first is placed on the floor of the nose, the second in the middle meatus between the inferior and middle turbinates, and the third in the roof of the nasal cavity and the anterior nasal vestibule. *Note:* This pledget technique can be used to make a cotton wick for the treatment of otitis externa.

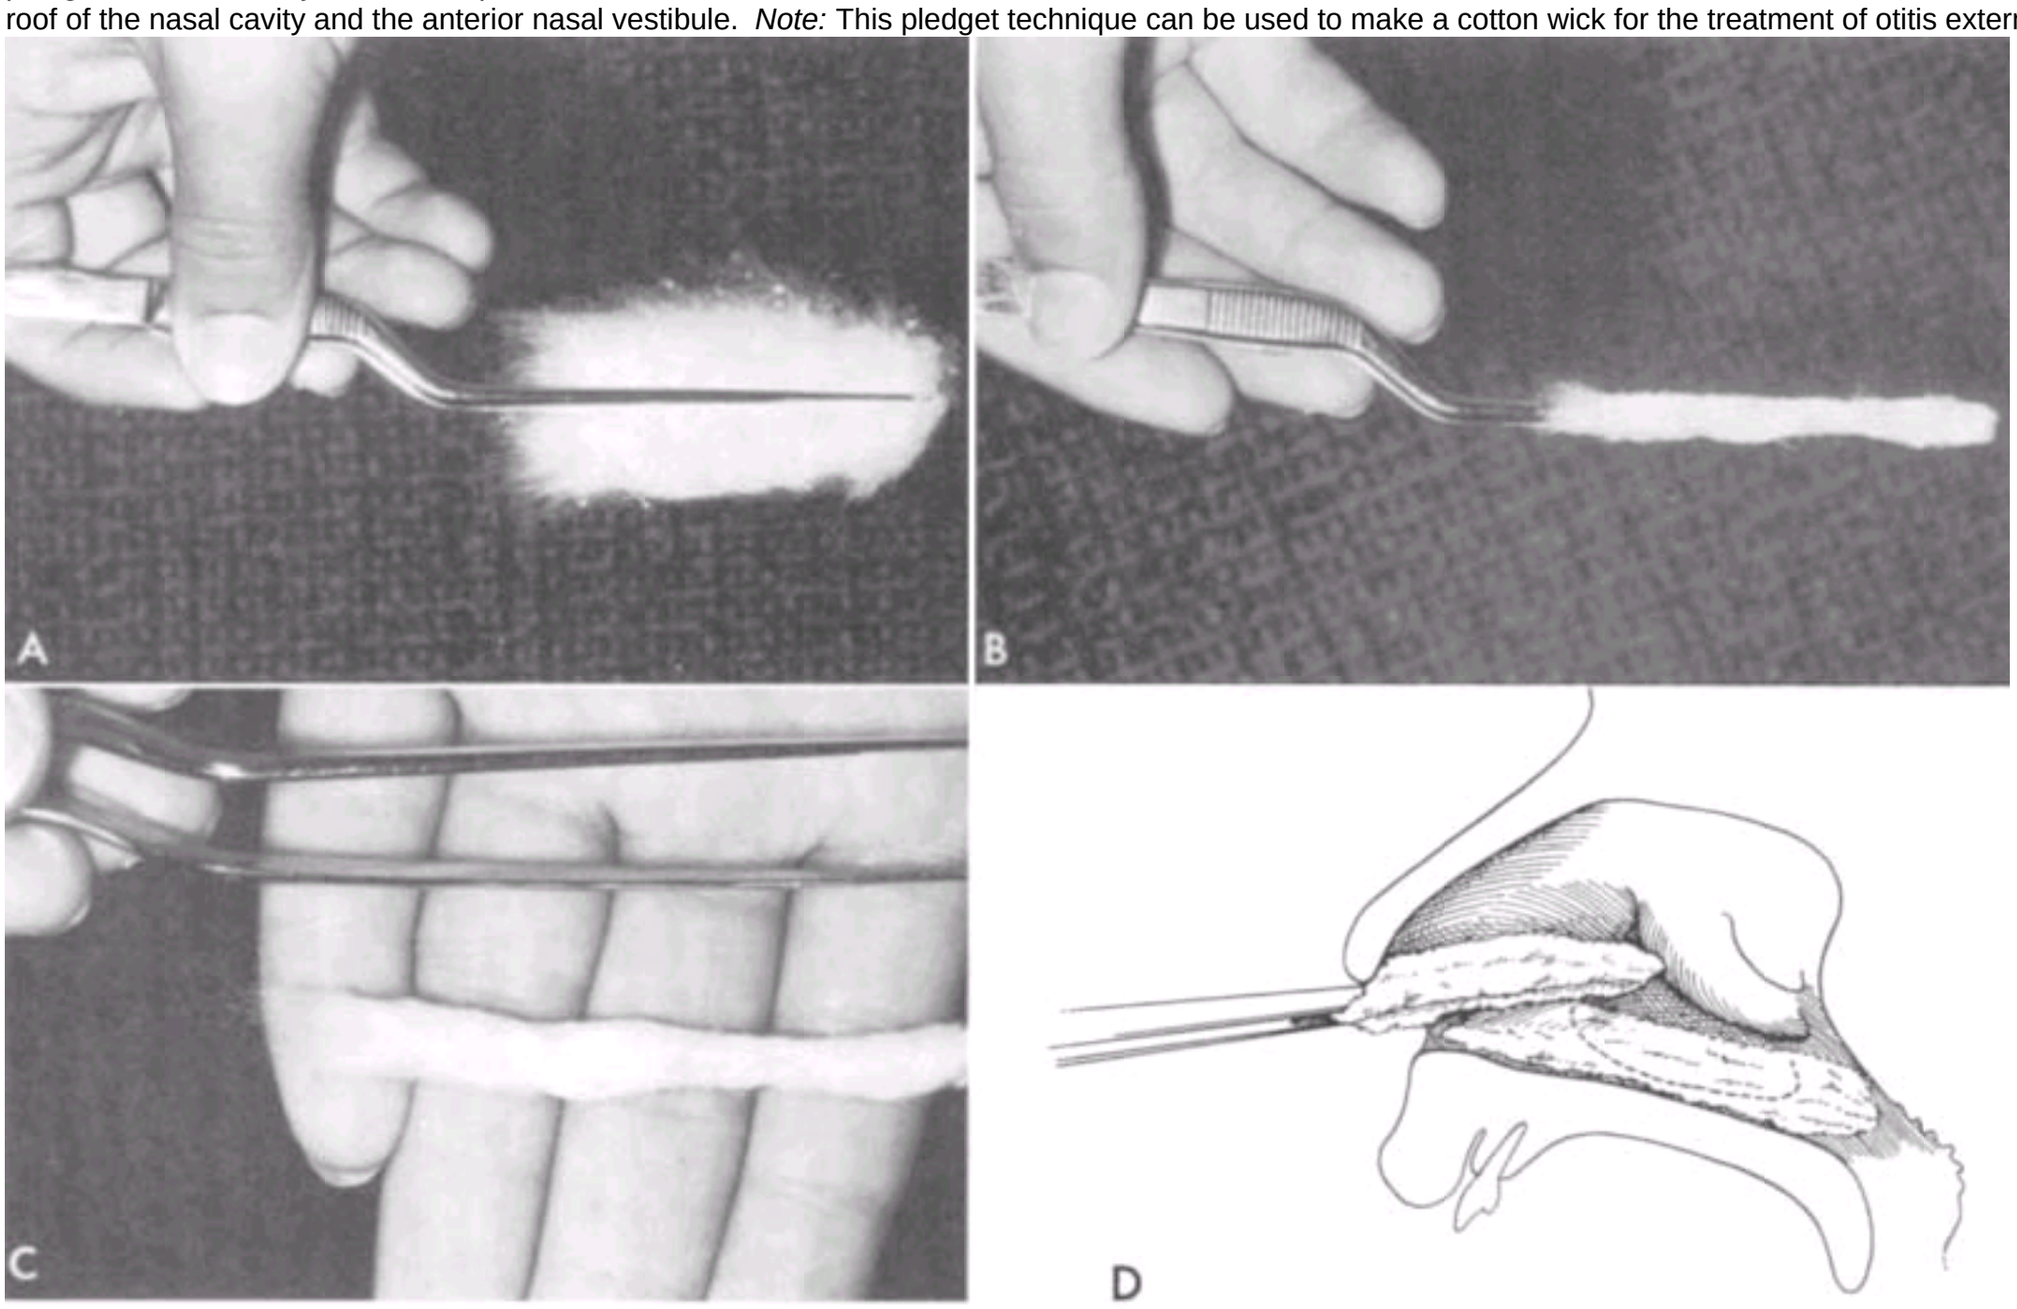

Figure 65-34 To examine a nose properly, a nasal speculum must be used. *A,* The clinician's index finger rests on the bridge of the nose, and the speculum is spread in an inferior-to-superior direction. *B,* It is *incorrect* to spread the speculum laterally or to use the instrument in an unsupported manner.

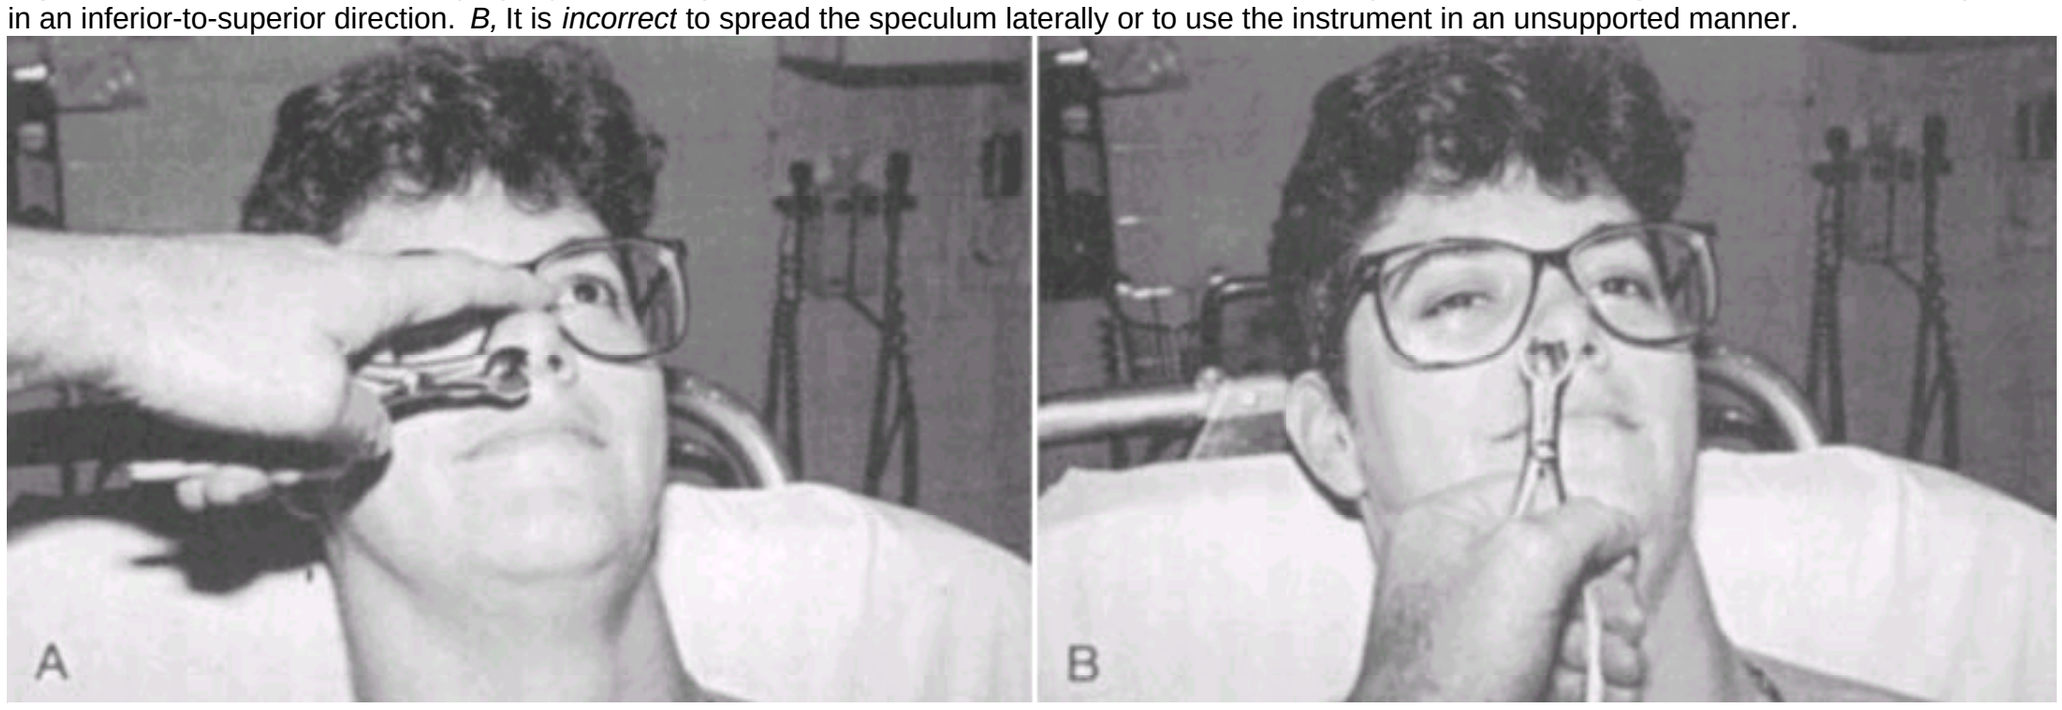

Figure 65-35 *A* and *B,* Correct position for examining and treating diseases of the nasal cavity. The patient is in the "sniffing" position, sitting upright or leaning slightly forward with the head only slightly extended. When the nasal tip is raised with the nasal speculum, the view is parallel to the floor of the nose and allows visualization of the entire nasal cavity. *C* and *D,* When told that their nose will be examined, most patients extend the neck and look toward the ceiling. In this position, only the most anterior portions of the nasal cavity are visible.

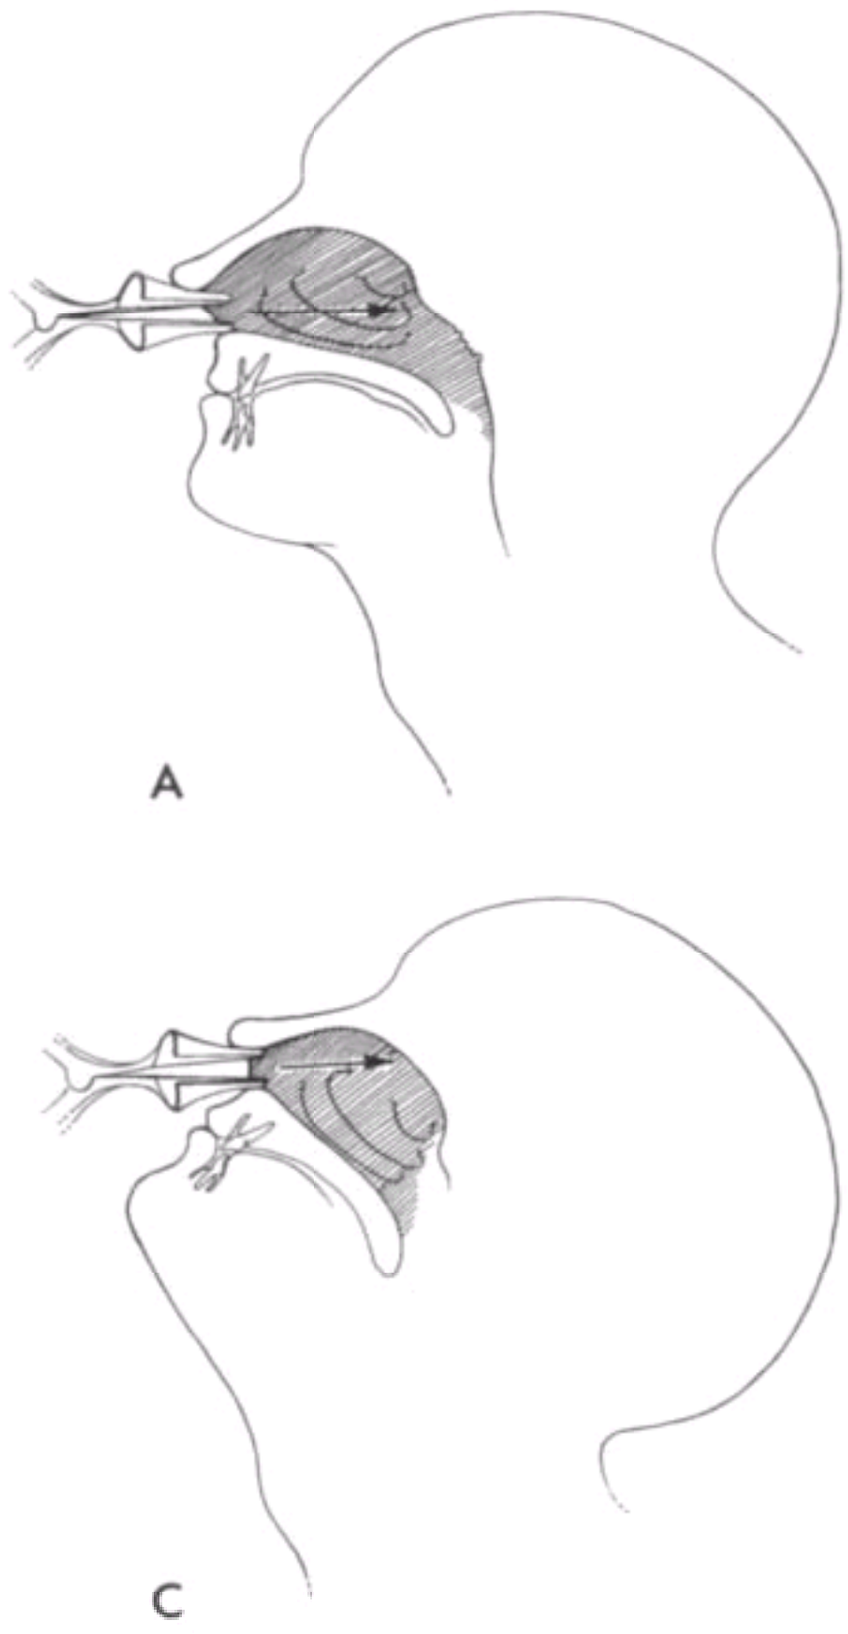

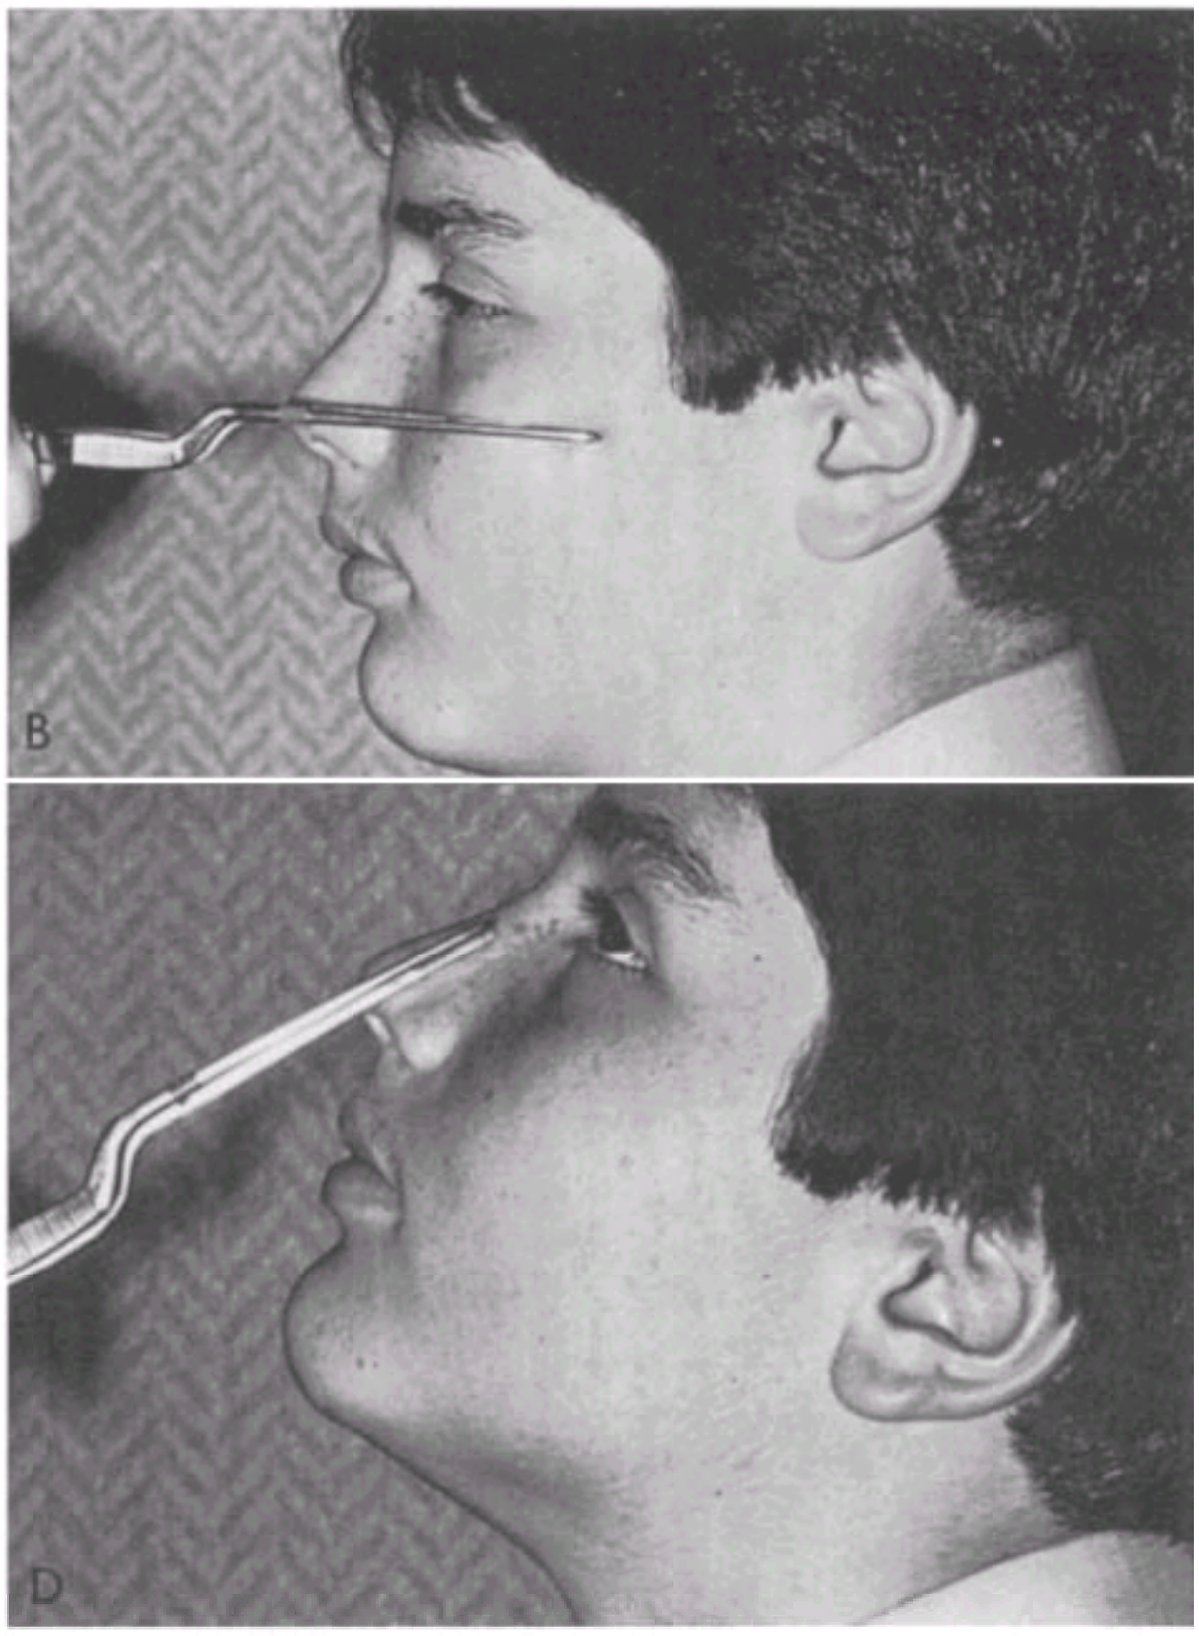

Figure 65-36 If an arterial bleeding site is found in the nasal septum, both hemostasis and anesthesia for cautery can be accomplished by injecting the mucosa at the base of the bleeder with a small amount of lidocaine with epinephrine via a tuberculin or insulin syringe. This procedure best follows an initial application of topical anesthesia.

Figure 65-37 Equipment used for treatment of epistaxis. *Top:* Electrocautery device and silver nitrate sticks. Left to right, bottom row: Merocel nasal tampon, posterior packing ball, Merocel nasal tampon with catheter included (Doyle Pack), anterior packing gauze with bayonet forceps, Foley catheter, Epistat dual balloon catheter.

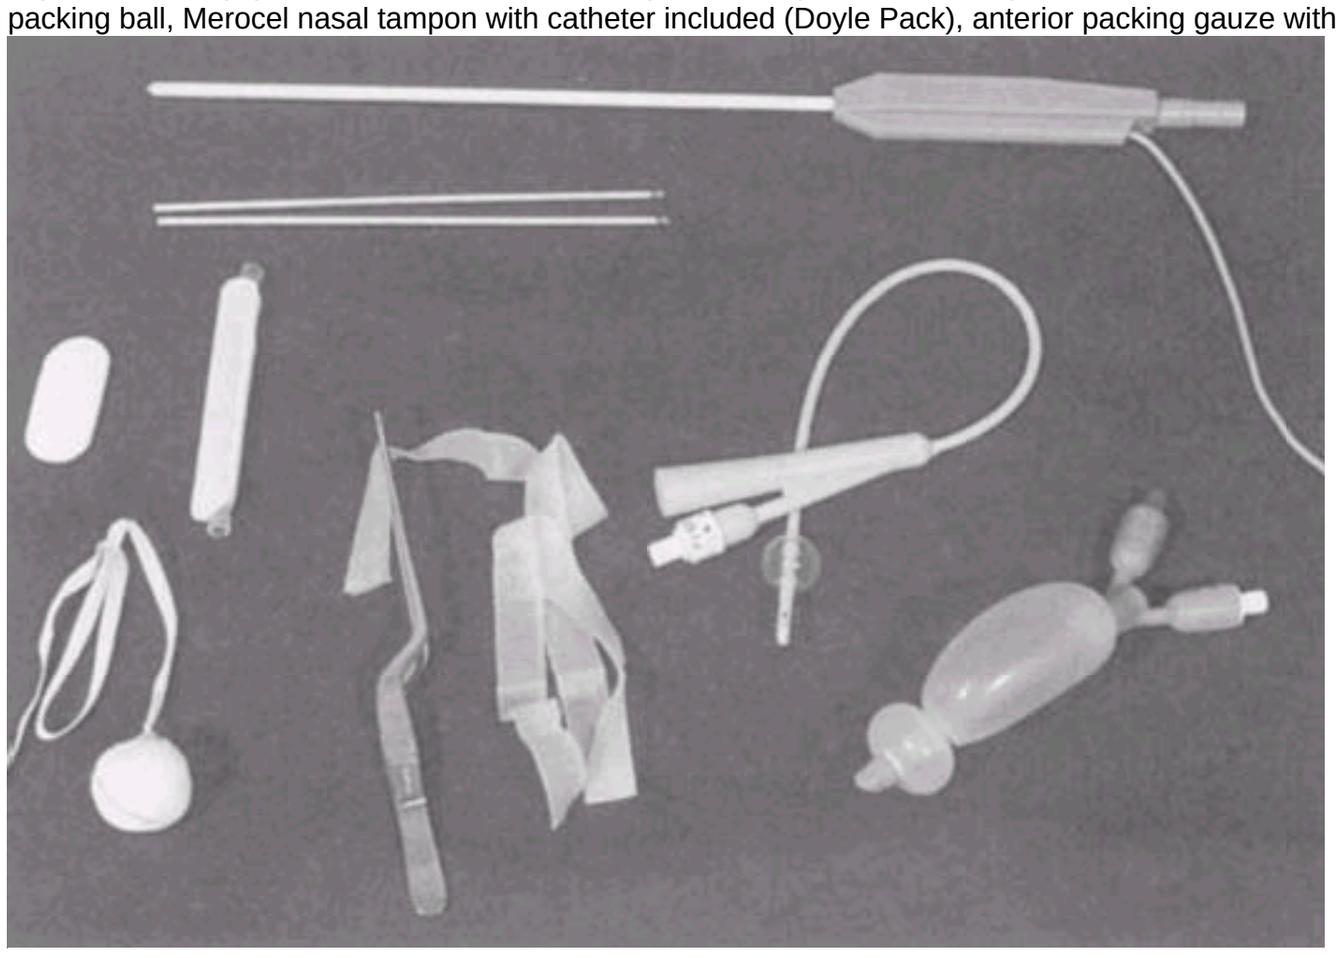

Figure 65-38 The key to placement of an anterior nasal pack that will control epistaxis adequately and stay in place is to lay the packing into the nasal cavity in an "accordion" manner, so that part of each layer of packing lies anteriorly, preventing the gauze from falling posteriorly into the nasopharynx. *A,* The first layer of 0.25-in. Vaseline gauze strip is grasped approximately 2 to 3 cm from its end. *B,* The first layer is then placed on the floor of the nose through the nasal speculum (not pictured here). The bayonet forceps and nasal speculum are then withdrawn. *C,* The nasal speculum is reintroduced on top of the first layer of packing, and a second layer is placed in an identical manner. After several layers have been placed, it is often useful to reintroduce the bayonet forceps to push the previously placed packing down onto the floor of the nose, making it tighter and more secure. *D,* A complete anterior nasal pack can tamponade a bleeding point anywhere in the anterior nasal cavity and will stay in place until removed by the clinician or patient.

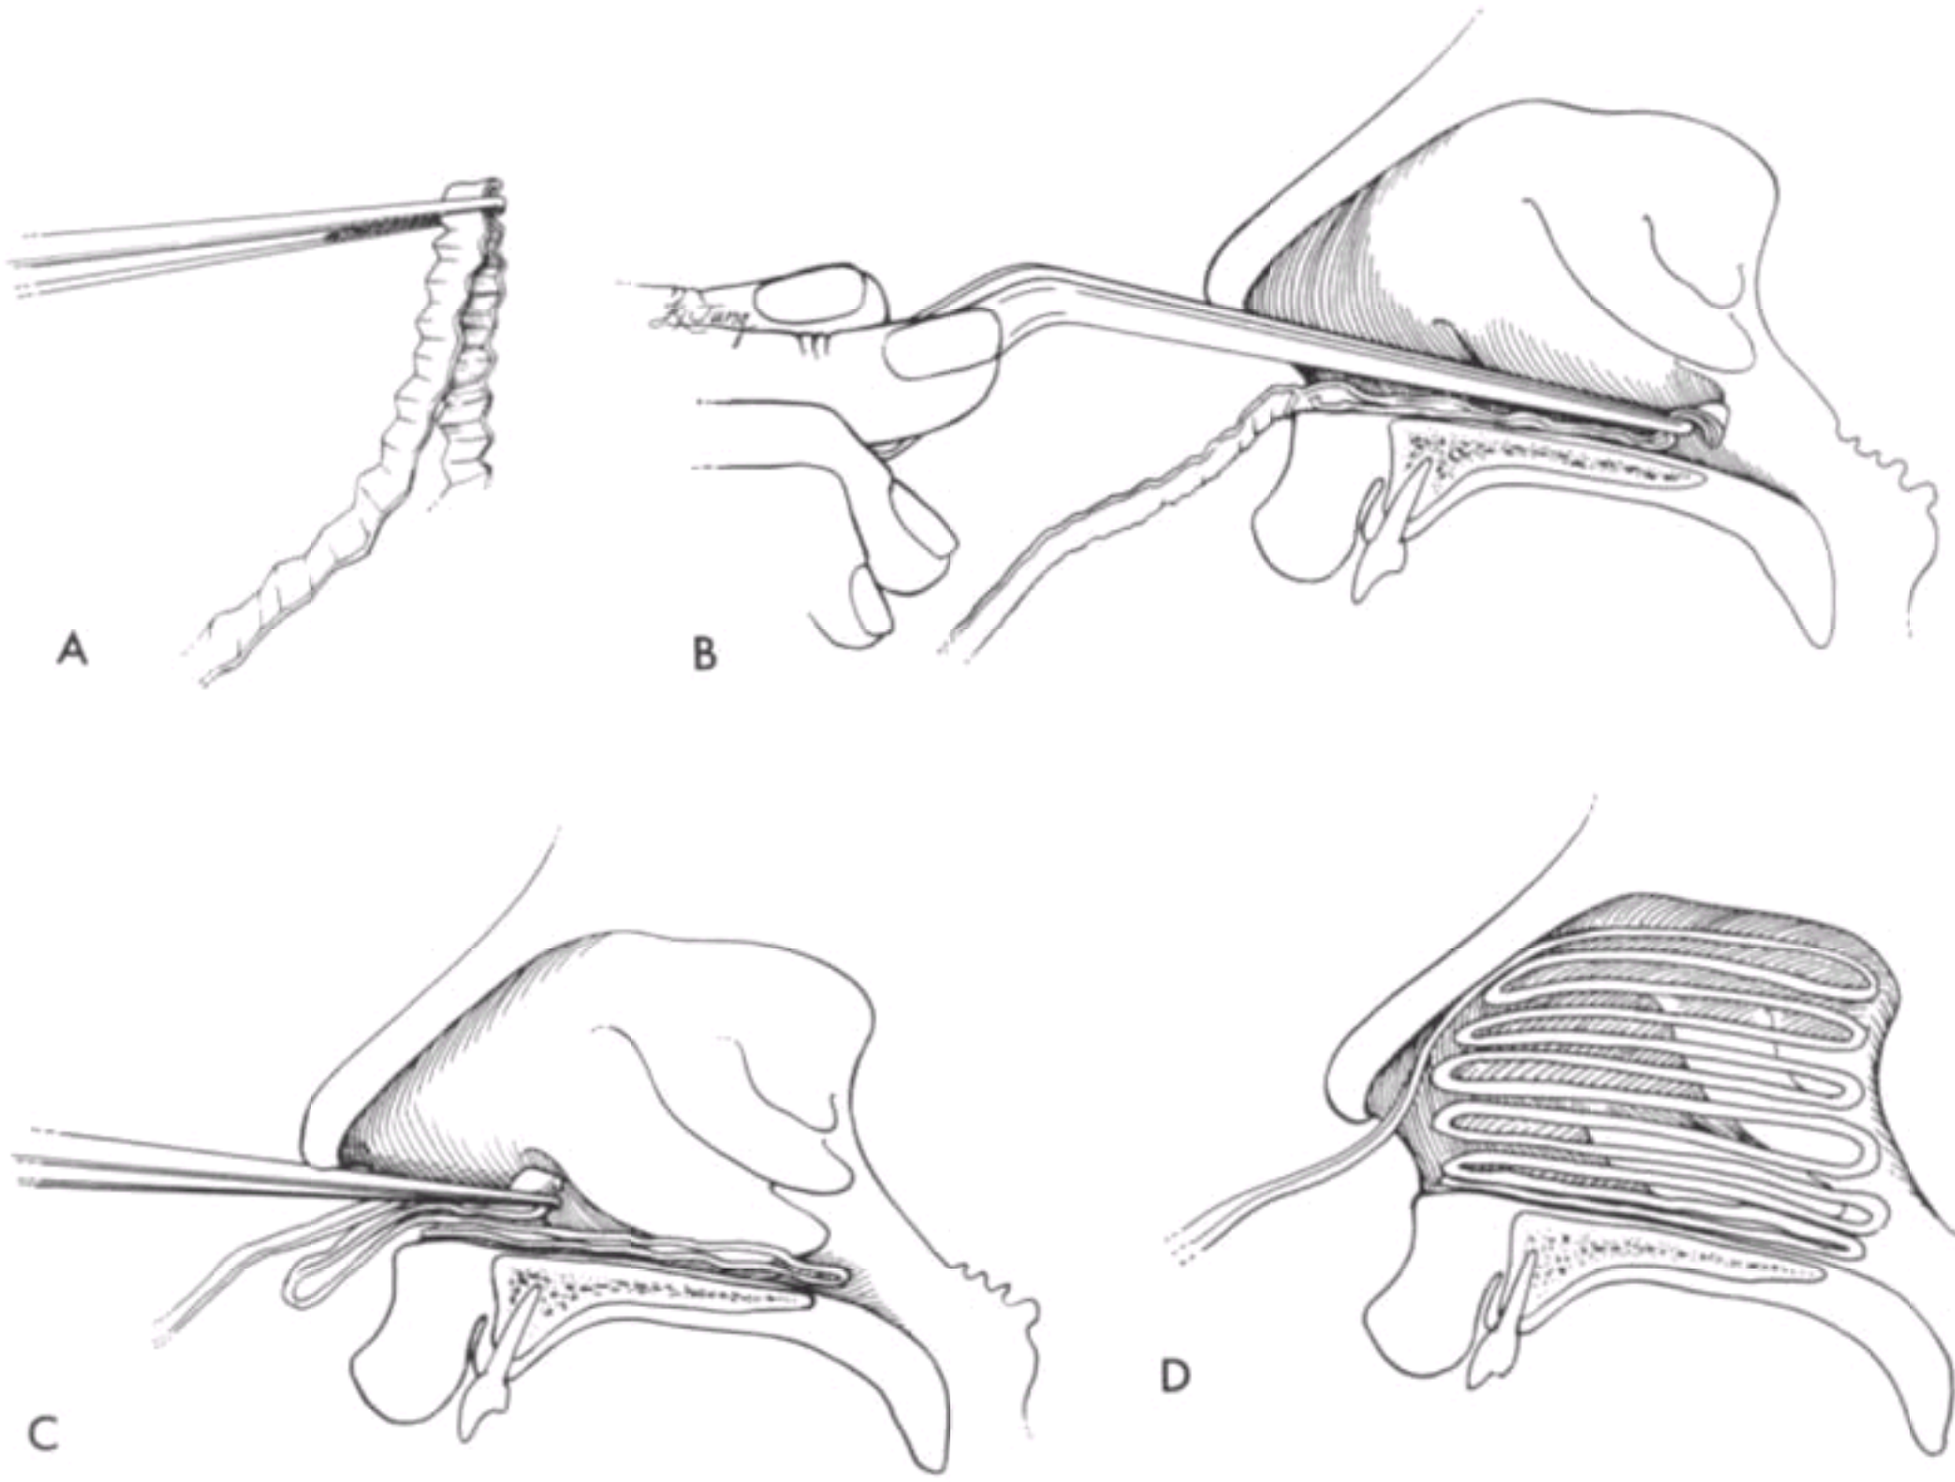

Figure 65-39 Nasal packing alternatives. *A,* Merocel nasal pack. (1) Merocel sponge compressed and expanded. To insert the sponge packing, lubricate the device with an antibiotic ointment and place it in the nasal cavity. (2) Some trimming of the product may be needed and prior use of topical anesthesia is advised. When the sponge is in place, hydrate it with saline. Expansion of the moist sponge will compress the bleeding site. (3) It may remain in place for up to 3 days. Rehydrate the sponge before removal. *B,* Epistat II nasal catheter. The catheter is usually left in place up to 3 days and can be used in outpatients. A hollow inner airway tube allows the patient to breathe.

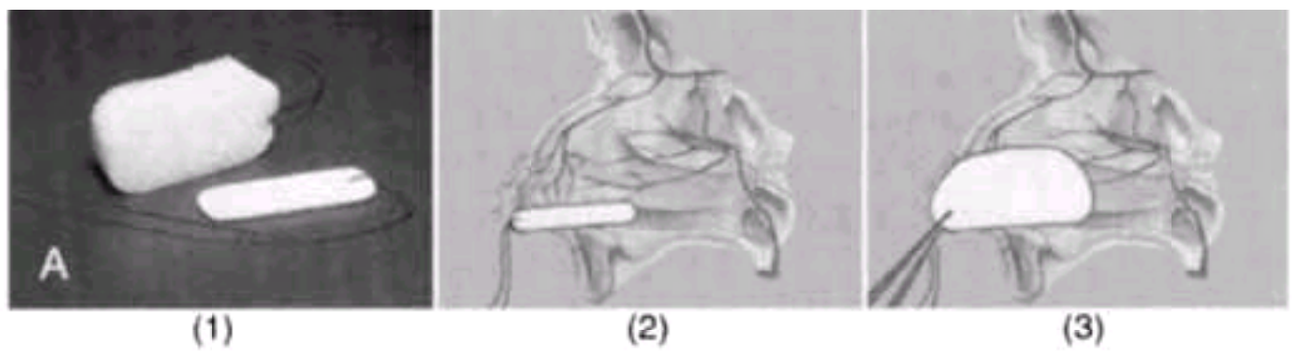
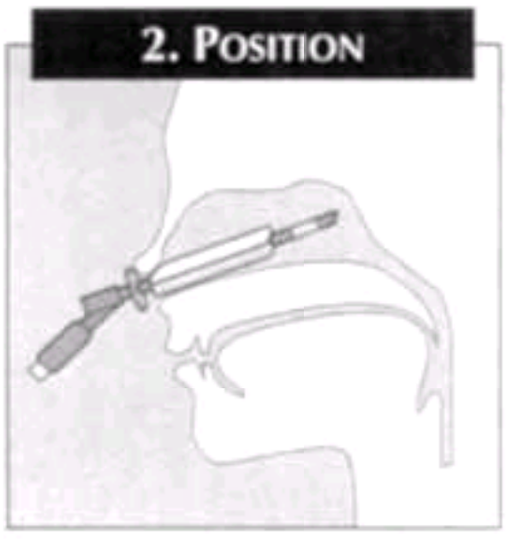


1. LUBRICATION

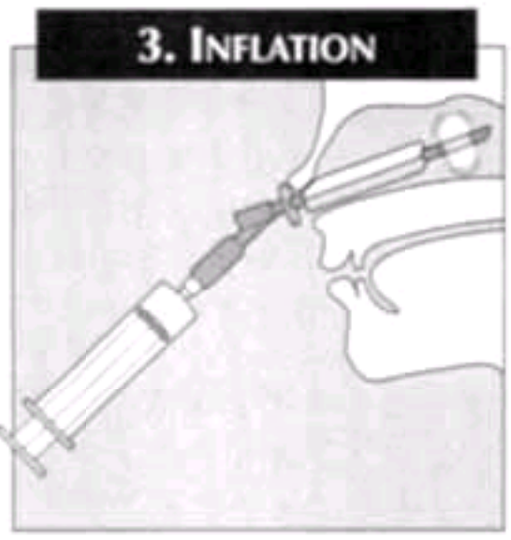
Clean blood clots from the nose. Use a topical anesthesia to numb the nose. Liberally apply antibiotic ointment or lubricant to the **EPISTAT II** Nasal Catheter.

2. POSITION



Position the EPISTAT II Catheter so the posterior balloon rests in the nasopharynx.

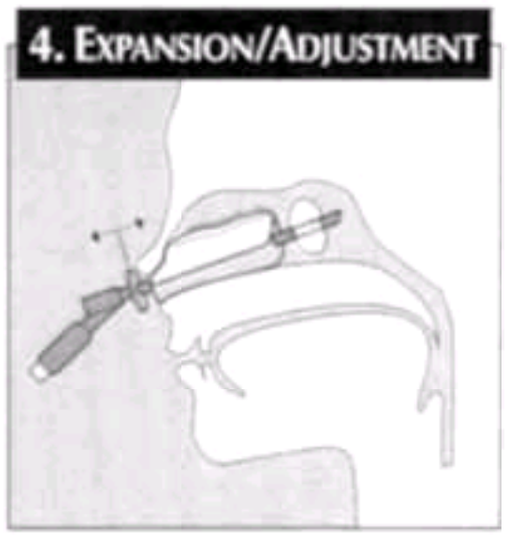
3. INFLATION



Using a syringe, inflate the balloon by injecting approximately 10cc sterile saline into the valve.

After inflation of the balloon, gently pull the catheter outward to position it in the nasopharynx.

4. EXPANSION/ADJUSTMENT



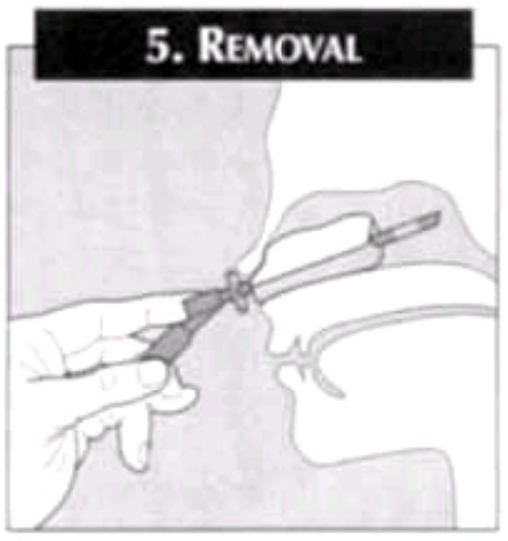
Hydrate the MEROCEL sponge with sterile saline until fully expanded.

Advance the retaining ring until it gently rests against the nose.

The 4" x 4" gauze pad can be placed between the nose and retaining ring for added comfort.

Check the catheter periodically. Release or add pressure as needed.

5. REMOVAL



Introduce a syringe firmly into the valve and withdraw the solution. Rehydrate the MEROCEL sponge with sterile saline until saturated (approximately 10-20cc).

Physicians recommend allowing the pack to rehydrate for 5-10 minutes before removal.

Slowly withdraw the catheter from the nose. The sponge can be left in place by removing only the catheter.

B

Figure 65-40 Examples of various packs for epistaxis in a cadaver model. *A*, The posterior Merocel sponge, not inflated, will stop most nosebleeds and is more comfortable than some balloon devices. *B*, Wetting the Rapid Rhino before placement activates the slippery covering for easier insertion. *C*, Anterior/posterior Rapid Rhino in place. *D*, Posterior pack with balloon inflated.

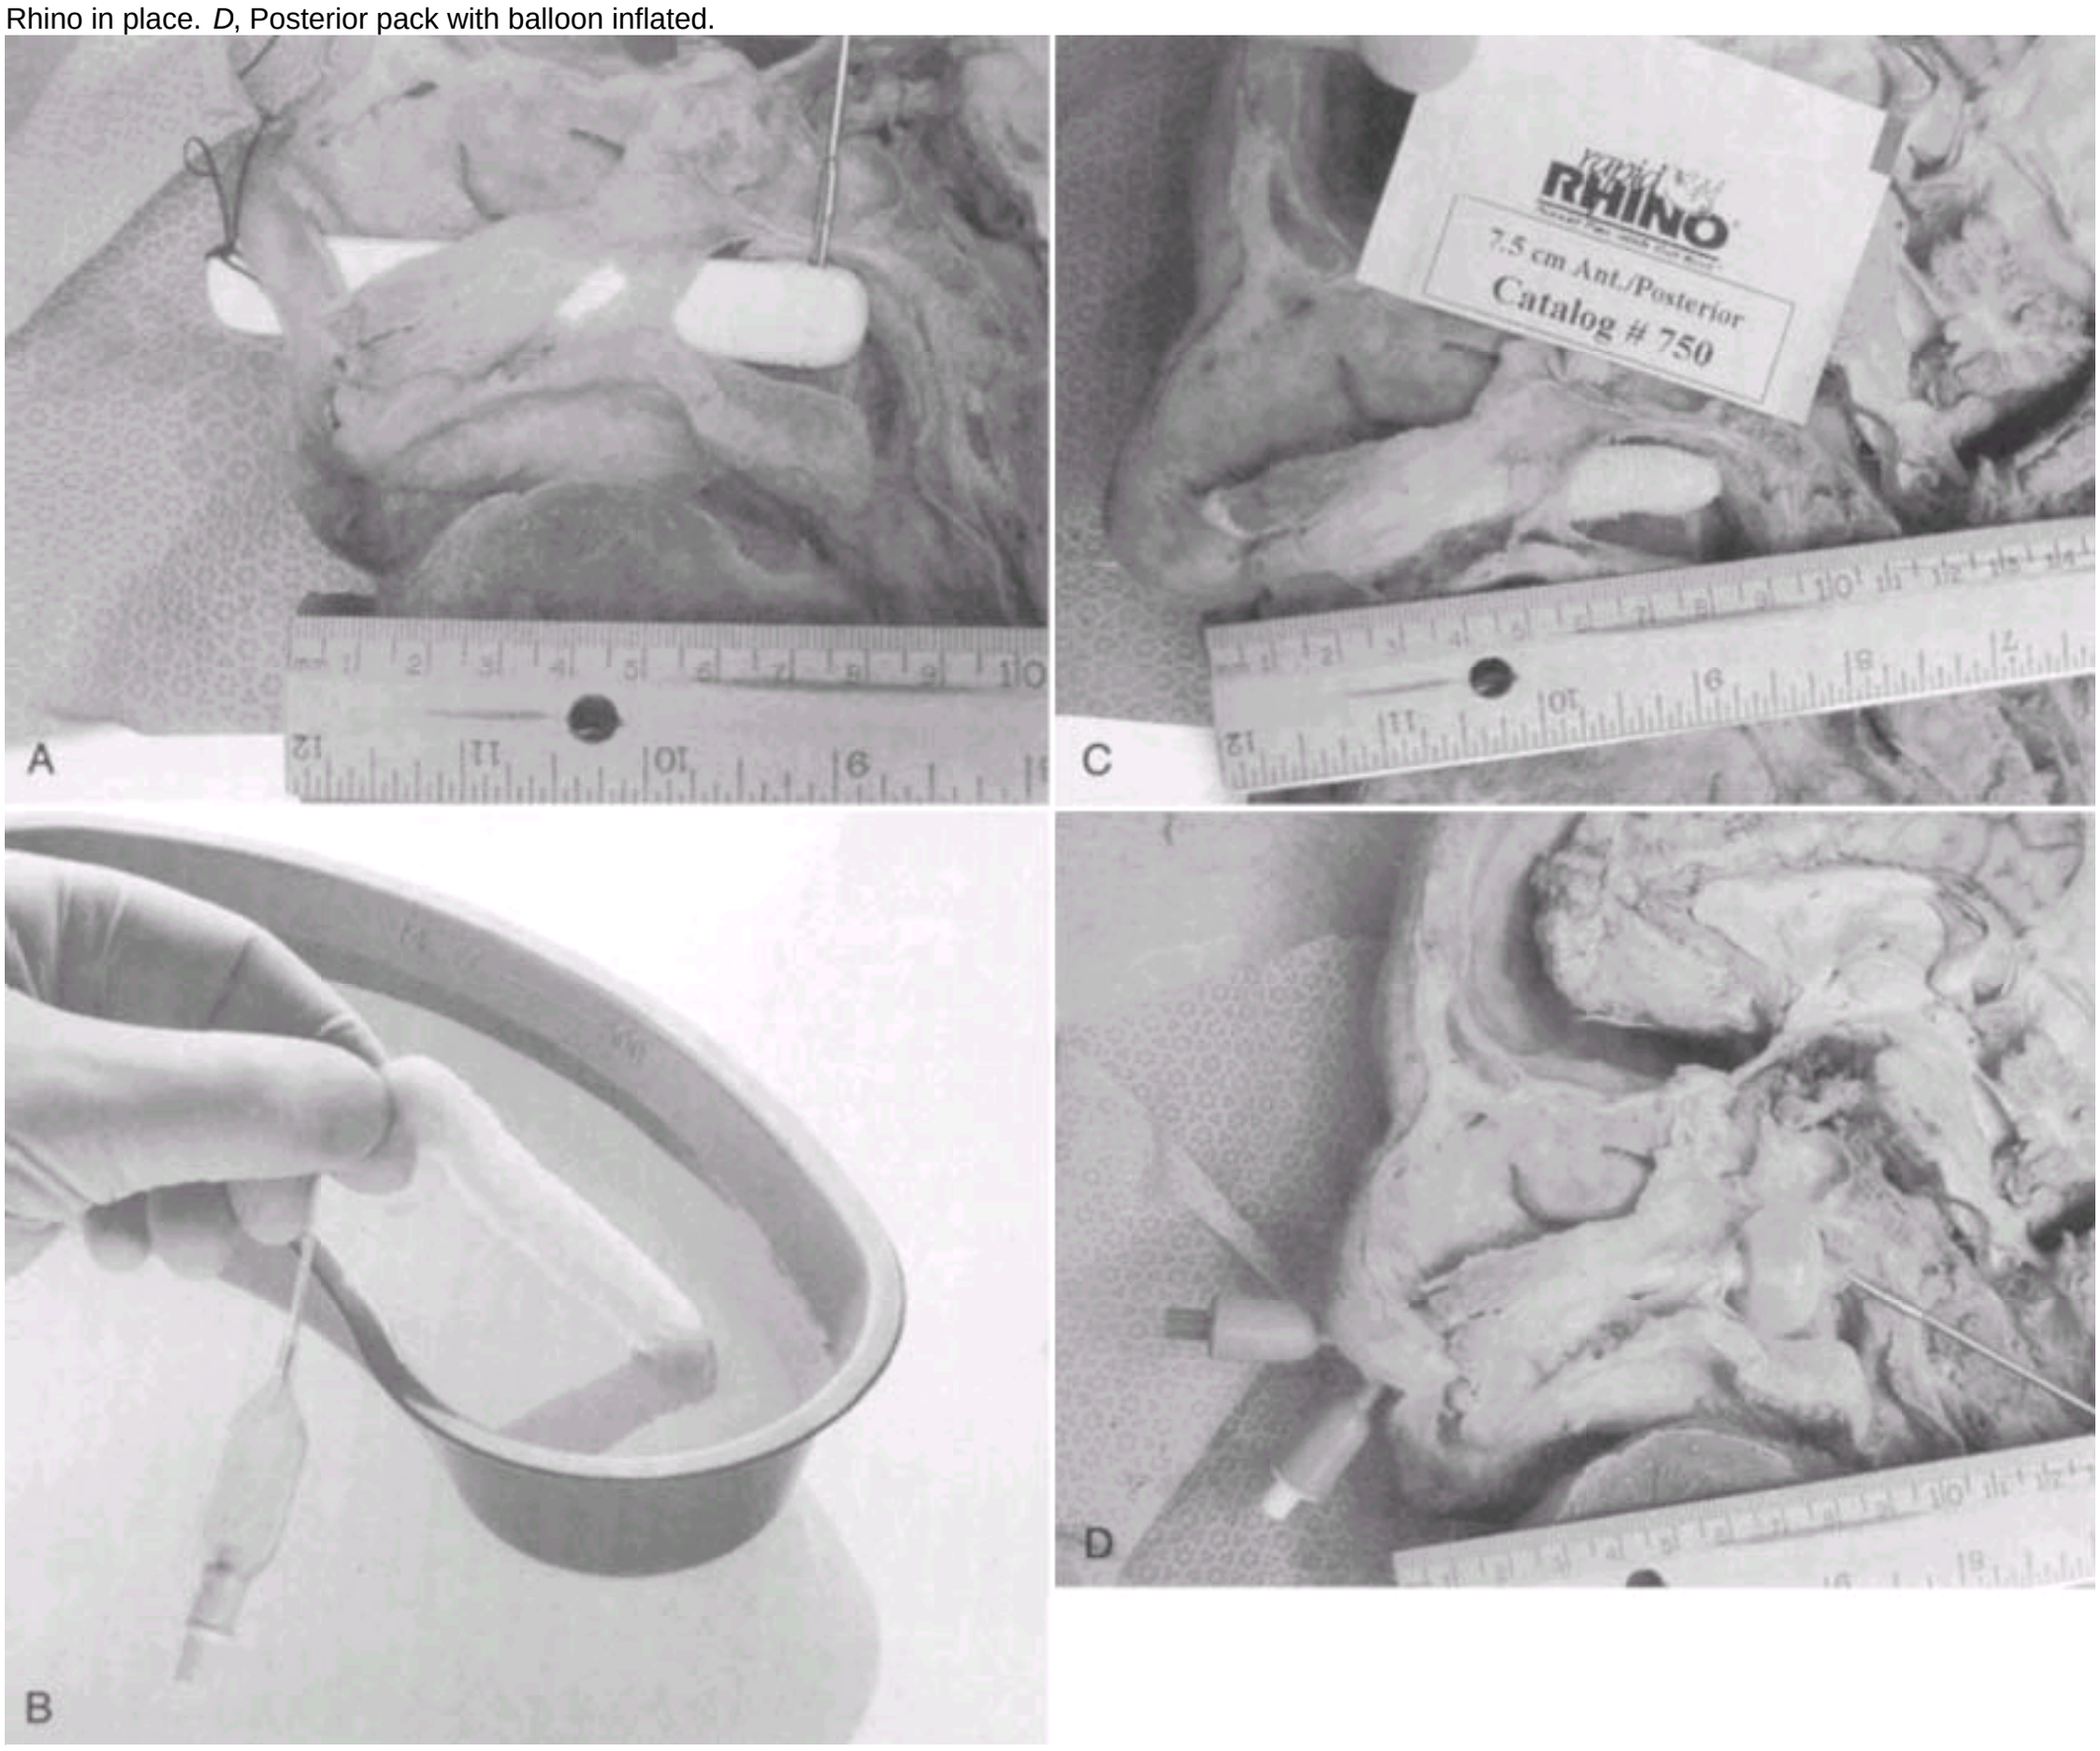


Figure 65-41 An expanding Merocel tampon is ideal for minor anterior bleeds. The dehydrated pack is trimmed to fit the nose and generously lubricated with antibiotic ointment. A swift single motion is used to insert the pack to its full length. The pack expands when hydrated with saline. The patient continues to keep the pack moist at home and it is again well hydrated just before removal.

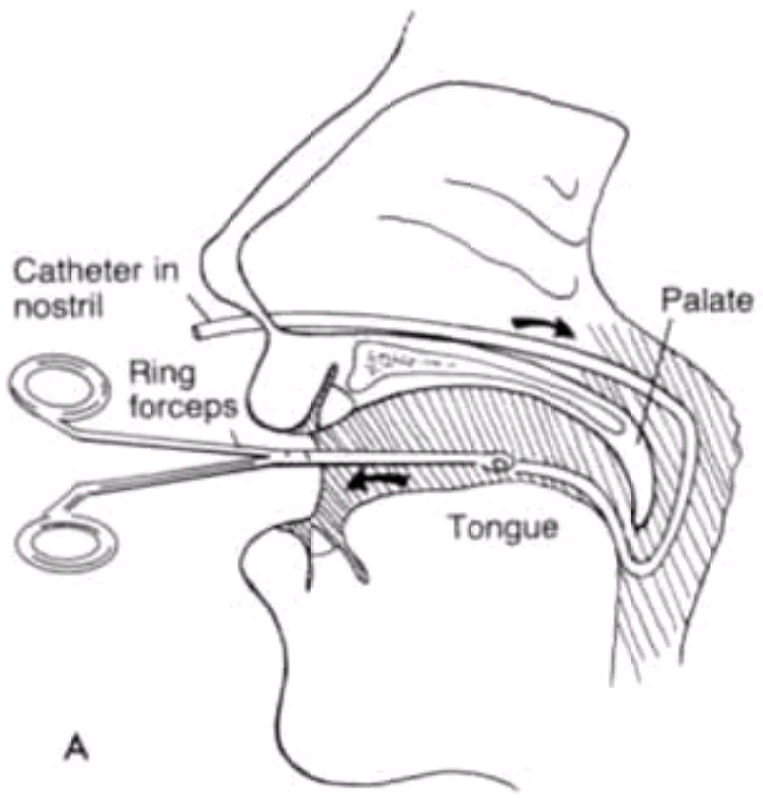
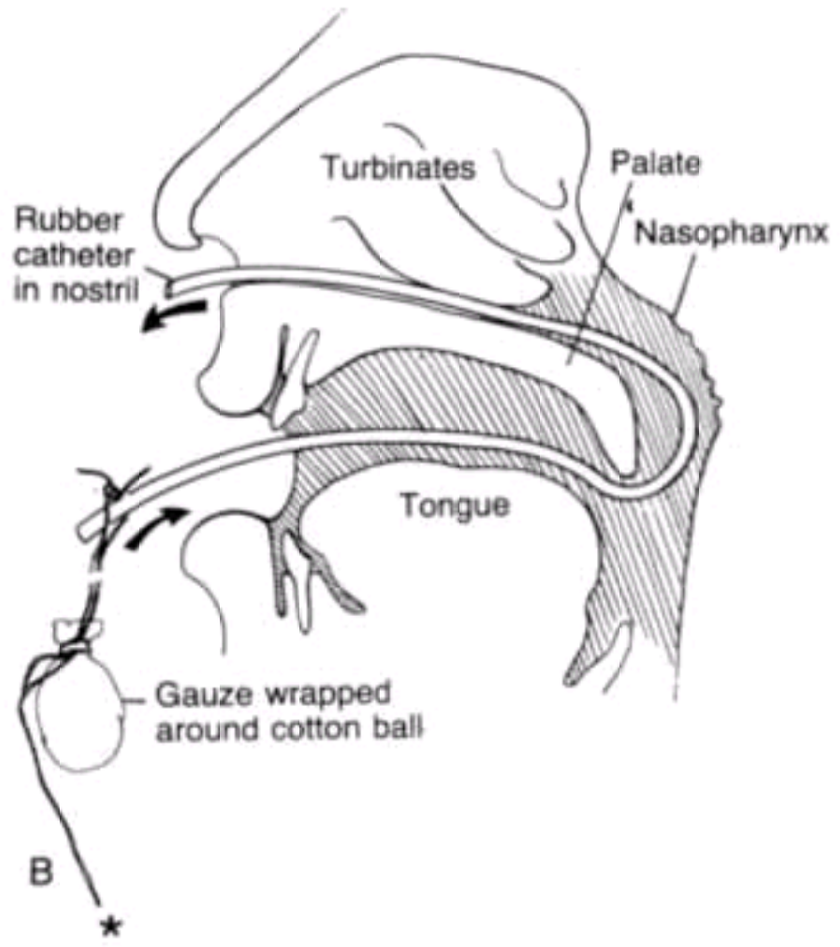
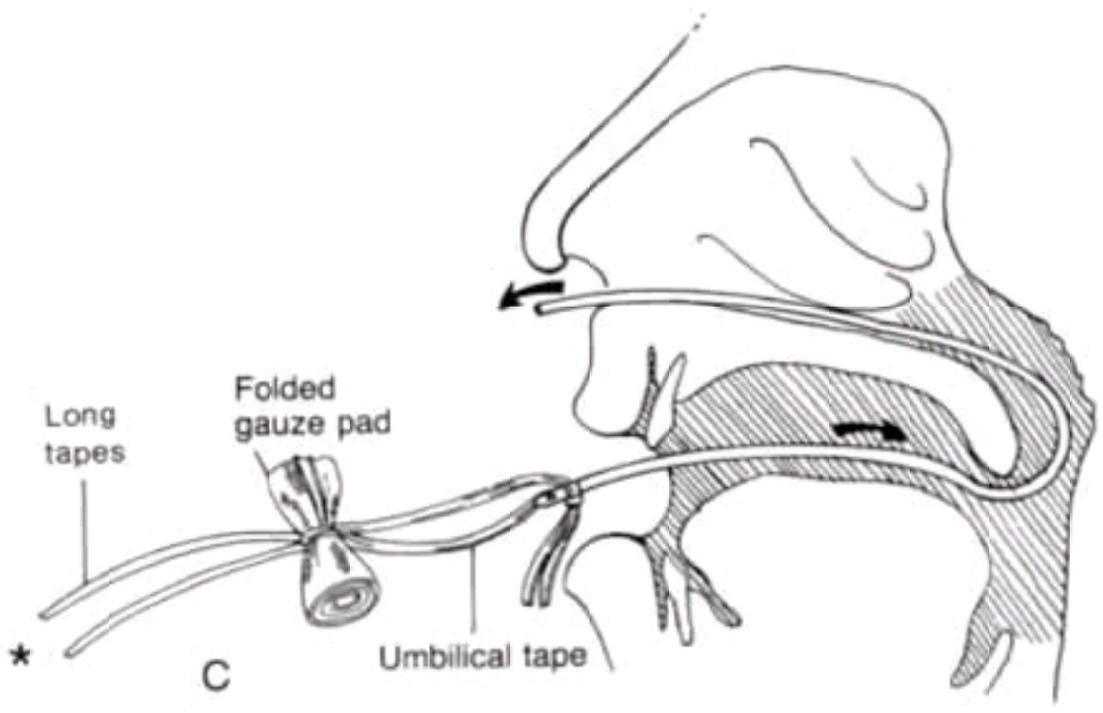
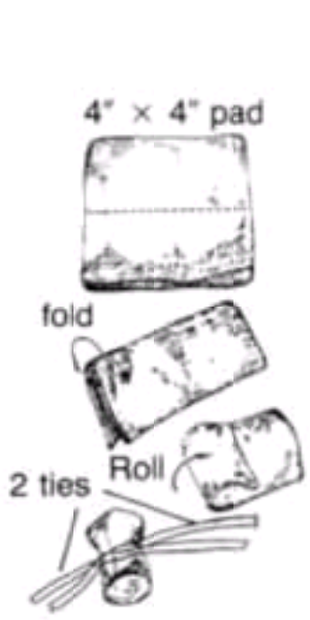
Figure 65-42a Posterior nasal pack. *A,* Following topical anesthesia, a red rubber catheter is passed through the nose and carefully grasped in the oropharynx with ringed forceps and brought out through the mouth. *B (upper right),* A posterior nasal pack made by wrapping a cotton ball in a 4 × 4-in. gauze pad and tying 2 long silk sutures or umbilical tapes around the neck of the pack. One tie must be left long so that it can be taped to the cheek until needed for removal of the pack. *C (c*enter), Alternatively, a gauze pad can be folded and rolled into a cylinder and tied with two strings. Two of the long strings are used to tie the pack to the tip of the catheter and the other two will be used to remove the pack. *D,* As an option, a second catheter, which has been passed through the nonbleeding side and brought out the mouth, can be used to retract the palate forward to aid in the placement of the pack (not shown). The optional "retraction" catheter is removed after the pack is in the proper position.









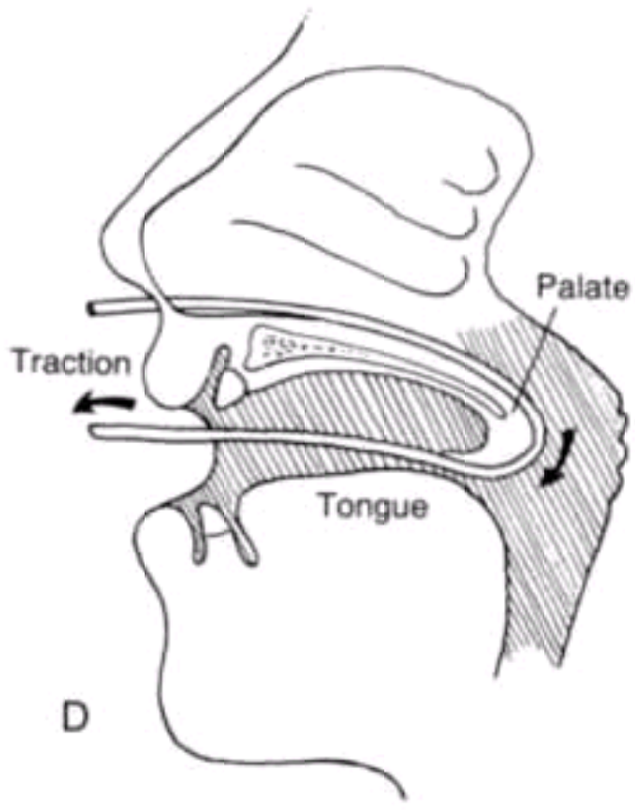


Figure 65-42b *E,* The pack is digitally guided into the nasopharynx. *F,* A gauze roll secures the pack to the nose and the rescue ties are taped to the cheek.

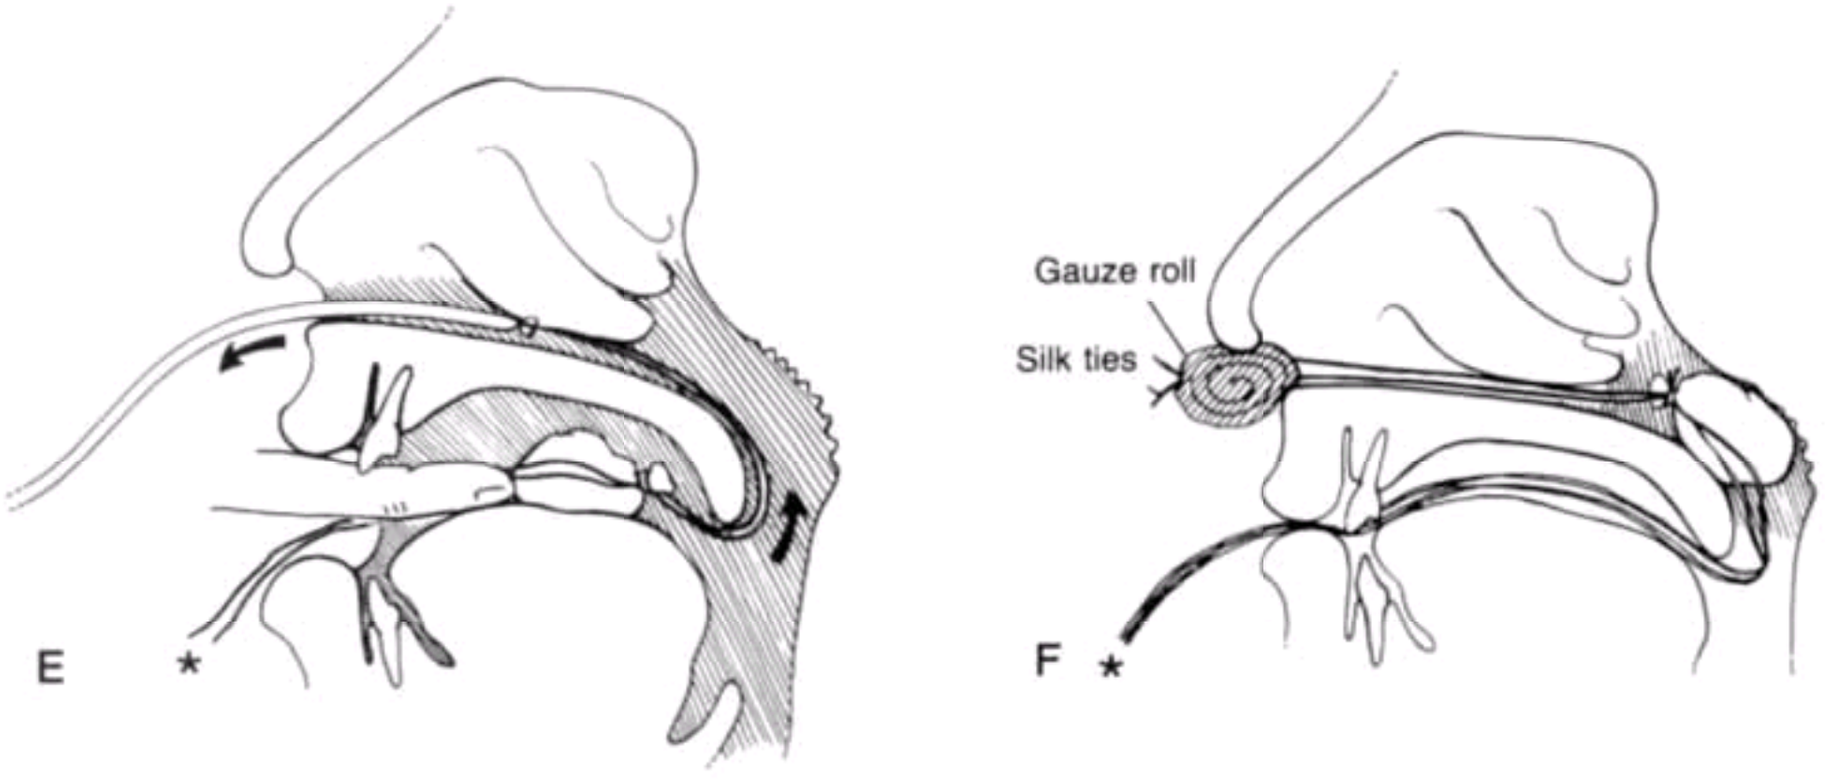

Figure 65-43 Foley catheter placed into the nasopharynx, inflated with water, and retracted into position. The distal tip of the catheter has been cut off. An anterior pack (not shown) is then placed around the catheter. The ala and columella are protected with gauze padding, and a plastic umbilical clamp or nasogastric clamp is applied to the catheter to maintain slight tension on the balloon.

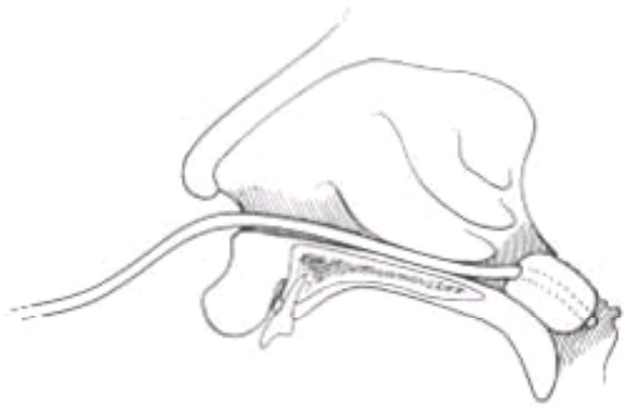

Figure 65-44 *A* and *B,* The balloon tamponade device serves as both an anterior and a posterior pack. It is easily inserted and is often successful for the temporary control of posterior epistaxis in the emergency department. *C,* Although often effective for hemorrhage control, balloon inflation within the nasal cavity can be quite painful and prolonged pressure on the nasal alae can produce tissue injury. Gauze should be placed between the external balloon and the skin of the nose. *(Courtesy of Xomed Inc, Jacksonville, FL) D*, Although alarming to the patient, blood in the eye from back bleeding via the nasolacrimal duct from a balloon pack is benign.

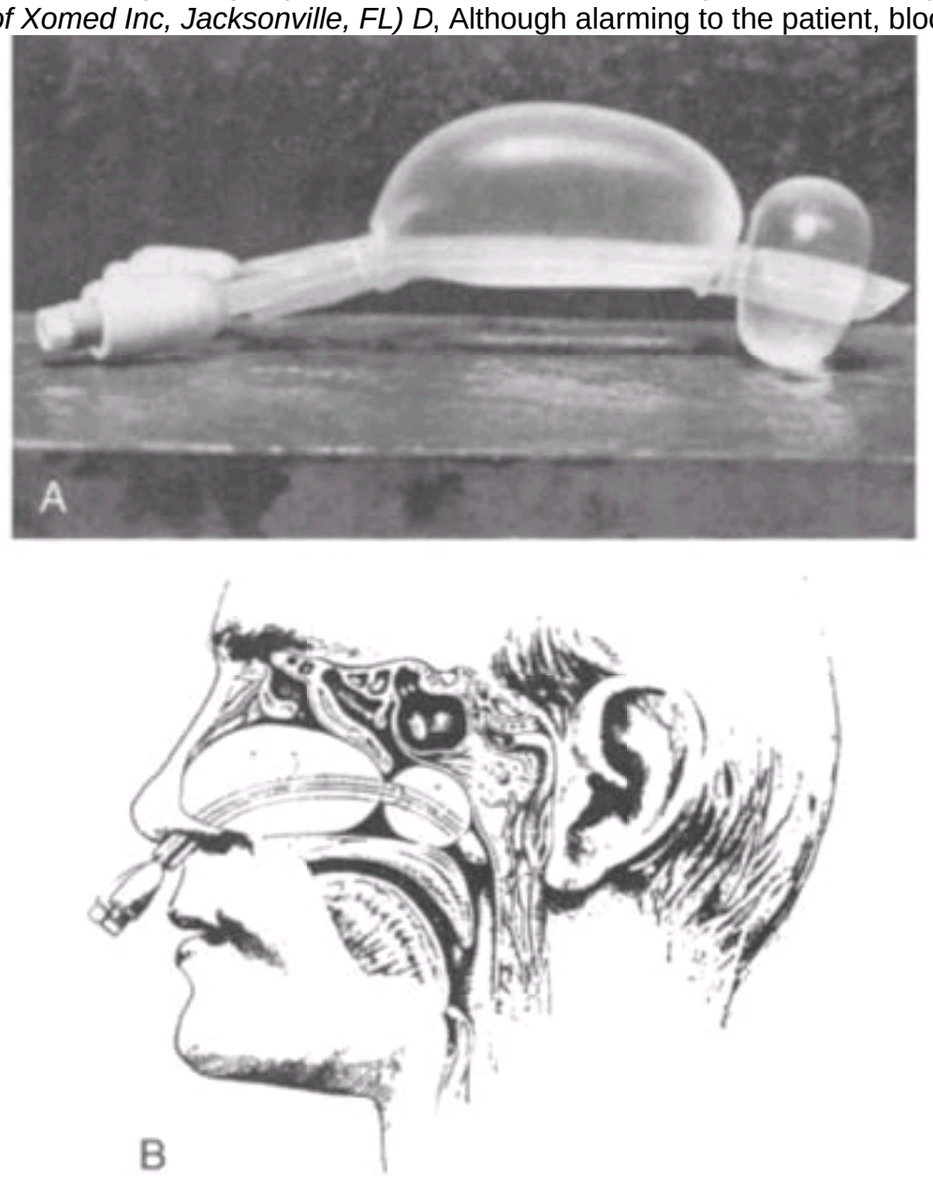

Figure 65-45 Xomed Rhinology Products. *A,* Xomed Epistat nasal catheter. *B,* Pope Flex-Pak nasal packing (shown expanded and compressed). *C,* Xomed Epistat II nasal catheter. *D,* Staxi-Stat pack without drawstring. *E,* Large Fast-Pak nasal pack with applicator. *F,* Weimert epistaxis packing. *G,* Small Fast-Pak nasal pack with applicator.

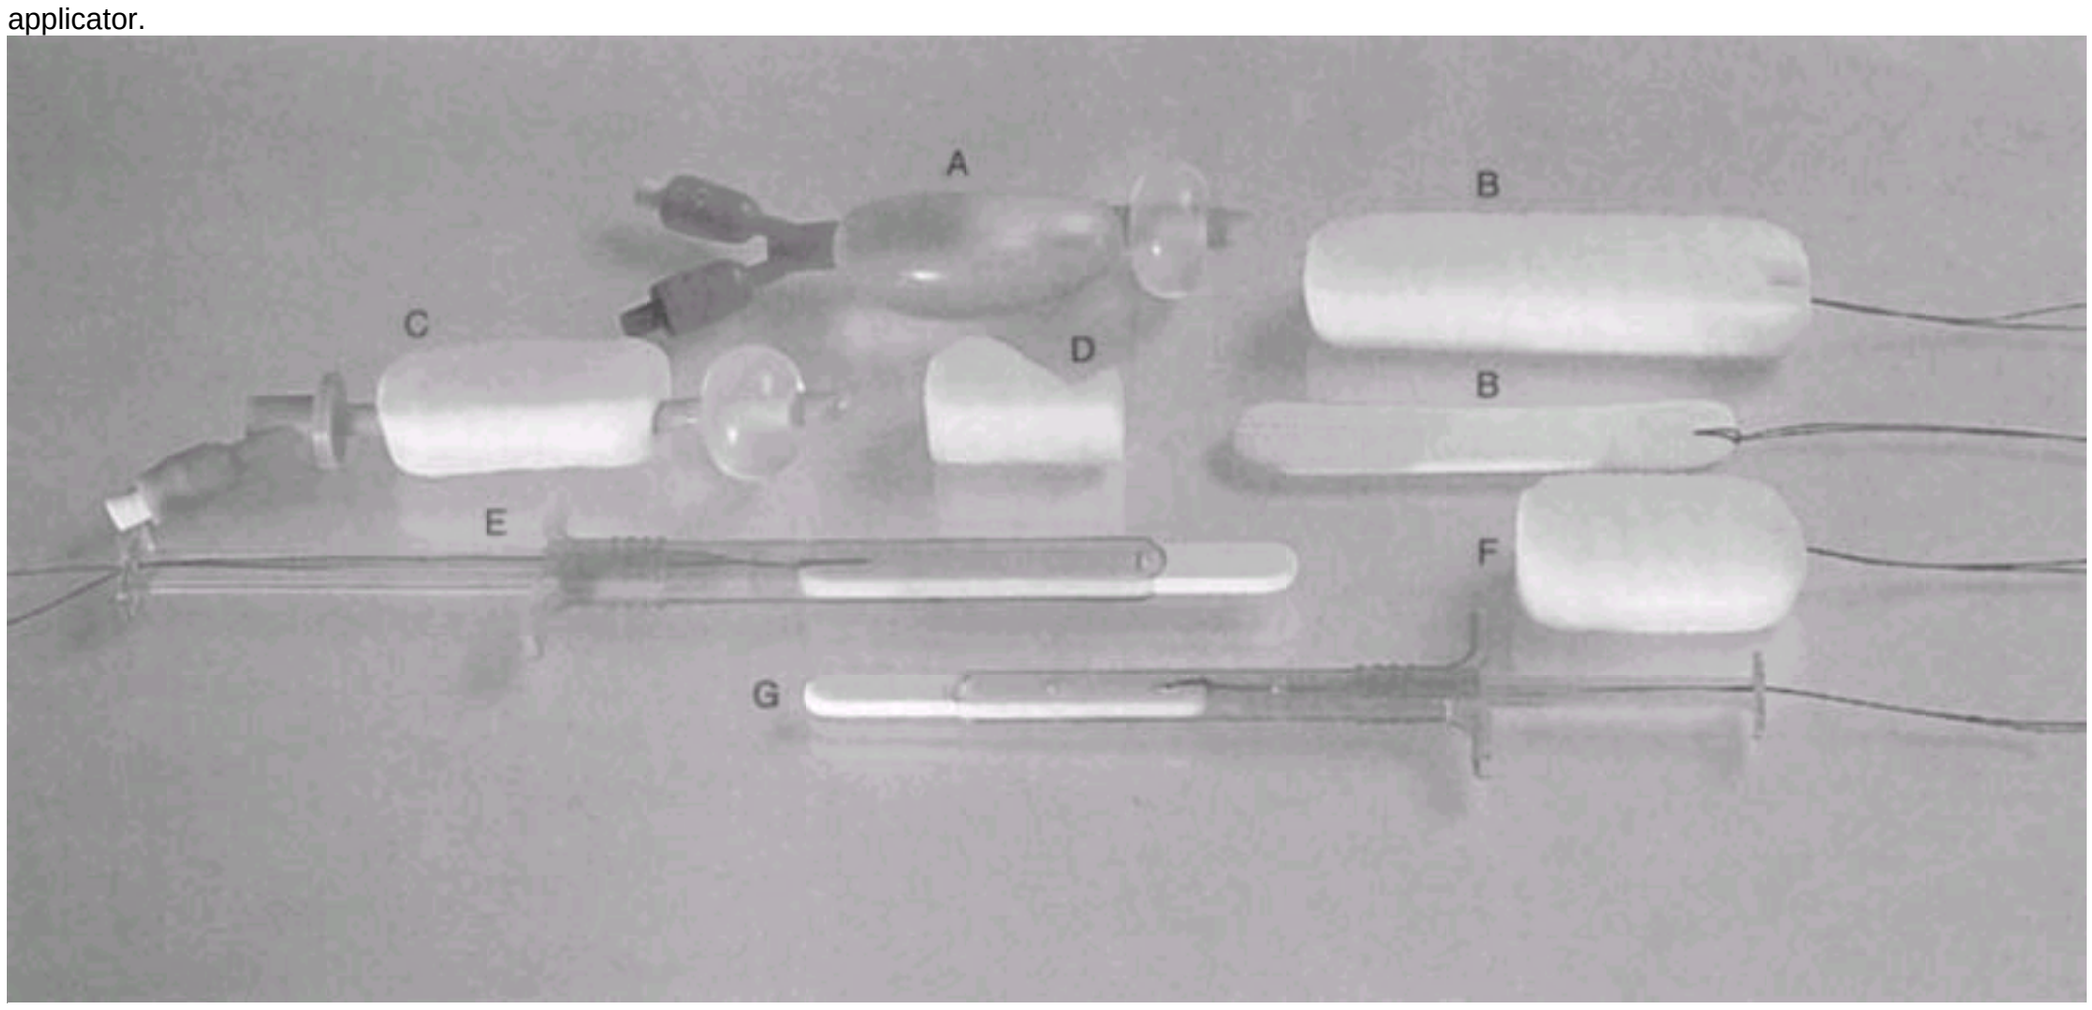

Figure 65-46 If visual inspection of the nose with a speculum does not rule out a septal hematoma, the clinician's gloved fingers, passed posteriorly along both sides of the septum, may reveal bulging or fluctuance.

Figure 65-47 *A*, A small left-sided septal hematoma. *B*, After applying appropriate topical anesthesia, supplemented with local infiltration, if necessary, a *horizontal* incision is made through the mucosa and the perichondrium covering the hematoma. *C,* A small cup forceps or scissors is used to remove enough mucosa to prevent premature closure of the wound and reaccumulation of hematoma. *D,* A sterile rubber band is then placed as a drain, and the naris is packed.

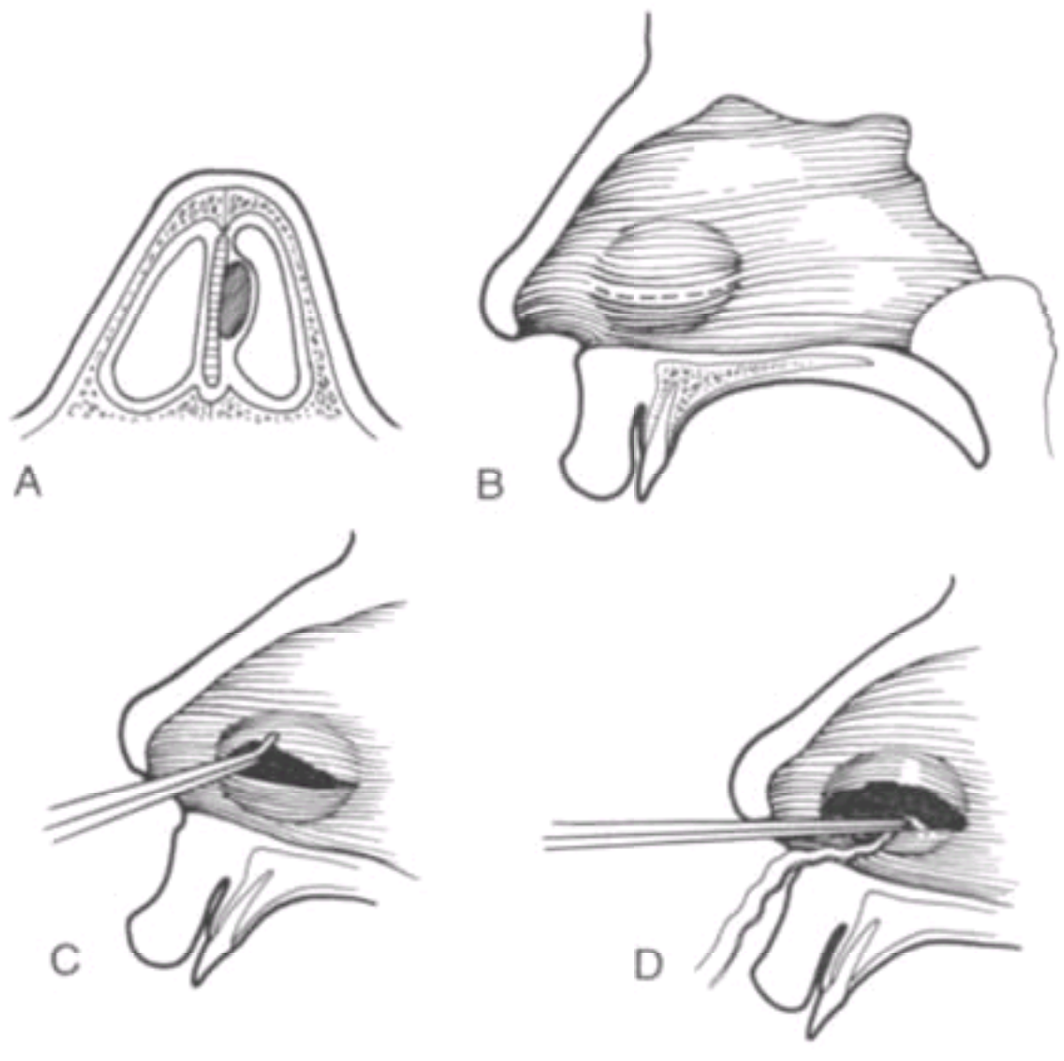

Figure 65-48 Reduction of a depressed and dislocated nasal bone fracture. This reduction is accomplished in two steps following anesthesia by first elevating the depressed nasal bone as illustrated and then manually displacing the pyramid to the midline. The handle of a scalpel may be used if an elevator is unavailable. *(From Adams GL, Boies LR Jr, Hilger PA (eds): Boies Fundamentals of Otolaryngology, 6th ed. Philadelphia, WB Saunders, 1989.)*

Figure 65-49 *A* and *B,* Fogarty balloon extraction of nasal foreign body. Insert the lubricated catheter tip above the foreign body, then gradually inflate the balloon. Slowly withdraw until resistance is met, then pull the object out of the naris.

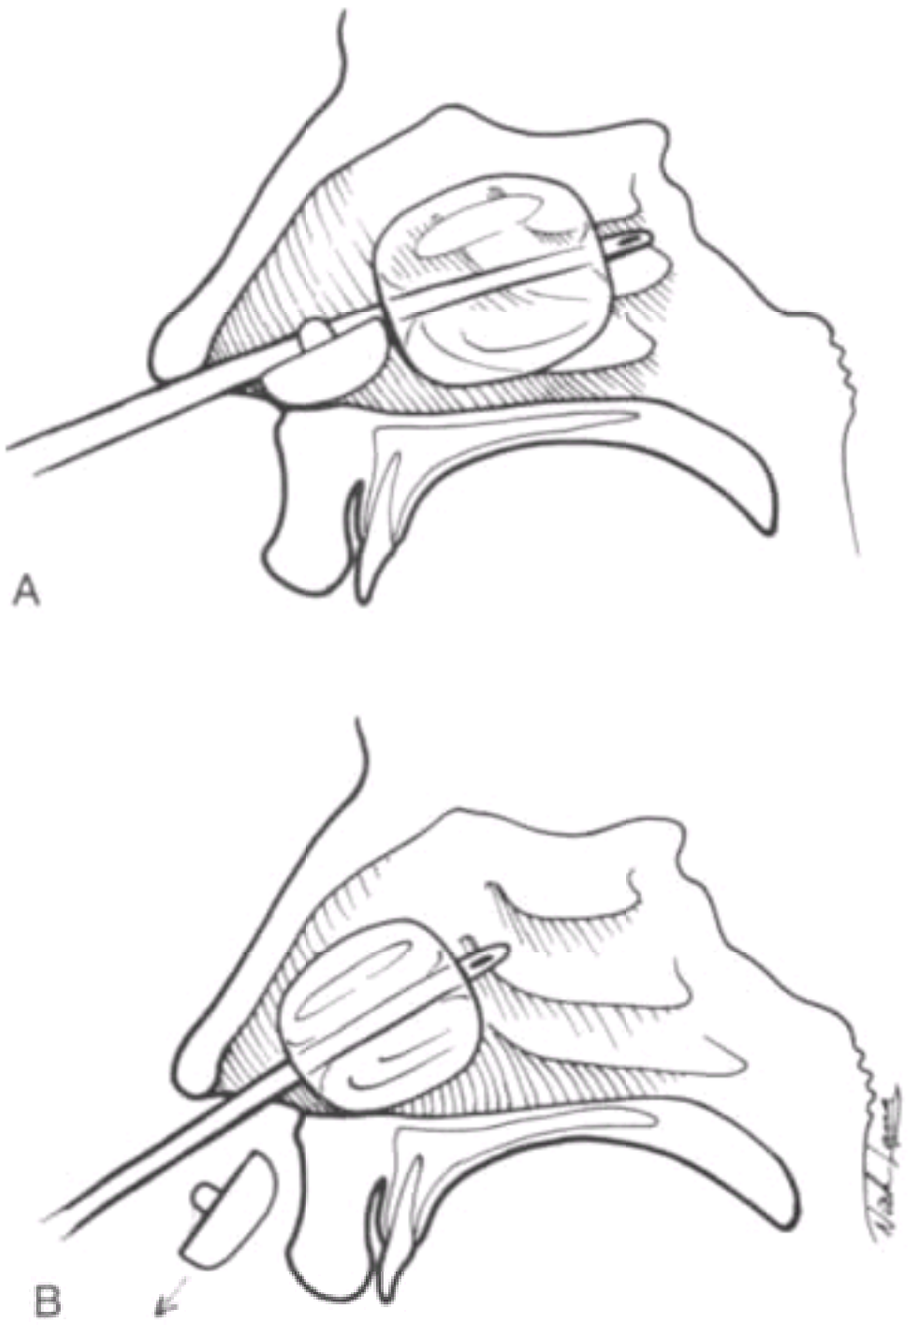

Figure 65-50 The Katz Extractor (InHealth Technologies, Carpinteria, CA) for oto-rhino foreign body removal shown with balloon inflated.

Figure 65-51 Bag-valve-mask technique to blow foreign body out of the naris. Ensure that the face mask forms a tight seal around the patient's mouth and that the unaffected nostril is completely occluded. Attempt to firmly compress the bag as the patient exhales (an assistant is helpful to hold the mask snugly and to occlude the other nostril). This technique works best with objects that completely occlude the nostril.

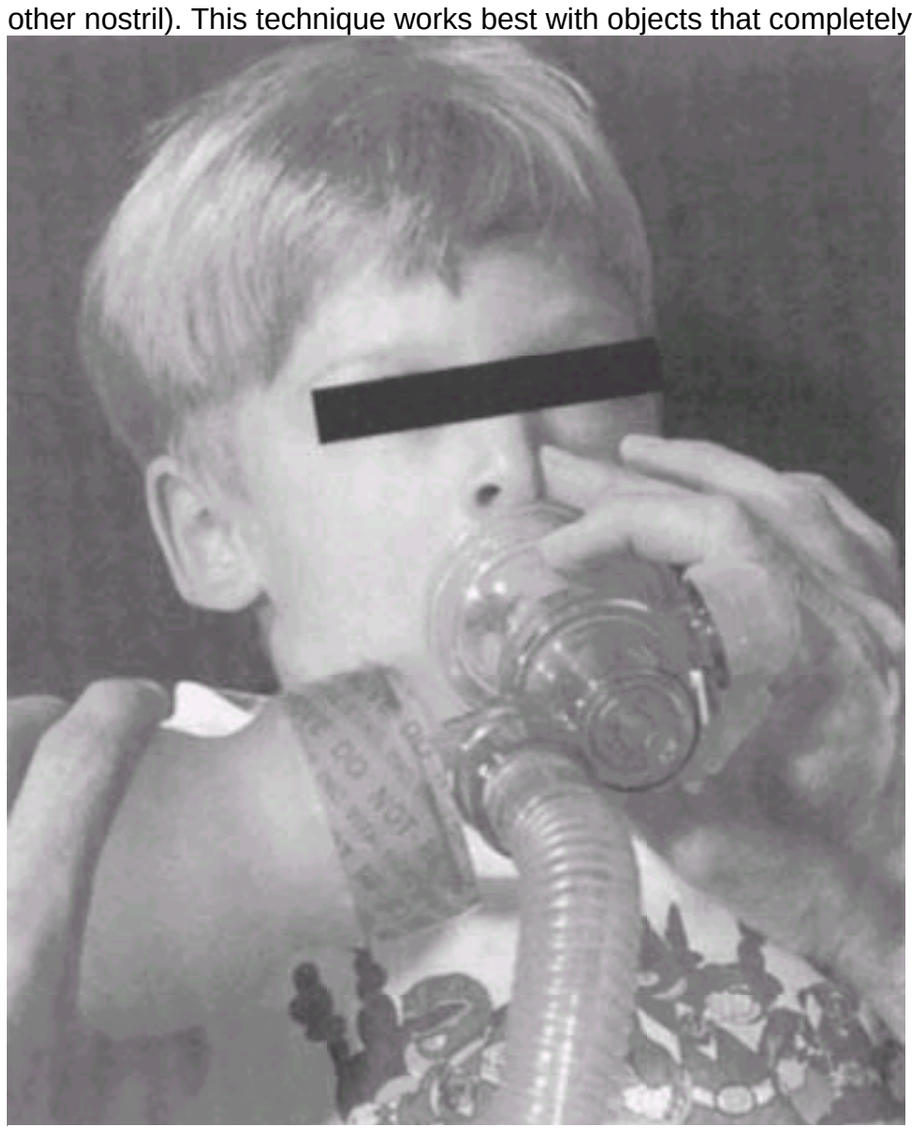

Figure 66-1 Muscles responsible for closing and excursive mandibular movements. Sagittal skull views illustrating the anatomical positions of the following muscles: *A,* Temporalis. *B,* Superficial masseter. *C,* Deep masseter. *D,* Medial pterygoid. *E,* Lateral pterygoid. *(From King R: Oral-Facial Emergencies-Diagnosis and Management, 1st ed. Portland, OR, JBK Publishing, 1994.)*

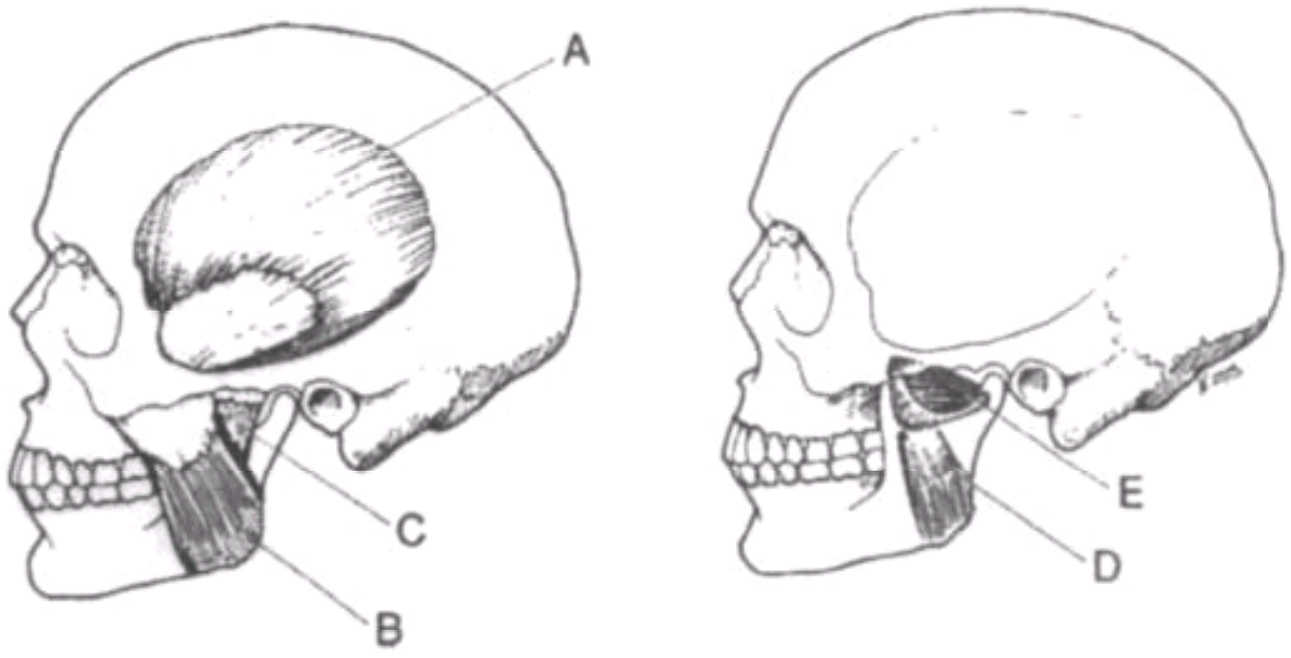

Figure 66-2 Muscles responsible for mandibular opening. Oblique skull views illustrating the anatomical positions of the following muscles: *A,* Mylohyoid. *B,* Anterior belly of the digastric. *C,* Posterior belly of the digastric. *D,* Geniohyoid. *(From King R: Oral-Facial Emergencies-Diagnosis and Management, 1st ed, Porland, Or: JBK Publishing, 1994.)*

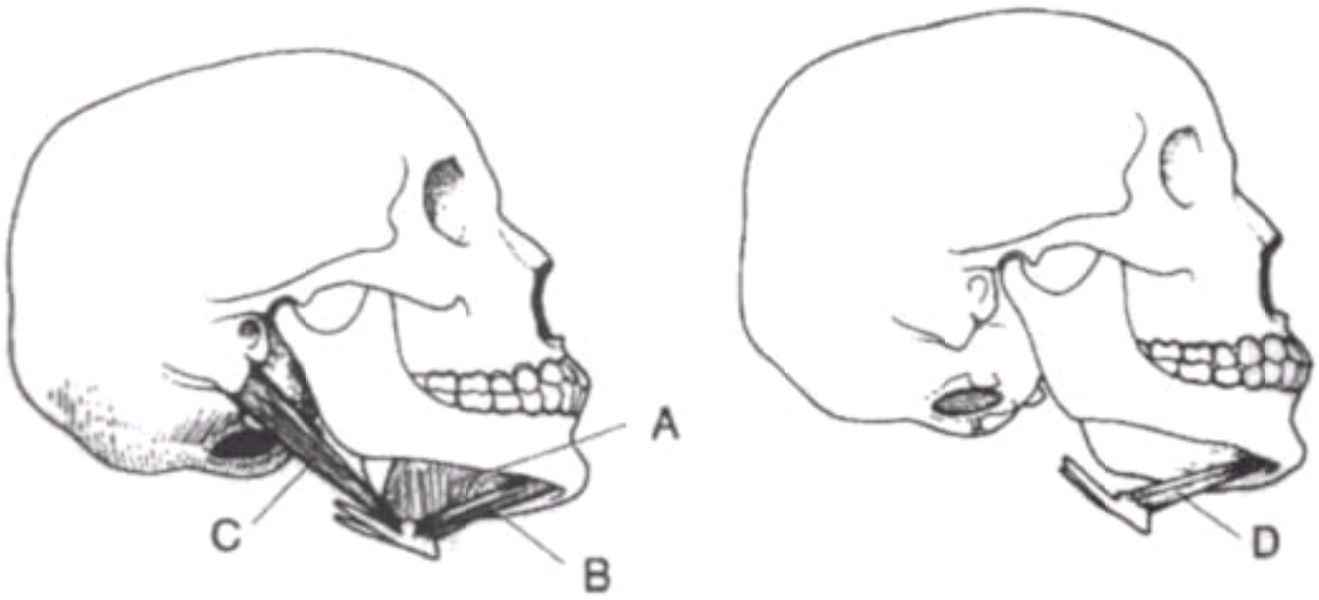

Figure 66-3 Axial view of the floor of the mandible. The arrows indicate the direction of pull of the lateral pterygoid, medial pterygoid, and mylohyoid muscles. *(From Eisele D and McQuone S: Emergencies of the Head and Neck, 1st ed. St. Louis, MO, Mosby, 2000.)*

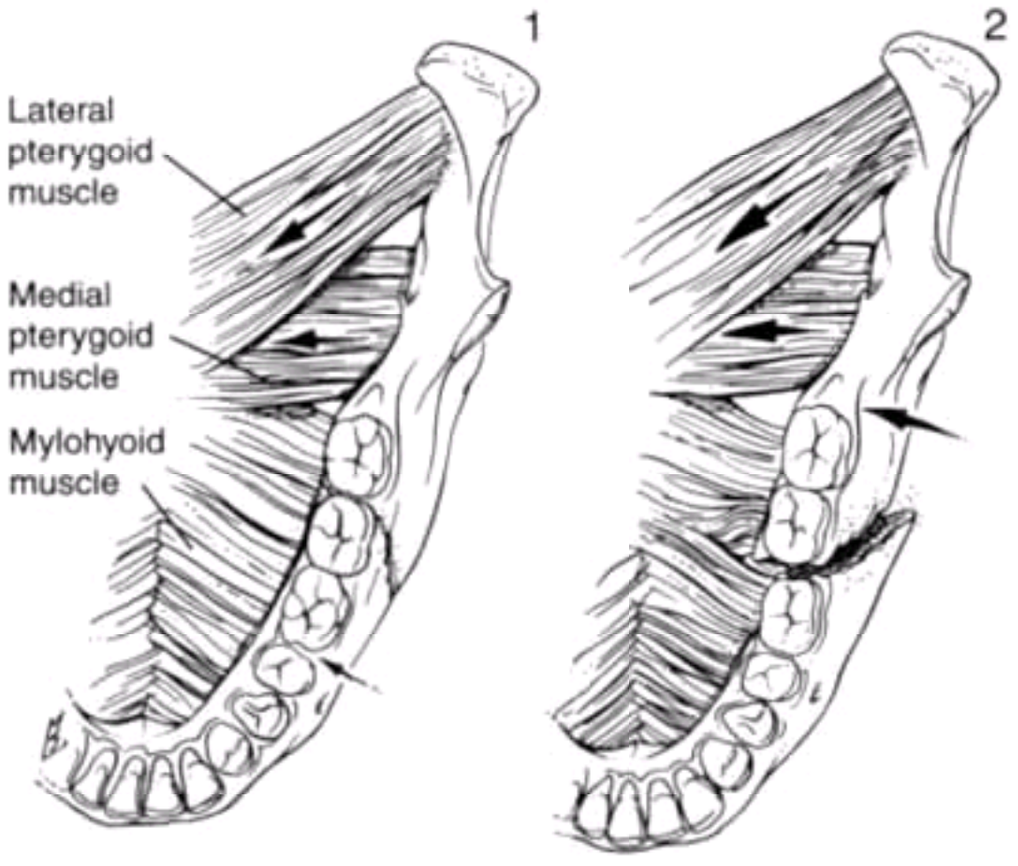

Figure 66-4 Anatomy of the mandible. *Top,* View from lateral (buccal) perspective. *Bottom,* View from medial (lingual) perspective. *(Redrawn from Grant JC: Grant's Atlas of Anatomy, 5th ed. Baltimore, Williams & Wilkins, 1962.)*

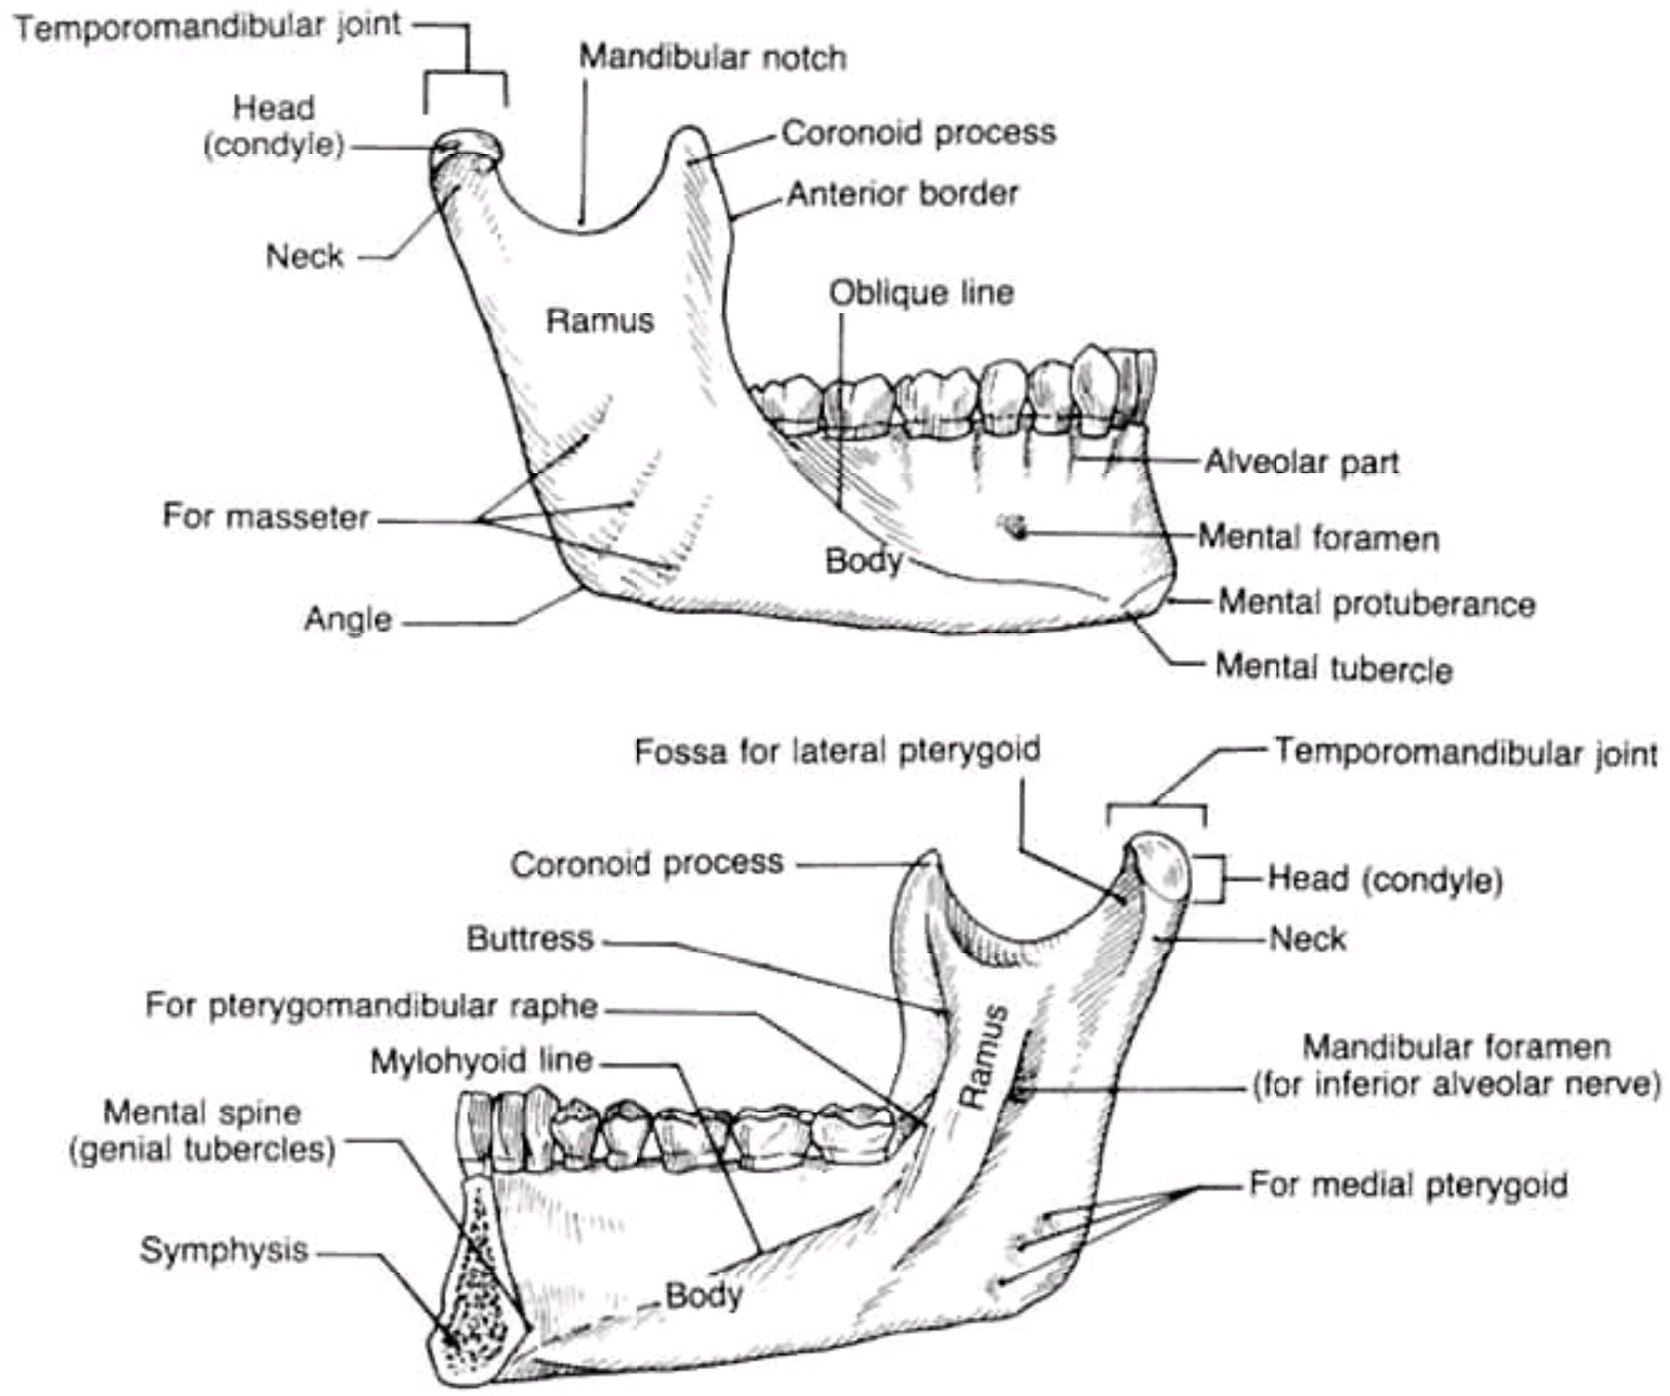

Figure 66-5 Classification of teeth. *Top left,* Lateral view. *Top right,* Medial view. *(Redrawn from Grant J, Basmajian J: Grant's Method of Anatomy, 7th ed. Baltimore, Williams & Wilkins, 1965.)*

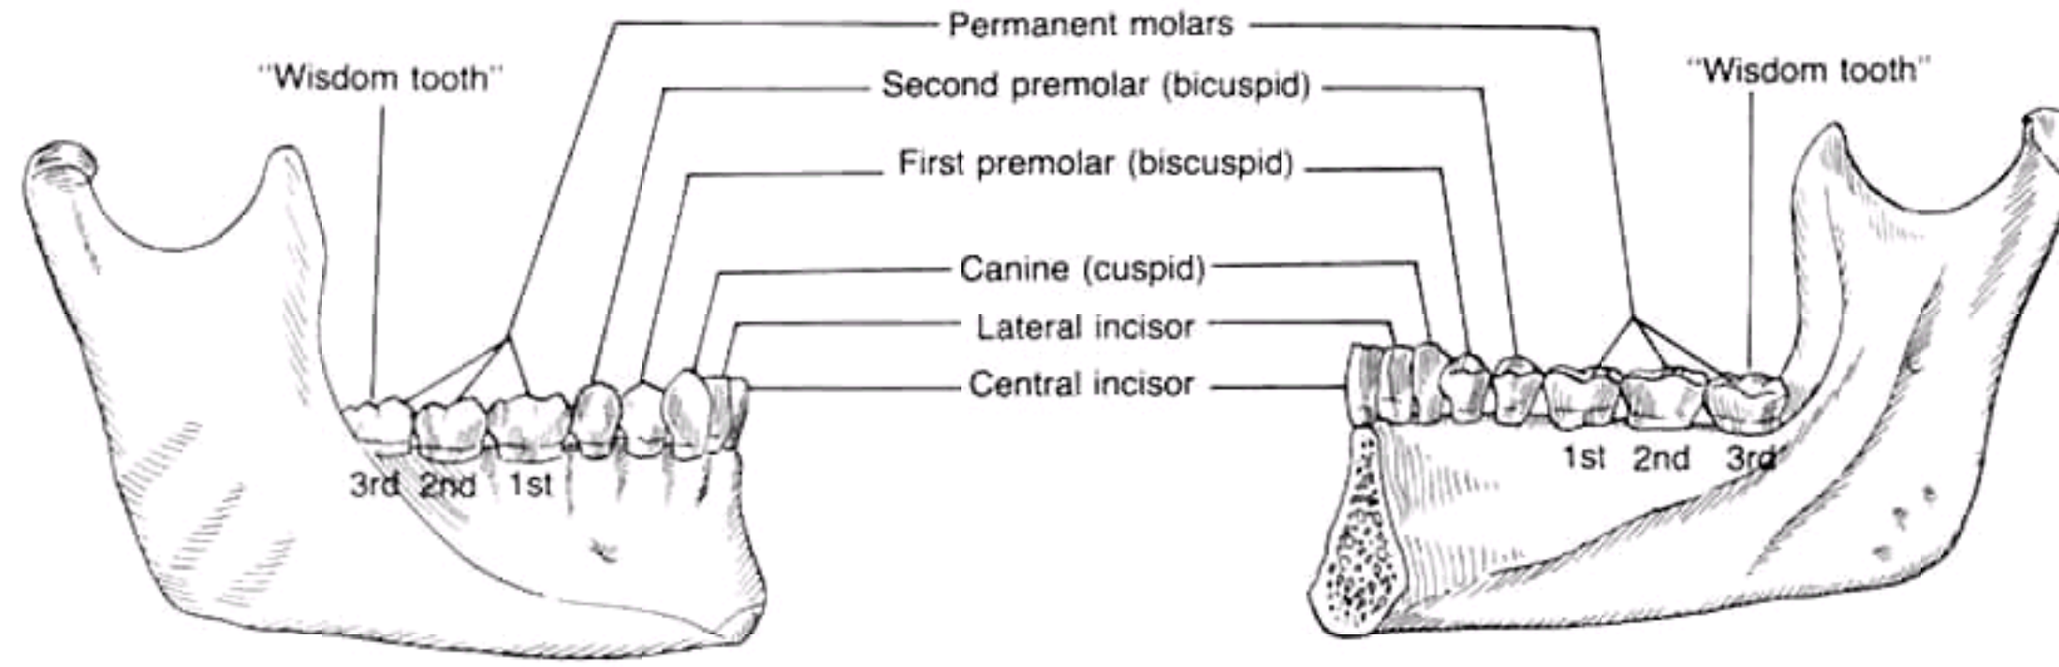

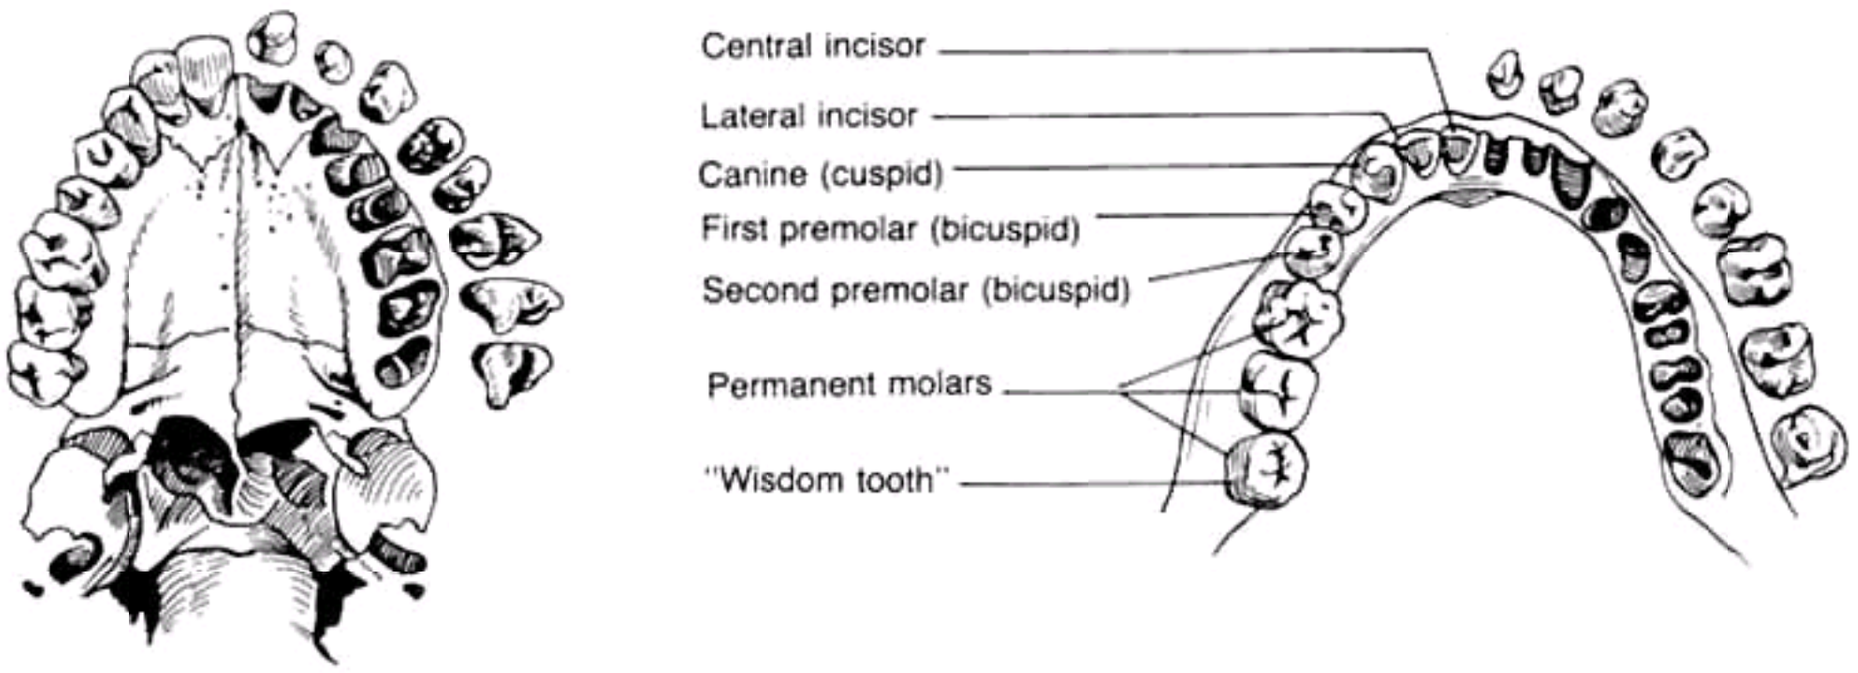

Figure 66-7 The dental anatomic unit.

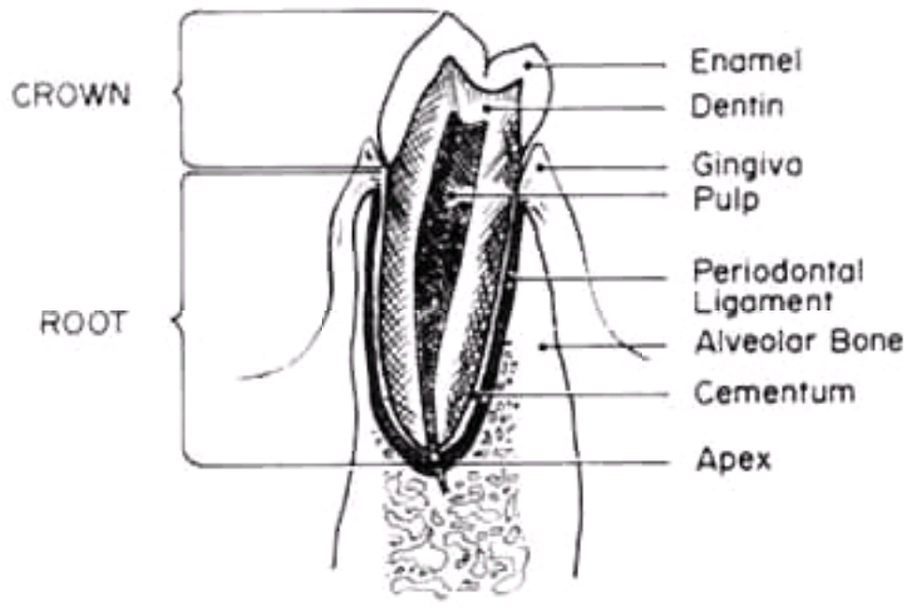

Figure 66-8 The Ellis classification for fractured alveolar teeth. The easiest method to classify fractured teeth is by description (e.g., fracture through the dentin of the first upper right molar).

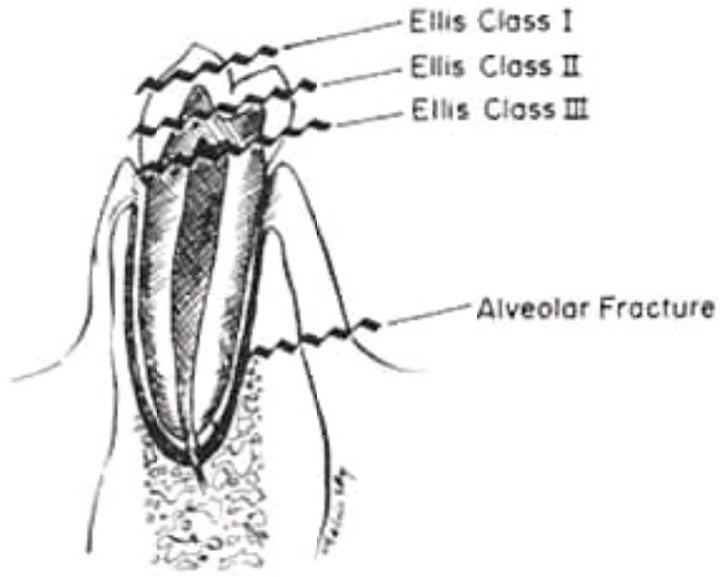

Figure 66-9 *A,* A common injury from a fist to the mouth results in a chipped tooth (here, fractured through the enamel only) and a laceration of the lip. One should always explore the mucosal laceration, looking for the missing piece of tooth. *B,* When this lip laceration was explored, a piece of tooth was found embedded within the laceration. If this foreign body is not removed, an infection is certain a few days later. *C,* Smoothing the enamel with a disc sander or an emory board will ameliorate the cosmetic deformity of a chipped tooth.

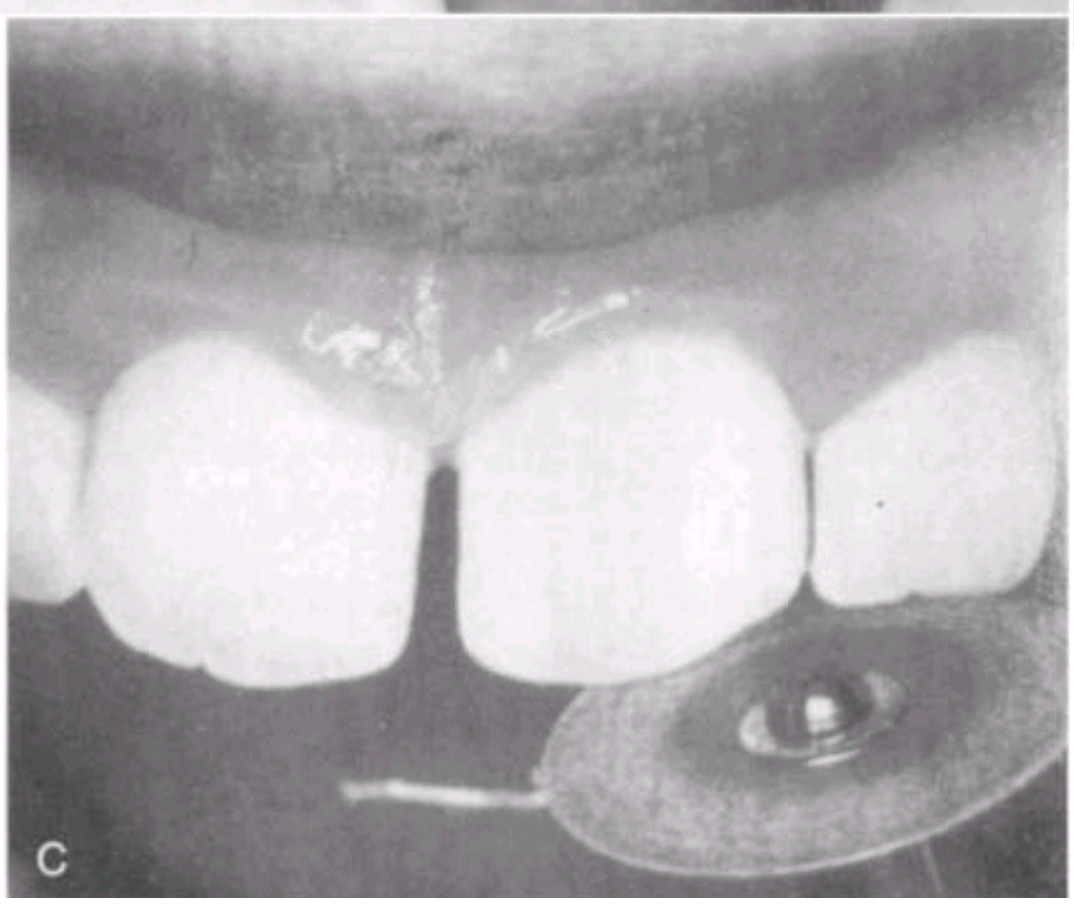

Figure 66-10 A fracture through the dentin.

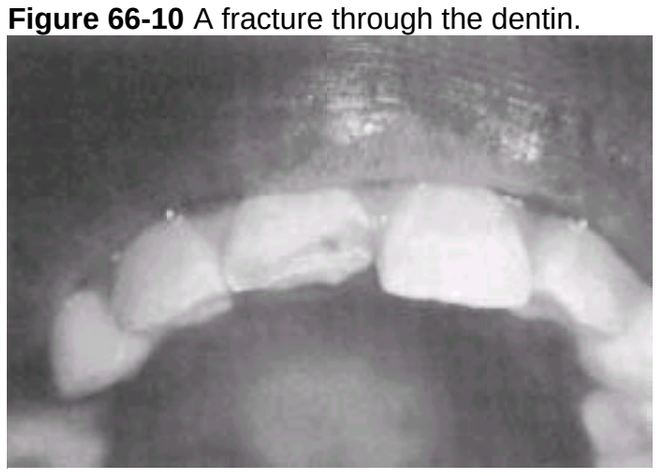

Figure 66-11 *A,* Calcium hydroxide paste is one acceptable material to cover dentin or pulp fractures. *B,* Mixing the calcium hydroxide paste with a spatula on a mixing pad. *C,* Application of the periodontal paste to the fractured surface of the tooth.

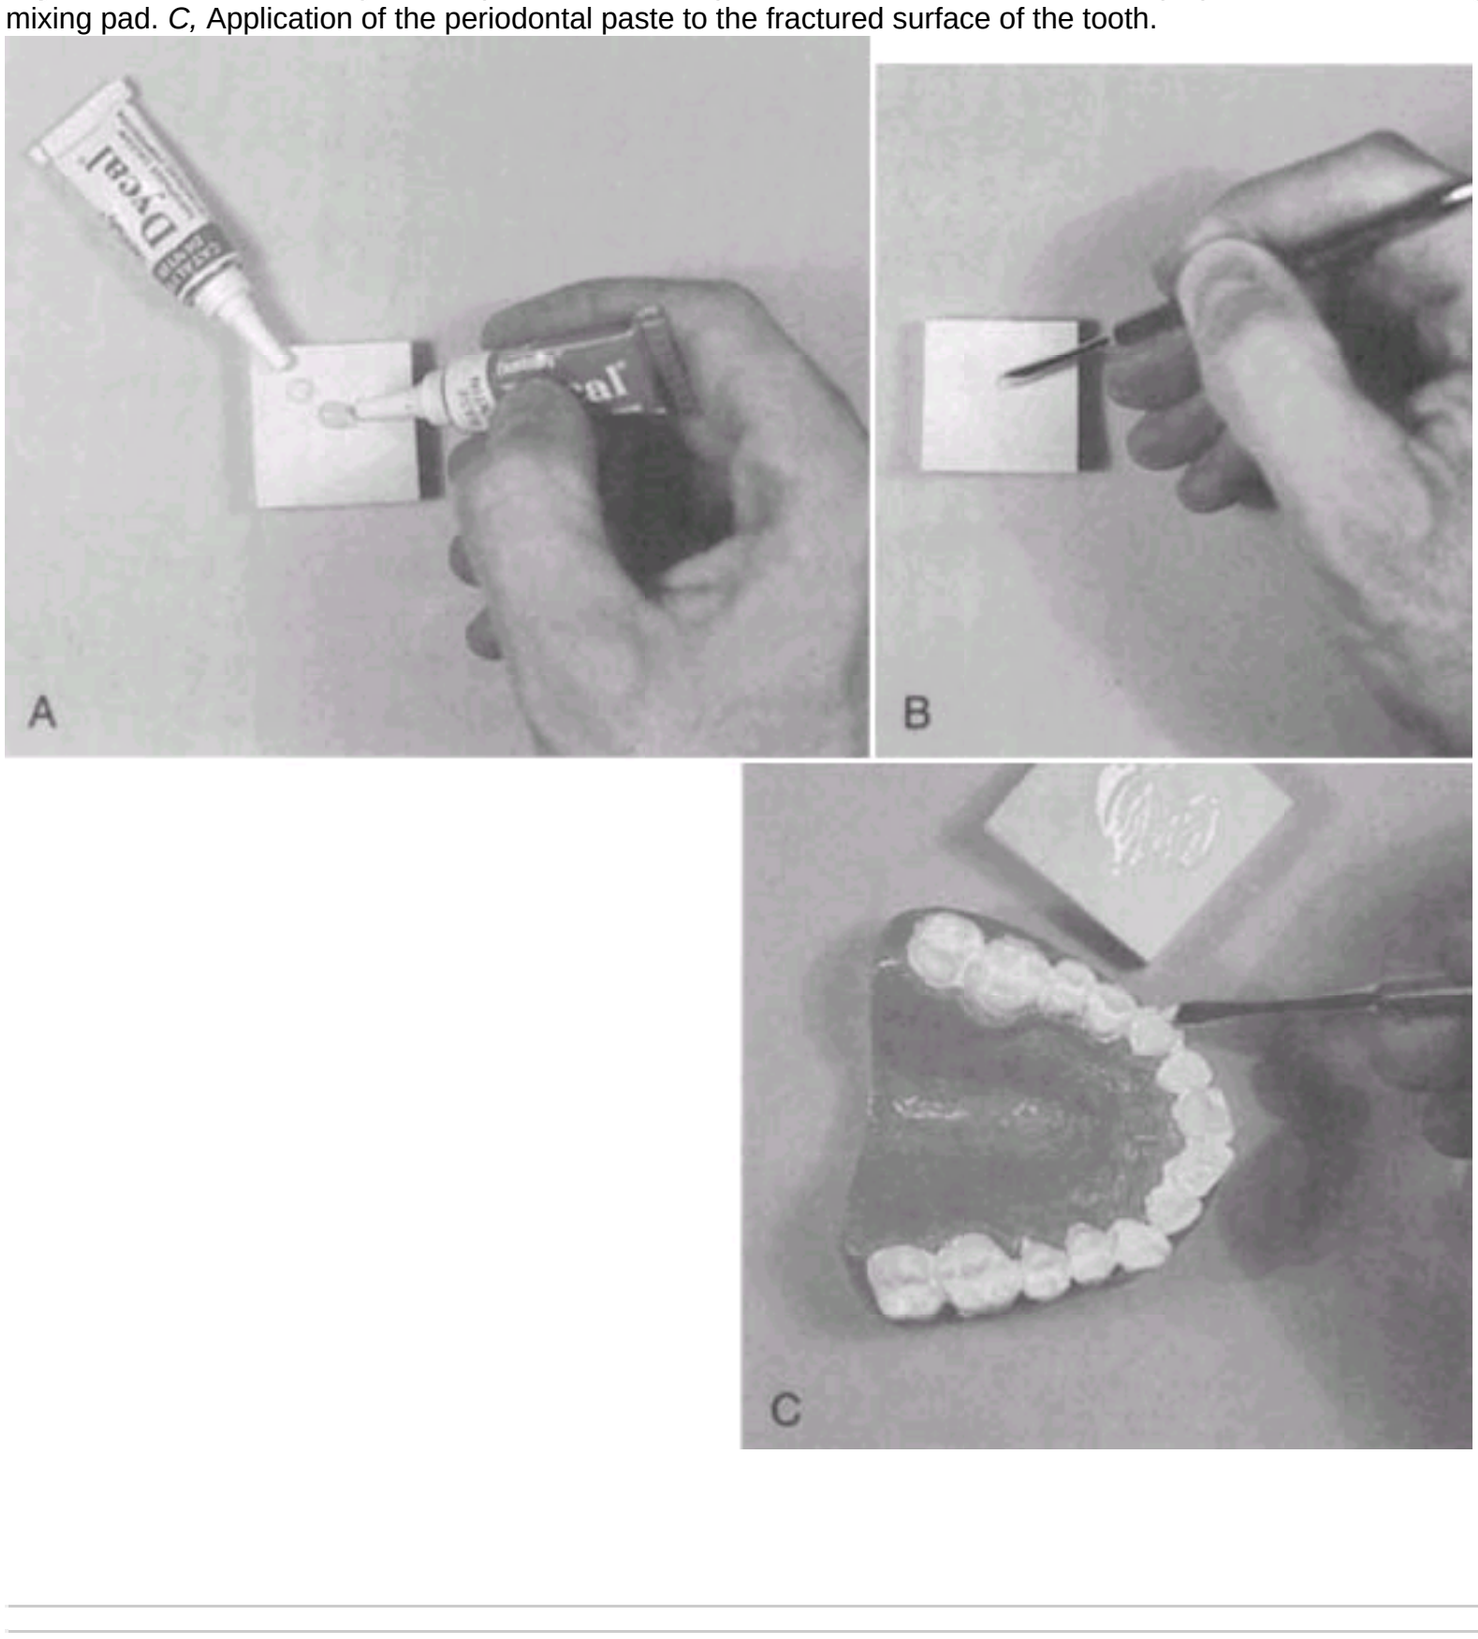

Figure 66-12 *A,* Covering the pulp fracture with calcium hydroxide paste. *B,* The calcium hydroxide paste hardens quickly in the moist environment of the mouth.

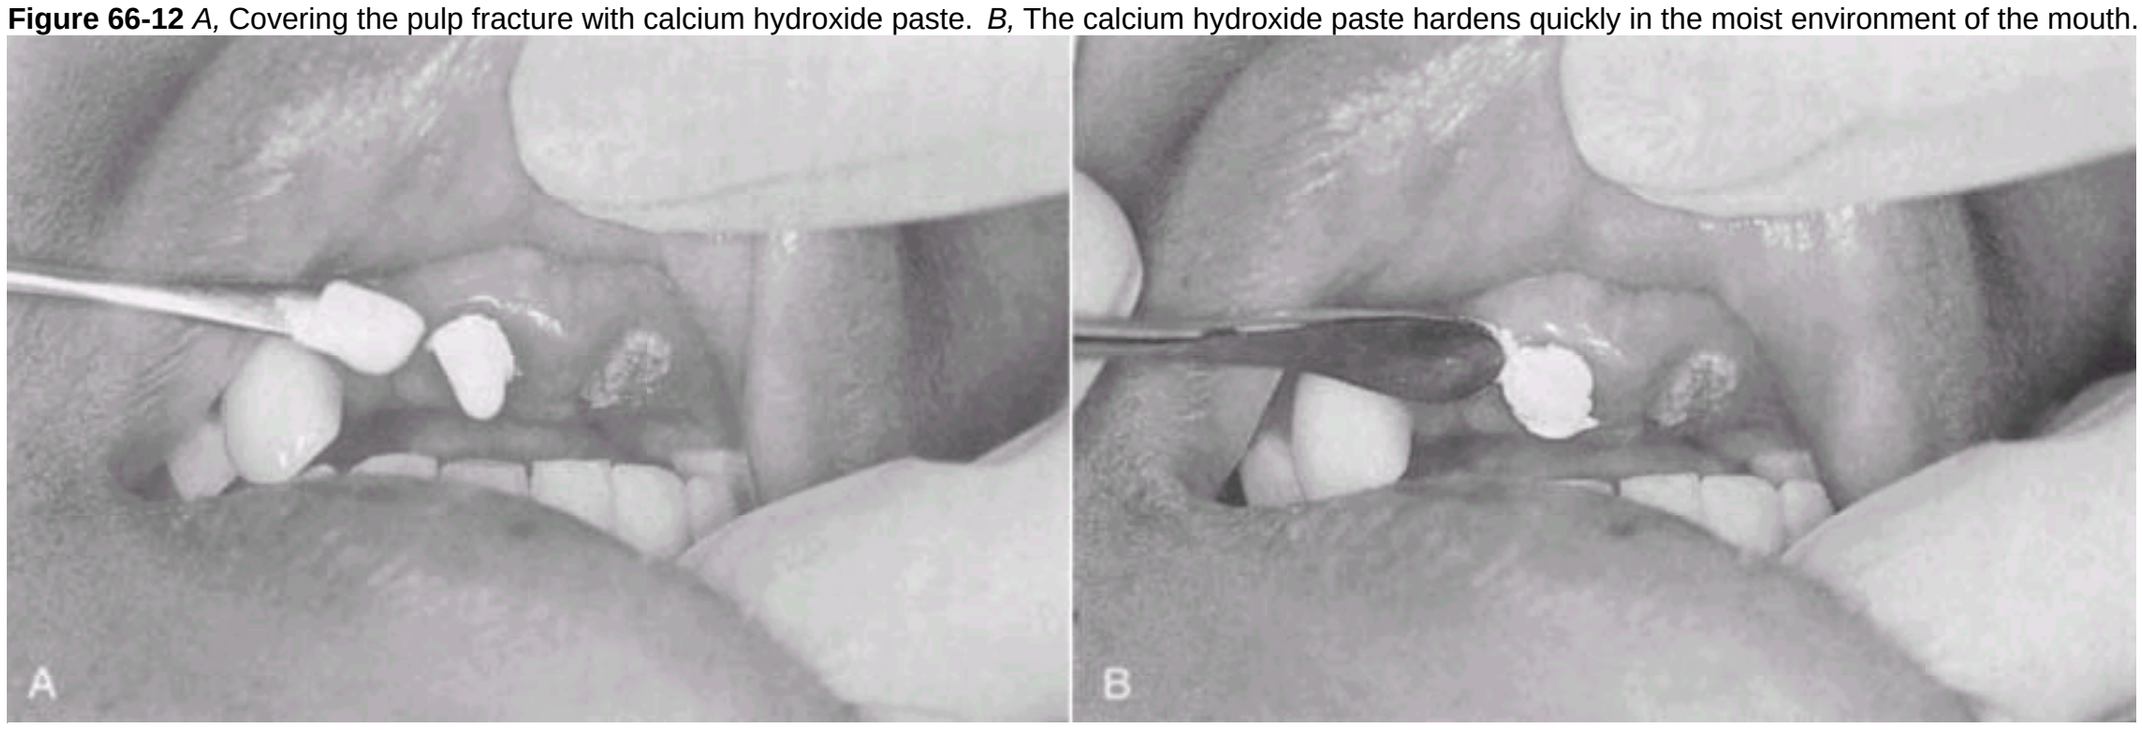

Figure 66-13 Extrusive luxation occurs when the tooth is forced partially out of the socket in an axial direction. *(From King R: Oral-Facial Emergencies-Diagnosis and Management, 1st ed. Portland, OR, JBK Publishing, 1994.)*

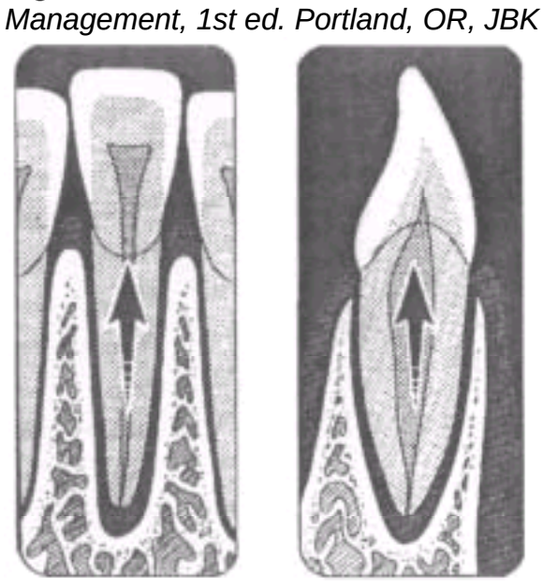

Figure 66-14 Intrusive luxation of a tooth compresses the periodontal ligament and vascular supply of the pulp. It may even crush the apical bone. *(From King R: Oral-Facial Emergencies-Diagnosis and Management, 1st ed. Portland, OR, JBK Publishing, 1994.)*

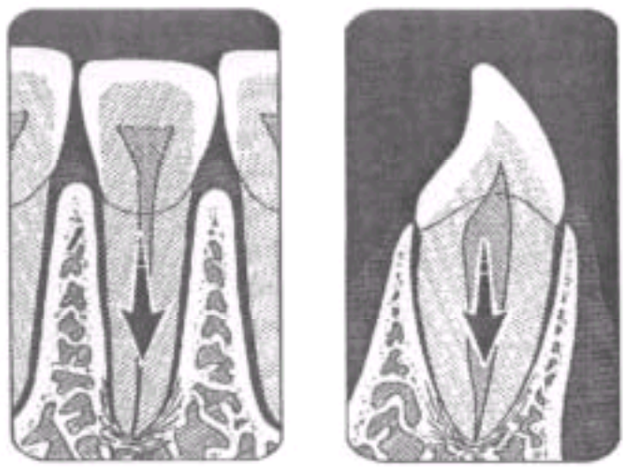

Figure 66-15 Intruded tooth secondary to trauma. On superficial examination it appears that the tooth was simply knocked out. A dental radiograph or CT scan is necessary to determine intrusion or avulsion. Intruded teeth create the potential for infection or cosmetic deformities. Intrusion of an upper tooth into the maxillary sinus can cause recurrent sinusitis. Teeth can also intrude into the nasal cavity and cause infection or bleeding, or they can be aspirated into the airway. The incisors are the most commonly intruded teeth. *(From Johnson R: The treatment of the traumatized incisor in the child patient. In University of Pennsylvania School of Dental Medicine: Continuing Dental Education, vol 2. Philadelphia, University of Pennsylvania, 1978.)*

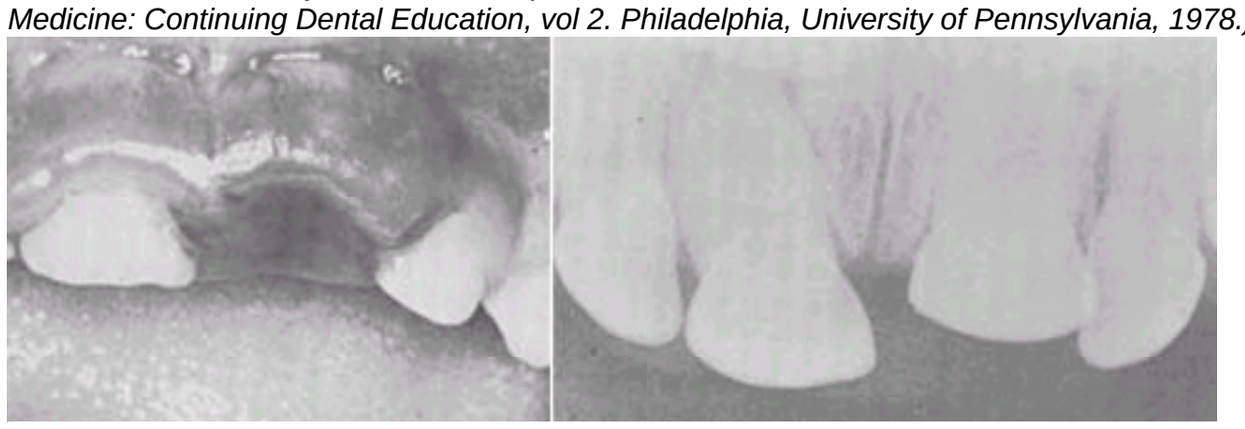

Figure 66-16 Lateral luxation occurs when the tooth is displaced in either a lingual, mesial, distal, or facial direction. Fractures of the alveolus frequently accompany lateral luxation injuries. *(From King R: Oral-Facial Emergencies-Diagnosis and Management, 1st ed. Portland, OR, JBK Publishing, 1994.)*

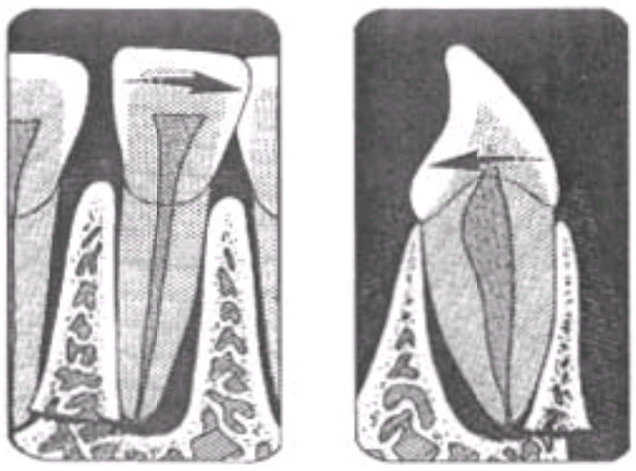

Figure 66-17 Application of Erich arch bars. *A through C,* A commercially available arch bar is shaped to fit the maxillary and mandibular arches. *D and E,* Stainless steel wire secures the bar to the necks of the teeth. *F,* The maxilla and the mandible are brought into occlusion and held in place with rubber bands. This technique is generally not used by the emergency clinician, but this equipment should be available for the oral or maxillofacial surgeon. *(From Converse JM: Reconstructive Plastic Surgery, 2nd ed, vol 2. Philadelphia, WB Saunders, 1977.)*

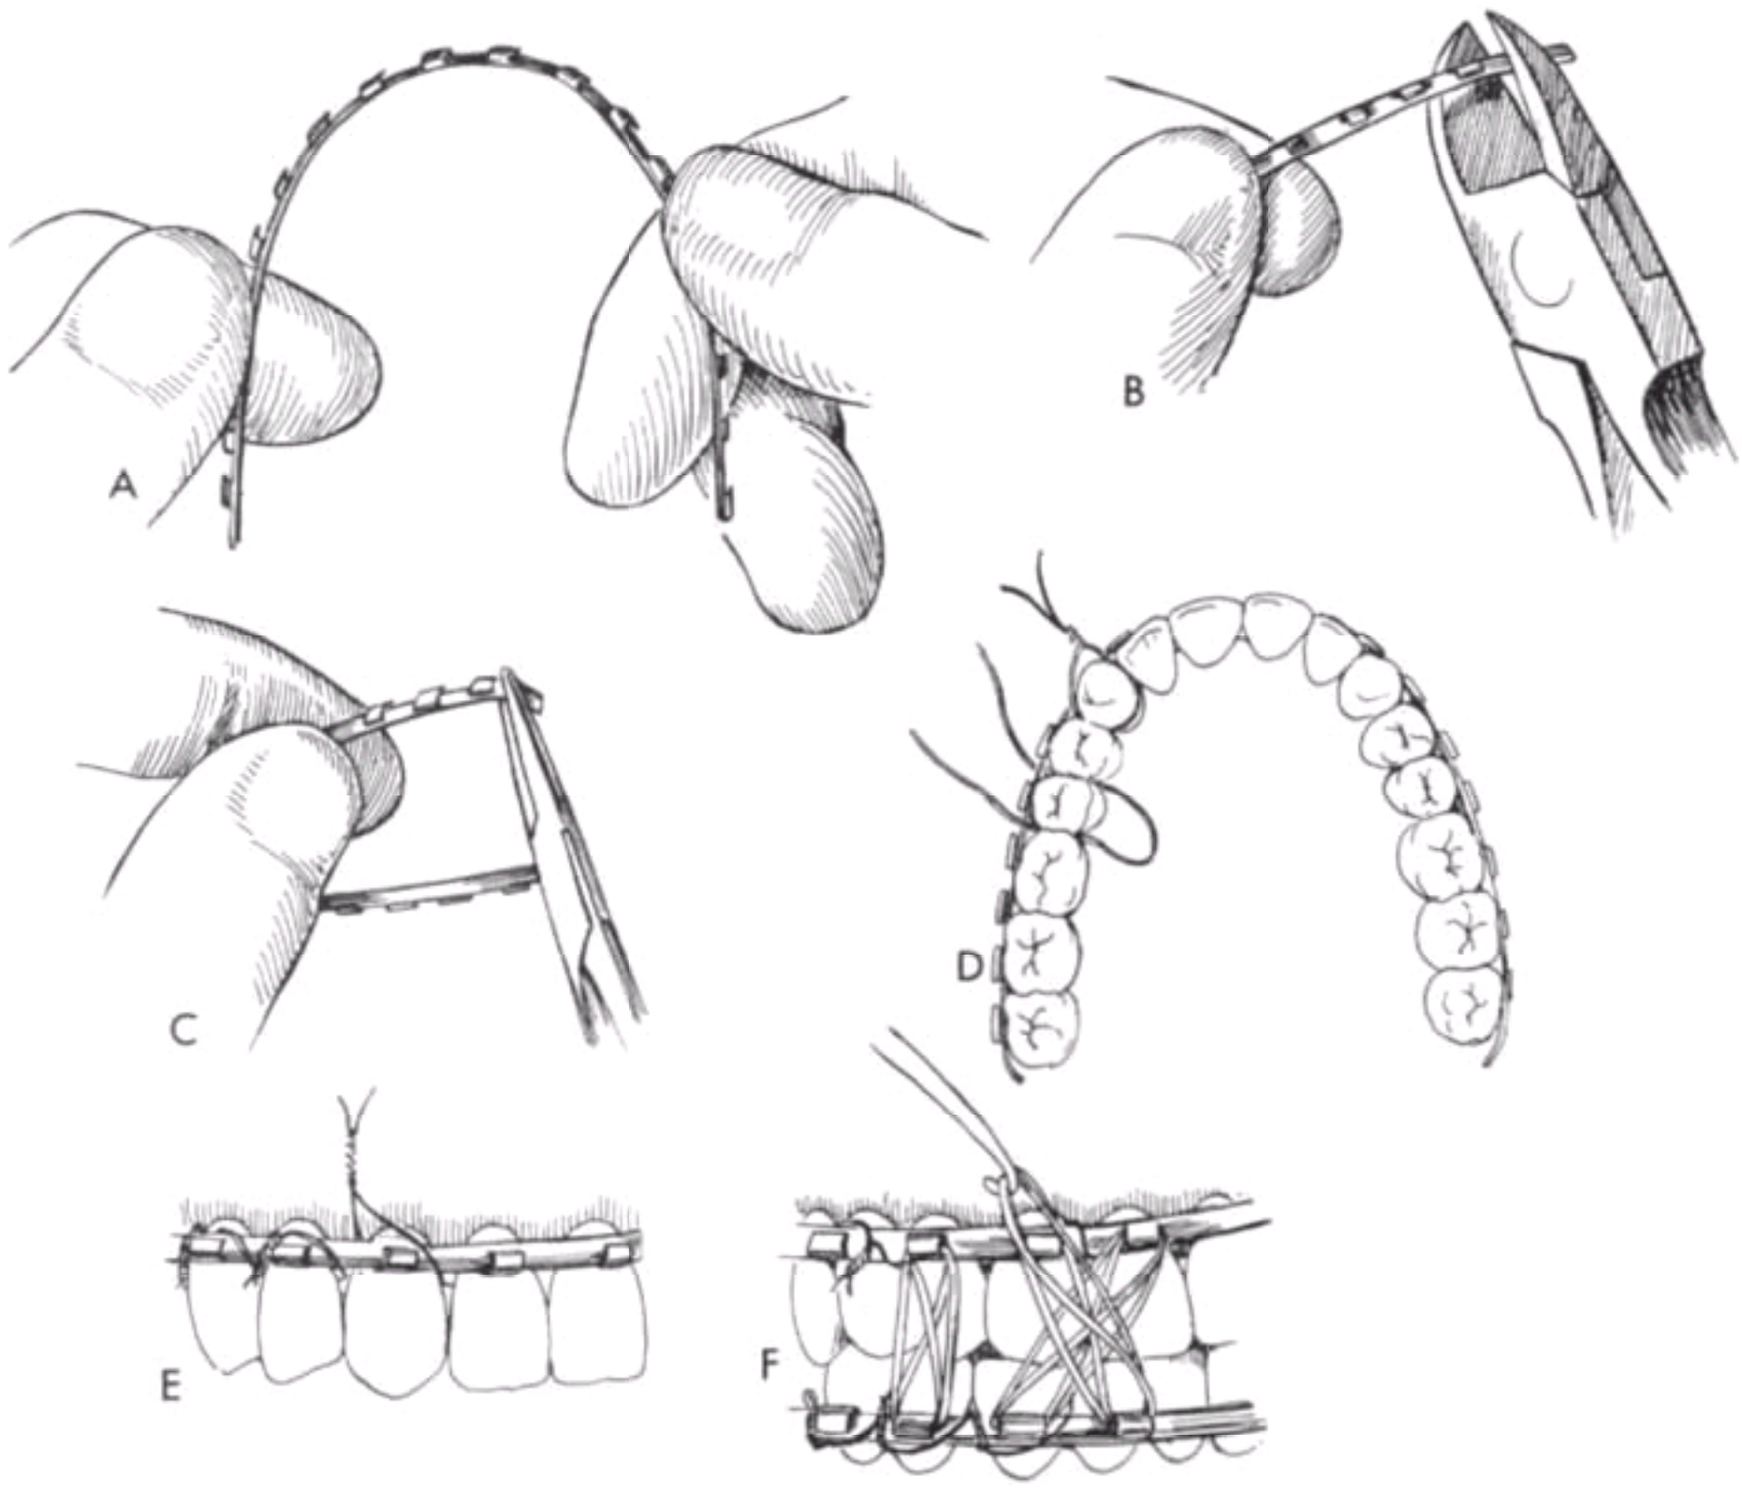

Figure 66-18 *A,* Squeeze out equal-sized ribbons of the periodontal paste. *B,* Mix the base and catalyst together with a tongue blade. *C,* Using moistened gloves, apply the paste to the dry enamel and gingiva.

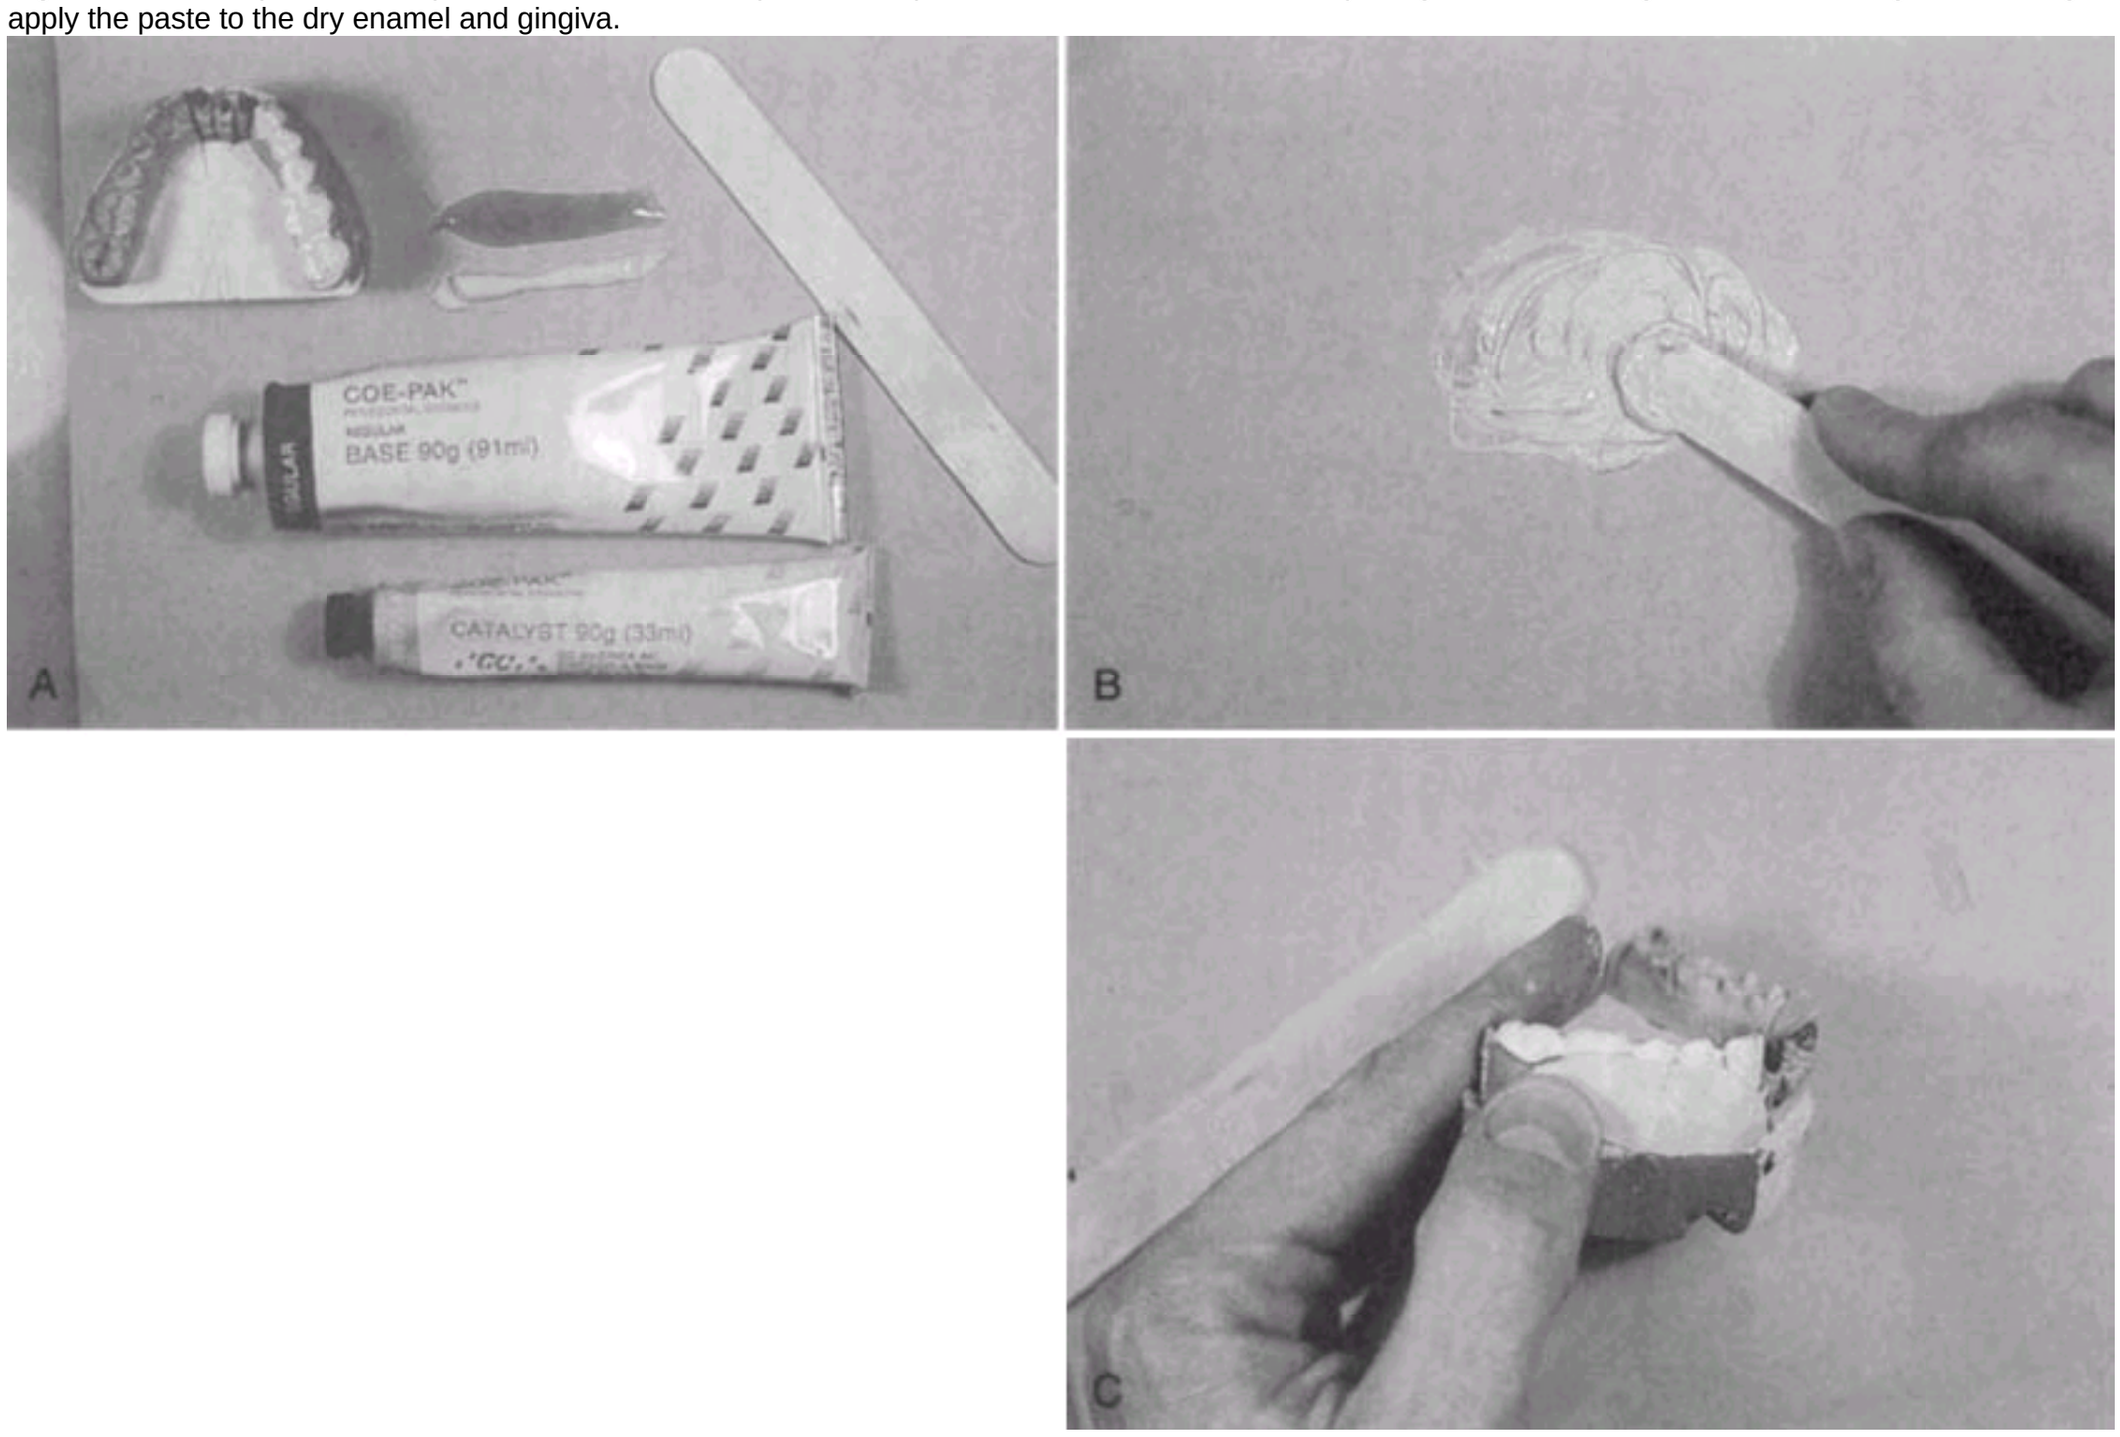

Figure 66-19 Application of periodontal paste. *A,* Equal-length ribbons of base and catalyst are squeezed onto the mixing pad. *B,* The base and catalyst are mixed together using a moistened spatula or tongue blade. *C and D,* Using moistened gloves, roll the mixture into a ribbon. *E through H,* Apply to the enamel and gingiva, extending the paste two teeth on each side of the loosened tooth. The paste adheres best when the surface of the enamel and gingiva are as dry as possible.

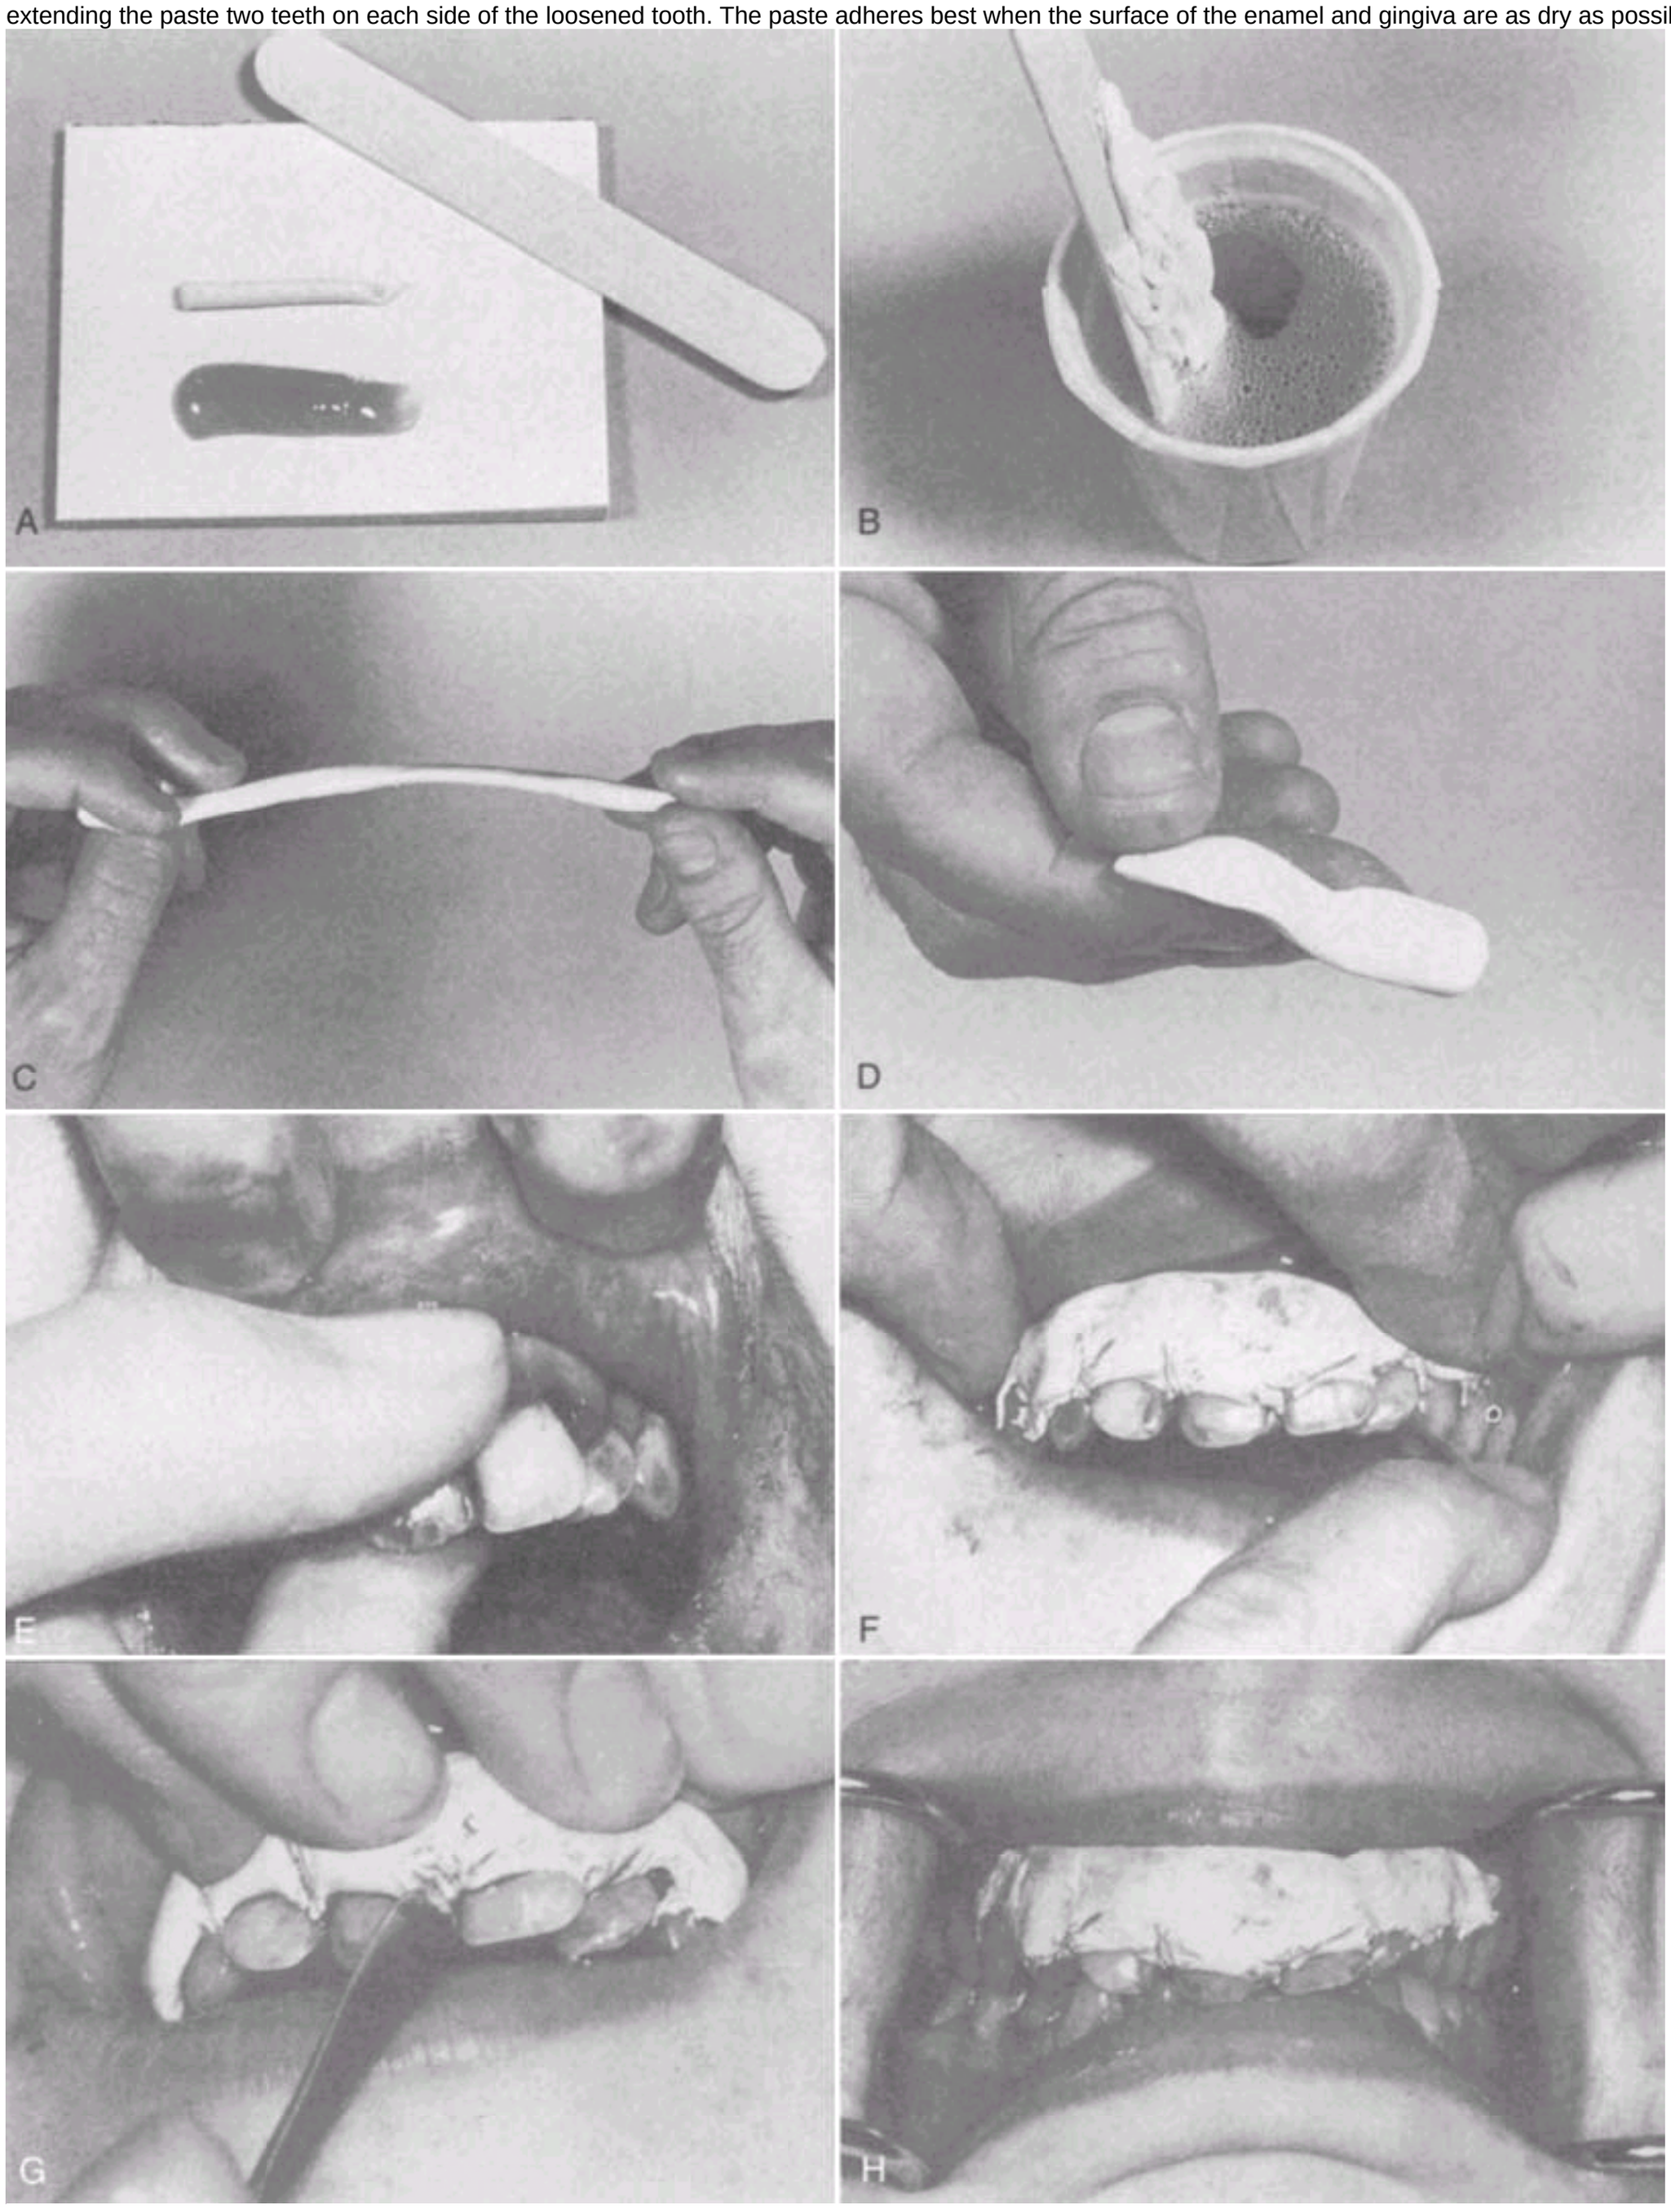

Figure 66-20 *A and B,* Equal amounts of the self-cure composite are placed on the mixing pad and mixed together. *C,* Subluxed teeth should be repositioned prior to application of the composite. *D,* The mixture is applied only to the dry enamel of the teeth. The composite should extend to one tooth on each side of the loosened tooth.

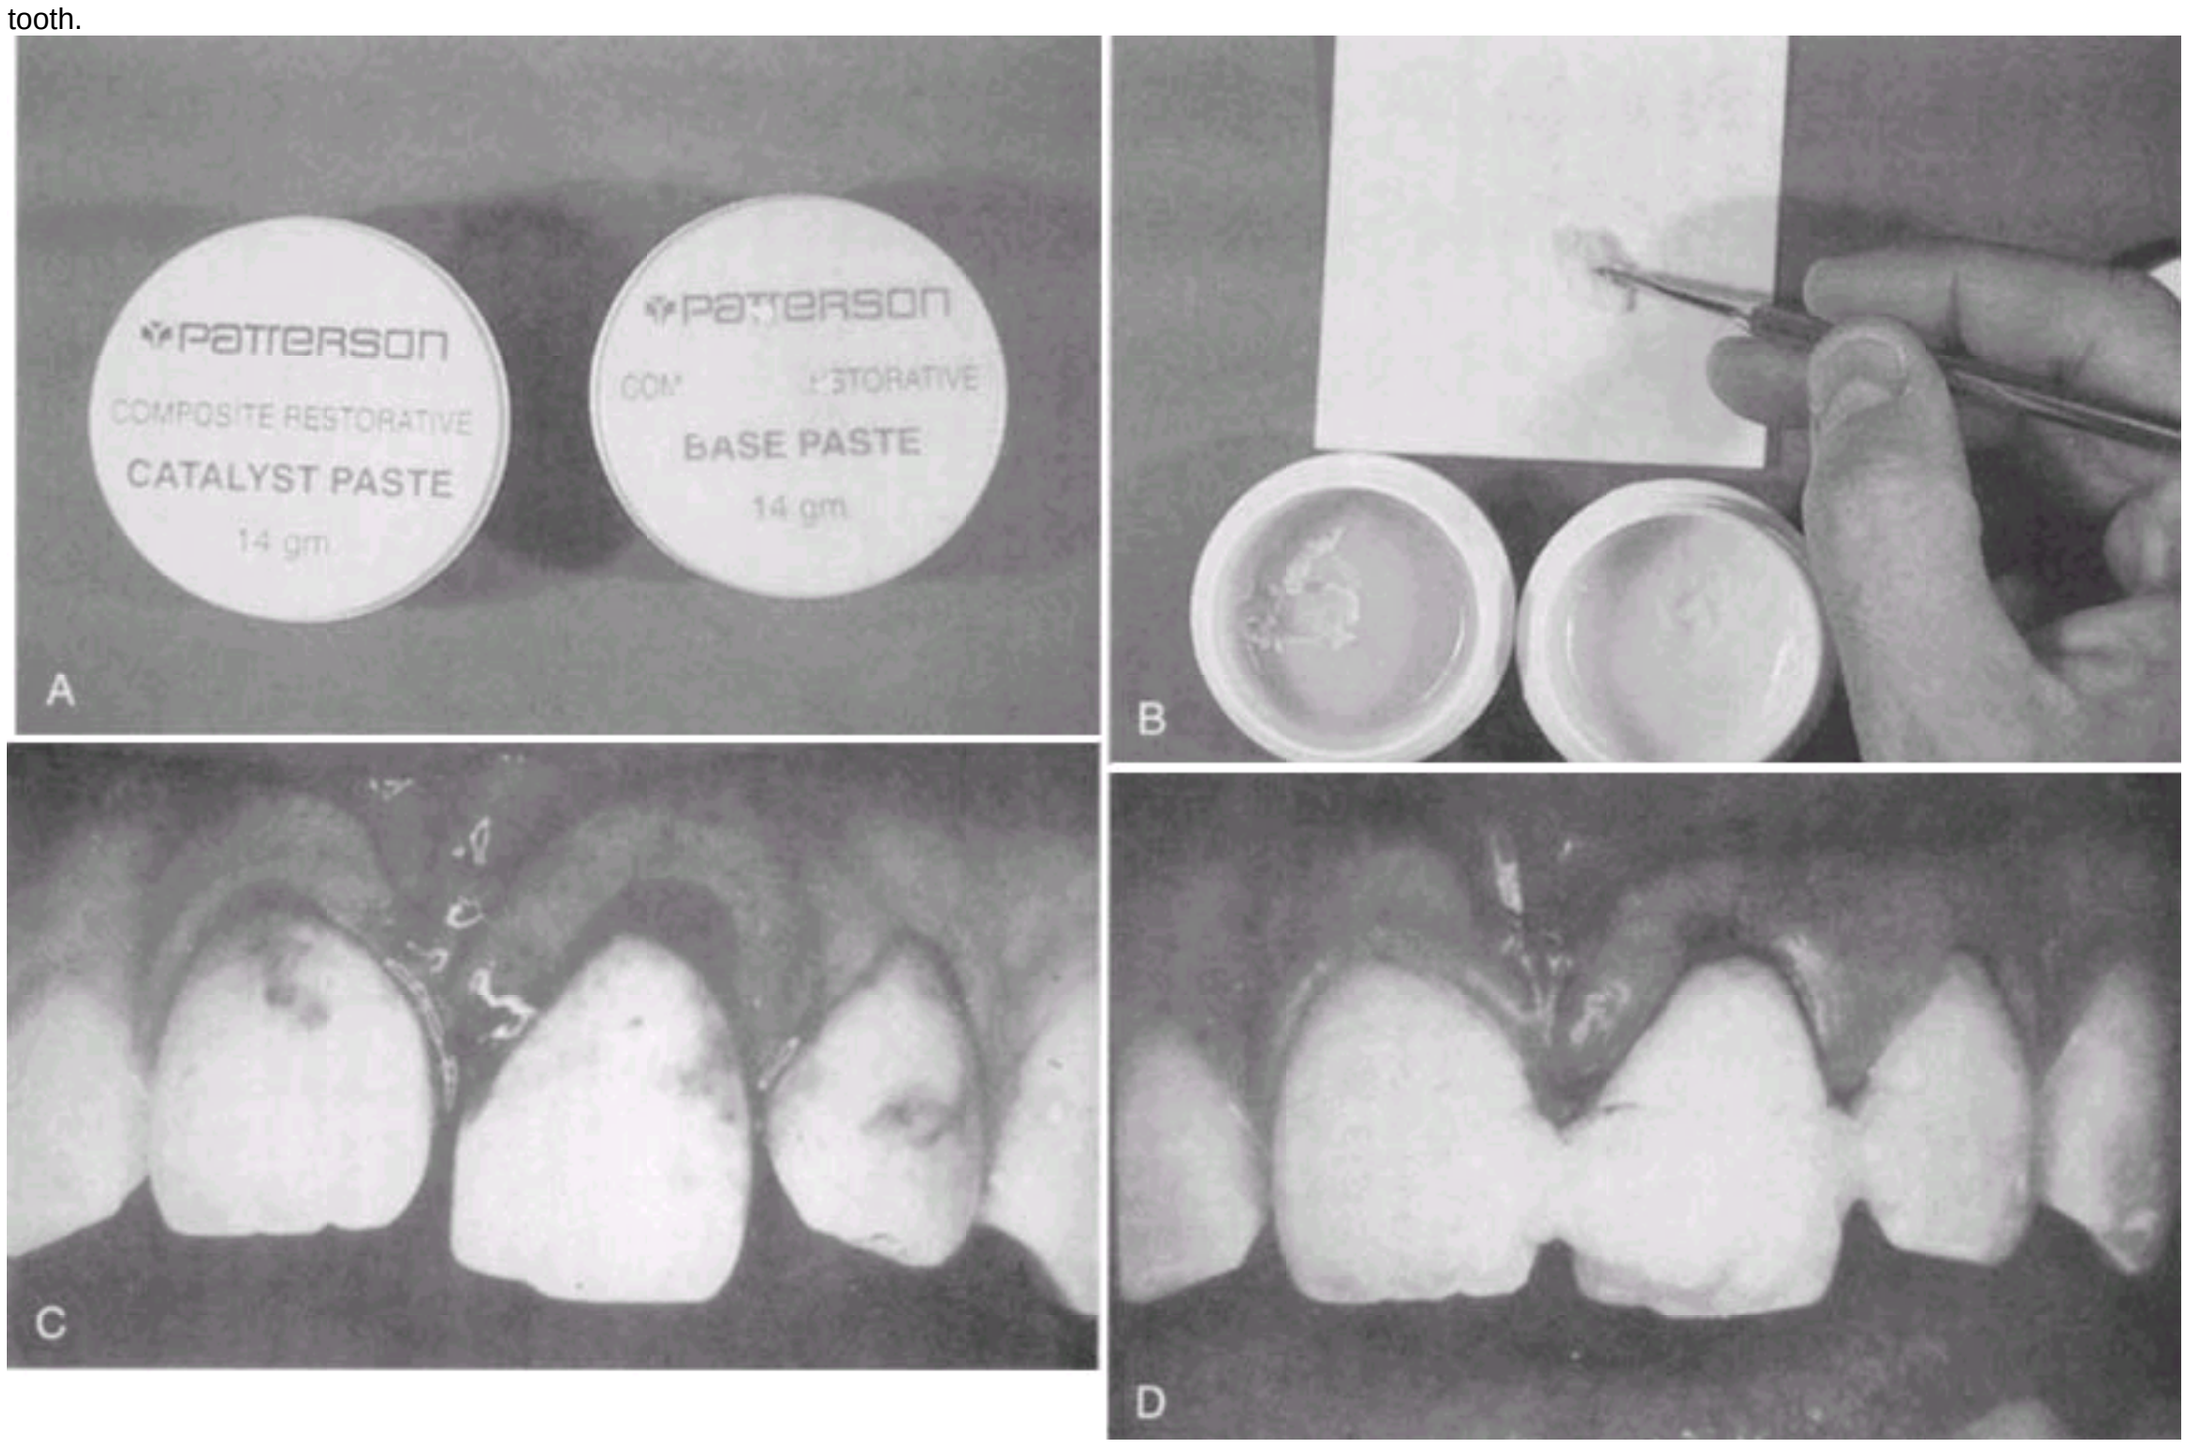

Figure 66-21 Using the "Save A Tooth" system, a tooth is placed into the container and closed. The preservative will increase the life span of traumatized periodontal ligament cells.

Figure 66-22 The Ora 5 Topical Bactericidal Agent can be applied to intraoral lacerations or injuries to help prevent infection.

Figure 66-23 *A,* Gingival lacerations sometimes leave little tissue for approximation. *B,* The teeth can be used as anchors for sutures and help approximate the lacerated tissue. *C,* Gingival lacerations usually heal rapidly. (See also Fig. 66-24 .)

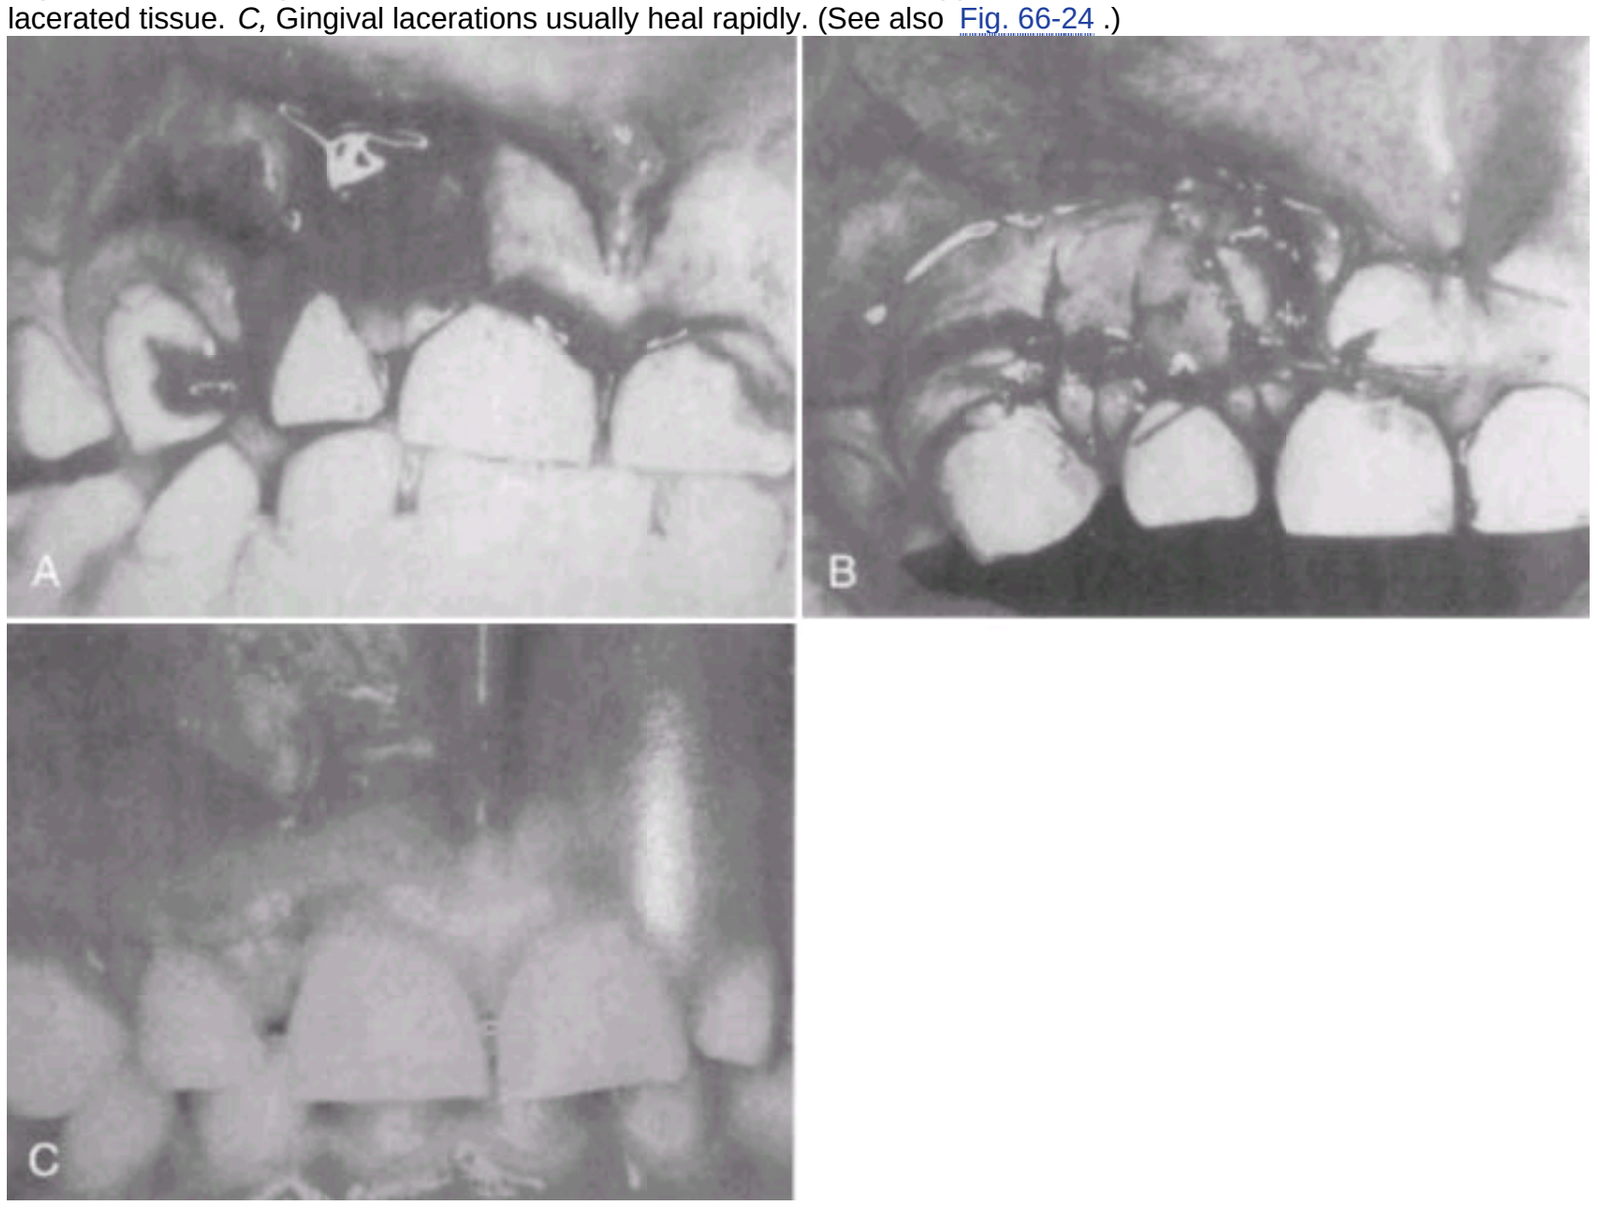

Figure 66-24 Repair of avulsed or lacerated gingiva. *A,* simple flap lap lacerations are approximated and closed with interrupted soft sutures, such as dexon or vicryl. *B,* Large gingival avulsions should be approximated to an anatomical position with interrupted sutures. *C1,* The exposed roots of the teeth should be covered. The thin and friable avulsed gingiva can not be sutured to the remaining gingiva or submucosal tissue. *C2,* The suture begins on the outer surface of the avulsed flap and is passed behind an anchoring tooth, like dental floss. The underside of the avulsed segment is then entered by the suture needle so the needle exits on the gingival surface. *C3,* Sutures pull the gingival to an anatomical position to cover the roots of the teeth and are tied on the outer surface. Sutures are removed in 5–7 days. See also Figure 66-23 .

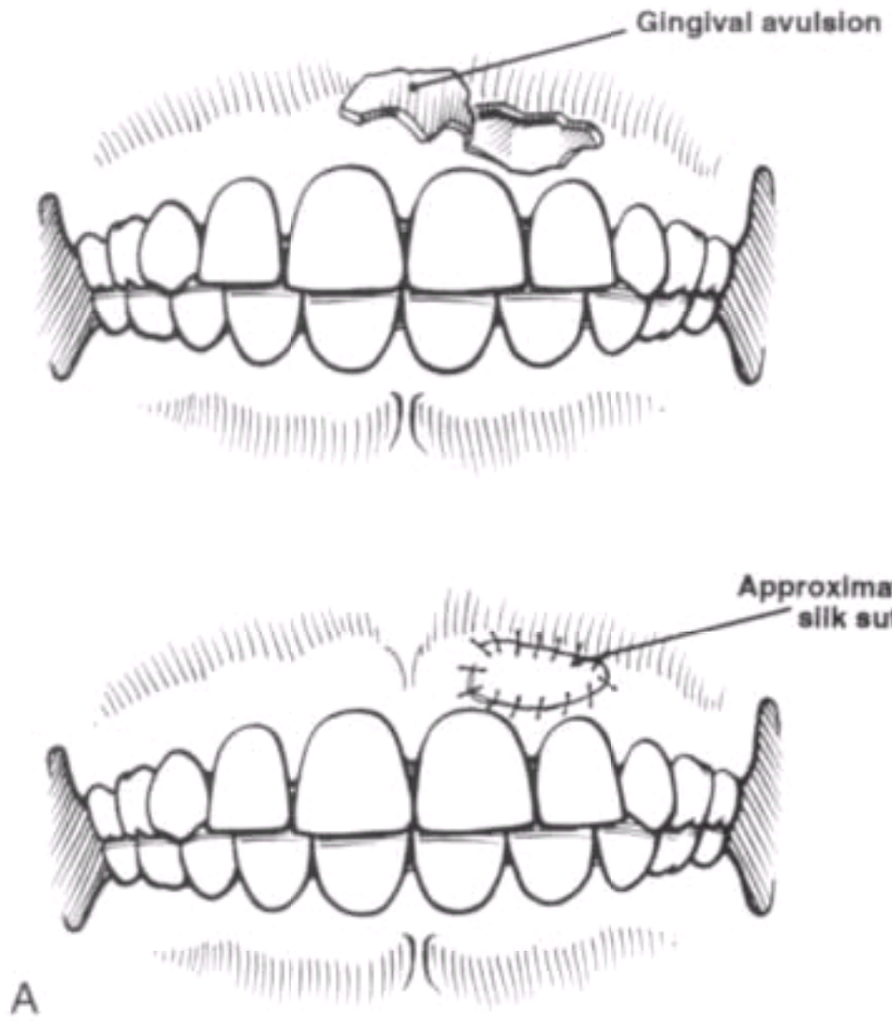

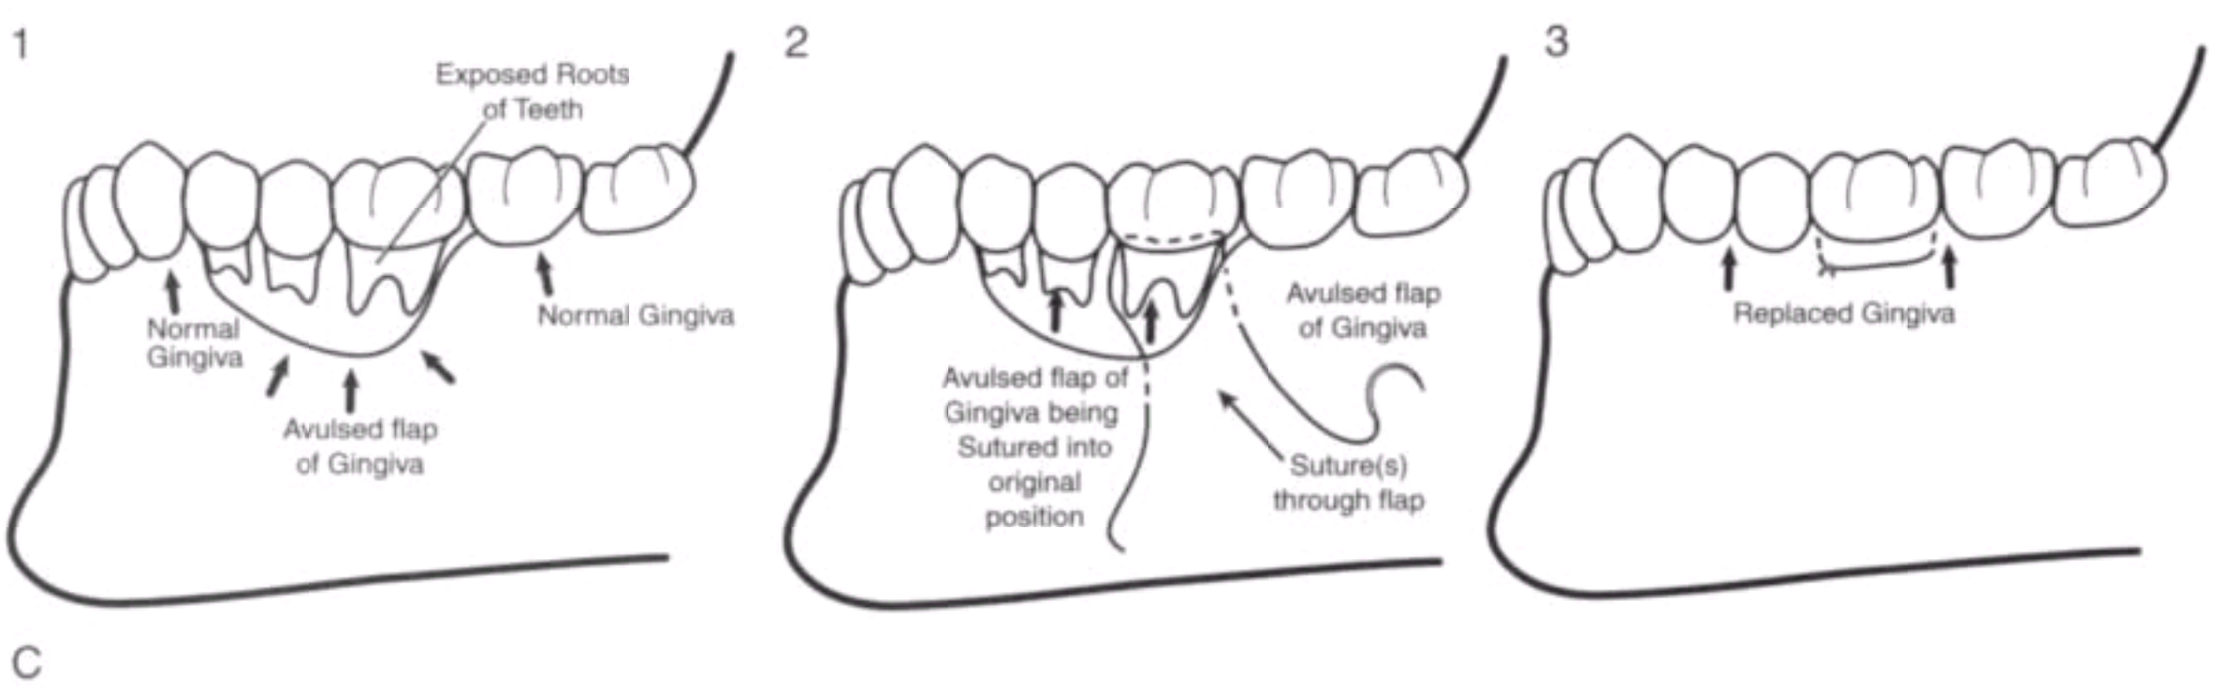

Figure 66-25 Dry Socket Paste. Apply alone or as a slurry mixed with Gelfoam into the socket to relieve alveolar osteitis pain.

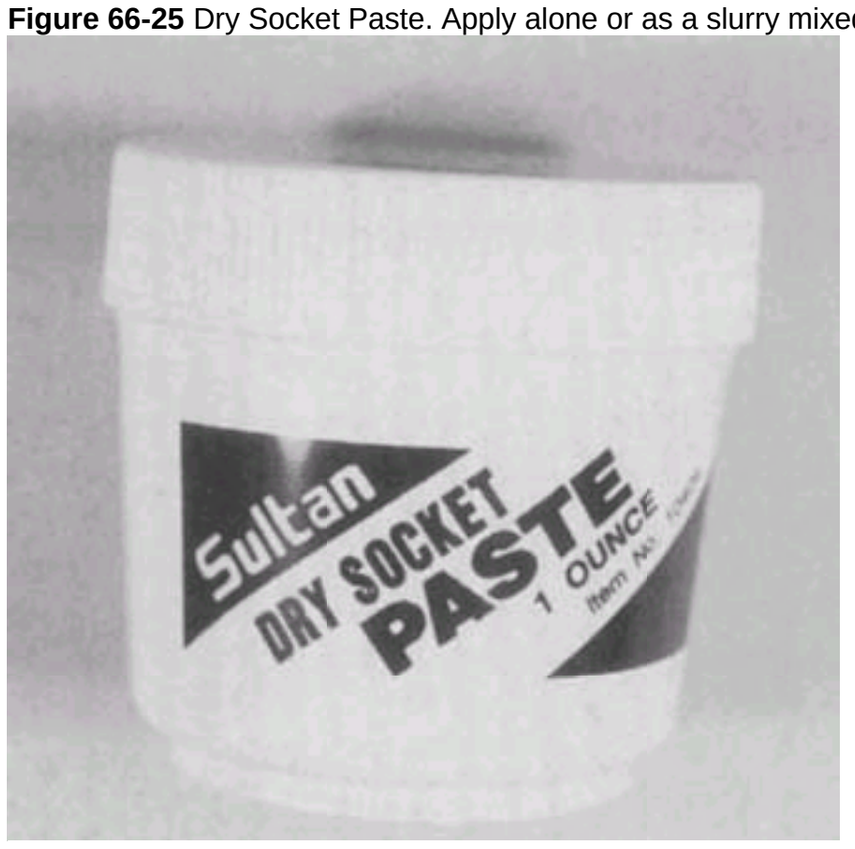

Figure 66-26 Equipment for incision and drainage of dental infection. From left to right on lower row. Cotton-tipped applicators, dental (aspirating) syringe with local anesthesia, topical anesthetic and 2 × 2 gauze, scalpel with No. 11 blade, hemostat, iris scissors, gauze (Nu-gauze) packing, and needle holder.

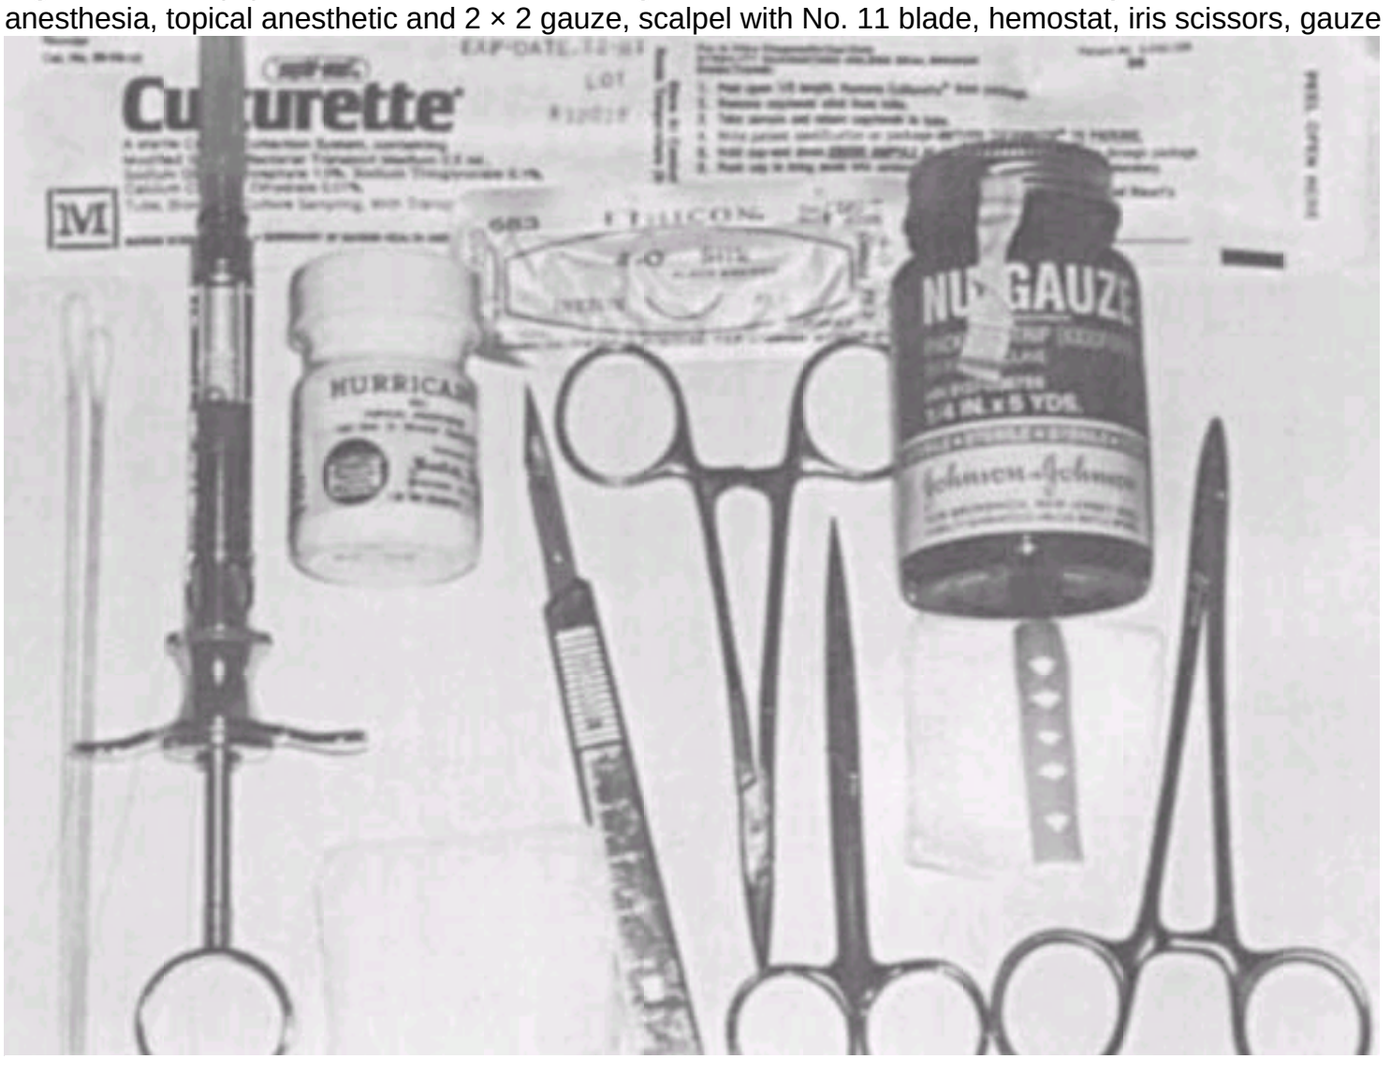

Figure 66-27 *A,* This patient presented with facial swelling up to the right eye. She had minor tooth pain but mostly complained of an ache in the face. X-rays revealed maxillary sinusitis with an air-fluid level. *B,* Intraoral examination revealed a pea-sized pointing abscess at the base of an upper tooth, the cause of sinusitis. *C,* Following local anesthesia, a blade incised the abscess, with drainage of copious pus. *D,* A hemostat was inserted into the abscess cavity to assure drainage, and a small piece of gauze was placed into the cavity. IV antibiotics (clindamycin) followed by oral antibiotics were given, the patient saw her dentist the next day, and plans to extract the tooth were made. She recovered fully.

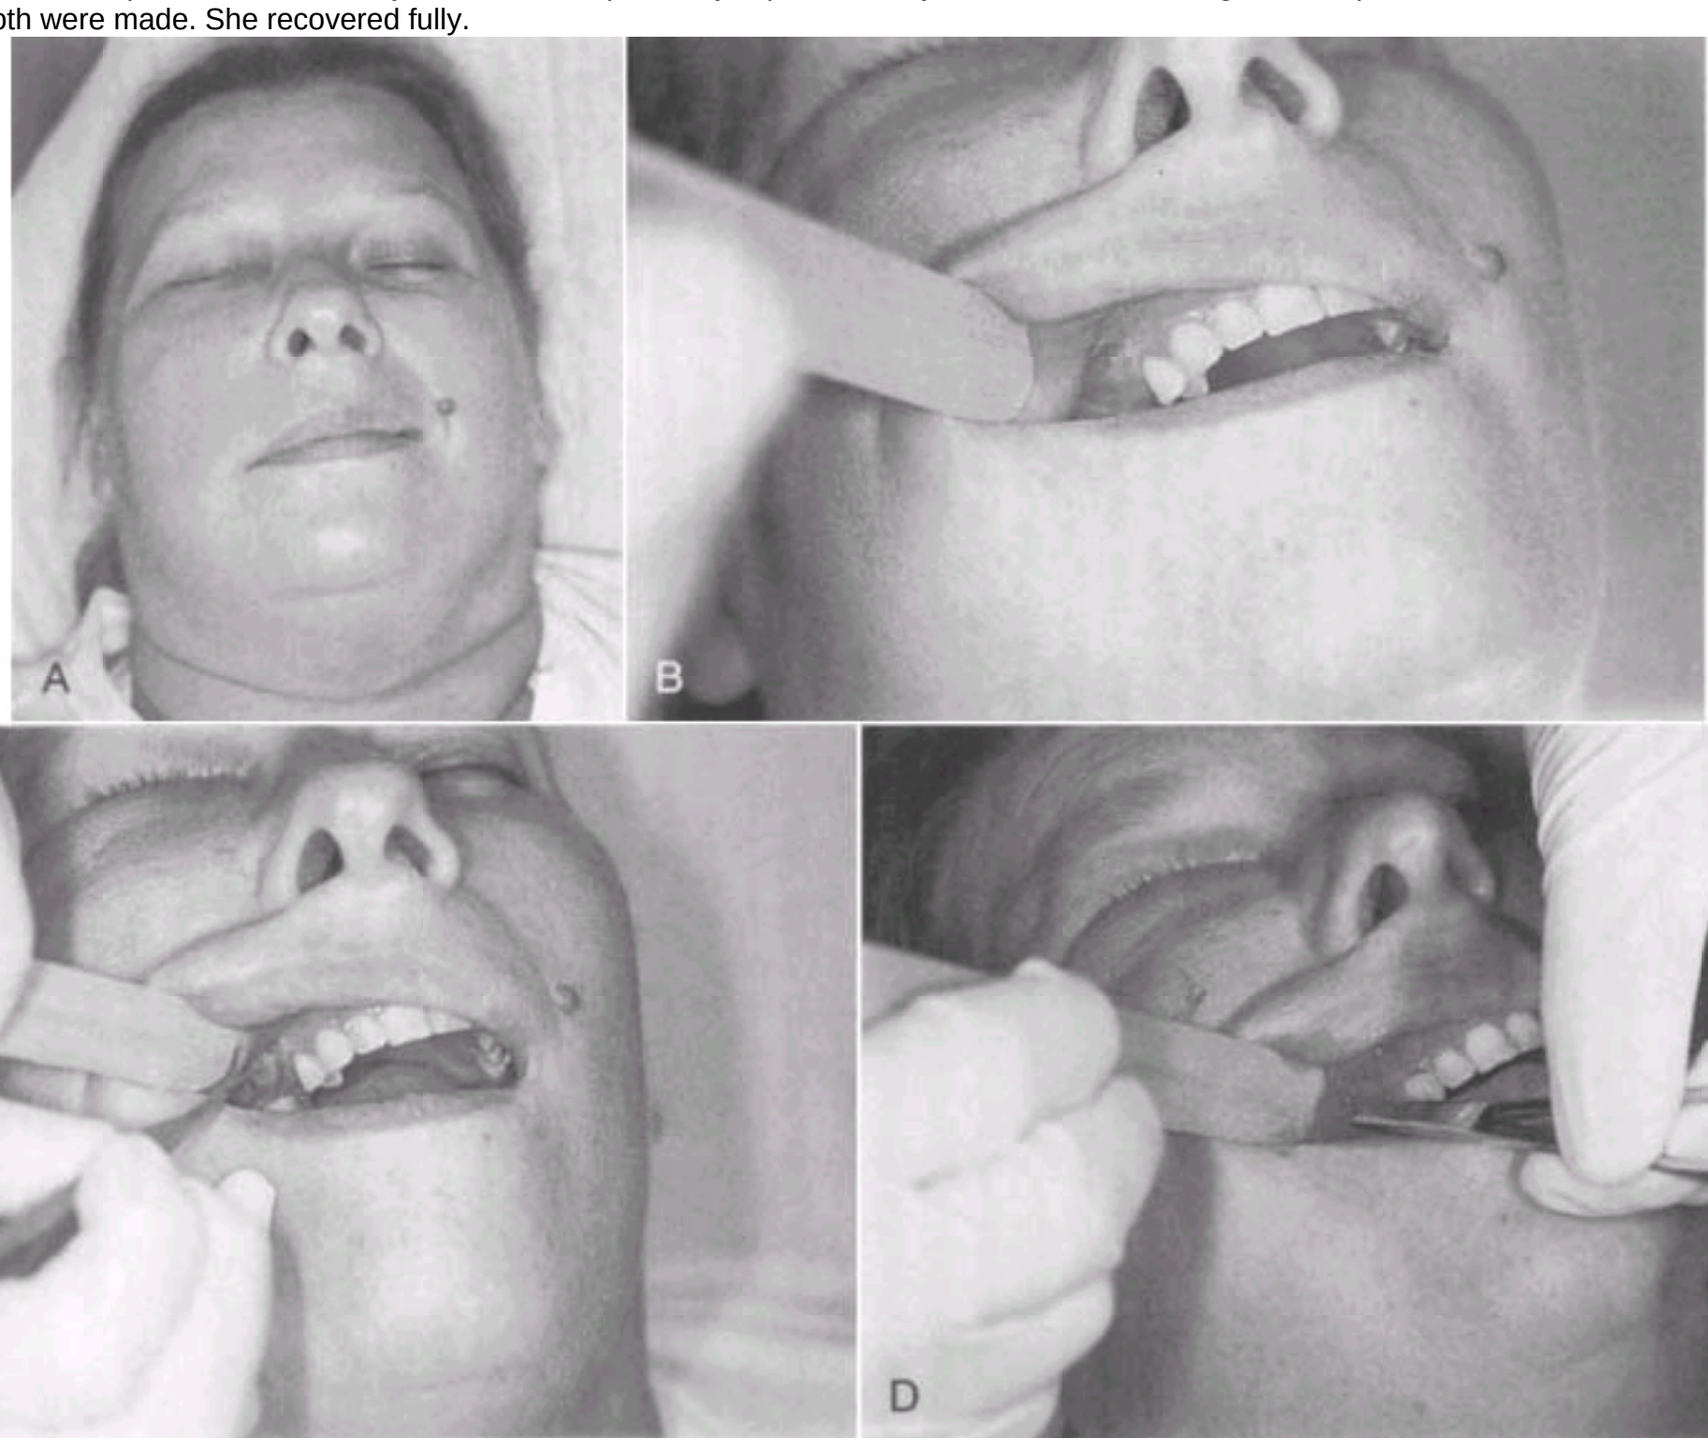

Figure 66-28 *A,* Most dental infections associated with facial swelling should be drained intraorally. Illustration of a facial abscess that points extraorally. *B through F,* Technique of cutaneous drainage in a second patient. *B,* Anesthetic infiltrated below abscessed area. *C,* Incision. *D,* Drainage with blunt dissection. *E,* Gauze packing. *F,* Gauze sutured in place. This step may be omitted if desired. *G and H,* Osteomyelitis of the jaw presenting as a dental problem. This patient had a toothache for weeks that had turned into an abscess pointing on the side of the face. She had been to several emergency departments and was given prescriptions for antibiotics. No history of trauma was forthcoming. *G,* An obvious pointing abscess over the mandible. *H,* A panorex x-ray revealed an old fractured mandible with osteomyelitis draining into the soft tissues.

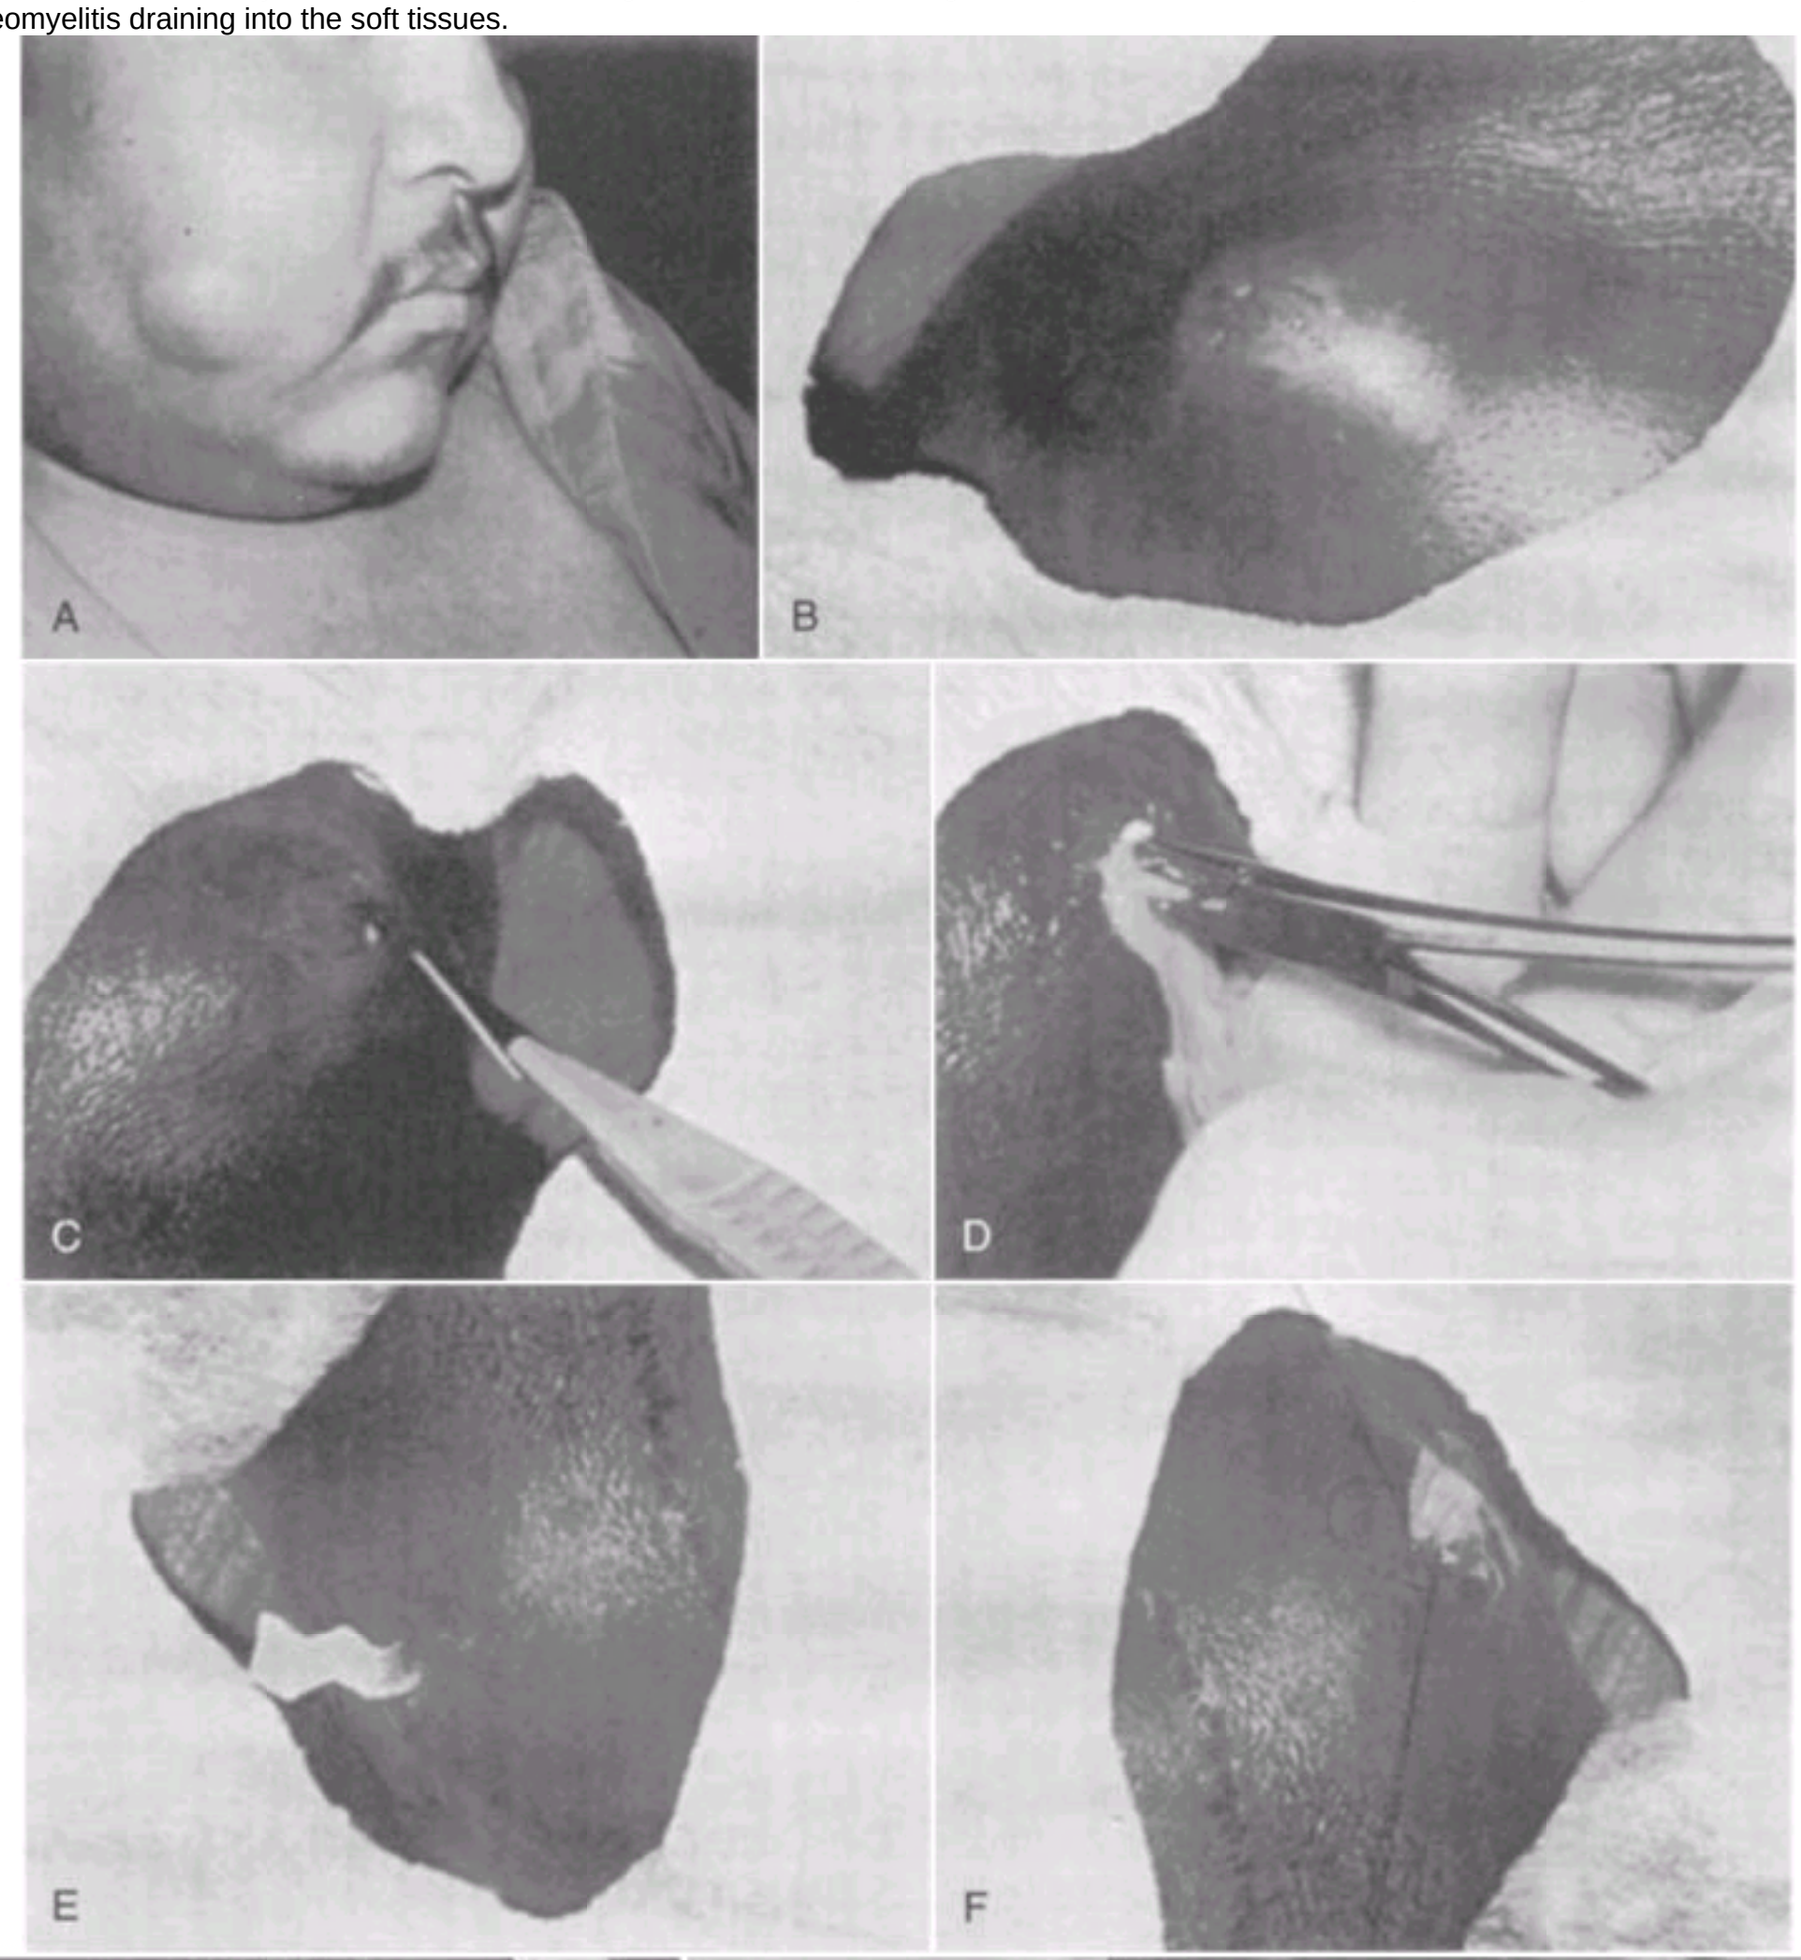

Figure 66-29 *A*, For persistent bleeding of a tongue, mucosa, or dental extraction site, topical thrombin can be sprayed onto gelfoam. *B*, A tongue laceration like this will heal well without sutures once bleeding is controlled. Topical thrombin may be an option if hemostasis is problematic.

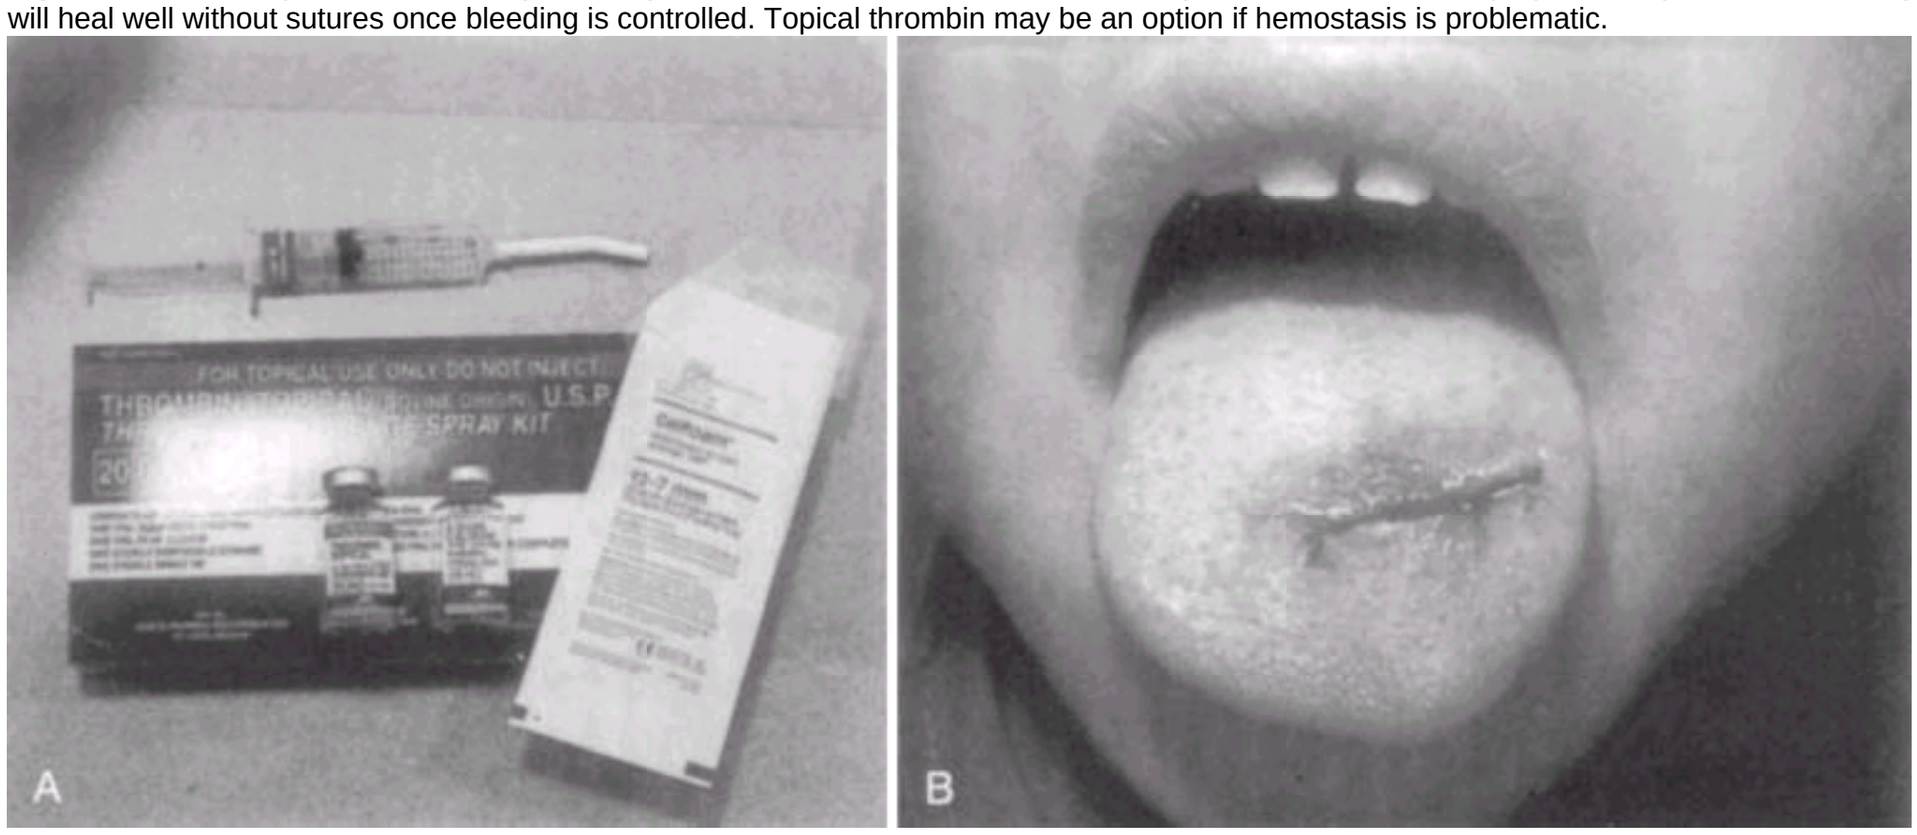

Figure 66-30 *A,* Location of temporal space abscesses. *B,* Route of infection into the buccal space, vestibular spaces, submandibular space, sublingual space, and palatal space. *(From Eisele D, McQuone S: Emergencies of the Head and Neck, 1st ed. St. Louis, MO, Mosby, 2000.)*

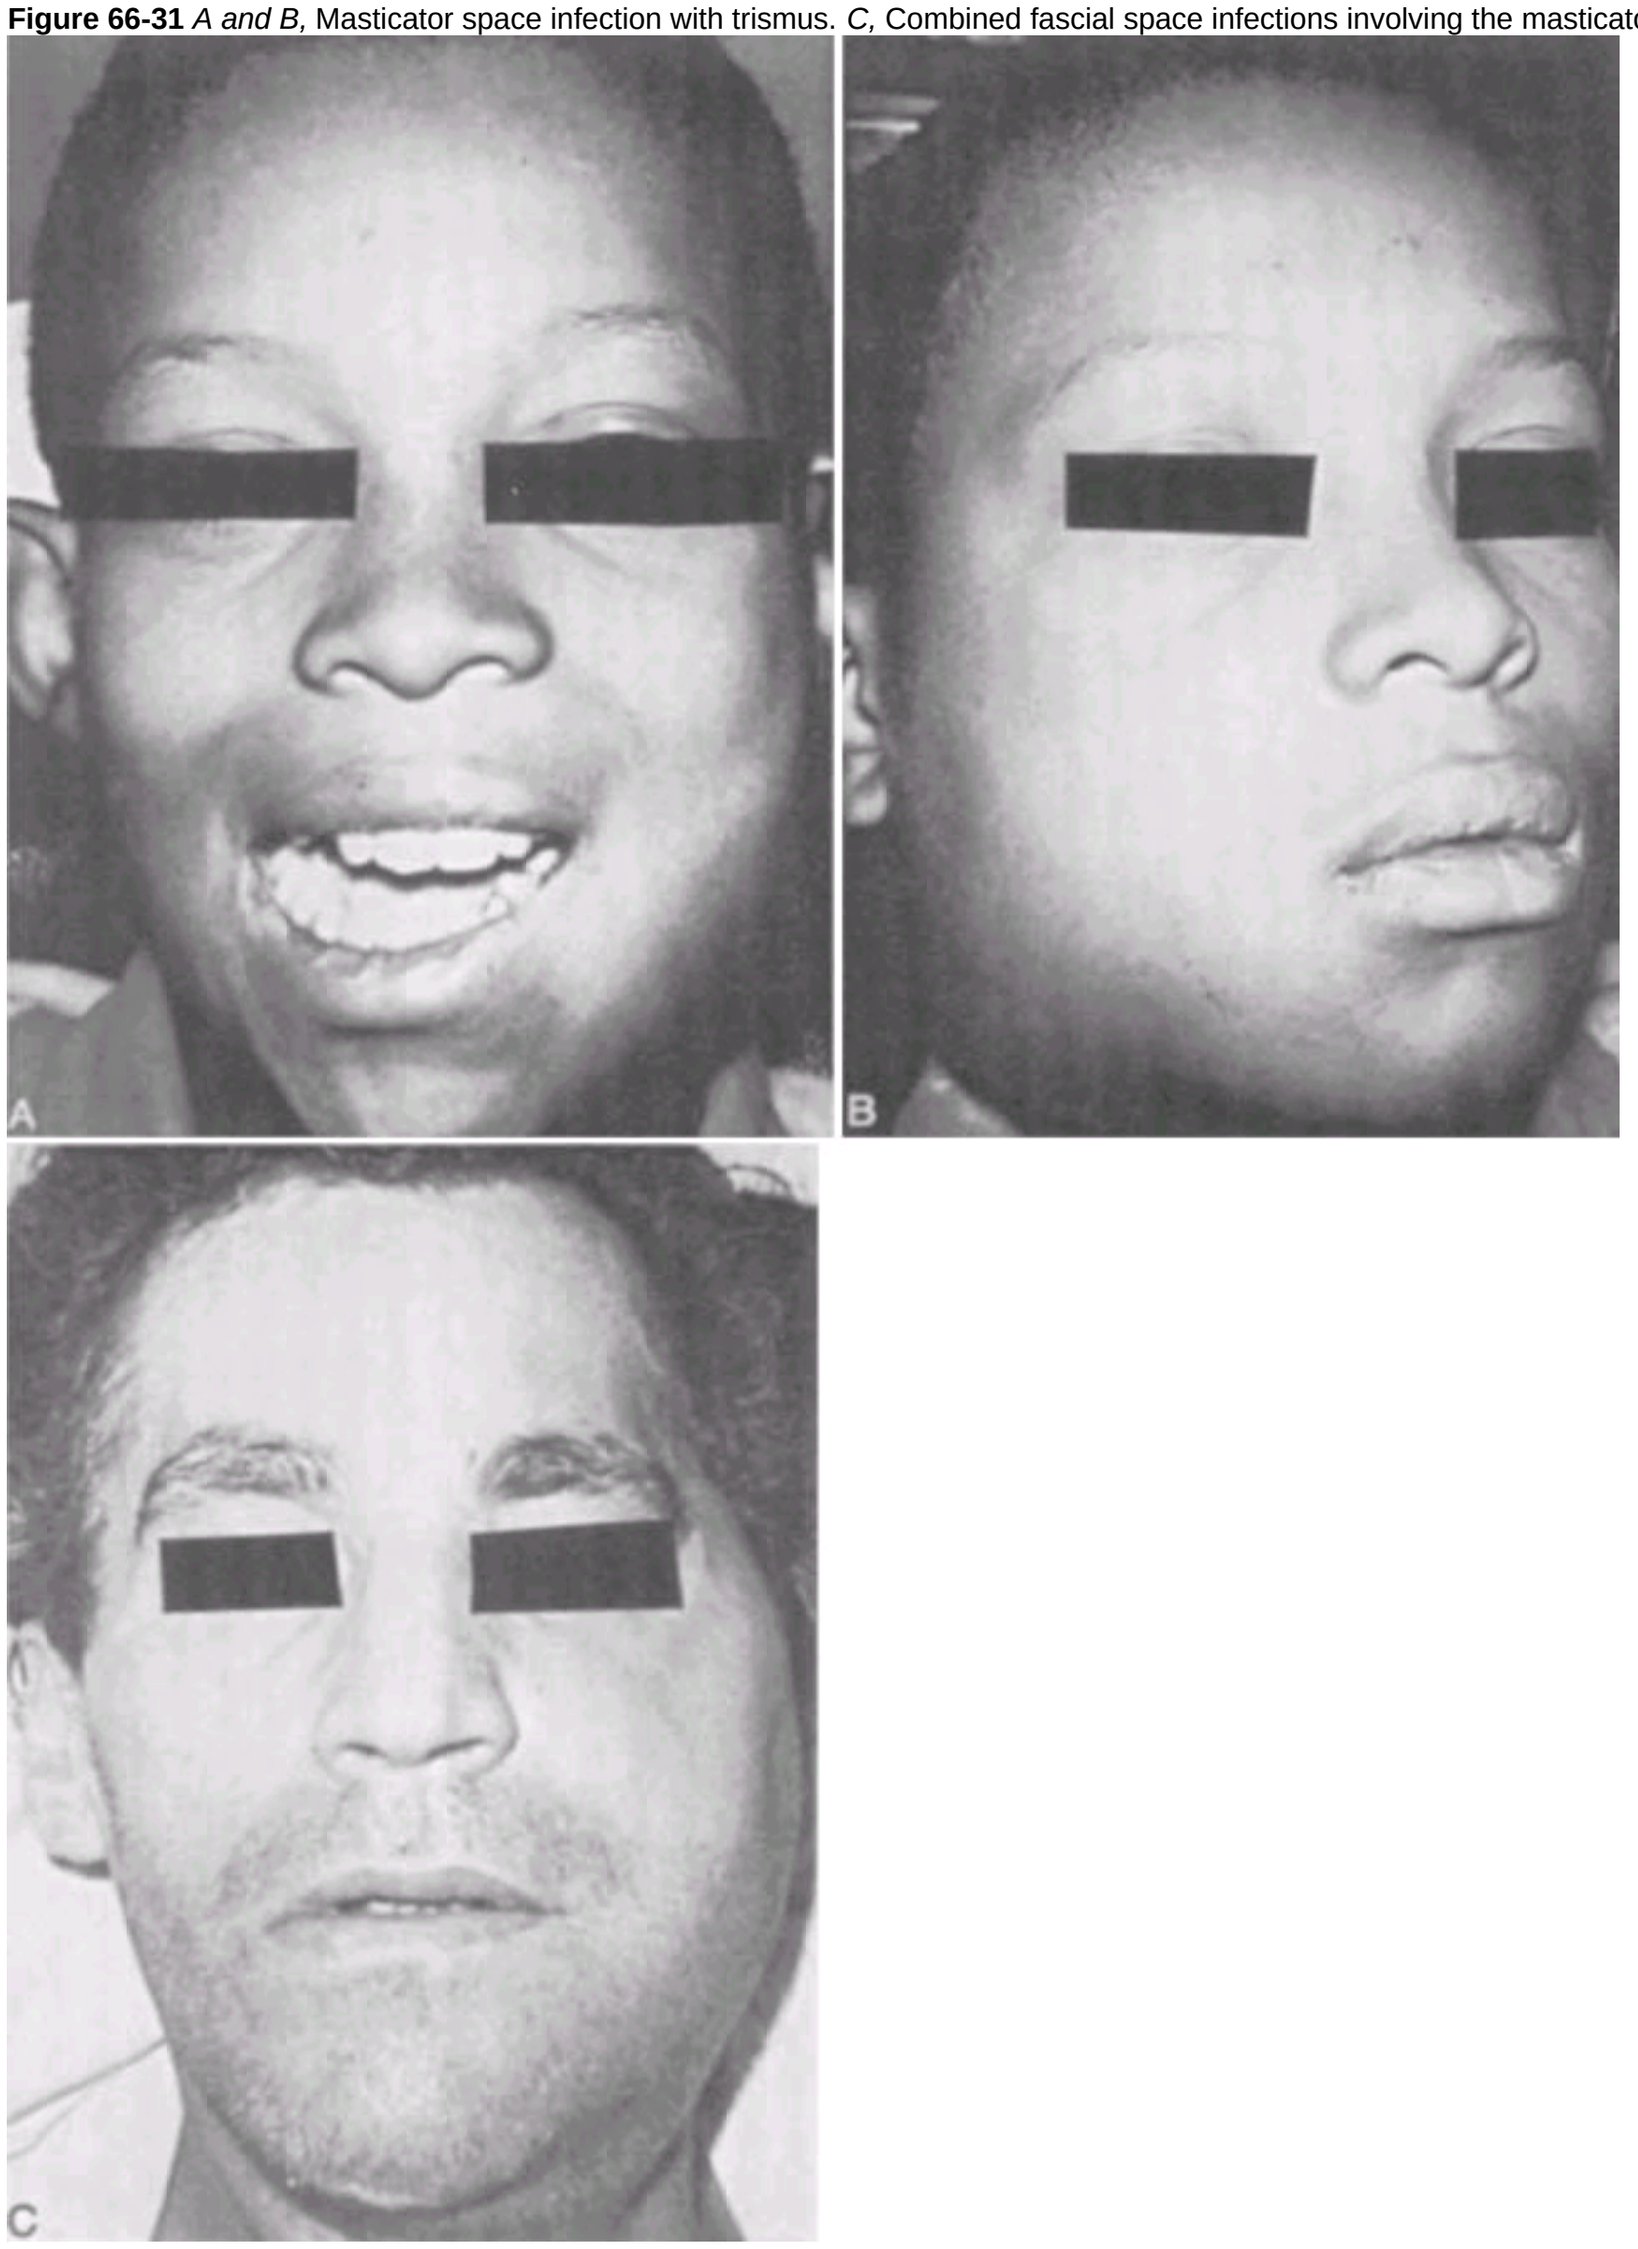

Figure 66-32 *A,* Ludwig angina may initially appear benign. *B,* In Ludwig angina, rapid progression may compromise the airway in a few hours.

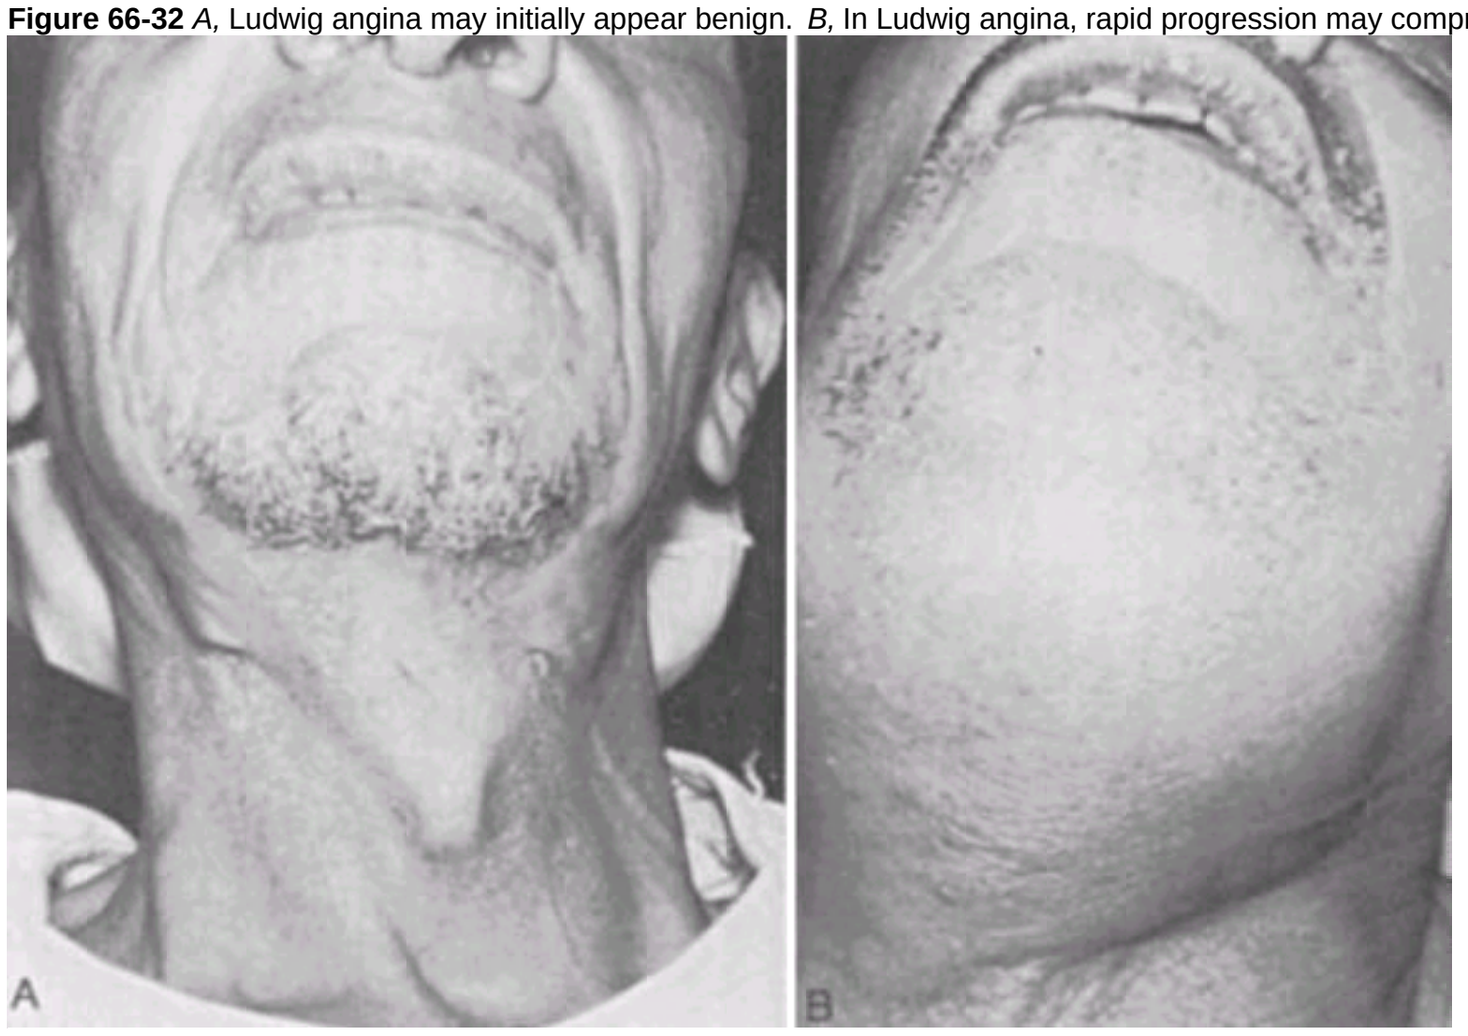

Figure 67-1 Electric thermometer (without probe). This is model 43TA with Fahrenheit and Celsius scales. Infrared tympanic membrane thermometers are acceptable alternatives, but the rectal probe has the advantage of providing a continuous readout. *(Image courtesy of Yellow Springs Instrument Company, Yellow Springs, OH.)*

Figure 67-2 Temperature conversion scale. To change Celsius (centigrade) to Fahrenheit, multiply the Celsius temperature by 9/5 and add 32. To change Fahrenheit to Celsius, subtract 32 from the Fahrenheit number and multiply by 5/9.

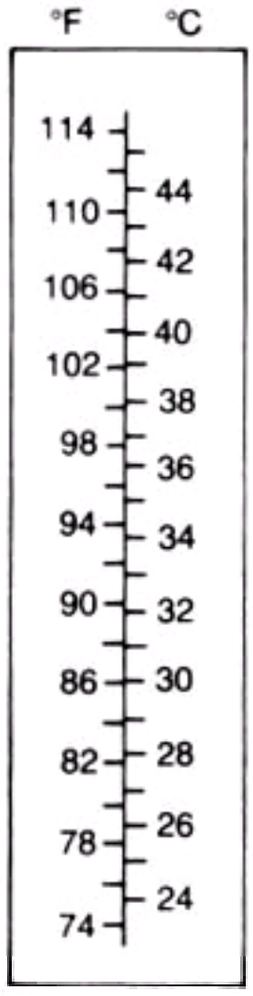

Figure 67-3 In severe hypothermia, the electrocardiogram (ECG) exhibits marked elevation of the J deflection, so-called Osborne waves. The height of the J wave is proportionate to the degree of hypothermia, and this finding is usually most marked in the midprecordial leads. The ECG is of a patient with sinus bradycardia, but approximately half of patients with a temperature below 32°C (89.6°F) develop slow atrial fibrillation, a rhythm that usually converts spontaneously with rewarming. *(From Marriott HJ: Practical Electrocardiology, 8th ed. Baltimore, Williams & Wilkins, 1988.)*

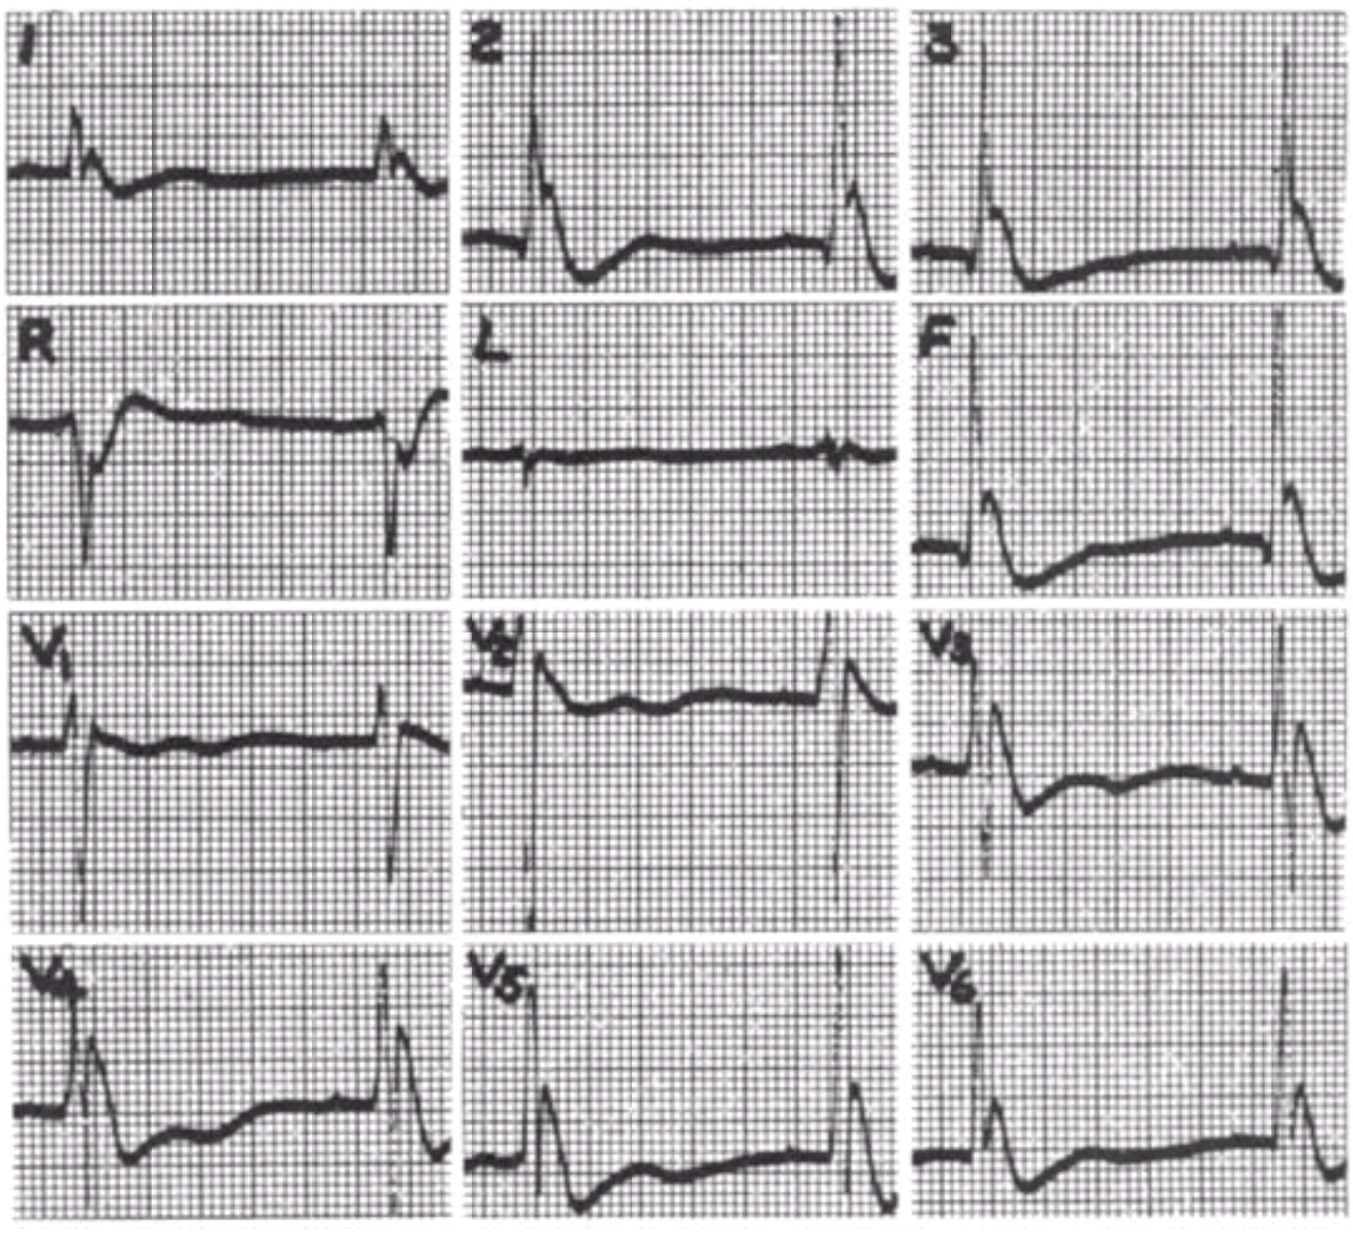

Figure 67-4 Passive external rewarming features. Further heat loss must be stopped through insulation and environmental manipulation. Damp clothing is removed. Dry, warmed blankets are applied. Warmed intravenous fluids are given to counteract the cold-induced diuresis. Internal heat generation is required for rewarming. Rewarming rates are relatively slow. Aggressive intervention with drugs and invasive monitoring may be more harmful than helpful in the otherwise stable hypothermic patient. Note the absence of tracheal intubation, central lines, and Foley catheter in the mild to moderately hypothermic patient.

Figure 67-5 Active external rewarming features. A heat source warms the skin. Traditionally, warm water immersion has been used (as shown). Rates of rewarming are very rapid in some series. There have been suggestions of increased mortality with this method when used for patients with moderate to severe hypothermia, but certain conditions may warrant its use. A major drawback is the inability to closely monitor the patient undergoing immersion. Use of warm air convection (e.g., use of Bair-Hugger device, Eden Prairie, MN), however, allows rewarming in the ED with full patient monitoring and less rapid vasodilation during rewarming.

Figure 67-6 Active core rewarming methods. Inhalation of warm, humidified air or oxygen causes gradual core rewarming and should be a *mainstay of rewarming therapy*. This method can be combined with other methods such as heated intravenous fluids. Peritoneal lavage is a more rapid method of core rewarming that requires placement of one or more intraperitoneal catheters. Other techniques are described in the text.

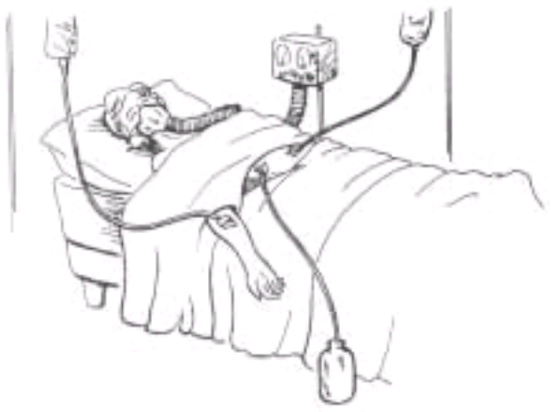

Figure 67-7 Active core rewarming cardiac bypass features. Bypass technology and a surgical team are needed. The rewarming rates are rapid. This method is useful in a patient with cardiac arrest; the technique is invasive, expensive, and technically difficult.

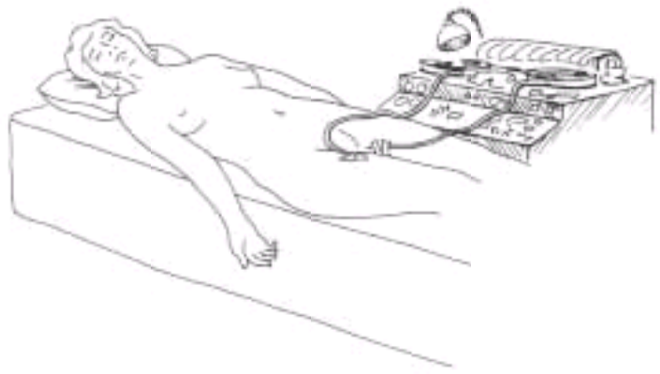

Figure 67-8 Active core rewarming open thoracic lavage features. The heart is warmed directly. This method requires surgical backup and is relatively invasive. The rewarming rates are rapid. An alternative that is more practical for the ED is pleural rewarming repeatedly using 200 to 300 mL warmed saline intermittently placed, then withdrawn through a chest tube (see text).

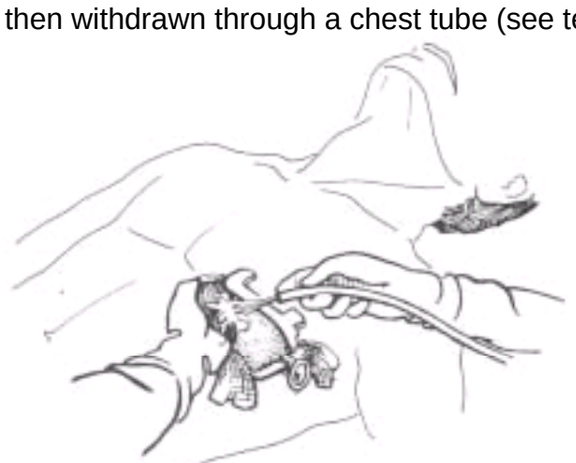

Figure 68-1 It is absolutely essential to rapidly lower the core temperature of a severely hyperthermic patient by instituting cooling techniques as soon as possible. Evaporative cooling (see text) is usually quite effective and technically easy. An alternative approach, albeit poorly studied, is to literally pack the patient in ice. In this case, plastic trash bags were used to hold the ice and to prevent water from dripping on the floor. A child's plastic wading pool is another option for this ice packing technique.

Figure 69-1 Longitudinal image of the gallbladder, demonstrating variability in tissue echogenicity. *A,* The anechoic appearance of fluid. Water, plasma, non-clotted blood, and urine will have the same appearance. *B,* The highly reflective appearance of a calcified stone in the gallbladder. Foreign bodies, needles, and bone will have a similar brightly echogenic appearance. *C,* The relatively hypoechoic appearance of tissue. Clotted blood, particulate material within fluid (lipid or purulent material) will appear the same, with echogenicity intermediate to bone and fluid.

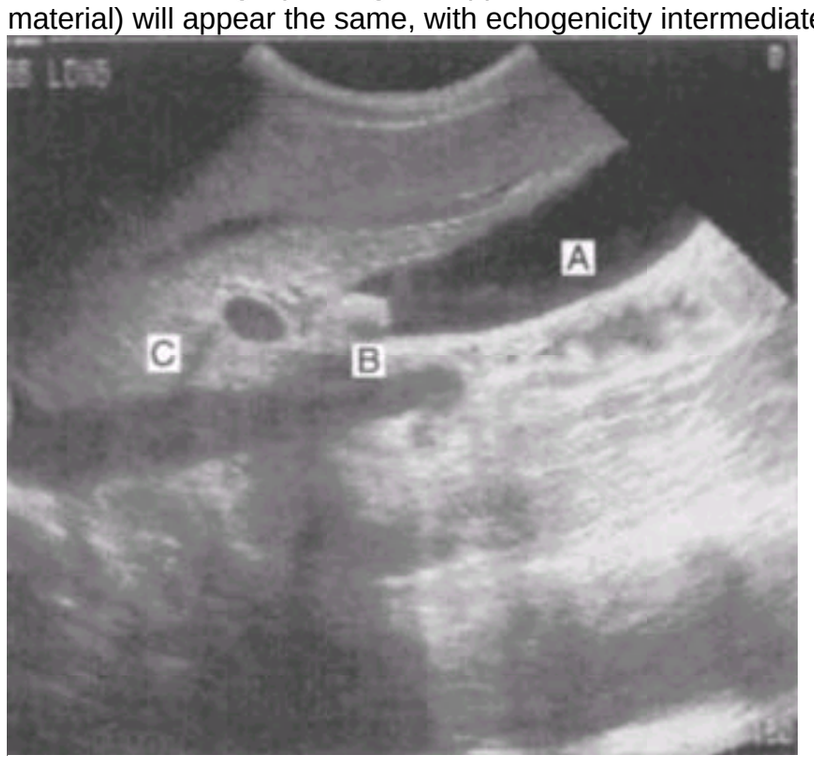

Figure 69-2 The curvilinear array probe is used for lower frequency (2.0 to 5.0 MHz) scanning of the abdomen and chest. It is best used for cardiac and abdominal imaging. The linear array probe is used for high frequency (6 to 10 MHz) scanning of superficial tissues, vessels, subcutaneous masses, and foreign bodies.

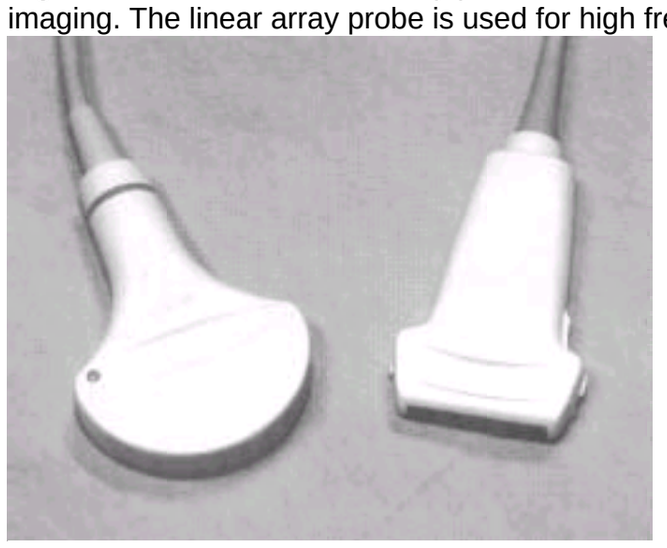

Figure 69-3 An ultrasound needle guide is ideally used to guide needle placement into deep or small structures. *(Courtesy of Dymax Corp, a subsidiary of Bard Access Systems.)*

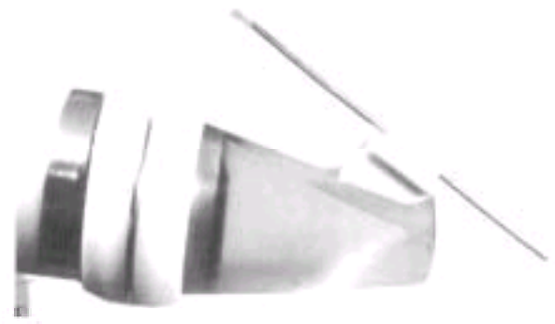

Figure 69-4 Imaging window for the internal jugular vein and carotid artery. The ultrasound probe should be covered with acoustic gel and then a sterile cover or glove. An additional layer of sterile gel should be placed over the cover. The probe is then placed parallel and superior to the clavicle over the groove made by the two heads of the sternocleidomastoid muscle. The probe should be pointed toward the patient's right. Care should be taken not to apply undue pressure on the probe to avoid compression of the easily collapsible internal jugular vein. Asking the patient to blow on his or her thumb or performing a Valsalva maneuver will increase the luminal diameter of the vein. *(Lydia F. Roberts, Photographer)*

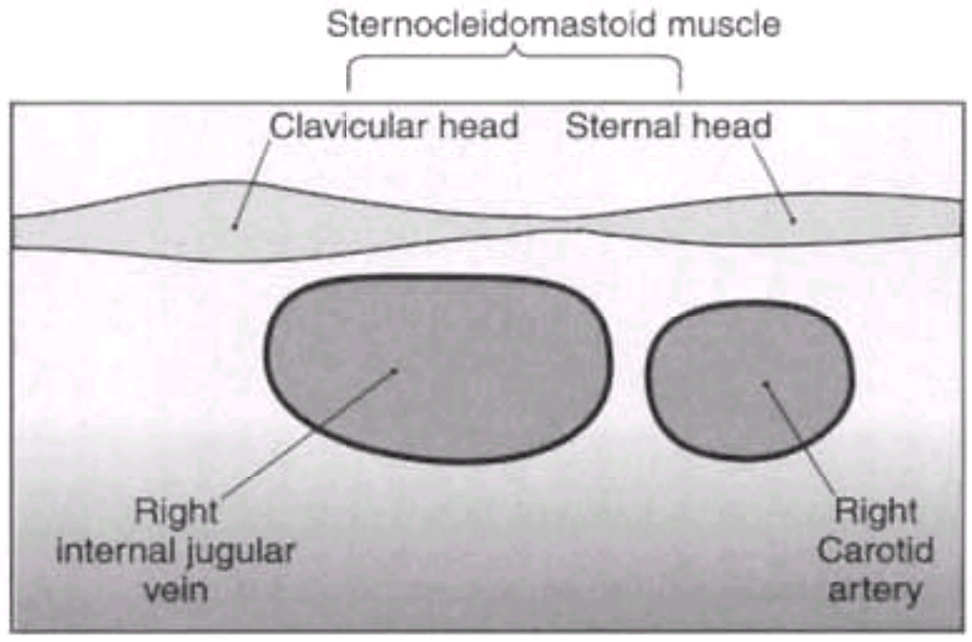
Figure 69-5 The internal jugular vein and carotid artery. *A,* Sonographic image; *B,* Schematic representation. The beam of the ultrasound should intersect the carotid artery and the internal jugular vein in a transverse or cross-sectional plane. The internal jugular vein is easily identified by its compressibility and response to Valsalva maneuvers (i.e., it increases in diameter).

A



B

Figure 69-6 *A* and *B,* Once the vein is positioned directly under the probe, needle aspiration can be attempted. If the site of skin puncture is correct, the needle will indent the vein and the vein will appear to collapse as it is entered.

Figure 69-24 Probe positioning for assessment of ankle effusion. The foot should be positioned in plantar flexion, and the transducer oriented longitudinally over the anterior surface of the tibia. Moving the transducer toward the foot and seeing the curved dome of the talus will identify the joint space. *(Lydia F. Roberts, Photographer)*

Figure 69-25 Sonographic appearance of the ankle. *A,* Normal; *B,* Effusion present; *C,* Schematic representation. An effusion will appear as an increased anechoic space at the anterior aspect of the tibio-talar joint. The optimal site for needle placement is where there is an anechoic space immediately under the probe.

Figure 69-26 Sonographic appearance of a retained metallic foreign body (*A*) and a retained glass foreign body (*B*). Foreign bodies are usually hyperechoic, and will appear as brightly echogenic structures, distinct from surrounding bone or calcifications. Clues to the location of a foreign body will be acoustic shadowing and reverberation artifact.

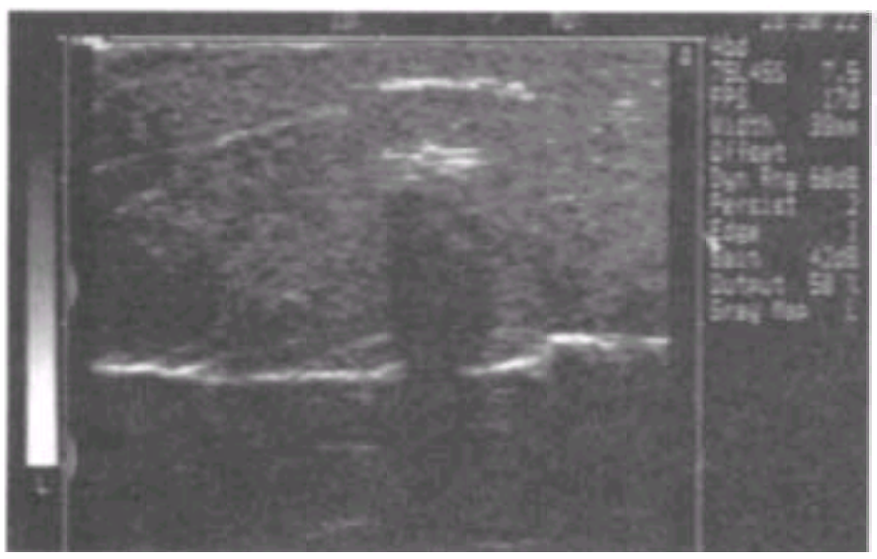

Figure 69-27 Sonographic appearance of the bladder in transverse view. The bladder will appear as an anechoic structure immediately beneath the skin surface, with a characteristic rhomboid appearance on transverse view.

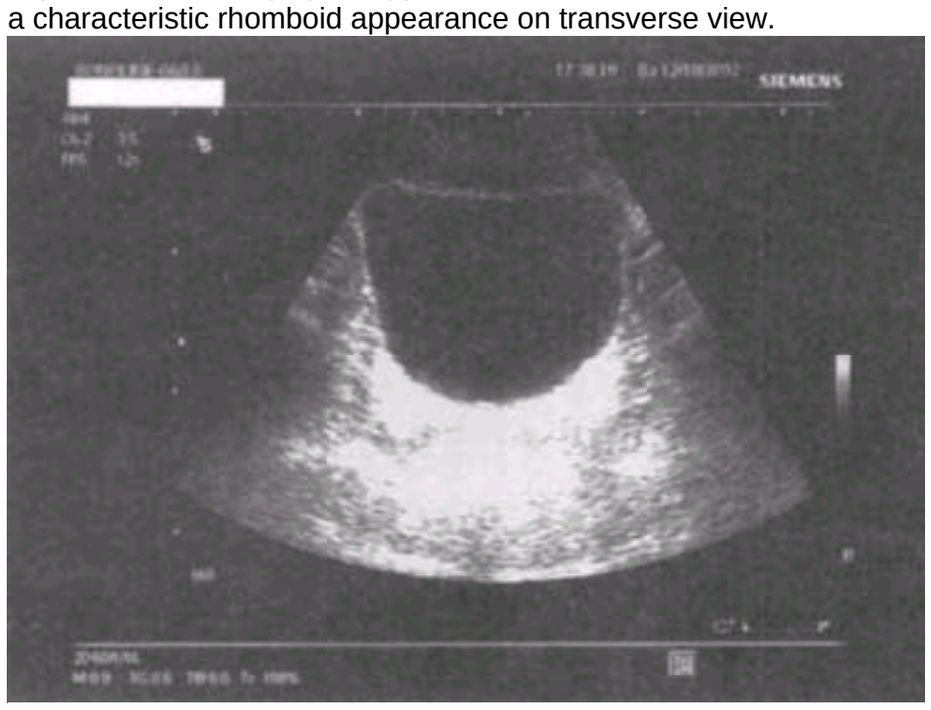

Figure 69-28 Sonographic appearance of a subcutaneous fluid collection. An abscess appears as a discrete anechoic area that may be surrounded by a brightly reflective wall. The fluid will be anechoic, but will often contain scattered echoes representing purulent material or necrotic debris. The fluid may also contain septations, which appear as echogenic walls traversing the fluid cavity.

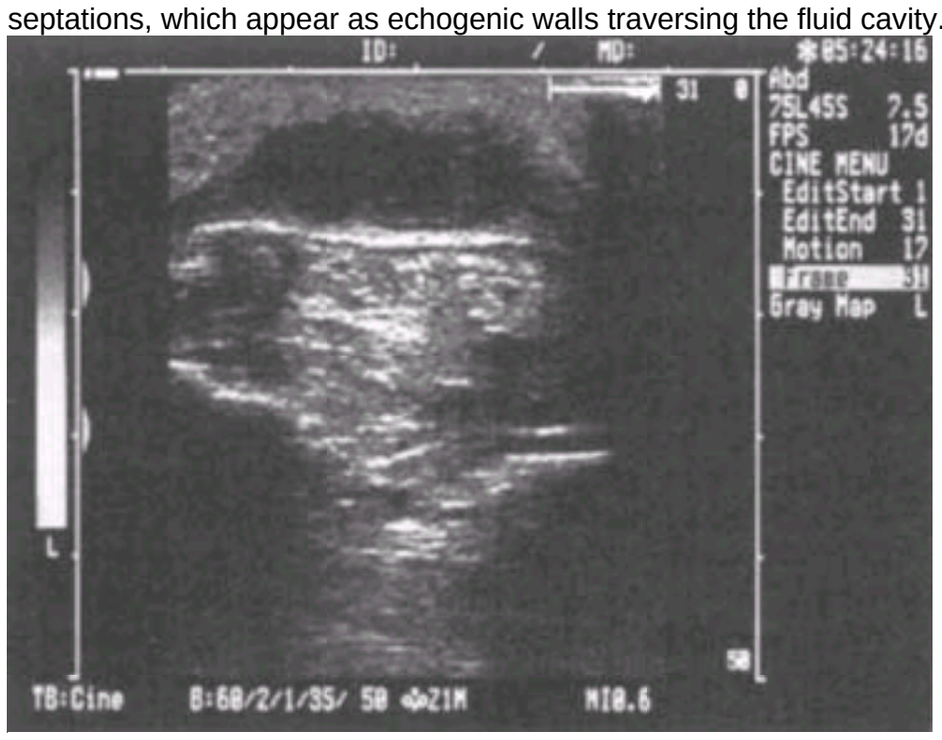

Figure 70-1 Algorithm for deciding method of obtaining urine specimen for evaluation of possible urinary tract infection. MSCC, midstream clean catch; SPA, suprapubic aspiration; UTI, urinary tract infection.

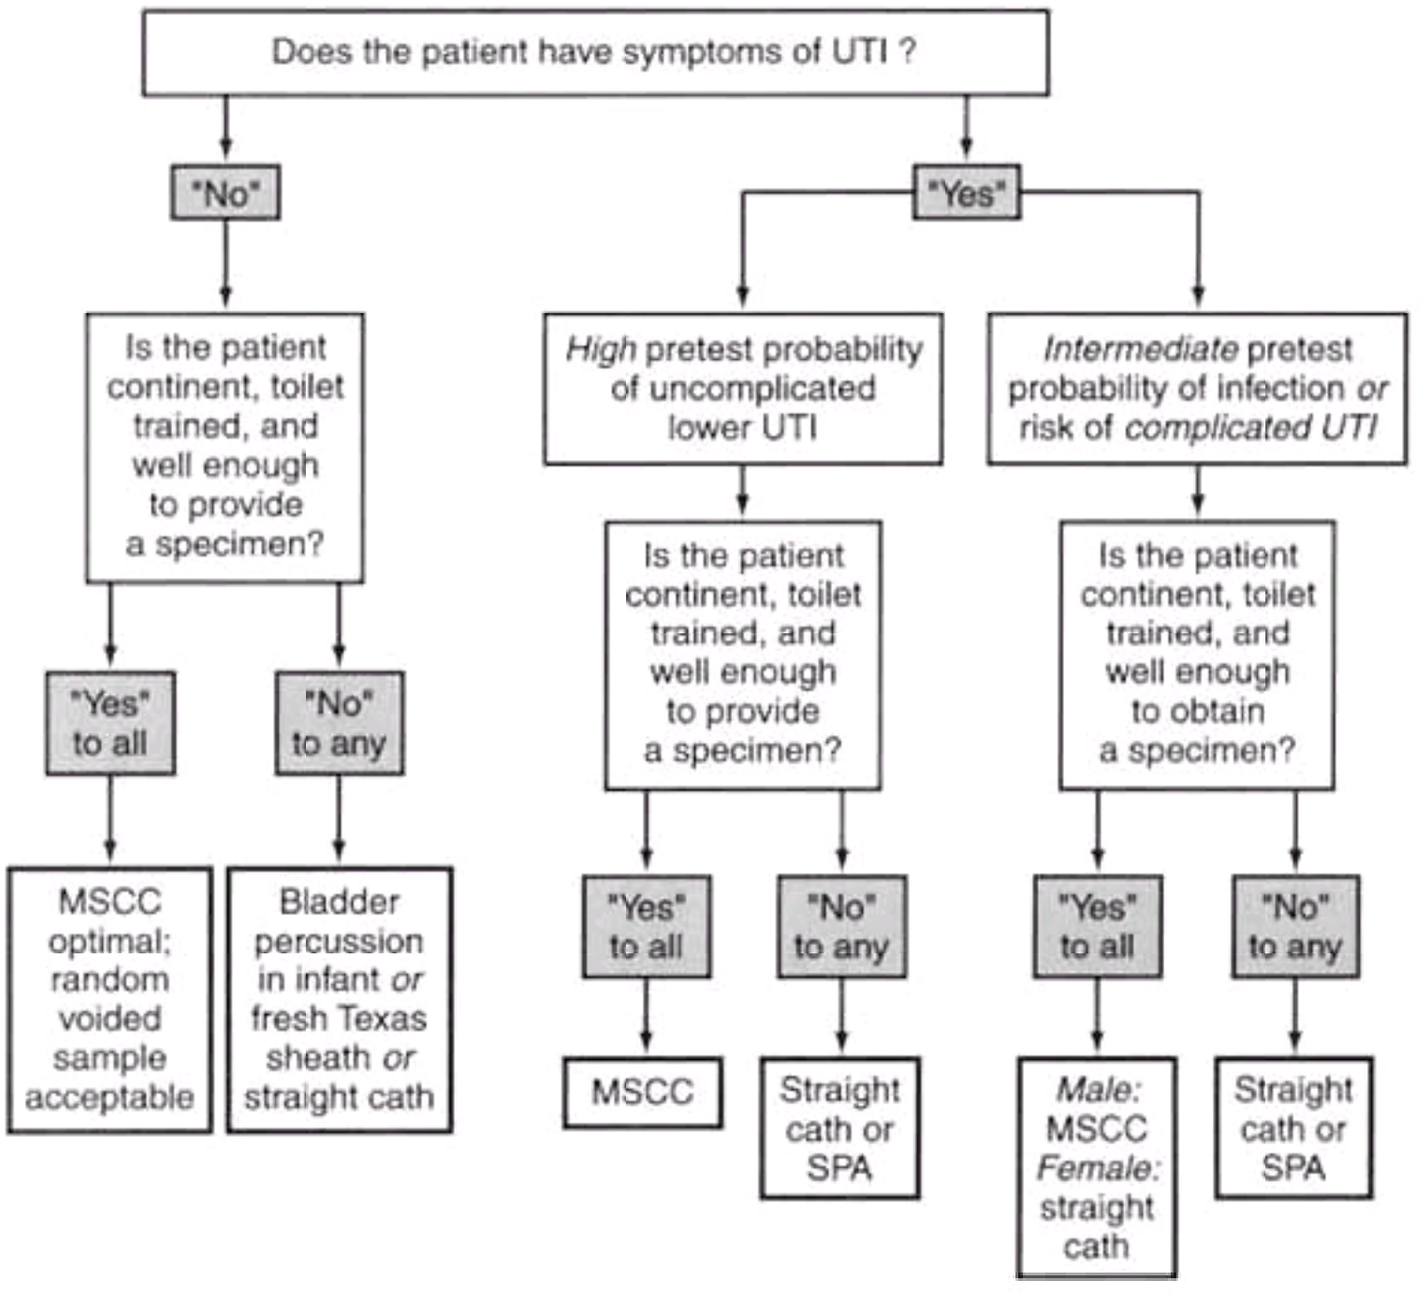

Figure 70-3 "Prism-shaped" calcium monohydrate crystals *(right)* resembling hippurate or urate crystals, and octagonal calcium dihydrate crystals *(left)*. *(Illustration by NJ Miller.)*

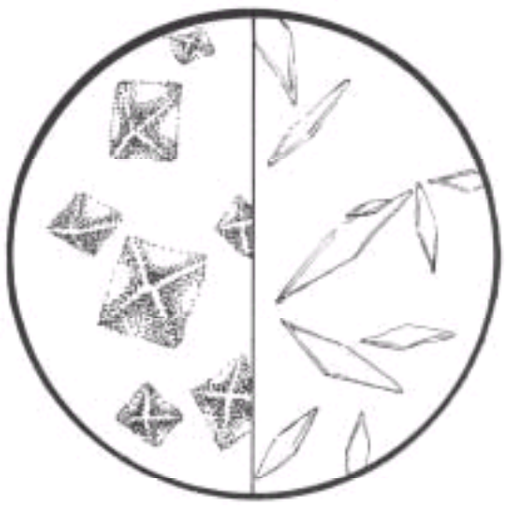

Figure 71-1 *A,* Recapping a needle by holding the cap in the hand is the most common way to sustain a needle puncture. *B,* It is best to discard the needle/syringe without recapping, but an alternative is to partially recap *without* holding the guard (needle cap), so that at least 80% of the needle is covered before completing the recapping with the second hand.

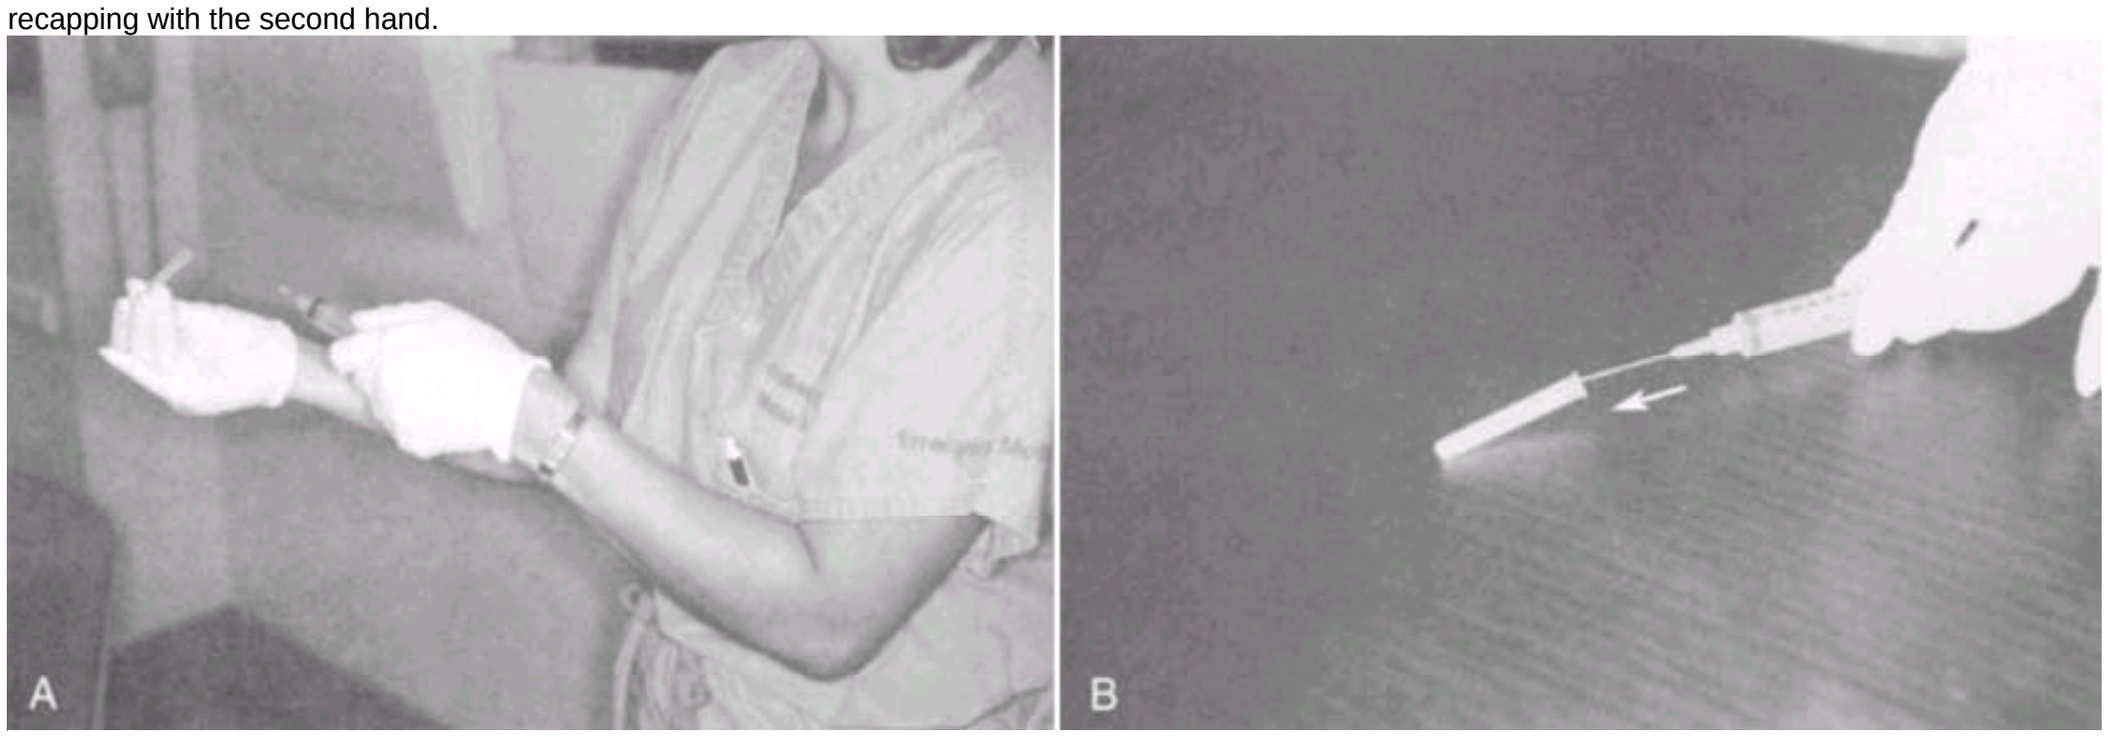

Figure 72-1 Procedural training at the bedside is an important part of learning a new skill. *A,* This ankle dislocation requires prompt relocation in the ED. *B,* The instructor first reviews the procedure with the trainee, including indications, contraindications, procedural steps, and complications. The trainee then performs the reduction while the instructor observes and provides guidance during the procedure. *C,* Following the procedure, the instructor examines the patient and assesses the adequacy of reduction.

Figure 72-2 Volunteers are ideal models for teaching certain noninvasive procedures such as splinting and casting.

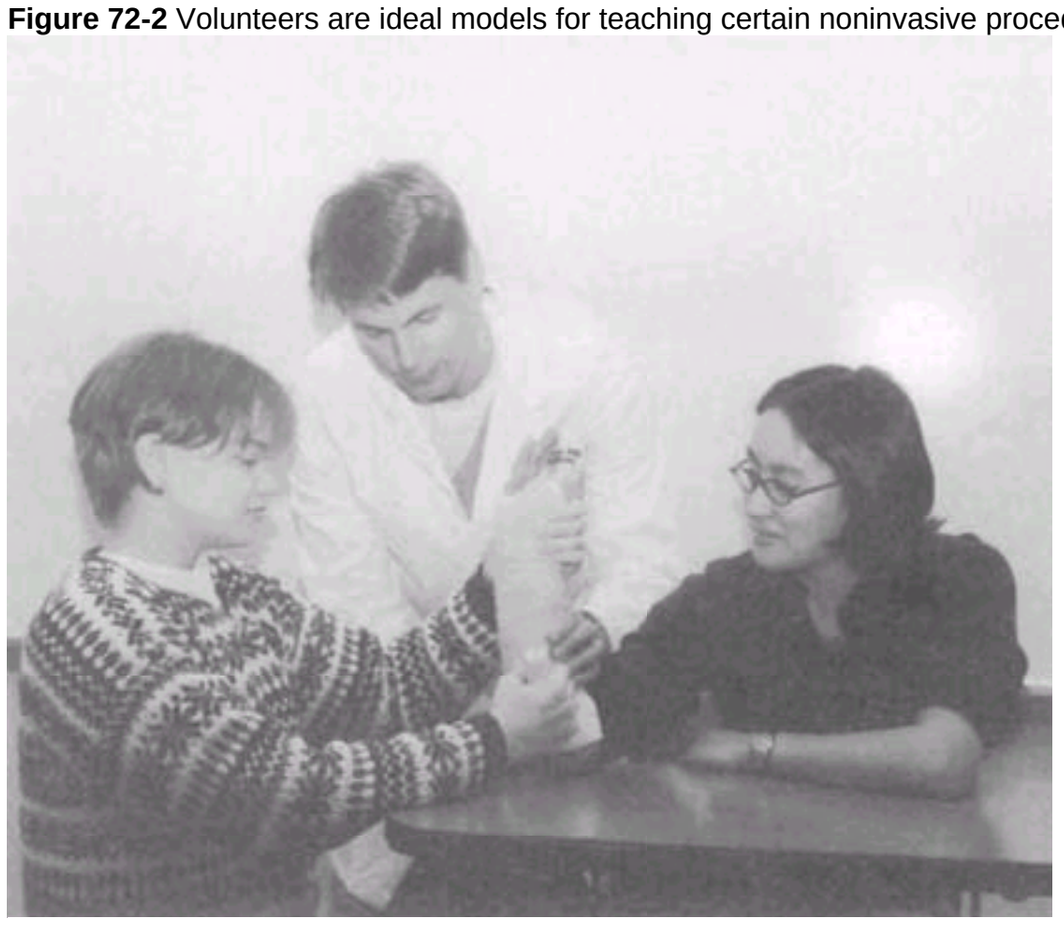

Figure 72-3 Mannequins are available to teach many procedures, including endotracheal intubation.

Figure 72-4 Human patient medical simulator. *A,* In the control room the educator is able to create and monitor clinical scenarios. *B,* The trainee performs electrical cardioversion on a human patient simulator and receives feedback from his actions by watching the monitor (successful conversion of ventricular tachycardia to sinus rhythm).

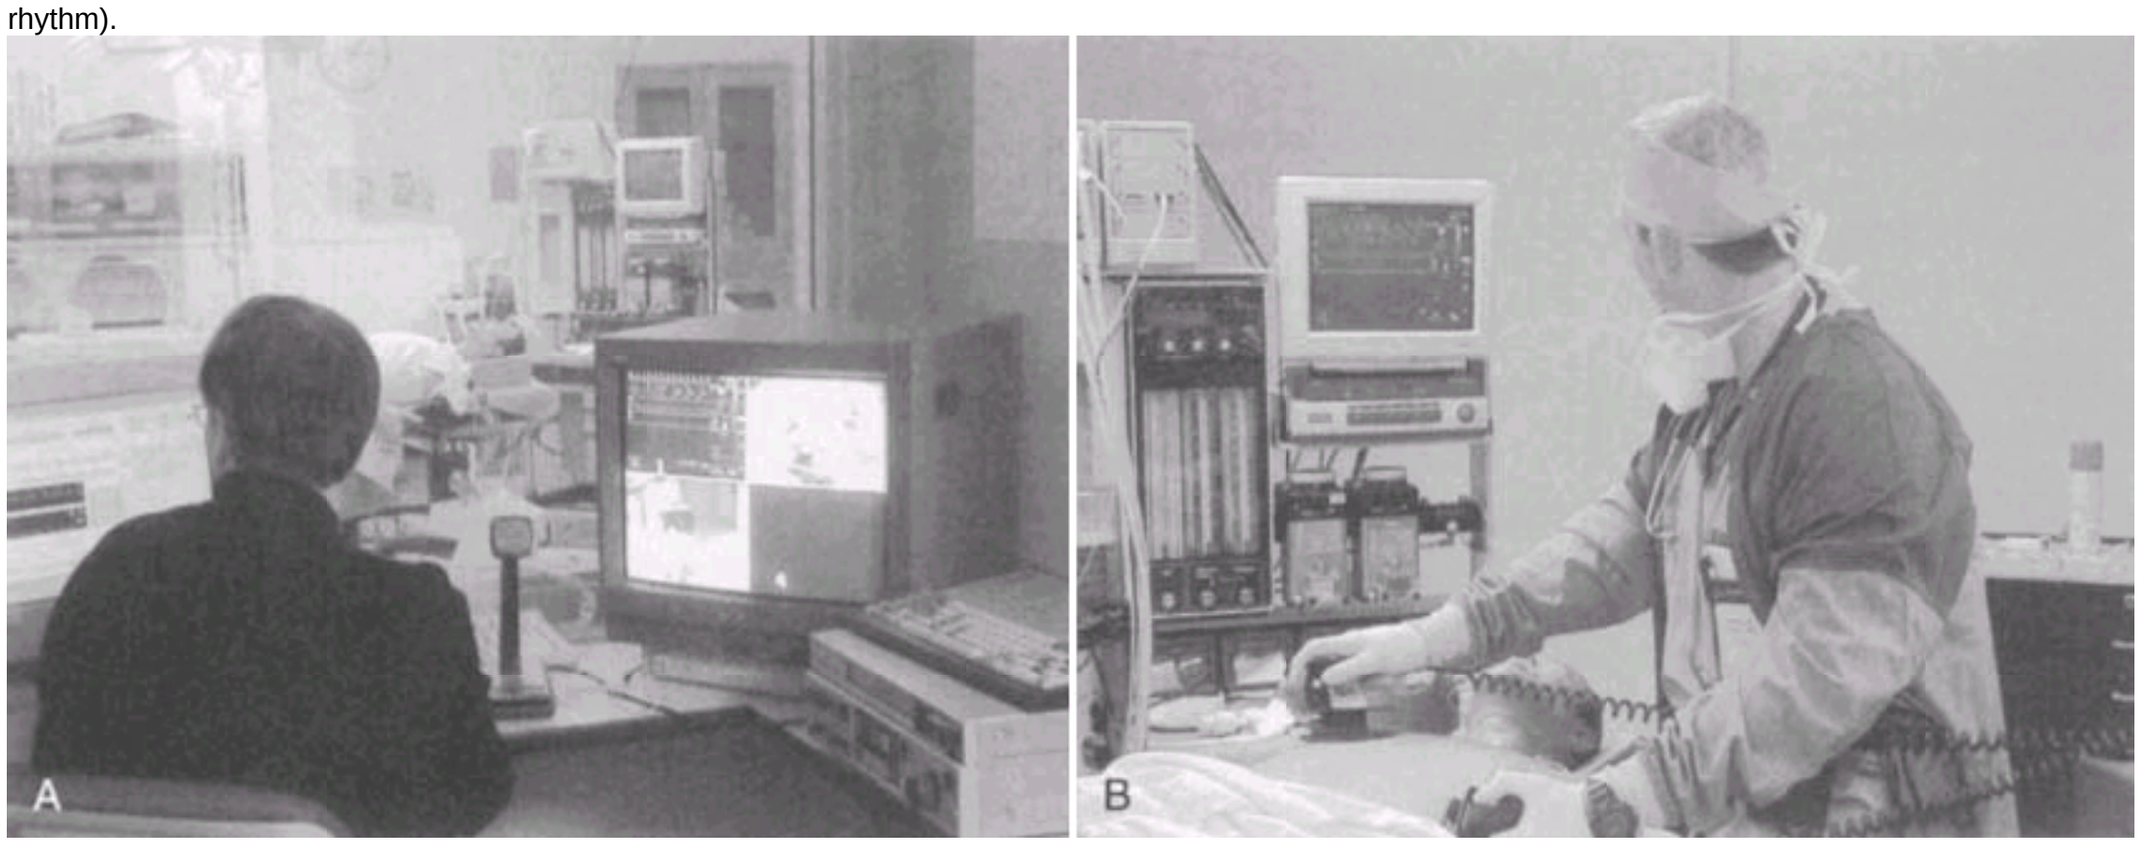

Figure 72-5 Isolated pig's feet are useful models to teach basic wound closure techniques.

Figure 72-6 In the live animal laboratory an instructor assists while the trainee performs a venous cutdown.
