CLINICAL PROCEDURES IN EMERGENCY MEDICINE
ISBN 0-7216-9760-7

Notice

Emergency Medicine is an ever-changing field. Standard safety precautions must be followed but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the treating physician, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the publisher nor the author assumes any liability for any injury and/or damage to person or property arising from this publication.

To Michael P. Spadafora, MD (1953–1999). A great guy whose talent, charisma, and friendship will be missed by many. You taught me more than I ever taught you, Michael, and life's just not the same without you.

To David K. Wagner, MD, Lewis R. Goldfrank MD, and Jerris R. Hedges, MD. Their prowess, prescience, and dynamism were obvious the first time I met them. And to Michael I. Greenberg, MD. As a toxicologist he was first my student, then my colleague, and now my mentor.

J.R.R.

This Fourth Edition of Clinical Procedures in Emergency Medicine *is dedicated to all the future generations of emergency physicians. As our specialty becomes an international discipline, this text in English, Italian, and Spanish is now found in many lands. Countless practitioners have expanded their knowledge and shared this information with their trainees. If a copy of this text can make a profound difference in at least one new emergency physician's career, we have served the future well.*

J.R.H.

This book is dedicated to all those who practice emergency medicine and to those that support them in their endeavors.

A.S.C.

To my wife Marcy, without a doubt the very best thing that has ever happened to me. Her kindness, patience, and devotion to family is surpassed by none. To my children, Adam, Arielle, and Allison, whom I love more than any words could ever express. And to my mother Eleanor, whose strength and courage in the face of adversity is an inspiration to everyone lucky enough to know her.

C.R.C.

To my son, Nicholas, and in memory of my daughter, Lauren; to Peter Pons, my favorite teacher; and to our residents so that when they are far away from this place of learning, they may confidently pick up the scalpel and perform these lifesaving procedures without hesitation—both quickly and competently.

C.B.C.

This effort is dedicated to the idealistic spirit that drives emergency physicians to seek excellence in the care of their patients. It is my hope that this book will be a valuable tool in their quest to bring order to the chaos of life in the ED.

I could not work on projects such as this without the support and unfailing generosity of my wife, Beverly. I offer my thanks to Bev for all she has given to me and to the specialty of Emergency Medicine.

S.C.D.

How This Book Should be Viewed by the Practicing Clinician

The editors and authors of this textbook strongly believe that the complex practice of medicine, the vagaries of human diseases, the unpredictability of pathologic conditions, and the functioning and responses of the human body cannot be defined, explained, or rigidly categorized by any written document. Therefore, it is *not* the purpose of this text to serve as an *authoritative source* on any medical condition or clinical intervention, nor an attempt to define a *standard of care* that should be practiced by all clinicians. We provide the physician with a literature-based database, and a reasonable clinical guide that is combined with practical suggestions. We offer a general reference source on a variety of conditions and procedures that may confront clinicians who are experienced in emergency medicine practice. This text cannot replace physician judgment, cannot describe every possible aberration or clinical scenario, and cannot define rigid standards for clinical actions or procedures. Every medical encounter must be individualized and every patient must be approached on a case-by-case basis. Some of the procedures described are common, while others are uncommon, rarely encountered, or best performed, given specific circumstances, by another practitioner with different training, experience, or logistical constraints. The procedures described herein do not constitute the expertise or the knowledge base to be possessed by all clinicians. Finally, many of the described complications associated with implementing complex medical and surgical procedures may be encountered, even when every aspect of the intervention has been performed correctly.

Foreword

The emergency physician has the unique responsibility of offering his or her skills at all times to all people (young and old, friendly and hostile, rich and poor). No other health providers are always collectively there at the entrance to the hospital. As emergency physicians, our responsibilities have grown and our horizons have been expanded because of our commitment to people. We have built a system that creates a caring environment from the home to the street and to the hospital, and a system that also integrates firefighters, police officers, paramedics, nurses, clerks, students, pharmacists, and physicians into this caring service. Each new clinical problem and each creative intervention has led to innovations in thought and technical advances. The Fourth Edition of Roberts and Hedges' text, *Clinical Procedures in Emergency Medicine*, takes another step in the pursuit of excellence in the provision of that care. The authors' detailed critical analyses of the studies pertinent to the use of each technique allow for a rigorous approach as to how, why, and when each procedure is indicated.

The past 30 years in the history of emergency medicine have seen a remarkably rapid evolution in care. Organized medicine has often been criticized for its inability to change thought patterns and approaches to care, but the ability to change current patterns is the recognized strength of emergency physicians. We have undertaken our responsibilities, created new relationships, and developed new perspectives on clinical medicine in an area where previously no one dared to serve. In the past, medical providers have also been criticized for not evaluating their clinical techniques and technology effectively. This text exemplifies and describes the tremendous progress in thought and technology that mark the success of emergency medicine in America today.

The rapid growth of prehospital care, the ever-increasing roles of emergency care, and the diversity of clinical issues and research dilemmas in emergency medicine have led to the development of a new type of physician in the emergency department. This text defines the breadth of academic and clinical emergency medicine and the enormous technical skill and intellectual responsibility required by each emergency physician.

These chapters are written by emergency physicians and other physicians working closely with emergency patients who have highly specialized knowledge in particular aspects of emergency medicine. Almost a third of these authors are new contributors to this edition. A reevaluation of the clinical and academic roles of the emergency physician has led to the refinement of this Fourth Edition. As the basic science and clinical practice of emergency medicine have further developed, this book has grown to represent a complete view of our specialty. This text offers a balanced analysis of the interventions at our disposal in the emergency department for the care of those with urgent and emergent problems. The authors attempt to simplify and clarify while focusing on knowledge and process with regard to the equipment we use in the environment where we practice. This text permits any practitioner the opportunity to perform his or her first emergency procedures with a foundation that emphasizes evidence and limits bias and ignorance.

This text has filled a void in medical practice. Procedural interventions in the emergency department had previously been largely undefined and certainly inadequately analyzed. The emergency physician who is trained in these techniques can develop the requisite technical skills and combine them with the warmth and humanity essential to render concerned, committed, and compassionate emergency care. Knowledge of these skills and their indications, as well as the risks and benefits of practice, will permit emergency physicians to achieve the highest level of service and will foster their potential to initiate quality research.

This book is also about motivating physicians to appreciate the clinical norms and expectations of our procedures. The editors have recognized for years many of the problems defined in the report *To Err is Human* released by the Institute of Medicine of the National Academy of Sciences in 1999. This text has moved the physician from anecdote to a rigorous analysis of procedures. The reader will not only feel more secure about performing an essential procedure, but he or she will also become more confident about not performing a procedure that entails more risk than benefit to an individual patient. The editors and authors have attempted to enhance education and limit the errors of commission as well as omission while improving the safety and occupational health of the emergency physician.

This book attempts to prepare the clinician for his or her role in the emergency department. Recognizing that the emergency department environment is by definition unpredictable and often chaotic, these authors have prepared us to change the human response in an attempt to make errors more difficult to commit.

Understanding the remarkable spectrum of responsibility of the emergency physician is our essential task. We shall succeed as health providers if we understand our patients and their needs, the pathophysiology of emergency medicine and its therapeutics, and our procedures and their pitfalls. The Fourth Edition of Roberts and Hedges' *Clinical Procedures in Emergency Medicine* provides enough thought-provoking information about medical technology to prepare the emergency physician to care for the emergency department patient in a humane and intellectually sound manner.

Although few physicians other than emergency physicians will use all the techniques and technology detailed in this text, many other physicians can and will profit immensely from its use. The techniques are well defined, well illustrated, and well referenced by clinicians who obviously use them daily. This text remains unique with respect to the depth and breadth with which the editors and authors critically evaluate the tools of our trade. The two leaders of our field, Roberts and Hedges, have been joined by four new associate editors. The addition of these respected emergency physicians

expands the text's excellent foundation of editorial contributions and ensures continued successful presentation of procedural techniques to help guide our clinical care.

The understanding and application of the principles defined in this edition should be considered essential for each emergency physician in his or her attempt to continuously improve the delivery of the best possible health care to our patients.

Section I - Vital Signs and Patient Monitoring Techniques

Chapter 1 - Vital Signs Measurement

Diane L. Gorgas

Documentation of temperature, pulse, respiration, and blood pressure is generally recommended for all emergency department (ED) patients, except those with the most minimal complaints. These measurements provide a unique, objective, capsule assessment of the patient's clinical condition. Vital signs indicate the severity of illness and may dictate the urgency of required intervention. Although a single set of values may suggest disease, the greatest utility of vital signs is their measurement over time. Deteriorating vital signs are an important indicator of a deteriorating physiologic condition, whereas improving values provide reassurance that an unstable patient is responding to therapy. Hence, when a patient undergoes treatment over an extended time, selected vital signs, particularly previously abnormal ones, should be repeated. In some circumstances, the monitoring of select vital signs should be continuous.

Vital signs should be measured and recorded at intervals dictated by the patient's clinical state (e.g., before and after fluid resuscitation, invasive procedures, or administration of medications with cardiopulmonary effects) or with any sudden change in the patient's clinical status. In addition, an abnormal vital sign can direct the clinician toward a group of diagnoses or a particular organ system for further evaluation. An abnormal vital sign may constitute the patient's entire complaint, as in the febrile infant, or be the only indication of the potential for serious illness, as in the patient with resting tachycardia. For these reasons, accurate determination and interpretation of vital signs are mandatory. Unfortunately, in many EDs, vital signs are not recorded reliably, accurately, [1] or with optimal frequency.[2] This can lead to delayed diagnosis or misinterpretation of the severity of an illness or injury.

Assessment of a patient's status and vital signs should begin in the prehospital setting in cases where Emergency Medical Service (EMS) transport is involved. EMS transport-induced stress can alter vital signs because of epinephrine and norepinephrine surges that commonly occur during transport. This has been shown to lead to increased heart rates of >10%.[3] Although prehospital vital signs need to be interpreted carefully, they should still be obtained and in the vast majority of situations, they are. The exception occurs in the pediatric population, especially those younger than 2 years of age. The lack of routine measurement of vital signs by EMS personnel in this group is largely due to the paramedic's or technician's lack of confidence in accurately measuring vitals signs in newborns, infants, and toddlers. [4]

In the ED, the accurate assessment and management of abnormal vital signs must reflect the priorities of resuscitation. Determination of airway patency with respiratory rate (RR) and pattern assumes first importance. Establishing the presence and quality of an arterial pulse is the second vital sign to be assessed, followed by blood pressure. Blood pressure and pulse are often evaluated in conjunction, as a measure of blood volume. Although body temperature is the last vital sign to be monitored during resuscitation, it has special importance for patients suffering from thermal regulation failure (see Chapter 67 and Chapter 68). The current chapter is organized according to the priorities of patient resuscitation and evaluation.

Additional "vital signs" recently introduced into emergency medicine are pulse oximetry, capillary refill, and the analogue or similar pain scale. The use of pulse oximetry is discussed subsequently (see Chapter 2). Capillary refill in general is considered part of the assessment of overall perfusion and most closely linked to circulatory volume and blood pressure in children. In accordance, capillary refill is covered under the blood pressure section. Assessment of pain as a vital sign is gaining acceptance. Mental status has also been proposed as a vital sign, as it can be viewed as a summation of measurable vital signs (blood pressure, heart rate, RR, and temperature). Significant aberrations in any of these quantifiable vital signs will cause mental status changes.

BACKGROUND

Early pulmonary medicine was dominated by the concepts of Herophilus (4th century B.C.) and Galen (131 to 200 A.D.), whose belief in the humoral theory of medicine dictated that the lungs functioned as a cooling device and site for generation of body humors. The pulmonary circulation was correctly described in the 13th century by Ibnan-Nafis; however, his observations passed unnoticed.

Respiratory physiology did not progress until the significance of the pulmonary circulation was recognized by Harvey in 1628. It was not until the 1700s that advances in physics and chemistry allowed the identification of gases involved in respiration. [5]

Sphygmology, or palpation of the pulse, was first appreciated by Herophilus. He believed that interpreting the pulse required a knowledge of both music and geometry and defined the characteristics of the pulse as size, frequency, force, and rhythm. Chinese clinicians (2nd century B.C.) timed the pulse by the RR of the examiner, believing that 4 pulsations/respiration was normal for adults. The study of pulses was greatly influenced by Galen, who expanded the subject into a rather complex and obscure art form, writing 18 books on the subject.[6]

Blood pressure was first measured directly in 1733 by Hales, who recorded the arterial pressures in a mare by cannulation with a brass pipe and a blood-filled glass column.[7] Frank used large-bore catheters connected to a rubber membrane in a 1903 manometer. [8] The invention of inflatable cuff manometers (Riva-Rocci, 1896) and the discovery of the arterial phase sounds (Korotkoff, 1905) allowed for the development of indirect blood pressure measurement. [7] [8]

The earliest recorded references to fever are from 6th century B.C. Akkadian cuneiform inscriptions, which appear to have adapted an ancient Sumerian icon of a flaming brazier to denote both fever and the local warmth of inflammation in a single ideogram. Clinical thermometry was introduced by Sanctorius in 1625. Mercury column thermometers were introduced by Fahrenheit in 1714. Although their routine use was supported by Boerhaave, thermometry was not established as routine clinical practice until the 1870s. [9]

TABLE 1-1 -- Normal Values for Vital Signs of Infants and Children (Mean ± SD)

	Age				
Parameter	***0–2 mo***	***3–12 mo***	***1–6 yr***	***7–12 yr***	***13–18 yr***
Breaths/min	—*	—*	24 ± 3	19 ± 2	17 ± 3
Pulse/min	126 ± 20	131 ± 20	88 ± 9	70 ± 8	64 ± 7
Systolic BP†	72 ± 10	95 ± 15	93 ± 13	100 ± 10	112 ± 12
Diastolic BP	51 ± 9	53 ± 10	55 ± 10	63 ± 10	67 ± 10

*For data on children 0 to 36 months, see Table 1-2 .
†As an estimate, for children 1 to 10 years: 2 × age (in years) + 90 mm Hg = 50th percentile for systolic BP.

NORMAL VALUES

The range of normal, resting vital signs for specific age groups must be recognized by the clinician to enable identification of abnormal values and their clinical significance. Normal ranges for vital signs also may be influenced by sex, race, pregnancy, and residence in an industrialized nation. These ranges have not been validated in ED patients, who may have many reasons for vital sign abnormalities, including anxiety; pain; and other forms of distress, in addition to altered physiology from disease states.

Published vital sign norms for children are not as well accepted as for adult patients. Table 1-1 and Table 1-2 report normal vital signs for children by age group as mean and standard deviations. In Table 1-1 , the values for pulse and blood pressure for 0- to 2-month-olds are adapted from studies of newborn populations (i.e., younger than 7 days).[10] [11] [12] During the newborn period, normal arterial blood pressure rises rapidly. Values for pulse and respiration in children older than 3 years reflect an average of male and female values for 0- to 1-, 3-, 9-, and 16-year-old populations. [13] The values for blood pressure reflect an average of male and female values for the 1- to 6-month and 3-, 9-, and 16-year-old populations. [12] Newer studies have reassessed reference values for RRs in children. [14] [15] [16] [17] [18] Table 1-2 reflects the age-related changes and the effect of the state of wakefulness in the RRs of children up to 3 years of age. [15] Hooker and colleagues measured resting RRs in pediatric ED patients up to age 18 years. [14] They noted considerable patient variability and somewhat higher RRs than are shown in Table 1-2 .

For the adult population, normal values for blood pressure are well established. Although there is an increase in systolic blood pressure with age, normotensive or normal systolic blood pressure is defined as 90 to 140 mm Hg, and normotensive or normal diastolic blood pressure is defined as 60 to 90 mm Hg. Although most patients have similar blood pressures in both arms, Pesola and coworkers found that 18% of their hypertensive

TABLE 1-2 -- Normal Respiratory Rates (Breaths/Min) for Children to Age 3 Years (Mean ± SD)

Age (mo)	Awake	Asleep
0–<2	48.0 ± 9.1	39.8 ± 8.7
2–<6	44.1 ± 9.9	33.4 ± 7.0
6–<12	39.1 ± 8.5	29.6 ± 7.0
12–<18	34.5 ± 5.8	27.2 ± 5.6
18–<24	32.0 ± 4.8	25.3 ± 4.6
24–<30	30.0 ± 6.2	23.1 ± 4.6
30–36	27.0 ± 4.1	21.5 ± 3.7

population[17] and 15% of their normotensive population [16] had a difference of >10 mm Hg in systolic blood pressure between arms.

The normal limits for resting heart rate of 60 beats/min and 100 beats/min were established by consensus in 1928 by the New York Heart Association. [19] Recent data indicate that 45 beats/min and 95 beats/min better define the heart rate limits of normal sinus rhythm in adults of all ages. Spodick recommends that the operational definition for the limits of resting heart rate in adults should be 50 beats/min and 90 beats/min. [19] [20] This view is widely supported among cardiologists. [21]

There is currently no consensus on what constitutes a normal adult RR.

Most studies on RR support 16 to 24 breaths/min as the norm for adults.

Pregnancy results in alteration of the normal adult values for pulse and blood pressure. RR is unchanged, although the physiologic hyperventilation of pregnancy is well recognized. This is a result of increased tidal volume and decreased residual and expiratory reserve volumes. [22] Resting pulse rate increases through pregnancy to 10% to 15% over baseline values. Norms for systolic and diastolic blood pressure are dependent on patient positioning. When the pregnant patient is sitting or standing, systolic pressures are essentially unchanged. Diastolic pressures decline until approximately 28 weeks' gestation, when they begin to rise to nonpregnant levels. When the pregnant patient is in the lateral decubitus position, both systolic and diastolic pressures decline until the 28th week and then begin to rise to nonpregnant levels (Table 1-3).[23]

RESPIRATION

Respiratory frequency reveals only part of the clinical picture. The pattern, effort, and volume of respiration may be more indicative of altered respiratory physiology. An abnormality in respiration may be a primary complaint or a manifestation of other systemic disease.

Physiology

Breathing is initiated and primarily controlled in the medullary respiratory center in the brainstem. The respiratory center is modulated by the pneumotaxic and apneustic centers in the pons. The pneumotaxic center limits the length of the inspiratory signal and therefore can greatly increase or decrease RR.

In addition to being modified by other areas of the brainstem, the medullary respiratory center is modified by voluntary centers in the cerebral cortex; pulmonary stretch receptors of the airways; type J or juxtapulmonary capillary

TABLE 1-3 -- Vital Signs During Pregnancy in the Lateral Decubitus Position (Mean ± SD)

	Trimester		
Parameter	***1st***	***2nd***	***3rd***
Pulse rate (beats/min)	77 ± 2	85 ± 2	88 ± 2
Systolic BP (mm Hg)	98 ± 2	91 ± 2	95 ± 2
Diastolic BP (mm Hg)	53 ± 2	49 ± 2	50 ± 2

receptors of the pulmonary capillaries; arterial baroreceptors of the carotid sinus; and receptors found in skeletal muscle, tendons, and joints. Central and peripheral chemoreceptors also influence RR.[24]

Indications and Contraindications

Generally, ED patients should have their RR documented during their evaluation. Repeated assessment and documentation of the patient's respiratory status are indicated in patients who present with an abnormal RR or a complaint referable to the airway or breathing.

The only contraindications to a careful measurement of RR are the scenarios of respiratory distress, apnea, or upper airway obstruction that require immediate therapeutic intervention. A measurement of RR and effort should be performed as soon as patient care demands allow it in these circumstances.

Observation and palpation of chest movement are the techniques most frequently used to monitor respiratory frequency and amplitude noninvasively. Discussion of inductive plethysmography and other noninvasive monitors are beyond the scope of this chapter. Periodic manual measurements as described later generally suffice for ED patients.

Respiratory status in both adults and children plays a crucial role in determining the overall assessment of illness. Although it is a sensitive yet nonspecific indicator of respiratory dysfunction, the RR can also predict nonpulmonary morbidity. Several prehospital- and hospital-based illness or injury severity scores feature RR as a cardinal value. An prehospital RR <10 or >29 is associated with a major injury in 73% of children. [25] Other studies have linked abnormal RRs to inhospital mortality and level of care required in the ED. [26] [27] Using tachypnea alone as a predictor for pulmonary pathology, infants with a RR of >60 are found to be hypoxic 80% of the time.[28]

Procedure

RR is the number of inspirations per minute. Generally, it is best measured with the patient unaware that breathing is being observed because awareness makes the patient conscious of the breathing pattern, which may alter the rate. Commonly, examiners count respirations while appearing to count the pulse. The RR is most accurately determined by counting for a full minute. Because the frequency is much less than the pulse, and breathing is less regular, an inaccurate measurement is more likely to occur if a 15-second interval is used.

Infants, in addition to being principally nasal breathers, are predominantly diaphragmatic breathers, and an infant's RR is easily determined by observing or palpating excursion of the chest or the abdominal wall. [29]

Complications

There are no inherent complications from measuring respiration by observation. Problems related to the measurement of RR are generally due to failure to recognize a patient in obvious respiratory distress or failure to monitor RR in a patient who may be at risk for respiratory depression (e.g., in the case of sedative-hypnotic or narcotic overdose).

Interpretation

Respiratory Rate

A limited number of studies have examined RRs. Hutchinson evaluated RRs in 1897 healthy males at rest and found that 91% had RRs between 16 and 24 breaths/min. He also noted that 30% had exactly 20 breaths/min.[30] Hooker and colleagues note that current texts vary considerably in their definitions of a normal RR and cite published values that range from 8 to 20 breaths/min. [31]

Hooker and associates, in a study that specifically investigated normal RRs in an ED, measured RRs in 110 afebrile ambulatory patients without respiratory complaints (53 females and 57 males).[31] They report a mean rate of 20.1 breaths/min. For patients whose RR was measured again before release from the ED, no significant difference was noted between initial and subsequent RRs. When analyzed by gender, females had a mean RR of 20.9 breaths/min and males had a mean RR of 19.4 breaths/min, a statistically significant difference. The researchers concluded that a normal RR in the adult patient population was 16 to 24 breaths/min. [31] This study also suggested a significant variability in the accurate measurement of RR by different examiners. Rates obtained by nurses versus medical students varied significantly, as did those obtained by medical students versus residents versus attending clinicians. [1]

Other studies have provided additional information on normal resting and sleep state RRs in children younger than 7 years. [14] [15] [16] [17] [18] RRs obtained with a stethoscope were higher than those obtained by observation (mean difference, 2.6 breaths/min in awake and 1.8 breaths/min in asleep children). Smoothed percentile curves demonstrated a larger dispersion at birth (5th percentile, 34 breaths/min; 95th percentile, 68 breaths/min), while at 36 months of age (5th percentile, 18

breaths/min; 95th percentile, 30 breaths/min) dispersion was less.

RR will generally increase in the presence of fever. It is often difficult to determine if tachypnea is a primary finding or simply associated with hyperpyrexia. Taylor et al.[32] studied 572 children younger than 2 years of age, 42 (7%) of whom were subsequently diagnosed with pneumonia and found that age-appropriate limits for resting tachypnea in the presence of fever could be defined. A sensitivity and specificity of 74% and 77% for pneumonia was achieved when children 6 months of age had a RR >59/min, those aged 6–11 months had a RR >52/min and those 1–2 years had a RR >42/min. Therefore, even in the face of physiologic compensation for fever, an interpretation of RR alone can help predict the presence of pulmonary disease.

Respiratory Pattern and Amplitude

Abnormal respiratory patterns may be characteristic of metabolic or central nervous system pathologic conditions. Hyperventilation and hypoventilation may result from an

extensive differential diagnosis including primary pulmonary disorders, such as pneumonia or chest wall pain. Respiratory disturbances also occur secondary to other disease processes. For example, *Kussmaul respiration* describes the hyperventilation pattern seen in diabetics with ketoacidosis. Abnormal respiratory patterns in adults can be used in differential diagnosis or in determining the location of central nervous system lesions.

The recognition of subtle tachypnea can be difficult in the emergency setting, although this can be the solitary harbinger of disease. Measurement of an accurate RR in this patient population is crucial. Another instance of pathology that can confuse the routine measurement of RR is diaphragmatic breathing or retractions. The variability in counting respiratory effort versus effective respirations is generally not appreciated in a single recorded value.

Respiratory patterns in children must be observed carefully. In infants, periodic breathing, which may be normal, must be distinguished from apnea. By definition, periodic breathing consists of three or more respiratory pauses >3 seconds in duration, with <20 seconds between pauses. There is no associated bradycardia or cyanosis. This contrasts with apnea, which is a particular problem in preterm infants. Apnea is defined as a respiratory pause of >20 seconds. It may be associated with bradycardia and hypoxia.[29] Periodic breathing and apnea are believed to be disorders on a continuum, both stemming from abnormal physiologic control of respiration. However, periodic breathing is considered a benign disorder, whereas infants with symptomatic apneic episodes resulting in an apparent life-threatening event (ALTE) are thought to be at increased risk for sudden infant death syndrome. [33]

PULSE

The pulse is examined primarily to establish cardiac rate and rhythm. However, palpation of peripheral pulses yields clues to cardiac disease, such as aortic insufficiency, and information about the integrity of the peripheral vascular supply. Doppler ultrasound provides a noninvasive method of assessing blood flow in the ED. It has utility in the location of a pulse, in the assessment of fetal heart tones beyond the first trimester, for evaluation of peripheral lower extremity vascular insufficiency, and for the evaluation of blood pressure in infants or in patients with low-flow states.

Physiology

Blood flowing into the aorta with each cardiac cycle initiates a pressure wave. Blood flows through the vasculature at approximately 0.5 m/sec; however, pressure waves in the aorta move at 3 to 5 m/sec. Therefore, palpated peripheral pulses represent pressure waves, not blood flow.

Indications and Contraindications

The evaluation of pulse presence and rate is indicated in most patients who present to the ED. Patients with minor complaints, believed unlikely to be related to a circulatory problem, do not require this measurement. The necessity of repeated evaluations is dictated by the clinical complaint and status of the patient. Detailed pulse assessment is essential in all patients with potential peripheral vascular insufficiency. Although an association between the absence of a radial pulse (or the absence of both radial and femoral pulses) and hypotension has been demonstrated for hypovolemic trauma patients, the variability in individual response prohibits the use of this parameter as an absolute gauge of blood pressure.[34] No contraindications exist to assessment of pulse, but a few cautionary notes about the examination of the carotid pulse should be kept in mind: Concurrent bilateral carotid artery palpation should be avoided, as this maneuver could endanger cerebral blood flow. In addition, massage of the carotid sinus, found at the bifurcation of the external and internal carotid arteries at the level of mandible angle, may result in reflex slowing of the heart rate (see Chapter 11). To avoid inadvertent carotid sinus massage, the carotid pulse should be palpated at or below the level of the thyroid cartilage. A rare risk of precipitating a cerebrovascular event by *vigorous palpation* of the carotid artery is present in adults with atherosclerotic disease. This risk may be minimized by prior auscultation of the carotid artery. If a bruit is present, the carotid pulse may be gently palpated, but avoid vigorous palpation.

Equipment

Assessment of the pulse may be performed by the clinician at the bedside with any timepiece that has a second-hand display. This allows simultaneous assessment of all characteristics of the pulse: its rate, rhythm, gross perfusion pressure, and upstroke. If continuous monitoring is deemed necessary, bedside cardiac monitors can constantly monitor heart rate and rhythm and may be more accurate indicators of a perfusing rhythm than cardiac auscultation. Pulse oximetry (see Chapter 2), although primarily intended to measure oxygen saturation, also may be used to monitor the pulse rate. In a critical care situation, more sophisticated invasive monitoring techniques are available (see Chapter 20) for arterial pressure measurement and rate assessment.

Procedure

Pulses are palpable at numerous sites, although for convenience the radial pulse at the wrist is routinely used. The examiner should use the tips of the first and second fingers to palpate the pulse. The two advantages to this technique are (1) the fingertips are quite sensitive, enabling the pulse to be easily located and counted, and (2) the examiner's own pulse may be erroneously counted if the thumb is used instead of the first and second fingers. Pulses are also easily palpated at the carotid, brachial, femoral, posterior tibial, and dorsalis pedis arteries. Palpation of the pulse at the brachial artery may facilitate the appreciation of pulse contour and amplitude. It is located at the medial aspect of the elbow and is more easily palpated when the elbow is held slightly flexed.[35] Pulse rate is ideally determined by counting the pulse for 1 minute, particularly if any abnormality is present. Common convention in acute care settings is the counting of a *regular* pulse for 15 seconds and multiplying the resultant number by 4 to determine beats/min.

In newborns, direct heart auscultation and umbilical palpation are the methods of choice to determine heart rate. Instantaneous changes in newborn heart rates are best

indicated for the resuscitation team by the examiner tapping out each heartbeat.[36] In unstable children, palpation of central arteries, particularly femoral and brachial pulses, is recommended over palpation of more peripheral arteries.

In most circumstances the palpated heart rate will approximate the actual heart rate within 2%.[37]

Interpretation

Pulse Rate

Individual physiology must be considered in pulse interpretation. In infants and children, pulse rate must be interpreted with reference to age. Pulse varies with respiration, increasing with inspiration and slowing with expiration. This is known as a *sinus dysrhythmia* and is physiologic.

Although bradycardia is defined as a heart rate of <60 beats/min in adults, a well-conditioned athlete may have a normal resting heart rate of 30 to 40 beats/min.[38] As discussed earlier, a redefinition of bradycardia to <50 beats/min and tachycardia to >90 beats/min has been proposed based on a normal healthy population.[19] [20] [39] [40] These definitions of normal represent the 95% of a population and do not speak to an individual's normal baseline rate.

The clinician must consider whether an abnormal pulse rate is a primary or secondary condition. The examination of the entire set of vital signs is instrumental in discerning the cause for the abnormal rate. For example, hyperthermia causes a sinus tachycardia. Drug fever, typhoid fever, and central neurogenic fever are suggested when no corresponding tachycardia is found in a patient with elevated body temperature. Hypothermia, with its reduced metabolic demands, may be associated with bradycardia.

Clinical evaluation of the patient with an abnormal pulse rate dictates a consideration of medications the patient may be taking or the presence of a mechanical pacemaker. Digitalis compounds, ß-blockers, and antidysrhythmics may alter the normal heart rate and the ability of this vital sign to respond to a new physiologic stress. These cardioactive medications may be causing the patient's heart rate abnormality.

Heart Rhythm

In addition to determining the pulse rate, information about the regularity of the pulse is obtained during palpation. An irregular pulse suggests atrial fibrillation or flutter with variable block, and accurate assessment of the pulse should be obtained by auscultation of apical cardiac sounds. The apical pulse is frequently greater than the peripheral pulse, reflecting inadequate filling time and stroke volume, with resultant non-transmitted beats. A greater pulse deficit generally reflects more severe disease.

Pulse Amplitude and Contour

Amplitude and contour of the pulse are generally assessed simultaneously. Figure 1-1 compares normal and abnormal pulse amplitudes and contours. Accurate examination and description provide additional clinical information. Superimposition of one pathophysiologic state on another may modify the pulse. For example, sepsis may manifest with variable pulse amplitude, depending on the stage in the development of the disease at which the patient presents. Early in sepsis, cardiac output increases and vascular

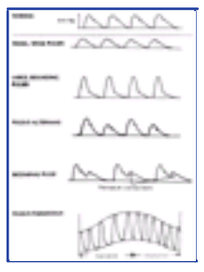

Figure 1-1 Examples of abnormalities of the arterial pulse compared with the normal pulse. The normal pulse pressure is approximately 30 to 40 mm Hg. The pulse contour is smooth and rounded. (The notch on the descending slope of the pulse wave is not palpable.) *(From Bates B: A Guide to Physical Examination and History Taking, 4th ed. Philadelphia, JB Lippincott, 1987.)*

resistance decreases, causing bounding pulses. In advanced sepsis or septic shock, falling cardiac output and increased vascular resistance are seen, and pulses are diminished.[41]

Definable age-related pulse amplitude and contour changes can be identified. Aging changes in the arterial pulse are explained by both an increase in arterial stiffness with increased pulse wave velocity and progressively earlier wave reflection. This leads to increased pulse amplitude in the elderly in all commonly measured sites (carotid, femoral, and radial).[42] In addition to these age-related changes, pulse wave analysis may be useful in determining arterial stiffness and the likelihood of atherosclerotic disease.[43] Although intriguing, the routine measurement of pulse amplitude is not reproducible by simple palpation but instead requires instrumentation not available in EDs.

Pulses During Cardiopulmonary Resuscitation

Palpated "femoral pulses" during chest compression may represent either forward arterial blood flow or "to-and-fro" movement of blood from the right heart to the venous system. A carotid pulse is preferred when assessing the adequacy of chest compressions during cardiopulmonary resuscitation (see Chapter 17).

ARTERIAL BLOOD PRESSURE

Changes in arterial blood pressure over time may indicate the success of treatment or the worsening of the patient's overall condition. An abrupt reduction in the patient's arterial blood pressure usually indicates the need for immediate intervention or reconsideration of therapy. The technique of arterial cannulation and direct intra-arterial blood pressure monitoring is discussed elsewhere (see Chapter 20). The current section discusses indirect blood pressure monitoring. Discussions of the specific use of the Doppler device for pulse and blood pressure measurement and the measurement of orthostatic blood pressure and pulse changes follow this section. As noted earlier, despite an association between the absence of a radial pulse (or the absence of both radial and femoral pulses) with hypotension, in the setting of trauma, the variability in individual response prohibits the use of this parameter as an absolute gauge of blood pressure. [34]

Physiology

Arterial blood pressure indicates the overall state of hemodynamic interaction between cardiac output and peripheral vascular resistance. Arterial blood pressure is the lateral pressure or force exerted by blood on the vessel wall. Arterial blood pressure indirectly measures perfusion, where blood flow equals the change in pressure divided by resistance.[8] However, because peripheral vascular resistance varies, a normal blood pressure does not confirm adequate perfusion. [44] Mean arterial blood pressure can be estimated by adding one third of the pulse pressure (i.e., the difference between the systolic and diastolic blood pressure) to the diastolic pressure.[8] [45]

Indications and Contraindications

Blood pressure measurement and documentation are essential for most ED patients seen for the first time. Patients with minor ambulatory complaints not related to the cardiovascular system may not receive blood pressure measurements in the ED. Patients with hemodynamic instability need frequent blood pressure monitoring.

In children, there is a significant amount of variability regarding standard situations requiring blood pressure measurement. In general, the younger the patient, the less likely a blood pressure will be obtained. [46] In newborns, infants, and even toddlers, capillary refill is frequently substituted for a standard blood pressure measurement, although viewing these tests as equivalent can lead to significant errors.

In low-flow states, Doppler measurement of blood pressure may be obtained rapidly. Repeated measurements will provide an evaluation of the adequacy of resuscitation in patients whose blood pressure cannot be auscultated by standard techniques. Placement of a catheter for direct intra-arterial measurement of blood pressure has a higher risk of complications, but it may be performed safely in the ED (see Chapter 20). In particular, direct measurement of arterial pressure during pulseless electrical rhythms may help to discriminate between severe shock and an otherwise non-resuscitatable status. [47] [48] [49] Alternative noninvasive devices for continuous blood pressure measurement are being introduced clinically, including the use of radial artery tonometry via a sensor applied over the radial artery in conjunction with an inflatable upper arm cuff. [50]

Relative contraindications to specific extremity blood pressure measurement include an arteriovenous fistula, ipsilateral mastectomy, axillary lymphadenopathy, lymphedema, and circumferential burns over the intended site of cuff application.

Equipment

The equipment required for indirect blood pressure measurement includes a sphygmomanometer (cuff with inflatable bladder, inflating bulb, controlled exhaust for deflation, and manometer) and a stethoscope or Doppler device (for auscultation) or an oscillometric device. [51] [52] [53] [54] A common practice in the prehospital and interhospital transport setting is to forego auscultatory blood pressure measurement with a stethoscope and instead obtain systolic values only via palpation of the first Korotkoff sound. This practice, although sometimes the only feasible method of obtaining any value in a noisy environment, poses significant potential for errors. In a study of critically ill patients transferred between hospitals, palpated systolic blood pressures underestimated manometric values by nearly 30%. [37] According to the American Heart Association Guideline, to ensure an accurate reading, the sphygmomanometer cuff should be of an appropriate size for the patient. The width of the bladder should be at least 40% of the distance of the limb's midpoint (i.e., from the acromion process to the lateral epicondyle). This published figure of ideal width, when studied in a validation review, may be higher up to approximately 50%. [55] The length of the bladder should be 80% of the midarm circumference or twice the recommended width.[45]

Manometers in common use are either an aneroid or a mercury gravity column. Both types of manometers are convenient for bedside use, although the mercury gravity column must be placed vertically to ensure accurate measurements. An aneroid manometer uses a metal bellows that elongates with the application of pressure. This elongation is mechanically amplified, transmitting the motion to the indicator needle.

Manometers require annual servicing. Mercury columns may require the addition of mercury to bring the edge of the meniscus to the zero mark. The air vent or filter at the top of the mercury column should also be checked for clogging. The aneroid manometer should be calibrated against a mercury column at least yearly. If the aneroid indicator is not at zero at rest, the device should not be used. [56]

Automatic sphygmomanometers may improve physiologic monitoring with alarm and self-cycling capabilities. They offer indirect arterial blood pressure measurement with little pain and lack the risks associated with invasive arterial lines. [57] Various manufacturers use oscillometric (Dinamap 845, Applied Medical Research, Tampa, FL), Korotkoff sound (Pressurometer, Avionics, Irvine, CA); and ultrasonic (Arteriosonde, Hoffmann-LaRoche Co, Nutley, NJ) techniques. Oscillometric blood pressure monitors detect motion of the blood pressure cuff transmitted from the underlying artery. A sudden increase in the amplitude of arterial oscillations occurs at systolic pressure and mean arterial pressure, and an abrupt decrease occurs at diastolic pressure.

Dinamap blood pressures obtained in 29 hemodynamically stable children (mean age, 18 months) demonstrated a smaller mean error (systolic, -0.24 vs 3.26 mm Hg) than auscultatory measurements in 20 children (systolic, -1.65 vs 6.68 mm Hg) using direct radial arterial pressures for comparison. [58] Park and Menard also found less variability with the Dinamap vs the auscultatory method in children. [59]

These results are not, however, generalizable to the neonatal population, where errors are commonly encountered even when exhaustive measures are taken to control the environment. [60]

In adult patients, numerous studies have focused on reliability of auscultory vs automated blood pressure measurements. Mercury column vs Dinamp readings showed increased disparity at systolic blood pressures >140 mm Hg, the range where accuracy should be most rigorously sought to correctly identify hypertension. In general, automated blood pressure readings yielded higher systolic blood pressures and lower diastolic values. [61] The range of error in automated devices was on average 4.0 to 8.6 mm Hg.[62] Unfortunately, these studies represent populations without critical illness and do not reflect accuracy of readings in the extremes of hypertension and hypotension. This makes generalization to an ED population difficult.

Procedure

Indirect blood pressure measurements may be obtained at the patient's bedside by palpation, auscultation, Doppler, or oscillometric methods. The technique is

straightforward and accurate when well-maintained, calibrated equipment is used by practitioners who follow accepted standards. The patient may be lying or sitting, as long as the site of measurement is at the level of the right atrium and the arm is supported. [45] [51] Interestingly, unless the arm is kept perpendicular to the body, measurements will be 9 to 14 mm Hg higher regardless of body position.[52] Hence, allowing the arm to be parallel to the body when supine, but supporting the arm perpendicular to the body when measuring the blood pressure in either the sitting or standing position may create a pseudo drop in blood pressure.

Palpation of arterial blood pressure requires cuff inflation to 30 mm Hg above the level at which a palpable pulse disappears. Once properly inflated, the examiner should palpate directly over the artery and deflate the cuff at 2 to 3 mm Hg per second. The initial appearance of arterial pulsations is reported as the palpable blood pressure. The same technique may be used with the Doppler device with the Doppler auditory signal replacing the palpated pulse. Arterial pressure measurement by palpation and Doppler yields only systolic blood pressure estimates. The Doppler method is preferred when obtaining blood pressures from infants. [63]

When auscultating the blood pressure at the brachial artery, the blood pressure cuff is applied about 2.5 cm above the antecubital fossa with the center of the bladder over the artery.[51] The bell of the stethoscope is applied directly over the brachial artery but with as little pressure as possible. [64] The systolic arterial blood pressure is defined as the first appearance of faint, clear, tapping sounds that gradually increase in intensity (Korotkoff phase I), whereas the diastolic blood pressure is defined as the point at which sounds disappear (Korotkoff phase V). [51] [64] In children, phase IV defines the diastolic blood pressure (Fig. 1-2). [12] Phase IV is marked by a distinct, abrupt muffling of sound when a soft, blowing quality is heard.

Measurement by auscultation over the brachial artery is preferred because of accepted standardization of measured values. Alternate sites include the radial, popliteal, posterior tibial, or dorsalis pedis arteries, although any fully compressible extremity artery may be used. Studies correlating direct and indirect blood pressure measurements have demonstrated a good correlation between these methods. [65] [66] [67]

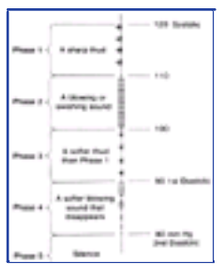

Figure 1-2 Korotkoff sounds. Systole—first audible sound. Diastole—sound disappears. *(From Burnside JW, McGlynn TJ: Physical Diagnosis, 17th ed. Baltimore, Williams & Wilkins, 1986.)*

There are situations in which it may not be feasible to obtain upper extremity blood pressure measurements because of patient access issues, particularly those encountered in the prehospital setting. Forearm measurements may be more easily obtained, and show fair correlation to standard upper extremity values (within 20 mm Hg in 86% of systolic measurements and 94% of diastolic measurements).[68] Alternatively, noninvasive finger blood pressure measurements have shown promise when compared to standard upper extremity readings. The overall discrepancy in an ED study was 0.1 mm Hg with a standard deviation of ±5.02 mm Hg when comparing finger blood pressures and invasive mean arterial blood pressure via radial artery cannulation. [69]

The accuracy of palpatory, Doppler, and oscillometric methods has also been demonstrated. [70] [71] [72] [73] However, when phase I and V Korotkoff sounds are used, indirect methods typically underestimate systolic and diastolic pressure by several mm Hg. [66] [74] In addition, during shock, palpatory and auscultatory methods underestimate simultaneous direct arterial pressure measurements.[75] The flush method, in which return of color after deflation of the cuff is used for estimating blood pressure in infants, may underestimate systolic blood pressure by up to 40 mm Hg. [74] This method is unreliable and is not recommended.

Complications

Complications of indirect blood pressure measurement are minimal when the proper procedure is followed. Inadvertent prolonged application of an inflated blood pressure cuff may

result in false elevation of diastolic pressure and in ischemia distal to the site of application, with attendant complications. [8] [53] Invasive blood pressure monitoring is associated with a number of potential problems (see Chapter 20).

Interpretation

Normal blood pressure increases with decreasing distance from the aorta. Blood pressure tends to increase with age and is generally higher in males. Individual factors that influence blood pressure include body posture, emotional or painful stimuli, environmental influences, vasoactive foods or medications, and the state of muscular and cerebral activity. Exercise and sustained isometric muscular contraction increase blood pressure in proportion to the strength of the contraction. [8] A normal diurnal pattern of blood pressure consists of an increase throughout the day with a significant, rapid decline during early, deep sleep. [76]

Normal lower limits for systolic blood pressure for infants and children can be estimated by adding 2 times the age (in years) to 70, with the result expressed in mm Hg. The 50th percentile for a child's systolic arterial blood pressure from 1 to 10 years of age can be estimated by adding 2 times the age (in years) to 90 mm Hg. Children older than 2 years are considered hypotensive when systolic blood pressure is <80 mm Hg. [77] Children, in particular, are able to maintain mean arterial blood pressure until very late during shock.[78] Thus the finding of a normal blood pressure in a child with signs of poor perfusion should not dissuade the practitioner from appropriate treatment. Adults are considered hypotensive if the systolic blood pressure is <90 mm Hg. When accompanied by signs of shock, immediate treatment is indicated. In patients with shock, blood flow cannot be reliably inferred from heart rate and blood pressure values. [79] [80]

Hypertension

Adults are hypertensive if either the systolic or the diastolic pressure consistently exceeds 140 or 90 mm Hg, respectively. [81] [82] The applicability of population norms for hypertension in a stressful emergency situation is controversial. One should not make diagnostic or therapeutic decisions based solely on an abnormal initial measurement. Patients with hypertension require repeat measurement to assess whether ED therapy is required. Because sustained hypertension may be seen in more than a third of initially hypertensive ED patients, careful evaluation and follow-up are required. [83]

The phenomenon of white coat hypertension (WCH) is defined as the persistent elevation of blood pressure in the clinical setting only. In order to strictly fit this definition, patients must have a normal ambulatory blood pressure outside of the clinical setting. WCH should not be confused with the white coat effect (WCE), a finding of increased blood pressure values in nearly all patients within the clinical setting. The white coat effect is used to characterize exaggerated hypertension in a normally hypertensive patient, frequently pushing moderately controlled hypertension readings into significantly higher readings while in the clinical setting. The prevalence of WCH is between 20% and 94%, depending on the frequency of clinical setting reassessment. [84] [85] [86] Patients in whom WCH or the WCE is most likely to occur are women, nonsmokers, and the elderly.[86] [87] It is unclear whether these patients who have isolated clinical setting hypertension (WCH) are at increased risk for developing hypertension and subsequent end-organ damage. [88]

Measurement Errors

Erroneous blood pressure measurements may result from several factors.[82] [89] Falsely low blood pressure may be caused by using an overly wide cuff, by placing excessive pressure on the head of the stethoscope, or by rapid cuff deflation. [90] [91] Falsely high blood pressure may be caused by the use of an overly narrow cuff, anxiety, pain, tobacco use, exertion, an unsupported arm, or slow inflation of the cuff.

In 470 unselected adults, investigators at Duke University found no spurious effect of cuff size in 350 patients weighing <95 kg and with an arm circumference <35 cm. However, in 120 patients weighing >95 kg and with an arm circumference >35 cm, the use of a large cuff reclassified 33% of those with systolic hypertension to borderline, 62% of those with borderline systolic hypertension to normal, and 79% of patients with borderline diastolic hypertension to normal. [92] Of note, 41% of

adults observed at the University of Pittsburgh required nonstandard size cuffs, and use of small cuffs was associated with a mean error of 8.5 and 4.6 mm Hg in the systolic and diastolic pressures, respectively. [93] Other studies have confirmed relatively high rates of inappropriately diagnosed hypertension among obese patients based on erroneous cuff size.[94]

Hypotensive patients have unreliable Korotkoff sounds. However, Doppler measurements are well correlated with direct arterial systolic pressure in hypotensive patients.[95]

An auscultatory gap can be appreciated in hypertensive patients and may mislead the examiner. It is heard during the latter part of phase I and should not be confused with diastolic readings. Auscultation until the manometer reading approaches zero should prevent misinterpretation. In patients with aortic insufficiency or hyperthyroidism, in persons who have just finished exercising, and in children younger than 5 years of age, the measurement of diastolic blood pressure should occur at Korotkoff phase IV.

Irregular heart rates also may interfere with accurate blood pressure determination. A second or third reading, with 2 minutes of deflation between recordings, should be used to obtain an average when premature contractions or atrial fibrillation is present. Ultrasonic methods may be more accurate during shock states and in infants for systolic blood pressure measurement.[85] [95]

Dewar demonstrated that hemiplegic patients may exhibit different blood pressures in affected and unaffected arms. [96] A flaccid extremity tended to yield lower systolic and diastolic pressures, whereas a spastic extremity tended to yield higher values than the extremity with normal motor tone. Although these differences are generally small, it is preferable to monitor blood pressure in the unaffected limb.

As noted earlier, numerous errors may occur in the measurement of accurate blood pressure. The only way to combat them is to first be cognizant of practices contributing to them. Unfortunately, few nurses can identify causes of potentially erroneous readings. In a study examining nurses' ability to accurately obtain readings, proper techniques in obtaining systolic blood pressure could be identified 61% of the time, diastolic blood pressure 71%, and an auscultatory gap 54%. Nurses were able to correctly determine faulty equipment 58% of the time, assess cuff size 57%, determine appropriate

inflation pressure 29%, determine appropriate deflation rate 62%, and determine correct arm positioning only 14%. [97]

Pulse Pressure

Increased pulse pressure (i.e., =60 mm Hg) is commonly observed in anemia, exercise, hyperthyroidism, arteriovenous fistula, aortic regurgitation, and patent ductus arteriosus. A narrowed pulse pressure (=20 mm Hg) may be a manifestation of hypovolemia, increased peripheral vascular resistance, or decreased stroke volume.

Differential Brachial Artery Pressures

The presence of systolic blood pressure differences between arms is suggestive of advanced focal atherosclerosis, coarctation of the aorta proximal to the left subclavian artery, aortic dissection, other aortic arch syndromes, or other vascular processes preferentially affecting one extremity. Although most patients have similar blood pressures in both arms, Pesola and coworkers found that 18% of their hypertensive population [17] and 15% of their normotensive population[16] had a difference of >10 mm Hg in systolic blood pressure. Others report that only 1.4% of elderly patients had a systolic brachial blood pressure difference of >10 mm Hg, although 6.5% had a difference exceeding 7.5 mm Hg.[98] Panayiotou noted that for most stroke patients, the difference between the paretic and normal arm was only 4 to 5 mm Hg.[99] However, differences of 9 to 12 mm Hg were noted for some patients. Hence, differential brachial blood pressures must be interpreted within the clinical context of the patient's presentation.

Pulsus Paradoxus

Normal respiration decreases the systolic blood pressure by approximately 10 mm Hg during inspiration. Pulsus paradoxus occurs when there is a >12 mm Hg decrease in the systolic blood pressure during inspiration. Pulsus paradoxus may occur in patients with chronic obstructive pulmonary disease, pneumothorax, severe asthma, and pericardial tamponade.[100] Other conditions such as an atrial septal defect, aortic insufficiency, and poor left ventricular compliance have been associated with pulsus paradoxus without pericardial fluid.

To measure a paradoxical pulse, the patient should be lying comfortably, at a 30° to 45° angle, and breathing normally in an unlabored fashion (unusual conditions in a patient suspected of cardiac tamponade, severe asthma or chronic obstructive pulmonary disease, or pneumothorax). [101] The blood pressure cuff is inflated well above systolic pressure and is slowly deflated until one first hears the systolic sounds that are synchronous with expiration (Fig. 1-3). Initially, one will hear the arterial pulse only during expiration, and it will disappear during inspiration. The cuff is then further deflated until arterial sounds are heard throughout the respiratory cycle. A paradoxical pulse can be palpated if it is very large. During palpation the pulse may completely disappear during inspiration. When present, this technique is a quick bedside confirmation of the possibility of severe tamponade. Palpation for this purpose is best done at peripheral arteries, such as the radial or femoral.

An alternative approach to measurement of pulsus paradoxus is to use a finger arterial pressure monitor (Finapres; Ohmeda, Englewood, CO) and to subtract the peak systolic blood pressure during expiration from the lowest systolic

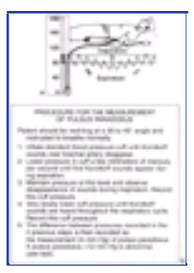

Figure 1-3 *A*, Measurement of pulsus paradoxus. Note that the systolic pressure varies during the respiratory cycle. *(From Stein L, Shubin H, Weil M: Recognition and management of pericardial tamponade. JAMA 225:504, 1973. Copyright 1973, American Medical Association. Reproduced by permission.) B*, Technique for the measurement of pulsus paradoxus.

blood pressure during inspiration. [102] The pulsus paradoxus obtained with this technique was found to have less variability (when compared to intra-arterial measurements) than with manual measurements. Furthermore, pulsus paradoxus obtained using the finger pressure monitor correlates well with the pulmonary index score in asthmatic children.[103] Changes in the pulsus paradoxus were found to correlate with other markers of clinical status and admission decisions.

If the difference between these inspiratory and expiratory pressures is >12 mm Hg, the paradoxical pulse is high. [104] Most patients with proven tamponade have a difference of =20 to 30 mm Hg during the respiratory cycle.[105] [106] This may not be true of patients with very narrow pulse pressures (typical of advanced tamponade), who have a "deceptively small" paradoxical pulse of 5 to 15 mm Hg. The relative decrease in pulsus paradoxus occurs because the paradoxical pulse is a function of actual pulse pressure, and the inspiratory systolic pressure may be below the level at which diastolic sounds disappear. [101] For this reason, the ratio of paradoxical pulse to the pulse pressure is a more reliable

measure. A paradoxical pulse >50% of the pulse pressure is abnormal.[101]

Pulsus paradoxus has been correlated with the amount of impairment of cardiac output by tamponade. In uninjured patients with pericardial effusion, a pulsus paradoxus >25 mm Hg (in the absence of relative hypotension) was both sensitive and specific for moderate or severe versus mild tamponade. [104] A similar study of

right ventricular diastolic collapse by echocardiography found that an abnormal pulsus paradoxus had a sensitivity of 79%, specificity of 40%, positive predictive value of 81%, and negative predictive value of 40%.[107] The absence of a paradoxical pulse does not rule out tamponade (see Chapter 16).

In the pediatric population, pulsus paradoxus has been studied to determine the disease severity of obstructive and restrictive pulmonary disease,[108] most commonly asthma. A value of 15 mm Hg or greater correlates well with clinical score, peak expiratory value, flow rate, oxygen saturation, and subsequent need for admission.[109]

Despite the disease entities that a widened pulsus paradoxus may suggest, it is a difficult task to perform adequately using only a syphgmomanometer. In a study by Jay et al., emergency clinicians and critical care specialists were unable to reliably measure pulsus paradoxus in a trained reference subject either by palpation or by syphgmomanometer. The variance of actual versus measured pulsus paradoxus was greater with increasing pulsus paradoxus values into the pathologic range, lowering significantly the positive predicative value of the test.[110] The author's conclusion was that new aids should be developed and used to reliably predict this important vital sign.

Shock Index

The ratio of the pulse rate over the systolic blood pressure has been suggested as a measure of clinical shock. The shock index (SI) has a normal range of 0.5 to 0.7. A number of clinical scenarios have been studied using the shock index as a predictor of severe illness or injury. A shock index >0.85 to 0.90 suggests acute illness in medical patients, as well as a marked increase in potential for gross hemodynamic instability in a trauma patient.[111] [112] [113] [114] In a study evaluating first-trimester pregnancy, those patients with a shock index >0.83 were 15 times more likely to be diagnosed with an ectopic pregnancy in the ED.[111] [115] However, some studies have found that the presenting pulse rate alone had nearly the same predictive power for severity of illness as the shock index. Further, Rady and coworkers demonstrated that although the SI appeared to correlate with left ventricular stroke work index, it had little correlation with systemic oxygen transport in hemorrhagic and septic shock.[112]

DOPPLER ULTRASOUND FOR EVALUATION OF PULSE AND BLOOD PRESSURE

Principles of Doppler Ultrasound

Doppler ultrasound is based on the Doppler phenomenon: The frequency of sound waves varies depending on the speed of the sound transmitter in relation to the sound receiver. Doppler devices transmit a sound wave that is reflected by flowing erythrocytes, and the shift in frequency is detected. Frequency shift can only be detected for blood flow >6 cm/sec.

Indications and Contraindications

Doppler ultrasound is commonly used in the ED for the measurement of blood pressure in low-flow states, evaluation of lower extremity peripheral perfusion, and assessment of fetal heart sounds after the first trimester of pregnancy. Doppler sensitivity allows the detection of systolic blood pressure down to 30 mm Hg in the evaluation of a patient in shock. In the patient with peripheral vascular disease in whom there is concern about the adequacy of peripheral perfusion, the ankle/brachial index provides a rapidly obtainable, reproducible, and standardized assessment. [116] Fetal heart sounds provide a baseline assessment of any patient with =12 weeks' gestation in whom there is possible abdominal trauma or fetal distress due to a pregnancy complication.

The use of Doppler ultrasound in the evaluation of deep venous thrombosis is a valuable tool; however, it requires specific training and experience to attain proficiency. Discussion of this topic is beyond the scope of this chapter.

Equipment

A nondirectional Doppler device has a probe that houses two piezoelectric crystals. One crystal transmits the signal and the other receives it. Reflected signals are converted to an electrical signal and fed to an output that transforms them to an audible sound. Two commonly used Doppler units are the pocket Doppler stethoscope (model BF4A, Medsonics, Inc, Los Altos, CA) and the ultrasonic Doppler flow detector (model 811, Parks Medical Electronics, Aloha, OR) (Fig. 1-4 and Fig. 1-5).

Probes with a frequency of 2 to 5 MHz are best for detecting fetal heart sounds. Frequencies of 5 to 10 MHz are appropriate for limb arteries and veins. The probes should be monitored periodically for electrical damage and integrity of the crystal. Sphygmomanometers used in conjunction with the Doppler device should be calibrated periodically, as described in the section on blood pressure evaluation.

Figure 1-4 Pocket Doppler stethoscope (model BF4A). *(Courtesy of Medsonics Inc, Los Altos, CA.)*

Figure 1-5 Ultrasonic Doppler flow detector with speaker and probes (model 811). *(Courtesy of Parks Medical Electronics, Aloha, OR.)*

Procedure

The Doppler probe is placed against the skin using an acoustic gel as an interface. The gel ensures optimal ultrasound signal transmission and reception and protects the crystals. In an emergency, water-soluble lubricant (e.g., Surgilube or K-Y jelly) may be substituted for commercial acoustic gel. The probe is angled at 45° along the length of the vessel to optimize frequency shifts and signal amplitude.

In the evaluation of peripheral perfusion, a sphygmomanometer cuff is placed proximal to the arterial pulse and inflated. The probe is placed over the arterial pulse and the cuff is slowly deflated. The pressure at which flow is first heard is the systolic pressure.

In the evaluation of peripheral vascular disease, the ankle/brachial index is determined. Both brachial arteries are examined at the medial aspect of the antecubital fossa. The probe is angled until the most satisfactory signal is obtained. The cuff is inflated and slowly deflated until the systolic pulse is heard. The procedure is repeated for the posterior tibial and dorsalis arteries of both lower extremities.

In the evaluation of fetal heart tones, variable positioning of the fetus may require examination at several locations over the uterus and angling of the probe to search for the optimal signal. It is best to begin in the mid-suprapubic area and to explore the uterus via angulation of the probe. Once tones are located, the probe can be moved along the abdomen to reach a position closer to the origin of the sound. Fetal heart tones are distinguished from placental flow by the discrete quality of the fetal heart tones and the rate of placental flow, which matches the maternal pulse.

Interpretation

As noted earlier, in low-flow states, Doppler ultrasound can detect a blood pressure as low as 30 mm Hg. The ankle/brachial index of each limb is calculated by dividing the higher systolic pressure of the posterior tibial or the dorsalis pedis artery of the limb by the higher of the systolic pressures in the brachial arteries. In normal individuals, the index should be >1.0. Patients with claudication have values between 0.6 and 0.8. Values <0.5 imply severe impairment and are consistent with rest pain or gangrene. [116] When the lower extremity has been amputated or is itself injured, brachial/brachial indices can be used (i.e., the systolic blood pressure of the injured or diseased upper extremity compared to the other. Patients with ankle/brachial index values of =0.9 have been found to have increased cardiovascular morbidity and mortality. [117] One study of 323 penetrating extremity wounds found the ankle/brachial index (or the brachial/brachial index) of <0.9 to be 72.5% sensitive and 100% specific for the 29 vascular injuries. [118] Segmental lower extremity pressure measurements may help to identify the level of obstruction (Fig. 1-6 Fig. 1-7 Fig. 1-8). [119] Obese patients, diabetic patients, or patients with calcified vessels that are not compressible may have abnormally high systolic pressures (e.g., 250 to 300 mm Hg) and indices that do not accurately reflect flow.

Normal fetal heart tones should be between 120 and 140 beats/min. Fetal tones may be heard as early as the 12th week of gestation.

ORTHOSTATIC VITAL SIGNS MEASUREMENT

Orthostatic vital signs are used to evaluate patients with fluid loss, hemorrhage, syncope, or autonomic dysfunction. They are also used to assess the patient's response to therapy. The practitioner is often concerned with the accurate detection of

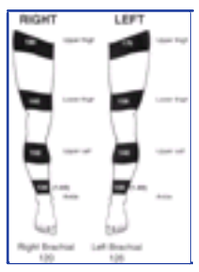

Figure 1-6 Typical pressures in a normal subject. Findings, based on resting pressures, show no evidence of occlusive disease of the large- or medium-sized arteries. Significant findings (normal) are as follows: (1) Ankle-to-brachial pressure index =1.0. (2) All pressure gradients <30 mm Hg. (3) Upper thigh pressure at least 40 mm Hg above brachial pressure. *(From Doppler Evaluation of Peripheral Arterial Disease: A Clinical Handbook. Fredericksburg, VA, Sonicaid, Inc. Reproduced by permission.)*

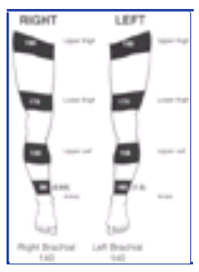

Figure 1-7 Typical pressures in a patient with obstruction of the popliteal or tibial arteries. Significant findings are as follows: (1) Ankle-to-brachial pressure index <0.9 in right leg. (2) Abnormally high gradient from ankle to below knee and again from below to above knee in right leg. (3) Upper thigh pressures are 50 mm Hg higher than brachial pressures, consistent with normal flow at the aorta-iliac level. Findings are suggestive of a right popliteal occlusion or an anterior and posterior tibial occlusion, or both. *(From Doppler Evaluation of Peripheral Arterial Disease: A Clinical Handbook. Fredericksburg, VA, Sonicaid, Inc. Reproduced by permission.)*

acute blood loss or volume depletion. When the clinical syndrome of shock exists, assessment of a blood volume deficit poses little difficulty. It is preferable, however, that volume loss be detected before loss of physiologic compensation and clinical shock occurs. This section addresses the utility of orthostatic vital signs in the detection and monitoring of acute volume depletion.

Many techniques have been advocated to assess volume status. Unfortunately, most procedures lack a database against which to judge their reliability. Recommended methods include evaluation of: skin color; skin turgor; skin temperature; supine, serial, and orthostatic vital signs; neck vein status; transcutaneous oximetry; and hemodynamic monitoring (e.g., monitoring of central venous pressure) (see Chapter 22). Serial vital sign measurements have been used for assessing blood loss, but they do not reliably detect small degrees of blood loss. [120] [121] [122] *Up to 15% of the total blood volume can be lost with minimal hemodynamic changes or any alteration of the supine vital signs.*[120] A decrease in the pulse pressure occurs with acute blood loss, [122] but the patient's baseline blood pressure values are often unknown. Clinical examination of neck veins adds useful information but is less precise than measurement of central venous pressure. Most clinicians use skin color, temperature, and moisture as a reflection of skin perfusion and sympathetic tone but not as an accurate guide to circulatory volume, because the vasomotor tone of the skin is affected by numerous diseases as well as by

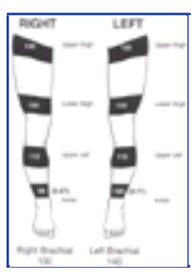

Figure 1-8 Typical pressures in a patient with obstruction of the abdominal aorta or bilateral iliac obstruction. Significant findings are as follows: (1) Ankle-to-brachial pressure index <0.9. (2) All segmental gradients <30 mm Hg. (3) Both upper thigh pressures relatively low with respect to brachial pressure. Findings are suggestive of severe aorto-iliac occlusive disease. *(From Doppler Evaluation of Peripheral Arterial Disease: A Clinical Handbook. Fredericksburg, VA, Sonicaid, Inc. Reproduced by permission.)*

emotional and environmental factors. Capillary refill has been advocated as an ideal noninvasive test for hypovolemia, but it has not been found to be accurate in adults [123] (see the following discussion regarding its use for children).

The ideal test for determining volume status would rapidly and accurately detect volume depletion of 5% or more using a noninvasive technique. At present, no such test exists. Orthostatic vital signs meet the criteria of being noninvasive and easily used at the bedside. However, *in patients with acute blood loss of <20% of total blood volume, orthostatic vital signs lack both sensitivity and specificity*.[124] Further, ethanol ingestion exaggerates postural pulse changes, thus mimicking the hemodynamic changes seen with acute blood loss. [125]

The medical literature is replete with unsubstantiated claims regarding what constitutes a positive or negative orthostatic test, and its value for estimating volume status may be overstated. Some authors[126] [127] have stated that postural hypotension or postural tachycardia occurs with varying degrees of hypovolemia, but they do not define specific criteria for a positive test. Other sources (without documentation) have perpetuated the notion that relatively small changes in the orthostatic blood pressure or the pulse are reliable in detecting hypovolemia. For example, Hayes and Briggs state erroneously that "a decrease of 10 mm Hg or more on assuming the sitting position indicates significant hypovolemia." [128]

The next section discusses the physiologic compensatory mechanisms that are activated by hypovolemia and postural tilting and the clinical use of orthostatic vital signs to detect acute volume loss.

TABLE 1-4 -- Homeostatic Mechanisms in Hemorrhagic Shock

Sympathetic reflex compensation
Arteriolar vasoconstriction
Venous capacitance vasoconstriction
Increased inotropic and chronotropic cardiac activity

Central nervous system ischemic response
Selective increase in cerebral and coronary perfusion by means of local autoregulation
Increased oxygen unloading in tissues
Restoration of blood volume
Renin-angiotensin-aldosterone axis activation
Antidiuretic hormone secretion
Transcapillary refill
Increased thirst resulting in increased fluid intake
Increased erythropoiesis

Physiologic Response to Hypovolemia

Acute blood loss decreases the pressure gradient between the venules and the right atrium. A fall in this pressure gradient decreases venous return. [129] As a result, cardiac output falls, and clinical manifestations of shock ensue. Several homeostatic mechanisms are initiated by acute blood loss (Table 1-4). The dominant compensatory mechanism in shock is a reduction in the carotid sinus baroreceptor inhibition of sympathetic outflow to the cardiovascular system. This increased sympathetic outflow results in several effects: (1) an arteriolar vasoconstriction, which greatly increases total peripheral vascular resistance; (2) a constriction of venous capacitance vessels, thereby increasing venous return to the heart; and (3) an increase of heart rate and force of contraction, which helps to maintain cardiac output despite significant volume loss. [130] These sympathetic reflexes are geared more for the maintenance of arterial pressure than for the maintenance of cardiac output (Fig. 1-9). The value of sympathetic reflex compensation is illustrated by the fact that 30% to 40% of the blood volume can be lost before death occurs while these reflexes are intact. When the sympathetic reflexes are absent, loss of only 15% to 20% of the blood volume may cause death. [130]

Several other reflexes maintain cardiac output in the presence of volume loss. The central nervous system ischemic response stimulates the sympathetic nervous system after the arterial pressure falls below 50 mm Hg and is responsible for the second plateau on the arterial pressure curve (see Fig. 1-9).[130] Other compensatory mechanisms that tend to restore the blood volume to a normal level include the release of angiotensin and antidiuretic hormone, which cause arteriolar vasoconstriction and conservation of salt and water by the kidneys. [131] A fluid shift from the interstitium to the intravascular space occurs, helping to restore blood volume over a longer period (1 to 40 hours). [132] [133]

When blood loss results in anemia, part of the loss in oxygen-carrying capacity is countered by an increase in tissue oxygen extraction. [134] Finally, the lost red blood cell mass is slowly replaced by erythropoiesis.

Several investigators have examined the changes in blood pressure and pulse that occur in the supine patient with blood loss. [120] [121] [122] Collectively these studies have shown

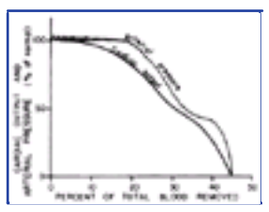

Figure 1-9 The effect of hemorrhage on cardiac output and arterial pressure. *(From Guyton AC: Textbook of Medical Physiology, 6th ed. Philadelphia, WB Saunders, 1981. Reproduced by permission.)*

variable individual hemodynamic responses to acute blood loss of up to 1 L. The frequent inability to detect significant volume loss with supine vital signs and the observation that patients with acute volume loss frequently develop syncope on rising led to the investigation of the use of orthostatic vital signs to detect occult hypovolemia.

Physiologic Response to Postural Changes

When an individual assumes the upright posture, complex homeostatic mechanisms compensate for the effects of gravity on the circulation to maintain cerebral perfusion. These responses include (1) baroreceptor-mediated arteriolar vasoconstriction, (2) venous constriction and increased muscle tone in the legs and the abdomen to augment venous return, (3) sympathetic-mediated inotropic and chronotropic effects on the heart, and (4) activation of the renin-angiotensin-aldosterone system.[135]

These compensatory mechanisms preserve cerebral perfusion in the upright position with minimal changes in vital signs. Currens found that when normal subjects stand, the pulse increases by an average of 13 beats/min, systolic blood pressure falls slightly or does not change, and diastolic pressure rises slightly or does not change.[136] These changes have been confirmed by others. [124] [125] [126]

In patients with *vasodepressor syncope*, the normal compensatory reflexes that preserve cerebral perfusion with postural changes are altered. The normal increased sympathetic tone on standing is paradoxically inhibited, and an exaggerated enhancement of parasympathetic activity (bradycardia) occurs, which can lead to syncope.[137]

Few data exist on the effect of acute blood loss on postural vital signs. One early study [122] looked at 23 young adult volunteers from whom 500 to 1200 mL of blood was withdrawn. They found no reliable change in the postural blood pressure, but a consistent postural increase in the pulse of 35% to 40% was noted after a 500-mL blood loss. In the 6 subjects who were bled approximately 1 L, only 2 were able to tolerate standing; each of them had a postural increase in pulse of >30 beats/min. The other four subjects experienced severe symptoms on standing, followed by a marked bradycardia and syncope if they were not allowed to lie down.

Knopp and colleagues[124] phlebotomized 450 to 1000 mL of blood from healthy volunteers. By using the criterion of a pulse increase of 30 beats/min or the presence of severe symptoms (syncope or near syncope) during a supine-to-standing test, they distinguished accurately between a 1000-mL blood loss and no blood loss. Changes in blood pressure and pulse were not evaluated in the symptomatic subjects. In this study population of 100 normal healthy volunteers with acute blood loss, the sensitivity and specificity using the aforementioned criteria for detecting a 1000-mL blood loss (Table 1-5) were both 98%, giving an accuracy of 96% (2% false-negative results and 2% false-positive results). The investigators were unable to consistently detect a blood loss of 500 mL by using these criteria. In a similar study by Kosowsky and coworkers,[138] the change in heart rate with postural changes after a 500-mL phlebotomy was more discriminatory for the blood loss than blood pressure changes or the change in bioimpedance-based stroke index changes. Of note, these authors found a heart rate change of =30 beats/min was 13.2% sensitive and 99.5% specific for the 500-mL blood loss vs a heart rate change of =20 beats/min that was 44.7% sensitive and 95.4% specific. Hence, the finding of a significant pulse rise, although insensitive for a 500-mL blood loss, was relatively specific in these healthy adult blood donors.

In the most recent meta-analysis of orthostatic vital signs, the authors concluded that a large postural pulse change (>30 beats per minute) *or* severe postural dizziness precluding the completion of vital sign measurements are required to clinically diagnose hypovolemia secondary to acute blood loss. However, the analysis demonstrates that orthostatic vital signs are often absent after *moderate* amounts of blood loss, significantly limiting the test's sensitivity (22%) in this scenario. [139]

Variables Affecting Orthostatic Vital Signs

Many conditions affect the compensatory mechanisms that allow us to assume the upright posture (Table 1-6).[135] Because of decreased vasomotor tone, limited

chronotropic response, and other factors, the elderly have a higher incidence of orthostatic

TABLE 1-5 -- Summary of Orthostatic Tilt Testing*

Test Procedure
1. Blood pressure and pulse are recorded after patient has been supine for 2–3 min
2. Blood pressure, pulse, and symptoms are recorded after patient has been standing for 1 min; the patient should be permitted to resume a supine position immediately should syncope or near-syncope develop
Positive Test
1. Increase in pulse of 30 beats/min or more in adults, *or*
2. Presence of symptoms of cerebral hypoperfusion (e.g., dizziness, syncope)

*The predictive ability of orthostatic vital signs to assess volume status is often *overestimated* in clinical practice. This suggested *guide* is based on the ability of the pulse change and patient symptoms to distinguish between no acute blood loss and a 1000 mL acute blood loss in healthy, previously normovolemic volunteers (sensitivity of 98% for detecting 1000 mL acute blood loss). [124] *This guide may not be applicable to elderly patients, sick children, medicated patients, and those with autonomic dysfunction.*

hypotension, which can lead to syncope and fall-related injury, [140] although carotid sinus hypersensitivity may play a greater role in geriatric syncope than orthostasis does.[141] Note that drugs that antagonize the normal autonomic compensatory mechanisms can also produce orthostatic changes. These changes can be severe enough to produce frank syncope, especially in the elderly. However, in one study of *euvolemic* adult volunteers, orthostatic changes in patients with diabetes or in those using various antihypertensive agents were similar to changes in normal adults. [142] Patients with hypertension may also have abnormal vasomotor responses to tilt testing, demonstrating more instability in small studies. [143]

Even in normal subjects, passive tilting generates a high incidence of orthostatic syncope. [144] Patients with chronic anemia (and a compensated blood volume) seem to have the same postural response as normal subjects.[145] Most of the conditions that affect postural blood pressure regulation involve a pathologic condition that affects the sympathetic nervous system. Orthostatic hypotension caused by autonomic insufficiency is usually not accompanied by tachycardia, whereas the orthostatic hypotension produced by acute volume depletion is commonly accompanied by a pronounced reflex tachycardia.

As noted in Table 1-6 , many conditions, diseases, and medications have been implicated as causing abnormal orthostatic vital sign changes. Most variables have been poorly studied. In the elderly, orthostatic vital sign changes in *volume-depleted* patients have not been studied. In studies of *normovolemic* nursing home patients, orthostatic hypotension has largely been attributed to autonomic dysfunction and its prevalence has been stated at anywhere from 8% to 40%. [146] In a study of patients 65 years or older, 28% had a drop in systolic blood pressure of >20 mm Hg. The study results showed no increased incidence of orthostatic hypotension among patients with chronic cardiovascular disease, disability, body mass index, or medications, although many of these comorbidities would seem intuitive to increase the risk of orthostasis.[147] Normovolemia orthostatic hypotension in the elderly has been loosely linked to long-term cardiovascular mortality and the risk of subsequent cerebrovascular accidents, but these results have not been consistently observed. [148] Ethanol ingestion exaggerates postural pulse changes up to 8 hours following ingestion,[125] thus mimicking the hemodynamic changes seen with acute blood loss. However, in the setting of ethanol intoxication and trauma, one must be vigilant for associated occult hemorrhage and not reflexively assign tachycardia to being a result of intoxication alone.

The utility of orthostatic vital signs in children has been questioned. Horam and Roscelli found that healthy adolescents had heart rate changes of 21.5 ± 21.2 beats/min with orthostatic measurements made after 2 minutes of standing.[149] They found similar variation in the systolic blood pressure change (+19 to -17 mm Hg). Bergman and colleagues found that 25% of clinically normovolemic children had a postural increase in pulse of >20 beats/min and 11% had a postural fall in systolic blood pressure of >20 mm Hg.[150] However, children with fever and diarrhea were included in this "normal" study group. Another study comparing mildly dehydrated children with normal children found a significant difference in the orthostatic rise in pulse between the two groups. [151] Using near-syncope or a change in heart rate of >25 beats/min, orthostatic vital signs have a specificity of 95%, a sensitivity of 75%, and a predictive

TABLE 1-6 -- Classification of Disorders of Postural Blood Pressure Regulation

I. Poor postural adjustment
A. Tall, asthenic habitus
B. Advanced age
C. Physical exhaustion
D. Prolonged recumbency
E. Prolonged weightlessness
F. Pregnancy
G. Gastrectomy
II. Orthostatic hypotension
A. Secondary orthostatic hypotension
1. Endocrinologic-metabolic disorders
a. Diabetes mellitus
b. Dopamine-ß-hydroxylase deficiency
c. Primary amyloidosis
d. Primary and secondary adrenal insufficiency
e. Pheochromocytoma
f. Primary aldosteronism with marked hypokalemia
g. Porphyria
2. Central and peripheral nervous system disorders
a. Intracranial tumors (parasellar and posterior fossa)
b. Idiopathic paralysis agitans
c. Wernicke's encephalopathy
d. Multiple cerebral infarctions
e. Brainstem lesions
f. Tabes dorsalis
g. Syringomyelia

h. Traumatic and inflammatory myelopathies
i. Guillain-Barré syndrome
j. Chronic inflammatory polyradiculoneuropathy
k. Peripheral neuropathies
l. Familial dysautonomia (Riley-Day syndrome)
3. Miscellaneous disorders
a. Ciguatera fish poisoning
b. Electrolyte disturbance
c. Hypochromic anemia
d. Hypovolemia
e. Medications
i. Alcohol
ii. Antihypertensives with central effects (methyldopa, clonidine)
iii. Antihypertensives with peripheral effects (prazosin, hydralazine, and guanethidine)
iv. Calcium-channel blockers
v. Diuretics
vi. Insulin
vii. Levodopa
viii. Marijuana
ix. Narcotic agents
x. Nitrates
xi. Psychotropic agents (tricyclic antidepressants, phenothiazines, monoamine oxidase inhibitors, minor tranquilizers)
xii. Sympatholytics
xiii. Sympathomimetic agents (prolonged use)
xiv. Vasodilators
xv. Vincristine sulfate
f. Extensive surgical sympathectomy
g. Chronic hemodialysis
h. Anorexia nervosa
i. Hyperbradykininism
B. Primary or idiopathic orthostatic hypotension
1. Idiopathic orthostatic hypotension (Bradbury-Eggleston syndrome)
2. Idiopathic orthostatic hypotension with somatic neurologic deficit (Shy-Drager syndrome)

Adapted from Thomas JE, Schirger A, Fealey RD, et al: Orthostatic hypotension. Mayo Clin Proc 56:117, 1981. Reproduced by permission.

value of 92% in detecting mild clinical dehydration in children. [151] No difference in orthostatic blood pressure was found between normal and dehydrated children. Considering resting tachycardia as a positive sign of dehydration increased the predictive value of the test. [152] The investigators concluded that in the appropriate clinical setting, an orthostatic increase in pulse >25 beats/min constitutes a positive tilt test, and an orthostatic pulse increase of <20 beats/min constitutes a negative test for hypovolemia.[151]

Another complicating factor in interpreting orthostatic vital signs is the development of *paradoxical bradycardia* in the presence of blood loss. Bradycardia in the face of hemorrhage has generally been considered a preterminal finding of irreversible shock, but bradycardia has been documented in hypovolemic, yet conscious, trauma patients. Several early studies [121] [122] noted that when orthostatic syncope occurred, it was accompanied by hypotension and often bradycardia. Many central nervous system factors can contribute to *vagalmediated* syncope in ED patients with acute traumatic blood loss. These factors include pain, the sight of blood, stress, and nausea. Several investigators [153] [154] have described women with hemoperitoneum secondary to ruptured ectopic pregnancy who were hypotensive but did not have tachycardia. Jansen reviewed other cases of this relative bradycardia that occurred in hypotensive patients with acute intraperitoneal bleeding and postulated a parasympathetic mechanism triggered by the presence of free blood in the peritoneal cavity. [155] This bradycardia may be reversed with atropine, but *aggressive fluid replacement is the treatment of choice* because anecdotal reports mention serious ventricular arrhythmias from atropine used in this setting. [156] Paradoxical bradycardia has also been described in patients with abdominal or thoracic trauma or arterial bleeding from extremity wounds. [156] This paradoxical bradycardia may be more frequently associated with rapid and massive bleeding, whereas patients with a more gradual blood loss tend to have a more typical tachycardiac response. When the patient's clinical presentation is consistent with volume loss or shock, the clinician should not allow the absence of tachycardia to change the assessment.

Indications and Contraindications

When the volume status of a patient is assessed by use of orthostatic vital signs, several points should be remembered. Many factors influence orthostatic blood pressure including age, preexisting medical conditions, the use of medication, and autonomic dysfunction (see Table 1-6). Data relating the effect of *blood loss* to orthostatic vital signs are limited to phlebotomized healthy volunteers. Great care must be used when extrapolating these data to patients with anemia, dehydration, or painful trauma. The clinician must consider

the clinical condition of the patient as well as the orthostatic vital signs in evaluating a patient for volume depletion.

Orthostatic vital signs are indicated as part of the evaluation of any patient with known or suspected volume loss or a history of syncope, except in the presence of the following contraindications: The use of orthostatic vital signs is unnecessary and dangerous in a patient with supine hypotension or the clinical syndrome of shock. Orthostatic vital sign evaluation also is contraindicated in patients with a severely altered mental status, in the setting of possible spinal injuries, and in patients with lower extremity or pelvic fractures.

The use of medications that block the normal vasomotor and chronotropic response to orthostatic tests also represents a contraindication to use of this test for assessment of volume status. However, when the patient's volume status is believed to be adequate and the clinician seeks to determine if specific medications may have affected the patient's ability to respond to postural changes, the test may be useful. In the latter situation, the primary finding may be the feeling of near-syncope with little or no change in vital signs.

Orthostatic vital signs are often used to assess a patient's response to therapy. In patients receiving intravenous rehydration therapy, serial orthostatic vital signs are

widely used to judge the end point to therapy before release. Johnson and colleagues used this technique to demonstrate that the individual orthostatic vital signs response to saline infusion in women with hyperemesis gravidarum was associated with other measures of rehydration, including weight gain and decreased urine-specific gravity.[157] Although the individual improvement in orthostatic vital signs in response to rehydration was of clinical value, the presenting orthostatic vital signs were considered insufficient as the sole indicator of clinical dehydration in this population.

Technique

Once the decision to obtain orthostatic vital signs has been made, blood pressure and pulse are recorded after the patient has been in the supine position for 2 to 3 minutes (see Table 1-5). The patient should rest quietly. No painful or invasive procedures should be performed during the test. Anxiety, fever, and other causes of resting tachycardia may make the test uninterpretable.[150]

The patient is then asked to stand, and the examiner should be prepared to assist the patient if severe symptoms or syncope develop. A supine-to-standing test is more accurate than a supine-to-sitting evaluation. Knopp and coworkers found that the supine-to-sitting test was not reliable for detecting 1000 mL of blood loss (55% false-negative results).[124] If severe symptoms develop (defined as syncope or extreme dizziness requiring the patient to lie down) on standing, the test is considered positive and should be terminated. If the patient is not symptomatic, the blood pressure and pulse should be recorded after the patient has been standing for 1 minute. This interval resulted in the greatest difference between the control and 1000-mL phlebotomy groups in the study by Knopp and colleagues. [124]

Complications

The possible complications of orthostatic vital sign assessment can be avoided if the aforementioned contraindications and precautions are remembered. Complications include syncope with a resulting fall and injury and the possibility of exacerbating an existing fracture or spinal cord injury.

Interpretation

Criteria for positive orthostatic vital sign changes are either tachycardia greater than a specific threshold (see later) or symptoms of cerebral hypoperfusion (e.g., near-syncope).[152] Although blood pressure changes may be seen, they are too variable to be an indicator of blood volume loss. Although specific population-based thresholds for pulse rate and blood pressure changes have some value for identifying patients at high risk for significant volume loss, great individual variability limits the use of this technique as a screening test. That is, a volume loss of 500 mL (and occasionally more) may be associated with a negative orthostatic vital sign assessment (see later).[138] [158] However, the use of serial measurements to ascertain the response to therapy of patients considered at risk for volume loss appears to have clinical utility.[157]

In the setting of possible blood loss, if the patient has a pulse rise of 30 beats/min or severe symptoms and if other complicating factors have been excluded, then blood loss is highly likely (2% false-positive rate). [124] [138] When evaluating the patient with moderate blood loss, there appears to be no advantage to using the shock index as a marker of hypovolemia vs previously published tilt test criteria. [159] The presence of a negative test indicates only that an acute blood loss of 1000 mL is unlikely (2% false-negative rate); a blood loss of 500 mL cannot be excluded (43% to 87% false-negative rate). [124] [138] [160]

In children, postural near-syncope or an orthostatic pulse increase of 25 beats/min may be a predictor of mild dehydration. The accuracy of these criteria is increased by the addition of resting tachycardia.[151] However, one cannot quantify the amount of volume depletion with this test in children.

Criteria for significant orthostatic blood pressure changes cannot be definitively set for the following reasons: (1) in the study by Knopp and coworkers, a lack of correlation between blood pressure in the phlebotomy and control groups was seen [124] ; (2) a large variability in postural blood pressures has been found in the adult ED population[161] [162] ; (3) results of studies using passive tilt tables cannot be extrapolated to the bedside use of orthostatic vital signs; (4) studies using healthy patients with acute blood loss may not reflect orthostatic changes that are seen in the elderly or those with chronic bleeding, dehydration, and various other medical problems; and (5) many studies of orthostatic changes never used a criterion standard (measurement of actual volume loss) in their determinations. Because of lack of agreement about the degree of postural blood pressure change that constitutes a positive test result, the most reasonable definition may be any postural fall in blood pressure that results in symptoms of cerebral hypoperfusion. [163]

CAPILLARY REFILL

The capillary refill test is a measurement of the time interval from the release of nailbed or soft-tissue pressure (sufficient to blanch the nailbed or superficial soft tissue) until the return to normal coloration. Delayed capillary refill is an indication of reduced skin turgor, often as a result of volume depletion. Measurement of the capillary refill time interval

appears to be somewhat accurate in children, but its accuracy in assessing dehydration and reduced perfusion in adults is highly suspect. [123] [164]

Physiology

Skin elasticity is the characteristic that allows skin to spring back to its original shape after it has been deformed. One sign of decreased elasticity is skin tenting. The normal fullness of blood vessels or capillaries is referred to as *turgor vitalis*. The presence of normal skin turgor is a sign of adequate circulatory perfusion, because the speed of refilling the capillary bed after compression is responsible for the return of color to the skin. [36]

Indications and Contraindications

There are no specific contraindications to performing capillary refill measurements in ED patients. However, the capillary refill time interval should not be obtained in a dependent extremity, a recently burned or injured extremity, or at the site of an infection or acute injury. Frequent monitoring of capillary refill is useful in accessing responses to rapid fluid resuscitation in children. Because capillary refill is available without additional equipment and takes only a few seconds to perform, it is a useful bedside assessment of perfusion and dehydration.

Procedure

The preferred sites for performing capillary refill are the nailbed, the thenar surface of the palm, and the heel. The current standards are best developed for capillary refill obtained at the nailbed. [164] Regardless of the site chosen, the extremities should be positioned at about the level of the right atrium. The minimum pressure necessary to produce blanching yields the most reproducible values. Timing can be performed with a stop watch or simply by counting out "one-thousand-one, one-thousand-two" for approximation of the interval. The relative apparent simplicity of the test notwithstanding, significant interobserver reliability has been noted in obtaining measurements.[165] A repeated measurement should be obtained at the same location as the initial test, because alternate sites may have different capillary refill times.

Interpretation

The normal capillary refill interval increases with age, degree of dehydration, and degree of hypoperfusion. Hypothermia, hyponatremia, congestive heart failure, malnutrition, and edema all increase the capillary refill interval. Environmental conditions, which can falsely alter capillary refill, are the ambient temperature [165] and the quality of ambient lighting. [166] Fever does not appear to prolong or shorten capillary refill time. [167]

The main difficulty in interpreting the capillary refill interval is that normal values in healthy patients fall into a wide range. In 30 normal infants from 2 to 24 months of age, the mean capillary refill interval was 0.8 ± 0.3 seconds. Measurements obtained from the nailbed were more reproducible than those from the heel. Dehydration was strongly correlated with a capillary refill time of >3 seconds and suggested a fluid deficit of >100 mL/kg. [164] The presence of delayed capillary refill >2 seconds when combined with any two or more of absent tears, dry mucous membranes, or ill general appearance can predict clinical dehydration (>5% deficit of body weight) in children (age 1 month to 5 years) with a 87% sensitivity and 82% specificity. [167]

The role of serial capillary refill interval measurements for assessing the response to rehydration in adults is unknown. However, the test does not appear to be useful for assessing acute blood volume loss. In adults, the capillary refill interval was found to be less sensitive and less specific than orthostatic vital signs for detecting a 450-mL blood loss during blood donation. [123]

TEMPERATURE

Accurate measurement of body temperature is an essential part of clinical medicine. When taken in the context of other vital signs, abnormalities of core body temperature are excellent guides to the severity of illness.

Detection of abnormal body temperature facilitates proper diagnosis and evaluation of presenting complaints. [168] [169] [170] [171] [172] [173] [174] [175] [176] The inability to maintain normal body temperature is indicative of a vast number of potentially serious disorders, including infections, neoplasms, shock, toxic reactions, and environmental exposures.[168] [171] Fever in neutropenic, immunocompromised, and intravenous drug-abusing patients may be more reliable than laboratory tests or physician assessment in diagnosing serious illness. [171] Infants are particularly sensitive to thermal stress and may demonstrate lower body temperatures during asphyxia or necrotizing enterocolitis.[172] [173] [174] Normalization of body temperature following intervention may have important prognostic and therapeutic implications. [171]

Physiology

Under normal conditions, the temperature of deep central body tissues (i.e., core temperature) remains at 37 ± 0.6°C (98.6 ± 1.08°F). [175] [176] Core body temperature can be maintained within a narrow range while environmental temperature varies from as much as 13 to 60°C (55 to 140°F), [177] whereas surface temperature rises and falls with environmental and other influences. Maintenance of normal body temperature requires a balance of heat production and heat loss. Heat loss occurs by radiation, conduction, and evaporation. Approximately 60%, 18%, and 22% of heat loss, respectively, occurs by these methods. Heat loss is increased by wind, water, and lack of insulation (e.g., clothing). Sweating, vasodilation, and decreased heat production serve to decrease temperature, whereas piloerection, vasoconstriction, and increased heat production serve to increase body temperature. Heat production is increased by shivering, fat catabolism, and increased thyroid hormone production.

Temperature control occurs by feedback mechanisms operating through the preoptic area of the hypothalamus. Heat-sensitive neurons in this area increase their rate of firing during experimental heating. Receptors in the skin, spinal cord, abdominal viscera, and central veins primarily detect cold and provide feedback to the hypothalamus, which signals an increase in heat production. Stimuli that change the core body temperature result in reflex changes in mechanisms that increase either heat loss or production. [177]

Indications and Contraindications

Clinicians generally measure body temperature to determine if it is outside the normal range and as an indication of pathologic conditions that can affect core body temperature. Because actual core body temperature measurement requires the placement of invasive monitors, such as an esophageal or a pulmonary artery probe, clinicians commonly use estimates of core body temperature, which conveniently and safely assess abnormalities of core temperature. Unfortunately, all noncore body sites and methods have inherent accuracy limitations, which clinicians have come to accept in assessing most patients.

Oral temperature measurement requires a cooperative adult or child, generally older than 5 years. Patients who are grossly uncooperative, hemodynamically unstable, septic, or in respiratory distress (with a RR >20) require another method of temperature measurement. [178] This group includes children younger than 5 years and patients who are intubated.

Special techniques of measuring actual core body temperature may be indicated in certain patients (e.g, those with profound hypothermia, frostbite, or hyperthermia). Measurement of core body temperature is indicated in these individuals because it accurately measures treatment effects. This is the group of patients who will also benefit most from continuous temperature measurements.[179]

Measurement Sites

Core Body Temperature

It has been demonstrated that the following sites accurately reflect core body temperature and its changes: esophageal (in the distal third of the esophagus), the tympanic membrane (using *direct thermistor contact* at the anterior inferior quadrant of the tympanic membrane),[180] [181] and the pulmonary artery temperature.[182]

Other sites may represent core body temperature under certain conditions. For example (1) the rectum, when the temperature is obtained at least 8 cm from the anus using an indwelling thermistor and the body temperature is relatively constant, and (2) the bladder when measured with an indwelling thermistor. [128] [183] Data on core temperature in pediatric patients is limited and it is unclear if bladder, rectal, or oral temperature is a good measurement of core body temperature in children. [184]

Peripheral Body Sites Approximating Core Body Temperature

Oral temperature measurement with a digital electronic probe is commonly used for ambulatory patients. [185] Advantages include convenience, timing, safety, and availability. Disadvantages include various factors that affect clinical accuracy and sensitivity. Electronic oral temperature probes must be covered with disposable covers, although these have been shown not to be completely effective in preventing probe contamination with microorganisms. [186] Although there are no absolute contraindications for oral temperature assessment, patients with factors shown to produce unreliable results (see later) require temperature measurement at other sites.[178] [187] [188]

Rectal temperature is often considered the criterion standard of body temperature for ambulatory patients and is often routine for children younger than 3 years. [189] Advantages include accuracy, sensitivity, and availability. One intensive care unit study found rectal probe temperatures to demonstrate limited variability or bias when compared with pulmonary artery temperatures.[190] Disadvantages include longer intervals for measurement, safety concerns, and inconvenience. Neutropenia and recent rectal surgery represent relative contraindications to rectal temperature measurement. [191] Placement of a rectal probe thermometer may produce autonomic changes in patients with acute myocardial infarction. [192]

Body temperature measured as a function of infrared radiation (IR) detected from the ear, including the auditory canal and tympanic membrane (TM), is easy to use, hygienic, convenient, and quick. [193] The noncontact IR ear thermometer has been studied under a variety of clinical conditions. [194] Concerns have been raised over the accuracy of these thermometers in screening for fever in children younger than 3 years of age. [195] [196] Romano and colleagues found the Thermoscan Pro-1 IR thermometer to perform similar to rectal probe temperature, but the FirstTemp IR thermometer displayed considerably more variability. [190]

Intensive care studies have compared infrared thermometry to pulmonary artery core temperatures and found a sensitivity of detecting fever to be 58% and a specificity of 94%. Double ear thermometry (measuring values at both right and left TMs and calculating the mean) increased the sensitivity and specificity to 61% and 95%.[197] Increased variability of tympanic temperatures vs oral temperatures was also found in the critical care population. [198]

In the ED setting, infrared tymponometers have undergone limited scrutiny. In 100 children, TM, rectal, and axillary temperatures were obtained with statistically significant differences noted. [199] In a similar ED-based study, 95 geriatric (older than 60 years of age) patients had oral, TM, and rectal temperatures measured with fevers missed with both oral and tympanic readings, as compared to rectal readings. [200] In another study of 100 adult ED patients, the TM and rectal temperatures showed generally good agreement, but the TM temperature missed 4 of 10 patients with a fever (>38.5°C). [201] The authors also noted that the temperature difference between TM and rectal temperature readings was greater in the presence of cerumen impaction. Special patient populations deserve separate attention. First, when a neonatal population is examined, significant variability is noted with TM temperatures, making rectal thermometers the standard. [202] Second, a theoretical

disadvantage of TM temperatures might be a falsely elevated estimate of the core temperature in the presence of otitis media. However, in one study tympanic thermometers accurately reflected oral temperatures in children with otitis media. [203]

Although not a likely ED concern, prehospital providers who might wish to measure IR tympanic temperature at low ambient temperatures should be aware that below 24.6°C the TM readings will greatly underestimate core temperature. [204] EMS personnel should also be aware that in a cohort of exhausted marathon runners, rectal and IR tympanic temperatures have only moderate correlation.[205] Hence when hyperthermia or hypothermia is clinically suspected and the IR tympanic temperature does not confirm an abnormal temperature, a rectal temperature should be considered.

Axillary and tactile temperature assessment have been demonstrated to be unreliable and insensitive. They should not be used as screening methods for core temperature abnormalities in the ED.[206] [207] [208] Similarly, the use of liquid crystal chemophototropic strips applied to the skin of the forehead

are not accurate for single measurement or fever screening. [209] [210] Single-use Tempa-DOT thermometers, which show increasing temperature dot darkening with increasing temperature, have been adopted by many EDs. The sensitivity of these thermometers for fever identification remains to be determined. The most rudimentary method for temperature measurement, parental assessment by tactile touch, is associated with a measured fever approximately 75% of the time. [211] Clinician estimation of fever is almost identical (70%). [212]

Equipment

Mercury-in-glass thermometers remain popular despite requiring longer equilibration times and having cumbersome cleansing requirements. Electronic methods of temperature measurement are based on the thermocouple principle. Modern electronic thermometers signal once extrapolation of the temperature-time curve occurs. [212A] Current in vitro standards call for an accuracy of ±0.1°C (±0.18°F) over the range of 37 to 39°C (98.6 to 102.2°F). [213] Thermistor probes (i.e., small thermocouples with instantaneous readouts) for esophageal and vascular temperature measurement provide continuous temperature readouts when attached to a potentiometer. [9] Thermistor products are available for esophageal, bladder, and rectal probes (Mallinckrodt Medical, Inc, St. Louis; or Yellow Springs Instruments, Yellow Springs, OH) with appropriate readout monitors.

Noncontact IR ear thermometers were introduced in 1985. These thermometers were initially used only in hospitals, but they are now sold over the counter for home use. The IR ear thermometers work by incorporating an IR sensor in the field of view of the IR emissions from the ear. Ear IR thermometers generally detect naturally occurring IR emissions over a brief time period, generally <1 sec. The emissions are converted to an electrical analog signal, which is digitized and analyzed by a microprocessor with resultant digital display. [214] The primary determinant of radiation emission is the temperature of blood perfusing this area, and the warmest spot in the auditory canal is the TM. Thus, current IR ear thermometers are operator-dependent in the same fashion that otoscopy requires proper positioning to enable the examiner to "see" the TM.[215]

Various IR ear thermometers are available commercially (Table 1-7) with varying operating temperature ranges, features, and reported accuracy. Clinical data assessing relative performance of the many commercial devices are limited. In one study comparing many of these IR thermometers, the Pro-1 and FirstTemp gave significantly higher readings. [215]

Procedure

Temperature measurement begins with body site selection. Consideration should be given to the accuracy of using a site to reflect core temperature, the site sensitivity to temperature changes, convenience, time required, safety, and site availability. [191] [216]

When reusable probes are used, the thermometer end should be covered with a probe cover. Temperature measurement continues with insertion of the temperature probe and probe equilibration with the temperature of local body tissues. Proper placement of temperature probes significantly influences results for oral, rectal, esophageal, and vascular temperatures.[175] [217] [218]

Sublingual oral temperatures should be obtained in either right or left posterior sublingual pocket, with the mouth closed. [217] The patient should be sitting upright or lying, holding the base of the probe with one hand.[185] Rectal temperatures require removal of clothing, lubrication of the probe, and gloving of personnel. They should be obtained with the patient relaxed in the left or right lateral decubitus position. Gentle insertion to 3 to 5 cm should ensure accurate, atraumatic results. [175]

Axillary temperatures are frequently used for neonatal patients in incubators because of convenience. The technique is not indicated unless other sites are unavailable.[207] [219]

Although not commonly used, temperature measurement in a freshly voided urine specimen can validate temperature measurement at other body sites. A nomogram of expected urinary temperatures has been derived from measurements of oral and urinary temperatures in 55 subjects (Fig. 1-10).[220]

Placement of an esophageal catheter for measurement of core body temperature is similar to placement of a nasogastric or orogastric tube (see Chapter 41). In this case, the distal tip of the esophageal catheter contains a thermistor to measure body temperature. In normal adults, the catheter is inserted approximately 34 cm deep into the esophagus, with the objective of locating the probe tip at the level at which the esophagus is between the aorta and the left atrium. The catheter is connected to a potentiometer and allowed to equilibrate briefly before a body temperature reading is taken.

For pulmonary artery (PA) catheter assessment of core body temperature, a PA or thermistor-tipped catheter is placed into the PA. A detailed discussion of the placement of PA catheters is beyond the scope of this chapter. Once a PA catheter is in the correct position, the temperature value may be obtained by using the potentiometer attached to the distal thermistor. Because of the risks associated with catheter placement, PA temperatures are generally reserved for patients with another clinical indication for PA pressure monitoring.

Complications

Complications associated with axillary, oral, ear IR, and liquid crystal thermometers are rare or unreported. Tympanic membrane perforation and pain have been reported as complications of thermistor probe placement in the auditory canal. Complications associated with rectal temperature measurement are extremely rare, but include rectal perforation, pneumoperitoneum, bacteremia, dysrhythmias, and syncope. [191] [216] Falsely low but supranormal rectal temperature measurements may be seen during shock. [221] Rectal temperatures also may lag behind core temperature changes.

Complications associated with esophageal temperature measurement include those associated with placement of an orogastric or nasogastric tube (see Chapter 41). Confirmation of accurate placement can be verified with a chest radiogram. In addition, spurious temperatures may arise from an improperly calibrated potentiometer, a damaged thermistor, or a proximal esophageal location. Mechanical ventilation or thoracotomy can falsely lower measured esophageal core temperatures.

Interpretation

Normal values for body temperature are affected by the following variables: (1) site and methods used for measurement, (2) perfusion, (3) environmental exposure, (4) pregnancy,

TABLE 1-7 -- Commercial Infrared Ear Thermometers*

Brand Name	Manufacturer[§]	Temperature Range (°C)[¶]	Read Modes	Response Time (sec)	Continuous Mode	Charge Use Time	Warranty	Anti-Theft	Offsets (°C)[£]

¶Thermometers listed meet laboratory standards of the American Society for Testing and Materials (±0.1°C).

£ Temperature value, which is added to unadjusted infrared ear thermometer reading to estimate body temperature at specific sites.

†A "pediatric" infrared ear thermometer (Pedi-Q) is also available from this manufacturer.

‡Not intended for professional use.

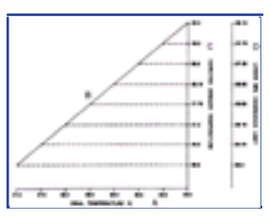

Figure 1-10 Relationship between oral and urinary temperatures constructed as a nomogram. Urinary temperatures are consistently within 1 to 1.5°C of simultaneously obtained oral temperatures and within 2°C of rectal temperatures. To use the nomogram, locate the oral temperature on the horizontal axis (*A*) and draw a perpendicular line to intersect the diagonal border of the graph (*B*). Follow the dotted horizontal line to the right to determine the expected urinary temperature on the longitudinal axis (*C*). The far right-hand scale (*D*) provides a 99% confidence level for the lower range of expected urinary temperatures and finding a value below the 99% confidence level is essentially diagnostic of a factitious fever. *(From Murray HW, Tuazon CU, Guerrero IC, et al: Urinary temperature: A clue to early diagnosis of factitious fever. N Engl J Med 296:23, 1977. Reproduced by permission of the New England Journal of Medicine.)*

(5) activity level, and (6) time of day. Clinicians must interpret body temperature with knowledge of the range of normal values at the intended site of measurement. Although the core body temperature remains nearly constant (37.0 ± 0.6°C or 98.6 ± 0.18°F), the surface temperature rises and falls with changes in ambient temperature, exercise, and time of day. The definition of fever varies by the site of measurement and is defined by a temperature >2 standard deviation (SD) above the mean. Fever has been defined as an oral temperature =37.8°C (=100.0°F),[222] a rectal temperature =38.0°C (=100.4°F),[223] or an IR ear temperature =37.6°C (=99.6°F).[224] Based on the measurement of temperatures in normal, healthy infants, Herzog and Coyne recommend that fever should be defined as rectal temperature =38°C in infants younger than 30 days old; =38.1°C in infants 30 to 60 days (1 month); and =38.2°C in infants 60 to 90 days old (2 months).[225] Hypothermia has been defined as a core body temperature <35°C (<95°F), whereas hyperthermia has been defined as a core body temperature >41°C (>105.8°F), with accompanying symptoms and signs.[226] A useful nomogram and formulae for conversion of °C to °F are provided in Figure 1-11 .

Temperature probes that require the transfer of heat energy from local tissues to the temperature probe require a period of equilibration and reliable tissue contact at the intended body site. Acceptable equilibration times for mercury-in-glass thermometers for oral, rectal, and axillary sites are 7, 3, and 10 minutes, respectively. Used in a predictive mode, electronic digital thermometers generally require 30 seconds for oral or rectal temperature equilibration. The predictive mode uses temperature changes vs time to predict an equilibration temperature.

Normal ranges and suggested febrile thresholds for common body sites and methods should be considered in the interpretation of temperature values (Table 1-8). The interpretation of temperature measurements during clinical assessment must consider the use of antipyretics, level of activity, pregnancy, environmental exposure, and patient age. The duration of antipyresis with acetaminophen or aspirin is 3.5 to 4 hours. When both drugs are given together, the duration of action may be extended up to 6 hours.[227] Body temperature is increased during sustained exercise, during pregnancy and during the luteal phase of the menstrual cycle. Temperature also increases in later afternoon during diurnal variation. Body temperature is generally reduced with advanced age.

The interpretation of temperatures obtained with pulmonary artery or esophageal thermistors is generally straightforward. Comparison of measured values to the expected normal range should be performed to determine if the patient has an abnormal core body temperature. In addition to improper placement of the thermistor, sources of temperature error include an improperly calibrated potentiometer or thermistor, damaged thermistor, or improper placement. The biomedical staff at the institution should periodically verify readout and calibration of these instruments.

Figure 1-11 Temperature conversion scale. To change Celsius (centigrade) to Fahrenheit, multiply the Celsius temperature by 9/5 and add 32. To change Fahrenheit to Celsius, subtract 32 from the Fahrenheit number and multiply by 5/9.

TABLE 1-8 -- Normal Ranges and Suggested Febrile Thresholds for Human Body Temperature (in Healthy Resting Patient)

Body Site	Type of Thermometer	Normal Range (°C)	Fever (°C)
Core[*]	Electronic	36.4–37.9	38.0
Oral	Mercury-glass, electronic	35.5–37.7	37.8
Rectal	Mercury-glass, electronic	36.6–37.9	38.0
Ear	Infrared emission	35.7–37.5	37.6[†]

*Temperature obtained with a properly positioned pulmonary artery, esophageal, or tympanic membrane thermistor.

†For unadjusted ear temperature using Thermoscan Pro-1 (Thermoscan, Inc, San Diego, CA).

Oral temperature measurements are affected by ingestion of hot or cold liquids, [191] tachypnea,[228] and cold ambient air.[229] Smoking appears to result in little change in oral temperatures.[188] [191] Therefore, before taking an oral temperature, the examiner should inquire about these features and possibly delay taking the temperature. Also, Erickson found a 2.7°C (4.9°F) reduction of oral temperature measurement when the probe was placed under the tip of the tongue instead of under the posterior sublingual pocket. [187] When using a mercury-glass thermometer, optimum placement time was found to be 7 minutes for oral temperatures in children. [230] Given the extrapolation that occurs with rapid reading thermocouple devices and IR detectors, it is not surprising that the sensitivity of these devices (whether oral or tympanic) for fever (as detected by oral mercury thermometers) is only 86% to 88%. [231] Hence, many practitioners have adopted the adage that when a temperature is suspected or crucial in decision making, but not evident with an oral thermocouple probe or IR tympanic thermometer, measurement with a glass, mercury thermometer is indicated.

Axillary temperatures obtained in 108 children by Kresch had a sensitivity of only 33% and a specificity of 98% for fever. [207] Ogren obtained similar results using an electronic thermometer in the axilla.[232] Hence, axillary temperatures should not be used to screen for fever.

When rapid changes in body temperature occur, oral and tympanic temperature measurements appear to be more reliable than rectal temperature. In 20 adults examined during open-heart surgery, oral temperatures showed a better correlation with blood temperature during rapid cooling and rewarming. [218] In 12 adults, the average rectal temperature lag during warming was 5.3 minutes during water immersion and 3.8 minutes during exercise. [233] Sublingual (oral) temperature delay (1.3 and 0.9 minutes for the 2 experiments, respectively) was less than auditory canal delay (1.1 and 4.1 minutes, respectively) in temperature response.

Infrequently, ED patients require constant monitoring of temperature (e.g., in cases of hypothermia or hyperthermia). This can usually be performed using a bladder or esophageal probe attached to a potentiometer. Patients with indwelling central venous or pulmonary arterial catheters may have electronic thermistors inserted into the central circulation to measure core body temperature. As noted earlier, rectal temperature measurements are less desirable for monitoring patients undergoing rapid core temperature changes. Periodic IR tympanic temperature monitoring may represent one useful option in the hypothermic patient. [234]

The interpretation of ear IR temperatures requires a knowledge of the mode of thermometer operation and ambient temperature. Cerumen occlusion of the ear canal may produce a false low reading.[235] Most IR ear thermometers have different modes that allow users to predict the equivalent temperature at other body sites. IR ear thermometers appear moderately sensitive for fever.[195] [196] If these devices are used, the clinician must be aware of the potential for a false low temperature. When in doubt, the measurement should be repeated with a more standard method.

CONCLUSION

Vital signs must always be interpreted in relationship to each other to obtain a more complete clinical picture. All vital signs are subject to errors in measurement and therefore must be verified when the initial result does not match the clinical presentation. Abnormal vital signs may lead the clinician to a diagnosis, and abnormalities should be explained within the context of the patient's illness.

Acknowledgment

The editors and author wish to acknowledge the significant contributions of Jody Riva Lewinter, Thomas E. Terndrup, Terry M. Williams, and Robert K. Knoop to this chapter in previous editions.

Chapter 2 - Use of Monitoring Devices for Assessing Ventilation and Oxygenation

Jerris R. Hedges
William E. Baker
Richard Lanoix
Dan L. Field

Ensuring delivery of oxygen (O_2) to the cell is the primary critical action in emergency medicine. Without O_2 to fuel cellular energy production, the cells ultimately falter and the organism dies. Except during cardiopulmonary bypass, tissue perfusion depends on an adequate inspired O_2 content, ventilatory effort, alveolar gas exchange, blood O_2 carrying capacity, and cardiac output. This chapter covers emergency department (ED) assessment of spontaneous ventilation and O_2 delivery and noninvasive means of monitoring and improving inspired O_2 concentration and spontaneous ventilation.

BACKGROUND

Respiratory illness has been poorly understood until recent times. The Talmud, the ancient law book of the Israelites, blames the etiology of asthma-like illness on a malignant spirit. Later, Celsus (AD 25), an encyclopedist of the late Roman period, noted a favorable prognosis for a respiratory illness if the "expectoration is white as if mucus from the nose, but unfavorable if sputum is purulent, and accompanied by fever," descriptions that are consistent with chronic bronchitis and pneumonia. Celsus recommended bleeding, purgatives, emetics, and diuretics; this therapy was less preferable perhaps to his prescription for phthisis (tuberculosis), for which he recommended a leisurely sojourn down the Nile and drinking tea and honey. [1]

The Greek word asthetaμa signified panting and was applied generally to difficult breathing and respiratory illness; the term eventually gave rise to the word *asthma*. The earliest comprehensive distinction between asthma and other respiratory diseases came from Aretaeus of Cappadocia, who first recognized and recorded the chronic recurrent nature of the disease. [2]

TABLE 2-1 -- Causes of Respiratory Failure*

Neurologic	Muscles and Chest Wall	Oropharynx	Lower Airway	Lung Parenchyma	Heart
Drug overdose	Myopathy	Foreign body	Tracheobronchitis	Adult respiratory distress syndrome	Pulmonary edema
Stroke	Myasthenia gravis	Laryngospasm	Tracheal stenosis		
Central hypoventilation	Kyphoscoliosis	Tonsillar hypertrophy	Bronchospasm	Emphysema	Mitral stenosis
Guillain-Barré syndrome	Flail chest			Pneumonia	
Head trauma				Interstitial pneumonitis	
Poliomyelitis					
Botulism					

*Disease at any level of the respiratory system, central or peripheral nervous system, bellows mechanism, or heart may cause respiratory failure.

In 1698, Sir John Floyer wrote the first book devoted entirely to asthma and recorded the first description of pulsus paradoxus. Atropine therapy began in England in 1802, and in 1830 John Eberle deduced that "it is highly probable, therefore, that asthma consists essentially in a peculiar irritation of the pneumogastric nerves (vagus), in consequence of which the smaller bronchial tubes and air-cells are thrown into a state of spasmodic constriction." [3]

The American Thoracic Society statement on asthma in 1962 is an often-quoted definition of the disease: "asthma is a disease characterized by an increased responsiveness of the trachea and bronchi to various stimuli and manifested by a widespread narrowing of the airways that changes in severity either spontaneously or as a result of therapy." The term *asthma* is not appropriate for bronchial narrowing, which results solely from widespread bronchial infection; from destructive diseases of the lung, as in pulmonary emphysema; or from cardiovascular disorders.

Asthma is the most common chronic disease of childhood and among the most frequent complaint of adults, resulting in 2 million outpatient visits per year; it is also the most common cause of absence from school and work.[4] Asthma, depending on one's definition, affects between 7 and 20 million people in the United States and is especially prevalent among those living below the poverty level. [5] The National Center for Health Statistics estimates that asthma affects 9.7 million people in the U.S. population and chronic obstructive pulmonary diseases (COPDs) afflict up to 14 million adults, with similar economic consequences. [6] Although many investigators and studies distinguish between asthma (pure reactive airway disease) and COPDs, which include chronic bronchitis (airway inflammation with increased mucus secretion) and emphysema (airway destruction and loss of airway elasticity), clinically the distinction is blurred by the similarities in ED management. In fact, the current literature cites studies that can document little to distinguish the response of either entity to bronchodilators. [7] These diseases must, however, be separated from other causes of dyspnea and respiratory distress (Table 2-1), many of which are associated with wheezing.

PULMONARY FUNCTION TESTING

Airway maintenance and breathing are given primacy in the ABCs of emergency medicine. Clinical assessment always begins with the patient's ventilatory function. The clinician notes quickly the patient's mental status, level of distress, skin color, character of effort, use of accessory muscles, presence of diaphoresis, lung sounds, and vital signs. In conjunction with this clinical overview, a brief clinical history provides

the clinician with sufficient information on which to initiate therapy.

Unfortunately, the clinician's initial clinical impression of the patient's ventilatory status is based on imprecise subjective findings that may not detect serious illness in all patients. The ability of experienced clinicians to detect compromised pulmonary function when compared with pulmonary function testing seems only moderately better than chance alone.[8] In the study by Godfrey and coworkers, the sensitivity of clinical impression did not improve when the clinicians underwent training on the common and more subtle signs of respiratory distress.[8] Patients also appear superior to clinicians in predicting their own pulmonary function [9] and in assessing day-to-day variation in disease, using pulmonary function testing as the standard. [10]

Regardless of the initial clinical presentation, results of treatment in a subjectively asymptomatic patient with reactive airway disease will reach, at best, only 40% to 50% of predicted normal pulmonary function and 60% to 70% when all abnormal physical signs have resolved. [11] This potentially undetected degree of dysfunction may contribute to recrudescence. Objective measures of pulmonary dysfunction serve both to quantify results of therapy and as possible predictors of admission.

Spirometry has been used for decades by pulmonary specialists to assess airway limitation. The spirometric measurements were originally validated based on comparisons with clinical and body plethysmographic data. The terminology of pulmonary function testing was derived from the various measured subsegments of spirometry (Fig. 2-1). More recently, inexpensive handheld electronic meters have replaced formal spirometry in many clinical settings. These devices accurately measure or calculate the peak expiratory flow rate (PEFR), forced expiratory volume in 1 second (FEV_1), forced vital capacity (FVC), and percent FEV_1/FVC.[12] The Wright peak flow meter (Fig. 2-2) was originally designed by Wright and McKerrow for use in their pneumoconiosis unit in

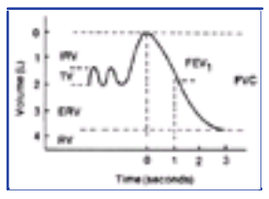

Figure 2-1 Time-forced vital capacity (FVC) is the volume of gas forcibly expelled following a maximal inspiration. Forced expiratory volume in 1 second (FEV_1) is the volume of gas expelled during the first second of the forced expiration. The other lung volumes obtainable are the tidal volume (TV), which is the volume of gas moved during quiet respiration; the inspiratory reserve volume (IRV), which is the volume of gas that can be inspired in addition to the tidal gas volume; and the expiratory reserve volume (ERV), which is the volume of gas that can be forcibly expired at the end of a tidal expiration. Some gas cannot be expired and remains in the chest. This is known as the residual volume (RV).

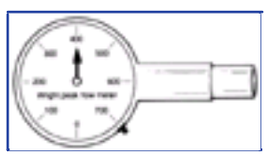

Figure 2-2 Wright peak flow meter. After resetting the dial to zero, the patient inhales fully and exhales forcefully through the disposable paper mouthpiece. The best of three attempts is recorded. A tight seal of the lips around the mouthpiece is required.

1959. Subsequently, development of compact, less complex, and less expensive calibrated spring-mechanism peak flow meters have allowed for widespread use in acute care and home settings (Fig. 2-3). These peak flow meters also have been successfully used as an adjunct in the assessment of pediatric patients. In the acute clinical situation, PEFR meter readings correlate well with formal spirometry, offer simplicity, and reduce the need for patient cooperation. [13]

Indications and Contraindications

In the ED, acute respiratory diseases such as asthma and chronic lung diseases make up the bulk of the situations requiring the objective assessment of ventilatory status. ED pulmonary function testing with either a peak flow meter or spirometer provides objective data on pulmonary status and patient response to therapy. These tests may assist the clinician in determining patient disposition [14] and may facilitate patient transfer at the time of admission by providing an objective and reproducible measure of the patient's failure to improve. Studies have found excellent correlations between PEFR and FEV_1, [13] [15] as well as between Wright and mini-Wright meters.[16] One investigation has evaluated PEFR for aiding differentiation of congestive heart failure from chronic lung disease in the patient with moderate to severe dyspnea.[17] Although opportunities will be infrequent, clinicians evaluating neuromuscular diseases affecting ventilatory function, such as the Guillain-Barré syndrome, may find these techniques useful in both initial and ongoing assessment. Near or true respiratory arrest may be the only true contraindication to obtaining these measurements because of limited patient cooperation and delay of immediate therapy.

Figure 2-3 Mini-Wright peak flow meter. The indicator arrow is moved back to zero. The patient inhales fully and then exhales forcefully through the disposable paper mouthpiece. The best of three attempts is recorded. Patient cooperation and a tight seal of the lips around the mouthpiece are required.

Equipment

A *spirometer* is a tube connected to a bellows-type device that communicates with a recording device. The subject breathes in and out through an orifice, causing expansion and contraction of the bellows, which in turn activates the recorder that traces a curve corresponding to the lung volume. This traditional volume method is complex and cumbersome. Handheld electronic spirometers now available use sensing devices either to translate the pressure of exhalation (e.g., Respiradyne, Kendall Healthcare Products Company, Ocala, FL, Fig. 2-4) or to detect the number of rotations of a small turbine (e.g., Pocket Spirometer, Micro Medical Instruments, Rochester, NY) by an optical system. Both systems are self-calibrating, take little practice to use, and can calculate PEFR, FEV_1, and FVC. Some systems, such as the transducer-based Respiradyne, also give additional calculated information such as percent FEV_1/FVC and forced mid-expiratory flow rate ($FEF_{25-75\%}$). Results are displayed digitally and maintained in memory until cleared.

Peak flow meters are simple mechanical devices that use the force of exhalation to rotate or push a membrane-coupled measuring arm or spring-loaded piston to statically record a position of maximum flow. Several brands of peak flow meters are commercially available including the Pulmo-Graph (De Vilbiss Healthcare Inc., Somerset, PA), Assess (HealthScan Products Inc., Cedar Grove, NJ), Wright Pocket (Ferraris Medical International, Holland, NY), and the Mini-Wright (Clement Clark International, Columbus, OH). Low-flow units designed for children are also available.

Procedure

The operation of peak flow meters and electronic spirometers is similar in many ways. Disposable mouthpieces are inserted

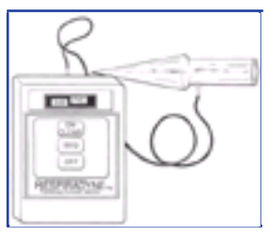

Figure 2-4 The Respiradyne portable spirometer. The device is turned on or "cleared" from the last effort. The patient exhales forcefully into the handheld mouthpiece following maximal inhalation. The "sequence" button permits selection of the desired spirometry measurements. The best of several tries should be recorded.

or attached. If the mouthpiece is to be reused by patients sharing a common meter (during serial evaluations), the "mouth" end should be identified with pen or tape to limit the possibility of spreading infection between patients. The electronic devices must be switched on for a 30-second self-calibration period. Both the handheld spirometers and the peak flow meters can be operated with the same respiratory maneuver: a maximal inhalation followed by a maximum forced expiration into the mouthpiece. The key is to have the patient exhale as rapidly as possible in order to achieve a brief, forceful exhalation rather than a slow, prolonged exhalation. Three attempts are standard, and the highest value is recorded, provided the best two of three readings are within 10% of each other. [18] Children as young as 3 years have consistently achieved the level of cooperation necessary to perform PEFR testing. [19]

Interpretation

Although intraindividual peak flow variability is low, [20] variability between different brands of calibrated spring mechanism peak flow meters may be significant. Flow measurements of four brands studied at low to medium flows differed by as much as 100 L/min, [21] and accuracy waned with age of the device. [22] This information should be considered when interpreting PEFR values both clinically and in the literature. Likewise, measurement of serial PEFRs should be done on the same meter. Altitude minimally affects PEFR interpretation; readings at 1400 m underestimate PEFR by 5.3% to 6.9%. [20] As with FEV_1 measurement, patient size affects PEFR and is most important when interpreting readings in children. Most charts of normal PEFRs in pediatric patients are based on height. As age and height are also related, some investigators have developed age-PEFR charts. [14] [23] Having a measuring tape secured to the wall alongside a chart of normal values in an accessible area enables the clinician to quickly interpret the PEFR of a child. Table 2-2 lists approximate peak flow and spirometric values for various degrees of obstruction in adults and Figure 2-5*A* and *B* demonstrate percentile charts of PEFR vs height in boys and girls. These charts were constructed from data obtained by Carson and coworkers in 2752 healthy children in Dublin. [23] Normal PEFRs do vary in children based on a number of variables including race, geographic location, and local environment. [23] [24] [25]

The use of PEFR measurements to predict the need for admission early during ED treatment found that in severely compromised adults (i.e., with initial PEFRs <16% of the predicted value), an improvement in PEFR <60 L/min after the first epinephrine treatment indicated the need for admission. [26] Similarly, an initial FEV_1 of 0.6 L and a post-treatment

TABLE 2-2 -- Approximate Values for Spirometry and Peak Flow for Various Degrees of Obstruction in Adults

	FEV_1 (L)	FEV_1 /FVC (%)	Peak Flow (L/min)
			550–650 (males)
Normal	4.0–6.0	80–90	400–500 (females)
Mild	3.0	70	300–400
Moderate	1.6	50	200–300
Severe	0.6	40	100

Peak flow and spirometry values vary with height, sex, and distance above sea level; men and taller persons in general have larger flow rates. The reduced barometric pressures found at higher elevations also increase airflow.

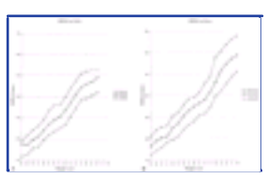

Figure 2-5 Peak expiratory flow rate vs height for girls (*A*) and for boys (*B*). These figures were constructed from Carson and coworkers' unsmoothed data obtained from 2752 healthy children in Dublin. *(From Carson JWK, Hoey H, Taylor MRH: Growth and other factors affecting peak expiratory flow rate. Arch Dis Child 64:96, 1989.)*

FEV_1 of 1.6 L were predictive of the need for inpatient therapy. [27] PEFR values of <100 L/min initially and <300 L/min after treatment were predictive of the need for inpatient therapy in a follow-up study. [15]

These studies have been challenged due to lack of blinding. A subsequent study found that neither the initial PEFR reading nor the response to the first bronchodilator treatment was helpful in predicting admission. [28] In fact, in this double-blind study, with strict admission criteria and with the additional use of nebulized bronchodilators, <50% of those requiring admission were detected by initial measurements. However, measurements performed later in therapy, just before release, were more accurate in predicting relapse. Similarly, in a series of 83 COPD patients, a post-treatment FEV_1 <40% of predicted value identified patients requiring admission (i.e., at high risk for relapse [>30%] if sent home). [29]

As with adults, initial spirometric values are weakly associated with pediatric asthma admission decisions. [30] [31] However, children with PEFRs >60% of expected *after* treatment with nebulizer therapy can be considered in the category "admission probably unnecessary," and those with PEFRs <40% can be considered in the category "admission probably necessary." [14]

These studies indicate that when initial flow rates are extremely poor, admission is likely, because a brief course of therapy in the ED is unlikely to provide sufficient improvement. However in patients with less severe flow rates, the decision to admit should be based on the patient's response to therapy (which is dependent in part on the form of therapy and the duration of the therapy chosen). Prediction of the need for admission based on PEFR and FEV_1 values obtained shortly after presentation is largely unsuccessful because of patient response variability and the option of more prolonged, aggressive ED therapy.

Hence, in adults, initially low flow rates (PEFR <100 L/min) and spirometry values (FEV_1 <1.0 L) identify sick patients with the potential need for admission or close follow-up. Patients with PEFR or FEV_1 values of <40% of predicted normal values after bronchodilator therapy probably require admission. Also, one can reserve blood gas analysis for patients with poor initial flow measurements or lack of improvement in pulmonary function (or hypoxia based on oximetry) and hence reduce the expense and morbidity of evaluation for reactive airway disease. [32] [33]

PULSE OXIMETRY

Pulse oximetry has made a significant contribution to noninvasive monitoring of oxygenation in a wide variety of clinical situations. Pulse oximetry requires no special training, is noninvasive, is inexpensive, gives continuous real-time estimates of arterial saturation in the range of 80% to 100%, and provides an early warning of diminished perfusion while avoiding the discomfort and risks of arterial puncture. As a result, it has become the standard of care during procedures requiring general anesthesia,[34] and it is gaining wide acceptance in pre-hospital care, [35] neonatal and pediatric critical care, [36] adult ED care,[37] and other clinical areas. [38] [39]

Background

Oximetry was first developed in Germany in 1932 by Nicolai, Kramer, and Matthes. The principle of oximetry is based on the Beer-Lambert law, which states that the concentration of an unknown solute dissolved in a solvent can be determined by light absorption. Early oximeters relied exclusively on this spectrophotometric principle, using a finger or an ear as a curette containing hemoglobin, compressing these tissues to obtain a bloodless baseline absorption, and warming them to obtain a signal from maximally arterialized tissue.

Pulse oximetry, combining the principles of optical plethysmography and spectrophotometry, was invented by Aoyagi and coworkers in 1974. [40] However, it was not until 1980 that the pulse oximeter reached modern form, consisting of a probe and an onboard computer. [41] The probe, set into a reusable clip or a disposable patch, is made up of two photodiodes producing light at 660 nanometer (nm) (red) and at 900 to 940 nm (infrared), and a photodetector, which is placed across a pulsatile vascular bed such as the finger or ear (Fig. 2-6). These particular wavelengths are used because the absorption characteristics of oxyhemoglobin and reduced hemoglobin are quite different at the two wavelengths. The majority of light is absorbed by connective tissue, skin, bone, and venous blood. The amount of light absorbed by these substances is constant with time and does not vary during the cardiac cycle. A small increase in arterial blood occurs with each heartbeat, which results in an increase in light absorption (Fig. 2-7). By comparing the ratio of pulsatile and baseline absorption at these two wavelengths, the ratio of oxyhemoglobin to reduced hemoglobin is calculated.

Because the pulse oximeter uses only two wavelengths of light, it can only distinguish two substances. As a result, pulse oximeters measure "functional saturation," which is the percentage of oxyhemoglobin compared to the sum of the oxyhemoglobin and reduced hemoglobin. The disadvantage of functional saturation is that the denominator does not include other hemoglobin species that may be present, such as carboxyhemoglobin and methemoglobin. The advantage is that the use of only two wavelengths in the oximeter reduces

Figure 2-6 *A*, Pulse oximeter sensors attached to digits. *B*, Pulse oximeter sensors attached to the dorsum of the nose and the earlobe. Only one site is measured at a time.

device cost, size, and weight. The CO-oximeter, one example of a commercially available in vitro oximeter and the standard by which pulse oximetry is calibrated, uses four or more wavelengths, measures the "fractional saturation," and is able to measure additional hemoglobin species.

The arterial O_2 saturation (SaO_2) measures the large reservoir of O_2 carried by hemoglobin, 20 mL of O_2/100 mL of blood, compared with the arterial O_2 partial pressure (PaO_2), which only measures the relatively small amount of O_2, approximately 0.3 mL of O_2/100 mL of blood, dissolved in the plasma. The SaO_2 correlates well with the PaO_2, but the relationship is nonlinear and is described by the oxyhemoglobin dissociation curve (Fig. 2-8). For the hypoxic patient, small changes in SaO_2 represent large changes in the PaO_2, because these SaO_2 values fall on the steep portion of the curve. Conversely, measurements of SaO_2 are relatively insensitive at detecting significant changes in PaO_2 at high levels of oxygenation because these SaO_2 values fall on the plateau portion of the curve.

Currently available pulse oximeters are accurate and precise when saturations range from 80% to 100%. [42] [43] This range is satisfactory, because for most patients an O_2 saturation of 80% is as much an urgent warning as one of 67%.

Clinical Utility

Pulse oximetry has been suggested as an additional vital sign. [39] By providing the clinician with either continuous or frequent intermittent estimated SaO_2 measurements, pulse oximetry offers a more physiologic means of assessing the adequacy of oxygenation than the arterial blood gas. The latter must be drawn from an arterial source and quickly transported under specific conditions to a machine that is often distant from the patient's bedside. With pulse oximetry, the test results are available at the bedside without an invasive arterial procedure. Note that as described earlier, measurement of SaO_2 is determined from blood gas measurements coupled with knowledge of actual hemoglobin levels in a patient's blood. The SaO_2 measurement is estimated using pulse oximetry (SpO_2). In this chapter we equate SaO_2 and the two measures and an SpO_2. We address potential differences in the interpretation

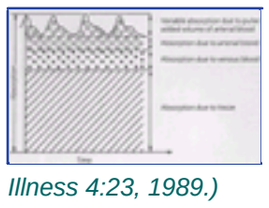

Figure 2-7 Factors influencing light absorption through pulsatile vascular bed. *(From McGough EK, Boysen PG: Benefits and limitations of pulse oximetry in the ICU. J Crit Illness 4:23, 1989.)*

section in the next section. A detailed review of pulse oximetry is provided elsewhere. [44]

All recommended uses of pulse oximetry fall into one of two broad categories. First, as a real-time indicator of hypoxemia, continuous monitoring of pulse oximetry can be used as a warning system, as many (but not all) adverse patient events are associated with arterial desaturation. [45] The second broad use of pulse oximetry is as an end point for titration of therapeutic interventions.

Although limited data address the clinical efficacy of routine monitoring of pulse oximetry in intensive care or ED settings, several studies have addressed operating suite and recovery room use that allow extrapolation. [46] [47] [48] These studies reported a decreased incidence and duration of desaturation episodes, fewer adverse impact events in the recovery room, and a shortened time to discovery of hypoxia. Therefore, routine monitoring of pulse oximetry in the critically ill patient population should result in fewer episodes of severe arterial desaturation and more rapid recognition of the adverse physiologic events that produce arterial desaturation. Patient outcomes should be improved with therapeutic interventions resulting from immediate knowledge of an unfavorable SaO_2. [49]

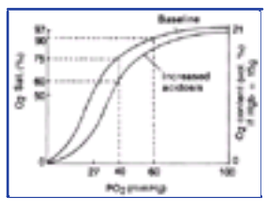

Figure 2-8 Oxyhemoglobin dissociation curve.

Indications

Some clinical applications of pulse oximetry is indicated are shown in Table 2-3 . Of note regarding assessment of respiratory illness severity in children, clinically unrecognized hypoxia (SaO_2 <92%) has been documented by pulse oximetry in preschool children with respiratory symptoms.[50] Also, an initial SaO_2 <91% in children with bronchospasm, regardless of subsequent improvement with ED management, has been associated with increased morbidity and need for admission.[51] As an additional "vital sign", SaO_2 monitoring affords the opportunity to assess both oxygenation and perfusion. This screen is helpful in those patients with suspected sepsis.

Procedure

The location for the probe is determined by the clinical situation and available probes. A reusable clip-on probe makes the digits easily accessible. Little is needed in the way of preparation, and

TABLE 2-3 -- Clinical Applications of Pulse Oximetry

During emergency airway management
Assess need for further airway management
Assess adequacy of preoxygenation before endotracheal intubation
Monitor ventilator and FiO_2 changes
Provide early indicator of ventilator dysfunction
Assist routine weaning of O_2 therapy, but not mechanical ventilation
Oxygenation monitor
Monitor patients with lung dysfunction for unexpected hypoxic events
Monitor during procedures including systemic sedation
Monitor oxygenation during interhospital and intrahospital transfer
Assess acute childhood asthma
Additional "vital sign"

as mentioned subsequently, even nail polish may generally be left on. Other sites include the earlobe, the nasal bridge or septum, the temporal artery, and the foot or palm of an infant. Tape and splints can be used to secure the digit probe and to minimize motion.

After placement of the probe, the machine is turned on. The computer analyzes the incoming data to identify the arteriolar pulsation and displays this in beats per minute; newer devices also display a pulse plethysmograph. Simultaneously, O_2 saturation is displayed on a beat-to-beat basis. Some machines have hard copy capability and can provide paper documentation of the patient's status. If the oximeter fails to detect pulsatile flow, either the reading will not display or the SaO_2 value will be given with a poor signal quality warning, depending on the machine. It is valuable to evaluate serial measurements and to verify that measurements correlate with other clinical markers.

Interpretation

Patients with good gas exchange have O_2 saturations between 97% and 100%. When the SaO_2 falls below 95%, hypoxia is present, although patients with COPD may live in this range. Oxygen saturations below 90% represent relatively severe hypoxia. Children with SaO_2 values <92% often require admission for O_2 and additional therapy.[50] [51] Although hypoxia is common with pneumonia, room-air SaO_2 values =98% have been reported in 45% of children with pneumonia.[52] In adults and older children with reactive airway disease, as with PEFR and spirometry, a low isolated early measurement of SaO_2 does not mandate admission because of the wide variability of response to therapy.[53] [54] However, low SaO_2 readings should be heeded as important clinical warning signs.

Although pulse oximetry represents a significant advance in noninvasive monitoring, clinicians must recognize and understand its limitations. Pulse oximetry measures O_2 saturation. In comparison to arterial blood gas determination or end-tidal CO_2 (carbon dioxide) monitoring, which is discussed later, pulse oximetry provides no direct information on pH or $PaCO_2$ levels, and only indirectly assesses the adequacy of ventilation. Witting and Lueck have empirically demonstrated that a room-air SaO_2 value =97% strongly rules against hypoxemia and moderate to severe hypercapnia.[55] Their validated study of patients with respiratory complaints receiving arterial blood gas analysis found good discrimination with a room-air SaO_2 value =96%. For hypoxia (PaO_2 <70 torr), this value was 100% sensitive (95% CI 95% to 100%) and 54% specific (95% CI 45% to 64%). For hypercapnea ($PaCO_2$ >50 torr), this value was 100% sensitive (95% CI 70% to 100%) and 31% specific (95% CI 25% to 38%). Kelly and colleagues found a cut-off of a room-air SaO_2 value =92% as more accurate for identifying hypoxia in chronic obstructive pulmonary disease patients.[56]

During both conscious sedation and general anesthesia, monitoring of ventilation is a more desirable goal for prevention of hypoxia than simple pulse oximetry. Hypoventilation and resultant hypercapnia may precede a decrease in hemoglobin O_2 saturation by many minutes. Furthermore, supplemental O_2 may mask hypoventilation and CO_2 retention by delaying the eventual O_2 desaturation for which pulse oximetry monitoring is designed to recognize. One animal study demonstrated that in preoxygenated animals, airway obstruction could be detected within 10 seconds using capnography, but SaO_2 values did not change during the 180-second study periods.[57] Several other pulse oximeter limitations have been noted and are summarized in Table 2-4 .

Effects of Dyshemoglobinemias

Carboxyhemoglobin results in falsely high SaO_2 estimates of hemoglobin O_2 saturation.[58] Low quantities of methemoglobin (MetHb) will reduce a pulse oximeter reading by about half the actual MetHb percentage.[59] However, even large quantities of MetHb (>10%) can result in a stable pulse oximeter reading of 85% regardless of the actual SaO_2 . In summary, in patients with methemoglobinemia or with elevated carboxyhemoglobin levels, the reading on the pulse oximeter does not accurately depict quantitative hemoglobin O_2 saturation changes.[60] [61] The pulse oximeter will variably *underestimate* the percentage of abnormal hemoglobin; a CO-oximeter is required for confirmation of these conditions and quantitative analysis.

Fetal Hemoglobin

Newborn full-term infants can have up to 75% of total hemoglobin in the form of fetal hemoglobin.[62] Pulse oximeters remain accurate in the presence of fetal hemoglobin.[63] However, a CO-oximeter will erroneously interpret the carboxyhemoglobin level to be elevated, and the oxyhemoglobin level to be artificially reduced.[64] Therefore, when fetal hemoglobin levels are high, CO-oximetry readings should not be used to confirm pulse oximetric readings. It should be noted that

newborns normally have up to 5% carboxyhemoglobin.

Low Perfusion

To function properly, pulse oximeters require a pulsating vascular bed. Hypotension with vasoconstriction, hypothermia, or the administration of vasoconstricting drugs may reduce the pulsatile component to <0.2% of the total signal. At this level, the true signal cannot be distinguished from background noise. Under these conditions, many pulse

TABLE 2-4 -- Factors Affecting Pulse Oximetry Readings

Severe anemia: Satisfactory readings obtained down to hemoglobin level of 5 mg/dL
Motion-artifact: See text regarding probe sites
Dyes: Transient effect unless methemoglobinemia results
Light-artifact: Minimize by covering probe with opaque material
Hypoperfusion: Inadequate pulse signal will display
Electrocautery: Minimize by increasing the distance of the sensor from the surgical site
Deep pigmentation: Use fifth finger, earlobe, or other area of lighter pigmentation
Dark nail polish: Remove with acetone or place sensor sideways on digit
Dyshemoglobinemias (e.g., carboxyhemoglobin and methemoglobin): Falsely elevate saturation reading
Elevated bilirubin: Accurate up to bilirubin level of 20 mg/dL in adults; no problem reported for jaundiced children
High saturation: Pulse oximetry not useful for monitoring hyperoxemia in neonates
Fetal hemoglobin: No effect on pulse oximetry; falsely reduced CO-oximetry readings
Venous pulsations: Artificially lower O_2 saturation; choose probe site above the heart
Dialysis graft (A-V fistula): No difference from contralateral extremity unless fistula produces distal ischemia

oximeters display a message indicating an inadequate pulse signal. A change in the location of the sensor to an area with higher perfusion, such as an earlobe, may improve the pulse signal. [65]

Intravenous Dyes

A number of dyes and pigments interfere with the accuracy of pulse oximetry. [66] [67] Methylene blue, the treatment for methemoglobinemia, absorbs light at 660 nm, similar to the absorption of reduced hemoglobin, and can artificially lower pulse oximeter saturation readings to as low as 1%. Low readings also can be seen with other intravenous dyes such as indigo carmine, indocyanine green, and fluorescein, although the rapid clearance of these agents minimizes the phenomenon. [68] [69]

Bilirubin

Hyperbilirubinemia does not affect the accuracy of pulse oximetry measurements. However, hyperbilirubinemia may have an effect on absorption at the lower wavelengths used by CO-oximeters, resulting in a discrepancy between pulse oximeter and CO-oximeter readings. [70]

Skin Pigmentation

Pulse oximeter accuracy is somewhat reduced by deeply pigmented skin. This effect is likely due to a shift in the light-emitting diode's output spectrum as the light output is increased. This effect is small and results in only a slight decrease in accuracy over a large number of samples. [70] Placing the probe on an area of lighter pigmentation, such as the fifth finger or an earlobe, has been suggested as a means to minimize this effect.

Nail Polish

Conflicting data exist about the effect of nail polish on the accuracy of pulse oximeter determinations. Mounting the probe side-to-side on the finger was found to be as accurate as readings on uncovered nails. [71] This technique also circumvents the problem of only partial placement of the probe because of very long fingernails, which may cause a low O_2 saturation reading. An alternative solution to the problem of nail polish is to remove it with acetone. The accuracy of SaO_2 readings in the setting of synthetic nails is unknown. If a poor signal is obtained in the setting of a synthetic nail, either the synthetic nail should be removed or an alternative site for placement used.

High Saturation

Because the O_2 dissociation curve plateaus at saturation levels >90%, a large increase in PaO_2 results in a small increase in saturation. Therefore, an error of a few percentage points could represent a large error in PaO_2. This is inconsequential for most adult patients but is of extreme importance for neonates at risk of retinopathy caused by hyperoxemia.

Venous Pulsations

Increased venous pulsations resulting from right heart failure, tricuspid regurgitation, or placement of a tourniquet or blood pressure cuff above the probe can interfere with accurate readings and lead to artificially lower O_2 saturations, because the pulse oximeter interprets any pulsatile measurement as arterial. [72] Placing the probe on a site above the heart may improve accuracy. Some pulse oximeters have the capability to synchronize pulsations at the probe site to electrocardiographic (ECG) signals, thus enhancing the signal-to-noise ratio.

Anemia

Because pulse oximeter measurements depend on light absorption by hemoglobin, they become less accurate and reliable in conditions of severe anemia. However, accuracy is not diminished until the hemoglobin content is <5 mg/dL. [73] [74]

Ambient Light

As the pulse oximeter's photodetector is nonspecific, high-intensity ambient light can produce interference. Surgical, fluorescent, and heating lamps are the common sources of this interference. This problem can be corrected by wrapping the probe with a light barrier, such as a dark cloth or other opaque material. [65]

Motion

Motion of the probe can produce considerable artifact and inaccurate pulse oximetry readings. However, this phenomenon is transient and seldom influences

assessment. Correlating a pulse oximeter signal with an ECG waveform[70] or using alternate probe sites, such as the ear or toe, also may reduce motion artifact.

Probe Site

The finger is the most common probe site used for adult pulse oximetry. If the finger is inaccessible or unsuitable, other probe sites, such as the earlobe, nose, and forehead (using reflectance instead of transmittance), may be used. It should be noted, however, that the forehead and nasal bridge probes may be less accurate than the finger and ear probes.[70] In infants and small children, an adhesive sensor unit is preferred. Probes also can be secured in place over the heel or lateral foot using a gauze or Coban wrap. Common sites of attachment include the great toe, the heel, and the lateral aspect of the foot.

Electrocautery

Electrical interference from devices such as electrocautery also can impair the accuracy of pulse oximetry. This interference can be reduced by increasing the distance between the surgical site and the probe.

Conclusions

Pulse oximetry is a widely available and relatively inexpensive technology that provides an easy, noninvasive, and generally reliable method to monitor oxygenation. As measurements are continuous, pulse oximetry allows for earlier detection of clinically unsuspected hypoxic episodes than does intermittent arterial blood gas analysis. Frequent measurements should lead to earlier corrective measures with the prevention of adverse consequences.

CARBON DIOXIDE MONITORING

Capnometry is a noninvasive method used to assess the adequacy of ventilation by measuring the CO_2 concentration of exhaled air. With an intact pulmonary circulation, CO_2 is present in tracheal but not esophageal gas efflux. The absence of CO_2 in an endotracheal tube indicates esophageal intubation, technical malfunction, circulatory arrest, circuit disconnection, or intraluminal/extraluminal tube obstruction. The continued presence of CO_2 in the expired air confirms tracheal intubation. In addition, capnometry provides a measure of systemic

metabolism and circulation that may be continuously monitored. Although the measurement of $PaCO_2$ via arterial blood sampling is the most direct method of evaluating ventilation, it is invasive, costly, and provides only intermittent data.

Capnography, introduced into clinical practice by Smalhout and Kalenda in the mid-1970s, [75] displays the CO_2 measured by capnometry graphically with respect to time throughout the respiratory cycle. The capnogram is the displayed waveform of breath-to-breath variations in the expired CO_2 concentration, and characteristic variations in its shape are associated with specific abnormalities. [76]

Indications

Verification of Endotracheal Tube Placement

In an emergency situation, the clinician desires a quick and reliable method to verify correct placement of an endotracheal tube (ETT). Traditional clinical methods of evaluating ETT placement (breath sounds, chest movement, epigastric auscultation), although adequate in the majority of circumstances, are not fail-safe. [77] Although direct cord visualization reliably assesses ETT passage into the trachea, such visualization is not always possible. Additionally, an ETT may become dislodged even after correct placement as a result of head movement or patient positioning. Numerous studies in animals and humans under controlled and emergency conditions support the use of CO_2 measurement in expired air as a means of ETT placement confirmation.[60] [77] [78] [79] This technique is described in more detail in Chapter 4 .

Systemic ("Conscious") Sedation

Many procedures performed in the ED are facilitated by sedation. The use of hypnotic doses of benzodiazepines can result in respiratory depression, and opioid analgesics predictably reduce ventilatory drive and the normal response to both hypoxia and hypercarbia. Moreover, the combination of benzodiazepines and opioids substantially increases the incidence of hypoxemia and apnea as compared with the effects of either agent alone. [80]

Monitoring of ventilation, perfusion, and oxygenation increases the safety of sedation. As mentioned earlier, pulse oximetry indirectly assesses ventilation. Although hypoventilation, hypercarbia, and apnea ultimately lead to a decrease in O_2 saturation on pulse oximetry, hypoxia is preceded by a rise in end-tidal CO_2 partial pressure ($PetCO_2$).[81] [82] Hence, combining exhaled CO_2 monitoring with pulse oximetry should further enhance the safety of systemic sedation.

Nasal cannula (side-stream) CO_2 analyzers have made continuous $PetCO_2$ monitoring possible during systemic sedation. Nasal cannula-derived $PetCO_2$ values correlate well with $PaCO_2$ in awake, spontaneously breathing patients and may be as accurate as those obtained from an ETT. [82] Two beneficial features of the $PetCO_2$ monitor are immediate evidence of changes in the respiratory pattern by observation of the capnographic waveform and an audible apnea alarm. This latter feature is especially valuable after completion of emergency procedures when personnel are less likely to be at the bedside and patient stimulation is minimized.

Cardiopulmonary Resuscitation and Shock Resuscitation

The role of $PetCO_2$ for monitoring the effectiveness of cardiac compressions, estimating the potential for cardiac resuscitation, and detecting restoration of spontaneous circulation is discussed in more detail in Chapter 17 . A proposed related use is the difference between $PaCO_2$ and $PetCO_2$ (i.e., the $P(a\text{-}et)CO_2$ gradient) as a measure of under-resuscitation in traumatic shock. [83]

Mechanical Ventilation

Many emergency clinicians manage ventilated patients past the initial resuscitation phase while they are awaiting patient transfer to a critical care unit or during further diagnostic testing. Capnography can noninvasively and continuously monitor for ventilation failure (e.g., discontinuities in the ventilator circuit, CO_2 rebreathing) and assess changes in mechanical support, including weaning from the ventilator. [84]

Contraindications

In the critically ill patient, capnography may not be an adequate substitute for arterial blood gas sampling during adjustments of or weaning from mechanical ventilation. In such patients, $PetCO_2$, when used, should be correlated with $PaCO_2$ measurements via arterial blood gas analysis. That is, $PetCO_2$ values should be used as a supplement to, rather than as a replacement for, $PaCO_2$ values.

In spontaneously breathing patients, side-stream analyzers with nasal cannula sampling techniques must be used with caution, because ambient air may be entrained and therefore dilute $PetCO_2$ measurements. Moreover, the accuracy of monitoring $PetCO_2$ by this method is critically dependent on the relative placement of the sampling tube in the patient's naris or nasopharyngeal airway relative to the source of supplemental O_2 . The presence of mouth breathing also can dilute $PetCO_2$ values when nasal cannulas are used.

In children with fast ventilatory rates and low tidal volumes, a side-stream analyzer with a slow sampling flow rate underestimates the $PetCO_2$. Sampling flow rates of 150 mL/min yield consistently accurate estimates of $PaCO_2$ and an acceptable capnogram in neonates, infants, and children. [85] Adult-size disposable end-tidal CO_2 detectors are not recommended in children who weigh <15 kg, because their small tidal volumes may be diluted in the large (38 mL) dead space of the device, resulting in failure to detect CO_2 appropriately. [78] [86]

Equipment

Of the two quantitative methods of CO_2 gas analysis used in hospitals, mass spectrometry and infrared absorption spectrophotometry, only the latter is used commonly in the intensive care unit and ED. Qualitative CO_2 -sensitive colorimetric technology also is available. A product comparison of the many commercial capnography devices has been published elsewhere. [87]

The two types of infrared capnometers used with intubated patients are:

1. The mainstream (in-line) capnometer, which consists of a transducer housed in an airway connector and placed in-line with the patient's breathing circuit (Fig. 2-9). The transducer contains the infrared light source and photodetector, heated to approximately 40°C to prevent condensation. Mainstream sampling allows

the capnometer to directly assess the patient's respiratory circuit. Hence, gas analysis is nearly instantaneous (<500 msec). The major disadvantage is the weight associated with the airway connector attached to the

proximal end of the ETT. Examples of these devices are the Nellcor Stat-CAP N60B and Ultra-CAP N6000B (Nellcor Inc., Pleasanton, CA). The former device is a portable, battery-operated instrument that provides continuous qualitative readings. The latter device is a bedside monitor that displays both a continuous waveform and numeric information.

2. The side-stream or diverting capnometer actively withdraws gas from the patient's airway via a sampling tube, and the concentration of CO_2 is measured in the machine rather than in the ETT (Fig. 2-10). The major advantage of side-stream analyzers is their applicability to nonintubated patients. Their major disadvantage is a slower response time, because expired gas must be transported to the capnometer itself for analysis. Slower response time results in dispersal of the gas bolus due to convection and diffusion during transit through the sampling catheter. These factors result in an underestimation of $PetCO_2$, particularly in children who have high ventilatory rates and small tidal volumes. Response times of side-stream analyzers are dependent on the aspiration flow rate, sampling tube length, and tubing diameter. To achieve predictable $PetCO_2$ values and CO_2 waveforms, the response time of the analyzer must be less than the respiratory cycle of the patient.[88] The optimal gas sampling flow rate is considered to be 50 to 200 mL/min, which ensures that the capnographs are reliable in both children and adults.[89] Despite a water trap, side-stream analyzers also are affected by secretions, saliva, and water condensation.

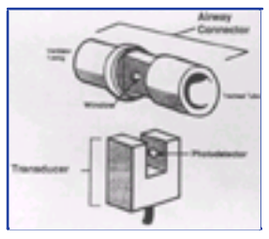

Figure 2-9 Schema of mainstream analyzer used for capnography. Transducer to measure CO_2 is placed in-line of airway connector. Infrared light source (not indicated) resides opposite photodetector in transducer. *(From Szalfarski NL, Cohen NH: Use of capnography in critically ill adults. Heart Lung 20:363, 1991.)*

Qualitative, lightweight, disposable end-tidal CO_2 detection devices are based on colorimetric changes. A pH-sensitive chemical indicator is enclosed in a plastic housing and is connected to the gas stream between the ETT and the ventilator. The concentration of CO_2 in ambient air or the esophagus is <0.3%. These devices change color when the concentration of CO_2 is higher than 4% or 5.4%. The color varies as the CO_2 level increases and decreases between expiration and inspiration. The devices are designed to function for approximately 2 hours. The response time of the device is sufficiently fast to detect changes of CO_2 breath by breath.[90] In addition to their portability and single-patient use, these devices have the advantage of not requiring electrical power. Originally, the disposable CO_2 detectors were only available for attachment to ETTs (EASY-CAP and Pedi-CAP, Nellcor Inc., Pleasanton, CA). Chemical CO_2 detection devices, built into disposable bag-valve ventilation devices, are now available for ED use (CAPNO-FLO, Kirk Specialty Systems, Carrollton, TX). Both systems have components for adult and pediatric patients.

Procedure

For mainstream capnometers, simply place the airway connector in-line between the ETT and respiratory circuit. For side-stream or diverting capnometers, position the sampling tube in the naris via nasal cannula, nasopharyngeal tube, or other adapters available with particular machines. After sufficient warm-up time, a continuous recording of the capnogram or a digital display of a $PetCO_2$ value will display depending on the type of machine used. The chemical CO_2 detection devices are ready to use after attachment to the ETT (EASY-CAP, Pedi-CAP), or they come as a component of the bag-valve device (CAPNO-FLO).

Interpretation

Various factors result in either increased or decreased (or even absent) $PetCO_2$ (Table 2-5). With regards to the measurement device, a continuous recording of the capnogram is more advantageous than simply a digital display of a $PetCO_2$ value.

TABLE 2-5 -- Various Factors That Influence $PetCO_2$

	Factor			
Effect on $PetCO_2$	***CO_2 Production***	***Pulmonary Perfusion***	***Alvelor Ventilation***	***Technical/Mechanical Errors***
Increased				
Fever	Sodium bicarbonate	Hypoventilation	Rebreathing	Leaks in breathing system
Thyrotoxicosis	High cardiac output	Bronchial intubation	Exhausted CO_2 absorber	Faulty ventilator
Malignant hyperthermia	Hypertension	Parital airway obstruction	Inadequate fresh gas flow	Faulty valves
Decreased or Absent				
Hypothermia	Hypovolemia	Hyperventilation	Partial airway obstruction	Circuit disconnection
Low cardiac output	Pulmonary embolism	Apnea	Tracheal extubation	Sampling tube leak
Hypotension	Cardiac arrest	Total airway obstruction		Malfunction of ventilator

A normal capnogram has four phases (Fig. 2-11). At the onset of exhalation (point B) respiratory gases are free of CO_2, because they represent the anatomic dead space. The steep rising slope of segment B–C represents the emptying of rapidly exchanging alveoli. Segment C–D represents the emptying of uniformly ventilated alveoli, where the concentration of exhaled CO_2 is nearly constant. True end-tidal CO_2 ($PetCO_2$) is the highest concentration measured during the alveolar plateau (point D) and immediately precedes the onset of the next inspiratory cycle. Inspiration is represented by the rapidly descending limb of the capnogram (segment D–E) and, unless significant CO_2 rebreathing occurs, return of the CO_2 concentration to near zero (baseline).

At the end of exhalation, the composition of expired air closely reflects that of alveolar air. Under normal conditions, the alveolar CO_2 reflects the CO_2 present in mixed venous blood ($PvCO_2$), which equilibrates with the resultant value for arterial blood ($PaCO_2$). Under normal conditions, only a small gradient (<6 mm Hg) exists between $PaCO_2$ and $PetCO_2$.[91] The $P(a\text{-}et)CO_2$ gradient is increased with age, COPD, pulmonary embolism, decreasing cardiac output, hypovolemia, and anesthesia

itself.[92] [93] [94] In the paralyzed and ventilated patient without underlying lung disease, the

Figure 2-11 The four phases of a normal capnogram. Exhalation begins at point *B*. The steep ascending limb (segment *B–C*) represents rapidly exchanging alveoli. Segment *C–D* is the alveolar plateau representing uniformly ventilated alveoli, with a nearly constant CO_2 concentration. $PetCO_2$ is the highest point on the alveolar plateau (point *D*) and immediately precedes the next inspiration. Segment *D–E* rapidly descends to the original baseline (zero in normal subject) during inspiration (segment *A–B*). *(Courtesy of Novametrix Medical Systems, Inc., Wallingford, CT.)*

$PetCO_2$ can be used to estimate the $PaCO_2$ and thus guide ventilation in the head-injured patient. [95]

The principal determinant of the size of the $PaCO_2$ -$PetCO_2$ gradient ($P[a\text{-}et]CO_2$) is the matching of ventilation and perfusion (V/Q). The major cause of V/Q mismatch is dead space ventilation, in which lung units have more ventilation than perfusion. As a result, the end-tidal gas contains less CO_2, and $PetCO_2$ values are lower, causing large differences in the $PaCO_2$ -$PetCO_2$ gradient.[94] [95] [96] [97] In this situation, the alveolar plateau (see Fig. 2-11, segment C–D) will not be flat, but rather will have a slow, rising expiratory upstroke (Fig. 2-12). In a normal patient, the alveolar plateau is flat because the expired gas from all lung units have similar V/Q relationships.[93] If the patient has significant maldistribution of ventilation, exhaled gas will have varying concentrations of CO_2, because the CO_2 concentration from some airways will be low, representing dead space ventilation, whereas the CO_2 concentration from others will be high. Only when a distinct alveolar plateau is present can it be assumed that true alveolar gas is being sampled and analyzed. [84]

In the setting of under-resuscitation of traumatic shock, the $P(a\text{-}et)CO_2$ gradient will be elevated. Tyburski and colleagues

Figure 2-12 Capnogram of patient with adult respiratory distress syndrome and pneumonia. Lack of a normal alveolar plateau is evident. *(From Szalfarski NL, Cohen NH: Use of capnography in critically ill adults. Heart Lung 20:369, 1991.)*

noted that a postoperative $P(a\text{-}et)CO_2$ gradient of >9 torr was associated with death in multiple-trauma patients. [83]

Intubation Assessment

False-positive capnographic tracings associated with esophageal intubation that closely mimic successful ETT intubation may occur in patients who have recently ingested carbonated beverages or antacids and those receiving mask ventilation with resultant gastric insufflation of CO_2-containing gases. [98] However, after 3 to 6 esophageal ventilations, $PetCO_2$ concentration rapidly declines as gastric CO_2 is washed out and diluted with fresh gas (Fig. 2-13).[99] [100] Tracheal ventilation will, of course, continue to produce a normal waveform.

After initial successful ETT placement and confirmation, changes in the CO_2 waveform can provide immediate detection of tube-related adverse events. When the ETT is partially obstructed, the capnogram will have a slow upstroke without a significant change in the $PetCO_2$ (Fig. 2-14).[84] [99] Bronchospasm and COPD exacerbations produce obstruction to expiratory gas flow, thus increasing the slope of the expiratory upstroke. With inadvertent extubation, the capnogram shows a sudden drop in $PetCO_2$ (the same change that occurs when the tube becomes completely obstructed or malpositioned in the esophagus) (Fig. 2-15 and Fig. 2-16). [99] ETT cuff leaks yield low $PetCO_2$ values because of the partial escape of the expired gas around the tube.

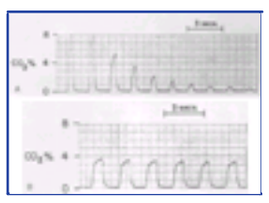

Figure 2-13 Esophageal capnogram after ingestion of carbonated beverage. *A*, CO_2 is clearly present as the esophagus is ventilated. The CO_2 concentration rapidly dissipates to the nonphysiologic range. *B*, The normal tracheal capnogram obtained simultaneously from the same experimental animal is shown. *(Modified from Garnett AR, Gervin CA, Gervin AS: Capnographic waveforms in esophageal intubations: Effect of carbonated beverages. Ann Emerg Med 18:387, 1989.)*

Monitoring Ventilation

Capnography is useful in diagnosing and monitoring maldistribution of ventilation during mechanical ventilation. In patients with a large V/Q mismatch, the capnogram will have a continued rise throughout the expiratory phase (see Fig. 2-12) and will lose the normal alveolar plateau. When this waveform occurs, the measured end-tidal CO_2 may not represent a good estimate of $PaCO_2$. However, by monitoring the slope of the expiratory phase on the capnogram, the efficacy of therapy can be evaluated. For example, in the case of asthma, as bronchospasm resolves, the slope of the expiratory phase will become less steep and the alveolar plateau better defined as a result of improved distribution of ventilation. [84] [101]

Furthermore, as the $P(a\text{-}et)CO_2$ gradient is sensitive to increases in dead space, this gradient can be used to evaluate changes and trends in dead space ventilation in critically ill patients with significant intrapulmonary shunting. [102] [103] It also can be used as a guide to determine the best positive end-expiratory pressure (PEEP) level for optimal oxygenation. Because a low $P(a\text{-}et)CO_2$ gradient implies the optimal V/Q relationship, the level of PEEP that produces the lowest $P(a\text{-}et)CO_2$ gradient is the level at which optimal alveolar recruitment occurs. [79]

In well oxygenated animals subjected to airway occlusion or extubation, changes in capnography occur considerably more quickly than vital sign changes or pulse oximetry changes.[57] The observational study of Miner and colleagues demonstrated that patients undergoing procedural sedation could demonstrate $PetCO_2$ >50 torr, an absolute change of >10 torr, or an absent waveform before a change in pulse oximetry. [104]

Excluding airway mishaps, ventilator setting changes, and circuit discontinuities, a sudden drop in end-tidal CO_2 may be an early indicator of shock or pulmonary embolism.[75] [105]

A dip in the plateau (curare cleft) (Fig. 2-17) indicates a spontaneous respiratory effort during mechanical ventilation [106] [107] and may be an early clue to the waning effects of a paralytic agent. Capnometry may also be especially useful in assessing the adequacy of hyperventilation in the

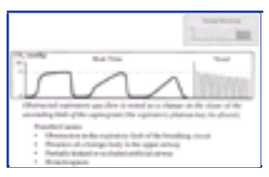

Figure 2-14 Partial endotracheal tube occlusion and other obstructions in the breathing circuit or airway. Note slurred upstroke of CO_2 waveform and absence of expiratory plateau. *(Courtesy of Novametrix Medical Systems, Inc., Wallingford, CT.)*

hemodynamically stable patient with head trauma. Other capnography patterns and their clinical significance are demonstrated in Figure 2-18 .

OXYGEN THERAPY

Earlier sections have dealt with ventilation and assessment of oxygenation. Delivery of O_2 is impaired in many clinical situations. Neurologic dysfunction is an early sign of hypoxemia. Otherwise-healthy individuals begin to experience short-term memory loss, euphoria, and impaired judgment when the PaO_2 level approaches 55 mm Hg. Progressive loss of cognitive and motor function, increasing tachycardia, and other physical signs occur when values are between 30 and 55 mm Hg. When levels are <30 mm Hg, the patient loses consciousness. PaO_2 is

Figure 2-15 Malposition of endotracheal tube in the esophagus. Note loss of capnographic waveform. *(Courtesy of Novametrix Medical Systems, Inc., Wallingford, CT.)*

a function of the fraction of inspired O_2 tension (FiO_2), the alveolar ventilation, and the relative distribution of both ventilation and perfusion in the lung. Supplemental O_2 can increase the amount of O_2 dissolved in blood enough to deliver one third of the body's resting metabolic requirements. This section reviews the noninvasive delivery of supplemental O_2.

Indications

Oxygen therapy is generally indicated when hypoxia is present (PaO_2 <60 mm Hg or SaO_2 <90% to 95%). Clinical situations that are commonly associated with hypoxia and generally benefit from supplemental O_2 include pulmonary disease, cerebrovascular accidents, gastrointestinal bleeding, shock, and trauma. Supplemental O_2 also is indicated when hypoxia is anticipated from a procedure such as intubation or

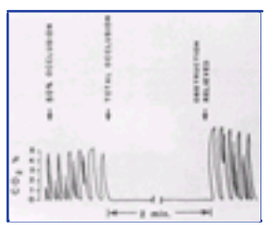

Figure 2-16 Occlusion of the endotracheal tube. Note that occlusion of a properly placed tube yields the same flat capnogram as esophageal intubation or accidental extubation. *(From Murray IP, Modell JH: Early detection of endotracheal tube accidents by monitoring carbon dioxide concentration in respiratory gas. Anesthesiology 59:345, 1983.)*

before a procedure in which intravenous analgesia may cause respiratory depression.

High altitude also results in hypoxia. At 7000 ft the barometric pressure is 564 mm Hg, the atmospheric partial pressure of O_2 is 116 torr, and the arterial partial pressure of O_2 (with healthy lungs) is approximately 63 torr. Commercial airlines maintain cabin pressures at levels between 5000 to 8000 ft at most cruising altitudes, and close to 10,000 ft temporarily under certain circumstances. Patients with chronic hypoxia may require supplemental O_2, and they must contact the airline before flying to make appropriate arrangements (the reader is referred elsewhere for a review of air travel and

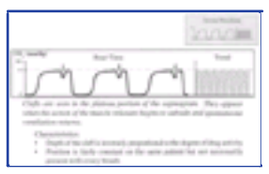

Figure 2-17 Capnogram of patient receiving assist-control ventilation and vecuronium paralyzation. *(Courtesy of Novametrix Medical Systems, Inc., Wallingford, CT.)*

O_2 therapy).[108] Oxygen is specifically indicated for carboxy-hemoglobinemia; 100% O_2 reduces the half-life of carboxy-hemoglobin from a mean of 5 hours to 1 hour; hyperbaric (more than 1.0 atm) O_2 can lessen this time by half again. However, discussion of hyperbaric O_2 therapy is beyond the scope of this chapter.

Contraindications

Paraquat turns O_2 into free radicals, thus making O_2 a substrate of the poison. Similar toxins in this group include bleomycin, cyclophosphamide, doxorubicin, ozone, and nitrous dioxide.[109] [110] Hence, O_2 therapy in the absence of documented hypoxia is contraindicated for this group of toxins.

Fears of ventilatory shutdown in the presence of CO_2 retention have made clinicians hesitant to give supplemental O_2 in amounts greater than 2 L/min. However, if hypoxia remains after low-flow O_2 is initiated, the O_2 delivery must be increased. Continuous monitoring of spontaneous respiration is required in this setting, and preparations to perform intubation should be made to assist the patient's ventilation if indicated. Note that inspired O_2 levels may actually rise with low-flow O_2 therapy as respiratory effort wanes, because less room air is entrained with shallow breaths; significant exacerbation of ventilatory failure has been documented with even 1 L/min of O_2 by nasal cannula.[111] However, a high CO_2 level is not a contraindication to appropriate O_2 therapy.

Equipment

The two most common sources of O_2 for hospital patients are wall outlets linked to a large reservoir of liquid O_2 and O_2 tanks (green by convention) of various sizes, listed in Table 2-6 . Both provide outlet pressures in the range of 30 to 50 psi. An approximation of the amount of time left in a given tank at a given flow rate may be calculated using the following formula:

Minutes of O_2 = gauge pressure (psi) × cylinder factor/flow rate (L/min)

Figure 2-18 *A–F,* Various abnormal capnography patterns and their causes. *(Courtesy of Novametrix Medical Systems, Inc., Wallingford, CT.)*

Cylinder factors are shown in Table 2-6 . Alternatively, a simple computer program that can estimate the duration of O_2 remaining in a tank based on the previous variables is available. [112] The numerous methods available to deliver O_2 from the source to the patient are listed in Table 2-7 .

Nasal cannulas can provide low-flow O_2 supplementation when accurate control of O_2 concentration is unimportant, as inspired concentrations vary considerably depending on patient tidal volume and inspiratory flow rate. [113] Rough guidelines for the *theoretical maximum* inspired O_2 concentration related to O_2 flow rates are listed in Table 2-7 . Importantly, the actual inspired O_2 will be less than the theoretical

TABLE 2-6 -- Oxygen Cylinders (Approximate Values)

Cylinder Type	Volume (L)	Cylinder Factor	Hours of O_2 at 2 L/min
D	450	0.20	3.5
E	650	0.28	5.0
G	5600	2.41	44.0
H, K	6900	3.14	58.0

maximum, due to mouth breathing, poor fitting devices, and inaccurate flow settings. Similarly, some mask systems are designed to be used without Venturi inserts, and package inserts indicate the range of inspired O_2 concentration based on O_2 flow rates. As with nasal cannulas, inspired O_2 concentrations vary considerably (may be upward of 10% greater than predicted by package inserts) depending on the patient's breathing pattern (rate and tidal volume).

Venturi systems should be used in patients with CO_2 retention for whom tight control of inspired oxygen is required. A partial nonrebreathing mask incorporates a 200 mL reservoir that effectively delivers an inspired FiO_2 of 60% to 80% in most patients. The system uses a 200 mL reservoir bag, initially filled with O_2 . Inspiration at high flow rates generally empties the reservoir and exhalation fills it with the first 200 mL of expired gas, which is mostly derived from the dead space of the upper airway and thus contains a high FiO_2 . A true nonrebreathing mask contains 2 types of valves and is capable of delivering close to 100% O_2 . One valve prevents exhalation gas from entering the reservoir bag. The second type has two valves on the mask that allow exhalation, concurrently preventing ambient air from entering the

TABLE 2-7 -- Oxygen Delivery Systems

System	Flow Rate (L/min)	FIO_2* (% Oxygen)	Advantages	Disadvantages
Nasal cannulas	1	25	Simple, comfortable, inexpensive, allow eating and drinking	Can cause local irritation and drying of mucous membranes (primarily for flow rates >4 L/min)
	2	29		
	3	33		
	4	37		
	5	41		
	6	45		
Simple oxygen masks	>5 L/min	35–50	Deliver higher flow rates than nasal prongs	Must be removed for airway care, eating, and drinking
Masks with reservoir bag	Up to 15 L/min	60	Higher FIO_2 at lower flow rates	Risk of atelectasis and oxygen toxicity (with prolonged use)
Venturi masks	4	24–28	More precise control of final oxygen concentration	Same as above
	6	31		
	8	35–40		
	10	50		
Reservoir nebulizers, including CPAP, T-tubes	40+ L/min	60–90	Can deliver increased humidity, positive pressure	Risk of barotrauma

*The *theoretical maximum* FIO_2 . In clinical practice the FIO_2 will be lower.

inhalation circuit. To comply with safety regulations designed to prevent asphyxiation should the O_2 supply be interrupted, many manufacturers remove one of the valves located on the mask, somewhat limiting the concentration of O_2 delivered.

Procedure

Supplemental O_2 should be given to increase the PaO_2 to between 60 and 80 mm Hg or between 90% and 95% SaO_2 . In attempting to deliver high concentrations of O_2 to a nonintubated patient, the challenge is to provide enough O_2 at flow rates sufficient to meet the patient's demands. A simple method of assessing the adequacy of O_2 delivery with a medium flow system is to add water mist to the O_2 (through a humidifier) and to visually observe the pattern of mist flow at the mask. Mist should escape from the side holes of the mask during both inspiration and expiration. If mist is not visualized to escape during inspiration, ambient air is being inspired by the patient (effectively reducing inspired O_2 concentration) and a higher flow system is required. Bedside pulse oximetry can provide prompt monitoring of changes in SaO_2 , allowing adjustments to be made without repeated arterial blood gas determination. Pulse oximetry values generally equilibrate within 5 minutes of an oxygen delivery adjustment. [114]

Evidence of CO_2 retention, such as decreasing mental status and failing respiratory drive, indicates the need for an arterial blood gas determination to document the $PaCO_2$; however, the decision to intubate generally should be made on clinical grounds. The need to humidify bedside low-flow O_2 is unproven. [110] [115] Table 2-8 lists the steps required to provide O_2 from cylinders.

Complications

Three distinct areas of risk accompany supplemental O_2 use: (1) respiratory dysfunction, (2) cytotoxic injury, and (3) physical hazards. Respiratory dysfunction results from CO_2 retention and atelectasis. Variations in CO_2 level provide the main stimulus to breathe in normal subjects. Patients with COPD have a decreased sensitivity to CO_2 levels secondary to chronic exposure to higher CO_2 levels, and hypoxia provides backup support for the respiratory drive. Oxygen given in sufficient amounts can remove the remaining chemical stimulus to respiration and has the potential to cause respiratory shutdown.

The complete abolition of the hypoxic drive has been reported to require a PaO_2 of 200 mm Hg. However, administration of 100% O_2 to 22 patients with COPD in acute respiratory distress (mean baseline blood gas values: $PaCO_2$ = 65 mm Hg, PaO_2 = 38 mm Hg) for 15 minutes resulted in only a transient decrease in minute ventilation.[116] The lowest values for minute ventilation were reached between 20 and 180 seconds from onset of inhalation, followed by a slow rise over the next 12 minutes to within 93% of the control value. The decrease was the result of falls in both tidal volume and respiratory rate; however, after 15 minutes, these parameters had returned to baseline levels. Despite little difference in

TABLE 2-8 -- Operation of Oxygen Cylinders

1. Secure the tank in an upright position so that it will not move or fall while being manipulated.
2. Remove the cylinder seal ("E" tank) or cylinder cap ("G," "H" tank).
3. Turn the cylinder valve on and off quickly to clear ("crack") the valve. On the "E" tank, this is done with a wrench; on the "G" or "H" tank, it is done with the cylinder handle.
4. Check the yoke to ensure that it is compatible for use with oxygen and place it on the cylinder. Make sure the fittings are compatible.
5. Tighten the yoke, making certain that any necessary gasket is in place.
6. Close the needle valve.
7. Slowly open the cylinder valve until the pressure maximizes.
8. Observe that the cylinder contains an adequate supply of gas.
9. Connect the desired secondary delivery system (e.g., nasal cannula).
10. Open the needle valve so that the desired oxygen flow registers on the flow meters.

these parameters at the 15 minute point, $PaCO_2$ had risen a mean of 23 mm Hg, and PaO_2 had risen a mean of 225 mm Hg.[117] The mechanism leading to atelectasis is less clear. Elevated O_2 levels may affect underperfused or underventilated pulmonary segments by decreasing hypoxic vasoconstriction. The increased perfusion could lead to greater absorption of the remaining gas, destabilizing the alveolar units and bringing on collapse. [118]

Cytotoxic damage, theoretically secondary to free radical production, leads to tracheobronchitis and adult respiratory distress syndrome (ARDS) manifested by pulmonary edema and focal lung collapse with pulmonary fibrosis as a long-term consequence. The mechanism of damage has been shown experimentally to include oxidation of carbohydrates with disruption of cell surface receptors, DNA-RNA alterations, lipid peroxidation, and protein denaturation. Administration of an inappropriately high level of O_2 does not usually produce consequences within the time frame of the ED visit. The risk of O_2 toxicity depends on several factors, including O_2 tolerance (the state of biologic resistance to O_2-induced damage, which is itself dependent on antioxidant defenses, age, and nutritional and hormonal factors), concentration of O_2 delivered, and duration of treatment. The goal is to deliver the least O_2 required to achieve adequate tissue levels. During resuscitation and most emergency care, 100% O_2 can be delivered safely to most patients without fear of cytotoxic injury. Healthy adult volunteers have received 100% O_2 for up to 6 hours without evidence of pulmonary injury. Except in special circumstances, such as paraquat poisoning, O_2 at concentrations of =50% is safe for 2 to 7 days. [110]

Physical risks associated with O_2 therapy include trauma associated with tank explosions, fire hazard, local irritation, and drying of mucous membranes.

NONINVASIVE PRESSURE SUPPORT VENTILATION

Noninvasive pressure support ventilation can be used to deliver increased airway pressure in several modes: (1) pressure increases solely during inspiration (i.e., delivery of inspiratory positive airway pressure [IPAP]) to supplement ventilatory mechanics; (2) continuous steady positive airway pressure maintained throughout the ventilation cycle (i.e., expiratory positive airway pressure [EPAP], also known as continuous positive airway pressure [CPAP]) to improve alveolar oxygen exchange; or (3) a combination of both modalities to achieve both goals. During noninvasive pressure support ventilation, a tight, well-fitting mask is placed over the patient's mouth and nose or just over the nose.

Mask CPAP treatment of cardiogenic pulmonary edema was first described more than 50 years ago[119] and has been shown to be a useful adjunct in the treatment of acute cardiogenic pulmonary edema. Mask CPAP results in early physiologic improvement and reduces the need for intubation and mechanical ventilation in patients with pulmonary edema.[120] [121] [122] It also reduces total hospital costs for patients with severe cardiogenic pulmonary edema. [123] Use of mask CPAP to deliver PEEP has aided the treatment of other forms of respiratory failure including those due to pulmonary infections, trauma, and obstructive lung disease. Historically, patients with respiratory failure secondary to *Pneumocystis carinii* pneumonia who required mechanical ventilation had in-hospital mortality rates as high as 86% to 94%; however, those who were judged to require mechanical ventilation, but who were instead treated with mask CPAP, had in-hospital mortality rates of 22% to 55%. [124] [125] [126] Mask CPAP may be efficacious in the treatment of respiratory failure secondary to other pulmonary infections. [127] [128] Further, mask CPAP (either by full-face or nasal mask) may obviate the need for intubation and mechanical ventilation in acute exacerbations of COPD. [129] [130] [131]

The general use of IPAP for respiratory failure has recently been reviewed. [132] The use of combined IPAP and EPAP in the ED and critical care setting appears promising.[133] [134] [135] [136] This technique is also known as bi-level positive pressure ventilation, because it allows the clinician to deliver different inspiratory and expiratory pressures. This technology offers the opportunity to both support mechanical ventilation and improve oxygen exchange through an enhanced functional residual capacity. In essence, a mask device provides the ventilation and PEEP that was once possible only with the use of tracheal intubation and a standard ventilator.

Indications and Contraindications

Noninvasive pressure support ventilation is indicated to treat impending ventilatory failure and avoid intubation and standard mechanical ventilation, with their associated morbidity and mortality. Noninvasive pressure support ventilation seems best applied to patients whose respiratory failure is expected to quickly respond to medical therapy, as continuous long-term mask CPAP or ventilation requires close attention.

Noninvasive pressure support ventilation for acute respiratory failure requires an alert patient capable of protecting the airway and handling secretions. Other contraindications include an inability to obtain a good mask fit, cutaneous irritation from the mask, and inability to cooperate with the therapy. Finally, intubation and standard ventilation is preferred for patients who require total ventilatory support, because the mask may slip and effective ventilation may cease.

Equipment

Although numerous systems that provide CPAP are on the market, they are infrequently used in the ED. A small, noninvasive bi-level positive pressure ventilation system (BiPAP System, Respironics Inc., Murrysville, PA) that permits use of a nasal (rather than facial) mask alone *in lieu* of tracheal intubation may be most useful in the ED.[136] Therefore, an overview of the use of the BiPAP System is given in the next section. The advantage of the BiPAP System is that it supplies air or O_2 at pressure and flow rates that are suitable for assisted *inhalation and expiration* by sensing the patient's spontaneous breathing efforts and automatically adjusting to compensate for variations in ventilatory requirements, even in the presence of airway leaks. *Importantly, this device is not intended to be a life support ventilator, because it is used only to temporarily augment spontaneous breathing.* Regardless of the system used, close attention to manufacturer guidelines is advised.

Procedure

Before initiation of this technique, the patient must be informed of the purpose of the nasal mask and cooperate.

It helps to discuss an alternative therapy should this technique not meet the patient's needs and to reassure the patient that the operator will stay with him or her until a comfort level with the mask and ventilator system is obtained. Baseline vital sign and oxygenation measurements are made.

The patient should be treated in a closely monitored setting where his or her vital signs and respiratory status are closely monitored.

Despite intervention with this system, emergent intubation and mechanical ventilation may become needed. Equipment for airway support (e.g., O_2 source, tubing, bag-valve mask, laryngoscope, suction equipment, and various airways) should be immediately available.

The BiPAP System components are assembled and connected to oxygen—generally at the same flow settings as the patient is currently receiving (generally at 10 to 15 L/min). The pressure tubing is attached to the airway pressure monitor and the pressure monitor is turned on; the main system is then turned on and a ventilation mode selected. Generally, the system will be used in the spontaneous ventilation mode (i.e., to support spontaneous ventilations) with an initial EPAP setting of 3 to 5 cm H_2O and an IPAP setting of 8 to 10 cm H_2O.

Ideally, a mask sizing gauge (Fig. 2-19) is used to choose a mask size that does not place direct pressure on the bridge of the nose, the lateral *ala nasi*, the inferior nasal septum, or the lip. The mask may be initially held in place by the operator as the patient adjusts to the ventilatory support. With the mask in place, the BiPAP System settings are modified to optimize patient ventilatory status (Fig. 2-20). As the patient becomes more comfortable, the mask is secured in place on the face using self-adhesive binding straps (Fig. 2-21). If time permits, the headgear straps may be loosely attached before placement and the mask slipped over the head as a unit; the straps are then tightened.

Figure 2-19 Use of template to size nasal mask for BiPAP System. *A*, The nasal mask sizing gauge is placed over the patient's nose. The size that comes close to, but does not touch, the nose in three locations is selected. *B*, The sites to avoid direct contact: (1) just above the junction of the nasal bone and cartilage; (2) on the sides of both nares; and (3) just below the lowest point of the nose, above the lip. *Remember to use the smallest size mask that will sufficiently cover the nasal area.* Too small a mask will produce skin discomfort or injury. Too large a mask will increase air leak. *(Courtesy of Respironics Inc., Murrysville, PA.)*

The patient is encouraged to breathe with the mouth closed. The facial mask fit should be adjusted for comfort and to minimize air leak, especially about the eyes. When the patient has accepted the mask and the clinical status has stabilized, the patient may be permitted to speak and even to eat small amounts.

Adjustments in the EPAP and IPAP settings are generally made in 2 cm H_2O increments. Near optimal settings can generally be attained within 10 minutes. Periodic blood gas measurements should be coupled with ongoing vital sign and pulse oximetry measurements. When available, a CO_2 device side-flow catheter can be placed under the nasal mask for monitoring exhaled CO_2 levels. Increases in IPAP settings generally increase tidal volume and decrease CO_2 levels, whereas

increases in EPAP generally increase functional residual capacity and increase O_2 levels. The concentration of inspired oxygen also can be modified by changing the O_2 flow rate. High levels of EPAP or IPAP can induce PEEP-related reductions in cardiac preload. Further, although the system can adjust for some air leak about the mask, higher pressures require a tighter mask fit and can increase patient discomfort.

If the patient's hypoxic drive is diminished, decreased spontaneous ventilatory effort may be noted. If this situation occurs, the BiPAP System should be changed to the "spontaneous/timed" mode, which permits spontaneous breaths but imposes a mandatory ventilation if an extended ventilatory pause is noted. When initiating this mode, the clinician generally sets the respiratory rate at 10 breaths/min. At this setting, when a breath does not occur within 6 seconds of the preceding breath, a mandatory breath is provided.

If the patient requires a brief period of hyperventilation to help coordinate ventilatory efforts, the BiPAP System can be

Figure 2-20 Control panel of BiPAP System. Note control setting for ventilation mode in lower left corner (see text for use of settings). For spontaneously breathing patients in respiratory distress, the "spontaneous" mode is generally selected and IPAP and EPAP settings selected. *(Courtesy of Respironics Inc., Murrysville, PA.)*

Figure 2-21 BiPAP System nasal mask in place on patient. *(Courtesy of Respironics Inc., Murrysville, PA.)*

set to the "timed" mode and a respiratory rate of 15 to 20 breaths/min can be initiated. In this mode, the %IPAP time must be set by the operator. A %IPAP of 30% produces an inspiratory-to-expiratory (I:E) ratio of 1:2.3, whereas a %IPAP of 40% produces an I:E ratio of 1:1.5.

Aerosolized medications can be delivered either through in-line "T-pieces" in the BiPAP System circuit or through standard mouthpiece units (see following section).

Complications

Complications from this therapy include facial irritation, abrasion, or even facial necrosis; conjunctivitis due to mask air leak; aspiration; and gastric distention. A wound care dressing on the bridge of the nose may reduce skin abrasion. [135] Nasogastric tubes have been used to relieve gastric distention, although a nasal mask system is less likely to produce gastric distention. Additionally, although the pressures used are generally low, all of the complications of positive pressure ventilation may be seen with this technique.

Conclusions

Positive pressure ventilation modalities offer the promise of averting the need for intubation and mechanical ventilation in certain groups of patients with acute respiratory failure. The procedure for instituting these therapies is relatively simple and may even have potential in the pre-hospital setting. Additionally, although best studied in adults, these therapies have been applied to pediatric patients, [137] [138] and pediatric masks are available commercially.

Section II - Respiratory Procedures

Chapter 3 - Basic Airway Management and Decision-Making

Diamond Vrocher
Laura R. Hopson

Although it is common knowledge that airway management is the first priority in the management of any seriously ill or injured patient, its importance is often overlooked. Failure to treat airway management as the top priority can lead to serious errors in patient care and often presages a cycle of patient deterioration and misguided therapeutic intervention. Even when its importance is fully recognized, airway management can be one of the most difficult components of a resuscitation. Because of the sheer variety of airway difficulties that are possible, even the most skilled resuscitator can find the task challenging. *Simply stated, it may be impossible to adequately manage an airway in an emergency situation in a timely enough fashion to prevent deterioration or assure a successful resuscitation.* Blood, loosened teeth, vomitus, swollen or distorted landmarks, immobility of the jaw or cervical spine, and variations in anatomy all may present formidable barriers to successful management. When airway obstruction occurs in conjunction with reflex clenching of the jaws and possible cervical spine injury, conventional airway management tools may be ineffective. Time pressures imposed by the need to avoid cerebral anoxia force difficult decisions such as whether the neck can be moved, whether paralyzing agents should be administered, or whether a surgical airway is needed. Tools must be immediately available, skills must be well-honed, and decision-making must be sharp if optimal emergency airway management is to occur. Massive neck and upper airway swelling from angiotensin-converting enzyme (ACE)-inhibitor angioedema can essentially prohibit a successful airway, even by surgical means.

Some solutions to the many obstacles faced in emergency airway management are presented in this and the following chapters. Minimally invasive approaches to airway establishment and emergency airway decision-making are described first in the current chapter with more advanced techniques covered in following chapters. Decision algorithms are presented to help assemble the pieces of the airway management puzzle into a logical framework.

DECISION-MAKING IN AIRWAY MANAGEMENT

The resuscitator must have many tools at hand to deal with the acutely compromised airway. It is important to be proficient in many different techniques and to tailor their use to the needs of the individual patient. Rescuers should practice potential scenarios before facing patients with a compromised airway in the clinical situation. Failure to do so may lead to unnecessarily aggressive management in some situations or to irreversible hypoxic injury as a result of unnecessary hesitation in others. Deciding on who requires intervention in the field, and who can be supported adequately enough until definitive hospital management can be obtained, is a formidable task for even the most skilled clinician.

Several parameters must be assessed quickly before an airway management choice can be made. The parameters to be considered are as follows:

1. Adequacy of current ventilation
2. Potential for hypoxia
3. Airway patency
4. Need for neuromuscular blockade (muscle tone, teeth clenching, severe obstructive pulmonary disease, or asthma)
5. Cervical spine stability
6. Safety of technique and skill of the operator

Consideration of these factors should guide the clinician in selecting the optimal technique. This initial choice is often straightforward. Difficulty may arise precipitously when the initial choice fails. Time then becomes critical as the risk of irreversible hypoxic injury rises. Anxiety increases and error potential compounds under these circumstances. Forethought and practice are invaluable when making these decisions.

Schemata offered in Figure 3-1 and Figure 3-2 outline a logical approach to airway management. Figure 3-1 presents the nonsurgical approaches with end points of either success or the decision to pursue surgical management. Note that a prolonged duration of hypoxia may hasten a decision in favor of surgical airway management. Figure 3-2 addresses choices once the decision has been made to manage the airway surgically. Consideration of patient condition, security of the airway approach, and the invasive nature of the procedure are factors to be weighed in the final decision.

ESTABLISHMENT OF AIRWAY PATENCY

The first concern in the management of a patient in critical condition is adequacy of the airway. Partial or complete airway obstruction must be overcome quickly. In some cases, such as an airway obstructed by a tongue, simple maneuvers will suffice. In other cases, particularly those in which multiple agents are combining to block the airway, the task will be formidable. The tongue, dentures, swollen or distorted tissues, blood, and vomitus are common obstructing agents that compromise airway patency. Clearing obstructing agents may be made more difficult by muscular activity due to reflex stimulation or patient efforts to improve oxygenation. Moreover, the neck motion required for suction and intubation must be carefully managed in the setting of potential cervical spine instability.

The wide availability of pulse oximetry monitors has greatly improved our ability to monitor oxygenation for patients at risk of airway or ventilatory compromise. [1] These monitors are accurate under most conditions, [2] and clinically subtle deterioration can be quickly recognized using the monitors. They are standard equipment in emergency departments (EDs), intensive care units, and operating rooms. Pulse oximetry is discussed in more detail in Chapter 2 .

Airway Maneuvers

Partial or complete airway obstruction resulting from *lax musculature* and *tongue occlusion* of the posterior pharynx may be overcome by a variety of maneuvers, including the neck-lift and head-tilt method, the jaw-thrust method, and the chin-lift method. In a study of 120 anesthetized patients whose airways

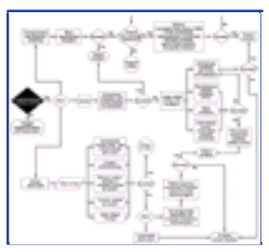

Figure 3-1 Nonsurgical airway management algorithm.

were obstructed by their tongues, Guildner concluded that the chin lift was the easiest to perform and produced the greatest airway patency of the three methods tested. [3] The chin-lift method has been shown conclusively to increase the airway diameter in pediatric patients. [4] Both the chin-lift and jaw-thrust methods have the additional advantage that neck extension is unnecessary (Fig. 3-3 , Table 3-1 and Table 3-2).[3]

Partial airway obstruction in the patient with a decreased level of consciousness is commonly due to posterior displacement of the tongue. This may be recognized readily in the presence of snoring or stridor, but an apneic patient or one who is moving minimal air may not exhibit any audible evidence of airway obstruction. Either a jaw-thrust or chin-lift maneuver should be performed on every unconscious patient. When uncertain about cervical spine status, the neck must be maintained in the neutral position. If the patient was found with a flexed or extended neck, the neck should first be restored to neutral position with gentle longitudinal traction. The chin-lift or jaw-thrust method is then performed. These maneuvers usually clear airways obstructed as a result of lax pharyngeal musculature or posterior displacement of the tongue. The neck-lift and head-tilt maneuvers described in cardiac life support courses should not be used when cervical spine injury is suspected, because the extension of the spine produced during the maneuver endangers the spinal cord.

Partial or complete airway obstruction can be the result of upper airway hemorrhage, accumulation of the patient's own secretions, foreign body aspiration, vomitus, or fractured dentition. If foreign body aspiration is suspected, the rescuer should perform a subdiaphragmatic abdominal thrust (Heimlich maneuver). [4] When stability of the spine is a concern, application of the subdiaphragmatic thrust should be limited to the supine method described for unconscious victims. Potential risks of a subdiaphragmatic thrust include stomach rupture, esophageal perforation, and mesenteric laceration, compelling the rescuer to weigh the benefits of its application. [5] [6] [7] [8] [9] [10]

Figure 3-2 Surgical airway management algorithm.

The Chin-Lift Maneuver

To perform the chin-lift maneuver, the rescuer places the tips of the fingers, volar surface superiorly, beneath the patient's chin. The jaw is lifted gently forward. The patient's mouth is opened by drawing down on the lower lip with the thumb of the same hand. [3] Mouth-to-mouth resuscitation or other means of positive-pressure ventilation is provided if the patient is not ventilating spontaneously.

The Jaw-Thrust Maneuver

The jaw-thrust maneuver is the second choice, again because neck extension is not necessary. Forward traction on the mandible is achieved by using two hands to grasp the mandibular rami and pull them forward.

The Subdiaphragmatic Abdominal Thrust

The subdiaphragmatic thrust is a method to relieve a completely obstructed airway. The technique was popularized by Dr. Henry Heimlich and is commonly referred to as the *Heimlich maneuver*.[11] The technique is most effective when a solid food bolus obstructs the larynx. Although a subject of controversy, a role for the maneuver has not been found for the resuscitation of near-drowning victims. [12]

The conscious patient with an obstructed airway exhibits increased respiratory effort, anxiety, aphonia, and, occasionally, cyanosis. In the conscious patient, the maneuver is performed with the rescuer positioned behind the upright patient. The rescuer's arms are circled about the patient's midsection with the radial side of the clenched fist placed in the epigastrium of the patient. Care is exercised to position the fist midway between the umbilicus and the xiphoid of the patient. After proper positioning, the rescuer grasps the fist with the opposite hand and delivers an inward and upward thrust to the abdomen. A successful maneuver will cause the obstructing agent to be expelled from the patient's airway by the force of air exiting the lungs. [13]

An unconscious, supine patient must be handled differently: The rescuer kneels next to the patient's pelvis facing cephalad. The palmar bases of the hands are

placed in an

Figure 3-3 Illustration of maneuvers for opening the airway. *A,* Neck lift. *B,* Chin lift. *C,* Jaw thrust. *(From Guildner CW: Resuscitation—opening the airway: A comparative study of techniques for opening an airway obstructed by the tongue. JACEP 5:588, 1976. Reproduced by permission.)*

overlapping fashion on the epigastrium at the same spot as that used in the upright patient. Inward, upward thrusts are delivered in this fashion with the same objective. [13]

Abdominal thrusts are relatively contraindicated in pregnant patients and others with protuberant abdomens. A chest compression identical to chest compressions delivered during cardiopulmonary resuscitation (CPR) may be used instead. Chest compressions may create greater peak airway pressures than a Heimlich maneuver, although this is controversial.[14] A combined (simultaneous) chest compression and subdiaphragmatic abdominal thrust may produce even higher peak airway pressures. Hence, a combined maneuver should be considered in the case of total airway obstruction that is unresponsive to simple Heimlich maneuver. [15]

Visceral injury can occur with the Heimlich maneuver.[5] [6] [7] [8] [9] [10] Excessive force or improper technique may be responsible in such cases. Nonetheless, the technique can be life-saving

TABLE 3-1 -- Subjective Evaluation of Effectiveness of Techniques on Patients Not Making Any Respiratory Effort (n = 120)

and should be used when needed. Attention to proper execution may limit complications.

Positioning

Positioning the patient who has sustained multiple trauma can be a problem. Spinal injury and airway access priorities dictate that the patient should be kept in the supine position while immobilized on a backboard. Turning the patient on the side allows upper airway hemorrhage, secretions, and vomitus to drain externally rather than to collect in the patient's mouth, which can lead to aspiration and airway obstruction. However, there is evidence suggesting that rotating the patient to the lateral decubitus position may not prevent aspiration. [16]

Guidelines for patient positioning must take into account the status of the patient's spine and the use of gravity to enable secretions to drain rather than accumulate in the airway. The following is a judicious approach to airway management in a patient *with spontaneous respiration*:

1. Initial airway maintenance accomplished by the chin-lift maneuver and the application of cervical stabilization (see Chapter 47).
2. Immobilization of the patient on a spinal backboard.
3. With the position of the neck controlled, transportation of the patient on the side to facilitate airway drainage.

Suctioning

Patient positioning and airway opening and clearing maneuvers are often inadequate to achieve the degree of airway

TABLE 3-2 -- Effectiveness of Techniques for Opening Airway in Patients with Complete Respiratory Obstruction Who Are Making Spontaneous Respiratory Effort (n = 30)

	Neck Lift		Chin Lift		Jaw Thrust

patency desired. Ongoing hemorrhage, vomitus, and particulate debris often require suction to clear and maintain the respiratory passage. Three basic types of suctioning tips are available (Fig. 3-4). Each is suited to different types of airway obstruction problems.

Dental tip suction is most useful for clearing particulate debris from the upper airway. Vomitus is most readily cleared with this tip because it is least likely to become obstructed itself by particulate matter. The *tonsil tip (Yankauer)* suction device is used most effectively to clear upper airway hemorrhage and secretions. Its design is

intended to prevent the obstruction of its tip by tissue and clot. The rounded tip is also less traumatic to soft tissues. The catheter tip works well for suctioning the trachea and bronchi through a tracheal tube, but it is inferior to the other tips for suctioning the oropharynx.

The dental tip device should be used during the resuscitation period and should be ready at the bedside. The dental tip allows rapid clearing of both particulate matter and hemorrhage, thereby expediting airway control. A limiting feature of many suction catheters is the diameter of the tubing. Large particulate emesis may obstruct the standard ¼-inch diameter catheter.[17] A ?-inch diameter suction catheter (Conmed Corp) has been shown to significantly decrease suction time of viscous and particulate material, potentially decreasing the risk of aspiration. [18]

Stabilization of the patient with multiple injuries may involve use of all three types of suction tips. The tonsil or dental tip should be attached to the suction source during the interval between patient evaluations because it is most likely to be the one needed on short notice. All suction apparatus must be immediately available, and everyone participating in a resuscitation should be familiar with the suction equipment and *know how to turn it on* during an emergency. In the resuscitation rooms, suction equipment should always be connected and ready to operate. Interposition of a suction trap at the base of the dental tip suction device prevents clogging of

Figure 3-4 Three types of suction tips: dental, tonsil, and catheter. *(From Clinton JE, Ruiz E: Trauma Life Support Manual. Minneapolis, MN, Hennepin County Medical Center, 1982.)*

the tubing with particulate debris. A trap that fits directly onto a tracheal tube has been described; use of this device still allows effective suctioning during intubation (Fig. 3-5).[19]

No specific contraindications to airway suctioning exist. Complications of suctioning may be avoided by anticipating problems and providing appropriate care before and during suctioning maneuvers. Nasal suction is seldom required to improve oxygenation (except in infants), because most adult airway obstruction occurs in the mouth and oropharynx. Vigorous nasal suction can induce epistaxis and further complicate an already difficult airway. Epistaxis may be avoided by limiting the force applied during suctioning. Vasoconstrictor drops or spray constrict the nasal mucosa and may reduce the injury potential in patients who require repeated nasopharyngeal suctioning.

Prolonged suctioning should be avoided because it may lead to significant hypoxia, especially in children. *Suctioning should not exceed 15-second intervals*, and the provision of supplemental oxygen before and after suctioning should be routine (see also Chapter 7). Naigow and Powasner found that suctioning consistently induced hypoxia in dogs and that it was best avoided by hyperventilation with high-concentration oxygen before and after suctioning. [20]

Figure 3-5 The Ruben suction booster, which is designed to allow high-capacity suctioning through the endotracheal tube during intubation. Schematic diagram: *A,* Tracheal tube connection. *B,* Connection to suction. *C,* Introducer opening in the closed position. *D,* Opening that is kept closed when suction is needed through the tracheal tube. Note: All suction should be done under direct vision. *(From Ruben H, Hansen E, MacNaughton FI: High-capacity suction technique. Anaesthesia 34:349, 1979. Reproduced by permission.)*

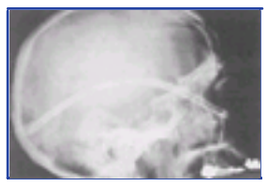

Figure 3-6 Intracranial intubation. Lateral skull x-ray showing nasogastric tube placed into brain through skull fracture. *(From Clinton JE, Ruiz E: Trauma Life Support Manual. Minneapolis, MN, Hennepin County Medical Center, 1982.)*

Extreme care should be exercised when a basilar skull or facial fracture is suspected, because communication between nasal and intracranial cavities may exist and allow the inadvertent placement of nasal suction tubes in the cranial cavity (Fig. 3-6).

Generally, it is best to perform suctioning *under direct visual inspection* or with the aid of the laryngoscope. Forcing a suction tip blindly into the posterior pharynx can injure tissue or convert a partial obstruction to a complete obstruction.

Artificial Airways

Indications and Contraindications

Once the airway has been opened through various maneuvers and suctioning, the patient may require further temporary support to maintain airway patency. The semiconscious patient who is breathing with an adequate rate and tidal volume at the time of the chin-lift maneuver may develop hypoxia because of recurrent obstruction if the maneuver is discontinued. Oxygen supplementation and an artificial airway may be all the support that is necessary. The use of an artificial airway also allows more efficient use of rescuer skills and relief from fatigue that is caused by the continuous application of chin-lift or jaw-thrust maneuvers.

Positive-pressure ventilation with a bag-valve-mask (BVM) device may be necessary to bolster the patient's inadequate ventilatory effort or to provide total ventilation in cases of apnea. By maintaining airway patency, artificial airways may facilitate both spontaneous and bag-mask ventilation.

Airway Placement Technique

The simplest artificial airways are the oropharyngeal and nasopharyngeal airways (Fig. 3-7). Both are intended to prevent the tongue from obstructing the airway by falling back against the posterior pharyngeal wall. The oral airway also may prevent teeth clenching. The oropharyngeal airway may be inserted by either of two procedures. One approach is to insert the airway in an inverted position along the patient's hard palate. When it is well into the patient's mouth, the airway is rotated 180 degrees and advanced to its final position along the patient's tongue, with the distal end of the airway lying in the hypopharynx. A second approach involves performance of a jaw-thrust maneuver, either manually or with a tongue blade, and the simple advancement of the airway into the mouth to its final position. No rotation is performed when the airway is placed in this manner. Once inserted, the oral airway may have to be taped in place to prevent expulsion by the patient's tongue. The oropharyngeal airway will keep the mouth partially open and prevent clenching of the teeth, which can obstruct an orogastric or orotracheal tube.

The nasopharyngeal airway is likely an overlooked technique to assure a patent airway in an otherwise stable patient. The soft tube is placed by gently advancing the airway into a nostril, directing the tip along the floor of the nose toward the nasopharynx. When in final position, the flared external end of the airway should rest at the nasal orifice. Either of these two airways provides airway patency similar to that in a correctly performed chin-lift maneuver, but the nasal airway may be better

tolerated by the semiconscious patient. Since the nasal tube is about the same size as an endotracheal tube, some clinicians place the nasopharyngeal airway to gently dilate the nasal passages before attempting blind nasotrachael intubation, but this technique is neither standardized nor well studied (Fig. 3-8).

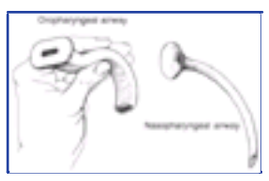

Figure 3-7 Simple artificial airways: oropharyngeal and nasopharyngeal. *(From Clinton JE, Ruiz E: Trauma Life Support Manual. Minneapolis, MN, Hennepin County Medical Center, 1982.)*

Figure 3-8 Some clinicians place a nasopharyngeal tube to dilate the nasal passage prior to blind nasotrachael intubation.

Complications

Few complications are encountered with the use of oral or nasal airways. The oropharyngeal airway may cause airway obstruction if during its placement the tongue is pushed against the posterior pharyngeal wall. Care in placement will prevent this. In the semiconscious patient with intact reflexes, the gag reflex may stimulate retching and emesis. If gagging is a persistent problem, the airway should be removed and a nasal airway or tracheal intubation should be considered. If the patient with airway compromise is comatose and lacks a gag reflex, the oropharyngeal airway *should not be used as a definitive airway*; tracheal intubation should be used instead.

The nasopharyngeal airway may offer an advantage over the oropharyngeal airway in that the nasopharyngeal airway is less likely to induce gagging. When placing a nasopharyngeal airway, care must be exercised not to induce epistaxis, and extreme caution is indicated in patients with a suspected basilar skull fracture or facial injury. All potentially unstable patients with oral or nasal pharyngeal airways should be observed constantly, because these devices are temporary measures and cannot substitute for tracheal intubation.

BAG-VALVE-MASK VENTILATION

Indications and Contraindications

Although the BVM method of ventilation appears to be simple and effective, it can be difficult to perform correctly. BVM ventilation should be used by experienced individuals who are able to ensure a tight mask seal in situations requiring positive-pressure ventilation. The BVM often is used with an oropharyngeal or nasopharyngeal airway in place.[13] Predictors of difficult BVM ventilation are shown in Table 3-3 .[21]

Inexperience is a relative contraindication to the use of a BVM. A rescuer who is not skilled with the BVM will achieve much better ventilation with mouth-to-mouth or mouth-to-mask breathing than with a BVM. Concern regarding transmission of infectious diseases has reduced the willingness of the lay public and health professionals to perform mouth-to-mouth ventilations.[22] However, only 12 cases of infectious

TABLE 3-3 -- Risk Factors for Difficult Mask Ventilation [21]

Presence of beard
Body mass index >26 kg/m^2
Lack of teeth
Age >55 yr
History of snoring

disease transmission from mouth-to-mouth or mouth-to-tube ventilation have been confirmed in the last 30 years, making CPR ventilation a relatively safe procedure (Table 3-4).[23]

Although BVM ventilation may provide excellent respiratory support in the anesthetized, paralyzed patient in the operating room, the device frequently is of marginal value during CPR, during an ambulance run, or in the combative patient. The three major problems encountered with BVM ventilation are inadequate tidal volumes, inadequate oxygen delivery, and gastric distention. A tight mask seal is mandatory to prevent loss of tidal volume and to ensure oxygen delivery during ventilation. Achieving a tight mask seal requires excellent procedural technique, and is much easier to achieve in the controlled setting with an anesthetized, paralyzed patient. Another hazard of BVM ventilation occurs when vomitus, blood, or other debris is present in the mouth or pharynx. The foreign material may be insufflated down the trachea if it is not cleared before ventilation.

Ventilation Technique

Achieving adequate tidal volume with BVM ventilation requires a tight mask seal and appropriate compression of the bag. The ideal tidal volume for BVM ventilation is 5 to 6 mL/kg, or approximately 500 mL for an adult.[24] A variety of mask configurations are available to facilitate a tight seal, but none substitutes for the practiced skill of the rescuer. For the single rescuer, only one hand can be used to achieve the seal because the other must squeeze the bag. The rescuer must apply pressure anteriorly while simultaneously lifting the jaw forward. The thumb and index finger provide anterior pressure while the fifth and fourth fingers lift the jaw. In pediatric patients the E-C clamp technique is used: The thumb and index finger form a "C" while providing anterior pressure over the mask, while the third, fourth, and fifth fingers form an "E" to lift the jaw (Fig. 3-9). *Dentures generally should be left in place to help ensure a better seal with the mask.*

It has been suggested that effective BVM ventilation during CPR requires two hands and, therefore, two rescuers. [25] We suggest using the two-rescuer technique (see Fig. 3-9*B*)

TABLE 3-4 -- Reported Infections (Since 1965) Acquired by Mouth-to-Mouth or Mouth-to-Tube Ventilation During CPR [23]

Organism	Cases
Mycobacterium tuberculosis	1
Neisseria meningitides	4
Shigella sonnei	1
Salmonella infantis	1
Helicobacter pylori	1
Herpes simplex virus	3
Neisseria gonorrhoeae	1

Figure 3-9 Bag-valve-mask ventilation is very difficult for one person to do *(A),* and it frequently fails to deliver adequate tidal volumes, especially during cardiopulmonary resuscitation. With the two-person method *(B),* one person uses both hands to hold the mask firmly against the face and extend the head. The other person uses both hands to squeeze the bag. Dentures are generally left in place to help provide a better-fitting mask. *(From Jesudian MC, Harrison RR, Keenan RL, Maull KI: Bag-valve-mask ventilation: Two rescuers are better than one. Crit Care Med 13:122, 1985.)*

whenever it is practical. The presence on the BVM device of a pop-off valve may further frustrate ventilation efforts in the patient with reduced compliance.

All BVM devices should be attached to a supplemental oxygen source (with a flow rate of 15 L/min) to avoid hypoxia. A significant problem with the BVM method is the low percentage of oxygen achieved with some reservoirs. The amount of delivered oxygen is dependent on the ventilatory rate, the volumes delivered during each breath, the oxygen flow rate into the ventilating bag, the filling time for reservoir bags, and the type of reservoir used. The commonly used corrugated tube reservoir is dependent on ventilatory technique and does not alert the rescuer to changes in oxygen flow. A 2.5-L bag reservoir and a demand valve are the preferred supplementation technique during BVM ventilation.[26]

Pediatric BVM devices should have a minimum volume of 450 mL. Pediatric and larger bags may be used for ventilation of infants with the proper mask size, but care should be taken to administer only the volume necessary to effectively ventilate the infant. Pop-off valves should be avoided because airway pressure under emergency conditions may often exceed the pressure of the valve.[13] BVM ventilation may be the preferred method of prehospital airway support in children under the age of 12 years. Although the final outcome of out-of-hospital pediatric resuscitation is generally poor, Gausche et al. [27] reported that neurologic outcome and ultimate

survival rates of prehospital pediatric resuscitations by Emergency Medical Service (EMS) providers with BVM ventilation were as good as with tracheal intubation.

Complications

Hypoventilation often occurs because of improper technique including poor sealing of the mask, failure to achieve airway patency, and delivery of insufficient tidal volume. Proper training is necessary to avoid these errors. Gastric distention can occur if air is insufflated down the esophagus, increasing the risk of regurgitation and aspiration. When assistance is available, the application of firm posterior pressure on the cricoid ring helps reduce gastric inflation during BVM ventilation. [28] [29] The technique must be used carefully in infants, whose airway is more pliable and subject to obstruction with excessive cricoid pressure. Even with proper BVM technique, aspiration can occur. The rescuer must be vigilant to recognize complications early and take corrective action. Under most situations, however, some gastric dilation will occur even with strict attention to detail. Minor gastric distention should not be considered substandard under the setting of prolonged BVM ventilation.

INTERMEDIATE AIRWAYS

Intermediate airways are those interventions that go beyond the maintenance of a patent airway. They represent a midpoint between airway establishment and true airway control by maneuvers such as tracheal intubation and tracheotomy. Many devices are available and no one technique is universally used. No agreed-upon standard of care has been promulgated for these devices, and their use varies by location and clinician experience. The devices described in this section allow ventilation across the larynx but do not involve complete airway control. These devices include the esophageal obturator airway (EOA), the esophageal gastric tube airway (EGTA), the laryngeal mask airway (LMA), and the esophageal-tracheal Combitube (ETC) airway (Sheridan Catheter Corp., Argyle, NY). Two are designed to occlude only the esophagus (EOA and EGTA), one (LMA) seals the larynx at the hypopharynx level, and one (ETC) offers the versatility of use whether placed into the esophagus or the trachea. There are several newer supraglottic ventilation devices, including the cuffed oropharyngeal airway (COPA), the airway management device (AMD), and the laryngeal tube (LT). Each is designed for use in the unconscious patient who requires positive-pressure ventilation. The esophageal cuff or seal built into these devices reduces gastric content aspiration. The EOA and EGTA have a relatively high complication rate and therefore are becoming less common as other ventilation devices are becoming available.

Esophageal Obturator Airway and Esophageal Gastric Tube Airway

The EOA and the EGTA maintain airway patency in ways similar to the oral and nasal airways, but they also protect the airway by occluding the esophagus to reduce gastric distention

and regurgitation. The face mask permits use of these airways as positive-pressure ventilating devices. Air insufflated through the airway traverses the upper airway before crossing the larynx and entering the trachea. Ventilation from the EOA exits the airway through numerous ports in its hypopharyngeal portion (Fig. 3-10*A* and *B*). Ventilation from the EGTA is identical to mask ventilation, with the addition of esophageal occlusion. A port is available on the EGTA to vent the stomach. The attractiveness of the EOA and the EGTA for use in the apneic patient stems from their retention of much of the simplicity of the artificial airway with the addition of an important feature of more complicated airways—some protection against regurgitation and reduction of gastric distention.

Indications and Contraindications

The EOA and EGTA are indicated when positive-pressure ventilation is needed but neither BVM ventilation nor tracheal intubation can be performed safely, effectively, and rapidly. The EOA can be placed more quickly than a tracheal tube, [30] [31] and there are fewer intubation failures with the EOA than the tracheal tube. [32] The EOA and EGTA cannot be used in the awake patient with an intact gag reflex, and they are not available in pediatric sizes. They are relatively contraindicated in the presence of active oropharyngeal bleeding, suspected esophageal injury, caustic ingestion, or a history of esophageal disease. As a precaution against pressure-related complications, it is recommended that these devices be left in place for no longer than 2 hours. It must be recognized that the EOA and the EGTA are *temporary* forms of airway control, most suitable for use in out-of-hospital settings.

Placement of EOA/EGTA

The head is in the neutral position during placement of the EOA and the EGTA. Neck motion is unnecessary. The rescuer

Figure 3-10 *A,* Esophageal obturator airway. Correct placement of the esophageal airway with the cuff inflated in the esophagus caudad to the bifurcation of the trachea. *(From Clinton JE, Ruiz E: Trauma Life Support Manual. Minneapolis, MN, Hennepin County Medical Center, 1982.) B,* Esophageal obturator airway. *(From Jacobs LM: The importance of airway management in trauma. J Natl Med Assoc 80:873, 1988.)*

grasps and pulls the jaw forward. At this point, the rescuer inserts the assembled airway with the mask attached. The obturator tip is directed into the patient's posterior pharynx with gentle, steady pressure. The obturator is advanced down the esophagus until the mask rests flush against the face of the patient. Figure 3-10*A* illustrates the correct position at placement. The cuff should lie in the esophagus just distal to the carina of the trachea. The rescuer postpones inflation of the balloon until proper position is confirmed. The patient is ventilated with a tight mask seal on the face, and the lungs are auscultated. For effective ventilation, the mask seal must be tight. Breath sounds should be audible bilaterally. Unilateral breath sounds or failure of auscultation should lead the rescuer to reassess the airway placement. Pneumothorax or hemothorax may explain unilateral sounds, as may inadvertent main stem bronchus intubation. Tracheal intubation will result in the absence of breath sounds. The possibility of bronchial or tracheal intubation requires removal and replacement of the airway. Once satisfactorily placed, the esophageal balloon is inflated with 20 to 25 mL of air.

Complications

The complications of the EOA and EGTA are well reported. Hypercarbia from inadequate ventilation occurs more commonly with EOA than tracheal intubation. [33] [34] Unrecognized tracheal intubation may occur in 2.9% to 5% of patients with up to a 100% mortality due to airway occlusion. [31] [35] Esophageal injury may also occur, ranging from small lacerations in 8.5% of patients [32] to esophageal rupture.[36] [37] [38]

Under ideal circumstances, tracheal intubation should be performed before removal of the EOA, because vomiting often occurs following deflation of the balloon and EOA removal. If the EOA cuff has been overinflated, it may partially occlude the trachea and make intubation difficult. In such

cases, the balloon is partially deflated to facilitate tracheal intubation.

The Laryngeal-Mask Airway

The LMA (Intavent International SA, Henley-on-Thames, England) functions intermediately between an oropharyngeal airway and an endotracheal tube. It was developed for use in the operating room as an alternative for endotracheal intubation, but it has also been recommended for use in difficult intubations and for rescue ventilation in emergency resuscitations. [39] [40] The LMA is considered a temporary adjunct until tracheal intubation can be established. [39] Since the introduction of the original LMA, several variations have become available. The original LMA, which is available in both reusable (LMA Classic) and disposable (LMA Unique) varieties, consists of a tube fitted with an oval mask, rimmed with an inflatable cuff (Fig. 3-11*A*). The mask is intended to reside

Figure 3-11 Laryngeal mask airway (LMA). *A*, inflated LMA outside of the body. *B*, LMA in place with cuff overlying larynx. *C*, LMA placement into the pharynx. *D*, LMA placement using the index finger as a guide. *(From Basket PJF, Brain AIJ: The use of the LMA. In Basket PJF, Brain AIJ (eds): Cardiopulmonary Resuscitation Handbook. London, Intavent Research, 1994.)*

in the hypopharynx rather than on the face. It is inserted digitally until its tip meets resistance in the upper esophageal sphincter. The cuff is then inflated, forming a seal around the glottic opening (see Fig. 3-11*B*). The result is a relatively secure airway. However, it cannot be considered to protect against gastric regurgitation. Leakage of the hypopharyngeal mask allows aspiration of emesis and gastric distention may occur with misplacement.

One variation, the Proseal LMA, has a parallel drainage tube attached to the airway tube that is designed to reduce gastric insufflation and allow gastric drainage by a nasogastric tube, potentially decreasing the risk of aspiration. [41] Another variation, the intubating LMA (LMA Fastrach) is designed to facilitate blind tracheal intubation while allowing continuous positive-pressure ventilation. [42] The LMA and the intubating LMA (ILMA) have become part of the standard airway armamentarium for many rescuers, both in the hospital and prehospital setting. [43] Although the standard LMA can

act as a conduit for tracheal intubation, there are several advantages to the ILMA. [44] Insertion of the ILMA is easier than the standard LMA when the head and neck must be maintained in the neutral position, [45] and the ILMA allows for passage of a larger tracheal tube (up to 8-0). [40] Thus far, the Proseal LMA's role in the setting of difficult intubation or rescue ventilation has not been studied, and it is mainly used in the operative environment.

Indications and Contraindications

The LMA is indicated for patients requiring an airway who cannot be endotracheally intubated or cannot be ventilated with a BVM. The most frequently cited example is a patient whose anatomy prevents visualization of the larynx. Contraindications include the inability to open the patient's mouth, vomiting, or the need for high pulmonary inflation pressures. [40]

Placement of LMA

After selecting the appropriate size (Table 3-5) [40] the LMA is checked for possible air leaks by inflating and deflating the cuff. If the patient has a gag reflex, deep oropharyngeal topical anesthesia or conscious sedation must be administered. Although the sniffing position is preferred for the standard LMA, placement is 95% successful when the neck and head are held in the neutral position, as would be necessary with cervical spine immobilization. [45] The posterior surface of the mask is lubricated and the mask is oriented so its opening faces the tongue. With the index finger of the dominant hand placed on the proximal aspect of the mask, the mask is inserted into the mouth, firmly against the hard palate (see Fig. 3-11*C*). The index finger (or thumb) may also be used as a guide during advancement (see Fig. 3-11*D*). With one smooth motion, the mask is advanced until resistance is encountered. With the tip of the mask thus seated in the upper esophageal sphincter, the cuff is inflated. The lungs are auscultated to confirm correct placement.

Preparation for ILMA placement is similar to LMA placement. The preferred patient position for ILMA is with the head and neck in a neutral position. [46] The posterior surface of the mask is lubricated, and the mask is oriented so the opening is facing the tongue. While holding the ILMA by the handle, slide the mask along the hard palate and then downward until resistance is felt at the base of the hypopharynx. The cuff is then inflated, and position is confirmed by auscultation of the lungs. [40]

After successful placement of the LMA, several methods are available to achieve subsequent endotracheal intubation. The

TABLE 3-5 -- Laryngeal-Mask Airway (LMA), Disposable LMA, and Intubating LMA Size Recommendation Based on Weight [40]

Weight	LMA	Disposable LMA	ILMA
<5 kg	1	—	—
5–10 kg	1.5	—	—
10–20 kg	2	—	—
20–30 kg	2.5	—	—
30–50 kg	3	3	3
50–70 kg	4	4	4
70–100 kg	5	5	5
>100 kg	6	—	—

Note that only the standard LMA is available for patients <30 kg.

first method is simply to pass an appropriately sized endotracheal tube down the lumen of the LMA, rotate the tube 90 degrees so that the tip easily passes through the fenestrations, and advance it through the larynx to the trachea (Fig. 3-12). Success rates vary widely from 0% to 93% depending on operator experience and technique. [47] [48] [49] The second method involves the use of a tracheal tube exchanger or gum elastic bougie passed blindly down the lumen of the LMA and into the trachea. The LMA is then removed and an endotracheal tube is passed over the tracheal tube exchanger. [50] [51] [52] The more flexible bougie may be preferable, as the tube exchanger has been shown to pass into the esophagus in up to 70% of attempts. [53] The third and most dependable method of intubation with an LMA in place is via a fiberoptic scope. A lubricated, appropriately sized endotracheal tube is mounted over a fiberoptic scope, and this combination is advanced through the lumen of the LMA out through the mask and through the larynx. The scope is then removed, but the LMA may be left in place with the cuff deflated. If the LMA must be removed after a tracheal tube has been successfully placed through it, pass a tracheal tube exchanger down the tube, remove the tracheal tube/LMA combination, and replace it with a tracheal tube. After any manipulation of the LMA or with any tracheal tube placement, ventilation of the lungs must be confirmed.

Blind tracheal intubation via an ILMA has a success rate of greater than 90%. [42] [54] [55] [56] [57] Either the silicone ETTs which accompany the ILMA or a standard ETT may be used for tracheal intubation. First, the tube should be thoroughly lubricated and then advanced into the ILMA. If the ETT advances past the 15 cm mark with minimal resistance, it likely is entering the trachea. It should then be advanced to appropriate depth and the cuff should be inflated. Resistance may be encountered at 15 cm due to inappropriate seating or size of the ILMA. If the ETT cannot be passed blindly after repositioning the ILMA, a fiberoptic scope may be passed to guide tracheal intubation. Confirmation of tube position should be

Figure 3-12 Blind passage of an endotracheal tube through the laryngeal mask airway. *(Courtesy of the Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

standard procedure. Following tracheal intubation, the ILMA may be removed by deflating the ILMA cuff and withdrawing the ILMA over the ETT. A flexible rod at least 20 cm long should be used to stabilize the ETT during ILMA removal. [58]

Complications

Although the LMA works well in most cases, this airway has several significant drawbacks. Aspiration is always a possibility, because the cuff does not provide a watertight seal. Laryngospasm can occur if adequate anesthesia is not achieved. A significant air leak around the cuff may occur when high airway pressures exist, leading to poor ventilation. Finally, while success rates in the operating room range from 94% to 98%, [59] success rates in difficult emergency airway management vary between 76% and 100% depending on the background and training of the clinician. [60] [61]

Conclusion

The LMA is a blindly placed intermediate airway that should be considered in patients who require establishment of an emergency airway but cannot receive endotracheal intubation. The technique is quick and simple, and requires a minimum amount of training. [61] [62] Perhaps the best feature of the LMA and ILMA is the ability to blindly transition from an intermediate airway to definitive airway control, providing an invaluable resource in the setting of the difficult intubation.

The Esophageal-Tracheal Combitube

The ETC is an intermediate airway device that can be placed blindly and rapidly. [63] It allows for effective ventilation and oxygenation when placed in either the esophagus or the trachea. The ETC is successfully placed in 72% to 95% of patients by prehospital providers. [64] [65] [66] The device has two lumina running parallel to each other. One is perforated at the level of the pharynx and occluded at the distal end, similar to the EOA. The second lumen is open at the distal end, resembling an endotracheal tube. The device has two balloons: a proximal pharyngeal balloon that occludes the oropharynx by filling the space between the base of the tongue and the soft palate and a smaller, distal cuff that serves as a seal in either the esophagus or trachea (Fig. 3-13).[67] [68] The Combitube has compared favorably with the endotracheal tube with respect to ventilation and oxygenation in cardiac arrest situations. [63] [69] While it may provide some degree of protection from aspiration, [70] complete airway control should not be assumed.

Indications and Contraindications

The ETC is superior to the EOA because no face mask seal is necessary and the risk of complications is lower. [67] The ETC should be used in an unresponsive person who requires an airway when tracheal intubation is not successful or practical. The ideal situation for ETC use is in the prehospital setting by a rescuer not skilled in tracheal intubation. The ETC should not be used in patients with an intact gag reflex and is not recommended in patients younger than 16 years or shorter than 5 feet tall. It is contraindicated in suspected caustic poisonings or proximal esophageal disorders.

Placement of ETC

The device is held in the dominant hand and gently advanced caudally into the pharynx while the nondominant hand grasps the tongue and jaw between the thumb and index finger. The tube is passed blindly along the tongue to a depth that

Figure 3-13 Esophageal-tracheal Combitube (ETC) airway. *(From Frass M, Frenzer R, Zdrahal F, et al: The esophageal tracheal Combitube: Preliminary results with a new airway for cardiopulmonary resuscitation. Ann Emerg Med 16:770, 1987.)*

positions the printed rings on the proximal end of the tube between the patient's teeth or alveolar ridge. [71] If resistance is met in the hypopharynx, the tube should be removed and bent between the balloons for several seconds to facilitate insertion. [71] After insertion, the pharyngeal balloon is filled with 100 mL of air, and the distal cuff is subsequently filled with 10 to 15 mL of air. The large pharyngeal balloon serves to securely seat the ETC in the oropharynx and to create a closed system in the case of esophageal placement. Because up to 91% of placements are esophageal, [66] ventilation is begun through the longer (blue plastic) connector associated with the esophageal lumen. Chest rise and good breath sounds without gastric insufflation confirm effective placement in the esophagus. However, gastric insufflation without breath sounds and chest rise indicate a tracheal positioning of the tube and require changing the ventilation to the shorter (clear plastic) tracheal lumen. Auscultation of breath sounds over the lateral lung fields confirms endotracheal placement of the Combitube. If the tube is in the esophageal position, gastric suctioning can be accomplished by passing a catheter through the open lumen into the stomach while the patient is being ventilated via the other port. [66]

An alternative method to identify position is to attach an aspirating device (see Chapter 4) to the tracheal or clear plastic shorter tube. The inability to easily aspirate air confirms esophageal placement, necessitating ventilation via the longer blue esophageal tube. In the patient with ventilatory effort, CO_2 detector devices also may be useful.

A patient who has been successfully resuscitated with an ETC positioned in the esophagus should ultimately receive a definitive airway. The steps required to place a tracheal tube in this setting are detailed in Chapter 4 but consist generally of deflating the large pharyngeal balloon and, with the distal balloon still inflated, intubating around the ETC.

Complications

Inappropriate balloon inflation and incorrect ETC placement can lead to air leaks during ventilation. The most common placement error is an improper insertion angle. A more caudal, longitudinal direction is recommended, as opposed to an anteroposterior direction of insertion. Another caveat is

that the ETC must be maintained in the true midline position during insertion to avoid blind pockets in the supraglottic area, which prevent passage of the tube. [66] Attention to the ring markings on the tube at the level of the incisors ensures proper positioning of the tube. One must remember to first inflate the oropharyngeal balloon before inflating the distal balloon. Although unlikely, esophageal injury is theoretically possible with overinflation of the distal balloon.

Cuffed Oropharyngeal Airway

The cuffed oropharyngeal airway (COPA) is a standard oropharyngeal airway with a cuff at the distal end and a standard 15 mm connector at the proximal end. [72] When inflated, the cuff is seated in the hypopharynx. When used with a BVM, the COPA allows for greater tidal volumes than either a standard oropharyngeal airway or a BVM alone.[73] The role of the COPA for resuscitation has not been fully defined. Rees has shown that basic life support providers can use the COPA effectively with minimal instruction. [74] [75] The COPA is indicated for the unresponsive patient who may need ventilation assistance when no other airway is available or practical. Relative contraindications include vomiting and an intact gag reflex.

The COPA is inserted in a similar fashion to a standard OP airway. With the cuff deflated, it is placed in an inverted fashion along the hard palate. It is then rotated 180 degrees while advancing toward the base of the tongue. The cuff is then inflated. The COPA may be secured with either tape or an accompanying strap.

Complications of the COPA include airway obstruction and minor trauma to the pharynx. [72] [73] The COPA should not be considered a definitive airway.

Laryngeal Tube and Airway Management Device

The laryngeal tube (LT) and airway management device (AMD) are separate intermediate airways with a similar design. Both are single-lumen tubes with oropharyngeal and esophageal cuffs and a ventilation port between the cuffs. [76] The AMD has the capability of gastric decompression by partially deflating the esophageal cuff, then passing a nasogastric tube through the lumen. Ventilation and gastric decompression cannot occur simultaneously. [77] The LT has a single port that inflates both cuffs.

The LT and AMD are currently under investigation to determine their clinical efficacy and practicality. Early studies show mixed results. Fifty clinicians and nurses were able to correctly place an LT and adequately ventilate a mannequin in 95% of attempts. [78] However, in an observational study of the AMD, experienced anesthesiologists were unable to establish an airway in 10/104 patients in whom an AMD was attempted. [77]

The LT and AMD have similar indications as the LMA and Combitude. They are indicated in the unresponsive patient who requires airway control but in whom tracheal intubation is difficult or impractical. They are contraindicated in awake patients, caustic ingestions, and in patients with known proximal esophageal disease.

The LT and AMD both are inserted blindly, and both can be inserted with the head and neck in a neutral position. The tube is advanced until the indicator marks are at teeth level, and the cuffs are inflated. The AMD oropharyngeal cuff should be inflated prior to the esophageal cuff. Placement should be confirmed by routine methods.

Complications of the AMD may include airway obstruction, glossal venous congestion, coughing, and minor oropharyngeal trauma. [77] [79] LT complications are predicted to be similar, but have not been described in the medical literature. Neither the AMD nor the LT should be considered a definitive airway, and aspiration is a potential complication. The AMD and LT should be left in place until the trachea is intubated.

SPECIAL CONSIDERATIONS

Cardiac Arrest

Mouth-to-mouth and BVM ventilation may suffice for out-of-hospital care with short transport times or for the initial few minutes of ventilation in cardiac arrest. However, optimal BVM ventilation during CPR is impossible. Mouth-to-mouth and BVM ventilation are adequate and effective in the anesthetized or paralyzed patient with an empty stomach in the absence of chest compression, but they are inadequate for prolonged ventilation in the patient in cardiac arrest. Proper BVM ventilation is probably harder to master than tracheal intubation, and prolonged attempts during CPR usually only distend the stomach and give the uninitiated a false sense of security. While BVM ventilation will suffice for the first few minutes of a resuscitation, patients in cardiac arrest should be orotracheally intubated when logistically feasible. No specific timeline or standard can be advanced because of the varying clinical circumstances surrounding cardiac arrest. If orotracheal intubation is impossible due to lack of skill or a difficult airway, an LMA or ETC may be placed until definitive airway control can be established. Most cardiopulmonary arrests are not associated with cervical spine injury. When there is suspicion of cervical injury, the following precautions should be followed.

Potential Cervical Spine Injury

Any patient who has sustained a significant injury has the potential for cervical spine injury. Approximately 1.5% to 3.0% of initial survivors of all types of major trauma seen in EDs have significant cervical spine injury. [80] It is interesting to note that this prevalence is not increased in the setting of significant head injury. [81] Also, gunshot wounds to the head that do not involve direct neck penetration are not considered high risk for concomitant cervical spine injury. [82] [83]

In patients with multiple injuries, the possibility of cervical spine injury warrants caution when considering tracheal intubation involving the use of the laryngoscope. If the patient needs tracheal intubation, an assistant should provide in-line manual stabilization of the neck while minimizing axial traction or lateral neck motion. When done cautiously, oral intubation of the unconscious spinal cord-injured patient may be as safe as other techniques, including intubation with fiberoptic guidance. [84] Multiple studies in patients with a cervical spine injury have not demonstrated neurologic deficits following orotracheal intubation. [85] [86] [87]

Note that mouth-to-mouth and BVM ventilation frequently require some degree of neck extension to open the airway. A cadaver study demonstrated increased neck motion with BVM ventilation when compared to various intubation

techniques, including oral intubation, lighted stylet-guided oral intubation, and nasotracheal intubation. [88] BVM techniques may, therefore, be less desirable than the other methods of ventilating the patient with a potential cervical spine injury. However, this may be the clinician's only immediate option.

Potential Epiglottitis/Supraglottitis

Epiglottitis is often considered a disease of children between the ages of 2 and 8 years, but it is being recognized in adults with increasing frequency. [89] [90] Currently epiglottitis is quite rare in children in the United States because of the use of immunizations against *Haemophilus influenzae*, the most common etiology. Adults are currently at greater risk for epiglottitis than are children in this country.

The classic scenario is that of an adult or child sitting upright, drooling, or spitting up oral secretions rather than swallowing. The voice may sound muffled. There is a history of a relatively abrupt onset of a sore throat that rapidly becomes more painful. Children commonly present with a high temperature, but adults usually are only mildly febrile. The disease is especially treacherous in children because of their small airways and their tendency to panic when an oral examination or insertion of an intravenous (IV) line is attempted. Small children are most calm when allowed to sit on a parent's lap. An oxygen mask with a flow rate of 10 L/min should be held by the parent several centimeters from the child's face. If the child is using accessory muscles to breathe, every attempt should be made to keep the child calm. If a lateral radiograph of the neck taken on inspiration can be obtained without disturbing the child, it will often establish the diagnosis. On radiography, the inflamed epiglottis often appears thickened and rounded. The hypopharynx is dilated above the obstruction.

In cases of respiratory compromise, an epiglottitis protocol should be implemented rapidly. The otolaryngologist, anesthesiologist, and respiratory therapist must be notified. A preestablished protocol can save many minutes of time otherwise spent trying to reach all of the personnel needed to manage this critical emergency. [91] When a child is suspected of having epiglottitis based on history and clinical presentation, the safest course of action to establish the airway should be pursued. The emergency clinician should accompany the child at all times and be prepared to intervene until the airway is secure. Otolaryngologist notification should be included in the protocol because a tracheostomy may be necessary. [91] [92] When operating room space or personnel are not available immediately, ED personnel must be prepared to manage the airway.

If the child lapses into a coma or stops making ventilatory efforts, the first step is to attempt to force oxygen past the obstruction by using mouth-to-mouth respiration or a BVM apparatus. Because the obstruction is edematous supraglottic tissue and epiglottis, positive-pressure ventilation often can displace the edema enough to allow adequate ventilation. Moving the patient to a prone position may cause the epiglottis to fall forward, causing decreased airway resistance and improved ability to ventilate the patient. [93] If this is unsuccessful, the emergency clinician should attempt oral intubation. However, a normal larynx will not be visible because of the edema. The operator should attempt to pass an endotracheal tube through the slit-like opening that remains for the supraglottic airway. An assistant can compress the chest to force bubbles through the airway, as a means of locating the airway. [94] The assistant can also palpate the larynx and the trachea to detect the tube's entry into the trachea. If orotracheal intubation fails, the intubator should go directly to transtracheal needle ventilation (TTNV) (see Chapter 6). The obstruction of epiglottitis is mainly inspiratory, so there should be no difficulty with chest hyperinflation with intermittent TTNV. This method should ease subsequent orotracheal intubation, because the path of the airway should be readily apparent as exhaled gases pass through it.

In general, cricothyrotomy and tracheostomy are not feasible in the emergency setting for small children with epiglottitis because of technical and procedural complexities. It is recommended that all children with acute epiglottitis receive tracheal intubation. [95] If the child is not in distress, an IV line can be established before intubation for appropriate drug administration, although some operators prefer to delay IV placement until after inhalation anesthesia.

Adults and cooperative older children with suspected epiglottitis can be examined directly. It is good practice to visualize the epiglottis and the vocal cords of the stable older patient with laryngeal tenderness who is complaining of a severe sore throat or difficulty swallowing. A mirror, fiberoptic scope, or a right-angle scope can be used to do this (see Chapter 65). In epiglottitis, the pharynx and tonsils usually do not appear inflamed, a finding that might otherwise explain the symptoms. Adults with epiglottitis do not always need to be intubated if rigorous monitoring can be accomplished, a skilled intubator is immediately available, and the patient is not in distress. [89] Orotracheal intubation for epiglottitis is not as difficult in adults as it is in small children. Transtracheal needle ventilation can also be used in adults who are difficult to intubate.

Jaw Clenching

Hypertonus induced by neurologic dysfunction is a common complicating factor of airway management, especially in the patient with multiple injuries, drug overdose, or seizures. Jaw clenching may be a lethal complication when it prevents clearing of blood, vomitus, or foreign bodies in the airway. No more difficult airway problem exists than occlusion of the nasal and oral passages by vomitus while the patient's teeth are tightly clenched. Respiratory efforts may lead to severe aspiration, and although the hypertonus gradually gives way as the brainstem becomes progressively hypoxic, the cerebrocortical hypoxic insult sustained in the process may be irreversible. Various disease states can lead to a similar scenario in which the jaws are clenched in the presence of upper airway hemorrhage or the accumulation of secretions.

Jaw clenching and cervical spine injury can, of course, occur together. At times, the blind nasotracheal route of intubation may be adequate for airway management while minimizing the risk of further spine injury. However, at least a small degree of spontaneous air movement should be present for the blind nasotracheal approach to be successful. Although a serendipitous success may occur in the apneic patient, it is recommended that time not be wasted on this approach in the completely apneic patient.

Neuromuscular blocking agents are generally an effective means to overcome jaw clenching in the breathing patient. Both neuromuscular depolarizing and nondepolarizing agents may be administered intravenously to induce paralysis and

allow orotracheal intubation. Neuromuscular blocking agents and their administration for intubation are discussed in Chapter 5 .

Apnea with Airway Obstruction

Despite the many nonsurgical approaches to tracheal intubation discussed in this chapter, the patient who is apneic secondary to deep airway obstruction may be served best by a surgical airway. When maneuvers to relieve airway obstruction are unsuccessful and direct laryngoscopy is not possible or cannot rapidly alleviate the obstruction and permit ventilation, the operator should rapidly move to a surgical airway approach (see Chapter 4).

CONCLUSION

Airway management is the most fundamental aspect of emergency care. Every rescuer must know basic airway maneuvers and be able to use them instinctively. When basic maneuvers fail, airway management rapidly becomes more complex. Familiarity with the ingenious intermediate airway devices can often reverse a deteriorating situation and provide the rescuer with a temporary solution to an airway dilemma. When basic and intermediate maneuvers fail, complexity, risk, and exigency mount. Choices become more critical and complications more likely. Advance consideration of situations represented in the airway management algorithms is a wise practice for the emergency clinician. It may hasten accurate decision-making when time becomes critical. In this chapter, we have described basic and intermediate airway techniques and offered a logical schema for their use in the patient with an acutely compromised airway. Subsequent chapters deal with the more advanced airway techniques of tracheal intubation and cricothyrotomy.

Chapter 4 - Tracheal Intubation

Michael Lutes
Laura R. Hopson

Although some patients simply cannot be successfully intubated in the emergency department (ED) by any clinician, most patients can be intubated. Therefore, tracheal intubation is generally considered the most definitive means of airway control. As discussed in Chapter 3 , the decision to tracheally intubate must consider the patient's physiologic status, anticipated patient care needs, clinician experience, and features related to preparation for the procedure. This chapter discusses the indications for tracheal intubation in greater detail as well as the preparation for intubation and the key steps and modifications of the actual procedure. Chapter 5 discusses the pharmacologic adjuncts (including pharmacologic paralyzing agents) for facilitating tracheal intubation and their administration. Chapter 5 discusses more invasive means of establishing an airway and ventilating the patient. The general decision-making that is relevant to these techniques has been presented in Chapter 3 and should be reviewed before proceeding with this chapter.

GENERAL PREPARATION

Preparation is the key to successful airway management. Two general areas of preparation should be addressed before undertaking the first attempt at definitive airway management in a clinical setting. The first is mental and physical preparedness. The second is the assembly of essential intubation equipment. Note that the following discussion describes the ideal situation. Often patients require intubation under less than ideal circumstances, and lack of formal or sequential training should not deter attempts at intubation when the patient is in extremis. The best way to learn intubation is to perform the procedure in the emergency setting under supervision of an experienced clinician. As with any medical procedure, there is no classroom instruction or textbook that teaches all of the nuances of the procedure that are encountered in real life, or that can produce the milieu in the ED.

Mental and physical preparation comes from reading about the procedures, discussing the principles and details with instructors, practicing the techniques on intubation mannequins or in the animal laboratory, and finally performing the technique under supervision in a controlled clinical setting. Studies addressing various approaches to tracheal intubation are generally performed under optimal conditions (i.e., with equipment available and appropriate preparatory training). Also, often hidden within the study findings are individual learning curves. Therefore, it is overly optimistic to expect to match the success reported in the literature when first attempting a new intubation technique. However, the goal of preparation is to be as high on the learning curve as possible before the first clinical application of a new intubation technique. Further, continued rehearsal and application of the techniques that have been learned are important for skill maintenance.

Each approach to tracheal intubation has a preferred training format. Orotracheal intubation, for example, may be simulated with a mannequin, whereas retrograde intubation is best learned using an animal or cadaver model. Orotracheal intubation is likely to be successful on the first attempt, whereas considerable practice is required for facile use of the scope for fiberoptic intubation. In preparation for managing critical airway problems, maximal hands-on training is desirable.

The second general area of preparation is material preparedness (i.e., the immediate availability of all essential equipment required to optimally perform the airway maneuvers that are within the capabilities of the care provider). This may be accomplished by the wall-mounting of essential resuscitation equipment. [1] Alternatively, dedicated adult and pediatric airway carts or tackle boxes may be used for placement of the equipment in an open, organized, and labeled manner that can be regularly checked (Fig. 4-1).[2] Seldom used but potentially life-saving equipment should be clearly identified in an easily accessible location such as a dedicated difficult airway cart. The worst moment to realize that a vital piece of equipment is missing is when a patient's life depends on it. The importance of this concept cannot be overstated. Technical expertise cannot substitute for the lack of essential equipment.

In airway management, failure has ominous consequences. Mental, physical, and equipment preparation maximizes the chances of success.

AIRWAY ANATOMY

Requisite for a discussion of airway management procedures is a common understanding of airway anatomy and its terminology (Fig. 4-2*A* and *B*). The following terms are used frequently in this chapter:

Arytenoid cartilages
—the paired cartilages forming the posterior aspect of the laryngeal inlet.
Nasal Cavity
—from the external nares to the choana.
Nasopharynx
—from the end of the nasal cavity (choana) to the level of the soft palate.
Oropharynx
—soft palate to the upper border of the epiglottis.
Hypopharynx (laryngopharynx)
—epiglottis to the lower border of the cricoid cartilage.
Vallecula
—the space at the base of the tongue formed posteriorly by the epiglottis and anteriorly by the anterior pharyngeal wall.
Laryngeal inlet
—the opening to the larynx bounded anterosuperiorly by the epiglottis, laterally by the aryepiglottic folds, and posteriorly by the arytenoid cartilages.
Piriform fossae (recesses)
—the pockets on both sides of the laryngeal inlet separated from the larynx by the aryepiglottic folds.
Corniculate cartilage
—the posteromedial portion of the arytenoid cartilage.
Cuneiform cartilage
—the anterolateral prominence of the arytenoid cartilage.
Glottis
—the vocal apparatus, including the true and false cords and the glottic opening.
Glottic opening (rima glottidis)
—the opening into the trachea as seen from above through the vocal cords.

Figure 4-1 Adult airway cart. Equipment and materials are visible, labeled, and accessible. *(Concept and design by Dr. Ernest Ruiz, Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

OROTRACHEAL INTUBATION

Indications and Contraindications

Any clinical situation in which a definitive airway is necessary, and limited neck motion is permissible, is an indication for orotracheal intubation. Many of these situations, including cardiac arrest, airway compromise in infection and trauma, and airway obstruction are discussed in detail in Chapter 1 . Most orotracheal intubations are accomplished using a direct laryngoscope. An unstable cervical spine injury is a relative contraindication to direct laryngoscopy, but should not preclude definitive airway management when clinically indicated.

Equipment

Laryngoscope

Facility in the use of the direct laryngoscope is a prerequisite for orotracheal intubation. Various adult and pediatric blade sizes are available. There are two basic blade designs—curved (MacIntosh) and straight (Miller and Wisconsin). Slight variations in laryngoscopic technique follow from one's choice of blade design, which is often a matter of personal preference. The tip of the *straight blade* goes under the epiglottis and lifts it directly, whereas the *curved blade* fits into the vallecula and indirectly lifts the epiglottis via the hyoepiglottic ligament to expose the larynx. Special blades designed for the anterior larynx include the Siker and the Belscope (Avulunga Pty Ltd, New South Wales, Australia).

Each blade type has advantages and disadvantages. The straight blade is often a better choice in pediatric patients, in patients with an anterior larynx or a long floppy epiglottis, and in individuals whose larynx is fixed by scar tissue. It is less effective, however, in patients with prominent upper teeth, and it is more likely to break teeth. Use of the straight blade is also more often associated with laryngospasm due to its stimulation of the superior laryngeal nerve, which innervates the undersurface of the epiglottis. A straight blade may inadvertently be advanced into the esophagus and initially present one with unfamiliar anatomy until it is withdrawn. The blade has a light bulb at the tip that may slightly hamper vision. The wider, curved blades are helpful in keeping the tongue retracted from the field of vision, allowing for more room in passing the tube in the oropharynx, and they are generally preferred in uncomplicated adult intubations. Aside from patient considerations, some clinicians prefer the curved blade because they find it requires less forearm strength than the straight blade.

Tracheal Tubes

The standard adult endotracheal (ET) tube measures approximately 30 cm in length. Tube size is typically printed prominently on the tube and is based on the *internal diameter* (ID), measured in millimeters. The range is from 2.0 to a 10.0 mm, increasing in increments of 0.5 mm. The outer tube diameter is 2 and 4 mm larger than the internal diameter.[3] Tubes are also imprinted with a scale in centimeters that indicates the distance from a tube's distal tip.

Adult men generally accept a 7.5 to 9.0 mm orotracheal tube, whereas women can usually be intubated with a 7.0 to 8.0 mm tube. In most circumstances, tubes smaller than these should not be used because airway resistance increases as tube size decreases. However, in emergency intubations, particularly if a difficult intubation is anticipated, many clinicians choose a smaller tube and change to a larger tube later. Although generally an acceptable practice, it should be avoided in the burn patient because swelling may prohibit subsequent tube placement. For nasal intubation, a slightly smaller tube than would be used for orotrachael intubation (by 0.5 to 1.0 mm) is chosen.

Correct tube size is especially important in the pediatric population (Table 4-1). Because most patients younger than

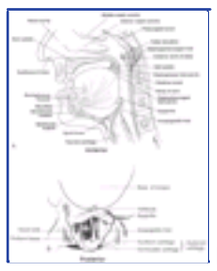

Figure 4-2 *A*, Lateral (sagittal) view of the upper airway. *(A from Snell RS, Smith MS (eds): Clinical Anatomy for Emergency Medicine. St Louis, Mosby-Year Book, 1993, p 16.) B*, View of larynx, epiglottis, and vocal cords as seen with laryngoscope (not shown) in place.

8 years are intubated with an uncuffed tube, adequate tube size is necessary to provide a good seal between the tube and the upper trachea. A cuffed tube is used in children with decreased lung compliance who may require prolonged mechanical ventilation. In a child, the smallest airway diameter is at the cricoid ring rather than at the vocal cords, as in adults. Hence, a tube may pass the cords but go no farther. Should this occur, the next smaller sized tube should be passed.

In infants and children, the following formula is a highly accurate method for determining correct tracheal tube size:

Tube size = [4 + age (years)]/4

For most clinical situations, however, using the width of the nail of the little (5 th) finger as a guide is sufficiently accurate and has been shown to be more precise than finger diameter (Fig. 4-3).[4]

A standard tracheal tube uses a high-volume, low-pressure cuff to avoid pressure necrosis of the tracheal lining. A clinical test for determining correct cuff inflation is to slowly inject air until no air leak is audible while the patient is receiving bag-tube ventilation. This usually occurs with 5 to 8 mL of air if the proper-sized tracheal tube has been selected. Many clinicians use the tension of the pilot balloon as a guide to cuff inflation; slight compressibility with gentle external pressure indicates adequate inflation for most clinical situations. For long-term use, cuff pressure should be measured and maintained at 20 to 25 mm Hg. Capillary blood flow is compromised in the tracheal mucosa when the cuff pressure exceeds 30 mm Hg. In emergency situations, the balloon may simply be inflated with 10 mL of air and adjusted when the patient's condition has stabilized.

Adult ET tubes will accept a standard adaptor on which the ventilator tubing will fit. Pediatric tubes require a special adaptor with a distal end small enough to accommodate the small tube sizes.

Preparing for Intubation

Before intubating, the following steps should be taken in chronologic order: (1) confirm that the required intubation equipment is available and functioning; (2) position the patient correctly; (3) assess the patient for difficult airway; (4) establish intravenous (IV) access, time permitting; (5) draw up essential drugs; and (6) attach the necessary monitoring

TABLE 4-1 -- Tracheal Tube Sizes for Average Patients*

Age	Size (Fr)	Internal Diameter (mm)	Equivalent Tracheotomy Tube Size
Premature			
Newborn	12	2.5	00
6 mo	16	3.5	00–0
1 yr	20	4.5	0–1
2 yr	22	5.0	1–2
4 yr	24	5.5	2
6 yr	26	6.0	3
8 yr	28	6.5	4
10 yr	30	7.0	4
12 yr	32	7.5	4
14 yr	34	8.0	5

Male	36–40	7.5–9.0	6
Special cases			8–10

Modified from Applebaum EL, Bruce DL: Tracheal Intubation. Philadelphia, WB Saunders, 1976.

*A slightly smaller size may be required for nasotracheal intubation.

devices. In the haste of the moment, it is a common error to fail to position the patient properly or to proceed with the procedure before the proper equipment is assembled and checked. Simple omissions, such as failing to restrain the patient's hands, removing dentures, or misplacing the suction device, can seriously hamper the performance of the procedure. One suggested preintubation checklist is presented in Table 4-2 .

In addition to the preparation necessary for optimum patient care, the clinician should also minimize exposure to potentially infectious materials (see Chapter 71). Generally, the clinician should wear gloves and eye/mouth protection to guard against exposure to patient secretions.

The ET tube cuff should be checked for leaks by inflating the balloon before attempting intubation. The tube is prepared for placement by passing a flexible stylet down the tube to increase its stiffness and enhance control of the tip of the tube. *The stylet should not extend beyond the eyelet of the tube.* The tube is then bent in a gradual curve with a more

Figure 4-3 Pediatric endotracheal tube size estimation using fingernail width of the 5th finger.

TABLE 4-2 -- Suggested Preintubation Checklist

1. An assistant should be in the room watching the cardiac monitor, blood pressure, and O_2 saturation while observing the patient for signs of decompensation. The assistant should be instructed to inform the operator if more than 30 sec have elapsed without ventilation.
2. An IV infusion should be running properly. Oxygen should be administered to the patient.
3. Draw the necessary drugs (e.g., atropine, lidocaine, paralyzing agent, induction agent).
4. Attach the bag-valve-mask to an oxygen source (rate of 15 L/min).
5. If used, a stylet should be inserted properly into the tracheal tube.
6. Check the integrity of the balloon on the tracheal tube.
7. Have tape or commercial tube stabilizer available.
8. Check laryngoscope light source. Have a second light source, a selection of blades, and additional endotracheal tubes available.
9. Turn on the oral suction device and place the suction tip under the mattress to the left of the patient's head. Prepare the catheter suction for postintubation use.
10. Place the syringe to inflate the endotracheal tube balloon on the stretcher to the right of the patient's head. An option is to attach a syringe to the pilot balloon of the endotracheal tube.
11. If the patient is awake, restrain the hands.
12. Remove the patient's dentures (delay this action until immediately before intubation if patient is being bag-mask ventilated).
13. Check the cardiac monitor leads and the rhythm strip immediately before the intubation attempt.
14. Check for optimal head positioning: neck slightly flexed and head extended on the neck (conditions permitting). May be facilitated by placing a towel under the patient's occiput to raise it 10 cm.
15. Have an aspiration device for esophageal detection or an end-tidal CO_2 detector at the bedside.
16. Radiology department should be alerted for the postintubation chest radiograph.

acute angling in the distal one-third to more easily access the anterior larynx. The tip and cuff of the tube are lubricated with viscous lidocaine or a water-soluble gel.

The patient should be positioned to optimally align the oral, pharyngeal, and laryngeal axes (Fig. 4-4). The desired position was aptly described by Magill to make the patient appear to be "sniffing the morning air," with the head extended on the neck and the neck slightly flexed relative to the torso. A small towel under the occiput (to raise it 7 to 10 cm) may facilitate positioning in the adult, but not in the child. Positioning of the head and neck is a critical step; suboptimal head positioning may be a common reason for intubation failures.

The Difficult Airway

Most difficult intubations are predictable if the clinician has time to evaluate the patient before securing the airway. Unfortunately, most intubations in the emergency setting are not elective, nor do they lend themselves to careful evaluation for their degree of difficulty. Unlike the anesthesiologist who evaluates the airway and intubation nuances on the night before surgery, the emergency clinician must often proceed with an intubation that only turns out to be "difficult" when

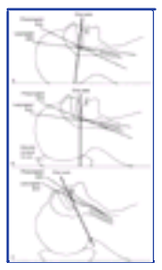

Figure 4-4 Head positioning for tracheal intubation. *A,* Neutral position. *B,* Head elevated. *C,* "Sniffing" position, with flexed neck and extended head. Note how flexing the neck and extending the head to line up the various axes allows for intubation. This position creates the shortest distance and straightest line between the teeth and vocal cords.

the patient cannot be readily intubated. Perhaps the most frequently encountered condition associated with a difficult intubation is the agitated or combative patient. Fortunately, this condition can often be readily eliminated through pharmacologic intervention (see Chapter 5). The classic parameters that predict a difficult intubation include a history of previous difficult intubation, prominent upper incisors, limited ability to extend at the atlanto-occipital joint, [5] poor visibility of pharyngeal structures when the patient extends the tongue (Mallampati classification, or the tongue/pharyngeal ratio) (Fig. 4-5*A*),[6] limited ability to open the mouth (suggested by a space less than three fingerbreadths between upper and lower incisors), [7] a limited direct laryngoscopic view of the laryngeal inlet, [7] and a short distance from the thyroid notch to the chin with the neck in extension (Fig. 4-5*B*). [8] In emergency airway management, many of these predictors are not obtainable. An extensive history is rarely available, the patients are frequently uncooperative, and the presence of trauma limits movement of the neck. Fortunately, some of the key predictors are apparent simply by observing the external appearance of the patient's head and neck.

Patients with neck tumors, thermal or chemical burns, traumatic injuries to the face and anterior neck, angioedema, infection of the pharyngeal and laryngeal soft tissues, or previous operations in or around the airway suggest a difficult intubation because distorted anatomy or secretions may compromise visualization of the vocal cords. Facial or skull fractures may further limit airway options by precluding nasotracheal intubation. Patients with ankylosing arthritis or developmental abnormalities, such as a hypoplastic mandible or the large tongue of Down syndrome, are difficult to intubate because neck rigidity and problems of tongue displacement can obscure visualization of the glottis.

Besides these obvious congenital and pathologic conditions, the short, thick neck poses the greatest difficulty for performing orotracheal intubation. Obese patients with a "short" neck are common and present some of the most difficult airways in the ED. In such individuals, the larynx is anatomically higher and more anterior, which makes it harder to visualize the vocal cords. These individuals are easily identified by observing the head and neck in profile. A mentum to hyoid distance less than three fingerbreadths also suggests a difficult airway. In such patients, apply laryngeal pressure and consider using the straight blade. Use of other options, including nasotracheal intubation, may be required. Facial hair can make forming a tight seal with the bag mask difficult and should alert the clinician that attempting to adequately ventilate the patient by that means may be difficult, if not impossible.

It should be emphasized that some patients, despite normal-appearing anatomy and the absence of a complicating history, are unexpectedly difficult to intubate. One must be prepared for this rare but inevitable occurrence.

Procedure

Adults

Direct laryngoscopy.

The clinician is stationed at the patient's head (Fig. 4-6). The patient is generally supine *with the head at the level of the clinician's lower sternum*. Attempting to intubate a patient on a low stretcher is a common error. To maintain the best mechanical advantage, the clinician keeps his or her back straight and does not hunch over the patient; any bending should occur in the knees. The left elbow is kept relatively close to the body and flexed to provide better support. In the severely dyspneic patient who cannot tolerate lying down, direct laryngoscopy can be performed with the patient seated semi-erect and the laryngoscopist on a step stool behind the patient. [9]

The laryngoscope is grasped in the left hand with the blade directed toward the patient from the hypothenar aspect of the clinician's hand. The patient's lower lip is drawn down with the right thumb, and the tip of the laryngoscope is introduced into the right side of the mouth. The blade is slid along the right side of the tongue, gradually displacing the tongue toward the left as the blade is moved to the center of the

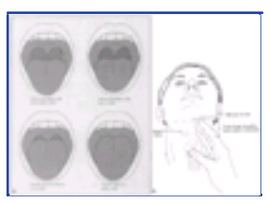

Figure 4-5 *A*, Mallampati classification predicting difficulty of intubation based on visibility of intraoral structures: Intubation should pose no difficulty in patient in class I or II, moderate difficulty in class III, and severe difficulty in class IV. *(A from Whitten CE: Preintubation evaluation: Predicting the difficult airway. Emerg Med 21:111, 1989.) B*, A difficult intubation also may be expected if the distance from the mentum of the chin to the hyoid bone in an adult is less than three fingerbreadths when the head is extended. Patients with a shortened distance often have a hypoplastic or poorly developed mandible or a short, thick neck, resulting in an anterior larynx that may be best approached with the straight blade and cricoid pressure.

mouth. If the blade is initially placed in the middle of the tongue, the tongue will fold over the lateral edge of the blade and obscure the airway. *Placing the blade in the middle of the tongue and failing to move the tongue to the left are two common errors preventing visualization of the vocal cords* (Fig. 4-7*A–C*).

As the blade tip approaches the base of the tongue, the clinician exerts force along the axis of the laryngoscope handle, lifting upward and forward at a 45° angle. The epiglottis should come into view with this maneuver. It may help to have an assistant retract the cheek laterally to further expose the laryngeal structures. Bending the wrist should be avoided because it can result in dental injury if the teeth become a fulcrum for the blade.

The step following visualization of the epiglottis depends on which laryngoscope blade is used. With the curved blade, the tip is placed into the vallecula, the space between the base of the tongue and the epiglottis. Continued anterior elevation of the base of the tongue and the epiglottis will expose the vocal cords. If the blade tip is inserted too deeply into the vallecula, the epiglottis may be pushed down to obscure the glottis. [6] When using the straight blade, the tip is inserted under and slightly beyond the epiglottis, directly lifting this structure. The jaw and larynx are literally suspended by the blade. If the straight blade is placed too deeply, the entire larynx may be elevated anteriorly and out of the field of vision. Gradual withdrawal of the blade should allow the laryngeal inlet to drop down into view. If the blade is deep and posterior, the lack of recognizable structures indicates esophageal passage; gradual withdrawal should permit the laryngeal inlet to come into view. The use of the curved and straight laryngoscope blades is illustrated in Figure 4-7*D* and *E* .

Proper neck positioning and pressure (cephalad, dorsally, and rightward) on the larynx by an assistant will facilitate visualization and intubation of an anterior larynx. The "BURP" (backward, upward, rightward pressure) maneuver consists of displacing the larynx as far posteriorly and superiorly as possible and slightly to the right. Use of this technique allows greater visualization than simple backward pressure or no pressure in patients with incompletely visualized airways on initial

inspection.[10] If the vocal cords are not visualized or are incompletely visualized, the clinician may wish to apply external laryngeal manipulation, also called bimanual laryngoscopy. To perform this maneuver, the laryngoscopist holds

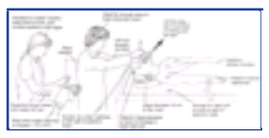

Figure 4-6 Proper positioning of clinician, patient, and assistant for tracheal intubation.

the laryngoscope in the standard fashion and places the right hand on the patient's thyroid cartilage to determine the best position of the larynx from the intubator's perspective. The thyroid cartilage is manipulated until optimal visualization of the vocal cords is obtained. An assistant then holds pressure in the same position and the clinician places the ET tube as described later. Levitan demonstrated in a videographic study that use of this technique by novice intubators improved percentage of glottic opening scores by an average of 57%.[11] This is demonstrated in Figure 4-8 .

If the vocal cords are still not seen, a tracheal tube introducer may be used (Smiths Industries Medical Systems, Keene, NH). This device, also known as the "elastic gum bougie," is a long, semirigid introducer that is placed, using the laryngoscope, through the laryngeal inlet and into the trachea. [12] The tracheal tube is then passed over the introducer and the introducer is withdrawn. If resistance is met in passing the tracheal tube, rotate the tube 90° counterclockwise and advance the tube. A study of 200 patients in the anesthesia literature reported a 96.5% success rate for gum bougie insertion within 2 attempts. The success rate for passing the ET tube over the bougie was 99% within 2 attempts.[13] A curved or "coude tip" bougie is best suited for aiding in difficult intubations. The curved tip provides tactile feedback as it passes along the tracheal rings. The straight tipped gum bougie should be reserved for changing of ET tubes. [14]

Tube passage.

Once the vocal cords have been visualized, the final step is tube passage under direct vision through the vocal cords and into the trachea. The tube is held in the clinician's right hand and introduced from the right side of the patient's mouth. The tube is advanced toward the patient's larynx at an angle, not parallel with or down the slot of the laryngoscope blade. This way, the clinician's view of the larynx is not obstructed by the hand or the tube until the last possible moment before the tube enters the larynx. If the patient is not chemically paralyzed, the tube should be passed during inspiration, when the vocal cords are maximally open. It enters the trachea when the cuff disappears through the vocal cords. The tube is advanced 3 to 4 cm beyond this point. It is not enough to see the tube and the cords; the tube must be seen passing through the vocal cords to ensure tracheal placement.

When the vocal cords are stimulated, laryngospasm—the persistent contraction of the adductor muscles of the vocal cords—may prevent passage of the tube. Inadequate anesthesia is often the cause. Pretreatment with topical lidocaine decreases the likelihood of this occurring. Lidocaine, 2% or 4%, can be sprayed directly on the cords. An infrequent but effective route for achieving tracheal anesthesia is via transtracheal puncture, injecting a bolus of 3 to 4 mL of lidocaine through the cricothyroid membrane. Laryngospasm is usually brief and often followed by a gasp. The clinician should be ready to pass the tube at this moment. Occasionally, the spasm is prolonged and needs to be broken with sustained anterior traction applied at the angles of the mandible—the jaw lift. At no time should the tube be forced because permanent damage to the vocal cords may result. Consideration should be given to using a smaller tube. Prolonged, intense spasm may ultimately require muscle relaxation with a paralyzing drug (see Chapter 5). The pediatric patient is far more prone to laryngospasm than an adult. [15] In a child, if vocal cord spasm prevents tube passage, a chest thrust maneuver may momentarily open the passage and permit intubation. [16]

Positioning and securing the tube.

The ET tube should be secured in a position that minimizes both the chance of inadvertent endobronchial intubation and the risk of extubation. The tip should lie in the midtrachea with room to accommodate neck movement. Because tube movement with both neck flexion and extension averages 2 cm, the desired range of tip location is between 3 and 7 cm above the carina. [17]

On a radiograph, the tip of the tube should ideally be 5 ± 2 cm above the carina when the head and neck are in a neutral position. On a portable radiograph, the adult carina overlies the fifth, sixth, or seventh thoracic vertebral body. If the carina is not visible, it can be assumed that the tip of the tube is properly positioned if it is aligned with the third or fourth thoracic

Figure 4-7 Common problems encountered with the laryngoscope: *A,* Laryngoscope blade under the middle of the tongue, with the sides of the tongue hanging down and obscuring the glottis. *B,* Tongue not pushed far enough to the left, obscuring the glottis. *C*, Correct blade position with tongue elevated and to the left. *D,* Use of the curved (MacIntosh) laryngoscope blade. *E,* Use of the straight (Miller) blade.

vertebra. In children, the carina is more cephalad than in the adult, but it is consistently situated between T3 and T5. In children, T1 is the reference point for the tip of the ET tube.[18]

An estimate of the proper depth of tube placement, before radiograph confirmation, can be derived from the following formulas, the lengths representing the distance from the tube tip to the upper incisors in children[19] [20] and from the upper incisors[21] or the corner of the mouth[22] in adults:

Children: Tracheal tube depth (cm) = age (years)/2 + 12
Adults: Tracheal tube depth (cm) = 21 cm (women)
Tracheal tube depth (cm) = 23 cm (men)

Figure 4-8 The epiglottis is elevated and visualization of the vocal cords is improved by pressure on the hypoepiglottic ligament and external laryngeal manipulation. *(Courtesy*

In adults, this method has been shown to be more reliable than auscultation in determining the correct depth of placement. [21]

The cuff is inflated to the point of minimal air leak with positive-pressure ventilation. In an emergency intubation, 10 mL of air is placed in the cuff, and inflation volume is adjusted after the patient's condition is stabilized.

After tracheal tube placement, both lungs are auscultated under positive-pressure ventilation. Care is taken to auscultate laterally because midline auscultation may lead to an erroneous impression of tracheal placement when the tube is actually in the esophagus. With the tube in position and the cuff inflated, the tube is secured in place. Commercial ET tube holders, adhesive tape, or umbilical (nonadhesive cloth) tape can be attached securely to the tube and around the patient's head (Fig. 4-9 and Fig. 4-10). The tube should be positioned in the corner of the mouth, where the tongue cannot expel it. This position is also more comfortable for the patient and allows for suctioning. A bite-block or oral airway to prevent ET tube crimping or damage from biting is commonly incorporated into the system used to secure the tube.

Unintentional extubation can have disastrous consequences, particularly if the patient was difficult to intubate initially. Care should be taken to secure the endotracheal tube immediately after placement has been confirmed. Orotracheal intubation is associated with a higher rate of unplanned extubation than is nasotracheal intubation. [23] During transport of the intubated patient, one person should be designated to tend to the ET tube to avoid accidental extubation. Inadequate sedation is another risk factor for accidental extubation. [23] The use of chemical or physical restraints may be necessary to prevent extubation in the agitated or confused patient.

Obstetric Patients

Pregnant patients present unique challenges in airway management, and knowledge of the changes that occur in the anatomy and physiology of the obstetric patient is important to ensure safe care of the mother and her unborn child. Functional residual capacity is significantly reduced in pregnancy due to the enlarged uterus, which displaces the abdominal organs and elevates the diaphragm. This decline in functional residual capacity is most pronounced in the supine position, [24] causing the rapid desaturation seen in the preintubation period. Adequate preoxygenation is therefore of great importance in the pregnant patient. Airway management can also be complicated by the development of hypotension in the supine position as a result of compression of the vena cava by the gravid uterus. This supine hypotension can be prevented by maintaining a pregnant patient at a minimum tilt of 15° to the left. In the trauma setting, this position can be maintained by placing a wedge-shaped foam pad or blankets under the long spine board.

Airway anatomy is also altered in pregnancy. Engorgement of oropharyngeal and nasal mucosa leads to easily provoked bleeding with manipulation. The generalized edema of pregnancy does not spare the structures of the airway and the clinician should be prepared to use smaller ET tubes (6.0 to 7.0). [25] [26] Advanced gestation has been shown to correlate with higher maternal Mallampati scores. [27] Equipment for dealing with difficult airways should be ready when ET intubation of the patient is anticipated. If emergency Caesarean sections are performed in the ED, contingent plans for the maintenance of anesthesia and the care of neonates should also be made.

Pregnant patients are at higher risk for aspiration during emergency airway procedures. The relaxed tone of the lower esophageal sphincter and delayed gastric emptying contribute to this risk. The principles of rapid sequence intubation with maintenance of cricoid pressure should be followed if at all possible when intubating the obstetric patient.

Infants and Children

Appreciation of the anatomic differences between children and adults is helpful when intubating the pediatric patient (Table 4-3 and Fig. 4-11). Infants' proportionately larger heads naturally places them in the "sniffing position," so a towel under the occiput is rarely necessary. The large head can even result in a posterior positioning of the larynx that prevents visualization of the vocal cords; a small towel under the child's shoulders should correct this problem. The head also may be floppy, and it can be stabilized by an assistant during intubation. The child's increased tongue-to-oropharynx ratio and shorter neck hinder forward displacement of the tongue and, coupled with a U-shaped epiglottis, can make visualization of the glottis difficult. Consequently, direct laryngoscopy in the infant and young child is generally best performed with a straight blade: Miller size 0 for premature infants, size 1 for normal-sized infants, and size 2 for older

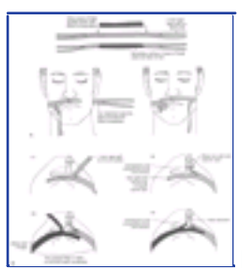

Figure 4-9 Two views (*A* and *B*) of technique for taping the tracheal tube. It is important to secure the tracheal tube properly. The method illustrated can be replaced by using a commercial holder or tracheostomy cloth tie. Avoid taping the lips.

children. The infant's larynx lies higher and relatively more anterior. One can have an assistant lightly apply laryngeal pressure, or the clinician can use the little finger of the hand holding the laryngoscope blade for this purpose (Fig. 4-12). If no laryngeal structures are visible after laryngeal pressure, the blade should be gradually withdrawn. Inadvertent advancement of the blade into the esophagus is a common error.

Confirmation of Tracheal Intubation

Clinical Assessment

The best assurance of tracheal placement is for the clinician to see the tube pass through the vocal cords (Table 4-4). Absent or diminished breath sounds, vocalization, increased abdominal size, and gurgling sounds during ventilation are clinical signs of esophageal placement. However, esophageal placement

Figure 4-10 This disposable endotracheal tube holder provides a firm anchor on which to tape the tube, while also serving as a bite block. *(Courtesy of Precision Medical, Northampton, PA.)*

is not always obvious. One may hear "normal" breath sounds if only the midline of the thorax is auscultated. The presence of condensation of the ET tube as a means of confirming tracheal placement may also be misleading. Blinded observers noted condensation of the ET tube during ventilation in 23 out of 27 esophageal intubations in an animal model. [28] One way to clinically assess tracheal placement after a ventilation or during spontaneous respiration is to note whether air is felt or heard to exit through the tube following cuff inflation. If the tidal volume is adequate, the exit of air should be obvious. It is important to note that when an appropriately sized tube is placed in the trachea, the patient cannot groan, moan, or speak. Any vocalization suggests esophageal placement.

Asymmetrical breath sounds indicate probable main stem bronchus intubation. Due to the angles of takeoff of the main bronchi and the fact that the carina lies to the left of the midline in adults, right main stem intubation is most common and is indicated by decreased breath sounds on the left side. When asymmetrical sounds are heard, the cuff should be deflated and the tube withdrawn until equal breath sounds are present. Bloch and colleagues report accurate pediatric tracheal positioning if after noting asymmetrical breath sounds, the tube is withdrawn a defined distance beyond the point at which equal breath sounds are first heard—2 cm in children younger than 5 years and 3 cm in older children. [29]

Esophageal Detector Device

An aspiration technique used to determine ET tube location was first described by Wee in 1988. [30] The technique takes advantage of the difference in tracheal and esophageal resistance to collapse during aspiration to locate the tip of the tracheal tube. Following intubation, a large syringe is attached to the end of the ET tube and the syringe plunger is withdrawn. If the tube is correctly placed in the trachea, the plunger will pull back without resistance as air is aspirated from the lungs. However, if the tracheal tube is in the esophagus, resistance is felt when the plunger is withdrawn, because the pliable walls of the esophagus collapse under the negative pressure and occlude the end of the tube. Another device using the same principle as syringe aspiration is the self-inflating bulb (e.g., Ellick device).

In the initial study conducted in the operating room setting, [30] the tube placement was correctly identified in 99 of 100 cases (51 esophageal, 48 tracheal). The result was considered equivocal in the remaining case. That tube was removed and found to be nearly totally occluded with purulent secretions. Slight resistance was noted in one patient with a right main stem intubation; resistance decreased when the tube was pulled back. Before use, the esophageal detector device must always be checked for air leaks. If any connections are loose, the leak may allow the syringe to be easily withdrawn, mimicking tracheal location of the tube.

A guideline to follow when using the aspiration technique is to apply constant, slow aspiration to avoid tube occlusion from tracheal mucosa drawn up under high negative pressure. If the tracheal tube is correctly placed, 30 to 40 mL of air can be aspirated without resistance. If air was initially aspirated and then some resistance is encountered, the tracheal tube should be pulled back between 0.5 and 1.0 cm and partially rotated. This takes the tube out of the bronchus, if it has been placed too deeply, and changes the orientation of the bevel if the tube has been temporarily occluded with tracheal mucosa. Air is easily aspirated if the tube was in the trachea, but repositioning will make no difference if the tube was in the esophagus. The syringe aspiration technique can be used before or after ventilation of the patient. Continuous cricoid pressure should be applied pending tube confirmation. Inflation of the tube cuff has no effect on the reliability of the test. [31] This device is reliable, rapid, inexpensive, and easy to use. [32] A squeeze-bulb aspirator can be used as an alternative to the syringe technique. [33] [34] The bulb is attached to the ET tube and squeezed; if the tube is in the esophagus, it is often accompanied by a flatus-like sound followed by absent or markedly delayed refilling. Insufflation of a tube in the trachea is silent, with instantaneous refill. An early study with the Ellick evacuator bulb device reported that 87% of esophageal intubations were identified. [33] A later study using a slightly different bulb device (Respironics, Murrysville, PA) found that all 45 esophageal intubations were detected. [34] The device is cheap, easy to use, and operable single-handedly in <5 seconds. [33] [34] The bulb should not be used in freezing temperatures due to a loss of elasticity.

Confusion may occur if the esophageal tube is tested more than once, because subsequent inflations may be silent. On repeated assessments, a false-positive refilling of the bulb may occur due to instillation of air during the first attempt. This observation has led to a recommendation that the bulb be compressed before it is attached to the ET tube. Delayed though complete refilling may occur with bronchial tube placement or in the more pliable pediatric airway. The bulb suction modification of the aspiration technique has not been studied as thoroughly as the syringe technique.

End-Tidal CO_2 Detector Devices

A high level of CO_2 in exhaled gas is the physiologic basis for capnography and the principle on which end-tidal CO_2 ($ETCO_2$) detectors were developed (see Chapter 2). The most commonly available devices for emergency use are colorimetric indicators, which correspond to CO_2 levels flowing through the device when placed on the tracheal tube adapter. The typical device displays opposite colors (e.g., yellow and purple) to indicate the low level of CO_2 in esophageal gas versus the higher level in gas exhaled from the respiratory tree. Handheld quantitative or semiquantitative electronic CO_2 monitors are also available.

TABLE 4-3 -- Comparison of the Airway in the Adult and Child

Comparison	Child	Adult	Clinical Consequences or Adjustments for Child
Head	Proportionately larger (up to about age 10 yr)	Proportionately smaller	Child naturally in sniffing position when supine. Do not place towel under occiput; may benefit from elevation of shoulders. Large head may be "floppy," requiring assistant to hold head still during intubation.
Teeth	Easily knocked out	Stable unless decay or trauma is a factor	Teeth may be knocked out and aspirated or forced into trachea.
Tonsils or adenoids	Large and friable	Generally not a problem	Nasotracheal intubation in child may cause excessive bleeding. Adenoid or tonsil tissue may plug endotracheal tube or cause airway obstruction from aspiration.
Tongue	Relatively larger	Relatively smaller	Difficult to displace the tongue anteriorly in child. Consider using straight blade.
Larynx	Opposite C2, C3	Opposite C4–C6	The more superiorly located larynx, the "anterior" larynx, is more difficult to visualize. Consider using straight blade.
Epiglottis	U-shaped, shorter, stiffer	Flatter, more flexible	Epiglottis more difficult to manipulate in child, may fold down and obstruct view with curved blade. Consider using straight blade.
Vocal cords	Concave upward. Anterior attachment of cords lower than posterior, creating a slant	Horizontal	Concave shape does not affect intubation, but it may affect ventilation. For partial airway obstruction or to break laryngospasm, consider positive pressure ventilation with jaw lift to open arytenoids. Anterior superior slant of the vocal cords may cause the endotracheal tube to hang up on anterior commissure as it passes into larynx. Rotate tube 90° counterclockwise. Overextension of the neck may cause partial airway obstruction due to airway collapse.
Length of trachea	Relatively shorter	Relatively longer	Short trachea increases likelihood of main stem bronchus intubation. Follow the formula for correct depth of placement (cm depth = 0.5 age (yr) + 12) measured from the corner of the mouth. Double black line on endotracheal tube should pass just beyond the cords.
Airway diameter	Relatively smaller; smallest diameter is at the cricoid ring	Relatively larger; smallest diameter is between vocal cords	Laryngoscope-induced trauma, edema, and foreign material will significantly alter airway diameter. Be gentle. Extremes of flexion or extension may kink airway. If trouble with bag-valve-mask ventilation, reassess the degree of head flexion or extension. Cricoid pressure may cause complete airway obstruction. Endotracheal tube may pass through cords but be too large to pass through cricoid ring. If unable to pass into trachea, use the next smaller tube.
Residual lung capacity	Relatively smaller	Relatively larger	Child may become hypoxic more quickly than adult. Closely monitor O_2 saturation and avoid prolonged periods without ventilation.

A multicenter study of a colorimetric device demonstrated an overall sensitivity of 80% and a specificity of 96%. [35] In patients with spontaneous circulation and the tracheal tube cuff inflated, the sensitivity and specificity rose to 100%. The poor sensitivity seen in cardiac arrest (69%) is due to the fact that low exhaled CO_2 levels are seen in both very-low-flow states and in esophageal intubation. The device must therefore be used with caution in the cardiac arrest victim. Levels of CO_2 return to normal after return of spontaneous circulation in these patients. Further, colorimetric changes may be difficult to discern in reduced lighting situations, and secretions can interfere with the color change. Regardless of the monitoring device, patients in cardiac arrest should be ventilated for a minimum of 6 breaths before taking a reading. Otherwise, recent ingestion of carbonated beverages can result in spuriously high CO_2 levels with esophageal intubation. [36] Colorimetric changes do not rule

out glottic positioning of the ET tube tip. Adequate ventilation and oxygenation may be achieved in the glottic position, but the risk of aspiration in the absence of a protected airway and the potential for further tube dislodgement remain. Glottic positioning may be difficult to detect clinically. The only signs may be persistent cuff leak or dimished chest rise with ventilation. Radiographic evidence or direct visualization confirms the diagnosis. [37]

Figure 4-11 Sagittal sections of the neck of an adult (*A*) and an infant shortly after birth (*B*). Different vertebral levels in these age groups are shown. Note that in children, the neck is shorter and the larynx is located more cephalad. *(From Snell RS, Smith MS (eds): Clinical Anatomy for Emergency Medicine. St Louis, Mosby-Year Book, 1993, p 16.)*

Comparison of Detector Devices

In the setting of spontaneous circulation, both syringe aspiration and $ETCO_2$ detection are highly reliable means of excluding esophageal intubation. An animal study comparing these techniques with clinical assessment and measuring the speed and accuracy of tube placement determination demonstrated that both the syringe esophageal detector device and $ETCO_2$ detection were highly accurate, approaching 100%. [38] The

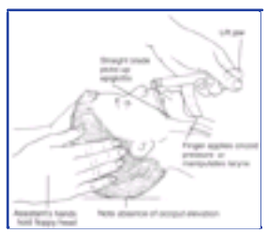

Figure 4-12 Oral intubation in a child, using a straight blade. The proportionately large, floppy head of the child may present some difficulty, and an assistant may be required to hold the child's head straight.

esophageal detector device was more rapid with determination in 13.8 seconds vs 31.5 seconds for $ETCO_2$ detection. The detector device remained accurate when air was insufflated into the esophagus for 1 minute, simulating unrecognized esophageal placement. Clinical assessment alone yielded an alarming 30% rate of failure to identify esophageal intubation. In the setting of cardiac arrest, the aspiration method is more reliable than CO_2 detection, because its accuracy is not dependent on the presence of blood flow.

The sonomatic confirmation of tracheal intubation (SCOTI) device is a battery-operated, handheld monitor designed to confirm ET tube location. It is a third-generation esophageal detection device and operates based on acoustic differences in air in the rigid trachea and collapsible esophagus. A trial of the device in both ED and surgical patients reported a sensitivity and specificity of 93% and 98% respectively. [39] However, experience with the device is necessary in order to appropriately interpret its readings. Also, the device must be calibrated before each use. The SCOTI device is not reliable in spontaneously breathing patients.

At present, there is no perfect device for the confirmation of ET tube placement in all situations. The clinician should be aware of the limitations of each device and ideally should rely on information from multiple sources of information to ensure correct placement of the ET tube.

Complications

Failure to achieve adequate ventilation and oxygenation is the most serious complication of tracheal intubation. The potential for hypoxia exists just before intubation as more conservative methods are attempted and fail, during a difficult intubation when ventilation is halted for intubation attempts, and after intubation when esophageal intubation goes

TABLE 4-4 -- Assessing Proper Tube Placement

Test	Interpretation
Observe tube pass through the vocal cords	Accurate way to ensure placement; if in doubt, look again after intubation
Auscultation of breath sounds over the chest	May be misleading, especially if only midline is examined; listen in both axillae
Auscultation over the stomach	Gurgling indicates esophageal placement
Condensation (fog) forms inside tube with each breath	Quite reliable
Observe chest rise with positive pressure and fall with release	Generally reliable but may be absent in patients with small tidal volume or severe bronchospasm
Feel air exiting from end of tube following inflation	Reliable
Air remains in lung after end of tube is occluded and exits when occlusion is removed	Reliable but one may "ventilate" a closed area of the esophagus
Ask patient to speak; listen for moaning or other sounds	If tube is in proper place, no sound is possible
Chest radiograph	Generally reliable but can be misleading
End-tidal CO_2 measurements	CO_2 not persistently detected if esophagus is intubated
Aspiration technique	Tracheal location with patent tube if 30–40 mL of air is aspirated without resistance; probable esophageal location if unable to aspirate syringe easily or delayed bulb refill
Fiberoptic bronchoscope	Reliable if tracheal rings are seen down endotracheal tube
Lighted stylet down endotracheal tube	Reliable if transillumination seen in low midline neck

undetected. Because irreversible cerebral anoxia occurs within minutes, conservative airway management maneuvers should be limited to 2 to 3 minutes; failure to achieve adequate oxygenation should lead to a quick decision to intubate.

As a guide, intubation attempts should be limited to the amount of time a single deep breath can be held. This is especially important in a child, because the functional residual capacity of a child's lungs is less than that of an adult. Historically, the maximum recommended duration of an intubation attempt in an apneic patient has been 30 seconds, followed by a period of bag-valve-mask ventilation before intubation is attempted again. Longer intubation attempts are permissible, however, when guided by accurate data from an oxygen saturation monitor. Oxygen saturation may remain in the normal range for minutes, especially in patients who have been adequately pre-oxygenated. Assuming optimal preoxygenation to a saturation >98%, attempts at intubation should be halted for bag-mask ventilation whenever the O_2 saturation drops below 92%.

Assessment of tube location is the top priority immediately after its passage. The best assurance of tracheal placement is for the clinician to see the tube pass through

the vocal cords. Techniques to assess tube placement are discussed earlier. Another method of reliably determining tracheal tube location uses the fiberoptic scope. Passage of the scope through the tube with visualization of tracheal rings confirms ET placement as well as the position within the trachea. The placement of a lighted stylet down the tracheal tube and successful transtracheal illumination also reliably predicts ET placement. [40]

The clinician should be aware of the potential for vomiting following removal of a tube from the esophagus. Cricoid pressure should be applied during tube removal and maintained until intubation is successful. Alternatively, the first tube can be left in the esophagus to serve as temporary gastric venting until tracheal intubation is achieved. Suction must be readily available should vomiting occur.

Although seldom associated with serious complications, unrecognized positioning of the ET tube tip in the right mainstem bronchus may cause hypoxia as well as unilateral pulmonary edema.[41] A chest radiograph should be taken shortly after the intubation to confirm tube positioning. Endobronchial intubation was clinically unrecognized without a chest film in 7% of prehospital intubations in one study. [42] Persistent asymmetrical breath sounds after correct tube positioning suggests unilateral pulmonary pathology (e.g., main stem bronchus obstruction, pneumothorax, or hemothorax).

Prolonged efforts to intubate may also cause cardiac decompensation. Pharyngeal stimulation can produce profound bradycardia or asystole; when feasible, an assistant should follow the cardiac rhythm throughout the intubation. Atropine should be available to reverse vagal-induced bradycardia that may occur secondary to suctioning or laryngoscopy. Prolonged pharyngeal stimulation also may result in laryngospasm, bronchospasm, and apnea.

Complications may also result from the application of cricoid pressure. Cricoid deformation is proportional to the force applied during the application of cricoid pressure. This deformation may result in expiratory obstruction in up to 56% of patients at 44 Newtons but only 2% at 30 Newtons. [43] However, BURP maneuvers may increase obstruction even at low pressure.

One should check for loose or missing teeth before and after orotracheal intubation. Any avulsed teeth not found in the oral cavity warrant a postlaryngoscopy chest film to rule out aspiration of a tooth. Swallowed teeth are of no consequence. Broken teeth are the most common complication of laryngoscopy. [44] Laceration of the mucosa of the lips, especially the lower lip, may also occur. Tracheal or bronchial injuries are rare but serious, usually occurring in infants and the elderly as a result of decreased tissue elasticity. [45]

Vomiting with aspiration of gastric contents is another serious complication that can occur during intubation. Case reports of both ARDS and chronic lung disease are thought to be due to the aspiration of activated charcoal. [46] [47] Patients who are obtunded, at risk for seizures, or vomiting should be considered for tracheal intubation before the administration of activated charcoal.

Controversy exists regarding exacerbation of cervical spine injuries during orotracheal intubation in the trauma patient. A cadaveric study of intubation under fluoroscopy showed that the greatest degree of motion occurs at the

occiput-C1 junction and decreases with each sequential interspace. [48] Manual in-line immobilization did not significantly limit motion at any level in this study. Neither manual in-line immobilization nor traction significantly reduced motion at a surgically created ligamentous injury at the C4–C5 level. Complete immobilization of the cervical spine likely cannot be completely achieved by means readily available in the ED, but attempts should still be made to minimize movement with manual in-line stabilization and use of proper intubation technique. However, concern for a cervical spine injury should not deter the clinician from securing a patient's airway when clinically warranted. Exacerbation of a cervical spine injury remains largely a theoretical concern, while in contrast, inadequate ventilation and failure to adequately secure the airway occurs regularly in the emergency setting.

Intubation may also be complicated by a persistent air leak. This is generally caused by failure of either the cuff or pilot balloons or by positioning the cuff balloon between the vocal cords. If the cuff balloon is leaking, the tracheal tube must be replaced (see Changing Tracheal Tubes later in this chapter). If the pilot balloon is determined to be leaking, however, this can usually be remedied without changing the tube. [49] An incompetent one-way balloon valve can be fixed by placing a stopcock into the inflating valve. Reinflation of the cuff followed by shutting off the stopcock should solve the problem. If the leak involves the pilot balloon itself, or if the distal inflation tube has been inadvertently severed, cut off the defective part and slide a 20-ga catheter into the inflation tube. Then connect the stopcock to the catheter, inflate the cuff, and close the stopcock.

Tracheal stricture used to be a significant late complication of long-term intubation with low-volume high-pressure cuffs. The standard use of high-volume low-pressure cuffs has markedly decreased the incidence of this complication. [50] Tubes with high-pressure cuffs are obsolete and should be avoided.

Summary

Orotracheal intubation is the primary method of definitive airway management. In the comatose patient, it is usually accomplished rapidly and without difficulty. The easy intubation is frequently successful in the hands of the novice; the difficult intubation often proves challenging even for the experienced clinician. Rapid-sequence induction has increased the use of orotracheal intubation as the first-line approach in various clinical situations and settings (see Chapter 5). Once the patient's breathing and protective reflexes are removed, however, the clinician has the supreme responsibility of safely reestablishing them. A mastery of the technique of orotracheal intubation is essential.

MODIFIED OROTRACHEAL INTUBATION

Intubation with an Intermediate Airway in Place

Esophageal Obturator/Gastric Tube Airway in Place

The unconscious patient requiring ventilatory assistance may benefit from temporary use of the esophageal obturator airway (EOA) or similar device, as described in Chapter 3 . Although the EOA may provide effective ventilation, it is, at best, a temporary measure. An ET tube generally provides more safe, convenient, and effective airway control. Therefore, the EOA should be replaced as soon as the patient's clinical condition permits and personnel skilled in ET intubation are available.

Removal of the EOA from the esophagus often results in gastric regurgitation. Therefore, ET intubation must be performed around the EOA to protect the patient from aspiration. The process is begun by hyperventilating the patient through the EOA. The EOA mask is then removed, and the EOA tube is moved to the left side of the patient's mouth. Laryngoscopy and intubation are then performed in the usual fashion. The EOA balloon may cause resistance to passage of the tracheal tube, requiring the volume of the EOA balloon to be reduced. After passage of the orotracheal tube, the clinician deflates the EOA balloon completely and slides it out of the patient's esophagus. If resistance is met, the clinician must be sure that the esophageal cuff has been deflated completely.

Esophageal-Tracheal Combitube (ETC) in Place

Combitubes placed in the esophagus will generally require replacement with a tracheal tube. The inflated pharyngeal balloon prevents tracheal intubation around this airway. This proximal balloon must be deflated before attempting tracheal intubation. If intubation is still not possible, the ETC may need to be removed; the stomach should first be emptied via a gastric tube placed through the esophageal port of the airway. Suction is readied, the distal balloon is deflated, and the patient is quickly intubated.

Laryngeal Mask Airway in Place

The trachea can often be intubated with the laryngeal mask airway (LMA) left in place. The various approaches to intubation with an LMA in place are discussed in Chapter 3 (see Figs. 3-11).

Bullard Laryngoscope

A recent development for intubating the difficult airway is the Bullard laryngoscope, an anatomically shaped rigid fiberoptic laryngoscope that provides an indirect view of the larynx (Fig. 4-13). Because no manipulation of the neck is necessary, it is especially well suited for the patient with potential cervical spine injury. Indeed, in the anesthetized patient, the Bullard laryngoscope has been found to cause less head extension and cervical spine extension than the conventional laryngoscope. [51] The addition of an intubating stylet attached to the laryngoscope has resulted in increased ease and speed of intubation, and the technique appears to be effective regardless of the patient's head and neck anatomy.[52] Because alignment of the oropharyngeal and laryngeal axes is not required, the Bullard laryngoscope offers the advantage provided by a conventional fiberoptic scope but requires less training to gain proficiency in its use. [53]

Indications and Contraindications

The Bullard laryngoscope is indicated in patients with anticipated difficult airways who require definitive airway control. It can be used in awake as well as unresponsive patients.[54] Marked impairment of mouth opening is a contraindication to the use of a laryngoscope. However, because the Bullard laryngoscope follows the contour of the mouth and hypopharynx, only 2 cm of occlusal opening is necessary for the

Figure 4-13 Bullard laryngoscope. Anatomically shaped laryngoscope visualizing the glottis; tracheal tube is mounted on the attached stylet for easy tracheal passage. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

introduction of the scope and an ET tube. The laryngoscope itself requires only 6 mm of mouth opening for insertion. [55]

Procedure

The technique for introducing the Bullard laryngoscope blade is similar to that for direct laryngoscopy. The clinician, standing at the patient's head, opens the mouth with the left thumb while holding the head stable. As the scope blade is introduced into the oropharynx, the handle is rotated to follow the curve of the hypopharynx until the handle is fully vertical. The tip of the blade can be used to lift the epiglottis, but visualization of the larynx is usually possible without this maneuver. Only minimal force is exerted along the axis of the handle. Intubation of the larynx can be accomplished using a styletted ET tube or an ET tube with a directional tip (Endotrol; Mallinckrodt, Critical Care, Glens Falls, NY). The technique is generally successful when using the new Bullard intubating stylet. [52]

Awake intubation using the Bullard laryngoscope can be performed comfortably using topical anesthesia and light IV sedation. [54] Adult and pediatric Bullard laryngoscopes are available, and the scope has been used successfully in neonates. [53] The Bullard scope can also be used in conjunction with nasotracheal intubation to visualize proper tube placement.

Complications

The major difficulty in using the Bullard laryngoscope is the inability to visualize the larynx because of blood, emesis, or secretions. Another reason for failure is the inability to place the blade tip under the epiglottis. [52]

Summary

The Bullard scope is useful in the difficult airway uncomplicated by blood and excessive secretions. In the all-too-common setting of blood and secretions, however, the inability to visualize the vocal cords significantly limits the utility of this device in emergency airway management.

NASOTRACHEAL INTUBATION

Nasotracheal intubation was first described by Magill in the 1920s. The tube may be placed blindly or with the aid of a laryngoscope or bronchoscope. Blind nasotracheal intubation can be one of the more technically demanding airway approaches, with the outcome being heavily dependent on the skill and experience of the clinician. The primary advantage of the blind technique is that it minimizes neck movement and does not require opening the mouth.

General Indications and Contraindications

Nasotracheal intubation is technically more difficult than oral intubation, but it has definite advantages. It is especially suitable for the patient with a short, thick neck or other anatomic characteristics that would make orotracheal intubation difficult. It also requires minimal preparation.

Blind nasotracheal intubation is possible with the patient in the sitting position, a distinct advantage when intubating the patient with congestive heart failure who cannot tolerate lying flat. In fact, patients in respiratory distress are the easiest to intubate blindly because their air hunger results in increased abduction of the vocal cords, which facilitates tube entry into the trachea.

A nasotracheal tube has advantages that extend beyond the immediate difficulties of airway control. The patient cannot bite the tube or manipulate it with the tongue. Oral injuries may be cared for without interference by the tube. A nasotracheal tube is more easily stabilized and generally easier to care for than an orotracheal tube. It is better tolerated by the patient, permitting easier movement in bed, and produces less reflex salivation than do oral tubes.

Nasal intubation should be avoided in patients with severe nasal or midface trauma. In the presence of a basilar skull fracture, a nasotracheal tube may inadvertently enter the cranial cavity. [56] The technique should be avoided in patients in whom thrombolytic therapy is being considered. Nasal intubation is relatively contraindicated if the patient is taking anticoagulants or is known to have a coagulopathy. Because the sound of air passing though the vocal cords guides proper tube placement, nasotracheal intubation is not recommended in patients without spontaneous respirations.

Blind Placement

Blind nasotracheal intubation is the most common form of nasotracheal intubation in the emergency setting. Danzl and Thomas reported a success rate of 92% in a large series of ED patients, but success rates are highly dependent on clinician skill. [57]

Indications and Contraindications

Any patient requiring airway control who has spontaneous respirations is a candidate for blind nasotracheal intubation. Specific indications that favor this approach over others are (1) short, thick neck, (2) inability to open the mouth, (3) inability to move the neck, (4) gagging or resisting the use of the laryngoscope, and (5) oral injuries.

Apnea is the major contraindication to blind nasotracheal intubation. Attempts to place the tube without respirations as a guide are futile. Relative contraindications include basilar skull fracture and nasal injury. [56] [58] Furthermore, significant bleeding may occur if the patient is receiving anticoagulants or has a coagulopathy. Blind nasotracheal intubation should be avoided in patients with expanding neck hematomas. Patient combativeness, if not controlled with sedation, is also a contraindication.

Some would argue that inability to open the mouth is a relative contraindication, because emesis may be induced and the vomitus could not be cleared. The clinician must exercise judgment in the individual case and be prepared to use neuromuscular blocking agents or bypass the upper airway with a surgical technique if such a complication develops.

Procedure

The patient is placed in the "sniffing" position with the proximal neck slightly flexed and the head extended on the neck. In preparation for intubation, the clinician constricts the nasal mucosa of both nares, using either 0.25% to 1.0% phenylephrine drops, oxymetazoline (Afrin) spray, or 4% cocaine spray. Topical anesthesia of the nares, oropharynx, and hypopharynx with lidocaine spray (10%) is also indicated if time permits. If available, cocaine is ideal because it is both a vasoconstrictor and an anesthetic—caution is necessary in hypertensive patients. The most patent nostril is chosen. In the cooperative patient, this can be determined simply by occluding each nostril and asking the patient which one is easier to breathe through. The most patent nostril can also be identified by direct vision, or by gently inserting a gloved finger lubricated with viscous lidocaine, full length into the nostrils. If time is not an issue, an effective method to dilate the nasal cavity and administer the anesthetic is to pass a lidocaine gellubricated nasopharyngeal airway (nasal trumpet) into the selected nostril. This airway is left in place for several minutes, and progressively larger trumpets are introduced.

After preparation of the nostril, a well-lubricated 7.0 or 7.5 ET tube is inserted along the floor of the nasal cavity. The tube is not directed cephalad, as one might expect from the external nasal anatomy, but rather is directed straight back toward the occiput, along the nasal floor. Twisting the tube may help bypass soft tissue obstruction in the nasal cavity. It is sometimes recommended that the tube's bevel be oriented toward the septum to avoid injury to the inferior turbinate. However, such an event is rare. At 6 to 7 cm, one usually feels a "give" as the tube passes the nasal choana and negotiates the abrupt 90° curve required to enter the nasopharynx. This is the most painful and traumatic part of the procedure and must be done gently. If resistance persists despite continued gentle pressure and twisting of the tube, the passage of a suction catheter down the tube and into the oropharynx may allow for successful passage of the tube over the catheter. [59] If this fails, the other nostril should be tried. In an attempt to avoid this difficulty from the outset, a controllable-tip tracheal tube (Endotrol, Mallinckrodt Medical Inc, St Louis) may be used. The tube allows the clinician to increase the flexion of the tube, facilitating passage past this tight curve. One study found that the Endotrol tube enhanced first-attempt success with blind nasotracheal intubation. [60] A study of paramedic-performed blind nasotracheal intubation reports success rates of 58% using standard ET tubes versus 72% success with directional tip control ET tubes. [61]

As the tube advances through the oropharynx and hypopharynx and approaches the vocal cords, breath sounds from the tube become louder and fogging of the tube may occur. At the point of maximal breath sounds, the tube is lying immediately in front of the laryngeal inlet. The tube is most easily advanced into the trachea during inspiration, when the vocal cords are maximally open. As the patient begins to breathe in, the tube is advanced in one smooth motion. If a gag reflex is present, the patient usually coughs and becomes stridulous during this maneuver, suggesting successful tracheal intubation. The absence of such a response should alert the clinician to probable esophageal passage. If there is a delay in advancing the tube, oxygen can be added to the end of the tube to increase inspired oxygen. Once the tube is in the trachea, vocalization should cease. Persistent vocalizations suggest esophageal intubation. Breath sounds coming from the tube and tube fogging are other signs of ET placement. Reflex swallowing during blind nasotracheal intubation may direct the tube posteriorly toward the esophagus. If this occurs, the conscious patient should be directed to stick out the tongue to inhibit swallowing and prevent consequent movement of the larynx. Application of laryngeal pressure may also help avoid esophageal passage.

Following intubation, both lungs are auscultated while positive-pressure ventilation is applied. If only one lung is being ventilated, the tube is withdrawn until breath sounds are heard bilaterally. The optimum distance from the external nares to the tube tip is about 28 cm in males and 26 cm in females. [62] After verification of tracheal placement, the cuff is inflated and the tube is secured.

Technical Difficulties

The nasotracheal tube may slide smoothly through the hypopharynx and into the trachea on the first pass. Unfortunately, this is not always the case; in an operating room series, the first attempt was successful in <50% of cases. [63] When the initial pass is unsuccessful, there are 4 potential locations of the tip of the tube: (1) anterior to the epiglottis in the vallecula, (2) on the arytenoid or vocal cord, (3) in the piriform sinuses, or (4) in the esophagus.

Observation and palpation of the soft tissues of the neck during attempted passage of the nasotracheal tube are helpful in finding the misplaced tube. Before reattempting placement, the tube is withdrawn slightly; it is not removed from the nose, because this will create additional trauma to the nasal soft tissues. The possibility of cervical spine injury must be kept in mind when considering corrective maneuvers. Any maneuver that moves the neck significantly should not be used if alternatives are available. Methods for achieving success when difficulties with tube placement are encountered include the following.

Anterior to the epiglottis.

Difficulty advancing the tube beyond 15 cm or palpation of the tube tip anteriorly at the level of the hyoid bone suggests an impasse anterior to the epiglottis in the vallecula. Withdrawing the tube 2 cm, decreasing the degree of neck extension, and readvancing the tube will frequently remedy this problem.

Arytenoid cartilage and vocal cord.

Contrary to the classic teaching, [64] recent studies have demonstrated a propensity for a nasotracheal tube, when placed through the right nares, to lie posteriorly and to the right as it approaches the larynx. [55] [65] It is not surprising, then, that the most common obstacles to advancement of the nasotracheal tube are the

Figure 4-14 Common problem with blind tracheal tube passage through the larynx. *A,* Tip of tube caught on the arytenoid cartilage. *B,* Rotation of tube 90° counterclockwise orients the bevel of the tip posteriorly and allows passage into the larynx. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, MN.)*

right arytenoid and vocal cord. No data are available on the common obstacles encountered if the tube is placed in the left nares. If the tube appears to be hanging up on firm, cartilaginous tissue, withdraw the tube 2 cm, rotate it 90° counterclockwise, and readvance the tube. This maneuver orients the bevel of the tube posteriorly and frequently results in successful passage (Fig. 4-14). Another technique is to pass a suction catheter down the tube; it often will pass through the larynx without difficulty and the tube can then be advanced over the catheter (Fig. 4-15). [66] [67]

Piriform sinus.

Bulging of the neck lateral and superior to the larynx indicates tube location in a piriform sinus. The tube should be withdrawn 2 cm, rotated slightly away from the bulge, and readvanced. An alternate method is to tilt the patient's head toward the side of the misplacement and reattempt placement. [68]

Esophageal placement.

Esophageal placement is indicated by a smooth passage of the tube with the loss of breath sounds. The larynx may be seen or felt to elevate as the tube passes under it. Assisted ventilation will usually produce gurgling sounds when the epigastrium is auscultated. The tube should be withdrawn until breath sounds are clearly heard, and passage should be reattempted while pressure is applied

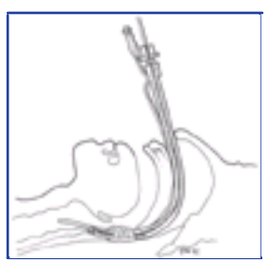

Figure 4-15 Use of suction catheter to aid in passage of nasotracheal tube caught at laryngeal inlet. The suction catheter is passed down the tracheal tube and into the trachea. The tracheal tube is then passed over the suction catheter, and the catheter is removed. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

to the cricoid. Increased extension of the head on the neck during placement may help. If attempts continue to result in esophageal misplacement, the following maneuver may result in successful tracheal intubation: from the precise point at which breath sounds are lost, the ET tube is withdrawn 1 cm. The cuff is inflated with 15 mm of air, resulting in an elevation of the tube off the posterior pharyngeal wall and angling it toward the larynx. The tube is then advanced 2 cm; continued breath sounds indicate probable intralaryngeal location. At this point, the cuff is deflated and the ET tube is advanced into the trachea (Fig. 4-16). This technique may be particularly useful in the patient with cervical spine injury, because it requires no manipulation of the head or neck. [69] This maneuver, when used on the first pass in 20 patients in the operating room, was successful in 75% of cases. [63] One should bear in mind, however, that these patients were paralyzed and thus did not experience the laryngospasm that may be encountered in a breathing patient. The use of topical anesthesia is recommended. Alternatively, if a controllable-tip ET tube (Endotrol) is used, the tip can be flexed anteriorly to help avoid esophageal placement. [60] Remember that the tip is very responsive to pulling on the ring. A common mistake is to exert too much force on the ring, resulting in the tube curling up short of the larynx, thus preventing tube advancement. There has been a case report of an Endotrol tube "kinking" at the point of sharpest curvature, causing difficulty with suctioning but no problems with ventilation. [70]

Laryngospasm.

Laryngospasm is common when attempting nasotracheal intubation. It is usually transient. The tube is withdrawn slightly and the clinician should wait for the patient's first gasp; advancement of the tube at this precise moment is frequently successful, as the vocal cords are widely abducted during forced inhalation. Laryngeal anesthesia should

Figure 4-16 Use of tracheal tube cuff inflation to aid in nasotracheal intubation. *A,* Tracheal tube is pulled back after esophageal passage. *B,* Once breath sounds are heard, cuff is inflated with 15 mL of air and is readvanced into the laryngeal inlet. Once seated in the inlet, the cuff is deflated and the tube is advanced into the trachea. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

also be assessed, and if IV and nebulized lidocaine have already been administered without success, transcricothyroid anesthesia (e.g., 2 mL of 4% lidocaine) should

be considered.[71] Occasionally, a jaw lift is necessary to break prolonged spasm. Another option is to use a smaller tube.

Placement Under Direct Vision

This technique combines elements of oral and nasotracheal intubation. The indications and precautions are similar, and the importance of considering cervical spine injury is identical. Likewise, the need for jaw opening by physical or pharmacologic means is unchanged. This method is preferred to orotracheal intubation if the presence of an orotracheal tube might interfere with the repair of an oral injury. It is also useful when blind nasotracheal intubation has failed.

Preparation of the nose and nasopharynx and passage of the tube into the oropharynx are the same as described for blind nasotracheal intubation. It is with the introduction of the laryngoscope that the technique changes.

Laryngoscopy, as described with orotracheal intubation, is used to visualize the vocal cords and the tip of the ET tube. With the Magill forceps in the right hand, the ET tube is grasped proximal to the cuff (to avoid damage to the balloon) and directed toward the larynx (Fig. 4-17). An assistant advances the tube gently while the clinician directs the tip into the larynx and trachea. Cricoid pressure may facilitate the passage. Often the larynx can be manipulated sufficiently with the laryngoscope so that the clinician can advance the tube with the right hand and guide it between the cords without using the Magill forceps. Occasionally, the natural curve of the tracheal tube guides it through the cords without any manipulation. The cuff is inflated, and both lungs are auscultated to ensure ventilation. When placement is satisfactory, the tube is secured.

Complications

Epistaxis is the most common complication of nasotracheal intubation. However severe epistaxis was encountered in only 5 of 300 cases reported by Danzl and Thomas.[57] Tintinalli and Claffey reported severe bleeding in 1 of 71 cases and less serious bleeding in 12 others. [72] Bleeding is usually not a problem unless it provokes vomiting or aspiration, a serious potential problem in obtunded patients with a clenched jaw or a

Figure 4-17 Nasotracheal intubation with the aid of a laryngoscope and Magill forceps. Note that the forceps do not pull the tube—they only serve to guide the tip of the tube through the vocal cords while an assistant advances the tube. The cuff is frequently damaged if it is grasped.

decreased gag reflex. Other immediate complications include turbinate fracture, intracranial placement through basilar skull fracture, retropharyngeal laceration or dissection, and delayed or unsuccessful placement. [56] [73] [74] [75] Complications may be minimized by selection of a smaller tube and by gentle technique.

Sinusitis in patients with nasotracheal tubes is common and can be an unrecognized cause of sepsis. [76] Rare but potentially fatal delayed complications include mediastinitis following retropharyngeal abscess [77] and massive pneumocephalus.[78]

Because most complications occur during tube advancement through the nasal passage and proximal nasopharynx, the complications of blind nasotracheal intubation and placement under direct vision are largely the same. However, retropharyngeal laceration and esophageal intubation are more of a threat in blind placement techniques because they are more likely to go unrecognized. [72] One unique problem associated with nasotracheal intubation is damage of the tube cuff with the Magill forceps.

Summary

Nasotracheal intubation is being used less frequently than in the past because clinicians are increasingly comfortable using oral intubation in the patient with potential cervical spine injury. In addition, emergency clinicians frequently use paralytics to facilitate orotracheal intubation. Nevertheless, nasotracheal intubation remains an effective and potentially life-saving approach to the difficult airway and should be a dependable part of the armamentarium of all clinicians who are active in emergency airway management.

GUIDED INTUBATION TECHNIQUES

Digital Intubation

Digital intubation uses the index and middle fingers to blindly direct the ET tube into the larynx. It is particularly well adapted to the prehospital situation in which a trapped victim cannot be positioned for intubation. A prehospital series of 66 digitally intubated patients demonstrated an 89% success rate. [79]

Indications and Contraindications

Digital intubation is indicated in the deeply comatose patient whose larynx cannot be visualized and who has a contraindication to nasotracheal intubation. Advantages include speed and ease of placement, immunity to anatomic constraints and other difficulties visualizing the larynx, and little neck movement. Contraindications are primarily precautions to protect the clinician: Digital intubation should not be attempted on any patient who presents a significant risk of biting. This includes the calm and awake patient as well as the agitated patient.

Procedure

The patient's head and neck are placed in neutral position. The clinician stands at the patient's right side, facing the patient. The clinician's left index and middle fingers are introduced into the right angle of the patient's mouth and are slid along the surface of the tongue until the epiglottis is palpated. The tip of the epiglottis is palpated at 8 to 10 cm from the corner of the mouth in the average adult. The use of a stylet in the tube is optional; the largest reported series had good success without a stylet.[79] For the clinician with short fingers or a patient with an anterior larynx, a stylet is advantageous. If a stylet is used, it is placed in the tube and bent into the form of an open "J" with the distal end terminating in a gentle hook. A lubricated tube is introduced from the patient's left between the tongue and the rescuer's two fingers (Fig. 4-18). The tube is cradled between two fingers and the tip is guided beneath the epiglottis. Gentle anterior pressure directs the tube into the larynx. If the clinician has sufficiently long fingers, they can be placed posterior to the arytenoids, acting as a "backstop" for the tube to both avoid esophageal passage and to assist in laryngeal placement. [80] If a stylet has been used, it is withdrawn at this time while simultaneously advancing the tube. An alternative to using a stylet for directing the tube anteriorly is to select an ET tube with a controllable tip (Endotrol, Mallinckrodt Medical Inc, St Louis).

A variation on the technique of digital intubation has been described for intubating the newborn. [81] Only the index finger is used to guide the tube into the larynx. The end of the tube is bent and both the tube and the finger are moistened with sterile water. The index finger of the nondominant hand follows the tongue posteriorly to easily palpate the epiglottis and paired arytenoids. The thumb of the same hand may be

Figure 4-18 Digital intubation. The tracheal tube is cradled between the index and middle fingers and guided into the glottic opening. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

used to apply cricoid pressure to steady the larynx. The ET tube is held in the dominant hand and advanced using the non-dominant index finger as a guide (Fig. 4-19). The tube snugs up (encounters subtle resistance) as it enters the trachea, and palpation of the tube through the trachea provides further confirmation of correct placement. A styletted tube, shaped in the form of a J, is usually desired until familiarity with the procedure is achieved.

Complications

The risk of esophageal intubation is always present and, being a blind procedure in deeply comatose or cardiac arrested patients, the potential for esophageal misplacement is increased. If used in patients with a gag, induction of emesis with aspiration is a possibility. A high incidence of left main stem intubations was noted in a cadaveric study, [82] but clinical confirmation is lacking. The greatest risk seems to be to the clinician, whose fingers may be bitten.

Summary

While most recent experience with digital intubation in adults has been prehospital, there is no reason why it should be confined to this setting. The majority of moribund ED patients who defy orotracheal intubation are never given a trial of digital intubation. This omission undoubtedly deprives some patients of expeditious airway management.

Lighted Stylet Intubation

This technique uses a battery-operated lighted stylet that is placed in an ET tube and used to guide the tube into the trachea by transilluminating the soft tissues of the neck. First described in 1957 by MacIntosh and Richards, [83] it was designed to aid in managing the difficult airway. It has also been shown to be a useful means of determining the position of the tracheal tube. [40] Some newer devices incoporate fiberoptic capabilities or audio feedback to facilitate intubation. [84]

In the operating room, the Tube Stat lighted stylet (Concept Corp, Clearwater, FL) has been 99% to 100% successful. [85] [86] The requirement that the overhead lights be dimmed during the procedure has limited its use in most emergency settings. In a small prehospital study, 88% of patients were successfully intubated by clinicians using a lighted stylet.[87] The majority of the failures occurred in the setting of bright sunlight and in patients who had vomited. A

Figure 4-19 Digital intubation in the neonate. The tube is guided using only the index finger to palpate the epiglottis and laryngeal inlet. A stylet is optional. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

newer device (Trachlight, Laerdal, Inc, Starger, Norway) with a brighter light source and adjustable length, appears to have solved this problem. In a series of 96 patients, many with a history of difficult intubation, all but 1 were successfully intubated in ambient light with this device using either the oral or nasotracheal route. [88] Consistent with other series, the only failure was in a morbidly obese patient. Several studies have shown that time to intubation is equivalent or shorter using a lighted stylet vs standard orotracheal intubation. [84]

Indications and Contraindications

The patient with a difficult airway in whom direct laryngoscopy has failed is a candidate for light-guided tracheal intubation. A multiple trauma patient with airway

bleeding is a prime example. The patient who has been pharmacologically paralyzed and cannot be intubated with direct laryngoscopy is another example. The lighted stylet may also be helpful in successfully completing a difficult nasotracheal intubation. One advantage of this technique over nasotracheal intubation is that it can be used in the apneic patient.

Because lighted stylet intubation is a blind approach, it should be avoided in patients with expanding neck masses and patients with airway compromise presumed due to a foreign body. Massive obesity is the most common cause for failure with this technique because of the difficulty transilluminating the generous soft tissue.

Preparation

The function of the bulb of the lighted stylet should be checked before use. The patient's head should be placed in a neutral or, if cervical spine injury is not a concern, the sniffing position. The awake patient should have the oropharynx and hypopharynx sprayed with lidocaine and sedation should be administered as indicated.

Procedure

The lubricated lighted stylet is inserted into a tracheal tube 2.5 mm or larger (pediatric stylets are available) until the bulb lies just distal to the side port but not protruding from the end of the tube.[84] This unit is bent in the shape of a hockey stick with a 90° curve beginning just proximal to the tube cuff. The clinician stands at the head of the patient. When this is not possible, the patient can be approached from either side. The tongue is grasped with gauze and pulled forward. Another means of exposing the oropharynx is to grasp the jaw between

Figure 4-20 Lighted stylet intubation. Use of the Trachlight for endotracheal intubation using transillumination of soft tissues as a guide to placement. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

the thumb and the fingers (Fig. 4-20). The light is turned on and the unit is inserted into the mouth, following the curve of the tongue into the oropharynx. A transilluminating glow indicates the location of the tube tip. Application of cricoid pressure may enhance transillumination. [40] The overhead light should routinely be dimmed if feasible. Positioning is optimal when the glow emanates from the midline at the level of the hyoid bone. Holding the lighted stylet steady, the tube is slid off and advanced into the trachea. If the glow is located elsewhere, the unit should be withdrawn 2 cm or cocked back and repositioned as indicated by the light. If no light is seen, the tube is in the esophagus and should be pulled back, laryngeal pressure applied, and, if necessary, the head extended slightly. After passage, the tube should be checked for correct positioning and then secured.

Complications

Earlier reports noted complications resulting from an equipment failure and lost bulbs, but these technical problems have been corrected. No complications have been noted in the recent literature, but this may only reflect the limited use of this technique in uncontrolled settings. A blinded study of pathologic specimens did not show any evidence of burn injury in the tracheal mucosa in cats intubated with the Trachlight. [84]

Summary

Lighted stylet intubation is a safe, rapid, and highly successful method that has a definite place in the management of the difficult airway. Improvements in the device have made its use more practical in most settings in which emergency airway management is performed.

Intubation Over a Fiberoptic Bronchoscope

Use of the flexible fiberoptic bronchoscope as an aid to tracheal intubation is an alternate method of in airway management in the ED. In this setting, success approximates 80%, with the most common cause of failure being the inability to visualize the glottis secondary to blood and secretions. [89] [90]

Flexible fiberoptic endoscopy is often the best method for intubating the awake patient with a difficult airway. It can be accomplished using the nasal or oral route and is better tolerated than direct laryngoscopy. It also may be effective in the comatose patient when more conventional methods have failed. It provides excellent visualization of the airway and permits the evaluation of the airway before tube placement. The greatest obstacle to success is obscured visualization secondary to blood, secretions, or fogging. The expense of the equipment, its fragility, and the time required to achieve technical proficiency are additional drawbacks.

Indications and Contraindications

Common indications for emergency fiberoptic intubation include the unstable cervical spine, expanding neck masses, upper airway infection, facial and airway burns, and anticipation of a difficult intubation due to abnormal anatomy. It may also be helpful in guiding blind nasotracheal intubation that is initially unsuccessful.

Contraindications to fiberoptic nasotracheal intubation are similar to those for nasotracheal intubation: severe midface trauma and coagulopathy. Although there are no clear contraindications to fiberoptic orotracheal intubation, active airway bleeding and vomiting are relative contraindications because successful fiberoptic intubation is rarely achieved in these settings. If the clinician is inexperienced in fiberoptic intubation, apnea is another relative contraindication to its use.

Equipment

Fiberoptic scopes are graded according to their external diameter (in millimeters). A practical size for an intubating scope is 3.5 mm. Although it is physically possible to pass a 4.0 mm (0.5 mm larger) tracheal tube over the scope, the fit is quite tight. As a rule, the tracheal tube should be at least 1 mm larger than the intubating scope. The size of the working channel—the port to which suction or oxygen is applied and through which fluid or catheters may be passed—is another important dimension when evaluating fiberoptic scopes. Large working channels are desirable.

Procedure

The optimal positioning of the neck is in extension, as opposed to the cervical flexion desired when using direct laryngoscopy. Extension allows for better visualization of the glottis by elevating the epiglottis off the posterior pharyngeal wall. This is especially pertinent in the comatose patient who lacks the muscle tone necessary to maintain an open airway. Problems with the tongue and soft tissues falling back and obscuring fiberoptic scope view are effectively managed by applying a jaw lift or pulling the tongue forward and away from the soft palate and posterior pharyngeal wall. This maneuver also moves the epiglottis away from the posterior pharyngeal wall, facilitating exposure of the cords. Extending the head on the neck may accomplish the same objective.

Nasotracheal approach.

The nasal approach is preferred to the oral approach because the angle of insertion allows for easier visualization of the larynx and because patient cooperation is not as critical. Also, in the unconscious patient, the tip of the scope is less likely to impinge on the base of the tongue with a nasal approach.

The nose is prepared using a vasoconstrictor and topical anesthetic agent as described for nasotracheal intubation. Using an aerosolized anesthetic agent, it is important to obtain sufficient hypopharyngeal anesthesia to minimize gagging and laryngospasm once the procedure begins. The well-lubricated ET tube may be placed in the nostril first, and the scope passed through it, or the ET tube can be mounted over the scope and the scope first passed through the nostril. The advantage of the former is that it avoids the possibility of nasal secretions covering the scope and obscuring the view. Disadvantages are that nasotracheal placement may cause bleeding and, in some patients, the tube may not pass easily into the nasopharynx.

The most patent nostril is prepped and the ET tube is advanced until it makes the bend into the nasopharynx in the manner described under nasotracheal intubation. If negotiating this bend is difficult, a well-lubricated fiberoptic scope can be placed through the tube and into the oropharynx to serve as a guide for the ET tube. Once the tracheal tube is in the oropharynx, thorough oropharyngeal suctioning should be performed before introducing the scope into the ET tube. The fiberoptic scope is then advanced toward the larynx; the epiglottis and vocal cords are seen with little or no manipulation of the tip of the fiberoptic scope in 90% of patients. [91] As the scope is advanced, the cords are kept in view by frequent minor adjustments of the scope tip.

In the comatose or obtunded patient, the tongue and other soft tissue may obscure the view of the larynx; this can be alleviated by having an assistant pull the tongue forward or apply a chin or jaw lift. The scope is advanced through the larynx to the level of the midtrachea and the ET tube is passed over the firmly held fiberoptic scope into the trachea (Fig. 4-21). It is helpful to remember that in adults the average distance from the naris to the epiglottis is 16 to 17 cm; if the scope has been advanced much beyond this distance and the glottis is still not seen, the scope is probably in the esophagus. [92] If the scope meets resistance at about this same level and only a pink blur is visible, the scope tip is probably in a piriform sinus; transillumination of the soft tissues may be present to confirm this as well as to indicate what corrective maneuvers are necessary.

The greatest impediment to successful fiberoptic intubation is the inability to visualize the larynx because blood or secretions have covered the optical element and cannot be removed. The best time to suction is before introducing the fiberoptic scope, actively suctioning the oropharynx just before scope insertion. Once the scope is in place, minor secretions can be suctioned through the fiberoptic suction port. Significant blood and secretions, however, are best removed by insufflation of oxygen through the suction port and out the tip of the scope, serving simultaneously to remove blood and secretions, defog the tip, and increase the inspired O_2 content. The setup required for insufflation should be immediately available, if not already attached to the suction port before scope insertion. Once the scope has entered the trachea, difficulty may be encountered in advancing the ET tube into the trachea. The tip of the tube most commonly catches on the right arytenoid cartilage or vocal cord; withdrawing the tube 2 cm, rotating it counterclockwise 90°, and readvancing the tube should result in successful tracheal intubation (see Fig. 4-14).

Orotracheal approach.

Oral fiberoptically guided intubation is indicated when contraindications to nasal intubation are present, the most common being severe midface trauma, or when the clinician is more comfortable with this approach. The oral approach is more difficult than the nasal approach because the path of the scope is less defined by the surrounding soft tissue and the tip of the scope is more likely to impinge on the base of the tongue or vallecula. Attention to keeping the scope in the midline and elevating the soft tissue by pulling the tongue forward or applying the jaw lift will minimize this difficulty. Another disadvantage of the oral approach is that the oropharyngeal axis is not as well aligned with the larynx as is the nasopharyngeal axis and thus more scope manipulation is required to visualize the larynx.

The drawbacks of the oral approach can be minimized by using an oral intubating airway. This adjunct resembles an oropharyngeal airway but is longer and has a cylindrical passage through which the fiberoptic scope and tracheal tube are passed. The tip of this airway lies just cephalad to the epiglottis and assures midline positioning and a predictable place from which to advance the scope (Fig. 4-22).

The patient must be adequately anesthetized or obtunded to minimize the gag reflex. Topical anesthesia is achieved by

Figure 4-21 Fiberoptic nasotracheal intubation. Note use of the fiberoptic scope as a guide over which the tracheal tube is passed. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

spraying a 4 or 10% solution of lidocaine into the oropharynx. A degree of laryngeal and tracheal anesthesia may be achieved by a transoral spray using the laryngeal tracheal anesthetic (LTA) set. EMLA cream is also safe and effective in achieving topical anesthesia of the airway. [93] Time permitting, the tongue should first be anesthetized using a small globule of EMLA on a tongue depressor left in place for 1 to 2 minutes. Next, a cotton tip applicator may be used to apply the cream to the remainder of the oropharynx. This procedure should be repeated until the gag reflex is greatly diminished or absent or a total 4 grams of cream are used. This dose has been shown not to result in lidocaine toxicity. A well-lubricated fiberoptic scope, premounted with an ET tube, is then placed through the oral intubating airway and the trachea is fiberoptically intubated. The ET tube is advanced over the scope into the trachea, frequently requiring the same counterclockwise manipulation as described with the nasal approach. After successful intubation, the intubating device can be left in place as a bite block, or it can be removed over the ET tube after removal of the tube adapter. Some oral intubating airways can be removed from the mouth without disconnecting the ET tube adapter.

Complications

Complications of fiberoptic orotracheal intubation include prolonged intubation attempts as well as vomiting and laryngospasm in the underanesthetized patient. Oxygen saturation monitoring should alert the clinician to hypoxemia from prolonged intubation attempts. Most complications seen with fiberoptically guided nasotracheal intubation are associated with passing the ET tube through the nasopharynx. Epistaxis is most common, followed by other nasopharyngeal injuries. A rare but potentially significant complication may result if on blind advancement of the fiberoptic scope through the ET tube, the tip of the scope exits through the distal side port. [94] Attempts at passing the ET tube through the larynx will fail because the tube tip, now extending off the midline, will catch on the laryngeal structures. This complication is avoided if the scope is introduced before tracheal tube placement.

Summary

The primary advantage of fiberoptic intubation is its ability to negotiate difficult airway anatomy. It is noninvasive and well tolerated. Its major limitation in the emergency setting is lack

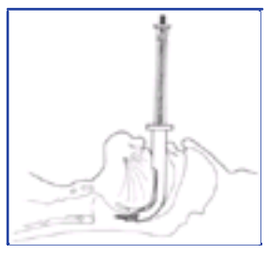

Figure 4-22 Fiberoptic orotracheal intubation. A fiberoptic scope is passed through a hollow oral airway device to help position the scope and tube and to protect them from being bitten during fiberoptic oral intubation. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

of visibility in the presence of blood and secretions. The fiberoptic scope requires more practice than other methods of airway management; the first experience using the scope should not be in the setting of an emergency airway problem. Once familiarity and facility with the scope are acquired, fiberoptic intubation can be used early in the management of the difficult airway rather than as a last resort after repeated failed attempts using conventional techniques.

Magnetically Guided Orotracheal Intubation

Magnetically guided orotracheal intubation is a novel technique of guided ET intubation. The technique uses a strong magnet over the cricothyroid membrane to guide a standard ET tube containing a stylet with a magnetized tip. A study of novice intubators reports an overall success rate of 80% using this technique on a mannequin in a rigid cervical collar. [95] The same study reports a 67% rate when the vocal cords were not visualized. A study of anesthesiologists using a similar technique in elective surgical patients reports a 92.5% first attempt success rate and 100% success within 2 attempts. [96]

Indications and Contraindications

Magnetically guided intubation may be a useful adjunct for the intubation in situations where the vocal cords are difficult to visualize due to anatomic limitations of the patient or the presence of blood or vomitus in the airway. Its use has not been studied in patients with pacemakers or implantable debrillators and should be avoided in this population.

Procedure

A flexible stylet with a magnetic tip is inserted into a standard ET tube. A laryngoscope is then inserted into the oropharynx in the standard fashion. The epiglottis must be visualized to prevent the tip of the ET tube from entering the vallecula. The vocal cords, however, do not necessarily need to be visualized for successful intubation. The ET tube is then placed in the oropharynx with its tip posterior to the epiglottis. A second magnet is then placed over the cricothyroid membrane. The ET tube is then advanced, with magnetic attraction drawing the tip anteriorly through the vocal cords. [95]

Complications

No specific complications of magnetically guided intubation have been reported. The risk of unrecognized esophageal intubation always exists. Again, the effect of the magnets on pacemakers and implantable defibrillators is unknown and use of this technique should be avoided in these patients.

Summary

Magnetically guided orotracheal intubation has not been widely studied, but appears to be a safe and effective adjunct in management of the difficult airway.

Retrograde Intubation

Retrograde orotracheal intubation is a technique of guided ET intubation using a wire or catheter placed percutaneously through the cricothyroid membrane or high trachea and exiting through the mouth or nose. An ET tube is then passed over this guide and advanced through the vocal cords into the trachea. Introduced by Butler and Cirillo in 1960, [97] the technique has undergone several recent modifications that have enhanced its value as a means of establishing a definitive airway when more conventional techniques have failed.

Indications and Contraindications

Retrograde intubation is indicated when definitive airway control is required and less invasive methods have failed. Indications include trismus, ankylosis of the jaw or cervical spine, upper airway masses, unstable cervical spine injuries, and maxillofacial trauma. It can be used to convert transtracheal needle ventilation (see Chapter 6) into a definitive airway. Its successful use has been described in a 1-month-old with developmental abnormalities. [98] It is particularly helpful in the trauma patient with airway bleeding that prevents visualization of the glottis. [99]

Contraindications to this procedure include the availability of a less invasive means of airway control and inability to open the mouth. A relative contraindication is the apneic patient who cannot be effectively ventilated using the bag-valve-mask; in this setting it is advisable to first establish transtracheal needle ventilation (see Chapter 6) before attempting retrograde intubation or to go directly to cricothyrotomy.

Equipment

Materials include the following: (1) local anesthetic and skin preparation materials, (2) 18-ga needle, (3) 60 cm epidural catheter-needle combination or 80 cm (0.88 mm diameter) spring guidewire (J-tip preferred), (4) hemostat, (5) long forceps (e.g., Magill) for grasping wire in pharynx, (6) ET tube of appropriate size, (7) syringe for tube cuff, and (8) materials for securing the tube. A prepackaged alternative is the Cook Retrograde Intubation Set (Cook Critical Care, Bloomington, IN), which also contains a sheath.

Procedure

Three anatomic landmarks must be located by palpation: the hyoid bone, thyroid cartilage, and cricoid cartilage. The skin

overlying the cricothyroid membrane is prepped and anesthetized. Next, the lower half of the cricothyroid membrane is punctured with a needle directed slightly cephalad. The bevel should also face cephalad. Air is aspirated to confirm needle tip position within the lumen of the larynx (see also Chapter 6). An alternative entry point is the high trachea, usually through the subcricoid space, using the same steps as described for the cricothyroid membrane.

The syringe is removed and the wire is then passed through the needle and advanced until it is seen in the patient's mouth, with the help of the laryngoscope, or until it exits the nose. If the wire is found in the hypopharynx, it is grasped with the Magill forceps and drawn out through the mouth. The needle is removed from the neck and the end of the wire is secured at the puncture site with a hemostat. The oral end of the wire is then threaded in through the ET tube side port—not the end of the tube—and advanced up the tube until it can be grasped by a second hemostat. Threading the wire through the side port allows the tube tip to protrude 1 cm beyond the point at which the wire enters the larynx. The wire is then pulled taut and moved back and forth to ensure that no slack remains.

The ET tube is then advanced over the wire until resistance is met. This is the most critical point in the procedure; because this is a blind technique, it may be difficult to determine whether the tube has entered the trachea or is hung up on more proximal structures. If the ET tube has successfully passed through the vocal cords and it is being restricted by the guidewire as it traverses the anterior laryngeal wall, one should feel some caudally directed tension on the wire at its laryngeal insertion point. If this does not occur, the tip of the ET tube may be proximal to the vocal cords, either in the vallecula, the piriform sinus, or abutting the narrow anterior aspect of the vocal cords. If in doubt, pull the tube back 2 cm, rotate it 90° counterclockwise, and readvance the tube. This will usually result in successful passage through the larynx. [92] When satisfied that the tube has entered the trachea, the tube should be stabilized and the guidewire pulled out through the mouth. The tube is then

advanced farther into the trachea.

The classic method of retrograde intubation, as described earlier, has undergone modifications that facilitate passage of the ET tube through the glottis. A significant advance has been the addition of a plastic sheath that is passed antegrade over the wire until it meets resistance where the wire penetrates the laryngeal mucosa (Fig. 4-23).[100] This sheath needs to be stiff enough to effectively guide an ET tube, yet small enough to easily pass through the vocal cords without impinging on supraglottic or glottic structures. Once the sheath comes to rest against the anterior laryngeal wall, the wire is withdrawn from the mouth and the sheath is advanced. With the sheath well within the trachea, the ET tube is passed over the sheath. Any resistance that may be encountered at the arytenoids or vocal cords can usually be remedied by pulling the tube back 1 to 2 cm and rotating it counterclockwise 90°. One advantage of the antegrade sheath is that it lies freely in the larynx, allowing for a more posterior passage through the widest distance between the cords. The wire, however, pulls the ET tube anteriorly toward the narrow commissure of the vocal cords and is more likely to result in impingement of the tube on the cords. Also, the use of the sheath permits unrestricted advancement of the ET tube, whereas a wire entering the larynx 1.0 to 1.5 cm below the vocal cords prevents the tube from advancing more than this distance before removal of the wire.

If no sheath is available, consider placing the needle inferiorly in the subcricoid space, thereby increasing the distance the ET tube can be advanced before being stopped by the wire.[101] This will decrease the likelihood of dislodging the ET tube tip when the guidewire is withdrawn.

Up to this point, blind retrograde intubation has been described. A further modification of the technique allows for visualization using a fiberoptic scope. [102] In addition to the scope, an extra-long guidewire (e.g., 125 cm, 0.025 cm Teflon-coated J-wire) is also required. The procedure is the same as previously described up to the point at which the wire is withdrawn from the mouth. At that point, with an ET tube mounted on a lubricated fiberoptic scope, the long guidewire is passed retrograde up through the end of the fiberoptic scope and out the suction port. The fiberoptic scope is then advanced over the guidewire and through the cords, coming to rest against the anterior laryngeal wall (Fig. 4-24). The wire is withdrawn from the suction port and the scope is advanced into the trachea. The ET tube is then slid off the fiberoptic scope, and visualization guarantees correct ET placement. The scope is then withdrawn and the lungs are auscultated.

Complications

The complications of retrograde intubation are largely related to cricothyroid membrane puncture (see Chapter 6). Hemorrhage is minimized by taking care to puncture the cricothyroid membrane in its lower half (to avoid the cricothyroid artery). Subcutaneous emphysema may occur, but it is of no clinical significance because no air is insufflated during this technique. A small incidence of soft tissue infection is reported with translaryngeal needle procedures, but this can be minimized by ensuring that the wire is withdrawn from the mouth rather than the neck.

The final complication, the failure to achieve intubation, has been mitigated by the addition of the antegrade sheath over the wire.

Summary

Retrograde intubation is an underused technique for achieving ET intubation in a patient who cannot be intubated by less aggressive means. It is more invasive than fiberoptic intubation but requires less skill. Whereas retrograde intubation usually takes several minutes to complete, [80] the patient can undergo bag-mask ventilation through much of the procedure. Recent modifications in the technique guarantee this method a prominent place in the management of the difficult airway, particularly when active bleeding compromises the airway.

CHANGING TRACHEAL TUBES

The tracheal tube with a leaking cuff is a vexing problem, especially if the original intubation was difficult. A method of replacing the tube without losing control of the tracheal lumen is preferred. This can be achieved by passing a guide down the defective tube, withdrawing the tube while leaving the guide in place, and introducing a new tube over the guide and into the trachea.

A number of different guides have been described (e.g., simple nasogastric tubes, 18 Fr Salem sump tubes [Table 4-5], feeding tubes), but they are poor substitutes for a designated tube exchanger such as the TTX "tracheal tube exchanger" (Sheridan Catheter Corporation, Argyle, NY) or a similar commercially available device. The advantages of the

Figure 4-24 Fiberoptic scope as an aid in retrograde intubation. Once the retrograde wire (long) is placed and retrieved superiorly, the wire is threaded through the tip of the fiberoptic scope and out through the suction port. The scope is then advanced until it passes through the vocal cords, stopping at the anterior laryngeal wall. The wire is withdrawn through the suction port, the fiberoptic scope is advanced into the trachea, and the tracheal tube advanced over the scope into the trachea. The fiberoptic scope is then withdrawn. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

designated tube exchanger are that it is stiff enough to prevent dislodgment when the ET tube is introduced, it is ready to use without modification, it has a printed scale to aid in determining depth of placement, and if replacement is prolonged, the patient may be oxygenated using the exchanger and wall oxygen.

Procedure

Before the procedure, the patient is properly sedated or restrained. The patient is hyperventilated before placing the guide through the existing tube. The guide is lubricated and advanced into the defective tube so that it is well within the tracheal lumen (adults, 30 cm). While applying cricoid pressure (Sellick maneuver), the defective tube is withdrawn over the guide, and care is taken not to dislodge the guide when removing the tube. The replacement tube is then slid over the guide and is gently advanced into the trachea (Fig. 4-25). At this juncture, it may be helpful to perform a jaw thrust or chin lift to facilitate passage through the pharynx. Resistance may be encountered at the laryngeal inlet or vocal cords; if this occurs, withdraw the tube 1 to 2 cm, rotate it 90° counterclockwise, and readvance it. With the tube clearly in the trachea, remove the guide, inflate the cuff, and ventilate the patient. After correct placement has been verified, the new tube can be secured.

Benumof describes a technique in which a bronchoscope with an ET tube jacketed over the proximal end is first passed into the trachea with the defective ET tube still in place.[103] A tube exchanger capable of jet ventilation is then passed through the defective tube. The defective tube can then be withdrawn and the new ET tube can be passed over the bronchoscope. The tube exchanger can be withdrawn once placement of the new tube is confirmed. This technique permits direct visualization of the placement of a new tube and a fail-safe means to ventilate the patient should difficulties arise.

Complications are related to the time required to change the tube. A successfully performed procedure can be accomplished within 30 seconds. Laryngeal injury from forcing the guide or the tube is a possibility to consider when replacing a tube.

CONCLUSION

Airway management in the critically ill or injured patient with acute airway compromise is a most demanding task for the emergency clinician. Mastery of oral and nasotracheal

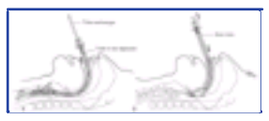

Figure 4-25 Replacing damaged tracheal tube. *A,* Placement of tracheal tube exchanger down damaged tube and deep into trachea (*open arrow*) followed by removal of tracheal tube (*solid arrow*). *B,* Replacement tube is passed over tube exchanger into trachea, followed by removal of tube exchanger. *(Courtesy of Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, MN.)*

TABLE 4-5 -- Procedure for Changing an Orotracheal Tube Using a Salem Sump Nasogastric Tube as a Guide

1. Cut off the proximal 6- to 8-cm flared end of an 18 Fr Salem sump nasogastric tube.
2. Test the balloon or cuff of the new tracheal tube. An 8.0-mm tracheal tube should be used. Remove the proximal adapter from the new tracheal tube.
3. Sedate the patient and restrain the hands as necessary. Preoxygenate as much as possible.
4. Lubricate the entire length of the nasogastric tube with water-soluble (K-Y, Lubrifax) lubricant.
5. Advance the nasogastric tube as far as possible into the trachea through the existing tracheal tube.
6. Deflate the balloon of the existing tracheal tube and remove it. *Now only the nasogastric tube remains in the trachea, to be used as a guiding stylet.*
7. Thread the proximal end of the nasogastric tube through the distal end of the new tracheal tube. This is facilitated by the use of a hemostat.
8. Advance the new tracheal tube over the guide until the nasogastric tube exits through the proximal opening in the new tracheal tube.
9. Grasp the exiting nasogastric tube, have an assistant *lift the patient's jaw*, and advance the tracheal tube over the guide into the trachea. If resistance is encountered, rotate the tube 90° counterclockwise.
10. Remove the guide.
11. Replace the adapter on the new tracheal tube, inflate the cuff, and ventilate the patient. Confirm proper placement of the new tube.

intubation and a facility with various guided intubation techniques, plus competence with the surgical approaches, is necessary to meet all emergency situations that might occur. Preparation (including mastery of technique), advance preparation of equipment, and experience in clinical decision-making are essential. Scenario visualization is one means of practicing the difficult decisions that will afford the patient the most expeditious and safest means of airway control available under the circumstances.

Chapter 5 - Pharmacologic Adjuncts to Intubation

Laura R. Hopson
Steven C. Dronen

Endotracheal intubation in the acute care setting presents a challenge distinct from that associated with intubation of the fasted, premedicated patient in the operating room (OR). The emergency department (ED) patient is frequently uncooperative and unstable and may have medical problems that are completely unknown to the treating clinician. Often within a matter of minutes, the clinician is expected to simultaneously accomplish many formidable tasks: assess and control the airway, as well as to diagnose and manage other life-threatening problems.

In 1979, Taryle and colleagues reported that complications occurred in 24 of 43 patients intubated in a university hospital ED. They called for improved house officer training in endotracheal intubation, as well as "more liberal use of the procedures used in the OR, such as sedation and muscle relaxation." [1] Since the report of Taryle and others, training programs in both critical care and emergency medicine have been greatly expanded, resulting in significant improvement in the expertise of clinicians who provide acute airway management.[2] Simultaneously, the use of established pharmacologic adjuncts to intubation previously available only in the OR has increased.[3] [4] [5] [6] [7] [8] [9] In addition, new drugs that are potent, rapid-acting, and safer have been developed, giving the clinician greater ability to tailor therapy to specific clinical problems.[10] [11] Because of these developments, clinicians now may not only concentrate on the manual skill of intubation, but also skillfully use drugs to achieve specific objectives. These objectives may include (1) immediate airway control necessitating induction of anesthesia and muscle relaxation; (2) provision of analgesia and sedation to the awake patient; and (3) minimization of intubation adverse effects, including systemic and intracranial hypertension.

This chapter reviews the pharmacology and use of the drugs that are currently available to facilitate intubation in the acute care setting.

RAPID-SEQUENCE INDUCTION OVERVIEW

In the critically ill patient who may be hypoxic, hemodynamically unstable, agitated, uncooperative, and at risk of further deterioration, it is frequently necessary to gain immediate control of the airway. In recent years the technique of rapidly inducing anesthesia (rapid-sequence induction [RSI]) as a means of airway control has gained broad acceptance among emergency clinicians. RSI as practiced in the ED is a modification of the process initially described in the anesthesia literature and used to minimize the risk of aspiration in patients with full stomachs who require anesthesia. There is also a subtle but significant modification of the intent of RSI as practiced in the ED. Whereas anesthesiologists have used RSI to intubate patients requiring anesthesia, emergency clinicians commonly use RSI to induce anesthesia in patients requiring intubation.

Airway control in the ED is obviously not the same as planned intubation prior to general anesthesia in the OR. While some techniques and medications are similar, ED airway control cannot simply be accomplished by "calling anesthesia." The anesthesia team may serve as backup, but it is not standard that airway control await the arrival of an off-site team. What is standard is that the total process is accomplished with the personnel and resources available in the ED, with the prudent use of anesthesia specialists in select cases and for procedures and equipment not available in all settings. As described by Stept and Safar, [12] general anesthesia RSI includes 13 steps, several of which are not practical or relevant to the ED setting. In the ED, RSI is begun by placing the patient on 100% oxygen, for at least 2 to 3, and ideally 5, minutes. The intent is to denitrogenize the lungs and build an oxygen reserve that will last several minutes should intubation prove to be difficult. Under optimal conditions, breathing 100% oxygen for 3 minutes has been demonstrated to maintain acceptable oxygen saturation for 8 minutes. [13] The same study demonstrated that 4 maximal breaths of 100% oxygen from a face mask maintained acceptable saturation for 6 minutes. Comparable results should not be expected in the ED setting because of differences in the underlying health and cooperation of the patient population. While preoxygenation should be maintained for the longest period practical prior to beginning intubation, the ideal situation and circumstances are not always present, and clinical judgment is the deciding factor for this portion of RSI.

During the period of preoxygenation, the airway should be assessed to determine the likelihood of a difficult intubation while establishing an intravenous (IV) line, placing the patient on cardiac and pulse oximetry monitors and assembling all necessary equipment for oral intubation and potentially cricothyrotomy. A defasciculating dose of a non-depolarizing neuromuscular blocking agent is commonly recommended 2 to 3 minutes prior to administration of succinylcholine, although the advantages of this time-consuming step are poorly documented and generally overstated. General anesthesia is then rapidly induced with one of the agents discussed later in this section, followed immediately by muscle paralysis with succinylcholine at a dose of 1.5 to 2.0 mg/kg. Cricoid pressure is applied by an assistant as consciousness is lost. After the onset of adequate relaxation, orotracheal intubation is performed, and correct tube placement is verified. Cricoid pressure can then be released and ventilation with 100% oxygen begun. Mask ventilation prior to intubation is unnecessary if adequate preoxygenation occurs. In fact, mask ventilation should be avoided because of potential gastric distention and passive regurgitation. Mask ventilation should be used only if adequate oxygenation cannot be ensured and then should be performed gently in association with cricoid pressure. If a first intubation attempt is unsuccessful, bag-mask ventilation with cricoid pressure may temporize until a repeat orotracheal attempt or an alternative approach to intubation is made. In the event of failure to expeditiously accomplish orotracheal intubation, cricothyrotomy generally should be performed in order to secure the airway. The protocol for ED-based RSI is described in Table 5-1 .

Endotracheal intubation and RSI have also expanded beyond the ED into the prehospital setting. Using an RSI protocol of a sedative plus paralytic for non-cardiac arrest patients, success rates at intubation in the field have ranged from 92% to 98%, [3] [14] [15] [16] which is similar to rates achieved in the ED.[15] As in the ED setting, without a full complement of medications, prehospital intubation becomes significantly more difficult with success rates dropping to approximately 60%[14] [17] largely due to patient combativeness, preexisting muscle tone, and intact airway protective reflexes.

The impact of prehospital intubation on outcome remains controversial. Gausche and colleagues compared prehospital bag-mask ventilation and endotracheal intubation for critically ill and injured pediatric patients. [17] Their protocol did not include the use of sedatives or paralytics and had a 57% intubation success rate. A total of 820 subjects were analyzed for survival and neurologic outcome. The two groups were statistically equivalent (26% to 30% survival with 20% to 33% of those having a good neurologic outcome). Rates of vomiting, aspiration, and airway trauma were likewise similar. This study was performed in an urban environment with short Emergency Medical Service (EMS) transport times, which may limit its generalizability. Nonetheless, it has raised important and as yet unanswered questions

TABLE 5-1 -- Rapid-Sequence Induction Protocol

1. Preoxygenate (denitrogenize) the lungs by providing 100% oxygen by mask. If ventilatory assistance is necessary, bag gently while applying cricoid pressure.
2. Assemble required equipment:
• Bag-valve-mask connected to an oxygen delivery system
• Suction with Yankauer tip
• Endotracheal tube with intact cuff, stylette, syringe, tape
• Laryngoscope and blades, in working order
• Cricothyrotomy tray
3. Check to be sure that a functioning, secure IV line is in place.
4. Continuously monitor the cardiac rhythm and oxygen saturation.
5. Premedicate as appropriate:
• *Fentanyl:* 2 to 3 µg/kg given at a rate of 1 to 2 µg/kg/min IV for analgesia in awake patients
• *Atropine:* 0.01 mg/kg IV push for children or adolescents (minimum dose of 0.1 mg recommended)
• *Lidocaine:* 1.5 to 2 mg/kg IV over 30 to 60 seconds
6. Induce anesthesia with one of the following agents administered intravenously: thiopental, methohexital, fentanyl, ketamine, etomidate, or propofol. Apply cricoid pressure.
7. Give succinylcholine 1.5 mg/kg IV push (use 2 mg/kg for infants and small children).
8. Apnea, jaw relaxation, and/or decreased resistance to bag/mask ventilations (use only when pre-RSI oxygenation cannot be optimized by spontaneous ventilation) indicate that the patient is sufficiently relaxed to proceed with intubation.
9. Perform endotracheal intubation. If unable to intubate during the first 20-second attempt, stop and ventilate the patient with the bag-mask for 30 to 60 seconds. Follow pulse oxymetry readings as a guide.
10. Treat bradycardia occurring during intubation with atropine 0.5 mg IV push (smaller dose for children; see item 5).
11. Once intubation is completed, inflate the cuff and confirm endotracheal tube placement by auscultating for bilateral breath sounds and checking pulse oxymetry and capnography readings.
12. Release cricoid pressure and secure endotracheal tube.

about the necessity of prehospital endotracheal intubation if the airway is able to be adequately managed by other means.

In contrast, Winchell and Hoyt, in a retrospective review of 1092 blunt trauma patients with a Glasgow Coma Scale (GCS) score of less than 9, showed that prehospital intubation reduced mortality from 36% to 26% with the impact most pronounced among the most severely injured. [18] As with the previous study, this one also evaluated orotracheal intubation without any pharmacologic adjunct with 66% of subjects able to be intubated in the field.

Bochicchio and colleagues compared brain-injured patient outcomes in patients with and without prehospital RSI. [18A] They found that patients receiving prehospital intubation versus those intubated at the hospital had a higher mortality rate and more ventilator days. Although the equivalence of the patient groups upon paramedic arrival is unknown, this study does suggest that prehospital RSI and intubation may adversely affect outcomes. Further prospective evaluation with evaluation of prehospital physiology and notation of preexisting aspiration will be required for resolution of this prehospital controversy.

The two general types of drugs used most commonly as part of RSI protocols are anesthetic agents and neuromuscular blocking agents. These are discussed in greater detail in the following section.

ANESTHETIC AGENTS

A number of diverse drugs are routinely used in the ED to induce anesthesia prior to intubation. These include thiopental, methohexital, ketamine, etomidate, and propofol. Midazolam and fentanyl may also be used, but these two agents are more commonly used at low doses to facilitate procedural sedation (see Chapter 34). The choice of a particular anesthetic agent depends to a great extent on the experience and training of the clinician, patient hemodynamic factors, and to a certain extent on institutional protocols governing use of these agents. Drugs commonly used and their doses are listed in Table 5-2 .

Barbiturates: Thiopental and Methohexital

The barbiturates, particularly thiopental, have been the traditional agents used for RSI in the OR. These agents are used less often in the ED setting because of their reputation as cardiorespiratory depressants. Of these two agents, methohexital is used more commonly in the ED because of its extremely rapid onset and short duration of action.

Pharmacology

Following IV injection, the ultrashort-acting barbiturates bind rapidly to plasma proteins, particularly albumin. Unbound

TABLE 5-2 -- Recommended Anesthetic Doses for Rapid-Sequence Induction

Drug*	Dose
Thiopental	3–5 mg/kg IV
Methohexital	1–3 mg/kg IV
Fentanyl	5–15 µg/kg IV
Ketamine	1–2 mg/kg IV
Etomidate	0.3 mg/kg IV
Propofol	2 mg/kg IV

*Any one of these can be used before the administration of a neuromuscular blocking agent to induce anesthesia (see text).

barbiturate quickly accumulates in highly vascular organs, reaching peak brain levels in as short a time as 50 seconds. The drugs then diffuse from the brain, ultimately reaching equilibrium between the intracerebral and plasma concentrations. Degradation occurs primarily in the liver, producing inactive metabolites that are excreted in the urine or gut, depending on the drug used. Single-pass hepatic clearance is substantially higher for methohexital than for thiopental, which accounts for the former drug's shorter duration of action. The period of anesthesia following a single IV dose of methohexital is 4 to 6 minutes, compared with 5 to 10 minutes for thiopental. [19] [20]

Barbiturates are central nervous system (CNS) depressants that are capable of producing mild sedation to deep coma. They do not block afferent sensory impulses to a significant extent and therefore should be used in conjunction with an analgesic agent such as fentanyl if a painful procedure is to be performed. However, it is common practice to intubate patients who have received only barbiturates. [20]

The advantages of barbiturates as adjuncts to intubation include their high potency, rapid onset, and short duration of action, traits they share with fentanyl and midazolam. The barbiturates are also known to reduce cerebral metabolism and oxygen consumption and, secondarily, cerebral blood flow and intracranial pressure (ICP). [21] [22] For this reason, thiopental is considered the agent of choice for anesthesia induction and maintenance in patients with elevated ICP. Some have stated that thiopental is the drug of choice to temporarily anesthetize the hypertensive patient with a head injury before intubation. It has not been proved, however, that barbiturates exert a protective effect on the CNS when used for a short period of time during RSI. Moreover, their use in trauma patients may lead to systemic hypotension and impaired cerebral perfusion pressure that may offset the theoretic advantages of barbiturate therapy.

Dose

The recommended dose of thiopental is 3 to 5 mg/kg intravenously administered as a 2.5% solution over 60 seconds. Normal saline should be used as a diluent. Methohexital is given at 1 to 3 mg/kg intravenously over 30 to 60 seconds.

Adverse Effects

It has been stated that barbiturates are "fatally easy" to use. [20] This is an overstatement that reflects improper use of the drugs more than an inherent danger associated with their proper use. The most significant complication of barbiturate therapy is depression of the vasomotor center and myocardial contractility leading to significant hypotension. One study showed an average decrease in mean arterial pressures during RSI with thiopental to be 40 mm Hg. [23] This may be particularly pronounced in the presence of hypovolemia or cardiovascular disease.

Barbiturates also depress the brainstem respiratory centers when given rapidly or in large doses. This effect may be accelerated by simultaneous treatment with opioids. Patients with asthma or chronic bronchitis may experience bronchospasm. Laryngospasm may occur in patients who were anesthetized lightly with barbiturates during manipulation of the upper airway. Laryngospasm usually responds to positive-pressure ventilation or paralysis with succinylcholine. In addition, the high pH of the barbiturate solution can cause tissue necrosis following extravascular administration and severe pain, vessel spasm, and thrombosis following intra-arterial infusion.

Etomidate

Etomidate is an ultrashort-acting nonbarbiturate hypnotic agent that has been used successfully as an anesthesia induction agent in Europe since the mid-1970s and in the United States since 1983. Only recently has it been used as an adjunct to intubation in the ED. A potentially significant benefit of etomidate in the emergency setting is its lack of cardiode-pressant effects. [24] [25] Several smaller, case series have now demonstrated its safe and effective use in ED RSI, [26] [27] [28] [29] [30] and extensive experience exists with its use in anesthesia induction for both pediatric and adult patients.

Pharmacology

Etomidate is a carboxylated imidazole that is both water- and lipid-soluble. The drug rapidly accumulates in vascular organs, reaching peak brain concentrations within 1 minute of IV infusion. [31] Sleep is produced within 1 arm-brain circulation time and lasts less than 10 minutes following a single bolus infusion. [32] Redistribution of the drug is quite rapid (distribution half-life, 2.6 minutes), which accounts for the short duration of action. Etomidate is rapidly hydrolyzed in the liver and plasma,

forming an inactive metabolite excreted primarily in the urine. [31]

Etomidate acts on the CNS to stimulate ?-aminobutyric acid receptors and depress the reticular activating system. After IV infusion, etomidate produces electroencephalographic (EEG) changes similar to those produced by barbiturates as patients pass rapidly through light to deep levels of surgical anesthesia. Because etomidate has no analgesic activity, [31] it should be used in conjunction with an analgesic such as fentanyl when painful conditions are being treated; although, as with barbiturates, it is commonly used as a sole sedative agent for intubation. Etomidate decreases cerebral oxygen consumption, cerebral blood flow, and ICP but appears to have minimal effects on cerebral perfusion pressure. [33] At therapeutic doses, etomidate is characterized by hemodynamic stability without significant changes in mean arterial pressures, [25] [26] [29] although a slightly increased heart rate may be observed. [34]

Dose

The recommended dose is 0.3 mg/kg intravenously. There is virtually no accumulation of the drug, and anesthesia may be maintained through repeated or continuous dosing.[35]

Adverse Effects

The most common side effects of etomidate are nausea and vomiting, pain on injection, and myoclonic jerks. [36] Pain on

injection occurs in up to two thirds of cases. Use of a large vein, simultaneous saline infusion, and opioid premedication are reported to reduce this side effect. [37] Myoclonic activity has been reported in about one third of cases and is believed to be caused by disinhibition of subcortical activity rather than CNS stimulation. Furthermore, myoclonic activity does not represent seizure activity. [31] However, myoclonic jerks may be misinterpreted as seizure activity.

Since first reported in the early 1980s, prolonged infusions of etomidate have been associated with suppression of adrenal function. When used for sedation over periods of days, the drug is linked with increased mortality in critically ill and injured patients presumably due to insufficient cortisol production. [38] [39] Suppression of adrenal function is due to competitive enzyme inhibition by etomidate during the cortisol biosynthesis pathway. Several small case control studies have attempted to examine the impact of singles doses of etomidate on adrenal function. These have shown some degree of altered function that may persist for up to 12 to 24 hours after even a single dose. However, as yet, no evidence exists to suggest that this is clinically significant. [28] [30] [40]

Ketamine

Pharmacology

Unique among anesthetic agents currently in use, ketamine produces a dissociative anesthesia characterized by excellent analgesia and amnesia despite the appearance of wakefulness. As a drug that is potent and relatively safe and possesses a rapid onset and brief duration of action, ketamine fits the profile of a drug that could be used effectively to facilitate intubation. It does, however, possess a number of pharmacologic properties that limit its use to selected circumstances.

Ketamine is a water- and lipid-soluble drug with rapid penetration into the CNS. Like the barbiturates, ketamine accumulates rapidly in highly vascular organs and then undergoes redistribution. The half-life of redistribution from plasma to peripheral tissues is 7 to 11 minutes, and the half-life of elimination is 2 to 3 hours. Degradation occurs primarily in the liver. [41]

Unlike other anesthetic agents that depress the reticular activating system, ketamine acts by interrupting association pathways between the thalamocortical and limbic systems. Characteristically, the eyes remain open, and patients exhibit spontaneous, although not purposeful, movements. Increases in blood pressure, heart rate, cardiac output, and myocardial oxygen consumption are seen—effects that are most likely mediated through the CNS. In vitro studies indicate that ketamine is a myocardial depressant, but the CNS-mediated pressor effects generally mask the direct cardiac effects. [42] [43] Respirations are initially rapid and shallow after ketamine administration, but they soon return to normal.

Other features of ketamine anesthesia include increased skeletal muscle tone, preservation of laryngeal and pharyngeal reflexes, hypersalivation, and relaxation of bronchial smooth muscle. ICP is increased, most likely as a consequence of increased cerebral blood flow. [41]

Ketamine has been recommended for anesthesia induction in children because of its relative safety and the infrequency of postanesthesia emergence reactions in this group. There is no evidence, however, that it offers any advantage over commonly used agents. Ketamine also has been recommended for the unstable critically ill patient, because it does not depress the cardiovascular system. [44] [45] This recommendation is too vague to be useful to the clinician, and it ignores the fact that ketamine is potentially harmful in patients with cardiac ischemia (because it can increase myocardial oxygen consumption) or acute intracranial pathology (because it can increase ICP). Ketamine may be useful during hemorrhagic shock because of its cardiostimulatory effect. Its administration to patients in shock has been reported to cause a fall in blood pressure only when the shock state has been prolonged. [46] [47]

The most promising use of ketamine as an intubation adjunct has been in the setting of acute bronchospastic disease. Ketamine relaxes bronchial smooth muscle either directly, through the enhancement of sympathomimetic effects, or through the inhibition of vagal effects. Ketamine is commonly considered as an adjunct to intubation in the decompensated asthmatic patient, and the intramuscular (IM) route may be considered if IV access is impossible. Ketamine also increases bronchial secretions, which may decrease the incidence of mucous plugging commonly reported in autopsies of asthmatic patients. [48] Clinical studies have demonstrated a reduction in airway resistance and an increase in pulmonary compliance that occur within minutes of ketamine administration. [49] [50] L'Hommedieu and Arens[9] reported prompt improvement in respiratory acidosis in five asthmatics intubated with ketamine and succinylcholine.

Dose

The recommended dose of ketamine before intubation is 1 to 2 mg/kg administered intravenously over 1 minute. Anesthesia occurs within 1 minute of completing the infusion and lasts 5 to 10 minutes. A small dose (0.5 to 1 mg/kg) may be given 5 minutes after the initial dose if there is a need to maintain anesthesia. The simultaneous administration of succinylcholine and midazolam is recommended to provide adequate muscle relaxation and to decrease the incidence of postanesthesia emergence reactions, respectively. The IM dose for intubation has not been well studied, but a suggested dose is 4 mg/kg. Onset of action occurs within 2 to 3 minutes. The deltoid muscle is theoretically the preferred site because of its good vascularity.

Adverse Effects

A side effect that has greatly limited the use of ketamine is its tendency to produce postanesthesia emergence reactions, a characteristic that it has in common with the structurally similar drug phencyclidine. The reactions may be marked and distressing to the patient; symptoms include floating sensations, dizziness, blurred vision, out-of-body experiences, and vivid dreams or nightmares. The reported incidence of these reactions varies from 5% to 30%. [51] [52] They are less common in children than in adults.

Of the drugs that have been evaluated for their ability to suppress postanesthesia emergence reactions, the benzodiazepines show the most promise. Both diazepam and lorazepam are useful, but the latter is more effective, most likely owing to its enhanced amnestic effect. [53] [54] [55] [56] Midazolam, likewise, is highly effective at doses of 0.07 mg/kg,[57] and may be the preferred agent as it has potent amnestic effects and a short duration of action. White [58] reported a 55% incidence of postemergence dreaming in patients receiving ketamine and complete suppression of dreaming with the addition of midazolam. Evidence also suggests that midazolam may inhibit the cardiostimulatory effects of ketamine.

Although ketamine produces excellent analgesia and is relatively safe, its use as an agent to facilitate intubation is somewhat limited. The widely held belief that aspiration does not occur with ketamine because of preservation of pharyngeal and laryngeal reflexes is incorrect. [55] [60] Moreover, ketamine does not relax skeletal muscle. The production of desired intubation conditions often requires the simultaneous administration of a paralytic agent, thereby removing any upper airway reflexes.

Propofol

ED experience with propofol is limited, and it is uncertain whether it will have a significant role as an adjunct to intubation in this setting.

Pharmacology

Propofol is an alkylphenol sedative-hypnotic recently introduced for induction and maintenance of general anesthesia. The drug has no analgesic activity, but it does have an amnestic effect. It produces dose-dependent depression of consciousness ranging from light sedation to coma. Propofol is a highly lipophilic, water-insoluble compound that undergoes rapid uptake by vascular tissues, including the brain, followed soon afterward by redistribution to the muscle and fat. The drug is metabolized by the liver and excreted in the urine. [61] [62] [63]

Dose

Following an induction dose of 2 mg/kg intravenously, hypnosis occurs within 1 minute and lasts for 5 to 10 minutes. A smaller dose (1 to 1.5 mg/kg) is recommended in the elderly and when simultaneously administering other CNS depressants. Because propofol has a short duration of action and patients rapidly regain consciousness, repeat bolusing is not a practical way to maintain a desired level of anesthesia or sedation. [61] [62] [63] A slow drip infusion of 3 to 5 mg/kg per hour titrated to effect is the preferred technique. Conscious sedation may be achieved using a drip infusion beginning at 6 mg/kg per hour and *decreasing* the rate as the desired level of sedation is obtained. [64] [65]

Adverse Effects

Side effects of propofol include direct myocardial depression causing a moderate fall in blood pressure, particularly in the elderly, in hypovolemic patients, and when administered simultaneously with opioids. Propofol reduces cerebral blood flow and may cause mild CNS excitation activity (e.g., myoclonus, tremors, hiccups) during anesthesia induction. Pain on injection occurs commonly, even when the drug is infused slowly. [61] [62] [63]

NEUROMUSCULAR BLOCKING AGENTS

Overview

Neuromuscular blocking agents (NMBs) are the standard agents used to achieve muscle relaxation for intubation, because they permit complete airway control and greatly simplify visualization of the vocal cords. This is particularly important when intubation must be performed quickly under less than ideal circumstances. Sedatives may be used to provide some muscle relaxation, but this requires that they be administered rapidly and in large doses, risking depression of the cardiovascular system. The combination of a paralytic agent and a sedative or analgesic agent is generally superior to the use of either agent alone. A 1999 report showed an 18% failure-to-intubate rate with sedative alone compared with a 0% failure rate for sedatives plus paralytics. Procedural complication rates such as significant airway trauma and aspiration were also markedly higher in the group receiving sedation only. [66]

The only absolute contraindication to the use of NMBs is the inability to manage the airway once the patient becomes apneic. Although not absolutely contraindicated, it is relatively inhumane to paralyze and intubate an alert patient. A sedative or an analgesic agent should always be administered simultaneously if the patient is able to perceive pain.

Controversy surrounds the use of NMBs to facilitate intubation in the patient who may have a cervical spine injury. Despite claims to the contrary, there is no evidence that orotracheal intubation performed during in-line stabilization, with or without paralysis, is dangerous. Cadaver studies [67] [68] [69] purporting to demonstrate the dangers inherent in this practice simply do not simulate the condition of a living patient accurately. [70] Conversely, no studies prove conclusively that orotracheal intubation following the use of NMBs is a safe practice, but it has been performed for a number of years in ORs without reported detrimental effects, even in patients with unstable cervical spine fractures. [71] [72]

NMBs are classified as either depolarizing or nondepolarizing. Depolarizing agents mimic the action of acetylcholine (ACh), producing a sustained depolarization of the neuromuscular junction during which muscle contraction cannot occur. Nondepolarizing agents competitively block the action of acetylcholine at the neuromuscular junction and prevent depolarization. NMBs in common use and their dosages, onset, and duration of action are listed in Table 5-3 .

Depolarizing Agents

Succinylcholine

Pharmacology.

The standard depolarizing agent currently in use is succinylcholine, which was introduced in 1952. It has a chemical structure similar to that of acetylcholine and is therefore able to depolarize the postjunctional neuromuscular membrane. Administration is followed by a brief period of muscle fasciculation that corresponds to the initial membrane depolarization and muscle fiber activation. Unlike acetylcholine, which is released in minute amounts and hydrolyzed in milliseconds, succinylcholine requires several minutes for significant hydrolysis to occur. During this time, the neuromuscular membrane remains depolarized, but the muscles relax and will not contract again until the neuromuscular end plate and adjacent sarcoplasmic reticulum return to the

TABLE 5-3 -- Commonly Used Neuromuscular Blocking Agents

Agent	Dose (mg/kg)	Onset (min)	Duration (min)
Succinylcholine	1.5	1	3–5
Pancuronium	0.1	2–5	40–60
Vecuronium	0.1	3	30–35
	0.25	1	60–120
Atracurium	0.5	3	25–35
Mivacurium	0.15	2–3	15–20
Rocuronium	1.0	1–1.5	30–110

resting state and are again depolarized. Relaxation proceeds from the small, distal, rapidly moving muscles to the proximal, slowly moving muscles. The diaphragm is one of the last muscles to relax.[73]

Succinylcholine is rapidly hydrolyzed in the serum by the enzyme pseudocholinesterase. Only a small amount ever reaches the neuromuscular junction, and that portion is quickly drawn back into the serum by a concentration gradient produced by serum clearance. The duration of action of a single dose is 3 to 5 minutes. Relaxation may be maintained by repeated IV injections or a constant infusion. Prolonged or repeated use of the drug, however, may enhance its effects at either the vagal or sympathetic ganglia. Vagal stimulation may result in bradycardia and hypotension, as well as other muscarinic effects. These effects may be seen even at normal doses, particularly in children. [74] For this reason atropine pretreatment is recommended in all small children and in adults receiving multiple doses. [75] Prolonged neuromuscular blockade is uncommon but may occur in patients with reduced pseudocholinesterase levels.

Repeat dosing may also produce desensitization blockade in which the neuromuscular membrane returns to the resting state and becomes resistant to further depolarization and succinylcholine. [76] [77] Clinically this is indicated by an unsustained contraction in response to a tetanic stimulus and response to a test dose of edrophonium. [78] In general, there is little need for repeated doses of succinylcholine. If paralysis in excess of 3 to 5 minutes is desired, agents such as vecuronium or pancuronium should be used.

Succinylcholine, despite its many potential side effects, currently is the most frequently used agent for neuromuscular blockers in RSI due to its rapid onset and offset and reliable muscle relaxation characteristics.

Dose.

The recommended dose of succinylcholine is 1 to 1.5 mg/kg given intravenously. It is better to err on the side of too large a dose, thereby guaranteeing complete relaxation and avoiding the need for repeat dosing. Current evidence also suggests that dosage calculations, at least in adolescents, should be based upon actual as opposed to lean body mass due to alterations in both volume of distribution as well as pseudocholinesterase activity. [79] Neonates and infants require a slightly higher dose of succinylcholine (2 mg/kg intravenously), due to their higher volume of distribution. [80] *It is crucial that succinylcholine be administered as a rapid bolus. Slow administration may lead to incomplete relaxation. Use of a rapid 20- to 30-mL saline flush following IV administration may enhance its desired effect.*

Adverse effects.

There are a number of potential adverse effects of succinylcholine use. These include muscle fasciculations and their side effects, hyperkalemia, stimulation of

autonomic ganglia, malignant hyperthermia, prolonged apnea, histamine release, and elevation of ICP.

As noted previously, muscle fasciculations accompany the initial depolarization of the neuromuscular membrane. They may be prevented by preadministration of a subparalytic dose (0.01 mg/kg) of pancuronium or vecuronium. Fasciculations are most prominent in muscular adolescents but are uncommon in children. Their most frequent side effect is deep, aching muscle pain that may last for several days. [81] Fasciculations of the abdominal wall may elevate intragastric pressure and cause regurgitation of stomach contents. This is an uncommon complication that most often follows overzealous bag-mask ventilation before intubation. Distention of the stomach with air and failure to perform the Sellick maneuver (i.e., firm cricoid pressure to occlude the esophagus during airway management procedures) are more likely to cause vomiting than are muscle fasciculations alone. It is also important to note that oropharyngeal manipulation of the non-paralyzed patient is far more likely to cause vomiting than are succinylcholine-induced fasciculations.

Other reported but distinctly uncommon side effects of muscle fasciculations include elevations of intraocular pressure (IOP) and displacement of skeletal fractures or joint dislocations. The clinical significance of a transient rise in IOP in a patient with a penetrating eye injury is unknown. There has never been a reported case of vitreous expulsion occurring during rapid-sequence intubation with succinylcholine, despite its widespread use in open eye surgery. [82] Indeed, paralysis will prevent spontaneous patient motor activity such as coughing or gagging, both of which are associated with a greater risk of vitreous expulsion. The degree of elevation of IOPs with administration of succinylcholine is reported to range from 3 to 8 mm Hg. [34] [83] [84] [85] Blinking alone may raise IOP by 10 to 15 mm Hg, whereas more vigorous activity such as coughing, gagging, or crying may elevate IOPs by up to 70 mm Hg. [34] Although there may be theoretical advantages to using a nondepolarizing agent in patients with penetrating eye injuries, [86] a necessary intubation using succinylcholine should never be delayed or avoided because of this theoretical concern. [87]

The precise mechanism by which succinylcholine causes hyperkalemia is unknown, but it is thought to occur secondary to the asynchronous depolarization of muscle cells and resultant cellular injury. Hyperkalemia is associated with increased extrajunctional muscle acetylcholine receptors that develop secondary to prolonged diseases of the neuromuscular system. Susceptibility may occur within 5 to 7 days and persist indefinitely. Hyperkalemia is not prevented with defasciculating doses of nondepolarizing agents. The elevation in serum potassium may occur in normal patients following standard doses, but is typically clinically inconsequential. Elevations of less than 0.5 mmol/L (mEq/L) are seen following a 1 mg/kg dose. [88] In certain pathologic states the hyperkalemic response may be as much as 5 mmol/L. These conditions include late severe burns, [89] major muscle trauma,[90] spinal cord injury, muscular dystrophy, and other upper motor neuron diseases. [91] [92] These large elevations occur only in patients who have had significant tissue injury or muscle denervation for several days or weeks before succinylcholine use. Succinylcholine is not contraindicated in the acute initial management of patients with these injuries. Succinylcholine is also not contraindicated in normokalemic patients with renal failure as the magnitude of rise in serum potassium is the same as in patients with normally functioning kidneys. [93] A recent retrospective review of succinylcholine use in 38 operative cases with moderate pre-RSI hyperkalemia (5.6 to 7.6 mmol/L) suggests that the risk of hyperkalemia-related complications may be lower than feared. [94] Regardless, succinylcholine is best avoided (given other equally effective pharmacologic options exist) in the setting of known or suspected preexisting hyperkalemia (e.g., renal failure patients not receiving regular dialysis or demonstrating a wide-QRS complex.

Malignant hyperthermia is a rare complication with an autosomal dominant inheritance pattern. It occurs in approximately 1 in 15,000 children and 1 in 50,000 adults. [95]

The clinical syndrome consists of high fever, tachypnea, tachycardia, cardiac arrhythmias, hypoxia, acidosis, myoglobinuria, and impaired coagulation. Unabated muscle contractions mediated by abnormal calcium channels are believed to be the physiologic basis for this condition. [96] Treatment includes aggressive cooling measures (see Chapter 68), volume replacement, and correction of hypoxia and acid-base and electrolyte abnormalities. Dantrolene sodium, a direct-acting skeletal muscle relaxant, has been shown to be effective in reducing the muscle hypermetabolism that causes the fever. [97]

An associated abnormal response to succinylcholine is isolated masseter spasm. [98] Barlow and Isaacs reported two cases in which masseter spasm was the first abnormality noted in fatal episodes of malignant hyperthermia. [99] Masseter spasm may be more common in patients with neuromuscular disorders such as myotonia congenita.

Concern has also been raised over the use of succinylcholine in the pediatric population due to rare case reports of hyperkalemic cardiac arrests following administration to children with undiagnosed myopathies. Succinylcholine is currently recommended for use in pediatrics only under emergency circumstances when the airway must be rapidly secured. [80]

Prolonged apnea may occur because of decreased pseudocholinesterase levels (e.g., in hepatic disease, anemia, renal failure, organophosphate poisoning, pregnancy, chronic cocaine use, advanced age, bronchogenic carcinoma, or connective tissue disorders) or, more commonly, because of the inheritance of an atypical pseudocholinesterase present in about 0.03% of the population. This atypical enzyme has both a decreased affinity for the succinylcholine molecule and a decreased ability to hydrolyze it. The period of apnea is therefore increased from 3 to 5 minutes to up to several hours. Patients with markedly decreased levels of normal cholinesterase experience only a two- to threefold increase in the duration of apnea. [100] Patients with cocaine intoxication may experience prolonged muscle relaxation if given succinylcholine, because cocaine is competitively metabolized by the cholinesterases.

The magnitude and significance of the increase in ICP that occurs with succinylcholine use remain controversial. [101] [102] [103] [104] [105] Increases in the range of 5 to 10 mm Hg have been reported by several investigators, but other researchers have shown no increase, nor is there evidence of neurologic deterioration associated with these transient elevations in ICP. Mechanisms that have been proposed to explain the elevated ICP include (1) a direct effect of fasciculations, (2) an increase in cortical electrical activity with a resultant increase in cerebral blood flow and blood volume, and (3) sympathetic postganglionic stimulation. Minton and colleagues have demonstrated that pretreatment with vecuronium (0.14 mg/kg) reduces the rise in ICP following succinylcholine administration from mean values of 5 mm Hg to 1 mm Hg.[106] It has been postulated that nondepolarizing blockade prevents muscle spindle firing and the increase in cortical activity that may lead to increased ICP. Pretreatment with a nondepolarizing agent may not be practical when intubation must be performed rapidly; furthermore, the dose that has been shown to be effective is itself a paralyzing dose and would obviate the need for succinylcholine. Limited studies have thus far been performed to evaluate the significance of this rise in ICP in a brain-injured human patient population. These have thus far shown no significant change in EEG or ICPs with succinylcholine; however, the small size of the studies limits the ability to draw conclusions about clinical outcomes. [80] [107] [108]

At present, questions concerning the safety of succinylcholine in the setting of acute intracranial pathology do not have clear answers. The drug has been used widely and successfully in this setting, and its continued use is supported by this experience. The very real risk of airway compromise and secondary cerebral insult due to hypoxia from delayed or failed intubation must always be weighed against the uncommon and theoretical harmful effects mentioned earlier.

Nondepolarizing Agents

Nondepolarizing agents act in a competitive manner to block the effects of acetylcholine at the neuromuscular junction. Drugs in this class include pancuronium, atracurium, vecuronium, mivacurium, rocuronium, and *d*-tubocurarine. These drugs, particularly the intermediate-acting agents vecuronium and atracurium, have fewer side effects than succinylcholine and have the potential for reversal. However, they generally have longer onset and duration of action than succinylcholine, making them less attractive choices for rapid intubation. *In most instances, succinylcholine remains the agent of choice to facilitate emergency intubation*, and nondepolarizing agents are indicated to maintain paralysis after intubation. Of note, the new nondepolarizing agent, rocuronium, has an onset of action within 1 to 1.5 minutes, which may permit its use for rapid-sequence intubation when succinylcholine is contraindicated.

Because nondepolarizing agents act competitively, increasing the concentration of acetylcholine may reverse their effects. Cholinesterase inhibitors such as neostigmine or edrophonium may be used, but not until some spontaneous signs of reversal are seen. Thus, the concept of reversal is of limited clinical importance in the ED. When reversal is required, neostigmine 0.02 to 0.04 mg/kg is given by slow IV push. Additional doses of 0.01 to 0.02 mg/kg may be given in 5 minutes if reversal is incomplete, but the total dose should not exceed 5 mg in the adult. Atropine 0.01 mg/kg (with a *minimum* dose of 0.1 mg for children and a maximum dose of 1 mg for adults) should be given concurrently with neostigmine to block its cholinergic effects. [109] [110] [111]

Of the nondepolarizing agents, pancuronium has been used the most widely, but its comparatively slow onset of action, long half-life, and greater incidence of side effects make it less than ideal for ED use. Vecuronium and atracurium are preferable in most instances when a longer duration of paralysis is required.

Pancuronium

Pancuronium is an aminosteroid derivative that is primarily excreted in the urine within 1 hour of IV administration. [111] Classified as a long-acting agent, its onset and duration of action are dose-related.

Dose.

Following the recommended 0.1 mg/kg IV dose, paralysis occurs within 2 to 5 minutes and lasts approximately 60 minutes. Paralysis may be maintained safely by repeated bolus or drip infusion. Because the effects of the drug are cumulative, repeating the original dose significantly lengthens the duration of paralysis.

Adverse effects.

Relatively few adverse effects are associated with the use of pancuronium. Many patients experience an increase in heart rate, blood pressure, and cardiac

output because of the vagolytic effect of the drug. Ventricular tachycardia and severe hypertension have been reported but are quite rare. [112] [113] Pancuronium may cause histamine release that results in bronchospasm or anaphylactic reactions. [114] Prolonged paralysis may also occur, primarily in patients with myasthenia gravis or with significant impairment of renal function. One consensus panel recommends pancuronium for maintaining paralysis, except in patients with cardiac disease or hemodynamic instability.[115] The panel recommended vecuronium for the latter patient groups.

Vecuronium, Atracurium, Mivacurium, and Rocuronium

Vecuronium and atracurium are intermediate-acting agents with an onset of action of about 3 minutes and a duration of action of 30 minutes. Mivacurium has an onset of action of 2 to 3 minutes and a duration of action of 15 to 20 minutes. Rocuronium has an onset of action within 1 to 1.5 minutes and a duration of action of 20 to 75 minutes (longer in geriatric patients). These drugs represent significant advances over pancuronium in that they have minimal cardiovascular effects, cause little histamine release (with the exception of mivacurium), [80] and lack cumulative effects.[116]

Dose.

The recommended doses of vecuronium, atracurium, mivacurium, and rocuronium are listed in Table 5-3 . Use of a larger than recommended dose will hasten the onset of action but greatly prolong the period of paralysis. For example, vecuronium at a dose of 0.25 mg/kg intravenously will cause paralysis in as little as 1 minute, but the period of paralysis will last 1 to 3 hours. [117] [118] Because a rapid onset of action comparable to succinylcholine is achieved at high doses of intermediate-acting agents, they may be used as the sole agents to facilitate intubation, particularly if a long period of paralysis is desired after intubation. However, the use of succinylcholine prior to intubation and an intermediate-acting agent at a normal dose after intubation provides rapid intubating conditions and better control over the duration of paralysis.

Rocuronium, a structural analogue of vecuronium, is emerging as an alternative for RSI when succinylcholine is contraindicated. At doses of 0.6 to 1.2 mg/kg, rocuronium consistently provides good to excellent intubating conditions within 1 minute of administration. The duration of action is dose-dependent ranging from 20 to 75 minutes.[119] [120] OR- and ED-based studies have demonstrated its clinical utility and safety in RSI protocols. [27] [119] [120] [121] [122] [123] [124] [125] Other newer and shorter-acting agents are currently under development and study. One promising agent (rapacuronium) has been withdrawn from the market because of associated bronchospasm.[126]

Paralysis induced by vecuronium or atracurium may be maintained by repeat bolus or drip infusion. Unlike both pancuronium and succinylcholine, there are no side effects specifically related to repeated dosing in the ED. A repeated dose of 0.01 to 0.02 mg/kg of vecuronium will extend the period of paralysis 12 to 15 minutes.

ANALGESIA AND SEDATION

Overview

An alternative to the induction of anesthesia in patients requiring intubation is the use of local anesthetic and sedative agents in the conscious patient. The availability of relatively effective and safe anesthetic agents such as etomidate make this a less attractive alternative than in the past, but clinicians may find maintaining some degree of wakefulness desirable in specific patients. Laryngoscopy in the awake patient has been likened to the "mouth being held open with a wrench." [127] Nasotracheal intubation is also an extremely unpleasant experience. The upper airway is richly innervated by sensory branches of the fifth, seventh, ninth, and tenth cranial nerves. In addition to pain fibers, there are stretch receptors that stimulate coughing and gagging reflexes with even minor airway manipulation. It is therefore essential that adequate analgesia be provided before intubation in all but the most extreme circumstances. Treatment options include topical application of anesthetic agents to the pharyngeal and tracheal mucosa and IV infusion of analgesic or sedative agents.

Local Anesthesia

Local or topical anesthesia techniques may be used in patients who are awake, either in place of—or as a supplement to—IV analgesia or sedation. They are particularly useful as adjuncts to nasotracheal intubation but do not generally provide the degree of analgesia or relaxation desirable for orotracheal intubation. In addition, the time required to achieve good topical anesthesia may limit the usefulness of these techniques in emergency situations.

Topical anesthesia may be achieved by direct application using laryngoscopy, by cricothyroid membrane puncture, or by inhalation of a nebulized anesthetic.

Direct Application Using Laryngoscopy

Achieving anesthesia of the oral and pharyngeal mucosa is a relatively simple procedure using commonly available agents such as 4% lidocaine or benzocaine-tetracaine-butamben-benzalkonium (Cetacaine). Achieving anesthesia of the hypopharynx is more difficult, because optimal results require application of the anesthetic to the epiglottis and vocal cords under direct vision.

This procedure begins with spraying the tongue and pharynx with a topical agent. Note that use of atomization devices which attach to standard syringes (e.g., Mucosal Atomization Device [MAD], Wolfe Tory Medical, Inc., Salt Lake City, UT) can provide effective drug dispersal without a forceful spray. The more forceful pressurized canister sprays commonly provoke a cough reflex. After allowing at least 2 to 3 minutes to permit numbing of the tongue and pharynx, the epiglottis and vocal cords are visualized using a laryngoscope and are sprayed directly with the anesthetic agent. Even if laryngoscopy is not used to facilitate this procedure, it is at best an unpleasant experience. It is also time-consuming because of the inherent delay associated with mucosal absorption of an anesthetic agent. An alternative is percutaneous injection of an anesthetic agent into the trachea at the level of the cricothyroid membrane. [128] [129]

Cricothyroid Membrane Puncture

The cricothyroid membrane is identified in the trapezoidal space between the cricoid and thyroid cartilages. After appropriate skin preparation with an alcohol or povidone-iodine (Betadine) swab, the overlying tissue and membrane are punctured with a 22-gauge needle in the midline and just above the superior border of the cricoid cartilage. Care should

be taken to maintain the needle in the midline at all times to avoid injury to the recurrent laryngeal nerves. The needle should be advanced until air can be aspirated, indicating placement of the tip in the trachea. A volume of 2 mL of 4% lidocaine is then injected rapidly. Alternatively, 3 to 4 mL of 1% or 2% lidocaine, as used for local anesthesia, may be injected if the 4% concentration is not available. Typically this will precipitate a cough, which adequately distributes the anesthetic over the upper trachea, vocal cords, and epiglottis.

Nebulized Anesthesia

This simple and painless technique can be used to facilitate awake intubation when the patient's condition is stable enough to permit a several-minute delay. [130] The anesthetic is delivered using a standard nebulizer and face mask connected to an oxygen source that delivers 4 to 8 L/min. A volume of 4 mL of a 4% lidocaine solution is nebulized over about 5 minutes. Bourke and colleagues reported achieving consistently good topical anesthesia using this technique, although their patients were often premedicated with opioids, sedatives, or both. [131]

Intravenous Analgesia and Sedation

The IV infusion of analgesic or sedative agents either alone or in combination can be used to facilitate relatively painless intubation. Depending on the clinical situation encountered, the doses of these drugs may be titrated to produce alterations of consciousness ranging from light to deep sedation. When used to facilitate orotracheal intubation, these drugs are frequently administered in conjunction with succinylcholine, thus producing a state of complete muscle relaxation, good analgesia, reduced anxiety, and loss of recall for the event. Ideally, drugs used for this purpose are characterized by high potency, rapid onset of action, short half-life, and minimal potential for cardiorespiratory depression.

The most commonly used classes of drugs for sedation prior to intubation are opioids and benzodiazepines. Anesthetic agents previously discussed, in particular the barbiturates, may also be used as sedatives, although in lower doses than required for RSI.

Opioids (Fentanyl)

Although any of several opioids administered IV could be used to induce sedation, only fentanyl will be discussed because it possesses significant advantages over other opioid agents.

Pharmacology.

Fentanyl is a synthetic opioid related to the phenylpiperidine family. Since its introduction in 1968, fentanyl has been used widely in a variety of settings, often replacing meperidine as the agent of choice for rapid short-term analgesia. [132] [133] [134] [135] [136] Its favorable pharmacologic properties include a highly lipophilic nature, rapid serum clearance, high potency, and minimal histamine release. [137] [138] [139] [140] Fentanyl crosses the blood-brain barrier rapidly, producing analgesia in as little as 1 to 2 minutes. Serum levels decline rapidly from peak concentrations because of extensive tissue uptake. [141] [142] Unlike morphine, the brain concentration of fentanyl falls in conjunction with the serum level. The duration of analgesic action is 30 to 40 minutes, although at high doses a second peak of activity may be seen several hours later because of the release of the bound drug from tissue stores. Fentanyl is about 50 to 100 times as potent as morphine. [143] This unique combination of potency and short half-life permits the administration of numerous small doses that can be titrated to the desired clinical effect. Similar to other opioids, fentanyl is competitively reversed with naloxone or nalmefene.

Dose.

The relative safety of fentanyl permits considerable latitude in dosing. When used as a primary anesthetic agent for major surgical procedures, doses ranging from 50 to 100 µg/kg produce minimal side effects.[144] Comparatively tiny doses produce sedation, and 3 to 5 µg/kg, given at a rate of 1 to 2 µg/kg per minute, is generally an effective analgesic dose. More rapid administration will cause greater depression of the level of consciousness. Mostert and coworkers reported successful awake intubation in 99 of 103 patients who were administered an average cumulative dose of 3.7 µg/kg. [137] Most of these patients were able to follow commands, and many recalled the events surrounding the intubation. A small percentage could not be intubated even after receiving 500 µg of fentanyl.

Larger doses, perhaps up to 25 µg/kg, may be needed to produce ideal intubating conditions, although if given rapidly, 10 µg/kg is usually adequate. However, even this lower dose is more likely to produce anesthesia than sedation and it may cause a longer period of unresponsiveness than is desirable. It is preferable to use a low dose of fentanyl (2 to 3 µg/kg) for analgesia combined with a paralytic agent (e.g., succinylcholine) to produce adequate muscle relaxation and a sedative (e.g., midazolam) to reduce anxiety and produce amnesia for the event.

Adverse effects.

Unlike other opioids, fentanyl causes little or no histamine release, and its use is seldom associated with emesis or hypotension. It is probably the safest opioid to use in the hypovolemic patient. Fentanyl also has significantly fewer emetic effects than other opioids. Adverse effects that have been reported with fentanyl are few and primarily follow the rapid IV infusion of very large doses. Like other opioids, fentanyl may cause rigidity of the skeletal musculature, including the chest wall and diaphragm. Typically this occurs with doses in excess of 15 µg/kg, but it has also been reported with doses as low as 10 µg/kg and may be related to too rapid administration.[137] [145] The muscular rigidity may be prevented or treated with standard doses of succinylcholine or naloxone. [146] Grand mal seizures have also been reported but are very uncommon.[147] [148] [149] Chudnofsky and colleagues[8] reported a complication rate of less than 1% in 841 ED patients treated with fentanyl. The most common complication was respiratory depression, and it generally occurred when fentanyl was given in combination with other CNS depressants.

Benzodiazepines (Midazolam)

Pharmacology.

The benzodiazepines are a widely used class of drugs characterized by anxiolytic, hypnotic, sedative, anticonvulsant, muscle relaxant, and amnestic effects. Several of these properties make the benzodiazepines ideal adjuvant agents for intubation, particularly when used in combination with opioids. It is important to remember that benzodiazepines do not have analgesic effects. Although they may produce excellent sedation and impair the patient's memory of an unpleasant experience, they will not prevent the pain associated with intubation. Diazepam has been used widely to facilitate intubation, but its use has been supplanted in recent years. Diazepam has a variable onset of action and a long elimination half-life, and it causes significant infusion site pain and frequently phlebitis when given intravenously.

Midazolam has, to a great extent, replaced diazepam as a preoperative sedative agent. [150] [151] Midazolam is also used widely as an anesthesia induction agent, even in high-risk elderly and cardiac patients. [152] [153] [154] Compared with diazepam, the primary advantages of midazolam include a twofold increase in potency, a shorter half-life, and a lessened potential for cardiorespiratory depression. Midazolam possesses a unique imidazole ring that is stable and water-soluble in an acid medium but highly lipophilic at physiologic pH.

Because it does not require suspension in propylene glycol, midazolam is not a tissue irritant. It causes minimal pain on injection, is rarely associated with phlebitis, and can be given intramuscularly when a very rapid onset of action is not required. The highly lipophilic character of the drug permits rapid accumulation in the CNS with onset of sedation in as little as 1 to 2 minutes. Rapid penetration into fatty tissue coupled with extensive binding to plasma proteins causes a prompt fall in serum levels after IV administration. This may account for the paucity of side effects outside the CNS. The half-life of elimination is 1 to 4 hours and is dependent on release of the drug from adipose tissue and protein-binding sites. The period of sedation following a single IV dose is considerably shorter. Emergence from a 0.15 mg/kg dose occurs in 15 to 20 minutes.[155]

Clinical experience using midazolam for sedation before the performance of surgical and dental procedures or as an adjunctive agent for the induction of anesthesia is considerable. Baker and Gordon reported the use of midazolam to achieve conscious sedation in 400 ambulatory surgery patients. [151] Used in combination with either fentanyl or ketamine, midazolam was considered to be both effective and safe.

Dose.

The recommended dose for moderate sedation with midazolam is 0.05 to 0.1 mg/kg given in 1-mg boluses and not exceeding 2.5 mg over 2 minutes. Doses up to 0.1 mg/kg are often needed to produce good conditions for intubation. All patients receiving midazolam should be monitored closely, and skilled personnel prepared to manage the airway should be present.

Adverse effects.

Although midazolam was initially touted to be free of cardiorespiratory side effects, recent experience suggests that the potential adverse effects of midazolam are quite similar to those of other benzodiazepines. A small increase in heart rate is seen frequently, as is a small decrease in systolic blood pressure. [156] Changes in blood pressure may be exaggerated in the presence of hypovolemia. [157] Cardiac index and coronary artery blood flow are generally not affected. Respiratory depression may occur even at standard doses but most often follows rapid administration of an excessive dose. Respiratory depression is also more likely to occur in debilitated or elderly patients and in those simultaneously receiving opioids. Reports of fatalities soon after midazolam's introduction in the United States prompted changes in the recommendations for its use. These included lowering of the dosage schedule, reduction of the speed of administration, and careful patient monitoring during administration. [158] The effects of midazolam are rapidly reversed by the administration of the benzodiazepine antagonist flumazenil. One case report has also implicated midazolam in the development of laryngospasm, which, as with respiratory depression, responded to treatment with flumazenil. [159]

Limited information is available on the use of midazolam to facilitate ED intubation. Wright and colleagues reported its use in 289 ED patients, 20 of whom were undergoing intubation.[160] The overall complication rate was 1.4%, including 2 cases of hypotension and 2 cases of respiratory depression. In every case, patients had received other drugs in combination with midazolam that may have been responsible for the observed adverse effects. Most patients in their study (71%) also received fentanyl. The midazolam-fentanyl combination readily permits titration to the desired level of sedation, and has a rapid onset and short duration of action. [161] [162] A study by Silivotti and colleagues of various induction agents for endotracheal intubation suggested that use of midazolam alone may be associated with suboptimal intubating conditions and increased difficulty with the performance of endotracheal intubation. [23] In the prehospital setting, hypotension with midazolam was found to be dose related[163] and thus should be used cautiously in patients with hypovolemia or traumatic brain injury, or both.

PREVENTING THE COMPLICATIONS OF INTUBATION

Overview

Numerous reports have highlighted physiologic responses to trachael intubation, and have attempted to define their immediate or long-term adverse effects and to offer interventions to ameliorate potential organ injury. While it is certain that intubation and adjunct medications will alter reflexes, ICP, blood pressure, and pulse rate, and may induce cardiac rhythms disturbances, the actual clinical consequences of these commonly observed changes are largely unknown. Clinical experience suggests that most transient alterations in physiology that occur with ED intubation produce no specific or readily documented long-term sequelae, or are often consequences that cannot be easily monitored or cannot be prevented. The prudent clinician is aware of the potential adverse effects of intubation and is cognizant of potential methods to minimize them. Most importantly, however, it is the careful monitoring of the post intubation milieu that will guide specific interventions. Overzealous attempts to suppress those physiologic responses that normally accompany airway manipulation may be counterproductive and are to be avoided. Although it would be desirable to provide airway control under the best of circumstances and with the least amount of injury to the patient, at this juncture the ideal approach to the physiologic responses to intubation are simply unknown. Most information has been extrapolated from experimental animal models or from the anesthesia experience, but similar issues may not apply to the milieu of the ED experience. The following discussion serves as a general clinical guide to the previous considerations, but at this juncture no specific standard of care can be promulgated.

The Pressor Response

The pressor response to stimulation of the pharynx, larynx, and trachea was first described by King and coworkers in 1951. [164] This reflex, mediated by the sympathetic nervous system, consists of a transient increase in blood pressure and pulse rate. The stretching of the hypopharynx that occurs with laryngoscopy is the most common precipitant of the pressor response, but any manipulation of the upper airway, including

nasotracheal intubation or suction, may elicit a potent response. [165] [166] [167] An increase in plasma catecholamines, including adrenaline and noradrenaline, is found in association with the pressor response. [168] [169]

Considerable variation exists in the magnitude and duration of the pressor response. Studies of young healthy normotensive subjects have shown that an average increase of 20 to 25 mm Hg in mean arterial pressure occurs with laryngoscopy and intubation. [170] [171] [172] [173] [174] The magnitude of the response increases as the duration of the stimulus increases, reaching a peak at 45 seconds. Data from controls in several studies of patients with a broad spectrum of medical problems reveal blood pressure increases ranging from 14 to 48 mm Hg, with an average of about 30 mm Hg. Similarly, the increase in heart rate ranges from 8 to 45 beats/min, with an average of approximately 30 beats/min. Typically these elevations last less than 5 minutes. The magnitude of the pressor response may be increased in hypertensive patients and those with cardiovascular disease, even if the underlying hypertension is adequately controlled before intubation.

In addition to sinus tachycardia, a number of dysrhythmias have been reported following intubation. These are primarily ventricular in origin and include ectopic beats, bigeminy, and, occasionally, short runs of ventricular tachycardia. Bradyarrhythmias have been reported uncommonly. Electrocardiographic changes suggestive of ischemia have been reported, particularly in patients with dramatic increases in blood pressure. [175] [176] In 1977, Fox and colleagues reported two patients, [177] both of whom deteriorated after induction of anesthesia and orotracheal intubation. This report has been widely quoted as evidence that the pressor response should be prevented. However, no studies have reported comparative data and none have established a direct relationship between the response and subsequent clinical deterioration in a large patient population. It is also unclear that attenuation of the pressor response will prevent dysrhythmias or electrocardiographic evidence of ischemia, although intuitively it is prudent to avoid sudden increases in blood pressure in unstable patients with acute cardiac or vascular disease.

Multiple studies have evaluated procedures to pharmacologically block the pressor response. Lidocaine has been the most extensively evaluated, but the results of these studies are inconclusive. [172] [178] [179] [180] [181] Although it appears that lidocaine given at 1.5 to 2 mg/kg may blunt the response, it is not clear that the reductions reported (10 to 15 mm Hg and 20 beats/min) are of any clinical significance. Other drugs, including thiopentone, sodium nitroprusside, labetalol, nitroglycerin, verapamil, nifedipine, clonidine, fentanyl, sufentanil, etomidate, and magnesium have shown variable responses. [182] [183] [184] [185] [186] [187] [188] [189] [190] [191]

Of these drugs, fentanyl may be the most effective. It completely suppresses the pressor response at anesthetic doses of 50 µg/kg, [192] [193] but considerably smaller doses may also be effective. Two studies [171] [173] have shown marked suppression of the response at doses of 5 to 6 µg/kg, although in both studies patients also received 5 mg/kg of thiopental. Fentanyl has also been shown to blunt the pressor response when administered in conjunction with etomidate. [190] The 1998 SHRED study evaluated the pressor response to RSI comparing thiopental, fentanyl, and midazolam as induction agents. [23] Midazolam, which was also associated with the poorest intubating conditions and most attempts required for intubation, showed a mean heart rate increase of 17 beats/min. Thiopental, likely due to its direct myocardial depressant and venodilatory effects, decreased mean arterial pressures by about 40 mm Hg. Fentanyl recipients maintained a relatively neutral hemodynamic profile during intubation. Use of paralytics during intubation did not appear to alter the hemodynamic response associated with each sedative agent. A recent study isolated the effect of laryngoscopy from the effect of tube passage into the trachea. Adachi and colleagues found that pretreatment with 2 µg/kg of fentanyl could blunt the hemodynamic effects of tracheal tube passage, but not the hemodynamic effects of laryngoscopy. [194]

It is important to note that even those studies demonstrating blunting of the pressor response failed to demonstrate that this provided any real benefit to the patients. It is likely that the pressor response is innocuous in the vast majority of patients, but it may be exaggerated and potentially harmful in the presence of preexisting hypertension and cardiovascular disease [177] or in patients with other vascular comorbidities such as esophageal varices in whom sudden changes in hemodynamics may be detrimental. [195] In addition, the pressor response may contribute to the rise in ICP that follows laryngoscopy, and therefore it is potentially harmful in patients with intracranial pathology. Administration of lidocaine or fentanyl to blunt the pressor response is appropriate in these subsets of patients.

Intracranial Hypertension

Physical stimulation of the respiratory tract by maneuvers such as laryngoscopy, tracheal intubation, and endotracheal suctioning is commonly associated with a brief rise in ICP. The exact mechanism responsible for this rise in ICP is unknown. One potential mechanism is the coughing and gagging that frequently follows manipulation of the upper airway and subsequent transmission of intrathoracic pressure to the cerebral circulation. An alternative explanation is the catecholamine release that accompanies laryngoscopy, causing a rise in mean arterial pressure and cerebral perfusion pressure. A small rise in ICP has also been reported following administration of succinylcholine. The value of using pretreatment with defasciculating doses of NMBs to prevent ICP rises is unknown. [196]

Although the exact significance of a transient rise in ICP is unknown, it is logical to assume that it may be detrimental in patients with head trauma or intracranial hypertension. A number of drugs including lidocaine, succinylcholine, and the majority of the anesthesia induction agents have been studied to determine whether their use prevents this response. Many of the existing clinical data are not particularly relevant to the ED setting because they are derived from patients in various stages of general anesthesia, often incorporating a wide variety of drug combinations and doses.

Lidocaine may be an effective agent either because it prevents coughing associated with airway manipulation or because it blunts the pressor response and the resultant rise in cerebral perfusion pressure. At a dose of 1.5 mg/kg intravenously, lidocaine suppresses coughing induced by citric acid inhalation [197] and at 2 mg/kg intravenously, it suppresses coughing associated with intubation. [198] However, studies have demonstrated conflicting results regarding lidocaine's ability to suppress the rise in ICP that follows airway manipulation. [198] [199] [200] [201] Optimal results have been demonstrated in paralyzed patients, suggesting that paralysis may be the best

TABLE 5-4 -- Sample Protocol for Intubation for a Head-Injured Adult Patient

1. Preoxygenate with 100% O_2 for 2–3 minutes.
2. Administer 1.5–2 mg/kg lidocaine.
3. Administer 0.01 mg/kg vecuronium (OPTIONAL).
4. Sedate with 3–5 µg/kg fentanyl.
5. Induce anesthesia with 0.3 mg/kg etomidate.
6. Paralyze with 1.5 mg/kg of succinylcholine.
7. Apply cricoid pressure and perform intubation.
8. Maintain postintubation analgesia and sedation.
9. Maintain paralysis if indicated (vecuronium 0.1 mg/kg).

method to suppress coughing and resultant ICP elevations during intubation. [202] Thus, the use of lidocaine to prevent coughing may have a role only when paralysis is not an option. In the paralyzed patient, lidocaine's effectiveness is uncertain, but it may be beneficial in blunting the pressor response and, secondarily, ICP elevations.

There is good evidence that deep general anesthesia prevents the rise in ICP associated with intubation, although depending on the drug used, anesthesia may compromise cardiovascular performance and critically reduce cerebral blood flow. [203] [204] [205] Consequently, the ideal anesthetic agents to facilitate intubation of patients with acute intracranial pathology may be those that have minimal effects on cardiovascular performance such as etomidate or fentanyl. Etomidate has been demonstrated to prevent changes in both cerebral perfusion pressure and ICP following tracheal intubation of patients with space-occupying intracranial lesions. [33]

At the present time, the clinical consequences of intubation-induced physiologic changes are not thoroughly understood, nor is the role of drugs in preventing these changes clear. Despite this lack of data, it may be prudent to attempt to protect patients at theoretic risk. The approach outlined in Table 5-4 is recommended.

CONCLUSION

This chapter has described a number of pharmacologic adjuncts that permit a much more sophisticated approach to intubation of the critically ill patient. As the expertise of clinicians practicing in the acute care setting increases, it is appropriate that they incorporate these adjuncts into their airway management protocols. The agents discussed in this chapter are representative of drugs currently used to facilitate intubation in U.S. EDs.

Chapter 6 - Cricothyrotomy and Translaryngeal Jet Ventilation

Sharon E. Mace
Jerris R. Hedges

Although intubation is the usual method of definitive airway control, clinical situations occur in which intubation is difficult, impossible, or contraindicated. Under these circumstances, cricothyrotomy may be the quickest, easiest, safest, and most effective way to obtain an airway. [1]

Cricothyrotomy is the procedure by which an opening is made in the cricothyroid membrane (Fig. 6-1) to establish an airway. Cricothyrotomy is also known as a laryngostomy, laryngotomy, cricothyrostomy, or coniotomy. *Surgical* cricothyrotomy is the use of a blade to create the opening in the cricothyroid membrane. Once access to the airway is created, oxygen is administered through the opening in the cricothyroid membrane. A needle or small cannula also can be passed percutaneously (i.e., *needle* cricothyrotomy) through

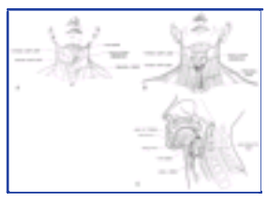

Figure 6-1 Anatomy of the neck. *A*, Surface anatomy of the neck, showing important external landmarks. *B*, Anterior view of the neck, showing various internal structures (overlying superficial skin and structures removed to show cricothyroid membrane). *C*, Lateral view of the neck, showing various structures.

the cricothyroid membrane to permit *translaryngeal jet ventilation*. Cricothyrotomy procedures differ from *tracheostomy,* in which entry into the airway is at a lower point (i.e., between the tracheal rings).

An emergency cricothyrotomy allows oxygenation and prevents hypoxemia and its complications, including anoxic encephalopathy and death. Management of the airway is of paramount importance, because the clinician has only 3 to 5 minutes in which to obtain an airway and achieve effective ventilation to prevent the complications of hypoxemia.[2]

BACKGROUND

The importance of securing an airway has been recognized since ancient times. Egyptian tablets dating from 3600 B.C. depict a surgical tracheostomy. [3] Historical records give credit for the first tracheostomy to Asclepiades of Prusa in 124 B.C. [4] In the 2nd century A.D., Galen suggested tracheostomy as the treatment for emergency management of airway obstruction[5] and Antyllus performed a tracheostomy with an incision between the third and fourth tracheal rings. [6]

In the United States, tracheotomies were a known procedure even in colonial times. In 1796, tracheotomies were advocated as a possible treatment for drowning victims.[7] Perhaps the first recorded "successful" case of a surgical cricothyrotomy was in 1852. The cricothyrotomy was successful, but the patient died later from airway stenosis, a complication of the procedure.[8] In 1886, the tracheostomy

mortality rate was about 50%, with a high complication rate from airway stenosis, which was usually fatal. [9]

Although tracheotomies and cricothyrotomies were successful and life saving, they were generally done only on severely hypoxic, terminally ill patients, thus contributing to the high morbidity and mortality of the surgical procedure. The fear of complications with the surgical procedure led to a reluctance of the clinician to actively intervene until the patient was near death. "Certainly the delay due to this great dread of tracheostomy was itself largely accountable for the fatality attending its performance."[10]

In 1909, Jackson described the surgical technique for tracheostomy and the factors that are critical for successful tracheostomy or cricothyrotomy. [11] These factors, which are still important today, include (1) obtaining the best airway control possible before surgery; (2) using local anesthesia initially rather than sedation or general anesthesia, which can lead to respiratory arrest in patients with an already compromised airway (although sedation and general anesthesia may be acceptable if the patient is already intubated); (3) emphasizing careful, precise surgical technique with good exposure; (4) using an inert, appropriate-sized and shaped tracheostomy tube; and (5) ensuring meticulous postoperative care, which helps avoid contamination or infection and other complications. He noted a surgical mortality of approximately 3%, which is similar to that reported in current series.

Jackson achieved worldwide recognition and patient referrals regarding cricothyrotomy complications. In 1921, Jackson published an investigation of 200 patients referred to him with tracheal stenosis.[12] The study was biased in that patients who did well and had no surgical complications (e.g., no laryngeal stenosis) were not referred to Jackson. Many of the patients had stenosis because of their underlying medical condition and not because of the procedure. Factors relating to surgical technique and postoperative care were not controlled, including aseptic technique, location of the opening in the larynx, and size and type of the tracheostomy tube. Jackson condemned cricothyrotomy because of the complication of subglottic stenosis.

Years later, Brantigan and Grow reported the results of cricothyrotomy on 655 patients. [13] Only 8 patients (0.01%) developed airway stenosis, and none of the patients developed chronic subglottic stenosis. Major vessel hemorrhage and operative misadventures were absent, and the complication rate, which included minor problems, was only 6.1%. The literature supports their conclusions that cricothyrotomy is a safe and effective procedure for airway management with relatively few complications.[14] [15] [16] When examined at bronchoscopy, no signs of laryngeal stenosis or damage have been noted in patients with cricothyrotomy. [17] Animal studies have documented a normal larynx after cricothyrotomy.[18]

ANATOMY

Knowledge of the anatomy of the neck and the upper airway is essential when performing a cricothyrotomy. The essential anatomic landmarks include the hyoid bone, the thyroid cartilage, the cricoid cartilage, and the tracheal rings (see Fig. 6-1).

The hyoid bone is located midway between the mental protuberance of the mandible and the third cervical vertebra. The midpoint of the body of the hyoid is also the transverse midpoint of the neck and can function as an anchor for stabilizing the airway in an edematous neck. The thyroid cartilage and the cricoid cartilage, both part of the larynx, and the tracheal rings are the major supporting structures of the airway. The trachea is the downward continuation of the larynx. Cartilaginous rings that are deficient posteriorly support the trachea. Posteriorly, the trachea lies against the esophagus.

The thyroid cartilage consists of two approximately quadrilateral-shaped laminae of hyaline cartilage that fuse anteriorly to form the laryngeal prominence. This structure calcifies with age. Above the laryngeal prominence is the superior thyroid notch, where the two laminae are separated. The anterior superior edge of the thyroid cartilage, the laryngeal prominence, is known as the Adam's apple and is usually easily seen in men. Except in the infant, the markedly obese patient, or the patient with massive neck edema, the laryngeal prominence of the thyroid cartilage is usually easily recognized and is palpable. It is probably the most important landmark in the neck when performing a cricothyrotomy.

The cricoid cartilage is the only circumferential ring in the larynx. It is shaped like a signet ring with the shield located posteriorly. The cricoid cartilage forms the inferior border of the cricothyroid membrane. The thyroid cartilage forms the superior border of the cricothyroid membrane.

The highly vascular thyroid gland lies over the trachea at the level of the second and third tracheal rings. If the tracheal rings or the thyroid gland is encountered when performing a cricothyrotomy, then the clinician is too low in the neck and must redirect the incision superiorly toward the cricoid and thyroid cartilages. Avoid the thyroid gland, because marked bleeding may occur if it is injured.

The cricothyroid membrane is a dense fibroelastic membrane located between the thyroid cartilage superiorly and the cricoid cartilage inferiorly; the cricothyroideus muscles bound it laterally. The cricothyroid membrane covers an area that is trapezoidal in shape. The average size of the cricothyroid membrane in the adult is approximately 22 to 30 mm wide and 9 to 10 mm high. Palpating a notch, a slight indentation or dip in the skin, inferior to the laryngeal prominence, can identify the cricothyroid membrane. The cricothyroid membrane is located approximately 2 to 3 cm below the laryngeal prominence in an adult.

Several anatomic and physiologic features make the cricothyroid membrane an excellent choice for gaining access to the airway. The membrane is immediately subcutaneous in location. It does not calcify with age. It has no overlying muscles or fascial layers and no major arteries, veins, or nerves are in the region. Although the right and left cricothyroid arteries, branches of the right and left superior thyroid arteries, respectively, transverse the superior part of the cricothyroid membrane (i.e., nearer the thyroid than the cricoid cartilage) and anastomose in the midline, these vessels generally have not been found to be of clinical significance when performing a cricothyrotomy.

Anatomic Variations

The larynx has a few anatomic features that vary according to age and sex. In children, the larynx is much higher than it is in the adult. The larynx descends from approximately the level of the second cervical vertebra at birth to the level of the fifth or sixth cervical vertebra in the adult.

The laryngeal prominence, the angle at which these two laminae of the thyroid cartilage meet anteriorly, varies from

90 to 120°. This angle is smaller in the male, which makes the laryngeal prominence meet at a more acute angle, or a sharper, more prominent point, than in the female.

In infants, the prominent structures in the anterior neck are the hyoid bone and the cricoid cartilage. The laryngeal prominence does not develop until adolescence and young adulthood.

A few vascular anomalies in the neck may result in a major artery crossing the midline of the neck. This is usually not a problem, because these vascular anomalies are almost always located lower in the neck.

SURGICAL CRICOTHYROTOMY

Indications

There are several potential indications for cricothyrotomy (Table 6-1). The most common indication is inability to perform endotracheal intubation because intubation is either contraindicated or cannot be done easily and quickly. This decision is always best made by the clinician at the bedside using clinical judgment to weigh the individual circumstances, resources and expertise. This procedure can be a formidable task in children, and in the struggling hypoxic patient.

Clinical conditions in which endotracheal intubation is difficult at best and is often impossible may include significant bleeding of any of the structures in the upper airway (e.g., massive oral, nasal, or pharyngeal hemorrhage), massive emesis or regurgitation, masseter spasm, clenched

TABLE 6-1 -- Indications for Surgical Cricothyrotomy

Failure of oral or nasal endotracheal intubation
Massive oral, nasal, or pharyngeal hemorrhage
Massive regurgitation or emesis
Masseter spasm
Clenched teeth
Structural deformities of oropharynx, congenital or acquired
Stenosis of upper airway (pharynx or larynx)
Laryngospasm
Mass effect (cancer, tumor, polyp, web, or other mass)
Airway obstruction (partial or complete)
Nontraumatic
Oropharyngeal edema
Laryngospasm
Mass effect (cancer, tumor, polyp, web, or other mass)
Traumatic
Oropharyngeal edema
Foreign body obstruction
Laryngospasm
Obstruction secondary to a mass effect or displacement
Stenosis
Traumatic injuries making oral or nasal endotracheal intubation difficult or potentially hazardous (relative)
Maxillofacial injuries
Cervical spine instability
Need for prolonged intubation
Need for definitive airway during procedures on face, neck, or upper airway
Laryngeal surgery
Oral surgery
Maxillofacial surgery
Laser surgery
Bronchoscopy

teeth, spasm of the larynx or pharynx (or both), laryngeal stenosis, and structural deformities of the upper airway (e.g., congenital or acquired abnormalities or deformities of the oropharynx). Whenever several unsuccessful attempts at endotracheal intubation or a rescue airway procedure cause an inordinate delay in airway control and oxygenation, cricothyrotomy is indicated to prevent cerebral anoxic damage. [19]

Obstruction of the upper airway is another indication for cricothyrotomy. [20] It has been stated that patients who are completely obstructed or in extremis are best managed by establishing an airway via the cricothyroid membrane. [21] When simple airway procedures are unsuccessful, cricothyrotomy should be undertaken without delay.

When maxillofacial, cervical spine, head, or soft tissue neck injuries are present, several factors may prevent intubation. These factors include (1) gross distortion of structures, (2) airway obstruction, (3) disruption of upper airway structures, (4) massive emesis, (5) significant hemorrhage, (6) patient discomfort, and (7) the possibility of aggravating existing or suspected injuries that would result in additional damage. In such patients, cricothyrotomy is an excellent alternative for obtaining definitive control of the airway. [22]

Cricothyrotomy is an option (1) for patients with a known cervical spine injury or a high probability of cervical spine injury in whom definitive airway control is needed before the cervical spine can be assessed and (2) for patients with certain head injuries, especially basilar skull fractures or cribriform plate fractures. Gerling and associates have demonstrated that cricothyrotomy can be done with only 1 to 2 mm of anterior-posterior displacement in an unstable cadaver model. [23] Hence, in trauma patients with known or anticipated cervical spine injury, cricothyrotomy may minimize movement of the neck during airway maneuvers. [24] Alternatively, careful *in-line stabilization of the neck with minimal movement during direct laryngoscopy is a relatively safe alternative during emergent intubation of the trauma patient*. [25] [26] [27]

Cricothyrotomy has several advantages over tracheostomy when prolonged intubation is needed (Table 6-2). [28] [29] Cricothyrotomy has been used for definitive airway control before elective surgery of the face, head, and neck. [30] Translaryngeal jet ventilation has become a routine method of ventilation during procedures (both endoscopy and surgery) on the upper airway. [31] This ventilation technique allows better access to and visualization of the upper airway for the surgeon or endoscopist than is possible with intubation from above the larynx, which often obscures and limits the surgical field. It also decreases the chance of flames or a "miniexplosion," which may occur during laser surgery or during other procedures that require flammable anesthetics or other gases. [32]

Cricothyrotomy vs Tracheostomy

The decreased incidence of complications with cricothyrotomy compared with that of tracheostomy is due at least partly to anatomy. [33] Anatomic considerations make tracheostomy a relatively complicated and difficult procedure. Many delicate complex structures in the neck lie in close proximity to the trachea. Less encroachment on the mediastinum occurs with a cricothyrotomy than with a tracheostomy, because the cricothyroid membrane is farther away from the mediastinum and other critical structures. Early complications, including

TABLE 6-2 -- Advantages of Surgical Cricothyrotomy Over Tracheostomy

Advantages due to anatomic considerations
Immediate subcutaneous location (vs deep dissection)
Absence of critical structures overlying cricothyroid membrane
Easily seen landmarks, recognizable from the surface anatomy
Less chance of esophageal injury (circumferential cricoid cartilage vs deficient tracheal cartilage posteriorly)
Farther away from mediastinum, dome of pleura (less encroachment on thoracic structures)
Overall advantages
Easier to do, faster, safer
Does not need to be done in an operating room
Less need for hyperextension of the neck
Better cosmetic appearance of scar (shorter, less adherent)
Decreased incidence of late complications (e.g., swallowing problems, voice disturbances, fistulas, erosion of innominate artery)
Decreased incidence of early complications (e.g., pneumothorax, pneumomediastinum, mediastinal perforation, esophageal injury) because of less encroachment on the mediastinum and other critical structures
Can be done quickly by nonsurgeons
Requires a minimum of instruments

pneumothorax, pneumomediastinum, and mediastinal perforation, occur less often with cricothyrotomy. Because the tracheal cartilage, unlike the cricoid and thyroid cartilage, is deficient posteriorly, the chance of damage to the posterior structures (e.g., esophagus) lying immediately behind the airway is greater with a tracheostomy. The incidence of late complications, including fistulas, erosion of the innominate vessels, swallowing problems, and voice disturbances, is less with cricothyrotomy.

Cricothyrotomy is preferred over tracheostomy for definitive emergency management of the airway when intubation is impossible or contraindicated. The few exceptions are in children 5 years old or younger (although some recommend needle cricothyrotomy with translaryngeal jet ventilation rather than tracheostomy) and for transection of the trachea with retraction of the distal trachea into the mediastinum.

Contraindications

Cricothyrotomy has relatively few contraindications (Table 6-3). Cricothyrotomy should not be done in patients who can be quickly, easily, and safely intubated. Transection of the trachea with retraction of the distal end is a contraindication to cricothyrotomy. A fractured larynx or other significant damage to the larynx or cricoid cartilage is another contraindication. [34]

Factors shown to be associated with subglottic stenosis include prolonged intubation, underlying laryngeal disease, and younger age (e.g., infants and small children).[35] Some believe that these conditions are relative contraindications to cricothyrotomy and that a cricothyrotomy should be converted immediately to a surgical tracheostomy.[36] Current studies indicate that subglottic stenosis is not a common complication of cricothyrotomy, even in the presence of laryngeal pathology, and that patients can have a cricothyrotomy for months without having subglottic stenosis. These considerations (i.e., prolonged intubation and underlying

TABLE 6-3 -- Contraindications to Surgical Cricothyrotomy

Absolute contraindications
Endotracheal intubation can be accomplished easily and quickly, and no contraindications to endotracheal intubation are present
Transection of trachea with retraction of distal end into the mediastinum
Fractured larynx or significant damage to the cricoid cartilage or larynx
Relative contraindications*
For infants and toddlers (<5 yr) transtracheal ventilation may be preferred over surgical cricothyrotomy
Bleeding diathesis
Patients with massive neck edema (may use modified technique for these patients)
Acute laryngeal disease

*Relative contraindications may be overlooked in the true emergency situation because it is more important to obtain an airway and to avoid hypoxemia.

laryngeal disease) are no longer absolute contraindications to cricothyrotomy.

A bleeding diathesis is not an absolute contraindication to emergency cricothyrotomy, because it is easier to obtain hemostasis with a cricothyrotomy than with a tracheostomy. Cricothyrotomy has been used successfully in patients requiring airway control following thrombolytic administration. [37] Loss of cervical landmarks with massive neck edema makes the procedure more difficult, although one approach using a measured estimation of the cricothyroid membrane location in this setting is promising.[38] These relative contraindications may be overlooked in a true emergency (i.e., when obtaining an airway is imperative).

Equipment

In the out-of-hospital setting, the only essential items are a sharp blade and a hollow tube to maintain the airway. In the emergency department (ED), the optimal instruments needed for surgical cricothyrotomy should be easily accessible. A sterile tray containing all the necessary instruments in an organized fashion should be part of the standard equipment stocked in the major resuscitation area (Table 6-4). Prepackaged percutaneous kits (e.g., Melker Emergency Cricothyrotomy Kit, Cook Critical Care, Bloomington, IN) using a wire-guided approach to aid location of the cricothyroid membrane and thus direct the skin incision are available.

TABLE 6-4 -- Equipment for Surgical Cricothyrotomy Tray

Scalpel with No. 15 blade and scalpel with No. 11 blade
Tracheal dilator (Trousseau dilator) or spreader
Two hemostats
Scissors
Tracheal hook
Needle holder
Tracheostomy tube (appropriate-size Portex or Shiley tubed—No. 5–6 in an adult)
25-ga needle and syringe containing lidocaine with epinephrine (for local anesthesia)
Preparation solution
Sterile gauze pads
Sterile tracheal suction catheter
Suture or circumferential tie (to secure tracheostomy tube in place)

An appropriate-sized tracheostomy tube should be selected (Table 6-5). Secretions obstruct a small tube more easily, whereas a large tube may damage the surrounding cartilage and lead to a fractured larynx. In an adult, a tracheostomy tube with an 8-mm internal diameter (ID), such as a No. 5 Portex or Shiley tube, is usually an appropriate size (see Table 6-5).

If an appropriate-sized tracheostomy tube is not available immediately, an endotracheal tube can be used as is or modified for use as a tracheostomy tube (Fig. 6-2). The uncuffed (proximal) end of the endotracheal tube is cut to an appropriate length (see Fig. 6-2*A*). The adapter is then attached to the cut end (see Fig. 6-2*B*), and the modified endotracheal tube is inserted like any tracheostomy tube. After insertion, the cuff of the endotracheal tube should be inflated, if possible.

The essential supplemental equipment for airway management, specifically supplemental oxygen, suction, and a bag-valve device, should be readily available.

Procedure

Preparation and Positioning

In a truly emergent situation, rapid airway access is critical, and there may not be enough time even for local anesthesia. Because of the dangers of respiratory depression in a patient who may have a compromised airway already, sedation and general anesthesia may be contraindicated. Ketamine is a potential alternative for some struggling patients whose agitation hampers the procedure.

The patient is positioned to expose the neck and its landmarks. If there are no contraindications, such as known or suspected cervical spine injury, the *patient's head should be hyperextended. Extension of the neck aids identification of the anatomy and control of the cricoid space*.

The cricothyroid membrane is located by identifying the dip or notch in the neck below the laryngeal prominence. The cricothyroid membrane is bounded by the thyroid cartilage superiorly and the cricoid cartilage inferiorly. The landmarks are most easily found by placing the index finger on the prominence of the thyroid cartilage and slowly palpating downward until the finger "drops off" the thyroid cartilage

TABLE 6-5 -- Tracheostomy Tube Sizes

Age	Internal Diameter of Tracheostomy Tube (mm)	Holinger or Magill Tube Size	Internal Diameter of Endotracheal Tube (mm)
Premature (<1.8 kg; <4 lb)		000	2.5
Premature (=1.8 kg; =4 lb)		00	2.5
Newborn	2.5	00 or 0	3.0
0–6 mo	3.5	0	3.5
6–12 mo	4.0–4.5	1	4.0
1 yr	4.5–5.0	1 or 2	4.5
2 yr	5.0	2	5.0
4 yr	5.5	3	5.5
6 yr	6.0	4	6.0
8 yr	6.5	4	6.5
10 yr	7.0	4	7.0
12 yr	7.5	5	7.5
14 yr	8.0	5	7.5
Adult female	8.0–8.5	5	7.5–8.5
Adult male	8.5–9.5	6	8.0–9.0

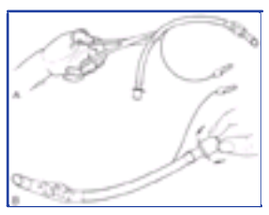

Figure 6-2 Modification of an endotracheal tube for use as a tracheostomy tube. *A*, An appropriate-sized endotracheal tube is cut to an appropriate length. *B*, An adapter is attached to the cut end before the modified endotracheal tube is inserted into the larynx via the opening in the cricothyroid membrane.

and onto the cricoid membrane (Fig. 6-3*A*). When the tip of the finger is in the proper position, the hard cricoid cartilage may be palpated with the fat pad of the index finger. If time permits, local anesthesia and skin preparation with povidone-iodine may be used. The skin and subcutaneous tissue immediately above the cricothyroid membrane may be infiltrated using lidocaine with epinephrine.

Incision and Tube Placement

A skin incision is made over the cricoid membrane. A midline longitudinal (vertical) skin incision about 3 to 4 cm long is made for an emergency cricothyrotomy. For an elective cricothyrotomy, a more cosmetic 2-cm transverse (horizontal) skin incision can be made. A longitudinal skin incision is preferred during an emergency,

because if the skin incision is too high or too low, a longitudinal skin incision merely needs to be extended, thus saving time and avoiding a second incision. As an option, one can insert a 20- to 22-ga needle through the cricothyroid membrane and confirm intra-airway positioning by aspirating air. The needle can be left in place to serve as a guide for the surgical procedure and then removed before insertion of the tracheostomy tube. Commercial kits containing guidewires for this approach are available and in cadaver models have resulted in smaller, more accurate skin incisions. [39]

The larynx is stabilized by holding it between the nondominant thumb and middle finger or by using a tracheal hook. After the skin incision, a short horizontal (transverse) stabbing incision about 1 cm long is made in the lower part of the cricothyroid membrane (i.e., nearer the cricoid cartilage than the thyroid cartilage to avoid the cricothyroid arteries). The stabbing incision is made in such a way that only the tip of the scalpel blade enters the trachea (see Fig. 6-3).

Curved Mayo scissors are inserted beside the scalpel blade and then spread horizontally to widen the space. An alternative method is to widen the opening by using a scalpel handle and turning the scalpel 90° ("longitudinally" with respect to the patient) instead of using curved Mayo scissors. The scalpel handle then is removed and a tracheal (Trousseau) dilator or curved hemostat is inserted into the incision site in

Figure 6-3 The procedure for surgical cricothyrotomy. *A*, Locate the cricothyroid membrane. The insert shows further anatomic details of the region. *B*, A longitudinal skin incision is made over the cricothyroid membrane. *C*, The larynx is stabilized with the thumb and middle finger or a tracheal hook (held in the nondominant hand) while an incision is made in the cricothyroid membrane. *D*, The surrounding anatomy of the neck is shown, with the incision being made in the cricothyroid membrane. *E*, After the incision in the cricothyroid membrane is widened using hemostats, curved Mayo scissors, or the blunt end of the scalpel, the tracheostomy tube is inserted between the curved hemostats or tracheal dilator. *F*, Lateral view, showing insertion of the tracheostomy tube.

the cricothyroid membrane. The dilator is then opened to enlarge the opening in the cricothyroid membrane.

When attempting to insert the tracheostomy tube, the larynx may be displaced posteriorly. Posterior displacement of the larynx may make it difficult or impossible to insert the tracheostomy tube. Stabilization of the larynx (preferably with a tracheal hook) is important to lift and hold the larynx anteriorly in proper anatomic position so that this potential problem can be avoided. The tracheostomy tube is inserted between the tracheal dilator blades. Alternatively, curved hemostat blades may be used (see Fig. 6-3*E*). The dilator or hemostat is then removed. The cuff of the tracheostomy tube is inflated. One cadaver study suggests that insertion of the tracheostomy tube during use of the tracheal dilator limits tube passage more than when the tracheal hook alone is used for laryngeal stabilization. [40]

An alternative to use of the tracheal hook for stabilization of the trachea indirectly by elevation of the larynx has been described by Brofeldt and colleagues. [41] In their technique, the tracheal hook is placed in the opposite direction (i.e., aligned caudally rather than cephalically) to allow elevation of the cricoid ring and overlying structures. The operator stands to the left of the patient's neck and faces the patient's thorax as if performing an oral endotracheal intubation. Using this technique, Brofeldt and colleagues have advocated a rapid, four-step approach composed of (1) palpation of the cricoid membrane using external landmarks, (2) horizontal stab through skin and cricothyroid membrane together using a No. 20 scalpel, (3) tracheal hook traction applied caudally at the cricoid cartilage, and (4) intubation (Fig. 6-4). A further modification of the technique using a "Bair Claw" device (Fig. 6-5) rather than a tracheal hook to stabilize the cricoid ring has been found to reduce the time to procedural completion by 18 seconds. [42]

In an adult, a No. 5 or 6 Shiley tracheostomy tube is usually an appropriate size (No. 5 for an adult female and No. 6 for an adult male). If edema is present, a smaller (No. 4) Shiley tube may be used. Other tube size guidelines are provided in Table 6-5 .

If a tracheostomy tube is not available immediately, then an endotracheal tube can be used as a temporary airway device. The endotracheal tube can be replaced later when an appropriate-sized tracheostomy tube is available.

The lungs are ventilated, and proper tube placement should be ensured. The tracheostomy tube is secured in place via a circumferential tie around the neck or by suturing. After confirming proper tube placement, the tracheostomy tube may be attached to a ventilator or a bag-valve device. Flexible connector tubing is recommended to avoid excessive forces on the tracheal wall during mechanical ventilation.

Precautions

The skin incision and the incision in the cricothyroid membrane should not be made too far laterally (see Fig. 6-1 and Fig. 6-3*A*). A central incision will decrease the chance of hemorrhage due to laceration of vessels. The skin incision should not be made too far caudally in the neck, thus avoiding hemorrhage from and damage to the thyroid gland.

The stabbing incision should be made in the lower half of the cricothyroid membrane (i.e., nearer the cricoid cartilage than the thyroid cartilage) in an attempt to avoid bleeding from the cricothyroid arteries, which course superiorly across the cricothyroid membrane near the lower edge of the thyroid cartilage.

Transection of the cricoid cartilage or tracheal rings should be avoided. These structures help maintain the stability of the laryngeal lumen. Injury to these structures may predispose to late complications, including subglottic stenosis.

The scalpel should be directed in a caudal direction, so that injury to the vocal cords is avoided. The vocal cords are located above the cricothyroid membrane and are protected by the thyroid cartilage on three sides. When a cricothyrotomy is being done, the needle or scalpel should be directed posteriorly at a 90° angle to the cricothyroid membrane (see Fig. 6-3).

The clinician should avoid making a blind stab with the scalpel in the region. Controlled, anatomically placed incisions will minimize hemorrhage and injury to any of the adjacent structures.

The handle of the scalpel should be held in such a way that only the tip of the scalpel blade can enter the trachea during the stab incision through the cricothyroid membrane. For control, the clinician should place the thumb and index finger low on the handle of the scalpel (just above the scalpel blade). A controlled stab incision should help avoid injury to the posterior wall of the trachea, esophagus, and other posterior structures by limiting the depth of scalpel insertion.

Placement of too large a tracheostomy tube through the cricothyroid membrane should be avoided. Placement of an oversized tracheostomy tube can lead to a fractured larynx.[26] In the adult, the average size of the cricothyroid membrane is about 2 to 3 cm wide and 1 cm high. Thus, the appropriate tracheostomy tube in an adult is one with an 8- to 9-mm internal diameter (a No. 5 in an adult female and a No. 6 in an adult male) unless edema is present, in which case a smaller size (No. 4) is used.

The Patient with Massive Neck Swelling

One method of surgical cricothyrotomy uses the hyoid bone as a landmark and an anchor to stabilize the mobile airway in a patient with massive neck edema. [43] [44] The horizontal midpoint of the body of the hyoid is also the midpoint of the neck. The key measurement in this technique is distance from the angle of the mandible to

the mental protuberance of the chin (line *A'* on Fig. 6-6). Distances can be measured using a piece of suture or a string. This distance from the angle of the mandible to the mentum is divided in half.

A point is identified on the anterior midline of the neck below the chin (point *C*), which equals line *B'* or one half the length of line *A'* (see Fig. 6-6). A needle is placed at a point *C* and directed toward the midline so that it will reach an imaginary line connecting both angles of the mandible. The tip of the needle should hit the hyoid bone. A large-bore (e.g., 18-ga spinal needle) should be used, as the needle must be long enough to pass through massive neck swelling and hit the hyoid bone. If the hyoid bone is not found, the angle of the needle should be adjusted.

When the hyoid bone is found, the needle is left in position, and a No. 11 blade is inserted along the needle tract until the hyoid bone is reached. A skin hook is placed alongside the scalpel's tract and under the hyoid bone to retract the hyoid superiorly and anteriorly. A longitudinal skin incision is made inferiorly from the skin hook with care taken to stay in the midline. The hyoid bone acts as a fulcrum, holding and stabilizing the larynx in position, so that the incision will stay in the midline despite massive swelling of the neck. The incision

Figure 6-4 Rapid, four-step cricothyrotomy technique. *A,* Step 1: Palpation (location of cricoid membrane externally). *B,* Step 2: Incision (horizontal incision of skin and soft tissues through cricoid membrane). *C,* Step 3: Traction (caudal traction on cricoid ring). *D,* Step 4: Intubation (passage of tracheal tube). *(Reproduced from Brofeldt BT, Panacek EA, Richards JR. An easy cricothyrotomy approach: the rapid four-step technique. Acad Emerg Med 3:1060, 1996.)*

is extended caudally over the thyroid cartilage until the cricothyroid membrane is exposed. The remainder of the procedure follows the routine steps for cricothyrotomy.

The only additional supplies needed for this modification of cricothyrotomy in patients with massive neck edema are the suture (or string) to measure the distance from the angle of the mandible to the mentum of the chin and an 18-ga spinal needle to find the hyoid bone.

Infants and Children

Cricothyrotomy, as with tracheostomy, is technically much more difficult in infants and children than in adults and may have a higher rate of problems or complications. Because the laryngeal prominence is not well developed until adolescence and young adulthood, the most prominent structures in the anterior neck of the infant or child are the hyoid bone and the cricoid cartilage. In children younger than 5 years old, the cricoid is the narrowest part of the airway, and the cricothyroid membrane is quite small. Furthermore, the larynx is higher, relatively less accessible, and smaller in the child than in the adult.

Some advocate tracheostomy rather than cricothyrotomy in infants and children (when endotracheal intubation is contraindicated or impossible), because of the difficulty in palpating and identifying the important landmarks of the neck, and because of the small diameter of the cricoid cartilage. Others note that emergency surgical cricothyrotomy has fewer complications than emergency tracheostomy in infants and children. It has been suggested that a cricothyrotomy be converted to a tracheostomy when the infant or child is stabilized, to reduce the possibility of subglottic stenosis.

Complications

The incidence of complications for an elective surgical cricothyrotomy is approximately 6% to 8%. The complication rate for an emergency cricothyrotomy ranges from 9% to 31%.[45] [46] The complication rate for emergency cricothyrotomy compares favorably with that for tracheostomy, which has an average complication rate of approximately 45%.[47] The mortality rate for cricothyrotomy of 0.15% is less than that for tracheostomy, which is 1.6% to 5.0% and as high as 16% in one series. [48] [49] [50] In general, there has been a higher incidence of complications with cricothyrotomy in infants and children than in adults. This is also true for tracheostomy. Tumor, inflammation, other masses, certain congenital anomalies, and significant trauma may distort the anatomic features of the neck and airway, creating additional difficulty in performing a cricothyrotomy and increasing the complication rate for this procedure.

Minor complications are more common than serious complications (Table 6-6). Early complications are more

Figure 6-5 "Bair Claw" device. *A,* Device shown without scalpel. During the tracheal tube intubation procedure, the device is used as a caudally directed tracheal hook with slight spreading of the arms of the hook. In this manner the device both stabilizes the distal trachea and provides exposure of the lumen. *B,* Device shown attached to scalpel. During the initial incision, the device is attached to the No. 20 scalpel and passively placed through the cricothyroid membrane during the initial horizontal incision. The "claws" of the device are then released and the scalpel removed. The device is then rotated into position and used as outlined above. *(Davis DP, Bramwell KJ, Hamilton RS, et al. Safety and efficacy of the rapid four-step technique for cricothyrotomy using a Bair Claw. J Emerg Med 19:125, 2000.)*

frequent than late complications. In one series of patients who had emergency cricothyrotomies, the overall incidence of complications was 23% with no long-term complications.[51] Complications may be more common when the procedure is performed under suboptimal conditions. In one Emergency Medical Service (EMS) system, EMS personnel used surgical cricothyrotomy in 56 of 376 patients requiring emergency airway intubation. [52] In 79% of those receiving cricothyrotomy, prior orotracheal intubation attempts were unsuccessful (mean of 1.9 attempts per patient). There were six failed cricothyrotomy attempts, one case of excessive bleeding, and one episode of patient agitation. Generally the cricothyrotomy procedure was judged to be acceptable (64%) or functioning marginally (16%) upon arrival at the hospital.

Under ideal conditions, the most common complications are bleeding, incorrect site of tube placement, unsuccessful tube placement, and prolonged procedure time (see Table 6-6). The overall procedure time for cricothyrotomy should be <3 minutes. It is not unusual for surgical cricothyrotomy to be completed in 30 to 60 seconds. Cadaver studies have suggested that the rapid, four-step technique allows a more rapid intubation over standard surgical cricothyrotomy with a similar complication rate.[39] [42] [53]

Bleeding from the procedure is usually minor and occurs early. Packing the cricothyrotomy site with gauze can usually

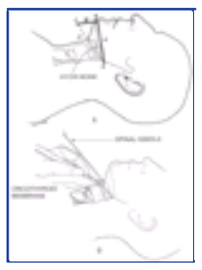

Figure 6-6 Modification for a patient with a massive neck swelling (see text). *A*, Landmarks in the neck. *B*, The procedure for a patient with a massive neck swelling uses a spinal needle to find and identify the hyoid bone; the skin incision is then made in the midline, moving inferiorly from the midpoint of the hyoid bone past the thyroid cartilage until the cricothyroid membrane is exposed. Care is needed to *avoid* a high incision through the thyrohyoid membrane above the thyroid cartilage.

control such bleeding. It is unusual for bleeding vessels to require ligation. Persistent hemorrhage is usually attributable to vessels located at the edges of a transverse skin incision. This complication is minimized if a longitudinal skin incision is made. [54] Potential bleeding may be minimized by making the stab incision in the lower part of the cricothyroid membrane near the cricoid cartilage to avoid the cricothyroid arteries. Major bleeding generally has not been a problem. [55] [56] One cadaver study noted a high number of small vessels in the region of the cricothyroid membrane that are at risk during a cricothyrotomy. [57] Hence, hemorrhage could still be a problem even if the technique of cricothyrotomy is done correctly and all the guidelines for the procedure are followed. Even a small amount of bleeding could be life-threatening if it occurs endotracheally, with resultant pneumonitis or suffocation. [58] The mortality from acute bleeding during a tracheostomy has been attributed to airway obstruction from the blood and not from volume loss. [59] In the management of postcricothyrotomy or post-tracheostomy bleeding, the airway is protected if the tracheostomy tube is in place and the cuff is inflated. If the airway is protected, then hemorrhage control (i.e., local

TABLE 6-6 -- Complications of Surgical Cricothyrotomy

Immediate or early complications
Common
Bleeding, hematoma
Incorrect tube placement
Unsuccessful tube placement
Prolonged procedure time
Subcutaneous emphysema
Obstruction
Infrequent

Mediastinal perforation
Pneumothorax, pneumomediastinum
Vocal cord injury
Laryngeal fracture or disruption of laryngeal cartilage
Aspiration
Late complications
Most common
Obstructive problems
Voice changes or dysphonia
Infections
Late bleeding
Persistent stoma
Subjective feeling of lump in the throat
Infrequent complications
Subglottic or glottic stenosis
Tracheoesophageal fistula
Tracheomalacia

pressure on the bleeding vessels and, if necessary, ligature) can be done in a controlled fashion.

An incorrectly placed transverse skin incision may lead to bleeding and incorrect or unsuccessful tube placement. Too low a skin incision may lead to tube placement between the tracheal rings. In an emergency, a longitudinal skin incision is preferred, because a misplaced longitudinal skin incision, whether too high or too low, can be easily extended. [60] Davis and colleagues suggest that injury to the cricoid ring by a tracheal hook represents a theoretical risk with the rapid, four-step technique of Brofeldt and colleagues. [61] Yet in another cadaver study of the rapid, four-step technique, the use of the "Bair Claw" device was not associated with cricoid injury. [42]

Other less common complications include infection and airway obstruction. [62] An indwelling tube will become colonized by bacteria even if meticulous care is taken, and infection can result. Infection can occur in the structures or tissues of the neck and in the tracheobronchial tree. Potential infections include cellulitis, perichondritis, abscess in the incision site, and laryngotracheitis.

Acute airway obstruction can occur with tracheostomy or cricothyrotomy. In a correctly placed tube, the most common cause of acute airway obstruction is a mucus plug. A mucus plug that causes obstruction should be cleared from the airway by careful suctioning, using sterile technique (see Chapter 7). If this cannot be accomplished, then the entire tracheostomy tube may need to be changed. Less frequently, acute airway obstruction can be caused by overinflation of the tracheostomy balloon with herniation of the balloon over the tip of the tracheostomy tube or by retrograde intubation of the pharynx. [63] The tracheostomy tube can be passed into a subcutaneous fascial or tissue plane instead of into the trachea. This complication can occur during insertion of the tracheostomy tube or, more commonly, during a tube change, especially during the immediate postoperative period.

Long-term complications following cricothyrotomy are unusual. [64] The major long-term complication is a change in voice or dysphonia. [65] Laryngeal damage may occur secondary to a laryngeal fracture caused by using a tracheostomy tube that is too large for the size of the cricothyroid membrane. Dysphonia can also be caused by direct injury to the vocal cords.

Other late and rare complications include a suture sinus, a subjective feeling of a lump in the throat, a persistent stoma, chondritis of the thyroid or cricoid cartilage, and subglottic or glottic stenosis. Swallowing problems have been reported in tracheostomy patients [66] but not in cricothyrotomy patients.

Airway stenosis is a potential complication whenever a tube is placed in the airway. Airway stenosis can occur with intubation, cricothyrotomy, or tracheostomy. The most common cause of subglottic stenosis is endotracheal intubation and not cricothyrotomy or tracheostomy. [67] The pathophysiology of subglottic stenosis involves

mucosal ulceration and damage secondary to a tube eroding the mucosal surface and laryngeal disease along with bacterial colonization of the region. Excessive cuff pressures, frequent tube motion, and rigid tubes that are anatomically incorrect contribute to mucosal damage. The use of flexible, anatomically correct tubes with low-pressure cuffs and flexible tubing between the tube and the ventilator will minimize mucosal damage.

Prolonged endotracheal intubation followed by tracheostomy or cricothyrotomy is associated with a higher incidence of subglottic stenosis than with either endotracheal intubation or the surgical procedure (tracheostomy or cricothyrotomy) alone. [68] The airway stenosis produced by an indwelling tube is generally located at the cuff site of the tube. If airway stenosis occurs with a standard tracheostomy, the stenosis occurs quite distal in the trachea, thus making it difficult to reach during surgical repair. Early aggressive surgical management of granulation associated with mucosal injury has been successful in limiting chronic airway stenosis. [69] There are other theoretical complications of cricothyrotomy. These include pneumothorax, pneumomediastinum, major vessel hemorrhage, tracheoesophageal fistula, and esophageal perforation. These complications are seen with tracheostomy but have not yet been reported as complications of cricothyrotomy. [70] [71]

The complications of asphyxia, including dysrhythmias and cardiac arrest, during the performance of tracheostomy or cricothyrotomy are generally due to the lack of adequate oxygenation and not to a vagal reaction. Because cricothyrotomy is one of the easiest, quickest, and safest ways to achieve definitive airway control and oxygenation, the complications of hypoxemia should occur less commonly than with tracheostomy when performed in critically ill patients.

PERCUTANEOUS TRANSLARYNGEAL JET VENTILATION (NEEDLE CRICOTHYROTOMY)

Overview

Needle cricothyrotomy is a percutaneous technique in which a needle is placed through the skin, the subcutaneous tissue, and the cricothyroid membrane without using a formal incision. This airway access procedure is *ideally* followed by intermittent

high-pressure administration of oxygen through the cannula in the cricothyroid membrane (*translaryngeal jet ventilation*). Only when a sufficiently large catheter (generally =3 mm ID) is inserted, can a low-pressure ventilation source (e.g., bag-valve device) be used to partially support ventilation in the adult. However, a low-pressure ventilation source can be effective for ventilation through a 12- to 14-ga IV catheter in very small infants (5 kg) and may partially support ventilation in larger infants without complete airway obstruction.

The technique of puncture of the cricothyroid membrane is relatively simple and has many uses, ranging from obtaining sputum samples to giving local anesthesia before intubation to ventilating the patient. [72] [73] Whether the lungs can be ventilated adequately via a cannula in the cricothyroid membrane has been debated. We now know that percutaneous translaryngeal ventilation can be an effective and relatively safe procedure for obtaining and maintaining an airway for extended periods of time provided that appropriate equipment and techniques of ventilation are used. [74]

Historically, oxygen was simply passed through the needle or cannula in the cricothyroid membrane (*apneic oxygenation*). In this way, hypoxia was treated, and tissue oxygenation was generally adequate. Clinical studies and animal experiments noted that although the partial pressure of O_2 (pO_2) was adequate, CO_2 was retained, and the elevated partial pressure of CO_2 (pCO_2) led to respiratory acidosis. The oxygenation could be maintained for only about 30 minutes because of the severe hypercapnia and resultant respiratory acidosis, even when the hypoxia was treated successfully. [75] This procedure, whereby oxygen is run continuously through a needle or cannula in the cricothyroid membrane, is referred to as *translaryngeal oxygenation*.

The solution to avoiding a rise in pCO_2 and respiratory acidosis is to ventilate the patient, allowing time for both inhalation and exhalation, thus simulating normal respiration. [76] Intermittent bursts of oxygen provide sufficient "tidal volume" and time for exhalation, thus avoiding hypercapnia and respiratory acidosis. *Translaryngeal jet ventilation* is the ventilation of the lungs by intermittent bursts of oxygen through a needle or cannula in the cricothyroid membrane. The technique can supply adequate ventilation up to high degrees of airway obstruction. Percutaneous *transtracheal jet ventilation* is the same procedure except that the cannula is placed through the larynx into the trachea.

Physiology

The idea of gas insufflation via an opening in the trachea was described in the early 17th century, [77] although the current usage of the technique has only become popular in the last 25 years. A lack of understanding of the differences between transtracheal oxygenation and ventilation and a failure to standardize the technique itself (with regard to such factors as pressure, volume, intermittent vs continuous administration of air vs oxygen, size of opening in the membrane, and location of opening in the airway) has led to conflicting reports in the literature and to many misconceptions. [78]

Studies as early as 1909 showed that animals could survive for approximately 30 minutes when oxygen was given via a needle placed in the cricothyroid membrane. [79] Reed and coworkers, in 1954, showed that animals could be kept alive for a longer period of time with a normal pH if they were ventilated with intermittent bursts of compressed air instead of a continuous flow of oxygen. [80] The key to avoiding respiratory acidosis and maintaining a normal pH was the use of a method allowing for adequate ventilation, not just a continuous inflow of oxygen or air (as with apneic oxygenation).

A popular misconception is that percutaneous transtracheal ventilation is a temporizing procedure, good for only 30 minutes at best. Animal experiments and clinical studies have demonstrated that transtracheal ventilation is an effective, quick, fairly simple, and safe way to obtain and maintain an airway for a prolonged period of time. [81] Percutaneous translaryngeal ventilation with an adequate-sized cannula, appropriate ventilation pressures, sufficient tidal volumes, and adequate exhalation times can provide adequate ventilation for extended periods. [82]

Transtracheal jet ventilation has been used extensively as a means of ventilation during surgery and procedures of the upper airway. [83] [84] Translaryngeal jet ventilation may be used even with partial airway obstruction. [85] [86] Percutaneous translaryngeal jet ventilation is a rapid procedure for obtaining airway control in both elective and emergency situations in patients of all ages and in many clinical situations. [87] [88] [89]

The advantages of needle cricothyrotomy with translaryngeal jet ventilation over surgical cricothyrotomy include (Table 6-7) faster performance (may take only 10 seconds), easier performance, less equipment and smaller surgical setup required, no need for an assistant, smaller scar, less bleeding, expulsion of oropharyngeal secretions and other particles or small objects from the proximal trachea, less tracheal erosion, and less frequent subglottic or glottic stenosis (see Table 6-6). Some of the advantages are a result of the smaller size of the opening and the percutaneous technique.

The disadvantages of percutaneous transtracheal jet ventilation are (1) incomplete control of the airway, with a greater potential for aspiration than with a cuffed tracheal tube; (2) likelihood of barotrauma (subcutaneous emphysema or pneumothorax) if exhalation is inadequate and airway pressure is elevated; and (3) inability to perform adequate suctioning through a percutaneous catheter setup. Airway protection during transtracheal ventilation is attained by positioning the patient to allow drainage of secretions away from the larynx during expiration, so upward gas flow through the larynx causes secretions and blood, for example, to be blown away from the larynx. [90]

TABLE 6-7 -- Advantages of Percutaneous Translaryngeal Ventilation vs Surgical Cricothyrotomy

Faster (i.e., may take as little as 10 sec vs 30 sec to 3 min for surgical cricothyrotomy)
Less bleeding (due to smaller opening, smaller incision)
Simpler technique, easier to perform
Does not need an assistant, can be done by nonsurgeons
Requires fewer instruments
Lesser need for extensive surgical setup (lighting, equipment, and preparation)
Smaller scar (stoma is only as large as the size of the tube)
Less tracheal erosion
Less subglottic or glottic stenosis
Forces oropharyngeal secretions out of the proximal trachea
May force foreign body out of proximal trachea with a partial airway obstruction
Can be performed in patients, of all ages

Indications

Indications for needle cricothyrotomy with translaryngeal jet ventilation are similar to those for surgical cricothyrotomy. Cricothyrotomy is indicated in any situation in which intubation is contraindicated or cannot be performed (see Table 6-1). Failure to achieve endotracheal intubation in a timely fashion, and a subsequent inordinate delay in definitive airway control and oxygenation, is an indication for needle or surgical cricothyrotomy to prevent hypoxemia.

Percutaneous translaryngeal ventilation can be used in a patient with airway obstruction, but it requires an adequate-sized catheter or catheters. [91] [92] Translaryngeal ventilation has been recommended as the procedure of choice for airway control and oxygenation during surgery and procedures on the upper airway. [93] Percutaneous translaryngeal ventilation has been used as an elective procedure and in patients of all ages in an emergency (even premature infants), for extended periods of time.[94]

Contraindications

The absolute contraindications to surgical or needle cricothyrotomy are (1) the ability to accomplish endotracheal intubation easily and rapidly; (2) retraction of the distal end of the trachea into the mediastinum after tracheal transection; and (3) occurrence of known significant direct damage to the cricoid cartilage or larynx (see Table 6-3).[95]

Known complete airway obstruction requires an adequate-sized catheter or catheters to avoid barotrauma and hypercarbia. Barotrauma with high pressures occurring in the trachea can lead to complications such as a pneumothorax or pneumomediastinum, or both, during percutaneous transtracheal ventilation. [96] If intratracheal pressures =20 cm H_2O are maintained, the complication rate of percutaneous transtracheal ventilation is low. If complete upper airway obstruction is present, surgical cricothyrotomy is preferred over percutaneous translaryngeal ventilation, although percutaneous translaryngeal ventilation could be used with partial or complete airway obstruction provided appropriate-sized catheters are used. [97]

Relative contraindications to percutaneous translaryngeal ventilation are different from those for surgical cricothyrotomy. Age younger than 5 years has been mentioned as a relative contraindication to surgical cricothyrotomy. Age is not a factor in percutaneous translaryngeal ventilation. Some authors recommend percutaneous translaryngeal ventilation as the invasive airway procedure of choice in infants and young children, especially in an emergency. [98]

Equipment

Translaryngeal jet ventilation requires three components: an oxygen supply at 50 psi, an in-line one-way "valve" to allow for the intermittent administration of oxygen, and a needle or cannula with a bore =13 or 14 ga in the cricothyroid membrane (Table 6-8).

Oxygen Supply

The oxygen supply must be at a pressure of 50 psi to deliver enough volume to ventilate the lungs rapidly between periods of exhalation through the glottic opening. An oxygen source of 50 psi can be obtained by attaching a connector to the piped

TABLE 6-8 -- Equipment for Needle Cricothyrotomy and Translaryngeal Jet Ventilation

Oxygen source
High-pressure oxygen source at 50 psi
Deliver 100% oxygen at 20 bursts/minute with I:E = 1:4

High-pressure tubing (to be attached to cannula or catheter and oxygen at other end with the manual jet ventilator device in the middle)
Manual jet ventilator device (Y-connector or push-button device) to allow for ventilation with inhalation and exhalation
Cannula
Large bore (=13- or 14-ga needle) with a Teflon or plastic cannula or, alternatively, one of the commercial cricothyrotomy devices, or 9 Fr catheter

I, inhalation; E, exhalation.

oxygen wall line found in any ED, attaching the tubing to the flush valve of an anesthetic machine, or attaching the oxygen tubing directly into an oxygen tank line (regulator) but not to the flow valve of the oxygen cylinder. The oxygen tanks in ambulances or other patient transport vehicles for prehospital care should have two components: (1) an outlet that leads directly into the cylinder line, and (2) a simple, easy-to-connect device that allows the oxygen hose to be quickly attached to the outlet.

Stewart recommends unscrewing the demand valve connection from the oxygen regulator of the tank and rapidly connecting the oxygen hose that has a nipple in place for fitting into the outlet. [77] He suggests leaving a small wrench fastened to the oxygen hose to allow a rapid transfer.

Two key points should be remembered: (1) high-pressure tubing should be used throughout the system, and (2) all connections and attachments should be well secured to avoid any disconnection under high pressure. Ligatures or other fasteners may be helpful in securing the attachments.

"Valve" Apparatus

It is essential to have the proper attachment for delivery of oxygen to the cannula or needle. Whatever the device or valve apparatus selected, it is critical to have all of the equipment ready, all of the connections available, and everything easily accessible. The apparatus can be gathered together and placed in one bag or kit and should be stored with the other airway management equipment.

First, high-pressure tubing goes from the oxygen source at 50 psi to a manually controlled device, which is then connected via high-pressure tubing to the cannula or needle in the cricothyroid membrane (Fig. 6-7). Stewart[78] recommends the manual valve by Instrumentation Industries (Bethel Park, PA), although others such as the Manujet by VBM (Germany) are also available.[77] A list of other "valve" apparatus options with varying costs ($5 to $200) has been published elsewhere. [99]

Note that standard commercial demand valves deliver only 60 cm H_2O (approximately 0.9 psi).[95] Systems using makeshift bag-valve assemblies (Fig. 6-8) do slightly better, but may deliver as little as 12 to 15 L/min of oxygen using 14- and 13-ga catheters, respectively.

Cannula or Needle

The third piece of equipment required is the cannula. A 13- or 14-ga needle catheter with a length of about 2 cm (or 1 inch) or a 3-mm ID cannula is preferred for percutaneous

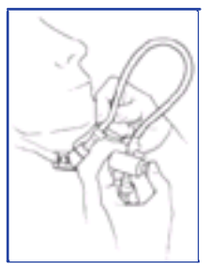

Figure 6-7 The equipment for translaryngeal ventilation. One-way valve used to control ventilation. Note that tubing is attached at the neck to the hub of the cricothyrotomy device, or if a tracheostomy is in place, the insufflation catheter can be passed into the tracheostomy tube.

translaryngeal ventilation. The size of the needle or cannula is critical. [100] Too small a cannula will not allow for sufficient ventilation, causing hypercapnia and even hypoxemia to develop.

Modifications for the cannula have been suggested: side holes, a slight curve, and a plate or flange. The advantage of side holes is that they will help keep the end or point of the cannula away from just one area of the tracheal wall. Thus, the full force of the 50 psi oxygen source is not directed at just one area of the laryngeal wall but is distributed in the larynx. The shape of the cannula may facilitate its initial placement or enhance complications. A fixation plate, flange, or side handle helps secure the cannula into place. A snug fit of the cannula will help prevent subcutaneous emphysema and ventilation of overlying soft tissue.

The use of a large-bore cricothyrotomy catheter (9 Fr ID with 13 Fr outside diameter [OD] and length of 6 cm) has been recommended instead of a 14-ga IV catheter. The large-bore cricothyrotomy catheter has several advantages: less chance of kinking or plugging up, improved mechanical structure, and the ability to be used with jet ventilation or bag-valve device ventilation. [101] [102]

Commercial Kits

Cannulas designed for cricothyrotomy or percutaneous translaryngeal ventilation are commercially available (Table 6-9). Several studies suggest that the "commercial" kits may have a higher complication rate due to a higher puncture/insertion force or a curved shape with more frequent posterior perforation, or both. [103] [104] [105] [106] [107] Placement of a commercial device may take longer than the traditional surgical cricothyrotomy. [108] [109] [110] One study suggests that procedural inexperience may be the primary factor causing delays whether with a percutaneous, wire-guided approach (Arndt Emergency Cricothyrotomy Catheter set, Cook Critical Care, Bloomington, IN) or via traditional surgical cricothyrotomy. [111] The use of

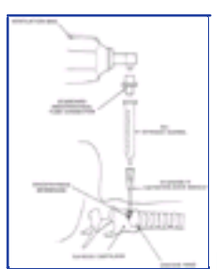

Figure 6-8 A simple setup for translaryngeal ventilation using standard equipment found in any emergency department. This setup is inadequate for adults. High-pressure (50 psi) ventilation systems (see Fig. 6-7) are optimal. Even with the pressure relief valve on the bag-valve device turned off, only a suboptimal pressure can be developed. However, this technique may be satisfactory in infants and small children.

one commercial cricothyrotomy device (Pertrach) is shown in Figure 6-9 .

Ventilation

Ventilatory parameters may be critical in preventing barotrauma and significant hypotension and in eliminating hypoxemia and hypercarbia. Animal studies suggest that the minute volume as reflected by a short inspiratory and a prolonged expiratory phase is an important parameter. [89] [97] [98]

Bag-valve devices should not be used for ventilation of adults or children unless a large catheter (3 mm ID) has been passed. The clinician should verify that adequate tidal volumes are being delivered with this technique by monitoring for hypoxemia.

Procedure

The actual technique of needle cricothyrotomy with translaryngeal jet ventilation is fairly simple (Fig. 6-10). The anatomy, landmarks, and several of the steps in the technique are identical to that for surgical cricothyrotomy (see Fig. 6-1 and Fig. 6-3).

A small 3- to 5-mL syringe containing 1 to 2 mL of sterile normal saline or water is attached to a large-bore needle (13 or 14 ga). If lidocaine will be injected, then 1 to 2 mL of 1% lidocaine without epinephrine should be in the syringe.

TABLE 6-9 -- Commercial Devices

Commercial Cricothyrotomy Devices
There are many commercial cricothyrotomy devices. A few of them are listed below. Mention is not intended to imply endorsement of these devices.
1. NU-TRAKE and PEDIA-TRAKE are distributed by International Medical Devices, Inc., PO Box 408 Canoga Park, 19355 Business Center Drive, Suite 8, Northridge, CA 91324, or PO Box 408 Canoga Park, CA 91305; phone (818) 701-5433 or (800) 522-LIFE (outside California)
2. Pertrach: Pertrach, Inc., 900 Davisson Run Rd, Suite 301, Clarksburg, WV 26301, phone (304) 624-7122 or (800) 736-3194
3. Abelson cricothyrotomy cannula: Gilbert Surgical Instruments, 115 Harding Ave, PO Box 458, Bellmawr, NJ 08031, phone (609) 933-2770
4. Quick Trach emergency cricothyrotomy device for adults and infants: VBM Medizintechnik GMBH, D-7247 Sulz am Neckar, Germany, phone (07454)6211; telefax (07454)4953
5. Portex Mini Trach Kit
6. Melker emergency transcricothyrotomy catheter set: Cook Critical Care, PO Box 489, Bloomington, IN 47402; phone (800) 457-4500
Commercial Transtracheal Puncture Devices
Also designed for transtracheal puncture, the Trans-Cricothyrotomy device is distributed by VBM Medizintechnik (same address and phone as above)
Commercial Manual Ventilator Devices
1. Manual valve that allows for the flow of oxygen when the control button is pushed. Manual Valve, by Instrumentation Industries, Bethel Park, PA
2. Manujet: a manual jetting device by VBM Medizintechnik GmbH, Bruhlstrasse 10, 0–727 Sulz am Neckar, Germany

If the patient is responsive, 1 to 2 mL of lidocaine may be injected into the larynx to prevent reflex coughing when the needle or cannula enters the larynx.

While the dominant hand (usually the right) holds the syringe, with the needle directed caudally at <45° to the skin, the other hand (nondominant) holds and stabilizes the larynx. The thumb and middle fingers of the nondominant hand stabilize the cricoid cartilage, and the index finger palpates the cricothyroid membrane.

The needle is inserted through soft tissues, the skin, and the cricothyroid membrane (see Fig. 6-10). While negative pressure is exerted on the barrel of the syringe, the needle is inserted through the cricothyroid membrane into the larynx. Air bubbles in the fluid-filled syringe signify entry into the larynx. After entering the larynx, the cannula is advanced into the larynx, and then the needle is removed. The cricothyroid membrane should be punctured in the inferior aspect (i.e., nearer the cricoid cartilage than the thyroid cartilage) to avoid the cricothyroid arteries (see Fig. 6-3*A*).

If there is much resistance to the needle's or catheter's passage through the skin, subcutaneous tissue, or cricothyroid membrane, kinking or bending of the catheter may occur unless a stiffer catheter is used. A small nick in the skin may be needed to facilitate passage through the dermis into the subcutaneous tissue. A percutaneous dilational or Seldinger guidewire technique may result in fewer complications. [112] [113]

The cannula is secured by suturing it to the skin or by placing a circumferential tie around the neck. The oxygen source is connected to the cannula. It is critical that the proximal end of the cannula be snug or tightly fitting and securely held around the puncture wound opening. If it is not securely held in place, subcutaneous emphysema will result or the cannula may be dislodged from the larynx, or both. A trial of several bursts of oxygen flow is recommended to make certain that the cannula is correctly placed and the setup is working and ventilating properly.

The hypoxic patient should receive 100% oxygen in intermittent bursts <50 psi at a rate of 20 bursts per minute. For children, 30 psi has been recommended. The percentage of inspired oxygen concentration can then be adjusted, depending on blood gas results. The inspiratory phase or insufflation with the burst of oxygen should last approximately 1 second, and the expiratory phase long enough to allow for adequate exhalation (2 to 9 seconds has been suggested).

Precautions

The location of the needle puncture (or incision) in the skin and cricothyroid membrane is critical. The preferred location is near the midline in the inferior aspect of the cricothyroid membrane, just above the cricoid cartilage. The needle (or scalpel) is directed at an approximately 45° angle to the skin in a caudal direction. The key landmarks in the neck should be identified before inserting the needle-cannula combination into the cricothyroid membrane.

Too small an opening in the cricothyroid membrane leads to hypoxemia, hypercapnia, and respiratory acidosis. In an adult, a 13- or 14-ga needle or larger bore with a 3-mm ID is needed to provide an adequate-sized opening.

Use of a bag-valve device or a demand valve resuscitator apparatus to ventilate a patient through a translaryngeal cannula is generally inadequate. Using a 50 psi oxygen source, up to 89 L/min can be delivered through a 13-ga cannula, and up to 72 L/min can be delivered through a 14-ga cannula. [95] Additional side holes or ports in the cannula to allow for the additional egress of oxygen into the trachea and to limit the obstruction of the cannula by mucus plugs are desirable.

During the insufflation phase of percutaneous translaryngeal ventilation, secretions in the upper airway are blown out of the mouth and nose. It is recommended that personnel stand clear of the patient's face to avoid being sprayed with secretions when oxygen exits through the patient's glottis and pushes oropharyngeal secretions out the glottis and then out the nose and mouth. This may be a useful side effect if partial upper airway obstruction is present, as with a foreign body (e.g., a bolus of meat or a peanut), because some of the delivered volume of air exiting through the patient's glottis might dislodge such a foreign body. The risk of aspiration is decreased or eliminated by lowering the head. The proximal end of the cannula should be snug against the puncture wound to minimize localized subcutaneous emphysema and should be secured in place to prevent the cannula from being dislodged.

Complications

The exact incidence of complications with percutaneous translaryngeal ventilation is not known, but it is thought to

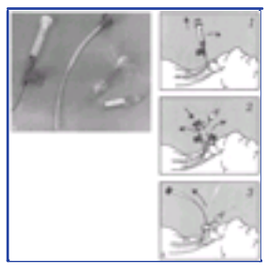

Figure 6-9 *A*, Commercial device used in performing a cricothyrotomy with a modified Seldinger technique. The adult Pertrach percutaneous emergency airway provides a means of rapidly inserting a tube into a patient's trachea (through either the cricothyroid membrane or trachea) in certain clinical situations. It provides an adequate airway that can, by its standard 15-mm adapter, be used to allow the patient to breathe. The unit allows full control of the airway with inflation of the cuff. The pediatric device is provided uncuffed in three sizes for infants and children of various sizes. The 15-mm adapter is part of each unit. (Tracheostomy *only* is recommended in children and infants.) *B*, Method of establishing an airway with the Pertrach cricothyrotomy kit: (1) The 14-ga needle is inserted into the trachea through a cricothyroid membrane or upper trachea. Placement in the airway is verified by drawing air. The syringe is removed. (2) The dilator is placed to its hilt into the tracheostomy tube, and both are inserted as a single unit. The leader of the dilator is inserted into the trachea through the needle, which is then split and removed. The dilator and trachea tube are inserted into the trachea. Note that a small skin incision at the puncture site is needed to facilitate passage of the tracheal tube. (3) The dilator is removed. The cuff can then be inflated and a respirator applied. *(Courtesy of Pertrach, Inc., Clarksburg, WV 26301.)*

Figure 6-10 The procedure for transtracheal ventilation. *A*, The cricothyroid membrane is punctured with the needle or catheter aimed caudally at approximately a 45° angle. *B*, The inner needle has been removed, and the catheter is hooked up to a manual in-line device and then to a source of oxygen. A valve device or tubing modification as shown in Figure 6-7 is also required.

be low, considering that the complication rate of translaryngeal puncture alone is in the range of 0.03% to 0.8% (Table 6-10).[114]

Bleeding can occur at the site of the needle puncture, but this is usually not a major problem. Hemoptysis may occur but is infrequent. Fatal hemorrhage secondary to transtracheal aspiration for sputum cultures has been reported, [56] although no bleeding fatalities secondary to percutaneous transtracheal ventilation have been reported.

Minor bleeding is the most common complication of a surgical cricothyrotomy, whereas subcutaneous emphysema is the most frequent complication of percutaneous translaryngeal ventilation. With percutaneous translaryngeal ventilation, subcutaneous emphysema will occur if egress of gas is prevented by inadequate exhalation (e.g., with occlusion of the mouth and nose or with inadequate cannula size). The development of subcutaneous emphysema with percutaneous transtracheal ventilation is often immediate and dramatic. If this complication does occur, the subcutaneous emphysema may be gently squeezed away from the midline and the trachea can often be recannulated and successfully ventilated. Subcutaneous emphysema can be decreased or avoided by making sure that the flange or hub of the cannula fits securely against the skin.

Barotrauma secondary to high airway pressures may occur if percutaneous translaryngeal ventilation is used when

TABLE 6-10 -- Complications of Percutaneous Translaryngeal Jet Ventilation

Common
Subcutaneous emphysema—most common (less occurrence if there is a "secure" fit at the skin)

Kinking of the catheter
Blockage or obstruction of the catheter
Coughing (in a conscious patient)
Infrequent
Bleeding (minor), hematoma
Infections
Aspiration
Incorrect or unsuccessful catheter placement
Prolonged procedure time
Persistent stoma
Subjective feeling of a "lump in the throat"
Pneumatocele
Serious, rare complications
Barotrauma (secondary to high airway pressures, more common with complete airway obstruction)
Pneumothorax
Pneumomediastinum (less occurrence if high airway pressures are avoided, and not performed with complete airway obstruction)
Mediastinal perforation
Esophageal perforation
Dysphonia or voice changes (secondary to vocal cord injury, laryngeal fracture, or disruption of laryngeal cartilage)
Potential or theoretical complications (not yet commonly associated with percutaneous translaryngeal jet ventilation, although reported with tracheostomy and other airway procedures)
Subglottic/glottic stenosis
Tracheoesophageal fistula
Damage to laryngotracheal mucosa (such as tracheobronchitis)
Swallowing problems

complete airway obstruction is present. Such barotrauma could lead to serious complications, including pneumothorax, pneumomediastinum, and subcutaneous emphysema.

Another side effect that can occur in the conscious patient is coughing with each burst of oxygen. A few milliliters of lidocaine may be injected into the larynx to help prevent coughing when the cannula enters the larynx. The initial instillation of lidocaine solution will precipitate a brief coughing episode, but further coughing should be minimized. However, because the patient undergoing cricothyrotomy in the ED is almost always critically ill and is rarely conscious, coughing is usually not a problem.

Percutaneous translaryngeal ventilation for an extended period of time can dry the membranes of the airway unless appropriate humidification is obtained. Techniques or devices for humidification are available. [115]

One complication that may occur with needle cricothyrotomy is kinking of the catheter as it enters the neck. This problem can be overcome if a stiffer catheter is used. A 14-ga (1 ¼-inch) catheter or any device approximately 2 cm long from the hub or flange of the cannula has been recommended as the best length, because it puts the tip of the catheter in the middle or midstream of the airway.

Infection, ranging from cellulitis, perichondritis, or laryngotracheitis, is a possible complication of percutaneous translaryngeal ventilation, but it has not been reported in most series. Careful technique and follow-up care should help prevent these complications of infection and obstruction by blockage of the tube.

Damage to the laryngotracheal mucosa, including necrotizing tracheobronchitis, from percutaneous translaryngeal ventilation is a theoretical complication that has not been reported. Most studies have concluded that percutaneous translaryngeal ventilation or high-frequency jet ventilation may be performed "without undue risk of tracheobronchial injury."[116]

Blockage or obstruction of the tube from bleeding or from a mucus plug occurs infrequently, although such blockage can cause acute airway obstruction. Additional small holes near the tip of the catheter may help to prevent this problem.

A pneumatocele caused by incorrect needle placement is a rare and benign complication that can be treated by aspiration with a needle. Misplacement of the cannula can lead to tracheal, mediastinal, or esophageal perforation if the needle is advanced too far. Other complications that occur with surgical cricothyrotomy could occur with needle cricothyrotomy, such as damage to the laryngeal cartilage, which may cause dysphonia or voice changes.

CONCLUSION

Cricothyrotomy is a simple, reliable, rapid, and effective means of achieving airway control and ventilation. It has relatively few complications. The value of cricothyrotomy as a life-saving procedure in emergency situations has been clearly demonstrated, and its usefulness has been well established in emergency care. Both surgical cricothyrotomy and needle cricothyrotomy with translaryngeal jet ventilation can be used for an extended period of time if appropriate ventilation factors are maintained. Cricothyrotomy has also gained acceptance as an elective procedure for surgical access to the airway. In many instances, cricothyrotomy is the airway procedure of choice.

Chapter 7 - Tracheostomy Care and Tracheal Suctioning

Kathleen A. Neacy

TRACHEOSTOMY CARE

Tracheostomy patients may present to the emergency department (ED) with respiratory compromise, recent and long-term postoperative complications related to the tracheostomy, or, most commonly, with complaints unrelated to the tracheostomy itself. The emergency clinician's evaluation, based on the clinical scenario, includes assessment of the tracheostomy site's appearance and function, appropriate routine care, cleaning and suctioning of the apparatus and site, and initial management of life-threatening complications. This chapter will review tracheostomy equipment, routine suctioning and hygiene, early and late postoperative complications, and procedures and techniques helpful in managing routine and emergent tracheostomy problems. In addition, tracheal suctioning techniques will be reviewed.

Background

Tracheostomy has been performed since 2000 B.C. and is one of the oldest reported surgical procedures in the medical literature. Mortality associated with tracheostomy is low. Most tracheostomies are performed electively, with a postoperative complication rate of 10% to 40%. [1] Emergent tracheostomy is indicated under certain circumstances, such as laryngeal trauma, when emergency orotracheal intubation or cricothyrotomy may be complicated or contraindicated. The complication rate for emergent tracheotomy is several-fold higher than reported with elective tracheostomy. [2]

Elective tracheostomy can be performed in the operating room, using an open technique, or at the bedside in the intensive care unit, using a percutaneous dilation technique (PDT). The surgical site is located between either the first and second, or the second and third tracheal rings. With open tracheostomy, the anterior trachea is generally sutured to the skin until tract maturation occurs, 4 to 5 days postprocedure. PDT eliminates the need to transport critically ill patients to the operating room. In addition, the use of blunt dissection and dilation, combined with a tightly fitting tracheostomy tube, contributes to a lower postoperative bleeding rate. [3] The smaller stoma created with PDT lead to complications such as difficult replacement following displacement in the immediate postoperative period, and stomal occlusion or stenosis.

Newer procedures reviewed in this chapter include transesophageal puncture for voice restoration, minitracheostomies for tracheal suctioning, and transtracheal catheter placement for low-flow oxygen administration.

Indications for Tracheostomy

Commonly accepted indications for tracheostomy include chronic respiratory insufficiency, airway obstruction, and impaired secretory clearance. Patients with chronic respiratory insufficiency who require prolonged ventilation often undergo tracheostomy to avoid long-term complications of orotracheal intubation, including laryngeal dysfunction or subglottic stenosis. Causes of upper airway obstruction that may result in tracheostomy include head and neck cancers, trauma, infections, angioedema, and foreign bodies. Long-term pulmonary toilet can be enhanced with elective tracheostomy in patients who have impaired cough reflexes, increased secretions, or ciliary dysfunction. [4] In the pediatric population, tracheostomy is performed most frequently for upper airway obstruction, ventilator dependence, laryngeal diversion, and central hypoventilation syndrome. [5]

Indications for emergency tracheostomy are rare, as orotracheal intubation or cricothyroidotomy are most often used for emergency airway management. Laryngeal trauma, edema of the oropharynx, fractured mandible, and uncontrolled upper airway hemorrhage are reported indications for emergency tracheostomy. [6]

Tracheal Anatomy, Physiology, and Surgical Considerations

The adult trachea is approximately 10 to 12 cm in length. Forming the anterior and lateral walls of the trachea are 18 to 22 incomplete cartilaginous rings. A fibromuscular sheet completes the posterior wall, which lies anterior to the esophagus. The interior diameter of the adult trachea is approximately 12 to 25 mm, and is lined with mucosa, covered by respiratory epithelium. [4] Blood supply to the trachea comes from branches of the inferior thyroid artery. The innominate (bracheocephalic) artery lies in proximity to the tracheostomy stoma. From its origin at the aortic arch, it courses between the sternum and the anterior trachea, veering right at the sternomanubrial joint. The location of the innominate artery is important, as erosion of the anterior tracheal wall can lead to a major life-threatening bleed from this artery (see *Complications, Bleeding* later).

The recurrent laryngeal nerve supplies innervation to most intrinsic laryngeal muscles and innervates the mucosa below the vocal cords. Efferent vagal fibers stimulate bronchoconstriction, mucosal secretions, and vasodilation. Efferent sympathetic fibers of the pulmonary plexus stimulate tracheal bronchodilation and vasoconstriction.

The upper airway, including the oropharynx and nasal passages, filter particulate matter, humidify inspired air, and aid in expectoration of secretions. These functions are reduced in patients with tracheostomy. [7] Placement of a tracheostomy bypasses humidification and results in formation of thick, dry secretions. [9] Normal mucociliary clearance is often impaired due to increased viscosity of respiratory secretions, underlying chronic illness, and respiratory infections, particularly due to mycoplasma or viral pathogens. [10] Tracheostomy weakens the anterior tracheal wall, allowing possible tracheal collapse. The cough mechanism, also important in tracheal secretory clearance, is often blunted in tracheostomy patients. [10] Normally, the epiglottis and vocal cords close to trap air in the lungs and raise intrathoracic pressure prior to a cough. Patients with a tracheostomy tube are generally unable to generate sufficient pressure to initiate a strong cough and facilitate airway clearance. [8] Physiologic PEEP (positive end-expiratory pressure) is eliminated in patients unable to maintain a closed glottis.

Immune responses are often blunted in patients with tracheostomies due to underlying illnesses, chemotherapy, or

acquired immunosuppression. Pulmonary macrophage and polymorphonuclear cell function in particular are impaired. [10]

Evaluation of the Tracheostomy Patient

Independent of a patient's presenting complaint, a thorough assessment of the airway, respiratory status, and indwelling device should be undertaken in any ED patient with a tracheostomy and respiratory complaint. Tube occlusion, dislodgment, or fracture should be considered. The clinician should verify snug placement of the tracheostomy tube, the presence of blood or secretions, integrity of the skin at the tracheostomy site, and the patient's ability to speak or mentate. A rapid physical examination should help differentiate between tracheostomy complications and other etiologies as the basis of a patient's problem.

Historical components of the evaluation include the indication for tracheostomy placement, the length of time from tracheostomy to ED presentation, and previous complications. Other historical considerations that may be helpful in the ED evaluation include planned or existing voice prosthesis surgeries, previous bleeding

complications or strictures, and whether permanent tracheostomy or planned decannulation of the tracheostomy site is anticipated. Changes in the efficacy of home ventilator or tracheostomy care may help identify potential problems, including increased oxygen use, increased suctioning, equipment failure, or skill in out-of-hospital tube changes.

Complications of Tracheostomy

Obstruction

Any tracheostomy patient who presents with respiratory distress should first be assumed to have a partially or completely obstructed tracheostomy tube. [11] Improper maintenance and poor attention to routine tracheostomy care in the outpatient setting are common, exemplified by the observation that a plugged tube accounted for 30% of ED presentations for respiratory distress in one review. [12] Plugging occurs most commonly with dried respiratory secretions and, less often, with blood or aspirated materials. Secretions may act as a ball valve, allowing air in, but restricting outward ventilation. [4] Granuloma formation just distal to the tube may also cause obstruction. Some patients and caretakers simply do not understand the principles of tracheostomy care, and fail to routinely clean the tube, or fail to even understand the function of an inner cannula.

Emergent management includes high-flow oxygen, and preparing for immediate tube exchange (see *Tube Exchange Technique*, later). Obstructions at the exterior tracheal tube opening can be manually removed. The inner cannula should be removed and cleaned of dried secretions. If no inner cannula is in place, the tracheostomy tube can be suctioned to remove obstructing plugs (see *Suctioning*, later). Instillation of normal saline to loosen thick secretions can be helpful with a critical patient, but is no longer recommended in routine suctioning. [13] [14] If evidence of obstruction persists, the outer tube should be removed and replaced. Persistent respiratory insufficiency despite these maneuvers should lead the clinician to consider other etiologies for the patient's complaints. [11]

Prior to hospital discharge, Rumback and colleagues evaluated tracheostomy patients with a trial of occlusion of their tracheostomy catheter with the tracheal cuff deflated.[15] If the patient developed significant hemodynamic changes (>15% change in respiratory rate, heart rate, or blood pressure), oxygen desaturation of <90% or other signs of respiratory distress or diaphoresis while under observation, they were investigated for potentially obstructive tracheal lesions (e.g., granulation tissue, tracheal stenosis, tumor, edema). Surgical interventions or downsizing of the tracheal tube were undertaken before the patient was released. A modification of their protocol in the ED after the clearing of secretions and resolution of obstructive symptoms will identify patients at risk for subsequent airway obstruction and for whom further otolaryngologic consultation is warranted.

Dislodgment

Tracheal tube displacement can occur when traction is placed on the tube, especially when it is manipulated for ambu-bag or ventilator connections. Long tracheostomy tubes can be dislodged inferiorly, causing the tip to abut the mucosal wall of the trachea, or obstruct at the level of the carina. The clinician should determine that the tube flanges rest snugly at the skin. Lateral neck x-rays may reveal that the tracheostomy tube opening abuts the anterior tracheal wall or obstructs the tracheal lumen. Gentle manipulation of the tube or repositioning may resolve the obstruction. Since flexion of the neck can cause downward displacement of the tube as much as 3 to 4 cm,[6] gentle extension of the neck may restore air flow. Tracheal tubes connected to respirators should be secured with tube supports or holding arms.

False Passage

Creation of a false lumen can occur during tracheal tube replacement, or during repositioning of a dislodged tube. Subcutaneous air, crepitus, or distortion of the anterior neck landmarks may indicate placement of the tracheostomy tube into a soft tissue lumen anterior to the trachea. Abdominal distention after bagging may indicate tracheal tube placement through a tracheoesophageal (TE) fistula. Expeditious removal and replacement of the tracheostomy tube are required if a false passage is suspected.

Fracture

Tracheostomy tube fractures occur infrequently, and are more common with metal tubes. Tube fracture is presumed secondary to metal fatigue and interactions with respiratory secretions. Tube fractures occur most frequently at the juncture of the flange and the tube connection. [16] Lateral neck radiographs may show air outlining the cannula at the flange.[16] A fractured tube fragment may displace inferiorly, obstructing the tracheal lumen. Management should include replacement of the tube and possible bronchoscopy for retrieval of the tube fragment, if present. [17] Cardiac complications have been reported with aspiration of tracheostomy tubes. [17]

Tracheal Cuff Complications

Complications related to the tracheostomy tube cuff include cuff perforation, resulting in poor seal and increased aspiration risk; over-inflation, causing pressure on or impingement of the esophageal lumen; and distention of the cuff distal to the tracheal tube, causing obstruction of the tracheal tube opening. Mucosal injury is much less common since the use of low-pressure cuffs became standard. Pain with ventilation or swallowing, inadequate oxygenation despite correct tube placement, or presence of gastric secretions in the tracheostomy tube may indicate cuff problems. Appropriate measures include verification of appropriate inflation pressures (18 to 23 mm Hg),

and cuff position. If these symptoms persist, the tube should be replaced.

Bleeding

Bleeding complications account for 20% of ED tracheostomy presentations. [12] Minor bleeding occurs in up to 30% to 40% of patients and 0.2% to 10% having massive, or life-threatening bleeding complications. [4] [6] [18] Sources of bleeding include small, superficial blood vessels at the tracheostomy site, granulation tissue, thyroid vessels, anterior jugular veins, and the bracheocephalic (innominate) artery. Bleeding from esophageal or gastric sources may present as tracheal bleeding if a TE fistula is present,[4] or if the patient has aspirated blood. Erosion of a major vessel from the cuff or tip of the tube is responsible for 10% of all tracheostomy hemorrhage, and for most tracheostomy-related deaths. The innominate artery is the most commonly involved vessel. [19] Thyroid artery bleeding occurs in 5% of patients during the immediate postoperative period, but rarely accounts for ED presentations.

Early bleeding, within the first 4 weeks postoperatively, is most commonly incisional. However, 85% of tracheoinnominate artery fistula bleeds are reported within the first postoperative month.[4] Tracheoinnominate artery fistula occurs in approximately 2% of patients with tracheostomies, and has a 50% to 75% mortality rate, despite identification and emergent management. [6] [12] The innominate artery crosses from left to right as it moves superiorly, and lies immediately anterior to the trachea at the level of the superior thoracic inlet. Risk factors for developing a tracheoinnominate artery fistula include placement of the tracheostomy stoma below the third tracheal ring, caudal migration of the tracheostomy tube from leverage on the tube, and presence of a more cephalad-coursing innominate artery, the latter more prevalent in thin, young patients. [12] Pressure exerted by the distal tracheostomy tube or cuff causes erosion of the anterior tracheal wall into the vessel, and subsequent bleeding. Brisk bleeding from the tracheostomy, hemoptysis, or a history of either complaint should alert the clinician to the possibility of a life-threatening bleed. Many patients experience a "sentinel" bleed hours or days before a catastrophic bleed. Some patients may report only a new cough or retrosternal pain. [19] Any history or evidence of 10 mL or more of blood should be presumed arterial.

Visualization of the bleeding site can be attempted in stable patients. A bleeding innominate artery will be located at or below the sternal notch, in the anterior tracheal wall. If significant tracheal bleeding is present, hyperinflation of the tracheostomy tube cuff should be attempted to compress the artery against the sternal wall. If this is unsuccessful, the patient should have an endotracheal tube inserted through the oropharynx, with the cuff positioned at the level of the upper sternum, and hyperinflated. Digital pressure applied through the tracheal stoma, compressing the anterior tracheal wall against the sternum, should be done for continued bleeding (Fig. 7-1). Digital pressure is considered the most reliable technique to stop hemorrhage [12] and may provide control of bleeding during transport to the operating room. Emergent surgical consultation is mandatory.

Management of Minor Bleeds

Incisional bleeding or bleeding from granulation tissue is usually confined to the skin surrounding the stoma. Bloody secretions issuing from the tracheostomy tube may represent

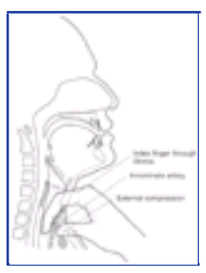

Figure 7-1 Control of innominate artery bleed by digital pressure. When major bleeding occurs and a cuffed tracheostomy tube is present, overinflation of the tube cuff may temporize (see text). When unsuccessful or a cuffed tube is not available, use the illustrated maneuver; digital pressure should be applied to the anterior tracheal wall through the tracheostomy. The index finger is placed within the trachea and then pulled against the anterior tracheal wall, allowing the airway to remain partially open. The artery is compressed between the index finger and the thumb—placed over the anterior neck. Digital compression of the innominate artery is a temporizing procedure, until definitive (operative) management of the bleed is obtained.

diffuse tracheitis, rundown bleeding from the skin or thyroid, or superficial tracheal ulceration from suctioning or tracheal tube pressure. Examination of the stoma site and tube gauze may indicate the source and volume of blood loss. The tracheal lumen may be visualized with a nasopharyngoscope. The proximal trachea and inner stoma can also be visualized by inserting a small pediatric laryngoscope blade into the stoma. Superficial erosions should be differentiated from active bleeding. Clots in the trachea should not be disturbed, as this may increase the rate of hemorrhage.

Incisional or stomal bleeding can usually be controlled by cauterization or packing the wound with petroleum jelly gauze. [6] After examination and management of minor bleeding, the tracheostomy tube should be replaced. Careful suctioning following tube replacement should confirm resolution of superficial bleeding, or identification of secondary sources of bleeding.

If stomal bleeding or intratracheal sites do not account for bleeding, other sites should be considered. Gastrointestinal bleeding may be identified by placement of an NG (nasogastric) tube. The nasopharynx and oropharynx should also be examined for possible bleeding sources. Mucosal bleeding from radiation therapy may occur above the level of the tracheostomy stoma and be present in tracheal secretions.

Infection

Infections are common in patients with tracheostomies and account for approximately 50% of ED presentations. [12] Underlying medical conditions, impaired host defense mechanisms, and poor nutrition all increase susceptibility to infection. Additional contributing factors include contamination of the tracheostomy stoma, the presence of an indwelling device, and exposure to flora colonizing ventilator tubing.

Hackeling reported 18 ED patients diagnosed with tracheostomy-related infections. Four had paratracheal cellulitis, and 14 were diagnosed with bronchitis, tracheitis, or pneumonia. The infectious agents cultured most frequently in tracheostomy-induced cellulitis included *Staphylococcus aureus, Pseudomonas* species, and *Monilia*.[12] Because some degree of aspiration occurs in 65% to 85% of all patients with tracheostomies, [20] enteric organisms are commonly cultured from the sputum of tracheostomy patients. Accurate identification of infectious organisms from carefully obtained sputum samples is essential in this population. Colonization of the stoma is common, but infection is unusual. Peristomal cellulitis can usually be treated with oral outpatient antibiotics. The most feared complications from cellulitis are mediastinitis, mediastinal abscess, and paratracheal abscess. Pain with breathing or swallowing or signs of systemic infection should be investigated for these complications, usually by obtaining a computed tomography (CT) scan.

In Hackeling's review, all tracheostomy patients with infections other than cellulitis were admitted for intravenous antibiotics. Depending on the patient's presentation, a cautious approach to management of infections in this population seems warranted.

Tracheal Stenosis and Tracheomalacia

Tracheal stenosis and tracheomalacia are late complications of tracheostomy, and often present weeks to months after decannulation. Tracheal stenosis can occur at the subglottic area, stoma, or cuff. [6] Pressure on the tracheal lumen from the tracheostomy tube or cuff can cause epithelial destruction, tracheitis, ulceration, persistent inflammation, and subsequent stenosis. [6] Rigid tube systems with excessive motion and pressure points can lead to stenosis at the stoma site. [6] Cough, retained secretions, and progressive dyspnea on exertion usually herald the onset of clinically significant stenosis. Symptoms become evident when the tracheal diameter is narrowed by 50% to 75%. Stridor occurs when the tracheal lumen is =5 mm. [6]

Weakening of the tracheal cartilages from pressure necrosis may cause luminal widening and tracheomalacia. Tracheostomy tube loosening can result, as can tracheal collapse. Pediatric patients are less able to tolerate cartilaginous weakening and tracheomalacia. Cuff over-inflation and tracheal wall dilation can be detected on chest radiography. [6]

Tracheal stenosis can be accurately identified in the ED using laryngoscopy. [12] CT scans are not sensitive in detecting stenosis. Definitive diagnosis is obtained by bronchoscopy, with operative dilation of the stenosis, or resection of granulation tissue being the most common treatment.

Relief of any associated respiratory compromise is problematic because a high-grade stenosis may make endotracheal intubation difficult or impossible. If attempts to intubate fail due to this type of obstruction, temporizing measures can be taken while awaiting transport to the operating room. The patient should be placed on high-flow humidified oxygen and positioned with the head elevated. Application of nebulized bronchodilators or racemic epinephrine may be helpful.

Tracheoesophageal (TE) fistula

Early TE fistulas can occur if a puncture wound or small laceration is made in the anterior esophagus during tracheostomy surgeries. Delayed TE fistulas can occur from a poorly fitting tracheostomy tube impinging on an NG tube, through the common wall of the anterior esophagus. Symptoms of a TE fistula include persistent leak around the cuff, abdominal distention, or evidence of aspiration. The clinician may be able to auscultate breath sounds simultaneously over the lung fields and epigastrium. Bronchoscopy or swallowing studies can aid in making the diagnosis.

Routine Tracheostomy Care

Routine tracheostomy care is focused on maintenance of a patent tube through removal of respiratory secretions. Most tracheostomy tube obstructions occur from the accumulation of dried secretions at the tube tip or within the inner cannula. Intermittent or continuous inhalation of humidified air decreases mucus viscosity and reduces the accumulation of secretions.

The routine cleaning of the tube and inner cannula can effectively reduce accumulation of dried secretions. The inner cannula fits snugly into the tracheostomy tube, and can be easily removed without disturbing tracheostomy tube placement. It should be soaked in hydrogen peroxide solution for 10 to 15 minutes and scrubbed lightly with a soft brush to remove encrusted secretions. [9] The tracheostomy tube flanges should be cleaned with dilute hydrogen peroxide if dried blood or secretions have accumulated. All airway equipment should be thoroughly rinsed in sterile saline before reinserting, as hydrogen peroxide may cause mucosal irritation and increased tracheal secretions. [8]

Suction alone is the preferred way to initially remove excessive secretions. Instillation of normal saline into the tracheostomy tube to loosen secretions is no longer

initially recommended for routine suctioning. Saline and mucus are immiscible. The common practice of instilling 5 to 10 mL of sterile saline may potentially hamper oxygenation, especially during suctioning. Instillation of saline elicits a cough in most patients, usually preceded by forceful inspiration that may draw loose airway material and organisms into the lower respiratory tract. Dislodgment of tube encrustations by a similar mechanism may have the same undesirable effect. For these reasons, instillation of saline for routine tracheostomy care is discouraged. [13] [14] [21] However, the use of saline for thick secretions not responding to routine suction may be needed. The administration of supplemental oxygen can generally control any mild hypoxia associated with aspiration of the small amount of saline used to soften the thick secretions.

Stomal wound care is enhanced by changing tube ties that have been contaminated with secretions, by routine cleansing of the tube flanges, and by using precut tracheostomy gauze. Loose fibers from hand-cut gauze may induce inflammatory changes at the stomal site. [8]

Changing a Tracheostomy Tube

Indications

Tracheostomy tract maturation is generally completed by 5 days postoperatively. Since most tracheostomy patients who

present to the ED do so beyond this time frame,[12] routine changes of most tracheostomy tubes can be safely done in the ED. Indications for tracheostomy tube exchange, electively or emergently, include cuff rupture or leak, peritubal leak caused by tracheomalacia, complete or partial tube occlusion, or conversion to an alternate tube style (e.g., unfenestrated to fenestrated). [22] Routine cleaning of the tube also requires removal and exchange, often done by the patient at home every few weeks.

Few contraindications to tube exchange exist. The clinician should consider whether further tissue trauma or hemorrhage may occur as a result of the procedure [22] and anticipate possible complications, including loss of the airway, before undertaking the tube exchange.

Equipment and Setup

Tracheostomy tubes may be made of metal (Jackson), plastic (Shiley), silicone, or nylon. The main components are an outer cannula, used to secure the tube to the skin, an inner cannula, which has a standard 15-mm respiratory connector for attachment to a bag-valve device or ventilator tubing, and an obturator, the smooth blunt end of which facilitates tracheostomy tube insertion (Fig. 7-2). The outer cannula is the more permanent portion of the tube, as it remains in place unless there are complications. Air exchange is accomplished through the lumen of the inner cannula. *It is imperative to note that the inner cannula contains the adapter for a standard ambu bag. Without the inner cannula, effective ventilations cannot be maintained since a seal cannot be obtained between the ambu bag and the outer cannula.* The inner cannula is removable, and fits snugly into the outer cannula. The inner cannula is the portion of the tube that is routinely removed, cleaned of secretions, and replaced to provide the

Figure 7-2 Tracheostomy tube *(top)* with inner cannula and attached ambu bag adaptor *(middle)* and obturator *(bottom)*.

airway. An obturator has a rounded or cone-shaped distal end, and fits snugly inside the inner cannula, generally extending several millimeters beyond its distal end. The obturator is solid and has no lumen; therefore, it has no purpose except as an aid in tube passage.

The size of the tracheostomy tube is usually stamped on the flange of the outer cannula, and indicates the tube's inner diameter (Table 7-1). The tube is secured in place by ties that tether the flange and should be tightened so that one finger can be placed snugly between the tracheostomy ties and the patient's skin.

Cuffed tracheostomy tubes are used for patients on long-term mechanical ventilation, or those at risk of aspiration. In addition to preventing ventilatory volume loss during positive pressure ventilation and reducing the risk of aspiration, inflation of the cuff prevents diversion of expired air across the vocal cords; therefore, speech is not possible with cuffed tubes.

Most low-volume, high-pressure cuffs have been replaced by high-volume, low-pressure cuffs that reduce mucosal injury and the risk of tracheal erosion or stenosis.[23] The cuff is inflated by attaching a syringe to the Leur-lok port at the proximal end of the pilot balloon. Cuff inflation can be verified by palpating the pilot balloon. The cuff pressure can be determined by connecting the Leur-lok port to a manometer. Recommended cuff pressures are between 18 and 23 mm Hg. [5] [24]

Uncuffed tubes can be used in patients with adequate ventilatory effort, who are awake and at low risk of aspiration. Depending on the size of the tracheostomy tube and how much of the tracheal diameter the tube fills, air can bypass the tracheostomy tube and be transmitted across the vocal cords. Digital occlusion of the tracheostomy, or use of specialized valves attached to the tube opening, can occlude expired air from the tracheostomy, and enhance voice production. Certain tracheostomy tubes have single or multiple fenestrations, which allow air to be transmitted over the vocal cords. Fenestrations are generally located at the superior, posterior arch of the tracheostomy tube and are sometimes also found on the inner cannula.

In an emergency, the proper sized replacement tracheostomy tube may not be available. In such instances a standard *endotracheal* tube may serve as a temporary replacement. Usually a smaller tube than would be used for orotracheal intubation is used. In the adult, a 6- to 7.5-size tube may be accommodated by the stoma and trachea. This tube should not be advanced more than is necessary to provide ventilation. The cuff may be cautiously inflated to assure a proper seal.

TABLE 7-1 -- Tracheostomy Tube Recommended Sizes

Age	Size	Inner Diameter (mm)	Outer Diameter (mm)
Premature	00	3.1	4.5
Newborn-3 mo	0	3.4	5.0
3–10 mo	1	3.7	5.5
10–12 mo	2	4.1	6.0
13–24 mo	3	4.8	7.0
2–9 year	4	5.0	8.5
10–11 year	6	7.0	10.0
12-older	6 or larger		
	8	8.5	12.0
	10	9.0	13.0

Adapted from Mullins et al: Airway resistance and work of breathing in tracheostomy tubes. Laryngoscope 103:1367, 1993.

Very short tracheal tubes that maintain the tracheostomy opening, but do not protrude into the tracheal lumen, are available. Known as tracheal buttons, these devices are used during weaning to maintain stoma patency. Tracheal buttons can become displaced into the tracheal lumen if not correctly tethered, and may become clogged with secretions.[25] Speaking valves, such as the Passy-Muir (Passy-Muir, Inc., Irvine, CA) or the Shiley-Phonate (Mallinckrodt Medical, St. Louis) may be present. These devices generally clip or twist on to the 15 mm coupling of the tracheostomy tube or inner cannula. Speaking valves should be removed before changing a tracheostomy tube.

Procedure

Tracheostomy supplies and adjunct airway equipment should be at the bedside before beginning the procedure. The flange on the patient's indwelling tracheostomy tube will have a size stamped on it; replacement tubes available should include this size and one or two sizes smaller. Component parts should be inspected prior to use. They should fit together easily, and if a cuff is present, it should be inflated to check for leaks. A nasopharyngoscope or red rubber catheter may facilitate tube exchange if a modified Seldinger technique is used (Fig. 7-3). Additional airway equipment, including endotracheal tubes, laryngoscope, suction catheters, and oxygen should be at the bedside, in case difficulties in tube exchange are encountered. A list of recommended equipment is outlined in Table 7-2 . Soft

Figure 7-3 Changing a tracheostomy tube. *A,* Before the old tube is removed, a small red rubber catheter (or other guide catheter) is passed into the proximal trachea. *B,* The tracheostomy tube has been removed over the catheter, and only the catheter remains in the trachea. The catheter serves as a guide for easy and atraumatic insertion of a new tube. Note that the neck should be slightly hyperextended. *C,* A new tracheostomy tube, without the obturator is threaded over the guide catheter; once the tube is in place, the catheter is removed. Similarly, if the tracheostomy tube has already been removed, the catheter may be passed through the stoma before a new tube is advanced. Note that an obturator or inner cannula is *not* used when changing a tube with this technique.

restraints or anxiolytic medication may be used at the clinician's discretion.

Ideally, the patient should be preoxygenated prior to tube exchange, either by providing supplemental oxygen with a face mask applied over the tracheostomy stoma or by manual bagging. However, patients with significant tube obstruction require immediate relief of the obstruction, and preoxygenation may not be possible. [11] The patient should be positioned with the neck slightly *hyperextended*. Flexion of the neck may misalign tissues and hamper attempts at tube passage. Adults may sit or lie down. Small children should be placed supine. A towel roll under a child's shoulders may facilitate mild hyperextension.

The new tracheostomy tube should be lubricated with water-soluble lubricant prior to insertion. The patient's cuff should be deflated, and the indwelling tube should be removed in one fluid movement, following the arch of the tube. *With the obturator inserted,* the new tube should be inserted smoothly, with the same sweeping motion. The operator's wrist motion should simulate the curve of the tube as it advances (Fig. 7-4). Tracheal hooks or a dilator may help to hold the stoma open. The obturator is immediately removed and the inner cannula placed inside the tube (if desired). No attempt to force placement should be made, and the clinician should stop insertion if resistance is met. Creation of a false passage into the soft tissue planes of the neck or posterior trachea is possible with potentially devastating consequences.

TABLE 7-2 -- Bedside Equipment for Tracheostomy Tube Changes

Tracheostomy Tube
Size matched to patient's indwelling tube
1–2 sizes smaller
Obturator in place
Oxygen source
Suction catheters
Water-soluble lubricant
Ambu bag
10-mL syringe (to deflate and reinflate cuff, if present)
Visualization of tracheal lumen
Tracheal hook
Light source (nasopharyngoscope)
Pediatric laryngoscope
Guide for tube placement
Red rubber catheter
Fiberoptic laryngoscope
Securing tube
Cloth umbilical tape
Precut tube gauze
Intubation supplies for emergent orotracheal intubation

A modified Seldinger technique can aid in tube placement. A small-diameter (14 French [Fr] or smaller) red rubber catheter may be threaded through the indwelling tracheostomy tube, and held in place while the original tube is removed. [26] A new tube, without an obturator, may then be threaded over the catheter until seated in the trachea. Weinmann and Bander reported a modified Seldinger technique using an airway exchange catheter that allows jet or bag ventilation into the trachea during tube exchange.[22] This adjunct provides intratracheal oxygen delivery if hypoxemia is a threat.

If a tube is being replaced after accidental dislodgment, visualization of the stoma may be more difficult. Insertion of a pediatric laryngoscope blade with light source may assist in exploration of the wound and airway visualization. [12]

Following tube insertion, the obturator is immediately removed, and, if appropriate, the inner cannula is inserted. Note that the obturator occludes the tube's lumen, and it should be immediately removed. The patient can, however, breathe normally with only the outer cannula in place. Tracheal tube ties should be applied with the patient's neck in slight flexion. The tethers should be tightened enough so that only one finger can fit between the patient's neck and the tube tie.

Confirmation of correct tube exchange is obtained by patient reassessment, and auscultation of adequate inspiratory and expiratory breath sounds. The clinician should be able to feel, as well as hear, breaths out of the tube when it is correctly placed. [12] Visual confirmation of placement can be done by inserting a nasopharyngoscope through the tube. Visualization of tracheal rings verifies intraluminal tracheal position.

TRACHEAL SUCTIONING

Tracheal suctioning removes secretions or aspirated material from the upper airway in patients whose cough is impaired, or in whom an artificial airway is in place. Tracheal suctioning can be performed through an orotracheal or tracheostomy tube, through a minitracheostomy in the cricothyroid

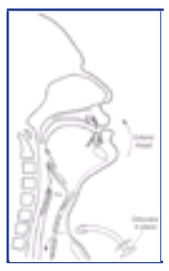

Figure 7-4 The tracheostomy tube should be inserted with a gentle rocking motion of the wrist. Insertion should follow the curve of the tube, as diagrammed above. If any resistance is met during insertion, the clinician should discontinue insertion and identify the obstruction. A pediatric laryngoscope or other light source may be helpful in visualizing the tracheal lumen prior to insertion. *(Adapted from Hackeling et al: Emergency care of patients with tracheostomies: A 7-year review. Am J Emerg Med 16:681, 1998.)*

membrane, or through the nasopharynx. Indications, basic procedures, and complications are similar with each technique.

Indications and Contraindications

The accumulation of secretions or aspirated material in the trachea impairs gas exchange and promotes atelectasis. Patients prone to increased volume of secretions are those with obstructive pulmonary diseases, bacterial infections, and pulmonary edema. Patients with a decreased level of consciousness, respiratory muscle weakness, pain, or an artificial airway often have cough reflexes that are ineffective in clearing airway secretions. [27]

The primary indication for tracheal suctioning is to remove secretions in order to enhance oxygenation, or to obtain samples of lower respiratory tract secretions for diagnostic tests.[11] In the ED, tracheal suctioning is usually performed following endotracheal intubation to clear the airway of aspirated material or secretions.

Bronchopulmonary toilet is indicated when secretions are visible in the endotracheal tube or at the orifice of the tracheostomy tube. The presence of coarse rales, rhonchi or tubular breath sounds, acute or worsening dyspnea, or arterial oxygen desaturation may indicate the need for tracheal suctioning. [11] Patients should be suctioned when clinical

symptoms warrant rather than routinely according to a predetermined schedule. [27] [28] [29]

Relative contraindications to tracheal suctioning include severe bronchospasm, which may worsen with suctioning, and persistently raised intracranial pressure, which is exacerbated by suctioning.[28] Bronchodilators, sedatives, or paralytics may alleviate the symptoms mentioned previously. Tracheal suctioning should be undertaken with caution in patients with cardiovascular instability, due to the risk of inducing dysrhythmias. However, when oxygenation is significantly impaired, expeditious suctioning should be done using techniques that minimize these potential complications. [11]

Equipment

Suction equipment should be assembled at the patient's bedside, and the patient should be placed on a cardiac monitor and pulse oximeter. Standard resuscitation medications and equipment should be immediately available.

Suction catheters are available in different lengths, diameters, and configurations of distal ports. The diameter of the catheter should not exceed one-half of the internal diameter of the tracheal tube. An approximate Fr gauge size is usually twice the tracheal tube size number; for example, a number 12 Fr catheter would be appropriate for suctioning a size 6 tracheostomy tube. A catheter that is too small will not adequately remove secretions, and one that is too large will obstruct airflow around the catheter during insertion. Evacuation of airway gases by an oversized catheter may result in alveolar collapse and hypoxemia.

Catheter tips are designed to maximize removal of secretions without causing mucosal invagination and trauma. Tips may have single or multiple side ports, usually proximal to the distal tip. Coude tips are available that allow selective suctioning of mainstem bronchi. Most authors agree that mucosal injury from suctioning is not related to the tip design, but to vigorous or extensive suctioning at high vacuum pressures. [8] [28]

A closed system airway encases a suction catheter in a sterile sheath attached to ventilator tubing, which allows tracheal suctioning to be performed without interrupting ventilatory support. In high-risk patients, including those requiring PEEP to maintain oxygenation, continued ventilatory support may reduce the risk of suction-induced hypoxia and dysrhythmias.[28] Closed system catheters are reusable, and changed approximately every 24 hours. They have not been shown to increase the incidence of nosocomial pneumonia.[28]

Suction tubing and vacuum settings should be checked before the procedure. Optimal vacuum settings should provide effective removal of secretions while minimizing mucosal trauma. Current recommendations are 60 to 80 mm Hg for infants, 80 to 120 mm Hg for children, and 120 to 150 mm Hg for adults.[28] [30] To assess suction pressures, the clinician can obstruct the catheter by kinking the distal segment and simultaneously occluding the side thumb port while the catheter is attached to wall suction. Catheter patency can be checked by suctioning sterile saline through the catheter prior to tracheal suctioning.

Additional equipment helpful for nasotracheal suctioning includes nasal trumpets, water soluble lubricant, and topical anesthetic agents. Sterile sputum traps can be used if sputum samples will be sent for microbiology or cytology studies.

Procedure

Sterile technique should be used throughout all suctioning procedures. Equipment should be inspected prior to use (see earlier). Unless contraindicated, elevate the head of the patient's bed to maximize diaphragmatic excursion.

All patients should be preoxygenated prior to suctioning. For nonventilator-dependent patients, application of humidified air through a face mask placed over the tracheostomy is recommended.[9] The rate of oxygen flow should be 10 to 15 L/min through the face mask. Patients suctioned through a minitracheostomy should have the face mask placed over the nose and mouth, as should patients suctioned nasotracheally. The face mask can be moved to the mouth only for nasal insertion of the catheter. The patient should take 5 to 10 deep breaths of 100% oxygen before suctioning, and between aspirations. [27]

Ventilated patients can be preoxygenated by increasing FiO_2 (to 1.0), tidal volume and respiratory rate, or some combination of these. [8] [31] Most ventilators require a 1 to 2 minute "washout" period before new FiO_2 levels are reached, so it may be necessary to bag the patient just before suctioning. Four to 10 breaths should be delivered before each suctioning pass, and following completion of the procedure.

Hyperinflation and hyperventilation carry the risk of over-distention lung injury. The clinician should anticipate possible complications, such as pnuemothorax during

preoxygenation.

Catheters should be inserted into the trachea smoothly, without applying suction. [30] The catheter is advanced until resistance is met, usually at the carina, and withdrawn 1 to 2 centimeters. Irritation of the carina typically elicits a vigorous cough reflex, which should be allowed to subside before proceeding. Suction is applied as the catheter is withdrawn, and should be limited to 10 to 15 seconds' duration. Some authors recommend intermittent application in place of continuous suctioning.[30] Gentle rotation of the catheter as it is withdrawn may facilitate removal of secretions. The catheter can be flushed with sterile saline between passes, and the patient should be oxygenated between suctioning attempts. No more than three suction passes should be performed in succession.

The common practice of instilling saline into the tracheal tube to elicit a cough or loosen secretions is no longer supported for hospitalized patients. [29] [30] The viscosity of airway secretions does not change with saline instillation. [13] Systemic hydration and application of humidified air will decrease mucus viscosity more effectively. In addition, instillation of saline can have a detrimental effect on oxygenation, which may last up to 5 minutes postprocedure. [14] Theoretically, the cough stimulated by saline instillation may drive secretions or microorganisms into the lower airway. [13] However, one survey demonstrated that 70% of respiratory therapists and 20% of nurses continue to routinely instill saline prior to suctioning. [21]

The recommendations presented earlier also do not address the ED patient with a critical airway obstruction due to inspissated secretions. Of note, Hudak and colleagues studied oxygen saturation and amount of secretions suctioned, with and without saline instillation prior to suctioning. The mean weight of secretions removed increased after instillation of saline, but it is not clear whether mucus or recovered saline accounted for the increased weight. They reported no instances of oxygen desaturation as a result of saline instillation prior to suctioning. [32] The usual instillation of 5 to 10 mL of saline is consistent with volumes infused during

endotracheal drug administration, which are generally well tolerated. Nonetheless, when saline instillation is used for unusually thick secretions in a patient with respiratory symptoms, supplemental oxygen is advised.

Clotted blood or other thick secretions that are not removed by suctioning may be retrieved by extraction with a No. 6 Fr Foley catheter. The catheter is passed beyond the occluding material and inflated. The material is pulled ahead of the catheter during its withdrawal. [11]

Patients should be monitored throughout the procedure for signs of cardiac dysrhythmias or hypoxia, and the procedure should be stopped if either is evident (see *Complications*, later). Causes of hemodynamic instability should be addressed before continuing with suctioning. However, if marked respiratory distress is presumed secondary to significant tracheal obstruction, expeditious suctioning should be done to reduce the obstruction.

Nasotracheal Suctioning Techniques

Nasotracheal suctioning has been used to avoid intubation intended solely for removal of secretions. [33] It should be instituted if audible evidence of secretions in the central airway persist despite a patient's best cough effort. Infants with thick nasopharyngeal secretions may also benefit from tracheal suctioning if deep nasal suctioning does not clear the upper airway. Suspicion or evidence of epiglottis or croup are absolute contraindications to the procedure; occluded nasal passages, nasal bleeding, laryngospasm, and coagulopathy are relative contraindications. [33]

A nasopharyngeal airway ("trumpet") is placed in the adult patient's nare to decrease nasal mucosa irritation and to help direct the suction catheter toward the airway. Topical anesthetic jelly can be applied to the nasal mucosa for patient comfort. The patient's reflex to swallow the catheter may be reduced by asking the patient to stick his or her tongue out or manually applying traction to the tongue of a patient unable to voluntarily comply. The catheter is advanced through the nare before attaching it to wall suction. When the catheter is properly positioned over the airway, the clinician should be able to hear air movement through the proximal catheter. The catheter is advanced into the trachea until resistance is met, and withdrawn 1 to 2 centimeters. Endotracheal suctioning is completed as described earlier. [33]

Minitracheostomy Suctioning Procedures

The minitracheostomy ("minitrach") was designed to improve tracheal hygiene in patients with intact cough reflexes, normal ventilatory function, and vocalization. The minitrach serves as a small port solely for suctioning secretions. Commonly, a 4 mm indwelling, cuffless cannula is inserted through the cricothyroid membrane into the trachea. Patients suctioned through a minitrach are at lower risk for the gagging and aspiration associated with blind endotracheal suctioning because they are able to maintain laryngeal and glottic function. [27] Because of small airway diameters, the minitrach is rarely used in children.

The technique used to suction through a minitrach is the same as that for tracheostomy suctioning. The smaller port size may require that smaller catheters be used. Most patients with minitrachs are decannulated before discharge from the intensive care unit, and uncommonly present to the ED.

Complications of Suctioning

Complications that occur during or after suctioning are relatively common, and can result in significant morbidity. Fortunately, most complications can be anticipated, and simple maneuvers can reduce their incidence and severity.

Hypoxemia from suctioning may be transient, but has the potential to cause increased intracranial pressure (ICP), dysrhythmias, or death. Cerebral hypoxia during suctioning may contribute to the genesis of intracerebral hemorrhage in neonates. [34] A number of factors contribute to suctioning-related hypoxia, including interruption of mechanical ventilation, aspiration of air from the respiratory tract, and suctioning-related atelectasis. In-line suction catheters can be used with ventilator-dependent patients, to allow continuous oxygen delivery and positive pressure ventilation during suctioning. Catheters should be sized appropriately (see procedure described earlier) to reduce the evacuation of airway gases during suctioning, and help prevent atelectasis. Suctioning passes should be limited to 10 to 15 seconds' duration and to only three suction passes in succession. The patient should also be reoxygenated between suctioning passes and after the procedure. Reducing or discontinuing routine saline instillation into the trachea before routine suctioning is also recommended. [14]

Measurements of arterial oxygen saturation may not be sufficient to assess hypoxia following suctioning. It has been shown that oxygen consumption increases during suctioning despite insignificant changes in oxygen saturation. This increase in oxygen consumption was more marked in patients who displayed a vigorous cough, agitation, or resistance to suctioning. [35]

Dysrhythmias due to suctioning may be caused by hypoxia, increased myocardial oxygen consumption, vagal stimulation, or catecholamine release. Vagal stimulation caused by suctioning or rough movement of the endotracheal tube can cause bradycardia and possible hypotension. Bradycardia in the setting of hypoxia potentiates ventricular dysrhythmias, including ventricular fibrillation. Nebulized or intravenous atropine is recommended for bradycardias, and can be used as pretreatment in patients at risk for bradycardia, including infants. Digoxin enhances vagal activity and may potentiate the vagal stimulation of endotracheal suctioning. [28] Sympathetic stimulation may occur as a result of hypoxia, pain, or stress of the procedure. Pain medication, anxiolytics, or preparation of the patient for the procedure may blunt the sympathetic response. Suctioning should be terminated immediately if any new dysrhythmia is evident.

Increase in ICP during suctioning is well documented. [36] [37] [38] The theoretical risks of increased ICP include decreased cerebral perfusion pressure in patients with compromised cerebral blood flow, inducing cerebral hypoxia, worsening cerebral edema, and possibly contributing to intraventricular hemorrhage in neonates. [31] [34] [35] There is no common agreement on the underlying cause of increased ICP during suctioning. [39] Mean ICP increases occur in a stepwise fashion with repeated suctioning; this effect is reversed if manual hyperventilation is extended to 60 seconds between suctioning passes. [39] Kerr suggested that decreases in Pa_{CO2} can minimize suctioning-induced ICP elevation, and advocated increasing the rate of manual hyperventilation from 12 breaths/min to 30/min. This study demonstrated a transient decrease in Pa_{CO2} with this rate, with a corresponding

decrease in ICP during suctioning.[31] Long-term reduction in Pa_{CO2} is not advocated. Mean arterial blood pressure also increases with suctioning, but this may be protective of cerebral oxygenation by increasing the cerebral perfusion pressure. Cerebral vasodilation after preoxygenation has been suggested as a mechanism that maintains cerebral oxygenation, even when transient increases in ICP occur during suctioning. [37] Vigorous coughing and increases in intrathoracic pressure are possible causes of increase in ICP. Instillation of lidocaine into the trachea can help suppress coughing. Pretreatment with fentanyl, or thiopental has not shown a significant effect in blunting the increase in ICP during suctioning. However, intravenous lidocaine (1.5 mg/kg), intratracheal lidocaine (2 mL of 4% solution) or temporary paralysis may attenuate ICP increases in patients with severe head injury. [11] In patients without evidence of increased ICP, routine pretreatment with drugs to prevent increased ICP is probably unnecessary. [11] Preoxygenation and hyperventilation are simple maneuvers that should be carried out in all patients.

Atelectasis can occur when airway gases are suctioned rapidly. This complication is reduced by choosing a suction catheter that is less than one-half the diameter of the artificial airway, and by controlling the time and suction pressure applied during suctioning (see earlier, *Procedure*). Postprocedure hyperventilation can treat suction-related atelectasis. [11]

Mucosal injury is a common complication of tracheal suctioning. Invagination of the mucosa into the side ports of the catheter occurs during suctioning, causing tracheal mucosa to become denuded, edematous, and more likely to bleed. Mucosal damage also interferes with mucociliary transport. Tracheitis, indicated by blood-streaked secretions or a persistent hacking cough, can occur as the result of frequent or improperly performed suctioning. [11] To reduce tracheitis, 1 mL of 1% lidocaine may be instilled into the trachea.

Suctioning technique appears to be more important than catheter tip design in reducing mucosal injury. Suctioning should be performed only when clinically indicated to reduce repeated airway trauma. The length of time suctioning is performed should be limited to 10 to 15 seconds, and appropriate vacuum pressures used. Bronchoconstriction may be triggered by suctioning. Cessation of the procedure, application of positive pressure ventilation, or use of bronchodilators should help resolve this complication.[11]

Sudden death has been reported during tracheal suctioning, and is likely due to one or more of the complications discussed here. Cardiopulmonary resuscitation equipment and medications should be available to the clinician before the procedure is initiated. [11]

Transesophageal Puncture for Voice Restoration

Transesophageal puncture (TEP) has evolved into the most widely used and accepted technique for voice rehabilitation. Originally developed in the 1980s, it can be done as a primary or secondary procedure, following laryngectomy or pharyngeal surgeries.

A puncture site is instrumented through the anterior esophagus and posterior tracheal wall, and the TEP prosthesis is inserted after dilation of the wound. Production of speech with TEP is similar to that of esophageal speech. The mucosa vibrate in segments of the pharyngeal esophagus resulting from air flow.

TEP Complications

Operative and immediate postoperative complications of TEP are infrequent. [40] Long-term complications include stomal stenosis, aspiration of the prosthesis, fistula leakage, TEP necrosis, and swallowing impairment. Reported infectious complications associated with TEP include deep neck abscess, aspiration pneumonia, and cervical cellulitis. [41]

While few TEP complications are life-threatening, the practitioner should be aware of several considerations with this device. Thick or inspissated secretions, especially after radiation therapy, or food may accumulate above the TEP, causing airflow obstruction in the upper airway. Acute changes in voice production or decreased ability to speak warrant consideration of prosthesis dislodgment, occlusion, or erosion due to infectious etiologies, especially fungal. [42] Esophageal edema causing dysphagia and loss of TEP speech has been reported [42] and should be differentiated from other etiologies of esophageal obstruction. The clinician should ascertain the presence of TEP by history or medical records, assess airway and esophageal patency, and determine if the patient has experienced changes or difficulties in voice production. Infectious complications should be sought and treated in the ED, maintaining a high degree of suspicion for fungal etiologies. In stable patients, management of prosthesis complications most often can be referred to the specialist, generally an otolaryngologist. Communication with the specialist should include consideration of prosthesis leak, dislodgment, obstruction, or infections.

Transtracheal Oxygen Delivery Systems

Low-flow oxygen administration is prescribed for patients who have adequate ventilatory function, but suffer from chronic hypoxia. Patients with chronic obstructive pulmonary disease, pulmonary fibrosis, sleep apnea, [43] lung cancer, and alpha-1 antitrypsin deficiency are often candidates for outpatient use of supplemental oxygen.[44] [45] Traditionally, supplemental oxygen has been delivered by nasal cannula. Although technically simple, nasal cannula use has numerous side effects including nasal mucosa drying and epistaxis, ear discomfort, and contact dermatitis from oxygen tubing, [44] and dry throat.[45] Delivery of oxygen via nasal cannulae is also very inefficient because it occurs only during inspiration, and oxygen must traverse the anatomical dead space of the nares and hypopharynx.

Transtracheal oxygen (TTO) delivery systems can be used in place of nasal cannula to enhance the efficiency of oxygenation, reduce complications, and improve patient comfort and compliance.[46] Low-flow oxygen (2 to 10 L/min) is delivered directly into the trachea through a narrow (7 to 11 Fr) catheter. Typically, the catheter sits in the trachea with its tip 1 to 2 cm above the carina.[44] The catheter can have single or multiple distal ports for oxygen flow.

TTO is administered throughout all phases of the respiratory cycle [43] and directly into the trachea, bypassing the upper airway dead spaces. For these reasons the required oxygen flow rates are decreased, often by 50% or more.[46] Gas mixture in the distal trachea is more effective in eliminating carbon dioxide. Clinically, these systems reduce the work of breathing and exertional dyspnea.[44] The catheter is held in place by a thin band or necklace through two openings in the flange. The catheter stoma is generally created at the base of the neck, and can be hidden under clothing.

The surgical procedure is often done as an outpatient, under local anesthesia. Initially, a small stent is placed percutaneously into the anterior neck, and replaced with a TTO catheter when the tract matures, usually in 1 to 2 weeks.[44] Once the tracheocutaneous fistula has epithelialized, the catheter may be inserted and changed safely by the patient at home. Early catheter changes may be done in the clinician's office over a guidewire, if the integrity of the stoma is questionable.

Early complications (within 3 months of the procedure) occur in approximately 30% of patients [44] [45] and include bleeding at the stoma, infection, pneumothorax, costochondritis,[47] ejection of the catheter from coughing,[48] and inability to replace the catheter after dislodgment. [45] Pneumomediastinum and sudden death were reported as possible early complications. [49] Late complications include mucus plugging, bleeding, infections, and hemoptysis [44] [45] [48] and occur in >75% of patients.[45]

Regular maintenance includes cleaning and changing the catheter. One milliliter of sterile saline is inserted into the catheter, and a cleaning rod is inserted as far as possible. The cleaning rod is inserted and removed three times to remove secretions from the catheter lumen. Catheters are changed according to manufacturer's recommendations, from twice daily to once every 2 weeks, or as needed. The stoma should be cleaned twice daily, and inspected for signs of infection. All catheter maintenance procedures should be done while the patient is given supplemental oxygen by nasal cannula.

Dyspnea or increased cough may indicate catheter obstruction by mucus or from kinking, or that the catheter tip is located cephalad to the stoma. A whistling sound from the oxygen tank humidifier may indicate obstruction within the catheter or oxygen tubing. Cellulitis around the stoma, subcutaneous air, or dislodgment of the catheter should be evident on patient examination.

In the ED, the catheter can be cleaned or replaced if obstruction is suspected. A catheter change should be done by modified Seldinger technique if the stoma tract has not healed or appears infected. Water-soluble lubricant should be used for catheter changes. If changing the catheter does not relieve obstruction, and the patient's airway is intact, increasing the intrathoracic pressure may help increase the force of the cough. The patient may sit upright, holding a pillow to his or her abdomen, and coughing forcefully after three deep inspirations. This maneuver may help mobilize secretions or small mucus plugs in the airway. Dyspnea and cough

should lessen with effective removal of obstructions.

Bleeding complications at the catheter site can be managed with gauze packing or cauterization, if minor. If significant bleeding is identified or suspected, emergency consultation by a specialist should be arranged, and definitive airway management applied as clinically indicated. Management of skin and pulmonary infections is similar to that discussed for tracheostomy care.

TRANSTRACHEAL NEEDLE ASPIRATION

Transtracheal needle aspiration is an infrequently performed procedure used to obtain tracheal sputum samples for microbiology. It offers the advantage of providing access to lower respiratory secretions in patients for whom accurate and timely identification of infectious agents is desired. Cultures of lower respiratory tract secretions obtained by transtracheal needle aspiration are more predictive of pulmonary infection than are those obtained from expectorated washed sputum. [11] Transtracheal aspiration specimens have been shown to be especially useful in diagnosis of unusual pulmonary infections, including those caused by anaerobic bacteria, tuberculosis bacilli, *Aspergillus, Pneumocystis carinii*, and hospital-acquired and partially treated pneumonias. [11]

Indications and Contraindications

The primary clinical indication to perform transtracheal needle aspiration is to obtain sputum samples from patients unable to generate an adequate expectorated sample. This population may include obtunded patients or those with underlying pulmonary or neurologic illnesses that limit ability to cough. Several contraindications to the procedure exist. These include the presence of bleeding diatheses, distorted anterior neck landmarks, hypoxia, and the patient's inability to remain supine and cooperate with the procedure. Aspiration of sputum from patients with chronic bronchitis may yield false-positive cultures. [11]

Equipment

Commercially available intravenous catheter sets that contain an introducer needle, a J-wire guide, and tracheal catheter are available. The catheters are generally 15 to 20 cm in length, and 16- to 18-ga in diameter. An additional 10 to 50 mL syringe is needed to collect the sputum sample. Previously discussed recommendations to limit the use of saline for sputum collection also may apply to this procedure. However, the literature does not provide data or specific recommendations regarding saline instillation for this procedure.

Procedure (Fig. 7-5)

The patient should be placed on a cardiac monitor and given supplemental oxygen. Cardiac resuscitation equipment should be readily available. Sterile procedure, including skin preparation and draping, should be used. The patient should be supine, with a small towel or pillow between the shoulder blades, to allow full extension of the neck. The cricothyroid membrane should be identified by palpation, and a small weal of local anesthetic injected into the skin above this landmark.

The introducer needle is inserted into the trachea through the cricothyroid membrane, with the needle tip directed inferiorly. Aspiration of air through the needle confirms intratracheal placement. The guidewire is subsequently threaded

Figure 7-5 Transtracheal aspiration. *A*, Position of patient. *B*, Anatomic landmarks. *C*, Technique of puncture. The Intracath needle or J-wire introducer needle is inserted just above the cricoid cartilage through the cricothyroid membrane with its bevel up at a 45° angle to the skin. *(From Eknoyen G: Medical Procedures Manual. Chicago, Year Book Medical Publishers, 1981. Reproduced by permission.)*

through the needle, and the needle removed. The catheter can then be advanced over the guidewire. A sterile syringe is applied to the catheter, and sputum is aspirated from the tracheal lumen with gentle suction. A small aspirate amount is suitable for analysis. After sputum has been obtained, the catheter is removed, and direct pressure is applied to the puncture site. The patient should avoid therapies that stimulate coughing for 24 hours after the procedures. [11] Antitussive medications may be helpful.

Complications

Complication rates for transtracheal needle aspiration are low, and can be managed by similar techniques described elsewhere in this chapter. Cardiac dysrhythmias may be induced by vagal stimulation or hypoxia. Preoxygenating the patient should ameliorate hypoxia, and atropine may be required for bradydysrhythmias. Some patients develop subcutaneaous emphysema, which is usually self-limiting and can be minimized by reducing the amount and force of the patient's cough. Digital pressure will control most bleeding that develops. [11]

CONCLUSION

In the infrequent instances in which tracheobronchial secretions are not obtainable from expectorated sputum and when accurate bacteriologic diagnosis is essential to care of the patient with a pulmonary infection, transtracheal needle aspiration is a relatively safe, practical method for obtaining a sample. The procedure has low morbidity, high yield, and high diagnostic accuracy. [11]

SUMMARY

Knowledge of tracheal procedures, especially those related to tracheostomy care, is essential for the emergency clinician. Management of tracheostomy related hemorrhage, infection, and airway obstruction are important emergency skills. Awareness of newer tracheal and esophageal voice devices and their potential complications will also help guide the care of patients with these devices. Although transtracheal suction is rarely used today, it provides an important diagnostic alternative for patients with unusual pulmonary infections who do not require intubation.

Chapter 8 - Mechanical Ventilation

Heatherlee Bailey
Lewis J. Kaplan

Initiating mechanical ventilation (MV) in the emergency department (ED) is an integral part of emergency medicine practice. However, increasing evidence holds that the manner by which human lungs are mechanically ventilated may be as deleterious as helpful. [1] The traditional view of MV as little more than a formulaic prescription that will fit virtually all patients equally well is to be discarded as a gross misunderstanding of pulmonary pathophysiology at best. Every ED clinician should embrace the firmly established paradigm of pulmonary protective ventilation and oxygenation strategies as a cornerstone of care. This chapter will address indications for MV, new strategies for safe ventilation and oxygenation, survival advantages that accrue from such interventions, complications of positive-pressure ventilation, and advanced modes of MV. One key to providing excellent ED care is to recognize when airway control and MV are warranted.

INDICATIONS FOR MECHANICAL VENTILATION

There are wide-ranging reasons for patients to require MV in the ED, and there are no absolute contraindications. Many time-honored indications for invasive ventilation are now identified as appropriate indications for noninvasive ventilation and will be addressed later. Current indications for endotracheal intubation may be separated into several categories based on the urgency of the airway need: (Emergent, Urgent, Delayed, and Elective). Emergent intubation is for patients who require immediate airway protection and MV on arrival to the ED. These patients tend to be *in extremis*, either suffering from shock with decreased oxygen delivery (DO_2) or having an absent or unprotected airway. These problems may cause hypoxemia or hypercarbia with acidosis, or both. Urgent intubation is for patients who require assistance within the first few minutes of arrival. It is used in patients who have impending airway loss. Patients who have increased work of breathing with worsening hypoxia and rising CO_2, or those with emerging injury complexes that may compromise the airway or thoracic cage may also require urgent intubation.

Delayed intubation is for patients who are stable for the initial and secondary assessment, but then require mechanical assistance. This scenario may arise for numerous reasons, including progression of the disease process despite therapy or inadequate improvement with treatment. Transport to a noncritical care area with a patient who has potential for airway loss is another reason for delayed intubation to occur. [2] More ED clinicians are facing the challenge of patients requiring delayed intubation because of increasing demands on the health care system. Patients are spending more time in the ED before admission due to the shortage of critical care beds and appropriately trained nurses. [3] This health care crisis allows the ED doctor to see these patients when they decompensate due to disease progression or treatment failure (when they normally would have already been in the intensive care unit [ICU]).

Elective intubation is for patients who will require airway protection and MV to facilitate care of organ systems besides the respiratory tract. A common example is for airway control for an invasive procedure. This last category is not common in the ED. If a patient needs to leave the department for a test or for transfer to another institution and there is potential for airway compromise during the transfer/procedure, then elective intubation is indicated. Emergency clinicians are acute care airway specialists and it is their responsibility to ensure patient safety.

In order to initiate and sustain appropriate MV, it is important that the ED clinician understand basic principles, standard equipment, goals, settings, and monitoring strategies for patients on MV.

BASIC PULMONARY PHYSIOLOGY

Minute Volume and Alveolar Ventilation

The volume of air that moves in and out of a patient's lungs per minute is termed the minute volume ($?V_E$). $?V_E$ is the product of tidal volume (V_T) and respiratory frequency or rate (f):

$?V_E = V_T \times f$

Tidal volume can be further broken down into alveolar volume (V_A) and dead space volume (V_D):

$V_T = V_A + V_D$

In healthy young persons, the anatomic dead space is accounted for by the trachea and the larger airways and is approximately 2.2 mL/kg of lean body weight. In disease states, in addition to the anatomic dead space, there is also a variable amount of "pathologic" dead space corresponding to ventilated alveoli and respiratory bronchioles that are not adequately perfused. The sum of the anatomic and pathologic dead spaces is often referred to as the physiologic dead space.

Alveolar minute ventilation ($?V_A$) is the product of rate times V_T minus dead space:

$?V_A = (V_T - V_D) \times f$

$?V_A$ and the rate of CO_2 production by the body ($?V_{CO_2}$) determine the partial pressure of CO_2 in the alveoli ($PACO_2$), which is approximately equal to the systemic arterial CO_2 tension ($PaCO_2$). This relationship is as follows:

$PaCO_2 ? PACO_2 = k \times (?V_{CO_2} / ?V_A)$

The value of the constant (k) is 0.863 when the partial pressure of CO_2 is measured in millimeters of mercury at 37°C saturated with water vapor. $?V_{CO_2}$ is measured in milliliters per minute, and $?V_A$ is measured in liters per minute. Understanding basic pulmonary physiology is essential to understanding how to initiate MV; it ensures that the method of gas delivery meshes with the patient's underlying physiology to avoid ventilator-induced lung injury. Clinicians must also understand the basics of ventilator operation and order writing.

EQUIPMENT—STANDARD OPTIONS

Regardless of which ventilator one uses, a limited number of standard features are common to each of them. This discussion explores machine features and settings.

Control Mechanisms

Volume-Cycled.

With this target, the ventilator seeks to deliver a preset amount of gas. The time of gas flow is determined by the set volume (V_T), flow (?Q), and the waveform of gas delivery (see later). When the set V_T is reached, gas flow is terminated and expiration passively begins. An advantage is that this method delivers a constant V_T. Unfortunately, it does not take into account dynamic changes in lung compliance, which may alter the ability of the lung to accept delivered gas in gas-exchanging alveoli. This is the most common mode used in the United States.

Pressure-Cycled.

With this target, the ventilator alters gas flow to achieve and maintain airway pressure at a preset level for the duration of a preset inspiratory time (T_i). Gas flow is terminated when the preset change in pressure is achieved. The pressure is maintained with a variable or intermittent ?Q for the set T_i. Gas flow is adjusted to not exceed a set pressure limit (i.e., pressure-limited or pressure-controlled ventilation). One problem with this method is that the volume received by the patient is variable. The delivered volume is determined by the patient's lung and chest wall compliance, the airway resistance, as well as the T_i and pressure target. An advantage is that airway pressures are tightly managed to limit or eliminate alveolar overdistention and to reduce ventilator-induced lung injury. [5] In the setting of hypoxemia, the inspiratory time may be increased quite precisely to increase the mean airway pressure and thus oxygenation; this strategy is much more difficult, if not impossible, to manipulate using volume-cycled ventilation.

Modes

Controlled Mechanical Ventilation/Assist Control (CMV/AC).

This ventilator mode provides breaths, known as machine breaths, at a preset rate. If the patient tries to breathe faster than the set rate, he or she can initiate additional breaths known as spontaneous breaths. In volume-cycled ventilation (VCV), the spontaneous breath receives the same V_T that is set for the machine breath, regardless of how much gas the patient wants to receive. For the patient to trigger the ventilator to initiate flow for a spontaneous breath, the airway pressure must decrease by a preset amount below PEEP. The amount of decrease necessary to open the inflow valve is the sensitivity setting. This is typically 0.5 to 2 cm H_2O pressure. The higher the sensitivity, the greater the work of breathing required to trigger a breath.

Intermittent Mechanical Ventilation (IMV)/Synchronized IMV (SIMV).

This ventilator mode provides breaths at a preset rate (machine breath) similar to the AC mode. The patient can initiate an additional spontaneous breath, but only receive a spontaneous V_T that reflects the depth and time spent in inspiration. For each of these nonmandatory (i.e., spontaneous) breaths, the patient receives no support from the ventilator and has a high work of breathing. Thus, SIMV is typically partnered with Pressure Support Ventilation (PSV—see later) to aid in spontaneous breathing support and to overcome the intrinsic resistance of breathing through long tubes and the endotracheal tube with a diameter smaller than the patient's native airway. The synchronized version of IMV allows the ventilator to coordinate spontaneous and machine breaths to prevent it from delivering a scheduled breath on top of a spontaneous breath (excess V_T delivered) or during exhalation from a spontaneous breath (exhalation compromised by positive airway pressure). Both conditions were a problem with the original IMV mode. This could lead to elevated airway pressures, alveolar overdistention, and biotrauma. [4]

Each of these modes (CMV/AC and IMV/SIMV + PSV) may be combined with either a volume target or a pressure target to achieve the desired minute ventilation (see above).

Continuous Positive Airway Pressure (CPAP).

CPAP is another positive-pressure, spontaneously breathing mode. It is most commonly used in isolation for those with chronic obstructive pulmonary disease (COPD) or obstructive sleep apnea via a tight-fitting nasal or full face-mask. In patients with an endotracheal tube (ETT) or tracheostomy tube, CPAP is typically used as a weaning mode in combination with PSV. The CPAP level when transitioning from IMV/PSV or AC mode should be the PEEP level that was being used. Reducing the CPAP below the previous PEEP may result in loss of alveolar recruitment, atelectasis, hypoxia, and an increased work of breathing.

Adjunct Ventilator Settings

Oxygen.

The percentage of inspired O_2 (FIO_2) is set in a range from 21% (room air; not generally indicated) to 100%. In the ED it is common to start at 100% FIO_2 to ensure adequate oxygenation and titrate the FIO_2 down to nontoxic levels ($FIO_2 < 0.60$) following the SaO_2 via the pulse oximeter (SaO_2 90% ? pO_2 60 torr). In theory, placing the patient on 100% FIO_2 may lead to alveolar collapse due to absorption of all the oxygen in that alveolus. Recall that room air is principally N_2 mixed with O_2 and a number of inert gases. If there is only O_2 delivered to an alveolus, and that O_2 is absorbed, there will be no nonabsorbed gases to keep open the alveolus. This is known as absorption atelectasis and leads to V/Q mismatch when present. Thus, some practitioners recommend using 95% O_2 as the upper limit of FIO_2.

PEEP.

This is the pressure in the airway at the end of exhalation. PEEP helps keep the large noncartilaginously supported airways and the smaller alveoli open to prevent collapse, atelectasis, and hypoxia at the end of expiration. The required ventilation to compensate for this triad commonly worsens lung compliance and is associated with ventilator-induced lung injury. The useful PEEP range is from 3 to 20 cm H_2O.[6] In general most patients should be started on a PEEP of 5 cm H_2O. This is considered a physiologic level. PEEP can be increased by 3 to 5 cm H_2O every 10 to 15 minutes as needed/tolerated for patients who remain hypoxic. The initial goal is to reduce the FIO_2 to nontoxic levels ($FIO_2 < 60\%$). This goal is coming under increasing scrutiny as new information challenges the timeframe and concept of O_2-induced lung injury at FIO_2 levels >0.6. [7]

PEEP is used to increase functional residual capacity (FRC) and move the zero pressure point of each alveolar unit more proximal in the airway so as to prevent early alveolar collapse.[8] By so doing, PEEP increases the available number of alveolar units that can participate in gas exchange. The

primary effect of PEEP on gas exchange, however, is to improve oxygenation, not CO_2 removal. CO_2 clearance is rather efficient and will be well preserved in situations where oxygenation is not. By opening one alveolar unit, the tendency of the adjacent unit is to open as well (i.e., alveolar codependency; Fig. 8-1).[9] Excessive PEEP will compromise hemodynamics. Therefore, there are two primary questions to ask when using PEEP to augment oxygenation: What is the "optimal PEEP," and is the current amount of PEEP compromising the patient's hemodynamics?

There are several ways to determine the "optimal PEEP." One way is to increase the PEEP until there are no longer increases in the pO_2. This method, however, may result in several untoward events. First, oxygen tension may steadily increase, but pCO_2 may increase as well from alveolar overdistension. With overdistension, the alveolar pressure may exceed pulmonary arteriolar pressure and actually decrease pulmonary blood flow and CO_2 clearance. Second, alveolar overdistension may increase total intra-thoracic pressure and therefore diminish venous return and hence cardiac output. Third, decreased venous return may result in cerebral venous hypertension as indicated earlier. The "optimal PEEP" for one organ system may be deleterious for another. For example, the optimal PEEP for ideal oxygenation may be the worst PEEP for cerebral venous drainage.

A better method of determining the "optimal PEEP" relies on measuring oxygen delivery and oxygen consumption. PEEP may be increased until there is no further increase in oxygen delivery, and no increase in oxygen consumption.[10] This method does require a pulmonary artery catheter to be in place for determination of $?DO_2$ and $?VO_2$. In many institutions, the application of PEEP above 10 cm H_2O pressure in a

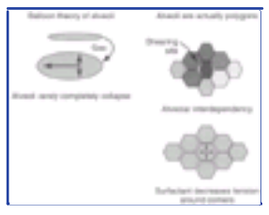

Figure 8-1 Alveolar interdependence. Note that alveoli are not round in shape; instead, they are polygons. Polygons have corners and may have two opposing surfaces that may adhere to one another via surface tension. Surfactant works to reduce this surface tension and allow alveoli to open with reduced shear stress at the junction of closed and open alveoli. Alveoli are connected via the pores of Kohn. This allows opening alveoli to pull a relatively closed alveolus open while equalizing pressure between adjacent alveoli. The central alveolus on the right is fairly closed in the upper diagram, but is pulled open by its neighbors as they expand and accept gas.

multiply injured patient necessitates a pulmonary artery catheter being placed to make such determinations regarding oxygen extraction. An alternative is to increase PEEP until a complication of PEEP occurs (e.g., pCO_2 elevation, hypotension), and then reduce PEEP if needed (inability to tolerate hypercapnia), or expand the patient's intravascular volume to combat decreased venous return. The authors favor the placement of a pulmonary artery catheter in these situations to accurately guide therapy and know the patient's $?DO_2$ and $?VO_2$ status.

Another excellent method of determining the "optimal PEEP" is guided by assessing changes in plateau pressure with changes in PEEP. As PEEP is increased from a minimal level, the patient's peak airway pressure as well as plateau pressure will increase by the amount of the applied PEEP. However, when the "optimal PEEP" for the lung units is achieved, the plateau pressure will no longer increase; in fact, as the lung is optimally recruited, the peak and plateau pressure may decrease as there is more volume of lung available to receive a set V_T. Once this level is exceeded, however, there will be further increases in plateau pressure beyond the incremental increase in PEEP as the units overdistend. Therefore, the clinician must readily identify the plateau in the plateau pressure trend. The same relationship may be displayed graphically in the dynamic pressure-volume loop (Fig. 8-2). The lower limb of the loop represents the pressure required to open the alveolar units.[11] In the absence of PEEP (or inadequate PEEP), this limb is prolonged and flattened and has an inflection point far to the right of the origin of the loop (Fig. 8-3). As PEEP is progressively increased, the inflection point travels to the left. When the "optimal PEEP" is achieved, there will be a rapid upstroke of the loop as the vast majority of the functional lung units are already open and ready to be ventilated (see Fig. 8-2). This strategy is known as the "open lung model" of MV.[11]

PEEP is not without untoward side effects, and increased levels of PEEP can lead to hemodynamic compromise.[12] This occurs from increased intrathoracic pressures leading to cardiac compression and collapse, principally of the right

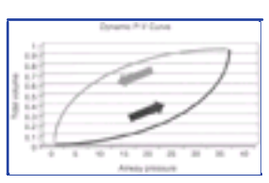

Figure 8-2 Dynamic pressure-volume loop. Note that as soon as there is delivered pressure to the airway, there is an increase in measured tidal volume. The lower arrow denotes inspiration while the upper arrow indicates exhalation. This indicates that the airways are open and do not need to be forced open by increasing the pressure in the airway. If this latter case were true, then the P-V loop would initially be flat along the X-axis.

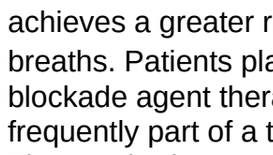

Figure 8-3 Inadequate PEEP and the P-V loop. Compare this curve to that in Figure 8-2 . Note that the loop is initially flat (lower segment) along the X-axis. Once the airway pressure is high enough to open the alveolar units, each increase in airway pressure is matched by a corresponding increase in tidal volume.

atrium. It is imperative that the patient be adequately resuscitated as volume depletion compounds this problem. Desired levels of PEEP simply may not be possible because of deleterious effects on cardiac output.

Pressure Support Ventilation (PSV).

This mode augments spontaneous ventilation in the IMV/SIMV and CPAP modes. There is gas flow during inspiration for each spontaneous breath to help the patient overcome the resistance of the circuit and to achieve an acceptable V_T. The range is from 0 up to 35 cm H_2O pressure; some ventilators may deliver PSV that achieves a greater range. The average starting point is 10 cm H_2O. PSV is adjusted as needed so that the spontaneous V_T approximates the set V_T for mandatory breaths. Patients placed on the combined mode of CPAP/PSV *must* be spontaneously breathing. PSV-based ventilation must *never* be combined with neuromuscular blockade agent therapy, or death from apnea, hypercarbia, and hypoxia will result. PSV is commonly used to aid in weaning from IMV-based ventilation and is frequently part of a transition strategy from IMV to CPAP.[13] In this way, PSV is used to eliminate the work of breathing improved by the ETT and the ventilator tubing. The required amount of pressure support to overcome the tube-induced resistance has been well documented (Table 8-1).[14] It is imperative not to lower the PSV during weaning below that required to overcome the resistance imposed by the diameter of the ETT or tracheostomy tube as the work of breathing may precipitously rise. Unlike AC or SIMV, PSV does not have a preset T_i. In fact, the time at which the gas flow terminates for each PSV breath is determined by an algorithm that in most older ventilators is not manipulable.

For instance, a patient breathing on CPAP/PSV on a Puritan-Bennett 7200 ventilator would have his or her maximal inspiratory flow required to achieve the set pressure support level measured. As the patient's airways progressively fill with gas, the patient draws in gas at a slower rate, and the machine needs less of a flow rate to maintain the airway pressure. When the machine flow rate decreases to 25% of the previously measured maximal inspiratory flow rate, all gas flow ceases. This termination occurs whether the patient is done inspiring or not. This algorithm may lead to significant patient-ventilator dysynchrony.[15] Newer ventilators, such as the Hamilton Gallileo, allow user adjustment for such dyssynchrony. A common resolution using such a PSV device is either patient sedation or an increased level of pressure support so that the patient receives his or her desired amount of gas before gas flow termination.

Inspiration:Expiration (I:E) Ratio.

The normal I:E ratio in a spontaneously breathing, nonintubated patient is 1:4.[14] Intubated patients commonly achieve I:E ratios of 1:2. Shorter ratios may lead to

decreased exhalation by compromising exhalation time (T_e). In its extreme form, inverse ratio ventilation (IRV), the normal pattern of breathing is reversed. There is a longer time spent in inhalation to allow a longer time for oxygenation. Longer inspiratory times allow for better matching of alveolar regional time constants. [16] The decrease in expiratory time can lead to air trapping, elevated airway pressures, and rising pCO_2. These problems lead to hypercapnia, respiratory acidosis, and auto-PEEP.[16] Auto-PEEP is additional pressure that is generated within the airways from trapped gas that should have been exhaled, but for various reasons (commonly obstruction to exhalation such as COPD), was not.

Auto-PEEP can cause hemodynamic instability secondarily to decreased venous return just like high levels of PEEP. [17] Auto-PEEP may be detected in two ways: (1) evaluating the flow-time trace or (2) disconnecting the patient from the ventilator and listening for additional exhaled gas after an exhalation has already occurred. [11] The flow-time trace will demonstrate that the exhalation is not yet completed before the next breath has been initiated (Fig. 8-4). Auto-PEEP is a real potential when one initiates IRV for the management of hypoxemic respiratory failure. One can initiate IRV most easily in pressure cycled ventilation (PCV) where the operator sets the T_I directly. With VC ventilation, one can achieve a similar gas delivery by adjusting the flow rate of each breath to adjust the I:E ratio; that the Q needs to be adjusted on a breath-by-breath basis makes this impractical.

?Q.

This is the rate of gas delivery (L/min). The range of flows that can be achieved by current ventilation is from 10 to 160 L/min. Common flow settings are from 40 to 75 L/min. The higher the rate, the faster the ventilator will reach its set volume or pressure. A faster rate allows for a longer exhalation time, but due to the shortened inspiratory time, hypoxia can result. A slower rate allows for longer time in inhalation and improved oxygenation but a shortened expiratory time, which may lead to retained CO_2 and auto-PEEP from inadequate T_e (Fig. 8-5).

Waveforms

Square.

Once the maximal inspiratory ?Q is achieved, the gas flow is constant until the set volume is delivered. When that point is reached, the gas flow is terminated. This waveform is best for patients with COPD and those suffering from head injury because gas delivered with this waveform allows for a longer T_e and lower mean airway pressure (P_{aw}-mean). The longer T_e is beneficial for patients with restrictive airway disease such as COPD. Spending a longer time in exhalation allows for improved venous drainage from the brain. The drawback to this waveform is an increased P_{aw}-peak, often requiring a lower V_T or ?Q. This can lead to inadequate alveolar recruitment in patients with acute lung injury.

Decelerating (Ramp).

Once the maximal inspiratory flow is reached, the rate of gas delivery immediately begins to slow in a preprogrammed fashion. Therefore, relative to the

TABLE 8-1 -- Initial Ventilator Settings

Type of Ventilation	Comments
Volume Cycled Ventilation (volume set, pressure varies)	
Mode: SIMV	If patient is paralyzed: IMV = AC ventilation
Rate: 10–12/min	Target normal $?V_E$
V_T : no acute lung injury: 10 mL/kg acute lung injury or ARDS: decrease V_T : 6–7 mL/kg	Increased survivorship in ARDS with decreased V_T ventilation
FIO_2 : 0.4–0.95	Titrate to pO_2 > 60 mm Hg
PEEP: 5–20 cm H_2O pressure	Titrate to pO_2 > 60 mm Hg and FIO_2 = 0.6
PSV: 10–35 cm H_2O pressure	Target V_T spont = V_T set
Waveform: decelerating ramp	Use square wave form in COPD only
Peak Airway Pressure: <35 cm H_2O pressure	(Noted on dial on ventilator) Peak pressure >35 cm H_2O associated with lung injury
Sigh: 0–2/min	Optional—use with decreased respiratory rate to maintain alveolar recruitment
Temperature: 35°C	Not efficacious in rewarming or cooling
Flow Rate (?Q): start at 60 L/min (range 45–75)	Titrate to P_{aw}-peak and pO_2
	Decrease ?Q for hypoxemic patients
	Increase ?Q for patients with air hunger
Pressure Cycled Ventilation (pressure set, volume varies)	
Mode: SIMV	If patient is paralyzed: IMV = AC
Rate: 10–12/min	Decrease rate to allow longer time to exhale and to increase CO_2 clearance
PC: 2/3 of prior peak airway pressure or prior plateau pressure	Titrate to peak airway pressure-V_T curve (hysteresis curve)
T_i : start at 2 sec and increase to increase mean airway pressure and pO_2	Increased T_i will lead to IRV: will need heavy sedation and/or paralysis
FIO_2 : 0.4–0.95	Titrate to pO_2 > 60 mm Hg
PEEP: 5–20 cm H_2O pressure	Titrate to pO_2 > 60 mm Hg and FIO_2 = 0.6
PSV: 10–35 cm H_2O pressure	Target V_T spont = V_T set
Waveform: decelerating ramp	Use square wave in COPD only
Temperature: 35°C	Not efficacious in rewarming or cooling
Note:	
1. Use inspiratory time cycled PVC to precisely control I:E ratio. IRV is used to manage hypoxia but may lead to hemodynamic instability owing to decreased venous return and decreased cardiac output.	
2. Best to titrate ventilator settings to the shape of the pressure-volume curve (need ventilator with a graphics package, a.k.a. "open lung model").	
Special Circumstances	
1. Severe acute lung injury—consider permissive hypercapnia. If able to achieve pO_2 > 60 mm Hg on FIO_2 = 0.6, the pCO_2 may be allowed to be >40 mm Hg if pH > 7.25. Further attempts to raise $?V_E$ to decrease pCO_2 may induce additional lung injury.	

2. Asthma—defect is decreased gas flow. In conventional ventilation use higher flow rate and lower respiratory rate to allow more time for exhalation.
3. Traumatic brain injury—Do not lower pCO_2 < 35 mm Hg, as it may induce severe cerebral vasoconstriction and lead to cerebral ischemia. The goal is normal pCO_2 : 35–40 mm Hg. Acceptable to hyperventilate for a patient with an acute herniation syndrome as a bridging maneuver for definitive therapy.
4. PEEP—used to raise alveolar recruitment and increase pO_2 in patients with hypoxemic respiratory failure. Caution: excessive PEEP can lead to hypotension from diminished venous return. Initial treatment of this hemodynamic instability is with volume replacement and lowered PEEP if possible.
AC, assist control; **ARDS,** acute respiratory distress syndrome; **FIO_2 ,** percent of inspired oxygen; **I:E,** inspiratory:expiratory; **IMV,** intermittent mechanical ventilation; **IRV,** inverse ratio ventilation; **MAP,** mean arterial pressure; **P_{aw} -peak,** peak airway pressure; **PEEP,** positive end-expiratory pressure (5 cm H_2O is considered physiologic); **PSV,** pressure support ventilation; **PC,** pressure control (setting); **?Q,** flow rate; **SIMV,** synchronized intermittent mechanical ventilation; **T_i ,** time in inspiration; **?V_E ,** minute ventilation; **V_T ,** tidal volume.

square waveform, longer time is spent in inhalation to deliver the set V_T or achieve the target pressure, which allows for improved oxygenation. This waveform also achieves a lower P_{aw} -peak and higher P_{aw} -mean.

Sine Wave.

Not useful in critically ill patients.

Accelerating.

This is the flow pattern for neonatal gas intake and is generally not used in adult ventilation unless one must use the Siemens Servo 900 ventilator, which has only two options: square or accelerating.

Sighs.

This is a large single breath or large multiple breaths, both designed to help maintain alveolar recruitment by ventilating a patient on a periodic basis at close to vital capacity. There is controversy regarding the utility of the sigh option with regard to alveolar overdistention. [18]

Pause.

This is a variable used on the Siemens Servo 900 ventilator to alter the I:E ratio. This is technically complex for anyone not working with ventilator setup on a daily basis. It is much easier to directly adjust the T_i/T_e on more modern ventilators. A pause is useful to determine the Plateau Pressure on the Puritan Bennett 7200 or the Infrasonics Adult Star ventilator (as a point measurement). If a short pause is used to measure plateau pressure, the authors suggest no

Figure 8-4 Identifying auto-PEEP with the flow-time trace. The X-axis is time while the Y-axis is flow rate in L/min. Deflections above the X-axis indicate inspiration, while deflections below represent exhalation. In this example, the flow pattern is ramp (decelerating). Note that as the respiratory rate increases (decreased time for exhalation), the flow has not yet returned to baseline (a), indicating incomplete exhalation when compared to the following breath (b).

longer than 0.5 seconds as the pause duration; remove the pause when the measurement is completed.

NEW MODES

Airway Pressure Release Ventilation (APRV)

APRV is essentially a high level CPAP mode that is terminated for a very brief period. The CPAP level may be as high as 40 or more cm H_2O pressure. The long time during which the high-level CPAP is maintained achieves oxygenation while the short release period achieves CO_2 clearance (Fig. 8-6). The long time during which the high-level CPAP is present results in substantial recruitment of alveoli of markedly different regional time constants at rather low gas flow rates and lower airway pressures (by comparison with conventional ventilation strategies). The establishment of

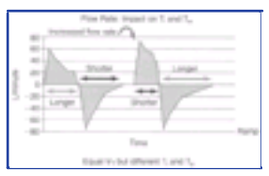

Figure 8-5 Effect of flow rate on inspiratory and expiratory times. Note that as the flow rate changes, there are corresponding alterations in the effective time for inspiration and exhalation. Deflections above the X-axis (time) indicate inspiration, while those below indicate exhalation. The delivered tidal volume for each cycle is the same, but the inspiratory and expiratory times are different.

intrinsic PEEP by the short release time enhances oxygenation. CO_2 clearance is aided by recruitment of the patient's lung at close to total lung capacity (TLC); elastic recoil creates large-volume gas flow during the release period. This is a fundamentally different mode from cyclic ventilation. This mode allows the patient to spontaneously breathe during all phases of the cycle. This mode is enabled to succeed by having a floating valve that is responsive to the patient's needs regardless of the location within the respiratory cycle. In other words, the patient is allowed to breathe in or out during the high-level CPAP phase as well as during the release phase. Accordingly, the sequence is called a phase cycle; there is no set inspiratory or expiratory time, and no readily identifiable respiratory rate in the traditional sense. During the high-CPAP phase, a patient may exhale 50 to 200 or more mL of gas as his or her lung volume becomes full of gas; this is not a full exhalation and the release of excess gas should not be counted as a breath.

Given the spontaneous nature of the mode, there should be virtually no need for continuous infusions of neuromuscular blocking agents in patients placed on this mode of ventilation[19] ; exceptions to this observation do occur for the management of ICP but not for oxygenation or clearance of CO_2 . This may result in a shorter length of ICU stay and a reduced incidence of prolonged neuromuscular blockade syndrome. Furthermore, since patients may be ventilated at lower airway pressures than using cyclic ventilation, there is a reduced need for pressor support of hemodynamics to ensure oxygen delivery. [19] Moreover, there is a reduced sedative need as patients are more comfortable on this spontaneous mode than on cyclic ventilation. [19]

Hemodynamic assessment using a pulmonary artery catheter in patients on APRV has been investigated. The pulmonary artery occlusion pressure (PaOP) must be read at the middle or end of the release phase to maintain the fidelity of the reading. Reading the PaOP at any other point in the cycle will give a significantly different value by comparison with the end expiratory reading obtained using pressure-cycled ventilation. [20] Transport of patients on APRV with a P_{aw} -high (sustained peak P_{aw}) > 20 cm H_2O pressure should be with the patient attached to the ventilator instead of being hand ventilated. [21] Hand ventilation is unable to match the manner of gas delivery and pressure dynamics that the patient requires. Attempts at hand ventilation, even with an appropriately set PEEP valve, are frequently complicated by unexpected hypoxemia and hemodynamic instability.

Proportional Assist Ventilation

Ventilators that are capable of performing in this mode will be able to assess on a breath-by-breath basis how much work of breathing support the patient needs to achieve the targets and goals that the clinician sets. [22] The unique features of this type of ventilation promise to reduce inadvertent airway injury, and, in many ways, serve as a self-weaning ventilator mode. As the patient requires less support, the ventilator delivers less support. Current data are lacking to determine if this will realize a shortened length of ventilator support for those with acute respiratory failure.

Permissive Hypercapnia

As stated, excessive P_{aw} -peak may be quite detrimental. One means of limiting P_{aw} -peak, and thereby offer protection from

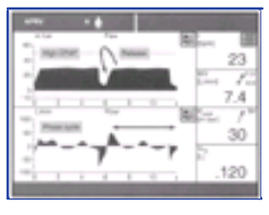

Figure 8-6 Airway Pressure Release Ventilation (APRV)—airway pressure-time and flow-time traces. Note that the peak airway pressure (P_{aw} -high) is maintained for a long period. This phase establishes oxygenation (T_{high}). There is a short period of release when most CO_2 is cleared (T_{low}). Note that the bottom trace is flow over time. The combined time for the T_{high} and T_{low} is known as a phase cycle. Note that the number of phase cycles is not the respiratory rate as patients breathe within the entirety of the T_{high} . As the release phase is initiated, the flow rate is identified as negative and is of a high rate (here approximately 7.5 L/min), consistent with significant alveolar recruitment. During the high CPAP phase, the patient is allowed to exhale (negative deflections on the flow-time trace). Thus, APRV is quite dissimilar from traditional cyclic ventilation. This unique mode is made possible by a floating valve system.

the trauma of ventilation, is to decrease the delivered V_T until an acceptable and less deleterious P_{aw} -peak is achieved (=35 cm H_2O). However, changes in P_{aw} -peak may alter the pH-pCO_2 balance. If the pH is =7.25, and the patient can tolerate the elevated pCO_2 while still remaining well oxygenated, then the ?V_E is not increased. Alternatively, the f may be decreased in similar fashion, but usually not <8 breaths per minute. This paradigm is known as permissive hypercapnia and the concept represents a major departure from previously accepted tenets of MV, which mandated that MV should always achieve a normal pCO_2 .[24] Clearly, many patients can safely tolerate pCO2 elevations that have in the past been thought to be harmful. A slower respiratory rate reduces the shear forces active across the alveolar common walls by allowing for fewer openings and closings per minute. [25] The side effect of such a rate reduction is greater time for exhalation that may lead to alveolar collapse and increased shear stress at the junction of open and closed alveoli. Nonetheless, a greater T_e helps prevent auto-PEEP, alveolar overdistention, and hemodynamic embarrassment. Likewise, a reduced V_T also helps prevent alveolar overdistention.

While these features appear very attractive, permissive hypercapnia is not entirely benign. An elevated pCO_2 triggers cerebral vascular vasodilatation, which leads to increased cerebral blood flow and possible elevated intracranial pressure (ICP). [26] Increased ICP > 20 mm Hg can be detrimental in patients suffering from head injury or cerebral ischemia.[27] In patients with acute lung injury complicating traumatic brain injury or stroke, such a management strategy is optimally accompanied by a measure of cerebral perfusion to evaluate for hyperemia, or ICP monitoring to assess for intracranial hypertension from increased CO_2 tension.[28]

Hypercapnia also shifts the oxyhemoglobin dissociation curve to the right, leading to increased early unloading of O_2 at the tissue level. Hypercapnia also creates an acidosis that may initiate myocardial depression, dysfunction of pH dependent enzyme kinetics, and distorted cellular metabolism. [29] Severe acidosis, pH <7.2, may be effectively countered by using an $NaHCO_3$ infusion. This proper intravenous infusion can be created by mixing 1 liter of D_5W and 150 mEq of sodium bicarbonate, creating a sodium content similar to that of lactated ringers solution (130.4 mEq/L). Alternatively, if 150 mL of D5W are removed before adding the 150 mL of $NaHCO_3$

, then the resultant Na^+ concentration is 150 mEq/L and approximates 0.9% normal saline solution. A common additional repair of the increased pCO_2 if the pH is <7.2 is to increase the respiratory rate to increase the $?V_E$ while maintaining the "lung protective low tidal volume." This strategy is quite similar to the ARDSNet protocol that is commonly used for volume ventilation of patients with acute lung injury or ARDS (see later). [30]

Prone Positioning

Multiple authors have proposed gravity as an effective aid in lung recruitment for those patients with severe or refractory hypoxemia. [31] [32] Several studies have identified benefits in terms of increased pO_2 following pronation. [31] [32] Several areas remain unresolved. It is unclear who will maximally benefit (up to one third have no benefit), how many proning cycles per day and for what duration are most beneficial, and for how long to continue pronation once it has been initiated. What is clear is that chest geometry is critical in successful pronation [31] (Fig. 8-7). Patients with ovoid chests have little benefit from pronation as there are relatively equal lung volumes that exchange the superior and inferior positions when the patient is placed prone. Patients whose thoracic cage is more triangular have a greater volume of lung posteriorly (while in the supine position) that is able to exchange with a smaller volume of anterior lung. This patient population benefits from pronation.

Similarly, patients with small cardiac volumes benefit more than those with large volumes as there is more lung behind the heart to recruit with the pronation maneuver (see Fig. 8-7). It is quite clear that pronation is a challenging and potentially dangerous maneuver in a patient with invasive lines and an endotracheal tube in place, although no increase in unintentional extubations was noted in a study by Gattinoni et al. [31] This risk of tube or catheter dislodgement or malposition is compounded by the altered hemodynamics in a patient who is not yet volume-replete, especially after trauma. Thus, pronation cannot be recommended as first-line therapy for

Figure 8-7 Chest geometry and prone position. Note that ovoid chest geometry results in equal volumes above and below the transverse axis leading to no change in recruited lung volume with pronation. Triangular chest geometry leads to a significant increase in lung volume with prone positioning. This is by virtue of the large volume of lung that lies posterior to the transverse plane with the patient in the supine position. Increases in cardiac volume reduce the available retrocardiac lung volume and impair the effectiveness of prone positioning with regard to pulmonary recruitment.

hypoxemia in the ED. Instead, it is best reserved for the more controlled environment found in the ICU. Moreover, it is the author's experience that pronation use has been virtually eliminated since using APRV as the rescue mode of choice for refractory hypoxemia.

VENTILATOR ORDER GOALS

Minute Ventilation ($?V_E$).

This is the amount of gas delivered to a patient over a minute. It is calculated by multiplying the patient's respiratory rate by the tidal volume ($f \times V_T$) for patients without spontaneous breaths. It is conveniently determined by the ventilator and can be read directly for those with and without a spontaneous component to their $?V_E$. The need for $?V_E$ varies with the patient's condition, body mass, co-morbidities and acid-base status. For example, a patient who has a metabolic acidosis from diabetic ketoacidosis needs an elevated $?V_E$ to decrease pCO_2 and acutely buffer the acidosis. Thus, the emergency provider should determine what $?V_E$ range the patient will need and set the f, V_T, or PCV/T_i to compensate for the increased metabolic acid load. A normal $?V_E$ is 7 to 10 L/min.

Spontaneous Minute Ventilation.

This is the $?V_E$ derived from spontaneous breathing. During weaning, progressive increases in this parameter are expected as mandatory breaths are decreased or eliminated.

Spontaneous Tidal Volume.

See SIMV and PSV earlier.

Peak Airway Pressure (P_{aw}-peak).

This is the maximum amount of reflected pressure in the patient's airway. This peak occurs during inspiration—an important concern because of the well-documented relationship of elevated airway pressure (and volume) causing biotrauma. [4] Excessive P_{aw}-peak (>35 cm H_2O) commonly leads to alveolar overdistention and injury, causing release of inflammatory mediators and complications including pneuomothoraces, pneumatoceles, pulmonary interstitial emphysema, pneumomediastinum, acute lung injury and acute respiratory distress syndrome (ARDS). The peak airway pressure and alveolar overdistension are best evaluated using the pressure-volume curve, looking to abrogate any increases in airway pressure that are not accompanied by increases in delivered volume (Fig. 8-8). Increases in airway pressure without accompanying increases in V_T lead to a plateau of the P-V curve, known as the "bird's beak" profile. This profile is a reasonable indicator of alveolar overdistension and airway injury.

Plateau Pressure.

This is the pressure reflected from the airways once the full set volume or targeted pressure change has been achieved. It is a reflection of pulmonary compliance, airway resistance and elastance. It is not directly manipulable, but may be impacted by V_T, ?Q, PCV, T_i, and PEEP. It does provide a basis for the initiation of other modes of ventilation and is quite useful in that regard (see APRV earlier).

Mean Airway Pressure (P_{aw}-mean).

The area under the pressure-over-time curve (Fig. 8-9) may be calculated and represents the mean airway pressure. The P_{aw}-mean correlates most closely with the achieved pO_2 in volume-cycled or pressure-cycled ventilation modes. The longer the T_i, the greater the P_{aw}-mean. When a patient has hypoxemia and the clinician wants to change the ventilator orders, *it is important to not reduce the P_{aw}-mean as a result of the change in therapy* since a decreased P_{aw}-mean consistently leads to a decrease in pO_2.

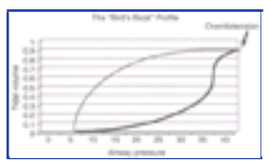

Figure 8-8 Alveolar overdistension is reflected in the increase in airway pressure without any concomitant increase in tidal volume. This pressure-volume curve pattern approximates a "bird's beak" profile.

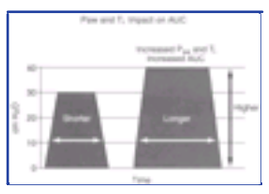

Figure 8-9 Mean airway pressure and the pressure-time trace. Note that the greater the maximum airway pressure and the longer the T_i, the greater the area under the curve (AUC) described by the positive-pressure (inspiratory) limb of the respiratory cycle. The increase in mean airway pressure (area under the curve) is the principal correlate of oxygenation in volume or pressure-cycled ventilation.

COMPLICATIONS OF MECHANICAL VENTILATION

Pneumothorax.

Pneumothorax unassociated with thrauma in a mechanically ventilated patient typically stems from alveolar overdistension (continuous or episodic) that leads to alveolar rupture and escape of gas into the pleural space. [36] Patients on positive-pressure ventilation should have their pleural space drained to prevent progression to a tension pneumothorax with hemodynamic compromise. Loculated pneumothoraces may be successfully drained percutaneously under ultrasound or CT guidance. Successful drainage of airspace disease leads to enchanced liberation from MV. [23] Pneumothorax or tension pneumothorax may also result from aggressive and incorrectly performed bag-valve-mask ventilation. Patients with intrinsic lung disease such as COPD or asthma are more prone to pneumothorax than the average patient due to the abnormal structural integrity of their alveolar air spaces. [37]

A simple pneumothorax may be drained by surgical tube thoracostomy with a small-bore tube (24 French [Fr]), a commercially available pneumothorax kit (Arrow), or a pigtail catheter placed into the pleural space using the Seldinger technique (see Chapter 10). Each of these catheters should be placed to a chest drainage collection unit that incorporates a water seal chamber as well as a variable suction control. Persistent airleaks initially require continuous suction (usually 20 cm H_2O suction) to evacuate the pleural space and promote coaptation of the visceral and parietal pleurae. Reduction of suction and placement on water seal alone follows the resolution of the air leak. Chest tube removal may proceed directly from water seal if there is no pneumothorax on chest film, or may follow a test period of tube clamping and subsequent radiographic evaluation. The authors favor a 4-hour period of clamping as a recurrent pneumothorax is easily treated by unclamping a tube instead of placing a new one.

Not all patients with a pneumothorax require invasive techniques to evacuate air from the pleural space. It is important to recognize that small pneumothoraces occurring in *spontaneously breathing patients* (i.e., negative-pressure ventilation) may be reevaluated in 4 to 6 hours with a repeat CXR, and drained only if they are expanding. This option is *not* advised for patients on any form of positive-pressure ventilation as a simple pneumothorax may rapidly become a tension pneumothorax with subsequent hypotension and death. Tension pneumothoraces may be recognized by tachycardia, hypotension, elevated P_{aw}-peak (if mechanically ventilated, tachypnea if not), jugular venous distension (if not intravascularly depleted), thoracic resonance by percussion *on* the affected side, diminished or absent breath sounds *on* the affected side, and tracheal deviation *away from* the affected side. Clearly, not all signs or symptoms are present in all patients and treatment is dictated by the patient's clinical condition.

Certain patients develop loculated pneumothoraces or fluid collections. If the collections are either single *or* immediately adjacent to one another *and* readily identified, they may be drained using ultrasound guidance at the bedside. [38] However, the loculations are frequently in inaccessible areas, or are difficult to image with ultrasound. Therefore, CT scanning of the thorax provides precise anatomic definition of the presence and number of loculated collections, as well as a guide for the interventional radiologist. The authors have successfully used CT-guided drainage of loculated pleural collections (air and fluid) to assist weaning of head-injured patients from mechanical ventilator support. [23]

Biotrauma.

This term refers to the self-sustaining process of lung injury from MV that follows alveolar overdistension or rupture, alveolar hypoperfusion, and repetitive shear stresses across alveolar walls. Originally this problem was thought to be from too much pressure (barotrauma). [39] Current principles hold that elevated airway pressures are a straightforward reflection of excess volume delivered to a lung that cannot accept that much gas (i.e., volutrauma: excess volume is delivered). [13] When this process is active in a patient on MV, it is termed volume induced lung injury. Lung injury is an inhomogeneous process with areas of normal lung immediately adjacent to quite diseased and injured segments. [40] Thus, the healthy and compliant segments with shorter regional time constants will readily accept gas, while their neighbors with reduced compliance and longer regional time constants will not. The end result is overdistension of the compliant segments, alveolar injury, and the liberation of inflammatory cytokines, chemokines, and activation of endothelin and arachidonic acid pathways, as well as the expression of adhesion molecules along the vascular endothelium. [4] This leads to infiltration of inflammatory cells, their destructive lysosomal enzymes, and the induction of toxic oxygen metabolites. Avoiding this inflammatory cascade is an intelligent means of protecting a patient's lungs from volume induced lung injury. Such a notion has given rise to lung-protective ventilator strategies based on the low tidal volume ventilation (6 to 7 mL/kg body weight).

Hemodynamic Compromise.

In all circumstances, the volume of venous return exactly matches the cardiac output volume. Any process that impedes venous return will decrease the available volume that establishes cardiac output. For patients on positive-pressure ventilation, each gas delivery increases the intrathoracic pressure while exhalation decreases that pressure. Therefore, venous return principally occurs during exhalation. If the ventilator orders are constructed in such a way as to lead to increased intrathoracic pressure during exhalation, then venous return will be

reduced. Variables that can lead to this circumstance are increased PEEP, auto-PEEP, and inverse ratio ventilation. Recall that venous return depends not only on a relatively negative pressure within the thoracic cavity, but relies on a sufficient amount of time for flow into the thoracic vasculature and right side of the heart. Thus, significantly high respiratory rates may compromise venous return as well. An additional untoward side effect of impaired venous return is cerebral venous hypertension from impeded venous drainage. Since there are no valves between the cerebral parenchyma and the right atrium, increased pressure on the right atrium reduces cerebral venous flow and may contribute to cerebral ischemia in patients with traumatic brain injury or stroke, especially in the patient with compromised systemic hemodynamics. Such patients are prone to watershed infarction; cerebral venous hypertension may increase this risk.

Ventilator Associated Pneumonia.

The association between the duration of endotracheal intubation and the promotion of pneumonia is quite clear. In fact, the likelihood of developing a pneumonia is four times greater for patients in a surgical ICU than those in a medical ICU. [41] Endotracheal intubation for >12 hours increases the risk threefold. [41] Early pneumonias (<72 hours post intubation) are typically with community-acquired pathogens and may be adequately treated with American Thoracic Society (ATS) Class A or B agents. [42] Late pneumonias (>72 hours) typically stem from nosocomial pathogens that may be resistant to community antibiotics. [42] Such patients need to have empiric coverage for *Pseudomonas*, methicillin-resistant *Staphylococcus aureus* (MRSA), and the other SPACE microbes (*Serratia*, *Pseudomonas*, *Acinetobacter*, *Citrobacter*, and *Enterobactericiae*). Empiric coverage for fungi are not warranted except in special circumstances (recrudescent pneumonia in a patient already on broad-spectrum antibiotics for >7 days with negative cultures; solid organ transplant patient after implanatation for >4 months; poly-site positive fungal cultures or fungemia). Unequivocally, clinical estimation of pneumonia is correct at best 33% of the time. [43] The most sensitive and specific test to diagnose pneumonia in a patient with a radiographic infiltrate, fever, leukocytosis, and purulent secretions is bronchoscopy and bronchoalveolar lavage with quantitative cultures. [44] This strategy provides strong evidence of the exact pathogen(s), eliminates treating nonpathogenic microbes that are upper airway colonizers, and provides confidence in withholding antibiotic for the diagnosis of "no pneumonia," as many other diagnoses can present with a similar clinical picture (Fig. 8-10).

Nosocomial pathogens commonly have multiple resistance profiles, typically plasmid-mediated. Resistance pressure from the use of third-generation cephalosporins has led to the establishment of Vancomycin resistant enterococci (VRE) as well as extended spectrum ß-lactamase producing (ESBL) organisms of which *Klebsiella* is the prototype. [45] Plasmid-mediated resistance to fluoroquinolones parallels the rise of ESBL-producing organisms. [46] Empiric antibiotic selection should be derived from each hospital's local antibiogram based on likely pathogens. A ß-lactamase inhibitor combination paired with an aminoglycoside and vancomycin are the authors' empiric agents of choice based on their local antibiogram for Ventilator associated pneumonia. Should the reader's microbiology lab identify an ESBL-producing pathogen, the appropriate antibiotic class of choice is carbapenem. [47] Carbapenems consistently demonstrate excellent efficacy in eradicating ESBL-producing

microbes.

Figure 8-10 Confounders in the diagnosis of pneumonia. Fever, leukocytosis, radiographic infiltrate, and sputum production do not necessarily indicate the diagnosis of pneumonia. Multiple other causes should be considered as well so that one does not apply antibiotics when there is no infectious agent to address. ALI = acute lung injury, ARDS = acute respiratory distress syndrome.

ADJUNCTIVE THERAPIES

$ß_2$ -Agonists.

These agents stimulate ß-adrenergic receptors in bronchial smooth muscle, and induce muscle relaxation. This reduces airway resistance and improves gas flow through the conducting airways.[48] The $ß_2$ -agonists also inhibit MAST cell degranulation, leading to ameliorated immune stimulation of the reactive airway. The most widely used agent in ICUs in the United States is albuterol. This agent may be administered via a side port of the ventilator circuit using a metered dose inhaler (MDI; cost-effective). Alternatively, albuterol may be delivered by placing an in-line nebulizer device between the circuit and the ETT, or on a side port on the ventilator tubing's inspiratory limb (ventilator tubing-dependent). Many patients may develop bronchoconstriction and wheezing when mechanically ventilated without a preexisting history of reactive airways disease. $ß_2$ -agonists should be administered to patients who have poor air movement, wheezing, or both. A physiologically appropriate means of detecting and following bronchospasm is the Peak-plateau gradient. A normal gradient is <4 cm H_2O pressure; increased values indicate increased airway resistance. The efficacy of treatment with $ß_2$ -agonists, intravenous magnesium, or diuresis may be assessed by following the changes in this gradient.

Acetylcholine Antagonists.

The main utility of this class of agents is to dehydrate secretions although these agents may also block cholinergic-mediated bronchospasm. The most common agent is ipatropium bromide (Atrovent), an atropine derivative that has twice its biopotency on an eqimolar basis. Ipatropium is commonly prescribed in combination with $ß_2$ -agonists every 4 to 8 hours. As with albuterol, ipatropium may be administered by MDI or nebulizer. Ipatropium is rarely used in isolation for the therapy of bronchospasm.

Mucolytics.

The prototype for this class is n-acetylcysteine (NAC). NAC is believed to reduce the adhesion of mucous strands to each other as well as the luminal surface of the alveoli and larger airways. It may be administered by nebulizer or lavage routes; no MDI equivalent is available. NAC has the unfortunate side effect of inducing mucosal

inflammation in an unpredictable fashion when used for >24 hours. However, for the first 24 hours, NAC may provide significant benefit in liberating densely inspissated secretions from dependent portions of the airways.

Recruitment Maneuvers.

These maneuvers are designed to apply consistent but well-regulated pressure to partly or completely closed alveoli to reintroduce gas into those segments.[49] The targeted segment(s) are those with poor compliance and long regional time constants. The area of interest is placed in a nondependent position (i.e., for left lower lobe benefit, place the left side of the patient up and right side down), and the patient is hand-ventilated using a bag-valve device attached to the endotracheal tube. An in-line pressure monitor is needed. The patient will usually require sedation to comply with the maneuver—fentanyl and midazolam are ideal. The clinician then applies pressure to the bag to achieve 35 cm H_2O pressure and holds it for 4 to 6 seconds, after which the patient is allowed to exhale. This cycle is repeated for up to 5 minutes. A second examiner listens to the area of interest for an increase in breath sounds. The recruitment may be terminated when there are good breath sounds on two consecutive maneuvers. Recruitment maneuvers may be combined with chest physiotherapy for added benefit; chest physical therapy should, in general, precede the recruitment maneuver.

Bronchoscopy.

See nosocomial pneumonia earlier.

Bronchoscopy/Bronchoalveloar Lavage (BAL).

With MV, the normal bacterial, viral, and secretion clearance mechanisms of the mucociliary elevator are compromised. Accordingly, excellent pulmonary toilet is required to prevent secretion impaction, atelectasis, pneumonitis, pneumonia, intrapulmonary shunt, or ventilation perfusion mismatch. Despite seemingly adequate nursing or respiratory therapist care of a patient's airways, atelectasis, mucus plugging, and segmental or subsegmental airway obstruction and collapse may occur. Several initial maneuvers are indicated, including: alveolar recruitment, chest physiotherapy, postural drainage, and aerosolized bronchodilator therapy. Frequently, these maneuvers resolve the elevated P_{aw} -peak and hypoxemia that are the markers of complications. When these initial therapies fail, a more invasive approach is warranted.

The traditional approach to clearance of inspissated secretions is therapeutic bronchoscopy. The adult flexible fiberoptic bronchoscope has an outer diameter of 3.3 mm and a working channel for suctioning of 2.5 mm. Therefore, an ETT of size =8.0 is ideal as it will permit easy passage of the bronchoscope and allow for adequate MV of the patient. However, airway mucosal irritation is a powerful sympathetic stimulant. Tachycardia, systemic hypertension, and bronchospasm commonly complicate therapeutic bronchoscopy. In the setting of intracranial hypertension, the clinician must take steps to blunt any potential sympathetic stimulation. Mucosal irritation may be minimized by careful bronchoscopic technique that avoids impacting and suctioning the sidewalls. Additionally topical or systemic lidocaine will also blunt mucosal irritation. Preprocedure ß-blockade with a relatively short-acting agent like esmolol will blunt the tachycardia and elevated dP/dt that accompanies heightened sympathetic tone. This will diminish any increase in cerebral blood flow that accompanies sympathetic discharge. Adjuvant therapy with narcotic analgesia, with a short-acting agent like fentanyl, will enhance sedation and ameliorate pain from mucosal injury. When these measures fail, significant sedation and cerebral protection may be achieved with cautious administration of barbiturates like sodium pentothal. Pentothal therapy may also be complicated by systemic hypotension. Alternatively, for very short procedures, etomidate is an excellent and powerful sedative that has the unique advantage of inducing diminished ICP. Thus, excellent intravenous access for fluid or inotrope administration is mandatory when using barbiturates. A postprocedure CXR is indicated to assess the results of the bronchoscopy, and to assess for complications such as a pneumothorax or ETT malposition.

When a specimen is obtained, it should be examined by Gram stain as well as culture for bacteria, viruses, fungi, or AFB when indicated. These results will help guide initial antibiotic therapy if the patient's clinical condition indicates infection (i.e., mucosal erythema, leukocytosis, fever, hypotension). The culture results are *qualitative* only and serve to identify which organism(s) are present, but not the bacterial burden. Accordingly, the utility of such results has been derided as being no more useful that an aspirate obtained by a closed suction system. However, a closed suction system does not allow directed suctioning of a particular side of the airway. In fact, the right side is more frequently suctioned than the left based on the straighter geometry of the right mainstem bronchus. To combat the geometry, "steerable" suction catheters that allow for directed lavage and suctioning are available. Furthermore, the suction catheter is enclosed within a sleeve that protects it from contamination during passage through the ETT and upper airways.

With both the "steerable" catheter system and therapeutic bronchoscopy, the techniques may be modified so as to allow for *quantitative* assessment of the bacterial/viral/fungal burden. The technique is called bronchoalveolar lavage, and relies on wedging the tip of the fluid instillation/suction catheter into a broncho-pulmonary segment, instilling a known amount of fluid (usually 180 mL of NSS in 60-mL aliquots), and recovering that fluid for analysis. An adequate recovery is >50% of the instillate volume. Moreover, there are criteria for the diagnosis of infection (bacteria >300 CFU/mL).[50] The criteria are liberalized (>500 CFU/mL) if the lavage and aspirate were performed in a larger airway such as the bronchus intermedius, instead of a segmental orifice such as the superior segment

of the lower lobe.

Another modality that may be useful in the diagnosis of pulmonary infection is the bronchoscopically directed "protected brush biopsy." [51] In this technique, the bronchoscope is advanced into the area of interest, and a sheathed brush is advanced through the working channel into the airway. Then the brush is extruded and worked back and forth against the airway to "biopsy" adherent microbes and airway mucosa. The brush is withdrawn into the sheath, and the entire assembly is withdrawn. The brush is then cut off and incubated in culture media. This technique has numerous advantages in that upper airway secretions may be suctioned without fear of contaminating the specimen and obtaining spurious results. By comparison, the standard BAL technique requires that the operator guide the bronchoscope into the affected region without suctioning so as to not contaminate the subsequently aspirated lavage sample. The downside to protected brush biopsy is that mucosal injury, bleeding, and pneumothorax occur more commonly than with bronchoscopically directed or steerable catheter BAL. Regardless of the technique used, the clinician must match the sample results with the patient's clinical picture.

Gastric Content Aspiration and Pneumonia.

Additional consideration is needed to avoid gastric acid blockade in patients who require prolonged intubation and MV. Gastric acid inhibition has, in some studies, been associated with a higher rate of nosocomial pneumonia than in patients who received ulcer prophylaxis with sucralfate alone. [52] It is believed that the gastric acid milieu destroy refluxed bacteria and that most nosocomial pneumonias occur because of aspiration of gastric contents. It is important to recall that aspiration may occur simply by "wicking" of gastric secretions along an indwelling nasogastric tube that stents open the upper and lower esophageal sphincters, as well as by vomiting and passage of gastric contents along the sides of the cuffed endotracheal tube. Aspiration of gastric acid with intubation (the most common scenario) does not require antibiotic therapy, nor is it improved by the administration of glucocorticoids or the use of immediate bronchoscopy (unless there is large airway obstruction). The clinical syndrome of sterile gastric content aspiration is Mendelson syndrome.

Heliox Therapy.

The interface of gas with airways creates a certain amount of friction. Heavier gases lead to greater amounts of friction than lighter gases. The more friction generated, the greater the work of breathing for a given gas. Severe asthma commonly entails significant work of breathing and may lead to respiratory failure from respiratory muscle fatigue. Altering the gas composition from N_2:O_2 to He:O_2 provides for a lighter gas that requires less work of breathing. Different percentage mixtures of He:O_2 (Heliox) are prepared and commercially available (e.g., 70% O_2 and 30% helium). Successful resolution of impending respiratory failure has been achieved using this strategy. [53] *Note that this is not a commonly used therapy, but an important adjunct to have available when the need arises.*

Negative-Pressure Ventilation.

This unique mode of ventilation is best achieved using the Hayak Oscillator, a device produced in Israel. Its appearance is quite similar to a Cuirasse vest, but the driving negative-pressure source is quite different. The Hayak Oscillator features independent controls for the application of negative pressure as well as positive pressure, frequency of cycling between negative and positive pressure (inspiration and expiration), a chest physiotherapy mode for sputum expectoration (useful for those with cystic fibrosis), as well as a cardiopulmonary resuscitation mode. It is not widely used in the United States, but has demonstrated use in the cystic fibrosis patient population and during upper airway surgery, when an indwelling ETT would be a significant obstruction. [54]

SPECIAL TOPICS

Asthma.

Fortunately, most patients with asthma are easily managed with combination therapy such as ß $_2$ agonists, acetylcholine antagonists, and glucocorticoids. A true management challenge is the critically ill asthmatic. These patients are different from others with asthma exacerbation in that they require intubation and MV. [33] Unlike many other disease states, asthmatics are not immediately improved by positive-pressure ventilation; asthmatics often become acutely worse before any improvement from intubation and ventilation is realized. After intubation, the asthmatic's P_{aw} -peak is usually elevated. This leads to various problems including, but not limited to, early termination of a volume cycled breath (excessive airway pressure limiting the breath), impaired gas exchange (increased V_D/V_T), and the induction of "biotrauma" (see later). A slower respiratory rate allows for a longer time in exhalation. A prolonged T_e is essential for the patient with restrictive disease. In volume-controlled ventilation, a lower respiratory rate with a low V_T , as in the ARDSNet protocol may be used for the management of life-threatening asthma. [30] With pressure-controlled ventilation (as discussed earlier), the set pressure may generate an inadequate V_T based on the restrictive component of the exacerbated asthma. It is essential that bronchodilator and anti-inflammatory therapy (i.e., glucocorticoids) be pursued in conjunction with positive-pressure ventilation for an optimal outcome.[34] A diligent search should be undertaken to discern any potential triggers (e.g., infection) that may be eliminated to hasten recovery and limit the duration of MV. Appropriate sedation is critical to ensure adequate gas exchange; it enables the patient to "synch" with the ventilator and not trigger early volume cycled breath termination. If sedation alone is inadequate to reduce the restriction imposed by the chest wall or intra-abdominal contents, pharmacologic relaxation is then indicated (although uncommonly required). Heliox therapy has also been used with success for the failing asthmatic as a means of avoiding intubation in select patients (see Heliox section).[35] APRV has been used for severe life-threatening asthma; insufficient data are currently available to recommend this as front-line therapy. Its role may be as a salvage mode for asthmatics with refractory hypoxemia.

Ventilator Weaning Protocols and Pathways

A well-designed weaning protocol is an invaluable aid in reducing the length of stay in the ICU. An appropriate protocol will enable the respiratory therapist and bedside nurse to initiate the weaning process each day before clinician evaluation. Computer order entry may create an ICU admission data set that automatically activates such a protocol once the entry criteria are met (i.e., the cause of respiratory failure is improving or has been eliminated, $FIO_2 < 0.50$, PEEP < 10 cm H_2O, and no pressors other than dopamine at <5 µg/kg per minute or Epi or NorEpi at < 0.05 µg/kg per minute). A ventilator pathway to chart and modify the progress of each patient through his or her MV needs is a useful tool. Such a pathway allows clinicians to regularly review a patient's progress along what would be considered a "usual course" for someone requiring MV. Deviation from this course should prompt an investigation into the cause(s). A pathway is also an excellent tool to use as a platform for quality assurance and improvement review.

Neuromuscular Blockade

Neuromuscular blocking agents are used to induce muscular paralysis for various reasons including, but not limited to, reducing peak airway pressures during MV, reducing total body oxygen consumption, protecting life-sustaining indwelling devices, and placing an artificial airway. Agent selection entails consideration of factors identical to those surrounding analgesic and sedative selection. Commonly used agents include pancuronium, vecuronium, and cisatracurium. All may be given by bolus or continuous infusion. Only pancuronium and vecuronium have active metabolites and reportedly result in prolonged neuromuscular blockade in some patients following cessation of drug therapy. [55] Furthermore, aminoglycosides, for

instance, may potentiate the effect of neuromuscular blocking agents, thus reducing the amount of drug necessary to achieve the desired paralysis. [56] The authors prefer cisatracurium for neuromuscular blockade as it undergoes Hoffman elimination in the plasma and is therefore independent of renal or hepatic metabolism. However, the authors also rarely use neuromuscular blockade outside of the operating room except when placing an endotracheal tube.

Paralysis is commonly titrated to an effect monitored by a peripheral nerve monitor applied over the ulnar or other peripheral nerve distribution. [57] No blockade results in four twitches of the adductor pollicis muscle resulting from four supra-maximal triggering stimuli; complete blockade yields no response. A common goal of blockade is enough agent to result in two twitches out of a "train of four." Another goal of twitch monitoring is to avoid over-paralysis, to diminish the risk of prolonged neuromuscular blockade following withdrawl of the agent. If, however, zero twitches are required to achieve the goals of therapy, then the monitor cannot monitor over-paralysis at all. Additionally, if feasible, many clinicians allow patients to emerge from paralysis once each 24-hour period to perform a neurologic assessment and help ensure return of neuromuscular function following cessation of drug therapy. There are no data to support this practice as a preventive measure, but it seems to make intuitive sense. There is a growing trend to avoid chemical relaxation throughout the United States; chemical relaxation is rare in the European Union for patient management in the critical care arena.

The myriad potential complications of neuromuscular blockade have been described in detail in standard anesthesia texts. However, two important complications deserve mention: prolonged paralysis syndrome [55] and the polyneuropathy of critical illness. [58] The postparalysis syndrome is diffuse motor weakness associated with elevated creatine kinase levels (MM fraction), and preserved sensory nerve function on electromyography and nerve conduction velocity testing. By comparison, critical illness polyneuropathy involves both sensory and motor nerves, and is less frequently associated with neuromuscular blocking agents as an etiologic cause. Critical illness polyneuropathy is believed to be principally related to the underlying disease and carries a less favorable prognosis for recovery than postparalysis syndrome. There are some data implicating the amino-steroid structure of vecuronium and pancuronium in the pathogenesis of either of the complications mentioned previously by drawing a parallel between the neuromuscular blockade polyneuromyopathies discussed earlier and those identified in patients on long-term steroid regimens. However, data are currently inconclusive as to the exact etiology of the syndromes discussed earlier.

Sedation

Patients on MV commonly require some sedation, which can be provided in an intermittent bolus fashion or by continuous infusion. Clinician monitoring of the depth and adequacy of sedation is feasible in an interactive patient. When patients require sedation for agitation control, are mechanically ventilated, or are chemically relaxed, the sedative assessment ability of the clinician is severely impaired. Additionally, since the use of pharmacologic paralysis presents the external appearance of a quiet, restful patient, it is important to have some means of titrating sedation to an appropriate level. The authors favor using a modified single

Figure 8-11 The Bispectral Index monitor (Aspect Medical, Nantucket, MA). This is a pole-mounted device that attaches to the patient's forehead and provides a modified single-lead electroencephalogram whose power spectrum undergoes a Fourier transformation to yield a numeric representation of the level of sedation.

lead electroencephalogram montage known as the Bispectral index (Fig. 8-11). This device integrates a power spectrum of the coherence of electrical activity of the monitored areas of the brain and translates the information into an analog value ranging from 0 to 100. [59] Lower numbers indicate deeper levels of sedation. This device has been successfully used in the operating room to monitor and titrate the level of benzodiazepine or propofol sedation for surgical procedures. [60] Further

experience is being gained in the ICU titration of therapy in pharmacologically paralyzed patients as well as monitoring serial changes following central neuraxial injury or illness that results in brain death. The authors have used BIS monitoring to decrease sedative agent usage and cost in intubated neuromuscularly blocked and sedated patients in the critical care setting. [61]

Neonatal Ventilation

It is clear that neonatal ventilation is not simply ventilation of small adults. The vast majority of neonatal ventilation is performed as pressure-controlled ventilation, albeit with smaller volume targets than in adults (i.e., same mL/kg body weight but smaller changes in pressure to achieve the smaller needed volumes). Note, however, that neonatal ventilation may also be performed using volume-controlled ventilation. Not all ventilators can deliver the small volumes required for this kind of ventilation, and special ventilators dedicated to neonatal ventilation have been developed (e.g., Babylog by Drager, Bird Ventilator). Many adult ventilators are equipped with a software package that allows the microprocessor that controls pressure, flow rates, and volume to perform well in this application (e.g., Drager E_4 with Neoflow, Siemens Servo 300C). Furthermore, there are hybrid modes such as pressure-support ventilation volume guarantee (PSV-VG) that combines the best of both worlds.[62] One simply sets a pressure

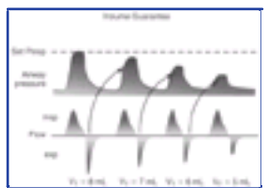

Figure 8-12 Volume guarantee ventilation. Note that the ventilator uses the prior breath to determine how much support is required to achieve the desired tidal volume and remain within the set pressure limit.

support limit as well as a desired volume for each breath. The ventilator then determines on a breath-by-breath basis how much pressure support is required to achieve the set target and remain within the pressure limit (Fig. 8-12). In this way, the mode is also self-weaning; as the patient's need for support decreases, the support, in fact, decreases (Fig. 8-13). Since the equipment varies at each institution, clinicians are urged to familiarize themselves with the available ventilator and how to use it. Guidance from a neonatal intensivist in conjunction with a respiratory therapist is ideal.

Noninvasive Ventilation

Intubation, MV, and its sequelae may be avoided in a select group of patients suffering from acute respiratory failure by using noninvasive ventilation (NIV) techniques (see chapter 2). It

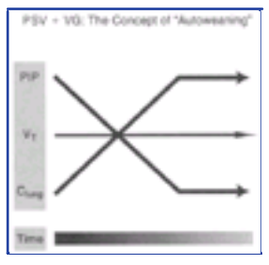

Figure 8-13 Pressure support volume guarantee ventilation. As the compliance of the lung (C lung) improves, the positive inspiratory pressure (PIP) decreases while maintaining a constant tidal volume (V_T). When the pressure support volume is reduced to an acceptable minimum level, weaning has been achieved and the patient should be evaluated for liberation from mechanical ventilation.

is important to recall that if the patient's physiology requires definitive airway control, NIV is not appropriate. This modality may be effectively used in patients who do not wish to be intubated (e.g., end-stage COPD) and in patients who need time for medical therapy to achieve its goals (e.g., congestive heart failure). In general, NIV is commonly used for temporary ventilatory and oxygenation support (i.e., <24 hr). Patients requiring longer acute management are optimally managed by tracheal intubation and MV.

For NIV to be used, three things must be true: the airway must be patent, the respiratory drive must be intact, and the patient must be cooperative (i.e., awake and alert). It is imperative that the patient understands the roles of the machine and the mask to aid with compliance and technique efficacy. It is essential to use the correct size mask to maintain a good seal for optimal results and to lessen the risk of injury from an inappropriately tight or ill-fitting mask. For nasal masks, there is a template to help the therapist select the most appropriate piece of equipment. The potential benefits of NIV over MV are a decrease in potential airway injury, nosocomial airway and tracheobronchial tree infection, and probably a shorter length of stay in a monitored bed or ICU. [63] Documented risks include barotrauma (volutrauma), pressure necrosis of the facial skin, subcutaneous tissue and musculature, and gastric dilation followed by vomiting and aspiration or hemodynamic compromise.[64] Two main types of NIV are available in the ED—CPAP and bi-level positive airway pressure (BiPAP).

Continuous Positive Airway Pressure

CPAP is a widely used type of noninvasive ventilatory support. This modality delivers a variable gas flow to achieve a constant airway pressure. It is commonly used in patients with obstructive sleep apnea to prevent upper airway collapse. [65] All forms of NIV require some type of tight-fitting mask to maintain a good seal (Fig. 8-14). The CPAP mask is a full-face mask. It must be properly fitted to the patient for both efficacy and complication avoidance (i.e., pressure necrosis). The full-face mask may be intolerable for some patients as it may induce a sense of confinement and claustrophobia. Acutely ill patients are also unable to remove the mask to eat as they are dependent on the airway pressure for oxygenation and ventilation. For the acutely ill patient in the ED, CPAP may help reduce the work of breathing while facilitating CO_2 clearance and O_2 onloading.

Bi-Level Positive Airway Pressure

BiPAP is a combination of PSV and CPAP (Fig. 8-15). The clinician can set two different pressure levels for the patient: (1) inspiratory positive airway pressure (IPAP), which is delivered during inspiration, and (2) expiratory positive airway pressure (EPAP), which is applied during exhalation. In general, IPAP exceeds EPAP. This modality is pressure limited, and flow is triggered by either the patient's inspiratory effort, or a time limit between cycles.

In the patient-triggered mode, the device senses the onset of inspiration, and the preset IPAP cycle is initiated. When the patient finishes inhalation, IPAP is cycled off, and the airway pressure is allowed to decrease to the preset EPAP level. The average starting range for IPAP is 8 to 10 cm H_2O while EPAP is 3 to 5 cm H_2O. Adjustments of these levels are

Figure 8-14 *Continuous positive airway pressure* (CPAP) mask. This is a nasal CPAP mask and has a low-pressure bladder around the rigid mask. There is a hook-and-loop closure strap system to secure the mask to the patient. Care must be taken to ensure a proper fit. The goal is to achieve a tight seal without creating undue pressure on the skin, nose, or other bony

prominences of the head, thus avoiding pressure necrosis.

generally made in 2 cm H_2O increments. Generally, increases or decreases in each are titrated to patient comfort (both IPAP and EPAP), SaO_2 (IPAP and EPAP), and the volume of gas that is moved (IPAP). A general approach is to increase IPAP until achieving reasonable V_T and pCO_2. If oxygenation remains inadequate, then EPAP is usually increased. Adjusting FIO_2 is somewhat more difficult with BiPAP than with other modes of invasive or NIV.

The BiPAP machine is connected to oxygen. It is run at the same flow rate that the patient required immediately before implementing NIV. Recall that the final FIO_2 is a blend of entrained room air and the bleed-in rate of O_2 from the pure 100% O_2 source (wall or tank). Each breath may therefore deliver a different final FIO_2 dependent on patient comfort and the respiratory effort.

When initiating BiPAP, the initial maneuvers are similar to initiating CPAP. An appropriate size full-face mask is chosen

Figure 8-15 The BiPAP machine. Each hospital may have a different BiPAP device. The key features are an O_2 connection to bleed-in O_2, a rate control, and separate controls for the level of inspiratory positive pressure (IPAP) and expiratory positive pressure (EPAP), as well as separate timing controls for IPAP and EPAP. Clinicians should familiarize themselves with the unique features of the device available at their institutions.

using the guide mentioned earlier. The mask should not place direct pressure on the bridge of the nose, the lateral ala, the inferior nasal septum, or the lip. The patient can participate in his or her care by initially holding the mask in place while the therapist adjusts the settings and the patient adjusts to the sensations and pressure (airway and mask). The mask is secured in place by using adjustable velcro straps. With the nasal mask it is important to encourage the patient to breathe with the mouth closed; in general, nasal BiPAP is quite difficult and not recommended for the acutely ill patient. It is important to check the fit of the mask for air leaks as they diminish the efficacy of the modality in proportion to the size of the leak. It is possible to obtain near-optimal settings in about 10 minutes.

Patients undergoing NIV need close monitoring and observation. [66] Patients initiated on BiPAP therapy should not be admitted to the general medical floor; step-down level care

is a minimum while ICU level care is optimal. Each hospital will have admission criteria for the care of patients on NIV that is driven by both clinician and nursing protocols designed to provide safe care of patients with potentially unstable airways and respiratory dynamics. Accordingly, these patients should be initially observed on continuous SaO_2 and hemodynamic monitoring of heart rate, blood pressure and respiratory rate. If available, continuous end-tidal CO_2 monitoring may be beneficial. An arterial blood gas should be obtained after initiating BiPAP therapy to assess CO_2 clearance and pH-pCO_2 balance. Titration of O_2 flow rate may be performed using SaO_2 monitoring instead of repeat analysis of arterial blood gases. In general, increases in IPAP will increase the V_T and lower CO_2, while increases in EPAP will increase FRC and increase O_2. BiPAP has been successfully used in the ED and in the postoperative ICU setting for short-term respiratory support in patients with a correctable underlying cause of their respiratory failure. [67]

Evaluation Adjuncts

The totality of the ventilator prescription interacts with the patient's pulmonary system in ways that may be assessed. The most straightforward is physical examination (see section on endotracheal intubation). However, the end result of the ventilator prescription is commonly evaluated using an ABG analysis. This directly measures pH, pCO_2, and pO_2 while the remainder of the values, including base excess (deficit), are calculated from an algorithm. Additional information that is frequently available as part of the ABG analysis usually includes Hgb or Hct, Na^+, K^+, Ca^{2+} (ionized), glucose, and lactate.

End-Tidal CO_2 Analysis, Capnometry, and Capnography (see Chapter 2)

Additionally, the flow pattern of exhaled gas as measured by the expired CO_2 concentration over time is evaluated by CO_2 capnometry (numeric data) or CO_2 capnography (graphic analysis). [69] Capnometry (quantitative measurement of CO_2) is a useful means of noninvasively tracking a patient's CO_2 tension. The principle behind capnometry is that the CO_2 measured at the end of a tidal exhalation ($ETCO_2$) will approximate the alveolar CO_2 and thus the blood pCO_2. If the $ETCO_2$ measurement and the arterial pCO_2 correlate, then changes in minute ventilation that are designed to produce a certain pCO_2 may be followed without the need for ABG determination. In normal lungs, the $ETCO_2$ is 1 to 5 mm Hg less than the pCO_2 as a consequence of heterogeneous alveolar expiratory dynamics (i.e., alveolar unit heterogeneity with regard to time constants for alveolar gas flow). $ETCO_2$ measurement may be accomplished by three means: infrared spectroscopy (most common), chemical analysis (common, qualitative only), and mass spectroscopy (uncommon and expensive).

Infrared capnometry passes a narrow band of infrared light through a sample of gas and determines the CO_2 concentration by analyzing the amount of light absorbed by the CO_2. Access to exhaled gas through the ventilator circuit occurs by way of either mainstream or sidestream sampling. The mainstream sensors are directly in line with the breathing circuit and pose two hazards and one disadvantage: (1) weight and rotational torque on the endotracheal tube, (2) an increase in dead space, and (3) the need to heat the sensor to avoid condensation. Sidestream analyzers continuously obtain gas

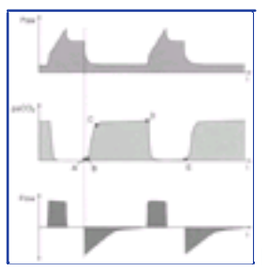

Figure 8-16 The end-tidal CO_2 ($ETCO_2$) trace. This diagram of an $ETCO_2$ capnograph represents normal exhalation flow dynamics. As exhalation progresses, the measured CO_2 rises and eventually plateaus. At the end of the plateau, immediately before the downstroke of the trace is the point at which the $ETCO_2$ value is measured and reported (i.e., point "D"). No other values are reported on the $ETCO_2$ capnometer. Thus in the absence of the capnograph, all other information is unavailable to the clinician. Abnormalities in endotracheal tube position, blockage of the airway (complete or partial), as well as correct endotracheal tube placement, are identifiable by evaluating the $ETCO_2$ tracing. *(Reproduced with permission from Drager Medical.)*

through a side port attached to the endotracheal tube, and have two disadvantages: (1) the small port is easily occluded with secretions, and (2) they are slower than mainstream analyzers. Capnometry helps ensure that the ventilator is indeed connected to the patient, and allows determination of dead space relative to tidal volume (important in patients with large anatomic dead spaces, severe lung injury, or both). However, much more information can be obtained from the graphic display of exhaled CO_2 over time (capnography).

In particular, a normal exhaled CO_2 tracing plateaus at the end of exhalation (Fig. 8-16). If there is chronic obstructive airways disease, or a significant amount of air trapping from auto-PEEP, the tracing will not plateau due to the prolonged expiratory phase required to empty the alveoli (Fig. 8-17). The presence of significant auto-PEEP may indicate increased intrathoracic pressure, impeded venous return, and thus secondary intracranial venous hypertension. Auto-PEEP may also be detected on ventilators equipped with a graphic display of flow or volume over time. However, as most ventilators in use are not so equipped, an $ETCO_2$ monitor tracing may serve as a reasonable substitute. Capnography has also been used to determine the optimal level of PEEP, [70] adequacy of cardiopulmonary resuscitation,[71] and detection of pulmonary embolus.[72] In the authors' opinion, all critically ill mechanically ventilated patients with

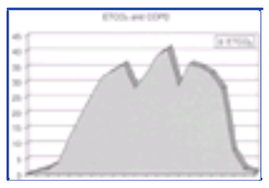

Figure 8-17 The $ETCO_2$ tracing in COPD—identification of auto-PEEP. In this diagram of an $ETCO_2$ trace in a patient with COPD who is being ventilated at a high respiratory rate, one may detect the presence of auto-PEEP based on the abnormal expiratory flow pattern. A similar suggestion could be obtained by interrogating the flow-time trace as well.

traumatic brain injury should be attached to a capnograph/capnometer device. Infrared capnography is the current standard of care in the operating room for CO_2 detection. In the near future, estimates of metabolic rate may be available on a breath-by-breath basis using a capnometry platform.

Chemical analysis of exhaled CO_2 has been effectively used for several years to confirm endotracheal placement of artificial airways. [73] The presence of CO_2 in the exhaled gas causes a color change in the monitoring device. The device is disposable, and placed between the ETT and the high-flow O_2 bag-value unit. It does not impede ventilation. In the authors' institutions, these relatively inexpensive devices are kept in all of the airway management carts, the ICUs, and the ED, and are routinely used in confirming airway placement.

Radiography.

A standard portable anteroposterior chest radiograph following the initiation of MV (and endotracheal tube placement) is the existing standard of care. It is not recommended to send a newly intubated patient requiring MV out of the ED to obtain a chest film.

RESPIRATORY THERAPY

The trained, certified respiratory therapist may be the clinician's "best friend" with regard to MV. These individuals may be invaluable in helping the clinician achieve the desired goals of MV. They are generally more familiar with individual machine performance characteristics than is the typical clinician, and they are responsible for ensuring that the device is functioning properly and with appropriate alarm limits. Multiple studies have documented that respiratory therapist-driven weaning protocols achieve a more rapid liberation from MV than those driven by clinicians. [68] To achieve these results, a weaning protocol is ideally developed in a multidisciplinary fashion, activated by clinician order, and then implemented by the therapists. The clinician is again engaged when the patient either fails to progress along the pathway, or has achieved extubation criteria. Only in rare circumstances is the clinician creating the settings on the ventilator—this is the purview of the respiratory therapist. If the clinician wants to manipulate the ventilator directly, advanced training and local hospital credentialing may be recommended.

CONCLUSIONS

MV is a complex process that requires dedication on the part of the clinician. Usually, the least difficult aspect of initiating MV is establishing an airway. The ED clinician should recall that the early period of MV may set the tone of events related to the remainder of the patient's course on the ventilator. Optimally, the ED clinician should be familiar with the spectrum of ventilatory modes available for use in the hospital; ventilator prescriptions are not ideally managed in a "one prescription fits all" fashion. Alternatives to endotracheal intubation should be considered in select patient populations. Medical adjuncts frequently enable the clinician to manage difficult ventilation issues while optimizing pulmonary dynamics. Difficult ventilatory issues (e.g., refractory hypoxemia) may be best co-managed with a dedicated intensivist in the ED if the patient cannot be rapidly transferred to the ICU.

CASE MANAGEMENT

Placing a patient on a ventilator and managing the setup and changes in ventilation requirements are formidable tasks for any clinician. The following section presents a step-by-step approach to managing two individual patients who require MV. A number of practical and logistical issues, types of ventilators, various modes of ventilation, and practical settings and subsequent changes are illustrated.

Case Scenarios

Case 1

An 18-year-old otherwise healthy 60-kg female presents with an overdose of benzodiazepines. She requires intubation for airway protection and ventilatory support. There is no evidence of aspiration or an intrinsic lung problem.

Volume-Cycled Ventilation

Devices Reviewed.

Puritan Bennet 7200, 7200a, or 7200ae or the Drager Evita 4 Pulmonary Workstation.

Target $?V_E$.

7.2 L/min. It is reasonable to assume a normal need for $?V_E$ since she has no evidence of hypoperfusion or infection, and she has not ingested any medications known to cause a metabolic acidosis that would require a higher $?V_E$ to buffer by induced hypocarbia.

Mode.

Since this patient has preserved spontaneous respirations, it is reasonable to allow her to continue to do so since she is not presenting problems with an increased work of breathing (nonlabored respirations, no accessory muscle use, no stridor, no wheezing, and no hypoxia). This means that one must couple the SIMV mode with PSV to eliminate work of breathing increases associated with the resistance of the artificial airway. Depending on the model of 7200 ventilator, the

Figure 8-18 The Puritan-Bennett 7200 Model ventilator. Note that on this particular ventilator, the controls are grouped into three distinct areas of the ventilator faceplate. To the left of the picture are display areas in green that indicate pressures (top), rate and I:E ratio (middle), and volumes (bottom). At the very top of the green section is an analog pressure meter to confirm pressures in the case of a liquid-crystal display (LCD) malfunction. The center portion (blue) houses the data entry keypad, the alarm limit-setting buttons, waveform selection, sighs, and 100% O_2 for suctioning button. Note that the "++" button is the selector to change between options that are displayed in the horizontal LCD bar above the keypad. Function 10 is the function to set the pressure support and is accessed by using the "++" key until the number 10 appears. One must then press Enter to access the function. The top of the blue section has the PEEP/CPAP knob, as well as the displays for peak flow, FIO_2 , set rate, and tidal volume. The gray section to the right indicates the alarm status as well as the alarm silence button.

Figure 8-19 Faceplate for the Drager Evita 4 Pulmonary Workstation. Note that the liquid-crystal display (LCD) screen is colored and has controls embedded in the screen to adjust the individual mode settings. The righthand controls on the front of the device control the kind of screen display, the silence button, and the standby button.

mode settings will either appear along the bottom or the left side (Fig. 8-18). Using the Drager E_4 , the mode will appear in the lower right hand side of the touch screen (Fig. 8-19).

Rate and Tidal Volume.

12 breaths per minute and 600 mL (7–10 mL/kg). These must be considered together to achieve the desired $?V_E$. This setting will guarantee the desired $?V_E$ even if the patient continues to develop respiratory depression from the benzodiazepine ingestion. It will allow her to take additional breaths using the following PSV settings if she so desires or needs to overcome an increased CO_2 production or a metabolic acidemia from an as of yet unidentified source.

Oxygen and Oxygen Adjuncts.

Start with an FIO_2 = 1.0 and PEEP = +5 cm H_2O pressure. As FIO_2 and PEEP both impact pO_2 , it is logical to consider their settings together. Since one wishes to guarantee that there is no hypoxemia to impact anaerobic metabolism, it is common practice to begin with a high FIO_2 and then reduce the FIO_2 to nontoxic levels using pulse oximetry (goal $FIO_2 < 0.60$). On the 7200 series, the FIO_2 is set using the O_2 concentration button in the central portion of the ventilator faceplate; the FIO_2 is directly entered using the numeric keypad followed by the enter key (see Fig. 8-18). On the E_4 , the FIO_2 is set by touching the faceplate numeric symbol for FIO_2 (it turns yellow), and then rotating the knob on the lower right of the ventilator faceplate to achieve the desired setting; the knob must then be pressed to signal the ventilator that you wish to accept the value (symbol reverts to green).

It is reasonable to start with a relatively low level of PEEP and evaluate the pO_2 that is achieved at the delivered FIO_2 . On the 7200, the PEEP is indicated by the PEEP/CPAP button (see Fig. 8-18). On the E_4 , the PEEP is set directly on the faceplate using the same technique as for setting the FIO_2 . The evaluation of the adequacy of the set FIO_2 and PEEP on pO_2 is easily performed by assessing the Alveolar-arterial gradient (A-a gradient; normal gradient = 50). High A-a gradients may trigger an increase in PEEP to increase FRC and pO_2 .

Pressure Support Ventilation.

Initiate PSV at 10 cm H_2O pressure, and then titrate up or down to achieve a spontaneous breath V_T approximately equal to that of the set V_T. On the 7200, the value displayed for each spontaneous breath is one breath behind what one observes in the patient. The value is displayed after depressing the tidal volume key in the grouping with ?V_E and spontaneous ?V_E (see Fig. 8-18); the V_{Tspont} will not display if one depresses the central keypad labeled tidal volume, as this key gives one the set V_T and displays its figures in the LCD bar in the middle of the faceplate (see Fig. 8-18). On the E_4, PSV is adjusted by activating the touchpad button labeled PSV. The knob is rotated to achieve the desired setting and then depressed to accept that setting (see Fig. 8-19).

Gas Delivery Waveform.

Begin with a decelerating waveform. Recall that the ramp waveform immediately begins to decrease flow after achieving the maximal inspiratory flow that one sets. This is a standard setting for the authors. The three waveforms are indicated by the three white buttons on the lower central portion of the 7200 faceplate (see Fig. 8-18); press "Enter" after selecting the waveform that is to be activated. On the E_4, the waveform may be manually selected using the setup function under "Modes," or it will be automatically selected by the E_4 using the Auto-flow feature. Auto-flow auto-matically retards flow if the maximal pressure limit is achieved, or increases flow if the patient desires more flow for a larger breath at that time. To manually set the waveform, Auto-flow must be disabled (*not recommended*).

It would not be unreasonable to start with a square waveform in this patient with normal lungs, but there is no downside to beginning with a ramp delivery pattern. The crucial information that one needs is the grouped evaluation of waveform coupled with maximal inspiratory ?Q, and the resultant P_{aw}-peak. These data are complemented by using concomitant pressure-volume curve analysis. Since the vast majority of the 7200 ventilators are not so equipped (but instead have a separate graphic display chip and display screen), the discussion assumes that the clinician is blind to the waveforms. A later discussion under Pressure Controlled Ventilation explores the use of the P-V curve and may be applied in volume ventilation as well (waveform display is standard for the E_4).

Maximal Inspiratory Flow (aka Peak Inspiratory Flow; ?Q).

Set the initial ?Q at 60 L/minute. One would set a lower ?Q if the patient had hypoxemia (?Q = 50 L/min) or a higher flow (?Q = 70 L/min) if the patient had exhalation obstruction (e.g., COPD), then evaluate the resultant P_{aw}-peak. Problems generally arise if the P_{aw}-peak is too high rather than being too low. If the P_{aw}-peak is low and the patient is well oxygenated and has an acceptable CO_2 clearance for his or her current pH, then no changes are required. If the P_{aw}-peak is too high, intervention is warranted (see discussion of P_{aw}-peak). A useful paradigm is to decide if the set V_T is simply too large (base the V_T on ideal body weight, not actual or adjusted, as the lung volume is a function of the thoracic cage size and is not influenced by the addition of adipose mass). If the V_T is appropriate, reduce the flow rate by 5 L/minute and re-evaluate; repeat if necessary. If the patient is on a square waveform, change to the decelerating setting. In general, if the ?Q is reduced to 40 L/minute and the P_{aw}-peak remains high, then one of the following conditions are true: (1) the V_T is, in fact, too large for the available lung mass, (2) there is a tube obstruction (partial), (3) the patient has a pleural space occupying disorder (pneumo-, hemo-, hemopneumo-, or hydro-thorax), (4) the patient requires a different mode, or (5) there is a ventilator dysfunction.

Writing the Orders.

The order on the chart may be best indicated as follows:
Initiate: (S)IMV at 10 ventilations/min
V_T at 600 mL
FIO_2 at 0.95
PEEP at +5 mmHg
PSV at +10 cm H_2O

Flow = 60 L/minute; Ramp waveform

Titrate PSV to achieve V_{Tspont} ~ 600 mL

Obtain ABG 20 minutes after initiating settings; notify clinician with results

Obtain STAT portable chest film to verify—endotracheal tube placement, initiation of MV; notify clinician when CXR obtained

Pressure Controlled Ventilation

Devices Reviewed.

Infrasonics Adult Star, Drager E_4 Pulmonary Workstation

Target ?V_E.

Since this is the same patient, the target remains unchanged at 7.2 L/minute. How one achieves this target is the subject of the following discussion.

Mode.

Similar to ?V_E, the mode remains the same. On the Adult Star, the mode is accessed in the second screen. Press the change screen button on the lower aspect of the display console; this will change to the second screen. Use the knob on the lower right of the console to move from one selection to another (selection will highlight). Then press the knob to access the values and rotate the knob until the desired mode appears. Press the knob again to accept. The E_4 has a mode known as PCV+. This is already set up as an SIMV-PCV-PSV mode. The settings are accessed under the Mode screen as in volume-cycled ventilation discussion, and are adjusted using the touch-rotate-press scheme reviewed earlier.

Rate.

While the rate remains the same, there is no set V_T. Instead, one must set the desired pressure change above PEEP and for the duration of that pressure change, and evaluate for the resultant tidal volume. While the goal resultant V_T may be identical to the V_T one sets in volume ventilation, one achieves that V_T in a fashion designed to limit the P_{aw}-peak and (usually) prolong the time spent in inspiration.

PC, T_i, and V_T-resultant.

In this patient with normal lungs, initially set pressure control (setting) = 20 cm H_2O pressure and T_i = 1.0 sec. The PC of 20 stems from starting with a PEEP of 5 cm H_2O pressure. Therefore, the combined P_{aw}-peak will be PC + PEEP, or 20 + 5 = 25 cm H_2O pressure. This is a safe pressure and what one might expect as the P_{aw}-peak if the patient were on a volume-cycled ventilation. Alternatively, one may use the upper pressure limit of normal, 35 cm H_2O and subtract from that the amount of initial PEEP (in this case 5 cm H_2O pressure), and then multiply the difference by ?. In this case the starting pressure would be 20 cm H_2O (35 - 5 × 2/3).

For a patient who is already on MV, take the current P_{aw}-peak, subtract the PEEP, and again multiply by ?. When setting up pressure-cycled ventilation on the Adult Star, all settings must be addressed before the mode can be activated. Thus, one will not have a mixed group of settings at any time.

The E_4 will allow one to change screens and input settings in a similar fashion but will not change the active ventilator settings until the operator accepts all of those mode settings.

One significant difference in pressure-cycled ventilation is that the pressure cannot exceed 25 cm H_2O pressure (*in this example*), and the amount of time in inspiration is longer than in volume-cycled ventilation. One must then look for the tidal volume that results from this combination. Each perturbation in resultant V_T has multiple repair strategies in PCV.

A discussion of T_i and I:E ratio is appropriate as the T_i setting directly influences the resultant I:E.

Inspiration:Exhalation (I:E) Ratio.

A normal I:E ratio is 1:3–4 for each breath cycle in a healthy individual. Assuming a rate of 10 breaths per minute, each respiratory cycle is 6 seconds. For a normal I:E ratio of 1:3 at this rate, there are 1.5 seconds spent in inspiration (T_i) and 4.5 seconds spent in exhalation (T_e). It is then imperative to evaluate the V_T -resultant and ?V_E. If these are low, the PC may be increased. If high, the PC may be decreased. T_i may be adjusted as well. Inspiration is the time for oxygen exchange. If the patient is hypoxic, the inspiratory time may be increased to increase the mean airway pressure and the time spent in inspiration in an oxygen-rich environment. For patients with severe hypoxemia, such a strategy may require inverse ratio ventilation (IRV) where the time spent in inspiration vastly exceeds the time available for exhalation. The extreme range of pressure-controlled IRV on the vast majority of ventilators is approximately 4:1. IRV is a distinctly unphysiologic and uncomfortable mode on which to breathe. Patients generally require heavy sedation and commonly in combination with neuromuscular blockade to tolerate IRV. The unique challenges of monitoring and achieving adequate sedation in patients on neuromuscular blockade have been reviewed elsewhere. [74]

Oxygen, Oxygen Adjuncts, and PSV.

FIO_2 , PEEP, and PSV remain the same as in volume-cycled ventilation settings.

Maximal Inspiratory Flow and Waveform.

In pressure-cycled ventilation, the goal is to allow the ventilator to adjust the flow setting in response to the patient's unique breath-by-breath change in compliance, resistance, and elastance. Thus, setting ?Q at its maximal value is ideal (Start: 160 L/min; E_4 : autoflow). As in volume-cycled ventilation, the ramp waveform is ideal.

Writing the Orders.

The order on the chart may be best indicated as follows:
Initiate: (S)IMV at 10 ventilations/min
PC at 20 cm H_2O
Ti at 1 second
FIO_2 at 0.95
PEEP at +5 cm H_2O
PSV at +10 cm H_2O

Flow = maximum value; Ramp waveform

Titrate PSV to achieve V_{Tspont} ~ 600 mL

Obtain ABG 20 minutes after initiating settings; notify clinician with results

Obtain STAT portable chest film to verify endotracheal tube placement, inititation of MV; notify clinician when chest film obtained

Note: There is no order to notify the clinician if the V_T -resultant is less or greater than anticipated. One should be at the bedside when ventilation is initiated and directly evaluate to adjust the parameters. Once the appropriate settings are achieved, then such an order is advisable as the clinician will want to evaluate changes in the patient's dynamics.

Waveform Analysis (See Earlier Section on Waveforms).

It is logical to evaluate not only the achieved gas delivery volume, but how the patient's lung receives the volume. This is currently best performed by using the dynamic P-V curve. Each change in ventilator prescription is best evaluated by reexamining the P-V curve profile as well as the flow-time trace. On the Adult Star, the screen must be changed twice. Then rotate the knob to reach the bottom of the screen on the left. Select graphics. This will bring up the P-V curve as well as the flow-time trace (Fig. 8-20). On the E_4 , the graphics are accessed by selecting values measured from the righthand column of white static buttons. Then touch the field labeled loops. This will bring up the P-V curve (Fig. 8-21). The green box in the upper right-hand corner of the PV-curve box will have a menu of other traces and loops—the flow-time trace is found there by selecting its label and pressing the knob.

Case 2

A 45-year-old, 70-kg male presents with high fevers, cough, and shortness of breath. The ED portable chest film demonstrates bilateral infiltrates as well as lower lobe air bronchograms. While awaiting admission to the hospital for presumed community-acquired pneumonia, the patient develops hypoxia, suffers respiratory failure, and requires urgent intubation.

Volume-Cycled Ventilation

Mode.

SIMV—As before, allow the patient to breathe spontaneously when the short acting neuromuscular blockers or heavy sedative (e.g., etomidate, fentanyl, midazolam) used to facilitate intubation wears off.

Target ?V_E .

Given the likely acidosis, this patient's ?V_E needs to exceed the lower limit of normal value. Thus, a target of 9.8 L/minute is a 40% increase above the baseline that one would expect for a slenderly built gentleman.

Rate and V_T .

An initial rate of 14 is ideal and may be coupled with a normal V_T of 700 mL. It is OK to use a normal tidal volume to start as the patient does not have a history of intrinsic pulmonary disease. One must evaluate the resultant P_{aw} -peak after starting at this setting. One may also need to reduce the tidal volume and increase the

rate if the P_{aw} -peak is high and no other mode of ventilation is available.

Alternatively, were one to follow the ARDSNet recommendations, a starting V_T of 450 to 500 mL would be ideal.[76] The required rate would be 20 breaths per minute to achieve the target ?V_E . Recall that this strategy may not clear CO_2 as efficiently as a slower rate and a larger V_T given a larger V_D/V_T ratio.

FIO_2 and O_2 Adjuncts.

Begin with a high FIO_2 (0.95 to 1.0) to ensure adequate oxygenation. Titrate as before. Initiate PEEP at a minimum of 5 cm H_2O since one will need to maintain FRC and alveolar recruitment. Starting at a higher level may result in hemodynamic compromise in a patient who likely has intravascular volume depletion. Once the patient is volume-replete, titrate to achieve the optimal PEEP as explained earlier. It is best to start with a decelerating wave form since one may assume that the infected and collapsed segments will have much longer regional time constants than their neighboring alveolar segments. Thus, a longer T_i is ideal for alveolar recruitment. Moreover, a slow flow rate will

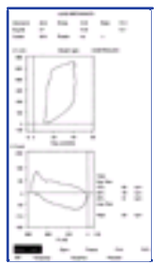

Figure 8-20 The pressure-volume curve on the Adult Star ventilator. Note that the curve is identical to the type of curve one would obtain on the E_4 with the exception of color and the ability to freeze a reference curve for comparison. Here it is accompanied by the flow-time loop, as well.

complement the decelerating waveform and further prolong the T_i . It is reasonable to start with a ?Q of 50 L/minute and evaluate SaO_2 and P_{aw} -peak.

Pressure Support.

Start with a higher PSV than the last patient since one may assume that the pulmonary compliance will be less than in a patient with normal lungs. Initiate PSV at 15 cm H_2O pressure and titrate as before to achieve similar V_T with the machine and spontaneous breaths.

Pressure-Cycled Ventilation

Neither the mode nor the target ?V_E are different. Instead of V_T , one must set PC and T_i .

Rate.

This is not as straightforward as in volume-cycled ventilation. A higher rate to clear CO_2 in volume-cycled ventilation will lead to reduced T_e in PCV if one is using a long T_i (see later). Thus a slower rate will allow for more time spent in recruitment, and more efficient CO_2 clearance than would be achieved with a higher rate. One must recall that the V_D/V_T ratio also governs the efficiency of CO_2 clearance, not just the total amount of gas that is cycled in 1 minute. Thus start with a rate of 10 breaths per minute, not 14 as in volume cycled-ventilation.

PC and T_i .

As described earlier, start with a PC level that is either related to the volume-cycled ventilation P_{aw} -peak or

Figure 8-21 Pressure-volume curve on the E_4 . This display may be brought up as a solo display, or integrated into other multi-display screens as indicated above. One accesses the menu on the lower right of the screen by activating the "values measured" button on the right of the faceplate (not the liquid-crystal display [LCD] screen). Then press Loops. The device will either display a continuous set of loops, or a reference and a single breath (yellow button illuminated on the appropriate green icons).

the maximal airway pressure that one will tolerate (35 cm H_2O pressure). In this example, use a longer T_i (start at 2.0 sec; resultant I:E at rate = 10 is I:E::1:2) given the prolonged regional time constants to manage hypoxemia, as a larger V_T will require excessive PC and lead to ventilator-induced lung injury. Progressively increase the T_i for failure to resolve hypoxemia. In this patient, one may ultimately need to employ IRV to reverse hypoxia.

Set the maximal inspiratory flow and waveform as described earlier. The subsequent evaluation is unchanged from Case 1.

Hypoxia Rescue Strategy

The authors recommend APRV as their rescue mode of choice for refractory hypoxemia. Only three ventilators at present can perform in APRV mode: the Drager Evita 4 Pulmonary Workstation, the Nellcor-Puritan Bennett 840, and the Hamilton Gallileo. The E_4 will be used as the prototype for this chapter.

Assume that your patient has refractory hypoxemia on either volume-cycled ventilation or pressure-cycled ventilation. The goal is to restore oxygenation in a rapid, safe, and efficacious fashion. Typically, these patients will have problems with airway pressures during volume-cycled ventilation, or inadequate V_T on pressure-cycled ventilation; many will be pharmacologically relaxed to tolerate pressure-cycled ventilation-IRV, or the ARDSNet protocol for lung protective ventilation. APRV represents a low-pressure, easy-to-use mode that rapidly corrects hypoxemia, and more slowly corrects hypercarbia while preserving spontaneous respiration. Indeed, the benefits of APRV are lost if the patient is chemically relaxed. [75]

Figure 8-22 Intrinsic PEEP (PEEPi). The E_4 will measure the intrinsic PEEP as well as the trapped volume responsible for that PEEPi. The function is accessed by using the "special procedure" button on the righthand side of the faceplate, activating the "start" button on the liquid-crystal display [LCD] screen, and then depressing the knob to initiate the procedure. In this example, the PEEPi is 0.4 cm H_2O pressure and represents a volume of 155 mL (0.155L) of gas.

Determine the P_{aw} -plateau on the prior ventilator settings as well as the PEEP. Then start APRV using a long time at the high CPAP level; APRV is found under the mode settings menu, and the settings are manipulated in the same fashion as using the other modes on the E_4 (touch, rotate knob, push to accept). If the prior P_{aw} -plateau was 28, then start with P_{aw} -high at 28 cm H_2O pressure. The length of time at that pressure is T_{high} ; start at approximately 6.0 seconds (<4.5 seconds is not APRV by definition). Next, set the P_{aw} -low at 0, and the release time (T_{low}) at 0.8 seconds. Keep the FIO_2 at the same settings as in the prior mode. Leave the rise time at 0.20 (default setting), and activate automatic tube compensation (compensates for intrinsic tubing resistance much like PSV). These are approximate settings that need to be adjusted based on the pressure-over-time curve, the release volumes, and the patient's response.

First, recall that the time for gas flow is quite long by comparison with cyclic ventilation. Thus, release volumes may be smaller than one would desire for a V_T on conventional ventilation. Oxygenation will be enhanced despite the small volumes due to the efficiency of exchange based on exceptional alveolar recruitment. Adjusting the pressure to which the airway pressure is allowed to drop at the end of the release phase may be done in one of two ways: setting a P_{aw} -low or adjusting the T_{low} to achieve a trace that drops to ? of the amplitude of the P_{aw} -high (see Fig. 8-6). Either method is successful. If the release volumes are <5 mL/kg body weight, the authors advocate increasing the P_{aw} -high as the initial maneuver up to a maximum of 35 cm H_2O pressure. The authors have increased pressure beyond this in an awake patient who could report discomfort with no untoward consequences, but would recommend further increases in the T_{high} before exceeding 35 cm H_2O pressure.

Next, check the intrinsic PEEP to see if the PEEPi achieved equals at least the PEEP set on the prior mode; generally, the PEEPi will be greater than the prior PEEP, mandating an evaluation of blood pressure. PEEPi is found using a special procedure button on the right of the ventilator; press start procedure to obtain the PEEPi as well as the trapped volume that has generated the intrinsic PEEP. The screen will enter freeze mode after making the measurement; remember to unfreeze it by depressing the freeze button on the right of the ventilator faceplate (Fig. 8-22).

Typically, the patient's pO_2 and SaO_2 will rise rapidly (within a few minutes of starting the mode).[19] Failure to do so has been associated with endotracheal tube malfunction, pneumothorax, and, most commonly, inadequate pulmonary blood flow associated with intravascular volume depletion or inadequate cardiac output. [19] Weaning from ARPV is quite simple once the proximate cause of the hypoxemia has been corrected. The authors simply decrease the P_{aw} -high by 2 cm H_2O pressure every 2 hours until the P_{aw} -high = 10 cm H_2O pressure. If the patient is comfortable, well saturated, on minimal pressor support, and has manageable secretions coupled with an acceptable mental status, then endotracheal tube removal is appropriate.

Acknowledgment

Chapter 9 - Thoracentesis

Barbara Blok
Ana Ibrado

The term *thoracentesis* is derived from the Greek *thorakos* (chest) and *kentesis* (to pierce). Classically, this refers to any maneuver whereby a sharp object introduces a conduit between the intrathoracic cavity and the atmosphere, allowing air or fluid to exit. The clinical presentation and management of pneumothorax is covered in Chapter 10 . In contrast, this current chapter concentrates on the identification and management of fluid accumulations in the chests of patients who present to the emergency department (ED).

BACKGROUND

Thoracentesis was first described by Hippocrates as a procedure to relieve disease and potentially cause demise. [1] Various approaches and instruments for piercing the chest have since been developed. In the mid-1800s, Boerhaave introduced a flexible tube designed to evacuate a hemothorax. [2] In 1852, Bowditch described thoracentesis for the first time in American medical literature, coining the term "paracentesis thoracis." [3] Shortly thereafter, Hunter began using the newly designed hypodermic needle as an instrument for thoracentesis.[2] Hewett introduced the technique for continuous aspiration in 1876. [4] The 20th century forced the discovery of antiseptics and sterile techniques to further improve outcomes from chest drainage.

Advances in science also enabled a better understanding of the structures surrounding the lungs and the mechanisms by which disease processes result in fluid accumulation in the thorax. Characterizations of these collections have changed from observation of turbidity to a host of chemical markers, histologic markers, and bacterial stains and cultures. Furthermore, identifying the complexity of these fluid collections has been accompanied by increasing use of advanced radiologic techniques from plain films to magnetic resonance imaging (MRI). Together, these advances provide the ED clinician with an ordered approach to the patient with indications for thoracentesis.

ANATOMY AND PHYSIOLOGY OF THE PLEURAL SPACE

During embryologic development, lung buds grow out of a median mass of mesenchymal tissue into future thoracic cavities. This maneuver creates two linings: the visceral pleura, which wraps the lungs; and the parietal pleura, which lines the inner surface of the thorax and diaphragm and meets the visceral pleura at the root of the lungs in the mediastinum. The space between the two linings is called the pleural space. [5]

Understanding basic anatomy is important as it underlines the similarities and differences between the two linings, which in turn determine the physiology and pathophysiology of the pleural space. Both visceral and parietal pleura are thin layers of connective tissue, each embedded with capillary beds that generate both hydrostatic and oncotic pressures. The differences in these pressures from species to species have been the subject of intense study. While the majority of pulmonology research supports the belief that fluid flows from the parietal pleura and is absorbed in the hydrostatically permissive visceral pleura, there is also evidence supporting the concept that both tissues have a net fluid flow into the pleural space, and that this fluid is removed in bulk by the lymphatic system.

A schematic of the relationship between parietal and visceral pleura, as well as the diaphragm and cardiovascular/lymphatic systems is shown in Figure 9-1 .

The visceral pleura is supplied by the bronchial arteries and empties into the pulmonary veins. In this system, the hydrostatic water pressure (H_2O) in the capillary beds, which leads to fluid movement out of capillaries, is measured at about 24 cm H_2O, while the hydrostatic pressure within the pleura generated by the negative pleural pressure is -5 cm H_2O. This generates a total capillary outflow pressure of 24 - (-5 cm), or 29 cm H_2O. The opposing pressure, that which keeps fluids in the capillaries, is the oncotic pressure, measured at about 34 cm H_2O. The small amount of fluid in the pleural space also carries enough protein to generate an oncotic pressure of 5 cm H_2O. This generates a total capillary inflow pressure (opposing force) of 34 - 5 cm, or 29 cm H_2O. Total capillary inflow pressure (29 cm H_2O) minus total capillary outflow pressure (29 cm H_2O) equals a net fluid gradient of virtually zero. [6] This well-matched pressure system within the visceral pleura supports the idea that fluid generally does not flow out of, and may even be absorbed by, the visceral pleura in the healthy state. However, the visceral pleura wraps the lungs, making it directly susceptible to

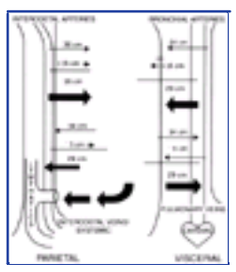

Figure 9-1 Schematic of relationships between the parietal and visceral pleura.

diseases within the lung parenchyma as well as fluid accumulation in the alveoli during pulmonary edema. Furthermore, because the pulmonary veins drain into the left ventricle, cardiac dysfunctions that result in increased left ventricular failure also affect fluid flow across the visceral pleura.

In contrast, the parietal pleura is supplied by the intercostal arteries and empties into the intercostal veins. Intercostal circulation reflects systemic pressure and naturally carries a higher hydrostatic pressure than the pulmonary vascular bed. In humans, this hydrostatic pressure is measured at about 30 cm H_2O. The parietal pleura is exposed to the same negative intrapleural pressure of -5 cm H_2O. Therefore, the net capillary outflow pressure from the parietal pleura is 30 - (-5 cm), or 35 cm H_2O. As plasma oncotic pressure is similar in both capillary beds, the opposing oncotic pressure in the parietal pleura is also around 29 cm H_2O. Therefore, total capillary inflow pressure (35 cm H_2O) minus total capillary outflow pressure (29 cm H_2O) generates a net gradient of about 6 cm H_2O from the parietal pleura into the pleural space in the healthy state. As a result, proper functioning of all these structures allows for a small amount of fluid, estimated at 0.26 mL/kg body mass, separating visceral from parietal pleura at any time. [7]

While it makes sense that this small amount of separation facilitates lung movement, obliteration of this space, as in the case of pleural symphysis, does not result in significant abnormalities in lung function. [8] [9] A more recent proposition for the role of the pleural space is to allow for pulmonary edema to escape the lung and decrease its effects on lung function. Fluid accumulated in the lung interstitium has been shown to flow quickly into the pleural space, where its effect on pulmonary function is minimal, while preserving oxygen exchange in the lung parenchyma. [10]

Pleural fluid generated over time is removed in bulk from the pleural space by the lymphatic system. The parietal pleura is embedded with large lymphatic stoma. These conduits allow particles as large as 10 MU to pass and drain the pleural space fluid in bulk through the lymphatic sinuses and into the mediastinal lymph nodes. Over the course of a day the lymphatic system maintains a pleural space outflow of 0.1 mL/kg per hour minimum, with a 30-fold capacity of 3 mL/kg per hour. [11] [12]

From this design, it is clear how various disease states can result in a pleural effusion simply by increasing the volume of fluid movement into the pleural space beyond the capacity of the lymphatic draining system or by decreasing the efficiency of the lymphatic draining system. Increasing the intravascular hydrostatic pressure or decreasing the intravascular oncotic pressure can increase fluid movement into the pleural space. Inflammatory, ischemic, or histologically destructive processes may compromise the lymphatic drainage, leading to an increase in pleural fluid.

THE ETIOLOGY OF PLEURAL EFFUSIONS

Pleural effusions are either transudates or exudates (Table 9-1). Distinguishing between transudates and exudates narrows the differential diagnosis and directs management and therapy. Generally, transudates are straw-colored and serous in appearance. Although they can be blood tinged, they have very low cellular and protein content. This is expected as transudates result from high intracapillary hydrostatic pressures and fluid

TABLE 9-1 -- Etiologies of Pleural Effusion

Transudates	
Most common	Congestive heart failure
	Cirrhosis
Less common	Nephrotic syndrome
	Peritoneal dialysis
	Pulmonary infarct (embolus)
	Superior vena cava obstruction
	Myxdema
	Meig syndrome
	Acute atelectasis
Exudates	
Most common	Bacterial pneumonia
	Malignancy
	Pulmonary infarct (embolus)
	Trauma
Less common	Other pneumonias

shifts to achieve equilibrium. In contrast, exudates result from either increased capillary permeability or destruction of barrier tissues, and generally contain high levels of protein and cellular components.

Transudates: Overwhelming the System

The most common cause of transudates is congestive heart failure (CHF). Left ventricular dysfunction leads to increased hydrostatic pressure in the pulmonary veins, resulting in an increased movement of fluid into the pleural space. When the increased fluid volume in the pleural space exceeds the lymphatic capacity for drainage, a pleural effusion develops. Additionally, the increased systemic hypertension associated with CHF also increases fluid flow from the parietal pleura and decreases lymphatic flow out of the thorax.[6] [13] Any process that results in compromised left ventricular output can result in a pleural effusion, including myocardial infarction, pericarditis, constrictive cardiomyopathy, and pericardial effusion from various disease processes.

Patients with cirrhosis are frequently hypoalbuminemic, leading to a chronic state of decreased plasma oncotic pressure. The imbalance between the hydrostatic and oncotic forces in the pleural space results in an effusion. [14] Alternatively, in normal situations, an intact parietal pleura over the stretchable diaphragm prevents the influx of intraperitoneal fluid into the thoracic cavity. Experiments have shown that high volumes of ascites can stretch the diaphragm enough to allow fluid to pass through preexisting

microdefects. In these cases, chest tube placement reduces both the pleural effusion and the ascites. Similarly, removal of the ascitic state also prevents the resulting effusion.[15]

The same mechanism is thought to explain acute hydrothorax, which occurs in approximately 10% of patients on continuous ambulatory peritoneal dialysis (CAPD). This occurs within the first several months after the start of CAPD. The transdiaphragmatic communications can close spontaneously on relief of pressure and volume, although recurrent episodes usually require surgical correction and chemical pleurodesis. [16]

Nephrotic syndromes also lead to protein loss and an imbalance between hydrostatic and oncotic pressures, which may result in pleural effusion. An important disease process to consider in patients presenting with nephrotic syndrome and pleural effusion, however, is pulmonary embolism (PE). [17] Patients with nephrotic syndromes have an increased incidence of thromboembolic events, which can also cause pleural effusion. A steadfast search for PE as the reason for effusion is

therefore warranted.

Superior vena caval obstruction is more common in neonates, in whom as much as 200 mL/kg per day of pleural fluid production is seen. [18] The accumulation is believed to result from obstruction of lymphatic drainage into the venous system. In adults, however, pleural effusions are not as common with superior vena caval syndromes. Therefore, in these cases, concurrent lymphatic obstruction by malignant disease should be strongly considered.

Exudates: Pathology of Tissues, Destroying the System

The main mechanism of cancer-related pleural effusions is obstruction. First, by direct metastasis to the parietal pleura, malignant tissues either block or destroy lymph stoma, thereby preventing outflow. Second, intrathoracic neoplasms, (e.g., lung cancer, metastatic breast cancer and lymphoma), involve mediastinal lymph nodes; thereby decreasing outflow. Bronchogenic carcinoma can obstruct a mainstem bronchus, causing the remaining lung to expand or, more likely, the hemithorax to collapse, thereby increasing negative pleural pressure and pulling fluid into the pleural space. Because these are mechanical entities that overwhelm the system, the protein levels in these effusions are low like transudates. Malignant effusions, however, have high lactate dehydrogenase (LDH) levels, fulfilling Light's criteria as an exudate. Other less common mechanisms involving neoplasm include: metastasis to the visceral pleura; increasing capillary permeability; and obstructing the thoracic duct, thereby creating a chylothorax. [19]

Bacterial pneumonia affects about 4 million Americans a year, 20% of whom require hospitalization. Of those hospitalized, 40% develop effusions. [20] A pleural effusion associated with bacterial pneumonia, lung abscess, or bronchiectasis is a parapneumonic effusion. [21] Empyema, on the other hand, is defined as pus in the pleural space, with or without an associated pneumonic process. [22] In the first stage of the parapneumonic effusion, called the exudative stage, fluid flows from the capillaries of the visceral pleura secondary to increased permeability rendered by the surrounding inflammation or pneumonitis. In the second, fibropurulent stage, a large accumulation of fluid containing cells, bacteria, cellular debris, and fibrin deposits on both the visceral and parietal pleura. This leads to formation of loculations. Loculations contain the empyema, preventing it from spreading, but also make it very hard to drain even with large chest tubes. In the last, organizational stage, fibroblasts grow from both pleural and form a tough peel that encases the lung and renders it functionless. In the worst cases, the empyema will drain spontaneously through the chest wall (*empyema necessitates*) or into the lung (*bronchopleural fistula*).[6] Numerous bacterial and fungal infections have been shown to result in effusions and fistulae. Fungal infections can begin in the pleural space, specifically postinstrumentation, and in the immunocompromised patient.

Nonpulmonary processes that give rise to empyemas include esophageal perforations, pneumothorax, subdiaphragmatic infections, septicemia, and manipulation or instrumentation within the thoracic cavity.

Pleural surfaces, in patients with rheumatoid arthritis with pleural effusions are inflamed and thickened, sometimes with vesicles and granules, all of which increase permeability and result in an effusion characteristically low in glucose and high in rheumatoid factor. [23] Systemic lupus erythematosus (SLE) and drug-induced lupus pleuritis, in contrast, have high glucose levels and lower LDH levels. Drugs known to have lupus-like syndromes include hydralazine, procainamide, isoniazid, phenytoin, and chlorpromazine. The following drugs reportedly cause pleuropulmonary reactions and pleural thickening and effusions rich in eosinophils: nitrofurantoin, dantrolene, methylsergide, and bromocriptine. Amiodarone also causes severe pulmonary toxicity and pleural effusions. Other disease processes that compromise the pleura include mesotheliomas, asbestosis, tuberculous pleuritis, viral infections, and fungal infections that primarily affect the pleural space (e.g., pleural aspergillosis, blastomycosis, and coccidioidomycosis). [24]

Entamoeba hystolytica trophozoites form abscesses in the liver. The abscesses can cause effusion by diaphragmatic irritation and the resulting sympathetic effusion. More dramatically, these abscesses can rupture through the diaphragm and result in a unique pleural fluid often described as "chocolate sauce" or "anchovy paste," which is rich in cytolytic enzymes, blood, and liver tissue. These are large effusions accompanied by sudden, severe pain; respiratory distress; and occasionally shock.[25] *Echinococcus granulosus* is a tapeworm that also forms pulmonary, splenic, and hepatic hydatid cysts, and presents with the same dramatic rupture as Entamoeba in about 5% of cases. When rupture occurs, however, 50% of the time it is accompanied by simultaneous rupture into the tracheobronchial tree. These patients cough up large amounts of pus and cysts. Echinococcal scolioces and hooklets are also abundant in the pleural fluid. [26]

Pancreatitis can present as either acute pancreatitis, chronic pancreatitis with pseudocyst, or pancreatic ascites. Pleural effusions due to acute pancreatitis are sympathetic effusions and usually on the left side. Effusions in pancreatic ascites, as with all other ascites, result from transfer of ascitic fluid through diaphragmatic defects and are characterized by extremely high amylase levels. [27] In contrast, pleural effusions in chronic pancreatitis with pseudocyst result from the development of sinus tracts between the pancreas and the pleura, usually through the aortic or esophageal hiatus, known as the pancreaticopleural fistula. This third mechanism leads to massive chronic pleural effusions, which reaccumulate rapidly. [28]

Yellow Nail Syndrome is the triad of deformed yellow nails, lymphedema, and pleural effusions. It is possible,

however, that each finding occurs at a different stage in the patient's life, making the presence of all three unlikely. The underlying defect is hypoplastic lymphatic vessels.[6]

Entities of Both Transudate and Exudate Nature

Of the 500,000 persons that have a PE each year, at least 30% develop a pleural effusion. [29] Therefore, when the etiology for the effusion is unclear, strongly consider a PE. PEs cause effusion by obstruction of the pulmonary vessels, leading to right-sided failure and an increased hydrostatic pressure in the parietal pleura. In this case, the fluid is transudative. Alternatively, when blood supply to pulmonary vasculature is removed, the parenchyma distal to this point undergoes ischemia and infarcts, leading to increased capillary permeability in the visceral pleura. This results in an exudative pleural effusion. Meig syndrome is the triad of ascites, pleural effusion, and benign ovarian tumor. An exudative pleural effusion is believed to result from the movement of ascitic fluid through diaphragmatic pores or defects. In addition, high systemic pressures can also generate a transudative effusion through increased fluid movement from the parietal pleura. [30]

Traumatic Injuries

Esophageal rupture can result from forceful vomiting as in the case of Boerhaave syndrome, or from instrumentation as in the case of endoscopy, Blakemore-Sengstaken tube placement, or rigid nasogastric tube placement. Hemothorax can result from sharp traumatic injuries, subclavian vein or artery cannulation, pulmonary embolism, aortic aneurysm, and supratherapeutic levels of anticoagulant. Chylothorax develops from acute disruption of the thoracic duct, usually in the setting of trauma. These are usually large-volume effusions that accumulate over an extremely short period of time, rapidly compromising both oxygenation and circulation.

DIAGNOSIS OF PLEURAL EFFUSION

Clinical Diagnosis

The three most common symptoms related to pleural effusions are chest pain, cough, and dyspnea. Parietal pleurae have nerve fibers; therefore, pleuritic chest pain is more indicative of localized irritation of the parietal pleura. Pain can often be referred to the abdomen via innervation of the intercostals. Chest pain solely from fluid collection is a dull ache. Involvement of the mediastinal pleura, because of innervation of the phrenic nerve, results in chest pain with ipsilateral shoulder pain. Lower chest pleuritic pain with shoulder pain is pathognomonic for diaphragm involvement. Significant fluid accumulation compresses the lung parenchyma, causing the opposing bronchial walls to touch, thereby stimulating a cough reflex. [6] Patients with large effusions have surprisingly acceptable arterial blood gases and evacuation of large effusions does not necessarily dramatically improve dyspnea. [6]

Because pleural effusions result from many disease processes, physical examination of the patient should involve all systems in search for other signs of a suspected disease. Lung examinations should be conducted to evaluate lung pathology and determine the extent of the effusion. While most patients will have equal hemithoraces and normal intercostal spaces, taking a few minutes to observe these is actually useful in determining action. Large effusions can result in increased hemithorax and bulging intercostal spaces on the side of the effusion. On palpation, tactile fremitus is either reduced or completely absent over the effusion, as fluid separates the lung from the thoracic wall and absorbs vibrations from the lung. Percussion over the effusion produces a characteristic dullness, which shifts when the patient changes position if the fluid is free-flowing. In general, auscultation reveals decreased to absent breath sounds depending on the size of the effusion. Pleural rubs may be appreciated if there is pleural irritation, but are often difficult to auscultate until after fluid evacuation. Palpation, percussion, and auscultation are all useful in determining the top of the effusion. However, depending on the noise level in the ED, the suspicion of complicated fluid collections, or in the patient with prior multiple thoracic instrumentations, radiologic studies can be very useful.

Radiologic Diagnosis

Understanding the appearance of effusions on plain chest x-rays requires three key concepts: (1) Effusions, when free-flowing, follow the force of gravity and accumulate in the most dependent parts of the thoracic cavity. (2) Lungs recoil proportionately when they collapse secondary to elastic recoil. This means that a collapsed lung will retain its original shape, although smaller, and float on the fluid. (3) Fluid layers evenly anterior to posterior in the upright position.

Underlying air and mass densities will affect the appearance of fluid on x-ray and must be considered when reviewing chest radiographs. [31]

On a chest x-ray, the most easily recognized abnormality that relates to a pleural effusion is the blunting of the lateral costophrenic angle on a posterior-anterior (PA) or anterior-posterior (AP) view (Fig. 9-2). At least 175 mL are needed to cause blunting, but as much as 500 mL of pleural effusion may be present without blunting.[32] [33] On a PA radiograph, pleural fluid appears like a meniscus, curving downward toward the mediastinum and higher laterally against the lateral wall in the PA view. Similarly, in the lateral view, the fluid level appears "lowest" midway through the thoracic cavity and highest at the anterior and posterior margins. In both cases, the true height of the pleural effusion coincides with the highest point on the meniscus. Pleural fluid can be encapsulated by tissue adhesions in parietal, visceral, or interlobar surfaces within the thoracic cavity. Because these adhesions anchor the fluid collection, loculated effusions are often described as D-shaped (Fig. 9-3) and are best diagnosed with either ultrasound or computed tomography (CT) (see later).

In subpulmonic effusion, the fluid remains infrapulmonary and does not cause blunting of either the lateral or posterior costophrenic angles on the upright radiograph. As much as 1000 mL of fluid may be present. The following features should raise suspicion for a subpulmonic effusion on the upright radiograph (Fig. 9-4): (1) an elevated hemidiaphragm; (2) the elevated hemidiaphragm peaks more laterally than expected, with a steep lateral slope; (3) pulmonary vessels are not clearly visible below the surface of the hemidiaphragm on lateral projection; (4) flat appearance of the

Figure 9-2 Right-sided pleural effusion. Posterior-anterior (PA) radiograph demonstrates blunting of right costophrenic angle. Both PA and lateral radiographs demonstrate the appearance of a meniscus.

posterior aspect of the hemidiaphragm on lateral projection. [34] A lateral decubitus view of this patient will show free-flowing pleural fluid parallel to the x-ray table.

Bilateral decubitus radiographs should be obtained when a pleural effusion is seen. A true simple pleural effusion will follow gravity and layer in one level below the floating lung. Unusual shapes reflect the presence of loculations, contained abscesses, and masses. The second view, a lateral decubitus view on the opposite side, draws the fluid toward the mediastinum and allows visualization of the lung parenchyma to determine the presence of infiltrates or masses (Fig. 9-5).

In the case of a massive pleural effusion, the entire hemithorax is opacified (Fig. 9-6). In such films, identification of mediastinal shift is a key to identifying the underlying process. In the absence of a diseased lung or mediastinum, large fluid accumulations should push the mediastinum contralaterally. When the mediastinum shifts toward the effusion, lungs and mainstem bronchi are likely diseased or obstructed, or both. When the mediastinum is fixed midline, it is likely to be invaded by a tumor.[34] [35] Differentiation of these disease processes is best done with CT.

Figure 9-3 Loculated pleural effusion. This posterior-anterior radiograph demonstrates the D-shaped appearance of a right-sided loculated pleural effusion.

CT is more sensitive than plain film in detecting very small amounts of effusion and can readily assess the extent, number, and location of loculated pleural effusions. Loculated lesions can appear vague on plain film. In the distinct anatomical relationships shown on cross-sectional views in CT, free-flowing pleural fluid will form a sickle shape in the most dependent regions (Fig. 9-7) while loculated fluid collections will remain lenticular and relatively fixed in space. Additionally, CT assesses pleural thickening, irregularities, and masses that are suggestive of malignancy and other diseases which result in exudative effusions. With IV contrast dye, CT differentiates lung parenchymal disease such as lung abscess, which may be confused with empyema. [36] CT is also useful in the identification of mediastinal pathology. Finally, CT may also be useful in differentiating ascites from pleural effusion, which can be difficult to differentiate on plain radiographs. On CT, pleural effusions displace the diaphragmatic crus (displaced crus sign). They also obliterate the interface between liver and fluid (interface sign) and the bare area, a potential space behind the liver accessible only to pleural fluid (bare area sign) (Fig. 9-8).[37] [38] [39]

Figure 9-4 Subpulmonic effusion. This posterior-anterior radiograph demonstrates an elevated left hemidiaphragm that peaks more laterally than expected. A decubitus radiograph in the same patient demonstrates the free-flowing fluid.

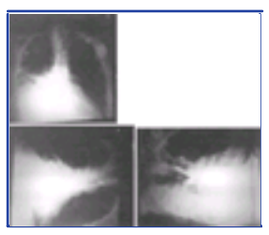

Figure 9-5 Bilateral decubitus radiographs. This patient's right-sided pleural effusion appeared on the posterior-anterior radiograph. Bilateral decubitus views demonstrate the free-flowing nature of the effusion and allow visualization of the lung parenchyma.

Ultrasound is advantageous for assessment of pleural effusions because it is easy and noninvasive. It can also be performed at the bedside. Although some details can only be seen with CT, ultrasound can identify fluid loculations, separate fluid from pleural thickening, and distinguish solid from pleural effusions especially in fluid collections that look solid in

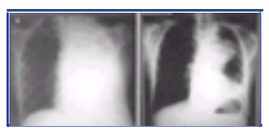

Figure 9-6 Massive pleural effusion. A repeat radiograph after thoracentesis demonstrates underlying mass.

freeze-frame. Real-time Doppler ultrasound may be more useful, as gray-scale ultrasound has a false-positive rate of 10%. [40] Ultrasound can also be used to identify both pulmonic and abdominal etiologies of the pleural effusion (Fig. 9-9).[39] [40] [41]

MRI has limited use in evaluating pleural effusions. In extreme cases where complex loculations hinder accurate

Figure 9-7 Pleural effusion. Sickle appearance of a free-flowing pleural effusion on computed tomography scan.

localization of fluid collections, the multiplanar ability of the MRI may provide some advantage. MRI is superior to CT in determining diaphragmatic injury and is safe and noninvasive.[34] [42] [43]

INDICATIONS

Thoracentesis is performed for either diagnostic or therapeutic purposes. Diagnostic thoracentesis evaluates the cause of a pleural effusion and requires removal of 50 to 100 mL of pleural fluid for laboratory studies. Most new effusions require diagnostic thoracentesis, an exception being a new pleural effusion with a clear clinical diagnosis (e.g., CHF) with no evidence for superimposed pleural space infection. The usual goal of therapeutic thoracentesis is to help relieve the dyspnea associated with a large pleural effusion, but it may also aid the radiologic work-up of a patient with a large effusion. Therapeutic thoracentesis typically requires removing a much larger volume of pleural fluid.

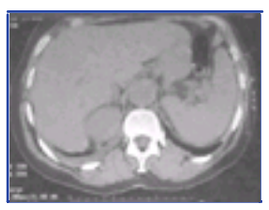

Figure 9-8 The bare area sign. A computed tomography scan demonstrates the obliteration of the potential space behind the liver with pleural fluid.

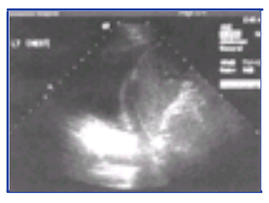

Figure 9-9 Pleural effusion. Ultrasound demonstrates the appearance of pleural fluid.

CONTRAINDICATIONS

There are no absolute contraindications to thoracentesis. It is generally recommended that patients with severe clotting abnormalities, including a platelet count <50,000 or prothrombin time or partial thromboblastin elevations of greater than twice the normal range, have platelet or factor replacement, or both, before the procedure. Patients with mild to moderate abnormalities do not require replacement before the procedure. [44] All patients with coagulation abnormalities, including those with renal failure, should be watched closely for bleeding following the procedure. Another relative contraindication is cellulitis or herpes zoster at the needle puncture site. One should attempt an alternative patient position to avoid skin puncture through these skin lesions, when possible. Extreme caution should also be exercised when performing thoracentesis on patients who are undergoing mechanical or manual ventilation.

PROCEDURE

Thoracentesis is generally an elective procedure, before which informed consent should be obtained and documented according to hospital policy. Because the procedure performed by experienced hands has a lower incidence of complications, [45] appropriate supervision by a person knowledgeable in the procedure should occur when possible. Sterile techniques should be followed through the entire procedure to avoid infection.

CHOOSING A TECHNIQUE

Several techniques for performing thoracentesis are possible (Fig. 9-10). The needle technique uses a simple 20- or 22-gauge (ga) needle. The needle catheter technique uses a plastic- or Teflon-coated catheter, which is inserted over or through a needle and subsequently left in the pleural space during fluid removal. Needle-catheters are commonly marketed and sold as preassembled thoracentesis kits. Two advantages of needle-catheter systems are: (1) a one-way valve that prevents air entry into the catheter during fluid

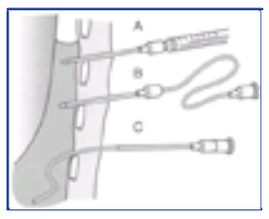

Figure 9-10 Techniques for through-the-needle catheter thoracentesis. Separate intercostal spaces depict the steps. *A,* Needle placement into pleural space. *B,* Catheter insertion through needle. *C*, Withdrawal of needle after catheter advancement.

collection and (2) an available blunt spring-loaded safety cannula that extends beyond the sharp needle tip once the pleural space is entered, protecting the lung from puncture or laceration.

Studies to determine the relative safety of needle and needle-catheter systems have had varied results. [46] [47] [48] It is generally recommended that the smallest possible needle be used. With diagnostic procedures, where only small volumes of fluid are being withdrawn, the needle technique is recommended. In therapeutic maneuvers, either technique is generally believed to be safe. The needle catheter approach avoids prolonged insertion of a needle in the pleural space while large volumes of fluid are removed.

For small or loculated effusions, suspicion for adhesions, the presence of relative contraindications, and in cases where iatrogenic pneumothorax may cause significant respiratory compromise, as with severe underlying lung disease or mechanical ventilation, needle placement under ultrasound guidance may be preferable. Ultrasound-guided needle placement for thoracentesis is associated with a significantly lower rate of complications as compared to clinically guided needle placement.[47] [48] CT-guided needle placement has also been successful in draining small pleural effusions. [49]

EQUIPMENT

Table 9-2 lists the equipment needed for thoracentesis and fluid collection. As with any procedure, appropriate preparation is essential for success.

PATIENT AND EQUIPMENT PREPARATION

A patent intravenous line should be established before initiation of the procedure in most cases. A red-top specimen tube for serum protein and LDH can be drawn at the time of IV

TABLE 9-2 -- Equipment for Thoracentesis

Basic procedure kit
Sterile towel
Sterile drape with fenestration
Basin for prep solution
Syringe(s) (10- to 20-mL)
Needles (22- and 25-ga) for infiltration
Sterile gauze pads
Povidone iodine
Local anesthetic (e.g., 1% lidocaine)—10 mL
Heparin—1 mL (see text)
Atropine—available at bedside
Syringe (50- to 60-mL) for aspiration
Sterile drainage tubing
Three-way stopcock
Needle or needle catheter (depending on technique)
Hypodermic needle (18- to 22-ga, 1 ½- to 2-in)
Over-the-needle catheter (16- to 20-ga needle)
Through-the-needle catheter (14- to 18-ga needle)
Scalpel (for needle catheter technique only)
Sterile specimen bowl or vacutainer bottle
Containers for analysis
Iced blood gas syringe
Red-top specimen tube
Purple-top specimen tube
Sterile transport media for culture or 10-mL sterile container
5 red-top specimen tubes for cytology or 10- to 50-mL plain bottle
Sterile dressing

placement. Atropine should be immediately available in the case of a vasovagal reaction during the procedure. Oxygen saturation should be monitored by pulse-oximetry and supplemental oxygen should be given as needed.

The 50- to 60-mL collection syringe should be premoistened with 1 mL of heparin (100 U/mL) to keep the pleural fluid from clotting if the procedure is for diagnostic purposes. Using a sterile technique, the skin is prepped with antiseptic in a wide area around the thoracentesis site. Sterile towels or a sterile drape should be placed around the site.

TERMINATION OF PROCEDURE

It is necessary to understand the end points of a procedure before its initiation. The most common indication for termination of thoracentesis is removal of a desired volume of fluid. For diagnostic thoracentesis the procedure is terminated upon removal of 50 to 100 mL of fluid. For therapeutic thoracentesis the procedure is terminated upon relief of patient dyspnea, or when 1000 mL of fluid have been withdrawn. Larger volumes of fluid may be removed if monitoring of the pleural pressures occurs. Pressure monitoring is not standard in the ED and in emergent situations the procedure can be done without monitoring. When feasible, pleural pressure measurements can be obtained by using a U-shaped manometer. Once 1000 mL of fluid have been removed, pleural pressures should be measured every 200 mL for the second liter and every 100 mL thereafter.[50] The procedure should be terminated once the pleural pressure exceeds -20 mm Hg.[50] [51] This, in theory, will help avoid significantly negative pleural pressures, which

have been associated with both symptomatic hypovolemia and the potentially fatal complication of reexpansion pulmonary edema. The actual benefit of this technique in reducing reexpansions problems is not known. The procedure should also be terminated if aspiration of air occurs, indicating lung puncture or laceration, unless the needle is 20-ga or smaller, making significant pneumothorax unlikely. Finally, a change in patient symptoms, including abdominal pain and worsening shortness of breath, should raise the suspicion of a patient complication and halt the procedure.

INSERTION SITE AND PATIENT POSITION

Figure 9-11 illustrates patient positioning for thoracentesis. Upright positioning is the preferred technique for draining most pleural effusions. With this technique, the patient is positioned sitting erect on the edge of the bed with extended arms resting on a bedside table. If the effusion is sufficiently large, the patient should be allowed to lean forward slightly while supported by the bedside table. The height of the effusion is then located clinically by dullness to percussion and a decrease in tactile fremitus. Never rely on the chest radiograph to determine the level of effusion as the radiographic level changes with patient positioning and respiration. Locate and mark the posterior rib at least one interspace below the top of the effusion. In all cases, the lowest level recommended is the eighth posterior intercostal space. The thoracentesis site

Figure 9-11 Positioning of patient for drainage of pleural effusion. *A,* Upright positioning. The broken line indicates midscapular line. *B,* Lateral decubitus positioning. The broken line indicates posterior axillary line. *C,* Supine patient positioning. The broken line indicates mid-axillary line.

should be at this level in the midscapular or posterior axillary line. If the patient is too ill to sit upright, use the lateral decubitus position with the side of the effusion down and the back at the edge of the bed. The needle insertion site in this position is the posterior axillary line. Alternatively, the patient may be positioned supine, with head elevated as much as possible. The needle insertion site in this position is the mid-axillary line. For both of these alternative positions, the fluid level must be determined clinically by dullness to percussion and a decrease in tactile fremitus. The needle should not be placed lower than the eighth intercostal space.

ANESTHESIA AND PLEURAL FLUID LOCALIZATION

Using a 25-ga needle attached to a syringe containing 5 to 10 mL of 1% lidocaine or equivalent anesthetic, raise a skin wheal at the upper edge of the previously selected rib in the midscapular or posterior axillary line. The upper edge of the rib is used to avoid accidental trauma to the neurovascular bundle, which runs at the inferior margin of each rib. The 25-ga needle is withdrawn and a 3.75-cm 22-ga needle is attached to the syringe of local anesthetic. This needle can both deliver anesthetic along the track of the thoracentesis catheter and serve as a small finder needle to identify the depth of penetration needed, as well as the presence of fluid at that level. Insert the 22-ga needle through the wheal and

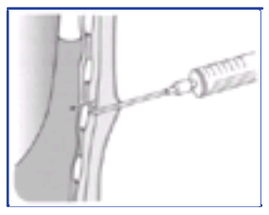

Figure 9-12 "Walking" the anesthetic needle over the superior aspect of the rib.

generously infiltrate the subcutaneous tissue and muscle down to and including the periosteum of the rib. With each 1 to 2 mm of needle advancement, the subcutaneous tissue and muscle are aspirated and then infiltrated with small alignots of the anesthetic. While the aspiration-infiltration process is continued, the needle is then "walked" above the superior edge of the rib and advanced through the intercostal space until the pleural space is entered (Fig. 9-12). Hold the needle perpendicular to the chest to avoid inadvertent trauma to the neurovascular bundle of the adjacent rib. Upon entering the pleural space, a pop may be felt. Aspirate fluid to ensure that the pleural space has been reached. Next, grasp the needle at the skin with the thumb and index finger and withdraw it. This allows for measurement of the proper depth of penetration needed during subsequent needle insertion. If no fluid is encountered, this is consistent with a "dry tap." A dry tap in the setting of a free-flowing pleural effusion indicates that either the needle is too short, or that the site chosen is too low or too high. A longer needle such as a spinal needle may be needed for a patient with significant subcutaneous tissue. If air bubbles are encountered, the lung parenchyma may have been entered, in which case the site is likely too high. If no fluid or air are encountered, the site is likely too low. If a dry tap occurs during fluid localization and the patient has no new symptoms, reevaluate the patient position and fluid level, administer local anesthetic as needed, and reattempt to aspirate fluid with the needle. If the repeat attempt is unsuccessful, obtain fluid under ultrasound guidance.

NEEDLE INSERTION TECHNIQUE

This technique uses a 3.75- to 5-cm, 20- or 22-ga needle. The needle and a 50- or 60-mL syringe are attached to a three-way stopcock. A drainage tube is attached to the stopcock. The lever of the stopcock is set to allow passage of fluid between the needle and the syringe. The depth of the pleural space as determined from the anesthetic/finder needle is now marked on the larger aspiration needle by gently grasping the needle with the index finder and thumb. The pleural space is again entered through the previous anesthetic site while gentle negative pressure is applied via the syringe. Attention to the indicated depth will prevent insertion of the needle farther than necessary, thus decreasing the chance of puncturing or lacerating the underlying lung. Fluid is first aspirated with the syringe. The stopcock lever is then turned to prevent entry of fluid back into the needle, and the fluid is expelled through the drainage tube into a sterile container or sterile vacuum bottle, where it can subsequently be transferred into appropriate specimen tubes. This process of aspirating and expelling the fluid is repeated until an adequate amount of fluid is obtained. Alternatively, fluid may be allowed to drain directly from the needle and three-way stopcock through high-pressure tubing into a vacuum bottle. The stopcock lever should be turned to prevent entry of air or fluid back into the needle when changing bottles.

Once an indication for discontinuing the procedure has been met, remove the catheter and cover the entry site with a sterile bandage.

OVER-THE-NEEDLE-CATHETER INSERTION TECHNIQUE

This technique uses an 8-French (Fr) catheter mounted on an 18-ga introducer needle. The 50- or 60-mL syringe and drainage tubing are attached to the three-way stopcock. The stopcock is adjusted to allow passage of fluid into the syringe and then this collection apparatus is temporarily set aside. The needle-catheter unit is attached to a 10- or 20-mL syringe. A small skin pierce with a scalpel at the selected insertion site is required to ease the entry of the catheter through the skin. The depth of the pleural space as determined from the anesthetic needle is now marked by gently grasping the needle-catheter unit with the index finger and thumb. The needle-catheter unit is advanced through the anesthetized area into the pleural space while constant, gentle, negative pressure is applied to the syringe. As fluid is encountered, the needle-catheter unit is angled slightly caudally. The catheter is then advanced into the pleural space while holding the needle steady. The needle is withdrawn and the exposed lumen of the catheter hub is covered with a finger to prevent the entry of air. The three-way stopcock with the attached 50- or 60-mL syringe and drainage tube is now attached to the catheter hub. Fluid is first aspirated with the syringe. The stopcock lever is then turned to prevent passage of fluid into the catheter, and the fluid is expelled through the drainage tube into a sterile container or sterile vacuum bottle, where it can subsequently be transferred into appropriate specimen tubes. This process of aspirating and expelling the fluid is repeated until an adequate amount of fluid is obtained. Alternatively, fluid may be allowed to drain directly from the needle and three-way stopcock through high-pressure tubing into a vacuum bottle. The stopcock lever should be turned to prevent entry of air or fluid back into the needle when changing bottles. If the catheter tip has multiple side ports for fluid entry, care must be taken to avoid withdrawing the catheter from the chest during fluid removal. This might expose a side port and allow air entry into the pleural space. Once an indication for discontinuing the procedure has been met, remove the catheter and cover the entry site with a sterile bandage.

THROUGH-THE-NEEDLE CATHETER TECHNIQUE

This procedure uses a 14- to 18-ga needle through which a flexible catheter is inserted into the pleural space. The catheter is withdrawn from the needle before the procedure. The catheter and drainage tubing are attached to the three-way stopcock and the stopcock is adjusted to close the catheter to the passage of air or fluid. This collection apparatus is temporarily set aside. The empty outer needle is attached to a 10- or 20-mL syringe. The depth of the pleural space as determined from the anesthetic needle is now marked by gently grasping the needle with the index finger and thumb. The needle is inserted into the pleural space through the anesthetized area while constant, gentle, negative pressure is applied via the syringe. Once fluid is encountered, the needle is held securely as the syringe is detached. The needle hub must be covered with a finger to prevent passage of air into the pleural space. The needle is then held securely and angled caudally as the catheter is inserted through the needle into the pleural space and advanced to the hilt of the needle or until resistance is encountered. The needle is withdrawn from the chest, leaving the catheter in the pleural space. The needle guard is then attached to the needle tip to prevent shearing off of the catheter. The catheter *must not be drawn back through the needle* because this may lacerate the catheter and allow its free entry into the pleural space. The catheter is then held securely to the chest wall without bending or kinking. The 50- or 60-mL syringe is now attached to the three-way stopcock. The stopcock lever is turned to allow passage of fluid into the syringe. Fluid is first aspirated into the syringe. The stopcock lever is then turned to prevent passage of fluid into the catheter, and the fluid is expelled through the drainage tube into a sterile container or sterile vacuum bottle, where it can subsequently be transferred into appropriate specimen tubes. This process of aspirating and expelling the fluid is repeated until an adequate amount of fluid is obtained. Alternatively, fluid may be allowed to drain directly from the needle and three-way stopcock through high-pressure tubing into a vacuum bottle. The stopcock lever should be turned to prevent entry of air or fluid back into the needle when changing bottles. If the catheter tip has multiple side ports for fluid entry, care must be taken to avoid withdrawing the catheter from the chest during fluid removal. This might expose a side port and allow air entry into the pleural space. Once an indication for terminating the procedure has been met, remove the catheter and cover the entry site with a sterile bandage.

PEDIATRIC PATIENTS

The indications and contraindications for performing thoracentesis are much the same in children as in adults. Positioning is also similar, but will likely require an assistant to help hold the patient and prevent patient movement. Sedation may be helpful when respiratory distress is minimal. The effusion level is again determined clinically by dullness to percussion and a decrease in tactile fremitus. The needle insertion site should not be lower than the eighth intercostal space in the posterior axillary line. Any technique as described for the adult patient may be used, but the smallest possible needle or needle-catheter is recommended.

POSTPROCEDURE RADIOGRAPH

In many centers chest radiographs are routinely obtained after thoracentesis to evaluate for procedure-related pneumothorax. This practice has been challenged and considered unnecessary as a routine procedure. The risk for pneumothorax following thoracentesis is low in patients who require a single needle pass, have no risk for adhesions, and have no new symptoms during or after thoracentesis. [52] Supporting this, studies have demonstrated that routine chest radiographs are not necessary after uncomplicated thoracentesis. [53] [54] A chest radiograph should be obtained in patients who require multiple needle passes, are at risk for adhesions, have aspiration of air, or develop any new symptoms during or after thoracentesis. Additionally, it is reasonable to obtain a postprocedure radiograph in patients who are at risk for future decompensation from expansion of a small asymptomatic pneumothorax, including those with severe underlying lung disease and who are receiving mechanical ventilation.

PLEURAL FLUID ANALYSIS

Pleural fluid analysis should occur in an organized and thoughtful pattern based on clinical suspicion for a disease process. Fluid examination in all cases begins with visual inspection. Effusions may range from clear to turbid. The presence of blood suggests trauma, malignancy, pulmonary infarct, or tuberculosis (TB). White or milky fluid suggests the presence of lipids, while purulent, malodorous fluid indicates empyema. Pleural effusion containing food particles is highly suggestive of esophageal rupture. The odor of urine suggests urinothorax. Once the general nature of the fluid has been investigated, selected testing is usually required. Table 9-3 indicates the proper collection volumes and containers to analyze for specific parameters. Table 9-4 lists common conditions and the associated pleural fluid findings.

The first step in pleural fluid evaluation in the laboratory is its categorization as exudative or transudative. In some cases it may be reasonable to hold off on further testing until this decision guides the clinician or is requested by a consultant. Given the practicality of the situation and the logistics of selective and progressive testing, some clinicians order a battery of screening tests based on the most logical etiology. As a general rule, collect samples in all appropriate containers at the time of the procedure should additional tests be required.

The pathophysiology of each category is discussed earlier in this chapter. Table 9-1 lists the common etiologies of transudates and exudates. Light et al. published criteria for separating transudates from exudates in 1972 based upon measurements of serum and pleural fluid protein and LDH. [55] The value for LDH was subsequently changed to accommodate variations in assay conditions. [56] These criteria have since become known as Light's criteria (Table 9-5). An elevated pleural protein occurs secondary to obstruction of lymphatic drainage or increased capillary permeability while elevations of LDH are believed to be due to pleural inflammation. Hence, elevations of protein or LDH are consistent with exudative effusions. Although more recent studies have failed to reproduce the exact sensitivity and specificity as described in Light's original study, modifications of Light's criteria have failed to improve overall accuracy of diagnosing exudates. [57] [58]

TABLE 9-3 -- Diagnostic Pleural Fluid Specimens

In All Cases:
6.5-mL plain (red-top) specimen tube
Lactate dehydrogenase (LDH)
Glucose
Protein
5-mL EDTA (lavender-top) specimen tube
Appearance
Color
Specific gravity
Cell counts
Differential counts
Crystals
If Exudate or Clinically Indicated:
6.5-mL plain (red-top) specimen tubes
Amylase
Triglycerides, cholesterol (lipoprotein electrophoresis)
Complement levels
Rheumatoid factor
Countercurrent immunoelectrophoresis (CIE)
Carcinoembryonic antigen (CEA)
10-mL sterile container
Gram stain
Aerobic cultures
Anaerobic cultures
Acid-fast bacilli culture and stain
Fungal culture and stain
10–50 mL
Cytology
5-mL heparinized (green-top) specimen tube
Lupus erythematosus cells
2-mL iced heparinized syringe
pH

EDTA = ethylene diamine tetra-acetic acid.

Other possible markers have not shown significant improvement in sensitivity and specificity over Light's criteria. [59] [60] [61] An exception to using Light's criteria for separating transudates from exudates may be in the setting of CHF. Effusions in CHF are due to increased capillary hydrostatic pressure and are therefore transudes. However, it has been shown that diuretic use increases the pleural fluid protein and LDH concentrations, making the fluid appear exudative by Light's criteria. [62] [63] This is hypothesized to be due to diuretic-induced shifting of fluid out of the pleural space. In the diuretictreated CHF population, therefore, measuring the serum-to-pleural effusion albumin gradient is recommended over Light's criteria. [60] [64] If the serum albumin minus the pleural fluid albumin is >1.2 g/dL, the patient likely has a transudative effusion and no further fluid analysis is necessary. Finally, with patients in whom no blood is obtained, a measured pleural fluid LDH >307 IU/L *or* a measured pleural fluid cholesterol >60 mg/dL, when used together, identifies exudates with reasonable accuracy. [59] [65]

Once a fluid is classified as transudative, it typically requires no further fluid analysis, and therapy is directed at the underlying cause of the effusion (CHF, nephrosis,

etc.).

In the presence of an undiagnosed exudative effusion, however, more extensive fluid evaluation is required. Clinical suspicion for an underlying disease process should guide additional fluid evaluation (Table 9-6), but all undiagnosed exudates, at a minimum, should have pleural fluid sent for cell count with differential, gram stain, culture, cytology, and glucose.

Exudates typically have a pleural fluid white blood cell (WBC) count of >1000 cells/mm ^{3} . Counts may reach levels >10,000 cells/mm^3 , most commonly with parapneumonic effusions.[66] The differential cell count can be useful in identifying the cause of an exudative pleural effusion. A predominance of PMNs indicates an acute process affecting the pleural surface, such as infection or pulmonary infarct. A predominance of mononuclear cells is consistent with a more chronic pleural process, including malignancy, TB, PE, and viral pleuritis. [29] If the differential lymphocyte count is >50% of the total WBC count, the effusion is considered lymphocytic. A lymphocytic pleural effusion is suspicious for TB, but may also be caused by cardiac bypass surgery, malignancy, chylothorax, and atypical infections.[67] Eosinophil counts of >10% are uncommon, but have traditionally been associated with blood or air in the pleural space.

If the fluid appears bloody, a fluid cell count and hematocrit should be obtained. In general, the presence or absence of red blood cells (RBCs) is not useful in determining the etiology of the effusion because it takes a minute amount of blood to cause a blood-tinged appearance. A grossly bloody pleural effusion or RBC count of >100,000 cells/mm^3 is suggestive of trauma, malignancy, or pulmonary infarction, [66] but a lack of RBCs does not exclude these diagnoses. Grossly bloody pleural fluid with a hematocrit of >50% of the peripheral hematocrit often requires tube thoracostomy.

The concentration of glucose in exudates is extremely variable and generally does not correlate with any specific disease process. Routine measurement of pleural fluid glucose for exudative effusion is recommended. A low glucose concentration (<60 mg/dL) narrows the differential diagnosis to empyema, ruptured esophagus, complicated parapneumonic infection, malignancy, and TB. [29] Keep in mind, however, that these diagnoses are not *excluded* by a high or normal pleural fluid glucose. Additionally, in exception to the rule described earlier, patients with active rheumatoid arthritis and rheumatoid pleural effusion will commonly have an extremely low pleural fluid glucose concentration (<20 to 30 mg/dL). [68] Comparatively, in systemic lupus erythematosus, pleural fluid glucose levels are usually normal. [69]

Evaluation for TB should occur if it is clinically suspected or if the pleural fluid is lymphocytic. Pleural fluid acid-fast bacillus staining and culture, which are infrequently positive, should be ordered. [70] Newer markers, including adenosine deaminase, polymerase chain reaction (PCR), and interferon gamma, have been found useful in the diagnosis of tuberculous pleural effusions. A pleural fluid adenosine deaminase level above 40 U/L is highly suggestive of TB. [67] [70] [71] Additionally, the presence of tuberculin sequences by PCR and elevations of gamma-interferon levels have shown increased sensitivity over pleural fluid staining and culture. [71] The availability of laboratory testing for these markers is currently limited.

Concerns about malignancy or the setting of an undiagnosed exudate are indications for cytologic evaluation. At least 50 mL of pleural fluid is required for this evaluation. Unfortunately, the initial pleural fluid cytology is often negative in malignant pleural effusions. [66] Repeated pleural samples increase the yield of malignant cells.

Pleural pH measurement provides useful information regarding pleural inflammation. Normal pleural fluid pH is approximately 7.64. Pleural fluid pH <7.3 indicates pleural inflammation. The differential diagnosis of pleural fluid acidosis includes not only empyema and complicated parapneumonic

TABLE 9-4 -- Diagnostic Features of Pleural Fluid

Pleural Fluid	Description	WBC Count	Predominant Leukocyte	Glucose	pH	Comments
Exudates						
Parapneumonic	Turbid	Elevated	P	Low	>7.3	If pH <7.2, may need thoracostomy tube; CIE may identify some aerobic bacteria
Empyema	Turbid, purulent	Elevated	P	Low	<7.3	Positive gram stain, culture; CIE may identify some aerobic bacteria
Tuberculosis	Straw color, serosanguinous	<10,000	M or P	Low	<7.4	Positive AFB stain, culture or pleural biopsy
Malignancy	Turbid, bloody	<10,000	M	Low	<7.3	Positive cytology, pleural biopsy, CEA
Pulmonary embolism or infarction	Straw color, bloody	Elevated	M or P	Serum	7.4	Hypoxia; positive lung scan
Collagen vascular disease	Turbid	Variable	M or P			Positive serum ANA, pleural complement
Rheumatoid arthritis	Green	Variable	M or P	Very low	<7.3	Elevated pleural rheumatoid factor
Systemic lupus erythematosus	Yellow	Variable	M or P	Serum	>7.3	Positive pleural LE cells
Hemothorax	Bloody	Variable	P	Serum	<7.3	Hematocrit >50% peripheral level
Chylothorax	White, cloudy	Variable	M			Elevated pleural triglycerides; chylomicrons present; positive Sudan III stain
Pancreatitis	Turbid, serosanguinous	Elevated	P	Serum	>7.3	Pleural amylase > serum
Esophageal rupture	Turbid, bloody	Elevated	P		<<7.3	Pleural amylase elevated
Transudates						
Congestive heart failure	Clear, straw color	<1000	M	Serum	7.4	Clinical features
Cirrhosis	Clear, straw color	<500	M	Serum	7.4	Clinical features
Nephrotic syndrome or hypoproteinemia	Clear, straw color	<1000	M	Serum	7.4	Clinical features
Transudate or exudate	Straw color to bloody			Low		Obstructive uropathy; pleural creatinine > serum
Urinothorax						

AFB, acid-fast bacilli; ANA, Antinuclear antibody; CEA, carcinoembryonic antigen; CIE, countercurrent immunoelectrophoresis; LE, lupus erythematosus; M, mononuclear cells (e.g., lymphocytes, macrophages, mesothelial and plasma cells); P, polymorphonuclear cells; WBC, white blood cell.

TABLE 9-5 -- Light's Criteria

Pleural fluid is classified as an exudate if any one of the following three criteria are met:
Pleural fluid:serum protein ratio >0.5
Pleural fluid lactate dehydrogenase (LDH) >2/3 upper limit of serum reference range
Pleural fluid:serum LDH ratio >0.6

effusion, but also malignancy, TB, esophageal rupture, and collagen vascular disease. [72] Measurement of pleural pH is essential in the evaluation of suspected parapneumonic effusions since hydrogen ion concentration is a key factor in the management algorithm. The fluid must be collected anaerobically, but may be transferred from the initial 50- or 60-mL syringe into a heparinized blood gas syringe, [73] and then left at room temperature for up to 1 hour before laboratory analysis [74] without affecting the accuracy of the results. Because of these specifics regarding the collection and evaluation of pleural fluid pH, pleural fluid should routinely be transferred to a heparinized blood gas syringe and placed on ice while awaiting the decision for pH testing. The evaluation of a suspected parapneumonic effusion is described further as follows.

Pleural amylase evaluation should occur in the setting of suspected esophageal rupture or pancreatitis. [75] Elevations of pleural fluid amylase >100 U/L are seen in various cases including malignancy, post cardiac bypass surgery, esophageal rupture, pancreatitis, and ruptured ectopic pregnancy. Routine measurement of pleural fluid amylase levels rarely provides useful information.

White or milky fluid or concerns about thoracic duct injury should lead to analysis for pleural fluid triglycerides. Rarely, a longstanding benign effusion, such as one due to TB or rheumatoid disease, may have a similar gross appearance due to accumulation of cholesterol, lecithin, or globulin-rich fluid. This effusion is termed pseudochylothorax. Effusions with triglyceride concentrations of >110 mg/dL are uniformly chylous in nature. [76] The etiologies of chylous effusions include thoracic duct injury due to surgery, malignancy, trauma, and pleuritis.

Patients with suspected parapneumonic effusions warrant rapid evaluation and outcomes risk assessment based on pleural anatomy, pleural fluid bacteriology, and pleural fluid chemistry. [77] All parapneumonic effusions require at least

TABLE 9-6 -- Selective Evaluation of Exudates Based on Clinical Suspicion

Pleural Fluid Assay	Diagnosis Suspected
Amylase	Pancreatitis, esophageal rupture
Triglycerides	Chylothorax, intrathoracic TPN infusion
Glucose	Rheumatic effusion
Urea or creatinine	Urinothorax
Cytology	Malignancy
Albumin (with serum measurement)	CHF (after diuretics)
Adenosine deaminase, gamma interferon, PCR	TB (lymphocytic effusion)
Hematocrit	Hemothorax
pH	Parapneumonic effusion, empyema

CHF, congestive heart failure; PCR, polymerase chain reaction; TB, tuberculosis; TPN, total parenteral nutrition.

diagnostic thoracentesis with the goal of identifying complicated parapneumonic effusions. Treatment before the organizational stage is ideal. Patients at high risk for poor outcome require complete drainage of the pleural space. This includes patients with large or loculated effusions, pleural thickening on CT scanning (the pleural peel), aspiration of frank pus, and pleural fluid pH of <7.2.

COMPLICATIONS

The most frequently reported complication of thoracentesis is pneumothorax, which has a reported incidence of 4% to 19% in several studies. [45] [47] [52] Thoracostomy tubes were required in <50% of the post-thoracentesis pneumothoraces in each study. The mechanism for this complication is puncture of the lung or inadvertent air entry through the needle or catheter during the procedure. Pneumothorax should be suspected if there is aspiration of air during fluid removal or if the patient develops new symptoms during or after the procedure. Procedure-related factors contributing to pneumothorax include an inexperienced operator, therapeutic taps, and use of needles >20-ga. [45] [46] [48] [78] The risk of pneumothorax may be increased in patients with underlying chronic obstructive pulmonary disease. [79]

Cough precipitated during the procedure is another frequently encountered complication. Although typically considered a minor complication resulting in only patient discomfort, it may be associated with the creation of an iatrogenic pneumothorax. [78] [80] The procedure should be terminated if persistent patient coughing occurs.

Patient discomfort is reported frequently with pneumothorax. Adequate local anesthesia and judicious use of analgesics should eliminate this complication.

As with all procedures, there is potential for infection, estimated at 2%. The risk is kept low with proper attention to patient preparation and sterile technique.

Other serious complications that have been reported in <1% of procedures include: hemothorax, splenic rupture, abdominal hemorrhage, unilateral pulmonary edema, air embolism, and catheter fragment left in the pleural space. [78]

Hemothorax may be suspected by a rapid accumulation or reaccumulation of pleural fluid or by a change in patient vital signs following the procedure. Hemothorax may be due to laceration of the lung and diaphragmatic, intercostal, or internal mammary vessels. Careful attention to technique, such as avoiding the superior portion of the intercostal space, never puncturing medial to the midclavicular line, and not penetrating too deeply into the thorax during needle insertion, should be practiced. Hemothorax requires appropriate surgical consultation and drainage via a thoracostomy tube.

Puncture of the spleen or liver through the diaphragm may result in localized organ hematoma or hemoperitoneum. [80] Clinically this is suspected when the needle pass does not yield pleural fluid (dry tap) and is followed by a patient complaint of abdominal pain. If this diagnosis is suspected, appropriate resuscitation is the initial treatment, followed by a diagnostic imaging study, preferably CT scan. If the patient is hemodynamically unstable, bedside ultrasound and immediate surgical consultation should occur.

Inadvertent shearing of the plastic catheter may occur when a through-the-needle catheter technique is used. Securing the needle with a needle guard after it has been withdrawn from the chest prevents this complication. In addition,

the catheter should not be withdrawn through the needle at any time. Should a catheter be left in the chest, a method of percutaneous retrieval may be performed by radiology.

Postexpansion pulmonary edema is a rare and unexplained complication associated with rapid reexpansion of the lung. Symptoms include dyspnea, tachypnea, tachycardia, cough, and frothy sputum. [81] It is postulated that this can be avoided by monitoring the pleural pressures carefully after 1000 mL of fluid have been withdrawn and discontinuing the procedure when the pleural pressure are >20 mm Hg. [50] [51]

Chapter 10 - Tube Thoracostomy

Thomas D. Kirsch
John P. Mulligan

Tube thoracostomy is used to evacuate an abnormal accumulation in the pleural space. Conditions that may require treatment with a tube thoracostomy include pleural effusions, purulent fluid from an infection (empyema), or lymph fluid (chylothorax). Trauma is a common indication due to accumulations of blood or air.

The first modern methods to evacuate pleural contents were developed in the 19th century, but these techniques were not widespread until 1918, when they were used treat postinfluenza empyema. Military experience demonstrated that thoracic drainage combined with antiseptics and antibiotics reduced the mortality from thoracic trauma from 62.5% during the Civil War, to 24.6% in World War I, to 12% in World War II. [1]

PATHOPHYSIOLOGY

The pleural space is a potential space that separates the visceral and parietal pleurae with a thin layer of lubricating fluid. The parietal pleura covers the interior of the chest cavity, while the visceral pleura covers the lungs. They are both smooth, serous membranes. Normally there is a slight negative pressure in the pleural space that keeps the lung inflated. With normal inspiration, an increased negative intrathoracic pressure is developed in the chest cavity. This pressure is then transmitted to the pulmonary parenchyma, causing expansion of the lung from an influx of air into the lungs via the trachea. The addition of blood, fluid, or air in the pleural space interferes with normal inspiratory inflation, although the body can tolerate some violation of this space. Large amounts of fluid or air compromise respiratory function and induce symptoms of dyspnea, pleuritic chest pain, and anxiety. A progressive accumulation, such as occurs with a tension pneumothorax, leads to cardiovascular compromise in addition to severe respiratory dysfunction. The degree of respiratory compromise depends on the volume of pleural space occupied by the fluid or air, the baseline pulmonary status of the patient, and the integrity of the chest wall.

Pneumothorax

When the resting negative pressure that normally exists in the pleural space is lost, the lung will collapse. Air can enter the pleural space from the outside, as with a penetrating injury, or from the lung, as when a bleb ruptures. A pneumothorax is any collection of air in the pleural space, either as a result of trauma or as a spontaneous occurrence. Pneumothorax may complicate procedures such as transthoracic biopsies, thoracentesis, subclavian venous cannulation, or positive pressure ventilation. [2]

Spontaneous Pneumothorax (Fig. 10-1)

A spontaneous pneumothorax can be either "primary" or "secondary." A primary spontaneous pneumothorax results from the rupture of a subpleural bleb in a patient *without* other underlying lung disease. This is six times more common in men than women. The "typical" patient suffering a spontaneous pneumothorax is a tall, thin, 20- to 40-year-old male smoker. Symptoms can occur with rest or with activity. Common symptoms include the sudden onset of pleuritic chest pain and dyspnea. Occasionally pain is absent. Secondary spontaneous pneumothoraces are more common and occur in patients *with* underlying lung or pleural disease. The most common cause is emphysema, followed by chronic bronchitis, asthma, tuberculosis, pneumonia, bronchiectasis, atelectasis, pulmonary fibrosis, lymphoma, and a foreign body. Less common causes include pulmonary infarction, scleroderma, rupture of a hydatid cyst, and alpha $_1$ -antitrypsin deficiency. Neoplasm is a common cause in older patients. Patients with Marfan syndrome, acquired immunodeficiency syndrome, and *Pneumocystis carinii* pneumonia are also at increased risk. Morbidity and mortality increases for patients with underlying lung disease. Most patients will seek medical attention within 24 hours of onset. However, some patients can tolerate even a complete pneumothorax for surprisingly long periods of time. Certainly, many individuals will experience a small spontaneous pneumothorax, never seek medical attention, and the process will resolve spontaneously. Bilateral spontaneous pneumothoraces may occur in up to 10% of cases, but progression of a spontaneous pneumothorax to a tension pneumothorax is very rare.

Traumatic Open Pneumothorax

An open pneumothorax ("sucking chest wound") occurs when the chest wall is penetrated and the negative intrapleural pressure that keeps the lung expanded is lost because outside air enters the pleural space. With small defects a tension pneumothorax may develop because air enters, but does not exit, the pleural space with each inspiration. If the wound has a diameter larger than the trachea, air moves preferentially through the chest wall opening, rather than down the trachea, with each respiratory attempt. In this circumstance the lung will not expand and no ventilation will occur.

Figure 10-1 Simple pneumothorax, anteroposterior chest radiograph view. Note absence of lung marking on the affected side and deviation of the trachea contralaterally.

Traumatic Closed Pneumothorax

A closed pneumothorax may result from an injury or may occur spontaneously, but the chest wall remains intact. A pneumothorax following blunt chest trauma is usually due to a rib fracture that injures the lung and allows air into the pleural space. A closed pneumothorax can also occur without a rib fracture when an alveolus or bleb ruptures due to the abrupt increase in intrathoracic pressure against a closed glottis, such as seen with blunt chest trauma or during cardiopulmonary resuscitation. The air leak from a closed pneumothorax may be self-limited, or may progress to a tension pneumothorax.

Tension Pneumothorax

Tension pneumothorax usually results from traumatic causes, but rarely it may be from a spontaneous lung collapse (Fig. 10-2). Fractures of the trachea or bronchi, a ruptured esophagus, the presence of an occlusive dressing over an open pneumothorax, or chest compressions may result in tension pneumothorax. The risk is also increased for patients with chest trauma who are undergoing positive-pressure ventilation. Because

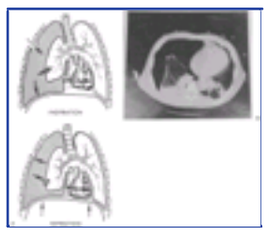

Figure 10-2 *A*, Tension pneumothorax. With inspiration air enters the pleural space from the outside or from a puncture in the lung, or both. Upon expiration, the air leaks are closed, trapping increasing amounts of air in the pleural space. Cardiac filling and eventually cardiac output are compromised. *(From Vukich DJ, Markovchick VJ: Pulmonary and chest wall injuries. In Rosen P, Barkin RM, Braen CR, et al (eds): Emergency Medicine: Concepts and Clinical Practice. St Louis, Mosby-Year Book, 1988. Reproduced by permission.)* *B*, A thoracic computed tomography (CT) scan demonstrating a tension pneumothorax. In general, whenever a tension pneumothorax is suspected, treatment should be initiated before obtaining a CT scan *(Courtesy of H.K. Liang).*

of this, any patient with a penetrating thoracic injury (even without immediate evidence of a hemo- or pneumothorax) may be a candidate for a "prophylactic" chest tube before mechanical ventilation.

A tension pneumothorax occurs when a pulmonary or bronchial injury creates a ball-valve mechanism that leads to the progressive accumulation of air in the pleural space. The negative intrathoracic pressure during inspiration draws air into the pleural space. During expiration the relative increase in intrathoracic pressure closes the tissue flap and restricts the outflow of air. As more air collects and the intrapleural pressure rises on the injured side, the mediastinum shifts toward the uninvolved side, obstructing venous return to the right atrium. Progressive hypoxia and CO_2 retention may lead to the cardiovascular collapse. In addition to the cardiac effects, a tension pneumothorax reduces functional capacity of the lung and leads to a ventilation-perfusion mismatch.

Hemothorax

Hemothoraces may be caused by injuries to the heart, lungs, great vessels, intercostal arteries or veins, mediastinal veins, chest wall vessels, or fractured ribs. Bleeding from the lung

---

parenchyma is low pressure, and is usually self-limited or ceases when a chest tube is placed. Intercostal artery, pulmonary artery, and internal mammary artery bleeding can be profuse and usually requires surgical intervention.

Chylothorax

Chylothorax results from an injury to the thoracic duct from central line placement, operative injury, or chest trauma. The chyle initially collects extrapleurally, and may not begin to fill the pleural cavity for 2 to 10 days. As a result there are few initial symptoms related to a thoracic duct injury. As the fluid accumulates, patients eventually develop dyspnea and other findings similar to any pleural fluid collection. The diagnosis is made by a thoracentesis that demonstrates a milky white fluid with a high fat and lymphocyte content and 4 to 5 gm/dL of protein. The definitive treatment is either by repeated thoracentesis or tube thoracostomy combined with parenteral alimentation until the volume of chyle decreases.

Empyema/Effusions

An "empyema" is defined as infection or gross pus in the pleural space. Empyema occurs in 1% to 2% of hospitalized patients with community-acquired pneumonia. Most cases are associated with parapneumonic effusions caused by a mix of anaerobic and aerobic bacteria. The remainder of empyemas result from the complications of thoracic surgical procedures or thoracic trauma, or from esophageal perforation or subdiaphragmatic infection. *S. aureus* is the most common isolate. See chapter 9 for a discussion of effusions.

DIAGNOSIS

Symptoms

Symptoms in patients with abnormal collections of fluid or air in the pleural space may range from asymptomatic to respiratory arrest. Specific symptoms range from mild dyspnea and pleuritic chest pain for small disruptions, to severe dyspnea and pain, with a feeling of impending doom, for those with a tension pneumothorax. A cough may also be present. The severity of symptoms depends on the size of the pneumothorax, rapidity of accumulation, age of the patient, mobility of the mediastinum, and the presence of any underlying lung disease. Severely injured patients may be unable to relate symptoms, rendering the physical examination and chest radiograph as essential to diagnose a pneumo- and hemothorax. A tension pneumothorax must be considered in any patient with sudden respiratory or cardiac deterioration. Other possible causes of sudden cardiopulmonary decompensation include pericardial tamponade, massive pulmonary embolus, myocardial infarction, respiratory failure from reactive airway disease, and pneumomediastinum. A tension pneumothorax must also be considered in intubated patients who become difficult to ventilate, develop increased airway pressure, elevated central venous pressure, or elevated pulmonary artery pressure. Awake patients with tension pneumothorax rapidly develop severe dyspnea, restlessness, agitation, and a feeling of impending doom. They are usually tachycardic and tachypnic but quickly progress to hypotension.

With a spontaneous pneumothorax, 95% of patients complain of the sudden onset of sharp or pleuritic chest/shoulder pain, or both. Sixty percent of patients experience dyspnea and 12% have a mild cough. Dyspnea and anxiety are more common in older patients.

The symptoms of a hemothorax are similar to a pneumothorax, but may be accompanied by hypotension as blood accumulation in the pleural space increases. The onset of symptoms for effusions is usually much more gradual with increasing shortness of breath and dyspnea on exertion.

Physical Examination

Unstable Patients.

During the initial ("ABC") phase of resuscitation, the vital signs often point to the presence of a tension pneumothorax. This diagnosis must be considered for patients who are tachycardiac, hypotensive, and dyspneic. Once the airway is cleared, a rapid assessment of the breathing must be conducted. Unfortunately no single examination is completely reliable and so multiple examinations must be conducted rapidly. Observation of the chest wall movement and neck may reveal asymmetric chest expansion, distended neck veins, or a deviated trachea. Auscultation may demonstrate unilateral diminished or absent breath sounds. A pulsus paradoxus may be detected. There may be hyperresonance to percussion unilaterally. *Subcutaneous emphysema* that develops in the absence of an open chest wound should be assumed to have been produced by a pneumothorax (Fig. 10-3). An early sign of tension pneumothorax in an intubated patient is difficulty in maintaining ventilation or a marked increase in airway pressures.

For unstable trauma patients the diagnosis of a tension pneumothorax may be confirmed or made by needle or catheter thoracentesis. Logistics of a resuscitation may not allow time for the results of a radiograph. The diagnosis can be confirmed when there is a rapid release of air through the needle during both inspiration and expiration as the pneumothorax decompresses. The patient's vital signs should rapidly improve, as the air that was trapped in the pleural space is allowed to escape. In one prospective study, the sensitivity, specificity, and diagnostic accuracy of auscultation for hemo/pneumothorax was 84%, 97%, and 89%, respectively. A false-negative auscultation is more likely than a false-positive one. Since the specificity of auscultation is high, chest tubes may be placed before radiographic confirmation if the clinical situation warrants. [3]

Stable Patients.

For more stable patients the physical examination may indicate the presence of a pneumo- or hemothorax, but a chest radiograph is usually necessary for the definitive diagnosis. Physical findings may include tachypnea, tachycardia, unilaterally decreased breath sounds, decreased tactile fremitus, increased resonance with percussion, or subcutaneous (SQ) emphysema, but the examination may reveal no abnormalities with a small pneumothorax. A pneumothorax of 10% to 20% will unlikely be diagnosed by ausculation of the lungs, since a small pneumothorax will produce only very subtle, or undetectable, changes in breath sounds. Pleural fluid collections and hemothoraces can be difficult, if not impossible, to detect by physical examination, particularly with <500 mL of fluid in the pleural space. Breath sounds may then decrease and percussion of the bases may be dull. Lung function may not become compromised until

Figure 10-3 *A*, Following a successful cardiopulmonary resuscitation and intubation from respiratory arrest, this patient began to deteriorate. Marked subcutaneous emphysema was noted in the scrotum and abdominal wall. Curiously, little air could be palpated in the chest or neck, the usual place for air to accumulate. Assuming that the air must have come from the lungs, the scenario led to the clinical diagnosis of a tension pneumothorax. *B*, Following the placement of a chest tube, the vital signs quickly stabilized. Due to the urgency of the situation, the thoracostomy tube was performed before obtaining an x-ray, and the rush of air obtained upon entering the pleural cavity, and the normalization of vital signs, retrospectively confirmed the tension pneumothorax.

patients lose up to 40% of their blood volume into the pleural space. These patients may then present primarily in hypovolemic shock. For patients with blunt chest trauma, with a normal physical examination, including no chest tenderness, a radiograph may not be necessary. [4]

Parapneumonic empyemas often present with fever, cough, chest pain, dyspnea, and purulent sputum. The physical examination will reveal diminished breath sounds, dullness to percussion, egophony, and diminished tactile fremitus on the involved side. For postsurgical and posttraumatic empyema the patient will develop a fever, the pleural fluid drainage may be excessive and become purulent, and respiratory symptoms may worsen.

Radiography

Plain Radiographs.

A chest radiograph is essential to diagnose a pneumothorax in the stable patient. However, any patient with a possible tension pneumothorax should not be sent to radiology unless accompanied by a clinician capable of performing a tube thoracostomy or chest decompression. The best films for a hemothorax or pneumothorax are an *upright* posteroanterior (PA) and lateral chest radiograph, but for unstable patients a portable supine anteroposterior (AP) view may be the only film possible. A supine chest radiograph of a patient with a hemothorax with up to 1000 mL of blood may only demonstrate slight differences in the densities of the lung fields. On an upright chest radiograph, at least 300 to 500 mL of fluid is needed before costophrenic angle blunting can be detected (Fig. 10-4).[5] Fluid in the pleural cavity will form a miniscus, and a straight line on an upright chest radiograph is essentially an air/fluid level signifying the presence of a pneumothorax as well as a hemothorax.

It has traditionally been touted that the *expiratory* upright PA chest x-ray is the best radiograph to detect a pneumothorax. Theoretically the lung is more collapsed during expiration, accentuating the pneumothorax. However, when studied prospectively, there is no detectable benefit of the expiratory film, and certainly both projections need not be routinely taken. [6] While there is no downside to initially ordering an expiratory radiograph, the upright *inspiratory* x-ray is recommended as the initial film of choice. This projection is preferred because of its comparable sensitivity and specificity when compared to the expiratory projection, and the superior

ability of the inspiratory radiograph to detect other abnormalities such as pneumonia, cardiac, and pleural disease.

For stable patients other radiographic views can be helpful. To look for a hemothorax, the best additional views are bilateral decubitus chest radiographs. If a single decubitus film is obtained, the injured side should be up. For a small pneumothorax an upright expiratory chest radiograph can occasionally be helpful, as well as cross-table lateral and oblique views of the chest.

On a chest radiograph the partially collapsed lung of a pneumothorax appears as a visceral pleural line with no pulmonary markings beyond it. Other radiographic findings include hyperlucency of the affected hemithorax, a double diaphragm contour, increased visibility of the inferior cardiac

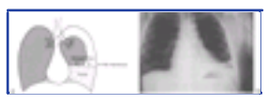

Figure 10-4 *A*, Hemopneumothorax. Note that whenever the top of the accumulated fluid is seen as a straight line as opposed to a meniscus, a pneumothorax must also be present. *B*, Following a stab wound to the chest, this radiograph demonstrated an air-fluid level (straight line) in the left hemithorax. A 10% pneumothorax is difficult to see on the poor quality film, but the air-fluid level means that a pneumothorax must be present. Otherwise, the fluid would form a meniscus tracking up the lateral chest wall. On a supine film, this subtle finding may not be appreciated.

border, better visualization of the pericardial fat at the cardiac apex, and possibly a depressed diaphragm. If *SQ air* is noted on the chest x-ray of a patient with blunt chest trauma, it can be assumed that the air came from an injured lung, and that a pneumothorax exists, or soon will.

With a tension pneumothorax the chest radiograph reveals a depressed hemidiaphragm with lung collapse on the affected side and a shift of the mediastinum and trachea to the opposite side. With a bilateral pneumothorax no mediastinal shift may be seen. Localized areas of tension pneumothorax may result from adhesions. Patients with adult respiratory distress syndrome on positive end-expiratory pressure have developed a localized subpulmonic or paracardiac tension pneumothorax despite indwelling thoracostomy tubes.

When a patient is supine a small pneumothorax may collect in various areas. The most common area for air to accumulate is anteromedial, which is seen as a radiolucent band that enhances the heart border. With subpulmonic air the visceral pleura is outlined by a radiolucent band superior and parallel to the diaphragm.

If a patient with a pneumothorax is to be observed, there are systems that measure the size of a pneumothorax to ensure it is not expanding. The simplest and most reliable way is to measure the distance from the lateral lung margin to the lateral chest wall on a chest radiograph taken during full inspiration. This method will also roughly estimate the percentage of the pneumothorax (Fig. 10-5).

Chest Computed Tomography (CT) Scan.

With increased usage of CT scanning to evaluate chest trauma, it has become obvious that standard radiographs have missed many pneumothoraces and hemothoraces in the past. Such abnormalities may be present in up to 10% of trauma patients with "normal" chest x-rays. [7] [8] [9] The clinical significance of these small, previously undetected, occult injuries is likely not great, and it has been suggested that a small pneumothorax seen onlyon CT scan may be left untreated, and simply observed, in the otherwise stable patient. Many patients with a pneumothorax seen only on CT scan may also safely undergo positive-pressure ventilation without the placement of a chest tube.[9]

CT scans are not routine for the diagnosis of a hemo- or pneumothorax, but they offer invaluable information on the etiology of such abnormalities. A CT scan is often used to evaluate patients with a spontaneous pneumothorax to assess the need for surgery. A CT scan may be useful when the diagnosis is unclear, or when looking for small amounts of pleural fluid. A chest CT scan is more accurate than a chest radiograph to estimate the size of a pneumothorax. [10] CT scans are particularly useful to determine if an empyema is loculated or draining successfully.

INDICATIONS FOR TUBE THORACOSTOMY

Pneumothorax

There is considerable controversy over the treatment of a non-tension pneumothorax. Clinicians use individual approaches because no agreed-on standard of care exists for many situations involving minor lung collapses. Many patients with a pneumothorax will require tube thoracostomy, but a significant number can be managed conservatively. Chest tube placement may be unnecessary in patients with isolated small or moderate traumatic pneumothoraces in the absence of respiratory compromise, concomitant injuries, or when positive-pressure ventilation will not be required. Otherwise healthy, reliable, and minimally symptomatic patients with no underlying lung disease and small pneumothoraces (<10% to 20%) are often treated by observation alone. Aspiration of a pneumothorax may be useful, but it has had variable success. The insertion of a small-bore chest catheter in stable but symptomatic patients who require lung expansion is often recommended. For these patients prolonged suction is rarely required, and the tube can simply be attached to a Heimlich valve or underwater seal. [11] [12] The American College of Chest Physicians has developed guidelines for the management of primary and secondary spontaneous pneumothoraces. These guideline are not always applicable to the emergency clinician and promulgate a conservative approach that may

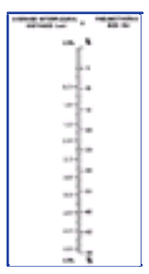

Figure 10-5 Nomogram for the prediction of pneumothorax size from an average interpleural distance (see text). The interpleural distance is measured in centimeters from the outer edge of the collapsed lung to the inner aspect of the chest wall (i.e., parietal pleura to visceral pleura). *(From Rhea JT, DeLuca SA, Greene RE: Determining the size of pneumothorax in the upright patient. Radiology 144:733, 1982. Reproduced with permission.)*

not be reasonable for all patients. The recommendation that catheter aspiration is not an acceptable method for the initial treatment of a primary pneumothorax has met with significant criticism. Nonetheless, the guidelines are helpful (Table 10-1).

Without any intervention or continuing air leak, a small pneumothorax will resolve over days to weeks. Supplemental oxygen will speed this process by increasing the rate of pleural air absorption, but this common intervention has no proven applicability in the emergency department (ED). Patients managed by observation alone should remain in the ED for 3 to 6 hours under close observation for serial examinations and a repeat chest radiograph. If the pneumothorax has not progressed, the reliable patient with access to health care can be discharged with instructions to return immediately if symptoms increase, to minimize his or her activities, and to follow up for repeat examinations and chest radiographs.

For patients with traumatic etiologies, the rapidity and type of treatment depends primarily on the stability of the patient; a hypotensive patient with a tension pneumothorax requires immediate decompression with a chest tube or needle thoracostomy, while a patient with normal vital signs anda small pneumothorax may be observed. Emergent needle thoracostomy is only a temporary solution, and once done necessitates an ipsilateral tube thoracostomy. Other factors that modify the treatment include the patient's age, the size of the pneumothorax, whether there are bilateral pneumothoraces, and whether the current episode represents a recurrence. A tube thoracostomy may not be necessary for a small traumatic pneumothorax with no associated rib fractures. Remember that a chest tube is often the safest and most expedient course, and one cannot be faulted by such expectant definitive treatment. A chest tube removes all doubt since it evacuates the intrapleural air and blood, prevents further accumulation, and allows monitoring for persistent air leaks.

Because of the risk of a tension pneumothorax, a chest tube should be considered for all patients with a penetrating chest injury if positive-pressure ventilation will be used or if they will be transported a long distance for definitive care. However, CT scans of trauma victims have demonstrated that many patients with small pneumothoraces that would have escaped detection by standard radiographs have safely undergone positive-pressure ventilation without developing a clinically evident pneumothorax. Close observation for signs of a tension pneumothorax is necessary if a chest tube is not placed and positive-pressure ventilation is used.

The treatment of a spontaneous pneumothorax is controversial. Patients can be observed, treated by aspiration, or may require a tube thoracostomy (see Table 10-1). Patients can be observed if they are asymptomatic; have no underlying pulmonary disease; and have a small (<20%), pneumothorax. Initially they should be observed in the hospital to prove they are stable, and then followed as outpatients with serial chest radiographs. Some authors recommend that a spontaneous pneumothorax be treated with catheter aspiration, followed by 6 hours of observation before discharge from the ED. However, these studies have been small, have shown inconsistent results, and have found a high recurrence rate. Other techniques include the use of pigtail catheters and small-bore thoracostomy tubes introduced over a wire.

The underlying lung pathology of a patient with a spontaneous pneumothorax is best initially evaluated by CT scan. Often this is followed by diagnostic or therapeutic visual inspection of the lung and pleural space by thoracoscopy. Extensive evaluation is not, however, usually recommended for the first episode of a small primary pneumothorax. When patients have recurrent spontaneous pneumothoraces, further evaluation (CT scan, thoracoscopy) and evaluation for surgical treatment are indicated. Patients who have had one spontaneous pneumothorax have a 30% to 50% chance of recurrence within 2 years, and after the second pneumothorax there is a 50% to 80% of a third. Surgery may be recommended for a first pneumothorax in the following situations: life-threatening tension pneumothorax, massive air leaks with incomplete reexpansion, an air leak persisting 4 days after a second tube has been placed, associated hemothorax with complications, identifiable bullous disease, and failure of easy reexpansion in patients with cystic fibrosis.

Hemothorax

Tube thoracostomy is also used to monitor the amount and rapidity of blood output, which determines the need for additional interventions, including a thoracotomy. About

TABLE 10-1 -- Guidelines of the American College of Chest Physicians for the Management of Primary and Secondary Spontaneous Pneumothorax

Primary Spontaneous Pneumothorax
Clinically Stable Patients with Small Pneumothoraces: *
Clinically stable patients with small pneumothoraces should be observed in the emergency department for 3 to 6 h and discharged home if a repeat chest radiograph excludes progression of the pneumothorax (good consensus). Patients should be provided with careful instructions for follow-up within 12 h to 2 days, depending on circumstances. A chest radiograph should be obtained at the follow-up appointment to document resolution of the pneumothorax. Patients may be admitted for observation if they live distant from emergency services or follow-up care is considered unreliable (good consensus). Simple aspiration of the pneumothorax or insertion of a chest tube is not appropriate for most patients (good consensus), unless the pneumothorax enlarges. † The presence of symptoms for >24 h does not alter the treatment recommendations.

Clinically Stable Patients with Large Pneumothoraces: *

Clinically stable patients with large pneumothoraces should undergo a procedure to reexpand the lung and should be hospitalized in most instances (very good consensus). The lung should be reexpanded by using a small-bore catheter (=14F) or placement of a 16F to 22F chest tube (good consensus). Catheters or tubes may be attached either to a Heimlich valve (good consensus) or to a water seal device (good consensus) and may be left in place until the lung expands against the chest wall and air leaks have resolved. If the lung fails to reexpand quickly, suction should be applied to a water-seal device. Alternatively, suction may be applied immediately after chest tube placement for all patients managed with a water seal system (some consensus).

Reliable patients who are unwilling to undergo hospitalization may be discharged home from the emergency department with a small-bore catheter attached to a Heimlich valve if the lung has reexpanded after the removal of pleural air (good consensus). Follow-up should be arranged within 2 days. The presence of symptoms for >24 h does not alter management recommendations.

Secondary Spontaneous Pneumothorax

Clinically Stable Patients with Small Pneumothoraces: *

Clinically stable patients with small pneumothoraces should be hospitalized (good consensus). Patients should not be managed in the emergency department with observation or simple aspiration without hospitalization (very good consensus). Hospitalized patients may be observed (good consensus) or treated with a chest tube (some consensus), depending on the extent of their symptoms and the course of their pneumothorax. Some of the panel members argued against observation alone because of a report of deaths with this approach. Patients should not be referred for thoracoscopy without prior stabilization (very good consensus). The presence of symptoms for >24 h did not alter the panel members' recommendations.

Clinically Stable Patients with Large Pneumothoraces:

Clinically stable patients with large pneumothoraces should undergo the placement of a chest tube to reexpand the lung and should be hospitalized (very good consensus). Patients should not be referred for thoracoscopy without prior stabilization with a chest tube (very good consensus). The presence of symptoms for >24 h did not alter the panel members' recommendations.

Terms	**Definition**
Spontaneous pneumothorax	No antecedent traumatic or iatrogenic cause
Primary spontaneous pneumothorax	No clinically apparent underlying lung abnormalities or underlying conditions known to promote pneumothorax (e.g., HIV disease)
Secondary spontaneous pneumothorax	Clinically apparent underlying lung disease
Pneumothorax size	Determined by distance from the lung apex to the ipsilateral thoracic cupola at the parietal surface as determined by an upright standard radiograph
Small pneumothorax	<3 cm apex-to-cupola distance
Large pneumothorax	=3 cm apex-to-cupola distance
Clinical stability	
Stable patient	All of the following present: respiratory rate, <24 breaths/min; heart rate, >60 beats/min or <120 beats/min; normal blood pressure, room air O_2 saturation, >90%; and patient can speak in whole sentences between breaths
Unstable patient	Any patient not fulfilling the definition of stable
Drainage tubes	
Small chest tube or small percutaneous catheter	=14Fr
Moderate-sized chest tube	16Fr to 22Fr
Large chest tube	24Fr to 36Fr
Simple aspiration	Insertion of a needle or cannula with removal of pleural air followed by immediate removal of the needle or cannula

From Baumann MH, Strange C, Heffner JE, et al: Management of Spontaneous Pneumothorax: An American College of Chest Physicians Delphi Consensus Statement. Chest 119:590, 2001.

*See Definition of Terms.
†This recommendation has been criticized and many authorities recommend that simple catheter aspiration is the logical first approach. (Miller AC, Harvey J: Guidelines for the management of spontaneous pneumothorax. BMJ 307:114, 1993. Miller AC, Harvey J: Pneumothorax: What's wrong with simple aspiration? Chest 120:1041, 2001.)

three-fourths of patients with a traumatic hemothorax can be managed by tube thoracostomy and volume replacement alone. For the remaining, immediate or delayed elective thoracotomy may be required. The indications for surgery following a hemothorax are somewhat controversial (Table 10-2). Early institution of blood replacement is recommended for patients with massive hemothorax (>2000 mL), since these are often associated with continuing hemorrhage. Autotransfusion of the shed blood is desirable if the technique is available (see Chapter 28).

TABLE 10-2 -- Indications for Surgery After Tube Thoracostomy Based on the Results of the Thoracostomy

Massive hemothorax, >1000–1500 mL initial drainage
Continued bleeding
>300–500 mL in first hour
>200 mL/hour for first 3 or more hours
Increasing size of hemothorax on chest film
Persistent hemothorax after 2 functioning tubes placed
Clotted hemothorax
Large air leak preventing effective ventilation
Persistent air leak after placement of second tube or inability to expand lung fully

Empyema

The treatment of patients with empyema depends on the severity of their infection and their underlying condition. Some patients with empyema can be treated with serial thoracenteses, but most will require continuous drainage with a tube thoracostomy. Thoracoscopic decortication represents definitive therapy for severe cases. Usually a diagnostic thoracentesis is done first to assess the fluid for signs of infection. Thick pus on thoracentesis, a positive Gram stain fluid glucose <60 mg/dL, pH <7.20, or elevated lactate dehydrogenase are associated with effusions requiring chest tube drainage. Once an empyema is detected, therapy should not be delayed because the fluid can become loculated within hours. The tube is left in place until the volume of the pleural drainage becomes clear yellow and is <150 mL in 24

hours.

An empyema that fails to resolve on the chest radiograph within 48 hours requires chest CT scan and a careful review of antibiotic choice. Multiloculated effusions are best managed with thoracoscopic decortication.

CONTRAINDICATIONS

For unstable injured patients with a pneumo- or hemothorax, there are no absolute contraindications to a tube thoracostomy. In critical patients the placement of a chest tube is often performed empirically, since procedures to confirm the presence of, assess the extent of, or prove the absence of pathology are prohibited by logistics of the resuscitation. In the stable patient, relative contraindications include anatomic problems such as the presence of multiple pleural adhesions, emphysematous blebs, or scarring. Coagulopathic patients should be evaluated for clotting factor replacement before any invasive procedure.

TREATMENT

Treatment of a Tension Pneumothorax During a Resuscitation

If a patient is undergoing resuscitation and is in extremis, the clinician rarely has time for formal tube thoracostomy, and needle decompression is simply not effective within seconds. Based on clinican findings or circumstances (such as a stab wound to the chest, markedly abnormal breath sounds, cyanosis, tracheal deviation, marked SQ air, and hypotension) it is suggested that the chest cavity be ventilated by immediate measures. It is assumed that the patient is intubated so one merely needs to create an exit for the air that is compressing the lung and shifting the mediastinum (Fig. 10-6). A scalpel is used to open the skin and SQ tissue by making a deep 3 to 4 cm incision over a rib in the upper chest wall at the anterior axillary line. A large *closed* Kelly clamp or scissors are used to blindly stab through the pleural via the skin incision. The instrument is guided over the top of the rib and once a pop is felt, indicating penetration of the pleura, the blades of the instrument are opened. This will allow for the immediate egress of air and the tension will be relived enough to allow the ventilated patient to normalize respiratory and cardiovascular function. When the immediate emergency is controlled, an appropriately sized chest tube is inserted through the incision. This is usually a nonsterile procedure.

Prehospital Treatment

Emergent needle thoracostomy may be used in the prehospital setting or when a patient suspected of having a pneumothorax rapidly deteriorates or presents in extremis. The needle (or catheter) may then be attached to a flutter valve (fashioned from the fingers of a surgical glove), underwater seal, or commercially available one-way (Heimlich) valve to allow for the continued drainage of the pneumothorax. The definitive treatment of a tension pneumothorax is tube thoracostomy.

For a more stable open pneumothorax, prehospital treatment involves the application of a sterile dressing over a penetrating wound to act as a one-way (flap) valve. This allows air to exit the pleural space but blocks air reentry through the wound. The patient is instructed to perform the Valsalva maneuver after deep inspiration or to cough just as the dressing is placed. Ideally, a sterile dressing of petrolatum-impregnated gauze that extends 6 to 8 cm beyond the wound in all directions is used. This underlying dressing should then be covered by gauze dressings and secured with tape on three sides only.

Equipment

Examples of instruments in a tube thoracostomy tray are listed in Table 10-3 . Since the contents of these trays vary among hospitals, emergency clinicians should familiarize themselves with the trays before an emergency. Additional important materials are listed in Table 10-4 . If possible, all equipment should be organized before beginning the procedure.

The most commonly used chest tubes are clear plastic, straight tubes with a series of holes along the distal length and open at both ends. To assess depth of insertion, a *radiopaque strip runs along the length that is commonly interrupted by the last hole*. Sizes used for adults vary from 12 to 42 French (Fr), with smaller tubes used for pneumothorax, and larger (a minimum of 36 Fr) for hemothorax and empyema (see Table 10-1 for the definition of chest tube sizes). The largest possible tube should be used to drain a hemothorax. For pediatric patients, No. 14, 16, 20, and 24 Fr tubes are adequate. Before insertion, the beveled (extrathoracic) end of the tube is cut squarely to better fit the commonly available connectors.

Figure 10-6 During a resuscitation involving a tension pneumothorax, there may be no time for a chest tube and needle decompression may not be effective rapidly enough. Under these circumstances the pleural cavity can be vented in seconds. This assumes that the patient is intubated. *A*, A No. 10 scalpel is used to make a deep incision in the skin and subcutaneous tissue over the fourth or fifth rib in the anterior axillary line. *B*, A long *closed* Kelly clamp (or scissors) is inserted over the top of the rib and stabbed into the pleural space. A pop is usually felt. *C*, Once the instrument is in the pleural space, it is opened wide to create a rent in the parietal pleura. Air should immediately vent. If the patient is intubated, normal cardiorespiratory function can be maintained. A chest tube is then inserted. (See also Figure 10-11 Figure 10-12 Figure 10-13 Figure 10-14 .)

PROCEDURE

Before any procedure, gown, glove, mask, and goggle precautions must be used.

Tube Location

A chest tube placed anywhere in the pleural cavity will drain blood, fluid, or air.

A chest tube that is performing its intended function, regardless of its location, can be left in place until an elective tube can replace it. However, traditional sites are usually chosen. For a pneumothorax the classic location for a thoracostomy tube was in the second intercostal space in the midclavicular line, but in practice this site is usually only used for needle decompression of a tension pneumothorax. The most common location for a chest tube is the mid- to anterior axillary line (Fig. 10-7). It is cosmetically preferable and better tolerated. Recommendations for location vary from the fourth to the eighth intercostal space, but most often the fourth or fifth intercostal space is used. This is roughly at the level of the nipple or the inferior scapular border in most patients. The entrance site should be lateral to the edge of the pectoralis major and breast tissue. *A more superior position should usually be chosen since the external landmarks can be misleading and chest tubes are more often placed too low rather than too high.* The diaphragm of a

supine patient who is not taking a deep breath is much higher than most clinicians suspect.

There is no evidence in adults that tube location affects the ability to drain fluid collections. As the lung expands and the pleural space becomes smaller, air and fluid will follow the path of least resistance and enter a functioning drainage tube, regardless of the tube's location. Therefore, a tube anywhere in the pleural space should adequately drain a hemothorax of unclotted blood, as long as there are no loculations.

Before insertion the tube should be held beside the chest wall. The tube's tip should be near the clavicle to estimate the distance the tube should be advanced from the incision site to the apex of the lung. For a hemothorax, the tube is directed toward the diaphragm. A clamp may be placed on the tube to mark the maximum length the tube is inserted. Make sure this location is sufficient to ensure that the *last drainage hole will be within the pleural space*. This method helps to minimize subsequent repositioning of the tube. During emergency placement, it is common, yet usually clinically inconsequential, to advance the tube too far. In markedly obese patients it is common to fail to advance the tube far enough, thereby not assuring that the last hole is in the pleural space.

Patient Preparation

Patients should be started on nasal oxygen and placed on continuous pulse oximetry monitoring. For stable patients the use of parenteral analgesics or conscious sedation should be routine. For anterior axillary line insertions, the head of the bed should be elevated 30 to 60° (Fig. 10-8). This lowers the diaphragm and decreases the risk of injury to the diaphragm, spleen, or liver. The arm on the affected side is placed over the

The midaxillary line placement is usually preferable for all chest tubes, regardless of pathology. Always avoid the breast tissue, even in prepubescent girls. Note that placing the tube too far posteriorly will not allow the patient to lie down comfortably.

patient's head and restrained in that position. The other arm can be restrained comfortably at the patient's side. The area where the tube will be inserted should be sterilized with a povidone-iodine solution and draped with sterile towels.

Anesthesia

With the use of parenteral analgesics, conscious sedation, and generous local anesthesia, the insertion of a chest tube should

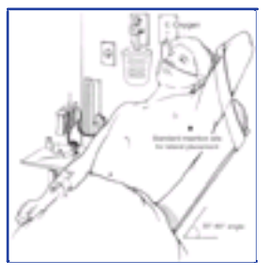

Figure 10-8 To insert a chest tube, the patient is placed semi-erect with the ipsilateral shoulder abducted and preferably restrained. Supplemental oxygen is recommended.

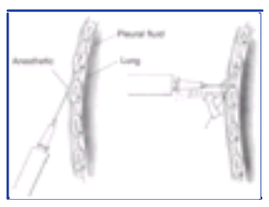

Figure 10-9 Insertion of a chest tube can be relatively painless with proper infiltration of the skin *and pleura* with local anesthetic. The liberal use of 1% lidocaine with epinephrine (maximum lidocaine dose, 5 mg/kg) is recommended. *(Redrawn from Hughes WT, Buescher ES: Pediatric Procedures, 2nd ed. Philadelphia, WB Saunders, 1980, p 234.)*

be relatively painless. Since the procedure can be extremely painful, up to 5 mg/kg of locally injected 1% lidocaine (Xylocaine) with epinephrine (1:100,000) can be used (Fig. 10-9). Note: Each mL of 1% lidocaine contains 10 mg of lidocaine. First inject the anesthetic in the SQ area with a small-bore (27-gauge [ga]) needle in the area of the skin incision. Then generously infiltrate the muscle, periosteum, and parietal pleura in the area of the tube's passage. This may require a larger-bore needle (21- or 23-ga). A common error is inadequate local anesthesia; another error is to forget that additional anesthetic may be required throughout the procedure.

In an elective situation an alternative is to use intercostal nerve blocks above and below the rib spaces of the incision and insertion. The needle and syringe may also be used to aspirate and find the pleural cavity in the area of insertion (Fig. 10-10). If air or fluid are not found, the insertion site should be changed. Once the tube is in place, anesthetic may be administered through the chest tube and instilled into the pleural space to reduce the severe irritation of the pleura. One approach for stable patients is to administer 10 mL of 0.5%

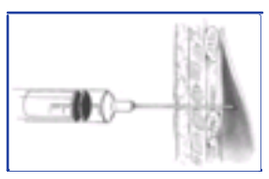

Figure 10-10 Use of the anesthetic needle to puncture the parietal pleura and establish the presence of blood or air in the pleural space. This procedure is not only diagnostic, but also may be a temporary therapeutic maneuver in a patient with tension pneumothorax. *(Redrawn from Richards V: Tube thoracostomy. J Fam Pract 6:631, 1978.)*

bupivacaine through the chest tube while the patient is lying on the contralateral side. [13] After 5 minutes without drainage of the thorax, standard gravity or vacuum drainage is reinitiated. Parenteral analgesic agents should be used as needed to control the pain associated with the initial injury and the procedure.

Insertion

The initial skin incision must be of adequate size. A common mistake is to make the skin incision too small so that it is difficult to create an adequate track for either the thoracostomy tube or an exploring finger. One method is to make the initial skin incision at an intercostal space lower than the thoracic wall entry site so that the tube may be "tunneled" up over the next rib. This is thought to provide a better seal against air leaks, although the efficacy has not been substantiated (Fig. 10-11). With a No. 10 blade, make at least a 3- to 4-cm transverse

Figure 10-11 The skin wound is made one intercostal space below the space through which the tube will pass *(A)*. By spreading tissue with scissors *(B)*, dissection is carried subcutaneously to the pleural lining. The pleura is entered with a blunt Kelly or Tonsillar clamp *(C)*. A common error in technique is to attempt to insert a large chest tube through a skin incision that is too small. *(Redrawn from Hughes WT, Buescher ES: Pediatric Procedures, 2nd ed. Philadelphia, WB Saunders, 1980, p 237.)*

incision through the skin and the SQ tissues directly over the rib located one interspace beneath the rib the tube will pass over. Using blunt dissection with a large Kelly clamp or scissors, a track is created over the rib above by pushing forward with the closed points and then spreading and pulling back with the points spread. To avoid the intercostal vessels and the nerve (located on the inferior margin of each rib) the track should pass immediately over the superior surface of the lower rib in the chosen intercostal space (Fig. 10-12). Then push through the muscle and parietal pleura with the closed points of the clamp until the pleural cavity is entered. This often takes considerable force and may require a twisting motion with the clamp. A palpable pop may be felt as the pleura is penetrated. A rush of air or fluid should occur at this point. The tips of the clamp, still within the pleural cavity, are spread widely and withdrawn to make an adequate pleural entry (Fig. 10-13). Penetrating the pleura is usually the most painful portion of chest tube placement and it is nearly impossible to completely anesthetize this portion of the procedure.

Once the pleura has been penetrated, the clinician inserts a gloved finger into the chest wall track to verify that the pleura has been entered and that no solid organs are present. The finger may be swept inside the cavity to assure that pleural adhesions are absent. The finger is left in the pleural space as a guide, and the tube is passed over, under or beside the finger into the pleural space (Fig. 10-14). This step allows the clinician to feel the tube passing into the pleural cavity, and avoids

SQ dissection with the tube. Some clinicians prefer passing the tube alone, while others recommend that the tube be held in a large curved clamp, with the tube tip protruding from the jaws (Fig. 10-15). The tube is directed superiorly

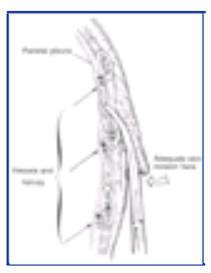

Figure 10-12 Location of the intercostal neurovascular bundle, running inferiorly and slightly medial to the rib. *(From Millikan JS, Moore EE, Steiner E: Complications of tube thoracostomy for acute trauma. Am J Surg 140:739, 1980.)*

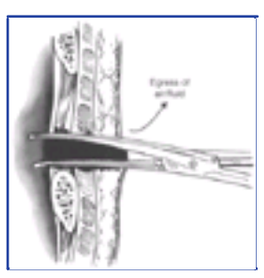

Figure 10-13 One accomplishes blunt dissection by forcing the closed points of the clamp forward, then spreading the tips and pulling back with the points spread. Note that the clamp should be spread in a direction parallel with the ribs (See Fig. 10-6); not perpendicular to the ribs as suggested in the figure. The drawing emphasizes the placement of the instrument *over* the rib. A rush of air or fluid signifies penetration into the pleural space. *(From Bricker DL: Safe, effective tube thoracostomy. ER Reports 2:49, 1981.)*

and posteriorly. The tube is then advanced superiorly, medially, and posteriorly until the marker clamp that was previously attached touches the chest wall. Alternatively, the tube may be advanced until pain is felt or resistance is met, and then pulled back 2 to 3 cm. Ensure that all the holes in the

Figure 10-14 Using the finger as a guide to ensure entry into the pleural cavity, one places the tip of the tube into the pleural cavity. *(From Millikan JS, Moore EE, Steiner E: Complications of tube thoracostomy for acute trauma. Am J Surg 140:739, 1980.)*

Figure 10-15 The tube is grasped with the curved clamp, with the tube tip protruding from the jaws.

tube are within the pleural space. A common error, especially in obese patients, is to fail to advance the chest tube far enough into the pleural space, leaving the drainage holes in the SQ tissue. The tube can then be rotated 360° to reduce the likelihood of kinking. Although not crucial for initial treatment, the tube can initially be directed inferiorly if only fluid is to be evacuated.

The tube is attached to the previously assembled water seal or suction setup by means of a sterile serrated connector before the clamp is released. Asking the patient to cough and thereafter observing bubbles in the water seal chamber is a good way to check system patency.

Confirmation of Tube Placement

Immediately after tube placement a finger can be passed along the tube to verify that it enters the pleural cavity. Condensation on the inside of the tube and audible air movement with respirations, the free flow of blood or fluid, and the ability of the operator to rotate the tube freely after insertion are also indicators that the tube is in the pleural space.

The definitive assessment of tube placement is the chest radiograph (Fig. 10-16). A simple pneumothorax should resolve within a few minutes of continual suction. If the radiograph continues to demonstrate a pneumothorax, consider that the tube may not be in the pleural cavity, the most proximal hole is outside the chest cavity, or a large air leak from the tracheobronchial tree may be delaying expansion.

In an emergency it is deceptively easy to advance a chest tube in a SQ plane outside of the pleural space, usually a course that follows the ribs posteriorly. Using a finger in the pleural space helps negate this action, and the error is easily detected by a radiograph.

The development of palpable SQ air is another complication of chest tube placement. It usually is limited to the insertion site and minimized with proper technique. Patients placed on positive pressure ventilation who have a continued air leak can develop significant disseminated SQ emphysema.

Figure 10-16 Subcutaneous (SQ) placement of a chest tube (*arrows*) can occur, as the tube can dissect through tissue planes with relative ease. If this tube had been directed posteriorly, the radiograph would erroneously "confirm" intrapleural placement despite the tube being SQ throughout its entire course.

Securing the Tube

The chest tube position should be verified on a chest radiograph before definitively securing the tube. Numerous methods to secure a tube are acceptable. One common way to secure the tube is to sew it to the skin with large 0 or 1-0 silk sutures. Nylon sutures are acceptable and more easily found, but they tend to slip on the surface of the chest tube. One common method is to use the "stay" suture. With this technique the same suture that is used to close the skin incision is also used to hold the tube (Fig. 10-17). After this suture is used to close the skin incision at the site of tube insertion, the ends are left long. Then they are wrapped and tied

repeatedly around the

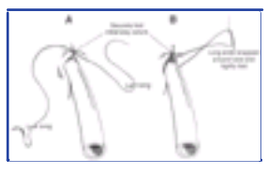

Figure 10-17 A "stay" suture is first placed next to the tube to close the skin incision. *A,* The knot is tied securely and the ends, which will subsequently be wrapped around the chest tube, are left long. *B,* The ends of the suture are wound twice about the tube tightly enough to indent the tube slightly and are tied securely.

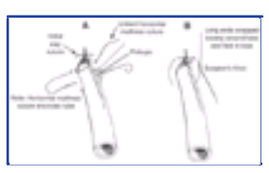

Figure 10-18 *A,* A horizontal mattress suture is placed around (above and below) the tube and is held only with a surgeon's knot. *B,* The loose ends are also wrapped around the tube and are tied loosely in a bow to identify the suture. This suture will be untied and used to close the skin incision after tube removal.

chest tube and knotted securely. The sutures must be tied tightly enough to indent the chest tube slightly to avoid slippage. If the skin incision is not closed tight around the tube, an additional stay suture is used, or a simple suture is used.

At this point it is advisable to place a suture that can both help close the skin around the tube and subsequently close the incision after the chest tube is removed. A *horizontal mattress suture* is placed approximately 1 cm across the incision on either side of the tube, essentially encircling it (Fig. 10-18). This is closed with a knot that can be easily untied since it will be opened and retied to close the incision after the tube is removed.

An occlusive dressing of petrolatum-impregnated gauze should be applied where the tube enters into the skin. This should then be covered with two or more gauze pads with a Y-shaped cut from the middle of one side to the center. These are oriented at 90° to each other (Fig. 10-19). The shaved skin and the tube may be coated with tincture of benzoin and wide (8- to 9-cm) cloth adhesive tape used to hold the tube more securely in place.

The tube can be further secured with tape or elastic adhesive dressing by taping around the tube and pressing the tape

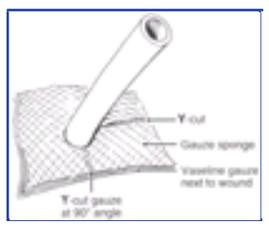

Figure 10-19 A dressing consisting of gauze sponges with a Y-cut is applied to the entry site to provide an air-tight seal. Two pieces are placed at angles.

together for 1 to 2 cm before applying the tape to the chest wall. Another method is to use two strips of tape applied with an "elephant-ear" technique at 90° to each other (Fig. 10-20). The tape is torn so that one end is split into three pieces extending halfway to the center. The two outside pieces are placed on the skin on either side of the tube site, and the center section is wrapped tightly around the tube. This is repeated with a second piece of tape placed at 90° to the first. Also securely tape the tube connections.

Drainage and Suction Systems

A basic understanding of the functions of chest tube drainage systems is necessary to prevent life-threatening complications associated with their use. Modern suction devices are much safer and easier to regulate than the old multi-bottle systems, but the older systems better demonstrate their mechanism of action. The self-contained apparatus used currently is merely a high-tech version of the old bottle system. There are two essential components to all systems: a one-way valve to allow air or fluid to drain out of the pleural space without allowing air back into the pleural space, and a suction mechanism to increase the rate of drainage. The following are general requirements for a drainage/suction system.

The simplest drainage device is a one-way valve without suction. This can be accomplished by either an underwater seal or with a flutter (Heimlich) valve attached to the end of the chest tube (Fig. 10-21). These valves allow one-way flow of air out of the chest but collapse during inspiration to prevent air from passing back into the chest. Normal respiration and coughing will create enough pressure to remove the excess air from the pleural space, and the lung will then expand. The Heimlich valve does not require suction and it may be used by outpatients. In reality, however, this theoretical advantage is rarely used by the emergency clinician.

Another simple device is the underwater seal method. In this system the intrapleural fluid or air exits under a small amount of water (the seal) and collects into a single collecting reservoir (Fig. 10-22). The intrathoracic pressure must be greater than the water pressure over the distal exit in the immersed tube to allow intrathoracic air or fluid to be expelled into the bottle. The water pressure that must be overcome to allow the expelling of air or fluid into the collecting device is the height of the water above the exit port on the tubing. Enough intrapleural pressure is easily accomplished with simple coughing unless the height of the fluid in the collecting apparatus becomes excessive. The water above the tube

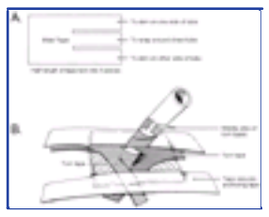

Figure 10-20 *A*, The distal half of a wide piece of tape is longitudinally split into three pieces. The two outside pieces are placed on the skin on either side of the tube, and the center strip is wrapped around the chest tube itself. *B*, This process may be repeated with a similar piece of tape placed at a 90° angle. The tape is securely anchored to the skin (benzoin is optional, but the skin must be clean and dry), and the torn tape is wrapped around the tube. Each anchoring piece is covered by another piece of tape.

acts as a seal because it is too heavy to be drawn back into the chest. This obviously requires that the collecting bottle be below the patient, usually on the floor. Inspiration cannot generate enough negative pressure to pull the collection bottle contents from the floor to the chest cavity. As the height of the collecting bottle is raised, less negative inspiratory force is required to suck the fluid in the bottle back into the chest. The problem with this system is that as the fluid collects in the reservoir, increasing intrathoracic pressure is needed to overcome the fluid pressure. To overcome this problem a two-bottle system is usually used (Fig. 10-23). The chest tube is connected to a collection reservoir that is then linked to a second bottle with 5 cm of water in the bottom. Suction can be applied to the two-bottle system by connecting a third connected chamber.

Suction is used initially for all patients with chest tubes placed for either pneumothorax or hemothorax. The suction device should have high suction flow (up to 20 L/min) and be able to keep the suction constant. A wall suction of 20 cm H_2O is normally used. Suction is useful for rapid initial expansion and drainage, but because of potential complications it should be replaced by a water seal once the expansion

Figure 10-21 A one-way Heimlich valve alone is usually sufficient to treat a pneumothorax, but should *not* be used to treat a hemothorax.

is satisfactory and there are no persistent air leaks. Suction can be added to a two-bottle system with a third bottle that is attached to an external suction (negative pressure) source (Fig. 10-24). *The amount of suction in the chest tube is dependent on the depth of water in the water seal reservoir, not by the suction from the wall valve.* When negative pressure from the suction source exceeds the depth of the water in the chamber, air enters from the top of the third tube, causing continuous bubbling. This prevents a further pressure increase in the chest tube. Since the suction applied to the end of the chest tube is dictated by the height of water in the container, and not by the dial on the wall suction, the loud bubbling heard from a chest tube collection device does not mean that

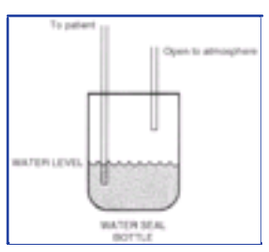

Figure 10-22 Single-bottle (water seal) collection device.

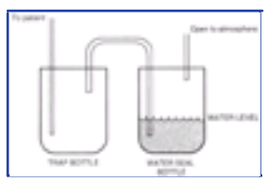

Figure 10-23 A two-bottle system. The "trap" reservoir proximal to the water seal keeps the accumulating drainage from affecting the water seal pressure.

suction is increased. The wall suction dial can be turned down until only occasional bubbling can be detected.

Current commercial systems provide "air leak chambers" to indicate the amount of an intrapleural air leak (Fig. 10-25). Bubbling in this chamber indicates the presence of an air leak, either in the drainage system or from the lung parenchyma. If an air leak is suspected from a lung injury, first confirm that the tube is not leaking, that its connections are tight, and that all holes of the chest tube are within the thorax. If the air leak is from the patient it is usually seen only with expiration or with coughing (forced expiration). Continuous air leaking, or a leak seen during inspiration, indicates a larger and possibly more significant injury. [14] Surgical intervention is indicated if an air leak persists for >72 hours or the lung is not completely reexpanded.

When the tube is functioning properly, the height of the fluid level in the drainage tube fluctuates with the respiratory cycle. Respiratory fluctuations can increase if the patient is making increased inspiratory effort due to airway obstruction or atelectasis. An absence of respiratory fluctuation or a decrease in the drainage implies that the system is blocked or that the lung is fully expanded. Thoracostomy tubes draining fluid are prone to blockage. If the tube is blocked, the chest tube or collecting tubing, or both, can be changed, "milked,"

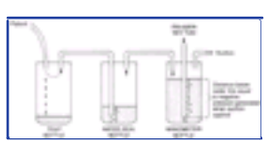

Figure 10-24 A 3-bottle system with fluid trap bottle, water seal, and adjustable vent tube. The height of the column of water in bottle 2 regulates the amount of suction applied, independent of the pressure on the suction valve. *(From Miller KS, Sahn SA: Chest tubes: Indications, technique, management and complications. Chest 91:258, 1987.)*

or "stripped" to dislodge clots. Although replacing the tube is a complicated process, the routine use of milking and stripping should be used sparingly because of the potentially high pressures generated. If the blockage is within the thorax, the tube can be *milked* by forcing air or fluid back into the chest. The tube must be clamped distally and then compressed and stripped to force the contents proximally. *Stripping* is the opposite maneuver in that the tube is clamped proximally and progressively compressed distally followed by a release to allow the tube to spring open. The sudden increase in negative pressure may extract clots and fluid from a more proximal location.

In any system the drainage reservoir must remain below the level of the chest to prevent the fluid in the collection system from reentering the chest. Simple respirations do not generate enough negative intrathoracic pressure to pull the water in the reservoir up to the height of the chest if the reservoir is kept on the floor. The length of the tubing must be sufficient to keep the reservoir below the level of the patient, but not long enough to cause it to form dependent loops of fluid or kinks. These dependent fluid loops require greater intrapleural pressure to drain. If they are high enough (15 to 25 cm H_2O), they cause a tension pneumothorax (Fig. 10-26). Similarly, as fluid accumulates in the water seal reservoir of a single bottle system, the immersed tip of the tube must be raised so that it stays 2 to 4 cm below the water surface to keep the pressure constant.

Occlusive clamping of chest tubes should only be performed with close clinician supervision. If an intrathoracic air leak is still present, clamping the tube may cause a tension pneumothorax. Patients with chest tubes in place are best transported with a Heimlich valve or water seal only, not with a clamped tube. Clamping the chest tube as a trial maneuver before removal of the tube is discouraged.

Prophylactic Antibiotics

The use of prophylactic antibiotics for patients with a chest tube placed in the ED is controversial. There is no agreed-on standard of care. Small controlled studies demonstrate a trend toward reduced empyema and pneumonia in patients treated with tube thoracostomy for penetrating trauma when cefonicid or cefazolin has been given at the time of chest tube

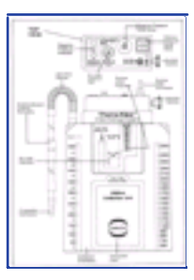

Figure 10-25 Diagram of a commercially available chest drainage system. Included is a 2500-mL fluid collection chamber, a suction control device, an air leak indicator, and a fluid sampling port. A separate attachment is available for autotransfusion. *(Courtesy of Davol, Inc, a division of CR Bard, Cranston, RI.)*

insertion and continued until removal. It would seem reasonable to administer prophylactic antibiotics to patients who receive an emergency and possibly nonsterile thoracostomy. [15] [16] The antibiotic chosen should cover *Staphylococcus aureus*.

It is less clear whether patients with blunt chest trauma or spontaneous pneumothorax who receive their thoracostomy under controlled and sterile conditions require antibiotic prophylaxis. Generally prophylactic antibiotics are not used under these circumstances.

Tube Removal

Chest tubes are generally removed when fluid loss is <200 mL/day and no air leak exists for a minimum of 24 hours. For pneumo- and hemothorax the use of preremoval radiographs is not necessarily recommended. For empyema the removal depends on the clinical and radiographic resolution of the infection.

To remove the chest tube, place the patient in a semi-upright position and remove the dressings. Prepare and drape

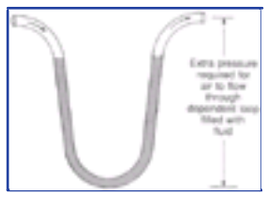

Figure 10-26 Dependent loops of fluid-filled tubing require positive intrapleural pressure greater than the vertical height of the fluid-filled loop for drainage to occur. *(From Batchelder TL, Morris KA: Critical factors in determining adequate pleural drainage in both the operated and non-operated chest. Am Surg 28:298, 1962.)*

the insertion site and follow sterile technique. If a pursestring suture was placed at the time of the insertion, then only sterile scissors are needed to cut the suture. If there is no pursestring suture, then suturing equipment will be needed to close the wound once the tube is removed. Additional equipment should be available to reinsert a chest tube if the lung collapses. A petrolatum- or antibiotic-impregnated gauze dressing should be prepared for covering the wound.

The pursestring suture that was previously placed should be loosened and readied for closing the wound. Then the skin loop of the suture holding the tube to the skin should be cut and removed from the skin. The tube should be clamped to prevent leakage of body fluids and then disconnected from the connecting tubing. The patient should inhale fully and perform a mild Valsalva maneuver. The tube is pulled out in one swift motion while the patient holds the breath. The pursestring suture is quickly tied and then covered with the occlusive dressing. The patient should be observed for 2 to 6 hours, with a chest radiograph obtained before discharge. Any increase in symptoms requires prompt reevaluation. After 48 hours, the dressing may be removed. Sutures may be removed in 7 to 10 days.

OTHER TECHNIQUES

Minicatheter Insertion

A less invasive alternative to traditional tube thoracostomy for patients with a simple pneumothorax is treatment with a minicatheter. Advantages of this technique include the ease of catheter insertion, decreased patient discomfort, less scarring, and decreased cost. After successful reexpansion of the lung, selected patients may be treated as outpatients with a Heimlich valve. Healthy patients with iatrogenic pneumothorax (e.g., following central line attempts, IV drug injection), victims of minor nonpenetrating chest trauma, and patients with spontaneous pneumothoraces are good candidates for catheter aspiration of the pneumothorax. Patients with underlying lung pathology, such as pneumonia, CHF, asthma, or emphysema, are generally not candidates for minicatheter use. The technique is somewhat less effective in patients with a spontaneous pneumothorax because of the continued air leak from ruptured blebs, but it has been 80% effective regardless of the size of the pneumothorax, and is associated with decreased pain and a shorter hospital stay.[17]

There are many protocols for using catheter aspiration as the first step in treating simple pneumothoraces. In general, patients with successful aspiration are observed in the ED for 4 to 6 hours, and if a repeat radiograph shows no reaccumulation of air, the catheter is removed. After 2 more hours of observation, another chest radiograph is obtained, and the patient is released if there is no recurrent pneumothorax. Patients with continued residual pneumothorax often receive a conventional tube thoracostomy, although selected patients can have the catherter attached to suction and admitted. Usually this catheter clogs or becomes nonfunctional in 24 to 48 hours because of the small lumen. This protocol leads to about a 60% success rate with simple aspiration. An additional 30% may respond to the use of a Heimlich valve with or without suction. About 15% of patients will eventually require a formal chest tube. Outpatient therapy consisting of a small catheter with an attached Heimlich valve may be the best strategy in select patients with a first-time spontaneous pneumothorax.

Some catheters are designed specifically for aspirating a pneumothorax. They are made of a soft, flexible, thrombosis-resistant, radiopaque material with multiple distal side ports. The pigtail catheter system is ideal for this procedure (Fig. 10-27) because its multiple holes help prevent obstruction or adherence to the pleura when under suction. A 14-ga IV catheter or an 8.5 Fr Arrow trauma catheter can also be inserted using the Seldinger (guidewire) technique. However, these catheters have only single distal holes, which can easily become obstructed or adhere.

Placement of a catheter into the pleural space is relatively simple. The patient is placed in a semi-upright position and the skin is prepared with appropriate antiseptic solution at either the fourth or fifth intercostal space at the anterior axillary line or the second or third intercostal space at the midclavicular line. A generous local infiltration of lidocaine is used for anesthesia. The exact technique depends on the type of equipment used, but most commonly it is a guidewire technique.

Guidewire (Seldinger) Technique for Catheter Aspiration

After skin preparation and sterile draping, a thin-walled 16-ga needle is advanced cephalad over the top of the rib at a 60° angle (Fig. 10-28). No attempt should be made to tunnel this tract since floppy catheters will not be easily passed unless they are advanced in a straight line. When the pleural space is identified by the aspiration of air into the syringe, the advancement of the needle is halted. A guidewire is inserted into the pleural space through the needle. Then the needle is removed while stabilizing the guidewire to prevent it from being pulled out. Now only the guidewire remains in the pleural space. A small incision is made in the skin with a No. 11 blade at the base of the wire to allow passage of the catheter through the skin. If the pigtail catheter system is used, a dilator is passed over the wire to clear a path through the soft tissues for the catheter. If a minicatheter is used, it has its own dilator/introducer. The minicatheter with an introducer is then threaded over the guidewire into the pleural space. The wire and dilator are removed, leaving the catheter in the pleural space. A three-way stopcock is attached to the catheter and air is then aspirated with a 60-mL syringe until resistance is felt. Alternatively, suction is used, since a number of aspirations may be required until all air exits. The catheter is then secured to the skin. Obtain a chest radiograph to determine if the lung is fully expanded. If residual pneumothorax is present, further aspirations can be attempted. If air cannot be aspirated, the catheter may be kinked or blocked with soft tissue. To relieve the blockage, place the patient in the full upright position and have him or her cough or take a deep breath. Alternately, the catheter can be withdrawn slightly or twisted gently.

Over-the-Needle Technique

Some commercial kits use a catheter over a long needle (Fig. 10-29). After preparation and draping, a small incision is made in the skin with a No. 11 blade. While constant suction is applied with an attached syringe, the needle and catheter combination is slowly advanced into the pleural space. When air is aspirated, the needle is no longer advanced and the catheter is then slid off the needle into the pleural space, ensuring that all side ports are within the pleural space. The catheter is then connected to a three-way stopcock, and air is aspirated with a syringe as described earlier.

Trocar Insertion

Chest tube insertion with a trocar is rarely used because of the risk of major complications to the heart, lung, and solid organs. Some clinicians use a trocar to stabilize the tube during careful guided insertion through a skin incision, but the technique of perforating the chest wall with a trocar/chest tube apparatus is discouraged.

TUBE THORACOSTOMY IN PEDIATRIC PATIENTS

Pneumothorax can occur in the neonatal population, often associated with resuscitative measures (such as mechanical ventilation) for meconium aspiration or prematurity. For the rest of the pediatric population, trauma is the most common cause.

The physical examination of the newborn with pneumothorax can vary from no abnormalities to cardiovascular collapse. Making this diagnosis in a newborn by physical examination alone is a great challenge and usually a radiograph is required because of the multiple causes of respiratory distress. Grunting respirations and tachypnea are often seen. Retractions or nasal flaring can be seen, and crepitus in the neck may be present. Cyanosis may be present or may occur only with crying or feeding. Irritability, restlessness, apneic periods, bradycardia, or tachycardia may be the only manifestation. Distention and tympany of the affected side may be found. A decrease in breath sounds is difficult to appreciate in any child because of the wide transmission of breath sounds throughout the chest and upper abdomen. With a tension pneumothorax, the cardiac impulse and the trachea may be shifted away from the affected side. The definitive diagnosis is made with radiographs taken in the AP and cross-table lateral projections. Small pneumothoraces may be seen

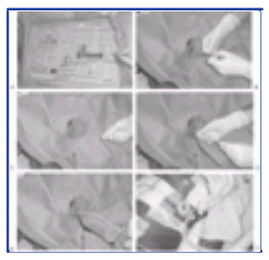

Figure 10-27 Aspiration of a pneumothorax (caused by subclavian vein catheterization) with an Arrow 14 Fr Percutaneous Cavity Drainage Catheterization Kit. This 23-cm pigtail multi-hole catheter is ideal for such purposes. Air can be aspirated from the catheter part with a syringe or the catheter can be attached to suction or a Heimlich valve. This catheter is not used for patients on a ventilator, those with continuing air leaks, or with a hemothorax. It is ideal for stable patients who have a primary pneumothorax or a collapse that can be expected to be stable if the lung is reexpanded (such as intravenous drug use induced, minor blunt trauma, secondary to central venous catheter insertion). *A*, Seldinger-type catheter kit demonstrating pigtail catheter and all necessary equipment, including local anesthesia, introducing needle and syringe, scalpel, guidewire, and dilator. *B*, After generous local anesthesia, the introducing syringe is advanced in *a straight line over the top of the fifth rib* until air is aspirated. Unless a straight track is created it will be difficult to advance the floppy catheter, and a tunneling approach cannot be used. *C*, The guidewire is advanced into the pleural space and the introducing needle is removed. *D*, Following puncture of the skin at the site of wire insertion with a scalpel, a dilator is advanced over the wire to create a track for the catheter. *E*, The pigtail catheter is advanced over the wire through the dilated tract, assuming its pigtail configuration when it is in the pleural space. A twisting motion may be needed to advance the catheter through the subcutaneous tissues. *F*, The catheter is advanced to the hilt and secured to suction. This catheter may be removed after a period of observation or the suction may be maintained for a few days. If used for a few days, the catheter will become clogged with mucus or blood, which may be cleared by injecting sterile saline through the device.

Figure 10-28 Seldinger technique for aspiration catheter insertion. *A*, Guidewire is passed through a needle over the rib into the pleural space. *B*, The needle is removed with the wire in the pleural space. *C* and *D*, A nick is made in the skin with a No. 11 blade, and the introducer and catheter are threaded into the pleural space. A twisting motion may be helpful. *E*, The guidewire and introducer are removed, leaving the catheter in the pleural space.

only on the lateral view, as the air collects at the top of the thoracic cavity.

In general, tube thoracostomy is the treatment of choice once a symptomatic pneumothorax is detected in infants. When signs of tension pneumothorax are present, immediate aspiration with a plastic catheter over-the-needle device is recommended. Small pneumothoraces (<20% of the hemithorax) in relatively asymptomatic infants (i.e., those who are without other problems and who do not require positive airway pressures) can be observed.

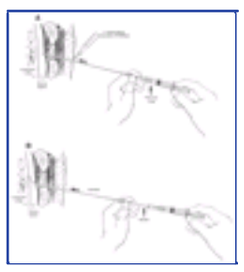

Figure 10-29 Over-the-needle catheter aspiration. *A,* A small nick is made in the skin with a No. 11 blade. The over-the-needle catheter is inserted through the nick into the pleural space. Proper placement is confirmed by the free flow of air into the attached syringe. *B,* The catheter is then threaded over the needle into the pleural space, and the needle is withdrawn.

Of all children with thoracic trauma, approximately one third will develop a pneumothorax, of which one third are isolated injuries. The high percentage of associated injuries in children with a pneumothorax also increases their mortality. [18]

The technique of tube thoracostomy in pediatric patients is essentially the same as that for adults, although an infant's size renders this procedure a formidable one. A successful placement should be viewed as technical accomplishment. The major difference lies in the size of the chest tube. No. 8 to 10 Fr catheters are used in premature infants (<3 kg), and No. 10 to 12 Fr catheters are used in newborns (3 to 5 kg). The size of the tube required increases with the patient's weight

TABLE 10-5 -- Approximate Pediatric Chest Tube Size by Weight in Kilograms

Weight (kg)	Chest Tube (Fr)
<3	8–10
3–5	10–12

6–10	12–16
11–15	17–22
16–20	22–26
21–30	26–32
>30	32–40

(Table 10-5). Various tube locations have been proposed, but recent studies have demonstrated the potential for breast deformities in adults if a midclavicular approach is used. Therefore it is recommended that in newborn infants chest tubes be inserted in the anterior axillary line through the fifth intercostal space after a skin incision 4 to 5 cm below the mammilla.[19] The other important difference is that for a

Recurrence of pneumothorax after chest tube removal

pneumothorax the tube should be directed anteriorly when inserted into the pleural space.

COMPLICATIONS

In general, if a chest tube is not functioning properly and the patient is deteriorating, the tube should be removed and inserted again, or another tube should be inserted.

The most common complications of chest tube insertion include infection, laceration of an intercostal vessel, laceration of the lung, and intra-abdominal or solid organ placement of the chest tube (Table 10-6). Local infection at the insertion site is common and related to the emergency nature of the procedure.

Intercostal arteries or veins may be lacerated, but can be minimized by using blunt dissection and carefully directing the tube just above the rib. The tube may adequately tamponade such bleeding, but sometimes the incision needs to be extended to ligate the bleeding vessel. If bleeding continues, a thoracic surgeon should be consulted. Injury to the lung and solid organs can be avoided by not using a trocar insertion technique and by carefully digitally exploring the pleura space before inserting the tube.

Failure of reexpansion of a pneumothorax may be due to a mechanical air leak, but it may also indicate a bronchopleural fistula, a continued parenchymal lung leak, or a bronchial injury. Tension pneumothorax can occur if a blockage in the drainage system at any point is associated with an air leak from the lung. Retained hemothorax may result from clotting or poor tube function. Reinsertion or placement of a second tube may be indicated if the first tube is not functioning properly. Often, an angled tube in the posterior diaphragmatic sulcus will promote drainage of a dependent fluid collection.

Reexpansion Pulmonary Edema.

The reexpansion of a pneumothorax or the evacuation of pleural fluid or blood has rarely been associated with unilateral pulmonary edema of the affected lung. The condition is rare, unpredictable, and may be severe. Pulmonary edema may be very symptomatic or merely a curiosity on the follow-up radiograph. Fatalities have been reported.[20] The condition may occur shortly after reexpansion or be delayed a number of hours. A common factor in these cases seems to be the prolonged period of time between pneumothorax and onset of treatment, but the exact time frame is quite variable. Usually the pneumothorax has been present at least 3 to 4 days. The proposed mechanisms include anoxic damage to the alveolar-capillary basement membrane from prolonged pulmonary collapse, loss of surfactant, or rapid fluid shifts. It has been theorized, but not substantiated, that reexpansion pulmonary edema may be ameliorated by a gradual, rather than sudden, evacuation from the pleural space. This is accomplished by removing air in small aliquots over 24 to 48 hours, rather than attaching the tube directly to suction. Treatment is supportive, occasionally requiring ventilatory support. Reintroduction of air back into the pleural space and temporary occlusion of the ipsilateral pulmonary artery have been other suggested, but unproven, interventions.

Acknowledgments

The authors would like to acknowledge Dr. Seth W. Wright for contributions made to this chapter in earlier editions and Dr. Pierre Theodore for his review and comments for this chapter.

Section III - Cardiac Procedures

Chapter 11 - Techniques for Supraventricular Tachycardias

John R. Krimm
Bohdan M. Minczak

In controlling or converting supraventricular tachycardias (SVTs) (Table 11-1), there are three avenues of therapeutic approach the clinician may use to achieve control. One is the time-honored use of the vagal reflex; the second is the therapeutic use of pharmacological agents; and the third is the monophasic or biphasic electrical cardioversion technique (Table 11-2). Electrical cardioversion is addressed in Chapter 12 .

VAGAL MANEUVERS

Anatomy and Physiology

The physiologic effects of pressure on the carotid sinus have been known for centuries. They were first described in the medical literature in 1799 when Parry wrote a treatise about the "symptoms and causes of syncope anginosa, commonly called angina pectoris." [1] [2] He noted that pressure on the bifurcation of the carotid artery produced dizziness and slowing of the heart. Thus, the term carotid derived from the Greek *karos*, meaning heavy sleep.

The bifurcation of the common carotid artery possesses an abundant supply of sensory nerve endings located within the adventitia of the vessel wall (Fig. 11-1). These nerves have a characteristic spiral configuration, continually intertwining along their course and eventually uniting to form the carotid sinus nerve. The afferent impulses travel from the carotid sinus via Herring's nerve or carotid sinus nerve to

TABLE 11-1 -- Potential Observations with Vagal Maneuvers in the Management of Tachydysrhythmias

1. Vagal maneuvers may slow the atrial rate in ventricular tachycardia (VT) or complete heart block and may therefore demonstrate previously hidden P waves or obvious atrioventricular (AV) dissociation.
2. Abrupt changes in the heart rate without conversion result from increasing AV block with increased vagal effect.
3. Gradual slowing of the ventricular rate suggests the presence of a sinus rhythm. Vagal maneuvers rarely decrease AV conduction in the presence of a sinus mechanism.
4. The dysrhythmias most likely to convert to sinus rhythm are paroxysmal atrial tachycardia (PAT) and paroxysmal nodal tachycardia.
5. Dysrhythmias associated with AV conduction defects (PAT with block, atrial flutter, and atrial fibrillation) infrequently convert to a sinus rhythm, but the ventricular rate slows. Rarely, atrial slowing will be sufficient to allow 1:1 AV conduction, which may actually increase the ventricular rate (Fig. 11-12).

the glossopharyngeal nerve (CN IX), thence to the vasomotor center in the medullary area (the *tractus solitarius*) of the brain stem. The vasomotor center is composed of three distinct areas, each with a distinctive function. The vasomotor center is located in the reticular substance of the medulla and in the lower third of the pons. This center transmits efferent impulses downward through the spinal cord and the vagus (CN X) nerve. The efferent impulses, which originate in the medial portion of the vasomotor center, travel along the vagus nerve (CN X) to the sinus node and the atrioventricular (AV) node of the heart. The medial portion of the vasomotor center lies in immediate apposition to the dorsal motor nucleus of the vagus nerve (CN X). These medial portion vasomotor center impulses decrease heart rates. Efferent impulses originating in the lateral areas of the vasomotor center travel along the sympathetic chain to the heart and to the peripheral vasculature (see Fig. 11-1). These sympathetic impulses control either vasoconstriction or vasodilation of the vascular system. A balance between the vasoconstriction and vasodilation maintains proper vasomotor tone. [3] [4]

The afferent nerve endings in the carotid sinus are sensitive to mean arterial pressure and to the rate of change of pressure. *Pulsatile stimuli* are more effective than sustained pressures in evoking a response. Elevated blood pressure stretches the baroreceptors, leading to increased firing of the afferent nerve endings. [3] Conversely, hypotensive states result in a drop in afferent firing, as the carotid sinus baroreceptors are exquisitely sensitive to low blood pressure.

The parasympathetic and sympathetic nervous systems play independent but coordinated roles in the carotid sinus reflex. Increased firing of the carotid sinus results in reflex stimulation of vagal activity as well as in reflex inhibition of sympathetic output. The parasympathetic effect is almost immediate; it occurs within the first second and causes a decrease in heart rate. The inhibited sympathetic effect, which causes a drop in blood pressure through vasodilatation, becomes manifest only after several seconds elapse [5] , and the full blood pressure change may not take full effect until a minute has elapsed. [6] The changes in blood pressure and heart rate are independent phenomena. Epinephrine blocks the reduction in blood pressure, while a fall in heart rate is blocked by the administration of atropine.

A cerebral effect, characterized by a loss of consciousness, was once thought to be due to stimulation of the carotid

Philadelphia, WB Saunders, 1974.)*

sinus. However, it is seen only when sufficient pressure is exerted to occlude the more distal temporal artery pulsation and when contralateral carotid disease is

present. This cerebral effect is now believed to be a result of decreased bilateral cortical perfusion.

The parasympathetic branch of the carotid sinus reflex supplies the sinus node and the AV node. The effect of the parasympathetic stimulation is to slow the heart rate. The sinoatrial (SA) pacemaker is more likely to be affected than the AV node, except when digitalis has been administered. [3] [6] [7]

Indications for Vagal Maneuvers

Vagal maneuvers, and in particular carotid sinus massage (CSM), may be a useful aid to the diagnosis of syncope in the elderly. Some 14% to 45% of elderly patients referred for syncope are thought to have carotid sinus syndrome (CSS). [7] [8] [9] CSS is defined as an asystolic pause greater than 3 seconds or a reduction of systolic blood pressure >50 mm Hg in response to CSM. It shares many characteristics with sick sinus syndrome, suggesting that both are manifestations of the same disease. CSS causes cerebral hypoperfusion leading to dizziness and syncope. Analysis of patients with the syndrome indicates that it results from a baroreflex-mediated bradycardia in 29% of patients, hypotension in 37%, or both in 34%. [10] [11] Therefore, syncope, near-syncope, or a fall of unclear etiology in the elderly are important indications for diagnostic CSM. [12]

The clinician can take advantage, however, of the similarity of the vagal effects of digoxin and the vagal maneuvers. Before starting digoxin administration in a patient, the practitioner can gauge the cardioinhibitory effect that will be achieved with the drug by first performing CSM. Significant slowing or block with CSM suggests a similar sensitivity to digoxin, and a smaller loading dose should be considered.

Vagal maneuvers are also indicated in settings in which slowing conduction in the SA or AV node could provide useful information (Fig. 11-2 Fig. 11-3 Fig. 11-4 Fig. 11-5 Fig. 11-6 Fig. 11-7 Fig. 11-8 Fig. 11-9). These settings include patients with wide-complex tachycardia in whom CSM aids in the distinction between SVT and ventricular tachycardia (VT). CSM can also elucidate narrow-complex tachycardia in which the P waves are not visible, or aid in detection of suspected rate-related bundle branch block or suspected pacemaker malfunction. After CSM, a wide-complex SVT may be converted to normal sinus rhythm, P waves may be revealed after increased AV node inhibition, or ventricular complexes may narrow as the ventricular rate slows. Because CSM slows atrial and not ventricular activity, AV dissociation may be more easily seen, indicating VT (Fig. 11-2). In rapid atrial fibrillation, or atrial flutter with 2:1 block, either P waves or irregular ventricular activity with absent P waves may be revealed. Sinus tachycardia may also be more apparent once P waves are unmasked by slowing the SA node (see Fig. 11-4). Adenosine may be used for the same diagnostic purpose in these situations as well. [13] In order of decreasing frequency, the electrocardiogram (ECG) changes seen with CSM and vagal maneuvers include those shown in Table 11-3 .

Equipment and Setup

As a precaution against hypotension and life-threatening dysrhythmias, an IV line with normal saline is often started before attempting any vagal maneuver, including the use of pharmacologic agents or electrical cardioversion. The patient should be placed on a cardiac monitor and pulse oximeter.

Figure 11-2 Ventricular Tachycardia. Carotid sinus massage (CSM) slows atria but not ventricles, thus establishing the presence of atrioventricular dissociation, supporting the diagnosis of ventricular tachycardia. The QRS measures 0.16 sec. Note the atrial rate slowing from 102 to 88 beats/min while the ventricular rate is unaffected. *(From Lown B, Levine SA: Carotid sinus—Clinical value of its stimulation. Circulation 23:766, 1961. Reproduced by permission.)*

Atropine and lidocaine, as well as a transvenous or transcutaneous pacemaker and defibrillator, should be readily available at the bedside. Oxygen and appropriate delivery systems plus standard airway management equipment should be readily available. The patient should be in the supine or *slight* reverse Trendelenburg position if it can be tolerated. Occasionally SVT will convert merely by lowering the back of the bed, presumably because the supine position results in a stretching of the carotid bulb, giving maximum baroreceptor sensitivity. The supine position may also prevent syncope in the event of a significant drop in heart rate or blood pressure.

Carotid Sinus Massage

Carotid sinus massage (CSM) is a bedside vagal maneuver technique involving digital pressure on the richly innervated carotid sinus. It takes advantage of the accessible position of this baroreceptor for diagnostic and therapeutic purposes. Its main diagnostic utility is in the differential diagnosis of syncope in the assessment of tachydysrhythmias and rate-related bundle branch blocks, and in clues to latent digoxin toxicity. Its main therapeutic application is for termination of SVTs due to paroxysmal atrial tachycardia (PAT).

A diagnostic indication for CSM is evaluating digoxin toxicity. Toxicity from digoxin depends more on the response of the host than on the actual digoxin level. In cases of suspected digoxin toxicity, before the level is available, or when the digoxin level is in the "normal range," CSM may be a useful diagnostic adjunct. Significant inhibition of AV node conduction associated with ventricular ectopy (see Fig. 11-9), especially ventricular bigeminy, should lead to the suspicion of digoxin toxicity. [1]

Other therapeutic uses of CSM have been made obsolete by current medical therapy. In 1961, Lown and Levine

Figure 11-3 Paroxysmal atrial tachycardia with variable block. Carotid sinus pressure uncovers P waves hidden in the ventricular complex. The upper strip resembles atrial flutter or atrial fibrillation with ventricular ectopic beats. The lower strip shows paroxysmal atrial tachycardia with variable block at an atrial rate of 166 beats/min. *(From Lown B, Levine SA: Carotid sinus—Clinical value of its stimulation. Circulation 23:766, 1961. Reproduced by permission.)*

described the dramatic effect CSM had in the 1920s on relieving acute pulmonary edema in a group of patients with hypertension and coronary artery disease. They reported: "Relief is immediate and coincides with the onset of bradycardia. In the majority, it is associated with a drop in blood pressure. The patient is promptly able to lie flat. Fear, dyspnea, and chest oppression disappear. ..." CSM also has been reported to relieve anginal pain. The technique may be useful when the diagnosis of angina is uncertain. [14] The advantage of the CSM technique over the use of nitroglycerin is unknown. Although CSM is no longer the first approach to either pulmonary edema or angina, it remains a therapeutic or adjunct diagnostic tool in some cases, or when modern pharmacological agents are unavailable. Because adenosine may not always be readily available, and because adenosine cannot be used to assess the sensitivity of the carotid sinus, CSM remains a useful bedside tool.

Contraindications

CSM is *contraindicated* in patients likely to suffer neurologic or cardiovascular complications from the procedure. Patients with a carotid bruit should not have CSM because of the risk of carotid embolization or occlusion. A recent cerebral infarction is a theoretical relative contraindication, because marginal reduction of cerebral blood flow may produce further infarction.

The presence of diffuse, advanced coronary atherosclerosis is associated with increased sensitivity of the carotid sinus reflex. This hypersensitivity is further augmented during an anginal attack or an acute myocardial infarction. Brown and coworkers found that the degree of carotid sinus hypersensitivity was directly proportional to the severity of coronary artery disease documented by cardiac catheterization. [18] Patients with acute myocardial ischemia or with recent

Figure 11-4 Sinus tachycardia. The sinus P wave is obscured within the descending limb of the T wave. Carotid sinus massage (CSM) transiently slows the sinus rate and exposes the P wave. The rate then increases. The strips are continuous. *(From Silverman ME: Recognition and treatment of arrhythmias. In Schwartz GR, Safar P, Stone JH, et al (eds): Principles and Practice of Emergency Medicine, vol. 2. Philadelphia, WB Saunders, 1978. Reproduced by permission.)*

myocardial infarction are already at higher risk of VT or ventricular fibrillation (VF). A CSM-induced, prolonged asystole may further predispose them to these dysrhythmias. Therefore, CSM should be avoided in these patients when pharmacologic alternatives are available.

Both digoxin and CSM act through a vagal mechanism to inhibit the AV node. Patients on digoxin may experience a greater inhibition of the AV node with longer AV block as a result. Patients with *known* digoxin toxicity should not have CSM, as AV inhibition may be profound. [19] However *cautious* CSM (as noted above) may be a useful diagnostic tool when the diagnosis is less certain.

Simultaneous bilateral CSM is absolutely contraindicated, because cerebral circulation may be severely compromised. Before attempting CSM, the clinician should first auscultate for carotid bruits on both sides of the neck. The presence of a bruit is a contraindication to massage.

Technique

The clinician should begin CSM on the patient's right carotid bulb, as some investigators have found a greater cardioinhibitory effect on this side [12] [15] [16] ; although no difference was found in one study.[10]

Keeping the patient relaxed is helpful for two reasons: A tense platysma muscle makes palpation of the carotid sinus

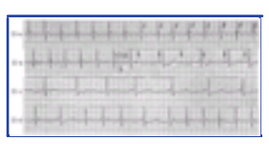

Figure 11-5 Sinus tachycardia with high-degree atrioventricular block. Arrows indicate sinus P waves. Strips II-a to II-d are continuous. The basic rhythm is sinus, but marked first-degree atrioventricular block is present. High-degree (advanced) atrioventricular block associated with transient slowing of sinus rate is produced by carotid sinus stimulation (CSS). *(From Chung EK: Electrocardiography, 2nd ed. New York, Harper & Row, 1980. Reproduced by permission.)*

difficult, and an anxious patient will be less sensitive to CSM as a result of heightened sympathetic tone.

With the head tilted backward and slightly to the opposite side, palpate the carotid artery just below the angle of the mandible at the upper level of the thyroid cartilage and anterior to the sternocleidomastoid muscle. Once the pulsation is identified, use the tips of the fingers to administer CSM for 5 seconds in a posteromedial direction, aiming toward the vertebral column. Although earlier practitioners used a longer duration of massage, a shorter period of massage minimizes the risk of complications and is adequate for diagnostic purposes in the majority of patients. [17] Pressure on the carotid sinus may be steady or undulating in intensity; the force, however, must not occlude the carotid artery. The temporal artery may be simultaneously palpated to ensure that the carotid remains patent throughout the procedure.

If unsuccessful, CSM may be repeated after 1 minute. If the procedure is still unsuccessful, the opposite carotid sinus may be massaged in a similar fashion. Simultaneous Valsalva maneuvers may also enhance carotid sinus sensitivity.

Complications

Neurologic complications of CSM are rare and are usually transient. In one review of neurologic complications in elderly

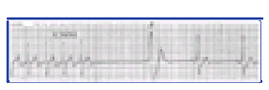

Figure 11-6 Paroxysmal atrial tachycardia. Carotid sinus massage (CSM) abolishes the dysrhythmia and results in a period of sinus suppression with a junctional (J) escape beat, followed thereafter by a sinus rhythm. Prolonged periods of asystole may produce anxiety in the clinician who is waiting for the resumption of a sinus pacemaker. *(From Silverman ME: Recognition and treatment of arrhythmias. In Schwartz GR, Safar P, Stone JH, et al (eds): Principles and Practice of Emergency Medicine, vol 2. Philadelphia, WB Saunders, 1978. Reproduced by permission.)*

patients undergoing this procedure, Munro and others found 7 complications from a total of 5000 massage episodes, for an incidence of 0.14%. [20] Reported deficits included weakness in 5 cases and visual field loss in two others. In one case, the visual field loss was permanent. Patients in this study were excluded from CSM if they had a carotid bruit, recent cerebral infarction, recent myocardial infarction, or a history of VT or VF. The duration of massage was 5 seconds. Lown and Levine described one patient with brief facial weakness during several thousand tests. [1] Carotid emboli and hypotension have both been implicated as possible causes of the neurologic deficits. Unintentional occlusion of the carotid artery, if the contralateral circulation is impaired, may also be responsible for some neurologic complications.

Cardiac complications include asystole, VT, or VF (Fig. 11-10). A normal pause of <3 seconds is part of the physiologic response to CSM; a longer pause may be diagnostic of carotid sinus syndrome. In a review of reported cases of ventricular tachydysrhythmias, 5 cases were described. [21] All 5 patients were receiving digoxin, and in several cases, VT or VF followed AV block. Digoxin is associated with more prolonged AV block resulting from CSM, perhaps leaving these patients more vulnerable.

Interpretation of Vagal Maneuvers

A pause >3 seconds, or a drop in systolic blood pressure >50 mm Hg in patients to whom CSM is administered while they are in a supine position, is diagnostic of the carotid sinus syndrome (Fig. 11-11). Patients should be supine during testing to reduce the risk of cerebral hypoperfusion. [12] [22]

Although the carotid sinus massage is one of the better known vagal maneuvers, a variety of other physical modalities are available to the clinician to affect a change in heart

Figure 11-7 Atrial flutter. Carotid sinus stimulation (CSS, *downward arrow*) produces marked slowing of the ventricular rate in atrial flutter. Note the obvious flutter waves with an atrial rate of 300 and a long period of ventricular standstill. Strips are continuous. *(From Chung EK: Electrocardiography, 2nd ed. New York, Harper & Row, 1980. Reproduced by permission.)*

rate. The anticipated rhythm response to different vagal maneuvers in the setting of different underlying rhythms is shown in Table 11-4 .

Valsalva Maneuver

In general, mean bradycardia changes are greatest for the Valsalva maneuver and the diving response. [3] [22] [23] During the Valsalva maneuver, intrathoracic pressures are increased, leading to increased arterial pressure. This increased pressure is transferred to the peripheral vascular system. Venous return to the heart is decreased, resulting in a decreased stroke volume. This is followed by increased venous pressure. All of these pressure changes lead to an initial increase in heart rate and carotid sinus pressure. As the maneuver is sustained, vagal tone is increased leading to a compensatory decrease in SA and AV conduction (the desired diagnostic/therapeutic response).

Contraindications

Patients must be able to cooperate with the clinician's commands. Remember that dyspneic or tachypneic patients may not be able to hold their breath for the period of time needed to complete the maneuver.

Technique

The patient is placed supine and a cardiac monitor is attached. Ideally, intravenous (IV) access is secured, and atropine, lidocaine, and defibrillation equipment are available. Have the patient take a deep breath and hold it. Instruct the patient to bear down and try to exhale without allowing the air to leave the lungs. The patient should try to hold this position for 10 to 20 seconds. [24] [25] An adjunct method is to have the patient take a deep breath, hold the breath and try to push the clinician's

Figure 11-8 Atrial fibrillation. Carotid sinus massage (CSM) slows the ventricular response transiently, revealing the fibrillating baseline. The ventricular rate subsequently accelerates. *(From Silverman ME: Recognition and treatment of arrhythmias. In Schwartz GR, Safar P, Stone JH, et al (eds): Principles and Practice of Emergency Medicine, vol. 2. Philadelphia, WB Saunders, 1978. Reproduced by permission.)*

hand off the patient's abdomen as the clinician gently pushes on the anterior wall of the abdomen.

Apneic Facial Exposure to Cold ("Diving Response," Diving Bradycardia) Technique.

This *technique* represents a variation on the simple valsalva maneuver. It has been found useful in children who may be unable to volitionally do a valsalva maneuver. Classically the technique consists of facial immersion, without breathing, for 15 to 30 seconds in cold water (0°C to 15°C). Alternatively ice water can be dripped into the nostril of a small child. Be sure to monitor the oxygen saturation closely when applying this technique to a small child.

The procedure is based on the classic diving reflex of bradycardia. Slowing of SVT to unmask the hidden, underlying rhythm is similar to the effects of CSM. The conversion of paroxysmal atrial tachycardia to sinus rhythm should be observed in 15 to 35 seconds. The procedure is convenient and noninvasive, and can be self-administered.[26] [27] [28] [29] [30] [31]

Oculocardiac Reflex (OCR, Trigeminovagal Reflex)

This reflex is clinically significant during strabismus surgery in children, although the manifestations of this reflex are not consistent. The oculocardiac reflex (OCR) is induced by pressure on the eyeball. Afferent pathway follows the long and short ciliary nerves to the ciliary ganglion. From there, it travels to the gasserian ganglion body along the ophthalmic division of the trigeminal nerve (CN V). The afferent pathway ends in the main trigeminal sensory nucleus in the floor of the fourth ventricle.[4] [23] [24]

Efferent impulses start at the vasomotor center and travel through the vagal nerve (CN X) and the sympathetic chain. Bradycardia results from increased parasympathetic tone.

Figure 11-9 Occult premature ventricular contractions. Carotid sinus massage (CSM) reveals ventricular extrasystoles, thereby explaining the cause of palpitation in this case. *(From Lown B, Levine SA: Carotid sinus—Clinical value of its stimulation. Circulation 23:766, 1961. Reproduced by permission.)*

Decreased sympathetic tone causes vasodilation. The cardiac effect stops when eye pressure is relieved. [23] Patients should be monitored to recognize ECG changes. Atropine should be available to reverse life-threatening bradycardia.

Contraindications

Common sense dictates that the clinician should try to elicit history of the following conditions prior to attempting the oculocardiac reflex: (a) recent retinal or lens surgery; (b) glaucoma; (c) thrombotic-related eye conditions, which all seem to be obvious possible contraindications. Care should be taken when pressing on the eye globe to prevent corneal or scleral injury.

Technique

With the eyelid closed, non-rotating pressure is applied to the eyeball for 10 to 20 seconds. There is no advantage to the use of either eye. Ventricular slowing and possible decrease in blood pressure should be observed almost immediately when the pressure is applied. The cardiac effect of bradycardia will cease when pressure is removed. As with all vagal maneuvers, monitoring, IV access, atropine, lidocaine, and defibrillation should be available during the procedure.

Summary

Berk and colleagues have demonstrated in healthy volunteers that cold-water face immersion and the Valsalva maneuver can produce a greater vagal response than CSM.[15] Mehta and colleagues also found that the Valsalva maneuver was more effective than CSM for conversion of induced SVT. [16] [32] The pneumatic antishock garment has also been used to similarly increase vagal tone by stretching the carotid bulb. [33]

TABLE 11-3 -- Order of *Decreasing* Frequency of Electrocardiogram Changes with Vagal Maneuvers

1. SA slowing, occurring in approximately 75% of cases (sinus arrest occurs approximately 3% of the time)
2. Atrial conduction defects, manifested by an increase in width of the P wave on the electrocardiogram
3. Prolongation of the PR interval and higher degrees of atrioventricular block, seen in approximately 10% of cases
4. Nodal escape rhythms
5. Complete asystole, defined as sinus arrest without ventricular escape lasting >3 seconds, occurring in 4% of cases
6. Premature ventricular contractions

SELECT PHARMACOLOGIC AGENTS

Digoxin

This time-honored drug was previously a mainstay for treatment of atrial fibrillation and atrial flutter. It is the only anti-dysrhythmic with inotropic properties, but is uncommonly used by the emergency clinician because of its long delay of onset.

Digoxin is a cardiac glycoside found in a number of plants. It is commonly extracted from the leaves of the *Digitalis lanata* plant, and increases the intracellular Na+ by inhibiting Na-K-ATPase. This is the enzyme that regulates the quantity of Na+ and K+ inside the cell. Intracellular increases in the sodium ion concentration stimulate sodium/calcium exchange, leading to increased intracellular Ca+. The increased intracellular calcium can lead to increased contractility.

Digoxin has both a direct action on cardiac muscles and an indirect action on the cardiovascular system. The indirect effects are mediated by the autonomic nervous system. The results of these actions are vago-mimetic effects on the SA node and the AV node.

The consequences of these combined actions are: (1) increased force and velocity of myocardial contraction (positive inotropic effect); (2) slowing of the heart rate and AV nodal conduction (vago-mimetic effect); and (3) decrease in symptomatic nervous system effects (neurohormonal deactivating effect). [34] [35] [36] [37] [38] [39]

Indications and contraindications.

Though its use in rate control of the ventricular response in chronic atrial fibrillation is well established, it is no longer the mainstay of therapy for narrow-complex tachycardias. Newer agents have replaced digoxin in the treatment and management of narrow-complex tachycardias. Its inotropic character is still widely used in the setting of heart failure.

Figure 11-10 A run of ventricular tachycardia is seen immediately after a supraventricular dysrhythmia is terminated by cardiac sinus massage (CSM). The patient remained asymptomatic, and a normal sinus rhythm was established spontaneously within a few seconds.

Use of digoxin should be avoided in the clinical settings of sinus node disease and AV blockade. It may cause complete heart block or severe sinus bradycardia. It should not be used in the presence of accessory bypass tract rhythms (Wolf-Parkinson-White [WPW]) or Long-Ganong-Levine [LGL] syndromes) as it may cause a rapid ventricular response or VF. Patients with idiopathic hypertrophic sub-aortic stenosis (IHSS), restrictive cardiomyopathy, constrictive pericarditis, or amyloid heart disease are particularly susceptible to digtoxicity. [40]

Dosage: IV loading dose of 10 to 15 mcg/kg followed by individual parenteral dosing until desired rate is achieved. [37] [38] [41] [42] [43] [44] [45] [46] [47]

Procainamide

Another time-honored antiarrhythmic, procainamide slows conduction and decreases automaticity and excitability of atrial, ventricular, and Purkinje tissue. It also increases refractoriness in atrial and ventricular tissue. Procainamide prolongs the QT interval with little effect on Purkinje fibers or ventricular tissue. [38] [41] [46]

Indications and contraindications.

The drug is used in the rhythm and rate management of SVT, SVT with aberrancy conduction (wide-complex SVT), atrial fibrillation/flutter associated with WPW conduction, and VTs. The advantage to using IV procainamide is the ability to convert to the oral form when rate control is achieved.

The loading interval for procainamide is 20 minutes. This limits use of the drug to clinical situations when time is not a critical factor in patient care. Long-term management in the emergency department (ED) necessitates monitoring of the plasma concentrations of procainamide and its NAPA metabolite. Hypotension and conduction disturbances (torsades de pointes, heart blocks, and sinus node dysfunctions) are often signs of high plasma levels. Caution should be used in patients with histories of hypokalemia, long QT intervals, or torsades de pointes. Hematologic and rheumatologic disturbances are factors in long-term use.

Dosages: Over 25 minutes, a loading infusion of 275 mcg/kg per minute is administered. This is followed by a maintenance infusion of 20 to 60 mcg/kg per minute. [48] [49]

Adenosine

The use of vagal maneuvers has been eclipsed in recent years by the use of adenosine. The drug is an endogenous, ultrashort-acting vagal-stimulating nucleotide that occurs in all body cells. Its primarily action is to slow conduction time through the AV node.

Extracellular adenosine is rapidly cleared from the circulation by the erythrocyte and vascular endothelium system,

Figure 11-11 Hyperreactive carotid sinus reflex. Gentle pressure was applied to the carotid sinus for 3 seconds, resulting in a pause in sinus rhythm of approximately 7 seconds. This syndrome may be the cause of syncope. *(From Bigger JT Jr: Mechanisms and diagnosis of arrhythmias. In Braunwald E (ed): Heart Disease, vol 1. Philadelphia, WB Saunders, 1980. Reproduced by permission.)*

which transports adenosine intracellularly. Once inside the cell, rapid metabolism occurs via a phosphorylation or deamination cycle, producing inosine or adenosine monophosphate. Adenosine produces a short-lived pharmaceutical response because it is rapidly metabolized by the described enzymatic degradation. The half-life of adenosine is <10 seconds with the metabolites becoming incorporated into the phosphate, high-energy pool. [37] [38] [46] [50]

Indications and contraindications.

(1) Most forms of paroxysmal supraventricular tachycardia (PSVT) involve a reentry pathway involving the AV node: Adenosine is effective because it depresses the AV node and sinus node activity. Adenosine is indicated for the conversion of PSVT associated with or without accessory tract bypass conduction (WPW, LGL). (2) The other use of adenosine is in diagnostic slowing of SVT to unmask atrial fibrillation, atrial flutter, or ventricular tachycardia. The diagnostic and therapeutic effects of adenosine on tachydysrhythmias are similar to those elicited by the vagal maneuvers. Adenosine's safety is derived from its short duration of action—usually about 10 to 12 seconds.

Adenosine *should not* be used in patients with a known history of second- or third-degree atrioventricular block or sick sinus syndrome, unless there is a functioning internal pacer. Adenosine *should not* be used in patients with an underlying accessory tract bypass conduction (WPW, LGL) in the setting of atrial flutter/fibrillation. In this circumstance the heart rate may accelerate when enhanced AV node blockade permits greater use of the bypass tract. Also, if the patient has a known

hypersensitivity to the adenosine, the drug should not be used.

Dosage: The recommended initial dose is a 6-mg rapid bolus over 1 to 3 seconds. The dose should be followed by a rapid 20-mL saline flush. If there is no response within 1 to

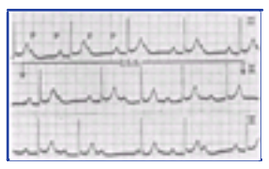

Figure 11-12 Acceleration of ventricular rate by carotid sinus stimulation (CSS). Continuous tracing. Upper strip shows 2:1 atrioventricular block: Atrial rate at approximately 102/min; ventricular rate at approximately 51/min. The second and third strips were recorded during and after CSS, when the atrial rate was reduced to 68/min; a 1:1 response occurs. *(From Lown B, Levine SA: Carotid sinus—Clinical value of its stimulation. Circulation 23:766, 1961. Reproduced by permission.)*

2 minutes, a 12-mg repeated dose should be administered in the same manner as the initial dose. This second dose should again be followed by a 20-mL saline bolus.

Side effects of adenosine are common and transient. They include flushing, dyspnea, and chest pain. Patients should be warned of a brief, but intense chest pressure. The use of 1 mg of midazolam (in the patient with an adequate blood pressure) intravenously before the adenosine is appreciated by patients treated with this agent. Important drug interactions include theophylline or related methylxanthines (caffeine and theobromine) that can block the adenosine receptor sites. Dipyridamole may block adenosine uptake and potentiate its effects. Dose adjustments or alternate therapies should be considered in these patients. [13] [37] [41] [46] [51]

Amiodarone

Amiodarone has become one of the workhorses of dysrhythmia treatment in the ED. As a Class III drug, amiodarone blocks the potassium channels, thereby prolonging repolarization and action potential duration, as well as, causing increased refractoriness of the atrial and ventricular tissues, the sinus and AV nodal tissues, and the Purkinje fibers. Amiodarone also blocks the sodium channel in depolarized tissues. At the sinus node and AV node, amiodarone slows depolarization in the SA node and slows conduction through the AV node. It blocks alpha and beta adrenergic receptors. Its calcium antagonist effect is minimal. [19] [38] [46] [52]

Indications and contraindications.

Amiodarone is used in the control of narrow-complex supraventricular and ventricular dysrhythmias. It is effective in the conversion of wide-complex tachycardias. These include atrial fibrillation and flutter with aberrancy, SVT with accessory pathway

TABLE 11-4 -- Ventricular Response to Carotid Sinus Massage (CSM) and Other Vagal Maneuvers

Type of Arrhythmias	Atrial Rate (bpm)	Response to CSM and Release
Normal sinus rhythm	60–100	Slowing with return to former rate on release
Normal sinus bradycardia	< 60	Slowing with return to former rate on release
Normal sinus tachycardia	> 100–180	Slowing with return to former rate on release, appearance of diagnostic P-waves
AV nodal re-entry	150–250	Termination or no effect
Atrial flutter	250–350	Slowing with return to former rate on release, increasing AV block: flutter persists
Atrial fibrillation	400–600	Slowing with persistence of gross irregular rate on release, increasing AV block
Atrial tachycardia w/block	150–250	Abrupt slowing with return to normal sinus on release, tachycardia often persists
AV junctional rhythm	40–100	None, +/- slowing
Reciprocal tachycardia using accessory (WPW) pathways	150–250	Abrupt slowing, termination or no effect, may unmask WPW
Nonparoxysmal AV junctional tachycardia	60–100	None, +/- slowing
Ventricular tachycardia	60–100	None, may unmask AV dissociation
Atrial idioventricular rhythm	60–100	None
Ventricular flutter	60–100	None
Ventricular fibrillation	60–100	None
First-degree AV block	60–100	Gradual slowing caused by sinus slowing, return to former rate on release
Second-degree AV block (I)	60–100	Sinus slows with increase in block, return to former rate with release
Second-degree AV block (II)	60–100	Slowing
Third-degree AV block	60–100	None
Right bundle branch block	60–100	Slowing with return to former rate with release
Left bundle branch block	60–100	Slowing with return to former rate with release
Digitalis toxicity-induced dysrhythmias	Variable	Do not attempt CSM

AV, atrioventricular; WPW, Wolf-Parkinson-White.

Adapted from Braunwald: Heart Disease. A Textbook of Cardiovascular Medicine, 6th ed. Philadelphia, WB Saunders, 2001, p 642.

conduction, and the rare adult junctional tachycardia. It is a strong second-line choice with procainamide for hemodynamically stable VT.

Its use can precipitate heart failure, hypotension, and severe bradycardia. When used with beta-blockers and calcium channel blockers, amiodarone increases the risk of hypotension and bradycardia. Torsades de pointes has been reported after the use of amiodarone in conjunction with drugs that prolong the QT interval.

Dosage: The IV dosage is 5 mg/kg (up to 150 mg over 10 minutes in adults; may repeat once if stable) given over 5 to 30 minutes, followed by a 0.4–0.8 mg/kg/hr maintenance infusion.[19] [35] [38] [46] [47] In adults the maximum daily dose is 2.2 gm/day.

Calcium Channel Blockers

Verapamil

Verapmil is a slow channel inhibitor, which exerts its rate reduction effect by controlling the calcium influx across the cell membrane of myocardial conduction and contractile cells. Verapamil prolongs the effective refractory period within the AV node and slows conduction. [3] [47]

Indications and contraindications.

Verapamil is effective in (1) converting narrow-complex PSVT to normal sinus rhythm, and (2) controlling the ventricular response in atrial fibrillation or atrial flutter, given that the atrial fibrillation or atrial flutter is not complicated by the presence of an accessory bypass tract (WPW, LGL).

Verapamil should not be used in the following settings: (1) atrial fibrillation/flutter with accessory bypass tract conduction; (2) coexistence of a sick sinus syndrome or second- or third-degree AV block unless an internal pacer is present; (3) severe left ventricular dysfunction (SBP < 90 mm Hg) or cardiogenic shock; and (4) patients with a known verapamil hypersensitivity. [13] [38] [41] [46] [47] [53]

Dosages: The initial adult dose is 2.5 to 5.0 mg IV over 2 minutes. If the initial dose is tolerated, but insufficient to affect the rhythm or rate, a repeat dose of 5 to 10 mg may be administered every 15 to 30 minutes to a maximum of 20 mg.[13] [38] [46] [47] [52] [54]

Diltiazem

Diltiazem works by inhibiting influx of Ca+ ions during cardiac muscle membrane depolarization. The therapeutic benefits in SVTs are derived from diltiazem's ability to slow AV nodal conduction and prolong AV nodal refractoriness. Its effects on AV nodal tissue are selective in that it reduces AV conduction in tissue responsible for the tachydysrhythmia but spares normal conduction tissue. [46] [47] [52] [54]

Indications and contraindications.

Its beneficial effects are (1) ventricular slowing of rapid atrial fibrillation/flutter without accessory bypass conduction, and (2) rapid conversion of narrow-complex PSVT to sinus rhythm.[38] [41] [52] [54] [55]

Diltiazem is contraindicated in the following settings: (1) sick sinus syndrome, second-degree block, and third-degree block, except in the presence of an internal pacer; (2) severe hypotension or cardiogenic shock; (3) diltiazem

---

hypersensitivity; (4) use of IV beta-blockade within a few hours of need to use diltiazem; (5) atrial fibrillation or flutter with coexisting accessory bypass tract conduction (WPW, LGL); and (6) VT.

Dosage: An initial dose of 0.25 mg/kg over 2 min can be followed by a repeat dose of 0.35 mg/kg over 2 min. Maintenance infusion should be at 5 to 15 mg/hr for adults.[19] [41] [52] [54]

ß-Adrenergic Blockade

ß-blockers are very useful agents for the control of ventricular response in PSVT, atrial fibrillation or flutter, and atrial tachycardia. It is generally considered that no ß-blocker offers a distinctive advantage over another because they can be titrated to the desired effect on dysrhythmias and hypertension. However, the drugs do differ regarding their adverse reactions, speed of onset, half-life, dosage regimens, contraindications, and drug interactions.

The electrophysiological effect of ß-blockers results from the inhibition of catecholamine binding at ß-receptor sites. Their actions are on cells that are most stimulated by adrenergic actions. Typically, these sites are the sinus node, the Purkinje fibers, and ventricular tissue. [3] [38] [46] [47]

Propranolol

Propranolol is the representative drug of the ß-adrenergic blockade agents and is considered nonselective with respect to its ß-1 and ß-2 receptor antagonism. Its ß-1 effect on the heart allows for its use in controlling rapid ventricular rates. Rate slowing is mediated by (1) slowing SA node impulse formation, and (2) depression of myocardial contractility. The usual effects on the ECG are rate reduction and prolongation of the PR interval without much of an impact on QRS and QT intervals.

Because it is relatively nonselective (having effects on both a-1 and ß 1 & 2 receptors), propranolol's contraindications are somewhat extensive. [38] [47] [56] ß-blockers should be used in patients with a history of diabetes, bronchospasm, bradycardia or heart block, prior use of calcium channel blockers, hypotension, or the presence of a vasospasm condition.

Dosage: In the adult, IV propranolol is given in boluses of 0.5 to 1.0 mg, over 1 to 2 minutes, every 10–15 minutes until the desired rate is achieved, or the appearance of side effects, or a total dose of 0.2 mg/kg has been administered. [38] [39] [41] [46] [56] Children should receive a loading dose of 0.01 to 0.1 mg/kg every 10 minutes (up to 1 mg maximum single dose) with titration to effect.

Esmolol

Esmolol is a ß-1-selective (cardiac) ß-blocker with rapid action and short duration of action. At therapeutic doses, it inhibits ß-1 receptors. At higher doses, the selectivity is lost and it affects ß-2 receptors in the lung and vascular system. Esmolol is rapidly metabolized in erythrocytes and has a half-life of about 2 minutes. Its elimination half-life is approximately 9 minutes. [46] [52]

Indications and contraindications.

Esmolol is indicated for the rapid conversion of SVT and the rapid control of ventricular rate in patients with nonpreexcitation, atrial fibrillation, or flutter. It may be effective as adjunct therapy in the ventricular tachycardia of *torsades de pointes*.[41] [46] [47] [52]

Esmolol should not be used in patients with second- or third-degree heart block, or in frank heart failure. Like all ß-adrenergic blockers, care should be exercised when used in patients with bronchospastic disease and diabetes.

Dosage: This drug has a complicated dose regimen. An adult loading dose of 500 mcg/kg is given over the first minute. This is followed by a maintenance infusion of 50 mcg/kg per minute over 4 minutes. If this is not successful, a second bolus dose of 500 mcg/kg followed by a maintenance infusion of 100 mcg/kg per minute over 4 minutes is started. This bolus/maintenance dosing can be repeated up to a maximum infusion rate of 300 mcg/kg per minute for 4 minutes. [46] [47] [52] Similar dosing has been recommended for children using a 100–200 mcg/kg maintenance rate between 100 mcg/kg increases in bolus doses.

Special Consideration of Anticoagulation in Atrial Fibrillation: Evaluation and Treatment

The most common sustained tachydysrythmia that presents to the ED is atrial fibrillation (AF). Its incidence in the general population is 1% to 2%. The incidence increases with age. Approximately 1% of the population under 50 years of age has AF while 8.8% of the population older than 80 years of age has AF. [57] The connection between AF, structural heart disease, and antecedent coronary artery disease is strong. Atrial fibrillation is relatively uncommon in acute myocardial infarction (11%). Where, its added presence is associated with a 40% mortality. [58] The long recognized association between valvular heart disease and atrial fibrillation has been well documented. Rheumatic valvular disease is the classic valvular disease associated with atrial fibrillation. There are, however, other dysrhythmias associated with atrial fibrillation including WPW syndrome, atrial tachycardia, sick sinus syndrome, and AV nodal reentrant tachycardias. Long-standing medical or cardiac conditions that have strong associations with atrial fibrillation are hypertension, cardiac myxomas, diabetes, thyroid disease, left ventricular dysfunction, congestive heart failure, pulmonary edema, chronic obstructive pulmonary disease, and pulmonary embolism. [36] [58] [59]

Atrial fibrillation was initially thought to be caused by abnormal pulse formation originating in the atria. The theory was that the atria, as a result of disease, drug toxicity, or excessive endogenous hormones (i.e., catecholamines) trigger spontaneous automaticity of a sufficient number of atrial cells in multiple atrial sites. The hypothesis was that the chaotic, simultaneous firing of atrial impulses travel to the ventricles over multiple irregular routes. The transmission of these erratic low-amplitude atrial or fibrillatory "f" waves through the AV node to the ventricle creates the classic irregularly, irregular rhythm. [58] [60]

In 1959 the Russian researchers Moe and Abildskov presented their hypothesis that atrial fibrillation was a self-sustaining rhythm, independent of multiple firing focus, which was later verified in 1985.[61] At that time an animal model was constructed, showing that four to six waves or "wavelets" were needed to sustain atrial fibrillation in a multiple circulating wave of atrial reentry. These wavelets interact to maintain the optimum atrial conditions needed to maintain sustained atrial fibrillation. [58]

TABLE 11-5 -- Guidelines for Anticoagulation in Atrial Fibrillation and Cardioversion

ATRIAL FIBRILLATION
I. Duration under 48 hrs
Low risk for thromboembolism
Immediate electrical cardioversion if unstable
No anticoagulation necessary
II. Duration greater than 48 hrs or undetermined
Intermediate to high risk for thromboembolism
Immediate electrical cardioversion if unstable
Stable clinical situation
Warfarin: International Normal Ratio 2.0 to 3.0 for 3 weeks ⇒
Cardioversion, then warfarin: INR 2.0 to 3.0 for 4 weeks;
OR,
Transesophageal echo (TEE) and heparinization
Left atrial appendage clot not present ⇒
Cardioversion, then continue warfarin: INR 2.0 to 3.0 for 4 weeks
Left atrial appendage clot present ⇒
Continue warfarin: INR 2.0 to 3.0 for 4 weeks, then cardioversion

Adapted from Pelosi and Morady: Evaluation and management of atrial fibrillation. Med Clin North Am 85(2) March 2001, p 225.

Any adverse effects from this tachydysrhythmia are related to the disruption of the normal filling and ejection components of the cardiac cycle, especially if the atrial fibrillation is accompanied by a rapid ventricular rate. Classically, patients with atrial fibrillation present with feelings of palpitations, exertional fatigue, dyspnea on exertion, and lightheadedness. Patients subsequently develop fluid overload, congestive failure, frank pulmonary edema, and myocardial ischemia. [58] [62] [63]

Treatment of symptomatic rapid ventricular response to atrial fibrillation focuses upon three treatment fronts: (1) slowing the rapid ventricular response, (2) conversion to normal sinus rhythm, and (3) prevention of thromboembolism. The next section will address the issue of anticoagulation and prevention of thromboembolism. [52] [58] [63] [64]

Thromboembolism as Related to Cardioversion

Restoration of symptomatic new-onset atrial fibrillation to normal sinus rhythm can be achieved with direct cardioversion using either monophasic or biphasic defibrillators. In life-threatening presentations, patients in atrial fibrillation are immediately cardioverted if the risk of continued atrial fibrillation outweighs the risk of thromboembolism (Table 11-5).[52] [58] [63] [65]

The current guidelines for treatment of symptomatic new-onset atrial fibrillation focus on the length of time the patient has been in atrial fibrillation or flutter. If a patient has been in atrial fibrillation for less than 48 hours, cardioversion can be performed without the need for anticoagulation. Some clinicians will perform a TEE prior to cardioversion, to assure the lack of cardiac thrombi, if this time frame is questionable or unclear. Studies have shown that staying under the 48-hour limit allows cardioversion to occur with the lowest risk for thromboembolism. [52] [58] [63] [66] For patients who have been in atrial fibrillation greater than 48 hours and are not in need of urgent care, the recommendation is anticoagulation to an INR of 2.0 to 3.0 for a 3-week duration before cardioversion. [56] If this approach is not clinically acceptable, the patient should have a transesophageal echo (TEE), and heparin therapy should be initiated.

If no left atrial appendage clot is visualized on TEE, the heparinized patient should be immediately cardioverted and continued to be anticoagulated for the next 4 weeks. If a left atrial appendage clot is visualized, the patient should be anti-coagulated to an INR of 2.0 to 3.0 for 3 weeks' duration and cardioverted (see Table 11-5).[67] [68] [69] [70] [71]

A synchronized shock from a monophasic or biphasic defibrillator (see Chapter 12) should be delivered with the patient sedated. Success rates with the biphasic defibrillators have been reported to be approximately 94% to 95%. [72] [73] [74] An alternative treatment strategy with a reported success rate of 50% to 70% is the use of ibutilide in a bolus infusion or the use of amiodarone. Caution must be exercised in the use of ibutilide in patients with prolonged Q-T intervals or severe left ventricular dysfunction. Ibutilide has a 4% risk of ventricular proarrhythmia. Pretreatment with ibutilide of patients to be electrically cardioverted can increase their chances for conversion successful to nearly 100%. [37] [38] [47] [75] [76] [77] [78]

Amiodarone has the advantage of being effective for tachydysrhythmias when the mechanism is unclear with either wide-complex or narrow-complex tachycardias. Central venous access is advised if concentrations greater than 2 mg/mL are to be used. In adults, amiodarone should be given as an initial bolus of 5 mg/kg over 20 to 30 minutes, followed by a maintenance infusion of 1.0 g/24 hours for a total of 48 to 72 hours. [35] [37] [42] [46]

Other drugs with good to excellent evidence in obtaining rate control in narrow-complex atrial fibrillation include verapamil, diltiazem, procainamide, and ß-blockers. [38] [41] [46] [47] [58] These agents can be used to provide rate control until electrical cardioversion at a subsequent time.

CONCLUSIONS

The advent of ß-blockers, calcium channel blockers, adenosine, amiodarone, and other effective medications to treat tachydysrhythmias—particularly the SVTs—has diminished the therapeutic use of the vagal maneuvers. However, the vagal maneuvers still remain an important diagnostic tool. These maneuvers are especially important in unmasking the underlying rhythms of narrow-complex tachydysrhythmias and in determining the presence of the carotid sinus syndrome in patients with syncope.

The advent of medications and defibrillators, which can quickly and safely control the rate in tachydysrhythmias, has given the emergency clinician a more varied and powerful armamentarium to be used in cardioverting these life-style and even life-threatening dysrhythmias to normal sinus rhythms.

Chapter 12 - Defibrillation and Cardioversion

Bohdan M. Minczak
John R. Krimm

DEFIBRILLATION

Ventricular fibrillation (VF) is a potentially lethal dysrhythmia that is frequently associated with sudden cardiac death. [1] [2] [3] In addition to being associated with sudden cardiac death (SCD), independent of myocardial infarction (MI), VF often occurs as a result of myocardial ischemia, myocardial infarction, undiagnosed coronary artery disease, and electrical injuries. Use of medications such as tricyclic antidepressants, digitalis, quinidine, and other proarrhythmics that cause Q-T segment prolongation has been implicated in precipitating VF. Furthermore, chest trauma, hypothermia, profound hyperkalemia/hypokalemia, hypocalcemia, hypercalcemia, and other electrolyte disturbances can induce conditions favoring the development of VF. Although significant mortality and morbidity occurs as a result of persistent VF,[3] aggressive, early recognition and treatment in the form of defibrillation, cardiopulmonary resuscitation (CPR) and medications can provide reasonable success in reestablishing a perfusing (hopefully supraventricular) rhythm. [4] [5] Spontaneous conversion of VF to sinus rhythm, although rarely reported, is highly unlikely. [6]

The most effective treatment of VF is timely defibrillation. [2] [7] [8] [9] A significant number of victims of SCD can potentially be saved if there is access to early defibrillation (defined as defibrillation under 4 minutes of onset). [4] [10] [11] [12] In addition, the provision of CPR and, in some instances, medication may increase the success rate of resuscitation and bring about return of spontaneous circulation (ROSC). [13] However, successful defibrillation implies delivering the appropriate amount of current or energy to the fibrillating myocardium, such that the chaotic electrical activity is terminated and a supraventricular perfusing rhythm is established.[14] The delivery of current to the myocardium should be such that minimal damage is done to the existing myocytes so further dysrhythmias are not perpetuated.[15] Development of new biphasic defibrillation waveforms has set the stage for decreasing damage and may enhance successful defibrillation. [16]

Depending on the duration of myocardial ischemia and VF, administration of CPR prior to defibrillation may be the most appropriate intervention to achieve a better outcome.[17] Once defibrillation is successful, victims of VF have a tendency to refibrillate and may need pharmacological prophylaxis. [18] [19]

Lack of success for in-hospital resuscitation appears to result from delays in time to first shock from collapse. [20] [21] The development of cardiac resuscitation teams for both in-hospital and pre-hospital arenas and the development of automatic external defibrillators (AEDs) have increased the potential for the provision of rapid access to defibrillation. Therefore, an increased awareness of the need for early access to defibrillation, a familiarity with the pathophysiologic timeline of VF, and the appropriate sequence of interventions may lead to greater success in defibrillation and more survivors of SCD both in and out of hospital.

BACKGROUND

In 1775, long before the description of ventricular fibrillation and defibrillation, Peter Christian Abildgaard, a Danish physician and veterinarian, studied the effects of electric shock on chickens. He noted that the first shock rendered the chickens "lifeless" while a second countershock across the chest "revived" them. [22] In 1947, Beck and coworkers[23] successfully terminated fibrillation in a human heart by application of current directly to the myocardium. Nine years later, Zoll and colleagues[24] reported the first successful cardiac defibrillation in a clinical setting using an alternating current (AC) electrical shock applied externally to the thorax.

The research efforts of Edmark et al.[25] and Lown[26] introduced the use of direct current (DC) in defibrillation, opening the path for the development of portable defibrillators. Subsequently, defibrillation could be applied in remote, non-critical care areas of hospitals, and ambulatory clinics. With the development of modernized, protocol-driven Emergency Medical Service (EMS) systems and the advent of the mobile intensive care unit (MICU) [27] [28] [29] defibrillation was extended beyond the confines of the hospital and made available to paramedical personnel. Advances in electronics, microchip technology, and computer applications of medical algorithms led to the development of the AED, which enabled the lay public (i.e., trained "first responders" such as emergency medical technicians, police, security officers, and civilian CPR-trained "first aiders") to safely provide early access to defibrillation in appropriate areas of the community. [30]

Although the basic concepts of defibrillation have not changed, current attention is being turned toward modifying the defibrillator output waveform to a "biphasic" waveform with the intent of minimizing the amount of myocyte-damaging energy being delivered to the myocardium. (Biphasic waveforms are discussed in more detail later in the chapter.) With better, easy-to-use and readily available equipment, "time to first shock" may be decreased and this may increase the percentage of SCD survivors.

INDICATIONS AND CONTRAINDICATIONS

Immediate electrical defibrillation of the fibrillating myocardium is currently the most effective treatment to promote a successful resuscitation. [7] If a patient is found unresponsive, pulseless, and apneic, it is reasonable to assume that the underlying cardiac rhythm is VF. [7] The possibility of spontaneous conversion to an effective perfusing rhythm, although rarely reported, is highly improbable. [6] Importantly, the probability of successful defibrillation diminishes rapidly over time (Fig. 12-1).[3]

Early treatment via defibrillation is critical to survival from SCD. Access to a defibrillator with "quick-look" paddles or an AED permit immediate monitoring/assessment of the arrested patient's rhythm before electrical defibrillation. These devices can be quite helpful in the emergent situation to determine if defibrillation is indicated. Patients who are unresponsive and who have regular tachydysrhythmias as diagnosed by

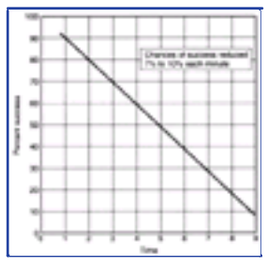

Figure 12-1 Success versus time; graph depicting relationship between survival to hospital discharge after ventricular fibrillation (VF) cardiac arrest and time interval between collapse and defibrillation. There is a 7% to 10% decrease in survival for each minute of VF duration. *(From Larsen MP, Eisenberg MS, Cummins RO, Hallstrom AP: Predicting survival from out-of-hospital cardiac arrest: A geographic model. Ann Emerg Med 22:1652, 1993. Reproduced with permission.)*

the "quick-look" method or an "unshockable rhythm" as determined by the AED are best treated with synchronized cardioversion. It is important to remember that if monitoring or an electrocardiogram (ECG) are not immediately available, an initial unsynchronized countershock "blind defibrillation" may be lifesaving. However, based on the current ubiquity of

Figure 12-2 Leads aVR, aVL, and aVF from an animal with electrically induced ventricular fibrillation (VF). From onset to 4.5 minutes, VF waves were obvious in all 6 frontal plane leads. At 5.0 and 5.5 minutes, lead aVR was a straight line. Note that aVR is the electrical sum of leads aVL and aVF. By 6 minutes, the null vector had changed, and VF was again evident in all 6 frontal plane leads. *(From Ewy GA, Dahl CF, Zimmerman M, et al: Ventricular fibrillation masquerading as ventricular standstill. Crit Care Med 9:841, 1981. Reproduced by permission.)*

"quick-look" paddles on modern manually operated defibrillators and the reliability of AEDs, "blind defibrillation" is rarely indicated. [4]

Regarding the sequence of defibrillation versus medications, current American Heart Association Guidelines [4] recommend that shocking the fibrillating myocardium takes precedence over administering medications. Review of the evidence regarding usefulness of the antiarrhythmic drugs has demonstrated that indeed the proarrhythmic effects of these drugs may decrease the possibility of a successful defibrillation. Furthermore, time delays in establishing intravenous access and endotracheal intubation may worsen electrical defibrillation outcome. [4]

In most resuscitations, CPR is initiated while the defibrillator is being readied. If the patient is unconscious, apneic, and pulseless, it is reasonable to assume that an episode of VF is occurring if cardiac monitoring is not available. In such instances, an immediate attempt at defibrillation is warranted. Although asystole and, more rarely, ventricular tachycardia (VT) may appear clinically similar to the scenario with VF, an immediate countershock is unlikely to worsen either clinical situation. This, however, should not be interpreted as an indication for shocking asystole, which does have significant adverse consequences (i.e., parasympathetic discharge that could lead to a high-level conduction block or myocyte damage, or both). [4] [14] [15] [31]

"Fine" VF can occasionally masquerade as ventricular standstill or asystole. Thus, the "quick-look" monitoring paddle electrodes should be rotated 90° from their original position or the monitor lead changed before the decision to withhold defibrillation in the victim of sudden death is made (Fig. 12-2).[32] [33] Likewise, low-voltage VF is not a contra-indication to defibrillation because it may reflect low monitor gain. Therefore, ECG gain should be maximized during the resuscitation effort of suspected VF, and a suspected problem with the monitor, lead selected, or paddle placement should be addressed before a decision to abandon defibrillation is made.

Administering more than three initial "escalating" or "stacked" countershocks before attempting interventions to ameliorate myocardial ischemia, acidemia, body temperature, or membrane stability is contraindicated because additional damage to the myocytes may occur, rendering the myocardium refractory to additional defibrillation.

CHARACTERISTICS OF VENTRICULAR FIBRILLATION

ECG Characteristics (ECG and the Electromechanical Physiology)

VF is characterized on the ECG by the presence of what appears to be a chaotic, random "squiggly line" (see Fig. 12-2). The actual display is one of rather low-amplitude baseline undulations that are variable in both magnitude and periodicity of the waveform. Care must be taken to ensure that appropriate electrode contact with the patient is maintained and that the leads are all appropriately attached so as not to interpret VF as artifact or vice versa. Although many consider VF to represent an electrically disorganized process, electrical directionality to depolarization (i.e., wavefronts) can exist [32] (see Fig. 12-2), manifesting the characteristic VF waveform or a flat line resembling asystole, depending on monitor lead orientation. It is therefore recommended that when assessing for the presence of VF versus asystole that several ECG leads be checked, differing by 90° in orientation and that the gain of the monitor be adjusted to the highest/most sensitive level. [4]

The resultant ECG tracing seen in VF is the resultant sum of voltage variations with respect to time from the discharge of multiple ectopic foci or "induced" ectopic pacemakers of the ischemic, hypoxic, electrically irritable ventricle. As the many electrical dipoles of myocyte depolarization travel through the ventricular myocardium, the randomness in the orientation of the positive leading edge of the dipoles causes the variation in the polarity of the ECG tracing. The combination of the mass of ventricular tissue undergoing VF and the sum of the dipole directions actually determines the amplitude of the undulations.

Mechanically, VF represents an uncoordinated and distinctly disorderly, ineffective contractile process. Usually the sinoatrial (SA) node depolarizes at an average rate range of 60 to 80 beats per minute. Subsequently, the atria are depolarized and the electrical depolarization front traverses the atrioventricular (AV) node. The impulse is slowed through the node, "decremental conduction," to allow for adequate ventricular filling. Upon activation of the bundle of His and the Purkinje fibers, the interventricular septum and the right and left ventricular free walls contract, decreasing ventricular volume and increasing ventricular pressure so that the blood can be propelled into the elastic aorta (i.e., the stroke volume is ejected from the ventricle). The lack of an organized ventricular systole causes a compromise in cardiac stroke volume. Subsequently, cardiac output falls, resulting in lack of adequate tissue perfusion, ischemia, and hypoxemia of the target organs. If left uncorrected, VF leads to irreversible tissue damage resulting in death.

At the tissue level, VF represents a disorganization of the orderly depolarization sequence that usually occurs in the ventricles. Normally, the refractory period of depolarized muscle prevents the development of reentrant ventricular rhythms by blocking the pathway of returning depolarization fronts. When ischemia, electrolyte disorders, cardiac drug toxicities, rapid ventricular rates, hypothermia, and certain other disorders exist, refractory periods may shorten or conduction velocities may tend to increase in certain areas of the ventricle. Wandering depolarization wavefronts can retraverse the nonrefractory areas of the ventricular myocardium, providing conditions in which a self-perpetuating, ectopic focus can develop. A combination of disorders of impulse formation (automaticity) and impulse conduction (reentry) contribute to the development of VF. [34] [35] The tendency for VF to occur is enhanced by, but is not entirely dependent on, premature ventricular impulses that occur during the "vulnerable" period of the cardiac cycle represented by early ventricular repolarization (Fig. 12-3).

Asynchronous ventricular depolarization may be confined to a small area of the ventricle if the remaining ventricle is refractory to further stimulation. Several studies have shown that a critical muscle mass is required for VF to be self-sustaining, possibly explaining why VF is so uncommon in infants undergoing resuscitation (who usually die from respiratory arrest). A large mass of muscle involved in asynchronous depolarization having a brief refractory period and a slow conduction velocity increases the tendency for the ventricles to fibrillate.

Cummins and coworkers[33] [36] have classified VF on the basis of average peak-to-trough wave amplitude (Table 12-1).

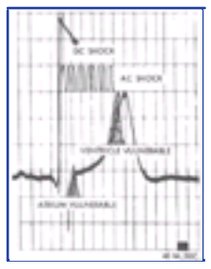

Figure 12-3 Phases of vulnerability for atrium and ventricle. Note that an alternating current shock of 0.20 seconds may end at the T wave even when synchronized with the R wave of the electrocardiogram. *(From Resnekov L: Theory and practice of electroversion in cardiac dysrhythmias. Med Clin North Am 60:325, 1976. Reproduced by permission.)*

TABLE 12-1 -- Classification of Ventricular Fibrillation (VF) Based on Mean Waveform (Peak to Trough Averaged over a 3- to 6-Second Interval) Amplitude

Terminology	Average Amplitude (mm)
Asystole	0 to <1
Fine VF	1 to <3
Medium VF	3 to <7
Coarse VF	7 to <12
Extra Coarse VF (V Flutter)	=12

Historically, it has been taught that coarse VF is easier to defibrillate than fine VF, and one of the functions of epinephrine in the setting of cardiac arrest is to coarsen fine VF to facilitate defibrillation. However, when subjected to study, this contention has been difficult to prove. Weaver and colleagues (Ann Intern Med 102:53, 1985) studied 394 patients with prehospital cardiac arrest and found that epinephrine did not augment the amplitude of VF. Although patients with coarse VF were not successfully defibrillated more often than those with fine VF, the postdefibrillation rhythm was frequently asystole (survival rate 6%) in patients with fine VF and a supraventricular rhythm (survival rate 36%) in those with coarse VF. In a canine study Jones and coworkers (J Electrocardiol 17:393, 1984) found more electrical similarities than differences in coarse and fine VF and concluded that the wave amplitude in early VF is due to electrocardiogram lead orientation rather than differences in the synchronization of electrical activity. The clinical importance of fine versus coarse VF is still unsettled. *(From Cummins RO, Stults KR, Haggar B, et al: A new rhythm library for testing automatic external defibrillators: Performance of three devices. J Am Coll Cardiol 11:597, 1988. Reprinted with permission from the American College of Cardiology.)*

They note that the amplitude of the VF waveform is associated positively with the probability of resuming a perfusing rhythm. However, the clinical importance of coarse versus fine VF in relation to ultimate survival is unclear. Signals that have an amplitude of <1 mm (when the monitor is calibrated at 10 mm/mV) should be considered to indicate asystole [33] [36] because countershock of such low-amplitude rhythms is only rarely associated with conversion to a perfusing rhythm. [37] [38] It has been reported that as VF continues in the face of ventricular ischemia/hypoxia for a time period exceeding *4 minutes*, the waveform of VF changes, decreasing in amplitude and progressing to asystole. [7] [39] This may be an indication that the myocytes are deteriorating and becoming unsalvageable with respect to VF unless some pharmacologic/mechanical resuscitation takes place first. [13]

A new approach to the analysis of VF is being explored. It is termed "AMSA," or an amplitude spectrum area. This methodology may prove to have the potential of enhancing the likelihood that an electrical countershock will restore a perfusing rhythm in a porcine model. This data, if proven useful, may allow more selective timing of shock administration and enhance the efficacy of defibrillation while decreasing myocardial damage from defibrillation. [40] Human studies of prehospital cardiac arrest ECGs suggest that the centroid frequency and peak power frequency of the ECG depicting VF may be predictive of successful countershock. [41] However, the

data to date has not led to any specific recommendations by the American Heart Association.

In summary, electrical defibrillation represents the simultaneous depolarization of sufficient ventricular tissue to render the tissue that is ahead of the VF wavefronts refractory to further electrical conduction. Following generalized depolarization, the sinus node or other pacemaker region of the heart with the highest degree of automaticity can then acquire dominance of a well-ordered depolarization-repolarization sequence. Application of the defibrillation current at various time points in the cardiac cycle may affect the outcome of the countershock. A more comprehensive discussion of this topic is contained in the cardioversion section of this chapter.

DEFIBRILLATOR CHARACTERISTICS

General standards and product evaluations for cardiac defibrillation devices are beyond the scope of this chapter. Rather, this section discusses the major components and design configurations of a prototypical defibrillator and how they relate to effective defibrillation. Only external cardiac defibrillators are discussed.

Defibrillators currently available can be subdivided into two general categories: manual and automatic. The manual defibrillator requires that the operator attach electrodes or use "quick-look" paddles to acquire the ECG. Then the operator must make the determination as to what intervention, if any, is appropriate. If there is a need to provide a countershock, the user must subsequently decide on the energy level (200J, 300J, or 360J) and the mode (synchronized for cardioversion [see section 2 of this chapter] or unsynchronized for defibrillation). Subsequently, the operator must actually depress the switches/buttons either on the defibrillation paddles or on the actual defibrillator to deliver the current (amperes) or energy (Joules) across the chest and myocardium.

The semi-AEDs require less operator manipulation. The AED is turned on, and voice or visual prompts, or both, guide the operator. The user applies self-adhesive pads with prefabricated conduction medium to the victim's chest, which both serve as ECG leads and defibrillation paddles. [42] The AED then analyzes the rhythm and advises the operator to press a "shock button," which delivers the shock to the victim of SCD, if a "shockable" rhythm (VF) or very fast VT (>180) is detected. [43] The algorithm used to analyze the acquired ECG waveform, the selected energy levels, and the actual sequence is preprogrammed by the manufacturer's medical director or can be modified by the clinician providing oversight in the use of this device. A fully automatic AED usually delivers a shock if indicated without user manipulation. These are used only in special situations. [4]

Waveforms

The first successful human defibrillation was performed using AC current. [23] Several years later DC current was shown to be more effective than AC current in accomplishing defibrillation. [44] Use of DC current also resulted in a significantly reduced incidence of postcardioversion dysrhythmias. [44] Only DC defibrillators are in clinical use today. Until recently, modern defibrillators delivered a "damped, monophasic, half-sinusoidal waveform" or a "trapezoidal truncated exponential decay" (voltage falling instantaneously) waveform. The trapezoidal waveform was modified to resemble a square waveform. The more square the waveform, the more effective it was for experimental defibrillation. [45] In a comparison of square waveforms and damped half-sinusoidal waveforms (voltage falling to zero gradually) for animal defibrillation, it was found that less peak current per kilogram was needed with the square waveforms, although the average current levels were equivalent. [46] This work was extended further, leading to the development of multiple new biphasic waveforms. These waveforms are achieved by manipulating the current (amperes), amplitude, duration, voltage, and ultimately the energy delivered to the myocardium.

In light of the current research into the utility of the various energy waveforms that modern day defibrillators

deliver, it would be useful to briefly describe/define terminology. Current output from a defibrillator is graphed with respect to time on an X-Y Cartesian plot. The form of the wave can be either "monophasic" or "biphasic." A characteristic monophasic wave is described as a rapid, positive, unidirectional increase in current flow to a predetermined peak with a return to baseline. If the return of the current to baseline is gradual, the waveform is termed a "damped" wave form (Monophasic Damped Sine-MDS waveform). These waves often resemble a sine wave (Fig. 12-4). If the return of the current level to baseline is paroxysmal/sudden, the wave is termed a "monophasic truncated exponential waveform-MTE waveform" (Fig. 12-5). If there is a rapid rise in current with respect to time with a slight plateau and then a subsequent paroxysmal/sudden reversal in current flow at a predetermined time until all of the energy is delivered with a return to baseline, this is termed a "biphasic" waveform because of the two "phases" in current flow, a positive and a negative phase. Essentially, for a biphasic waveform to occur, current travels from one pad or paddle to the other, then a reversal occurs so that current now flows from the second pad or paddle to the first. If the polarity/direction of the current flow is gradual, the wave is termed a "damped" waveform. If the current reversal is abrupt, the waveform is deemed a "truncated exponential waveform," hence the term "Biphasic Truncated Exponential Waveform—BTE waveform" (Fig. 12-6).

The highest current flow attained is termed the "peak" energy delivered. This, however, is not synonymous with the total amount of energy delivered. Energy is delivered throughout the duration or period of the wave. The current thinking is that if there is less peak energy and a smaller amount of energy delivered to the fibrillating myocytes, there will be less damage to the heart tissue. In addition, this may decrease the perpetuation of conditions favoring VF. This suggests that these waveforms will enhance defibrillation efficacy, decrease myocardial damage, and decrease post defibrillation arrhythmias. [47] [48]

The first biphasic AED approved by the Food and Drug Administration used a biphasic truncated exponential (BTE) waveform (see Fig. 12-6).[4] Additional experiments are being done to further explore various biphasic, rectilinear, first-pulse waveforms. The motive behind these modifications is to find an optimal waveform that will deliver the least amount of energy to the myocardium, thus decreasing the structural damage to the myocytes [31] while achieving successful defibrillation. [47] [49] [50] Injury to myocardial tissue has been associated with the peak current, not the amount of energy actually

Figure 12-4 Monophasic damped sine waveform (MDS) (Energy delivered versus time/msec.) *(Adapted courtesy of Cardiac Science, Inc., Irvine, CA.)*

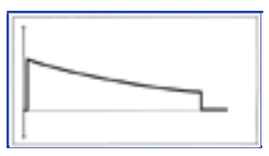

Figure 12-5 Monophasic truncated exponential waveform (MTE) (Energy delivered versus time/msec.) *(Adapted courtesy of Cardiac Science, Inc., Irvine, CA.)*

delivered to the myocytes.[51] With the biphasic defibrillators, lower energy levels (150 to 175 J) can be used without escalating the energy up to 300 J or 360 J. Experimental findings suggest that the clinical outcomes of these defibrillations are equivalent to those that used the escalating monophasic shocks. [52] There is data that also supports the claims that biphasic, low-energy defibrillations are efficient and cause less myocardial damage. [31] [53] However, the actual delivered energy is dependent on thoracic resistance/transthoracic impedance (TTI). Currently manufactured defibrillators are capable of determining TTI/resistance and can actually modify the waveform and thus the amount of energy delivered across the myocardium. A more detailed discussion of TTI is presented later in this chapter. In current clinical practice there is little clinical difference in the effectiveness of the currently available waveforms. The trend of the future will probably be to use biphasic, impedance-compensating defibrillators; however, currently, many monophasics are still in use. At this writing there is no convincing evidence to support the use of one defibrillator waveform over the other.

Stored Energy

Because the ability to defibrillate is dependent primarily on current delivered to the myocardium, [54] successful defibrillation depends on several factors—the energy stored in the battery and capacitor, the varying TTI, internal defibrillator energy

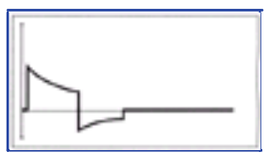

Figure 12-6 Biphasic truncated exponential waveform (BTE) (Energy delivered versus time/msec.) *(Adapted courtesy of Cardiac Science, Inc., Irvine, CA.)*

loss, and the waveform configuration. In addition, the "patient-defibrillator circuit" comprised by the patient, the electrode gel, the electrodes, lead wires, and defibrillator contribute to the outcome of a defibrillation attempt. Each defibrillator is calibrated by measuring the current delivered as a function of time across a 50-ohm impedance. It is important to note that defibrillators do not always deliver the energy indicated on the device. With a "stored" energy of 400 J (1 J = 1 watt-sec), from 155 to 410 J may be delivered. It stands to reason that the current (for a square waveform) delivered to the myocardium is related to the energy delivered by the defibrillator, the combined electrical impedance in the device and chest, and the duration of current flow:

Energy (J) = current (amperes)^2 × impedance (ohms) × duration (seconds)

Obviously, any increase in TTI will further reduce delivered current. With the development and refining of the biphasic waveform, and defibrillators that actually measure TTI/resistance and compensate for the patient defibrillator "circuit resistance," thus modifying the actual waveform of delivered energy, a more appropriate amount of current is delivered to the fibrillating myocardium. Furthermore, with better electrodes, more effective conductive material, and more efficient, smaller, lighter batteries, it is reasonable to assume that defibrillators of the future will be able to store energy for a longer time and be lighter and more portable. This may enhance compliance in the timely use of AEDs and early defibrillation.

Device Switches

Currently there are several manufacturers of electronic medical equipment. Although the equipment they manufacture may perform in a similar fashion (i.e., a defibrillator, an ECG monitor), it is vital that health care providers using the equipment be thoroughly familiar with the operation and layout of the controls in each particular unit. Furthermore, it is imperative that each piece of equipment be periodically tested to ensure optimal operation, battery charge, calibration, recording paper, and so forth.[4]

Most, if not all, currently used defibrillators have the capability of operating independently (i.e., via battery power) without a wall source of energy (i.e., AC plug to operate the monitor, event recorder, and charged capacitor and defibrillator battery). Older models may often have separate power switches for the accompanying monitor, recorder, and defibrillator, while newer units have a multi-function switch or dial. More advanced units may have pacer capability, 12-lead ECG capability, an automatic VF/VT rhythm detection option, rate alarms, sphygmomanometry, and pulse oximetry offered as options (Fig. 12-7 (Figure Not Available)). Some defibrillator monitors offer a radio-transmitter for telemetry monitoring. Currently used units have remote switches on the "quick-look" paddles to activate shock delivery. In addition, some units have energy- and event-recording switches on the paddles, giving the operator more control while in the proximity of the patient. With the discharge controls located on the paddle handles, this allows the operator the capability of positioning and holding the paddles in place while delivering the charge. Alternatively, there may be a separate control on the panel. The simultaneous activation of the control on both paddles is usually required for energy discharge.

Figure 12-7 (Figure Not Available) Hewlett Packard HP Codemaster 100/Laerdal Catalog.

The same device can be used for cardioversion as well as defibrillation (see the second section of this chapter). Before attempting defibrillation, the clinician must be completely familiar with the location and operation of the controls. This knowledge will minimize time lost fumbling with the equipment during a resuscitation of VF when time to first shock is critical to the success of the defibrillation.

Defibrillators also have a control permitting *synchronous cardioversion*. The clinician or other operator must be certain that the control is correctly set to the *asynchronous* mode to permit defibrillation; otherwise, the device in the synchronous mode would "wait" indefinitely for a repetitive series of R waves, not characteristic of VF, prior to discharging.

Energy settings may be determined by a switch or a dial setting or may be read off of a meter permitting a continuous range of settings. In each case the operator must be aware of the need to charge the device initially and to recharge after each discharge. The mechanism of charging the device may be intrinsic to the setting of the dial or meter but more commonly requires the use of a separate charge button on the device control panel or paddle handle. Full-charge accumulation usually takes from 2 to 5 seconds following activation of the charging mechanism.

Monitor controls permit alteration of lead-monitored, image size and often allow the selection of chest lead electrode versus paddle electrode monitoring. The latter is desirable when an initial "quick-look" rhythm evaluation is desired before placement of the chest lead electrodes. A hard copy paper recorder for documenting rhythms may operate in a real-time, delay, or standby mode.

Paddles or Electrode Pads

Previously, most commercial defibrillator devices were equipped with adult-sized paddle electrodes with diameters between 8 and 9 cm. Canine studies have shown that slightly larger (12.8 cm-diameter) paddles are more effective for defibrillation [55] and produce less myocardial injury. [31] Paddles that are slightly smaller (4.5 cm-diameter) produce greater damage at the same energies. The larger paddles may permit a greater amount of muscle to be depolarized while simultaneously decreasing the potentially damaging current density. If the paddles are too large with respect to the heart, the current

density may be less and defibrillation may be rendered less effective (Fig. 12-8 (Figure Not Available)). [42] Current recommendations from the Association for the Advancement of Medical Instrumentation are that a minimum electrode size of 50 cm^2 for each individual electrode be used. [56] The sum of the electrodes area should be a minimum of 150 cm^2 .[2] Although larger electrodes have been reported to have lower impedance, excessively large electrodes may hinder transmyocardial current flow.[57]

Some older defibrillators may still have a flat posterior ground shield rather than a second paddle for lateral chest wall placement. However, these are currently a rare find. The metal composition of the paddle electrode will affect TTI to the defibrillation discharge. Most modern defibrillators use stainless steel because of its durability, although copper alloys and several other metals provide a lower TTI.

Defibrillation can also be performed with self-adhesive electrode pads (8 to 12 cm in diameter) applied to the skin. Pads slightly smaller in size have also been found to be effective in short-term, acute applications. [58] The self-adhesive monitor/defibrillator pads appear to perform as well as or better than handheld paddles. [59] Stults and colleagues, in a controlled prehospital study, found that the use of self-adhesive pads shortened the time to successful defibrillation, reduced the number of countershocks, reduced the amount of rhythm artifact, and improved survival until hospital admission when compared with the use of standard hand-held paddles. [42] However, the expense of self-adhesive defibrillator pads has limited their general acceptance. If future studies support their superiority in other clinical settings, it is likely that the pads will gain wider acceptance.

Conductive Materials

Transthoracic impedance varies with the type of conductive material applied between the paddles and the chest wall. [60] The average adult human impedance is reported to range from 70 to 80 ohms (O). [53] [61] [62] The variability in impedance is contributed to body weight, chest size, chest hair, patient diaphoresis, serial shocks, paddle size, paddle contact pressure, phase of respiration, and type of conductive material used—saline-soaked pads or a specialized conductive paste. For

paddles that are 8.0 cm in diameter, the TTI is 91 ± 20 O for bare contact, 71 ± 11 O for saline-soaked gauze, and 64 ± 15 O for Redux Paste. Clearly, electrode-skin agents reduce impedance and allow more current to be delivered to the heart, but

Figure 12-8 (Figure Not Available) Current density/flow with respect to paddle placement. *(Adapted courtesy of Medtronic Physio-Control, Redmond, WA.)*

the ideal agent is the subject of some debate. Ewy and Taren recommend that Corgel, Redux Paste, American Writer, GE Gel, Electrode Jelly, or Trucon Electrode Paste be used to minimize impedance. Saline-soaked gauze pads may be used, although one must be careful not to allow the saline, coupling gels, or paste to flow into a "bridge" on the skin between the electrodes, creating a potential fire hazard. Although some form of coupling medium (e.g., paste, cream, gel, pad) should be used to reduce impedance, data conflict regarding which product is optimal. Although Redux Paste (Hewlett-Packard) has been associated with significantly lower TTI, a statistically significant increase in the success of defibrillation attempts has not been demonstrated with any specific product.

Hummel and coworkers investigated conductive materials with regard to their potential to overheat and to spark. [63] They found that the products that offer lower impedance (e.g., Redux Paste, Signagel) remained stable and did not spark after four or five defibrillation discharges, which was seen with the higher impedance products (e.g., Redux Cream, Aquasonic 100, EKG Sol, Spectra 360, and Derma-Jel). [63] With the advent of self-adhesive pads that serve as leads and paddles, conductive material will probably become more standardized.

Regarding diaphoresis and body hair, it is recommended that excessive perspiration be expediently wiped off if poor electrode contact is a problem. [4] If body hair causes poor adhesion and the possibility of electrical spark and arcing, it should be quickly removed. [64]

PROCEDURE

Victims suffering from sudden cardiac death (SCD) should be defibrillated as quickly as possible (Fig. 12-9). Current recommendations are that defibrillation be attempted up to three times prior to initiating CPR[4] [7] [65] unless additional personnel are on the scene and can perform CPR while the defibrillator device is being readied for use. Although survival from VF is highly dependent on many variables, the timeliness of defibrillation is the most important intervention determining the prognosis in cardiac arrest.[3] [9]

Upon recognition that a victim is unresponsive, apneic, and pulseless, help should be summoned immediately. However, this should not cause delays in the timely implementation of defibrillation. Saline-soaked pads or an alternate conductive medium should be applied to the chest where the "quick-look" paddles are going to be placed. Alternatively, a conductive material may be spread onto the entirety of the paddle's conductive surface prior to placement onto the victim's chest. However, care should be taken to avoid excess gel/paste on the paddles, because this could cause arcing or inadvertent harm to the operator. The paddles should then be firmly (25 lbs of downward force) applied to the chest wall and held there by the operator. This will optimize skin-electrode contact and decrease resistance. Also, this will ultimately enhance the appropriate passage of current through the heart during defibrillation. One paddle should be positioned to the right of the upper sternum below the clavicle. The second paddle is placed just to the left of the nipple in the midaxillary line and is centered in the fifth intercostal space (Fig. 12-10). Placement of both paddles close together on the anterior chest wall should be avoided. In some paddle sets, each paddle is labeled as either "sternum" or "apex" so that any rhythm detected on

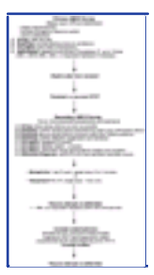

Figure 12-9 Ventricular fibrillation/pulses VT algorithm. *(From Guidelines 2000 for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. Circulation 102(Suppl 1):I-147, 2000.)*

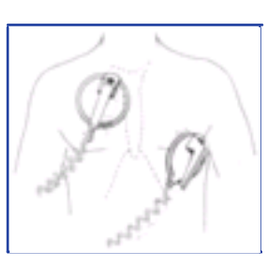

Figure 12-10 Anterolateral paddle electrode position. *(From Suratt PM, Gibson RS: Manual of Medical Procedures. St Louis, CV Mosby, 1982. Reproduced by permission.)*

the monitor can be properly aligned. This feature is irrelevant for defibrillation but is important for cardioversion (see the second section of this chapter). Anteroposterior paddle positioning is also acceptable and may deliver more current to the heart. In the patient with a normal cardiothoracic anatomy the anterior electrode can be placed to the left of the sternum over the precordium and the posterior electrode is placed just to the left of the spine directly posterior to the heart. In the tall, thin or emphysematous appearing patient the anterior paddle should be to the right of the sternum, as the heart is more retrosternal (Fig. 12-11).

With the monitor turned on and set to display the "paddle" electrodes, the rhythm is evaluated. If a flatline rhythm is detected, the operator must ensure that monitor gain is increased fully in order to rule out the presence of a "fine VF" tracing. Should the tracing remain flat during a brief pause in closed-chest cardiac massage, the paddles should be rotated 90° from the original position and the rhythm reassessed. The incidence of VF masquerading as asystole was approximately 2.5% in 1 prehospital study of patients with an initial flatline monitor rhythm. [33] Other conditions can cause a flatline rhythm during VF arrest. Cummins recommends that the rescuer also check all monitor cable connections to the patient and defibrillator, check the ECG size control, and check the power supply. [65] If VF is observed during any of these maneuvers, defibrillation should proceed without delay. Should a bradycardia or asystolic rhythm be detected, standard resuscitation measures, including basic CPR, correction of hypoxia, administration of catecholamines, correction of volume or cardiac filling deficiencies, and emergency cardiac pacing should be initiated when indicated. Although defibrillation should have no theoretical benefit for asystole, the use of countershock will result in the development of a QRS rhythm in a very small percentage of patients with flatline rhythms who receive such shocks. Presumably, such cases represent instances of fine VF simulating a flatline rhythm on the ECG.

In cases of "fine VF" in which a patient is wearing an implanted (subcutaneous) pacemaker, the pacer spikes may initially appear to be a paced but nonconducted rhythm; attention to the baseline and lack of ST changes characteristic of capture should reveal the true nature of the dysrhythmia. [66] Because injury to the pacemaker pulse generator[66A] and to the myocardium can occur by transmission of current down the pacing electrode, the clinician must be careful to situate the defibrillator paddle at least 1 inch (2.5 cm)[67] away from the pulse generator.[4]

Figure 12-11 Anteroposterior paddle electrode position. Use this placement in tall, thin individuals with retrosternal cardiac location. *(From Suratt PM, Gibson RS: Manual of Medical Procedures. St Louis, CV Mosby, 1982. Reproduced by permission.)*

In the presence of VF, the paddles should be immediately charged to a stored energy of 200 J for adults. Keep in mind that separate power switches may be needed to turn on the defibrillator and to store the charge. A button or a dial on the control panel usually sets the amount of charge. In most devices, the preset level of charge (energy) can be stored if a button on the "apex" paddle is depressed. *The clinician should always check to be certain that the defibrillator is not in the synchronous (cardioversion) mode.*

Once the paddles are charged, the clinician should instruct all personnel to " *STAND BACK*" from the patient and the stretcher to avoid stray discharge. The operator/clinician should then say aloud "I'M CLEAR, YOU'RE CLEAR, WE'RE ALL CLEAR" just prior to delivering the countershock. [4] However, there is no need for the individual who is bag-tube ventilating the patient to drop the bag and stand back *if their only contact is a rubber or plastic bag*. That individual is not touching conductive materials and will thus be protected from electrical shock. The defibrillator operator, in particular, must be sure that his or her only direct contact with the patient or stretcher is with dry paddle handles. The patient is allowed to exhale passively to minimize TTI, [68] while firm (25 lb) pressure is applied through the paddles to the thorax.[69] To minimize energy decay inside the device, the energy in the paddles is discharged through the chest as soon as possible after charging.

Simultaneous depression of both paddle discharge buttons is essential for discharge. Anticipation of

patient extremity motion subsequent to discharge of the paddles will minimize operator and patient injury.

Should no skeletal muscle contraction occur following simultaneous depression of the discharge buttons, the clinician should ensure that: firm chest wall contact has been made (some devices will not discharge without adequate contact), the device is set in the asynchronous mode, a charge has been stored, the defibrillator (not just the monitor) is turned on, and the battery is not depleted (when operating off the storage battery). If there is no muscle contraction even when these factors have been ruled out, a replacement defibrillator should be immediately brought into use.

After the first shock, the paddles should remain in place for 5 to 10 seconds to enable the clinician to check for an organized rhythm while ventilation is continued. While waiting to analyze the rhythm, the rescuer should recharge the paddles for an immediate second defibrillation (200 to 300 J for adults) should VF persist. Should VF continue after the second shock, an immediate third defibrillation (360 to 400 J for adults) should be given. Immediate recharging of the defibrillator and rapid succession in the administration of the shocks decreases chest wall impedance. If the third defibrillation is unsuccessful, closed-chest cardiac massage should be continued, hypoxia corrected, and a-agonist catecholamine (epinephrine) [70] [71] or naturally occurring antidiuretic hormone vasopressin [72] administered intravenously to elevate the diastolic pressure and to improve coronary perfusion. [4] [70] [71] [73] Following circulation of the catecholamine or vasopressin agent, an attempt at defibrillation should be repeated. Currently there are no data to suggest that "high-dose" epinephrine use is associated with superior long-term survival compared to standard doses in either children or adults. [74] Superiority of epinephrine versus vasopressin has not been satisfactorily established. [4]

Because excessive defibrillation energy may produce irreversible VF in the patient suffering toxic effects of digitalis, the lowest available energy level should be used for the initial defibrillation. If the initial energy dose is unsuccessful, the energy level can be increased cautiously for successive countershocks.

Additional therapy (see the following section) can be undertaken to enhance defibrillation. Adequate ventilation, cardiac massage, correction of electrolyte disorders, ischemia, and acidemia are intrinsic to every resuscitation. In addition, evaluation of the patient for hypothermia and rapid core rewarming when indicated should not be overlooked. When practical, electronic monitoring devices and transvenous pacemakers should be turned off or, preferably, disconnected from the patient to avoid equipment damage. Recently manufactured patient monitoring devices, however, have built-in protective filter circuitry, which makes equipment damage an unlikely occurrence.

ENHANCING DEFIBRILLATION SUCCESS

Early Defibrillation

Energy requirements for conversion of VF may increase dramatically shortly after the onset of VF. [69] The rationale for early defibrillation is that in the absence of adequate coronary perfusion, cellular metabolism continues with the depletion of energy substrates and the accumulation of toxic metabolites. Electrophysiologic changes secondary to cellular ischemia/acidemia develop rapidly and contribute to continued asynchronous transmission of VF wavefronts.

The American Heart Association Guidelines [4] support the belief that the most effective treatment for VF is early defibrillation [7] and that the probability of successful defibrillation decreases rapidly over time. [3] Clinical investigation of immediate defibrillation rather than drug therapy preceding defibrillation is limited. Martin and coworkers, in a retrospective analysis of prehospital VF resuscitation, found that survival until hospital discharge was increased when CPR followed by immediate defibrillation was used rather than CPR and drug therapy before countershock. [75] The group that received drug therapy first had a longer mean time until defibrillation (12 minutes additional), which was explained in part by the time required for IV line placement, drug administration, and drug circulation. The time lag until first shock may have confounded the results. Other studies describing treatment of prolonged VF suggest that CPR be performed for approximately 1 minute prior to administration of countershock.[17] The 2000 Guidelines suggest that administration of anti-arrhythmic medications may actually promote dysrhythmias. With the obvious controversies and confounders inherently present in these data, it is suggested that until further clinical studies are available, immediate defibrillation for VF appears to be the most appropriate course of action.

Current-Based Defibrillation

An alternative approach to defibrillation has been an attempt to use current-based (amperes) defibrillation. This approach would theoretically deliver the appropriate energy to the fibrillating myocardium by compensating for variations in thoracic impedance. Thus, patients with high impedance would not be victim to failed defibrillation secondary to insufficient energy delivery and patients with low impedance would not suffer myocardial damage due to excess current delivery. [48] [53] Based on monophasic damped sinusoidal (MDS) waveform research, it has been reported that 30 to 40 A is the optimal current necessary for defibrillation. Investigations are under way to determine values for biphasic waveform defibrillation. [76] Clinically, this is not an issue that the clinician has to adjust at the time of this writing. It may, however, modify future defibrillator design and enhance defibrillation outcome.

Transthoracic Impedance (TTI)

To accomplish successful defibrillation, sufficient current (amperes) must flow through the myocardium. Delivery of this current to the heart is dependent on the energy (joules) selected and the impedance or resistance (ohms [?]) to transmission of that energy from the paddles, through the chest wall and accompanying structures until the current traverses the heart itself. The greater the impedance or resistance, the less there is of delivered current. Reported values for human TTI using electrodes 8.0 cm in diameter range from 70 to 80 ohms with a mean of 75 ohms.[53] [61] [62] [77] We have previously discussed the factors that may affect TTI. The importance of paddle electrode composition and size, conductive materials applied paddle-to-chest-wall pressure, phase of ventilation, presence of excess chest hair, diaphoresis, and location of the paddle on the chest wall (Table 12-2) all contribute to TTI. All of these factors must be considered and dealt with to facilitate successful defibrillation.

TABLE 12-2 -- Determinants of Transthoracic Impedance*

Determinant	Effect
Interelectrode distance (chest size)	Larger distance ? higher impedance
Energy selected	Higher energy ? lower impedance
Electrode size	Larger electrode ? lower impedance
Electrode-skin couplants	Failure to use a couplant ? very high impedance
Previous shocks	Previous shock ? lower impedance, especially after first shock
Phase of respiration	Inspiration ? higher impedance
Electrode-chest contact pressure (handheld paddles)	Firm pressure ? lower impedance

*Lower impedance is preferred. Higher impedance lessens the current delivered to the heart. *(From Kerber RE: Electrical treatment of cardiac arrhythmias: Defibrillation and cardioversion. Ann Emerg Med 22:296, 1993.)*

The TTI of DC discharge also decreases with higher energy shocks, with increasing number of previous countershocks delivered (see Table 12-2)[77] [78] and with decreasing interval between the discharges. Unfortunately, each of the aforementioned maneuvers is also associated with an increased potential for myocardial injury.

When considering normal defibrillation, the chest should be relatively dry, a conductive medium must be appropriately placed onto the chest, and a good seal must be established between the chest and the paddles. The paddles should be of appropriate size. Twenty-five pounds of force should be applied to the paddles and chest. Discharge of energy should be done at the end of an expiration. Energy selected should be appropriate for the initial shock—usually 200 Joules. [4]

Nonetheless, one may be faced with the need to defibrillate a very obese patient who is unresponsive to standard paddle placement and maximum device energies. Should such a situation exist, the patient can be rolled on the side and anteroposterior defibrillation attempted. Should this prove unsuccessful, a second defibrillating device can be simultaneously charged and used to administer countershock immediately following discharge of the first defibrillator. It is interesting to note that a canine study of internal defibrillation indicated that two sequential shocks over different pathways reduced both total energy and peak voltage required to terminate VF.[79] Hence, sequential defibrillation using slightly different paddle placements may be beneficial independent of the concurrent reduction in TTI.

Energy Choice

Current International Liaison Committee on Resuscitation (ILCOR)/American Heart Association (AHA) guidelines recommend that energy for the first monophasic shock should be 200 J, and if unsuccessful, that the energy be escalated to 300 J or 360 J as needed. [4] [80]

Many investigators have referred to a so-called defibrillation energy threshold for converting VF. Davy and coworkers suggest that no unique defibrillation energy threshold exists for the in vivo heart. [81] Experimentally, they found that successful defibrillation was related to delivered energy, which follows a typical "dose-response curve." However, there is evidence for a defibrillation current threshold. [54]

Successful defibrillation is dependent on the simultaneous depolarization of a sizable mass of the myocardium resulting from the passage of current through the heart.

For a given thorax, defibrillation device, and defibrillation technique, more current is passed through the heart and, hence, more tissue is depolarized with larger energies. Once sufficient tissue has been depolarized, however, additional current is not desirable and may, in fact, produce additional tissue injury. Kerber and coworkers have suggested that the use of defibrillators that adjust defibrillation energy for the patient's TTI (measured by the device just before charging) may be one means to deliver an adequate current to the myocardium while minimizing potential harm as discussed earlier. [82] Such devices are not in routine use at present, but they may be helpful in the future for both the identification of high-impedance situations and adjustment of delivered energy. [48]

Several studies have supported the concept that when current needs cannot be predicted nor current delivery measured, a weight-adjusted dosage of energy is preferred for converting VF. Indeed, a dose based on the patient's weight has been found clinically useful for treating children suffering VF. [83] Other prospective human adult studies have questioned the importance of dose strength to conversion of VF. [84] [85] Weaver and coworkers, using monophasic waveforms for defibrillation, alternated treatment protocols to determine prospectively the merits of 175 J (200 J of stored energy) versus 320 J (400 J of stored energy) countershocks for defibrillation. [80] On test days, VF patients were shocked initially with 1 or 2 175 J discharges, and all subsequent shocks needed were 320 J. On alternate days, only 320 J shocks were given. The investigators found that 73% (n = 76) of the patients were defibrillated following the first 2 shocks in the low-energy group, whereas 81% (n = 77) of the patients were initially defibrillated in the high-energy group (difference not statistically significant). Asystole occurred in 19% of patients receiving high energy and in 12% receiving low energy. Transient or persistent heart block occurred in 25% of patients shocked with high energy versus 11% of patients shocked with low energy. Survival until hospital discharge was inversely related to the number of shocks required; no patients who required >8 shocks survived.

Weaver and associates concluded that low-energy (175 J delivered) countershocks were safe, effective, and less cardiotoxic. Obviously, many factors besides discharged energy play a role in successful defibrillation. Kerber found that defibrillation success rate is a unimodal function of transthoracic current. [86] The maximum defibrillation rate for their patients with a brief duration of VF (<1 minute) occurred at a peak transthoracic current of 38 to 41 amperes (A). Whether a similar optimum transthoracic current is found in patients with prolonged VF remains to be determined. Until energy levels based on measured TTI are shown to be predictive of defibrillation success in a variety of settings, most authorities recommend using an initial 200 J energy setting in adults. When 2 sequential defibrillations at this setting are unsuccessful, countershock at 360 J (or maximum output, if needed) is recommended (see Fig. 12-9).

Research suggests that biphasic shock waveforms can achieve successful defibrillation at energy levels <200 J and that this practice appears to be safe and effective. Escalation and nonescalation of energy has been explored. However, in clinical practice the recommendation [4] is to start with 200 J and increase energy as needed for successive shocks regardless of defibrillator used (monophasic/biphasic) at this time. It is likely that as biphasic defibrillators become

more prevalent, the recommended energy levels will be restructured.

Postdefibrillation Rhythms

Following defibrillation a number of cardiac rhythms may occur. Ultimate prognosis is linked to the rhythm that evolves during the first few minutes following defibrillation. In an evaluation of the prognostic significance of postdefibrillation rhythms in 94 patients, Hoffman and Stevenson [87] noted survival rates of 20% to 33% in patients who developed a supraventricular rhythm and 8% in those who developed an organized idioventricular rhythm; there were no survivors if defibrillation was unsuccessful or resulted in asystole or an unorganized rhythm. Survival rates may be influenced by the underlying condition or cause of the arrest or by subsequent drug therapy, but ultimate prognosis is dismal indeed if the first few attempts at defibrillation fail to restore a supraventricular rhythm.

There is the possibility that outcome of defibrillation may be related to the degree of myocardial injury incurred from defibrillation. However, data to support or refute this is being acquired. Biomedical engineers, clinicians, and researchers are working with waveforms, energy levels, and antiarrhythmic drugs to ultimately decrease myocardial injury with defibrillation. The ultimate goal is safe and effective defibrillation. The current recommendations are to terminate VF as soon as possible via defibrillation. If VF is suspected of having been present for several minutes (+/- 4 minutes), then doing a minute of CPR prior to defibrillation may be beneficial. This information is currently classified as "historical/anecdotal", although animal and preliminary clinical trials are supportive.

Drug Therapy

As previously noted, the most effective treatment modality for VF is defibrillation. [52] If after delivering three consecutive countershocks VF persists, additional interventions may be initiated to achieve termination of fibrillation. Although drug therapy is often an adjunct to defibrillation, *no medication has been proven to increase the rate of survival in cardiac arrest*.

As noted in the most recent Advanced Cardiovascular Life Support (ACLS) Algorithm and in the new AHA recommendations, [4] many previous interventions (such as drug therapy in the form of antidysrhythmics) have been deemphasized (e.g., epinephrine, lidocaine, bretylium, sodium bicarbonate). In addition, several new medications (i.e., vasopressin and amiodarone) have been introduced into the treatment regimen. Use of other medications (e.g., procainamide, magnesium sulfate) have limited application and are still being debated.

Before proceeding to administer additional shock and medications, correction of hypoxia and hypercarbia via airway management, bag-valve mask ventilation, and endotracheal intubation or airway adjuncts must be attended to immediately. Intravenous (IV) access for drug administration and blood sampling to guide further treatment should be established. Appropriate treatment of electrolyte disturbances like hyperkalemia/hypokalemia and hypomagnesemia will at best be presumptive in anticipation of laboratory results. The next most appropriate intervention should address return of blood flow to the heart and maintenance of aortic diastolic blood pressure, in an attempt to increase coronary perfusion, with the ultimate goal being to increase coronary artery perfusion pressures and decrease myocardial hypoxia/hypercarbia. If achieved, the increase in coronary blood flow during VF may remove some of the "toxic" metabolites from the fibrillating myocytes and may decrease the perpetuation of a reentrant depolarization wavefront. In addition, the drugs used should enhance cardiac function, potentiate the return of a spontaneous circulation and blood pressure, and shunt blood toward vital organs. [88] The physiological support for this proposed intervention is derived from the fact that endogenous catecholamine levels rise significantly after cardiac arrest. [89] This may be achieved by pharmacological intervention via vasopressors in the form of a-agonist catecholamines (epinephrine) or the alternative administration of the natural antidiuretic hormone (ADH; vasopressin). Amiodarone, a fairly new agent, may be considered, even before the "old classic," lidocaine. Drugs like magnesium sulfate, and procainamide may be considered. The role of sodium bicarbonate, although very limited, is also addressed in special situations. The specifics of these agents will be addressed later.

It should be noted that although adjunctive drug therapy is often used or advocated, there are no data supporting better long-term survival rates when *any drug therapy regimen is combined with defibrillation*. When evaluating any intervention, *it is paramount to focus on survival to discharge and not to be overly concerned with minor changes in initial resuscitation rates that merely provide ultimately unsalvageable patients with transient cardiac activity*.[90] Also, as a reminder, adjunctive therapy should not cause significant delay to subsequent defibrillation, if indicated.

Adrenergic Agents (Physiologic & Pharmacologic Effects; A Historical Perspective)

Drugs that stimulate a-adrenergic receptors have been advocated during cardiac arrest to increase myocardial and central nervous system blood flow during CPR. These agents may not enhance the ability to defibrillate VF, but they may enhance the development of a perfusing rhythm following defibrillation. [91] It is important to note that a agonists are potent vasopressors and that they increase systemic vascular resistance and elevate aortic diastolic pressure, resulting in increased coronary and carotid blood flow. This enhanced perfusion, and not direct ß-adrenergic stimulation, is credited with increased survival rates. [92] In fact, the ß-adrenergic properties of epinephrine have been postulated to be harmful because these pharmacologic effects increase myocardial oxygen consumption and reduce subendocardial perfusion. When isoproterenol, a potent ß agonist without a effects, was used during resuscitation, it did not favorably influence resuscitation rates. Epinephrine has been the vasopressor of choice during CPR. The ACLS algorithm recommends doses of 0.5 to 1 mg every 5 minutes. Large doses of epinephrine (0.2 mg/kg), 10 to 15 times higher than currently recommended, were touted to provide better initial resuscitation rates, but have not been shown to enhance ultimate survival rates. [74] [93]

A number of pure a agonists have been advocated to overcome the theoretical disadvantages of epinephrine. For example, Silvast noted similar resuscitation rates from prehospital cardiac arrest (e.g., from VF, asystole, and pulseless electrical activity [PEA]) when phenylephrine (1 or 2 1-mg boluses) was used in place of

standard doses of epinephrine. Methoxamine (10 to 20 mg) has also been used with success rates similar to those of epinephrine. [94] There is concern,

however, that although pure a agonists favorably augment peripheral vascular resistance, they do so at the expense of cerebral perfusion and myocardial blood flow.[95] [96] The specific role of these agents on defibrillation is unclear. Like high-dose epinephrine, the use of pure a agonists in facilitating defibrillation or enhancing long-term survival is not supported by current data. Although adherence to standard ACLS guidelines is logical until the benefits of alternative therapies are clarified, the role of adrenergic adjunctive drug therapy remains controversial. Nonetheless, epinephrine and vasopressin are included in the current VF algorithm and are discussed later. In an attempt to evaluate the usefulness of these agents we must closely review the scientific data supporting or refuting their use. The AHA in collaboration with the European Resuscitation Council and the Resuscitation Council of Latin America developed and published a list of criteria for evaluating and categorizing the information presented in the literature. A summary of these data is provided in Table 12-3 . These criteria are used to describe the usefulness of the proposed therapeutic intervention.

Epinephrine

Epinephrine hydrochloride is a catecholamine with a- and ß-adrenergic receptor-stimulating properties. Beneficial effects of epinephrine administration are attained via the a-adrenergic receptor-stimulating properties. [70] By administering epinephrine, there is an increase in myocardial and cerebral blood flow during CPR. [71] However, there are drawbacks in the use of epinephrine in that there may be an increase in myocardial workload with a concomitant decrease in endocardial perfusion, leading to the compromise of cardiac tissue. [97]

Epinephrine was initially used by surgeons in the operating room to restart an arrested heart. [98] [99] [100] They ascertained that a dose of 1 to 3 mg of epinephrine injected directly into the heart was useful in restarting the nonbeating heart. In the initial development of guidelines for cardiac resuscitation, a 1 mg intravenous (IV) dose of epinephrine was suggested. However, not all patients have a similar body weight and the concentration of the drug in the blood level was at best variable. When the dose response effects were studied regarding the administration of IV epinephrine, it was determined that epinephrine produced the most effective hemodynamic effects at a dosage of 0.045 to 0.2 mg/kg IV.[101] [102] [103] [104] This led to the recommendations of "high dose epi" in cardiac resuscitation. A subsequent outcome review regarding the efficacy of high-dose epinephrine demonstrated that although there may have been a greater rate of return of spontaneous circulation (ROSC) there was no significant increase in survival to hospital discharge. [101] [105] [106] [107] In fact, it has been reported that the use of high-dose epinephrine has led to worsening hemodynamic and neurological outcomes in many patients.[108] [109] However, a direct cause-effect relationship was not clearly demonstrated. In addition, epinephrine has been shown to be arrhythmogenic. The proposed mechanism for this arrhythmogenesis is believed to be the enhanced depletion of myocardial adenosine triphosphate (ATP) and an increase in lactate secondary to an increase in circulating epinephrine levels. [97] With ATP depletion, the sodium-potassium ATPase pump is impaired, causing an increase in the duration of the cardiac action potential due to delayed repolarization of the myocytes. This in turn leads to irregularities in various regions of the myocardium, favoring conditions for the propagation of an aberrant, reentrant depolarization. Furthermore, epinephrine has been shown to increase intrapulmonary shunting by 30%. [110] This results in significant desaturation of hemoglobin in the erythrocytes.

In light of this data, the current American Heart Association Guidelines [4] describe administration of 1 mg of epinephrine (IV) every 3 to 5 minutes as a Class Indeterminate recommendation (see Table 12-3). If this does result in a successful pharmacologic effect, higher doses of epinephrine (0.2 mg/kg IV) may be given, but are not recommended (Class IIb to III) and indeed may be harmful (see Table 12-3). The following section describes a potential alternative/addition to the use of epinephrine in VF; i.e., vasopressin.

Vasopressin

Vasopressin, also known as antidiuretic hormone (ADH), is a naturally occurring polypeptide hormone endogenously produced from within the cells of the hypothalamus. Vasopressin is stored in the posterior lobe of the pituitary gland and secreted during episodes of physiologic stress; such as dehydration, hypovolemia, hypernatremia, and hypotension. Some findings describe the release of high levels of endogenous vasopressin immediately after cardiac arrest. [111] In physiologic doses, this hormone increases the permeability of the distal convoluted tubule and collecting duct of the kidney, causing a decrease in the excretion of water by the kidney. If vasopressin is administered in a pharmacologic dosage, much higher than what would induce an antidiuretic effect, it acts as a *non-adrenergic* peripheral vasoconstrictor. It produces this effect by direct stimulation of V_1 receptors located on smooth muscle cells. Interaction of vasopressin with the V_1 receptor produces a whole compendium of results—peripheral vasoconstriction of the blood vessels in the skin, skeletal muscle, intestine, and fat, with less constriction of coronary and renal vascular beds and vasodilatation of the cerebral vasculature, resulting in a direct increase in blood pressure, pallor of the skin, intestinal cramps, nausea, bronchial constriction, an urge to defecate, and uterine contractions in women. [112] [113] Vasopressin also increases shunting of blood within the coronary and cerebral blood vessels, and promotes the local vascular endothelial release of nitric oxide, which concomitantly results in an increased flow of blood to the heart and brain. [114]

Many of the aforementioned characteristics of vasopressin are similar to the effects describing the actions of epinephrine. However, the pharmacologic actions of vasopressin have a few advantages over that of epinephrine—vasopressin is not adversely affected by acidemia, nor does vasopressin have any ß-adrenergic effects.[115] Vasopressin also has a half-life of about 10 to 20 minutes with intact circulation. This provides longer efficacy post administration and reduces the need for repeat dosing as is needed for epinephrine effects. Administration of vasopressin to victims of cardiac arrest during CPR in the field has been shown to increase both ROSC and survival to hospital admission. In addition, more of these patients survived to hospital discharge. [116] A later study of in-hospital cardiac arrest failed to yield significantly changed rates of survival of patients to discharge or change in neurological outcomes. [117] Based on the preceding information, the review committees for standardizing resuscitation [118] (the International Resuscitation Guidelines) have recommended vasopressin as a Class IIb (see Table 12-3) drug for VF or pulseless VT. A single one-time dose of 40 units IV of vasopressin may be used in lieu of the 1 mg dose of epinephrine after the first three unsuccessful shocks or after the

TABLE 12-3 -- Classes of Recommendations 2000: Classification of Therapeutic Interventions in Cardiopulmonary Resuscitation and Emergency Cardiac Care

1. Search for Evidence: Locates the Following	2. Consensus Review by Experts: Intervention Is Placed in Following Class	3. Interpretation of This Class of Recommendation When Used Clinically
Minimum evidence required for a Class I recommendation	***Class I: Excellent***	**Class I** interventions are always acceptable, proven safe, and definitely useful.
	Definitely recommended	
• Level of evidence: 1 or more RCTs	Supported by ***excellent*** evidence	
• Critical assessment: *excellent*	Proven efficacy and effectiveness	
• Results: homogeneous, consistently positive, and robust		
Minimum evidence required for a Class IIa recommendation	***Class IIa: Good to very good***	**Class IIa** interventions are acceptable, safe, and useful.
	Acceptable and useful	
• Level of evidence: higher	***Good/very good*** evidence provides support	• Considered standard of care: reasonably prudent physicians can choose
• Number of studies: multiple	Note: Contextual factors: In addition to level of evidence, these additional factors are considered in making final class of recommendation.	
• Critical assessment: *good to very good*		

• Weight of evidence/expert opinion: more strongly in favor of intervention than Class IIb		• Considered ***intervention of choice*** by majority of experts
• More long-term outcomes measured than Class IIb	Contextual factors include small magnitude of benefit; high cost; educational and training challenges; large difficulties in implementation; and impractical, unfavorable cost benefit ratios.	• Often receive AHA support in training programs, teaching materials, etc.
• Results: positive in majority of studies		*"Contextual" or "mismatch" factors may render an intervention Class IIa in one context and Class IIb in another (see Note).*
• Observed magnitude of benefit: higher than Class IIb		
Minimum evidence required for a Class IIb recommendation	***Class IIb: Fair to good***	**Class IIb** interventions are acceptable, safe, and useful.
	Acceptable and useful	
• Level of evidence: lower/intermediate	***Fair to good*** evidence provides support.	• Considered within "standard of care": reasonably prudent physicians can choose
• Number of studies: few	Note: Contextual/mismatch factors should not be used to avoid the trouble and expense of adopting new but clinically beneficial interventions.	
• Critical assessment: *fair or poor*		
• Weight of evidence/expert opinion: less in favor of usefulness/efficacy		• Considered *optional* or *alternative interventions* by majority of experts
• Outcomes measured: immediate, intermediate, or surrogate		
• Results: generally, not always, positive		
Evidence found but available studies have one or more shortcomings	***Class Indeterminate***	Note: Interventions classed
	Preliminary research stage	***Indeterminate*** can still be recommended for use, but reviewers must acknowledge that research quantity/quality fall short of supporting a final class decision.
• Promising but low level	Available evidence insufficient to support a final class decision	
• Fail to address relevant clinical outcomes	Results promising but need additional confirmation	
• Are inconsistent, noncompelling, or report contradictory results	Evidence: no harm, but no benefit	Do not use *Indeterminate* to resolve debates among experts, especially when evidence is available but experts disagree on interpretation. *Indeterminate* is limited to promising interventions.
• May be high level but report conflicting results	No recommendation until further evidence is available.	
Positive evidence completely absent *or* **Evidence strongly suggests or confirms harm**	***Class III: Unacceptable, no documented benefit, may be harmful***	Interventions are designated as Class III when evidence of benefit is completely lacking or studies suggest or confirm harm.
	Not acceptable, not useful, may be harmful	

RCT indicates randomized, controlled trial.

(From American Heart Association Guidelines 2000, Circulation 102(suppl):1, 2000. Reproduced with permission.)

administration of standard-dose epinephrine. If there is no evidence of success, 1 mg doses of epinephrine IV can be resumed every 3 to 5 minutes (Class Indeterminate) (see Table 12-3).

Lidocaine

Lidocaine has long been used to facilitate defibrillation. The rationale for use of lidocaine in VF is primarily based on anecdotal experience. Two studies of nonischemic canines have demonstrated that lidocaine increases the energy required for electrical defibrillation. [96] [119] Kerber and coworkers suggest that the elevation of the defibrillation threshold noted by others may be a function of the anesthetic used in the animal model and may not be a clinical factor. [120]

Lidocaine has complex effects on membrane responsiveness. Little change in conduction velocity occurs in normal myocardium, whereas conduction in ischemic tissue is decreased following lidocaine administration. Lidocaine increases uniformity of the action-potential duration and refractory period throughout the ventricles and can terminate ventricular reentrant rhythms. Lidocaine also raises the threshold for electrically induced VF in a canine CPR model within 5 minutes after administration, although the antifibrillatory effect is not sustained with a single bolus dose.

One retrospective study of prehospital VF arrests documented a small but statistically insignificant improvement in both defibrillation rate and survival when patients refractory to conventional therapy for VF were given lidocaine during the course of their resuscitation. Unfortunately, strict drug and therapy protocols were not followed, and variations in treatment may have masked a beneficial effect of lidocaine administration. Older clinical experience suggests that the drug may have value in aiding defibrillation. Unfortunately, this is an anecdotal generalization. Additional studies to ascertain the efficacy of lidocaine with respect to VF termination, the ability to facilitate defibrillation, survival to hospital admission, and ultimately to successful, functional discharge from the hospital have failed to demonstrate any significant benefit in administering lidocaine. [121] A study comparing survival of up to 1 hour post VF defibrillation, both with and without the use of lidocaine, found no significant differences in outcome between the 2 groups. [88] Together with the aforementioned study and a review of the data currently available by the participants of the International Guidelines Conference, the International Guidelines Committee has led participants to assign lidocaine to the Class Indeterminate (see Table 12-3).[118] Lidocaine is initially given as a bolus of 1 mg/kg to the VF sudden death victim who is refractory to conventional defibrillatory efforts. The bolus of lidocaine is suggested after the use of either epinephrine or vasopressin, or both. A second 1 mg/kg bolus can be given in 10 to 15 minutes. It is important to remember to reduce the maintenance dose (not the initial loading dose) of lidocaine in patients who have a history of hepatic or left ventricular dysfunction, or both. Currently, there is a relatively new agent available that has shown promise as an effective antiarrhythmic in VF. This drug may be an alternative to lidocaine. It is discussed in the following section.

Amiodarone

Amiodarone is a relatively new antiarrhythmic agent that has been introduced into the algorithm for the pharmacologic enhancement of VF defibrillation. Although amiodarone has been classified primarily as a class III antiarrhythmic agent-potassium channel blocker (using the Vaughn-Williams classification of antiarrhythmic drugs), it also has the properties of a class I, II, and IV antiarrhythmic drug; Class I—a sodium channel blocker, Class II—a noncompetitive alpha-beta blocker, and Class IV—a calcium channel blocker. Because of its diverse antiarrhythmic properties, amiodarone has gained acceptance as a useful drug during the management

of VF, refractory to pressors (epinephrine or vasopressin, or both), and a total of 4 defibrillation shocks.

As already mentioned, amiodarone is the only antiarrhythmic agent that manifests all 4 Vaughn Williams classes. [122] Amiodarone has been studied extensively in an attempt to determine its efficacy in enhancing termination of VF. [123] [124] [125] The data has demonstrated that amiodarone, with its lengthening of the cardiac action potential, prolongation of refractoriness of the myocytes, and deceasing cardiac oxygen consumption, is more effective than previously used agents such as lidocaine. In addition, amiodarone has important hemodynamic effects that favor its use: it increases coronary blood supply, dilates coronary arteries, causes peripheral arterial vasodilatation, improves cardiac pump performance in patients with compromised left ventricular function, and decreases systemic vascular resistance. [122] In addition, amiodarone rapidly distributes throughout adipose tissue, is highly bound to plasma proteins, and has an extensive half-life. The principle metabolite (desethylamiodarone or DEA) has properties to its parent compound, thus effectively increasing the duration of amiodarone effects in the dysrhythmic patient. This decreases the need for repeat/frequent dosing. Regarding pharmacokinetics, neither hepatic disease, renal insufficiency, age nor sex have any significant effects on the dosing of and physiologic effects of amiodarone.

Regarding side effects, the most common adverse side effect seen with IV amiodarone is hypotension (16%). This can be ameliorated by slowing the rate of infusion fluids, pressors, and chronotropic agents. Other adverse effects include: bradycardia (4.9%), liver function test abnormalities (3.4%), cardiac arrest (2.9%), VT (2.4%), congestive heart failure (2.1%), cardiogenic shock (1.3%), and AV block (0.5%). In light of these data, amiodarone is contraindicated in patients with cardiogenic shock, marked sinus bradycardia, and second- or third-degree AV block in the absence of a functioning pacemaker. However, in the situation of VF, the venue for the administration of amiodarone is modified.

Use of IV amiodarone in VF refractory to three initial countershocks has been demonstrated to improve survival to hospital admission by 29% (ARREST TRIAL). [125] In addition, the ALIVE trial (Amiodarone versus Lidocaine in Ventricular Fibrillation Evaluation) has shown amiodarone to be significantly superior to lidocaine terminating VF and increasing the number of patients who have survived to hospital admission in the prehospital setting. [50] Speculation on officially unreported data regarding survival to discharge from the ALIVE trial suggests that there may be a significant increase in survival of VF victims to hospital discharge. [126]

Currently, amiodarone is recommended after defibrillation and epinephrine or vasopressin, or both, in cardiac arrest with VF (Class IIB) (see Table 12-3). In cardiac arrest with VF, amiodarone is administered as a rapid 300 mg rapid infusion diluted in a volume of 20 to 30 mL of saline or dextrose in water. A 150-mg dose may be repeated followed by an infusion of 1 mg/min for 6 hours and then 0.5 mg/min to a maximum of 2.2 grams over a 24-hour period.

Procainamide

Procainamide hydrochloride, a sodium channel-blocking antiarrhythmic that prolongs the effective refractory period and slows conduction through the myocardial conductive tracts, is a drug that can suppress both atrial and ventricular arrhythmias. There is a dearth of studies addressing the use of procainamide in VF. However, there is one limited, retrospective study of only 20 patients that states that there may be a benefit from the use of procainamide in VF. Practical use of procainamide during VF cardiac arrest is limited because of the need to infuse procainamide slowly.

Procainamide should be avoided in torsades de pointes.

Magnesium Sulfate

Magnesium sulfate has limited use in the resuscitation of VF. Unless there is a predetermined knowledge that the victim of VF is in a low magnesium state, hypomagnesemia, or there is a manifestation of torsades de pointes, there is little indication for its use. However, a known or suspected magnesium deficiency may be treated with supplemental IV magnesium sulfate.

Physiologically, low magnesium states can interfere with the replacement of intracellular potassium. This in turn can lead to cardiac arrhythmias, symptoms of cardiac insufficiency,

and SCD. In an emergent situation, 1 to 2 grams of magnesium sulfate diluted in 100 mL of D_5W can be administered over 1 to 2 minutes. Care should be taken not to administer magnesium sulfate rapidly, as this could lead to subsequent hypotension or asystole. However, in the situation of VF/torsades thought to be due to hypomagnesemia, a more rapid administration can be carried out. [4]

Sodium Bicarbonate

The administration of sodium bicarbonate during CPR is controversial, and previous recommendations have been questioned for some time. [127] Although acidosis can reduce the responsiveness of the myocardium and vascular system to catecholamines, no clinical studies have supported the use of sodium bicarbonate for treatment of VF. Yakaitis and colleagues found that although acidosis did not alter defibrillation success in a canine model of brief VF (75 seconds), prearrest acidosis or hypoxia (in the absence of exogenous epinephrine) was rarely associated with resumption of perfusion. [128] Guerci and coworkers used a prolonged VF (20 minutes of CPR) canine model with epinephrine administration before defibrillation to assess the potential benefit of sodium bicarbonate administration. [129] These investigators failed to demonstrate an advantage from the use of sodium bicarbonate in either defibrillation success or maintenance of perfusion after defibrillation. The influence of acidosis on catecholamines appears to be most prominent at low doses and may not apply to the large amounts of epinephrine used during CPR. Current guidelines advocate the use of appropriate alveolar ventilation for the management of acidemia during cardiac arrest and in the immediate post-resuscitative period. If the patient is hyperventilated, thus removing excess carbon dioxide, an appropriate upward shift in pH will occur.

There are a number of theoretical reasons to avoid sodium bicarbonate therapy during cardiac arrest. Aside from the fact that it does not specifically facilitate defibrillation and may not be associated with a better final outcome, bicarbonate therapy will shift the oxyhemoglobin dissociation curve to inhibit oxygen release, induce hyperosmolar and hypernatremic states, produce paradoxical intracellular acidosis through an acceleration of CO_2 production, and exacerbate central venous acidosis. In addition, it may also cause a compromise in the coronary circulation.

Although sodium bicarbonate therapy should be considered for the patient with suspected or proven extreme acidosis, hyperkalemia, or both, it cannot be recommended for routine use as a standard part of the therapy for VF.

There are several exceptions to when bicarbonate may be beneficial in VF arrest; known preexisting metabolic acidosis, hyperkalemia, tricyclic overdose, or a prolonged resuscitation. Arterial blood gases with a bicarbonate and base deficit trend should be used to guide the administration of bicarbonate. 0.5 to 1 mEq/kg IV of sodium bicarbonate may be administered if the conditions noted earlier are suspected or present.

Bretylium Tosylate

Bretylium tosylate is a quaternary ammonium compound that has many complex actions on the cardiac action potential. However, it is noted for producing a hypotension and precipitating the release of catecholamines initially on injection with a subsequent postganglionic blockade. As of 1999 bretylium has been unavailable from the manufacturer. The scientific evaluation of bretylium regarding its efficacy in VF and hypothermic cardiac arrest has led to it being dropped from the current ACLS algorithms.

COMPLICATIONS

The major complications of DC defibrillation are (1) injury to skin and other soft tissue, (2) myocardial injury, and (3) cardiac dysrhythmias.

Soft Tissue Injury

When skin contact is firm and a conductive material is applied between the paddles and the chest wall, contact burns are usually minimal. Nevertheless, repeated countershocks can produce erythema of the skin resembling superficial first-degree burns. The presence of liquids (e.g., blood, IV solutions, vomitus, urine, excessive sweat) may permit the passage of current across the trunk. This electrical arcing will produce thermal burns (third-degree at times) and ineffective defibrillation. Hummel and coworkers have shown that repeated defibrillations using certain high-impedance conducting gels are associated with sparking and represent a fire hazard in an oxygen-enriched environment and an explosion hazard in the presence of nitroglycerin ointment or patches. [63] Intrathoracic injuries (extrinsic to the heart) are likely to occur but are difficult to document during the post-resuscitative period and to separate from cardiac injury (e.g., pulmonary edema). [130]

Myocardial Injury

The direct application of electrical countershock to the heart has long been known to produce epicardial and myocardial injury. Studies have demonstrated that closed-chest defibrillation is capable of producing cardiac injury. Electrical current rather than direct thermal injury produces injury. [31] [131] Multiple countershocks have been shown to produce ST segment elevation in animals and gradual cell necrosis (over days) with subsequent fibrosis. [132] The lesions are primarily subepicardial at the points of current entrance and exit. Animals receiving less than twice the defibrillation threshold value do not develop significant necrosis. The degree of cardiac injury correlates with increasing energy exposure.

Jones and coworkers, using an in vitro model, have created transient sarcolemmal microlesions during high-intensity electric field stimulation identical to that of defibrillation. [133] These lesions result in a "short-circuit" depolarization of the cells by loss of the normal sodium-potassium gradient across the sarcolemma. When the lesions are limited, the cell can recover after about 60 seconds. However, with extensive lesions, shock-induced cytosolic calcium overload can occur and result in post shock contracture.

The ability to document anatomic injury to the human heart is limited by the natural reparative process, concurrent ischemic processes producing similar microscopic changes, and the fact that several days are needed for the injuries to manifest themselves. Cardiac isoenzyme (CK MB) levels were shown to rise in patients undergoing elective cardioversion only if the cumulative delivered energy was >475 J. [134] Therefore, standard defibrillation should not generally interfere with the enzymatic diagnosis of myocardial infarction when defibrillation attempts are not excessive and given that fractionated isoenzymes are measured.

Animal studies have shown that ST segment elevation and pathologic changes are increased with more rapidly delivered discharges (1 or 3 seconds versus 15 seconds between discharges). [31] Furthermore, the cumulative energy correlates with myocardial injury for a given dosing schedule. [135]

Current research and development has led to the development of biphasic truncated energy delivery (i.e., biphasic truncated waveforms for DC defibrillators). In addition, newer model defibrillators are measuring the impedance to defibrillation current prior to actual discharge of the energy across the chest and myocardium. It is currently believed that this will lead to enhanced defibrillation success with less damage to the myocardium. This also should result in fewer adverse rhythms, e.g., persistent ventricular fibrillation, and fewer lethal arrhythmias post defibrillation, and less asystole and high-level heart blocks.

Cardiac Dysrhythmias

The rhythm that one obtains following defibrillation may be ventricular, supraventricular, or flatline (asystole). Laboratory studies have suggested a correlation between the severity of postdefibrillation dysrhythmias and the degree of myocardial damage produced. [136] Reducing the peak current delivered to the heart by changing the waveform of the discharge was associated with fewer dysrhythmias. Weaver and colleagues noted that asystole and transient heart block occurred more commonly with a higher discharge energy in prehospital VF patients. [80] Gueze and Koster also found that postdefibrillation dysrhythmias were more common following prolonged VF and higher-energy-level countershocks. [137] As stated earlier in this chapter, it is believed that the use of biphasic, impedance-compensated defibrillators will decrease the mortality and morbidity inherent to defibrillation countershocks.

Injuries to Health Care Providers

Any electrical device, including an improperly grounded or poorly insulated defibrillator, can cause injury to the device operator or to others in attendance. Other participants in a resuscitation who touch the patient or the stretcher can also serve as a ground for the defibrillator charge and can sustain electrical injury. Gibbs and coworkers estimate that the rate of paramedic injury during patient defibrillation is 1 per 1700 defibrillatory shocks. [138] They found only one paramedic who required hospital admission for therapy and monitoring of countershock ectopy. Improper use of the device for cranial countershock has been reported to produce short-term memory loss. [139] However, it must be borne in mind that such inappropriate use of these devices could easily cause much more serious injury. Fires resulting from defibrillator sparks in the presence of nitroglycerin patches or ointment, flammable gases, or an oxygen-enriched environment can also injure health care personnel as well as the patient.

SPECIAL TOPICS IN DEFIBRILLATION

Management of patients with an automatic implantable cardioverter defibrillator (AICD) is discussed in Chapter 13 .

Automatic External Defibrillators (in Hospitals)

AEDs (Fig. 12-12 (Figure Not Available)) have been developed with sophisticated digital software to take advantage of algorithms that can reliably recognize VF. [35] [65] These small, portable, battery-operated devices permit providers to defibrillate cardiac arrest patients without the need for human rhythm interpretation. [140] This advancement has taken defibrillation beyond the arena of the critical care setting such as the critical care unit (CCU), intensive care unit (ICU), emergency department (ED), or EMS vehicle and has extended the stage of defibrillation to include the lay public. The first effort to develop public access defibrillation was begun by Douglas Chamberlain in Brighton, England. AEDs were placed in/on trains, aircraft, and with families of high-risk cardiac patients. Extrapolation of the initial findings from these actions suggested that a significant increase in survival of prehospital cardiac arrest could potentially be achieved. [30] [141] [142] In light of these findings and the prior establishment of AEDs as a safe and effective resource for early defibrillation, [143] [144] an initiative to provide early, easy access to defibrillation and CPR by the lay public at various levels has been made. Early studies of these actions demonstrate an improved survival rate of victims of VF in prehospital SCD. In addition, a shorter time to defibrillation—"first shock"—and faster application of subsequent ACLS interventions [145] [146] were reported in the prehospital arena.

A group of investigators reviewed the data from in-hospital resuscitation of VF and discovered some unexpected and concerning results. Time to first shock by an in-hospital cardiac arrest resuscitation team did not occur for as long as 5 to 10 minutes. Furthermore, time to first shock was even longer in unmonitored hospital beds and diagnostic facilities. [20] These findings instigated a shift in the focus of in-hospital CPR

Figure 12-12 (Figure Not Available) SurVivaLink/Cardiac Science "Firstsave" Automatic External Defibrillator (AED). *(Courtesy of Cardiac Science, Inc., Irvine, CA.)*

training. Now the intent is to train nurses and clinical support personnel in CPR and AED technology. [147] [148] Current perception and prior research have led to the movement by various in-hospital committees and various hospital review councils to initiate placement of AEDs in various non-critical areas of hospitals. [149] [150] Also, current basic life support programs are being restructured to include AED application into the CPR training classes for general care nurses and first responders. [151] [152] Standard/typical manual defibrillators are having AED capabilities designed and built into them. This action is believed to lead to greater success rates in in-hospital resuscitations and provide the patient arriving into the ED with a better chance of survival to discharge. In fact, recommendations from the International Guidelines 2000 Conference [4] suggest that defibrillation be accomplished in 3± minutes from collapse within the confines of a hospital (Class I).

AED Application (Techniques)

Based on the design and programming of the newly devised AEDs, application and use of AEDs are quite simple. There are two major types of AEDs, fully automatic and semiautomatic. Fully automatic defibrillators are used only in special situations and are not be addressed in this chapter. The semiautomatic defibrillator is the type most commonly used in most emergency applications and is discussed in some detail here.

Various companies/vendors manufacture AEDs. However, the overall sequence of use is the same (Fig. 12-13).[42] [43]

Upon recognition of unresponsiveness in the victim, a call for help or 911, or both, if applicable, should be made. If the victim is found to be apneic and pulseless (i.e., no signs of spontaneous circulation), CPR should be initiated until an AED is brought to the scene/bedside. The AED should be placed to the left of the patient's head for the purpose of optimizing access to the patient and the AED controls. Subsequently, 4 "universal AED steps" should be completed:

1. **The AED should be turned on.** Power on is usually accomplished by depressing a switch or opening the cover of the AED. This will initiate a "self-check" of the AED. Subsequently there will be electronically synthesized voice prompts and, in many cases, visual instructions for the operator to follow (e.g., attach electrodes).
2. **Attach the electrode pads.** The pads used are self-adhesive and are placed over the skin. The correct position for pad placement is to the right of the sternum, just below the clavicle and lateral to the left nipple, about 7 cm below the axilla (Fig. 12-14). Care should be taken to avoid nitro patches or implanted defibrillators/pacemakers, or both, as they could result in poor current delivery or even explosion. The pads should be placed at least 2.5 cm (1 inch) away from these devices.[153] The pads function to monitor the rhythm and to deliver the defibrillatory shock. If the patient is very diaphoretic, a quick effort should be made to dry the chest with a dry cloth. If there is a problem with excessive chest hair, remove the pads and apply new ones. This will enhance contact, decrease TTI, and decrease potential artifact acquisition during the subsequent analysis of the rhythm. The position for placing the pads is often pictorially described on the pads or defibrillator.
3. **Analyze the rhythm.** Some AEDs are automatically programmed to analyze the rhythm once the electrodes are attached. Others will prompt the rescuer to depress an "analyze" button. To ensure that the analysis is not compromised, all contact with the patient should cease, including CPR, and no one should be in contact with the patient. All peripheral, nonessential, electronic devices should be turned off, if possible. The AED will then analyze the input waveform and provide an "advisory" if there is a shockable rhythm (i.e., VF). If a shock is "advised," the operator will proceed to the next step. If no shock is advised, CPR will be reinitiated.
4. **State "Clear the victim!" and press SHOCK.** Once a shock advisory has been given, state in a loud, definitive voice: "I'm clear, you're clear, everybody clear" and depress the shock button if it is safe to do so. No one should be in contact with the patient or any conductive material contacting the patient. The AED will then prompt the rescuer to either depress the analyze button or the AED will automatically analyze the rhythm. If another shock is advised, step 4 will be repeated until a volley of three successive shocks have been administered. These may be either escalated, with energy increasing or nonescalating, depending on the programming of the individual AED. If there is no success in achieving defibrillation, 1 minute of CPR is usually advised, followed by a repeat of steps 3 and 4 until 9 shocks have been delivered (see Fig. 12-13). In the hospital setting it is assumed that by the time algorithm for AED applications is exhausted, a resuscitation team will be at the victim's side to render further intervention if indicated.

Thump Defibrillation

The precordial thump consists of a firm, sharp, quickly delivered blow applied to the midsternum with a closed fist from a height of about 30 to 38 cm above the anterior chest wall of a pulseless patient. It is believed that such a blow is capable of generating approximately 5 J of energy. This, however, should only be considered when a defibrillator is not immediately available.

Although such a precordial thump may be of limited value in witnessed VT/VF arrests, Miller and associates noted no VF conversion in 23 prehospital VF patients. [154] Despite the fact that the rhythm was improved in 3 of 27 VT patients after a precordial thump, the rhythm deteriorated in 12 of the 27 and did not change in the other 12 patients. Caldwell and colleagues reported the results of a precordial thump in 68 cases of VT and 248 cases of VF. [155] They reported 26 favorable cardioversions, including in 5 patients in VF. Because successful internal defibrillation can occur with as little as 1 J following cardiopulmonary bypass, a vigorous precordial thump may create sufficient current flow to defibrillate the heart when the duration of arrest has been brief (i.e., witnessed cardiac arrest).

Special Situations: Transdermal Medications, Implantable Pacers/Implanted Automatic Cardioverter-Defibrillators

Care should be taken when defibrillating a patient with either a pacemaker or an implantable automatic cardioverter-defibrillator (AICD). Paddle/pad placement should be 2.5 cm (1 inch) away from the actual device to minimize the potential for perpetuation of artifact during rhythm analysis. Also, placing the paddles at an appropriate

distance from the

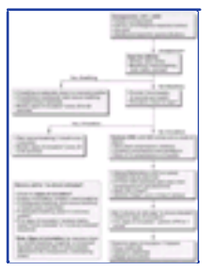

Figure 12-13 Automatic external defibrillator treatment algorithm for emergency cardiac care. *(From AHA Guidelines 2000, Circulation 102(suppl):1, 2000. Reproduced with permission.)*

ancillary device reduces the possibility of current scatter and diminution due to a potential increase in chest wall impedance. The same arguments hold true for placement of defibrillation pads and paddles away from nitroglycerine patches, nicotine patches, hormone replacement patches, and analgesic patches. There have been actual reports of injuries to the skin during defibrillation. [153]

Refractory Ventricular Fibrillation

The major determinants of successful defibrillation are the early use of countershock, adequate oxygenation, lack of serious metabolic derangements, and general health of the patient. Hargarten and colleagues note that few prehospital patients who remain in VF after the fifth shock are subsequently successfully converted to an effectively perfusing rhythm.[8] Kerber and colleagues note that patients who never defibrillated successfully despite multiple shocks had a prolonged duration of CPR preceding the first shock (21 ± 14 minutes) and systemic hypoxia and acidosis. [156] These conditions were noted to occur when initial cardiac arrest rhythm was asystole, severe bradycardia, or PEA.

A number of clinical conditions may result in the inability to convert VF initially or in the recurrence of VF following the first successful defibrillation. Patients with severe hypothermia are often refractory to initial defibrillation and

Figure 12-14 Correct automatic external defibrillator electrode placement on victim. *(From AHA Guidelines 2000, Circulation 102(suppl):1, 2000. Reproduced with permission.)*

generally require rapid core rewarming to be successfully defibrillated. Severe bradycardia will predispose to lethal escape rhythms, and emergency cardiac pacing may be required. Severe electrolyte disturbances, such as hypokalemia, hypomagnesemia, and hypocalcemia may precipitate refractory VF and be amenable only to the appropriate, rapid correction of the deficient electrolyte. Such situations may occur especially in fad dieters or abusers of diuretic medications. Uncorrected acidosis or hypoxia, such as that seen with drowning, may be the cause of persistent VF. In addition, excessive adrenergic stimulation, such as that seen with cocaine or amphetamine overdose, may require the use of a beta blocker or a mixed alpha beta blocker (e.g., labetalol) infusion before successful defibrillation. As a final note, following defibrillation, all patients should be treated with antidysrhythmic drug therapy to minimize the chance of recurrent VF.

CONCLUSION

Prompt recognition and electrical defibrillation is the preferred treatment for VF-related sudden death. Treatment should be initiated as early as possible with strict attention to selection of the proper energy dose as well as to minimization of TTI. Although repetitive high-energy shocks may be associated with myocardial injury, this factor has not been found to be a clinical problem at currently recommended energy levels. Current biphasic defibrillators may decrease myocardial injury and prove to be more successful in returning spontaneous circulation after VF.

Medications such as amiodarone, vasopressin, epinephrine, and lidocaine may have some benefit in decreasing the VF threshold and may be used at the discretion of the clinician. The clinical situation and patient history may be guides.

Pediatric Defibrillation

VF is much less common in children than in adults. In children causes are most likely sudden infant death syndrome or respiratory disease. [157] [158] [159] There is an age-related pattern in the occurrence of cardiac arrest in the pediatric population: About half of the cardiac arrests that occur in children are encountered before the age of 1 year. After 6 months of age, drowning and injuries are reported to be the major causes of death. The most common terminal rhythms reported in children under the age of 17 years are PEA, bradycardia, or asystole. [160] The etiology behind these pediatric arrhythmias is most often hypoxemia, hypotension, hypoglycemia, and acidemia. In addition, focal electrical ectopy is less likely to initiate VF in the young heart. A significant myocardial mass must be unstable and fibrillating before VF becomes established. In children (from birth to 8 years of age) with nontraumatic arrest, only 3% of the dysrhythmias are reported to be VF. In victims aged 8 to 30 years of age, the number of VF patients increases by almost 6-fold (17%). [161] Several subpopulations of pediatric patients at various ages with cardiomyopathy or myocarditis or those patients who have undergone heart surgery are at increased risk for a primary dysrhythmia.

The incidence of VF in cardiac arrest rhythms of pediatric patients is reported to be from 7% to 15%. [162] Others have reported that approximately 10% of reported pediatric cardiac arrest patients had VF. [163] In a retrospective prehospital study of pediatric patients, VF was reported to have been found in almost 20% of the cardiac arrest victims. [162] Patients who have been defibrillated from VF have been reported to have a higher survival-to-discharge rate than children who sustained asystole or PEA. [162] Therefore, there is a definite indication for early defibrillation in the pediatric population.

Procedure and Technique

The procedure for pediatric defibrillation (Fig. 12-15) is similar to the algorithm for adult defibrillation (see Fig. 12-13). However, there are a few differences that must be addressed. These differences are discussed in the following section.

Paddle/pad applications/conductive materials.

To acquire the electrical rhythm and subsequently administer an effective defibrillatory shock, appropriately sized pads/paddles must be correctly placed onto the chest. The appropriate size and placement of the paddles/pads will ensure that the appropriate current density be delivered across the myocardium to effectively defibrillate the myocytes. Furthermore, appropriate pad/paddle size (i.e., the largest surface area possible without direct electrode-to-electrode contact) will decrease TTI and enhance defibrillation. [164] To accomplish this, it is recommended that infant paddles be used in children who weigh <10 kg. However, larger paddles can be used if they do not contact each other; if contact is made between the paddles, an electrical arc or short could occur. [165] In children who weigh more than 10 kg (mean age 1 year), it is recommended that adult pads/paddles be used (8 to 10 cm in diameter). [166] Regarding enhancing skin contact and decreasing TTI, a conductive agent should be used. Never use dry paddles, as the resistance to current flow will be very large. However, refrain from using saline-soaked pads in children as they may cause arcing due to the proximity of the pads on the chest; remember that electricity will take the path of least resistance and that the current from defibrillation will travel across the chest if there is a saline bridge between the electrodes. Also, the use of ultrasound gel and alcohol pads is discouraged because of poor electrical conductivity and potentially high impedance. [62] Also, care should be taken with repeated shocks, because there have been reports of skin burns if inadequate contact and inadequate conductor gel is not used. [167]

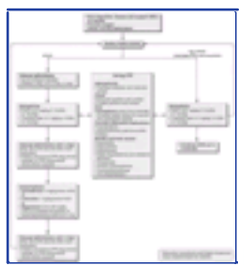

Figure 12-15 Pediatric pulseless arrest Pediatric Advanced Life Support treatment algorithm. *(From AHA Guidelines 2000, Circulation 102(suppl):1, 2000. Reproduced with permission.)*

The paddles or pads should be applied firmly to the chest—one to the right of the sternum, just below the clavicle, the other to the left of the left nipple, over the ribs (over the apex of the heart). An option when using self-adhesive pads is to place one pad just to the left of the sternum and the other over the back, approximating the position of the heart. [168]

Energy Selection and Pharmacotherapy

Currently there is no definitive evidence to support any specific energy for successful defibrillation in the pediatric population. However, available data have indicated that a dose of 2 J/kg (Joules/kilogram) may be used in the first shock attempt for children up to at least 8 years of age. [83] If this

action does not terminate VF, then the energy dose should be doubled to 4 J/kg and repeated. [169] A third shock may be given at the same energy dosage if there is still no success in defibrillation. The three shocks should be given in rapid succession, allowing time only for determination of the underlying electrical rhythm. If the first 3 initial shocks fail to terminate VF, then attention must be turned to identifying and treating hypoxia, acidemia, hypothermia, and if indicated administering pharmacological pressor agents such as epinephrine (1:10,000; 0.01 mg/kg) (intravenously or intraosseous [IO]) or (1:1000; 0.1 ml/kg tracheal tube) (see Fig. 12-15). Another defibrillatory shock (4 J/kg) should be administered 30 to 60 seconds post drug administration. CPR should be performed between interventions. If no success is achieved after 4 shocks, the agent amiodarone (5 mg/kg bolus IV/IO) (Class Indeterminate) may be administered (see Fig. 12-15). Use of amiodarone is suggested only on the basis of experience with adult victims to date. [125] Lidocaine (1 mg/kg bolus IV/IO) or high-dose epinephrine (Class IIb) may also be considered at this point if there is no success. Once the drugs have been administered, another shock at 4 J/kg should be delivered. It is also acceptable to administer three successive shocks in between drug interventions. [4]

Waveforms

Newly manufactured defibrillators and AEDs are using the biphasic waveform. As mentioned previously in this chapter, there are various forms of the wave (e.g.,

truncated, damped sinusoidal). This waveform has been described as being effective in achieving defibrillation at lower energy levels and as being less damaging to the myocardium.[52] Many new manual defibrillators and AEDs are being released for use with this new technology. However, data regarding the efficacy and use of the biphasic waveform in the pediatric population is limited as of this writing. Extrapolating from the data currently available in adult applications of biphasic defibrillation, it is the belief of these authors that biphasic waveforms will be in use in the near future in defibrillators designed for use in the pediatric population. Although use of the biphasic waveform allows for a decrease in the amount of energy needed to defibrillate, current guidelines suggest that the 2 J/kg and subsequently the 4 J/kg energy be used.[4] These energy selections may undergo modification as more high-level data is collected regarding biphasic defibrillation technology.

AEDs in Children

AEDs are now being used in adults in various areas with some success. However, pediatric AED applications are in the investigative stages. Data suggests AEDs can accurately detect VF in children of various ages. [170] [171] [172] However, current energy levels delivered by both the monophasic and biphasic defibrillators even at 150 to 200 J exceeds the 2 to 4 J/kg level. In fact, the energy actually delivered is more in the range of <10 J/kg in patients older than 8 years of age. This is based on a mean weight of 25 kg for an 8-year-old approximately 50 inches tall (128 cm). [173] Animal data suggests that this is still a safe dose for defibrillation in children. However, currently standard biphasic/monophasic AEDs are not recommended for use in children. [174] Some vendors have developed adapters to adjust energy delivery to the patient, but these AEDs are in limited distribution.

In summary, currently monophasic or biphasic AEDS are not recommended for use in children under 8 years of age or weighing <25 kg. However, there is speculation that AEDs will be modified to enable use of biphasic low-energy AEDs in the pediatric population.

CARDIOVERSION

Cardioversion is the application of direct electrical current across the chest or directly across the ventricle to normalize the conduction pattern of a rapidly beating heart. Defibrillation refers to application of electrical energy during the nonvulnerable period to restore a fibrillating ventricle to normal sinus rhythm.

The patient with a significant tachycardia may be asymptomatic or may complain of chest pain or discomfort, lightheadedness, or shortness of breath. These symptoms are the result of altered cardiovascular physiology. Rapid cardiac rhythms allow less time for ventricular filling, resulting in reduced preload and hypotension. The reduced preload as well as the increased ventricular work caused by the rapid heart rate may also result in ventricular ischemia. Pulmonary capillary wedge pressures may also rise despite shortened filling time, due to reduced ventricular compliance secondary to ventricular ischemia. Elevated pulmonary capillary wedge pressures can then lead to pulmonary edema.

Termination of rapid rhythms to alleviate or prevent these symptoms must occur quickly to prevent further deterioration. Persistently poor cardiac output due to rapid heart rate results in development of a lactic acidosis that further compromises cardiac function and makes cessation of the dysrhythmia even more difficult. Unchecked myocardial ischemia may lead to infarction with its attendant sequel. Drug therapy, rapid cardiac pacing, and cardioversion are the methods available to terminate tachydysrhythmias.

In many cases, direct-current cardioversion has specific advantages over drug therapy. The speed and simplicity of electrical cardioversion enhance its usefulness in the ED setting. Cardioversion is effective almost immediately, has few side effects, and is often more successful than drug therapy in terminating dysrhythmias. In addition, the effective dose of many antidysrhythmic medications is variable, and there is often a small margin between therapeutic and toxic dosages. Although they can often suppress an undesirable rhythm, drugs may also suppress a normal sinus mechanism or may create toxic manifestations that are more severe than the dysrhythmia being treated.

In the clinical setting of hypotension or acute cardiopulmonary collapse, cardioversion may be life saving. The key concepts in the use of this procedure include understanding the indications for its use, the equipment involved, the importance of adequate sedation, and the concerns for health-worker safety.

BACKGROUND

The first successful defibrillation of the human heart was performed in 1947 by Beck. By the 1960s, electrical energy was being used to treat dysrhythmias other than VF. AC remained in vogue until 1962, when Lown and colleagues advocated DC countershock as the method of choice for terminating atrial fibrillation. [175] The use of DC significantly decreased the incidence of VF following countershock.

A brief burst of electrical current momentarily causes depolarization of the majority of cardiac cells and allows the sinus node to resume normal pacemaker function. In reentrant

dysrhythmias, such as paroxysmal supraventricular tachycardia (SVT) and VT, cardioversion restores sinus rhythm by interrupting a self-perpetuating circuit. Cardioversion is much less effective in terminating tachycardias resulting from augmented automaticity, such as digitalis-induced dysrhythmias.

Monophasic versus Biphasic Wave Form Defibrillators

From the pioneering days of defibrillation technology in the 1950s until the start of the 20th century, traditional defibrillators generated a monophasic damped sine wave form to deliver the energy needed to convert tachydysrhythmias. Starting in the 1990s, biphasic technology was introduced for AEDs and automatic implantable cardiac defibrillators (AICD). The biphasic defibrillator is now positioned to replace the monophasic waveform defibrillator in all hospital-based defibrillators.

In contrast to the monophasic defibrillator, the biphasic wave generator delivers current in two directions. During the first phase, the biphasic current travels from one paddle to the other, similar to the monophasic wave form. However, during the second phase, the current *reverses* direction. This distinctive feature has been proven to lower the electrical threshold for successful defibrillation and cardioversion.

INDICATIONS AND CONTRAINDICATIONS

Cardioversion is indicated whenever a reentrant tachycardia causes unstable vital signs, ischemic chest pain, or otherwise significantly compromises cardiovascular or respiratory function. No specific parameters exist and the decision to perform cardioversion is best made on a case by case basis by the clinician at the bedside. It is also indicated on an elective basis when medical therapy has failed. In any situation where a prolonged rapid heartbeat can be anticipated to cause complications related to cardiac ischemia or dysfunction, early intervention with cardioversion may also be considered.

A reentrant tachydysrhythmia should be suspected when a sudden change in the heart rate occurs within a few beats. Unless the dysrhythmia is noted while the patient is being monitored, it can only be inferred from the patient's history of sudden onset of symptoms. In the unusual case of sinus node reentrant tachycardia, rapid onset and offset may be the only clue.[176] Other clues to the presence of a reentrant dysrhythmia are a history of Wolff-Parkinson-White syndrome or another known accessory pathway syndrome. Ventricular rates in excess of those predicted for age strongly suggest an accessory pathway.

Dysrhythmias due to enhanced automaticity will not be terminated by uniformly depolarizing myocardial tissue because a homogeneous depolarization state already exists. Enhanced automaticity is the cause of most cases of digitalis toxicity-induced dysrhythmia, sinus tachycardia, and, probably, multifocal atrial tachycardia. [177] Enhanced automaticity means that the threshold for phase 4 depolarization has been lowered or that the rate of ion leak during phase 4 has been accelerated. This effect on phase 4 depolarization is caused by alterations in the metabolic or chemical environment or on the cell membrane, causing pacemaker cells to fire more rapidly. Although cardioversion will not be successful in these cases, medications that suppress automaticity, including potassium and magnesium, may be useful.

In digoxin toxicity, cardioversion is not only ineffective, but it is also associated with a higher incidence of postshock VT and VF. [178] However, for a patient with a therapeutic digoxin level, the risk of cardioversion is no different from that of other patients. [179] Digoxin is still generally withheld for 24 hours prior to cardioversion as a precaution against inadvertently elevated levels. Pregnancy at any stage is not a contraindication to cardioversion. [180] [181]

Supraventricular Tachycardia with Aberrancy versus Ventricular Tachycardia

Determining the rhythm is critical for the clinician to make the appropriate clinical/pharmacologic intervention. However, at times SVT may manifest patterns on the ECG that look very similar to VT. An incorrect assessment of the ECG can prompt the clinician to implement a pharmacologic/therapeutic intervention which may result in cardiovascular collapse. Although a comprehensive discussion of SVT versus VT is beyond the scope of this chapter, some salient features to look for are presented herein to assist in the emergent decisionmaking process of the clinician.

A few caveats must be kept in the forefront when facing the task of discriminating between SVT and VT. A wide-complex tachycardia refers to a dysrhythmia where the ventricles beat at more than 100 beats/minute and the QRS duration is 0.12 seconds or more. [182] [183] The originating foci for these wide-complex tachycardias can be either supraventricular or ventricular. For a supraventricular focus to produce a wide-complex tachycardia, a preexisting or new onset intraventricular conduction block must be present, resulting in increased time of depolarization. Increased heart rate or ischemia can also precipitate the appearance of a wide-complex tachycardia when it is supraventricular in origin. If the focus of the tachycardia is below the AV node, the tachycardia is considered ventricular in origin. [182] Criteria to facilitate the process of discriminating between SVT and VT were compiled by Wellens and Brugada. The Wellens criteria use several clinical data points to help determine if the tachycardia is ventricular or supraventricular in origin. [182] The Brugada criteria extend the Wellens criteria and add a four-step decision-tree approach to the process.[185] Although the methods are not without pitfalls, a careful scrutiny of the ECG in light of the aforementioned criteria will usually lead to the appropriate diagnosis.[186]

Following are characteristics of SVT versus VT. Although the guidelines and criteria appear clear-cut, there are times when exceptions occur in the clinical setting (Table 12-4 , Table 12-5 , Table 12-6 , and Table 12-7).

Special Considerations: Wide-QRS-Complex Tachycardias

Wide-complex tachycardias (wide-complex SVT) are diagnostic challenges in clinical medicine. The criteria often used to define wide-complex SVT (WCSVT) is a tachycardia with a QRS duration of >0.12 seconds. It is important to differentiate the rhythm as one of the following: VT, SVT with aberrancy (LBBB or RBBB), or an accessory AV pathway ("pre-excitation"). The need for a proper diagnosis is obvious. Incorrect diagnosis and inappropriate treatment can be life threatening. This is especially true in misdiagnosing VT as SVT. Studies have shown that VT is often misdiagnosed, even with the

TABLE 12-4 -- Standard Criteria to Differentiate SVT from VT

Rate:	Too much overlap to make rate a useful criterion.
Regularity:	Grossly *irregular* complexes are likely to represent one of three conductions: (1) AF with aberrancy, (2) AF with conduction through an accessory pathway, or (3) irregular form of VT. Rates greater than 200 bpm with a wide-QRS-complex are highly suggestive of AF with aberrancy or AF with accessory pathway conduction.
AV Dissociation, Fusion Beats: (Table 12-6)	AV dissociation during tachycardia with a wide-complex is highly suggestive of VT.
QRS Axis:	Preservation of normal QRS axis in a wide-complex tachycardia favors a diagnosis of SVT with aberrancy. Change in axis or extreme left or right axis deviation is often seen in VT. Abrupt change in QRS morphology is frequently seen in VT but not in SVT.
QRS Duration:	QRS duration greater than 140 ms occurs more frequently in VT compared to SVT.
QRS Concordance:	Concordance in the precordial leads is rarely seen in SVT with aberrancy.
	Concordance supports a diagnosis of VT.
QRS Morphology:	*RBBB-shaped complex:* To distinguish RBBB aberration in SVT from VT, the presence of a triphasic pattern in V1 or a qRs pattern favors aberrancy. While a monophasic or biphasic QRS in V1 or an rS or QS complex in V6 favors VT.
	LBBB-shaped complex: SVT is suggested if the LBBB pattern has a small initial r wave with a steeply down sloping S wave. An initial r wave (>30 ms) and a notched, broad (>70 ms) down slope is favorable for VT. QS complex or a qR in V6 suggests VT.

ready availability of clinical and ECG criteria. In one study, VT was correctly diagnosed in 32% of patients presenting with wide-complex tachycardias. [184]

Etiology

Normally, ventricular depolarization is initiated when the His bundle depolarizes both ventricles simultaneously through the bundle branches and Purkinje fibers. Normal depolarization takes place within 80 to 120 ms. Prolongation of the QRS duration happens if (1) the ventricles are activated sequentially rather than simultaneously (this is the case in VT, bundle-branch blocks, or accessory pathway ventricular activation [WPW, LGL]), or (2) when His-Purkinje-myocardium

conduction is slowed from ischemia, drugs, or electrolyte disturbances.

Classification

Wide-complex tachycardias fall into three classifications based on mechanism: (1) VT, (2) SVT with aberration, and (3) pre-excitation tachycardia. VT is the most common cause

TABLE 12-5 -- Brugada Algorithm

First reported in 1991, this algorithm was designed to aid the clinician in diagnosing lethal VT from the less urgent SVT with aberrancy conduction. Taking the standard 8- to 10-point criteria used by cardiology at the time, Brugada et al. focused on four ECG criteria to aid in diagnosing VT versus SVT with aberrancy. To differentiate VT from SVT with aberrancy, the Brugada Algorithm uses the following ECG criteria. *First*, examine the ECG. Is the rhythm regular? An irregular rhythm highly suggests atrial fibrillation with aberrancy. Does the purposed dysrhythmia fit the clinical picture ascertained by the history? *Then*, ask the following questions:
• Absence of an RS complex in all precordial chest leads?
• R to S interval > 100 ms in one precordial lead? (measured from beginning of R to deepest part of S wave)
• Atrioventricular dissociation? (Table 12-4)
• Morphology criteria for VT present in precordial chest leads V1-2 and V6? (Table 12-4)
(A single "yes" response suggests VT Only when none of the VT criteria are affirmed is SVT diagnosed
Adapted from Brugada et al., 1991).
Wellens Criteria
In a landmark study published in 1978, Wellens et al. determined that the findings suggestive for a ventricular origin of tachycardia were the following * :
• QRS width over 0.14 sec
• Left axis deviation
• AV dissociation (Table 12-4)
• Certain configurational characteristics of the QRS morphology (Table 12-4)
AV, atrioventricular; ECG, electrocardiogram; QRS, QRS Interval; SVT, supraventricular tachycardia; VT, ventricular tachycardia. *Wellens et al., 1978

of wide-QRS-complex tachycardias. It is defined as 3 or more consecutive ventricular beats at a rate of 100 beats/minute. VT is further classified as nonsustained (tachycardia lasting <30 seconds) or sustained (tachycardia that lasts >30 seconds). Sustained tachycardia usually results in hypotension or syncope and requires termination intervention. SVT is a tachydysrhythmia using the normal AV conduction system for ventricular activation. This tachycardia originates in the SA or AV node. To sustain propagation, the AV node is recruited. Aberrancy refers to the existence of an aberrant or nontraditional conduction mechanism, resulting in a longer depolarization phase. SVTs with aberrancy by definition must result in wide-QRS-complex tachycardias. The two forms of aberration are fixed (i.e., a permanent bundle-branch block or functional block that is a rate-dependent bundle-branch block). The most common areas of the His-Purkinje functional block are in the left or right bundle-branches. Sudden acceleration is often the initiating cause of the SVT with aberrancy. The aberrancy is maintained by a continuous,

concealed, retrograde conduction pathway, which leads back into the blocked area.

For preexcitation wide-QRS-complex tachycardias, AV conduction occurs over two circuits: (1) normal AV nodal conduction or (2) through an accessory pathway. These two pathways create a reentry circuit. Aberration appears because of the presence of intraventricular conduction block. Preexcited tachycardia is any tachycardia where the ventricles are *antegradely* activated over an accessory pathway. The most common preexcited tachycardia is atrial fibrillation with ventricular activation over an accessory pathway.

Clinical Diagnosis

The directed history on presentation may provide the most valuable clues to the diagnosis of tachydysrhythmia. The on and off occurrence of tachydysrhythmia in the past, the age of the patient, and the age of past occurrence all are important indicators of preexcitation rhythms usually found in young patients. Sudden onset of tachydysrhythmia in the older coronary-prone patient or patient with structural heart disease points more toward ventricular tachycardias. Symptoms associated with the tachydysrhythmia are important clues in diagnosis. The young patient often has few if any symptoms when experiencing the wide-complex or narrow-complex SVTs. The older patient may experience the entire range of cardiac symptoms. Tachydysrhythmia present for long periods often defines SVT. Patients with SVT often have recurrent tachycardias from their childhood or early adulthood. Attention must be paid to the medications the patient is using. Antiarrhythmic medications have a

use-dependency property. Conduction velocity is slowed as rates increase. [187]

Electrocardiographic Criteria for Differentiating Ventricular Tachycardia from Wide-Complex Supraventricular Tachycardia

The clinician should not attempt the differential diagnosis of wide-QRS-complex tachycardias without the use of the 12-lead ECG and extended rhythm strip. A common error is to attempt to determine the cause of a tachycardia based only on the rhythm strip. A comparison of past ECGs is often helpful. Examination of the ECG should focus on the following areas: rate, regularity, AV dissociation, QRS axis, QRS duration, QRS concordance, and QRS morphology (see Table 12-4).

Treatment

Therapy is dictated by the specific wide-complex tachycardia and the patient's clinical presentation. The emergency clinician's initial approach must always be led, and modified if necessary, by the patient's presentation and subsequent changes. It is recommended in all cases of wide-complex tachycardias, and narrow-complex tachycardias, which are producing hemodynamic instability, that the clinician should immediately consider use of cardioversion. Synchronized monophasic or biphasic cardioversion is the appropriate first choice of treatment for these cases.

In patients with wide-complex tachycardias who are cardiovascularly stable, the therapeutic options are more diverse. Stable, wide-complex tachycardia can always be considered VT and treated according to current VT protocols. [188] Verapamil should never be used in unknown etiology wide-complex tachycardia. A reasonable treatment protocol for stable patients may be the use of adenosine, procainamide, lidocaine, and finally cardioversion. Amiodarone is effective for most SVTs and its use in stable unknown wide-complex SVT is both appropriate and safe. [189]

EQUIPMENT AND SETUP FOR CARDIOVERSION

The critical components of preparation for cardioversion are IV access, airway management equipment, drugs for sedation, monitoring equipment, and DC delivery equipment (cardioverter).

Secure IV access is essential for delivery of sedatives, antidysrhythmics, fluids, and, possibly, paralytic agents. Although many of these drugs are not used routinely, if they are needed, timing is likely to be critical. A saline lock catheter of at least 20 ga should be inserted and secured.

A significant and preventable complication of procedures involving sedation is hypoventilation leading to hypoxia. Airway management equipment includes working suction with tonsil-tipped device attached, bag-valve-mask apparatus, oxygen, and an appropriately sized laryngoscope and endotracheal tube. A pulse oximeter is generally recommended for patients undergoing conscious sedation. Another adjunct is continuous pCO_2 monitoring. A rising pCO_2 level will be an earlier clue to hypoventilation due to sedation than pulse oximetry because the O_2 saturation may remain normal for several minutes, especially if the patient has been preoxygenated.

Sedative medications should be ready for use in labeled syringes, with a prefilled saline flush. Antidysrhythmic medications for ventricular dysrhythmias (e.g., lidocaine and amiodarone) and for unexpected bradycardia (e.g., atropine) should be readily accessible.

The cardioverter device consists of 5 components (see Fig. 12-7 (Figure Not Available)): (1) a DC depolarizer, which provides varying amounts of electrical current; (2) an oscilloscope screen for monitoring heart rate and rhythm; (3) access to a continuous ECG readout to document the patient's course and response to treatment; (4) 2 removable electrode paddles that can be applied easily to the patient's chest wall; and (5) a synchronizer, permitting discharge of energy outside the vulnerable period of the cardiac cycle. The synchronizer permits triggering of the electrical discharge by the R or S wave of the ECG (see Fig. 12-3).

Paddles must be large enough to depolarize the majority of heart fibers simultaneously; therefore, most conventional paddles have an electrode diameter of at least 4 inches. Larger paddles also limit the risk of myocardial injury by decreasing the density of current passing through the myocardium.

TECHNIQUE

If time permits, metabolic abnormalities such as hypokalemia and hypomagnesemia should be corrected before attempting cardioversion. Hypoxia should be corrected with supplemental O_2 . If a patient has a metabolic acidosis, compensatory hyperventilation after endotracheal intubation may be indicated prior to cardioversion. Respiratory acidosis should always be treated prior to the use of sedative drugs.

Sedation and Anxiolysis

Cardioversion may be extremely painful or terrifying, and *patients must be adequately sedated prior to its use*. Patients who are not adequately sedated may experience extreme anxieties and fear.[190] Several IV medications are available for sedation of patients prior to cardioversion. These include etomidate (0.15 mg/kg), midazolam (0.05–0.1 mg/kg), methohexital (1 mg/kg), propofol (0.5–0.8 mg/kg over 3–5 minutes), and thiopental (3 mg/kg). [191] [192] In addition, fentanyl (1–2 mcg/kg), a synthetic opioid analgesic, is sometimes administered 3 minutes prior to induction. The above doses are commonly used, but the agents should be titrated to effect as outlined in Chapter 34 .

Midazolam (Versed) is probably the most commonly used agent, with deep sedation occurring about 2 minutes after IV injection. Although induction with midazolam takes slightly longer than the other medications, it has the advantage that a commercial antagonist, flumazenil, is available for reversal, if necessary. Small additional doses of fentanyl (1 to 1.5 mcg/kg) may be added for more profound sedation. Fentanyl can cause respiratory depression, but it is reversed with naloxone. Methohexital has the advantage of quick onset and somewhat shorter duration than midazolam, but it has a rare association with laryngospasm. All the drugs except etomidate cause a small drop in blood pressure.

In elderly patients the pharmacodynamics and kinetics of medications used for sedation/anxiolysis are altered by coexisting illness and polypharmacy, rather than by any intrinsic effect of old age. [193] Older patients with medical conditions such as congestive heart failure, renal failure, cancer, or malnutrition will therefore experience deeper, prolonged sedation with increased respiratory depression. Drug dose should be adjusted accordingly in these patients.

Cardioverter Use

Selection of synchronized or nonsynchronized mode is the next critical step. In "synchronized" mode, the cardioverter searches for a large positive or negative deflection, which it interprets as the R or S wave. It then automatically discharges an electric current that lasts <4 msec, avoiding the "vulnerable" period (see Fig. 12-3) during repolarization when VF may be induced. When the cardioverter is set to "synchronize," a brief delay will occur after the buttons are pushed for discharge, as the machine searches for an R wave. This delay may be disconcerting to the unaware operator.

If concern exists about whether the R wave is large enough to trigger the electrical discharge, the clinician can place the lubricated paddles together and press the discharge button. Firing should occur after a brief delay. When the R- or S-wave deflection is too small to trigger firing, change the lead that the monitor is reading or move the arm leads closer to the chest.

If there is no R or S wave to sense, as in VF, then the cardioverter will not fire. *Always turn off "synchronization" if VF is noted*.

Electrode Contact

A number of substances can be used to ensure good contact between the paddle and the skin, it is necessary that they be nonflammable and have a low electrical resistance. Conductive gel or paste is most commonly used, but waxy conductive pads are also available. Generous use of conductive gel on the underside and especially along the edges of the electrode paddles is essential, both to reduce TTI and to prevent skin burns. Paste should be applied liberally but must not run onto the skin between the paddles, because the paste may divert current over the skin surface and away from the heart. Even under ideal circumstances, only 10% to 30% of the total current passes through the heart, so diversion over the skin may significantly reduce the effectiveness of an electric discharge. Saline-soaked pads are therefore generally not desirable. Pregelled adhesive electrode pads are useful if available.

Wet Gel Electrodes

The tendency for solid gel electrode pads to burn patients during cardioversion has led to the re-introduction of wet gel electrodes. The return of the wet gel electrodes was centered on conductivity and skin coupling features. On both issues, wet gel electrodes performed better than solid gel electrodes.

Electrode Position

Electrode paddles may be positioned in 2 ways on the chest wall: (1) the anterolateral (or base and apex) position, with one paddle placed in the left fourth to fifth intercostal space, midaxillary line, and the other just to the right of the sternal margin in the second to third intercostal space (see Fig. 12-10); or (2) the anteroposterior position, with one paddle placed anteriorly over the sternum and the other on the back between the scapulae (see Fig. 12-11). The anterolateral position is used for emergent cardioversion, when placement of an electrode on the patient's back may not be feasible. Paddles should be pressed firmly against the skin to avoid arcing or skin burns.

Safety is a key concern in the performance of cardioversion. Any staff member acting as a ground for the electrical discharge can be seriously injured. The operator must announce "all clear" and give staff a chance to move away from the bed before discharging the paddles. Care must be taken to clean up spills of saline or water, because they may create a conductive path to a staff person at the bedside.

Energy Requirements

The amount of energy required for cardioversion varies with the type of dysrhythmia, the degree of metabolic derangement, and the configuration and thickness of the chest wall (see Table 12-2). Obese patients may require a higher energy level for cardioversion; the anteroposterior paddle position is sometimes more effective in these patients. If patients are shocked while in the expiratory phase of their respiratory cycle, energy requirements may also be lower.

Ventricular tachycardia in a hemodynamically stable patient should be treated with lidocaine followed by procainamide, and amiodarone if necessary. If these drugs are unsuccessful, cardioversion is then used. Cardioversion with 10 to 20 J is successful in converting VT in more than 80% of cases. Cardioversion will be accomplished with 50 J in 90% of

cases, and conversion should be initially attempted at this energy level. [194] Cardioversion should be synchronized unless the T wave is large and could be misread as the R wave by the cardioverter. If initial attempts of electrical cardioversion are unsuccessful, the energy level should be doubled, and doubled again if necessary, until a perfusing rhythm is restored. Immediately following conversion of VT, antidysrhythmic medication should be given to prevent recurrence.

Patients with pulseless VT should be initially shocked with 200 J, followed by 300 J if the first shock is not successful. Reentrant SVTs generally respond to

low-energy levels. Atrial flutter, for example, usually requires <50 J for conversion. [26] Cardioversion of atrial flutter in the ED is indicated when the ventricular rate is not slowing in response to pharmacologically enhanced AV-node blockade, or if the patient is unable to tolerate the aberrant rhythm.

The majority of patients with paroxysmal atrial tachycardia (PAT) respond to adenosine. If they do not, or if urgent conversion is needed due to high ventricular rate, electric countershock should be administered in the synchronized mode at 50 J, and doubled if necessary.

In atrial fibrillation, the response to cardioversion is dependent on the duration of atrial fibrillation and the underlying cause. Cardioversion is successful in 90% of cases secondary to hyperthyroidism but in only 25% of cases secondary to severe mitral regurgitation. [195] However, 50% of cases revert within 6 months, especially those with longstanding atrial fibrillation. [196] [197]

Most patients with atrial fibrillation do not require cardioversion in the ED unless their ventricular response is excessively rapid due to a bypass tract, as in Wolff-Parkinson-White syndrome. Atrial fibrillation may also require cardioversion when sequelae of rapid ventricular contraction are present or anticipated and the ventricular rate is not responding to drug therapy aimed at slowing AV node conduction. Conversion of atrial fibrillation generally requires more energy than the reentrant SVTs (about 100 J in most cases). [198]

Pediatric Cardioversion

Pediatric cardioversion is similar to adult cardioversion. As previously described, the purpose of the procedure is to depolarize the myocytes completely at the most opportune time, during the peak of the R wave, so as not to precipitate VF, and allow a slower perfusing rhythm to resume. However, the energy levels for pediatric cardioversion are different from the adult. In the pediatric procedure the initial recommended energy dose is 0.5 to 1 J/kg, while the defibrillator is in the *synchronized mode*. If needed, a repeated cardioversion may be attempted at 2 J/kg, again while the defibrillator is in the *synchronized mode!* Remember to re-synchronize the defibrillator after each cardioversion attempt and look for the appropriate markers on the monitor to ensure that the current is delivered at the appropriate phase of the cardiac cycle (see Fig. 12-3).

COMPLICATIONS OF CARDIOVERSION

Complications of cardioversion may affect the patient, particularly the patient with a cardiac pacemaker, as well as health care personnel at the bedside. Patient complications are dose-related and may involve the airway, heart, or chest wall, or they may be psychological.

Injuries to health care personnel with cardioversion/defibrillation include mild shock and burns. There is a reported incidence of 1 injury per 1700 shocks for paramedics in the field.[138] Of the 13 injuries reported in this study, 15% were due to equipment failures, 23% were due to injuries during testing or demonstrations, and 23% were due to arcing of the electric shock from the paddle to an electrode on the patient's chest, whereas the remainder were due to direct contact with the patient or with the stretcher.

Hypoxia may result if sedation is excessive or if the airway becomes compromised. With proper preparations and precautions, airway complications can be minimized. Respirations may also be depressed by any of the anesthetic agents, and adequacy of tidal volume must be continually assessed by either direct observation or end-tidal CO_2 monitoring. An assistant should be placed in charge of monitoring the patient's airway cardiac monitor, and pulse oximetry. Routine supplemental O_2 is suggested for all patients undergoing sedation.

Chest wall burns resulting from electrical arcing are generally superficial partial-thickness burns, although deep partial-thickness burns have occurred. [199] These are preventable by adequate application of conductive gel and firm pressure on the paddles. Paddles should not be placed over medication patches or ointments, especially those containing nitroglycerin, because electrical discharge may cause ignition resulting in chest burns. [200]

Cardiac complications following cardioversion are proportionate to the energy dose delivered. In the moderate energy levels used most commonly, the hemodynamic effects are small. At higher energy levels, however, complications include dysrhythmias, hypotension, and, rarely, pulmonary edema, which may occur several hours after the countershock.[201] A transient failure of myocardial O_2 extraction due to a direct effect on cellular mitochondria has been proposed as an explanation for some of these cardiac complications. [202]

The dysrhythmias following high-dose (approximately 200 J) direct-current shocks include VT and VF, bradycardia, and AV block, in addition to transient and sustained asystole. Sustained VT or VF was reported following 7 of 99 shocks in a study of patients undergoing electrophysiologic study and requiring cardioversion for VT, VF, or atrial fibrillation. [203] These episodes occurred only in the patients with prior VT or VF. Patients with ischemia or known coronary artery disease appear to be at much higher risk for significant postshock bradycardia, with rate support pacing required after 13 of 99 shocks in the study. Asystole requiring pacing occurred only once in 99 countershocks. Therefore, the proclivity for dysrhythmias is greater in high-dose cardioversion of an ischemic heart.

Two types of VF following cardioversion have been described. The first variety occurs immediately after countershock and is easily reversed by a second, nonsynchronized shock. This type of VF results from improper synchronization, with discharge of current occurring during the vulnerable period. The second variety, which is more ominous, occurs approximately 30 seconds to a few minutes following attempted cardioversion. This dysrhythmia is characteristically preceded by the development of PAT with block or a junctional rhythm. In affected patients, it may be very difficult to convert the dysrhythmia to a sinus rhythm. This phenomenon occurs in patients who have been taking digitalis glycosides and is presumably a manifestation of digitalis toxicity. [204] [205]

In the event of VF following cardioversion, the equipment and manpower should be present for immediate defibrillation.

If postcardioversion VF occurs, switch the cardioverter to "nonsynchronized" before attempting defibrillation. Electrical discharge will not occur in the "synchronized" mode, because the machine will be searching for a nonexistent R wave.

VF is much more likely to occur if depolarization occurs on the T wave. If a patient has large T waves in the lead selected for cardioverter sensing, the electric shock may discharge during the vulnerable period of the cardiac cycle, resulting in VF. [206] Always examine the complexes on the cardioverter monitor carefully for large T waves and, if necessary, change the sensing lead. A randomly firing pacemaker can also be sensed by the cardioverter, resulting in countershock during the vulnerable period. [207]

Transient and intermittent ST-segment elevation has also been reported to occur (though rarely) after cardioversion, with myocardial injury or coronary vasospasm offered as possible explanations. [208]

An increase in serum enzyme levels (creatine kinase, lactate dehydrogenase, aspartate aminotransferase) may also occur following cardioversion, and the incidence has been reported to be between 10% and 70%. The enzyme rise is usually a consequence of skeletal muscle injury rather than myocardial damage. Cardioversion does not alter the enzyme profile of patients with myocardial infarction. [209]

CONCLUSIONS

Cardioversion is a safe and effective method of quickly terminating reentrant tachycardia. Complications related to psychological trauma, respiratory depression, and unintentional health-worker shock can be avoided with proper precautions. Adequate sedation is essential. Synchronized shock should be administered after close scrutiny of the lead used for sensing, to be sure that the R or S wave is significantly larger than the T wave. Be prepared for postshock VT or VF, and if VF occurs, switch the cardioverter to "nonsynchronized" and defibrillate. Atropine and temporary pacing equipment should be available to treat postshock bradycardia, especially in patients with myocardial ischemia or infarction.

Chapter 13 - Assessment of Implanted Pacemaker/AICD Devices*

David W. Munter

Patients with permanent implanted pacemakers or automatic implantable cardioverter-defibrillators (AICDs) are commonly seen in the emergency department (ED). The frequency with which these patients present to the ED can be attributed to an aging population and increased usage of pacemakers and AICDs due to their technical sophistication and reliability. Fortunately the increased reliability of the devices has prevented a marked increase in patients presenting with true emergencies related to device malfunction. Complications, however, are not uncommon, with 7.4% to 15% of pacemakers failing in the first year. [1] AICD complication rates, including inadvertent shocks, occur in up to 34% of patients with the device. [2] Although the basic evaluation and treatment of patients with pacemakers or AICDs presenting with cardiac complaints is not substantially different from that of patients without the devices, a general knowledge of the range of potential problems and complications and techniques for evaluating or inactivating pacemakers or AICDs is desirable for emergency clinicians. However, these devices are complicated and most clinicians do not possess the expertise to fully evaluate them. Appropriate consultation, depending on the clinical situation, may be necessary.

BACKGROUND

The relationship between applied electricity and ventricular rhythms and arrhythmias has been understood since the late 1800s. [3] With the onset of cardiac monitoring techniques in the 1940s, the relationships between sudden death, cardiac syncope, ventricular fibrillation, and bradycardias began to be understood. [4]

The first pacemakers were developed by Zoll in the 1950s. [4] The units were transcutaneous and used primarily for Stokes-Adams disease (syncope secondary to bradycardia or asystole). These early units could only be used transiently and only in a hospital setting, as they created severe patient discomfort. [4] In 1958, the first long-term implanted pacemaker was used.[5] The indications for pacemaker use were rapidly expanded, as was the technology of the devices.

The first human defibrillation was performed intraoperatively in 1947 and the first transthoracic defibrillation in 1956. [6] Rapid defibrillation is now the standard of care for ventricular fibrillation, and its use has significantly increased survival of cardiac arrest. However, patients who survive cardiac arrest have a high risk of recurrent arrest, estimated at 22% to 60% in the first year.[7] [8]

AICDs were developed by Mirowski in the late 1960s, but they were not accepted by the medical community until the late 1970s. [3] In 1980, the first AICD was implanted in a human, followed by implantation in a series of patients [9] in whom an average 52% decrease in mortality was seen.[10] Between 1985 and 1990, more than 10,000 patients received AICDs, and the number continues to increase. [3]

PACEMAKER CHARACTERISTICS

Several hundred types of pacemakers are in use today.[1] The typical generator is a hermetically sealed device generall weighing <30 gm. Modern power sources are almost exclusively lithium-based batteries,[12] which have the advantage of a slow, steady, predictable decay rate. Half-lives of lithium batteries range from 75 to 144 months.[12] The generator is connected to sensing and pacing electrodes that are placed in various locations in the heart depending on the configuration of the pacemaker. Newer models are programmable for rate, output, sensitivity, refractory period, and modes of response, [11] and they can be reprogrammed radiotelemetrically after implantation.

Pacemakers are classified according to a standard five-letter code developed by the North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group (Table 13-1). The first letter designates the chamber that actually receives the pacing current, whereas the second letter denotes which chamber the pacemaker uses to sense intrinsic cardiac electrical activity. The third letter denotes the pacemaker's response to sensed intrinsic electrical activity (usually inhibited). The fourth letter refers to the pacemaker's rate modulation and programmability, whereas the fifth letter describes antitachycardiac features of the pacemaker. In normal practice, only the first three letters are used to describe the pacemaker (e.g., VVI or DDD). [13]

Pacemaker wires are embedded in plastic catheters. The terminal electrodes, which may be unipolar or bipolar, travel from the generator unit to the heart via the venous system. The typical entry point is the subclavian or cephalic vein. The terminal electrodes are placed in either the right ventricle or both the right ventricle and atrium, under fluoroscopic guidance. Proper lead placement is checked by electrograms checking sensing and pacing thresholds. [14] The typical radiographic appearance of an implanted pacemaker is seen in Figure 13-1 .

The pacemaker rate is typically programmed between 60 and 80 beats/min. A significantly different rate usually indicates malfunction. When the battery is low, the rate usually begins to drop, getting lower as the battery fades. The pulse generator output is the product of volts, milliamperes, and the stimulus duration, all of which may be preset or programmed. Sensing of intracardiac electrical activity is a combination of recognizing the characteristic waveforms of P waves or QRS complexes while also discriminating these from T waves or external interfering signals, such as muscle activity or movement. The pacing electrical stimulus is a triphasic wave consisting of an intrinsic deflection, far-field potential, and an injury current, which typically delivers a current of 0.1 to 20.0 mA for 2 msec at 15 V. [15]

Pacemakers have a reed switch, which may be closed by placing a magnet externally on the chest wall over the generator; this inactivates the sensing mechanism of the pacemaker, which then reverts to an asynchronous rate termed the *magnet rate*. Essentially the magnet turns the pacemaker into a fixed rate device. The magnet rate is usually, but not always, the same as the programmed rate.

AICD CHARACTERISTICS

The AICD consists of a pulse generator with sensing mechanism, battery, and attached lead system with sensing and shocking abilities. The pulse generator and battery are contained in a hermetically sealed titanium case weighing 250 to 300 g. This case is approximately 10.8 × 2 × 7.6 cm, with variations depending on the manufacturer. The battery is typically a lithium battery with a life span of approximately 100 shocks, [16] [17] although a maximum life span of 22 months was noted in one study.[7]

A variety of sensing and shocking leads are in use. Most current AICDs use two bipolar sensing electrodes that are secured in the epicardium, with two ventricular patches for shock delivery usually placed anteriorly and posteriorly over the left ventricle (Fig. 13-2 and Fig. 13-3).

A new AICD with a single transvenous lead containing both sensing and shocking components is also in use (Fig. 13-4). This model offers the advantage of obviating the need for cardiac surgery.

The electrical components of the AICD continuously monitor both rate and waveform [18] through separate sensing channels. Different models place different emphases on these channels depending on the patient's underlying disease. The rate-detection channel determines if a preset limit, individualized for each patient, is exceeded. The second channel analyzes the morphology of the waveform of intrinsic cardiac electrical activity. Essentially, variance from a baseline is measured to determine if a shockable rhythm is present. Normal sinus rhythm has periods of isoelectric activity (the baseline), but ventricular fibrillation or sinusoidal tachydysrhythmias typically lack these isoelectric segments.

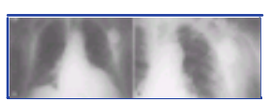

Figure 13-1 Radiographs of an implanted pacemaker showing battery and lead wires. *A*, standard view. *B*, Close-up view.

A malignant ventricular tachydysrhythmia is usually present for 5 to 15 seconds before the preset rate and morphologic criteria are met. [16] At this time, the AICD charges its capacitor and delivers a shock of 25 J. This shock is synchronized in the case of ventricular tachycardia and unsynchronized in ventricular fibrillation. The time from the initiation of the arrhythmia to delivery of the shock is from 10 to 35 seconds. The patient will clearly sense the discharge.

If arrhythmia persists after the first shock, subsequent shocks of 30 J are delivered, with each subsequent detection and shocking period lasting from 10 to 35 seconds. A total of four shocks are delivered if the rhythm is unchanged, after which the AICD does not deliver more shocks unless a subsequent change occurs in the rhythm that lasts >~35 seconds.[2]

The AICD case is implanted in a subcutaneous pocket in the abdominal wall (Fig. 13-5 and Fig. 13-6). The wires are run through a subcutaneous tunnel to the chest. A variety of surgical approaches to the heart are used. [19] The ventricular patches are sutured to the epicardium or parietal pericardium in roughly anterior and posterior positions on the left ventricle, depending on the surgical approach. The sensing electrodes may be placed in either the left or right ventricle.

In those patients in whom the new transvenous lead is used, thoracotomy is not needed—the AICD case is still in the typical abdominal position, and a submuscular patch is placed in the chest wall.

AICDs may be inactivated by a magnet, either purposely or inadvertently. They may also be interrogated via a radiotelemetry device (a procedure normally performed by a cardiologist).

Figure 13-2 Automatic implantable cardioverter-defibrillator (AICD). *(Courtesy of Medtronics Inc., Minneapolis, MN.)*

INDICATIONS FOR IMPLANTABLE DEVICE USE

Current indications for permanent pacemaker use include complete heart block, symptomatic type II second-degree block, second-degree block with episodic ventricular arrhythmias, sick sinus syndrome, symptomatic bradycardias with syncope or presyncope, hypersensitive carotid artery syndrome, type I block with infra-His bundle block, and certain subgroups of patients with triphasic and biphasic blocks at risk of developing sudden high-degree block. [14] [20]

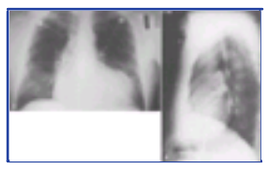

Figure 13-3 Posteroanterior *(A)* and lateral *(B)* chest radiographs demonstrating typical appearance of AICD with ventricular patches.

The use of AICDs is generally limited to patients who are at high risk of sudden cardiac death from ventricular arrhythmias. Currently accepted indications are a documented episode of hemodynamically significant, sustained ventricular tachycardia or fibrillation; ventricular arrhythmia refractory to standard antiarrhythmic therapy as demonstrated electrophysiologically; persistent electrophysiologically inducible ventricular arrhythmia despite best available drug therapy; and recurrent syncope in a patient with electrophysiologically inducible ventricular arrhythmia in whom no effective drug is tolerated or available. [3] [16] [21]

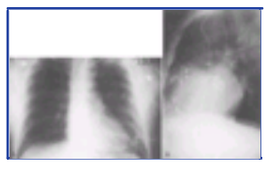

Figure 13-4 Posteroanterior *(A)* and lateral *(B)* chest radiographs demonstrating typical appearance of single-lead transvenous AICD.

Contraindications to AICD use are life expectancy of less than 6 months, New York Heart Association class IV heart failure, treatable causes of ventricular arrhythmias, or incessant or very frequent ventricular arrhythmias that result in rapid battery depletion.

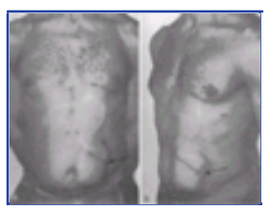

Figure 13-5 Typical external appearance of AICD implanted in the abdominal wall. *(Courtesy of Lawrence B. Stack, MD. From Munter DW, DeLacey WA: Automatic implantable cardioverter-defibrillators. Emerg Med Clin North Am 12:579, 1994. Used with permission.)*

COMPLICATIONS OF PERMANENT PACEMAKERS

Complications are commonly seen with permanent pacemakers. Failure rates in the first year postimplantation range from 7.4%

Figure 13-6 Radiographic appearance of the implanted AICD in the abdominal wall.

to 15.0%, most occurring within the first 30 days.[1] After this initial period, approximately 6% of pacemakers fail each year. [22]

Pacemaker failure can be categorized as failure to pace, failure to sense, failure to capture, inappropriate pacemaker rate, and other complications (e.g., vascular or infectious) (Table 13-2). Failure to sense is the most common problem, accounting for 32% to 57% of failure cases. [3] [22] [23]

Failure to Pace

This condition is characterized by the lack of production of pacemaker spikes despite the lack of intrinsic cardiac electrical activity or an intrinsic cardiac rate falling below the threshold for pacing. Causes of failure to pace include lead fracture or disconnection, battery depletion, component failure, and oversensing.

Lead fracture or disconnection may occur months to years after pacemaker implantation and may be due to inherent stress at the lead connection site. Blunt trauma may also cause lead fracture.[24] [25] [26]

Battery depletion is normally a *gradual process* and is usually detected on routine checkups before complete failure of the pacemaker. [23] Patients who have not had regular follow-up may present with previously undetected battery depletion.

TABLE 13-2 -- Complications of Permanent Pacemaker Use

Failure to pace (no pacemaker activity present)
Lead fracture
Lead disconnection
Battery depletion
Component failure
Oversensing
External interference
Failure to sense (constant pacemaker spikes despite ongoing intrinsic cardiac electrical activity)
Lead dislodgement
Lead fracture
Fibrosis around lead tip
Battery depletion
Pacer in asynchronous mode
External interference
Low-amplitude intracardiac signal
Failure to capture (pacemaker spikes but no subsequent cardiac activity)
Lead dislodgement including perforation
Lead fracture
Lead disconnection
Poor lead position
Fibrosis around lead tip
Battery depletion
Metabolic abnormalities
Medications
Inappropriate pacemaker rate (runaway pacemaker)
Pacemaker reentrant tachycardia
Resetting from external interference
Battery depletion
Other
Infections: pocket, wires
Lead displacement: cardiac perforation, tamponade, pericarditis, vascular perforation
Vascular complications: thrombosis, superior vena cava syndrome
Psychiatric: anxiety, panic attacks

Component failure may be due to various external influences including blunt trauma, therapeutic radiation, electrocautery, transthoracic defibrillation, diathermy, electroshock therapy for depression, magnetic resonance imaging (MRI), and extracorporeal shock-wave lithotripsy. [13] [23] [27] [28] [29] [30]

Pacemakers may oversense or misinterpret nonQRS complex electrical activity (e.g., P waves, T waves, muscular activity, or chest thumping). [23] If this activity is interpreted as a QRS complex, the ventricular spike will be inhibited. If, however, the pacemaker is dual chambered and the electrical activity is misinterpreted as a P wave, it will stimulate firing of the ventricular electrode, which can lead to overpacing. External stimuli can also be misinterpreted and lead to oversensing. This interference can include electrocautery, MRI, diathermy, transcutaneous electrical nerve stimulation (TENS), electroshock therapy, ultrasound dental scalers, static electricity, or vibration (e.g., from a tractor or helicopter). [27] [31] [32] [33] [34] [35]

Failure to Sense

This condition is characterized by the presence of constant pacemaker spikes despite ongoing intrinsic cardiac electrical activity that should inhibit the device. Failure of the pacemaker to sense cardiac electrical activity can be due to lead

dislodgement, lead fracture, normal development of fibrosis around the lead tip that occurs with time, battery depletion, external interference, or an intrinsically low-amplitude cardiac signal.

Lead dislodgement, the most common reason for failure to sense, can be due to an enlarged right ventricle, poor initial lead positioning, blunt trauma, or patient manipulation of the generator unit in the chest wall pocket (pacemaker twiddler's syndrome). [23] [36] [37] [38]

Fibrosis normally develops around the tip of the electrode, and this fibrosis can lead to abnormal sensing or higher required thresholds for pacing. [36]

Several cardiac and metabolic abnormalities cause the intrinsic cardiac electrical activity to be of lower than normal amplitude, causing undersensing of the QRS complexes.

Failure to Capture

This condition is the appropriate presence and timing of pacemaker spikes, but without resultant cardiac activity. Reasons for failure to capture include lead dislodgement (e.g., myocardial perforation), lead fracture, lead disconnection, poor lead position, lead tip fibrosis, battery depletion, and metabolic abnormalities (e.g., hyperkalemia) or medications (e.g., lidocaine, flecainide) that make the myocardium less responsive to electrical impulses. Lead dislodgement is the most common reason for failure to capture. [23]

Inappropriate Pacemaker Rate

This condition, also known as a *runaway pacemaker*, is a rare complication that is usually seen in dual-chamber pacemakers. [39] [40] In dual-chamber pacers, it is caused by an endless loop reentry tachycardia, often initiated by a retrograde P wave. [40] In older or single-chamber pacemakers, it can be due to component failure or battery depletion. [41] Component failure is rare, as almost all pacemakers have circuitry to prevent high discharge rates.

Figure 13-7 *A* and *B*, Appearance of fracture of atrial "J" retention wire. *A*, Radiographic appearance of fracture of atrial "J" retention wire. *B*, Diagram of fracture site. *(Courtesy of Telectronics Pacing Systems, Englewood, CO.)*

Other Complications

Infections including localized skin or pocket infections, more complicated infections along the route of the wires, or endocarditis occur in 1% to 15% of patients. [42] [43] [44] These infections are initially treated with broad-spectrum antibiotics against *Staphylococcus aureus*, but they often require removal of the pacemaker. [13] [44]

Lead displacement, in addition to causing failure to sense or capture, can cause injury to the myocardium including cardiac perforation with resultant tamponade or restrictive pericarditis, [36] [45] [46] and it is usually seen early after pacemaker implantation.

Fracture of the J-shaped retention wire within the lead can result in a protrusion of the wire outside the protective plastic coating. This protruding wire can then puncture the superior vena cava or right atrium, resulting in bleeding or cardiac tamponade. [47] Figure 13-7 illustrates this fracture.

Vascular complications include thrombosis or superior vena cava syndrome. Many pacemaker patients have a benign thrombosis of the upper arm or shoulder, but only about 2% have a serious thrombotic or embolic event. [44] Superior vena cava syndrome is a rare complication. [48]

Psychiatric complications include panic attacks and anxiety, which may prompt ED evaluation. [13] [44]

COMPLICATIONS OF AICDs

The most common complication is the delivery of inappropriate shocks by the device when not indicated by a tachydysrhythmia. Up to 35% of AICD patients receive inappropriate shocks.[49] Causes of inappropriate shock delivery include misinterpretation of sinus tachycardia, atrial fibrillation, muscular activity (e.g., shivering), T waves, or extraneous sources (e.g., pacemaker spikes or vibrations) as a shockable tachydysrhythmia. [50] [51] Likewise an unsustained tachydysrhythmia also may be shocked. Component failure, such

as electrode failure or migration, may result in false sensing and resultant shocking. Pacemaker magnet testing has produced inappropriate shocks resulting in ventricular fibrillation. [52]

Other reported long-term complications include interference with cardiac pacemakers, particularly after AICD discharge [53] [54] ; component failures such as patch migration or distortion,[55] lead fracture, generator case rotation or fracture, and battery depletion; constrictive pericarditis and pericardial effusions, [56] [57] [58] cardiac fibrosis, and atrial or ventricular wall perforations after repeated shocks [58] [59] ; abdominal pocket infections[60] ; thrombosis and pulmonary embolism; erosion into the lung with hemoptysis[61] ; patient trauma sustained during falls after delivery of a shock, either due to the physical "jolt" of the shock [62] or to suspected postshock bradycardia and hypotension[63] [64] ; and psychiatric disorders, such as adjustment disorder, panic attacks, or major depression. [65] [66]

The AICD may be inadvertently inactivated by any strong magnetic force including microwave ovens, industrial engines, metal detectors, magnets in speakers, refrigerator door magnets, bingo wands, and model airplane starters. [2] This inactivation is not normally noted until routine follow-up, but if the patient has a tachydysrhythmia, no shock will be delivered.

EVALUATION OF PACEMAKER PATIENTS

Pacemaker patients presenting to the ED for any problem that may be associated with the device should have an evaluation that includes investigation of potential pacemaker malfunction.

Historical Issues

Pertinent information about the pacemaker unit should be obtained. The brand and manufacturer, type (NBE code),* implantation site, programmed rate, and any changes seen during follow-up at a pacemaker clinic should be noted. The time of implantation is important as certain types of complications such as lead failure, migration, or perforation typically occur within 3 months, whereas generator or battery failure usually occur later. [36]

Some medications, such as lidocaine or flecainide, can raise myocardial thresholds to pacing, [23] and their use should be evaluated.

Patient symptoms that may be related to pacemaker failure should be ascertained. Chest pain may be due to cardiac ischemia, but pacemaker complications such as cardiac perforation, pericarditis, or infection may also be the cause.

Recent trauma, especially to the chest or back, can cause failure of the generator unit, lead fracture, or lead displacement. Recent cardioversion or defibrillation, MRI, diathermy, lithotripsy, or electroconvulsive therapy for depression can have the same effect. [24] [25] [26] [27] [28]

Symptoms of decreased cerebral perfusion, such as syncope, near-syncope, or orthostatic light-headedness, may indicate pacemaker malfunctioning that could lead to bradycardias. A runaway pacemaker can also cause these symptoms due to low cardiac output during the tachycardic phase.

Palpitations are more typically due to intrinsic cardiac activity, but pacemaker failure to sense can cause an irregular rhythm due to inappropriate generation of pacer spikes, which may be perceived by the patient.

The time and results of the last follow-up visit should be obtained if possible.

Physical Examination

The patient should be examined for potential pacemaker complications. The head and neck should be inspected for venous engorgement, which may indicate thrombosis or superior vena cava syndrome. [36]

The chest wall, and especially the pacemaker pocket, should be inspected and palpated for erythema, edema, tenderness, and location of the pacemaker generator. The initial course of the lead wires should also be palpated. If the generator unit is malrotated or in a position other than the original pacemaker pocket, this may indicate "pacemaker twiddler's syndrome" (i.e., purposeful or inadvertent manipulation by the patient), [37] [38] which can lead to lead dislodgement or disconnection.

The cardiac examination may be altered by the functioning of the pacemaker. A paradoxically split second heart sound is normal and is due to the origination of the pacemaker spike in the right ventricle. If the second heart sound is widely split, and widens more with inspiration, a left ventricular origin may be present due to cardiac perforation or lead migration. [36] A pericardial friction rub may be due to pericarditis, potentially from lead perforation. [45] A new murmur may be the result of infective endocarditis. [36]

X-Ray

A chest radiograph should be obtained and compared to old films, preferably ones taken shortly after implantation. Location of the generator and battery type should be ascertained. Lithium batteries are seen as a single radiopaque portion of the generator unit, whereas older pacemakers have four to five button batteries. Lead locations should be noted and migration should be sought. Lead presence outside the myocardial shadow is indicative of perforation. The connection site at the generator unit should be examined for disconnection. The lead wires should be traced and examined for fracture, or J retention wire fractures (see Fig. 13-7).

Electrocardiogram

The electrocardiogram (ECG) contains important information about pacemaker function and should be compared to old ECGs. An asynchronous mode pacemaker (i.e., VOO) will have regular pacer spikes followed by QRS activity. A left bundle-branch pattern is normal, as the lead is usually in the right ventricle. Absence of pacer spikes in the asynchronous mode is termed *failure to pace*. Absence of a QRS complex after a pacer spike represents failure to capture. Some pacemakers have a programmed feature called hysteresis, in which the intrinsic rate below which pacing is triggered is somewhat lower than the resultant pacing rate. Hence the pause following a spontaneous QRS complex may be longer than an R-R interval at normal pace.

Pacemakers that sense intrinsic cardiac activity and are inhibited by same (i.e., VVI) should only generate pacer spikes if the patient's intrinsic rate falls below the programmed rate. In this case, pacer spikes followed by QRS complexes, again in a left bundle-branch pattern, should be noted. Failure to pace or capture may be seen. Pacer spikes occurring despite an intrinsic rate above the programmed rate represent failure to sense.

Electrocardiograms from patients with dual chamber pacemakers (i.e., DDD) may demonstrate various rhythms. [36] These include the patient's intrinsic rhythm, atrial pacer spikes followed by a P wave and then an intrinsic QRS, or two pacer spikes sequentially followed by a P wave and then a QRS complex. Failure to pace, capture, or sense may again be noted.

The electrical axis of the pacer spike and paced QRS complex should be compared to old ECGs. A change of the pacer spike axis may signal lead migration. [36] Normally, the paced QRS complex is a left bundle-branch pattern. A right bundle-branch pattern may be due to left ventricular lead placement, but a change from old ECGs from a left to a right bundle-branch pattern may be due to migration of the lead or perforation of the ventricular septum.

Paced rates that are higher than the programmed rate can be due to pacemaker-mediated tachycardia, a reentrant tachycardia normally seen only in dual-chambered pacemakers, [39] [40] or runaway pacemaker, normally seen only in older pacemaker models and due to battery depletion or component failure. [41] External electrical sources can mimic pacemaker spikes and be misinterpreted as an inappropriate pacing rate. [36]

General Management

Patients who are found to have failure to sense or capture should undergo the basic evaluation outlined earlier; in addition, serum electrolyte assays should be performed to assess metabolic abnormalities. These patients and patients with infections, lead displacement, disconnection or fracture, or vascular complications will

*North American Society of Pacing and Electrophysiology-British Pacing and Electrophysiology Group generic pacemaker code (NBE code).

require cardiology consultation for intervention as determined by the etiology of the malfunction.

Patients who have failure to pace may undergo a magnet test in the ED to rule out battery depletion or oversensing.

Patients with pacemaker-mediated tachycardia or runaway pacemaker need prompt cardiology evaluation, and those with unstable conditions require acute intervention in the ED, as outlined in the next section.

Use of a Magnet in Pacemaker Assessment

Indications

Magnet testing of a pacemaker is used on patients with "failure to pace" to assess for battery depletion, component failure, or oversensing. It is also indicated for pacemaker-mediated tachycardia or runaway pacemaker in an attempt to terminate the rhythm.

Equipment and Setup

Typically, a ring magnet (Fig. 13-8) is used for this procedure. Different brands of magnets are also available for specific pacemakers, but in almost all cases, a standard pacemaker ring magnet will suffice. The patient should undergo a baseline ECG and should be on a cardiac monitor. Placement of a magnet on a pacemaker closes a reed switch and reverts the pacemaker to an asynchronous, or fixed rate, mode.

Technique

The location and orientation of the pacemaker generator should be ascertained by palpation. It is typically in the left or right upper chest wall (Fig. 13-9). The magnet is placed

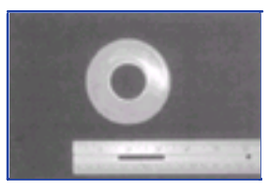

Figure 13-8 Ring magnet.

directly on the chest wall over the pacemaker generator (Fig. 13-10). A repeat ECG is obtained to compare to the baseline (Fig. 13-11 and Fig. 13-12). Some brands of pacemakers have either a several-second delay or a series of two to three rapid pacer spikes before reverting to the asynchronous mode. [36] If the patient has an underlying bradycardia associated with failure to pace that is corrected by magnet placement, the magnet should be left over the generator. Likewise, if a pacemaker-mediated tachycardia or runaway pacemaker is reverted to a normal rate or rhythm, the magnet should be left in place pending consultation with a cardiologist.

Complications

Incorrect alignment of the magnet may cause only intermittent pacing in the asynchronous mode. Some pacemakers react erratically to a non-brand-specific magnet; if this is considered an issue, attempt to obtain a brand-specific magnet.

Interpretation

In the case of failure to pace, three outcomes are possible: (1) The pacemaker will fire at its programmed rate (this is the expected outcome). In the case of failure to pace, this indicates that the pacemaker was oversensing and was inappropriately

Figure 13-9 Typical location of pacemaker pocket in upper chest wall.

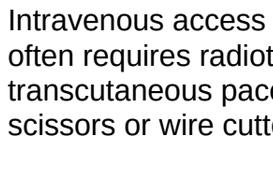

Figure 13-10 Application of ring magnet over pacemaker generator.

inhibited. The cause of the oversensing should then be investigated. (2) The pacer may not produce any spikes at all. This is indicative of component failure and requires cardiology consultation. (3) The pacemaker may produce spikes, but at a rate lower than the programmed rate, which is indicative of battery depletion; this also requires cardiology consultation.

Management of Pacemaker-Mediated Tachycardia or Runaway Pacemaker

Indications

These maneuvers are indicated for correction of an inappropriately high pacemaker rate.

Figure 13-11 Electrocardiogram of patient with a nonfiring pacemaker. Intrinsic cardiac rate is 80 beats/min, and no pacemaker activity is seen.

Equipment and Setup

Intravenous access should be obtained and the patient should be placed on a cardiac monitor. A baseline ECG should be obtained. Because the definitive treatment often requires radiotelemetric reprogramming of the pacemaker, a cardiology consultation should be obtained. A ring magnet will be needed as well as a transcutaneous pacemaker unit with pads. If open lead disconnection is required, local anesthetic, sterile drapes, scalpel blade and handle, hemostats, and Mayo scissors or wire cutters will be needed, as well as either a transcutaneous pacemaker or portable pacemaker unit with alligator clip.

Technique

The initial procedure is to place a ring magnet over the pacer generator as described earlier. If the pacer then reverts to an asynchronous mode at the appropriate programmed rate, the magnet should be left in place.

If magnet placement has no effect, then isometric pectoral exercises should be attempted.[13] [39] This is done by having the patient place his or her hand from the same side as the pacemaker generator onto the opposite shoulder and push against the shoulder as long and as hard as possible. This creates rapid muscle activity in the pectoral muscle surrounding the pacemaker generator, which may be interpreted as ventricular activity and inhibit the pacemaker, [39] [40] terminating the reentrant tachycardia.

If this maneuver is unsuccessful and the patient's condition is stable, continue to monitor the patient and await cardiology consultation. If the patient's condition is unstable, the next maneuver is to attempt a standard chest *(precordial)* thump.[13] [39] This is performed by firmly striking the midsternum with a clenched fist from a distance of 30 to 38 cm. This procedure may be repeated once if needed. [39]

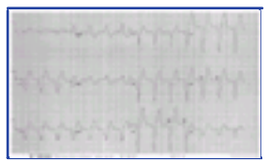

Figure 13-12 Electrocardiogram of same patient with magnet applied over pacemaker, producing a paced rhythm. Pacer spikes are evident (*arrows*) and the magnet rate is 85 beats/min. Note the left bundle-branch bundle typical of a pacer lead in the right ventricle.

If the chest thump is unsuccessful, attach transcutaneous pacemaker pads anteriorly and posteriorly, and attach the leads to the transcutaneous pacemaker generator. Pace the patient at an initial output of 2 to 5 mA and a rate of 40 beats/min. [39] This will stimulate chest wall movement that may be interpreted as ventricular activity and inhibit the pacemaker, terminating the reentrant tachycardia. Unipolar DDD pacemakers are normally inhibited at a low output. Bipolar DDD pacemakers often need higher outputs of up to 10 to 20 mA.[39] If increasing the output is unsuccessful, raise the transcutaneous pacing rate slightly to attempt to deliver chest wall stimulation outside the pacemaker's particular ventricular refractory period. [39]

If these maneuvers are unsuccessful and the patient is hemodynamically unstable due to the pacer-induced tachycardia, the solution of last resort is to cut the pacer leads from the generator unit. The generator unit should be palpated to ascertain position and orientation. Apply transcutaneous pacemaker pads and connect them to the transcutaneous pacemaker. This is a precautionary measure, as cutting the leads may lead to profound bradycardia or asystole. A portable pacemaker generator should be available. Use povidoneiodine for sterile preparation of the site over the generator and apply sterile drapes. Instill local anesthesia in the skin and subcutaneous tissue overlying the generator in the area of the lead connections. Make a skin incision with a scalpel, and expose the lead wires with blunt dissection. Alternatively, make an incision through the previous scar and remove the pacemaker unit. [41] Cut the lead wires close to the generator using Mayo scissors or wire cutters. At this point, the patient may require transcutaneous pacing. An alternate procedure is to insert a needle into the cathode (negative) lead wire (this is the only wire on unipolar models, and it is identified on bipolar units either by marking or by a white band). [41] Connect an alligator clip to the needle, and connect the alligator clip to the negative terminal of the portable pacemaker generator. Ground the positive terminal via an alligator clip to the subcutaneous tissue of the incision, and pace the patient using the portable generator. [41]

Complications

Incorrect alignment of the magnet may cause pacing only intermittently in the asynchronous mode. Some pacemakers will react erratically to a non-brand-specific magnet; if this is a problem, attempt to obtain a brand-specific magnet. There are no potential complications from isometric pectoral muscle exercise. Chest thumps can result in sternal or rib fractures, myocardial contusion, pulmonary contusion, extrasystolic complexes, or ventricular tachydysrhythmias. [39] Transcutaneous pacing to stimulate chest wall movement is normally uncomfortable for the patient and can also result in diaphragmatic or arm muscle stimulation as well. Open disconnection of the pacemaker lead wires can be complicated by unanticipated bleeding, difficulty exposing the generator unit, and subsequent infection. A more common complication is the termination of the paced rhythm, resulting in a profound bradycardia or asystole that requires ongoing transcutaneous or portable generator pacing.[41]

Interpretation

Correction of the pacer-induced tachycardia by lead disconnection only is generally indicative of component failure or

severe battery depletion, whereas termination by noninvasive procedures is more indicative of a pacemaker-induced endless loop reentrant tachycardia. [39] [41] [67]

EVALUATION OF AICD PATIENTS

Patients with an AICD who present to the ED can have noncardiac complaints unrelated to the AICD, cardiac complaints, or AICD-related problems, including AICD shocks. The evaluation should focus on potential AICD problems.

Historical Issues

Patients with AICDs have severe underlying cardiac disease, and will often present with cardiac chest pain, shortness of breath, or congestive heart failure. Potential AICD complications such as pericarditis, pericardial effusion, cardiac fibrosis, atrial or ventricular perforation, and infections of the wires or leads can all present with chest pain. Mortality in AICD patients is typically due to their underlying disease, and any complaints of chest pain must be pursued aggressively.

Generator pocket infections or wound infections will produce complaints of pain and fever.

The most common AICD-related complaint in patients presenting to the ED is that of one or more AICD shocks. Patients describe the shock as a feeling of being kicked or punched in the chest.[68] [69] The number of shocks received should be ascertained. Associated symptoms of syncope or near-syncope indicate a probable tachydysrhythmia and appropriate shock. Many patients fall down when they experience an AICD shock, and the presence of any fall-related trauma should be queried.

Physical Examination

The abdominal pocket and subcutaneous tunnel should be evaluated for signs of infection. Heart and lung sounds should be auscultated. A pericardial rub is indicative of pericardial fluid, which may be a result of pericarditis from the AICD. The patient should be examined for any signs of trauma if he or she fell.

X-Ray

A chest radiograph is generally not helpful, but one should be obtained and compared to old films to look for electrode fracture, displacement of sensing electrodes, and patch migration or distortion.

Electrocardiograms

An ECG should be obtained. Immediately after an AICD shock, the ECG often shows abnormalities such as ST-segment elevations or depressions.[59] [70] If these changes are due solely to the shock, they will resolve within 15 minutes. Otherwise, the ECG should be examined and compared to old studies for evidence of ischemia.

Use of a Magnet for AICD Inactivation

The patient who is experiencing inappropriate AICD discharges in the ED can be treated by magnet inactivation of the device similar to the approach described earlier for the pacemaker patient.

Technique

The method for inactivating an AICD device is outlined in Table 13-3 . The orientation of the device in the abdominal pocket should be determined, with the lead connections normally cephalad. A ring magnet is then placed over the corner adjacent to the lead connections (usually the upper righthand corner of the device) (Fig. 13-13). A series of beeping tones, which correspond to the sensed QRS complexes, will sound. In the absence of organized QRS activity, random beeps will sound.[68] When the magnet is left in place for 30 seconds, a continuous beep is heard. This indicates that the AICD is inactivated. The magnet should then be removed, and the AICD will remain inactivated. The AICD may be reactivated by applying the magnet for 30 seconds and removing it when the steady beep changes to intermittent beeping.

Clinical Follow-Up

The AICD patient who has component failure, such as patch migration or lead fracture or dislodgement; infection; vascular complications, such as thrombosis or perforation; or cardiac complications, such as perforation or pericarditis, requires cardiology consultation for admission.

The AICD patient who received a single shock and had prodromal symptoms indicative of low cardiac output should be evaluated for myocardial infarction, electrolyte imbalance, or drug toxicity, as well as for any sustained trauma. If findings of this evaluation are normal, the patient is usually released home after discussion with the cardiologist.[2]

The patient who received a single shock without related symptoms consistent with a ventricular tachydysrhythmia requires a more extensive evaluation including cardiac monitoring, determination of drug levels as appropriate, and electrolyte level measurement. [68] [69] [71] If the ED evaluation is normal, patients require cardiology consultation. The cardiologist normally interrogates the AICD using either phonogram or telemetry units. The decision to admit or release the patient with potential alterations of antiarrhythmic drug therapy is made based on the results of this testing.

Patients whose condition is unstable, who report more than one shock in succession or more than two single shocks in a 1-week period, or who have evidence of ischemia, electrolyte imbalance, or drug toxicity often require admission to a monitored setting for further evaluation and continued monitoring. [2]

TABLE 13-3 -- Method for Inactivation of AICD

1. Determine the orientation of the device in the abdominal pocket, radiographically or by palpation.
2. Place a ring magnet over the upper righthand corner of the device.
3. A beeping tone will sound, which corresponds with the sensing of QRS complexes.
4. Leave the magnet in place for at least 30 sec.
5. When the beeping changes to a continuous tone, the device is inactivated.
6. Remove the magnet.

Figure 13-13 Placement of magnet on AICD.

THE PACEMAKER/AICD PATIENT IN CARDIAC ARREST

Patients with pacemakers in cardiac arrest may require defibrillation or cardioversion, depending on their presentation. Although most pacemakers have circuitry that protects them from high current flows, various pacemaker-related problems can develop from defibrillation or cardioversion. These include damage to circuitry resulting in complete destruction, decrease in output, or runaway pacing; acute or chronic increases in the pacing threshold, which is normally temporary; undersensing lasting up to 10 days; reprogramming; resetting to a different mode, usually asynchronous; lead displacement; and myocardial thermal or electrical burns at the electrode-myocardium interface leading to ventricular fibrillation. [27]

Due to these potential complications, Barold and colleagues have suggested guidelines for defibrillation and cardioversion in pacemaker patients. [27] The first of these is use of the anterior-posterior paddle position, if possible, preferably with specific anterior and posterior paddles. When impossible, the paddles should be placed along a line perpendicular to the line between the pulse generator and the tip of the ventricular lead. For a patient with a pacemaker generator in the left upper chest wall, the appropriate paddle placement would be left lateral chest wall and right midsternal border. For a patient with a pacemaker generator in the right upper chest wall, the appropriate paddle placement would be left upper chest wall and right lower chest wall. Second, the paddles should be placed at least 10 cm from the pulse generator or lead. Third, because of potential damage to the pacemaker or leads, a transcutaneous pacemaker and pads should be readily available if needed, and standby cardiology consultation should be arranged in case emergent reprogramming is needed. Fourth, the patient must be admitted to the hospital and pacemaker functioning must be monitored carefully with repeated threshold testing.

Because of the lower current used by AICDs, the possibility of pacemaker damage from AICD discharge in patients with both is remote. [27]

The AICD patient who is in cardiopulmonary arrest may be managed in the same manner as patients without the device, with minor modifications. Cardiopulmonary resuscitation (CPR) and transthoracic defibrillation will not harm the AICD. [68] The AICD may spontaneously discharge without warning if the patient's rhythm meets the preset criteria for shocking. In the case of an AICD shock, medical personnel performing CPR may experience a mild electrical shock, [72] but to date no reports of injury to medical personnel from such a shock have been noted.

Some authors recommend leaving the AICD activated during cardiopulmonary arrest, [68] allowing it to discharge up to the maximum of four times allowed by the circuitry; but deactivation may be necessary to alleviate fears of medical personnel, to avoid AICD shock-induced arrhythmias, or if temporary cardiac pacing is needed. [2]

Defibrillation does not harm the device or circuitry, and may be performed with the usual technique, although a theoretical possibility exists that the epicardial patches can shield the myocardium from the delivered energy. For this reason, paddle placement over the apex and right sternum may be indicated for AICD patients with anterior and posterior myocardial patches, with anterior and posterior paddle placement in AICD patients with a single patch over the cardiac apex. [72]

CONCLUSION

Many patients have implanted pacemakers or AICDs. These patients have underlying cardiac disease and may present to the ED with various complaints. Complications associated with these devices are not uncommon. The evaluation of these patients must be directed toward the potential complications. Pacemaker function may be evaluated by ECG and magnet testing, but most problems will require cardiology consultation and intervention. Runaway pacemaker represents a true emergency and must be dealt with expeditiously. AICD complications can be initially evaluated in the ED, but they normally require specialized interrogation devices to analyze the problem. Patients with pacemakers or AICDs in cardiopulmonary arrest require modifications of standard paddle placement for defibrillation or cardioversion, and if an AICD is present, it may need to be deactivated with a magnet.

Chapter 14 - Basic Electrocardiographic Techniques

Richard A. Harrigan
Theodore C. Chan
William J. Brady

The electrocardiogram (ECG) is a graphic recording of the electrical activity of the heart. The heart itself is unique among the muscles of the body in that it possesses the ability to generate regular electrical impulses to produce rhythmic cardiac contractions. These impulses can be measured and recorded at the body surface. The standard ECG is obtained by applying electrode leads over the chest and limbs to record the electrical activity of the cardiac cycle. Developed in the early 1900s, the ECG remains the most important initial diagnostic tool for the assessment of myocardial disease, ischemia, and cardiac dysrhythmias.

Electrocardiography is performed widely throughout the health care field, including in ambulances, ambulatory clinics, emergency departments (EDs), and inpatient hospital units. Standard ECG machines are small, self-contained, and portable, allowing them to be used in virtually any setting. As a result, clinicians, nurses, and many other health care providers should be familiar with the procedure of standard 12-lead electrocardiography. Emergency clinicians should also be familiar with the alternative leads and other accessory techniques available in electrocardiography, as well as the pitfalls of lead misplacement, misconnection, and tracing artifacts.

BACKGROUND

In 1903, Dutch physiologist Willem Einthoven first published his recordings of the cardiac cycle using a new device, the string galvanometer. [1] Einthoven's instrument consisted of a thin silver-coated quartz filament stretched across a magnetic field. When an electrical current passed through the string, it caused movement from side to side. The filament was connected to electrode leads placed on the limbs to measure differences in potential caused by the electrical activity of the heart. Einthoven magnified these measurements with a projecting microscope and recorded them photographically. [2]

While others had previously recorded cardiac electrical activity, Einthoven's instrument laid the basis for modern clinical electrocardiography. His work described the standard frontal plane limb lead ECG using bipolar electrodes, and established standards for recording rate and amplitude. In addition, he described five separate electrical deflections, which he termed P, Q, R, S, and T, establishing basic ECG nomenclature. [3] Einthoven won the Nobel Prize in 1924 for his ECG recording machine, which has been called "probably the most sophisticated scientific instrument in existence when it was first invented." [4]

Thomas Lewis visited Einthoven's laboratory and recognized the potential clinical utility of the ECG machine. Lewis became the leading authority on electrocardiography in the early 1900s and was instrumental in the development and clinical application of this new technology. [2] Using the ECG machine, Lewis determined that atrial fibrillation was due to a "circus conduction" involving the auricle of the heart. He published much of his clinical work on ECGs in his landmark texts, *The Mechanism of the Heart Beat* in 1911 and *Clinical Electrocardiography* in 1913.[5] [6]

The development of smaller, portable bedside ECG recording machines after World War I led to their rapid dissemination and use in the clinical setting. In the early 1930s, Francis Wood and Charles Wolferth first reported the use of ECGs to differentiate cardiac and non-cardiac chest pain. [2] Along with Frank Wilson, their work also led to the development of the unipolar "exploring" electrode lead, which measured electrical activity anywhere in the body with a zero potential central terminal as a reference. These leads could be placed directly over the chest, forming the basis for the standard precordial leads. [7]

In 1938, the American Heart Association, in conjunction with the Cardiac Society of Great Britain, established the standard six precordial chest lead positions (V1–6).[8] These precordial leads, along with Einthoven's original bipolar limb lead system (I, II, III) and the augmented unipolar limb leads developed by Emmanual Goldberger (aVR, aVL, and aVF) in 1942, comprise the standard 12-lead ECG used today.

INDICATIONS

Numerous situations in the ED may require a 12-lead electrocardiogram—the typical ED patient undergoing electrocardiography has, in fact, approximately 3 indications for obtaining an ECG.[9] The most frequent indication for ECG performance in the ED is the presence of chest pain. Other reasons include dyspnea, syncope, diagnosis-based indications (e.g., acute coronary syndrome [ACS], suspected pulmonary embolism), and system-related indications (e.g., "rule out myocardial infarction" protocol, admission purposes, operative clearance).[9] Within a given diagnosis, the ECG may perform many functions. In the chest pain patient, for example, the ECG helps establish the diagnosis of ACS or, alternatively, some other noncoronary ailment. Moreover, it is used to select appropriate therapy, determine the response to ED-delivered treatments, establish the correct inpatient disposition location, and help predict the risk of both cardiovascular complication and death.

The initial 12-lead ECG obtained in the ED can be a helpful guide for determination of cardiovascular risk and, as such, the choice of in-hospital admission location. Brush and colleagues have classified the initial ECG into high- and low-risk groups. The low-risk electrocardiographic group had absolutely normal ECGs, nonspecific ST-T wave changes (NSSTTW), or no change when compared with a previous ECG. High-risk ECGs had significant abnormality or confounding pattern, such as pathologic Q waves, ischemic ST segment or T-wave changes, left ventricular hypertrophy, left bundle-branch block, or ventricular paced rhythm. Patients with initial ECGs classified as low-risk had a 14% incidence of acute myocardial infarction (AMI), 0.6% incidence of life-threatening complications, and 0% mortality rate. Patients with initial ECGs classified as high-risk had a 42% incidence of AMI; 14% incidence of life-threatening complications, and 10% mortality rate.[10] Another approach to risk prediction involves a simple calculation of the number of electrocardiographic leads with ST-segment deviation (elevation

or depression)—with an increasing number of leads being associated with higher risk. Along similar lines, the clinician can also predict risk with a summation of the total millivolts of ST segment deviation; once again, higher totals are associated with greater risk.[10]

BASIC EQUIPMENT

The 12-lead ECG.

Although there is variability depending upon the workplace, most ECG machines today are three-channel recorders with computer memory. Such multi-channel systems, recording electrical events in several leads concurrently, offer advantages over the antiquated single-channel recorder systems—capturing transient events on multiple leads simultaneously; banking the data in computer memory for storage, comparison, and transmission; and allowing for data presentation on a single sheet of paper.[11] The ECG tracing is printed in a standardized manner on a standardized paper by the electrocardiograph, which has default settings regarding the speed with which the paper moves through the machine, as well as the amplitude of the deflections to be made on the tracing. ECG paper is divided into a grid, with a series of horizontal and vertical lines; the thin lines are 1 mm apart, and the thick lines are separated by 5 mm. At the standard paper speed of 25 mm/sec, each vertical thin line thus represents 0.04 sec (or 40 msec), whereas the thick vertical lines correspond to 0.20 sec (or 200 msec). Recordings from each of the 12 leads are typically displayed for 2.5 sec by default setting; the leads appearing horizontally adjacent to each other are separated by a small vertical hashmark to represent lead change.

The standard ECG includes 12 leads derived from 10 electrodes placed on the patient; each is color-coded and represented by a two-character abbreviation (Table 14-1). The placement of limb leads on the left and right arms (LA and RA, respectively) and the left and right legs (LL and RL, respectively) by color can be recalled with the help of several mnemonics: "Christmas trees below the knees" (the green and red leads are placed on the lower extremities); "white on right and green to go" (the white lead is placed on the right arm and the green lead is placed on the leg that controls the gas pedal, while the red lead is correspondingly placed on the leg that is closer to the brake); and "smoke over fire" (the black left arm lead is placed over the red left leg lead, as with telemetric monitoring pads). Use of these mnemonics may help prevent right/left confusion during lead placement, as well as the

TABLE 14-1 -- Conventional Leads for the 12-Lead Electrocardiogram

consequences of limb lead reversal and misinterpretation of the ECG (see "Lead Misplacement and Misconnection," later in this chapter).

Standard 12 leads.

The standard 12-lead ECG depicts cardiac electrical activity from 12 points of view, or leads, which can be grouped according to planar orientation. Six leads (I, II, III, aVR, aVL, and aVF) are oriented in the frontal, or coronal, plane and derived from the four limb electrodes. The six precordial leads (V1, V2, V3, V4, V5, and V6) are oriented in the horizontal, or transverse, plane with each representing cardiac electrical activity from that perspective. Leads I, II, and III are termed limb leads; they are bipolar in that they record the potential difference between two electrodes (Fig. 14-1). The fourth electrode located on the right leg serves as an electrical ground. The positive poles of these bipolar leads lie to the left and inferiorly, approximating the major vector forces of the normal heart. This early convention was established so that the tracing would feature primarily upright complexes. In contrast, augmented leads aVR, aVL, and aVF are unipolar leads, with the positive electrodes located at the respective extremities. These augmented leads serve to fill the electrical gaps between leads I, II, and III. Lead aVR stands alone with a polarity and resultant orientation opposite the other limb and augmented leads. This is due to the fact that its positive electrode is located in the opposite direction (superior and to the right) of the major vector force of the normal heart (inferior and to the left); thus, its complexes usually appear "opposite" to most or all of those in the other leads.

Merging of the vector axes of the limb and augmented leads around a central axis yields a hexaxial system of representation of cardiac electrical activity in the frontal plane (Fig. 14-2). The six precordial leads, oriented in the horizontal plane, represent six unipolar electrodes with vector positivity oriented toward the chest surface, with the central terminal of the hexaxial system serving as a negative pole. In contrast to

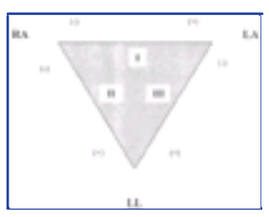

Figure 14-1 Bipolar limb leads. Leads I, II, and III are shown as a triangle, known as Einthoven's triangle. Left arm (LA), right arm (RA), and left leg (LL) placement is shown. These bipolar leads are oriented such that the positive poles lie inferiorly and to the left (given that the bottom apex of the triangle is directed toward the left leg)—as does the major electrical vector of the heart.

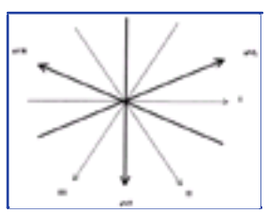

Figure 14-2 Hexaxial system of limb and augmented leads in the frontal plane. Each lead is separated by 30° in this frontal plane representation of the limb and augmented leads. Augmented leads are shown in boldface. Arrows denote positive polarity. Note that the inferior leads (II, III, aVF) logically lie at the bottom of this figure, and the lateral leads (I, aVL) lie on the left side of the figure, where the lateral aspect of the heart is located were this to be superimposed on a patient.

the frontal plane leads, the angles between each of the precordial leads in the horizontal plane are not equal; however, they can vary depending upon lead placement and body habitus.

Lead placement.

The four limb electrodes are conventionally placed on the extremities as follows: RA on the right wrist; LA on the left wrist; RL on the right ankle; and LL on the left ankle. Electrodes may be affixed more proximally on the limbs if necessary (e.g., amputation, severe injuries), ideally with a notation made on the ECG. [12] Others note that the electrodes may be placed on any part of the arms or legs, providing they are distal to the shoulders or inguinal/gluteal folds, respectively. [13]

The precordial leads should be placed as follows: V1—right sternal border, 4th intercostal space; V2—left sternal border, 4th intercostal space; V3—midway between V2 and V4; V4—left midclavicular line, 5th intercostal space; V5—left anterior axillary line, same horizontal level as V4; and V6—left midaxillary line, same horizontal level as V4 and V5. Note that V4 through V6 are placed at the same horizontal level, not all in the 5th intercostal space. If V5 and V6 are situated following the contour of the intercostal space rather than on the same horizontal level, they will be superiorly displaced as the ribs curve around the side of the thorax (Fig. 14-3).

Intercostal space number can be determined by first palpating the sternal angle (angle of Louis), which is the junction of the manubrium and body of the sternum. This transverse bony ridge is located about 5 cm caudad from the sternal notch in the adult. Immediately lateral and inferior to it is the second intercostal space; two spaces farther down lies the fourth intercostal space, where V1 and V2 should be placed. Alternatively, one can count down from the medial clavicle; beneath the clavicle lies the first rib, below which is the first intercostal space.

If the patient's anatomy or injury precludes placement of a precordial lead as described earlier, it is permissible to

Figure 14-3 Precordial lead placement for the standard 12-lead ECG. If multiple or repeat ECG tracings are anticipated, the original lead placements should be marked on the patient's chest wall or stick-on leads should be left in place after the ECG wires are removed.

attach it within the radius of the width of one interspace of the recommended position, with appropriate notation on the tracing. If the situation demands further displacement, it is recommended that the lead be omitted with appropriate documentation on the tracing. [12]

Pediatric lead placement.

In addition to the standard 12-lead tracing, leads V4R and V3R should also be recorded. These are mirror images of their left-sided counterparts (see "Additional Leads" later in this chapter). The chest of the tiny infant may not accommodate all the precordial leads; in such cases, the following array is recommended: V3R or V4R, V1, V3, and V6. Limb lead placement is as in adults. [14]

FEATURES OF THE ELECTROCARDIOGRAM

Discussion of the interpretation of the ECG is beyond the scope of this chapter. Other features of the procedure itself, including a description of the other data found on the ECG tracing, will be detailed later.

In addition to the patient demographic data that are entered by the operator, the tracing will often feature computations regarding rate, intervals, and axes along the top of the paper. On some tracings, a computer-generated "reading" will also be displayed at the top of the tracing. These interpretations are not infallible. A sample of nine of these programs was compared with the readings of eight cardiologists; the "gold standard" in this study was the clinical diagnosis made independently of the interpretations of these tracings, based on other objective data (e.g., echocardiography, cardiac catheterization). The performance of the programs was good, with correct interpretations in a median of 91% of cases, but the cardiologists were significantly better (median 96% correct). [15] Of note, this study did not evaluate interpretations

of acute ischemia and cardiac rhythm disturbance—perhaps the most critical issues in ECG interpretation.

Adjustable features.

Somewhere on the tracing, notation of the ECG paper speed (mm/sec), the calibration (mm/mV), and the frequency response in Hertz (Hz) will be evident (in Fig. 14-4 , these appear in the lower left corner of the tracing). *Calibration*, or standardization, refers to the amplitude of the waveforms on the tracing. It is usually set at a default value of 10 mm/mV, and is graphically depicted by a plateau-shaped waveform that appears at the extreme left side of the tracing, in front of the first complex (see Fig. 14-4*A*). This calibration can be modified by the operator, or by the computer itself, as was the case in Figure 14-4*B* , where the patient appeared to have acquired voltage criteria for left ventricular hypertrophy, when in reality the tracing was unchanged from his baseline (see Fig. 14-4*A*). Increasing the calibration to 20 mm/mV is helpful when trying to decipher P wave morphology. Decreasing the calibration to 5 mm/mV is helpful in cases wherein the amplitude of the QRS complex (usually in the precordial leads) is so large that it encroaches upon those of the adjacent leads. Standardization may not be uniform throughout a given tracing. At times the

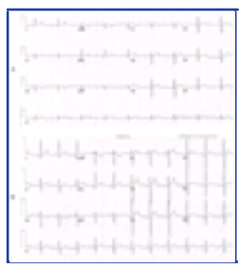

Figure 14-4 *A,* Normal 10 mm/mV calibration. Note the box-shaped mark to the left of the complexes; this is a graphic representation of the calibration for the tracing. This parameter should be routinely noted before ECG interpretation. Note the change in *B*. *B,* Abnormal 20 mm/mV calibration. The calibration in this tracing was (inexplicably and unexpectedly) changed to 20 mm/mV by the ECG, not by the operator. When compared with a baseline ECG, it appeared that the patient had developed voltage criteria for left ventricular hypertrophy as well as ST segment elevation. *A,* which was recorded minutes later with correction of calibration to the standard 10 mm/mV, was unchanged from baseline tracings.

calibration will be adjusted automatically by the electrocardiograph based upon the waveform amplitudes it perceives. For example, it is possible to have normal calibration (10 mm/mV) in the limb and augmented leads, with half-standard calibration in the precordial leads (5 mm/mV); this may occur in instances of marked left ventricular hypertrophy. In this case, the calibration pulse at the lefthand side of the paper will have a downward stairstep appearance.

Paper speed usually is set at a default of 25 mm/sec. It may be manipulated for purposes of deciphering a dysrhythmia, as described later in this chapter (see "Alteration in Amplitude and Paper Speed"). *It is important that the clinician examine all ECG tracings for standardization and speed parameters before attempting clinical interpretation.*

ADDITIONAL LEADS

Although not considered standard of care in the routine evaluation of patients in the ED, additional electrocardiographic leads have been investigated for the evaluation of the patient with possible ACS. These additional, or nontraditional, leads

include posterior leads (V7, V8 and V9), right ventricular leads (especially V4R), and procedural leads (transvenous pacemaker wire placement and pericardiocentesis). Acute posterior and right ventricular myocardial infarctions are likely to be underdiagnosed, as the standard 12-lead ECG does not assess these areas directly. The standard ECG coupled with these additional posterior leads constitutes the 15-lead ECG, the most frequently used extra-lead ECG in clinical practice.

15-Lead ECG.

In a study of all ED chest pain patients, Brady et al. reported that the 15-lead ECG provided a more accurate description of myocardial injury in those patients with AMI, yet failed to alter rates of diagnoses, use of reperfusion therapies, or change disposition locations. [16] Looking at a more select population of ED patients, Zalenski and associates investigated the use of the 15-lead ECG in chest pain patients with a moderate-to-high pretest probability of AMI, who were already identified as candidates for hospital admission. [17] In this 15-lead ECG study, the authors reported an 11.7% increase in sensitivity with no loss of specificity (i.e., no increase in false-positive findings) for the diagnosis of ST elevation AMI. They concluded that "the findings of ST elevation (STE) by use of these extra leads can strengthen the ED diagnosis of acute myocardial infarction on the initial tracing and may provide an indication for thrombolytic treatment." They further suggest that, in the diagnosis of posterior AMI, leads V8 and V9 are superior to reliance upon detecting the reciprocal ST segment depression seen in leads V1–V3.

Possible indications for 15-lead ECGs in patients with suspected acute ischemic heart disease include (1) ST segment depression in leads V1 through V3; (2) all STE inferior and lateral AMIs; or (3) isolated STE in leads V1 and V2, or both. These indications, despite their apparent clinical utility, remain unproved, and the 15-lead ECG is currently not considered standard of care for evaluation in the ED.

Posterior leads.

The posterior leads V8 and V9 are placed on the patient's back—V8 at the tip of the left scapula and V9 in an intermediate position between lead V8 and the left paraspinal muscles. An additional lead, V7, may also be placed on the posterior axillary line equidistant from lead V8 (Fig. 14-5). The degree of ST segment elevation in the posterior leads is often less pronounced compared with the STE seen in the standard 12 leads in patients with STE AMI. This diminution of posterior lead STE results from both the relatively greater distance of these leads from the posterior surface of the heart as well as presence of air and soft tissue between the epicardium and electrocardiographic leads.

Right-sided leads.

The right ventricular electrocardiographic leads are placed across the right side of the chest in a mirror image of the standard left-sided leads and are labeled V1R to V6R; alternatively, RV1 to RV6 is another commonly used nomenclature for this lead distribution (Fig. 14-6). Lead V4R (right fifth intercostal space mid-clavicular line) is the most useful lead for detecting STE associated with right ventricular infarction and may be used solely in the evaluation of possible right ventricular infarction. The STE that occurs in association with right ventricular infarction is frequently quite subtle, reflecting the relatively small muscle mass of the right ventricle; at other times, the STE is quite prominent, similar in appearance to the ST segment changes seen in the standard 12 leads.

Invasive procedural leads.

A patient may present with a severely compromising bradydysrhythmia and require a transvenous pacemaker. In such instances, the pacing wire must be

Figure 14-5 Posterior lead placement. Leads V7, V8, and V9 are placed on the same horizontal plane as V6, with V7 at the posterior axillary line, V8 at the tip of the left scapula, and V9 near the border of the left paraspinal muscles.

placed without the benefit of fluoroscopy. The wire can be advanced using electrocardiographic guidance. Such placement requires that the patient be connected to the limb leads of a grounded electrocardiographic machine and the pacing wire connected to the V lead. As the electrode enters the vena cava superior and high right atrium, the P wave and QRS complex

Figure 14-6 Right-sided lead placement. Right-sided leads RV1–RV6 are placed on the chest as a mirror image of the standard precordial leads.

will be negative. While traversing the atrium, the P wave and QRS complex will become positive, with the latter becoming larger as the ventricle is approached. If a balloon-tipped flotation catheter is used, the balloon should be deflated once in the right ventricle, and advanced until contact is made with the endocardium and the ventricle is captured. Ventricular wall contact is indicated by marked ST segment elevation.

In patients with suspected pericardial effusion who undergo urgent pericardiocentesis, an electrocardiographic lead may be placed on the syringe needle; this form of monitoring assists in the correct positioning of the catheter in the pericardial space. With advancement of the needle, ST segments are monitored. The sudden appearance of ST segment elevation indicates that the needle has moved too far internally (i.e., beyond the pericardial space) and has made contact with the epicardium.

ALTERNATIVE LEADS AND TECHNIQUES FOR RHYTHM ASSESSMENT

Electrocardiographic rhythm assessment depends on a clear signal of both atrial and ventricular electrical activity over a period of time. While continuous 12-lead ECG rhythm monitoring has the advantage of recording cardiac activity over multiple leads (thus maximizing atrial and ventricular monitoring), it is often impractical. Moreover, correct identification of the cardiac rhythm on ECG can be difficult depending on the clinical setting. Rapid atrial or ventricular rates, especially those above 150 beats/min, often lead to simultaneous or near-simultaneous deflections that can alter the usual waveforms or cause smaller deflections to be buried within larger ones (such as P waves buried within the QRS complex). In addition, rapid rates result in smaller, narrower waveforms that make visual recognition on the ECG challenging. Finally, assessment of atrial activity is generally more difficult due to the smaller electrical impulse and resulting ECG waveform that is generated by the atria.

A number of alternative techniques have been developed to improve rhythm assessment. These techniques include alterations in the standard 12-lead ECG, as well as the addition of non-standard leads to monitor cardiac, and particularly atrial, rhythm activity.

Alteration in amplitude and paper speed.

Most 12-lead ECG machines today allow alteration of both amplitude and paper speed from the basic 10 mm/mV and 25 mm/sec standards, respectively. Increasing the amplitude, most commonly to double the standard or 20 mm/mV, can increase the prominence of smaller deflections, such as the P wave, and improve recognition of the atrial rhythm (Fig. 14-7*A–D* Fig. 14-7*A–D*). In addition, clinicians have also used photocopy enlargements of the standard ECG to enhance smaller deflections visually.[18]

Increasing the paper speed, again most commonly to double the standard, or 50 mm/sec, has the effect of artificially slowing the rhythm. This technique is most advantageous when assessing patients with marked atrial or ventricular tachycardia. Increasing the paper speed exaggerates any existing irregularity (such as in atrial fibrillation) and can improve recognition of smaller deflections, such as P waves, in the presence of a significant tachycardia. Faster paper speeds also make it possible to measure short ECG intervals (such as P-R or R-R) more accurately (Fig. 14-8*A, B*).

Accardi et al found that overall diagnostic accuracy improved when clinicians were provided ECGs recorded at the faster 50 mm/sec paper speed, as opposed to a standard 12-lead ECG, in patients with narrow complex tachycardias. Moreover, they reported this improved rhythm assessment likely would have resulted in fewer treatment errors.[19]

Alternative leads.

Rhythm assessment often requires electrocardiographic monitoring over continuous periods of time, making the standard 12-lead ECG (requiring 10 electrodes), and even unipolar precordial V1 monitoring (requiring 5 electrodes), not feasible. A number of alternative lead systems requiring fewer electrodes have been described. Many of these systems use the limb bipolar leads (RA, LA, LL) in alternative positions over the chest. Leads I, II, or III are then recorded depending on the positions of the positive and negative electrodes.

Lewis leads.

In 1910, Thomas Lewis first described alternative positions for the RA and LL leads to enhance detection of atrial fibrillation. The RA lead was placed over the right second costochondral junction, while the LL lead was placed in the right fourth intercostal space 2.5 cm to the right of the sternum—leaving the LA and RL leads in their usual positions. Lewis[20] reported enhancement of atrial activity when the RA served as the negative electrode and LL as the positive electrode (lead II) with this new configuration. Other alternative lead placements to enhance atrial activity detection have also been described (Table 14-2 and Fig. 14-9).[21] [22] [23]

Vertical sternal "Barker" leads.

In this alternative lead system, the positive electrode is placed at the xiphoid process and the negative electrode is placed just below the suprasternal notch on the manubrium. Herzog et al[18] reported that vertical sternal leads produce a larger P wave than other systems, including the Lewis leads. In addition, the vertical sternal leads are placed over bone, which may reduce muscle activity artifacts on recordings (see Fig. 14-9).

Limb-precordium leads.

A sequential pattern of bipolar leads on the chest, termed limb-precordium leads, has been proposed in combination with the original Einthoven limb leads. In this system, standard limb leads are placed on the patient. The RA electrode is then repositioned sequentially at the fourth intercostal space just right of the sternum, fourth intercostal space just left of the sternum (low parasternal), 1st intercostal space just left of the sternum, and 1st intercostal space just right of the sternum (high parasternal). During this sequential mapping, tracings are recorded for leads I and II until atrial activity is identified. Brenes-Pereira reported that this mapping system allowed for the identification of P waves for a majority of patients when none was detected initially on a standard 12-lead ECG. [24]

MCL leads.

Modified bipolar chest leads (MCL) are the most commonly used leads for cardiac rhythm monitoring. The positive electrode is placed on the chest at a precordial position (V) concordant with the MCL desired (e.g., the V_1 position for MCL_1). The negative electrode is placed on the left shoulder. On standard ECG machines, the LA electrode is placed at V_1 , RA at the left shoulder, LL at V_6 , and RL at a remote location on the chest to serve as ground. Lead I would then reflect MCL_1 and lead II, MCL_6 . MCL_1 may be useful in distinguishing atrial activity, MCL_5 and MCL_6 more commonly in ST/T wave monitoring, and both MCL_1 and MCL_6 may be useful in evaluating wide complex tachycardias (see Fig. 14-9).[25]

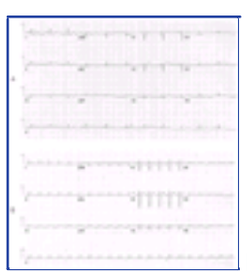

Figure 14-7a *A,* Baseline ECG of patient before development of abnormal rhythm (10 mm/mV). Note the P wave morphologies, especially in leads I, II, and V1. *B,* ECG during ectopic atrial tachycardia (10 mm/mV). Note the change in P wave morphology, especially in lead V1.

Esophageal leads.

The esophageal lead (E) was first described by Brown in the 1930s. [26] Since then, both unipolar and bipolar esophageal leads have been developed. [27] Because of its posterior location, this lead is often superior at detecting atrial deflections and recording the activity of the posterior surface of the left ventricle. The electrode, which is connected to the ECG machine by thin wires, is either swallowed, or passed through the nares, into the esophagus. Once in the esophagus, the location of

the electrode is determined either by fluoroscopy or by making a series of low-to-high esophageal recordings. The position of the electrode in the esophagus is adjusted by slowly pulling the electrode wire out the nares or mouth. For the normal adult, leads $E_{15–25}$ (electrode is located in the esophagus 15 to 25 cm from the nares) generally records atrial activity; $E_{25–35}$, activity of the AV groove; and $E_{40–50}$, activity of the LV posterior surface. The E lead should be recorded through lead channel I, simultaneously with the lead channel II and the other surface channels.

LEAD MISPLACEMENT AND MISCONNECTION

Limb lead reversals.

Whereas the limb electrodes are not often misplaced, the cables that link them to the ECG machine are at times improperly connected. This can result in "ECG changes" that are in actuality artifacts. There are a multitude of possibilities for misconnection of the limb leads; some of the most probable are summarized here. It is helpful to categorize these possibilities into those that are recognizable without comparison to an old ECG versus those that are not.

Recognizable without old ECG.

The most common of all misconnections is left and right arm lead reversal (Fig. 14-10). *The hallmark is a negative P wave and primarily negative QRS complex in lead I, creating a right or extreme axis deviation* (depending upon the QRS complex in lead aVF). Dextrocardia should also be considered with this

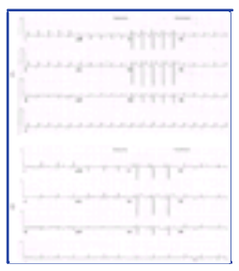

Figure 14-7b *C,* ECG during ectopic atrial tachycardia (20 mm/mV). The P waves are now easier to see in all leads. *D,* ECG after reversion to normal atrial focus (20 mm/mV). Contrast these accentuated P waves to those in *C*.

presentation; the pattern of precordial lead transition will differentiate between dextrocardia and arm lead reversal. Moreover, lead aVR is actually aVL in this circumstance, and thus may feature an upright QRS, which is highly unusual for aVR. [28] Transposition of the RA and LL cables is also easily recognized; all leads are upside down compared with the usual patterns, with the exception of aVL, which is unchanged.

Anytime the RL lead is transposed with another extremity lead, one of the limb leads will appear as virtually a straight line, and thus is easily recognized if this finding is not incorrectly ascribed to poor electrode contact or function. An exception to this rule is if the leg leads are reversed (RL ? LL), in which case the ECG is virtually identical to one with correct placement of the leads. Reversal of the leg leads is largely insignificant in that the potentials at the left and right legs are essentially the same.[29]

Recognizable with old ECG.

In addition to the reversal of the leg leads, one other limb lead reversal that is not readily recognizable without comparison to a prior tracing is transposition of the LA and LL leads. This causes reversal of lead I with II on the tracing, as well as aVL with aVF—both are difficult to discern at times without a baseline ECG for comparison. Furthermore, lead III will be upside down (although a negative QRS complex in III is not unusual), and aVR will be unchanged (Fig. 14-11*A, B*).[29]

Clues to limb lead reversal are summarized in Table 14-3 .

Precordial lead misplacement and misconnection.

Unlike the limb leads, the precordial electrodes are more prone to misplacement, especially when variations in body habitus (e.g., obesity, breast tissue, pectus excavatum, chronic lung disease) make proper lead placement more difficult. This may cause some variability in the amplitude and morphology of the complexes in the precordial leads; however, these changes are not usually grossly abnormal, and therefore can be difficult to detect. Variation often becomes evident when comparing the current tracing with an old ECG. [29] In such cases, it is useful to go to the bedside and examine where the electrodes were positioned relative to the recommended placement (see "Lead Placement" earlier in this chapter). One

Figure 14-8 *A,* ECG with tachycardia at normal paper speed (25 mm/sec). Because of the rapid rate, the actual P waves are difficult to discern, thus making rhythm determination difficult. The computerized interpretation is sinus tachycardia with first-degree AV block. *B,* ECG with tachycardia at double paper speed (50 mm/sec). With increased paper speed, atrial P wave activity is accentuated, demonstrated atrial flutter with a 2:1 AV block.

cannot ensure, however, that the baseline ECG was done with proper lead placement. When comparing the precordial leads on the current ECG with a baseline tracing, ST segment and T wave changes should be viewed in light of the relative morphologies of the associated QRS complexes. If there is a marked difference between the two tracings in the amplitude and polarity of the QRS complex in a given precordial lead, the corresponding ST/T wave changes may be due to lead

TABLE 14-2 -- Alternative Leads for Rhythm Assessment

Drury	2nd R costochondral junction	7th R costal cartilage
	Center of sternum	Inferior angle of scapula 2" right of spine
Schoenwald	3rd intercostal space along R sternal border	L leg
	3rd intercostal space along R sternal border	R arm
Lu	1st intercostal space directly above V1	Approximately 3" directly below V4
Vertical Sternal ("Barker" Leads)	Below suprasternal notch at manubrium	Xiphoid process

MCL_1	L shoulder (1 cm inferior to L mid-clavicle)	V1 (4th intercostal space R sternal border)
MCL_6	L shoulder (1 cm inferior to L mid-clavicle)	V6 (~6th rib mid-axillary line)

[1] First, set the ECG machine to record the rhythm strip using this lead. If the recoding rhythm strip is lead I, the RA wire becomes the negative electrode that is placed as noted in table, and the LA wire becomes the positive electrode that is placed as noted in the table. If lead II or lead III is the lead that is set to record the rhythm strip, the positive and negative electrodes will vary.
[2] Example: One way to record the Lewis lead: Set the ECG machine to record lead I, use the RA wire as the negative electrode, and place it in the R 2nd costochondral junction. Use the LA wire as the positive electrode and place it in the right 4th intercostal space, 1 inch right of the sternum. The Lewis lead may also be recorded on lead II and lead III, but the wires that serve as the positive and negative electrodes will vary.

placement, although cardiac ischemia cannot be completely excluded as the cause.

Misconnection of the precordial cables is usually easy to detect. The expected progression of P, QRS, and T wave morphologies across the precordium will be disrupted (Fig. 14-12*A, B*). An abrupt change in wave morphology evolution—followed by a seeming return to normalcy in the next lead—is a good clue to precordial lead misconnection.[29]

Figure 14-9 Alternative leads. The figure displays three of the more commonly used alternative lead strategies for atrial rhythm clarification (Lewis leads, vertical sternal or Barker leads, and MCL1), and ST/T wave monitoring (MCL6).

ARTIFACTS

Electrocardiographic artifacts are commonly encountered, yet not always easy to recognize. They can be attributed to either physiologic (internal) or nonphysiologic (external) sources; the former includes muscle activity, patient motion, and poor electrode contact with the skin. Tremors, hiccups, and shivering may produce frequent, narrow spikes on the tracing, simulating atrial and ventricular dysrhythmias (Fig. 14-13). [28] [30] A wandering baseline featuring wide undulations, as well as other "noise" on the ECG, can often be traced to patient movement and high skin impedance, leading to inadequate electrode contact to the skin. Minimizing skin impedance and artifacts may be achieved by (1) avoiding electrode placement over bony prominences, major muscles, or pulsating arteries; (2) clipping rather than shaving thick hair at electrode sites; and (3) cleaning and (most importantly) drying the skin surface before reapplying the electrode if the tracing features substantial artifacts.[28] [31] Nonphysiologic artifacts are most often due to 60-Hertz electrical interference, which is ascribable to various other sources of alternating current near the patient. This will manifest as a wide, indistinct isoelectric

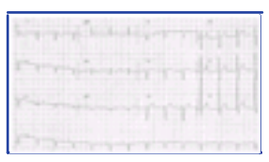

Figure 14-10 Arm lead reversal (LA RA). The most common of limb lead reversals, the clues lie in leads I and aVR. Lead I features a negative P wave, as well as a principally negative QRS complex and T wave. This could suggest dextrocardia, but the precordial leads demonstrate normal transition, which is not consistent with dextrocardia. Note also the unusual appearance of aVR in this tracing.

baseline. Other sources of nonphysiologic artifact include loose connections, broken monitor cables, and mechanical issues with the machine (e.g., broken stylus, uneven paper transport). The 60-Hz artifact due to electrical current interference can be minimized by shutting off non-essential sources of current in the vicinity, as well as straightening the lead wires so that they are parallel to the patient's body in the long axis. [28] [30] [32]

Differentiation of artifacts from true ECG abnormality is intuitively important; moreover, clinical consequences have been reported that are directly attributable to confusion of artifacts with disease. Unnecessary treatment and procedures—including cardiac catheterization, electrophysiologic testing, and even implantation of a pacemaker and an automatic defibrillator—have been reported. [33] Characteristics that may aid in differentiating artifacts from dysrhythmia include absence of hemodynamic instability during the event (or even absence of any symptoms); normal QRS complexes occurring during the dysrhythmia; instability of the baseline on the tracing during and immediately after the "dysrhythmic" event; association with body movement; and observance of "notches" amidst the complexes of the pseudodysrhythmia, which "march out" with the normal QRS complexes that precede and follow the disturbance. [34] [35]

CONCLUSION

Electrocardiography is a simple, noninvasive, and invaluable bedside test. While used principally for the diagnosis and treatment of cardiovascular disorders, it has numerous other applications as well. Knowledge of standard lead placement and the features of the 12-lead ECG are essential. Several features—including adjustment of calibration, paper speed, and the addition of multiple accessory leads—can add to the diagnostic sensitivity of the procedure. Strategic repositioning of limb and precordial leads as described will aid in the assessment of difficult atrial rhythms. The addition of other thorax leads, such as V8 and V9 (posterior wall) and V4R (right ventricle), will increase the sensitivity of the ECG for ACS involving those difficult-to-assess areas of the heart. Pitfalls include failure to recognize lead misconnection and misplacement, as well as artifacts.

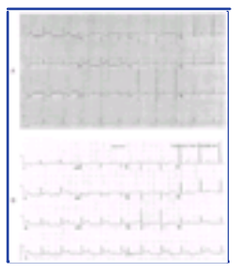

Figure 14-11 *A,* Limb lead reversal (LA ⟷ LL). A patient with a history consistent with ACS was brought to the ED after this ECG was recorded in a clinic. Leads I and aVL suggest an acute high lateral infarct but, surprisingly, there are no corresponding changes in leads V5 and V6. The deep T wave inversions in III and aVF were at first thought to be inferior ischemia or reciprocal changes (see also *B*). *B,* Correction of lead reversal (LA ⟷ LL). After the leads were reconnected, this tracing reveals an acute inferior wall MI, as well as deep T wave inversion in aVL—a harbinger of acute inferior MI. Comparing this tracing with that in *A,* note the following: lead I ⟷ lead II; lead aVL ⟷ aVF, and lead III is inverted. Thus, inferior changes become lateral, and lateral become inferior.

TABLE 14-3 -- Clues to Improper Limb Lead Connections

Reversed Leads	Old ECG Necessary for Detection?	Key Findings
LA RA	No	PQRST upside down in lead I
		Precordial leads normal (not dextrocardia)
LA LL	Yes	III is upside down
		I ⟷ II; aVL ⟷ aVF; aVR no change
LA RL	No	III is straight line
RA LL	No	PQRST upside down in all leads except aVL
RA RL	No	II is straight line
LL RL	Cannot detect change	Looks like normal lead placement
LA LL	No	I is straight line
RA RL		aVL, aVR are same polarity and amplitude *and* II is upside down III

Chapter 15 - Emergency Cardiac Pacing

Edward S. Bessman

The purpose of cardiac pacing is to restore or ensure effective cardiac depolarization. Emergency cardiac pacing may be instituted either prophylactically or therapeutically. Prophylactic indications include those situations where there is high risk of atrioventricular (AV) block, including certain toxidromes and instances of acute myocardial infarction. Therapeutic indications include symptomatic bradyarrhythmias, asystole, and overdrive pacing. Several approaches to pacing exist, including transcutaneous, transvenous, transthoracic, epicardial, endocardial, and esophageal. Transcutaneous and transvenous are the two techniques most commonly used in the emergency department (ED). Since it can be instituted quickly and noninvasively, transcutaneous pacing is the technique of choice in the ED. Transvenous pacing should be reserved for patients who require prolonged pacing or who have a very high (greater than 30%) risk of heart block. Transcutaneous pacing is generally a temporizing measure that may precede transvenous cardiac pacing.

EMERGENCY TRANSVENOUS CARDIAC PACING

The transvenous method of endocardial pacing is commonly used and is both safe and effective. In skilled hands, the semifloating transvenous catheter is successfully placed under electrocardiographic guidance in 80% of patients. [1] The technique can be performed in less than 20 minutes in 72% of patients and in less than 5 minutes in 30% of patients. However, in some instances anatomic, logistical, and hemodynamic impediments can prohibit successful pacing by even the most skilled clinician. As with other medical procedures, it should not be performed without a thorough understanding of its indications, contraindications, and complications. [2]

Background

The ability of muscle to be artificially depolarized was recognized as early as the 18th century. Initial efforts focused on the transcutaneous approach (see later in this section). Over the succeeding years, several scattered experiments were reported and in 1951 Callaghan and Bigelow first used the transvenous approach to stimulate the asystolic heart in hypothermic dogs. [3]

Furman and Robinson demonstrated the transvenous endocardial approach in humans in 1958. [4] They treated two patients with complete heart block and Stokes-Adams seizures, reconfirming that low-voltage pacing could completely control myocardial depolarization. The catheter remained in the second patient for 96 days without complication. Other early clinical studies proved that transvenous pacing is a valuable procedure in medicine. [5] [6] [7] Fluoroscopic guidance was used for placement of the pacing catheter in all of these studies.

In 1964, Vogel and colleagues demonstrated the use of a flexible catheter passed without fluoroscopic guidance for intracardiac electrocardiography. [8] One year later, this technique was used by Kimball and Killip to insert endocardial pacemakers at the bedside. [9] They noted technical difficulties including intermittent capture, difficulty passing the catheter, and catheter knotting in 20% of their patients. During the same year, Harris and associates confirmed the ease and speed with which this procedure could be accomplished. [10]

Before 1965 all intracardiac pacing was done asynchronously, which meant that the pacing catheter could cause electrical stimulation during any phase of the cardiac cycle. Asynchronous pacing frequently resulted in the pacemaker firing during the vulnerable period of an intrinsic depolarization; this occasionally caused ventricular tachycardia or fibrillation. In 1967 a *demand pacemaker generator* that sensed intrinsic depolarizations and inhibited the pacemaker for a predetermined period of time was used successfully by Zuckerman and associates in six patients. [11] Since then there has been steady progress in the design and functionality of pacemakers. Table 15-1 summarizes the four-letter code that is used to describe modern pacemakers (there is a fifth letter for combined pacemaker-cardioverter/defibrillators). The most commonly used emergency transvenous pacemaker is represented by the code VVI, meaning that the ventricle is paced, the ventricle is sensed, and when a native impulse is sensed, the pacemaker is inhibited. Dual chamber pacing (DDD or DDDR) is the preferred methodology for permanent pacing but is less commonly used emergently because of the increased complexity of the procedure (see later in this section).

Rosenberg and colleagues introduced an improved pacing catheter known as the Elecath semifloating pacing wire. [1] The Elecath was stiffer than the Flexon steel wire electrode that was in prevailing use. Rosenberg and coworkers achieved pacing in 72% of patients, with an average procedure time of 18 minutes. They also noted that 30% of their patients were paced in 5 minutes or less. [1] The technique of heart catheterization using a flow-directed balloon-tipped catheter was introduced by Swan and Ganz in 1970. [12] This concept was used successfully by Schnitzler and coworkers for the placement of a right ventricular pacemaker in 15 of 17 patients. [13]

In 1981, Lang and colleagues compared the bedside use of the flow-directed balloon-tipped catheter with insertion of a semirigid electrode catheter in 111 perfusing patients. [14] These researchers found a significantly shorter insertion time (6 minutes and 45 seconds compared with 13 minutes and 30 seconds), a lower incidence of serious arrhythmias (1.5% compared with 20.4%), and a lower incidence of catheter displacement (13.4% compared with 32%) with the balloon-tipped catheter. They concluded that the balloon-tipped catheter was the method of choice for temporary transvenous pacing (Table 15-2).

Kruger and associates retrospectively reviewed the experience of general internists with transvenous pacemaker placement under electrocardiogram (ECG) guidance. [15] They reported a 4% risk of complications and a 14% incidence of electrode malfunction, and these percentages were noted to be similar to those reported by university cardiologists. They concluded that pacemaker placement by primary care clinicians was safe and effective when done under ECG guidance without fluoroscopy.

Indications

The purpose of cardiac pacing is to stimulate effective cardiac depolarization. In most cases the specific indications for cardiac pacing are clear; however, some controversial areas

TABLE 15-1 -- Four-Letter Pacemaker Code

First Letter	Second Letter	Third Letter	Fourth Letter
Chamber-Paced	**Chamber-Sensed**	**Sensing Response**	**Programmability**
A = atrium	A = atrium	T = triggered	P = simple
V = ventricle	V = ventricle	I = inhibited	M = multiprogrammable
D = dual	D = dual	D = dual (A-triggered and V-inhibited)	R = rate adaptive
O = none	O = none	O = none	C = communicating
			O = none

remain. The decision to pace on an emergent basis requires knowledge of the presence or absence of hemodynamic compromise, the etiology of the rhythm disturbance, the status of the atrioventricular (AV) conduction system, and the type of dysrhythmia. In general, the indications can be grouped into those that cause either tachycardias or bradycardias (Table 15-3). Transcutaneous cardiac pacing has become the mainstay of temporary emergent cardiac pacing. It is often used pending placement of the transvenous catheter or as a means to determine whether potentially terminal bradyasystolic rhythms will respond to pacing.

Bradycardias

Sinus node dysfunction.

In a review of 200 initial pacemaker implants at Montefiore Hospital during 1975, 36.5% were used for sinus node dysfunction; 11.3% for sinus arrest; 20.2% for tachybrady (sick sinus) syndrome; and 5% for sinus bradycardia. [16] Patients without myocardial infarction who present with symptomatic sinus node dysfunction should be paced promptly if medical therapy fails. Escher and Furman note that pacing is indicated until the etiology of the dysrhythmia is clarified and stability is ensured. [17]

In the asymptomatic patient, a more intensive cardiac evaluation is required in order to decide whether pacing will be beneficial. This evaluation frequently includes

24-hour Holter monitoring, noting sinus node recovery times, and occasionally coronary care unit monitoring.

TABLE 15-2 -- History of Transvenous Pacing

Date	Investigator	Event
1700	Early investigators	First restimulation studies
1951	Callaghan & Bigelow	First transvenous approach in dogs
1952	Zoll	Transcutaneous cardiac stimulator
1958	Falkmann & Walkins	Implanted pacing wires after surgery
1958	Furman & Robinson	First transvenous pacer in humans
1964	Vogel et al.	Flexible electrocardiographic catheter without fluoroscopy
1965	Kimball & Killip	First bedside transvenous pacing
1966	Goetz et al.	Demand pacemaker developed
1967	Zuckerman et al.	Use of demand pacemaker clinically
1969	Rosenberg et al.	Semifloating pacing catheter
1973	Schnitzler et al.	Balloon-tipped pacers

Sinus bradycardia occurs in an average of 17% of patients with acute myocardial infarction. [18] It occurs more frequently in inferior than in anterior infarction and has a relatively good prognosis when accompanied by a hemodynamically tolerable escape rhythm. However, sinus bradycardia is not a benign rhythm in this situation; it has a mortality rate of 2% with inferior infarction and 9% with anterior infarction. [19] Several mechanisms have been suggested to explain sinus node dysfunction with infarction. Among these, ischemia of the node or its neurologic controls [19] and reflex slowing secondary to pain play dominant roles. [20] Sinus node dysfunction frequently responds to medical therapy but requires prompt pacing if this fails.

Asystolic arrest.

Transvenous pacing in the asystolic or bradyasystolic patient has little value. In one study of 13 patients who had suffered cardiac arrest, capture of the myocardium was noted in 4 patients, but there were no survivors. [21] Transvenous pacing alone may also not be effective in postcountershock pulseless bradyarrhythmias. [22] This failure of pacing has also been demonstrated with transcutaneous pacemakers, suggesting that failure of effective pacing is primarily related to the state of the myocardial tissue. [21] Pacing has no proven value in traumatic cardiac arrest. Other causes of failure to pace include catheter malposition and dislodgment of the pacing wire during closed-chest massage. [21] Cardiac pacing may be used as a "last ditch" effort in bradyasystolic

TABLE 15-3 -- Indications for Cardiac Pacing*

Bradycardias
Without myocardial infarction
Symptomatic sinus node dysfunction (sinus arrest, tachybrady [sick sinus] syndrome, sinus bradycardia)
Second- and third-degree heart block
Atrial fibrillation with symptomatic slow ventricular response
With myocardial infarction
Symptomatic sinus node dysfunction
Mobitz II second- and third-degree heart block
New left bundle-branch block (LBBB); right bundle-branch block (RBBB) with left axis deviation, bifascicular block, or alternating bundle-branch block
Prophylaxis—cardiac catheterization, after open-heart surgery, threatened bradycardia during drug trials for tachydysrhythmias
Malfunction of implanted pacemaker
Tachycardias
Supraventricular dysrhythmias
Ventricular dysrhythmias
Prophylaxis—cardiac catheterization, after open-heart surgery

*Many indications are relative and are dependent upon a variety of symptoms and parameters.

or asystolic patients but is rarely successful and is not considered standard practice. Early pacing is essential when done for this purpose if success is to be achieved [23] (see later in this section).

Atrioventricular block.

Atrioventricular block is the classic indication for pacemaker therapy. In symptomatic patients without myocardial infarction and in the asymptomatic patient with a ventricular rate below 40, pacemaker therapy is indicated. [24]

In patients with acute myocardial infarction, 15% to 19% progress to heart block: approximately 8% develop first-degree block, 5% develop second-degree block, and 6% develop third-degree block. [25] First-degree block progresses to second- or third-degree block 33% of the time, and second-degree block progresses to third-degree block about one third of the time. [26]

Atrioventricular block occurring during anterior infarction is believed to occur because of diffuse ischemia to the septum and infranodal conduction tissue. These patients tend to progress to high-degree block without warning and a pacemaker is often placed prophylactically. Some pacemakers are prophylactically paced on a temporary basis, even in the absence of hemodynamic compromise.

During inferior infarction, early septal ischemia is the exception and typically block develops sequentially from first-degree to Mobitz type I second-degree, then to third-degree atrioventricular (AV) block. These conduction abnormalities frequently result in hemodynamically tolerable escape rhythms because of sparing of the bundle branches. The hemodynamically unstable patient who is unresponsive to medical therapy should be paced promptly. Whether and when the stable patient should be paced is unclear, but placing a transcutaneous pacer is one option that can be tried before placing a transvenous pacing catheter.

One study, which reviewed the indications for temporary and permanent pacemaker insertion in 432 patients with myocardial infarction, concluded that patients with

second- or third-degree AV block should be paced. This recommendation was made due to a higher incidence of sudden death or recurrent high-degree block over the following year that was found in patients who were not continuously paced. [27]

Trauma.

Pacing is not a standard intervention; in traumatic cardiac arrest in selected cases, it may be considered. Several rhythm and conduction disturbances have been documented in the patient with nonpenetrating chest trauma. In these patients, traumatic injury to the specialized conduction system may predispose the patient to life-threatening dysrhythmias and blocks that can be treated by cardiac pacing. [28]

Hypovolemia and hypotension can cause ischemia of conduction tissue and cardiac dysfunction. [29] Marked bradyarrhythmias that persist even after vigorous volume replacement may rarely respond to cardiac pacing in patients with such trauma. [30]

Bundle-Branch Block and Ischemia

Bundle-branch block occurring in acute myocardial infarction is associated with a higher mortality rate and a greater incidence of third-degree heart block than uncomplicated infarction. Atkins and associates noted that 18% of patients with myocardial infarction had bundle-branch block. [31] Of these patients, complete heart block developed in 43% who had right bundle-branch block and left axis deviation, in 17% who had left bundle-branch block, in 19% who had left anterior hemiblock, and in 6% who had no conduction block. The investigators concluded that right bundle-branch block with left axis deviation should be paced prophylactically.

A study by Hindman and colleagues confirmed the natural history of bundle-branch block during myocardial infarction. [32] In their study, the presence or absence of first-degree AV block, the type of bundle-branch block, and the age of the block (new versus old) were used to determine the relative risk of progression to type II second-degree or third-degree block (Table 15-4).

Because of the increased risk, most should consider pacing the following conduction blocks: *new-onset* left bundle-branch block, right bundle-branch block with left axis deviation or other bifascicular block, and alternating bundle-branch block. [32] One authority recommends prophylactic pacing for all new bundle-branch blocks when myocardial infarction is evident. [33]

Whether to place a transvenous pacemaker prophylactically in patients with left bundle-branch block before insertion of a flow-directed pulmonary artery catheter (PAC) remains controversial. Some researchers strongly advocate this procedure because of the risk of transient right bundle-branch block and life-threatening complete heart block in association with the placement of a PAC. [34] One study notes that this risk is low in patients with prior left bundle-branch block but continues to recommend temporary catheter placement for all cases of *new* left bundle-branch block. [35] One solution to this problem is to place a transcutaneous pacemaker before catheterization as an emergency measure should heart block develop. In these cases, a temporary transvenous pacemaker can be placed in a semi-elective manner when needed. [36] In any event, the trend toward decreased PAC use, particularly outside of the critical care setting, makes it unlikely that this will be an issue in the ED. [37]

TABLE 15-4 -- The Influence of Different Variables on Risk of High-Degree Atrioventricular Block in Patients with Bundle-Branch Block During Myocardial Infarction

Indications for temporary and permanent pacemaker insertion. Circulation 58:690, 1978.)*

Tachycardias

Hemodynamically compromising tachycardias are usually treated by medical means or electrical cardioversion (see Chapter 12). Since 1980, there has been increased interest in pacing therapy for symptomatic tachycardias. Supraventricular dysrhythmias, with the exception of atrial fibrillation, respond well to atrial pacing. By "overdrive" pacing the atria at rates 10 to 20 beats/min faster than the underlying rhythm, the atria become entrained, and when the rate is slowed, the rhythm frequently returns to normal sinus. A similar procedure is done for ventricular dysrhythmias. [38] Overdrive pacing is especially useful for recurrent prolonged Q-T interval arrhythmias such as those seen with quinidine toxicity or torsades de pointes. [39] While an attractive thought, there is no reported experience with these techniques in the ED. Transvenous pacing may also be useful in patients with digitalis-induced dysrhythmias in whom direct current (DC) cardioversion may be dangerous or in patients in whom there is further concern about myocardial depression with drugs. [40]

Cardiac Pacing in Drug-Induced Dysrhythmias

Significant dysrhythmias can occur from excessive therapeutic medication (often in combination therapy) and from overdose of cardioactive medications. Because these drugs have direct effects on the myocardial pacemaker and conduction system cells, cardiac pacing is usually of little therapeutic value. Both bradycardias and tachycardias may result. Tachycardic rhythms from amphetamines, cocaine, anticholinergics, cyclic antidepressants, theophylline, and others do not benefit from cardiac pacing. A drug-induced torsades de pointes may theoretically be overdriven by pacing, but data on this technique are lacking. Any drug that affects the central nervous system (opiates, sedative-hypnotics, clonidine, and others) may produce bradycardia. Rare causes of toxin-induced bradycardia include organophosphate

poisoning, various cholinergic drugs, ciguatera poisoning, and, rarely, plant toxins. Cardiac pacing is not used for bradycardias from these sources; rather, the underlying CNS depression is addressed.

Severe bradycardia and heart block often accompany overdose of digitalis preparations, beta adrenergic blockers, and calcium channel blockers. While intuitively attractive, cardiac pacing is rarely successful in serious toxin-induced bradycardias. [41] [42] [43] [44] In beta-blocker overdose, pacing may increase heart rate but rarely benefits blood pressure or cardiac output. Worsening of the blood pressure may be seen from loss of atrial contractions with ventricular pacing. Likewise, calcium channel blocker overdose and digitalis-induced bradycardia and heart block rarely benefit from cardiac pacing. Pharmacologic interventions, such as digoxin-specific Fab, glucagon, calcium, and inotropic medications, and vasopressors remain the mainstay in the treatment of drug-induced dysrhythmias. Given the lack of success of pacing, possible downsides, and the greater effectiveness of specific antidotes, it is not standard to routinely attempt cardiac pacing in the setting of drug overdose. However, as a last ditch effort, cardiac pacing can be supported.

Contraindications

There are no absolute contraindications to transvenous cardiac pacing; however, the severely hypothermic bradycardic patient can often be managed without pacing. Severe hypothermia will occasionally result in ventricular fibrillation when pacing is attempted. Because ventricular fibrillation under these conditions is difficult to convert, caution is advised when considering pacing the severely hypothermic and bradycardic patient. Rapid warming is often recommended first, followed by pacing if the patient's condition does not improve.

Equipment

Several items are required to insert a transvenous pacemaker adequately. Like most special procedures, a prearranged tray is convenient. The usual components required to insert a transvenous cardiac pacemaker are listed in Table 15-5 .

Pacing Generator

Many different pacing generators are available, but in general, they all have the same basic features. The on/off switch frequently will have a locking feature to prevent the generator from inadvertently being switched off. An amperage knob allows the operator to control the amount of electrical current delivered to the myocardium, usually 0.1 to 20 mA. The pacing control mode is the gain control for the sensing function of the generator. By increasing the sensitivity, one can convert the unit from a fixed rate (asynchronous mode) to a demand (synchronous mode) pacemaker. In the fixed-rate mode, the unit fires despite the underlying intrinsic rhythm; the unit does not sense any intrinsic electrical activity. In the full-demand mode, however, the pacemaker senses the underlying ventricular depolarizations, and the unit does not fire as long as the patient's ventricular rate is equal to or faster than the set rate of the pacing generator. A sensing indicator meter and rate control knob are also present. An example of a pacing generator is shown in Figure 15-1 .

Pacing Catheters and Electrodes

Several sizes and brands of pacing catheters are available. In general, most range from 3 Fr to 5 Fr in size and are approximately 100 cm in length. Along the catheter surface are lines that are marked at approximately 10-cm intervals; these can be used to estimate catheter position during insertion. Two

basic types of pacing catheters are currently in use: (1) the flexible semifloating or floating catheter and (2) the rigid fixed-position catheter. [39]

The flexible catheters are more advantageous than the rigid catheter by virtue of the flexible catheter's ability to be inserted in low flow states, as well as in their decreased tendency to perforate the ventricle. For emergency pacing, the 4 Fr semifloating bipolar electrode with or without the balloon tip is used most frequently (Fig. 15-2). The balloon holds approximately 1.5 mL of air, and some of the injection ports have a locking lever to secure balloon expansion. Before insertion, the balloon is checked for air leakage by inflating it and immersing it in sterile water. The presence of an air leak is noted by a stream of bubbles arising at the surface of

the water. An inflated balloon helps the catheter "float" into the heart in low flow states but is obviously not advantageous in the cardiac arrest situation.

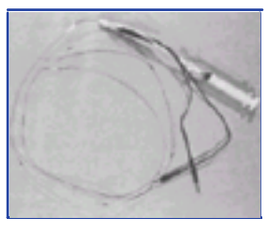

Figure 15-2 Balloon-tipped pacing catheter.

For all practical purposes, temporary transvenous pacing is accomplished with a bipolar pacing catheter. The terms *unipolar* and *bipolar* refer to the number of electrodes in contact with that portion of the heart that is to be stimulated. All pacemaker systems must have both a positive (anode) and a negative (cathode) electrode; hence, *all stimulation is bipolar*. In the typical bipolar catheter used for temporary transvenous pacing, the cathode (stimulating electrode) is at the tip of the pacing catheter. The anode is located 1 to 2 cm proximal to the tip, and the two electrodes may be separated by a balloon or an insulated wire. The distinction between the unipolar and bipolar pacing catheter is that a bipolar catheter has both electrodes in a relative close proximity on the catheter, and both may contact the endocardium. In the bipolar catheter, the electrodes are usually platinum rings that encircle the pacing catheter. When properly positioned, both electrodes will be within the right ventricle so that a field of electrical excitation is set up between the electrodes. With the bipolar catheter, the cathode does not need to be in direct contact with the endocardium for pacing to occur, although it is preferable to have direct contact.

A unipolar system is also effective but is used infrequently for temporary transvenous pacing. In a unipolar system, the cathode is at the tip of the pacing catheter, and the anode is located in one to three places: (1) in the pacing generator itself, (2) more proximal on the catheter (outside the ventricle), or (3) on the patient's chest. A bipolar catheter system may be converted to a unipolar system by simply disconnecting the positive proximal connection of the bipolar catheter from the pacing generator and running a new wire from the positive (pacing generator) terminal to the patient's chest wall. Such a conversion may be required in the unlikely event of failure of one lead of the bipolar system.

Theoretically, the field of electrical stimulation of a pacing catheter is equal to the distance between the electrodes. If the field of excitation is not close enough to the myocardium, depolarization will not occur. When a catheter is passed blindly in an emergency, it seems advantageous to ensure the best chance of capture by separating the electrodes by more than the standard 1 to 2 cm. A pacing catheter that uses this configuration (Davison pacing lead, Electro-Catheter Corporation, Rahway, NJ) is a hybrid of the standard bipolar and unipolar catheters. This catheter has the cathode at the tip, but the anode is situated 19 cm proximal to the tip. This configuration allows pacing with a very wide field of excitation. Pacing has been reported to occur with this catheter when the catheter is placed anywhere within the thoracic venous system. The catheter is a hybrid because both electrodes are present on the same catheter (bipolar), but both electrodes will not be positioned in the same cardiac chamber (unipolar).

ECG Machine

An ECG machine can be used to record the heart's inherent electrical activity during pacer insertion and to aid in localization of the catheter tip without fluoroscopy. The ECG machine must be well grounded to prevent leakage of alternating current, which can cause ventricular fibrillation. Such leakage should be suspected if interference of 50 to 60 cycles per second (Hz) is noted on the ECG.

The ECG machine should be placed in such a manner as to allow easy visibility of the rhythm during insertion. One method is to place the machine on the same side of the patient as the operator at the level of the midthorax (Fig. 15-3). Note

Figure 15-3 Position of an electrocardiogram device during femoral vein insertion of a pacemaker catheter. Operator is on right side of patient facing cephalad.

that the operator stands at the head of the patient during internal jugular or subclavian vein passage of the catheter and at the midabdomen for femoral or brachiocephalic vein insertion.

Introducer Sheath

An introducer set or sheath is required for venous access (see Chapter 22). Some pacing catheters are prepackaged with the appropriate equipment, whereas others require a separate set. The introducer set is used to enhance passage of the pacing catheter through the skin, subcutaneous tissue, and vessel wall. To allow passage of the pacing catheter, the sheath must be one size larger than the pacing catheter. A makeshift sheath can be made with an appropriate-sized intravenous (IV) catheter. For the 3 Fr balloon-tipped catheter, a 14-gauge, 1.5-to 2-inch IV catheter is suitable. The 4 Fr balloon-tipped catheter will also fit through a 14-gauge catheter or needle.

A balloon-directed pulmonary artery catheter (Paceport pacing system, American Edwards Laboratories, American

TABLE 15-6 -- Advantages and Disadvantages of Pacemaker Placement Sites

Venous Channels	Advantages	Disadvantages
Brachial	Very safe route	Often requires cutdown
	Vessel easily accessible, either by cutdown or percutaneous approach	Easily displaced and poor patient mobility
		Not reusable if cutdown technique is performed
		Catheter is more difficult to advance than with central or larger vessels
Subclavian	Direct access to right heart (especially via left subclavian)	Pneumothorax and other intrathoracic trauma are possible
	Rapid insertion time	
	Reusable	
	Good patient mobility	
Femoral	Direct access to right heart	Increased incidence of thrombophlebitis
	Rapid insertion time	Can be dislodged by leg movement and poor patient mobility
	Reusable	
		Infection
Internal jugular	Direct access to right heart (especially via right internal jugular)	Possible carotid artery puncture
		Dislodgment with movement of the head
	Rapid insertion time	Thrombophlebitis

Reusable	

Hospital Supply Corporation) has been developed. It has a separate lumen that allows the passage of a transvenous pacing catheter. [45] This catheter is 7.5 Fr and has an opening 19 cm from the catheter tip that allows passage of the 2.4 Fr pacing wire. This stainless steel wire is Teflon-coated for easy passage and has a flexible tip. Combination pulmonary artery or pacemaker catheters are also available but are not widely used in the emergency setting.

Overall, the key to success with this procedure is preparation. It is imperative that one examine all the components of the tray before starting the procedure and ensure that all wires, sheaths, dilators, and syringes fit as expected.

Procedure

Patient Preparation

Patient instruction is an extremely important aspect of any procedure. Frequently there is not enough time to give patients a detailed explanation. Nor to obtain written informed consent. Nonetheless, sufficient information should be provided so that the patient feels at ease. It is always prudent to obtain and document informed consent from the patient if possible prior to any invasive procedure, or to document that the circumstances did not allow informed consent. Patients should be assured that they will feel no discomfort after the venipuncture site has been anesthetized and that they will feel better when the catheter is in place and is functional. Continued reassurance is required during the procedure because patients are usually facing away from the operator and because their faces are often covered, they may be unsure of what is occurring. When appropriate sedation anxietolysis should be considered.

All operators should wear surgical masks, caps, gloves, and gowns to decrease the risk of infection before catheter placement. This aseptic precaution should also be explained to the patient.

Site Selection

The four venous channels that provide an easy access to the right ventricle are the brachial, subclavian, femoral, and internal jugular veins (Table 15-6). The route selected is often one of

personal or institutional preference. The right internal jugular and the left subclavian veins have the straightest anatomic pathway to the right ventricle and are generally preferred for temporary transvenous pacing. In some centers a particular site is preferred for permanent transvenous pacemaker placement, and, if possible, this site should be avoided for temporary placement.

The subclavian vein can be accessed by both an infraclavicular and a supraclavicular approach; the infraclavicular approach is most commonly reported for all temporary transvenous pacemaker insertions. This route is preferred because of its easy accessibility, close proximity to the heart, and ease in catheter maintenance and stability. The supraclavicular approach has been described in the literature for several years and has gained popularity among some clinicians. [46] [47] The *left* subclavian vein is preferred because of the less acute angle traversed when compared with the right-sided approach. However, a recent study reported safe and efficient emergency transvenous pacing via a right-sided supraclavicular approach. [48]

Some clinicians believe the internal jugular approach is as easy as and safer than subclavian catheterization. [48] Either site is acceptable. The right internal jugular vein is preferred because of the direct line to the superior vena cava. Problems with this approach include dislodgment of the pacemaker with movement of the head, carotid artery puncture, and thrombophlebitis (see Chapter 22).

During cardiopulmonary resuscitation, the use of the right internal jugular vein and the left subclavian veins for pacemaker insertion have been demonstrated to result in the highest rates of proper placement in the right ventricle. [49] The right internal jugular vein is the more direct route of the two and may be the most appropriate site. Because of the extremely low flow state during cardiopulmonary resuscitation, a larger (5 Fr), semirigid catheter may be a more appropriate choice than the 3 to 4 Fr catheters commonly used.

Femoral veins, like neck veins, are reusable and easily catheterized. Problems include easy dislodgment, infection, and increased risk of thrombophlebitis. [50] [51]

Brachial vein catheterization is easy to perform but results in a higher incidence of infection and vessel thrombosis. [52] In addition, the catheter is easily dislodged with arm motion. This approach is seldom used in the emergency setting.

Skin Preparation and Venous Access

The skin over the venipuncture site is cleaned twice with an antiseptic solution such as povidone-iodine and isopropyl alcohol. A wide area is prepared because of the tendency for guidewires and catheters to spring from the hands of the unsuspecting operator. Preparation of the skin is shown in Chapter 22 . Similarly, wide draping is carried out in the standard manner to maintain a sterile field and to allow clear visibility of the venipuncture site.

The infraclavicular approach is used in this chapter to illustrate venous access, although the mechanics are generally the same for other vascular approaches. The reader is referred to Chapter 22 for the specific techniques of venous access.

Occasionally a patient who already has a central venous line in place requires the emergent placement of a pacing catheter. An existing central venous pressure (CVP) line can be used to place the pacing catheter if the catheter lumen is large enough to accept a guidewire. The CVP line should be withdrawn 1 to 2 in. to expose an area of sterile tubing. The tubing is transected through a sterile area while being held

Figure 15-4 Insertion of the pacing catheter through the introducer sheath.

firmly at the skin level. A guidewire can then be passed through the tubing, and the tubing can be withdrawn, leaving only the wire in the vein. The guidewire and the tubing should never be released because embolization may result. An introducer unit can then be passed over the guidewire, as is done in the Seldinger technique (see Chapter 22), and the pacing catheter can be placed (Fig. 15-4).

Bedside ultrasound (US) can be useful as an aid to securing central venous access and its use in the setting of emergency transvenous pacing has been reported (see Chapter 69). [53] [54]

Pacemaker Placement

Electrocardiographic guidance.

The patient should be connected to the limb leads of an ECG machine, and the indicator should be turned to record the chest (V) lead.

With newer ECG machines, the pacemaker may be attached to any of the V leads (usually V_1 or V_5) that are displayed during rhythm monitoring. As the tracing on the ECG machine is slightly delayed with the newer devices, advancement of the catheter after initial insertion must be carefully evaluated. The pacing wire should be

inserted about 10 to 12 cm into the selected vein. The *distal* terminal of the pacing catheter (the cathode or lead marked negative, "-") must be connected to the V lead of the ECG machine by a male-to-male connector or by an insulated wire with an alligator clip on each end (Fig. 15-5). The pacing catheter is thus an exploring electrode that creates a unipolar electrode for intracardiac ECG recording. The ECG recorded from the

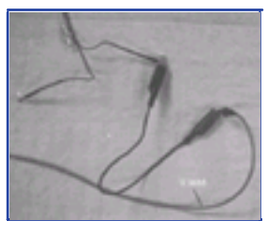

Figure 15-5 Using alligator clips to connect the *negative* lead of the pacemaker catheter to the V lead of an electrocardiographic machine.

electrode tip *localizes the position of the tip of the pacing electrode*. If a balloon-tipped catheter is used, the balloon is inflated with air *after* the catheter enters the superior vena cava.

The pacing catheter should be advanced both quickly and smoothly. The V lead should be monitored, and the P wave and QRS complex should be observed to ascertain the location of the pacing catheter tip. The use of an ECG to guide the placement of a pacing catheter is based on two concepts. First, the complex will vary in size depending on which chamber is entered. For example, when the tip of the pacing catheter is in the atrium, one will see large P waves, often larger than the corresponding QRS complex. Second, the sum of the electrical forces will be negative if the depolarization is moving away from the catheter tip and positive if the depolarization is moving toward the catheter tip. Therefore, if the catheter tip is *above* the atrium, both the P wave and the QRS complex will be negative (i.e., the electrical forces of a normally

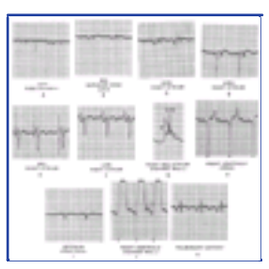

Figure 15-6 *A–K,* Intracardiac electrocardiography: Electrical signals of atrial and ventricular depolarization and repolarization from different vascular and intracardiac locations (see text). *(A–F and H–K from Bing OH, McDowell JW, Hantman J, et al: Pacemaker placement by electrocardiographic monitoring. N Engl J Med 287:651, 1972. G from Goldberger E: Treatment of Cardiac Emergencies, 3rd ed. St. Louis, CV Mosby, 1982, p 252.)*

beating heart will be moving away from the catheter tip). As the tip progresses inferiorly in the atrium, the P wave will become isoelectric (biphasic) and will eventually become positive as the wave of atrial depolarization advances toward the catheter tip. The ECG resembles an aVR lead initially when in the left subclavian vein (Fig. 15-6*A*) or midsuperior vena cava (Fig. 15-6*B*). At the high right atrium, both the P wave and QRS complex are negative; the P wave is larger than the QRS complex and is deeply inverted (Fig. 15-6*C* and *D*). As the center of the atrium is approached, the P wave becomes large and biphasic (Fig. 15-6*E*). As the catheter approaches the lower atrium (Fig. 15-6*F*), the P wave becomes smaller and upright. The QRS complex is fairly normal. When striking the right atrial wall, an injury pattern with a P-Ta segment is seen (Fig. 15-6*G*). As the electrode passes through the tricuspid valve, the P wave becomes smaller, and the QRS complex becomes larger (Fig. 15-6*H*).

Placement in the inferior vena cava may be recognized by a change in the morphology of the P wave and a decrease in the amplitude of both the P wave and the QRS complex (Fig. 15-6*I*).

Once the pacing catheter is in the desired position, the balloon is deflated by unlocking the port and removing the syringe. One should avoid drawing back on the syringe, because this may cause balloon rupture. If the operator suspects that the balloon may be ruptured, it should not be inflated. Instead, the pacing catheter should be withdrawn and the balloon checked for leaks. If a leak is found, a new pacing catheter should be used.

After successful placement of the catheter within the right ventricle, the tip should be advanced until contact is made with the endocardial wall. When this occurs, the QRS segment will show ST segment elevation (Fig. 15-6*J*). Ideally, the tip of the catheter should be lodged in the trabeculae at the apex of the right ventricle; however, pacing may be successful if the catheter is in various other positions within the ventricle or outflow tract.

If the pacer enters the pulmonary artery outflow tract, the P wave again becomes negative, and the QRS amplitude diminishes (Fig. 15-6*K*). If the catheter is in the pulmonary artery, the pacing catheter should be withdrawn into the right ventricle and readvanced. Sometimes a clockwise or counter-clockwise twist of the catheter will redirect its path in a more favorable direction. If catheter-induced ectopy develops, the catheter should be slightly withdrawn until the ectopy stops; then it should be readvanced. Occasionally an antidysrhythmic drug such as lidocaine may be needed to desensitize the myocardium. Once ventricular endocardial contact is made, the catheter is disconnected from the ECG machine. The proximal positive and negative leads are connected to their respective terminals on the pacing generator. The pacing generator is then set to a rate of 80 beats/min or 10 beats/min faster than the underlying ventricular rhythm, whichever is higher. The full-demand mode is selected, with an output of about 5 mA. The pacing generator is then turned on. If complete capture does not occur or if it is intermittent, the pacer will need to be repositioned. When proper capture occurs, the pacer is tested for optimal positioning. This is done by testing the thresholds for sensing and pacing and with chest radiographs, physical examination, and ECG.

Catheter placement without an electrocardiograph.

Occasionally it is necessary to use a transvenous pacemaker in an emergency setting when a well-grounded ECG machine is not available. Blind insertion of the transvenous pacing catheter is a safe and effective alternative to placement with ECG guidance. In this technique, the pacing catheter is placed 10 to 12 cm into the venous port and is connected to the pacing generator as noted previously. The pacing rate is selected at *twice* the intrinsic heart rate, and the output is set at an amperage that is too low to capture the ventricle, usually less than 0.2 mA. The unit is then turned on to first *sense* but *not* to pace. On entering the ventricle, the pacer will sense on every other beat. The balloon can then be deflated, the amperage can be increased to 4 to 5 mA for initiating pacing, and the pacemaker can be advanced to capture the ventricle. If this does not occur within an additional 10 cm, the pacing catheter should be withdrawn to its original position and then advanced again. As with ECG placement, proper positioning must be ensured.

In elective, nonemergent cases fluoroscopy is a valuable tool in the placement of transvenous pacemakers. Its use depends on the operator's preference, the patient's condition, and its availability. Generally transvenous pacemakers are not inserted under fluoroscopy without ECG monitoring because of the high incidence of ventricular dysrhythmias. [39]

If the cardiac output is too low to "float" a pacing catheter or if the patient is in extremis, there may not be enough time to advance a pacing catheter using the previously described techniques. Such a situation would be asystole or complete heart block with malignant ventricular escape rhythms (although one can make a case for transcutaneous pacing in such conditions). In such emergent situations, the pacing catheter is connected to the energy source, the output is turned to the maximum amperage, and the asynchronous mode is selected. The catheter is then blindly advanced in the hope that it will enter the right ventricle and that pacing will be accomplished. The pacing catheter is rotated, advanced, withdrawn, or otherwise manipulated according to the clinical response. The right internal jugular approach is the most practical access route in this situation. In such instances, there is the theoretic advantage of using the previously described Davison catheter, because one is interested in rapid capture only until the patient is stabilized.

Ultrasound guidance.

As bedside US has become more widely available in the ED, new uses have been discovered. One promising technique involves using US to assist with the placement of emergency transvenous pacing catheters.[55] [56] The advantages of US over fluoroscopy are its safety and ready availability. Further experience will be necessary to confirm its utility.

Dual Chamber Pacing

Synchronous pacing of the atria and ventricle through a *dual-chamber pacing catheter* that senses and paces both atria and ventricles (DDD mode) results in more physiologic pacing with further improvement in cardiac output. It also allows for variations in the atrial rate and improved coordination of atrial and ventricular contractions. This catheter is placed in the same manner as the ventricle-only pacing catheter (VVI mode) but requires greater skill and experience because of the need to properly place the catheter in both the atria and ventricle. When attaching the catheter to the pacing generator, it is important to ensure that the atrial catheter is connected to the atrial electrode and the ventricular catheter is connected to the ventricular electrode. There are devices that have dual-chamber pacemaking capability and can operate in a variety of modes, including DDD mode. However, it is seldom necessary to employ this modality in the ED.

Testing Threshold

The threshold is the minimum current necessary to obtain capture. Ideally, this is less than 1.0 mA, and usually it is between 0.3 and 0.7 mA. If the threshold is in this ideal range, good contact with the endocardium can be presumed.

To determine the threshold, the pacing generator should be placed in the full-demand mode at 5 mA with a rate of approximately 80 beats/min. The amperage (output) should then be reduced slowly until capture is lost. This current is the threshold. This maneuver should be carried out two or three times to ensure that this value is consistent; the amperage should then be increased to 2.5 times the threshold to ensure consistency of capture (usually between 2 and 3 mA).

If one reduces the output to below the threshold and then slowly increases it, there may be a difference in the point at which capture returns. This difference is called *hysteresis* and

represents the time interval between sensing and pacemaker firing. If the difference in capture current is greater than 20%, the pacing catheter should be repositioned, because serious dysrhythmias may result if the pacemaker fires during the vulnerable period of repolarization. [39] [57]

Testing Sensing

The sensing function should be tested in patients who have underlying rhythms. The pacemaker system is again set in full-demand mode with complete capture, and the rate is decreased until it is suppressed by the patient's intrinsic rhythm. This is done several times to ensure accuracy of the sensing function.

In bipolar systems, another method of evaluating the sensing mode is to take a unipolar ECG from each end of the bipolar lead on a chest lead at one-fourth standardization to permit observation of the entire complex. [39] The voltage of the QRS complex is multiplied by 4 and, if adequate, should be greater than the sensing threshold by greater than 1 mV (Fig. 15-7). Another method is to set the ECG machine on lead I and connect the wires from the proximal electrode to the right arm lead and the left arm lead to the distal electrode. A lead I is created, which, when the QRS voltage is multiplied by 4, should also be at least 1 mV more than the sensing threshold.

Securing and Final Assessment

After the pacemaker's position has been tested for electrical accuracy, the introducer sheath should be withdrawn (Fig. 15-8) and the catheter secured to the skin with suture (e.g., 4-0 nylon or silk). A fastening suture should be sewn to the skin and the catheter tied securely in place. The excess pacing catheter should be coiled and secured in a sterile manner along with the introducer. A large sterile dressing should be applied. Pacemaker function should again be assessed, and a chest film should be taken to ensure proper positioning. Ideal

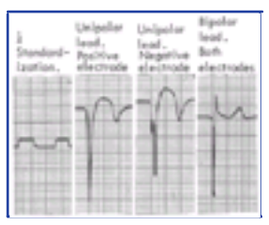

Figure 15-7 Testing unipolar sensing with a bipolar system. *(From Goldberger E: Treatment of Cardiac Emergencies, 3rd ed. St. Louis, CV Mosby, 1982.)*

positioning of the pacing catheter is at the apex of the right ventricle (Fig. 15-9).

A 12-lead ECG should be obtained after transvenous pacemaker placement. If the catheter is within the right ventricle, a left bundle-branch pattern with left axis deviation should be evident in paced beats (Fig. 15-10). If a right bundle-branch block pattern is noted, coronary sinus placement or left ventricular pacing due to septal penetration should be suspected.

With a properly functioning ventricular pacemaker, large cannon waves will be noted on inspection of the venous pulsations at the neck. This is caused by the atria contracting against a closed tricuspid valve. On auscultation of the heart,

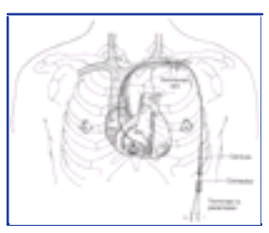

Figure 15-8 Pulling back the introducer sheath (cannula). RA, right atrium; RV, right ventricle; LV, left ventricle.

Figure 15-9 Normal pacemaker position on posteroanterior *(A)* and lateral *(B)* chest films. *(From Goldberger E: Treatment of Cardiac Emergencies, 3rd ed. St. Louis, CV Mosby, 1982.)*

a slight murmur secondary to tricuspid insufficiency from the catheter interfering with the tricuspid valve apparatus may be evident. [58] A clicking sound, heard best during expiration following each pacemaker impulse, may also be noted here and is believed to represent either intercostal or diaphragmatic muscular contractions caused by the pacemaker.[59] Note that this can also be a sign of cardiac perforation. [60] On auscultation of the second heart sound, paradoxical splitting may be noted. This represents a delay in closure of the aortic valve because of delayed left ventricular depolarization.

As in any procedure, the patient should then be assessed for improvement in his or her clinical status. An evaluation of vital signs, mentation, improvement in congestive symptoms, and urinary output must be noted. In addition, complications secondary to the procedure should be sought and treated as needed.

Complications

The complications of emergency transvenous cardiac pacing are numerous and represent a compendium of those related to central venous catheterization, those related to right-sided heart catheterization, and those unique to the pacing catheter itself (Table 15-7).

Problems Related to Central Venous Catheterization

Inadvertent arterial puncture is a well-known complication of the percutaneous approach to the venous system. [61] This problem is usually recognized quickly because of the rapid return of arterial blood. Firm compression over the puncture site will almost always result in hemostasis in 5 minutes or less.

Venous thrombosis and thrombophlebitis are also potential problems with central venous catheterization. Thrombophlebitis, which occurs early after insertion, is said to be a rare complication. Some experts believe that it can be managed without removal of the catheter or anticoagulation. [52] When thrombophlebitis occurs in long-term implanted pacemakers, removal and anticoagulation may be required. In one series, only 0.1% of permanent pacemakers were in this category, and in a small percentage of these, occult malignancies were found.[52] Complete thrombosis of the innominate vein is also a rare problem, with pulmonary embolism an even more uncommon event.[62] Femoral vein thrombosis, however, appears to be a much more common event associated with femoral vein catheterization. [50] [63] Studies using noninvasive techniques have shown a 37% incidence of femoral vein thrombosis, with 55% of these having ventilation-perfusion scan evidence of pulmonary embolism.[63] Thrombosis in the right atrium may also occur and has been treated successfully with thrombolytic agents. [64]

Pneumothorax is consistently a problem with the various approaches to the veins at the base of the neck. The decision to place a chest tube in patients with this complication depends on the size of the pneumothorax and the clinical status of the patient (see Chapter 10). In addition, laceration of the subclavian vein with hemothorax,[65] thoracic duct laceration with chylothorax, air embolism, wound infections, pneumomediastinum, hydromediastinum, [66] hemomediastinum, phrenic nerve injury,[67] fracture of the guidewire with embolization, [68] [69] and catheter or guidewire knotting[70] [71] are all potential complications. [39] [65]

Complications of Right-Sided Heart Catheterization

A common complication of the pacing catheter is dysrhythmia, with premature ventricular contractions being a common occurrence. One study noted a 1.5% incidence of serious dysrhythmias with a balloon-tipped catheter using ECG guidance, compared to a 32% incidence with the semirigid catheter using fluoroscopic guidance, suggesting that the balloon catheter was the preferred type of catheter. [14] Another study noted a 6% incidence of ventricular tachycardia during insertion. [50] The ischemic heart is more prone to dysrhythmias than the nonischemic heart. [72] The therapy for catheter-induced ectopy involves withdrawing the catheter from the ventricle. This usually stops the ectopy; however, if after repeated attempts it is found that the catheter cannot be passed without ectopy, myocardial suppressant therapy may be used to desensitize the myocardium.

Misplacement of the pacing catheter has been well studied. Passage of the catheter into the pulmonary artery can be diagnosed cardiographically by observing the return of an inverted P wave and the decrease in the voltage of the QRS complex. Misplacement in the coronary sinus may occur and should be suspected in the patient in whom a paced right bundle-branch

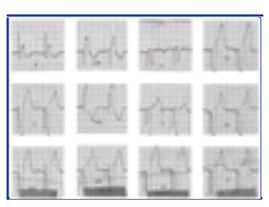

Figure 15-10 Electrocardiogram pattern of right venticular pacemaker.

pattern on the ECG is seen with right ventricular pacing (Fig. 15-11). Rarely, a right bundle-branch pattern can be seen with a normal right ventricular position; therefore, all right bundle-branch patterns do not represent coronary sinus pacing. [73] Further evidence for coronary sinus location can be obtained by viewing the lateral chest film. Normally, the catheter tip should point anteriorly toward the apex of the heart; however, with coronary sinus placement, the catheter tip is displaced posteriorly and several centimeters away from the sternum (Fig. 15-12). Other potential forms of misplacement include left ventricular pacing through an atrial septal defect or a ventricular septal defect, septal puncture, extraluminal insertion, and arterial insertions. [74]

Perforation of the ventricle is a well-described complication that can result in loss of capture, [75] hemopericardium, and tamponade.[76] [77] Reported symptoms and signs of this problem include chest pain, pericardial friction rub, and diaphragmatic or chest wall muscular pacing. [78] At least one case of a post-pericardiotomy-like syndrome and two cases of endocardial friction rub have been reported without perforation. [79] [80]

Pericardial perforation is suggested radiographically when the pacing catheter is outside or abuts the cardiac silhouette and is not in proper position within the right ventricular cavity (Fig. 15-13).[81] ECG clues include a change in the QRS and T wave axis or a failure to properly sense. In suspected cases, a two-dimensional echocardiogram usually demonstrates the catheter's extracardiac position. Uncomplicated perforation can usually be treated by simply pulling back the catheter and repositioning it in the right ventricle.

During the insertion of a temporary pacing catheter when a nonfunctioning permanent catheter is in place, there is a small risk of entanglement or knotting. This potential also exists with other central lines and Swan-Ganz catheters. Frequently these lines can be untangled under fluoroscopy using specialized catheters.

Local and systemic infections,[52] balloon rupture, pulmonary infarction, [82] phrenic nerve pacing,[83] and rupture of the chordae tendineae are also potential complications.[82]

Complications of the Pacing Electrode

The complications related to the pacing electrode can be separated into three groups: mechanical, organic, and electrical.

Mechanical failures include displacement, fracture of the catheter, and loose leads. Displacement can result in intermittent or complete loss of capture or improper sensing, malignant dysrhythmias, diaphragmatic pacing, or perforation. Displacement should be suspected with changes in amplitude, with vector changes greater

than 90 degrees, or with a change in threshold.[84] Frequently catheter fractures may be detected by a careful review of the chest film or may be suspected because of a change in the sensing threshold. As with displacement, intermittent or complete loss of capture may result.

Organic causes of pacemaker failure result in changes in the threshold or sensing function.[85] Progressive inflammation, fibrosis, and thrombosis may result in more than a doubling of the original threshold.[86] This may occur in 3 to 4 weeks and should be expected in prolonged temporary pacemakers. Physiologic and pharmacologic factors that affect the threshold have been studied. Sleeping, eating a heavy meal, lowered aldosterone concentration, potassium infusions,[87] and myxedema[88] all increase the threshold by raising the resting membrane potential. The threshold for cardiac pacing tends to decrease with exercise, sympathetic amines, glucocorticoids, and toxic levels of procainamide.[89]

TABLE 15-7 -- Complications of Transvenous Cardiac Pacing

Year	Author	No. of Patients	Catheter	Route	Result
1969	Rosenberg et al[1]	111	Flexon steelwire vs unipolar semifloating (ECG)	96 Subclavian	12 inconsistent pacing, 3 local infection, 2 pneumothorax, 1 subclavian artery puncture; 16% complication rate

In some patients the atrial contribution to ventricular filling is extremely important. Transvenous ventricular pacing results in loss of the atrial kick and ultimately a decrease in left ventricular stroke volume. This phenomenon is called *postpacer syndrome* and occasionally is severe enough to preclude the use of a pacemaker.[90] A bichamber sequential pacemaker that stimulates the atria and ventricles in sequential fashion is a viable alternative for patients unable to tolerate the loss of the atrial kick.[91]

Electrical problems with pacing include pacemaker generator failure, dysrhythmias, and outside interference. Electrical interference is of occasional importance during aeromedical transport.[92] Usually converting the unit to a fixed mode will permit continued pacing. Although ventricular tachycardia and ventricular fibrillation have been reported to result from pacemakers, these dysrhythmias are rare. Because of this, patients who present with such dysrhythmias should be evaluated for a nonpacemaker etiology.[93] Direct current cardioversion and electroshock therapy are safe procedures to carry out in patients who have pacemakers as long as the current does not go directly over the subcutaneous lead or generator pack.[94]

Conclusion

Temporary transvenous pacing is a rapid, safe, and reliable method for achieving effective electrical stimulation of the heart. Symptomatic bradycardias unresponsive to pharmacologic treatment and some tachycardias are indications for its use. In acute myocardial infarction, it serves both a therapeutic and a prophylactic function.

EMERGENCY TRANSCUTANEOUS CARDIAC PACING

Transcutaneous cardiac pacing (TCP) is a rapid, minimally invasive method of treating severe bradycardias and asystole. Electrodes are applied to the skin of the anterior and posterior chest walls, and pacing is initiated with a portable pulse generator. In an emergency setting, this pacing technique is faster and easier to initiate than transvenous pacing. Pulse generators are sufficiently portable to be used in EDs, hospital wards, intensive care units, and mobile paramedic vehicles.

Background

In 1872, Duchenne de Boulogne reported a successful resuscitation of a child by attaching one electrode to a limb while a second electrode was rhythmically touched to the precordium of the thorax.[95] Successful overdrive pacing of the human heart, using a precordial electrode, was reported by VonZiemssen in 1882. [96]

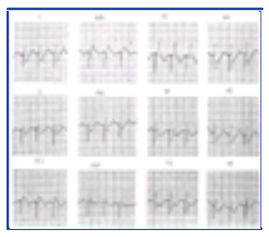

Figure 15-11 Coronary sinus pacing. Note the paced right bundle-branch block pattern.

In 1952, Zoll introduced the first practical means of TCP. Using a ground electrode attached to the skin and a subcutaneous needle electrode over the precordium, he reported the successful resuscitation of two patients in ventricular standstill. [97] One patient was paced for 5 days and subsequently was discharged from the hospital. Zoll later introduced a machine that delivered impulses lasting 2 msec through 3-cm-diameter metal paddles pressed firmly against the anterior chest wall. This device was the first commercial transcutaneous cardiac pacemaker. During the 1950s, Zoll and Leatham demonstrated the effectiveness of TCP in patients with bradycardia and asystole.[98] [99] [100] [101] Leatham used larger electrodes (4 × 6 cm) and a longer pulse duration (20 msec) to successfully pace two patients with bradydysrhythmias. [101]

Until the late 1950s, TCP was the only clinically accepted method of cardiac pacing. The original technique using bare metal electrodes had adverse effects, including local tissue burns, muscle contraction, and severe pain. [97] [101] With the development of the first implantable pacemakers from 1958 through 1960 and the improvement of transvenous electrodes during the early 1960s, TCP was rapidly discarded. [102]

Refinements in electrode size and pulse characteristics have led to the reintroduction of TCP into clinical practice. [103] [104] Increasing the pulse duration from 2 to 20 msec or longer was found to decrease the current output required for cardiac capture. [105] [106] Longer impulse durations also make the induction of ventricular fibrillation less likely. [105] Larger surface area electrodes (80 to 100 cm^2) decrease the current density at the underlying skin and therefore decrease pain and the possibility of tissue burns.[103]

Indications and Contraindications

General indications for cardiac pacing are discussed earlier. TCP is the fastest and easiest method of emergency pacing. This technique is useful for initial stabilization of the patient in the ED who requires emergency pacing while arrangements or decisions for transvenous pacemaker insertion are being made. The equipment is readily mastered, the procedure is fast, and it is minimally invasive. [104] [107] Refinements in equipment have made TCP the emergency pacing procedure of choice. TCP also is gaining widespread prehospital use in helicopter ambulance programs and inhospital use in the cardiac catheterization laboratory, operating room, intensive care unit, and on general medical floors.[108] [109] [110] The technique may be preferable to transvenous pacing in patients who have received thrombolytic agents. No central venous puncture, with the attendant risk of hemorrhage, is required. Limited experience suggests that TCP also may be useful in the treatment of refractory tachydysrhythmias by overdrive pacing.[111] [112] [113] [114] [115] Although small pediatric electrodes for TCP have been developed, experience with pediatric TCP has been limited.[116] [117]

TCP is indicated for the treatment of hemodynamically significant bradydysrhythmias that have not responded to atropine therapy. *Hemodynamically significant* implies hypotension, anginal chest pain, pulmonary edema, or evidence of decreased cerebral perfusion. This technique is *temporary* and is indicated for short intervals as a bridge until transvenous pacing can be initiated or until the underlying cause of the bradyarrhythmia (e.g., hyperkalemia, [107] drug overdose[118]) can be reversed. Although often unsuccessful, TCP may be

Figure 15-12 Coronary sinus position. *A,* Posteroanterior view. *B,* Lateral view. *(From Goldberger E: Treatment of Cardiac Emergencies, 3rd ed. St. Louis, CV Mosby, 1982.)*

attempted in the treatment of asystolic cardiac arrest. In this setting the technique is efficacious only if used early after arrest onset (generally within 10 minutes). [119] [120] TCP is not indicated for treatment of prolonged arrest victims with a final morbid rhythm of asystole. [117] [121] [122] [123]

Delay from the onset of arrest to the initiation of pacing is a major problem that limits the usefulness of TCP in prehospital care. Hedges and colleagues reported that everyday availability of pacing increased the number of patients who received pacing within 10 minutes of hemodynamic decompensation and increased long-term patient survival as well.[120] Prehospital pacing may be most useful in treatment of the patient with a hemodynamically significant bradycardia who has not yet progressed to cardiac arrest (e.g., heart block in the setting of acute myocardial infarction) or in the patient who arrests after the arrival of prehospital providers. [119] [120]

In conscious patients with hemodynamically stable bradycardias, TCP may not be necessary. It is reasonable to attach electrodes to such patients and to leave the pacemaker in standby mode against the possibility of hemodynamic deterioration while further efforts at treatment of the patient's underlying disorder are being made. This approach has been used successfully in patients with new heart block in the setting

Figure 15-13 A pacing catheter that is outside or abuts the cardiac silhouette and is not properly positioned within the right ventricular cavity suggests myocardial perforation. *(From Tarver RD, Gillespie KR: The misplaced tube. Emerg Med, Feb 29, 1988, p 97.)*

of cardiac ischemia.[124] Generally when a transvenous pace-maker becomes available, transvenous pacing is preferred because of better patient tolerance.

Equipment

Few medical product lines have changed as rapidly as commercial transcutaneous pacemakers. Patent controversy, corporate acquisitions, and rapid product evolution have all contributed to this rapid change. [125] Despite this instability in the marketplace, transcutaneous pacemakers are now standard equipment in most EDs and are rapidly spreading to other inhospital and prehospital care settings. The pacemakers introduced in the early 1980s tended to be asynchronous devices with a limited selection of rate and output parameters. Units introduced more recently have demand mode pacing and more output options and are more likely to be combined with a defibrillator in a single unit. Combined defibrillator-pacers offer advantages in cost, ease, and rapidity of use when compared with stand-alone devices. An example of one combined unit is shown in Fig. 15-14 . A full-featured stand-alone pacemaker is illustrated in Fig. 15-15 .

All transcutaneous pacemakers have similar basic features. Most allow operation in either a fixed rate (asynchronous) or a demand mode. Most allow rate selection in a range from 30 to 200 beats/min. Current output is usually adjustable from 0 to 200 mA. If an electrocardiography monitor is not an integral part of the unit, *an output adapter to a separate monitor is required* to "blank" the large electrical spike from the pacemaker impulse and allow interpretation of the much smaller ECG complex. Without blanking protection, the standard ECG machine is swamped by the pacemaker spike and is uninterpretable. This could be disastrous, because the large pacing artifacts *can mask treatable ventricular fibrillation*

Figure 15-14 Combined defibrillator-transcutaneous pacemaker unit (Zoll-PD). The unit defibrillates through standard hand held paddles and has additional cable connections for electrocardiograph monitoring electrodes and for pacing electrodes. *(Courtesy of ZMI Corporation, Cambridge, Mass.)*

(Fig. 15-16). Pulse durations on available units vary from 20 to 40 msec and are not adjustable by the operator.

Two sets of patient electrodes are usually required for operation of the device. One set of standard ECG electrodes is used for monitoring. The much larger pacing electrodes deliver electrical impulses for pacing. One pacing electrode is placed over the mid-dorsal spine, and the other is placed over the left anterior chest. The posterior electrode serves as the ground.

Newer combined defibrillator-pacemakers can use a single set of electrodes for ECG monitoring, pacing, and defibrillation. This approach makes use of the device simpler,

Figure 15-15 "Stand alone" transcutaneous pacemaker (Zoll NTP). This unit has a built-in monitor and strip chart recorder. *(Courtesy of ZMI Corporation, Cambridge, Mass.)*

although the ECG waveform and analysis may be suboptimal. Provisions generally are made for separate ECG monitoring electrodes for use as desired by the operator.

Technique

Pad Placement

The pacing electrodes are applied as shown in Figure 15-17 and are attached to the instrument cable. The anterior electrode (cathode, or negative electrode) is placed as close as possible to the point of maximal impulse on the left anterior chest wall. This electrode adheres to the skin and has a large surface area for electrical contact. The second electrode is placed directly posterior to the anterior electrode. Failure to capture may be due to misplacement of the electrodes, and failure to pace may be rectified with a small change in anterior electrode position. ECG electrodes (if used) are placed on the chest wall or limbs, or both, as required and connected to the instrument cable. Some clinicians prophylactically apply pacing electrodes to all critically ill patients with bradycardia to facilitate immediate TCP should decompensation occur.

There is little risk of electrical injury to health care providers during TCP. Power delivered during each impulse is less than 1/1000 of that delivered during defibrillation.[126] Chest compressions (cardiopulmonary resuscitation) can be administered directly over the insulated electrodes while pacing. [127] Inadvertent contact with the active pacing surface results only in a mild shock.

Pacing Bradycardic Rhythms

To initiate TCP, the pacing electrodes are applied, and the device is activated. In the setting of bradyasystolic arrest, it is reasonable to turn the stimulating current to maximal output and then decrease the output as appropriate after capture is achieved. In a patient who has a hemodynamically compromising bradycardia but is not in cardiac arrest, the operator should slowly increase the output from the minimal setting until capture is achieved. Rate and output selections are adjustable (Fig. 15-18). Generally a heart rate of 60 to 70 beats/min will maintain an adequate blood pressure (by blood pressure cuff or arterial catheter) or the desired degree of mentation.

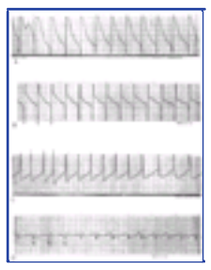

Figure 15-16 The top three rhythm strips *(A–C)* are taken from a standard wall-mounted electrocardiograph monitor. They all demonstrate large pacer spikes without capture. The underlying rhythm cannot be determined and could be treatable ventricular fibrillation. The bottom rhythm strip *(D)* demonstrates a tracing on the same patient with the external pacer monitor (special dampening). Note that the pacing spikes are much smaller, and it is easily seen that the underlying rhythm is asystole, without pacer capture. The presence of a T-wave after the QRS complex is a good indicator of ventricular capture.

Assessment of electrical capture can be made by monitoring the ECG on the filtered monitor of the pacing unit (Fig. 15-19). Additionally, bedside US may prove useful in determining ventricular capture.[128] [129] Ideally, pacing should be continued at an output level just above the threshold of initial electrical capture. One study in 16 normal male volunteers who were paced without sedation noted cardiac capture at a mean current of 54 mA (range, 42 to 60 mA).[130] Most subjects could tolerate pacing at their capture threshold; only 1 subject required discontinuation of pacing at 60 mA because of intolerable pain. Heller and associates compared subjective pain perception and capture thresholds in 10 volunteers paced with 5 different transcutaneous pacers. [131] Capture rates (40% to 80%), thresholds (66.5 to 104 mA), and subjective discomfort varied from pacemaker to pacemaker.

Failure to capture with TCP may be related to electrode placement or patient size. Patients with barrel-shaped chests and large amounts of intrathoracic air conduct electricity poorly and may prove refractory to capture. In one study, thoracotomy was found to nearly double the pacing threshold. [132] A large pericardial effusion or tamponade also will increase the output required for capture.[133] Failure to electrically capture with a transcutaneous device in these settings is an indication to consider immediate transvenous pacer placement.

Patients who are conscious or who regain consciousness during TCP will experience discomfort because of muscle contraction. [124] [130] [131] Analgesia with incremental doses of an opioid agent, sedation with a benzodiazepine compound, or both, will make this discomfort tolerable until transvenous pacing can be instituted.

Overdrive Pacing

Overdrive pacing[111] [112] [113] [114] [115] of ventricular tachycardia or paroxysmal supraventricular tachycardia is performed in patients who are stable enough to tolerate the brief delay associated with the necessary preparation for this technique. Little data exist on the efficacy or use of this procedure in the ED. The patient is sedated as explained earlier, pacing and monitoring electrode pads are placed in the standard position as detailed earlier, and brief trains (6 to 10 beats) of asynchronous pacing are applied. The pacer rate must be set approximately 20 to 60 pulses/min greater than the dysrhythmia rate. [134] Generally, an impulse rate of 200 pulses/min is used for ventricular tachycardias (rate generally 150 to 180 beats/min), and a rate of 240 to 280 pulses/min is used for paroxysmal

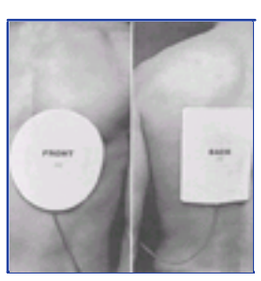

Figure 15-17 Correct placement of transcutaneous pacemaker electrodes (see text). *(Courtesy of ZMI Corporation, Cambridge, Mass.)*

supraventricular tachycardias (rate commonly 200 to 250 beats/min).

Because rhythm acceleration is possible during overdrive pacing, it is essential that full resuscitation equipment, including a defibrillator, be available at the bedside.

Complications

The major potential complication of TCP is *failure to recognize the presence of underlying treatable ventricular fibrillation*. This complication is primarily due to the size of the pacing artifact in the ECG screen, a technical problem inherent in systems without appropriate dampening circuitry.

A theoretical complication of TCP is the induction of dysrhythmias. In animal models using epicardial electrodes, the threshold current required to induce ventricular fibrillation decreases as electrical impulse duration increases. At a 10-msec impulse duration, ventricular fibrillation can be induced with currents as low as 25 mA delivered through epicardial electrodes.[105] Because TCP impulses are of even longer duration (20 msec) and of higher current (50 to 200 mA), there has been concern about possible induction of ventricular fibrillation during TCP. Studies of fibrillation thresholds using large *precordial* electrodes have shown the relationship of threshold-to-impulse duration to be the opposite of that seen with *epicardial* electrodes. With *cutaneous* precordial electrodes, the current required to induce ventricular fibrillation *increases* as pulse duration *increases*.[106] The apparent paradox may be explained by the differing nature of the electrodes. Epicardial electrodes are localized over a small area of the myocardium, whereas transcutaneous electrodes deliver a broad electrical charge to the myocardium as a whole. The implication is that longer impulse durations, although more dangerous with internal pacing, seem to decrease the chance of inducing ventricular fibrillation with

Figure 15-18 Rate and output selections.

TCP. Nonetheless, asynchronous TCP for tachydysrhythmias has been associated with rhythm acceleration and development of ventricular fibrillation. [113]

Experience with prolonged TCP in humans has not been extensive. Zoll and colleagues reported 25 humans paced for up to 108 hours with impulses of 20-msec duration.[100] Pacer-induced dysrhythmias did not occur. Leatham and associates paced 1 patient for 68 hours with impulses of 20-msec duration. [101] The patient died 2 days after pacing was discontinued. Pathologic examination revealed no evidence of pacerinduced myocardial damage. Madsen and colleagues paced 10 healthy volunteers at threshold for 30 minutes and found no enzyme or echocardiographic abnormalities. [135]

Studies of repetitive direct current countershocks in dogs have induced tissue damage with energy levels that are 1000 times greater than those required to pace the heart transcutaneously. In a canine study, 10 animals with chronic heart block that were paced for 60 minutes (20-msec duration at 80 beats/min with 8-cm-diameter cutaneous electrodes) did not develop pacer-related dysrhythmias. Serial cardiograms and cardiac enzymes revealed no evidence of ischemia or infarction. [136] Examination of the canine hearts after the dogs were sacrificed 72 hours after pacing did not reveal clinically significant myocardial damage. [137] A single primate paced for 1 hour with 20-msec impulses of 400 mA similarly had no evidence of tissue damage at autopsy and at microscopic examination after sacrifice 24 hours later.[138] Based on these studies, TCP appears unlikely to produce cardiac injury with short-term use in humans.

Soft tissue discomfort with the potential for injury may still occur with current transcutaneous pacemakers. One study with the Zoll transcutaneous pacemaker found only 2 of 30 subjects (patients and volunteers) who were paced while conscious required discontinuation of pacing owing to discomfort. [130] Most reported the

discomfort as "mild or moderate and easily tolerable." Sedation would presumably improve a conscious patient's ability to tolerate TCP.

Figure 15-19 Assessing electrocardiogram capture with TCP. Note that the monitor has been adapted to accommodate the large pacing artifact so as not to obscure the underlying ventricular activity.

Nonetheless, prolonged use may still induce local cutaneous injury; Pride and McKinley reported one 7-week-old child who was paced for 45 hours without a pad change and who developed third-degree burns.[139]

Conclusion

Devices that pace the heart externally have been available for clinical use since 1952. Technologic improvements have minimized the complications associated with earlier use of the transcutaneous route and have enabled the reapplication of this relatively old pacing technique to a select subset of cardiac emergencies. The introduction of combined defibrillator-pacemakers promises to make pacing more available in prehospital and health care settings. Although the technique is still not universally available, it is rapidly becoming the standard of care for resuscitation protocols and equipment. Pacing instituted earlier in the course of bradycardiac rhythms, including the prehospital phase of care, may improve the poor survival rate currently associated with these rhythms.

Chapter 16 - Pericardiocentesis

Richard J. Harper

Pericardiotomy under direct vision was first done in 1815, and in 1840 the first blind approach using a trocar was carried out successfully on a patient with tamponade from malignancy.[1] By the end of the 19th century, the trocar-and-cannula method of pericardiocentesis was commonly used. The subxiphoid approach was first described in 1911.

Blind, electrocardiography (ECG)-assisted pericardiocentesis has a significant morbidity rate, reportedly as high as 15% to 20%. [2] [3] For this reason ultrasound diagnosis of pericardial effusion with fluoroscopic or ultrasound guidance has become the standard for *elective* pericardiocentesis because of its lower (0.5% to 3.7%)[4] [5] [6] incidence of complications. Even if tamponade physiology is present, echocardiographic diagnosis and guidance is essential. The ECG-assisted blind pericardiocentesis technique remains the standard procedure only for truly *emergent* pericardiocentesis when a lengthy delay may be associated with obtaining and organizing ultrasound or fluoroscopic assistance. Echocardiographic diagnosis and guidance are described elsewhere (see Chapter 69).

CAUSES OF PERICARDIAL EFFUSION AND TAMPONADE

The medical literature concerning pericardiocentesis categorizes pericardial fluid collection as one of the following: acute hemopericardium (largely secondary to trauma) and pericardial effusion from other causes. This categorization is based on the fact that these two clinical entities are different in their time course, etiology, and treatment.

Acute Hemopericardium

Acute hemopericardium has several causes, including coagulopathies, cardiovascular catastrophes, and acute injury resulting from either blunt or penetrating trauma. All of these causes result in rapid accumulation of whole blood in the pericardial sac. The blood accumulates too fast for the relatively inelastic pericardial sac to stretch and accommodate the fluid. The result is cardiac tamponade produced by small fluid volumes and with an essentially normal pericardial size.

Penetrating Trauma

Traumatic tamponade due to penetrating trauma may result from obvious external injury such as knife or gunshot wounds, or it may be insidious, as seen with iatrogenic cardiac perforation during cardiac or vascular procedures.

In external penetrating trauma, tamponade is most commonly the result of a stab wound.[7] Approximately 80% to 90% of stab wounds to the heart demonstrate tamponade,[7] [8] compared with 20% of gunshot wounds. Stab wounds cause tamponade more often presumably because the pericardial rent is small enough to seal, trapping blood in the pericardial space. [7] [9] Larger pericardial wounds from gunshots generally drain into the pleural space and produce a hemothorax. [10] Cardiac tamponade is often suspected with anterior chest wounds, but it is imperative to remember that any penetrating wound of the chest, back, or upper abdomen may involve the heart.

Iatrogenic causes of cardiac tamponade are relatively uncommon but well-known complications of invasive or diagnostic procedures. Pacemaker insertion (either transthoracic or transvenous) and cardiac catheterization, including valvuloplasty and angioplasty, are two of the main causes, from the inadvertent penetration of cardiac chambers or coronary vessels.[11] [12] [13] Penetration of vascular structures is common during transthoracic pacemaker placement. [14] Tamponade is also seen as a complication after cardiac surgery, although it is usually anticipated, and mediastinal or pericardial drainage helps to control and prevent it. [11] [15] Pericardiocentesis itself can cause tamponade by lacerating myocardium or coronary vessels. [16] [17]

Cardiac tamponade may result from perforation of the right atrium or, less commonly, of the right ventricle or superior vena cava by a central venous pressure (CVP) catheter or subclavian hemodialysis catheter. [18] This event is usually not diagnosed early and is therefore often fatal. [19] Perforation may occur during placement or, more commonly, 1 to 2 days later, when the catheter erodes through tissue, particularly if a catheter made of stiff material is used or when the left internal jugular vein approach is used.[20] Tamponade from CVP line placement is seldom seen in the emergency department (ED) but must always be considered when there is sudden decompensation in a patient with a CVP line in place. Tamponade should always be considered when a patient deteriorates hemodynamically after an invasive diagnostic or therapeutic procedure involving the heart. Prevention involves proper placement of central venous catheters in the superior vena cava rather than the right atrium or ventricle.

Blunt Trauma

Blunt trauma may cause hemopericardium, most often as the result of major chest injury with associated rib and sternal fractures. Cases have been reported, however, in which tamponade occurred in blunt trauma with no obvious signs of injury to the thorax. [21] Such incidents may be more common than are clinically recognized, judging by the reports of constrictive pericarditis and pericardial defects found months to years later in trauma patients who were not originally noted to have effusion. Pericardial effusion due to blunt trauma may also be a late finding, becoming symptomatic 12 to 15 days after trauma. [22]

Severe deceleration injury may cause tamponade as a result of aortic or caval injury. [23] This appears to be an uncommon development, with two case series reporting tamponade in 3.6% (1 of 28 patients) and 2.3% (1 of 43 patients) of victims of aortic injury. [24]

Theoretically, cardiopulmonary resuscitation (CPR) can cause pericardial effusion secondary to the blunt trauma of chest compressions, broken ribs, or intracardiac injections. Early studies reported pericardial effusion in 1% to 3% of CPR survivors. [25] Echocardiographic studies showed small cardiac effusions (but not tamponade) in 12% of survivors, only 4% of whom had received intracardiac injections. [26] Thus, although case reports of tamponade exist,[27] [28] CPR and intracardiac drug injections are unlikely to cause significant effusion, much less tamponade.

Nontraumatic Hemopericardium

Nontraumatic but acute hemopericardium caused by a bleeding diathesis, aortic dissection and ventricular rupture behaves

much like traumatic tamponade because of its acute nature. These types of hemopericardium are less obvious in etiology than hemopericardium caused by external trauma.

Bleeding diathesis may cause spontaneous bleeding into the pericardial sac. The incidence of spontaneous pericardial tamponade in anticoagulated patients has been reported to range from 2.5% to 11%.[11] [29] Thrombolytic therapy has also been implicated in tamponade secondary to bleeding diathesis. Among 392 patients, only 4 (1%), all with large anterior myocardial infarctions, developed tamponade secondary to hemopericardium without ventricular rupture. [30]

A dissection of the ascending aorta may extend around the base of the aorta into the pericardial sac, causing dramatic, rapid, and usually fatal tamponade. This pathologic abnormality may be due to conditions such as syphilis, Marfan syndrome, or atherosclerosis. Infection may create pseudoaneurysms of the aorta, which also can present as tamponade.[31]

Ventricular rupture after myocardial infarction is a common source of acute hemopericardium. Although the prognosis is often grim, survival is possible with prompt recognition and definitive treatment. [32] [33]

Nonhemorrhagic Effusions

Nonhemorrhagic effusions usually accumulate slowly, allowing the pericardium to stretch and accommodate up to 2000 mL of fluid. [34] This slower accumulation, often over weeks to months, allows the circulatory system to adapt and permits more time for evaluation and treatment, even in a moderately hypotensive patient. [35] [36] In many cases of small nonhemorrhagic effusion, tamponade does not occur, and the effusion may resolve with treatment of the underlying disease or may be managed successfully by elective pericardiocentesis.

Many disease processes, ranging from the common to the rare (Table 16-1), can cause pericardial effusion. The cause of nonhemorrhagic tamponade may not be obvious on examination in the ED, and tamponade is frequently misdiagnosed as congestive heart failure or respiratory disease. Although neoplasm has generally been the most common underlying cause of nonhemorrhagic effusion, [29] [37] some reports[38] [39] have identified infectious complications of the human immunodeficiency

virus (HIV) as a common etiology of large nonhemorrhagic pericardial effusion and tamponade (Table 16-2).

HIV-related effusions have been ascribed to many opportunistic bacterial and viral infections, with mycobacterial infections being the most common. [38] [39] [40] Kaposi sarcoma and lymphoma[41] [42] have caused noninfectious pericardial effusions in HIV patients. Cancer is a prominent cause of nonhemorrhagic effusions; the pericardium is involved in 20% of patients with disseminated tumors [43] and 8% of all patients with cancer. [44] There is primary pericardial involvement in 69% of acute leukemias, in 64% of malignant melanomas, and in 24% of lymphomas; however, the incidence of actual tamponade in these malignancies is not known. Of metastases to the pericardium, 35% originate in the lung, 35% in the breast, 15% in lymphomas, and less than 3% in each of the other cancers. [44] Thus, any patient who is known to have one of these malignancies should be considered at risk for tamponade. Metastasis to the heart is usually a late finding in cancer, and other foci located elsewhere are usually evident. [45] Classic findings of tamponade, such as *pulsus paradoxus*, are frequently absent in cancer patients with tamponade, and their symptoms are usually attributed to their malignancy. [44]

Data from Guberman BA, Fowler NO, Engel PJ, et al: Cardiac tamponade in medical patients. Circulation 64:633, 1981; and Pories WJ, Caudiani VA: Cardiac tamponade. Surg Clin North Am 55:573, 1975.

Radiation pericarditis, particularly after treatment for Hodgkin's disease, is a common cause of effusion. [34] Effusion occurs in approximately 5% of those patients who receive 4000 rad to the heart.

Approximately 15% to 20% of patients on dialysis for renal failure develop pericarditis, and 35% of those with pericarditis

*_Note:_ Various complications related to human immunodeficiency virus (HIV) infections are now probably the most common causes of large nonhemorrhagic pericardial effusions. Effusions related to bacterial, viral, and mycobacterial infections and Kaposi sarcoma and lymphoma are common.

develop tamponade.[46] [47] Up to 7% of patients on chronic dialysis may have effusions, sometimes of 1 L or more. [45] Some series have reported tamponade in 34% of uremic patients who have effusions. [47] Pericardial effusion in renal failure may be managed with dialysis alone in many cases.

Thirty percent of myxedema patients may have pericardial effusions, but few have tamponade. [37] Most of the other etiologies listed in Table 16-1 are isolated case reports, and their exact incidences have not been determined.

Other Causes of Pericardial Tamponade

An interesting but rare cause of cardiac tamponade is pneumopericardium. Pneumopericardium is most commonly seen with pneumothorax and pneumomediastinum as a complication of respiratory therapy in infants, but it may also occur from similar barotrauma in adults. [48] Pneumopericardium also occurs spontaneously in asthma,[49] after blunt chest injury,[50] [51] and even after high-speed motorcycle rides.[52] Pneumopericardium is usually benign, but tension pneumopericardium has been reported as a cause of life-threatening tamponade after blunt chest trauma [51] [53] and after pericardiectomy.[54] The appearance of life-threatening pneumopericardium and tamponade has also been described immediately[55] and 6 days after penetrating chest trauma.[56]

PATHOPHYSIOLOGY OF TAMPONADE

The pericardium is a tough, leathery sac normally containing about 25 to 35 mL of serous fluid. [57] It is not rapidly elastic, although it does demonstrate stress relaxation within minutes of increased intrapericardial pressure, providing a slight ability to accommodate sudden increases in fluid. [58] As fluid accumulates, the first 80 to 120 mL is easily accommodated without significantly affecting pericardial pressure (Fig. 16-1).[59] However,

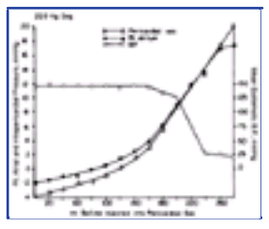

Figure 16-1 Production of cardiac tamponade by injections of saline into the pericardial sac. Although pericardial space can acutely accommodate 80 to 120 mL of fluid without a significant increase in pericardial pressure, note steep increases in pressure and drop in blood pressure at about 200 mL of saline. Once critical volumes are reached, very small increases cause significant hemodynamic compromise. *(From Fowler NO: Physiology of cardiac tamponade and pulsus paradoxus. II: Physiological, circulatory, and pharmacological responses in cardiac tamponade. Mod Concepts Cardiovasc Dis 47:116, 1978. Reproduced by permission of the American Heart Association, Inc.)*

if an additional 20 to 40 mL is rapidly accumulated, the intrapericardial pressure almost doubles, often leading to sudden decompensation. With effusions that develop over weeks to months, the pericardium lengthens circumferentially to a huge size and can accommodate liters of fluid.

Pericardial compliance, which helps determine the pressure-volume response curve (Fig. 16-2), [57] varies considerably in different individuals and various disease states. The

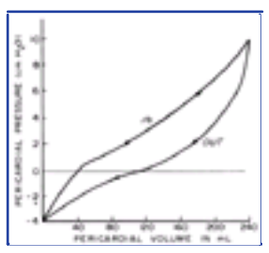

Figure 16-2 Relationship of intrapericardial pressure to volume of pericardial fluid. Note that pressure drops rapidly when a small amount of fluid is removed. *(From Pories W, Gaudiani V: Cardiac tamponade. Surg Clin North Am 55:573, 1975. Reproduced by permission.)*

pressure-volume relationship demonstrates hystersis; the withdrawal of a quantity of fluid drops the pressure more than the addition of the same amount of fluid raised the pressure.

As pericardial fluid accumulates, the increased intrapericardial pressure is transmitted across the myocardial wall and causes compression of the atria and perhaps the vena cava and pulmonary veins. This reduces right ventricular filling in diastole, producing decreased stroke volume and cardiac output. [60] Pulse pressure narrows as reflex sympathetic stimulation increases. Severe tamponade is produced with intrapericardial pressures of 15 to 20 mm Hg. [61]

As stroke volume decreases, heart rate increases to maintain cardiac output. Sympathetic discharge causes both arterial and venous vasoconstriction. [61] [62] Vasoconstriction increases venous pressure, which helps to restore the normal venousatrial and atrioventricular filling gradients. These compensatory mechanisms are often effective and may permit establishment of a new homeostasis with normal cardiac output.

With chronic effusion and in early tamponade, cardiac contractility is not affected, and myocardial perfusion is normal. [60] [63] [64] As pressure continues to increase, coronary perfusion pressure drops, so in its later stages, tamponade causes myocardial ischemia. Before hypotension occurs, left ventricular blood flow has already decreased 37%.[65] For comparable degrees of hypotension, experimental animals in hemorrhagic shock have five times greater coronary blood flow than animals in cardiac tamponade.[65] Severe experimental tamponade is followed by large increases in creatine kinase MB and microscopic evidence of cardiac injury resulting from ischemia.[66]

As intrapericardial pressure continues to rise, the heart's compensatory mechanisms fail. Myocardial ischemia and perhaps lactic acidosis from poor tissue perfusion may be the triggering events that disrupt the delicate equilibrium. [67] Atrial

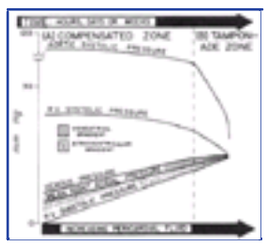

Figure 16-3 Summary of physiologic changes in tamponade. RV, right ventricle. *(From Shoemaker WC, Carey JS, Yao ST, et al: Hemodynamic monitoring for physiological evaluation, diagnosis, and therapy of acute hemopericardial tamponade from penetrating wounds. J Trauma 13:36, 1973; and Spodick D: Acute cardiac tamponade: Pathologic physiology, diagnosis, and management. Prog Cardiovasc Dis 10:65, 1967. Reproduced by permission.)*

pressure rises rapidly (Fig. 16-3). The atria and pulmonary circulation, being at much lower pressure than the systemic arterial pressure, are more vulnerable to the rising intrapericardial pressure. A "pressure plateau" occurs in which right atrial pressure, right ventricular diastolic pressure, pulmonary artery diastolic pressure, and pulmonary capillary wedge pressure are virtually identical.

This equalization of pressures leads to the echocardiographic hallmark of tamponade: right ventricular collapse. At this point hypotension is severe, bradycardia is common, and pulseless electrical activity (PEA) may occur. Unless intrapericardial pressure is immediately decreased, pulmonary blood flow ceases, and cardiac arrest follows.[67]

Total blood volume affects cardiac compensation, and it is possible to encounter a "low-pressure" cardiac tamponade. [68] The hypovolemic patient with tamponade has a decreased venous pressure, which not only decreases cardiac output, but also may obscure the diagnosis, because *distended neck veins or an elevated CVP are not present*. In a patient with a chronic pericardial effusion, the onset of hypovolemia can lower filling pressure enough to precipitate tamponade, and conversely, providing additional volume may temporarily offset increased pericardial pressure.

Ventilation and blood CO_2 levels have significant effects on cardiac tamponade. This is of particular significance, because trauma patients with tamponade may also have respiratory impairment. Pericardial pressure decreases 3 to 6 mm Hg with a hypocarbia of 24 torr and increases 2 to 4 mm Hg when the PCO_2 reaches 57 torr.[69] This degree of hypercarbia induced pericardial pressure rise can decrease cardiac output by 25%. Similarly, fluctuations in intrapleural pressure induced by intermittent positive-pressure ventilation are transmitted to the pericardial space and can reduce cardiac output another 25%. [70] The clinical implications of these findings are that patients suspected of having tamponade should normally be allowed to breathe spontaneously under careful monitoring and should not be ventilated

with positive pressure unless it is absolutely necessary, as their hemodynamic status may deteriorate precipitously.

DIAGNOSIS OF CARDIAC TAMPONADE

Patient Profile and Symptoms

Pericardial effusion is rarely diagnosed based on physical findings. In contrast, pericardial tamponade can be diagnosed based on clinical criteria, but specific clinical signs are often absent. Particularly in the setting of acute hemorrhagic tamponade, the time from the first signs of tamponade to full arrest may be brief. [71]

Classic clinical findings have been described for tamponade. However, these findings are often obvious only when the patient is unstable due to tamponade. Ideally, tamponade is diagnosed early, when the patient suffers no more than dyspnea, weakness, or perhaps right heart failure. It is common to attribute respiratory symptoms (e.g., dyspnea on exertion) to a more common condition such as heart failure or pulmonary pathology and to overlook pericardial effusion until the classic late signs (e.g., hypotension) appear. [72]

Acute pericardial tamponade may resemble tension pneumothorax, acute hemothorax, hypovolemia, pulmonary edema, or pulmonary embolism. Severe right ventricular contusion

can mimic the findings of tamponade. [73] The patient is often agitated or panic-stricken, confused, uncooperative, restless, cyanotic, diaphoretic, and acutely short of breath. In the late stages, the patient is moribund. Hypotension in the presence of severe cyanosis and distended neck veins is a helpful but late finding.

Physical Signs

The classic physical findings of tamponade were first characterized by Beck in 1935. He described two triads, one for acute and one for chronic compression. [74] The chronic compression triad consists of high CVP; ascites; and a small, quiet heart. The triad in acute compression consists of high CVP, decreased arterial pressure, and muffled heart sounds. Unfortunately, in most major trauma series, only about one third of patients demonstrate the complete acute triad, [67] [75] although almost 90% have one or more signs. [7] *The simultaneous occurrence of all three physical signs is a very late manifestation of tamponade and is usually seen most consistently shortly before cardiac arrest* (see Fig. 16-3).

Careful hemodynamic monitoring reveals earlier changes that indicate the progression of tamponade (Table 16-3). [76] In grade I tamponade, cardiac output and arterial pressure are normal, but CVP and heart rate are increased. In grade II tamponade, blood pressure is normal or slightly decreased, CVP is increased, and tachycardia persists. In grade III tamponade, the classic findings of Beck's acute triad occur. Although this sequence represents the natural history of acute tamponade, the time course varies. Some patients are stable at a given stage for hours; others proceed to cardiac arrest within minutes. [67] [76] Unfortunately, not all patients with early tamponade respond with a predictable pattern of change in vital signs. Brown and coworkers found that 6 of 18 patients with tamponade, defined through right heart catheterization, responded to tamponade with elevated systolic blood pressure. [77] After pericardiocentesis, these patients had a marked reduction in systolic blood pressure accompanied by increased cardiac output. All of these patients had previously been hypertensive.

Pulsus Paradoxus (see also Chapter 1)

Pulsus paradoxus is defined as an exaggeration of the normal inspiratory fall in blood pressure. [62] [75] A paradoxical pulse (pressure) is one of the classic physical signs of tamponade, but it is not pathognomonic. It is also caused by pulmonary emphysema, asthma, labored respirations, obesity, cardiac

TABLE 16-3 -- Shoemaker System of Grading Cardiac Tamponade

Grade	Pericardial Volume (mL)	Cardiac Index	Stroke Index	Mean Arterial Pressure	CVP	Heart Rate	Beck's Triad
I	<200	Normal or ?	Normal or ?	Normal	?	?	Venous distention, hypotension, muffled heart sounds usually not present
II	=200	?	?	Normal or ?	? (=12 cm H_2 O)	?	May or may not be present
III	>200	??	??	??	?? (up to 30–40 cm H_2 O)	?	Usually present

From Shoemaker WC, Carey SJ, Yao ST, et al: Hemodynamic monitoring for physiologic evaluation, diagnosis, and therapy of acute hemopericardial tamponade from penetrating wounds. J Trauma 13:36, 1973.

failure, constrictive pericarditis, pulmonary embolism, and cardiogenic shock. [7] [35] [67] Measuring the paradoxical pulse is difficult and time-consuming, and any frightened, hypotensive patient with labored breathing can demonstrate this finding (Fig. 16-4).

If the difference between inspiratory and expiratory systolic blood pressures is greater than 12 mm Hg, the paradoxical pulse is abnormally high. [78] Most patients with proven tamponade will demonstrate a difference of 20 to 30 mm Hg or more during the respiratory cycle. [7] [35] [67] This may not be true of patients with very narrow pulse pressures (typical of grade III tamponade); they will have a "deceptively small" paradoxical pulse of 5 to 15 mm Hg. The decreased *pulsus paradoxus* with hypotension occurs because the paradoxical pulse is a function of actual pulse pressure, and the inspiratory systolic pressure may be below the level at which diastolic sounds disappear. [62] For this reason, the ratio of the paradoxical pulse to the pulse pressure is a more reliable measure. A paradoxical pulse greater than 50% of the pulse pressure is abnormal. [62]

Pulsus paradoxus in tamponade has been correlated with the degree of impairment of cardiac output. In atraumatic patients, a 15% *pulsus paradoxus* in the face of relative hypotension was found in 97% of patients with moderate or severe tamponade and only 6% of patients with absent or mild tamponade. [78] A similar study of right ventricular diastolic collapse by echocardiography found that an abnormal *pulsus paradoxus* had a sensitivity of 79%, a specificity of 40%, a positive predictive value of 81%, and a negative predictive value of 40%. [79]

The absence of a paradoxical pulse does not rule out tamponade. Although the mean paradoxical pulse was 49 mm Hg in one series of nonhemorrhagic tamponade, [37] 23% of the patients had a paradoxical pulse of less than 20 mm Hg, and 1 patient had no measurable paradoxical pulse. An abnormal *pulsus paradoxus* has been reported to be absent in tamponade when there is an atrial septal defect, aortic insufficiency, localized collections of pericardial blood, or extreme tamponade with hypotension. [68] It may also be absent when left ventricular diastolic pressure is intrinsically elevated owing to poor left ventricular compliance. This was seen in one half of uremic patients with tamponade. [47] [80] In traumatic tamponade, *pulsus paradoxus* is deemed unreliable. [68] [80] [81] [82] In one study, only 35% of trauma patients had an abnormal paradoxical pulse when elevated CVP and decreased heart sounds were present. [82] In another study of 197 traumatic cases, only 8.6% of the diagnoses of tamponade were made by finding an abnormal *pulsus paradoxus*. [83]

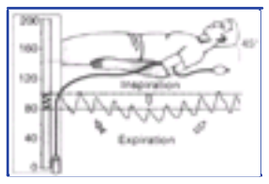

Figure 16-4 Normally systolic blood pressure drops slightly during inspiration. To measure *pulsus paradoxus*, the patient breathes normally while lying at a 45-degree angle. The blood pressure cuff is inflated well above systolic pressure and slowly deflated. When the pulse is first heard only during expiration, this is the upper value. The cuff is deflated until the pulse is heard during both inspiration and expiration, and this is the lower value. The difference in the two values is the amount of *pulsus paradoxus*. A difference of more than 12 mm Hg is abnormal.

Although the absence of a paradoxical pulse rules against severe tamponade, it does not completely rule it out. Whether time is taken to determine *pulsus paradoxus* depends on the patient's status. If the patient is moribund or rapidly deteriorating, taking time to check this parameter is obviously a poor choice of priorities.

Venous Distention

Venous distention, reflecting increased CVP, is also a late sign in cardiac tamponade (see Fig. 16-3). It may be masked by venoconstriction as a result of vasopressors (e.g., dopamine), intrinsic sympathetic discharge, or hypovolemia. [35] [67] [76] [81] Neck vein distention may be obvious clinically, but the measured CVP is more reliable than the presence of venous distention. The CVP reading should take into account positive-pressure ventilation and the effects of a Valsalva maneuver. Most patients with significant tamponade will have a CVP of greater than or equal to 12 to 14 cm H_2O.[81] *Hypovolemia changes the intrapericardial pressure-volume curve in tamponade and will lower the CVP reading at any given stage in the tamponade process.*

Animal studies have documented that right atrial pressure can be normal in tamponade when hypovolemia is present. One case of low-pressure cardiac tamponade was reported in a patient with no jugular venous distention, no paradoxical pulse, and a right atrial pressure of 8 mm Hg. [68] Thus, although the initial CVP reading is useful and diagnostic if grossly elevated (e.g., 20 to 30 cm H_2O),[54] [81] a series of CVP readings looking for an upward trend is the most sensitive diagnostic tool. [81] A rising CVP, especially when there is persistent hypotension, is extremely suggestive of tamponade in the trauma patient. In the rare case of the hypovolemic patient in whom tamponade is suspected but who demonstrates a low CVP, a fluid challenge will help clarify the situation and will also improve cardiac output at least temporarily.[68]

Ancillary Testing

Routine chest radiographs and electrocardiograms may be useful in increasing the level of suspicion for pericardial effusion and tamponade. Noninvasive diagnosis of effusion, however, must be made by computed tomography or, preferably, cardiac ultrasound. If available, bedside ultrasound is the fastest and most reliable for the emergency clinician to demonstrate a significant pericardial effusion, although it may not be diagnostic of tamponade.

Chest Radiographs

Chest radiographs are not useful in the diagnosis of acute traumatic tamponade, because *the cardiac size and shape do not change acutely*. However, the radiographs may reveal hemothorax, bullet location, or even pneumopericardium.

In the patient without trauma and with chronic effusion, a chest film often reveals an enlarged, sac-like "water bottle" cardiac shadow. Unfortunately, it is difficult to differentiate pericardial from myocardial enlargement, and radiographs cannot be used to distinguish between simple pericardial effusion and tamponade. One finding that is useful in identifying effusion on the plain chest film is the epicardial fat pad sign. The water density space between the radiolucent epicardial fat and the mediastinal fat represents the pericardial tissues and is normally less than 2 mm. An increase in this width suggests pericardial fluid or thickening (Fig. 16-5). This sign may be seen in 41% of upright lateral and 23% of frontal chest films in proven pericardial effusion. [84] The diagnostic value may be enhanced by using a supine rather than upright cross-table, lateral chest radiograph. Obtaining a supine lateral film increases the sensitivity of the epicardial fat pad sign from 31% to 51%. [85]

Electrocardiograms

Electrocardiograms may suggest, but should *not* be used to diagnose, pericardial effusion or cardiac tamponade. Most electrocardiogram changes, such as PR-segment depression, low-voltage QRS complexes, and electrical alternans, have acceptable specificity but poor sensitivity for pericardial effusion or tamponade.[35] [86] [87] Low voltage is defined as a QRS amplitude less than or equal to 5 mV in all limb leads (or a sum of the limb lead QRS amplitude less than or equal to 30 mV), and PR depression is defined as greater than or equal to 1 mV depression in at least 1 lead other than aVR. In a study correlating the electrocardiogram with echocardiographic evaluation, electrocardiogram signs had an overall sensitivity of only 1% to 17% and a specificity of 89% to 100% for pericardial effusion.[35] Others have demonstrated significantly higher sensitivity, i.e., in the range of 32 to 68% for voltage criteria. [88] PR-segment depression is the most common electrocardiogram finding in pericardial tamponade, and low voltage is most commonly associated with a moderate to large effusion. It is important to note that none of the ECG findings differentiate tamponade from effusion.

Electrical alternans is caused by pendulum motion of the heart within the pericardial sac. [89] Alternans of the QRS complex has been seen in about 22% of medical tamponade cases[72] but in only 5% of cancer patients with tamponade.[44] Electrical alternans of both the P wave and the QRS complex (total electrical alternans) is a rare finding, but when seen is thought to be pathognomonic of tamponade (Fig. 16-6).[35] [90] Like electrical alternans, low voltage may be a finding associated with tamponade, but not simple effusion.[91]

Echocardiography

Echocardiography is the best available tool for diagnosing pericardial effusion and has the further advantage of being noninvasive. [92] Echocardiography is very sensitive in the diagnosis of pericardial effusion and tamponade. [93] [94]

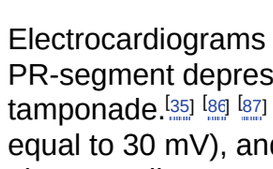

Figure 16-5 Epicardial fat pad sign. The water density space between the radiolucent epicardial fat and the mediastinal fat represents the pericardium and its contents and should be 2 mm or less. An increase suggests pericardial fluid or thickening. *A,* Left anterior-oblique chest film. *B,* Lateral chest film. In acute tamponade, the chest radiograph has very minimal diagnostic value.

The disadvantages of echocardiography are that it requires ultrasound equipment and is dependent on a skilled operator who is specifically trained in echocardiography. Even when immediately available, echocardiography may take at least 5 minutes, which may be too much time for a patient who is deteriorating rapidly. If the patient in not in full arrest and ultrasound is available, ultrasound should always be used to diagnose effusion and tamponade and to guide the procedure (see Chapter 69). Pericardial fluid is relatively easy

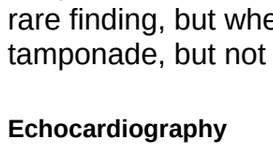

Figure 16-6 Overall, the electrocardiogram (ECG) has a low sensitivity for pericardial effusion or tamponade, but PR depression, low voltage, or electrical alternans may be seen. Lewis lead ECG showing total electrical alternans of both amplitude and configuration of P and QRS complexes. This is rarely seen but is highly suggestive of tamponade. Note that electrical alternans may not be evident in standard ECG leads. *(From Sotolongo RP, Horton JD: Total electrical alternans in pericardial tamponade. Am Heart J 101:854, 1981. Reproduced by permission.)*

to demonstrate with bedside ultrasound, but since many ill patients will demonstrate some pericardial fluid, bedside ultrasound may not be able to differentiate

incidental fluid from tamponade.

Computed Tomography

At some institutions, computed tomography (CT) is much more readily available than echocardiography. However, it requires that the patient be transported to the site of the CT equipment and patient stability must be considered. If clinically indicated, CT is effective in defining the presence and extent of pericardial effusion in the stable patient.[95] In certain circumstances, CT can provide a more definitive diagnosis than echocardiography. In one series, eight equivocal echocardiograms were evaluated by CT.[96] Two patients thought to have pericardial effusion by ultrasound were found by CT to have pleural effusions. Another patient with pericardial effusion by ultrasound was found by CT to have an epicardial lipoma. CT defined three loculated pleural effusions not seen by ultrasound. A final two patients had hemopericardium visualized by CT but not ultrasound. In circumstances where the patient is stable and ultrasound produces equivocal results or is not available, CT may provide a definitive diagnosis of pericardial effusion.

INDICATIONS FOR PERICARDIOCENTESIS

There are two indications for pericardiocentesis: (1) to diagnose the cause or presence of a pericardial effusion and (2) to relieve tamponade. The former is an elective procedure and ideally should be accomplished under ultrasound guidance. The latter may be semi-elective and performed with ultrasound guidance or emergent and performed blind with ECG assistance.

Diagnostic Pericardiocentesis

The use of pericardiocentesis for diagnosis of the etiology of nonhemorrhagic effusions is widespread, although opinions of its utility vary. [34] [97] [98] Neoplastic cells, blood, bacteria, viruses, and chyle can be sought. Measurement of pericardial fluid pH can be helpful, because inflammatory fluid is significantly more acidotic than noninflammatory fluid.[99] When a specific etiology is suspected, additional diagnostic testing may be useful (e.g., adenosine deaminase in tuberculosis, and carcinoembryonic antigen in suspected malignancy). [100]

The diagnostic accuracy of pericardiocentesis varies greatly from series to series, depending on the vigor with which a definitive etiology was sought and the prevalence of certain etiologies in the patient population under consideration. In one large series, fluid was obtained in 90% of the taps, but a specific etiologic diagnosis was obtained in only 24% of the fluid specimens. [29] Certain diagnoses are unlikely to be made from pericardial fluid. Pericardial fluid has been shown to give false-negative cytologic results in several cases of lymphoma and mesothelioma. [29] In HIV patients, effusions caused by Kaposi sarcoma and cytomegalovirus have been diagnosed by pericardial biopsy after fluid studies were non-diagnostic. [101] [102]

An alternative diagnostic tool is subxiphoid pericardiotomy. This technique, performed in the operating suite, obtains both fluid and a pericardial biopsy specimen. It is more likely to provide a definite diagnosis and has been performed safely without general anesthesia. [103] [104] In a prospective series of 57 patients, 36% obtained a definitive diagnosis; 40%, a probable diagnosis; 16%, a possible diagnosis; and 7% remained undiagnosed with subxiphoid pericardiotomy. [105] Although it is uncertain whether this technique is safer than ultrasound-guided pericardiocentesis, published reports show a low rate of complications in experienced hands. [105]

Regardless of technique, the need to sample small effusions or obtain pericardial tissue has been questioned. A prospective series found a diagnostic rate of 6% with pericardial fluid and 5% with pericardial tissue when a small persistent effusion was sampled for the specific purpose of diagnosis. In contrast, when patients from the same population had therapeutic intervention for tamponade, the yields from fluid and tissue were 54% and 22%, respectively. [98]

The use of pericardiocentesis as a diagnostic tool in traumatic tamponade is limited. When used diagnostically to determine the presence of pericardial bleeding in trauma, the procedure has a false-negative rate of between 20% and 40%. [81] [106] [107] [108] The reason for the high false-negative rate (defined as no blood aspirated) is well demonstrated by typical stab wounds of the heart.[8] [105] Ninety-six percent of the patients had blood in the pericardium, but it was clotted in 41% of the patients and partially clotted in another 24%. In only 19% was the blood completely fluid and thus capable of giving a true-positive result on pericardiocentesis.

Therapeutic Pericardiocentesis

Tamponade of Uncertain Etiology

The primary reason for performing pericardiocentesis in the ED is as part of the treatment for cardiac arrest or in peri-arrest situations. In particular, the presentation of PEA with elevated jugular venous pressure should cause immediate consideration of pericardiocentesis. In this setting, blind, ECG-guided pericardiocentesis can be life saving. However, the overwhelming majority of patients with PEA have neither significant effusion nor tamponade, and other etiologies for the PEA also should be sought. Pericardiocentesis also may be considered in other presentations of effusion with existing or incipient tamponade.

Tamponade Caused by Nonhemorrhagic Effusions

Pericardiocentesis is often, at least temporarily, therapeutic in cardiac tamponade. Most nonhemorrhagic effusions are liquid and can be drained easily through a small needle. Removal of even a small amount of fluid can immediately and dramatically improve blood pressure and cardiac output. Pericardiocentesis relieves tamponade due to nonhemorrhagic effusions in 60% to 90% of cases. [29] [37] [44] Patients in whom it fails often have purulent pericarditis or malignant invasion of the pericardium.

Pericardiocentesis without catheter placement may be much less useful for long-term management of these patients; 26% of the patients in the study by Guberman and coworkers eventually required pericardial resection. [37] In Krikorian's series, 24% of the patients were managed successfully with one pericardiocentesis, 37% needed multiple taps or an indwelling catheter, and 39% required surgical drainage. [29] Fifty-five percent of the last group had traumatic hemopericardium.

Patients with renal failure and pericardial effusion may be better managed by dialysis than pericardiocentesis. In one series, 63% of these patients were successfully managed with dialysis alone, and only 6% needed surgical treatment over the long term. [29] Tamponade is less frequent with pericarditis when it occurs within the first months of dialysis, and such patients are much more likely to be successfully managed without invasive intervention. [46] When invasive treatment is needed for dialysis patients, pericardiocentesis is probably a poor choice; 9 of 10 patients who received it had complications in one series, and it was the only invasive treatment that resulted in death.[46]

An algorithm for the urgent management of nonhemorrhagic cardiac tamponade is shown in Figure 16-7 .

Use in Hemorrhagic Tamponade

Pericardiocentesis is never the definitive treatment in hemorrhagic tamponad[110] [111]

Although aspiration of a small quantity of fluid may cause dramatic improvement, blood usually reaccumulates. [35] [90] Thus, patients with pericardial hemorrhage ultimately require thoracotomy to explore and repair the cardiac injury.

One of the greatest potential drawbacks of pericardiocentesis in traumatic tamponade is that it may delay thoracotomy. In one study of 25 trauma patients with cardiac injury,[110] all of those who were operated on within 2 hours of injury survived, regardless of age or type of wound. With greater delay, none survived. Sugg and colleagues, in a study of 459 similar patients, found a mortality rate of 43% when pericardiocentesis was the sole treatment, but only 16% when surgery was performed.[107] Most investigators agree that with early thoracotomy and little or no reliance on pericardiocentesis, the number of deaths due to stab wounds has decreased.[81] [108] [111] [112] Sugg and associates reported that 10 of 18 patients with traumatic tamponade who were managed by repeated pericardiocentesis alone died within 1 to 2 hours.[107] At autopsy, all patients had repairable wounds.

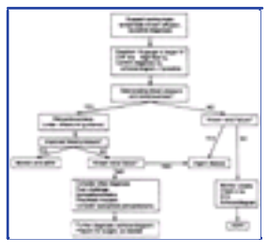

Figure 16-7 Management of *nontraumatic* cardiac tamponade. IV, intravenous line; CVP, central venous pressure; ECG, electrocardiogram.

Nonetheless, while other temporizing treatments are instituted (see discussion later in this chapter) and arrangements for definitive surgical treatment are being made, pericardiocentesis may temporarily improve the patient's hemodynamic situation (Fig. 16-8). Some clinical evidence supports the usefulness of pericardiocentesis as a temporizing measure. In a study of 174 patients with tamponade from penetrating trauma, 96 underwent operating room thoracotomy, 44 underwent ED thoracotomy, and 34 received only pericardiocentesis followed by observation. [83] Of those who underwent operating room thoracotomy, 68% were hemodynamically unstable, and preoperative pericardiocentesis decreased the mortality rate from 25% to 11%. Ninety-one percent of those who underwent ED thoractomy were unstable, and pre-thoracotomy pericardiocentesis decreased the mortality rate from 94% to 63%. For the unconscious and hypotensive or agonal patient, emergency thoracotomy is the preferred treatment (see Chapter 18).

When a trauma patient's condition is relatively stable, but a high level of suspicion for a penetrating cardiac wound is present, an alternative to thoracotomy is the subxiphoid pericardial window. [103] [113] [114] The procedure has been done under local anesthesia. Although it is possible to perform the procedure in the ED, [114] most authors believe the procedure should be reserved for the operating suite. [115] [116] [117]

CONTRAINDICATIONS

There is no absolute contraindication to pericardiocentesis. It should not be performed when better treatment modalities are immediately available (e.g., dialysis for uremic patients and immediate surgery for trauma patients). For diagnostic or non-emergent pericardiocentesis, echocardiographic or CT diagnosis is imperative. Ultrasound or fluoroscopic guidance should be used in all non-emergent situations.

EQUIPMENT FOR PERICARDIOCENTESIS

Fluoroscopic or Ultrasound Guidance

Pericardiocentesis is ideally performed in the cardiac catheter laboratory under fluoroscopic or echocardiographic guidance. In the ED, echocardiography is useful for directing pericardiocentesis. With ultrasound, the area of the heart with the greatest fluid accumulation can be accurately identified and its relationship to the body wall clarified.[118] [119] An entry site and angle of penetration can then be chosen that have the greatest likelihood of obtaining fluid while simultaneously avoiding vital structures. Ultrasonographic diagnosis and guidance is described elsewhere (see Chapter 69).

Electrocardiographic Assistance

Although the procedure can be performed with only a syringe and a spinal needle, electrocardiogram monitoring is desirable. An alligator clamp is used to connect the needle to *any* of the precordial leads (V leads) of a properly grounded electrocardiogram device (Fig. 16-9). Generally the V lead (usually V_1 or V_5), which permits a continuous display during rhythm monitoring, is used. When the alligator clamp connects the base of the pericardiocentesis needle to the V lead wire, the operator must set the machine to record the V lead as the rhythm strip.

Other Equipment

The traditional needle choice has been a 7.5- to 12.5-cm (3-to 5-inch), 18-ga spinal needle with an obturator. It is best to leave the obturator in the needle during initial passage through the skin to avoid obstruction of the needle lumen. More recently, the shorter Teflon-sheathed Intracath needle has been used. Alternatively, the clinician can use the guide

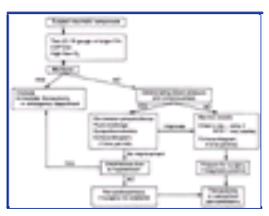

Figure 16-8 Management of *traumatic* cardiac tamponade. IV, intravenous lines; CVP, central venous pressure; ECG, electrocardiogram; R/O, rule out.

wire (Seldinger) technique, inserting a plastic catheter over a flexible guide or J wire. With this technique, an 18-ga, thin-walled needle is used for placement of the wire. The catheter (after removal of the accompanying introducer) may be left in place for prolonged drainage, if needed. [120] [121]

For drainage of blood, pus, or other viscous effusions, a large catheter such as a No. 7 to 9 Fr Cordis sheath should be inserted. [122] Alternatively, the guide wire technique can be used to insert a radiopaque, 16-ga, flexible, fenestrated, central venous catheter, which can then be connected to closed suction drainage

Figure 16-9 Equipment for emergent pericardiocentesis: long, 18-ga spinal needle; wire with alligator clips for connection to the electrocardiograph machine; and syringe (three-way stopcock optional). Sterile skin preparation and local anesthetic are also required.

and left in place for long periods of time. [123] Pigtail catheters with side and end holes or nephrostomy drainage catheters also can be used. [121] Multi-lumen catheter patency can be maintained by slow continuous flush with a heparinized saline solution. [121] Complete "sets" containing necessary equipment for placing a catheter using the guide wire technique are commercially available (Fig. 16-10), including sets designed for pediatric use. [124]

A three-way stopcock may be attached to the needle or catheter to allow removal of more than one filled syringe without much movement of the needle. The continuous

motion of the heart may require minor changes in needle or catheter position during the procedure. Lengthy or repeat drainage is much safer if the steel needle is withdrawn and a plastic catheter is left in place.

PROCEDURE

Temporizing Measures

While preparing for pericardiocentesis in the unstable patient or attempting to stabilize the patient while the operating suite is readied for thoracotomy or subxiphoid pericardiotomy, temporizing measures should be considered. In the patient with suspected tamponade and without jugular venous distention, the administration of a fluid bolus may improve hemodynamics.[68] In the setting of non-penetrating tamponade, a fluid challenge has been recommended [59] [125] ; animal experiments have found this to be beneficial, with or without nitroprusside for afterload reduction. [126] However, a follow-up prospective evaluation in patients with tamponade found no benefit from either fluid challenge or nitroprusside; cardiac output remained unchanged at a mean of 5.1 L/min, in contrast to 9.1 L/min after pericardiocentesis. [127] In the trauma patient with penetrating cardiac injury, fluid resuscitation may produce improvement or deterioration. Animal experiments indicate that the response depends on whether fluid infusion produces recurrent bleeding from the cardiac wound. [128] One report found that dextran solution for volume expansion produced significant hemodynamic improvement in patients with subacute ventricular free wall rupture after acute myocardial infarction. [32] In summary, judicious volume expansion may produce temporary beneficial hemodynamic results, but this is not uniformly true.

Vasopressors also have been recommended as a temporizing measure in tamponade. Dopamine, dobutamine, norepinephrine, and isoproterenol have been evaluated. Norepinephrine produced increased cardiac output in animal models of tamponade [129] [130] but failed to increase cardiac output in patients with malignant effusion.[129] Isoproterenol increased cardiac output in animal models but detrimentally affected cardiac blood flow. [129] Both dopamine and dobutamine have produced increased cardiac output and other improvements in hemodynamics in the setting of tamponade. [22] [127] Either of these agents may be helpful as a temporizing agent in tamponade, but dobutamine may be preferable on theoretical grounds because of its greater beta activity. [130]

Preparation

All necessary equipment must be checked and laid out in advance. Full resuscitation equipment must be on hand, including a defibrillator. The patient must have an IV line in place and be attached to a cardiac monitor. The non-emergent patient may require sedation, but in an emergency, pericardiocentesis is usually performed on patients who are already obtunded or unresponsive as a result of low cardiac output. Use of sedation in these patients not only is unnecessary, but also carries a high risk of hemodynamic or respiratory deterioration. Premedication of the patient with atropine may help to prevent vasovagal reactions. When possible, the presence of pericardial effusion and the optimal anatomic approach should be determined in advance by echocardiography. If surgery may be needed, preparations should already be under way to ensure prompt availability of both an operating room and a surgeon.

If the patient's clinical condition permits, the chest should be elevated at a 45° angle to bring the heart closer to the anterior chest wall. If the abdomen is distended because of gastric contents or previous positive-pressure ventilation, a nasogastric tube should be used to decompress the stomach. The entire lower xiphoid and epigastric area should be carefully prepared with 10% povidone-iodine solution and sterilely draped, if time permits.

If the patient is awake, the skin and the proposed route of the pericardial needle should be anesthetized by infiltration with 1% plain lidocaine or 0.5% bupivacaine. Note that the pericardium is very sensitive and should be anesthetized in patients who are awake. [120]

Anatomic Approach

The choice of anatomic approach in the past has been governed largely by conjecture and theory, not by actual study of patients with pericardial effusion. Traditionally the subxiphoid approach was preferred and recommended in most texts and articles as the optimal choice. However, two-dimensional echocardiography allows direct visualization in the individual patient of both the areas of maximal effusion and the location of vital structures. Studies of echocardiography-directed pericardiocentesis have found that the intercostal space near the heart apex is usually the best site for puncture, not the traditional subxiphoid approach. [119] [122] Careful cadaver studies have corroborated this finding, demonstrating greater safety with a parasternal approach in the fifth intercostal space and showing that the greatest number of injuries (usually to the right atrium) occurred with variants of the subxiphoid approach. [14] In contrast, studies of intracardiac injection using the same routes have found an increased incidence of pneumothorax when parasternal or intracostal approaches are used (see discussion of complications of pericardiocentesis). This risk may increase with underlying lung disease. Whenever time and the patient's condition permit, clinicians should rely on echocardiography to define the extent of and optimal approach to pericardial effusion. When time or circumstances prevent the use of ultrasound, the clinician should use the approach with which he or she is most familiar.

Parasternal Approach

In this approach, the needle is inserted perpendicular to the skin in the left fifth intercostal space medial to the border of cardiac dullness (Fig. 16-11). Older texts identify the puncture site as being at least 3 to 4 cm lateral to the sternal border to avoid the internal mammary artery. However, anatomic studies indicate that penetration immediately lateral to the sternum is less likely to cause this complication. [14]

Subxiphoid Approach

In the traditional subxiphoid approach, the needle is inserted between the xiphoid process and the left costal margin at a 30° to 45° angle to the skin (Fig. 16-12). Because the heart is an anterior structure, an angle greater than 45° may intercept the liver or stomach. In this approach, the needle enters the pericardium at the angle at which it becomes the diaphragmatic pericardium. Recommendations regarding needle aim vary widely, including among others the right shoulder, the

Figure 16-11 Parasternal approach for pericardiocentesis. The patient is depicted in a supine position, although a preferable position would be sitting at a 45° angle, if the patient's clinical condition permits. Note ECG monitoring via alligator clamp attached to lead.

sternal notch, and the left shoulder.[120] [125] The only anatomic study conducted demonstrated that the subxiphoid approach is likely to injure the thin-walled right atrium when one aims for the right shoulder.[14] Aiming for the left shoulder directs the needle toward either the left ventricle or the anterior wall of the right ventricle (Fig. 16-13).

Apical Approach

In the less commonly used apical approach, the needle is inserted 1 cm lateral and in the intercostal space below the apical beat, within the area of cardiac dullness; it is aimed toward the right shoulder. [120] If the apex cannot be palpated, the needle is inserted just inside the area of cardiac dullness. This area is close to the lingula and left pleural space, and pneumothorax is more frequent; a concomitant pleural effusion may be inadvertently tapped. In theory, this technique is used because the coronary vessels are small at the apex, and if a ventricle is entered, it is the thick-walled left ventricle, which is more likely to seal off any ventricular injury. Data are insufficient to say whether these theoretical advantages are clinically important. With echocardiographic guidance, the apical approach may be more commonly

used.[131]

Electrocardiogram Monitoring

After the skin has been punctured but before the pericardial needle is advanced, the needle obturator is removed, and an aspirating syringe is attached. At this time, electrocardiogram monitoring is begun. Attach a sterile electrical cord with alligator clips (see Fig. 16-9) from the pericardial needle to any precordial lead (V lead) of the electrocardiogram machine. The V lead is then recorded, as the needle becomes an "exploring electrode." The machine must be properly tested and internally grounded. Small current leaks can induce dysrhythmias.[35] The purpose of the electrocardiogram monitoring is to prevent ventricular puncture. When the needle touches the epicardium, a current-of-injury pattern, often simulating a wide complex PVC with an elevated ST segment, is noted on the electrocardiogram (Fig. 16-14). This current of injury may be local and could be missed if a lead other than a V lead is monitored or if a cardiac monitor (which has a lower

Figure 16-12 *A* and *B*, Xiphosternal approach for pericardiocentesis. The needle is aimed for the sternal notch or the left shoulder. Note the electrocardiography monitor. Although the patient is shown in a supine position, a preferable position would be sitting at a 45° angle, if the patient's condition permits. This general approach is also used for intracardiac injection of advanced cardiac life support drugs.

frequency response than the electrocardiogram machine) is used. Usually one notes ST-segment elevation on contact with the heart or pericardium in the absence of an effusion, but a premature contraction or other ventricular dysrhythmia also may be induced by direct mechanical stimulation of the ventricular epicardium by the needle. Contact with the atrium can cause atrial dysrhythmias, marked elevation of the PR segment, or atrioventricular dissociation.[16] If there is abnormal myocardial scarring secondary to infarction or other diseases or if there is malignant infiltration of myocardium, no current of injury may be generated.[17] Thus, electrocardiogram monitoring is not infallible in preventing myocardial penetration. In addition, the incessant motion of the heart makes it almost impossible to merely *touch* the epicardium.

With continuous electrocardiogram monitoring, the operator slowly advances the needle and syringe while gently aspirating. The needle will penetrate the pericardium (this is usually not palpable) at about 6 to 8 cm below the skin in adults and 5 cm or less below the skin in children.[57] The awake patient may complain of sharp chest pain as the sensitive pericardium is entered. As soon as pericardial content is aspirated, the needle should not be further advanced. If a current of injury is noted (see Fig. 16-14), the needle is touching epicardium and can easily lacerate myocardium or coronary vessels. The needle should be withdrawn a few millimeters until the current of injury disappears. At this point, the needle should be safely positioned in the pericardial space, although heart motion

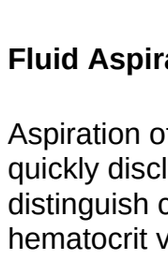

Figure 16-13 Subxyphoid approach to catheter placement into pericordial space. A short needle (16- or 18-ga) is inserted into the left xiphocostal angle perpendicular to the skin and 3 to 4 mm below the left costal margin *(A)*. After advancing the needle to the inner aspect of the rib cage, the needle's hub is depressed so that the needle points toward the patient's left shoulder. The needle is then cautiously advanced about 5 to 10 mm until fluid is reached *(B)*. The fingers may sense a distinct "give" when the needle penetrates the parietal pericardium. Successful removal of fluid confirms the needle's position. The syringe is then disconnected from the needle, and the flexible tip of the guide wire is advanced into the pericardial space *(C)*. The needle is withdrawn and replaced with a soft, multihole pigtail catheter (No. 6 to 8 Fr) using the Seldinger technique. After dilating the needle tract, the catheter is advanced over the guide wire into the pericardial space *(D)*. Once the catheter is properly positioned, aspiration of fluid should result in rapid improvement in blood pressure and cardiac output, a decrease in atrial and pericardial pressures, and a decrease in the degree of any paradoxical pulse *(E)*. Electrical alternans, if present, also decreases or disappears. *(From Spodick DH: The technique of pericardiocentesis. J Crit Illness 2:91, 1987.)*

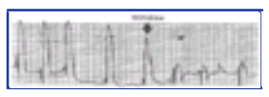

Figure 16-14 Current of injury. There is an obvious change in the electrocardiogram when the pericardiocentesis needle touches the epicardium. Following slight withdrawal *(arrow)*, the ST-segment elevation diminishes.

may quickly bring it back into contact with the myocardium. This is particularly a risk if the presence of a large effusion has not been demonstrated by ultrasound. If the scenario permits, some clinicians would now use the properly placed needle to pass a wire, then catheter, into the pericardial space, rather than attempting to drain the fluid or blood with the needle alone (see Fig. 16-13). This is a technically difficult procedure.

Fluid Aspiration and Evaluation

Aspiration of blood during pericardiocentesis raises the possibility of cardiac puncture. If fluoroscopy is available, the injection of a small amount of contrast will quickly disclose intracardiac placement. In other circumstances, the needle may need to be repositioned and the aspirate reexamined. Laboratory tests may help distinguish circulatory blood from hemorrhagic pericardial fluid. The latter should have a lower hematocrit measurement than venous blood. Substantially different hematocrit values rule out the possibility that the needle was in a cardiac chamber. Hemorrhagic pericardial fluid usually is about 0.10 pH unit lower than simultaneously obtained arterial blood.[99] Bloody pericardial fluid may clot, particularly when bleeding is brisk, so clotting of the aspirated blood does not eliminate the possibility of a pericardial source. Nonclotting blood is indicative of defibrinated pericardial blood. Practically, however, there is rarely time for such analysis.

If an indwelling catheter is to be placed, a guide wire is advanced through the needle (see Fig. 16-13). Then a dilator is passed over the wire to expand the needle tract. The guide wire should be maintained in sight and stabilized at all times. If intracardiac placement of the needle or guide wire is suspected, positioning must be verified by ultrasound or fluoroscopy or by using the techniques described earlier *before* the needle tract is dilated. Once the tract has been dilated, the pigtail catheter is placed over the guide wire. If the dilator is not used, particularly with the subxiphoid approach, the pigtail catheter tip may hang in the subcutaneous (SQ) tissue, making placement difficult.

After the catheter is placed, or if a decision is made to do a single aspiration, as much fluid as possible should be aspirated from the pericardium. The removal of even 30 to 50 mL may result in marked clinical improvement in patients with tamponade. The catheter may be placed for continuous or intermittent drainage. A chest film should be obtained after the procedure to rule out iatrogenic pneumothorax. Patients should be monitored closely for 24 hours for signs of reaccumulating fluid or iatrogenic complications from the procedure. Repeat ultrasound examination is recommended. Diagnostic evaluation of nonhemorrhagic fluid is similar to the analysis of pleural fluid (see Chapter 9).

COMPLICATIONS

The failure of pericardiocentesis to yield fluid ("dry tap") may be considered a complication, as the procedure has failed to achieve its desired result. If a dry tap is considered a complication, it is by far the most frequent one during blind pericardiocentesis. In addition, the pericardial needle can injure any organ within its reach, causing pneumothorax, myocardial or coronary vessel laceration, and hemopericardium. [112] Air embolism may be caused by air entering the heart. [132] The pericardial needle can also induce dysrhythmias from direct irritation of the epicardium or from small currents leaking from the connected electrocardiogram machine. [2]

Assessing the frequency of complication from pericardiocentesis is not straightforward. Changes in diagnosis of effusion by ultrasound or CT and guidance of the procedure by ultrasound or fluoroscopy have greatly reduced the likelihood of complication. [6] [131] [133] [134] [135] No recent data is available related to complications of blind or electrocardiogram-guided emergency pericardiocentesis. The complication rate is expected to be quite different. For example, Wong and colleagues reported that most complications occurred in patients who were found retrospectively to have no effusion. [3] The procedure is also performed frequently in moribund patients, and distinguishing between a poor outcome resulting from a poorly performed procedure as opposed to the underlying condition can be difficult.

A summation of the results of 5 recent reports on echocardiographically guided pericardiocentesis [6] [131] [133] [134] [135] includes 564 procedures with a 98% success rate. No deaths were reported. There were five incidents of pneumothorax, four reported cardiac punctures, one significant dysrhythmia, one hemothorax, one pericardial-pleural shunt and one instance of purulent pericarditis. The major complications will be discussed individually.

Cardiac Arrest and Death

Cardiac arrest and death is extremely rare in echocardiographically guided pericardiocentesis. In blind or ECG-guided pericardiocentesis, the patient is usually in full arrest and attribution of death to procedure or pre-procedure condition is nearly impossible. For example, in one series of 52 patients, the only death occurred in a patient in cardiogenic shock who had a nonproductive pericardiocentesis and who, on postmortem examination, had severe arteriosclerotic heart disease, not tamponade. [3] An additional case of cardiac arrest (successfully resuscitated) in this series was in a patient with a nonproductive pericardiocentesis; the cause of the arrest was not discussed. [3]

In a series of 352 pericardiocenteses performed under fluoroscopic guidance, only 2 deaths resulted. [4] Ultrasound or CT confirmation of effusion was used in all but 15 cases. The two deaths occurred during or after the procedure, but whether they should be attributed to the procedure is unclear. One patient with aortic rupture penetrating into the pericardial space died of cardiac arrest immediately after the puncture. The other death, in a post myocardial infarction patient with left ventricular aneurysm, was due to ventricular fibrillation that occurred about 15 minutes after the procedure.

Cardiac Chamber, Vessel, or Lung Laceration

Cardiac chamber, vessel, or lung laceration occurs more frequently during blind or ECG-guided procedures. Nonfatal cardiac puncture, pneumothorax, suppurative pericarditis, costochondritis, and pneumoperitoneum have been reported. [47] Most cardiac perforations occur in the right ventricle, but left ventricular [4] as well as atrial punctures have been reported. [16]

In Krikorian and Hancock's series, 13 of 123 patients developed hemopericardium as a result of pericardiocentesis, 1 as a result of a lacerated coronary artery. [29] One patient died from a punctured ventricle. Surgical control was necessary for four patients who developed tamponade, whereas eight patients with hemopericardium did not develop tamponade and were managed conservatively. Several cases of induced tamponade occurred in patients with platelet counts >50 × 10^9 /L.

Guberman and coworkers reported 3 right ventricular lacerations in 46 patients; 1 laceration was fatal. [37] Wong and colleagues found five right ventricular punctures, four in patients with nonproductive pericardiocentesis, but none causing any adverse sequelae. [3] In a series of dialysis patients, 9 of 10 receiving pericardiocentesis had serious complications, including 3 deaths and 2 myocardial lacerations. [46] Duvernoy and coworkers [4] reported 23 penetrations (all right ventricular except 2 in which both the right and left ventricles had been perforated), along with 4 cases of significant arterial bleeding in a series of 352 procedures.

Researchers differ in their opinions as to the adverse effects of ventricular puncture. Most ventricular punctures during the procedure occur in the lower aspect of the right ventricle. Because right ventricular pressure is lower, [57] puncture should cause less bleeding; however, the right ventricular wall is also thinner and more vulnerable to laceration. In a series of patients with ultrasound-directed pericardiocentesis, ventricular puncture still occurred in 1.5% but was without consequence due to small needle size. [122] In another study, right ventricular laceration occurred in one patient despite the use of echocardiography, producing tamponade and necessitating emergency surgery. [98] Of the 23 perforations in the series by Duvernoy and colleagues, [4] only 3 were considered "major" complications, with 2 of the patients requiring thoracotomy.

A small number of pneumothoraces and pneumopericardia have been reported in various series but have been without clinical consequence other than drainage. A single case of tension pneumothorax has been reported after pericardiocentesis, but a cause-and-effect relationship was unclear. [136]

Dysrhythmias

Serious dysrhythmias induced by pericardiocentesis are rare. Premature ventricular contractions (PVCs) occur commonly during the procedure and are benign in most cases. Most case series report no dysrhythmias. [3] [37] [47] [122] Krikorian and Hancock reported only 1 episode of ventricular tachycardia and several "hypotensive vasovagal reactions," which were associated with bradycardia and responded to atropine and fluid loading. [29] Duvernoy and colleagues [4] reported 1 case of ventricular tachycardia and 1 case of atrial fibrillation among 352 procedures. Maggiolini reported transient third-degree heart block in a single patient. [133]

Adverse Physiologic Consequences

There have been a few case reports of adverse consequences even when pericardiocentesis inflicts no injury. Most of these have to do with the fact that during pericardiocentesis, the stroke volume of the previously collapsed right ventricle increases 77% with the first 200 mL of fluid removed. [60] Generally, this increase in stroke volume is greater initially than that demonstrated by the left ventricle. This can have significant consequences for both right and left ventricular function. In three of six patients in whom large effusions were removed by pericardiocentesis, there was right ventricular dilation and overload, with abnormal septal motion and either no increase in right ventricular ejection fraction or a decrease. [137] These patients returned to normal hemodynamic status slowly.

Sudden pulmonary edema also has been reported after pericardiocentesis, presumably due to a sudden increase in venous return to the left ventricle at a time when peripheral vascular resistance is still high from compensatory cate-cholamine secretion. [138] [139] [140] Supporting evidence for this explanation is that right ventricular stroke volume increases more after relief of tamponade than the stroke volume increase of the left ventricle. [63] Circulatory collapse with persistently low arterial blood pressure has been reported in a patient who was drained of 700 mL of clear fluid at a rate of 100 mL/min. [141] These authors suggest that ketamine anesthesia may have played a role, but the relative ischemia created by tamponade, coupled with the sudden increase in left-sided preload, created a persisting imbalance. They recommend that pericardial drainage rate not exceed 50 mL/min. Given the rare occurrence of pulmonary edema or primary cardiac compromise, it is unclear that this recommendation is justified.

A case of brief profound bradycardia and rebound hypertension has also been reported after surgical relief of tamponade. [142] Such responses have not been noted in large series of patients receiving pericardiocentesis.

SUMMARY

In *nontraumatic patients,* tamponade should always be considered in the differential diagnosis of shock, especially in patients who are on anticoagulants, have had recent myocardial infarction, a history of pericardial disease, malignancy, or suspected aortic dissection or when a CVP catheter is in place. Tamponade should also be considered in the differential diagnosis when hypotension persists following closed-chest CPR or attempts at cardiac pacing. Its association with PEA should alert the clinician to the potential that tamponade exists.

In any patient with blunt or penetrating chest or upper abdominal trauma, the possibility of *traumatic tamponade* must also be considered. If clinical deterioration occurs in the ED pending operative care, temporizing pericardiocentesis should be considered if other therapy fails. When such a patient arrives with no obtainable blood pressure or in profound shock and unconscious, immediate thoracotomy and pericardiotomy are indicated after intubation. [111] [143] [144] Pericardiocentesis may cause a dangerous delay in this situation and has a low success rate.

Management of tamponade requires a sound understanding of pathophysiology; an ever-vigilant evaluation; and the knowledge of when the patient's clinical condition requires blind or ECG-guided pericardiocentesis as contrasted to the safer alternative of echocardiographically guided diagnosis and therapy.

Chapter 17 - Artificial Perfusion During Cardiac Arrest

Jim Edward Weber
F. Michael Jaggi
Emanuel P. Rivers

The modern era of cardiopulmonary resuscitation (CPR) was introduced by Kouwenhoven and colleagues in 1960 in a classic paper that brought together the concepts of mouth-to-mouth ventilation, closed-chest compression, and external defibrillation. [1] Although CPR and advanced cardiac life support (ACLS) interventions have saved many lives, overall survival after cardiac arrest remains low. [2] [3] [4] [5] [6] [7] [8] Evolving data from both laboratory and clinical studies suggest that restoration of heart function after cardiac arrest is related to the generation of adequate coronary perfusion. [9] [10] Despite this insight, artificial perfusion is the principal weak link in the resuscitation armamentarium. Subsequently, periodic revision of the recommended standards for CPR and the development of alternative methods of CPR are revisited by international resuscitation organizations as new science becomes available. [11] This chapter updates the current understanding of the mechanism of blood flow during CPR, reviews standard and alternative techniques of CPR, and summarizes methods for improving vital organ perfusion during cardiac arrest.

BACKGROUND

The mechanism of blood flow during CPR has been the subject of debate since the 1960s. Two mechanisms for blood flow have prevailed over time: the "cardiac pump" model and the "thoracic pump" model. Controversy continues over the nature of the pump at work during external chest compression. Future studies might help resolve this controversy, but now it seems that the driving force for blood flow produced by standard external chest compression is a combination of intrathoracic pressure fluctuations and direct cardiac compression. The current concept of blood flow during CPR is based on a combination of these models and provides the theoretical basis for the newer CPR techniques.

Kouwenhoven and colleagues first proposed the traditional cardiac pump mechanism of blood flow. [1] Pressure on the chest compresses the heart between the sternum and the vertebrae, forcing blood into the arterial circulation (Fig. 17-1 (Figure Not Available)). [12] Closure of the atrioventricular valves during chest compression was thought to prevent retrograde blood flow. With the release of chest compression, the heart expands and fills with blood. This model assumes that compression of the ventricles raises intraventricular pressure, rather than intrathoracic pressure, above that of the aorta and pulmonary artery, creating a pressure gradient that generates forward blood flow. The validity of this model has been questioned almost since its introduction. Several studies of simultaneous compression and ventilation have suggested that increases in intrathoracic pressure alone can produce forward flow of blood. Weale and Rothwell-Jackson, in 1962, showed that chest compression induces almost equivalent increases in arterial and venous pressures in animals, thus challenging the cardiac pump hypothesis. [13] They hypothesized that closed-chest compression creates a generalized increase in intrathoracic pressure that is transmitted equally to the heart and intra- and extrathoracic vessels, because the atrioventricular valves remain open (Fig. 17-2 (Figure Not Available)). [12] Additional evidence for the thoracic pump model has been provided by the reported success of cough CPR. During cough CPR, perfusion is maintained by intermittent increases in intrathoracic pressure by self-induced coughing.

Although multiple studies have been published in support of each of these models, [14] it is possible that neither fully explains blood flow during CPR. An alternative explanation is that both mechanisms play a role. Maier and associates studied the effect of varying the rate, force, and duration of compressions in CPR on large dogs.[15] These investigators demonstrated that the relative contribution of the thoracic pump and direct cardiac compression models to blood flow varied with the CPR technique used. Direct cardiac compression predominated when chest compressions were delivered at higher rates (high-frequency CPR), and the thoracic pump mechanism predominated in low-momentum compression techniques, such as simultaneous compression and ventilation (SCV) CPR. In addition, Babbs and coworkers noted that the optimal technique of CPR varied with the size of the experimental animal and the size of the pad performing chest compressions. [16] Large animals in arrest were more likely to benefit from SCV CPR than smaller animals. Direct cardiac compression was proposed to play a greater role in smaller animals. Interestingly, sustained intrathoracic pressure elevations can occur during CPR in the setting of increased airway resistance. [17] The inability to adequately exhale during CPR can lead to the auto-positive end-expiratory pressure (auto-PEEP) phenomenon. The presence of auto-PEEP can adversely impact cardiac filling and cardiac output.

In summary, the mechanism of forward blood flow during closed chest compression appears to be multifactorial. Key factors include body size, chest configuration (particularly anteroposterior diameter), previous thoracic surgery, molding of the chest with continued CPR, size of hand or paddle performing chest compressions, and rate and force of chest compressions. Knowledge of the mechanisms of blood flow during CPR allows the clinician to use alternative techniques that may provide better perfusion pressures during cardiac arrest. The optimal technique for CPR may not be the same in every patient. For example, obese patients with large anteroposterior diameters may benefit more from SCV; thin patients may benefit from faster compression rates. The key to clinical implementation of these changes is being able to assess perfusion during ongoing CPR. Advances in this area are discussed later in this chapter.

INDICATIONS AND CONTRAINDICATIONS

CPR is generally indicated for all patients in cardiac arrest. One contraindication to initiating or continuing CPR is when the provider has reason to believe that resuscitation will be a futile intervention. Often, for such patients, an advance directive that outlines the patient's preferences regarding resuscitative efforts is available. At other times, the patient's condition or response to resuscitative efforts will guide subsequent therapy. Details regarding the ethics and associated laws surrounding the initiation or continuation of resuscitative efforts for specific circumstances are beyond the scope of this text.

Figure 17-1 (Figure Not Available) Cardiac pump model of cardiopulmonary resuscitation. During the relaxation phase, negative intrathoracic pressure enhances blood return to the heart. During closed-chest compression, the heart is squeezed between the sternum and the spine, a pressure gradient is developed between the ventricles and great vessels, and antegrade flow occurs because of the one-way arrangement of heart valves. RV, right ventricle; LV, left ventricle. *(From Luce JM, Cary JM, Ross BK, et al: New developments in cardiopulmonary resuscitation. JAMA 244:1366, 1980. Copyright 1980, American Medical Association.)*

A special caution is warranted regarding new implantable left ventricular assist systems that serve as bridges until cardiac transplant or as mechanisms to enhance cardiac function in nonsurgical heart failure patients. These new devices can be operated by a hand pump in the setting of battery failure. When this condition is identified by the external hydraulic line or when described by family members, these patients should be resuscitated using the hand pump or a backup electronic pump. Although these patients can be resuscitated with standard cardiac drugs or cardioversion/defibrillation as warranted, they should not receive chest compressions.

Figure 17-2 (Figure Not Available) Thoracic pump model of cardiopulmonary resuscitation. Closed-chest compression causes a generalized increase in intrathoracic pressure that squeezes all structures, including the pulmonary reservoir, which is filled during the relaxation phase. A pressure gradient is developed, and blood flows into the head, because the thick-walled carotid artery remains patent while the thin-walled jugular vein is squeezed shut, or because of a venous valve. RV, right ventricle; LV, left ventricle. *(From Luce JM, Cary JM, Ross BK, et al: New developments in cardiopulmonary resuscitation. JAMA 244:1366, 1980. Copyright 1980, American Medical Association.)*

STANDARD CPR TECHNIQUE

Guidelines for the performance of CPR have been recommended by the American Heart Association and are revised

TABLE 17-1 -- Guidelines for Cardiopulmonary Resuscitation

	Adult	Child	Infant	Neonate
Compression rate (per min)	100	100	=100	120
Compression depth	4–5 cm	1/3–1/2*	1/3–1/2*	1/3*
Compression duration	50% of cycle	50% of cycle	50% of cycle	50% of cycle
Compression mode	Both hands	Heel of one hand	Apposed thumbs†	Apposed thumbs
Compression-to-ventilation ratio	15:2 (1 or 2 rescuers)	5:1 (1 or 2 rescuers)	5:1 (1 or 2 rescuers)	5:1 (1 or 2 rescuers)

From American Heart Association: Guidelines 2000 for cardiopulmonary resuscitation and emergency cardiovascular care. Circulation 102(suppl): I1, 2000.

*Anteroposterior diameter of chest.
†May be performed with ring and middle fingers one fingerwidth below intramammary line if rescuer hands are too small.

periodically to reflect ongoing research. [11] Current guidelines are summarized in Table 17-1 .

Traditionally, external chest compression was performed two fingerbreadths above the xiphoid-sternal notch, compressing the sternum 4.0 to 5.0 cm in the normal-sized adult. A simplified method of achieving correct hand position, particularly for lay rescuers, is "in the center of the chest, right between the nipples." The pressure is released completely after each compression, and an equivalent amount of time is allotted for relaxation as for compression. The chest compression rate was previously 80 to 100 per minute. Rescuers working within the range of 80 to 100 compressions per minute will naturally drift to the lower end of the range, especially when fatigued. Therefore, the newly recommended compression rate for adult victims is 100 compressions per minute. Two ventilations are given after each 15 chest compressions in one-rescuer CPR, and 2.0 seconds are allowed for each breath in order to provide good chest expansion. For adult victims, it is now recommended that 2 rescuers also use a compression-ventilation of 15:2. The compression-ventilation ratio of 5:1 results in interruptions, which subsequently lead to a marked reduction in blood flow and blood pressure. Once the patient is endotracheally intubated, the rescuer need not stop compressions for the ventilatory pause. Rather, ventilation should be performed asynchronously at a rate of 12 to 15 per minute.

In children (1 to 8 years), compressions are performed with the heel of one hand over the lower half of the sternum, ensuring that compressions do not occur on or near the xiphoid process. The sternum is depressed approximately one third to one half of the depth of the child's chest, which corresponds to a compression depth of approximately 2.5 to 4.0 cm, at a rate of approximately 100 compressions per minute. One or two rescuers providing compressions should pause after every fifth compression and provide effective ventilation.

Chest compressions in infants (younger than 1 year old) currently are performed 1 fingerwidth below the intramammary line. The sternum is depressed with 2 to 3 fingers to a depth of approximately one-third to one-half of the infant's chest (1.25–2.5 cm). The recommended compression rate in infants is at least 100 per minute. A 5:1 compression-to-ventilation ratio is maintained for both one- and two-rescuer CPR. The preferred two-rescuer technique for performing chest compressions in the infant is the two thumb-encircling hands technique. [18] [19] Using the same location, sternal depression is performed using the two apposed thumbs while the infant's chest is encircled with the back supported by the fingers of both hands. If the rescuer's hands are too small to encircle the chest, compressions may be performed with the ring and middle fingers one fingerwidth below the intramammary line.

Previous guidelines suggested that sternal compression depth for a neonate was 1.3 to 2.0 cm. Because these recommendations were considered complex and difficult to remember, a relative gauge that is sufficient to generate a palpable pulse or about one-third of the anteroposterior depth of the chest is preferred. Use of an absolute gauge for compression depth is discouraged. Chest compressions should be coordinated with ventilation at a ratio of 5:1 with a compression rate of 120 per minute.

MECHANICAL DEVICES FOR STANDARD CPR

Mechanical resuscitators that can provide standard chest compressions and ventilations during adult CPR have been developed. Early clinical studies have demonstrated that mechanical CPR devices are comparable to standard manual CPR.[20] [21] [22] Three human studies that compared mechanical with standard CPR demonstrated improvement in the concentration of end-tidal carbon dioxide (Pet CO_2) during mechanical external chest compression. However, no survivors were reported in any study.[20] [22] [23] In addition, one animal study showed improvement in the coronary perfusion pressure and Pet CO_2 concentrations, but again, revealed no survival advantage.[24] Nonetheless, the decay in quality of chest compressions with time periods as short as 5 minutes is well recognized. [25]

The nomenclature has been changed to differentiate the various types of mechanical adjuncts to reflect automatic versus manual devices and piston-type versus belt-type devices. Piston-type chest compression devices provide an acceptable alternative to standard manual CPR in circumstances that make manual chest compressions difficult. Advantages of mechanical devices include controlled, constant chest compressions; the elimination of operator fatigue; and the freeing of personnel to perform other functions. The most commonly used device is the Thumper Cardiopulmonary Resuscitator (Michigan Instruments, Inc., Grand Rapids, MI).

The Thumper

The Thumper is a gas-powered mechanical device that is in relatively broad use. This device consists of a compressed gas-powered plunger mounted on a backboard and a time-cycled volume ventilator (Fig. 17-3).

Figure 17-3 The Thumper Cardiopulmonary Resuscitator.

The Thumper delivers chest compressions at rates consistent with American Heart Association guidelines with a compression duration that is 50% of the cycle length. Every fifth compression is followed by ventilation with an adjustable tidal volume. The Thumper can be driven by wall oxygen at 50 psi or by standard portable oxygen tanks.

Setup of the Thumper

The Thumper can be positioned from either side of the patient. Care should be taken to ensure that the base plate is positioned horizontally under the patient's posterior thorax with the patient lying near the center of the backboard. After the arm/column assembly and piston are fitted on the base plate, the piston pad position should be adjusted so that the pad lies over the lower one third of the sternum. The compressor piston is positioned after the oxygen hose has been connected; therefore, CPR is not interrupted during assembly of the Thumper. The piston column is calibrated with rings, each indicating 1.25 cm of piston excursion. Before

§Only for use with active compression-decompression device.

the device is started, the piston height should be adjusted so that one ring is just visible on the piston column. With the Thumper operational, chest compressions should be adjusted to a depth of 5 to 6.25 cm or 20% to 25% of the patient's anteroposterior chest diameter, once the machine is in operation. The device should not be set to function at a predetermined chest compression force.

The ventilation hose can be connected to an endotracheal tube, an esophageal obturator, or a facemask. The Thumper uses a Patient Demand Valve (PDV) attached to the arm/column assembly and an associated tidal volume control that provides ventilation. The delivered tidal volume can be set from 400 mL to 1200 mL. The ventilation rate is preset to be synchronized with the Thumper chest compressions to provide ventilation on every fifth upstroke. The ventilator inspiratory-to-expiratory ratio is fixed at 1:2. It is pressure limited to 55 cm H_2O of airway pressure.

Use of the Thumper requires operation of 3 key switches: (1) RUN/STOP control, (2) the compression depth control, and (3) ventilation volume control. When a pause in compressions is required for other procedures, the operator can easily stop compressions by turning off the RUN/STOP control. Subclavian or jugular central lines can be placed with the Thumper in position, although it is recommended that the device be turned off during needle advancement to avoid arterial or lung injury. Defibrillation should be performed during the compression phase, when thoracic impedance is minimized.

ALTERNATIVE CPR TECHNIQUES

Because controversy continues as to the type of pump mechanism at work during chest compression, modifications of the standard CPR technique have been used in an effort to maximize coronary perfusion.[26] [27] [28] [29] [30] [31] [32] [33] [34] Proposed pumps include direct cardiac compression, intrathoracic pressure augmentation, abdominal pressure augmentation, or various combinations. The outcomes and recommendations of these alternative techniques are summarized in Table 17-2 .

Interposed Abdominal Compression CPR

The use of abdominal compressions during CPR evolved from the hypothesis that venous return might be improved and from laboratory observations that compression of the abdomen during cardiac arrest resulted in aortic pressure fluctuations similar to those with chest compressions. The technique of interposed abdominal compression (IAC)-CPR interposes abdominal compressions between chest compressions (Fig. 17-4).[35] [36] [37] CPR is performed using American Heart Association guidelines; however, during the relaxation phase, the abdomen is compressed. IAC-CPR has been studied extensively as a potential alternative to standard CPR using animal, human, and mathematical models.[38]

Four prospective randomized human clinical trials have compared IAC-CPR with standard CPR. [39] [40] [41] [42] Three of the studies involved in-hospital cardiac arrest victims, and reported improved return of spontaneous circulation (ROSC), [41] improved 24-hour survival, [41] [42] and improved survival to discharge [41] using IAC-CPR. No survival advantage using IAC-CPR has been demonstrated in the pre-hospital setting. [39]

IAC-CPR appears to be safe despite theoretical concerns over abdominal injury. Only one human case report described traumatic pancreatitis after IAC-CPR that was attributable to abdominal compression.[43] At the current time, IAC-CPR is not considered the technique of choice for external CPR because outcome benefits have been reported by only one center and the abdominal compression techniques used have not been consistent among studies. Also, use of IAC-CPR requires additional training and one additional rescuer to perform the technique. However, because of overall encouraging in-hospital results, supportive hemodynamic data, and apparent safety, the use of IAC-CPR is currently recommended as an acceptable alternative to standard CPR for

Figure 17-4 An artist's conception of basic rescuers performing interposed abdominal compression cardiopulmonary resuscitation. For clarity, both rescuers are shown on the same side of the victim. With two rescuers, the first compresses the chest and performs ventilation while the second compresses the abdomen. With three rescuers, ventilation, chest compression, and abdominal compression are performed by each individual. Ideally, the rescuer performing chest compressions is on the victim's right side and the rescuer performing abdominal compressions is on the victim's left side. *(From Voorhees WD, Niebauer MJ, Babbs CF: Improved oxygen delivery during cardiopulmonary resuscitation with interposed abdominal compressions. Ann Emerg Med 12:128, 1983. Reproduced by permission.)*

in-hospital resuscitation when sufficient personnel trained in the technique are available. [11]

High-Frequency (High-Impulse) CPR

Rapid manual CPR uses standard CPR techniques, but chest compressions are performed at a rate of 120 per minute. Animal data have shown that rates of 120 result in increased cardiac output, aortic pressure, coronary perfusion pressure, and blood flow as well as 24-hour survival. [15] [44] Swart and coworkers demonstrated that at a compression rate of 100 per minute, shorter compression duration (i.e., duty cycles less than 50% or "high-impulse" CPR) also improved resuscitation hemodynamics.[45] Kern and colleagues found that patients who had CPR with chest compression rates of 120 per minute had significantly higher levels of end-tidal CO_2 excretion (a surrogate for cardiac output) compared to patients with chest compression rates of 80 per minute. [46] Because survival studies have not been performed to clarify the effect of higher compression rates, high-impulse CPR should be considered an experimental technique and is not recommended for routine use in patients with cardiac arrest.

Vest CPR

The CPR vest was designed to take advantage of the thoracic pump mechanism of blood flow.[47] [48] [49] [50] Niemann and colleagues demonstrated hemodynamic improvement and 24-hour survival in animals receiving vest/binder CPR compared with standard CPR. [48] In contrast, Kern and coworkers found no improvement in resuscitation or 24-hour survival when vest CPR was compared with mechanical CPR.[49] Similarly, vest CPR proved to be of no benefit in one prehospital cardiac arrest study.[50] A recent study has reported improved 6-hour survival, but there was no improvement in survival to discharge. [7]

Randomized studies have not demonstrated harm with vest CPR. However, technical difficulties exist with the current device because of its size and subsequent energy requirements. The additional training and equipment requirements with CPR vests also add to the complexity of resuscitation. Despite these limitations, vest CPR is considered an acceptable alternative to standard CPR in the hospital or during ambulance transport, assuming there are an adequate number of well-trained personnel to properly perform CPR (Fig. 17-5).

Active Compression-Decompression

After publication of the initial case report in which a patient was resuscitated from cardiac arrest with the aid of a plunger, active compression-decompression (ACD)-CPR became one of the most heavily researched areas of advanced life support. [51] Standard CPR involves a forceful or active chest compression phase with elastic recoil of the chest wall during the relaxation phase (passive decompression). ACD-CPR involves both active compression and active decompression of the thorax using a device that consists of a circular suction cup with a handle and a force gauge that is applied to the midsternal chest (Fig. 17-6).[5]

At least 21 studies have evaluated the role of ACD-CPR in human cardiac arrest. [5] [51] [52] [53] [54] [55] [56] [57] [58] [59] [60] [61] [62] [63] ???[64] [65] [66] [67] [68] [69] [70] [71] Laboratory evidence has shown that ACD-CPR can decrease the venous system pressure to a greater extent than the arterial pressures during the

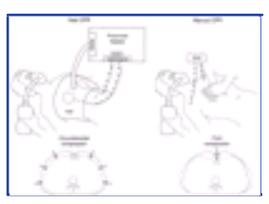

Figure 17-5 A comparison of vest cardiopulmonary resuscitation (CPR) and standard manual CPR. With vest CPR, a pneumatic system inflates and deflates a bladder surrounding the chest. The compression phase results in circumferential compression as opposed to point compression during manual CPR. The vest CPR system is equipped with defibrillator electrodes that monitor the patient's electrocardiogram as well as allow defibrillation without removal of the vest.

active decompression phase, resulting in improved venous return and increased CPR-diastolic coronary perfusion pressures. However, most human studies failed to

demonstrate long-term survival benefits. One study group demonstrated a neurologically intact survival benefit with the use of ACD-CPR. [58] However, these results should be interpreted with caution because the study investigators were unable to control for the use of ACD-CPR by basic life-support providers, and the resuscitation study team was unblinded to the technique used for external cardiac compression. Stiell and colleagues performed the most methodologically robust prospective study to date, and failed to demonstrate any significant benefits of ACD-CPR in either the basic or advanced life-support setting. [54] Despite the abundance of studies that have evaluated the role of ACD-CPR, meta-analysis of data is difficult because of inconsistent outcome definitions, inability to control for background confounders, differences in randomization schemes, and variability in prehospital response time for basic and advanced life support.

The use of ACD-CPR requires additional equipment and training. Additional concerns with ACD-CPR include difficulties with application of the technique, increased energy expenditure requirements, and mounting evidence of increased local trauma. [70] [71] However, since one center has demonstrated improvement in long-term outcomes, and most studies have not demonstrated harm, ACD-CPR has been approved as an acceptable alternative to standard CPR when rescue personnel are adequately trained to use this technique.

Chest Compression-Only CPR

Factors affecting widespread application of basic life support (BLS) techniques involve education of laypersons and acceptance of mouth-to-mouth ventilation. Current BLS techniques are difficult for laypersons to learn, retain, and correctly perform. [72] Surveys among laypersons, BLS instructors, and clinicians have reported resistance to performing mouth-to-mouth breathing for a stranger. [73] [74] [75] Correspondingly, the American Heart Association simplified the current requirements for and teaching of CPR. [11]

Data from 6 well controlled animal studies suggest that chest compression-only BLS performed by the lay public may be equally effective as standard BLS-CPR with rescue breathing using 24- to 48-hour survival as an outcome measure. [76] [77] [78] [79] [80] [81] Three important clinical trials corroborate these experimental data. Bossaert and colleagues found that when good-quality chest compression-only CPR was performed on prehospital cardiac arrest patients, there was no difference in long-term survival when compared with chest compression and ventilation CPR (15% vs. 12%). [82] Van Hoeyweghen and coworkers

Figure 17-6 The active compression-decompression (ACD) device uses a suction cup positioned at mid-chest at the level of the nipples. The device is pushed downward into the chest during the compression phase of CPR. The force of compression can be approximated by the gauge within the handle. During the decompression phase, the handle is actively pushed up and away from the chest while the suction keeps the device attached. This active withdrawal characterizes the decompression phase of CPR. The value of this adjunct is uncertain.

retrospectively found that only 10% of prehospital cardiac arrest patients who received chest compression-only CPR survived long term. This compares with a 16% survival rate for patients receiving good-quality chest compressions and ventilations, and a 7% survival rate when no bystander CPR was performed. [83] Hallstrom and colleagues reported that slightly more prehospital cardiac arrest patients survived in the chest compression-only CPR group than in the standard CPR group (14.6% vs. 10.4%). [84] Long-term survival following cardiac arrest with chest compression alone has been reported. Fifteen of the CPR-only cohorts from the Ontario Prehospital Advanced Life Support Study were discharged alive from the hospital, representing 3.6% of all study survivors. [85] However, some patients had hemodynamic compromise, rather than a true arrest, and this may have falsely inflated reported survival rates.

Continued efforts to improve and simplify BLS have led to the rationale for a "staged" approach for teaching BLS. [86] While CPR with compressions and ventilations remains the ideal method of maintaining blood flow until the arrival of emergency medical system personnel, chest compressions with an open airway at a rate of approximately 100 per minute is recommended if rescuers are unwilling or unable to perform mouth-to-mouth rescue breathing. [11]

Impedance Threshold Valve CPR

The reduction of intrathoracic pressures during ACD-CPR led to the recognition that occlusion of the airway during the chest wall decompression phase resulted in an additional decrease in negative intrathoracic pressure, and increased blood return to the chest. [65] Based on this mechanism, a small inspiratory impedance threshold valve (ITV) inserted into any respiratory circuit was developed to occlude the airway selectively during the decompression phase of CPR, without resistance to exhalation or active ventilation. [87] [88] The ITV has been shown to significantly increase vital organ flow when used with either standard CPR or ACD-CPR in a porcine model, and to decrease defibrillation energy thresholds when used together with ACD-CPR. [89] In patients undergoing ACD-CPR, the ITV cohort had significantly increased end-tidal CO_2 , systolic, diastolic, coronary perfusion pressures, and ROSC rates compared with patients treated with ACD-CPR alone. [88]

The potential benefits of the ITV are promising. However, comparative data with standard CPR and long-term survival data remain under study. Presently, the ITV is acceptable as an adjunct for use with a cardiac compression-decompression device to augment hemodynamic parameters. However, there are no data at this time to support the use of ITV with standard CPR.

Phased Chest and Abdominal Compression-Decompression (Lifestick CPR)

Lifestick CPR (Lifestick Resuscitator, Datascope Corporation, Fairfield, NJ) combines the hemodynamic advantages of IAC-CPR and ACD-CPR (Fig. 17-7). The device has adhesive chest and abdominal pads that are connected to an adjustable rigid frame with a handle at each end. The chest and abdomen are compressed in an alternating pattern by a single operator in a seesaw manner.

Tang and colleagues recently demonstrated higher resuscitation rates, 48-hour survival, and cerebral recovery with the Lifestick resuscitator compared to conventional chest compressions using a porcine model. [90] Correspondingly, using a mathematical model of adult human circulation, Babbs and colleagues demonstrated improved blood flow and systemic perfusion pressures with phased chest and abdominal compression-decompression compared to standard CPR. [91] Arntz and colleagues recently studied the feasibility, safety, and efficacy of the Lifestick compared with conventional resuscitation in a small cohort of 50 patients. [92] A

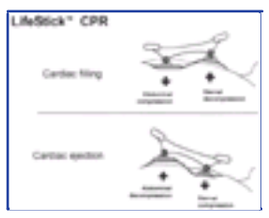

Figure 17-7 Lifestick Resuscitator used for active compression-decompression cardiopulmonary resuscitation (ACD-CPR).

significantly lower incidence of sternal fractures were found at autopsy with the Lifestick when compared to subjects receiving conventional CPR (3 vs. 9; $p < 0.05$). In addition, a higher proportion of patients with asystole or ventricular fibrillation achieved ROSC in subjects resuscitated with the Lifestick. However, no survival advantage was reported with the Lifestick over conventional CPR. [92] This method may prove to be a practical alternative to standard CPR in the future. However, large-scale clinical data are currently lacking, and the Lifestick Resuscitator remains experimental.

ASSESSMENT OF ONGOING CPR

The prognosis for resuscitation of patients in cardiac arrest depends on the no-flow interval before CPR is initiated, the time interval from collapse to defibrillation (if the rhythm is ventricular fibrillation), and the initial cardiac rhythm. Once the resuscitation efforts are initiated, there is no ideal criterion to judge the efficacy of CPR. In most animal and clinical studies, outcome (i.e., resuscitation or death) is the only criterion used. Recent studies have focused attention on assessing the effectiveness of ongoing resuscitation efforts, and identifying indices predictive of successful outcomes.

Pulses

Once considered a mainstay of CPR, the pulse check has been scrutinized for its reliability. [93] [94] Although femoral artery pulses are frequently assessed by medical personnel during CPR, accurate identification of a central pulse in a collapsed and unresponsive patient is extremely difficult. The clinician should exercise caution when making critical resuscitative decisions based on the presence or absence of a pulse. Palpating the pulse is also not an accurate means of assessing the adequacy of CPR because the pulse is more likely to represent the systolic-to-diastolic pressure gradient rather than the coronary perfusion pressure (CPP). In addition, femoral pulses perceived to be arterial may actually be venous. Blood frequently flows in a retrograde fashion to the lower half of the body during chest compression, because there are no valves in the inferior vena cava. The presence of carotid pulses may indicate forward blood flow with chest compression, but the extent of blood flow and, more importantly, tissue perfusion cannot be gauged by the presence or absence of a pulse.

Emerging data support the difficulties associated with pulse check interpretation. Flesche and colleagues studied the ability of trained medical professionals to accurately palpate central pulses in manikins as well as human models. [95] They found that fewer than 10% of medical students and trained rescuers detected an existing pulse in manikins, and it required 6 seconds to identify a pulse in healthy volunteers. Detecting pulses in collapsed and artificially ventilated patients is inherently more difficult. The carotid pulse check should under no circumstance be permitted to cause a delay in the decision to initiate CPR in an obviously lifeless person. Excessive time in locating a pulse and inaccurate determination of the presence of a pulse was reported to cause delays in chest compression or automated external defibrillator (AED) attachment in 10% of cardiac arrest patients. [11] Because of these difficulties, recent guidelines suggest that the "pulse check" should not be taught to lay rescuers.

Central Venous Oxygen Saturation

The ability to accurately predict ROSC and successful resuscitation based on surrogate markers of perfusion has been intensively studied. Mixed venous oxygen saturation obtained from pulmonary artery (S_{VO_2}) and central venous oxygen saturation (Sc_{VO_2}) have been shown to reflect the balance of systemic oxygen delivery (supply) to consumption (demand) in multiple disease states. [96] [97] [98] [99] [100] [101] The ultimate goal of artificial circulatory support is to maintain oxygen delivery as to avoid the complex cascade of events that results in cellular dysoxia and end-organ injury.

Although no single marker of perfusion is ideal, oxygen transport variables and mixed venous oxygen saturation provide the clinician with valuable physiologic information. Combined with other clinically important data (e.g., Pet_{CO_2}), mixed venous oxygen saturation can provide prognostic information as well as help guide the clinician in the post-resuscitative period. Pulmonary artery catheter placement is not necessary to analyze mixed venous blood. A number of studies have supported the use of central venous (right atrial or superior vena cava) blood for mixed venous blood (pulmonary artery) during spontaneous circulation, closed chest CPR, and circulatory failure. [102] [103] [104] [105] Emerman et al. reported no significant differences among pulmonary artery, central, and femoral venous blood gases during closed-chest CPR in animal models. [105] The close association between Sc_{VO_2} and S_{VO_2} allows placement of a central venous catheter as opposed to the more technically demanding pulmonary artery catheter.

The fundamentals of oxygen transport are beyond the scope of this text and are described in detail elsewhere. [106] Rivers and colleagues evaluated continuous central venous oxygenation saturations in 100 patients who experienced 68 episodes of cardiac arrest. [107] Central venous saturations were measured continuously by a fiberoptic catheter in the central venous location. ROSC was defined as an aortic blood pressure of at least 60 mm Hg for more than 5 minutes. Patients with a return of spontaneous circulation had a higher initial and statistically higher mean and maximal central venous oxygen saturation than those without a ROSC. No patient attained ROSC without reaching a central venous saturation of at least 30%. Furthermore, a central venous oxygen saturation of greater than 72% was 100% predictive of a ROSC.

Coronary Perfusion Pressure

As early as 1906, researchers noted the importance of achieving adequate diastolic pressure. [108] During diastole, the aortic pressure exceeds the right atrial pressure, resulting in blood flow to the coronary arteries. CPP represents the pressure gradient between aortic and right atrial pressures as measured during the relaxation phase of standard CPR. [109] [110] The resuscitation literature provides abundant evidence that CPP is the best hemodynamic predictor of ROSC. [10] [110] [111] [112] [113] [114] [115] [116] [117] A CPP of greater than 20 mm Hg in canine models and of greater than 10 mm Hg in swine is very accurate in predicting ROSC after electrical defibrillation. [115] [118] [119] The utility of monitoring CPP during human CPR has also been demonstrated. [9] Paradis and colleagues measured the CPP of 100 patients undergoing CPR. Only patients with maximal CPPs of 15 mm Hg or more had ROSC, and the fraction of

patients with ROSC was directly proportional to the CPP. Patients achieving a CPP of >25 mm Hg had a >80% likelihood of ROSC.

The traditional method of measuring CPP requires placement of a central venous line as well as an aortic arch catheter. The technical demands and time required for line placement, combined with the need for monitoring and signal amplification, make this modality somewhat limited in the everyday practice of emergency medicine. Rivers and colleagues, in an attempt to examine the validity of interchanging arterial sites, concluded that femoral artery relaxation-phase pressure was not statistically different from aortic relaxation-phase pressure. [120] Thus, substitution of a femoral artery catheter for the aortic arch line may encourage the clinical applicability of this potentially useful data.

In summary, the aortic diastolic pressure and CPP appear to be the best available criteria for assessing perfusion during CPR and correlate with survival in animal models. Although in the non-research setting, technical and time constraints associated with data retrieval may limit CPP usefulness outside of the research setting, these hemodynamic parameters appear helpful in directing resuscitative efforts.

End-tidal Carbon Dioxide Monitoring in Cardiac Arrest

The importance of Pet_{CO_2} monitoring was first recognized by Ruldolf Eisenmenger in 1929. [121] In a canine CPR model using the "biomotor," Eisenmenger very eloquently described the physiologic importance of monitoring Pet_{CO_2} and correlated subsequent values with the likelihood of "futility." Since then, researchers have made significant strides in defining the basic physiology of carbon dioxide production and removal in cardiac arrest states. [122]

Carbon dioxide is a byproduct of cellular metabolism that is eliminated primarily through the lungs. Blood transport occurs primarily as the bicarbonate ion with protein-bound transport contributing to a lesser degree. The partial pressure difference of CO_2 between the pulmonary capillaries and the alveoli accounts for the rapid diffusion of CO_2 into the alveoli. Normally, levels of alveolar carbon dioxide and therefore Pet_{CO_2} are determined by carbon dioxide production, alveolar ventilation, and pulmonary blood flow.

During low-flow states, Pet_{CO_2} levels reflect predominantly pulmonary blood flow; in cardiac arrest, the level is determined entirely by the cardiac output generated by

CPR.[123] [124] [125] [126] [127] [128] Falk and associates reported that PetCO_2 levels accurately reflected cardiac output in low-flow and no-flow states in 10 patients in an intensive care unit, thus correla ting Pet CO_2 and cardiac output.[127] Correspondingly, PetCO_2 values during CPR may offer prognostic information as to the likelihood of achieving ROSC. Sanders et al. studied the end-tidal CO_2 values in both in-hospital and prehospital cardiac arrest. [129] Resuscitated patients had higher initial Pet CO_2 levels (greater than 10 mm Hg). Over 20 minutes, Pet CO_2 levels averaged 18 mm Hg in survivors and 6 mm Hg in those who could not be resuscitated. Varon and colleagues reported similar findings; no patient in their study survived either in-hospital or prehospital cardiac arrest with a Pet CO_2 level of <14 mm Hg.[126] Levine reported that a PetCO_2 level of <10 mm Hg after 20 minutes of resuscitation in prehospital cardiac arrests with pulseless electrical activity was 100% predictive value of no ROSC.[130] Similar findings were reported by Cantineau and colleagues. [131] Thus, PetCO_2 measurement during resuscitation can be used to predict death in cardiac arrest patients with electrical activity but no pulse. Pet CO_2 has also been used to evaluate the effectiveness of chest compressions during cardiac arrest. As previously mentioned, palpation of peripheral pulses during CPR is often inaccurate. Paradis and others have demonstrated that a number of patients without palpable pulses do, in fact, have recordable blood pressures once invasive catheters are placed. [20] [132] Thus, monitoring of PetCO_2 may provide direct feedback as to the effectiveness of external chest compressions.

Measurement of exhaled CO_2 is highly accurate, whether by mainstream or side stream technology.[133] [134] [135] In mainstream sampling, a sensor is placed directly in the exhaled ventilator circuit. An infrared detector is placed in-line to afford real-time monitoring of the exhaled CO_2. Although highly accurate, error may occur if condensation accumulates on the sensor. Heated sensors have helped decrease the frequency of this problem. In a side-stream analyzer, a sample of air is aspirated to a distal sensor and analysis of the gas takes place away from the patient. This form of Pet CO_2 monitoring can be applied to non-intubated patients and is also very accurate. The disadvantages of side-stream analyzers include plugging of the sampling line from secretions and minor delays in response times. Both techniques use infrared spectrophotometry, whereby an infrared light is passed through the exhaled gas. The amount of light absorbed is proportional to the concentration of the exhaled CO_2 . Typically, most capnometers express the exhaled CO_2 as partial pressure as opposed to a percentage. The newer pH-sensitive paper exhaled CO_2 devices provide a more qualitative means of measuring exhaled CO_2 and have a role in endotracheal tube placement. Due to their semiqualitative limitations, a role in monitoring pulmonary bed perfusion is limited. However, Nakatani and colleagues found that qualitative Pet CO_2 estimates using the EASY CAP device (Nellcor, Inc., Hayward, CA) were associated with survival to hospital admission. [136] Similar results have been reported for children. [137]

When using PetCO_2 as a surrogate marker of cardiac output during arrest, one must be cautious of the pharmacologic effects of both epinephrine and bicarbonate. High doses of epinephrine given during CPR will typically result in a decrease in the Pet CO_2 level.[138] [139] The vasopressor effect of epinephrine leads to an increased afterload and a subsequent decline in cardiac output [138] ; epinephrine also decreases pulmonary blood flow and increases peripheral shunting. [140] These findings have been consistent in animal models, but not humans.[141] [142] Unlike epinephrine, bicarbonate given by bolus injection during a resuscitation results in a falsely elevated PetCO_2 . [143] Carbon dioxide production from the degradation of sodium bicarbonate is the cause of this transient but significant rise in the Pet CO_2 . When minute ventilation is held constant, the rise in Pet CO_2 is transient and lasts only a couple of minutes.

In summary, although debate continues over the exact correlation among Pet CO_2 , coronary, and cerebral perfusion pressures, [144] [145] PetCO_2 can be used as an adjunct to assess the efficacy and effectiveness of CPR. Ease of use, noninvasiveness, and the potential application in the prehospital setting make it an attractive modality. Combined with other clinically important data such as the length of down time and

duration of pulseless electrical activity, Pet CO_2 can guide the clinician in making decisions regarding the effectiveness of CPR as well as provide reassurance when to terminate resuscitative efforts. A PetCO_2 level of 10 mm Hg or less measured 20 minutes after the initiation of advanced cardiac life support accurately predicts death in normothermic cardiac arrest associated with pulseless electrical activity.

COMPLICATIONS

CPR as a clinical procedure remains a mainstay of cardiac arrest management. Although not detailed in this chapter, proper technique is essential for minimizing the risk of complications, which can include rib or sternal fractures, pneumothorax, gastric aspiration, abdominal solid organ injury, and gastric rupture. Bush and colleagues estimate that iatrogenic injuries occur in approximately 3% of children who receive CPR. [146] Because of this *low* rate of CPR-related trauma, observed injuries in children undergoing prehospital CPR may instead be the result of nonaccidental trauma. Iatrogenic injury rates with CPR in adults are several-fold more frequent. [147] [148] Although bleeding complications have been reported in patients who undergo CPR following thrombolysis, brief periods of CPR either before or after thrombolytic therapy are not contraindicated. [149] [150] [151]

SUMMARY

Regardless of the closed-chest CPR technique used, assessment of ongoing CPR efforts is desirable for rational management of patients in cardiac arrest. Hemodynamic monitoring, especially of the aortic diastolic pressure and aorta-to-right atrium perfusion gradient (CPP), currently represents the best indicator of adequate cardiac perfusion during ongoing CPR. Oxygen transport variables and mixed venous oxygen saturation provide the clinician with valuable physiologic information, and do not require the technically cumbersome placement of a pulmonary artery catheter. However, in most clinical cardiac arrest settings, it remains difficult to measure these hemodynamic parameters. Therefore, indirect indices of perfusion such as the use of Pet CO_2 may be useful in the overall evaluation of patients in cardiac arrest.

Despite considerable advances in CPR research, cardiac arrest carries a high mortality, and few survive to leave the emergency department (ED). The pervasive dilemma confronting emergency clinicians remains when to cease unsuccessful resuscitative efforts. Departmental guidelines are often based on the duration of CPR. Attempts at resuscitation often continue for prolonged periods of time and use considerable resources. Ongoing research suggests that interventions such as echocardiography and capnography may in the future yield accurate methods of predicting survival and certain death in the ED. [152]

Chapter 18 - Resuscitative Thoracotomy

Michael E. Boczar
Emanuel Rivers

Trauma is the leading cause of death in persons younger than 44 years old. [1] Cumulative trauma mortality has a steep curve in the initial hour after the incident, and 50% of deaths occur within the first hour. [2] Major improvements have been accomplished in the prehospital assessment, transport, and care of trauma victims. This has increased the number of patients arriving at the emergency department (ED) in various stages of shock, allowing emergency clinicians the opportunity to resuscitate patients who previously would have died at the scene. Penetrating cardiac injuries are an increasing cause of traumatic deaths in urban areas. [3] These patients, as well as others, represent a population for whom survival is occasionally possible if an aggressive approach using emergency department thoracotomy (EDT) is taken. Therefore, it is of paramount importance to recognize those patients who may respond to a resuscitative EDT. EDT is a dramatic and heroic intervention outside of the operating room and in the absence of trained cardiothoracic surgeons (Fig. 18-1). It is the rare patient who will survive this intervention, but exceedingly dismal survival rates do not negate the occasional dramatic save gleaned from EDT. EDT is more common in major university centers and Level I trauma centers, and it is not usually attempted outside this setting. Importantly, while this procedure may be in the realm of emergency medical practice, there is no standard of care that supports EDT as a procedure that must be undertaken by all emergency clinicians.

As a multidisciplinary specialist, the emergency clinician may find it necessary to perform procedures considered to be in the province of other specialties. EDT is one of these procedures and it is also one of the most invasive procedures performed in the ED. Thus there is often reluctance to perform ED and a tendency to delay its performance until a poor outcome becomes a certainty. However, the need for the emergency clinician to have an expertise in EDT is born of necessity. Few of the 6900 registered hospitals in the United States are Level I trauma centers with in-house surgical coverage, whereas nearly all hospitals provide 24-hour emergency clinician coverage. When a patient presents to the ED in extremis, an emergency clinician trained in EDT may perform this procedure without hesitation.

The focus of this chapter is threefold. The first is to discuss the indications and contraindications to the performance of an EDT. Mechanism of injury, prehospital/ED vital signs, as well as outcomes, significantly influence these decisions. The second is to discuss the pathophysiology and diagnosis of disease processes that would require such an invasive procedure. Finally, the technical aspects of performing an EDT will be discussed.

Although this chapter provides considerable detail of the rationale for and the technique of resuscitative thoracotomy, the emergency clinician should have a systematic plan *after opening the chest*. In the trauma patient receiving a resuscitative thoracotomy, the clinician seeks to relieve any cardiac tamponade; to support cardiac function (with direct cardiac compression, potential cross-clamping of the aorta to improve coronary perfusion, and internal defibrillation when indicated); and to control hemorrhage from the heart, pulmonary vessels, thoracic wall, and great vessels. Although certain circumstances may require this sequence of resuscitation to be altered, the emergency clinician should have a systemic plan prior to opening the chest. From an organizational standpoint, each institution should have guidelines for the initiation of resuscitative thoracotomy and subsequent patient care in the ED. Ideally, a plan of chest wound management after the EDT and immediate critical care should be established with the service that will provide surgical backup when members of the surgical team cannot be on site at the time of the resuscitation. With such a plan, the team approach to resuscitation allows for optimal patient care.

INDICATIONS AND CONTRAINDICATIONS

Chest Injuries (General)

The first successful thoracotomy was reported more than 100 years ago for a patient dying from a stab wound to the heart. Beall et al. [4] formally introduced EDT as a component of resuscitation of patients with penetrating chest injuries. The indications for EDT gradually expanded to include extrathoracic as well as blunt trauma. As a result, the overall survival rate became quite poor, fueling controversy over the indications for EDT. The decision to perform EDT must be made quickly

Figure 18-1 An emergency department thoracotomy is a dramatic and heroic intervention that has a very low survival rate. In the proper setting, its use can be advocated (see text). In this case of multiple gunshots, the abdomen was also opened in an attempt to cross-clamp the abdominal aorta, but no readily reversible pathology of the chest or abdomen was found.

and must be based on an understanding of which patients are likely to benefit from the procedure. The decision should be based on a realistic judgment that the patient has a chance of survival, but will not tolerate any delay in operative intervention.

The first decision point in determining which patients may benefit from an EDT is the paramedic's initial contact with the patient. [5] Important information in formulating a decision to perform an EDT includes the mechanism of injury, site of major injury and the time of injury, EMS arrival, and, when relevant, the time vital signs or cardiac electrical activity or both ceased.

An analysis of prehospital time in patients with penetrating chest trauma receiving EDT demonstrated that when times exceeded 30 minutes, no patient survived to be transferred out of the ED following EDT. For the patients with a prehospital time of less than 30 minutes, 63% were alive in the ED, although all patients subsequently died.[6]

For patients in cardiac arrest, tracheal intubation and duration of prehospital cardiopulmonary resuscitation (CPR) correlate with survival following thoracotomy. Recent observations suggest that 5 minutes of prehospital CPR approaches the limits of viability of *nonintubated* trauma patients. The value of field intubation is dramatic; the average time of CPR tolerated by intubated survivors is double that of nonintubated survivors (9.4 vs. 4.2 minutes). [7]

The type of electrical activity in conjunction with mechanism of injury is helpful in determining who may benefit from EDT. Asystole in the face of *blunt trauma* without vital signs in the field should be considered an absolute contraindication to EDT. Such patients simply do not survive, regardless of intervention. In contradistinction to many trauma centers, the Denver group[5] advocates performing EDT in those patients with blunt trauma and field vital signs if organized electrical activity is present. In the face of penetrating torso trauma, several studies have noted the presence of organized electrical activity to be associated with increased survival. [5] Those patients with a mechanism of penetrating torso injury with asystole as the presenting rhythm should still be considered as candidates for EDT. Branney et al. [5] noted 4 of 34 functional survivors who presented with this scenario. Danne et al. [8] reported a 5% survival in patients with penetrating chest trauma and asystole at ED presentation.

The mechanism of injury is of utmost importance when considering performing an EDT. In the largest EDT series to date, Branney et al. [5] reviewed 868 charts of 950 consecutive patients over 23 years. No blunt trauma patient without vital signs in the field survived after EDT. Survival following blunt trauma when field vital signs were present was 2.5%. Rhee et al.[9] examined 4620 cases of EDT from 24 studies over a 25-year period. The overall survival rate for penetrating trauma was 8.8%, while for blunt trauma it was 1.4%. Based upon these studies, the American College of Surgeons Committee on Trauma recommended *withholding EDT for patients with blunt trauma who arrest prior to ED arrival*.[10] In spite of this consensus, some centers' stance is that patients with blunt trauma with vital signs at the time of paramedic contact should still be considered for EDT. [5]

While survival remains the ultimate gauge of the effectiveness of EDT, it is appropriate to consider the quality of survival, specifically neurologic function. It is somewhat surprising that in general, survivors of EDT have good neurologic outcomes. Rhee et al. [9] reported that 280 of 303 (92.4%) patients discharged following EDT were neurologically intact. Moore et al. [11] reported the results of 146 emergency thoracotomies for mixed trauma, including 15 patients who survived resuscitation in the operating suite. Eighty percent (12 of 15) of these patients went on to become long-term survivors; 75% had full neurologic recovery. It is probably not possible to predict accurately which patients are likely to survive intact, but the Denver study demonstrated that all survivors with full neurologic recovery had respiratory efforts at the scene; in 75% of these patients, respiratory efforts were still present on arrival in the ED. The presence or absence of a palpable pulse was not an absolute prognostic indicator. Sixty-six percent of long-term survivors (11 patients with penetrating trauma and 1 with blunt trauma) had no detectable pulse on arrival in the emergency care unit.[11]

The first 24 hours following EDT will rapidly demonstrate which patients will become long-term survivors. The San Francisco experience with 168 emergency thoracotomies for mixed trauma illustrates that most patients with fatal injuries die within 24 hours. [12] Of patients surviving the first 24 hours, 80% (33 of 41) recovered and left the hospital. Full neurologic recovery occurred for 90% of these survivors. Overall, only 2.4% (4 of 168) remained severely disabled or in a persistent vegetative state. Of these 4 patients, only 1 (0.6%) lived beyond 2 months.

Cardiac Injuries—Penetrating

Those patients with vital signs following penetrating cardiac injury will present with symptoms consistent with pericardial tamponade or shock. The presentation is determined by wound size, presence of tamponade, rate of bleeding, chambers involved, and the patient's ability to compensate. Eighty percent of cardiac stab wounds result in pericardial effusion regardless of the presence of shock. [13] Tamponade may occur if the wound is less than 1 cm in size (dependent on the chamber involved) while wounds greater than 1 cm usually continue to bleed regardless of the chamber involved. Low-pressure atrial wounds usually form a thrombus before tamponade develops. The thicker-walled left ventricle may spontaneously seal stab wounds up to 1 cm in length. As little as 60 to 100 mL of blood that acutely fills the pericardium will impede diastolic filling, reduce stroke volume, reduce cardiac output, and increase catecholamine output.

Cardiac tamponade is the *decompensated* phase of cardiac function resulting from increased intrapericardial pressure (see also Chapter 16). The progression from compensated cardiac function to uncompensated tamponade can be sudden and profound. Although one may suspect tamponade based on well-described signs, the clinical diagnosis of pericardial tamponade in the unstable trauma patient is made difficult because of the combined effect of hemorrhagic and cardiogenic shock. The classic signs of Beck triad (distended neck veins, hypotension, and decreased heart sounds) have *limited diagnostic value* for acute penetrating cardiac trauma.[14] Additional signs of tamponade include tachycardia; *pulsus paradoxus*; elevated central venous pressure (CVP); persistently decreased central venous oxygen saturation, agitation and confusion (reflecting decreased cerebral perfusion); air hunger; and cold, clammy skin. Patients with a rising CVP and persistent hypotension should be presumed to have cardiac tamponade; however, there may be a poor correlation

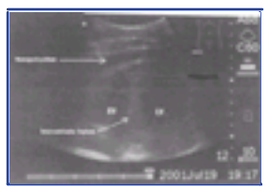

Figure 18-2 Bedside ultrasound demonstrating hemopericardium.

between CVP and the extent of tamponade, even when the blood volume has been corrected. [15]

Ultrasonography is being used with increased frequency to make the diagnosis of pericardial effusion and tamponade. Classic ultrasound findings are pericardial fluid with right atrial or right ventricular collapse during diastole. In trained hands, ultrasound is a sensitive and effective test that can be performed rapidly to assist in the evaluation of the trauma victim. The FAST examination (Focused Assessment with Sonography for Trauma) is a rapid bedside screening examination for the detection of hemopericardium and hemoperitoneum. Rozycki et al.[16] reported a sensitivity of 100% and a specificity of 97.3% for pericardial fluid using the FAST examination (see Fig. 18-2).

In addition to those factors previously discussed, survival following penetrating cardiac wounds is related to the mechanism of penetration with victims of stab wounds faring better than victims of gunshot wounds. Rhee et al.[9] noted that 16.8% of patients with stab wounds survived to hospital discharge following EDT. Branney et al.[5] reported 29% survival for stab wound victims presenting with tamponade, 15% survival in patients without tamponade, and 9% survival following absence of vital signs in the field.

In contrast, gunshot wounds are often large injuries, and are unable to seal themselves; only 20% present with tamponade. Penetrating cardiac injuries from gunshot wounds are more likely to present with profound hemodynamic compromise. Additionally, increasing popularity of larger caliber weapons has made it more difficult to resuscitate patients suffering from a gunshot wound to the chest. One study demonstrated that although 9% of patients were successfully resuscitated following a gunshot wound to the chest, all subsequently died from blast injury. [6] Of the 112 patients with penetrating gunshot cardiac wounds reviewed in the Denver study, [5] only 2% of patients survived neurologically intact.

Cardiac Injuries—Blunt

Blunt trauma to the heart ranges from minor contusion to frank cardiac rupture. Blunt cardiac rupture accounts for 5% of motor vehicle fatalities. [17] Approximately 20% of these patients will have a simultaneous aortic rupture.[6] In 1935, Bright and Beck made the observation that of 152 patients dying from cardiac rupture from blunt trauma, 30 patients lived 30 minutes or longer.[18] Fifty percent or more of patients with this injury present without vital signs to the ED. Branney et al. [5] observed a 2% survival rate for those resuscitated with EDT following blunt chest trauma. Survivors had vital signs in the field. The poor outcome associated with this type of injury may be secondary to poor cardiac function (secondary to contusion) even though mechanical causes of hemorrhage have been treated. Indications and contraindications for EDT for this mode of trauma have been discussed earlier in this chapter.

Pulmonary Injuries

Pulmonary injuries can be divided into three types: parenchymal, tracheobronchial, and large-vessel. Parenchymal and tracheobronchial injuries rarely require EDT. Most of these injuries are either rapidly fatal or can be adequately treated initially by tube thoracostomy.

Tracheobronchial injury is more common with blunt than penetrating trauma and most patients with this injury die at the scene. [19] The airway is usually maintained, even in the presence of a complete transection. The stiff tracheobronchial cartilage tends to hold the lumen open while the paratracheal and parabronchial fasciae preserve the relationship of proximal to distal bronchi. Ninety percent of tracheobronchial tears occur within 3 cm of the carina [20] and most commonly involve the main stem bronchi. Less frequently, vertical tears may occur along the membranous cartilage line of the trachea. Complete division of the trachea is extremely rare. Depending on the size and location of the injury, patients may present with massive hemoptysis, airway obstruction, and pneumomediastinum or pneumothorax, with or without tension. Massive subcutaneous emphysema and pneumomediastinum are usually seen, although up to 10% of patients with this injury initially will have no x-ray findings.[21] If hemorrhaging is profuse, or if the site of injury can be determined, the use of a bifid endotracheal tube or the unilateral intubation of a main stem bronchus will secure the airway.

Lacerations of the parenchyma unaccompanied by major vessel injuries generally respond to a tube thoracostomy. Although the associated hemothorax may be significant, re-expansion of the lung often halts or reduces bleeding. Reduction of parenchymal bleeding by negative pressure approximation of the visceral and parietal pleural surfaces is successful in 72% to 98% of cases. [22] If the initial chest tube drainage is more than 800 mL, with continued drainage at a rate of 50 mL every 10 minutes, or if there is persistent hypotension, immediate thoracotomy should be considered. Such patients are much more likely to have injuries to a major vascular structure than simple parenchymal injuries.

As with cardiac injuries, survival following EDT for pulmonary injuries is related to the mechanism of injury. Branney et al. [5] reported 17% survival following stab wounds, 3% following gunshot wounds, and 5% following blunt trauma.

Air Embolism

Presentation

Air embolism is a complication of pulmonary parenchymal injuries that requires immediate thoracotomy if there is hemodynamic instability. Until recently, the occurrence of air embolism following penetrating injuries of the lung had been

considered a rare event.[23] The preoperative and postmortem diagnosis of air embolism is difficult and it is likely that most air emboli are not detected. Air embolism is confirmed at thoracotomy by needle aspiration of a foamy air-blood admixture from the left or right ventricle or by visualization of air within the coronary arteries. Preoperative demonstration of air by aspiration from a central venous catheter or the femoral artery is rare, but it has been reported. [24]

Air embolism may appear in either the right or the left side of the circulatory system. Involvement of the right side of the circulation is referred to as *venous* or *pulmonary* air embolism. Generally, venous air is well tolerated, but death may occur when the volume of air reaches 5 to 8 mL/kg. The rate at which air moves into the circulation and the body's position are important determinants of the volume that can be tolerated. Death usually results from obstruction of the right ventricle or the pulmonary outflow tract. If the mean pulmonary arterial pressure exceeds 22 mm Hg, air may pass into the systemic circulation through a previously patent atrial foramen. Injuries of the vena cava or the right ventricle also can create portals of entry into the right circulatory system.

Air embolism involving the left side of the circulatory system is referred to as *arterial* or *systemic* air embolism. The lethal volume depends on the organs to which it is distributed. As little as 0.5 mL of air in the left anterior descending coronary artery has led to ventricular fibrillation. Two milliliters of air injected into the cerebral circulation can be fatal. Clinical manifestations of arterial air embolism are related to the involvement of the coronary or cerebral circulation. The distribution of arterial air is partly a function of body position.

Systemic air embolism following injury of the lung has only recently been described. The formation of traumatic bronchovenous fistulas creates potential entry points for air to move into the left side of the circulatory system. The only requirement is the formation of an air-blood gradient conducive to the inward movement of air. Although a lowered intravascular pressure from hemorrhage is a risk factor, the most important element in all reports of air embolism has been the use of

positive-pressure ventilation. [25]

In a review of 447 cases of major thoracic trauma, Yee et al. found adequate chart data to suggest the diagnosis of air embolism in 61 patients. [26] This incidence of 14% is remarkable in light of the small number of reported cases before 1973. [27] Blunt injury should not preclude consideration of this diagnosis, because 25% of patients with air embolism reported by Yee and coworkers had blunt trauma with associated lung injury secondary to multiple rib fractures or hilar disruption. The overall mortality was 56% (34 of 61 patients). Refractory cardiac arrest accounted for 63% of the operative deaths, with exsanguination or severe brain trauma as the cause in the remaining 37%.

The diagnosis of air embolism is easily overlooked because of the similarity of the signs and symptoms to those of hypovolemic shock. Two valuable signs that were present in 36% of patients were hemoptysis and the occurrence of cardiac arrest *after* intubation and ventilation. Additionally, postintubation circulatory and central nervous system dysfunction immediately following initiation of positive pressure ventilation and air in the retinal vessels is sufficient to make the provisional diagnosis of systemic air embolism. Focal neurological changes, seizures, and other central nervous system dysfunction in the absence of head injury are also suggestive.

Management

In those at risk for air embolism, spontaneous ventilation is preferred. A high index of suspicion with rapid control of the source of air embolism is essential. The patient should immediately be placed in the Trendelenburg (head-down) position to minimize cerebral involvement by directing the air emboli to less critical organs. Consideration may be given to isolating the injured lung if unilateral chest injury is present by selective intubation of the contralateral lung. If this step is unsuccessful, the next step should be a left anterolateral thoracotomy. The exposed thorax should be flooded with sterile saline. Peripheral bronchovenous fistulas can be identified by the bloody froth created during positive-pressure ventilation. A quick search for hilar injuries should be carried out in the patient with blunt trauma. If the source of air embolism is not readily apparent, a contralateral thoracotomy should be performed. Once the bronchovenous communication is controlled, needle aspiration of the residual air that commonly remains in the left ventricle and the aorta should be performed. If the patient is hypotensive, consideration should be given to aortic cross-clamping or occlusion. "Reflex" cross-clamping of the aorta before control of bronchovenous fistulas and removal of residual air will result in further dissemination of air to the heart and the brain.

Adjunctive Therapy

As mentioned earlier, air emboli traverse capillary beds if the blood pressure is high enough. After control of the bronchovenous fistula, a brief period of proximal aortic hypertension can be produced by cross-clamping of the descending aorta. Systemic arterial pressure should be maintained with adequate fluid resuscitation. Vasopressors such as dopamine, epinephrine, or norepinephrine may be required to increase systemic pressure in hopes to facilitate left to right passage of air bubbles. [28]

Left atrial pressure should be maintained at a high level. The ventilator inspiratory pressures should be kept as low as possible, and 100% oxygen should be used to facilitate diffusion of nitrogen from emboli. Additionally, high frequency ventilation, which allows for small volumes, has been used with success in individual patients. The most important adjunctive therapy is the use of hyperbaric oxygen.

Hyperbaric oxygen therapy is beneficial because it (1) compresses air bubbles; (2) establishes a high diffusion gradient, which greatly speeds the dissolution of the bubbles; (3) improves the oxygenation of ischemic tissues and lowers intracranial pressure; and (4) reduces the reperfusion injury that invariably follows the passage of bubbles. When it is available and logistically practical, hyperbaric oxygen therapy should be considered, *even though it may be many hours before it can be initiated*. Preferentially, treatment is begun within 6 hours of traumatic insult; however, the effectiveness of hyperbaric oxygen therapy is illustrated by cases of success and improvement even when as many as 36 hours elapsed before pressurization. [29]

Major Vascular Injuries

Mortality from major vascular injury has risen from less than 1% in 1947 to as high as 15% in recent years. [30] High-speed automobile accidents have accounted for some of this rise; however, major vessel injury is more frequent in penetrating trauma. In fact, 90% of major vascular injury is caused by

penetrating trauma, 10% by blunt trauma. Major vascular injury resulting in rapid deterioration following blunt or penetrating trauma requires the use of an EDT for diagnosis, resuscitation, and control of hemorrhage. Mavroudis et al. [31] reviewed 76 patients with thoracic vascular injury from mixed trauma that received an EDT because they were moribund or an immediate thoracotomy in the operating suite for hemodynamic instability. The three most common sites of vascular injury were the pulmonary artery (28% of cases), intercostal artery (23% of cases), and pulmonary vein (20% of cases). Aortic injuries account for only 12% of the injuries requiring immediate surgical intervention. However, even with immediate intervention, survival rates are low (14 to 29%). Air embolism was the cause of death in 18% of cases. [31] In the review by Branney et al., [5] 73 patients suffered great vessel penetrating injury with 1 survivor, while 30 patients were diagnosed with this injury from blunt trauma without any survivors.

Blunt and Penetrating Abdominal Injury

In the setting of penetrating abdominal injury, thoracotomy with cross-clamping of the thoracic aorta to control hemorrhage from the injury has been advocated. Because survival rates have been dismal for those undergoing this procedure, it is rarely performed, and its routine use is not recommended. The collective survival rate for 194 cases described in the literature is only 5%. [32] Conversely, Branney et al. [5] found that 8 of 76 (10%), of patients undergoing EDT for penetrating abdominal injury survived neurologically intact. While it is true that aortic cross-clamping does not substantially affect the rate and volume of bleeding from major venous injuries as well as from aortic collaterals, patients may benefit in other ways. The lack of blood volume following major vascular injury renders CPR ineffective. [33] Cross-clamping may reduce the volume of the vascular circuit during resuscitation and improve flow to vital organs.

Aortic cross-clamping for massive hemoperitoneum was originally conceived as a preoperative "prophylactic" procedure to prevent sudden hypotension following abdominal decompression. Applied in the operating room in this role, it is of clear benefit when systolic pressure cannot be raised above 80 mm Hg prior to laparotomy. [34] Kralovich et al. [35] studied the hemodynamic consequences of aortic occlusion in a swine model of controlled hemorrhagic arrest. Following hemorrhage and a period of apnea, animals were randomized into two groups dependent upon whether or not the thoracic aorta was occluded (blinded to the operators) for 45 minutes during resuscitation. There was no difference between groups in return of spontaneous circulation. However, the occluded aorta group experienced statistically greater impairments in left ventricular function and systemic oxygen utilization in the post resuscitation period. The animals required more volume and vasoactive therapy for hemodynamic optimization than the non-occluded animals.

Open-Chest Resuscitation for Nontraumatic Arrest

Failure to resuscitate patients from cardiac arrest is a result of (1) a delay in the onset of CPR, (2) the use of less than optimal resuscitative techniques, or (3) the intractability of the underlying disease process. Acute coronary syndromes account for nearly 500,000 deaths yearly, and approximately 350,000 of these deaths are from sudden death prior to hospital admission. At present, <10% of CPR attempts conducted outside of hospital special care units result in survival.

The first human survivor of open-chest CPR was reported in 1901. This technique of resuscitation was the method of choice throughout the first half of the 20th century. In 1960, Kouwenhoven published favorable survival rates using closed-chest CPR in humans. After further refinement by Pearson and Redding, closed-chest CPR gradually became the preferred method. Due to its ease of application, the American Heart Association recommended closed-chest CPR as the initial treatment for patients experiencing cardiac arrest.

The goal of CPR is the restoration of coronary perfusion pressure, which is the prime determinant for return of spontaneous circulation as established in animal models. Paradis et al. [36] found that a minimal coronary perfusion pressure of 15 mm Hg is required in humans to obtain return of spontaneous circulation. Although a coronary perfusion pressure of 15 mm Hg does not guarantee return of spontaneous circulation, there is 100% failure of resuscitation if this coronary perfusion

pressure is not attained.

Although there are a limited number of human studies on open-chest CPR, the hemodynamic superiority compared to closed-chest CPR is compelling. Del Guercio et al.[37] measured cardiac output during both closed- and open-chest CPR with in-hospital cardiac arrest patients. Open-chest CPR produced a mean cardiac index of 1.31 L/min per m^2 compared to 0.6 L/min per m^2 during closed-chest CPR. Boczar et al.[38] further examined 10 patients unresponsive to closed-chest CPR, and measured coronary perfusion pressure during closed-chest CPR followed by open-chest CPR. The mean coronary perfusion pressure in the closed-chest group was 7.3 mm Hg versus 32.6 mm Hg in the open-chest group. All patients obtained a coronary perfusion pressure of at least 20 mm Hg at some time during their open-chest CPR phase. This easily surpasses the minimal coronary perfusion pressure required for return of spontaneous circulation.

Although the prime objective of basic and advanced CPR is return of spontaneous circulation, maintenance of cerebral viability is also essential. Neuronal viability appears to be threatened by a cerebral perfusion pressure of less than 30 mm Hg or a cerebral blood flow of less than 15 mL/100 g per minute. The brain tolerates low flow (5 to 10 mL/100 g per minute) better than no flow or "trickle" flow (less than 5 mL/100 g per minute). Animal studies show that closed-chest CPR provides cerebral blood flow of 15% to 30% of pre-arrest values under optimal circumstances. Sterz et al.[39] used xenon-enhanced computed tomography to show that open-chest CPR generated near-baseline cerebral blood flow. An earlier study using closed-chest CPR showed global cerebral blood flow of approximately 50% of control values.

At present, the precise indication for open-chest resuscitation of nontraumatic arrests is undefined, and the procedure is not considered standard of care. However, in the setting of cardiac arrest from hypothermia, open-chest CPR may be considered. Cardiopulmonary or veno-veno bypass is the most rapid method of core rewarming, but it is rarely available on an immediate basis. Open thoracotomy with mediastinal irrigation has been used successfully for severe hypothermia with cardiac arrest. With severe hypothermia, ventricular fibrillation is resistant to chemical or electrical conversion, and

prolonged periods of closed-chest compression must be provided during the long process of rewarming.

Patients surviving neurologically intact in previously published case reports of open-chest resuscitation with direct cardiac rewarming had 30 to 180 minutes of internal massage.[40] This proves the ability of open-chest CPR to provide prolonged hemodynamic support. It should be noted that case reports also exist in which closed-chest CPR was maintained for prolonged periods of time during successful hypothermic resuscitation.[41] The rate of core rewarming with this technique can be as fast as 8°C per hour, and it preferentially rewarms the heart and lungs first. Such a rewarming sequence prevents "rewarming shock," which may occur if the extremities or abdomen rewarm first, producing metabolic and circulatory demands that exceed the capacity of the heart. Sterile saline heated in a microwave oven to 40°C can be poured slowly over the heart and into the thorax. Performing a thoracotomy for hypothermic arrest does not preclude the subsequent use of cardiac bypass. If there are no major contraindications to bypass, such as head trauma, open-chest resuscitation with mediastinal rewarming can be performed while arrangements for cardiac bypass are made.

In the setting of normothermic cardiac arrest, open-chest CPR may be considered. In spite of demonstrated hemodynamic superiority in both animal and human models of open-chest versus closed-chest CPR outcome benefit is lacking. Long-term survival is rare when the duration of closed-chest resuscitation is *continuous* for more than 30 minutes without cardiac response. The probability of long-term survival for witnessed medical arrests is approximately 86% during the first 10 minutes of resuscitation.[42] This is reduced to 30% by 16 minutes and becomes less than 1% after 30 minutes.[43] [44] This temporal survival profile is predicated on basic life support beginning within 4 minutes and advanced life support being initiated within 8 minutes of cardiac arrest.

Timing of the cardiac arrest appears to be essential in determining the outcome benefit from open-chest CPR. Most myocytes can tolerate up to 20 minutes of normothermic ischemic anoxia in vivo. In a canine study, Kern et al.[45] demonstrated a negative association between survival and duration of untreated ventricular fibrillation exceeding 20 minutes prior to open-chest CPR.

There is a paucity of human data evaluating a temporal window of effectiveness. A common theme in the literature of human open-chest CPR is that the technique was performed on the majority of patients that had no flow (unwitnessed arrest or lack of bystander CPR), and prolonged downtimes before the initiation of open-chest CPR. The clinician may consider open-chest CPR as his or her initial therapy of choice in the subgroup of patients with witnessed in-hospital cardiac arrest without significant underlying comorbidities, those with mechanical lesions, or those for whom standard CPR may be ineffective. The prehospital cardiac arrest patient who remains without a perusing rhythm after the initial defibrillation has a poor prognosis with conventional treatment. Whether open-chest CPR has a role in the management of these patients is not established and awaits randomized control trials.

EQUIPMENT

The clinician must carefully consider the instruments to be included in a resuscitation thoracotomy tray. The inclusion of too many instruments makes the tray cumbersome and delays the procedure. Nonessential instruments are best kept available in the resuscitation room in case they are needed for specific repair (e.g., Foley catheter for stellate wound tamponade).

The following items are essential for a thoracotomy tray:

- Scalpel with attached No. 20 blade
- Mayo scissors (or long Metzenbaum scissors)
- Rib spreaders
- Liebsche knife (or sternal osteotome with hammer)
- 2 tissue forceps (10 in.)
- 2 Satinsky vascular clamps
- 3 Hegar needle holders (10 in.)
- 2-0 or larger silk sutures on large-curve needle
- Teflon patches
- Suture scissors
- Aortic tamponade instrument
- Skin stapler (6 mm staples)

The following items are optional for the tray and can be supplied as needed by an assistant:

- 6 towel clips
- 4 to 6 hemostats (curved and straight)
- Metzenbaum scissors
- Right-angled clamp
- Foley catheter (20 Fr, 30-mL balloon)—sterile saline/syringe
- Chest tube (No. 30, Argyle)
- 12 lap sponges or gauze pads
- 6 towels

In addition, functioning suction and sterile suction tips, antiseptic solution, sterile gloves, a defibrillator with internal paddles, and overhead surgical lights are needed in the resuscitation room. In the unlikely event that the patient awakens during the procedure, sedative and analgesic agents should be available for sedation, amnesia, and pain control.

PROCEDURE

Preliminary Considerations

In the urban prehospital setting in which a trauma center is less than 15 minutes away, patients with penetrating thoracic injuries should receive immediate transportation with the shortest possible field time. Two studies suggest that this "scoop-and-run" approach provides a better survival rate. [46] [47]

For all trauma victims presenting to the ED with hypotension, the initial working diagnosis must be volume depletion. Other possibilities should be rapidly excluded, including tension pneumothorax, cardiac tamponade, air embolism, and neurogenic or cardiogenic shock. A useful algorithmic overview of the approach to chest trauma is shown in Figure 18-3 .

Because a large amount of blood may be lost into the chest, an autotransfusion system should be available (see Chapter 28). The use of autotransfusion has several benefits.[48] The most important advantages are (1) immediate availability of compatible, warm blood; (2) significantly higher levels of 2,3-diphosphoglycerate (DPG) than in stored blood; (3) elimination of transfusion diseases; (4) less risk of exhausting the banked supply of the patient's blood type; and (5) decreased exposure to the inflammatory mediators in stored blood.

Airway Control During Thoracotomy

Patients undergoing resuscitative thoracotomy in the ED require assisted ventilation. Airway control is best obtained

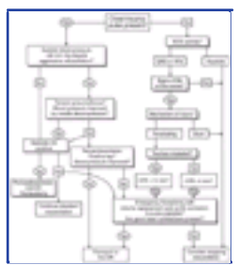

Figure 18-3 An algorithmic approach to chest trauma. QRS, organized electrical activity; VFib, ventricular fibrillation; (+)TAP, pericardial tap yielding blood; US, ultrasonography.

with standard orotracheal intubation, but exposure of the thoracic organs and surgical repairs or procedures may be hampered by frequent inflations of the left lung. Selective one-lung ventilation using a specialized double-lumen endotracheal tube is an established technique in thoracic surgery, but the availability of and experience with these devices is limited in the ED setting. The right lung often can be selectively intubated by blindly advancing a standard single-lumen endotracheal tube to a depth of 30 cm (measured at the corner of the mouth) in adult patients.[49] Although the left lung and the right upper lobe are not ventilated with the tracheal tube in this position, animal studies and preliminary data from humans suggest that selective right lung ventilation provides adequate oxygenation and ventilation for at least 60 minutes, thereby expediting the thoracotomy by minimizing the technical problems encountered by continual left lung inflation. [49]

Anesthesia and Amnesia

Comatose patients undergoing resuscitation may regain consciousness during a successful EDT, but the use of paralyzing agents may mask the return of awareness. The clinician must be cognizant of this phenomenon and administer adequate analgesia, amnestic, and muscle relaxing agents to the ventilated patient. Ketamine (2 mg/kg IV) and midazolam (0.10 to 0.2 mg/kg IV) have been recommended,[50] but ideally, agents such as etomidate with minimal effects on cardiovascular performance should be used. It would be prudent to administer anesthetic agents routinely if the paralyzed patient demonstrates perfusion during resuscitation.

Anterolateral Thoracotomy Incision

Prior to beginning the procedure, the patient should be intubated and manually ventilated. An assistant may pass a nasogastric tube, which will help differentiate the esophagus from the aorta (Fig. 18-4*A*), but the thoracotomy should not be delayed for this. If CPR is being performed, closed-chest compressions should be continued up to the point of the initial incision. Great care should be taken to avoid injury to any health care workers during performance of the incision. Universal precautions should be taken to avoid blood exposure and suction should be available to minimize contact with blood.

When the site of injury is unknown and the patient's status requires immediate intervention for possible intrathoracic injuries, a left anterolateral incision over the fifth rib with dissection into the fourth intercostal space provides the

Figure 18-4 Left anterolateral thoracotomy. *A,* Several towels or sandbags are placed under the left scapula and the arm is raised above the head. The patient should be intubated. A nasogastric tube can be inserted to facilitate differentiation of the esophagus from the aorta. *B,* The left anterolateral submammary incision is the suggested initial approach. Ideally the incision is made between the fourth and fifth ribs. Generally the incision is just inferior to the nipple (male) or along the inframammary fold (female). The incision begins on the sternum and extends to the posterior axillary line, where it should be deep enough to partially transect the *latissimus dorsi* muscle. *C, Dashes* indicate the incision site of the inframammary fold in women.

best access to the heart and great vessels. In the setting of cardiac arrest, time should not be taken to count the rib spaces. An incision just beneath the nipple in the male or along the inframammary fold in the female will approximate the fourth intercostal space (Fig. 18-4*B,C*). In patients with suspected left subclavian vessel injuries or aortic arch injuries, better exposure and control may be obtained through use of the third intercostal space.

The first sweep of the scalpel (No. 20 blade) should separate skin, subcutaneous fat, and the superficial portions of the *pectoralis* and *serratus* muscles. It is important to establish wide exposure from the outset by extending the skin incision past the posterior axillary line. To facilitate this action, quickly wedge towels or sheets under the left posterior chest and place the patient's left arm above the head (see Fig. 18-4*A*). Inadequate exposure, rib fractures, and additional delays occur when the skin incision is too limited.

Just before opening the pleura, ventilations should be stopped momentarily. This will allow the lung to collapse away from the chest wall. To enter the pleural space, a small incision is made in the intercostal muscles and one blade of the scissors is inserted. The intercostal muscles are then cut with the scissors to expose the thoracic cavity (Fig. 18-5*A*). The intercostal incision is placed just over the top of the fifth rib so as to avoid the intercostal artery. A scalpel may be used to divide the intercostal muscles but there is a greater risk of lung laceration. The use of Mayo or Metzenbaum scissors reduces this risk. Some surgeons prefer to begin the thoracotomy incision over the sternum, whereas others begin 2 cm lateral to the edge of the sternum, hoping to avoid the internal mammary artery. Should the internal

mammary artery be transected during the procedure, hemorrhage is generally minimal until after perfusion is reestablished. If bleeding actively, the internal mammary artery should be ligated or clamped.

After entering the pleural cavity and dividing the intercostals, the next step is to gain good exposure. This is accomplished by placing a chest wall retractor (rib spreader) between the ribs with the handle and ratchet bar directed downward (Fig. 18-5*B*). If the retractor is placed with the handle up, the ratchet bar will prevent extension of the incision into the right chest. Ribs may be broken during spreading, so care must be taken to avoid being cut on the sharp bone edges. If massive hemothorax is encountered, clots should be removed manually, blood suctioned, and towels used to absorb any blood that spills from the chest. When the site of injury is to the right of the heart and cannot be reached, a transsternal extension into the right chest is performed with a Liebsche knife or a sternal osteotome.

Pericardiotomy

If cardiac arrest has occurred, the question of whether to open the pericardial sac arises. If the myocardium cannot be visualized, the pericardium should be opened. However, in some cases, the myocardium can be evaluated through the intact pericardium such as a nontraumatic cardiac arrest. Nonetheless, if there is no other obvious injury in the chest and a cardiac injury is possible, the pericardium should be opened routinely,

Figure 18-5 *A*, When entering the pleural cavity, it is important to make the incision on top of the rib to avoid the intercostal vessels. Once a hole has been made into the pleural space, the incision is widened with blunt scissors by cutting the intercostal muscles. The fourth and fifth fingers of the operator's free hand are inserted into the pleural space to fend off the lung as the scissors divide the intercostal muscle. Momentary cessation of ventilation will collapse the lung. Alternatively, the right mainstem bronchus can be intubated, which permits continuous ventilation and oxygenation without inflating the left lung into the operating field. *B,* The incision must always be carried to the posterior axillary line to maximize exposure. The rib spreader should be placed with the handle laterally. Because it can be difficult to determine if tamponade has occurred using visual inspection alone, the pericardium must be opened to definitively determine if tamponade is present. Using tissue pick ups with teeth, the operator must press hard against the pericardium to engage it within the tissue pick ups. The incision is started near the diaphragm and anterior to the phrenic nerve, which is easily identified as a thick tendon-like structure. Using blunt scissors, the incision is carried to the root of the aorta.

because *it may be difficult to definitively rule out pericardial tamponade by visual inspection alone*.

If the clinician is confident that tamponade is not present, it is usually best to leave the pericardial sac closed while other life-threatening injuries are addressed. Opening the pericardium increases the risk of complications. For example, any delay in beginning cardiac compressions will add to the risk of cerebral damage. The myocardium or a coronary vessel may be injured, or the left phrenic nerve may be cut. If there has been previous pericardial disease, adhesions may be present. Attempts to separate these adhesions rapidly may result in tears of the atrial or right ventricular wall. The incidence of traumatic rupture of the atria or the right ventricle during massage is greater when the pericardium is open. With an intact pericardium, pressure is distributed over a larger area and the pericardial fluid seldom allows the compressing fingers to remain in one spot for a prolonged period.

Pericardiotomy is required if tamponade is present or suspected. This is performed in a location anterior and parallel to the left phrenic nerve. The incision begins near the diaphragm to avoid possible injury of the coronary arteries. The pericardial sac is lifted with forceps, and scissors are used to make a small hole in the sac; the scissors are then used to extend the incision in a cephalad direction along the anterior pericardium. The final incision should extend from the apex of the heart to the root of the aorta. When the pericardium is under tension, it may be difficult to grasp the pericardium with forceps. In that case, sharp, straight Mayo scissors are used to divide the pericardium by layers. If the heart is in arrest, speed is important, and sharp scissors should be used to "catch" the pericardium and to start the pericardiotomy. To do this, the point of the scissors is held almost parallel to the surface of the heart with enough pressure to create a wrinkle in the pericardium that can be punctured as the scissors are moved forward. Moderate pressure must be used to puncture the fibrous pericardium. The sudden "give" that occurs when the pericardium opens may result in a laceration of the myocardium if the point of the scissors is unnecessarily angled toward the heart. Clots of blood are removed from the pericardial sac by the sweeping motion of a gloved hand or with sterile lap sponges or gauze pads.

Direct Cardiac Compressions

Three techniques for cardiac compression have been advocated: one-handed compression, one-handed with sternal compression, and two-handed (bimanual) compression (Fig. 18-6). The *one-handed compression* method is performed with the thumb placed over the left ventricle, the opposing fingers over the right ventricle, and the apex of the heart resting in the palm of the hand. The *one-handed with sternal compression* method also is performed with the fingers flat. The fingers of the hand are held tightly together to form a flat surface over the left ventricle while compressing the heart up against the sternum. To perform the *two-handed compression* method, the left hand is cupped and placed over the right ventricle. The

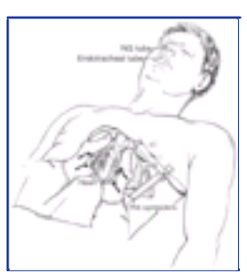

Figure 18-6 Two-handed method of cardiac massage. The ventricles are compressed toward the interventricular septum. Note how the hands flank the left anterior descending artery, which overlies the septum. Avoid using excessive finger *tip* pressure or lifting the heart, which slows ventricular filling by distorting the soft atrial caval junction.

fingers of the right hand are held tightly together to form a flat surface supporting the left ventricle. This flat surface compresses the heart against the cupped surface of the left hand. Of these three, the bimanual technique is consistently superior, and whenever possible, it is the preferred method. [51]

A difference of opinion exists regarding the optimal rate at which the heart should be compressed. Most recommend a rate of 50 to 60 compressions per minute; however, no physiologic data support such a recommendation. Johnson and Kirby studied the relationship of compression rate to cardiac output and blood pressure and found these parameters to be directly related. [52]

It is important to remember the following points while performing cardiac compression: (1) Finger *tip* pressure should be avoided at all times. Compression is performed using the entire palmar surface of the fingers. (2) Whichever technique is used, the force of compression should be perpendicular to the plane of the septum. The anterior descending coronary artery is located over the interventricular septum and is a helpful landmark to orient proper hand placement. It is clearly seen, with or without the pericardium open. (3) The fingers should be positioned so that the coronary arteries will not be occluded. (4) Venous filling of the heart is especially sensitive to changes in position. It is important to maintain a relatively normal anatomic position of the heart to *prevent* kinking of the vena cava and pulmonary veins. The heart should not be angled more than 30 degrees into the left chest. (5) It is also essential to completely relax the heart between compressions. If present, intra-arterial pressure monitoring is of tremendous value for assessing the consistency and effectiveness of compressions.

Control of Hemorrhagic Cardiac Wounds

One may partially control active bleeding from ventricular wounds by placing the finger of one hand over the wound while using the other hand to stabilize the beating heart. This maneuver buys time while the clinician prepares to repair the injury. The use of surgical staples for ventricular wound closure is an extremely rapid method for controlling hemorrhage (Fig. 18-7).[53] This technique may be particularly useful with large or multiple lacerations. Another advantage is that stapling does not expose the operator to the risk of a needle stick. Macho and coworkers reported a 93% success rate in temporarily controlling hemorrhage in 28 patients (33

lacerations) with penetrating injuries to both atria and ventricles using a standard skin stapler with wide (6 mm) staples placed at 5-mm intervals (Auto-Suture 35W, U.S. Surgical Corp., Norwalk, CT).[54] Control was rapid as 20 patients had hemorrhage control in less than 1 minute and less than 2 minutes in an additional six. The rotating long neck of the Ethicon Proximate Quantum Skin Stapler (Model PQW-35, Ethicon, Inc., Somerville, NJ) also is advantageous for obtaining proper orientation of the staples during placement. The successful use of staples has been duplicated in other centers. The staples may be left in place and reinforced or replaced on further wound exploration in the operating room.

Alternatively, the wound can be repaired by placement of several horizontal mattress sutures under the tamponading finger (Fig. 18-8). Nonabsorbable 2-0 silk sutures are customarily used. Smaller sutures should *not* be used, and nylon sutures should be avoided. Some clinicians prefer to use even larger silk sutures, such as No. 1 or 2 (note that this is *not the same as* 0 [1-0] or 0-0 [2-0] sutures). When multiple sutures are needed, they should all be in place before they are tied. This allows for a rapid and equal distribution of wound tension, which prevents tearing of the myocardium. [55] Passing the suture through Teflon pledgets also prevents the suture from cutting through the myocardium. It is especially important to use Teflon pledgets for reinforcement when the myocardium has been weakened by the blast effect of a bullet.[56] A readily available alternative to Teflon pledgets is the use of small rectangles of pericardial tissue cut from the opened pericardium.

With large wounds that cannot be palpably controlled, an incomplete horizontal mattress suture should be placed on either side of the wound (Fig. 18-9). The free ends are then crossed to stop the bleeding. The actual reparative sutures can then be accurately placed. It must be stressed that suturing the myocardium requires good technique. Excessive tension may tear the myocardium and aggravate the situation. Keys to success include the use of an appropriate-sized suture, a generous "bite" with the needle, and the application of only enough tension necessary to control bleeding.

If exsanguinating hemorrhage is not controlled by the aforementioned methods, temporary inflow occlusion can be used. Inflow occlusion may be applied intermittently for 60 to 90 seconds. During occlusion the heart shrinks, hemorrhage is controlled, and sutures can be placed in a decompressed injury. Two techniques that are useful are vascular clamping of the superior and inferior vena cava for partial inflow occlusion, [57] and the Sauerbruch grip (Fig. 18-10) for occlusion of the vena cava between the ring and the middle finger of the left hand for partial inflow occlusion. [58] The Sauerbruch grip can be performed quickly with the added advantage of cradling and stabilizing the heart during repair of wounds over either

Figure 18-7 Technique of cardiac stapling to temporarily control hemorrhage. An assistant can approximate tissues with fingertip pressure or, as illustrated, two half-horizontal sutures can be used to approximate the wound edges and reduce bleeding. A skin stapler with wide (6 mm) staples is used to place staples 5 mm apart. This technique may be used for atrial and ventricular lacerations. Following stabilization of the patient's condition, the wound is revised in the operating room.

ventricle or the left atrium. The Sauerbruch grip will only interfere with the repair of wounds involving the right atrium.

Insertion of a Foley catheter (20 Fr with a 30-mL balloon) through a wound is another technique for temporarily controlling hemorrhage. [59] Following insertion of the catheter, the balloon is inflated, the catheter is clamped to prevent air embolism, and gentle traction is applied (Fig. 18-11). Enough traction is applied to slow the bleeding to an acceptable level for visualization and repair. Attempts to achieve complete hemostasis with excessive traction may pull the catheter out and potentially enlarge the wound. The balloon will effectively occlude the wound internally. When repairing the wound, the operator must be careful with the suture needle to prevent rupturing the balloon. A purse string suture is commonly used. Temporarily pushing the balloon into the ventricular

Figure 18-8 *A*, Technique of repair. Multiple horizontal mattress sutures are placed 6 mm from the wound edge before tying. The wound is closed just enough to stop the bleeding. Teflon pledgets are used for reinforcement. Closure without pledgets incurs the risk of sutures ripping through the contracting myocardium. Similarly, the use of simple vertical sutures should be discouraged because of the risk of suture dissection through the myocardium. *B,* For repairs near a coronary artery, care is taken to pass the suture under the artery. Note that rectangles of pericardial tissue may be substituted for ready made Teflon pledgets.

lumen during needle passage is important to prevent rupture. Alternatively, the balloon can be temporarily deflated during suture placement. It is important to use normal saline when inflating the balloon. Use of air will result in air embolism if the suture needle ruptures the balloon.

Foley catheters have several advantages over other methods of controlling cardiac wounds. With the digital method,

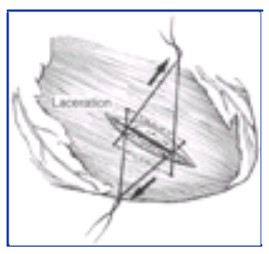

Figure 18-9 Hemorrhage control using two widely placed incomplete mattress sutures. An assistant then crosses the two "half-horizontal" sutures to bring the wound edges into apposition. By controlling the hemorrhage in this manner, the assistant's hands are outside of the operative field, fully exposing the wound edges. This facilitates a more orderly closure of the wound. Following repair of the wound, the sutures may either be removed or tied to each other.

Figure 18-10 Sauerbruch maneuver: the *method of choice* for reducing heavy bleeding from cardiac wounds. Venous inflow occlusion is achieved by using the first and second or second and third fingers as a clamp.

the fingertip will often slip if there is a strong heartbeat, the wound cannot be visualized during repair, and digital pressure significantly interferes with cardiac massage. Intermittent total venous inflow occlusion is an effective method of controlling bleeding and decompressing the heart, but such control will be at the expense of a poor cardiac output. Comparatively, the Foley catheter causes less cardiovascular interference, although inflation near the base of the ventricle may obstruct blood flow. Attempts to elevate the heart for control and repair of posterior cardiac wounds will often result in cardiac arrest by reduction of both venous and arterial flow. With posterior injuries, one cannot continuously view the wound for digital control of bleeding. Use of a Foley catheter does not require continued viewing after initial placement. If bleeding can be controlled, repairs in this location should await full volume expansion or cardiopulmonary bypass. [60] Regardless of location, the most valuable feature

Figure 18-11 Serial illustration. Gentle traction on an inflated Foley catheter will control hemorrhage and allow easy repair. The balloon is inflated with saline, and care is taken to avoid rupturing the balloon with the suture needle. This technique is particularly useful with injuries of the inferior cavoatrial junction, with posterior wounds, and during cardiac massage. Volume loading can be obtained by infusion of blood or crystalloid solutions through the lumen of the catheter. Care should be taken to avoid an air embolus through the lumen of the catheter during placement.

of Foley catheter use is the ability to control hemorrhage without interfering with cardiac compression.

Deliberate *fibrillation* (to halt myocardial contractions) should be considered as a last resort for repair of difficult wounds of the ventricle or the proximal aorta. Elective cardiac arrest is best tolerated if there is adequate blood volume and oxygenation before fibrillation. To induce fibrillation, the internal cardiac paddles are placed perpendicular ("on-edge") to the surface of the heart and are discharged at 20 J (Fig. 18-12).[57] This produces a local area of depolarization. The resulting disparity in relative refractory periods sets up a circus movement, which produces ventricular fibrillation. The heart should be massaged intermittently during repair, and the duration of fibrillation should not exceed 3 to 4 minutes.

Defibrillation is accomplished while the internal paddles are firmly pressed *tangentially* over the right and left ventricles. Following repair, the epicardium is often dry and should be moistened with saline to improve electrical conduction. An energy level of 20 J is used. If the initial attempt is unsuccessful, repeated shocks at the same setting should be used. Higher energy levels can cause myocardial necrosis. [61] Defibrillation through an intact pericardium also should begin with 20 J. If unsuccessful, the shock should be repeated once and then increased to between 40 and 60 J. Should internal paddles *not* be available, defibrillation using standard paddles placed *on the chestwall* is recommended.

Management of the wounded heart that has spontaneously arrested is controversial. Some clinicians have recommended a rapid repair of ventricular wounds while the heart is arrested. Others consider immediate cardiac massage and reversal of cardiac arrest to be more important. Immediate cardiac massage to maintain blood flow is probably the best approach. When cardiac arrest occurs, physiologic reserves have been depleted, and a delay for repair during arrest would only diminish the chance of a successful resuscitation.

Wounds of the atria are initially managed with partial occlusion clamps (Fig. 18-13). Because of the thin structure and instability of the atrial wall, digital pressure will not effectively stop bleeding. Injuries near the caval-atrial junction are not amenable to clamping. In this location a Foley catheter should be used to tamponade the wound (Fig. 18-14).[59] Care must be exercised to avoid obstruction of atrial filling with the inflated balloon. During wound closure, the catheter should

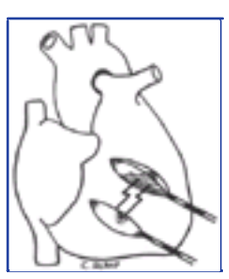

Figure 18-12 Technique for elective fibrillation: 20 J (watt-sec) is delivered through internal defibrillating paddles placed perpendicular to the epicardium. Coronary vessels should be avoided during paddle placement.

be pushed away from the ventricular wall or the balloon temporarily deflated to avoid rupture of the balloon. Skin staples also have been used for closure of atrial wounds. [54]

Wounds of the septa, valves, and coronary arteries require definitive repair in the operating suite. Hemorrhage from a coronary artery can generally be controlled with digital pressure. Ligation of a coronary artery should be avoided when possible.

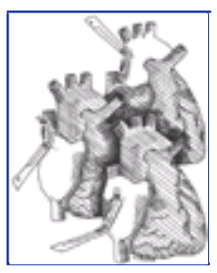

Figure 18-13 Use of a partial occluding clamp in different locations for control of bleeding and subsequent repair.

Control of Hemorrhagic Great Vessel Wounds

Wounds of the great vessels can be controlled with digital pressure or partial-occlusion clamps. Exsanguinating hemorrhage from the left subclavian artery can be prevented by cross-clamping of the intrathoracic portion of the artery. Cross-clamping of the right subclavian artery is very difficult. For injuries of this vessel, compression with laparotomy pads in the apex of the pleura from below, and the supraclavicular fossa from above (Fig. 18-15), will prevent further bleeding as the patient is stabilized and moved to the operating suite. [53]

Large or difficult vena caval injuries may be controlled with a temporary intravascular shunt to maintain venous return while providing vascular isolation of the injured segment.[62] This is a difficult and time-consuming procedure that is best done in the operating room, if the patient survives long enough.

Occasionally, fluid resuscitation can be accomplished by infusing fluid directly into the right atrium. The usual technique for placing atrial catheters using a purse string suture in the right atrium has several disadvantages. First, it is relatively time-consuming for a patient in cardiac arrest, and cardiac massage is often interrupted to allow suture placement. In addition, the suture may tear the atrial appendage, the suture holes are frequently associated with fluid leaks through the thin atrial wall, and the catheter can slide out of place. Samuelson described an innovative technique utilizing an umbilical cord clamp with a center hole (Fig. 18-16*A*). A standard umbilical cord clamp (Hollister, Inc., Libertyville, IL) is

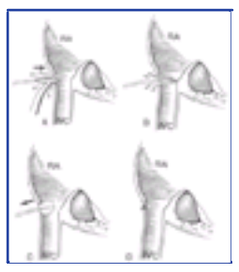

Figure 18-14 Wounds of the inferior cavoatrial junction are difficult to manage with simple vascular clamping. *A–D,* Use of a Foley catheter provides satisfactory control.

Figure 18-15 Cross-clamping for control of subclavian bleeding is difficult and time-consuming. Compression with laparotomy pads in the apical pleura from below and the supraclavicular fossa from above will control hemorrhage while the patient's condition is stabilized and the patient is transported to the operating room.

modified by drilling a hole through the center to match the size of standard IV tubing or whatever catheter is to be used. [63] The diameter of the hole should hold the catheter firmly enough to prevent slippage. These clamps, by necessity, must be prepared in advance and gas sterilized.

To place a catheter using this technique, the right atrial appendage is gently grasped between the left thumb and index finger. Scissors are used to create a small opening in the atrial appendage, and a previously flushed catheter is inserted into the right atrium. The umbilical cord clamp is placed over the catheter at the edge of the appendage and snapped shut (Fig. 18-16*B*). The cord clamp holds the catheter securely, provides good hemostasis, and does not interfere with the operative field.

Aortic Cross-Clamping

When the systolic pressure cannot be raised above 70 mm Hg, temporary occlusion of the descending thoracic aorta can maintain myocardial and cerebral perfusion (Fig. 18-17).[35] Kravolich et al. suggests that the benefit of significant improvement in coronary perfusion pressure may be overstated since both occluded and non-occluded groups attained the necessary increase in this parameter and return to spontaneous circulation. Selective clamping is necessary when the aorta has been injured with blunt trauma (Fig. 18-18). Aortic occlusion has a limited role in controlling hemorrhage below the diaphragm. When there is a tense abdomen with massive hemoperitoneum, aortic cross-clamping is clearly beneficial when applied just before laparotomy. This has been referred to as *prophylactic cross-clamping* to prevent a sudden drop in blood pressure when the abdomen is decompressed. [64] As a preoperative procedure, cross-clamping should be applied when the systolic pressure is less than 80 mm Hg in the setting of a tense abdomen.

Figure 18-16 *A*, Modified umbilical cord clamp. *B,* Modified umbilical cord clamp securing a catheter in the right atrial appendage.

The aorta lies immediately anterior to the vertebrae, actually lying on the vertebral bodies themselves. The esophagus lies anterior and slightly medial to the aorta. To expose the descending aorta, the left lung is retracted in a superomedial direction by an assistant. To achieve adequate exposure, it is sometimes necessary to divide the inferior pulmonary ligament (Fig. 18-19). The aorta can be quickly identified by advancement of the fingers of the left hand along the thoracic cage toward the vertebral column. On some occasions, the operator may choose to have an assistant simply occlude the aorta with digital pressure. Because both the aorta and esophagus are covered on their anterolateral surface by mediastinal pleura, the pleura must be opened and the aorta bluntly dissected away from the esophagus prior to clamping. To locate the aorta, use a DeBakey aortic clamp or a curved Kelly clamp for blunt dissection and spread open the pleura above and below the aorta (Fig. 18-20). The esophagus, which lies medially and slightly anteriorly, is separated from the vessel. It may be difficult to separate the esophagus from the aorta by feel in a hypotensive or cardiac arrest situation. A nasogastric tube passed from above may help identify the esophagus. When the aorta is completely isolated, the index finger of the left hand is flexed around the vessel and a vascular clamp is applied with the right hand. The brachial blood pressure should be checked immediately after the occlusion. If the

Figure 18-17 Manual cardiac massage and cross-clamping of the aorta to increase coronary and cerebral perfusion selectively.

systolic pressure is more than 120 mm Hg, the clamp should be slowly released and adjusted to maintain a systolic pressure of 120 mm Hg. [34]

Given the need for speedy intervention, the simplest and most desirable approach to aortic occlusion is to have an assistant digitally compress it or use the aortic tamponade instrument (Fig. 18-21). The application of vascular clamps risks significant complications, including injury to the vessel or adjacent structures, inadvertent dislodgment, or inadequate occlusion as a result of improper application. The aortic tamponade instrument, however, may be applied blindly to the vertebral column, permitting safe, quick, and complete aortic occlusion. [65] This technique may be most prudent when isolation of the aorta is difficult. The instrument's unique shape allows it to remain in place and to provide atraumatic occlusion with little interference in the operative field compared to digital compression. The degree of occlusion can be varied by the amount of pressure exerted by the operator.

Potential complications of aortic cross-clamping are multiple: ischemia of the spinal cord, liver, bowel, and kidneys. In addition, iatrogenic injury of the aorta and the esophagus may occur. Failure to monitor blood pressure every 60 seconds during aortic occlusion may result in cerebral hemorrhage or

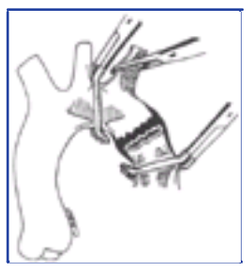

Figure 18-18 Traumatic rupture of the aorta. Three clamps are required for control. Back-bleeding will occur if fewer than three clamps are used.

Figure 18-19 Adequate exposure of the descending aorta may require division of the inferior pulmonary ligament.

left ventricular failure if pressure elevation is excessive. Fortunately, these complications are infrequent. In a report of 12 patients surviving EDT with cross-clamping

for as long as 60 minutes, no lasting impairments of renal, myocardial, or neurologic function were noted. [66] Whenever possible, the aorta was unclamped for 30 to 60 seconds every 10 minutes to increase renal perfusion. Final release of the aorta is always performed gradually.

INTERPRETATION AND HEMODYNAMIC MONITORING

Following EDT, the systolic blood pressure after the first 30 minutes of resuscitation may be used as a decision point for further treatment. A report of EDT for blunt and penetrating trauma demonstrates the relationship between blood pressure at 30 minutes and eventual outcome. [11] Of the 146 cases reviewed, 45 patients (31%) were transferred to the operating room following initial resuscitation and aortic cross-clamping when necessary. For those patients who survived with full neurologic recovery, the average systolic blood pressure after the first 30 minutes of resuscitation was 110 mm Hg. In those who were long-term survivors but had significant brain damage, the average systolic blood pressure was 85 mm Hg. No survivals were recorded when the mean systolic blood pressure was less than 70 mm Hg. Thus, the blood pressure response to EDT appears to be predictive of survival. For patients who remain lifeless with systolic blood pressures below 70 mm Hg despite control of hemorrhage, volume replacement, and cross-clamping for 30 minutes, Moore et al. [11] recommend that heroic measures be discontinued. Transfer of these patients to the operating room for definitive repair of these mortal wounds would be futile.

Figure 18-20 *A*, Identification of the aorta: in the posterior mediastinum the aorta lies directly anterior to the vertebral bodies. The esophagus is anterior and slightly medial to the aorta. In the lower thorax, both are covered on the anterolateral surface by mediastinal pleura, which must be dissected prior to isolating the aorta for cross-clamping. *B,* Aortic cross-clamping: Using blunt dissection, one spreads the pleura above and below the aorta. The vessel should be fully mobilized and clearly separated from the esophagus before clamping. It may be difficult to differentiate the aorta from the esophagus. The aorta is the more posterior structure and is in contact with the vertebral bodies. Passage of a nasogastric tube from above will often aid the rapid identification of the esophagus.

COMPLICATIONS

A variety of significant complications occur in patients surviving EDT, but most of these are related to the primary injury rather than the thoracotomy. Proper performance of the technique should avoid injury to intra-thoracic structures. Particular attention must be paid to the position of the left phrenic nerve and coronary arteries during pericardiotomy and repair of cardiac wounds. Infection of the wound and thoracic cavity is always a concern given the fact that the procedure is performed out of the operating room, under emergent conditions, and often by clinicians relatively inexperienced in the technique. Surprisingly, serious infection is uncommon. In a combined series of 142 EDTs, there were no reports of wound infections. It should be noted that most patients received antibiotics just before or during the procedure. As a general rule, excessive attention to antiseptic skin preparation should be avoided as it may unnecessarily delay performance of the procedure.[67] Antibiotics should be administered as soon as possible.

Another potentially serious complication of EDT is injury or disease transmission to health care workers. In an emotionally charged environment in which many clinicians are attempting to perform life-saving surgery under the harshest of conditions, it is easy to suffer a needle stick or scalpel or scissor injury. Seroprevalence of human immunodeficiency virus (HIV) in U.S. EDs is estimated to range from 2% up to 6% to 9% in urban areas.[68] Tardiff et al.[68] noted an HIV-positive rate of 7.2% in their study of trauma patients presenting to their urban ED.

Occupational exposure to both hepatitis B and C is of concern to health care workers, as well. Sloan et al. [69] found a 3.1% incidence of hepatitis B in trauma patients brought to their inner-city ED. Hepatitis C is now the most common viral hepatitis seen in health care workers since the advent of the hepatitis B vaccine. Approximately 2200 health care workers per year seroconvert following occupational exposure. One urban ED reported an 18% prevalence of hepatitis C in its ED patients.[70] Additionally, patients with penetrating trauma appear to be of greater risk of any type of occult infection. Clearly, the risk of exposure to staff must be kept in mind, and universal precautions should be rigorously followed. In addition, clinicians performing this procedure must be constantly attentive to their own safety and those of their coworkers. Although EDT must be performed rapidly in order to be of value to the patient, excessive haste is not warranted if it threatens the health of members of the medical team.

CONCLUSION

The growing incidence of penetrating trauma coupled with advances in prehospital care has increased the number of patients arriving to the ED requiring advanced resuscitation. For selected patients, an EDT may be life saving, although survival rates are minimal. Resuscitative thoracotomy is

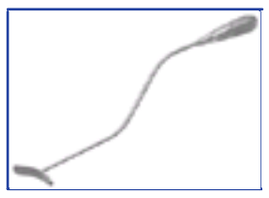

Figure 18-21 The use of a Conn aortic compressor is the method of choice for aortic occlusion because it is fast, does not interfere with the operative field, and is associated with minimal risk of injury. Alternatively, the more awkward technique of direct digital occlusion can be used. *(Courtesy of Pilling Company, Ft. Washington, PA.)*

usually attempted only in major trauma centers where surgical backup is immediately available or in smaller hospitals where a plan for post-thoracotomy care has been developed. The mechanism of injury in conjunction with the presence or absence of vital signs both at the scene and in the ED should be considered before an EDT is performed. Victims of penetrating trauma who had any vital signs at the scene are potential candidates for resuscitative thoracotomy and have a chance of survival. This procedure is most effective when it is used to prevent, rather than treat, a cardiac arrest. In contrast, the survival rates for victims of blunt trauma are negligible. With blunt trauma, resuscitative thoracotomy generally should be considered only when vital signs are still present on arrival at the emergency care unit.

Factors closely associated with patient outcome following resuscitative thoracotomy include: mechanism of injury; electrocardiographic activity; presence or absence of vital signs including neurologic function at the scene and on ED admission; and systolic blood pressure after aortic cross-clamping, if performed. The following points should be considered: (1) blunt trauma victims who lose their vital signs en route to the ED rarely survive despite thoracotomy, and they generally should not be candidates for resuscitative thoracotomy, (2) penetrating trauma victims who lose their vital signs en route to the ED may still survive and should receive an immediate thoracotomy, (3) further efforts generally should be discontinued following thoractomy when traumatic arrest patients do not exhibit cardiac activity or tamponade, (4) consider discontinuing further efforts following thoracotomy if the systolic pressure cannot be raised above 70 mm Hg after 30 minutes of maximum management.

Debate regarding *who* should perform an EDT is not necessary. It stands to reason that whoever performs this resuscitative procedure must be credentialed for the technical and critical care aspects of patient management. It is currently *not* a standard of care that all EDs have the capability of performing an EDT in the absence of surgical backup. Because aortic cross-clamping is only temporizing and should not exceed 30 minutes, rapid transfer of the thoracotomy patient to the operating room is desirable. Whenever possible, a plan of chest wound management and post-thoracotomy critical care should be established with the emergency clinician's surgical backup. With such a plan, a team approach to resuscitation and, hence, optimal patient care, is possible.

Section IV - Vascular Techniques and Volume Support

Chapter 19 - Pediatric Vascular Access and Blood Sampling Techniques

Marie M. Lozon

The tasks of sampling blood and obtaining vascular access in an infant or child can challenge and frustrate even the most skilled emergency clinician. In some instances, venous access simply cannot be obtained within the desired time frame, making vascular access one of the most difficult clinical procedures during resuscitation and treatment of the critically ill child. The use of invasive monitoring techniques with arterial and central venous catheters is commonplace in contemporary pediatric emergency and intensive care, but simple blood sampling and venous access remains a formidable challenge in the emergency department (ED).

This chapter reviews the basic principles and techniques of blood sampling, as well as selection and placement of intravenous (IV) and intra-arterial catheters in infants and children, including those placed in the central circulation. The use of umbilical catheters in newborns is also reviewed. Although rarely required, emergency cutdown is occasionally life saving, and a section of the chapter is devoted to this technique.

PATIENT PREPARATION AND RESTRAINT

Fear and anticipation of pain associated with procedures or injections makes the hospital experience traumatic for children. Before beginning any painful procedure in a child, the procedure itself and the reasons for it should be explained to the parents. In children capable of understanding, the procedure should be explained in developmentally appropriate language before starting and prior to each successive step. The use of deceptive phrases such as "This won't hurt" should be avoided. A gentle, honest explanation that the procedure will hurt a bit and "it is okay to cry, but not to move" will provide realistic expectations for the child and set limits as well. Depending on the situation, the parents should have the option to remain with their child during the procedure. [1] If they remain in the room, their role should be solely to provide comfort to the child and not to assist in any potentially painful procedure. Distracting the child with simple conversation regarding school, friends, hobbies, pets, or television shows can also decrease the level of the child's anxiety. Despite their seeming composure, the potential for parents to faint at the site of blood or needles should always be addressed. Parental injury under such circumstances can be a source of litigation against the clinician.

The success of blood sampling or obtaining vascular access is dependent on proper positioning and restraint of the patient. In most cases, this requires the assistance of at least one other staff person. For most procedures this entails restraint of the extremity a joint above and below the intended insertion site. Although most of these procedures can be performed quickly, sometimes a significant amount of time is required to complete venipuncture or cannulation in a neonate, during which time he or she can become cold from being exposed on the examination table (especially if very ill). Overhead lights or a warming bed are very useful for this age group to prevent accidental hypothermia.

In recent years, products to provide topical anesthesia prior to needle sticks have become available. Parents are often aware of these products and may ask for them for their children. While theoretically attractive, such measures are rarely practical in the acute care setting. In an emergency situation, waiting even a few minutes for IV access may not be possible, but in the appropriate clinical setting, spending the additional time to relieve pain and anxiety in certain patients is warranted. The topical use of lidocaine-prilocaine (also known as entectic mixture of local anesthetics or EMLA) cream has a proven track record for relieving pain associated with needle puncture.[2] However, optimal analgesia requires application 1 hour prior to the procedure, which may not be practical in some clinical settings. Newer products such as ELA-max cream (4% or 5% liposomal lidocaine) (Ferndale Laboratories, Ferndale, MI), which has a faster time to skin anesthesia than EMLA (30 minutes vs. 60) may be better suited for ED use.[3] Another advantage of ELA-max is its lack of the prilocaine (the active ingredient in EMLA), which has been associated with rare cases of methemoglobinemia. Liquid lidocaine iontophoresis uses small electrodes to deliver a low level of current, which causes drug molecules to rapidly pass through tissues (Numby Stuff electrodes with a Phoresor II, Iomed, Inc., Salt Lake City, UT). [4] This technique is quite useful to relieve the pain of needle sticks, but setup time and training make it less attractive than simple cream application for ED use. Iontophoresis electrodes may cause a mild stinging and warmth, which older children tolerate well, but may frighten younger ones. [5] [6] Iontophoresis works faster than EMLA,[7] with times to skin anesthesia as rapid as 13 to 20 minutes, but has not been compared to ELA-max. It has been demonstrated that triage nurses can prospectively identify children likely to need venipuncture and apply anesthetic cream early for increased efficiency. [8] Many of the more invasive and technically difficult procedures described in this chapter are performed in emergency situations, where sedation of the critically ill child may not be appropriate. Occasionally, however, sedation may be called for to reduce the trauma to the child and make the procedure easier to perform (see Chapter 34).

BLOOD SAMPLING TECHNIQUES

Capillary Blood Sampling

Indications and Contraindications

Capillary blood sampling, or heel stick puncture, is a frequently used technique to obtain blood samples in young infants. In older children and adults, this technique is often used to obtain blood samples from the finger, toes, and ear lobe when repeated measurements, such as blood glucose, are needed. Capillary blood sampling is most often indicated in a young infant when an adequate sample of blood can be obtained by the heel stick puncture technique and when an alternative technique is not practical. It is an option for obtaining "arterialized" blood for blood gas analysis when arterial access is unavailable, as in many chronically ill neonates and young infants, or when the clinician is not comfortable obtaining a percutaneous arterial sample. Noninvasive

monitoring techniques such as pulse oximetry (see Chapter 2) have reduced the frequency with which these samples must be taken.

Sampling from an area of local inflammation or hematoma should be avoided. Also, repetitive sampling from the same site may induce inflammation and subsequent scarring and hence should be avoided. In general, heel stick sampling is not ideal for blood gas analysis (1) when the infant is hypotensive, (2) when the heel is markedly bruised, or (3) when there is evidence of peripheral vasoconstriction. Capillary blood does not always produce an accurate analysis of arterial P_{O_2} . When the capillary P_{O_2} is greater than 60 mm Hg, the arterial P_{O_2} may be considerably higher, with possibly adverse consequences to infants receiving supplemental oxygen. In this situation, the use of either transcutaneous oxygen saturation or a transcutaneous P_{O_2} monitor may allow adjustment of the inspired oxygen concentration until either an arterial P_{O_2} or a repeat capillary P_{O_2} can be obtained. [9]

Equipment and Setup

The necessary equipment for capillary blood sampling is shown in Table 19-1 . A 3-mm lancet (Becton-Dickinson, Rutherford, NJ) or automated disposable incision device (e.g., Tenderfoot, Surgicutt) should be used to perform this procedure; a scalpel blade should not be used. The use of the former devices will prevent the puncture from penetrating more than the maximum safe distance. Blood collection is performed using either heparinized capillary tubes or 1-mL Microtainer tubes with a collector attachment (Becton-Dickinson, Rutherford, NJ). If capillary tubes are used, a clay or wax sealer will be needed to close off one end.

Technique

Although capillary blood sampling may be performed by the finger stick or heel stick methods, the latter will be described. The recommended sites for heel stick puncture are the medial-most and lateral-most portions of the plantar surface of the heel (Fig. 19-1), but not on the curve of the heel. [10] [11] This avoids penetration of the calcaneus and the risk of osteochondritis. Cautiously prewarming the foot for 5 minutes using a warm towel will produce hyperemia and will enhance blood flow. The foot is immobilized in a dependent position with one hand. After the heel is cleansed with alcohol and allowed to dry, the skin is punctured with the lancet (Fig. 19-2*A*). Allowing the alcohol to dry will avoid falsely high glucose levels in the specimen. Although it is tempting and commonly done, *squeezing of the foot should be avoided*, since this may inhibit capillary filling and may actually decrease blood flow. Furthermore, squeezing may dilute the sample with serum or tissue fluid and make analysis less accurate. If blood does not flow freely, another puncture may be required.

The first small drop of blood is wiped away with gauze, and another drop is allowed to form. A heparinized capillary tube is placed in the drop of blood, and the proximal end of the inverted tube is allowed to fill by capillary action (Fig. 19-2*B*). The tube (or tubes, if several tests will be needed) is sealed at one end by sticking the end into clay or wax before the tube is sent to the laboratory (Fig. 19-2*C*). If 1-mL Microtainer tubes are used, the tube is held at an angle of 30 to 45 degrees from the surface of the puncture site. The collector end is touched to the drop of blood, and blood is allowed to drain into the tube (see Fig. 19-2*B*). Gentle tapping

TABLE 19-1 -- Equipment for Capillary Blood Sampling

Blood collection tubes (capillary tubes or Microtainers)

Nonsterile examination gloves

of the tube will facilitate flow to the bottom. For heparinized tubes, blood should be collected until the level reaches the demarcation on the tube. Over- or underfilling of the tube may result in clotting or erroneous test results, or both. Once an adequate specimen is obtained, a dry dressing is applied to the puncture site.

When a heel stick is performed for arterialized blood samples, the technique used is similar to that discussed previously for routine blood sampling, with the following differences: The infant's foot must be wrapped in a warm towel for a few minutes. The first drop of blood must be discarded and the remaining blood allowed to flow freely into a heparinized capillary tube. The tip of the tube should be placed as near the puncture site as possible to minimize exposure of the blood to environmental oxygen and the tube should be filled as completely as possible. Collection of air in the tube as well as excessive squeezing of the foot should be avoided, because this may artificially lower the P_{O_2} . When the tube is full, the free end is occluded with the gloved finger to prevent entry of air, and both ends are plugged with clay or capped with adapters.

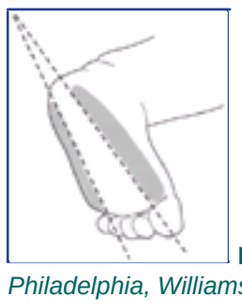

Figure 19-1 Acceptable sites for heel stick puncture illustrated by shaded areas. *(Adapted from the Textbook of Pediatric Emergency Procedures; Henretig FM, King C [eds]. Philadelphia, Williams & Wilkins, 1997.)*

Figure 19-2 *A*, The heel stick is performed on the lateral or medial aspect of the heel. *B*, The collector end of the Microtainer is touched to the drop of blood, and blood is allowed to flow down the wall of the tube to the bottom; or *C*, a heparinized capillary tube is placed in the drop of blood, and the proximal end of the inverted tube is allowed to fill by capillary action. *D*, The blood is maintained in the capillary tube using the index finger to maintain capillary tension on the end of the tube. *E*, When using a microtainer tube, the Microtainer is capped. *F*, when using a capillary tube, the ends are capped or (*G*) sealed with wax or clay. Avoid squeezing the foot, and keep the proximal end of the Microtainer below the puncture site. *(Adapted from the Textbook of Pediatric Emergency Procedures; Henretig FM, King C [eds]. Philadelphia, Williams & Wilkins, 1997.)*

Complications

When properly performed, heel sticks are associated with a low incidence of complications. Lacerations should not occur when the procedure is performed with a proper incision device. Heel sticks may cause infection (local infection, bacteremia, or osteomyelitis), scarring, and calcified nodules. [12] [13] [14] When the heel stick technique is used for the procurement of "arterialized" blood for pH, P_{CO_2}, and P_{O_2} analysis, the most important potential error is that false information (inaccurate P_{O_2}) may result in exposure of the infant to improper amounts of supplemental oxygen. Erroneous values due to hemoconcentration, hemolysis (squeezing heel too vigorously), or contamination with alcohol used for skin cleansing can also occur.

Interpretation

Numerous studies have compared the reliability of capillary blood with that of arterial blood for determination of pH, P_{CO_2}, and P_{O_2}. [15] [16] [17] [18] Although the results have been variable, most investigations have documented a reasonable correlation between arterial and capillary samples for pH and P_{CO_2} determinations (except when the patient is in shock or has an extremely high P_{CO_2}). Unfortunately, the P_{O_2} determination has not been found to be as reliable when performed on blood obtained by capillary sampling. Most studies indicate that the capillary (heel stick) P_{O_2} correlates poorly with the arterial P_{O_2}, especially if the arterial P_{O_2} is greater than 60 mm Hg. In nearly all situations, the capillary P_{O_2} is equal to or less than the arterial P_{O_2}, but in any individual case, one does not know how closely the capillary value approximates the arterial level. Therefore, *reliance solely on a capillary sample of blood for P_{O_2} measurement in an acutely sick infant may be fraught with potential risks*.

Venipuncture

Indications and Contraindications

Although many laboratory tests for the small infant may be performed on blood obtained by heel sticks, larger volumes of blood may be required, making heel sticks impractical. Hence venipuncture is the usual method used for obtaining larger quantities of blood for infants and children.

Venipuncture is also the recommended method to obtain blood for culture. The heel stick capillary tube procedure has been used in some centers for the procurement of blood from infants for cultures, [19] but there is a significant incidence of false-positive results with the technique. In the newborn infant, blood obtained immediately after sterile insertion of an umbilical arterial or venous catheter may be used for culture; even then, there is some controversy concerning the incidence of false-positive results. If venipuncture is unsuccessful, arterial blood may also be used to obtain blood cultures. When collecting blood intended for culture, the area of venipuncture should be prepared with both povidone-iodine and alcohol and allowed to dry. The blood culture collection bottle will likely state a desired volume of sample for optimal results, but 1.0 mL of blood is generally acceptable in a small infant. Iodine solutions and other detergents can irritate infant's skin; therefore, these should be washed off after blood is collected.

Femoral venipuncture for routine blood samples has long been discouraged, especially in children younger than 1 year of age, due to the risk of septic arthritis of the hip. [20] In an emergency setting or when few venous access sites exist,

TABLE 19-2 -- Equipment for Venous Blood Sampling in Infants and Children

Tourniquet (rubber band for scalp veins and tiny infants)
A 3-, 5-, or 10-mL syringe
A 21- or 23-ga butterfly needle
Evacuated blood tubes
Alcohol pads
Povidone-iodine swabs (if blood cultures are needed)
Sterile 2 × 2-in. or 4 × 4-in. gauze pads
Nonsterile examination gloves

blood for laboratory analysis may have to be obtained from such less desirable venous sites or from arterial puncture.

Equipment and Setup

The equipment required for venipuncture in an infant or child is listed in Table 19-2 . A small-gauge butterfly needle is usually preferred over a needle and syringe for obtaining blood in infants and young children, as it is easier to control once the vessel has been entered. Suction is also more controlled with the butterfly needle and syringe. The butterfly needle may also serve as an infusion line once adequate amounts of blood are obtained. The 23-gauge butterfly needle will generally suffice for venipuncture, regardless of age group. In older children and adolescents, a straight needle and syringe or the Vacutainer system (Becton-Dickinson, Rutherford, NJ) can be used much more easily than in infants. However, the negative pressure within the evacuated blood tube, once connected, may be sufficient to collapse the punctured vein. A 3- or 5-mL syringe is less likely than a 10-mL syringe to cause vein collapse in young infants.

Technique

Like adults, the usual site for venipuncture in infants and children is the antecubital fossa. However, any reasonably accessible or easily visible peripheral vein (e.g., on the scalp [for very small infants], hands or feet) may be used (Fig. 19-3). Veins on the dorsum of the hand can be used, providing they will not be needed for IV cannulation. The external jugular and femoral veins or arterial sites are rarely needed for routine samples in the stable patient.

All needed equipment should be assembled and ready for immediate use. The use of a topical anesthetic (e.g., EMLA, ELA-max) may be offered, if appropriate. Drawing blood from infants and small children is usually a two-person procedure. It should be emphasized that immobilization of the extremity is mandatory and this duty should not be relegated to a family member. The butterfly needle and the syringe can be attached either before or after skin penetration. However, if done before, the assembly should take place out of sight of the child. To minimize the number of venipuncture attempts, the optimal site for needle insertion should be chosen after a survey of the most prominent peripheral veins. If an extremity vein is to be used, a tourniquet should be applied proximal to the selected vein; in small infants, a rubber band will serve as an adequate tourniquet, but one must be certain to remove the rubber band following venipuncture.

The tourniquet should not be so tight as to impede arterial filling. The area surrounding the chosen site of skin penetration is cleansed with alcohol and allowed to dry.

Slight distal traction is applied to the skin to immobilize the vein, and the needle is inserted quickly through the skin and slowly into the vein at an angle of approximately 30 degrees, with the

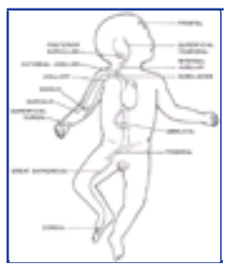

Figure 19-3 Venous access sites in the neonate and young infant. If venous access is unavailable, arterial blood may be used for most laboratory tests, including blood cultures.

bevel up (Fig. 19-4*A*). Successful vessel penetration is heralded by a flashback, or flow of blood, into the butterfly tubing. *Gentle suction is applied by slowly withdrawing the plunger of the syringe.* Alternatively, suction may be applied with a Vacutainer system in which the Vacutainer needle punctures the sealed end of the butterfly device (see Fig. 19-4*B*). If the suction is excessive, the vein will collapse, and blood flow will stop. If the required amount of blood is more than the capacity of the attached syringe, the tubing is pinched off, the filled syringe is removed, the next syringe is attached, and gentle suction is once again applied after release of the pinched tubing. After the required amount of blood is withdrawn, the needle is removed, and a sterile dressing and direct pressure are applied to the puncture site.

Although peripheral sites for venous or arterial sampling are preferable, the external jugular and femoral veins may be used in infants for the performance of a venipuncture during resuscitations or when peripheral sites are inadequate. The external jugular vein lies in a line from the angle of the jaw to the middle of the clavicle and is usually visible on the surface of the skin. The vein is more prominent when the infant is crying. An assistant is needed to restrain the infant in a supine position with the head and neck extended over the edge of the bed. Alternatively, a towel roll or pillow placed under the shoulders can be used. The head is turned approximately 40 to 70 degrees from the midline (Fig. 19-5), and the skin surrounding the area to be punctured is cleansed with alcohol. Finger pressure just above the clavicle will distend the jugular vein. Using a 21- to 25-gauge straight needle with a syringe or a 21- to 25-gauge butterfly needle attached to a syringe, the clinician punctures the skin and advances the needle slowly until the jugular vein is entered. The syringe is connected to

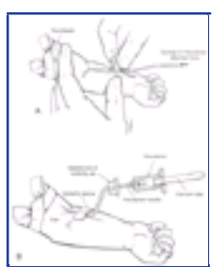

Figure 19-4 *A*, Technique for obtaining blood by antecubital venipuncture with a butterfly needle and a syringe. Once blood is obtained, the butterfly needle may serve as an infusion site. Note that this procedure often requires two persons to carry it out—one to hold the arm and insert the needle and the other to aspirate the blood. *B*, As an alternative to a syringe, a Vacutainer system may be used to apply suction. The Vacutainer needle punctures the sealed end of the butterfly set. Use of this method helps to prevent the premature clotting of blood that may occur if there is a delay in filling the collection tubes.

the needle at all times to maintain a constant negative pressure and avoid an air embolism. After the appropriate amount of blood is obtained, the needle is withdrawn, and slight pressure is applied to the vessel. The infant should be placed in an upright position after the needle is removed, and slight pressure should be continued for 3 to 5 minutes. Close observation of the puncture site should follow.

The femoral vein lies medial to the femoral artery and inferior to the inguinal ligament (Fig. 19-6 *A* (Figure Not Available)). Unlike for adults, the use of this vein for blood sampling is reserved for situations in which patients present in extremis and no other sampling sites are present. An assistant positions the hips in mild abduction and extension while the artery is palpated and its location identified by placing a mark on the abdomen just superior to the femoral triangle (see Fig. 19-6 *A* (Figure Not Available)). The femoral triangle is then prepared with alcohol; a povidone-iodine scrub is also recommended when obtaining blood cultures. The technique of needle insertion is similar to that for external jugular venipuncture (see Fig. 19-5). The clinician punctures the skin and then directs the needle or catheter toward the umbilicus at a 30- to 45-degree angle to the skin, remaining just medial to the femoral artery pulsation (Fig. 19-6 *B* (Figure Not Available)). A slight constant negative pressure is applied throughout

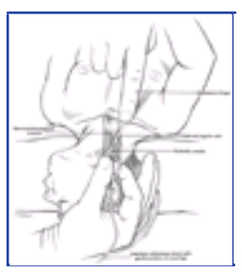

Figure 19-5 External jugular venipuncture. A syringe or a butterfly needle may be used. Venous distention is aided when an assistant's finger occludes the vein, or when the infant cries. The neck is extended, either over the side of the bed or by placing a rolled towel under the shoulders. This procedure requires two persons. Gloves should be worn.

insertion. After the needle enters the femoral vein, the desired blood samples are withdrawn, and the needle or catheter is removed (unless venous access with an IV catheter is desired). Pressure is applied to the femoral triangle for a minimum of 5 minutes, and the site is observed closely for recurrent bleeding.

Scalp veins can be very useful for venous sampling in small infants (younger than 3 months) when other options are not readily available. [21] The anatomic considerations and technique are discussed later in the section on peripheral venous cannulation. Care should be taken with venipuncture and cannulation of scalp veins near the face, as an infiltration could have negative cosmetic consequences. Although sampling or cannulating scalp vessels may be medically necessary, parents of tiny infants are often very upset by the site of their child's head being poked and every effort should be made to explain the rationale for the procedure.

Complications

Complications of venipuncture include hematoma formation, local infection, injury to structures adjacent to vessels, and phlebitis. All of these complications are uncommon. Special care should be used when puncture of the external jugular vein or femoral vein is attempted. Inadvertent deep puncture in the neck can produce injury to the carotid artery, the vagus or phrenic nerve, or the apex of the lung. In the femoral triangle, injury to the femoral artery, femoral nerve, and hip capsule may occur.[20] [22] However, such structures are unlikely to be injured when proper technique is used.

Arterial Blood Sampling

Indications and Contraindications

Arterial blood gas evaluation provides useful information that is essentially unavailable by other means (see Chapter 20) and is important for evaluation of respiratory status and acid-base equilibrium in infants or children with respiratory distress, shock, intoxication, diabetic ketoacidosis, or other metabolic derangement. Arterial blood may also be used for routine laboratory analysis if venous blood is difficult to obtain. Possible sites for arterial blood sampling include (1) radial, brachial, temporal, *dorsalis pedis*, and posterior tibial arteries; (2) umbilical arteries in the newborn infant; and (3) capillaries ("arterialized"). The radial artery is probably the

one most commonly used. The ulnar artery should not be the preferred site for arterial puncture to preserve the collateral circulation

Figure 19-6 (Figure Not Available) *A*, Anatomy of the femoral triangle. The vein is always medial to the artery. *B*, The needle insertion site is located one finger width below the inguinal ligament, just medial to the artery. Use the index and middle fingers to identify the course of the femoral artery. Contrary to the figure, keep both fingers proximal to the entry point of the needle to avert self-puncture. The needle is pointed medially toward the umbilicus at a 45° angle from the skin surface. *(From Pediatric Advanced Life Support Drug Lecture Slides, 1990. Reproduced with permission. Copyright American Heart Association.)*

to the hand, although some clinicians advocate performing punctures and catheterization of the ulnar artery. No vein or nerve is immediately adjacent to the radial artery, which minimizes the risk of obtaining venous blood or damaging a nerve. This is not the case with the brachial artery, and the risk of both complications appears to be greater when this artery is used.[23] Also, the brachial artery has little collateral circulation, causing many clinicians to avoid using it except in extreme circumstances.[24]

The temporal artery is also adjacent to a vein, and if the patient's head is in an oxygen hood, it is nearly impossible to obtain a sample in a steady state. Femoral arteries should not be used for obtaining routine blood samples from the infant or child. Transcutaneous monitoring of P_{O_2}, P_{CO_2}, and oxygen saturation may provide useful adjuncts to arterial sampling in many patients. Nonetheless, they do not replace intermittent arterial sampling, which remains necessary for the stabilization of infants and children and for verification of the accuracy of these noninvasive methods. One should avoid puncture of an artery when infection, burn, or other damage to cutaneous defenses exists in the overlying skin. The presence of adequate collateral circulation and any potential coagulation problems should also be addressed.

Equipment and Setup

The equipment required for arterial puncture in an infant or child is listed in Table 19-3 . A small-gauge butterfly needle is usually preferred over a needle and syringe for arterial puncture in infants and children. As in venipuncture, a 23-gauge butterfly needle is most often used, although in newborns, use of a 25-gauge butterfly may be beneficial. Some clinicians prefer to use a 25-gauge needle connected to a syringe, but use of a butterfly allows for better control of the needle while an assistant aspirates the syringe and may also permit a larger volume of blood to be withdrawn.

Technique

Since the radial artery (Fig. 19-7) is most frequently used to obtain intermittent arterial samples from infants and children, the technique for it will be described. Although the merit of the Allen test (see Chapter 20) has been challenged, it is prudent to first assess the adequacy of collateral circulation in the hand. Both radial and ulnar arteries are compressed. After a short time, compression of the ulnar artery is released while the radial artery remains compressed. Adequacy of collateral flow to the hand by the ulnar artery is marked by return of color to the hand. One should then heparinize a tuberculin syringe (or use a prepacked syringe with anticoagulant) if blood gases are being obtained. All heparin should be ejected from the syringe; a 23- or 25-gauge butterfly needle should then be attached to the syringe. The amount of heparin coating the barrel of the syringe is adequate to anticoagulate the sample; excess heparin may result in inaccurate P_{CO_2} determinations because of dilution of the blood sample.[25] [26]

The clinician should hold the infant's wrist and hand in the left hand (if the clinician is righthanded). The child's hand is held fully supinated with the wrist dorsiflexed. The pulsations of the radial artery should be palpable just proximal to the transverse wrist creases. A small indentation can be made in the skin with a fingernail to mark the insertion site. The area is cleansed with alcohol and allowed to dry. Topical anesthetic cream or an intradermal wheal of 1% lidocaine may be used if the clinical situation allows. The skin is penetrated at a 30° to 45° angle (Fig. 19-8), and while the plunger of the syringe is withdrawn, the needle is advanced slowly until the radial artery is punctured or until resistance is met

(Fig. 19-9). In contrast to the procedure in adults, it is necessary in infants to provide continuous, but gentle, suction on the plunger of the syringe. One can be sure that the radial artery is punctured when blood appears in the hub of the needle. Other clinicians prefer to attach the syringe to the butterfly needle only after blood return is noted and suction is thereafter applied.

If resistance is met while pushing the needle deeper or no blood returns, the needle is slowly withdrawn to the point at which only the distal needle tip remains beneath the skin, and then the procedure is repeated after checking the location of the pulse. Slight reorientation of the needle laterally or medially may be necessary. After the desired amount of blood is obtained, the needle is removed, and light pressure is applied for 5 minutes or longer to control bleeding.

Figure 19-8 For arterial blood sampling, the needle should be inserted under the skin at a 30° to 45° angle. A butterfly needle and syringe are used if larger volumes of blood are required. The wrist is held dorsiflexed by the nondominant hand.

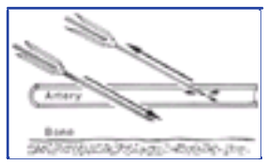

Figure 19-9 Resistance met during passage of the blood gas needle usually indicates contact with bone. The needle should be withdrawn slowly. If the needle has traversed both walls of the artery, blood will be obtained as the needle is slowly withdrawn into the arterial lumen.

Complications

The complications of radial artery puncture include infection, hematoma formation, arterial spasm, tendon injury, and nerve damage. [27] [28] With the use of proper technique, however, the complication rate is extremely low. If the infant starts to cry before blood is obtained, the P_{O_2} and P_{CO_2} may not reflect the infant's true steady state. Another potential problem is the dilutional effect of heparin on the P_{CO_2}. The heparin in the dead space of the tuberculin syringe may decrease the P_{CO_2} by 15% to 25% when 0.2 mL of blood is obtained and by approximately 10% with 0.4 mL of blood. This emphasizes the need for all heparin to be ejected from the dead space of the syringe *before the needle is applied*. The use of a syringe (e.g., Becton-Dickinson 1-mL U-100 insulin syringe) with minimal dead space or the use of syringes prepared with lyophilized heparin eliminates this problem (see Chapter 20). [29]

VASCULAR LINE PLACEMENT: VENOUS AND ARTERIAL

Intravascular lines are indicated when access to the venous or arterial circulations is necessary. An IV line may be positioned in peripheral veins (scalp, hand, forearm, foot, ankle, axilla, thigh) or central veins (superior vena cava via the internal jugular, axillary, superficial temporal, posterior auricular, or subclavian venous approach[21] [30] and the inferior vena cava via the umbilical or femoral venous approach). Likewise, intra-arterial lines may be positioned peripherally (radial, posterior tibial, dorsalis pedis, or superficial temporal arteries) or centrally (abdominal or thoracic aorta via an umbilical or femoral artery approach). Techniques to secure access to these intravascular spaces are discussed in the following sections (see also Chapter 20 Chapter 21 Chapter 22 Chapter 23). Remember to consider the use of topical anesthetic if the clinical situation warrants.

Peripheral Venous Catheterization: Percutaneous

Indications and Contraindications

In general, peripheral IV lines are indicated when the patient is unable to attain medical and nutritional goals with enteral

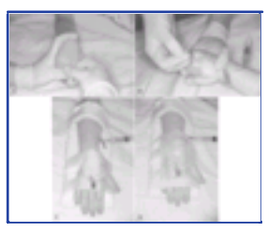

Figure 19-10 Technique for peripheral venous catheterization. *A*, The catheter is directed at a 10° to 20° angle toward the insertion site and advanced until blood return is seen in the catheter and hub. The stylet is removed, and the T-extension tubing is attached. *B*, Taping technique for butterfly and intravascular catheters using a crisscross pattern. *C*, Hand and forearm secured to an arm board. *D*, Covering with the plastic wrapper from the T-extension tubing for protection.

therapy. These lines provide maintenance fluids to support adequate hydration and serve as a route for administering medications. In the acute setting, peripheral IV lines provide a route for administering resuscitative medications and fluids as well as antibiotics.

Equipment and Setup

Materials needed for placement of a peripheral IV line in an infant are listed in Table 19-4 . The two devices commonly used for peripheral IV insertion are the butterfly needle and the plastic over-the-needle catheter. The former ranges in size from 21- to 27-ga. Butterfly needles are used primarily for infusions of short duration and are removed after completion. Examples of such use include certain chemotherapeutic agents and single-dose antibiotic administration. Due to their rigid nature, they tend to infiltrate very easily in the active child. Placement of a butterfly needle in a vein close to a flexor surface is contraindicated. For the most part, over-the-needle catheters, such as Angiocath, Medicut, or Quikcath, have become the mainstay of peripheral venous catheterization. These thin-walled, flexible catheters range in size from 14- to 24-ga. For infants, a 22- to 24-ga catheter will suffice in most cases. The selection of catheter size is dependent on the catheter's intended purpose. In general, the smallest gauge appropriate for the clinical situation should be used. Larger diameter catheters allow for rapid administration of fluids in emergency situations. The use of T-connector extension tubing connected to the catheter after insertion facilitates withdrawal of blood for specimen collection, makes flushing the catheter and maintaining patency easier (especially while taping and securing the IV), and allows for dressing changes without disturbing the IV dressing.[31]

Both commercially available and homemade devices are often used to protect the IV site from a child's attempts to remove it. An arm or leg board appropriate for the size of

TABLE 19-4 -- Equipment for Peripheral Intravenous Insertion in Infants and Children

22- or 24-ga venous catheters
Tourniquet (rubber band for infants)
IV solution and tubing
T-connector extension set
Pretorn tape (½-, 1-, and 2-in.)
Alcohol pads
Povidone-iodine swabs (for blood culture)
Arm or leg board
Non-sterile examination gloves
Sterile 2 × 2-in. or 4 × 4-in. gauze pads
Protective covering (container from IV catheter, T-extension set, or prefabricated cup)
IV fluid chamber with microdrip
A continuous infusion pump
Saline flush solution
3- or 5-mL syringes

the child should be handy to provide for stabilization of the extremity after insertion. In newborns or small infants, fashioning an arm board from two tongue depressors taped together and covered with 4 × 4-in. gauze will provide the appropriate length needed. One should have primed and ready an IV fluid chamber with microdrip and a continuous infusion pump. Fluid administration in an infant must be carefully monitored. *Macrodrip tubing and liter bottles should not be used*; inadvertent infusion of large amounts of fluids in an infant may be disastrous. An infusion pump is an ideal way of limiting fluid infusion while keeping the vein open.

Technique

A number of IV sites are available for placement of a peripheral IV needle or catheter in the infant (see Fig. 19-3). The most common sites chosen for IV insertion in infants and children are the superficial veins of the dorsum of the hand; the antecubital fossa; the dorsum of the foot; and, in newborns and small infants, the scalp.

The veins of the dorsum of the hand are the most often used. These vessels are relatively straight and lay flat on the metacarpals and therefore are stabilized without undue difficulty. If the hand is chosen, one should take into consideration the age and hand preference of the patient. Veins in the antecubital fossa (cephalic and basilic veins) are easily accessible; however, their angulation across the fossa may make advancement of the catheter difficult. These veins may not be easily visible and yet may be palpable. It is recommended to select the most distal vein that is large enough to accommodate the catheter and leave the larger, more proximal veins in case (1) initial attempts are unsuccessful or (2) prolonged IV therapy may be needed and percutaneous central venous catheter placement (e.g., peripherally inserted central catheter [PICC] line) is contemplated. Tributaries of the dorsal venous arch on the dorsum of the foot, like those on the dorsum of the hand, are relatively straight, and the extremity is easily immobilized after insertion. Because indwelling catheters in this location will prevent mobility, this site should be considered only in preambulatory patients or after attempts at other sites have been unsuccessful. The scalp veins are easy to cannulate, but their use is primarily limited to very small infants. If a peripheral vein on the hands, feet, or antecubital fossa is being used, the extremity can first be immobilized by taping it to an arm board, a padded splint, a full plastic IV fluid bag, or a sandbag. The particular site is a matter of preference, and the clinician should choose the vein that appears to be the easiest to cannulate.

With few exceptions, the same techniques used for IV insertion in adults may be used in infants and children, especially in the veins of distal extremities. If a peripheral extremity is used, a tourniquet may be placed proximal to the planned site of entry. Time permitting, nitroglycerin ointment (0.4 to 0.8 mg) is advocated by some clinicians to induce local vasodilation, thereby aiding venous cannulation. [32] Warming the extremity is a more accepted and commonly used maneuver. Some EDs use transillumination devices commonly found in neonatal intensive care units to assist in finding veins in infants. [33] [34]

If the clinical situation allows, a topical anesthetic (e.g., EMLA, ELA-max) may be appropriate. The tubing of the butterfly infusion set or the T-extension set should be flushed before venipuncture with a sterile IV solution, such as normal saline, to prevent air embolism. If a plastic catheter is used, the catheter, with stylet in place, is directed through the skin at a 10° to 20° angle (Fig. 19-10*A*). [35] The catheter with stylet is slowly advanced until blood return is noted. One then advances the catheter over the stylet into the vein. The stylet is removed, and the IV line is connected to the hub of the catheter by means of a T-extension set. After 1 mL of solution is flushed through the line, the site is inspected for signs of infiltration, such as hematoma or local swelling.

The catheter is fixed to the skin with a piece of 0.5 in. tape passed around and over the catheter hub and fixed to the skin. A second piece of tape is placed adhesive side uppermost under the catheter hub and crossed over the catheter in a V shape (Fig. 19-10*B*). The tubing of the T-extension set is looped back, and a piece of tape is placed midway over the tubing and secured to skin. This ensures against accidental dislodgment if the IV tubing is suddenly pulled. The hand and forearm are securely taped to the arm board for immobilization (Fig. 19-10*C*). The clear plastic wrapper of the extension tubing package (or perhaps a commercially available plastic dome protector or even a plastic medication cup cut in half) is then taped over the hub of the catheter as a protective covering (Fig. 19-10*D*). Occasionally the flow rate of the infusion may be positional, especially if the catheter spans a joint or abuts a venous valve. Careful repositioning or adjustment of the hand position or catheter with strategically placed sterile gauze or slight withdrawal of the catheter may be all that is required to remedy the problem.

If blood specimens or cultures are needed, one can obtain these simultaneously during IV insertion and spare the child an additional needlestick. The T-extension tubing and attached syringe should not contain any flush solution. After appropriate preparation of the insertion site and successful placement of the catheter into the vein, the T-extension tubing and syringe are connected to the hub of the catheter, and the blood is aspirated into the syringe. After the desired quantity is obtained, the syringe is removed, and the T-extension tubing is connected to the IV infusion tubing, and the infusion pump is

set at the desired rate. Remember to prepare the skin with appropriate povidone-iodine solution if cultures are needed.

If the scalp veins are used, the area surrounding the planned site of insertion can be shaved and cleansed with an iodine solution. Arteries and veins can usually be differentiated on the scalp because arteries are more tortuous than veins. [21] In addition, the flow of blood is away from the heart in arteries and toward the heart in veins. If an artery is entered during placement of the needle and fluid is infused, blanching will occur in the area. If this happens, the catheter or needle should be removed, light pressure should be maintained for 5 minutes, and the procedure should be repeated at another site. A rubber band may be used as a tourniquet around the scalp *(never the neck)* to produce venous dilation. One should always ensure that the rubber band is removed after venous cannulation. When removing this rubber band, it should be carefully slipped over the catheter or butterfly needle or cut with a pair of scissors. Although cutting the rubber band with scissors is often the easiest technique, the clinician must take care to hold both ends of the cut rubber band to avoid having the infant "snapped" by one or both ends of the rubber band. Placing a piece of tape on the rubber band before placement on the scalp will facilitate lifting the rubber band away from the scalp.

If a scalp vein butterfly infusion set is used, the wings of the butterfly are grasped between the thumb and forefinger, and the needle is introduced beneath the skin approximately 0.5 cm distal to the anticipated site of vein entrance (Fig. 19-11). The needle is advanced slowly toward the vessel until blood appears in the tubing, indicating that the vessel has been entered. The tourniquet should then be removed. The needle should be flushed with 0.5 to 2 mL of IV fluid, such as normal saline, to ensure that the needle is properly in place within the vein. If infiltration occurs, as noted by a subcutaneous (SQ) bump, the IV line should be removed and the process repeated at another site.

Figure 19-11 Using a rubber band as a tourniquet to distend the scalp veins, the needle is introduced approximately 0.5 cm distal to the anticipated site of the vessel puncture. Gloves should be worn.

After the wings are secured with tape, the tubing of the butterfly set should be taped in a loop on the scalp so that it is not inadvertently pulled. A wisp of cotton may be placed under the wings of the butterfly if the infusion is positional. A small cup may be taped over the wings and the needle to protect the IV line (Fig. 19-12). The catheter of the butterfly set should then be connected to the tubing from the IV system.

Complications

Complications of IV fluid therapy include infection [36] ; injection of sclerosing agents into the SQ space, with resultant necrosis and sloughing of the skin (especially in small infants)[37] ; air embolism,[38] and administration of inappropriate volumes of fluid. Because the life span of an IV needle or catheter is usually fairly short (less than 72 hours) in the small infant, the decision concerning elective removal and replacement of the IV system is not usually a problem. Of course, it is important to pay meticulous attention to sterility during insertion and maintenance of the IV system to decrease the risk of infection.

Peripheral Venous Catheterization: Venous Cutdown

Indications and Contraindications

With the development of small IV catheters and butterfly needles and the rapidity and safety of intraosseous (IO) cannulation (see Chapter 26), peripheral venous cutdowns are rarely used in infants. Even in experienced hands, a saphenous vein cutdown may take more than 10 minutes, may last no longer than percutaneous catheterization, and is associated with a higher rate of infection than other routes of vascular access. [39] [40] [41] Nonetheless, if peripheral venous, central venous, and IO cannulation cannot be performed, venous cutdowns may provide an alternative means of emergency venous access (see section on *Emergency Vascular Access* and

Figure 19-12 Protecting the intravenous line with a plastic medicine cup.

Chapter 23). For the purpose of illustration, the exposure and cannulation of the saphenous vein are discussed (Fig. 19-13 Fig. 19-13). The same principles apply when a cutdown is performed on an arm vein.

Equipment and Setup

Successful venous catheterization via cutdown in the small infant requires sterile instruments, an assistant, good lighting, and a selection of catheters. Silastic catheters, which can be obtained in 2, 3, and 4 Fr sizes (Dow-Corning Company), seem to remain patent longer, and can be sterilized with the instruments to make a "cutdown tray." Standard 19- to 22-gauge IV catheters (Angiocath, Deseret Medical, Inc., Sandy, UT) are also useful.

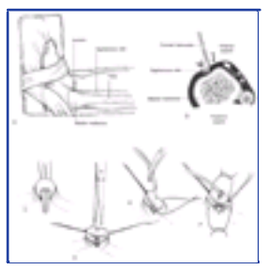

Figure 19-13a Venous cutdown (saphenous vein). *A*, Immobilization of the ankle and the site of skin incision. *B*, A curved hemostat scoops up the vein. The point of the hemostat should be kept against the bone. *C*, The vein is dissected free. *D*, With a proximal and distal tie to stabilize the vein and control bleeding, an incision is made in the upper one third of the vein. *E* and *F*, The infusion catheter is threaded into the vein lumen and advanced.

Technique

The clinician should begin with complete immobilization of the thigh, leg, ankle, and foot by taping them to a padded arm board, which in turn is attached to the table or bed where the procedure is being performed (see Fig. 19-13*A*). The area around the medial malleolus is prepared with a povidone-iodine solution and draped with sterile towels. Local anesthesia should be performed (intradermal 1% lidocaine) in an area about 1 cm proximal and 1 cm anterior to the medial malleolus. Fortunately, there are no major nerves or tendons that accompany the vein in this location (see also Chapter 23).

A tourniquet is placed in the mid-leg and a transverse skin incision is made (usually about 2 cm in length); a small mosquito hemostat is inserted into the wound, with the

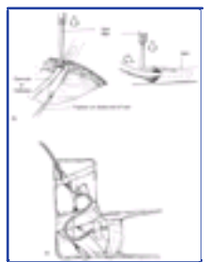

Figure 19-13b *G*, A vein lifter/dilator facilitates placement of the catheter into the vein lumen. *H*, The incision is sutured, and the catheter is secured. *(C from Suratt PM, Gibson RS: Manual of Medical Procedures. St. Louis, CV Mosby, 1982. Reproduced by permission.)*

concavity of the clamp upward. The tip of the hemostat is advanced to the bone in one corner of the wound, and all tissues lying against the bone and in the SQ region are "scooped up" with the hemostat (see Fig. 19-13*B*). This will invariably lift the vein out of the wound along with surrounding tissues. A fine forceps or a mosquito hemostat is used to separate and remove all nonvenous structures, leaving only the saphenous vein tented over the hemostat (see Fig. 19-13*C*). To avoid injury to the vein during dissection, one spreads the ends of the hemostat parallel to the direction of the vein, *never* transversely.

Two 4-0 silk sutures are passed under the vein; one silk suture is pulled distally to stabilize the vein, and the other suture is pulled proximal to the site of venipuncture. The distal suture may be tied, but if left untied, it can still be used for stabilization of the vein. Removal of the untied distal suture following vein cannulation may allow for subsequent vein recannulation following eventual catheter removal. If the distal suture is left untied, longitudinal traction on it permits hemostasis and continued exposure of the vein above the wound. Fine scissors or a scalpel blade may be used to make an oblique or V-shaped incision (venotomy) in the anterior vein wall between the sutures (see Fig. 19-13*D*).

The Silastic catheter (pre-filled with saline solution) is grasped with forceps and is advanced into the vein for a distance of 2 to 3 cm (see Fig. 19-13*E* and *F*). This is usually the most difficult and time-consuming portion of the procedure. A vein dilator or forceps may be used to hold open the incision in the vein (see Fig. 19-13*G*). Downward pull on the distal tie will give countertraction and will stabilize the vein during catheter advancement. The tourniquet is then removed. One ties the proximal suture around the vein with the catheter inside, taking care not to occlude the catheter by tying the suture too tight. If the distal suture was tied, the free ends of the suture can be tied around the catheter, providing additional stability to the catheter. If the distal suture was not tied, it is

now removed. When the distal suture is left untied, the proximal suture is still tied to secure the catheter, but the ends are left long so that the suture can be pulled out of the incision and removed to allow recannulation once the infusion catheter is removed.

Continued infusion of saline through the catheter from an attached syringe will ensure patency. The catheter is oriented into either corner of the incision, and the incision is closed with interrupted 4-0 nylon sutures. The skin suture nearest the catheter is wrapped around the catheter and tied to hold the catheter in place. Bleeding can be controlled with direct pressure. Antibiotic ointment is placed over the wound, and a sterile occlusive dressing is applied. The IV tubing is connected and taped securely to the footboard to prevent inadvertent removal of the catheter (see Fig. 19-13*H*).

Change the dressing carefully every day, using sterile technique with reapplication of antibiotic ointment. When cared for properly, catheters can remain in place for as long as 7 to 10 days. Generally, though, a line is replaced, using another site, after 3 to 4 days. Obviously, at the first sign of infiltration or infection the catheter must be removed. Unfortunately, once the vein has been used for a cutdown, it is usually rendered useless for future venous cannulation.

Mini-cutdown.

The cannulation of a small vein with a catheter or tube may be difficult and very time-consuming if one is not experienced in the technique. As an alternative, the

mini-cutdown procedure may be used. Once the vein is exposed through a skin incision and SQ dissection, it is cannulated directly with a standard IV catheter (Medicut, Angiocath) rather than nicked with a scalpel (Fig. 19-14). A silk suture or hemostat may be placed under the vein to immobilize it during puncture, but with the mini-cutdown technique, the vein is not tied off after being cannulated. The catheter will not be as secure with this modification, but the technique is useful when time is critical. The vein is not destroyed with this technique. In essence, the mini-cutdown uses the percutaneous technique of cannulation, except that venipuncture is performed through a skin incision under direct visualization (see Chapter 22 and Chapter 23).

Complications

In addition to the problems discussed previously, venous cutdowns can result in wound infections and phlebitis. Adjacent

Figure 19-14 The mini-cutdown procedure using a standard intravenous catheter over-the-needle system is technically easier than the full cutdown and may be preferred in an emergency.

structures may be injured during the incision and subsequent blunt dissection. When the mini-cutdown technique without ligatures is used, extravasation of infusate may result. Light pressure on the closed wound will generally prevent continued extravasation.

Central Venous Catheterization: Percutaneous

Percutaneous placement of central venous lines (CVLs) has become the technique of choice of many clinicians for securing central venous access in neonates and young infants (see Chapter 22).[39] This technique has largely supplanted the conventional technique of cutdown for central venous catheterization. Both percutaneous and venous cutdown catheterizations require central venous catheters, which can be purchased separately or within self-contained kits (Arrow International, Inc., Reading, PA; Gesco International, San Antonio, TX).

Indications and Contraindications

Percutaneous central venous cannulation is indicated to secure vascular access (1) when peripheral venous access is limited or impossible, (2) for emergency drug and fluid administration during cardiac arrest and shock, (3) when hyperalimentation and IV infusions are required for days to weeks, (4) when low-birth-weight neonates and young infants require central venous access, and (5) when precise hemodynamic monitoring is needed in a critically ill or injured child. Contraindications to percutaneous placement of central venous catheters include an uncorrected coagulopathy; local infections or burns at insertion sites; malformations or deformations that may distort vascular anatomy; vascular insufficiency of an extremity; obstruction or compression of the access veins by tumor, abnormal vessels, hematoma, thrombus, abscess, or malformation; or absence of access veins.[22] [43] Bacterial septicemia is a relative contraindication, and delaying placement of central venous access until cultures have been sterile for 48 hours is generally recommended.

Equipment and Setup

Percutaneous central venous catheterization in infants and children can be performed using any number of sterile over-the-needle catheters ranging in size from 22 to 16 gauge (choice depends on the age of the patient) and equipment similar to that used for percutaneous peripheral venous catheterization (see Table 19-4). If insertion of a larger indwelling catheter is desired, commercially available kits are convenient (Gesco International, Inc., San Antonio, TX; Arrow International, Inc., Reading, PA; Cook, Inc., Bloomington, IN). The catheters in these kits are typically made of a silicone elastomer, polyvinyl chloride, or polyethylene; some are available with an antimicrobial coating that helps prevent infection. Catheter length is variable, and 1- to 3-lumen catheters are available. Rapid volume replacement, as in the case of severe dehydration or acute blood loss from trauma, is best achieved by inserting a short, large-bore catheter for the initial resuscitation and stabilization. If the patient requires hemodynamic monitoring or multiple medication infusions, the catheter can be replaced later with a larger indwelling catheter using the Seldinger technique.

Other necessary equipment includes: sterile forceps and scissors; povidone-iodine solution; gauze pads; sterile drapes;

gowns; gloves; caps and masks; syringes (3 mL, 5 mL, and 10 mL); Tegaderm (Medical Products, Inc., St. Paul, MN), Op-Site (Smith and Nephew Medical, Massilon, OH), or other sterile transparent skin coverings; Luer-Lok three-way stopcocks; 0.25 to 1.0% lidocaine; flush solution (1 to 2 U heparin per mL normal saline), and IV tubing with a T-connector extension. Depending on the access vein to be used, restraint of the extremity, pelvis, or head may require a padded support, an assistant, or both.

Techniques

Percutaneous placement of central venous catheters can be accomplished using two methods that differ only in the use of a guidewire. The guidewire (Seldinger) technique is preferred when catheters are inserted into the femoral or subclavian vein. When using the basilic or cephalic vein of the forearm and antecubital space, axillary vein, or superficial temporal or posterior auricular scalp vein, many clinicians prefer to insert the catheter through an introducer needle. Details of the pediatric femoral, external and internal jugular, and subclavian and antecubital approaches follow.

Femoral catheterization.

The safety and efficacy of percutaneous femoral venous catheterization have been demonstrated. [44] Femoral venous catheterization is the central venous access route most commonly used in infants and children in emergency situations. [39] The femoral anatomy is easily learned, and the arterial pulse provides a landmark for catheter insertion. In case of inadvertent arterial puncture or venous laceration, hemostasis can be achieved by application of direct pressure. Also, femoral catheterization is less likely to interfere with emergency procedures in the region of the head, neck, and chest during medical or trauma resuscitations. In addition, the specific risks associated with subclavian and internal jugular vein catheterization (pneumothorax and carotid or subclavian artery puncture) are avoided. Risks of the procedure include thrombosis and infection; these can occur with any type of venous catheter.

Technique.

The child must be adequately restrained to permit exposure of the inguinal region. In some situations, it might be necessary to sedate the child to perform the procedure (see Chapter 34), but this should be done with caution in a child with marginal perfusion or respiratory compromise. Although data studying the use of this technique in the pediatric population are sparse, [45] [46] the use of ultrasound to locate the femoral artery may be helpful if the femoral arterial pulsation is not strong, if edema makes palpation of the artery difficult, or if the artery is difficult to locate when wearing gloves (see Chapter 69). Note that during cardiopulmonary resuscitation (CPR), palpable pulsations or Doppler tones in the femoral vein may be detected. Hence, if the vein is not found medial to the pulsations, catheterization of the pulsating vessel during CPR may be considered as a last resort when other options for vascular access or drug delivery are unavailable. Both groins are generally prepared with povidone-iodine in the event that the initial attempt is unsuccessful.

The introducer needle supplied with the kit can be used with or without a syringe to enter the femoral vein. The femoral artery is palpated with one finger, and the needle is placed in the skin just medial to the artery. One enters the skin at a 30° to 45° angle approximately 1 cm below the inguinal ligament. The general course of the needle is in a line directed toward the umbilicus. When blood return is noted, the wire is gently passed through the needle into the proximal vein. If a syringe has been attached to the introducer needle, continuous, gentle suction is applied while the needle is inserted. When the syringe is removed to insert the wire, a sterile gloved finger is often placed over the open hub of the needle to prevent air embolus or blood loss. The wire should not meet resistance when gently introduced and

the proximal end should always be visible protruding from the hub of the needle. If there is resistance to passage of wire, it should be removed to assess the needle's position within the vessel. If there is resistance to removal of the wire, the needle and the wire must be withdrawn together to prevent shearing off the end of the wire.[47] An alternative method that may be useful when placing the 4 Fr double-lumen Arrow catheter is to remove the tubing from a 21-gauge butterfly needle (Abbott Hospitals, Inc., North Chicago, IL) and use the needle to enter the vein (Fig. 19-15*A*). The butterfly needle is very easy to hold in a stable position and is also shorter than the needles supplied with the assembled kits. When blood return is obtained, the wire is passed through the butterfly needle into the proximal vein.

A small incision (1 to 2 mm) is then made along the wire's entry point at the skin to allow passage of the vein dilator (Fig. 19-15*B*) or the catheter itself. The incision is generally made with a No. 11 scalpel blade with the sharp edge of the blade pointed away from the wire. The dilator, if used, is advanced over the wire gently, then removed. The catheter, which has been flushed with saline, is then advanced over the wire into the vein; and the wire is then removed (Fig. 19-15*C*).[48] Occasionally it is useful to rotate and advance the dilator (or catheter) simultaneously as it enters the vein. Many times the dilator step is skipped in a critical situation and the catheter is placed directly after placement of the wire. Blood return is noted from the catheter ports, which are then flushed with a sterile saline solution. The catheter is subsequently secured with silk or nylon sutures (Fig. 19-15*D*). A sterile transparent skin covering placed over the exit site may be used as an impermeable dressing.

This technique is useful in children as small as 1000 g. When one is placing femoral venous catheters in children smaller than 1500 g, a smaller single-lumen catheter (3 Fr or 24-ga) should be used, because a larger catheter may occlude blood flow in the femoral vein.

External jugular venous catheterization.

The external jugular vein is superficial and easily visible. This site should be selected for catheterization only after catheterization of other, more peripheral sites has been unsuccessful. Also, the external jugular vein is undesirable as a primary catheterization site during resuscitative efforts, since manipulation of the head and neck may compromise management of the airway. In young infants, use of the Seldinger technique is difficult due to the short length of the infant's neck, as well as the low success rate of central venous catheter placement resulting from the acute angle of entry of the external jugular vein into the subclavian vein. [49]

Technique.

The external jugular vein lies in a line from the angle of the jaw to the middle of the clavicle and is usually visible on the surface of the skin. The vein is more prominent when the infant is crying. An assistant is needed to restrain the infant in a supine position with the head and neck extended over the edge of the bed. Alternatively, a towel roll or pillow placed under the shoulders can be used. The head is turned approximately 40° to 70° from the midline (see Fig. 19-5). The skin surrounding the area to be punctured is cleansed with

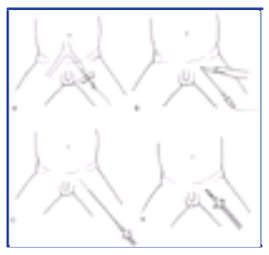

Figure 19-15 Technique for inserting a femoral venous catheter. *A*, A 21-ga butterfly catheter is used to enter the femoral vein, and the guidewire is passed through the butterfly needle into the proximal vein. Note that the tubing has been removed from a standard butterfly set. *B*, A small incision is made alongside the wire, and the dilator is advanced over the wire and into the vein. *C*, The catheter is advanced over the wire and into the vein. *D*, The wire is removed and the catheter secured. Note that many commercial kits have a self-contained 21-ga needle, making modification of a butterfly needle catheter unnecessary.

alcohol. The area is covered with a sterile drape, and 1% lidocaine may then be infiltrated into the skin. A finger may be placed just above the clavicle to distend the jugular vein.

Using an 18- to 22-ga catheter with a syringe, the catheter is aligned parallel to the vein, and the skin is punctured approximately one half to two thirds of the distance from the angle of the jaw to the clavicle. The catheter is advanced slowly until the jugular vein is entered. The syringe is connected to the catheter at all times to maintain a constant negative pressure and avoid an air embolism. After the appropriate amount of blood is obtained, the catheter is advanced and secured in place. If the Seldinger technique is used, proceed as described for femoral catheterization. The catheter should be passed far enough to reach the superior vena cavaright atrium junction. The catheter is checked for blood return, and the line is secured with sutures and a sterile occlusive dressing applied. A chest radiograph is warranted to assess the proper location of the catheter, as well as to rule out the possibility of an iatrogenically induced pneumothorax.

Internal jugular venous catheterization.

The internal jugular veins lie within the carotid sheath containing the carotid artery and vagus nerve. The lower part of the vein lies within the triangle formed by the sternal and clavicular heads of the sternocleidomastoid muscle and becomes more lateral and anterior to the artery as it joins the subclavian vein. The right internal jugular vein is preferred over the left, since the internal jugular and innominate vein and the superior vena cava form a nearly straight line into the right atrium. This lessens the chance for pneumothorax or injury to the thoracic duct (see Chapter 22). Like the external jugular, this site should be chosen for catheterization only after catheterization of other, more peripheral sites has been unsuccessful.

Technique.

Three approaches (the anterior, median or central, and posterior approaches as discussed in Chapter 22) to internal jugular catheterization are possible. The median or central approach is recommended in pediatric patients and will be described here. The child is positioned in the same fashion as that described for external jugular venous

catheterization. The medial or central approach uses the apex of the angle formed by the sternal and clavicular heads of the sternocleidomastoid muscle as the puncture site. If one could imagine a line from the mastoid process to the sternal notch, the apex of the angle formed by the two muscular heads would fall approximately along the middle third of that line. [47] The skin surrounding the area to be punctured is cleansed with alcohol. The area is covered with a sterile drape, and 1% lidocaine may then be infiltrated into the skin. An 18- to 22-ga needle with a syringe is used, and the needle is introduced at the apex of the triangle at an angle of 30 degrees downward relative to the coronal plane and directed caudad toward the ipsilateral nipple (Fig. 19-16 (Figure Not Available)). The needle is advanced slowly until the jugular vein is entered. The syringe is connected to the needle at all times to maintain a constant negative pressure and avoid an air embolism. After blood flow is obtained, the syringe is removed, and a finger is placed over the hub of the needle. A guidewire is then inserted during a positive-pressure breath or exhalation, the needle is removed, and a catheter is introduced using the Seldinger technique (see Chapter 22). The catheter should be passed far enough to reach the superior vena cava/right atrium junction. The catheter is checked for blood return, the line is secured with sutures, and a sterile occlusive dressing is applied. A chest radiograph is warranted to assess the proper location of the catheter, as well as to rule out pneumothorax.

Subclavian Venous Catheterization.

The subclavian vein is a popular route of central venous access in the adult patient but is used far less frequently in children. The technique is more difficult in the child because of the vessels' smaller size, as well as their more cephalad location under the clavicles. An infraclavicular approach to the subclavian vein has been used, but due to the high risks of pneumothorax and hemothorax, especially when performed during emergencies, this approach should be considered only if other

peripheral or central venous access sites are unobtainable. [39] [47] [50] The younger the patient, the higher the risks of these complications. Also,

Figure 19-16 (Figure Not Available) Technique for internal jugular venous catheterization (medial or central approach). The needle is inserted at the apex of the triangle formed by the sternal and clavicular heads of the sternocleidomastoid muscle. The needle is angled 30° downward relative to the coronal plane and directed toward the ipsilateral nipple. *(From Textbook of Pediatric Advanced Life Support, 1994. Reproduced with permission. Copyright American Heart Association.)*

subclavian venous access may interfere with resuscitative efforts or be unavailable due to the placement of cervical spine immobilization devices in a trauma patient.

Technique.

The technique for subclavian venous catheterization differs from that for the adult in that the approach to the vein is more lateral in children. The infraclavicular approach is described. The equipment needed is the same as that used for femoral catheterization. The patient is placed in the Trendelenburg position with the head turned away from the side to be punctured and a towel roll placed under the shoulders (Fig. 19-17 (Figure Not Available)). The right side is preferred, since the dome of the lung is more cephalad on the left side. The needle insertion site is at the distal one third of the clavicle in the depression created between the deltoid and pectoralis major muscles. The skin is prepped with antiseptic

Figure 19-17 (Figure Not Available) Technique for subclavian venous catheterization. The needle is inserted at the distal one third of the clavicle in the depression created between the deltoid and pectoralis major muscles. The needle should be parallel to the frontal plane and directed medially and slightly cephalad toward a fingertip placed in the sternal notch. The patient is shown in a 30° Trendelenburg position. *(From Textbook of Pediatric Advanced Life Support, 1994. Reproduced with permission. Copyright American Heart Association.)*

solution, the area covered with a sterile drape, and the skin infiltrated with 1% lidocaine.

The finder needle is introduced and advanced slowly while negative pressure is applied with the attached syringe. The syringe and needle should be parallel to the frontal plane and directed medially and slightly cephalad, beneath the clavicle toward the posterior aspect of the sternal end of the clavicle (i.e., with the lower end of the fingertip placed in the sternal notch). [39] The needle is advanced until blood return is obtained. The bevel of the needle is then pointed caudad to direct the guidewire to the superior vena cava. The wire is then inserted during a positive pressure breath or natural exhalation and the catheter is introduced over the wire using the Seldinger technique as previously described for femoral catheterization. As in adults, the cardiac monitor may show a rhythm disturbance if the wire is advanced too far. Auscultation of bilateral breath sounds should be performed and a chest radiograph obtained to confirm the proper positioning of the catheter in the superior vena cava, as well as to rule out procedural complications such as pneumothorax or hemothorax. The catheter is then secured in place with sutures, and a sterile, occlusive dressing is applied.

Antecubital access.

Percutaneous insertion of central catheters by way of peripheral antecubital veins is used most frequently to obtain central venous access in patients with very small caliber vessels (e.g., low-birth-weight neonates and very young infants). These PICC lines are small Silastic catheters ranging in size from 23- to 16-ga. [51] [52] These catheters are rarely inserted as an ED procedure; more often they are placed in a stable child who will require longer term fluid or nutritional therapy or an extended course of IV antibiotics. The most common sites include scalp, neck, and arm veins. The catheter is then threaded centrally. PICC lines offer several advantages over conventional peripheral IV catheters and percutaneous central venous catheters. They can remain in place for up to 3 months, sparing veins from multiple reinsertions with peripheral venous catheterizations; the long-arm catheter is simpler to insert than central venous catheters and poses no risk of producing a pneumothorax or hemothorax on insertion.

Technique.

The arm of the vessel to be cannulated is initially stabilized using a support board or the help of an assistant. The remainder of the procedure requires sterile technique. Povidone-iodine is used to cleanse the skin overlying the vessel to be cannulated, and 1% lidocaine is infiltrated at the skin site to be punctured. This skin site is punctured with an 18-ga needle to ease insertion of the introducer through the skin. The catheter to be inserted is chosen based on the size of the access vessel.

Typically a 23-ga silicone elastomer catheter with other needed accessories is used, as in a kit prepared by Gesco International, Inc. (San Antonio, TX). Advantages of this catheter include (1) a double-wing silicone adapter, which precludes the need to make homemade blunt-end adapters to fit small cannulas and simplifies the taping procedure, and (2) a breakaway introducer needle that can be peeled off the catheter, thereby precluding the need for sliding the introducer off the catheter and placing an adapter. Because the length of this catheter (33.5 cm) is longer than needed in low-birth-weight neonates and young infants, the distance from the insertion site to the superior vena cava-right atrium junction is estimated (i.e., by measuring the distance between insertion site and the right nipple [Fig. 19-18*A*]), and the catheter is cut 1 to 3 cm longer than the estimated distance to compensate for variability between the estimated and actual needed length of the catheter. The end of this catheter is then connected to a Luer-Lok stopcock and syringe and filled with flush solution; the catheter is then ready for use.

The 20-ga breakaway introducer needle (Gesco International, Inc.) is also filled with flush solution and then directed slowly through the insertion site and into the access vein. When blood return occurs, the catheter is picked up approximately 1 cm from its tip and guided into the introducer needle (Fig. 19-18*B*). The catheter is advanced in 1-cm increments until the previously estimated distance is reached (i.e., the catheter tip is at the superior vena cava-right atrium junction). The breakaway introducer needle is then withdrawn several centimeters from the insertion site before peeling the introducer off the catheter to avoid inadvertent catheter laceration. If accidental laceration occurs, blunt-end adapters should be readily available. An alternative method, the

Figure 19-18 Techniques for insertion of central catheters from peripheral veins. *A*, A tape measure is used to determine the catheter length. *B*, Placement of the catheter through the specialized breakaway butterfly-type introducer needle.

Microintroducer technique, introduces a guidewire through the catheter used to gain access to the vein. A small "nick" is made with a scalpel, as described previously for central venous catheters, and an introducer catheter is threaded over the wire to make a larger entry. Finally, the silicone PICC line is carefully threaded into the introducer catheter and advanced as described earlier. [53]

Immediately after catheter placement and withdrawal of the introducer needle, the clinician will be able to manipulate the position of the catheter until clotting starts to occur at the insertion site. After the sterile field is discontinued, the catheter should never be advanced. The function of the catheter is checked by withdrawing blood, by noting the presence of residual air bubbles within the catheter, or both. After the clinician is assured that no air bubbles remain in the line, the catheter is flushed. This catheter should be "easy" to flush; if it is not, the clinician should reposition the catheter and recheck its function. If the catheter remains difficult to flush, it should be considered clotted and should be removed. Alternatively, position may be confirmed by chest radiograph and fibrinolytic therapy used, if considered appropriate.

A transparent skin covering is placed and is removed only when the catheter is removed; it is not routinely removed as are coverings of some surgically placed central venous catheters. Stabilization sutures are not routinely placed during this procedure. Occasionally a small amount of bleeding occurs at the insertion site; this

generally stops spontaneously or with gentle pressure. With the three-way stopcock in place, central venous pressure measurement and infusion of medications, IV fluids, and hyperalimentation solutions can be performed. Many clinicians at centers that frequently perform PICC insertions use sonography or fluoroscopy to increase likelihood of successful catheter placement. [54]

Complications

The incidence of complications from central venous catheterization ranges from 10% to 50%. [52] [54] Infection and thrombosis are the major risks associated with these catheters. [43] [55] Other complications include accidental displacement, phlebitis, hemorrhage, hematoma, dysrhythmia, air embolus, vascular obstruction or perforation, right atrial perforation, and localized edema. Blood sampling from indwelling central venous lines must be performed with caution, because the risk of contamination increases each time the system is opened. Morbidity from complications can be minimized by removing catheters as soon as they are no longer needed.

Emergency Vascular Access

The first steps in managing pediatric resuscitations are to establish an adequate airway, ensure adequate ventilation, and enhance blood circulation. Maintaining or reestablishing adequate circulation often requires prompt access to the intravascular space for administration of fluids or medications, or both. The difficulty of obtaining venous access during pediatric resuscitations can be considerable. [56] [57] In the review by Rossetti and colleagues, IV access required 10 or more minutes in 24% of the cases. The average time required for a cutdown was 24 minutes. Children who were successfully resuscitated had vascular access achieved significantly sooner than those who were not resuscitated. Emergency IV access was most prolonged in children younger than 2 years of age. This last finding is important, since the majority of cardiopulmonary arrests in children occur in this younger age group.

If no IV line is available, appropriate drugs can be given via the endotracheal tube (see Chapter 27) while attempts at venous access are initiated. Resuscitation courses aimed at enhancing the emergency care of children now stress the early use of intraosseous access [39] (see Chapter 26). Now experts suggest that intraosseous or central venous access should be attempted concurrently with attempts at peripheral venous access when treating a child undergoing CPR or in extremis from shock. Intraosseous access was previously felt to be effective only in children near or under the age of 6. This limitation has since been abandoned. The femoral vein is usually the central vein of choice in emergencies, because its consistent anatomic location and large size make it the safest and easiest central vein to catheterize. The femoral vein also can be accessed with minimal interference to resuscitative efforts.

Umbilical Vein Catheterization

Indications and Contraindications

The major indication for umbilical vein catheterization is access to the vascular system for emergency resuscitation and stabilization of the newborn. The umbilical vein may also be used for exchange transfusions and short-term central venous access in newborns. The umbilical vein may remain patent for about a week after birth (sometimes longer). [58] In the neonate who presents to the ED requiring emergency access, a peripheral vein would be preferable, but attempting to cannulate one of the umbilical vessels could be life-saving. The procedure is technically easier than umbilical artery cannulation.

Equipment and Setup

The supplies and equipment for catheterization are listed in Table 19-5 . The infant is placed beneath a radiant warmer, and the extremities are restrained. Oxygen is administered as needed, and the audible beep on the cardiac monitor is turned on. The operator should wear a surgical cap and mask and a sterile gown and gloves.

Technique

Holding the umbilical stump up, the cord is scrubbed with a bactericidal solution. Pooling of liquid at the infant's side should be avoided, because this may be associated with blistering of the skin under a radiant warmer. The umbilical area

TABLE 19-5 -- Umbilical Vein and Artery Catheterization Equipment

Infusion solution (usually $D_{5–10}$ W with electrolytes. Some clinicians also add 1 unit heparin per milliliter of fluid to "prevent" clotting in the catheter)
Fluid chamber, IV tubing, infusion pump, filter (0.22 µm), short length of IV tubing, three-way stopcock
Umbilical artery catheter (3.5 to 5 Fr)
3-0 silk suture on a curved needle
Curved iris forceps without teeth
Small clamps, forceps, scissors, needle holder
Sterile drapes
Light source
10 mL of heparinized solution for flush (1 to 2 units heparin per milliliter of fluid)
Surgical cap, mask, gown, and gloves

is draped in a sterile fashion, with the infant's head left exposed for observation.

To provide hemostasis and to anchor the line after placement, a loop of umbilical tape or a purse string suture is placed at the junction of the skin and the cord (Fig. 19-19). The cord is cut with a scalpel about 1 cm from the skin, and the vessels are identified. The vein is usually located at 12 o'clock and has a thin wall and large lumen. It may continue to bleed after cutting, whereas the two arteries have thicker walls and smaller lumina, and constriction reduces bleeding after being cut. Occasionally a persistent urachus may be mistaken for the umbilical vein, but the presence of urine should identify the mistake.

The catheter (3.5 Fr [preterm infants] to 5.0 Fr [term infants]), which has been flushed with heparinized saline and attached to a three-way stopcock, is placed in the lumen of the umbilical vein and advanced gently. The catheter is advanced only 1 to 2 cm beyond the point at which good blood return is obtained. This is usually only 4 to 5 cm in a term-sized infant. If the catheter is pushed farther than this, it will do one of two things: It may enter the *ductus venosus* and then move into the inferior vena cava, or it may enter a branch of the portal vein within the liver (evidenced by resistance at 5 to 10 cm).

The *inferior vena caval site* may be a desirable location in some newborn infants in whom peripheral vascular access is limited and for whom central venous access is desired for central venous pressure monitoring or infusion of medications, high concentrations of glucose (greater than 10%), IV fluids, and hyperalimentation solutions. The catheter must be inserted approximately 10 to 12 cm in a term-sized infant to reach the inferior vena cava. The *portal vein site* can be verified by radiographs that document the placement of the catheter. Note that an umbilical venous catheter will proceed directly cephalad (without making a downward loop) until it passes through the *ductus venosus* (Fig. 19-20). Some practitioners use standardized graphs to estimate length of insertion, which are based on the shoulder-to-umbilicus length (Fig. 19-21*A*). Such graphs are useful if stored in the drawers of the warming beds used to resuscitate newborns and small infants, along with the catheters and other equipment. Shoulder-to-umbilicus length is the perpendicular line measured from the tip of the shoulder to the horizontal level of the umbilicus. Alternatively, if the graph is not available, the shoulder-to-umbilicus length multiplied by 0.6 gives an approximate insertion length that will result in the tip of the catheter above the diaphragm but below the right atrium, in

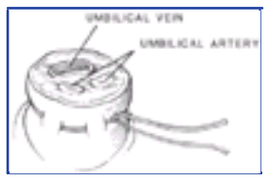

Figure 19-19 When placing an umbilical vein catheter, a pursestring suture or umbilical tape is passed around the base of the cord to provide hemostasis and to anchor the line.

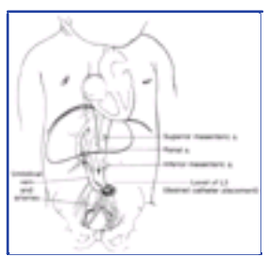

Figure 19-20 An umbilical vein catheter is directed toward the head and remains anterior until it passes through the *ductus venosus* into the inferior vena cava. *(From Ludwig S, Fleisher GR: Textbook of Pediatric Emergency Medicine. Baltimore, Williams & Wilkins, 1994.)*

the inferior vena cava.[58] There are also multiple regression formulae to estimate catheter length, based on birth weight, [59] but during a resuscitation, it is most prudent to gently pass the line only 4 to 5 cm in a term infant to avoid injecting hyperosmolar fluids into the portal vessels, which potentially could result in liver necrosis. Remember to account for the length of the umbilical stump in the calculation.

Air embolism may occur at the time of catheter removal if the infant generates sufficient negative intrathoracic pressure (as during crying) to cause air to be drawn into the patent umbilical vein. Therefore, caution must be used during catheter removal to ensure that the vein is promptly occluded (by tightening a pursestring suture or applying pressure on or just cephalad to the umbilicus).

Complications

Complications of umbilical venous catheters include hemorrhage, infection, injection of sclerosing substances into the liver (resulting in hepatic necrosis), air embolism, catheter tip embolism, and vessel perforation.[54] It is most important that one follow careful technique in insertion and maintenance of catheters to minimize such complications.

Umbilical Artery Catheterization

Indications and Contraindications

Umbilical artery catheterization is a useful procedure in the care of newborn infants who require frequent monitoring of arterial blood gases and arterial blood pressure, fluid and medication administration, and exchange transfusions. It is imperative for the clinician to remain aware of potential complications. [60] One of the two umbilical arteries may be cannulated for resuscitation purposes, but an umbilical vein is generally technically easier to cannulate and may be preferred in an emergency.

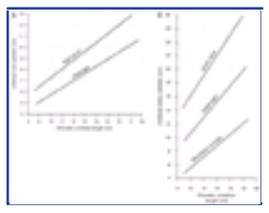

Figure 19-21 After measuring the shoulder-to-umbilicus length, a standardized graph can be used to determine the appropriate length of the umbilical venous catheter (*A*), or umbilical arterial catheter (*B*). The venous catheter should be inserted into the inferior vena cava below the level of the right atrium. The appropriate length of the arterial catheter depends on whether a "high" or "low" line is desired (see text for explanation). *(From The Johns Hopkins Hospital, Nechyba C, Gunn VL: The Harriet Lane Handbook: A Manual for Pediatric Home Officers, 16th ed. St. Louis, CV Mosby, 2002.)*

Equipment and Setup

The equipment required for umbilical artery catheterization is identical to that used for umbilical venous catheterization (see Table 19-5). Additional equipment needed for continuous arterial pressure monitoring and infusion should be readily available.

Technique

The technique of umbilical artery catheterization is similar to that described for umbilical vein catheterization in the preceding section. After the umbilical arteries have been located, the cord is grasped with a curved hemostat near the selected artery (Fig. 19-22). Using two hemostats to grasp each side of the cord and slightly evert the edges can sometimes aid in exposure of the arteries. Using the curved iris forceps without teeth, one gently dilates the artery, sometimes with repeated passes of the forceps. Umbilical artery spasm may make the procedure difficult. A 3.5 to 5 Fr catheter is attached to a three-way stopcock and flushed with sterile heparinized solution. The catheter may then be introduced into the dilated artery. A 3.5 to 4 Fr catheter is recommended for infants weighing less than 2 kg and a 5 Fr catheter for those weighing more than or equal to 2 kg.

When the catheter is being inserted, tension should be placed cephalad on the cord, and the catheter should be advanced with slow, constant pressure toward the feet (Fig. 19-23). Resistance is occasionally felt at 1 to 2 cm and should be overcome by gentle, sustained pressure. If the catheter passes 4 to 5 cm and meets resistance, this generally indicates that a "false passage" through the vessel wall has occurred. Occasionally one may bypass the perforation by attempting catheterization with the larger 5 Fr catheter.

The optimal position of the catheter tip in the descending aorta remains the subject of some debate. [59] [61] If a low (L3 to L4) position is desired, the catheter may be advanced 7 to 8 cm in a 1-kg premature infant or 12 to 13 cm in a full-term infant. Graphs are available to estimate the proper length of insertion for a high or low catheter location (see Fig. 19-21*B*). Once sterile technique is broken, the line may not be advanced. It is therefore preferable to position the catheter too high and to withdraw as necessary according to the location on a radiograph. After it has been positioned appropriately, the catheter should be tied with the previously placed suture (see Fig. 19-23) and taped to the abdominal wall (Fig. 19-24). A radiograph should be obtained and the catheter repositioned, if necessary, with the tip at the lower border of the L3 vertebra. Some clinicians prefer to place the catheter high (T6 to T9 vertebrae). There are no unequivocal data to support either preference.

Radiographs of an arterial catheter (Fig. 19-25) will show the catheter proceeding from the umbilicus down toward the pelvis, making an acute turn into the internal iliac artery, continuing toward the head into the bifurcation of the aorta, and then moving up the aorta slightly to the left of the vertebral column. [62]

Most unsuccessful umbilical artery catheterization attempts fail because the catheter perforates the arterial wall approximately 1 cm below the umbilical stump, where the umbilical artery begins curving toward the feet. In this instance, the catheter is advanced in the extraluminal space, and resistance is met at 4 to 6 cm. The following maneuvers make it possible to avoid perforating the umbilical arterial wall in most cases:

1. The catheter should be advanced slowly. When slight resistance is met at approximately 1 cm, the catheter should be advanced very gently with steady pressure. It should never be forced, because it will likely perforate the wall. A catheter or feeding tube with a molded tip

should be used. A catheter tip that has been cut with scissors is more difficult to insert and advance.
2. Because the artery curves toward the feet, the umbilical stump should be held with a curved clamp and should be pulled toward the head so that the catheter is inserted toward the feet in as straight a direction as possible.

Figure 19-22 The umbilical cord is grasped with a curved hemostat near the selected artery. The umbilical artery is then dilated with a curved iris forceps.

Complications

If the catheter becomes plugged or fails to function properly or if there is blanching or discoloration of the buttocks, the heels, or the toes, then the catheter should be removed at once. Umbilical arteries are most easily cannulated in the first few hours of life but may provide a viable vascular route as late as 5 to 7 days of age.

Complications include hemorrhage, infection, thromboembolic phenomena (especially to the kidneys, the gastrointestinal tract, and the lower extremities), aortic thrombosis, aortic aneurysm, vasospasm, air embolism, vessel perforation, peritoneal perforation, and hypertension. [54] [63] [64]

Percutaneous Arterial Catheterization

Indications and Contraindication

Despite the growing use of noninvasive devices for monitoring transcutaneous oxygen and carbon dioxide, percutaneous

Figure 19-23 The catheter is introduced into the dilated artery and advanced toward the feet. The suture placed around the base of the cord is tied to the catheter.

peripheral arterial catheterization is indicated when there is a need for frequent blood gas sampling, continuous arterial blood pressure monitoring, or both. Arteries used for peripheral catheters in infants include the radial, [65] ulnar, [66] femoral, [67] temporal, [68] and posterior tibial arteries. [69]

Percutaneous radial artery catheterization has become widely accepted and has been shown to be a safe method in infants and children. The catheter allows for preductal blood gas determinations if placed in the right radial artery. Only the procedure for radial artery catheterization is described here, but catheterization of other vessels is similar.

The following are contraindications to peripheral arterial catheterization:

- Situations in which adequate peripheral arterial samples can be obtained by percutaneous punctures
- Situations in which circulation of the extremity to be catheterized is compromised
- Situations in which occlusion of the vessel to be catheterized results in compromised perfusion of that extremity
- The presence of an ongoing bleeding diathesis
- The presence of localized infection or inflammation overlying the artery to be cannulated
- Situations in which intensive monitoring of line function is not available.

Figure 19-24 The tape is pleated above and below the catheter.

Equipment and Setup

The equipment needed for arterial catheterization is essentially the same as that required for percutaneous peripheral venous catheterization (see Table 19-4). The catheters used are usually 22- or 24-ga over-the-needle catheters, a T-piece connector, and a stopcock. One should connect the T piece and the stopcock and then fill them with normal saline solution. An infusion pump with heparinized saline (1 to 5 U/mL) should be readied. [70]

Technique

The procedure should be performed with good lighting and an adequate work area, with the infant's heart and respiratory rates monitored closely. The radial artery may be palpated proximally to the transverse wrist crease on the palmar surface of the wrist, medial to the styloid process of the radius. The artery is then compressed, and the hand and fingers are observed for color change. If blanching or

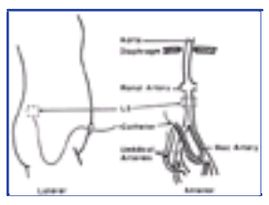

Figure 19-25 The umbilical artery catheter makes a loop downward before heading cephalad (schematic drawing of a radiograph interpretation).

cyanosis is noted (indicating poor collateral circulation), catheterization is not performed. If locating the artery by palpation is difficult, some clinicians find transillumination devices, [71] or Doppler probes helpful.

The infant or child's hand and lower forearm are secured to an arm board with the wrist dorsiflexed 45° to 60° with the aid of a roll of gauze placed underneath. Care must be taken to leave the fingers exposed to assess the peripheral circulation. The radial artery is palpated at the point of maximal impulse and can be marked with a gentle indentation by one's fingernail. The area over the radial artery is prepared with a povidone-iodine solution and washed with alcohol. Topical or local anesthetic (such as 1% lidocaine without epinephrine), or both, may be used at the planned insertion site. The catheter with stylet is inserted through the skin just proximal to the transverse wrist crease at a 10- to 20-degree angle (Fig. 19-26). The catheter with needle is advanced slowly until blood appears in the catheter hub, signifying puncture of

Figure 19-26 The catheter assembly is introduced into the radial artery through skin at a 10- to 20-degree angle. This is a smaller angle than is used for simple arterial puncture. Gloves should be worn.

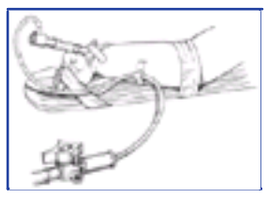

Figure 19-27 One technique of taping the arterial catheter. The arm board should be well padded and secured.

the anterior arterial wall. The catheter is slowly advanced until blood appears in the needle and then the needle angle is carefully lowered to approximately 10°. The catheter is slowly advanced over the needle into the lumen of the artery, and the needle is removed. The stopcock and T-piece connector are attached to the catheter hub. The stopcock is opened to the syringe to confirm pulsatile blood return. It is then flushed with 0.5 mL heparinized flush solution very gently to clear the catheter while the fingers and the hand are observed for evidence of blanching or cyanosis.

The puncture site is then covered with antibiotic ointment, and the catheter is fixed to the skin by a thin piece of tape placed adhesive side uppermost under the catheter hub and crossed over the catheter in a V shape. A second piece of tape is passed around and over the catheter hub and is fixed to the wrist (Fig. 19-27). A small piece of tape is used to attach the T-piece connector to the wrist area or to the splint. The fingers should be easily visible.

Only heparinized normal or half-normal saline is used for infusion. Some clinicians prefer to add 1 to 5 U of heparin per milliliter of infusion solution infused at a rate of 1 to 2 mL/hour. Medications, blood or blood products, amino acid solutions, IV fat solutions, and hypertonic solutions are not infused through the catheter.

The catheter must be removed when there is evidence of blanching or cyanosis or when it is impossible to withdraw blood from the catheter or difficult to flush the catheter.

Complications

Complications, which have been reported with every type of arterial catheter, include hemorrhage, thrombosis, spasm, infection, scars, air embolism, retrograde blood flow, transient elevation in blood pressure with rapid (less than 1 second) infusion, and nerve damage. Thrombosis or spasm may result in blanching or cyanosis of the extremity or skin.[72] There is potential for loss of digits, an entire extremity, or large areas of skin, as well as cerebral infarction with temporal artery catheters. [73] Saladino and colleagues note that complications from ED-placed arterial lines are uncommon and generally minor. [27]

Arterial Cutdown Catheterization

Indications and Contraindications

Arterial catheterization by cutdown on the posterior tibial artery, radial artery, and temporal artery may be indicated when the need exists for frequent monitoring of arterial blood gases or blood pressure and when percutaneous access is not possible. [69] Arterial cutdowns are contraindicated when (1) adequate peripheral blood gas samples can be obtained by percutaneous punctures or catheterization, (2) circulation of the extremity to be catheterized is compromised, or (3) occlusion of the vessel to be catheterized results in compromised perfusion of that extremity.

Equipment and Setup

Successful arterial cutdown catheterization in the small infant requires sterile instruments, an assistant, good lighting, and a selection of catheters. Previous clinical experience is helpful. The equipment required for performing an arterial cutdown catheterization can be found on a cutdown tray, available in most EDs. Also needed are a 22- or 24-ga over-the-needle catheter, T-extension connector tubing, stopcock, a 5- or 10-mL syringe filled with flush solution (normal saline with 1 to 5 U heparin/mL) and silk suture ties.

Technique

The anatomy (Fig. 19-28) and technique for posterior tibial arterial cutdown are described in detail (Fig. 19-29). The same technique is applicable for the radial artery. The clinician stabilizes the foot in a neutral position by taping the externally rotated lower leg to a splint. The *posterior* tibial artery is then localized by Doppler ultrasound just posterior to the medial malleolus. The operator prepares for the procedure by scrubbing and donning a gown and gloves; the foot is prepared with a povidone-iodine solution.

Following SQ injection of 1% lidocaine, a 5- to 7-mm transverse incision is made in the skin over the artery posterior to and at the midlevel of the medial malleolus (Fig. 19-29*A*). Using blunt dissection in a vertical direction (parallel to the vessels), the tissue is separated with a small, curved forceps, and the artery is identified. The artery courses with the vein just anterior and superficial to the nerve and is usually pulsatile. The artery is isolated by sliding a small, curved forceps beneath it and gently elevating the vessel (see Fig. 19-29*B*). Excessive

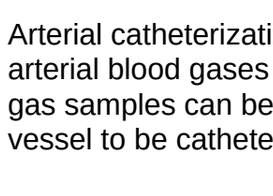

Figure 19-28 Anatomy of the posterior tibial artery and surrounding structures.

Figure 19-29 *A*, Posterior tibial artery cutdown technique. With the foot prepared and immobilized, a 5- to 7-mm incision is made in the skin posterior to and at the midline of the medial malleolus. *B*, A curved forceps and a silk suture are inserted beneath the posterior tibial artery, which courses just posterior to the medial malleolus.

manipulation of the artery can cause spasm; if this occurs, a few drops of 1% lidocaine applied locally may result in dilation. A silk tie (without a needle) is then placed beneath the artery to stabilize it during cannulation.

At a 10-degree angle, a 22-gauge Angiocath with the catheter bevel down is inserted into the artery over the surface of the forceps. When blood return is seen, the catheter is advanced over the stylet to its full length (Fig. 19-30). The needle stylet is then removed, and the catheter is connected to the T-connector tubing and a three-way stopcock that has

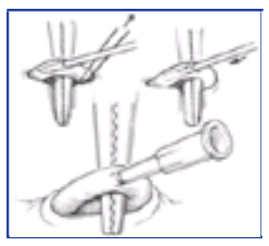

Figure 19-30 Technique of inserting the arterial catheter. A silk tie is used *only to stabilize the artery during cannulation.* It is never tied. The catheter is inserted under direct vision without making an incision in the vessel.

been prefilled with heparinized flush solution. Patency is checked by observation of blood return with pulsations; the catheter is then flushed slowly and gently. The silk suture is removed, and the skin incision is sutured. The catheter is sutured to the skin over the heel. The catheter and connector are then secured to the heel with tape (Fig. 19-31). The stopcock is then connected to the infusion line.

Complications

The complications of arterial cutdown are similar to those of percutaneous arterial catheterization. They include hemorrhage, thrombosis, or spasm resulting in loss of tissue; infections; permanent scars; and nerve damage. Complications have been reported with all types of arterial cutdown. Follow-up data and computed tomography data suggest an association

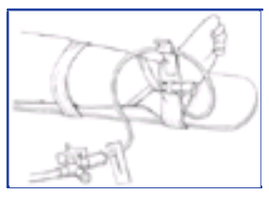

Figure 19-31 The skin incision is closed, and the catheter and connector are secured to the heel with tape.

between temporal artery catheterization by the cutdown technique and cerebral infarct that may result in hemiparesis. [74] Therefore, temporal artery catheterization should be the last choice for arterial catheterization.

Chapter 20 - Arterial Puncture and Cannulation

Dave Milzma
Tim Janchar

Arterial puncture remains the current standard for blood sampling of acid-base balance and true arterial blood gas. Arterial blood pressure is considered second only to heart rate as the most important vital sign. The absence of arterial blood pressure defines cardiac arrest and serves as the best endpoint of resuscitation. Blood pressure can be obtained by noninvasive methods either by auscultation or automated pneumatic cuff, both of which can be unreliable at times. Both methods have known inaccuracies in determining true systolic blood pressure, but reasonably good accuracy with regard to mean pressure. [1] [2] Intra-arterial cannulation with continuous blood pressure transduction and display is currently the accepted standard for comprehensive arterial pressure monitoring. [1] [3] It is an invasive modality and requires expertise and sufficient support to prepare for accurate monitoring on a continual basis. Accurate monitoring of arterial pressure reflects the force of systemic perfusion and is the most important determinant of cardiac work.

Early scientists reported cutting down to obtain direct measurement of arterial pressure in animal models. [1] [2] J.L.M. Poiseuille first introduced the use of a mercury manometer for the measurement of blood pressure in 1828. Advances came slowly until the space age in the 1960s introduced electrical monitoring of arterial pressure with transducers and recorders rather than simple mechanics, thus permitting mathematical waveform analysis in addition to visual analysis. More recent advances have included continuous, invasive monitoring of arterial blood gas values. [4] Even such new improvements as continuous monitoring still require arterial puncture and cannulation. In the future the traditional, macroscopic invasive approach will likely give way to noninvasive molecular analysis, capable of detecting changes in arterial oxygenation and perfusion before a measurable clinical presence. It is a distinct possibility that comprehensive noninvasive monitoring will be introduced and even become the standard before the next edition of this text.

INDICATIONS AND CONTRAINDICATIONS

Despite the advent of new, noninvasive monitoring of respiratory functions and venous marker tests, there remain many patients in the emergency department (ED) whose care and resuscitation would be enhanced from arterial puncture or cannulation (Table 20-1). The indications for direct, arterial placement of a catheter for blood pressure monitoring fall into three major categories [5] [6] :

1. *Direct arterial blood sampling.* Catheter access removes the need for multiple arterial punctures and allows for either repeat arterial blood sampling or the placement of new sensors for continuous monitoring of blood gas and other chemistry values.
2. *Continuous real-time monitoring of blood pressure.* Patients with acute hypo-perfusion and those receiving vasoactive drug infusion require the superior monitoring and moment-to-moment change detection afforded by arterial catheterization.
3. *Failure or inability to use indirect blood pressure monitoring.* Some acutely ill patients such as those with severe burns or morbid obesity may need ongoing perfusion monitoring that can best be accomplished by arterial catheterization.

Although acute respiratory decompensation and metabolic emergencies are the most common reasons for arterial blood gas sampling, all lab tests are possible from arterial sampling. Blood cultures from an indwelling arterial line have sensitivity and specificity equal to those of cultures obtained from a venipuncture site. [7] [8] Patients with respiratory illness can be managed without arterial puncture due to recent advances in noninvasive pulse oximetry and continuous end-tidal carbon dioxide monitoring, but there is still a role for arterial blood sampling. The initial correlation between noninvasive values with acid-base status via arterial sampling is still imperative in critical illness to set a baseline or verify a trend. Metabolic and electrolyte monitoring often require additional arterial sampling, especially in patients with severe diabetic ketoacidosis who require frequent pH, electrolyte, and glucose measurements for accurate treatment.

Arterial systolic and diastolic pressures can be continuously and accurately observed by arterial catheterization with an electromechanical pressure transducer attached to a monitor.[6] Such capabilities are routinely used in the operating room or intensive care unit (ICU) and prove most useful when available in an ED for critically ill patients. Many interventions, such as the long-term use of vasoactive drugs (e.g., nitroprusside and dopamine), are best administered with continuous arterial pressure monitoring. The response of trauma and cardiac patients to acute resuscitative efforts also may be more easily followed by the use of arterial catheterization.

Arterial puncture is used routinely by cardiologists and radiologists for cardiac and neuro-angiography. Angiography is becoming a less common indication for arterial puncture in the ED due to advances in ultrasound, computed tomography-angiography, as well as rapid and routine magnetic resonance imaging with intravenous contrast. However, angiography is still considered for suspected cases of peripheral arterial trauma, suspected aortic injury and aneurismal or embolic disease.

Few contraindications to arterial puncture exist; none are absolute, but should always be considered on a risk-benefit evaluation. For example, post-thrombolysis, arterial cannulation should only be performed if it will provide essential data that cannot be obtained by any other method and the patient's condition requires ongoing assessments. Once a patient has received thrombolytic therapy, single arterial puncture of the radial artery is preferred. Arterial pucture considerations should be considered before administration of thrombolytic agents. Arterial puncture can be performed in patients who are anticoagulated or who have other coagulopathies, but should be undertaken with extreme care in patients with disseminated severe coagulopathies.

There are definite reports of patients with complications from bleeding requiring transfusion. Some patients, all of whom were anticoagulated at the time of puncture, even suffered compression neuropathies secondary to hematomas as a result of arterial puncture. [9] Repeated arterial sampling in these patients should be accomplished by insertion of an

TABLE 20-1 -- Arterial Puncture and Cannulation

Indications	Relative Contraindications	Strict Contraindications
Blood gas sampling	Previous surgery in the area, especially cut-down	Inadequate circulation to the extremity
Continuous pressure monitoring		Raynaud syndrome
Frequent need for blood sampling (ongoing resuscitation)	Anticoagulation	Buerger disease (thromboangiitis obliterans)
	Coagulopathy	
Inotropic support—use of continuous infusion of vasoactive agents	Skin infection at the site	Full thickness burns
	Atherosclerosis	
Major surgery involving fluid shifts/blood loss	Inadequate collateral flow	
Hypothermia-induced or severe exposure	Partial thickness burns	
Diagnostic angiography		
Therapeutic embolization		

indwelling cannula to minimize the number of puncture sites in the arterial wall and should be performed by only the most experienced clinicians.

The presence of severe arteriosclerosis, with or without diminution of flow, is only a relative contraindication to arterial puncture, especially when followed by cannulation. Often patients require continuous hemodynamic monitoring for vasopressor administration. Combined with advanced cardiovascular disease, this makes invasive monitoring more valuable than most risks.[6] An alternative site should be considered if an isolated decreased palpable pulse or bruit is felt over a selected site. Evidence of decreased or absent collateral flow in areas where flow normally exists, such as a positive Allen test (discussed later in Techniques), should also lead one to consider an alternative site. One must avoid puncture of a specific arterial site when infection, burn, or other damage to cutaneous defenses exists in the overlying skin.

EQUIPMENT

To obtain a single sample of arterial blood by the percutaneous method, a 3-mL syringe (preferred and most common) is attached to a needle. Needle size should vary based on puncture location and patient size and age. Most adults should have a 20-gauge (ga), 2.5-in. needle for a femoral sample and a 1.25-in. 22- to 23-ga for a radial artery puncture. For pediatric arterial sampling, slightly shorter length needles in the range of 22- to 24-ga should be used in the same sites as in adults.

Precoated blood gas syringes allow for longer shelf life and ready use. If necessary, a regular syringe may be prepared with 1 or 2 mL of a heparinized saline solution (1000 IU/mL) drawn into the syringe to coat the barrel and needle. The heparin must be fully ejected through the needle immediately before puncture to minimize heparin-related errors.

Even dry heparin may produce arterial blood gas (ABG) result abnormalities due to a heparin-induced dilutional effect. [10] The newest blood gas and chemistry analyzers require only 0.2 mL of whole blood for accuracy and some point of care devices can perform analysis on drops of blood. However, sample sizes aspirated in heparin-coated syringes with <1.0 mL will result in heparin error to ABG values.

Stored heparin solution has a higher PO_2 and a lower PCO_2 than blood.[11] A dilutional effect from heparin would mean that the addition of 0.4 mL of heparin solution to a 2-mL sample of blood (dilution of 20%) will lower the pCO_2 by 16%.[10] Proper technique with full ejection of excess heparin will prevent such problems. A falsely low pCO_2 is the most clinically significant change caused by excess heparin. [10] [11] Neither pO_2 or pH levels are significantly altered by the addition of heparin in most instances, although a slight increase in pO_2 and minimal decrease in pH may occur if high concentrations of heparin are used (25,000 IU/mL). [12]

The fluid-filled recording systems used with arterial cannulation have a great influence on the accuracy of pressure measurements. The frequency responses of tubing, transducers, and other components of the monitoring system influence the measurement accuracy of systolic and diastolic pressures. Failure to recognize recording system artifacts will lead to errors in pressure interpretation. [2]

Various catheter types have demonstrated similar frequency response characteristics, but some studies have found more variable effects on complication rates. There is some debate over complications due to catheter composition, such as possible increased thrombosis with Teflon catheters. [13] [14] Another contributing element leading to thrombosis is catheter diameter; the incidence of thrombosis is inversely related to the ratio of vessel lumen to catheter diameter. [15] Thus, the risk for thrombosis decreases as the catheter diameter decreases. Incidence of thrombosis also increases with increased duration of catheter placement.

There are specific recommendations relative to vessel and puncture site location. Table 20-2 lists the usual equipment for arterial cannulation, although many kits contain most needed supplies. Shorter catheters are ideal for peripheral artery cannulation, whereas a longer catheter using the Seldinger technique is preferable for the femoral artery (Fig. 20-1). Some studies suggest that thrombosis is less likely with a nontapered catheter. [16] As mentioned in the preceding paragraphs, an 18- to 20-ga catheter should be used in adults to cannulate the femoral artery. Small children and infants require a 22- to 24-ga catheter, which may need to be inserted through a femoral cutdown technique. Older pediatric patients usually require 20- to 22-ga catheters, based on the patient's size.

The tubing that connects the catheter to the pressure transducer has a significant effect on monitoring system accuracy. The higher the frequency response of the entire system, the more accurate the determination of systolic and diastolic pressure; however, artifact also becomes more of a problem. [5] [17] Stiff, low-capacitance, plastic tubing should be used for arterial catheterization and monitoring. The electronic pressure transducer connection should be placed as close as possible to the patient and zeroed appropriately, because the frequency response of a tube is inversely related to its length. [17] [18] [19]

TABLE 20-2 -- Equipment for Insertion and Maintenance of an Indwelling Arterial Cannula

Percutaneous insertion
Iodophor solution (alcohol, only if patient is allergic)
1% lidocaine (without epinephrine)
10-cm × 10-cm dressing sponges
Adhesive tape
Iodophor ointment
Arm board for brachial, radial, or ulnar cannulations
Appropriate-sized intravenous catheters
Syringes
Pressure tubing
Two 3-way stopcocks
Pressure transducer
Connecting wire
Monitor display
500–1,000 mL Bag of normal or heparinized saline
Pressure blood infuser, set up with continuous flush device
Additional equipment required for cutdown insertion technique
Scalpel blade (No. 11)
4-0 nylon or silk suture on skin needle
Needle driver

The pressure wave produced with each contraction is transmitted from the artery through the catheter and connecting tubing to a measuring device. The arterial fluid wave is received by an electromechanical transducer, which changes the mechanical pressure wave into an electrical signal that can display on the monitor. With the use of minicomputers, various numerical values and hemodynamic paramenters can be displayed or stored for future analysis. Currently, electronic transducers are most commonly used, but the technology is likely to change. The most basic system for obtaining blood pressure values uses a manometer, which has been used since antiquity as the standard reference for measuring pressure. [20]

After arterial cannulation, a mercury manometer can be connected to the arterial system by a catheter filled with

Figure 20-1 Catheters for arterial cannulation. A standard intra-catheter for arterial cannulation may be used for direct vessel cannulation. Newer devices with a modified guidewire and quick-flash identifier (Arrow International, Inc. Reading, PA) or a needle with an attachable guidewire to aid cannulation are also available.

heparinized saline.[21] [22] The catheter is arranged to have a fluid meniscus at the same level as the heart when there is no pressure input. The meniscus is below an air column in a vertical tube long enough to avoid saline contamination of the manometer at maximal pressures (Fig. 20-2). Although excellent for recording steady pressures, it cannot respond to pressure changes more than a cycle every 2 to 3 seconds. Thus it displays only a mean value (mean arterial pressure [MAP]) in millimeters of mercury (mm Hg). Current high fidelity systems record pressure cycles up to 500 cycles/sec and display the systolic and diastolic pressure, MAP, trend monitoring, and other calculated hemodynamic values. [21]

A continuous method of pressure tubing flush is required to maintain the patency of the catheter lumen during intra-arterial pressure monitoring. A three-way stopcock through which the tubing is intermittently flushed (a minimum of every 15 to 30 min) with saline is a simple, effective method. Continuous flush devices push a set amount of fluid (usually 2 to 3 mL/hour) through the line. [6] A typical monitoring system that includes this device is shown in Figure 20-3 . The pressure transducer must be mounted at the level of the patient's heart.

Intravascular transducers are also available but have many potential disadvantages and are used infrequently. Most of the numerous brands are fragile, temperature sensitive, of variable quality, and much more difficult to place into vessels than catheters. Anecdotal findings of fibrin deposition on these devices have been noted, but no reports demonstrated any increased incidence of thrombus formation. The greatest advantage of these intravascular transducers is the continuous trending of arterial gas values and the elimination of potential error induced by catheters, stopcocks, and connecting tubing. [23] [24] Despite obvious advantages, the use of these expensive, disposable devices has yet to penetrate many EDs. Usage of these devices is likely to happen only after it occurs in other hospital settings, such as the ICU.[4] So many transducer and monitor combinations exist that a discussion of their relative merits is beyond the scope of this chapter.

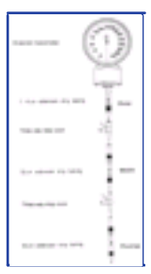

Figure 20-2 Assembly technique for anaeroid manometer system. The middle and proximal extension tubings contain heparinized saline. The middle extension tubing is arranged to form a fluid meniscus at the same level as the heart when the proximal stopcock is closed to the middle tubing (i.e., no pressure input). The distal extension tubing is filled with air and held vertically so that there is no saline contamination of the manometer at maximal pressures. Approximately 10 to 12 cm of air in the distal and middle tubings is optimal. The same system can be used with a mercury manometer in place of the anaeroid manometer. Sterility of the extension tubing and stopcocks is essential. *(From Zorab JSM: Continuous display of the arterial pressure: A simple manometric technique. Anaesthesia 24:433, 1969. SITE SELECTION

The radial, brachial, and femoral arteries are usually punctured for blood gas sampling in adults. Pediatric sites also include foot sites and the uterine artery in newborns.

The procedure is usually accomplished at the bedside using percutaneous methods similar to central venous catheter placement to cannulate arteries. Technique depends on site selection: Radial and dorsal pedalis artery cannulation is usually placed with an over-the-needle catheter with or without a guidewire. Larger vessels such as femoral or axillary always use needle puncture of the artery followed by the catheter placed over a guidewire (Seldinger technique). In decreasing order of frequency, the following arteries are used in adults and children: radial, femoral, brachial, axillary, dorsalis pedis, and ulnar. The temporal and umbilical arteries are often cannulated in infants and neonates. Such arteries, as well as the radial artery, are very safe for these patients (see Chapter 19).[25]

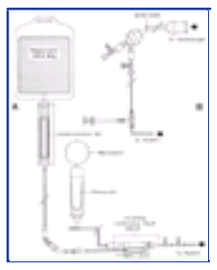

Figure 20-3 Arterial pressure monitoring systems. *A,* System for continuous flush. Heparin (2 mL of a 1:1000 unit solution) is added to a 1-L bag of normal saline, and the bag is pressurized to 300 mm Hg using a metered blood pump (not shown). The continuous flush device is set to deliver 3 mL/hour of the heparinized saline. A mechanical pressure transducer is depicted. The transducer device is a sterile, inexpensive, fully assembled monitor that can be used during patient transfer. Alternatively, the electronic transducer depicted in *B* may be used. *B,* System for manual flush. A heparinized saline flush solution can be injected manually through a syringe at the proximal or distal port. The transducer dome should be maintained at the level of the patient's heart. *(From Beal JM [ed]: Critical Care for Surgical Patients. New York, Macmillan, 1982. Reproduced by permission.)*

The potential consequence of complete blood flow loss through a vessel due to intraluminal thrombosis must be considered when choosing a site for arterial puncture. Since the most frequent complication of arterial catheterization is bleeding, the ability to control hemorrhage must also be considered. For these reasons, the radial and femoral arteries are favored due to their good collateral blood flow and ease of compression in case of hemorrhage. Patient comfort and nursing care concerns also should be considered during site selection.

The arterial pulse is palpated to ascertain the location of the vessel, and the overlying skin is prepared sterilely with an iodophor or other antiseptic solution. The patient's skin should then be anesthetized with a wheal of local anesthetic (1% lidocaine) without epinephrine placed through a small needle (25- or 27-ga). One study found no significant alterations in pCO_2 or pH from the pain or anxiety of an unanesthetized arterial puncture (Table 20-3).[26] If the patient is

TABLE 20-3 -- Parameters that Affect Interpretation of Arterial Blood Gases

Parameter	Heparin*	Air Bubble in Sample	Delayed Analysis?
pO_2	No significant change†	Elevated	Variable¶
pCO_2	Lowered‡	No significant changes§	Elevated£
pH	Unchanged‡	No significant changes§	Lowered£

*Use only 1000 IU/mL concentration. Fill dead space of needle and syringe only, and collect 3 mL of blood.
?Anaerobic storage at room temperature for 20 minutes results in no significant change.
†There are reports of slight increases in pO_2 with excessive heparin.
¶Changes unpredictable at 20 minutes, regardless of storage method.
‡The falsely lowered pCO_2 that occurs with added heparin is the most clinically significant change noted. pH may be decreased if a large volume of concentrated heparin (25,000 IU/mL) is used.
§If stored at 4°C for 20 minutes.
£Minimal changes up to 2 hours, if stored at 4°C.

cooperative (with careful discussion of the procedure before-hand), in extremis, or unresponsive to pain in the area to be punctured, this anesthetic infiltration may be omitted. If local anesthesia is to be performed, care must be taken to use a small amount of local anesthetic—a large wheal will obscure the pulse.

The arterial pulsation is then isolated with the index and middle fingers of the gloved, nondominant hand and the vessel course identified. The skin should be punctured through the anesthetic wheal, immediately distal to the palpated pulse under the index finger (Fig. 20-4). The older technique of placing the needle between the index and middle finger risks self-puncture and is no longer advised. The needle should be advanced slowly toward the pulsating vessel at an approximate 30° angle with the skin. A larger angle is required for femoral artery puncture. Once the needle enters the arterial lumen, the syringe plunger should be allowed to rise with the arterial pressure on its own in order to discriminate between chance of venous sampling. If no blood flow is obtained, the needle should be withdrawn slowly, because both walls of the vessel may have been punctured. A sample may be obtained during needle withdrawal. Redirection of the needle should occur only when the needle has been retracted to a location just deep to the dermis.

There are reports of using either hand-held Doppler or ultrasound probe to assist in vessel location for both venous and arterial puncture and cannulation. [27] Although viable in difficult cases, the clear majority of procedures should be accomplished without this extra delay or expense. However, both ultrasound and handheld Doppler have had increased usage due to improved technology and decreased costs. If used, the probe should be held over the artery proximal to the puncture site. An important indication of vessel identification is loss of audible pulsations with compression. After at least 1 to 2 mL of blood has been obtained, the needle is removed from the artery. Firm pressure is applied at the puncture site for a minimum of 5 minutes. If the patient is on anticoagulant therapy or has a coagulopathy, 10 to 15 minutes of pressure is required.

Proper handling of the sample and rapid analysis is very important.

When the needle is withdrawn, it is imperative to expel any air bubbles present in the syringe to avoid false elevation of the pO_2.[28] Removal of air is neatly and easily accomplished by tapping the inverted syringe (needle pointing to the sky) to force any air to the top; then carefully and slowly depressing the syringe plunger to push out remaining air. A gauze pad or alcohol wipe when pierced by the needle and placed at the hub will collect any expelled blood (Fig. 20-5). The needle is removed and the syringe is capped to ensure anaerobic conditions. Air in the sample will significantly increase the pO_2 (mean increase, 11 mm Hg) after 20 minutes of storage, even if kept at 4°C. The pH and pCO_2 are not significantly altered by air bubbles if the blood is stored at 4°C for 20 minutes without significant deterioration. [12] [28] If blood is stored at room temperature for longer than 20 minutes, the pCO_2 will increase and the pH will decrease, probably as a result of leukocyte metabolism. In a stored sample, the pO_2 varies to such an extent that the change is unpredictable for chemical interpretation at 30 minutes, regardless of storage method. High leukocyte or thrombocyte counts, such as those seen in leukemic patients, may shorten acceptable storage intervals. [29] [30]

In summary, arterial blood gas samples should always be kept on ice and analyzed within 15 to 20 minutes. Samples that cannot be analyzed any sooner should be considered faulted because they will not reflect real-time patient perfusion or oxygenation status.
