
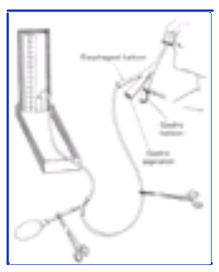

Figure 42-4 Esophageal balloon pressure measurement in the Sengstaken-Blakemore tube using a manometer. To inflate the esophageal balloon, the operator inserts one end of a Y connector to the esophageal balloon port, one end to a manometer, and one end to a bulb. At this point, no clamps are closed. The bulb is compressed until the manometer reads the desired pressure, and then the esophageal balloon port is clamped. Periodic readings to check the esophageal balloon pressure are subsequently taken by clamping the bulb port and unclamping the esophageal balloon port. The pressure in the esophageal balloon may vary with respirations and spasms, but the baseline pressure should not exceed 45 mm Hg. Most bleeding is controlled with pressures well below the maximum safe pressure. Note that standard toothed clamps are to be avoided (see text).

obtained to confirm proper positioning before restarting the inflation procedure.

When the gastric balloon, positioned correctly in the stomach, has been inflated with the recommended full volume (generally 450 to 500 mL) of air, the air inlet and pressure monitoring outlet of the gastric balloon are each clamped. The tube is then pulled back gently until the resistance of the diaphragm is firmly felt. With a small amount of tension on the tube, the proximal end is secured using a traction device. The tube kit generally includes a sponge rubber cuff, which can then be fixed at the nostril and taped, if that approach is used. If the tube has been passed orally, an external pulley traction device is preferred. Once the tube is secured in place, the gastric aspiration port is attached to high intermittent suction. A final check should be made by irrigating the tube with water under auscultation. Lavage the gastric port until clear.[15] If there is any question regarding correct tube position, obtain a repeat radiograph before proceeding.

If blood is detected continually in the gastric aspiration port (or in the esophageal aspiration port on a 4-lumen tube) despite lavage, the esophageal balloon should be inflated to the pressure recommended in the accompanying instructions (generally 30 to 45 mm Hg). Inflation of the esophageal balloon should be monitored continuously by a manometer attached to the esophageal balloon monitoring outlet. The esophageal balloon pressure should be maintained at the lowest level that will stop bleeding from each of the aspiration suction ports. In addition, the esophageal balloon pressure should not exceed the maximum listed in the instructions (generally 45 mm Hg). Once the balloon has been inflated to the desired amount, the port for the esophageal balloon is clamped, and periodic readings are taken.

If bleeding continues from the gastric aspiration port after full inflation of the gastric and esophageal balloons, it usually originates from a gastric rather than an esophageal varix. In this case, external traction on the tube should be increased. If a foam rubber block is used, the tube should be pulled to a more taut position and refixed to the nasal cuff at the point where the tube emerges from the nose. If the tube was passed through the mouth, and a trapeze-bar pulley system was used, adding traction is easy. An additional 0.45 to 0.91 kg (1 to 2 lb) of weight can be applied to the pulley system, in progressive steps (maximum of 1.1 kg [2.5 lb]). [15] The pulley system should be attached to the GEBT tube through use of a nonoccluding knot (e.g., bowline knot) passed around the area of the tube where all the respective ports separate. Tightening the knot directly onto the tube itself can occlude the ports.

Direct pressure from the tube can cause ulceration of mucosal surfaces within a matter of a few hours. Therefore, there should be frequent examinations to ensure that the tube is not placing excessive pressure on a given mucosal surface. If one is using an external pulley traction device, the angle of the tube, as it exits the mouth, is adjusted to minimize any such pressure by altering the location of the pulley. If the tube is passed through the mouth, precautions are also needed to preclude patient biting of the tube. A rubber or plastic mouthpiece should be placed in dentulous patients. Suction of the aspiration ports is then adjusted. The gastric

port should have intermittent 60- to 120-mm Hg suction, and the esophageal port (for 4-lumen tubes) should be attached to 120- to 200-mm Hg continuous suction. [15]

After bleeding has been controlled by the tamponade, the pressure in the esophageal balloon is generally reduced by 5 mm Hg every 3 hours (or as specified in product instructions), until an intraesophageal balloon pressure of 25 mm Hg (or as specified in instructions) is achieved without ongoing bleeding. Note that continual elevated balloon pressures (>30 mm Hg) on the esophagus for long periods of time can result in mucosal ischemia and may induce esophageal necrosis. [15] Therefore, it is recommended that periodic deflation of the esophageal balloon be undertaken for approximately 5 minutes every 6 hours. If bleeding can be controlled with an intraesophageal balloon pressure of 25 mm Hg, this pressure is generally maintained for the next 12 to 24 hours. [15] [20] The pressure in the esophageal balloon can transiently vary with respiration and esophageal spasm. This may result in intermittent increases in the measured pressure of 30 mm Hg above baseline, although this should only be for transient periods. If it remains high, air must be removed until the pressures are acceptable.

If a 3-lumen GEBT tube has been used, it will not have an esophageal aspiration port. Because the amount of oropharyngeal and esophageal secretions can exceed 1500 mL/day, additional suction proximal to the esophageal balloon must be provided. [15] This can be done with a standard 14 to 16 Fr NG tube passed to a position measured or calculated to be just above the esophageal balloon. This should be placed even if the esophageal balloon is not maintained in an inflated position, because an inflated gastric balloon will also interfere with the ability to swallow or pass secretions.

Once satisfactory positioning of the GEBT tube has been confirmed, the tube is generally then not disturbed for some 24 hours, unless necessary due to complications.[15] During this time, adjunctive therapy is ongoing and additional evaluation instituted. [20] These tubes are very uncomfortable, and patients should be provided with analgesics and sedation. In addition, soft restraints are needed on the arms to prevent the patient from dislodging the tube. If the bleeding does not remain controlled, other therapeutic interventions must be considered. These include endoscopic interventions with sclerotherapy, as well as emergency surgery. If these are not available, patient transfer may be necessary. [12]

COMPLICATIONS

Complications associated with the use of GEBT tubes are frequent and often very serious. [22] Mortality rates are high with patients in need of these devices. Table 42-1 lists both major and minor complications. Major complications have been reported to occur in 8% to 16% of patients. [2] Mortality directly related to use of these tubes is generally reported to be 3%. [15] [22] However, one study reported the GEBT tube directly caused death in 22% of the patients in which it was used. [7] This must be considered in the context that variceal hemorrhage itself carries a 20% to 80% overall mortality. [20] Therefore, use of a GEBT tube is sometimes viewed as a desperate measure for a desperate disease process. GEBT tubes can be temporizing or even life-saving, but the high associated complication rate requires an individual risk-benefit analysis for each patient in whom it is being considered.

Aspiration pneumonitis is probably the most frequent major complication. [22] This can result from aspiration of oral secretions, gastric contents, or, most commonly, blood. [2] The volume of aspiration can be substantial, and associated deaths

TABLE 42-1 -- Complications of Esophageal Balloon Tamponade Therapy

Complications	Common	Uncommon
Major	Aspiration pneumonia	Esophageal perforation
	Asphyxiation	Duodenal rupture
	Esophageal necrosis	Tracheobronchial rupture
		Periesophageal abscess
		Mediastinitis
Minor	Gastroesophageal ulceration	Epistaxis
		Pharyngeal erosions
	Regurgitation	Pressure necrosis of tongue
	Chest discomfort	
	Back pain	Hiccups
	Pressure necrosis of nose or lip	

have been reported. [2] [7] The likelihood of this complication can be decreased by evacuating the stomach prior to placement of the GEBT tube and having a low threshold for tracheal intubation to protect the airway. [19]

Asphyxia owing to airway obstruction has been reported to occur with dislodgment of the tube such that the esophageal balloon migrates into the oropharynx. [2] [5] This is more likely when the tube is passed through the nares such that the inflated esophageal balloon cannot pass through the nasopharynx, and it is one of the reasons that oral placement is preferred. Tube migration can be prevented by maintaining full inflation of the gastric balloon through periodic monitoring of pressures and radiographic reconfirmation. Of course, airway obstruction can be completely prevented by prophylactic tracheal intubation. If the tube suddenly migrates, resulting in an airway obstruction in a nontracheally intubated patient, the balloons must be immediately deflated and the tube extracted. This can be achieved most quickly by cutting across all of the tube lumens just distal to the bifurcation points. This will immediately vent all of the balloons, and the entire tube can be extracted. For this reason, it is recommended that surgical scissors be kept available at the patient's bedside whenever a GEBT tube is in place.

The other relatively common major complication is esophageal perforation or rupture. [7] [8] This occurs with overinflation of a misplaced gastric balloon and can be prevented through careful employment of the placement steps already outlined. However, this can also occur as a result of esophageal mucosal necrosis caused by excessive or prolonged pressure in the esophageal balloon. Crerar-Gilbert reported a case of massive esophageal rupture with the use of balloon tamponade and associated sclerotherapy. [9] The treatment is immediate removal of the GEBT and initiation of diagnostic studies (e.g., contrast swallow) and broad-spectrum antibiotics (for potential mediastinitis). Again, risk for this complication can be decreased by periodic deflation of the balloons at 6-hour intervals and limiting the amount of pressure in the esophageal balloon to the minimum amount necessary to control bleeding. This problem is also more common when the balloons are left inflated for more than 24 hours. [15]

Common minor complications include pain, discomfort, and local pressure effects of gastric or esophageal erosions or mucosal ulcers. [6] [22] These latter can be minimized by frequently checking and optimizing tube position to minimize pressure on the nasal or oral mucosa, the tongue, and other structures. Although less common, other complications can occur; these are also listed in Table 42-1 . [1] [13] [16] [17] [22]

INTERPRETATION

GEBT tubes are used to temporarily control bleeding varices. This is assessed by monitoring the rate of blood aspirated from the gastric and esophageal ports after tube placement. It is not uncommon for the GEBT tube to fail to control the hemorrhage.[14] [15] [20] When significant bleeding continues, consider correctable causes, which include malpositioned balloons, inadequate balloon pressures, and misdiagnosis of the site of bleeding (e.g., a duodenal ulcer instead of variceal source).[7] [15] When these have been addressed but bleeding continues, other therapeutic options must be considered, including sclerotherapy, angiographic embolization, and surgery (see Fig. 42-3).[12] [20]

CONCLUSION

Gastroesophageal balloon tamponade is an uncommon procedure in general, and particularly for emergency clinicians. Some emergency clinicians may not have performed this procedure previously. However, the procedure can temporarily control an exsanguinating hemorrhage from gastric or esophageal varices in about 80% of patients when other options are unsuccessful or unavailable. As such, the emergency clinician may periodically be called upon to place a balloon tamponade tube. Because of the high incidence of associated serious complications, the procedure should be used in carefully selected patients in whom the potential benefit is favorable, given the risk of exsanguination.

Each hospital is unlikely to stock more than one tube type, and this may not be the type most familiar to the clinician. However, currently most balloon tamponade tubes are fairly similar and are packaged with a complete set of instructions. These instructions must be carefully reviewed before tube placement. There can be great difficulty locating these tubes within the hospital when they are suddenly needed, so advance planning is recommended, when possible.

The most serious common complications are those of aspiration and airway occlusion. [22] A low threshold for prophylactic tracheal intubation is recommended. The most serious iatrogenic complication is due to balloon inflation of a misplaced tube, with resultant esophageal rupture. This is avoidable by carefully following the instructions and insisting on radiographic confirmation of tube position before fully inflating the balloons.

Chapter 43 - Decontamination of the Poisoned Patient

Christopher P. Holstege
Alexander B. Baer

The presentation of poisoned patients to the emergency department (ED) is a common occurrence. In 2000, the *Toxic Exposure Surveillance System* of the American Association of Poison Control Centers reported 2,168,248 toxic exposures and 920 resultant fatalities. [72] Of these total exposures, 264,526 (12.2%) were managed in a health care facility. A massive exposure to some very toxic agents (such as cyclic antidepressants, cardiovascular preparations, colchicine, cocaine, carbon monoxide, chloroquine, iron, cyanide, amanita mushrooms, paraquat, and many others) will likely result in severe morbidity or a fatality regardless of even the most sophisticated and timely medical intervention. With general supportive care and the use of a few specific antidotes, however, the mortality rate of unselected overdose patients is only 1% to 2% if the patient arrives at the hospital in time for the clinician to intervene.

The management of poisoned patients presenting to health care facilities initially focuses on confirming the diagnosis of a possible toxin exposure, providing standard cardiovascular and respiratory supportive care, and the use of a small cadre of specific antidotes. In selected instances, the prevention of further toxin absorption by various decontamination procedures may theoretically ameliorate morbidity or reduce mortality. Although a better final outcome from gastric decontamination may seem intuitively reasonable, there is no definitive evidence from prospective clinical trials proving that the use of various decontamination techniques positively alters the morbidity or mortality of the poisoned patient.

Before the availability of objective, experimental evidence addressing gastric emptying procedures, most clinicians instituted such procedures in the ED as a reflex response for the majority of patients suspected of drug overdose, often without much forethought, and certainly without confirming data. Significant controversy exists concerning the need for routine gastric emptying in the poisoned patient, and mounting evidence relegates any form of gastric decontamination to selected cases and individual specific scenarios. *At this time, it is the editors' opinion that there is no universally accepted standard of care that mandates any form of gastric decontamination as a routine medical intervention in the patient suspected or proved to have been exposed to a toxic substance.* (Note: This statement does not apply to ocular or dermal decontamination issues.)

Nonetheless, there may a selective role for gastric decontamination, and there will always be a role for clinical judgment. Since compelling circumstances may call for gastric decontamination, this chapter will discuss specific clinical procedures. These techniques include syrup of ipecac-induced emesis, gastric lavage, oral activated charcoal administration, and whole-bowel irrigation (WBI). Before performing these techniques, the clinician responsible for the care of the poisoned patient must clearly understand that these procedures are not without hazards, and any decision on their use must consider whether the benefit of decontamination outweighs any procedure-related harm.

GASTRIC DECONTAMINATION

Ipecac-Induced Emesis

Background

Syrup of ipecac is available as a nonprescription product in many countries, including the United States. It is prepared from the dried rhizome and roots of the *Cephaelis ipecacuanha* or *Cephaelis acuminata* plant, both of which contain the alkaloids emetine and cephaeline. These alkaloids are potent emetics inducing vomiting by both direct local gastrointestinal effects and central nervous system actions. Emesis following syrup of ipecac ingestion typically occurs within 20 minutes of ingestion and persists for 30 to 120 minutes. [91]

There have been numerous animal and human volunteer studies examining both the efficacy of syrup of ipecac to expel specific ingested agents from the stomach and its ability to decrease serum drug levels. [1] [20] [33] [35] [37] [47] [65] [84] [126] [129] [132] [137] [140] [146] In these studies, the amount of marker removed by syrup of ipecac was highly variable. Syrup of ipecac's efficacy at expelling experimental markers decreased as the administration time postingestion increased. Syrup of ipecac is of very limited benefit if more than 60 to 90 minutes have elapsed since the time of ingestion. Although syrup of ipecac may be effective in reducing the quantity of a drug absorbed, no studies have demonstrated that its use improves patient outcome. [65] [69] [87] [106] Saetta et al suggested in their study that syrup of ipecac may actually enhance gastric emptying and potentially facilitate drug absorption. [116] Ipecac use may delay the use of, or reduce the effectiveness of, other methods of decontamination.

Indications

The administration of ipecac in the ED is rarely indicated. Although theoretically some indications may arise in the ED, there is no standard of care that mandates its use in the management of the poisoned patient in the hospital. Even the historical use of ipecac-induced emesis in the home, prior to definitive medical intervention, has been questioned. The position statement written by the American Academy of Clinical Toxicologists and the European Association of Poisons Centres and Clinical Toxicologists (Fig. 43-1) declared that the routine administration of ipecac in the ED should be abandoned. [67] Bateman's review stated that "ipecac is effectively obsolete" in the management of the poisoned patient. [13] Whether specific subsets of poisoned (e.g., iron, lithium, mushroom) patients may benefit from syrup of ipecac has not been clearly delineated. If syrup of ipecac is administered to a patient, it should be given only to an alert, conscious patient who has ingested a potentially toxic amount of a poison no more than 60 minutes before administration.

Contraindications

The administration of syrup of ipecac is contraindicated in any person who demonstrates compromised airway protective reflexes or has the potential to lose such protective reflexes.[66] Its use should be avoided in persons who have ingested substances that could result in coma, seizures, cardiovascular collapse, or paralysis. Syrup of ipecac is also contraindicated in persons who have ingested corrosive substances (acids or

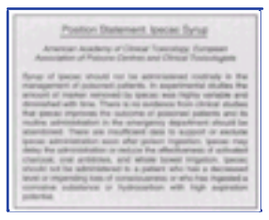

Figure 43-1 Position statement: ipecac syrup. *(From the American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists. Published in Clin Toxicol 35:699, 1997.)*

alkalis), hydrocarbons, or foreign bodies that could potentially result in airway obstruction. Caution should be exercised in using syrup of ipecac in patients who have medical conditions that could be further compromised by the induction of emesis, such as patients with bleeding diatheses.

Technique

Syrup of ipecac is sold in packages of 15 mL and 30 mL. It is administered orally in the following dosages:

- 0 to 6 months: No ipecac.
- 6 to 12 months: 10 mL ipecac plus 120 to 240 mL clear liquids.
- 1 year to 12 years: 15 mL ipecac plus 120 to 240 mL of clear liquids and repeat 15 mL ipecac if no vomiting occurs within 20 minutes of the first dose.
- Older than 12 years: 30 mL ipecac plus 240 mL of clear liquids and repeat 30 mL ipecac if no vomiting occurs within 20 minutes of the first dose.

Complications

The most commonly reported complications of ipecac administration include diarrhea, lethargy, and prolonged vomiting. [28] [36] [73] Other reported complications include pulmonary aspiration of gastric contents, bradycardia, cerebral hemorrhage, gastric rupture, gastric diaphragmatic herniation, Mallory-Weiss tear, and pneumomediastinum.[62] [63] [68] [115] [127] [135] [145] Prolonged emesis may result in the inability to subsequently administer charcoal.

Gastric Lavage

Background

Reports of the use of gastric lavage in the poisoned patient dates as far back as the early 19th century. [26] [58] Numerous animal and human volunteer studies have been conducted examining the effectiveness of gastric lavage in removing toxins from the stomach, especially in comparison to other gastrointestinal decontamination methods.[7] [10] [21] [25] [32] [33] [126] [129] [137] [143] [146] The reported efficacy of gastric lavage in removing markers from the stomach varies significantly in these studies. The difference in these study results is due in part to the variability of the methods used (different fluid instilled markers, animal models, positioning, amount of lavage and lavage tube sizes) and the time that elapsed from the instillation of the marker in the stomach until gastric lavage was performed. Even within individual studies, the range of effectiveness of gastric lavage to remove the marker varied considerably. For example, Tandberg et al performed gastric lavage 10 minutes after ingestion of the marker and reported its effectiveness to remove the marker varied from 18.9% to 67.7%.[126] There is a possible theoretical benefit of gastric lavage for the evacuation of a toxic liquid from the stomach. Grierson et al, however, were unable to demonstrate a significant benefit of an optimal lavage 1 hour after the ingestion of liquid acetaminophen, further casting doubt on the benefit of the procedure in the clinical scenario. [50]

Many of these studies do not replicate the typical clinical scenario encountered in emergency medicine. [79] The efficiency of gastric lavage to remove a marker significantly decreases with increasing time following ingestion. This is due to the fact that as time increases after ingestion, the more time there is for the marker to be absorbed and for the marker to pass out of the stomach. For example, Shrestha et al reported that greater than 70% of the marker used in their study passed out of the stomach by 60 minutes.[123] It is rare that gastric lavage can be performed within the first hour after toxic ingestion. Not only does it take time for these patients to present to the ED, but it also takes time for evaluation, stabilization, and for the gastric lavage to take place. For example, Watson et al reported that the mean time required by experienced emergency medicine nurses to perform lavage was 1.3 hours.[143] *Gastric lavage may also propel the marker from the stomach into the small*

intestine, decreasing the effectiveness of removing the toxin from the stomach and enhancing the rate of absorption.[116]

Gastric lavage is still considered as a potentially advantageous procedure because, to date, there have been no controlled studies that have included enough patients with confirmed life-threatening ingestions to adequately evaluate lavage versus no lavage. Only three major studies have been performed examining whether gastric lavage positively influences the outcome of poisoned patients. [69] [87] [106] In a study performed by Kulig et al, there was no difference in outcome among patients who received gastric lavage followed by charcoal vs charcoal alone when these were performed >1 hour after ingestion. [69] In patients who were treated within 1 hour of ingestion, gastric lavage followed by charcoal provided a small but statistically significant advantage over activated charcoal alone. Merigian et al, demonstrated that for symptomatic patients, the rate of intensive care admission and the need for intubation was significantly higher for those patients who received gastric lavage followed by charcoal than for those who received charcoal alone. [87] This increased admission and intubation rate was directly attributed to the aspiration of gastric contents owing to gastric lavage. Pond et al replicated the Kulig study. They found no difference in outcome between those who received gastric lavage followed by charcoal versus charcoal alone, regardless of time of performance of gastric lavage. [106] They concluded that "gastric emptying procedures can be omitted from the treatment regimen for adults after acute overdose, including those who present within 1 hour of overdose and those that manifest severe toxicity."

Indications

Based on the available literature, gastric lavage should not be routinely used in the management of poisoned patients [138] (Fig. 43-2). There is no universally accepted standard of care that can be applied to the use of gastric lavage in the unselected poisoned patient in the ED. Because there may be a theoretical benefit from gastric emptying, usually by lavage, under certain circumstances, a listing of circumstances that may increase the appropriateness of gastric emptying appears in Table 43-1 (Table Not Available) . It is stressed that these indications are theoretical, not evidenced based, and are the opinion of one toxicology textbook. Whether specific subsets of overdose patients may benefit from gastric lavage has not been clearly defined.

Only patients who have ingested a potentially life-threatening amount of poison where the procedure can be performed within 60 minutes should be considered candidates for gastric lavage. Oral charcoal alone is considered superior to gastric lavage if a drug is adsorbed by charcoal.

Contraindications

Although generally safe, gastric lavage is not an innocuous procedure. The performance of gastric lavage is contraindicated in any person who demonstrates compromised airway protective reflexes unless they are intubated. Many clinicians opt for lavage in a seriously ill patient who is intubated, because airway protection is already accomplished. Tracheal intubation, however, does not ensure a totally protected airway. *Paralyzing and intubating a patient merely to initiate gastric lavage is generally eschewed.* Gastric lavage is contraindicated in persons who have ingested corrosive substances (acids or alkalis), hydrocarbons (unless containing highly toxic substances such as paraquat, pesticides, heavy metals, halogenated and aromatic compounds), known esophageal strictures, or history of gastric bypass surgery. Caution should be exercised in performing gastric lavage in patients who have medical conditions that could be compromised by performing this procedure, such as patients with bleeding diatheses, and in combative patients.

TABLE 43-1 -- Factors that Cumulatively Increase the Appropriateness of Gastric Emptying

(Not Available)

From Smilkstein MJ: Techniques used to prevent gastrointestinal absorption of toxic compounds. Goldfrank's Toxicologic Emergencies, 7th ed., New York, NY. McGraw Hill, 2002.

Equipment and Preparation

If the decision is made to perform gastric lavage, careful attention to the details of the procedure results in increased safety for the patient and more effective removal of the ingested poison. Before lavage, the patient should have IV access secured and should have continuous cardiac monitoring and pulse oximetry. A large, rigid suction tip should be immediately available.

If the level of consciousness is significantly depressed or the patient's airway-protective reflexes are diminished, the airway should be protected with a cuffed endotracheal tube before initiation of gastric lavage. If the patient is highly anxious or agitated, small doses of a benzodiazepine (e.g., 1 to 2 mg midazolam IV) may be given. If the airway status is questionable, or has the potential to be compromised during the procedure, rapid-sequence induction and intubation should be considered. If patients are fully alert and awake, lavage may be done without tracheal intubation. The procedure should proceed deliberately without significant patient resistance. The procedure is intended to be therapeutic, not punitive. Antiquated arguments promulgating that a noxious lavage will keep patients from overdosing again should be abandoned.

The position of the patient during gastric lavage is important. All patients should be placed in the left lateral decubitus position with the head down (approximately 20° tilt on the table) (Fig. 43-3). This position diminishes the passage of gastric contents into the duodenum during lavage and decreases the risk of pulmonary aspiration of gastric contents

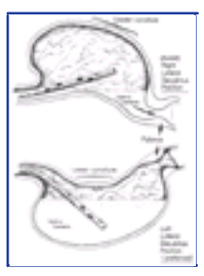

Figure 43-3 The effect of patient positioning on lavage. The left lateral decubitus position is preferred.

should vomiting or retching occur. The uncooperative patient's hands should be restrained to prevent removal of the gastric or endotracheal tube. Intubated patients on a ventilator may be lavaged in the supine position because of logistical reasons. *Under no circumstances should the nonintubated patient undergo lavage in the restrained supine position.* Such positioning invites aspiration and diminishes the patient's natural protective maneuvers, such as coughing and sitting up.

Most clinicians prefer the oral route for gastric lavage, but in selected circumstances, a standard large-bore nasogastric (NG) tube (Salem sump pump) may be used. Large-diameter gastric hoses with extra holes cut near the tip have been traditionally recommended for gastric lavage (Fig. 43-4). There are no convincing data on humans to refute or support this recommendation, and one study of a small number of dogs failed to show any difference in efficacy with lavage through a 32 Fr tube

compared with a 16 Fr lavage tube.[41] It is generally held that large-diameter NG or orogastric tubes (>1 cm) are more likely to retrieve particulate matter successfully. Smaller, more flexible tubes may kink and are significantly more difficult to pass. An NG tube may be passed through the mouth or nose, but orogastric hoses should not be passed through the nose. Because most pills disintegrate in the stomach in a few minutes, significant amounts of particulate matter may be retrieved with a large-bore NG tube, such as an 18 Fr Salem sump tube. Nasogastric tubes are considerably easier to pass, and are less traumatic for the patient (see Chapter 41). Nasogastric tubes are preferred for liquid ingestions.

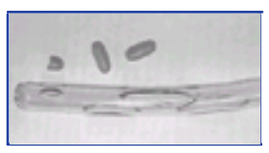

Figure 43-4 A large-diameter gastric tube. Note the extra side holes that have been cut near the tip. This is a theoretical advantage over a standard tube or a nasogastric tube. For small pill particles and liquids, a large-bore nasogastric tube may suffice.

In most cases a 36 to 40 Fr or 30 English gauge tube (external diameter 12 to 13.3 mm) should be used in adults and a 24 to 28 Fr gauge (diameter 7.8 to 9.3 mm) tube in children.[138] (See discussion of pediatric issues in Fig. 43-5 .) Before passage, the length of the tube required to enter the

Figure 43-5 Gastric lavage in a child is always problematic. Obviously, an adult-sized large-bore oral gastric tube cannot be used, but a nasogastric (NG) tube may suffice. Some pediatric textbooks recommend a 24 Fr oral gastric tube for toddlers, and a 36 Fr tube for adolescents. In this case, a child was found with an open bottle of digoxin, and it could not be determined if ingestion had occurred. She would not drink charcoal. The 18 Fr NG tube was used to attempt to aspirate digoxin from the stomach (none was recovered) and to instill charcoal. Some would suggest the oral route for this tube, but it was passed rather easily through the nose. An NG tube is not ideal for some ingestants (iron, sustained-release products), but most pills quickly dissolve in the stomach and the small particles can easily be removed with an NG tube. Although lavage may have been reasonable in this scenario, a potent and safe antidote for digoxin does exist. The common routine practice of passing an NG tube in a child who is unwilling to drink charcoal is controversial and likely done far too often for benign ingestions. *(Reprinted with permission from Elsevier [The Lancet, vol 338 (8778), 1991, pp 1313–1315].)*

stomach should be estimated by approximating the distance from the corner of the mouth to the mid-epigastrium; premeasurement avoids the curling and kinking of excess hose in the stomach (Fig. 43-6). Passage of an excessive length of hose may cause gastric distention, bruising, and perforation, whereas passage of an insufficient length of hose may result in lavage of the esophagus and the increased risk for emesis and aspiration. Commercial lavage systems are available and often use either a gravity fill-and-empty system with a Y connector (e.g., Travenol, Ethox) or a closed irrigation syringe system. Alternatively, an irrigation syringe can be used for intermittent lavage fluid input and withdrawal.

Technique

In most cases gastric lavage should be performed through an orogastric tube. Use of a standard NG tube may be adequate if only small pill fragments are present, but an NG tube is associated with two problems: It is of insufficient bore to produce satisfactory lavage of large particulate matter, and the larger bore tubes may cause epistaxis or damage to the turbinates. The latter problem may be obviated by oral passage. The gastric tube should be lubricated and passed gently to avoid damage to the posterior pharynx. A bite block or an oral airway should be used to avoid chewing of the orogastric tube and biting of the fingers of the inserter. If the patient is obtunded or paralyzed, the clinician may extend the jaw to facilitate passage. *Force should never be used to pass the tube.* Putting the patient's chin on the chest can facilitate passage of the tube into the esophagus once the pharynx has been entered (Fig. 43-7). Cough, stridor, or cyanosis indicates that the tube has entered the trachea; the tube should be withdrawn immediately and passage reattempted. Once the tube is passed, its intragastric location should be confirmed. Intragastric placement is usually evident on clinical grounds, and confirmed by auscultation of the stomach during injection of air with a 50-mL syringe and aspiration of gastric contents. In

Figure 43-6 Failure to premeasure a lavage tube before passage is a common error. Here a piece of tape marks the depth of proper passage to ensure that the tip is in the stomach without excess tubing that may hinder fluid egress.

Figure 43-7 Positioning the patient's chin on the chest can facilitate passage of the tube into the esophagus once the pharynx has been entered. Once the tube is positioned, lavage is performed in the left lateral decubitus position. If the patient begins to vomit, the tube is immediately withdrawn.

the intubated or obtunded patient or the young child, some clinicians consider confirming tube position radiographically before lavaging, although this is not routinely performed. A misplaced tube may irrigate the esophagus with a tube that has doubled back on itself during passage. The most serious complication is inadvertent passage of the tube into the lungs. Tracheal passage of a lavage tube should be readily obvious in the awake patient prior to lavage, and obtunded patients are intubated, obviating this problem. *If an awake patient begins to vomit during the lavage, immediately remove the tube to allow the patient to protect the airway.*

Before gastric irrigation, the gastric contents should be removed by careful gastric aspiration with repeated repositioning of the tube tip. With the Y connector closed system, lavage is performed by clamping the drainage arm of the Y adapter and infusing aliquots of fluid into the stomach from a reservoir (Fig. 43-8). The reservoir arm of the Y is then clamped, and the drainage arm is opened to permit gravity drainage of the stomach contents. The procedure is then repeated. Some resistance is produced by the Y connector and tubing. Suction can be applied intermittently to the drainage tubing to enhance stomach emptying.

Lavage can be performed adequately with tap water in adults. Because electrolyte disturbance has occurred in children who were lavaged with tap water, prewarmed (45°C) normal saline is generally recommended for children. [11] [27] [104] Warmed lavage fluid increases the solubility of most substances, delays gastric emptying, and theoretically should increase the effectiveness of the procedure. [83] [113] Small aliquots of lavage solution (200 to 300 mL in adults and 10 mL/kg body weight in children up to a maximum of 300 mL) should be repeatedly introduced into the stomach and removed. If larger amounts of fluids are used, there is a potential for an increased risk of washing gastric contents into the duodenum or the lungs, and much smaller amounts are not clinically practical because of the dead space in the tubing (approximately 50 mL in the 36 Fr

Figure 43-8 An example of the Y connector closed system with the patient in a left lateral decubitus position. Patients on a ventilator, or those who are intubated may be lavaged in the supine position due to logistic issues, but an awake nonintubated patient is never lavaged in the restrained supine position.

hose) and the increase in time that is required. The amount of fluid that is returned should approximate the amount that is introduced. Manual agitation of the patient's stomach by gently "kneading" the stomach with a hand placed on the abdomen may increase recovery. [83] Lavage should be continued until the lavage fluid becomes clear.

After gastric aspiration and lavage have been completed, a slurry of activated charcoal should be administered through the gastric tube. When no longer needed, the gastric tube should be pinched or clamped during its removal to avoid "dribbling" fluid into the airway. With the increasing use of repetitive doses of activated charcoal, the gastric tube is often left in place after the lavage procedure is completed. Because this large tube is irritating and may predispose the patient to gagging, drooling, or aspiration, it should be removed. The alert patient should take subsequent doses orally as necessary. The patient who remains obtunded may receive additional doses via a standard NG tube, although the high viscosity of the charcoal makes this route challenging. If endotracheal intubation was required prior to lavage tube placement, the endotracheal tube should *not* be removed until the patient is clearly awake and able to control his or her airway, because emesis is common after an overdose and in association with the procedure.

Complications

A correctly performed procedure is generally safe but there have been numerous complications associated with gastric lavage. The complications can be divided into those caused by mechanical trauma and those resulting from the lavage fluid.

Depending on the route selected for tube insertion, damage to the nasal mucosa, turbinates, pharynx, esophagus, and stomach have all been reported. [8] [34] [80] [142] After tube insertion, it is imperative to confirm correct placement. Scalzo et al found radiographically that 7 of 14 children had improper tube placement (too high or too low) despite positive gastric auscultation in all cases. [117] Although not a routine standard, radiographic confirmation of tube placement should be considered in young children and intubated patients. Instillation of lavage fluid and charcoal into the lungs through tubes inadvertently misplaced within the airways has been reported. [57]

During lavage, changes in cardiorespiratory function have been noted. Thompson et al, reported that during lavage, 36% of patients had atrial or ventricular ectopy, 4.8% had transient ST elevation, and 29% had a fall in oxygen tension to 60 torr or less. [134] Patients at greatest risk for these findings included the elderly, smokers, those with lung disease, or cyclic antidepressant overdose. Laryngospasm may also occur during gastric lavage. [138]

The lavage fluid itself is a potential source of complications. The large amount of fluid administered during lavage has been reported to cause patient fluid and electrolyte disturbances. These disturbances have been seen with both the use of hypertonic and hypotonic lavage fluids in the pediatric population. [11] [27] [104] Hypothermia is a possible complication if the lavage fluid is not pre-warmed.

Pulmonary aspiration of gastric contents or lavage fluid is the primary potential risk during gastric lavage, especially in patients with compromised airway protective reflexes.[81] Merigian et al, reported a 10% incidence of aspiration pneumonia in patients who received gastric lavage. [87] This risk is reduced by using small aliquots of lavage fluid, by adequately positioning the patient, and by intubating patients with compromised airway protective reflexes.

Excessive force should be avoided if the lavage tube cannot be easily removed. Kinking or knotting of the tube can occur, but occasionally a tube may become stuck because of lower esophageal spasm. If fluoroscopy demonstrates no deformation to the lavage tube, 1 to 2 mg of IV glucagon can be infused in an attempt to relieve lower esophageal spasm.[133] Surgical removal may be necessary if the gastric tube is deformed by kinking or knotting.

Activated Charcoal

Background

Activated charcoal is a carbon product that is subjected to heat and oxidized to increase the surface area and its capacity to adsorb substances onto the surface of the charcoal. A high surface charcoal, termed superactivated charcoal, is intermittently available to the clinician. Superactivated charcoal adsorbs more toxin per gram of charcoal and is recommended if available. Activated charcoal acts both by adsorbing a wide range of toxins present in the gastrointestinal tract and by enhancing toxin elimination, if systemic absorption has already occurred. It enhances elimination by creating a concentration gradient between the contents of the bowel and the circulation, but it also has the potential of interrupting enterohepatic circulation if the particular toxin is secreted in the bile and enters the gastrointestinal tract prior to reabsorption.[103] Oral activated charcoal is given as a single-dose or in multiple doses. The adsorptive capacity of charcoal depends on inherent properties of the toxin, and the local milieu, such as pH. Adsorption begins within minutes of contact with a toxin, but may not reach equilibrium for 20 to 30 minutes. Desorption of toxins from charcoal occurs over time, although this has little clinical significance for most patients and can be overcome by administering additional charcoal.

Indications

For years the administration of oral activated charcoal for essentially all overdoses has been routine. Clearly charcoal

binds many toxins in the gut, thereby decreasing some systemic absorption. Despite a lack of scientific data demonstrating a decrease in morbidity and mortality, and without firm evidence to support its widespread use, charcoal is a reasonable intervention for most poisoned patients presenting to the ED; if it can be easily and safely administered. The exact indications are not established, and no universally accepted standard of care has been promulgated. In the opinion of the editors, single-dose activated charcoal is indicated if the clinician estimates that a clinically significant fraction of the ingested substance remains in the GI tract, the toxin is adsorbed by charcoal, and further absorption may result in clinical deterioration. This will essentially always be a clinical decision, since adequated historical data may often be lacking. It may also be administered by multiple dosing, if the clinician anticipates that the charcoal will result in increased clearance of an already absorbed drug. In 1997, the American Academy of Clinical Toxicology released a position statement advising that activated charcoal should not be routinely administered but should be reserved for cases in which serious toxicity is anticipated [31] (Fig. 43-9). It is most effective within the first 60 minutes after oral overdose and decreases in effectiveness over time. Charcoal is generally considered to provide superior gut decontamination when compared to gastric lavage. Combining lavage and charcoal, although intuitively attractive, has no proven additional benefit.

Contraindications

The administration of charcoal is contraindicated in any person who demonstrates compromised airway protective reflexes, unless they are intubated. [31] It is contraindicated in persons who have ingested corrosive substances (acids or alkalis). Charcoal not only provides no benefit in a corrosive ingestion, but its administration could precipitate vomiting, obscure endoscopic visualization, and lead to complications if a perforation developed and charcoal entered the mediastinum, peritoneum, or pleural space. Charcoal should be avoided in cases of a pure aliphatic petroleum distillate ingestion. Hydrocarbons are not well adsorbed by activated charcoal and its administration

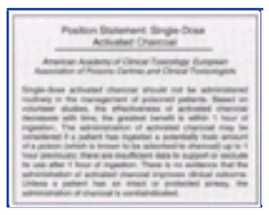

Figure 43-9 Position statement: single-dose activated charcoal. *(From the American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists. Published in Clin Toxicol 35:721, 1997.)*

could lead to further aspiration risk. Many hydrocarbons are potential systemic toxins (e.g., carbon tetrachloride and benzene) or are mixed with other potentially significant toxins such as pesticides. In these cases, data are lacking, but charcoal administration can be considered. Caution should be exercised in using charcoal in patients who have medical conditions that could be further compromised by charcoal ingestion, such as those with gastrointestinal perforation or bleeding. Charcoal is not indicated for isolated ingestions of ethanol, iron, or lithium because these substances are not adsorbed. If the airway is not secure, charcoal should be given with caution, to minimally symptomatic patients who have ingested a toxin that may suddenly induce seizures. Such as cyclic antidepressants and theophylline. Charcoal will adsorb cyanide, strychnine, and mercuric chloride. Because it is often impossible to determine the exact nature of an ingestion, a liberal use policy is advocated for potentially mixed overdoses.

The use of activated charcoal in the treatment of acetaminophen ingestion presents a special issue because the antidote, *N*-acetylcysteine, is approved only for oral use in the United States. Although activated charcoal could potentially prevent acetaminophen from reaching toxic concentrations in the blood, there are concerns that charcoal may also adsorb significant amounts of the antidote as well. Pharmacokinetic studies evaluating the effect of activated charcoal on *N*-acetylcysteine absorption have produced conflicting results. [39] [62] [97] The standard *N*-acetylcysteine dosing currently in use is much larger than needed to treat the vast majority of acetaminophen overdoses, and therefore no adjustment is required in this scenario. This issue is totally circumvented by the use of IV *N*-acetylcysteine. Although not FDA approved, the oral *N*-acetylcysteine preparations are universally used as an IV antidote, a technique recommended by the authors.

Charcoal administration by paramedics and other emergency response personnel should be performed with caution. The same indications and contraindications apply as for those patients who are in the hospital. The motion of the ambulance during transport may make the patient more prone to emesis. Either the spilling of charcoal or the vomiting of charcoal may result in significant contamination of the transport vehicle and subsequently place that vehicle out of commission until it can be cleaned.

Technique

There is no universally accurate dose for charcoal. A 10:1 ratio (charcoal:toxin) is recommended if the amount of ingestion is known. Charcoal dosing should be considered in light of the specific ingestion, but the recommended empiric doses of single-dose activated charcoal (standard aqueous products, such as Liqui-Char) are as follows[31] :

- Up to 1 year: 1 g/kg of body weight
- 1 year to 12 years: 25 to 50 g
- Older than 12 years: 25 to 100 g

If the ingestion were, for example, clonidine (0.1-mg tablets) or digoxin (0.25-mg tablets), this regimen would be more than adequate for even a massive overdose to achieve the desired 10:1 ratio. If the ingestion consisted of a large number of 325-mg aspirin tablets, or 240-mg verapamil tablets, the dosing regimen could be insufficient. If toxic medications with a high milligram dosage are ingested, it would be prudent to administer more charcoal than indicated by these guidelines. We recommend superactivated charcoal if it is commercially available. There is no known benefit of

mixing charcoal with a cathartic, and the combination is not suggested. Sorbitol increases the incidence of vomiting.

In many formulations the contents settle with time and vigorous shaking before administration is recommended. This should be followed by rinsing the container with a small amount of tap water prior to administering it to the patient, which will allow ingestion of the full dose. [66] Aqueous activated charcoal has a gritty texture that most patients find unpleasant and attempts have been made to improve the taste and texture. Mixing activated charcoal with chocolate milk, chocolate- or cherry-flavored syrup, or ice cream may increase palatability, but mixing with these additives has been suggested, though not proved, to cause a decrease in the adsorptive capacity of activated charcoal. [71] Rangan et al have recently reported no decrease in adsorption after mixing superactivated charcoal with a non-caffeinated cola. [111] Scharman et al demonstrated that a regular, sugared cola was favored by children over a diet cola, but it was very difficult to cajole even nonpoisoned children under age 3 years to drink a therapeutic amount of flavored charcoal. [119] It is very difficult to convince a toddler to drink a therapeutic dose of charcoal under the best of circumstances, questioning the long-held practice of keeping charcoal in the home to hasten the use of the antidote.

The patient should be given a brief (5- to 10-minute) period of time to drink the dose. If the dose is not consumed by that time, the clinician should consider giving the dose by NG tube to maximize charcoal efficacy. If a nasogatric tube is inserted, correct placement must be verified. Radiographic confirmation of tube placement should be considered in obtunded or intubated patients if doubts about placement exist (Fig. 43-10). Instillation of charcoal into the lungs through tubes inadvertently misplaced within the airways has been reported. [57]

Activated charcoal may be given orally if the patient is awake and cooperative or by NG tube if the patient is unconscious (Fig. 43-11). It may also be given through the lavage tube after gastric lavage (Fig. 43-12). The common tactic of passing an NG tube in the awake but uncooperative patient, merely to administer charcoal, is controversial. Such a scenario is more likely to result in trauma from the tube, a misplaced tube, or subsequent emesis from the rapid administration of charcoal. Given the unproven efficacy of charcoal, the editors advise against the *routine* insertion of an NG tube to simply administer charcoal in the awake and minimally symptomatic patient. Such a decision is, however, a clinical one that must be made based on the entire clinical milieu.

Complications

Charcoal is generally very safe and few adverse effects from the use of single-dose activated charcoal have been reported, despite its widespread use. There are no reports of gastrointestinal obstruction associated with single-dose activated charcoal. The most common complications of charcoal administration include constipation, diarrhea, and vomiting. [96] Pulmonary aspiration of activated charcoal is a dreaded complication that can result in pneumonitis, obstruction of the respiratory tree, and bronchiolitis obliterans. [14] [44] [80] [105] Aspiration of large amounts of charcoal can be fatal. [86] Risk factors for serious aspiration are large amounts of charcoal instilled over a short period of time, multiple dose charcoal in the setting of an ileus, charcoal administration in a patient who becomes obtunded, or the forced administration of charcoal via an NG tube, especially in a restrained supine

Figure 43-10 Radiographic confirmation of nasogastric tube placement before lavage or instillation of charcoal. Tracheal placement of a lavage tube is usually readily evident. Vomiting during lavage suggests that the tube has curved back into the esophagus. A confirmatory radiograph is suggested in the obtunded patient if gastric placement is questioned. Tracheal intubation precludes passage of a tube into the lungs, but it does not ensure proper gastric placement.

patient. Trivial aspirations of charcoal are common, even if the patient is intubated, and are usually innocuous.

Multiple Doses of Activated Charcoal

Indications

The use of multidose activated charcoal (MDAC) may be indicated in select cases. [30] Its use has been advocated for two purposes: first, to prevent continued absorption of a drug that may still be present within the gastrointestinal tract; second, to increase the clearance of a drug that has already been absorbed. The recommendations of various toxicology organizations for MDAC are presented in Figure 43-13 .

MDAC prevents continued absorption by either binding a drug that may be present throughout the gastrointestinal tract or binding a drug that exists as extended-release or enteric-coated preparations. MDAC enhances elimination of a drug by interrupting enterobiliary recirculation or augmenting enterocapillary exsorption.[96] By interrupting enterobiliary recirculation, charcoal binds to an active drug that is secreted by the biliary system, subsequently preventing reabsorption. By augmentation of enterocapillary exsorption, charcoal produces sink conditions that drive diffusion of drug from the capillaries into the entraluminal space, where it is subsequently eliminated. This process is called "intestinal dialysis". [70] Drug characteristics that are associated with enhanced systemic clearance with MDAC include a low intrinsic clearance, a prolonged distributive phase, low protein binding, and a small volume of distribution. [29]

Figure 43-11 If the overdose patient will voluntarily drink charcoal, there are few reasons to withhold it, even though a definite clinical benefit in the routine case cannot be proved. If a patient will not drink charcoal, patient management becomes controversial. Passing a nasogastric tube in a struggling patient or in a recalcitrant child merely to instill the unproven, but theoretically useful, antidote is not supported by scientific data. Nonetheless, it remains a common procedure. Although not always easy or pleasant, such an intervention is usually safe. Pulmonary aspiration, even in the awake patient, is the major downside. *Restrained supine patients are at greatest risk for aspiration, and that position should be avoided, even in the initially awake patient.*

MDAC has been shown to increase total body clearance of multiple drugs, including carbamazepine, [18] [90] [93] dapsone,[94] [95] phenobarbital,[15] [16] [19] [42] [47] [93] [107] [141] quinine, [74] [109] and theophylline.[5] [17] [30] [38] [43] [55] [76] [99] [101] [103] [110] [121] [122] [136] MDAC may be beneficial in the management of overdoses of the drugs listed in Table 43-2 . Despite the reported increase in drug clearance associated with the use of MDAC, improved clinical outcomes have not been definitively demonstrated. For example, Pond et al described 10 comatose patients following phenobarbital overdose who were randomized to receive either single-dose activated charcoal or MDAC.[107] Despite the fact that the MDAC group had a significantly shorter phenobarbital serum half-life, there was no difference between the groups in regard to the duration of intubation or hospitalization.

Contraindications

MDAC is contraindicated if there is evidence of bowel obstruction. An ileus is a relative contraindication. Many ill patients who develop an ileus may be selected candidates for MDAC if the airway is protected. The administration of MDAC is contraindicated in any patient who does not

Figure 43-12 Charcoal that is voluntarily swallowed or instilled via an oral-gastric lavage tube or nasogastric tube can induce emesis. This occurs in both the obtunded and awake patient. In this instance, the patient was unconscious from the overdose and the airway was protected with prior tracheal intubation. Although the intubation procedure does not totally exclude pulmonary aspiration, and it carries some morbidity in its own right, it is recommended prior to charcoal use in the patient who is not able to fully protect the airway. Patients who initially are asymptomatic or minimally affected but have ingested drugs that have the potential to produce rapid deterioration, seizures, or loss of airway protection make decisions on the use of charcoal difficult for the clinician. In borderline cases, some experienced clinicians avoid the use of charcoal altogether.

have an intact or protected airway. MDAC should be avoided in patients who have repetitive emesis, especially when associated with decreased mental status or a decreased gag reflex. The concurrent use of cathartics with MDAC remains unproved and is not recommended. [108] MDAC with cathartics should not be administered to young children because of the propensity for laxatives to cause fluid and electrolyte imbalance. For example, MDAC with sorbitol has been associated with hypernatremia and dehydration[2] [82] and MDAC with magnesium cathartics has been associated with hypermagnesemia, neuromuscular weakness, and coma.[56] [124]

Technique

The first dose of activated charcoal should be 1 g/kg (maximum of 100 g). If a cathartic is used, it should be administered only with the first dose of charcoal to decrease the risk of cathartic-induced electrolyte abnormalities that can potentially develop, especially in children. [2] [56] [82] [124] The initial dose of charcoal is followed by 0.5 g/kg (up to 50 g) of activated charcoal every 4 hours. If repeat examination reveals an absence of bowel sounds or reveals a distended abdomen, then MDAC should be terminated and the clinician should consider placement of a NG tube on low intermittent suction. Patients receiving MDAC may be at increased risk for emesis because of the larger total dose of activated charcoal received. The use of antiemetics may help decrease the incidence of vomiting associated with MDAC. [5] [22] [114] Charcoal therapy should be continued until

Figure 43-13 Position statement and practice guidelines on the use of multi-dose activated charcoal in the treatment of acute poisoning. *(From the American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists. Published in Clin Toxicol 37:731, 1999.)*

there is clinical improvement and plasma drug levels have fallen to acceptable levels.

Complications

The complications encountered in single-dose activated charcoal are also encountered in multiple dose activated charcoal. In addition, there have been reports of gastrointestinal obstruction and perforation from MDAC therapy, especially in conjunction with the ingestion of drugs with anticholinergic properties. [9] [48] [49] [112] [144]

TABLE 43-2 -- Drugs Whose Serum Clearance May Be Enhanced by Multiple Doses of Activated Charcoal

Aspirin
Caffeine
Carbamazepine
Cyclosporine
Dapsone
Digoxin
Disopyramide
Nadolol
Phenobarbital
Phenytoin
Quinine
Sotalol
Sustained-release thallium
Theophylline
Valproate
Vancomycin

Cathartic Use

Background

The use of cathartics is intended to decrease the absorption of substances by accelerating the expulsion of the poison from the gastrointestinal tract. Theoretically, this would also minimize the possibility of desorption of drug bound to activated charcoal. The majority of data suggest negligible clinical benefit from cathartic use. [3] [89] There is little evidence that a single dose of aqueous activated charcoal is significantly constipating; however, cathartics are often given for this potential problem.

Indications

The routine administration of a cathartic in combination with activated charcoal is not endorsed by the American Academy of Clinical Toxicology or the European Association of Poison Centres and Clinical Toxicologists. [12] Figure 43-14 gives a consensus recommendation on the use of cathartics. In addition, the administration of a cathartic alone has no role in the management of the poisoned patient.

Contraindications

Cathartics are contraindicated if there is volume depletion, hypotension, significant electrolyte imbalance, corrosive ingestion, ileus, recent bowel surgery, intestinal obstruction or perforation. The administration of cathartics is also

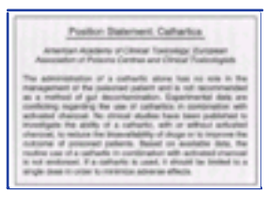

Figure 43-14 Position statement: cathartics. *(From the American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists. Published in Clin Toxicol 35:743, 1999.)*

contraindicated with patients who do not have an intact or protected airway. They should be avoided in patients who have repetitive emesis, especially when associated with decreased mental status or a decreased gag reflex. Cathartics should be used cautiously in young children and the elderly because of the propensity for laxatives to cause fluid and electrolyte imbalance.

Technique

There are two types of osmotic cathartics: saccharide cathartics (sorbitol) and saline cathartics (magnesium citrate, magnesium sulfate, and sodium sulfate). The optimal dose of sorbitol or magnesium citrate remains to be determined. The recommended dose of sorbitol is approximately 1 to 2 g/kg of body weight or 1 to 2 mL/kg of 70% sorbitol in adults and 4.3 mL/kg of 35% sorbitol in children (single administration only). [12] Many charcoal formulations come premixed with sorbitol, but there is considerable variation in sorbitol content: Liqui-Char with sorbitol contains 50 g of activated charcoal in 54 g of sorbitol; Actidose with sorbitol contains 50 g of activated charcoal in 96 g of sorbitol; activated charcoal USP with sorbitol contains 25 g of activated charcoal in 27 g of sorbitol; CharcoAid contains 30 g of activated charcoal in 110 g of sorbitol. The recommended dose of magnesium citrate is 250 mL of 10% solution in an adult and 4 mL/kg body weight of 10% solution in a child. Multiple doses of cathartics should be avoided.

Complications

The administration of sorbitol has been associated with vomiting, abdominal cramps, nausea, diaphoresis, and transient hypotension. [46] [55] [88] Because the sorbitol content varies between different charcoal/sorbitol combination products,

Figure 43-15 This "body packer" *(A)* attempted to smuggle more than 50 packets of heroin. All packets were passed intact after 12 hours of whole-bowel irrigation. Note the integrity of the carefully wrapped packets that were passed *(B)*.

attention should be paid to the sorbitol content in each brand to avoid excessive sorbitol administration. Multiple doses of sorbitol have been associated with volume depletion. [2] Multiple doses of magnesium-containing cathartics have been associated with severe hypermagnesemia. [56] [124] Children are particularly susceptible to the adverse affects of cathartics, and therefore cathartics should be used with caution, or totally avoided, in children.

Whole-Bowel Irrigation

Background

Whole-bowel irrigation (WBI) has emerged as the newest technique in gastrointestinal decontamination. It involves the enteral administration of an osmotically balanced polyethylene glycol-electrolyte solution (PEG-ES) in a sufficient amount and rate to physically flush ingested substances through the gastrointestinal tract, purging the toxin before absorption can occur (Fig. 43-15).[129] PEG-ES (CoLyte, GoLYTELY) is isosmotic, is not systemically absorbed, and will not cause electrolyte or fluid shifts. Available data suggest that the large volumes of this solution needed to mechanically propel pills, drug packets, or other substances through the gastrointestinal tract are safe, including in pregnancy and in young children. [128] [139]

Indications

WBI may be considered for ingestions of exceedingly large quantities of potentially toxic substances, ingestions of toxins that are poorly adsorbed to activated charcoal (e.g., iron, lithium), ingestions of delayed-release formulations, late presentation after ingestion of a toxin, pharmacobezoars,

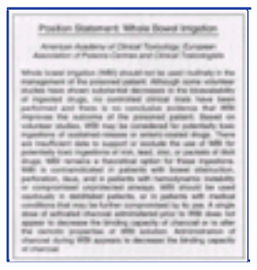

Figure 43-16 Position statement: whole-bowel irrigation. *(From the American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists. Published in Clin Toxicol 35:753, 1997.)*

and body stuffers or packers.[53] [60] [125] [129] WBI remains a theoretical option for these ingestions. There is no definitive evidence that WBI improves the outcome of the poisoned patient[131] (Fig. 43-16). Although not a proven procedure, WBI is often suggested by toxicologists. Its use is intuitively reasonable and supported by the editors. The most common indication for WBI in the ED is for the treatment of toxic sustained-release medications (such as calcium channel blockers, theophylline, and lithium) and iron tablets (Fig. 43-17).

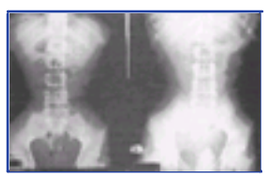

Figure 43-17 Whole-bowel irrigation is commonly recommended for the treatment of iron ingestion. These radiographs depict the effect of 5 hours of whole-bowel irrigation. Note the marked decrease of radiopaque pills in the gastrointestinal tract. Intact pills were recovered in the rectal effluent.

Contraindications

WBI is contraindicated in patients with gastrointestinal obstruction, perforation, ileus, and corrosive ingestion. It should also be avoided in patients with hemodynamic instability or an unprotected airway.[130] WBI should be avoided with patients who have repetitive emesis, especially when associated with decreased mental status or a decreased gag reflex. WBI should be used cautiously in debilitated patients.

Technique

PEG-ES is marketed in a powder form. Tap water is added to make a total volume of 4 L. The recommended rate of administration is as follows.[129]

- 9 months to 6 years: 500 mL/hour
- 6 years to 12 years: 1000 mL/hour
- Older than 12 years: 1500 to 2000 mL/hour

Cooperative patients with intact airway protective reflexes may drink the solution. The large volume and taste often limit even the most motivated patient's ability to comply. If the patient is unable or unwilling to drink this solution, it should be administered through a small-bore NG tube after placement is confirmed. Because it is common for WBI to be delayed while the patient and medical personnel attempt to administer the large volumes of WBI solution required to be effective, it is suggested that NG instillation be instituted early in the ED course (Fig. 43-18). Unconscious patients with protected airways may receive WBI. Pre-warming the irrigant to a temperature of approximately 37°C avoids the potential complication of hypothermia. To collect the waste products, the awake patient may need to be seated on a commode; a rectal tube will need to be placed in the obtunded patient. Many toxicologists recommend adding two to three bottles of activated charcoal to each liter of WBI solution. The benefit is unproved but there is little theoretical downside to this technique, and it is supported by the editors. The binding capacity of charcoal is decreased when combined with PEG-ES, but the clinical consequences of this observation are unknown. Empirically, metoclopramide may be coadministered to decrease nausea and facilitate GI passage.

The endpoint of WBI is until the arrival of clear rectal effluent and/or resolution of toxic effect. [130] There are rare case reports of late purging of drug packets, plant parts, and tablets

Figure 43-18 It is very difficult for even the most motivated patient to drink an effective volume of whole-bowel irrigation solution. To enhance compliance and to decrease vomiting, PEG-ES may be slowly and continuously administered via a nasogastric tube. An empty bag of saline is hung on an IV pole, the corner of the bag is removed, and the PEG-ES is poured into the bag. Standard IV tubing is connected to the proximal end of a nasogastric tube and the solution is infused continuously. In this picture, charcoal has been added to the whole-bowel irrigation solution. Metoclopramide was coadministered to reduce nausea.

after the arrival of clear effluent.[53] [118] Radiographic studies may also be beneficial to determine the endpoint in body packers or in patients who have ingested radiopaque medications.

Complications

There have been few reported complications from WBI therapy, especially pertaining to acute poisonings. Nausea, vomiting, abdominal cramps, and bloating have been described.[40] Nausea and vomiting may make administration of WBI difficult. Antiemetics and a 15- to 30-minute break followed by a slower rate may allow readministration. As discussed with the other methods of decontamination, attention should be directed to the airway and the potential for aspiration. Administration of a large amount of chilled or room temperature WBI fluid to pediatric patients could potentially cause hypothermia. Warmed fluid should be considered in these

patients. If activated charcoal is administered concurrently with WBI, there may be a desorption of toxin from charcoal. [52] [61] [77]

DERMAL DECONTAMINATION

Background

Numerous hazardous material (HAZMAT) incidents occur each year in the United States. The National Response Center Database, which tracks comparatively large incidents such as train derailments and industrial accidents, reported 34,360 HAZMAT incidents in 2001. [92] In 1996, 5502 HAZMAT events in 14 states involving 5887 substances were reported to the Hazardous Substances Emergency Events Surveillance System (HSEESS).[51] HAZMAT events frequently result in injuries, and the ED treatment of contaminated HAZMAT patients is not a rare event. Many of these patients transport themselves to the ED, including those involved in past terrorist events. For example, in the Tokyo sarin gas attack, 93% of 498 patients reporting to St. Luke's Hospital arrived by means other than ambulance. [100] The risk of injury to medical personnel incurred while treating contaminated patients is significant. Of the patients reported to HSEESS, emergency responders accounted for 10% of injuries and hospital personnel for 4.1% of injuries.[51] After the Tokyo attack, 13 of 15 clinicians (87%) reported symptoms while treating patients in the ED and 23% of involved hospital staff complained of acute poisoning symptoms.[96] Burgess et al reported that 13% of Washington state emergency care facilities had evacuated their ED or another part of the hospital for contamination during a 5-year period. [23] Ghilarducci et al (2000) surveyed Level 1 trauma centers in the United States and reported that only 6% had the necessary equipment required for safe decontamination, less than 36% of emergency medicine staff had received appropriate training in handling the contaminated patient, and 5.6% had experienced injuries to their staff due to contact with contaminated patients during a 1-year period. It is imperative that EDs have plans in place to handle patients who are exposed to potential toxins, provide adequate decontamination facilities, and ensure the safety of the treating medical staff.

Technique

There are a number of key components in the management of a hazardous materials incident and the care of the contaminated patients who present to the ED. [75] These components should include early recognition of a HAZMAT event, rapid activation of a plan to manage contaminated patients, initiation of primary triage, appropriate patient registration, patient decontamination, secondary triage, and final treatment.

First, the ED must be able to recognize that an event has occurred before contaminated patients gain entrance into the health care facility. Communication with local fire, police, and paramedics provides early detection of such events and allows preparation before patients arrive. Security should be arranged to prevent contaminated patients from entering the hospital, and a "lockdown" of the facility should be considered.

Second, the ED should have the authority to activate a plan expeditiously to prepare the decontamination facility and allow appropriate personnel to don personal protective equipment (PPE). If necessary, the hospital disaster plan should be activated quickly at the discretion of the ED attending clinician who is in contact with scene operations and incoming patients. Specific data to determine the appropriate level PPE to maintain hospital worker protection remains limited. Most chemical exposures do not pose a risk of secondary exposure. With unknown chemical and biologic exposures, level B and level A PPE, respectively, is recommended by OSHA. Fortunately, most chemical exposures are known. For those that occur in the workplace, Material Safety Data Sheets can be obtained and either the local poison center or the Agency for Toxic Substances and Disease Registry (ATSDR) can be contacted to obtain advice on what level of protection is appropriate.

Third, appropriate primary triage should occur. Contaminated patients should not enter the ED until proper decontamination has occurred to assure that the hospital staff will not get secondary contamination. Appropriate triage should then occur with experienced personnel performing an initial brief assessment of each patient.

Fourth, a brief sign-in process should capture the patient's name and date of birth with full registration to occur following decontamination. Contaminated clothing and valuables should be placed in an impervious bag to avoid potential off gassing. [54] [120]

Fifth, decontamination should be performed. The hospital ED should have preexisting hazardous materials incident protocols that designate the decontamination area and the triage and decontamination team. The decontamination area should meet several qualifications: (1) it should be secured to prevent spread to other areas of the hospital, (2) the ventilation system should be separate from the rest of the hospital or it should be shut off to prevent airborne spread of contaminants, and (3) provisions must be made to collect the rinsate from contaminated patients to prevent contamination of the facility and water supply. Some hospitals may have designated decontamination rooms. At most facilities, the best place to begin initial treatment and evaluation is outdoors (Fig. 43-19). Portable decontamination facilities are available, but their cost may be prohibitive for many institutions. A practical alternative is to have a warm shower nozzle, soap, and a wading pool available outside the entrance to the ED. A tent or screen can provide privacy. Decontamination should proceed by using soap and copious warm water irrigation. Starting from head to toe, irrigate the exposed skin and hair for 10 to 15 minutes and scrub with a soft surgical sponge with careful attention not to abrade the skin. Irrigate wounds for an additional 5 to 10 minutes with water or saline. Irrigate the eyes for 10 to 15 minutes with saline, directed away from the medial canthus to avoid forcing contaminants into the lacrimal duct. Longer irrigation times may be needed with strongly alkaline substances. Irrigate the nares and the ear canals with frequent suctioning if contamination is suspected. Clean underneath the nails with a brush. Stiff brushes and abrasives should be avoided as they may enhance dermal absorption of the toxin and can produce skin lesions that may be mistaken for chemical injuries. Sponges and disposable towels are effective alternatives.

Secondary triage should occur after decontamination. Patients with major or moderate casualties can then be transferred to areas designated for such cases. Those with minor or no injuries should be sent to appropriate holding areas for further evaluation. Medical care at this stage would then depend on the toxin to which the patient has been exposed and the potential toxicity of that agent.

Figure 43-19 Decontamination of personnel using copious water irrigation.

In order for the ED to care for the contaminated patient, protocols should be in place and regularly rehearsed by the facility. There are template protocols in both peer-reviewed literature and in the government literature. [24] [64] For example, guidelines for managing hazardous materials incidents are available from the Emergency Response and Consultation Branch (E57), Division of Health Assessment and Consultation, Agency for Toxic Substances and Disease Registry, 1600 Clifton Road NE, Atlanta, Georgia 30333.[78]

CONCLUSION

Gastric emptying techniques such as gastric lavage and ipecac-induced emesis are rarely being used to decontaminate the poisoned patient who presents to the ED. There may be future indications for these procedures with specific toxins. At this time the documented risks associated with these procedures should be carefully weighed in light of the rare indications. Activated charcoal as the sole means of gastric decontamination is increasing in popularity, but its efficacy has specific limitations. Protocols for the evaluation and treatment of asymptomatic or minimally symptomatic patients, who have not ingested significantly toxic substances, continue to evolve, and it has been suggested that these patients will do well regardless of therapy. The major issue currently facing the clinician is the choice of gastrointestinal decontamination in the significantly poisoned patient. The choice of decontamination method for these patients must be individualized using both evidence-based medicine and clinical acumen. No patient should undergo any of the available procedures unless it is anticipated that decontamination will provide clinical benefit.

Chapter 44 - Peritoneal Procedures

John A. Marx

Paracentesis and diagnostic peritoneal lavage constitute the two primary intraperitoneal procedures. They are fundamentally similar in purpose and design. However, the former is generally reserved for medical concerns and the latter for traumatic pathology.

DIAGNOSTIC PERITONEAL LAVAGE

Root and colleagues introduced diagnostic peritoneal lavage in 1964. [1] It has withstood the passage of more than 3 decades and remains a mainstay in the management of penetrating torso trauma. Following a blunt mechanism of injury, its greatest utility is as a triage tool in the hemodynamically unstable multiply injured patient. Otherwise, it serves with computed tomography (CT) and with the intent of rapidly discovering or excluding the presence of intraperitoneal hemorrhage, a purpose identical with that of ultrasound (US) in the diagnostic armamentarium of blunt trauma. [2]

While commonly referred to as *diagnostic peritoneal lavage* (DPL), this procedure comprises two distinct components: peritoneal aspiration and peritoneal lavage. Peritoneal aspiration, in which an attempt is made to retrieve free intraperitoneal blood, precedes lavage. A finding of intraperitoneal blood presages intraperitoneal organ injury and precludes the need for subsequent lavage. In the lavage portion, normal saline is introduced by catheter into the peritoneal cavity, recovered by gravity, and analyzed.

Peritoneal lavage can be used as a therapeutic tool in hypothermia and as a means of removing toxins. [3] It has also been used as a diagnostic instrument for suspected intra-abdominal infection and nontraumatic sources of hemorrhage. [4] [5] However, its primary use is as a determinant for the need for laparotomy following trauma, and this chapter focuses on that use.

Indications

Blunt Trauma

Prior to the advent of CT and US, DPL was the sole diagnostic option to physical examination for predicting the need for operative intervention (Table 44-1). It was integral both to the reduction of unnecessary laparotomies and to the discovery of unsuspected and life-threatening intra-abdominal hemorrhage in patients with significant closed head injury. [6] [7]

In a number of respected centers in the United States, DPL continues to be a focal diagnostic instrument. It serves two primary functions. [8] First, it can rapidly determine or exclude the presence of intraperitoneal hemorrhage (Table 44-2). Thus, the patient with a critical closed head injury, the unstable motor vehicle crash victim with multiple potential sources of blood loss, or the patient with pelvic fracture and retroperitoneal hemorrhage can be appropriately routed to life-saving laparotomy. [9] [10] Furthermore, given its exquisite sensitivity, a negative peritoneal aspiration allows the clinician to proceed to alternative management steps and the patient to forego unnecessary laparotomy. Second, DPL can be used in less exigent circumstances as a means of predicting solid or hollow visceral injury requiring laparotomy. [11] [12] In this venue, its sensitivity to the presence of hemorrhage may prompt unnecessary laparotomy in a small percentage of patients with self-limited lacerations of the liver or spleen. [13] [14] [15] [16] CT scan specifically evaluates all intraperitoneal structures as well as the retroperitoneum, a region inaccessible to DPL. Because resolution and the speed with which it can be undertaken have vastly improved, CT has become an invaluable adjunct in the management of blunt trauma. [17] [18] It is most useful in the identification of injury to solid organs with accompanying intraperitoneal hemorrhage and greatly assists nonoperative management of those injuries. Using DPL and CT in a complementary fashion can mitigate the number of unnecessary laparotomies while prompting therapeutic operations in other cases. The ability of CT to discern hollow viscus and pancreatic pathology has improved but remains inconsistent. [19] [20] With regard to hollow viscus injury, it is when serial clinical evaluations cannot be performed that gut perforation leads to preventable mortality. It is for this express scenario that certain authorities recommend the performance of DPL: following a negative CT or particularly one demonstrating free fluid without evidence of solid organ damage. [21] [22]

Experience with US in North America is meager in comparison with that in Western Europe (notably Germany) and Asia (notably Japan). In the past, US in the United States had been used exclusively for the detection and serial examination of traumatic pancreatic pseudocysts. There are two paradigms that have brought US to the forefront. First, this modality has been adopted as the primary triage instrument, in lieu of DPL, for the detection of intraperitoneal hemorrhage on the basis of identifying which pouches and gutters are fluid-filled. [23] [24] [25] [26] Clinical success in this role has been mixed with reported sensitivities for intraperitoneal hemorrhage of 65 to 95%. [27] [28] [29] [30] [31] [32] [33] Additionally, to be useful in this role, a competent technician, interpreter, and equipment must be present in real-time. It has been demonstrated that emergency clinicians and surgeons can be trained in this technique to a level of competence sufficient for this need. [34] In centers that rely upon US, DPL should serve as a reliable study when US equipment is unavailable, the US is technically difficult, or when the results

TABLE 44-1 -- Clinical Indications for Laparotomy after Blunt Trauma

Manifestation	Pitfall
Unstable vital signs with strongly suspected abdominal injury	Alternate sources of shock
Unequivocal peritoneal irritation	Unreliable
Pneumoperitoneum	Insensitive; may be due to pulmonary source or invasive procedures (diagnostic peritoneal lavage, laparoscopy)
Evidence of diaphragmatic injury	Nonspecific
Significant gastrointestinal bleeding	Uncommon, unknown accuracy

Determine presence of IPH or injury	Multiple trauma patients who require general anesthesia for other injuries	CT, US

CT, computed tomography; IPH, intraperitoneal hemorrhage; US, ultrasound.

of the US are indeterminate, especially when the patient demonstrates hemodynamic compromise.

Second, US can determine injury to solid viscera such as the liver, spleen, kidneys, and pancreas. This requires considerably greater expertise, and in most centers

US has not supplanted CT for this purpose. [35]

DPL is a readily available procedure that can be conducted rapidly in the safe confines of the emergency department (ED). The ability to undertake CT, in particular, or to a lesser extent, US in a similar manner requires careful consideration of clinical circumstances, equipment location, and the capabilities of available personnel (Table 44-3) (Fig. 44-1).[36] [37]

Penetrating Trauma

The advent of DPL was seminal in the promotion of selective management for penetrating abdominal injury. Here its role is more dominant than for blunt trauma due to the far greater likelihood of occult injury to hollow viscera and the diaphragm following a penetrating mechanism. [38] [39]

Instruments and missiles may penetrate the abdominal cavity via the anterior abdominal wall, flank, back, or low chest. [40] The intraperitoneal space is vulnerable if penetration occurs as high as the fourth intercostal space anteriorly and the sixth or seventh laterally and posteriorly, as the diaphragm may rise to these levels in the expiratory phase of respiration. [41] Coincident thoracic penetration has occurred in up to 46% of abdominal injuries. [42] [43] [44] The likelihood of retroperitoneal

*+ peritoneal aspirate mandates laparotomy, + red blood cell count only, warrants attention to pelvic fracture.
†Specific organ damage or fluid/blood suggesting injury.
‡US for OI much less reliable than for IPH.
§Institutional capability should be carefully considered.
?CT less reliable for HVI than for solid visceral injury.
¶Complementary to CT if HVI suspected.
£May be more appropriate if can be rapidly acquired or if CT primary study for BAD.

injury increases when the entry site is over the flank or back, but the prospect of intraperitoneal pathology remains considerable with cited incidences of 21 to 44% for the flank and 7 to 14% for the back (Table 44-4).[45] [46] [47]

Stab wounds.

Because only one fourth to one third of patients who sustain stab wounds to the anterior abdomen require laparotomy, diagnostic algorithms are used to decrease the rate of unnecessary operation.[38] [43] [48] [49] An optimal approach would not sacrifice sensitivity for morbid intraperitoneal injury. A pathway using a combination of clinical mandates, local wound exploration, and DPL is well established (Fig. 44-2). [50] These clinical mandates are reasonably accurate predictors of significant intraperitoneal injury (Table 44-5). Thus, the presence of one or more mandates suggests the need for urgent laparotomy and precludes the undertaking of other diagnostic studies.

DPL fills three roles in the evaluation of patients with abdominal stab wounds (Table 44-6): (1) rapid determination of the presence of hemoperitoneum, (2) discovery of intraperitoneal injury requiring operation in stable patients, and (3) the establishment of diaphragmatic violation. As is the case in blunt trauma patients, DPL can be invaluable as a rapid triage tool when the source of hemodynamic instability is not known. Pericardial tamponade, intrathoracic hemorrhage, and intraperitoneal hemorrhage may be contributory to hemodynamic instability or wholly causal. Again, as for blunt trauma evaluation, US is the only diagnostic modality for

Figure 44-1 Blunt abdominal trauma algorithm. BAT, blunt abdominal trauma; CT, computed tomography; D/C, discharge; DPA, diagnostic peritoneal aspiration; DPL, diagnostic peritoneal lavage; IP, intraperitoneal; IPH, intraperitoneal hemorrhage; LAP, laparotomy; SPE, serial physical examinations; US, ultrasound. *Determined by unequivocal free intraperitoneal fluid on ultrasound or positive peritoneal aspiration on diagnostic peritoneal lavage. †Can be unreliable because of closed head injury, intoxicants, distracting injury, or spinal cord injury. ‡One or more studies may be indicated. §Need for laparotomy is based on clinical scenario, diagnostic studies, and institutional resources. *(From Marx J: Abdominal Trauma. In Marx JA, Hockberger RS, Walls RM, et al. [eds]: Rosen's Emergency Medicine Concepts and Clinical Practice, 5th ed. St. Louis, CV Mosby, 2002, p 432.)*

intraperitoneal hemorrhage that is competitive for this role and carries the added advantage of scanning for intrapericardial and intrathoracic hemorrhage as well. [44] In the determination of injury following stab wounds, DPL carries 90% accuracy. [51] [52] [53] Serial examinations,[54] [55] [56] CT, and laparoscopy[57] [58] [59] [60] are alternative modalities in specific circumstances and centers.[61] Diaphragmatic rents created by stab wounds are generally small; thus, at the outset, they do not create apparent clinical or radiologic abnormalities. [62] [63] However,

TABLE 44-4 -- Injury Likelihood by Entry Site

	Intraperitoneal	Retroperitoneal	Diaphragm
Anterior abdomen	++	+	+
Flank	+	++	+
Back	+	++	+
Low chest	+	+	++

From Marx JA: Diagnostic peritoneal lavage. In Ivatury RR, Cayten CG (eds): The Textbook of Penetrating Trauma. Baltimore, Williams & Wilkins, 1996, p 336.

morbidity due to delayed herniation of bowel is common and substantive. [64] DPL is currently the most sensitive means of discerning this injury in the immediate

post-trauma phase.[51] Physical examination and CT are notoriously insensitive. Laparoscopy has demonstrated promise in experienced hands. [57] [58] For these small diaphragmatic wounds, the advanced radiologic tool called magnetic resonance imaging (MRI) may be diagnostic, but due to safety and accessibility concerns, it should be reserved for the non-acute phase of management.

Gunshot wounds.

Multiple organ injury is the rule following gunshot wounds, and mortality is significantly greater when compared with that for stab wounds. [65] The diagnostic approach is more conservative for gunshot wounds because the likelihood of intraperitoneal injury requiring operative intervention exceeds 95% when the projectile has entered the intraperitoneal cavity (Fig. 44-3).[66] [67] [68] If clinical mandates are met (see Table 44-5) or if peritoneal violation has occurred, most centers proceed to laparotomy.[50] One series,

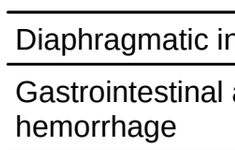

Figure 44-2 Anterior abdomen stab wound algorithm. *Plain films, ultrasound, laparoscopy, and computed tomography (CT) can assess peritoneal entry. †Laparoscopy or CT can complement or replace diagnostic peritoneal lavage. ‡Expectant management of injuries is infrequently attempted. D/C, discharge; DPL, diagnostic peritoneal lavage; LAP, laparotomy; LWE, local wound exploration; PEx, physical examination. *(From Marx J: Abdominal Trauma. In Marx JA, Hockberger RS, Walls RM, et al. [eds]: Rosen's Emergency Medicine Concepts and Clinical Practice, 5th ed. St. Louis, CV Mosby, 2002, p 427.)*

however, cited intra-abdominal injury in 70% to 80% of cases, supporting the contention that nonoperative management could be applied to a substantial percentage of patients. [69] DPL is reserved for two circumstances: (1) the wound tract is neither obviously superficial nor intraperitoneal, and (2) penetration is to the low chest, where diaphragmatic injury is more likely, yet the possibility of intraperitoneal injury exists.

Contraindications

Diagnostic peritoneal lavage can be undertaken in virtually any patient irrespective of age, pregnant state, or comorbid illness. Adjustment of the technique and site of performance allows relative contraindications to be overcome. Relative contraindications include prior abdominal surgery or infections,

TABLE 44-5 -- Clinical Indications for Laparotomy Following Penetrating Trauma

Manifestation	Premise	Pitfall
Hemodynamic instability	Major solid visceral or vascular injury	Thorax, mediastinum
Peritoneal signs	Intraperitoneal injury	Unreliable, especially immediately postinjury
Evisceration	Additional bowel, other injury	No injury in ¼ to ? of stab wound cases
Diaphragmatic injury	Diaphragmatic herniation	Rare clinical, radiographic findings
Gastrointestinal and vaginal hemorrhage	Proximal gut or uterine injury	Uncommon, unknown accuracy
Impalement in situ	Vascular impalement	High operative risk, pregnancy
Intraperitoneal air	Hollow viscus perforation	Insensitive; may be caused by intraperitoneal entry only or be due to cardiopulmonary source

Modified from Marx JA: Diagnostic peritoneal lavage. In Ivatury RR, Cayten CG (eds): The Textbook of Penetrating Trauma. Baltimore, Williams & Wilkins, 1996.

obesity, coagulopathy, and second- or third-trimester pregnancy. The sole absolute contraindication is when clinical mandates for urgent laparotomy already exist.

Technique

Preliminary Steps

The stomach and bladder should preferably be decompressed to prevent inadvertent injury. The patient is kept supine and administered sedation and analgesia as appropriate (see Chapter 34). This is most relevant when the semi-open technique is used and a trocar is passed through the peritoneum. DPL should be performed according to compliance with standards for body fluid precautions (see Chapter 71). Prior to making the skin incisions described later, the site of placement should be prepped with standard skin antiseptics (e.g., povidone-iodine) and appropriately draped. The operator should observe sterile precautions throughout the procedure. Prophylactic antibiotics are not indicated for routine DPL because local and systemic infections are rare. [52] [70]

Local anesthesia (1% lidocaine *with* epinephrine) should be infiltrated liberally into the area for incision and dissection (Fig. 44-4). It is best to delay the incision for more than 30 seconds following local anesthetic infiltration to permit local vasospasm, which minimizes wound bleeding during the procedure. Standard equipment for an open peritoneal lavage catheter placement is shown in Figure 44-5 .

Catheter Placement

DPL is performed via two basic methods: open and closed. The two open techniques are *semi-open* and *fully open*, and they typically require an assistant. DPL is clearly within the diagnostic armamentarium of the emergency clinician and surgeon. It may be undertaken by either or both in keeping with clinical policies established at the particular trauma center.

Open technique.

In the semi-open method, sharp then blunt dissection using a No. 11 scalpel and Army-Navy retractors, respectively, proceeds to the *rectus fascia* (Fig. 44-6*A* and *B*). The skin incision should be 4 to 6 cm in length. When the selected site is infraumbilical in the midline, the operator should reach the *linea alba*; its crossing bands of crural fibers may be apparent.[71] A small 2- to 3-mm opening is then made in the *linea alba*, preferably with a No. 15 scalpel blade (Fig. 44-6*C*). (The operator will notice a tough, gritty sensation when cutting the *linea alba* with the scalpel.) Towel clips can be placed through this opening to grasp each side of the *rectus fascia* (Fig. 44-6*D*). These two towel clips are then lifted to allow safe advancement of the catheter via trocar in a 45° to 60° caudad orientation through the peritoneum and into the peritoneal cavity (Fig. 44-6*E* and F).[72] [73]

TABLE 44-6 -- Indications for DPL Following Penetrating Mechanism

Purpose	Circumstance	Alternate or Complementary Diagnostic
Rapidly determine presence of IPH	Hemodynamically unstable SW or GSW to low chest, abdomen, flank, back	Ultrasound
Determine presence of organ injury	SW or GSW to low chest, abdomen, flank, back	Serial clinical examinations, CT, laparoscopy
Determine diaphragmatic violation	SW or GSW to low chest, upper abdomen	Laparoscopy

CT, computed tomography; GSW, gunshot wound; IPH, intraperitoneal hemorrhage; SW, stab wound.

To decrease the likelihood of penetrating underlying viscera, some operators advocate holding the fingers low on the catheter-trocar instrument such that on entering the abdominal peritoneum, the fingers will prevent deep penetration. Excessive pressure during trocar penetration is a common error. Steady "one-finger pressure" applied to the handle is sufficient to "pop" through the fascia and peritoneum. After controlled peritoneal penetration of 0.5 to 1.0 cm in the midline, the trocar is retracted 1.0 to 2.0 cm within the catheter, and the catheter is carefully advanced toward the pelvis. Some operators prefer to advance the catheter toward the right or left side of the pelvis. Use of a

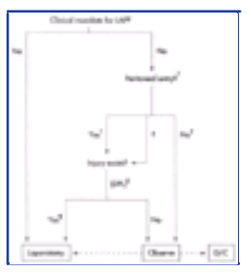

Figure 44-3 Gunshot wound algorithm. D/C, discharge; DPL, diagnostic peritoneal lavage; LAP, laparotomy. *Can be assessed by missile path, plain films, local wound exploration, ultrasound, and laparoscopy. †Most centers proceed to laparotomy if peritoneal entry is suspected. ‡Patients with documented superficial and low-velocity injuries can be discharged; unknown depth or high-velocity injuries require further tests or observation. §Serial examinations, laparoscopy, or a computed tomography scan can complement or replace diagnostic peritoneal lavage. ¶Expectant management of injuries caused by gunshot wounds is rarely attempted. *(From Marx J: Abdominal Trauma. In Marx JA, Hockberger RS, Walls RM, et al. [eds]: Rosen's Emergency Medicine Concepts and Clinical Practice, 5th ed. St. Louis, CV Mosby, 2002, p 430.)*

slight twisting motion during advancement may minimize visceral or omental injury.

The *fully open* technique extends the semi-open technique by one step. The opening in the *linea alba* is lengthened, and the peritoneum is opened to allow direct visualization during catheter placement into the peritoneal cavity.

The two open techniques can be accomplished with a single technician, but an additional pair of hands is advised in order to assist in retraction and handling of instruments. The fully open method is the more technically demanding and time-consuming. It is reserved for clinical circumstances in which the closed or even semi-open technique is not deemed safe or has been attempted and failed. These include pelvic fracture, pregnancy, prior abdominal surgery or infections, and obesity.

Closed technique.

With closed techniques, the catheter is introduced into the peritoneal space in a blind percutaneous fashion. [74] Formerly, this was accomplished via trocar. This has been abandoned in favor of the much safer but equally simple Seldinger (guide wire) method, in which a small-gauge guide needle is inserted into the peritoneal cavity in the infraumbilical midline (Fig. 44-7*A*). A flexible wire is then passed through the needle (Fig. 44-7*B*), and the needle is removed, allowing the over-the-wire placement of a soft catheter into the peritoneal cavity. A stab with a No. 11 scalpel at the entry site of the wire allows easier passage of the catheter through the abdominal wall (Fig. 44-7*C* and *D*). Rotating the catheter while pushing it over the guide wire is recommended to facilitate entry into the peritoneal cavity. The catheter is placed into the right or left pelvic gutter.

Figure 44-4 Local anesthesia is introduced at incision or puncture site. The patient is supine with the head of the bed elevated slightly.

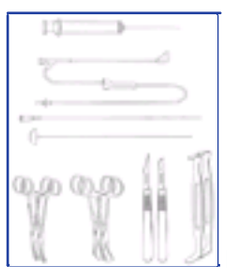

Figure 44-5 Standard equipment used for open lavage technique.

The wire is then withdrawn, and aspiration conducted, followed by lavage when necessary. The guide wire should always be controlled to avert intra-abdominal migration of the wire. Proponents of the guide wire technique promote its ease and rapidity. [75] [76] [77] [78] [79] Those who prefer the semi-open method argue that the time to peritoneal aspiration, the more critical interval, is minimally different, and that this method may have fewer complications and thus be more accurate than the guide wire technique. [80] [81] [82] [83] Note that time to aspiration for semi-open or closed approaches should entail no more than 2 to 5 minutes.

Site

The optimum location for DPL is at the infraumbilical ring, at the inferior border of the umbilicus (Table 44-7). Here, between the *rectus abdominis* muscles, there is adherence of the peritoneum and relative lack of vascularity and preperitoneal fat. [71] Closed DPL should always be conducted here. In the event of second- or third-trimester pregnancy, a suprauterine approach is used. If there is midline scarring, a fully open technique at the lateral border of the *rectus abdominis* in the left lower quadrant may be necessary. The left is preferred to avoid later confusion about whether an appendectomy has been performed. It is interesting to note that Moore and colleagues found no increase in complications or misclassified lavages when the closed technique was used in a small series of patients with prior abdominal surgery. [84] In the presence of a pelvic fracture, a fully open supraumbilical approach is recommended. This greatly decreases the likelihood of passing the catheter through retroperitoneal hematoma that has dissected from the fracture anteriorly and across the abdominal wall. [85] In penetrating trauma, DPL should not be conducted through the stab or missile entry site. Such an approach may contaminate the intraperitoneal cavity and potentially exacerbate abdominal wall bleeding, which could in turn lead to a false-positive result.

Aspiration and Lavage

Once the catheter has been placed successfully into the peritoneal cavity and the right-angle adapter, extension tubing, and a non-Luer-Lok syringe have been attached, aspiration is attempted (Fig. 44-8). The recovery of 10 mL of blood is considered positive, and the procedure terminated. In penetrating trauma, the acquisition of lesser amounts may be meaningful because of the tendency for the diaphragm and bowel to hemorrhage minimally when injured. However, there are no

established rules in this regard.

If little to no blood is aspirated, the peritoneal cavity is lavaged with either normal saline or lactated Ringer's solution (Fig. 44-9). A blood pressure cuff or blood infusion pump can be applied to the plastic intravenous (IV) bag to speed the influx (i.e., decrease lavage time), but they are rarely needed. Large-bore infusion tubing (e.g., urologic irrigation tubing sets, such as the Abbott No. 6544 cystoscopy/irrigation set) also shortens fluid influx time. The normal amount is 1 L in adults or 15 mL/kg in children. When possible, the patient is rolled or shifted from side to side after infusion to increase mixing. The IV bag or bottle is placed on the floor

(or below abdominal level), and the fluid is allowed to return by gravity.

The fluid may not continue to return because of several factors. Some IV tubing contains a one-way valve; if tubing with a valve was used in error, valveless tubing must be reinserted into the IV bag. Another reason for poor return is inadequate suction. This problem can be corrected by insertion of a needle into the second opening at the bottom of the IV bag or into the head of the IV bottle for aspiration of 10 mL of air. Alternatively, the catheter may be adherent to the peritoneum. If so, relieving some of the pressure in the IV bottle or gently wiggling and twisting the catheter as well as applying abdominal pressure may aid flow return.

It is generally accepted that the return of greater than or equal to 700 mL in the adult is adequate for interpretation of findings. However, as little as 10 to 20% of the infusate may give a representative sample for both gross and microscopic determinations. Only 10 mL of fluid from the return need be sent to the laboratory for cell count analysis; another 10 mL can be sent for enzyme analysis (see interpretation later in this chapter). Some operators prefer to leave the dialysis catheter in place until the returned fluid is analyzed. The clinician may wish to re-lavage when the initial results are borderline or an occult bowel perforation is suspected.

Complications

Local and Systemic

Local wound complications, including infection, hematoma, and dehiscence, have occurred in only 0.3% of patients in 2 large series. [51] [86] [87] Dehiscence with evisceration is likely an even more rare condition. [88] Systemic infection has been described rarely (Table 44-8).

Intraperitoneal

Iatrogenic intraperitoneal injury can be inflicted by the trocar, wire, and, rarely, the catheter. Virtually any structure in the peritoneal cavity can be breached, including the small and large bowel, the bladder, and major vessels. Typically, if the needle is the culprit, and even if the trocar is responsible, injury to these structures is minimal and self-limiting, and observation of the patient is sufficient.

Technical Failure

Inability to recover peritoneal aspirate or lavage fluid can result in a false-negative interpretation. This can occur in several circumstances. It follows unwitting placement of the catheter into the preperitoneal space, which is less likely to occur with either open technique. Compartmentalization of fluid by adhesions or obstructing omentum can impede egress of fluid. When a fully open supraumbilical or suprauterine technique is used, the catheter may be too short to access the depths of the intraperitoneal cavity. Finally, large diaphragmatic tears typical of blunt pathophysiology allow flow of lavage fluid from the intraperitoneal to the thoracic cavity. Saunders and colleagues compared percutaneous DPL versus the open technique in a prospective randomized trial. [89] Fluid obtained by the two techniques had similar test performance for intra-abdominal pathology. The open technique took on average more than 4 minutes longer to perform, but the percutaneous approach had an 11.2% (versus 3.8% with the open approach) technical failure rate.

False-positive findings can occur in two ways. First, iatrogenic misadventure can be responsible. Second, in penetrating trauma, particularly stab wounds, bleeding from the abdominal wall injury site into the peritoneal cavity can lead to positive findings when no injury to intraperitoneal structures has occurred. [52]

Interpretation

Gross Blood

The recovery of =10 mL blood via aspiration is considered a positive finding. Lesser-volume aspirates are generally discarded and are not factored into lavage analysis. Grossly bloody aspirates are typically indicative of solid visceral or vascular injury, with a positive predictive value >90%. [86] [90] Aspiration of blood is responsible for approximately 80% of true-positive DPL findings in blunt trauma and for 50% of those following stab wounds. [51]

A positive aspiration in the blunt trauma patient who is hemodynamically stable or has been resuscitated to apparent stability need not mandate urgent operation. Unnecessary laparotomy will occur if there has been minimal and self-limited damage to the liver, spleen, bowel serosa, or mesentery. [17] [91] In this situation, CT and clinical indicators should be used in concert with the DPL findings.

Red Blood Cell (RBC) Count

The recommended RBC threshold varies according to mechanism and, in the case of stab wounds, the external site of injury (Table 44-9). The optimum criterion will deliver excellent sensitivity, a high positive-predictive value, and, therefore, a minimum incidence of unnecessary laparotomy. Negative laparotomy incurs a prolongation of hospitalization and increases the cost of care, in addition to creating the potential for procedural complications. [92] [93] RBC counts greater than 10^5 /mm^3 (i.e., >10^5 /µL) are generally considered positive with a blunt mechanism or following stab wounds to the anterior abdomen, flank, or back. Counts of 20,000 to 100,000/mm^3 should be considered indeterminate. [51] [53] [94] [95] For stab wounds to the low chest, where the diaphragm is at increased risk of injury, the RBC criterion should be lowered to 5000/mm^3 to maximize sensitivity for isolated injury to this structure. [43] [51] [96] [97] With gunshot wounds to the abdomen or low chest, the same criterion is applied. This is intended to increase the sensitivity of the test, because intraperitoneal entry by a missile carries a likelihood of intraperitoneal injury of greater than or equal to 95%. [43] [69] [98] [99] An uncomplicated DPL should not create more than several hundred to several thousand RBCs in the peritoneal lavage fluid.

The incidence of false-positive RBC interpretation in the setting of pelvic fracture is considerable. However, aspiration of free blood in the critical pelvic fracture patient predicts active intraperitoneal hemorrhage in greater than 80% of cases. [100] A positive RBC count should generally prompt corroboration or refutation of intraperitoneal injury by CT. In this fashion, needed pelvic angiography and embolization will not be delayed unnecessarily should active intraperitoneal bleeding not be found (Fig. 44-10).

White Blood Cell (WBC) Count

An inflammatory peritoneal response occurs to a multitude of stimuli, including stool, blood, and enzymes. [101] The WBC count in lavage effluent was formerly touted to predict small

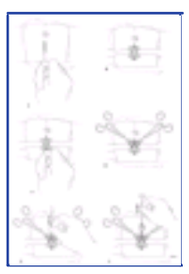

Figure 44-6 *A,* After bladder decompression (generally by Foley catheter placement), a 4- to 6-cm long vertical infraumbilical incision is made with a No. 11 scalpel. *B,* Blunt dissection using Army-Navy retractors is carried down to the *rectus fascia*. Crossing bands of crural fibers may be seen. *C,* A 2- to 3-mm incision is made through the *rectus fascia* in the midline (*linea alba*) with a No. 15 scalpel. *D,* Towel clips grasp each side of the *rectus fascia*, which is lifted prior to insertion of the trocar and diagnostic peritoneal lavage (DPL) catheter. *E,* The trocar with DPL catheter is passed at a 45° caudad angle into the fascial opening and through the peritoneum. Note that in the fully open method, the incision in the *rectus fascia* is extended, the peritoneum is directly visualized and incised, and the catheter alone is placed into the peritoneal cavity. *F,* As soon as the peritoneum has been entered, only the catheter is gently advanced into the peritoneal cavity while the trocar is withdrawn. It is often helpful to advance the catheter with a slight twisting motion and to direct it toward either the right or left pelvic gutter.

Figure 44-7 *A,* For the closed diagnostic peritoneal lavage (DPL) method using a guide wire (Seldinger technique), the needle is inserted into the peritoneal cavity in the midline just below the umbilicus and aimed slightly caudad. *B,* The flexible guide wire is passed through the needle and into the peritoneal cavity. Ideally, the wire should be directed toward the right or left pelvic gutter. The needle is withdrawn while the wire is stabilized with the operator's free hand at all times. *C,* A stab incision is made with a No. 11 scalpel immediately below the wire to permit easier passage of the DPL catheter. *D,* The DPL catheter is directed over the wire and into the peritoneal cavity using a slight twisting motion. The wire is stabilized by the operator at all times and removed after catheter placement. The catheter should be directed toward the right or left pelvic gutter when advanced.

TABLE 44-7 -- Preferred Site of Diagnostic Peritoneal Lavage

Clinical Circumstance	Site	Method

bowel injury but has since been proven unreliable.[102] It is insensitive in the immediate postinjury period, as 3 to 5 hours are necessary before the test becomes positive (Table 44-10).[103] [104] Moreover, a positive finding is likely to be falsely so. [103] [105] Therefore, the WBC level in and of itself should not determine the need for laparotomy.

Enzymes

Alkaline phosphatase is contained in intramural small bowel as well as in hepatobiliary secretions released into the proximal intestine. Amylase is contained in the latter only. Perforation of small bowel allows access of these two markers into the peritoneal cavity, where they can be recovered by peritoneal lavage. [106] [107] [108] While levels of the two markers usually rise in tandem, lavage amylase has been shown to be a more accurate marker than lavage alkaline phosphatase (see Table 44-10). In contradistinction to the WBC count, these tests will be positive in the immediate postinjury period. However, they may not be economical if used on a mandatory rather than a selective basis. Neither is helpful in discerning the presence of pancreatic pathology.

Miscellaneous

Routine bile staining, Gram stain, and microscopy to identify vegetable fibers are rarely productive and are of untested accuracy. Deck and Porter have reported that finding urine in the lavage fluid as evidenced by a straw color and creatinine in the peritoneal fluid should suggest an intraperitoneal bladder or collecting system injury.[109]

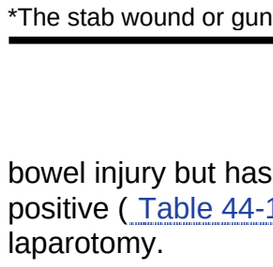

Figure 44-8 After attachment of the right angle connector and extension tubing, aspiration of the peritoneum is attempted.

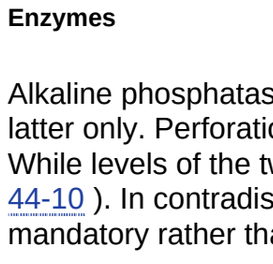

Figure 44-9 If the aspiration is negative, normal saline or Ringer's lactate solution is instilled through the catheter. *The IV tubing should have no valves in place.* After infusion, the fluid bag is placed on the floor and allowed to fill with peritoneal effluent via gravity.

Conclusion

DPL remains an invaluable diagnostic instrument in trauma. It should be used in common-sense fashion. Laboratory parameters are guidelines and should not be embraced to

PARACENTESIS

Ascites connotes an abnormal accumulation of fluid within the peritoneal cavity. The word derives from the Greek *askos,* which means bag or sack. It is a symptom with important diagnostic, therapeutic, and prognostic implications.

Therapeutic abdominal paracentesis is one of the oldest medical procedures, dating to approximately 20 BC. Paracentesis was first described in modern medical literature by Saloman at the beginning of this century, and it became a valued decompressive therapy. [111] With the advent of diuretics in the early 1950s, paracentesis fell out of favor as a treatment option. Controlled clinical trials in the late 1980s up to the present have restored its reputation by demonstrating the safety and efficacy of large-volume paracentesis in adults and children. [112] [113] [114] [115] [116] [117] [118] Because this mode is invasive and consumes clinician hours, it is generally reserved for the treatment of patients with chronic ascites who have tense ascites or whose condition is refractory to diuretic therapy. [115] [119] However, paracentesis remains an important diagnostic agent for patients with new-onset ascites or to determine the presence

of worrisome conditions, notably infection, in those with preexistent ascites. [120] [121]

Clinical Features

Determination of Ascites

Small amounts of ascites may be asymptomatic. Larger collections typically cause a sense of abdominal fullness, anorexia, early satiety, and perhaps nausea and abdominal pain. Considerable accumulations create symptoms of respiratory distress by virtue of restricting lung capacity. [122]

The most predictive history and physical findings for *excluding* the diagnosis of ascites are the absence of ankle swelling and increased abdominal girth and the inability to demonstrate bulging flanks, flank dullness, or shifting dullness. [123] [124] Positive predictors for the diagnosis are a positive fluid wave, shifting dullness, or peripheral edema. [125] [126]

Patients who lack obvious clinical markers may benefit from the performance of ultrasonography, which can discern the presence of as little as 100 mL fluid. [127] Endoscopic-guided ultrasound may discover just 10 mL. It is more sensitive than computed tomography in this respect and can assist in the identification of malignancy. [128] Additionally, it is a useful adjunct to determine the location of fluid that may be compartmentalized by preexistent infection or surgical adhesions.

Differential Diagnosis

The etiologies of ascites can be categorized in several ways. On a structural basis, these are divided into diseases of the peritoneum and diseases not involving the peritoneum. The former group includes infections, neoplasms, collagen vascular diseases, and idiopathic causes. The latter includes cirrhosis, congestive heart failure, nephrotic syndrome, protein-losing enteropathy, malnutrition, myxedema, pancreatic disease, ovarian disease, chylous effusion, Budd-Chiari syndrome, and hepatic venous occlusive disease. [121] [129] [130] Pathophysiologic categories are found in Table 44-11 . In this country, parenchymal liver pathology is overwhelmingly the most likely cause. Within this group, alcoholic liver disease is responsible for approximately 80% of cases (Table 44-12). [131] [132] Finally, ascites can be classified on the basis of a serum-ascites albumin gradient, that is, the difference between albumin values obtained simultaneously from serum and ascites samples (Table 44-13). [133]

Indications and Contraindications

Therapeutic paracentesis may be undertaken in the emergency setting to relieve the cardiorespiratory and gastrointestinal

manifestations of tense ascites.[134] [135] [136] Diagnostic paracentesis is indicated in any patient whose ascites is of new onset or to disclose the presence of infection in patients with known or suspected ascites, particularly in the context of alcohol-related cirrhotic liver disease. [137] [138] Diagnostic paracentesis is also useful in the management of the AIDS patient, in whom the etiology of ascites will be non-AIDS related in three-quarters of cases. [139]

There are few relative contraindications to abdominal paracentesis. Certain systemic and anatomic risks should be considered.

Systemic

Given the predominance of alcohol-related cirrhotic liver disease as the cause for ascites, as many as two-thirds to three-quarters of patients subjected to paracentesis will have a coagulopathy. However, the only prospective study to evaluate the complications of paracentesis determined that transfusion-requiring abdominal hematomas occurred in less than 1% of cases despite the fact that 71% of patients had an abnormal prothrombin time. [140] Because transfusion-requiring hematoma is so unlikely, even in this population, prophylactic administration of fresh frozen plasma or platelets imposes

considerable cost, in addition to the risk of post-transfusion hepatitis, with little net gain. [141] These data countermand older and conservative recommendations to administer platelets to patients with levels less than 50,000/mm^3 (i.e., <50 × 10^9 /L), or to give fresh frozen plasma to those with a prothrombin time exceeding 20 seconds (1.5 times the therapeutic level).[142] These agents should be reserved for clinically evident fibrinolysis and disseminated intravascular coagulation.

Anatomic

Structural impediments to the safe introduction of a paracentesis needle can include the bladder, bowel, and pregnant uterus. The bladder is normally tucked into the recess of the pelvis. However, neuropathically distended bladders caused by pharmacologic agents or medical conditions should preferably be emptied by voiding or by catheterization to avoid puncture. Intestines typically float in ascitic fluid and will move safely away from a slowly advancing paracentesis needle. [142] Even if penetrated by an 18- to 22-ga needle, leakage of intestinal contents will not occur unless the intraluminal pressure is 5- to 10-fold greater than normal conditions. [143] Therefore, US guidance may be indicated in cases of suspected adhesions or bowel obstruction. In second- and third-term pregnancy, an open supraumbilical or US-assisted approach is preferred.

The abdomen should be carefully inspected for evidence of abdominal hematoma, engorged veins, or superficial infection, and these sites should be strictly avoided.

Technique

Preliminary Actions

The operator should comply with guidelines for body fluid precautions (see Chapter 71). The patient should be carefully draped and the skin thoroughly prepped in sterile fashion to prevent the iatrogenic introduction of bacteria into the abdominal wall tract or peritoneal cavity.

Site of Entry

The preferred site is approximately 2 cm below the umbilicus in the midline (Fig. 44-11). The *fasciae* of the *rectus abdominis* join to form the fibrous, thin, avascular *linea alba*. [142] Large collateral veins may occasionally be present and should be avoided, as should suspected areas of skin infection. If the patient has midline scarring, the preferred alternate site is in either lower quadrant, approximately 4 to 5 cm cephalad and medial to the anterior superior iliac spine (see Fig. 44-11). The importance of remaining lateral to the rectus sheath is to avoid the inferior epigastric artery. Patients with a large quantity of ascites can readily undergo the procedure in the supine position with the head of the bed slightly elevated. Those with lesser amounts of fluid may profit from a lateral decubitus position with introduction of the needle into the midline or dependent lower quadrant (Fig. 44-12). Some clinicians prefer to use the lateral decubitus position routinely because the bowel tends to float upward and away from the path of the needle. Rarely, patients may need to be placed in a facedown, hands-on-knees position. [140] In the patient with multiple abdominal scars or suspicion of compartmentalized abdominal fluid for any reason, US guidance is prudent. [144]

Procedure

Following sterile preparation of the skin, local anesthesia is administered at the paracentesis site. A standard 3.8 cm (1.5 in.) metal needle is sufficient in most cases.[129] An 8.9 cm (3.5 in.) spinal needle may be required in obese patients. Plastic sheath cannulas tend to kink and run the risk of being sheared off into the peritoneal cavity.[118] A steel needle can be left in the abdomen during a therapeutic tap for intervals of an hour or more without injury. A smaller-gauge needle (20- to

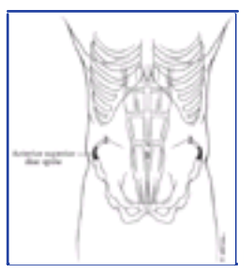

Figure 44-11 Preferred sites for paracentesis: *1,* Primary site is infraumbilical in midline through *linea alba*. *2,* Preferred alternate (lateral rectus) site is in either lower quadrant, approximately 4 to 5 cm cephalad and medial to the anterior superior iliac spine.

Figure 44-12 An alternative to the sitting or supine position for needle paracentesis is to place the patient in the lateral decubitus position. In this example the midline is aspirated, although the lateral rectus sites may also be used. Some prefer the lateral decubitus position routinely, because the bowel tends to float upward and out of the path of the needle.

22-ga) is appropriate for diagnostic taps, as these lessen the likelihood of postprocedural ascitic fluid leak through the wound site. However, large-volume therapeutic paracenteses benefit from 18-ga needles, as this permits expeditious outflow. [117] [145]

The needle can be inserted directly perpendicular at the preferred site. Certain authors prefer the "Z-tract" method wherein the skin is pulled approximately 2 cm caudad in relation to the deep abdominal wall by the non-needle-bearing hand while the paracentesis needle is being slowly inserted (Fig. 44-13).[146] The skin is not released until the needle has penetrated the peritoneum and fluid flows. When the needle is removed following the procedure, the skin will slide to its original position and help seal the tract. In any case, slow insertion of the needle in 5-mm increments is preferred. This

Figure 44-13 *A,* Z-tract method of paracentesis. The skin is pulled approximately 2 cm caudad in relation to the deep abdominal wall by the non-needle-bearing hand while the paracentesis needle is slowly being inserted directly perpendicular to the skin. *B,* After penetrating the peritoneum and obtaining fluid return, the skin is released. Note that the needle is now angulated caudally.

allows the operator to detect undesired entry of a vessel and helps prevent unnecessary puncture of small bowel. Continuous suction should be avoided as it may attract bowel or omentum to the end of the paracentesis needle with resultant occlusion. Once fluid is flowing, the needle should be stabilized to ensure a steady flow. If flow ceases, the needle should be gently rotated and advanced inward using 1- to 2-mm increments.

Complications

Complications can be divided into systemic, local, and intraperitoneal categories.

Systemic

An oft-cited but poorly documented concern is hemodynamic compromise caused by overzealous removal of ascitic fluid. Because upward of 6 L has been reportedly removed in less than 15 minutes without complication, certain authorities decry this issue as folklore. [147] [148] Others believe that rapid total paracentesis is accompanied by marked cardiovascular and humoral changes, some of which are explained by mechanical factors directly or indirectly related to relief of abdominal pressure.[149] [150] Other changes, including systemic vasodilation and humoral deactivation, are of a nonmechanical nature.

Because fluid and electrolyte shifts tend to be minimal following the removal of large amounts of fluid, [151] colloid infusion is considered strictly optional for paracentesis of more than 5 L and is not recommended for paracentesis of lesser volume. [120] [152] [153] When colloid is believed to be indicated, albumin has been the de facto choice. However, colloid dextran 70 is favored by some authorities due to cost and infection concerns. [154] [155] [156]

Local

Local complications include persistent ascitic fluid leak at the wound site, abdominal wall hematoma, and localized infection. Persistent fluid leak can be corrected with a single suture

at the site of puncture.[145] An abdominal wall hematoma requiring transfusion is very uncommon, but careful observation in such cases is necessary. [140]

Intraperitoneal

Intraperitoneal complications include perforation of vessels and viscera. [157] In experienced hands, these are uncommon, and in most circumstances they are self-sealing and clinically inconsequential. However, generalized peritonitis and abdominal wall abscess have been reported after paracentesis in rare cases. The most common cause of postparacentesis intraperitoneal hemorrhage is bleeding due to a coagulopathy, rather than large-vessel injury per se. [158]

Interpretation

Ascitic fluid should undergo gross inspection. Routine laboratory testing includes a differential cell count, albumin assay, and cultures (Table 44-14).

Inspection

Ascitic fluid is typically translucent and yellow. A dark greenish-brown hue may reflect biliary perforation. Cloudy fluid generally indicates particulate matter, including neutrophils: fluid with WBC counts greater than 5,000/µL (i.e., >5,000/mm ^{3}) are cloudy and those greater than 50,000/µL are purulent. An opaque, milky appearance may indicate elevated triglyceride levels. [159] A blood-tinged appearance requires at least 10,000/µL RBCs. This may

reflect an iatrogenic complication, malignancy, hemorrhagic pancreatitis, or tuberculous peritonitis, although the last diagnosis creates hemorrhagic-appearing fluid in less than 5% of cases. [140]

Cell Count

Several milliliters of ascitic fluid are sufficient to obtain a differential cell count. Cirrhotic ascites should generally contain less than 250 WBCs/µL (Table 44-15). However, because cells may exit through the peritoneal cavity more

TABLE 44-15 -- Ascitic Fluid Characteristics in Various Disease States

				Cell Count		
Condition	**Gross Appearance**	**Specific Gravity**	**Protein (g/dL)**	***RBCs, >10,000/µL***	***WBCs/µL (WBCs/mm^3)***	**Other Tests**
Cirrhosis	Straw-colored or bile-stained	<1.016 (95%)*	<25 (95%)	1%	<250 (90%),* predominantly mesothelial	
Neoplasm	Straw-colored, hemorrhagic, mucinous, or chylous	Variable, >1.016 (45%)	>25 (75%)	20%	>1000 (50%); variable cell types	Cytology, cell block, peritoneal biopsy
Tuberculous peritonitis	Clear, turbid, hemorrhagic, or chylous	Variable, >1.016 (50%)	>25 (50%)	7%	>1000 (70%); usually >70% lymphocytes	Peritoneal biopsy, stain and culture for acid-fast bacilli
Pyogenic peritonitis	Turbid or purulent	If purulent, >1.016	If purulent, >2.5	Unusual	>250; mainly polymorphonuclear leukocytes	Positive Gram stain, culture

*Since the conditions of examining fluid and selecting patients were not identical in each series, the percentage figures (in parentheses) should be taken as an indication of the order of magnitude rather than as the precise incidence of any abnormal finding.

slowly than fluid does, the WBC count can rise in the ascitic fluid during the procedure. [160] Thus, an upper limit for uncomplicated cirrhotic ascites is reported as 500 cells/µL.[161] [162] [163] Lymphocytes should predominate, and clinical signs or symptoms of peritoneal infection should be absent. [164] In cases in which spontaneous bacterial peritonitis is a clinical consideration, the WBC criterion is 250 WBCs/µL with greater than 50% polymorphonuclear leukocytes. [134] [137] [138] [164] [165]

Albumin

A serum-ascites albumin gradient can be obtained by simultaneous measurement of ascitic and serum-ascites albumin gradient. A serum-ascites albumin gradient greater than 1.1 g/dL indicates portal hypertension with greater than 95% accuracy (see Table 44-13). [166] [167] [168]

Culture and Gram Stain

The most valuable method for determining the presence of infection is culture. The sensitivity of this test is markedly increased by the direct inoculation of blood culture bottles at the bedside in contrast to simply delivering the ascitic fluid to the laboratory. [146] [169] Approximately 10 bacteria/µL of fluid is required for a positive Gram stain. Thus, the Gram stain is notoriously insensitive in spontaneous bacterial peritonitis in which the medium concentration of bacteria is 10^{-3} organisms/µL of fluid.[169] The Gram stain can only be expected to be helpful in cases of free gut perforation.

Miscellaneous

Optional tests include measurement of total protein, glucose, lactate dehydrogenase, and amylase. These will be beneficial in selected circumstances and need not be obtained on a routine basis. Immunosuppressed patients, including those with AIDS, should undergo microbiologic testing for opportunistic infections, including tuberculosis.[139] Cytologic analysis is recommended in patients with suspicious constitutional symptoms and signs. [170] [171] Triglyceride and bilirubin studies are indicated if the gross appearance of the fluid is suggestive of increased levels. [172]

Conclusion

Abdominal paracentesis is a straightforward, commonly used procedure in the ED, with few relative contraindications. The imperative of paracentesis is to disclose the presence of infection in the peritoneal cavity. It is also useful in the diagnosis of other conditions and contributes to the relief of manifestations of tense ascites.

Acknowledgments

Chapter 45 - Abdominal Hernia Reduction

David E. Manthey

When faced with a possible hernia, the emergency clinician must consider three issues: (1) Is the mass truly a hernia? (2) Is the hernia reducible or incarcerated? (3) Is the vascular supply to the bowel strangulated? An easily reducible hernia can be safely discharged for outpatient follow-up and repair while an incarcerated and/or strangulated hernia is a surgical urgency. Some seemingly incarcerated hernias can be reduced by persistent manipulation in the ED. The emergency clinician must differentiate among these entities.

Although there are many types of hernias, this chapter will address only those hernias amenable to reduction in the emergency department (ED). Groin hernias may be divided into inguinal and femoral. The inguinal hernias include direct, indirect, and pantaloon hernias. Abdominal wall (ventral) hernias include incisional, umbilical, epigastric, and spigelian hernias.

BACKGROUND

A hernia is defined as the protrusion of any viscus from its normal cavity through an abnormal opening. Approximately 5% of the male population and 2% of the female population develop hernias. [21] [24] Approximately 75% of all hernias occur in the groin and two thirds of these are indirect hernias. In fact, 90% of all cases in children and young adults are indirect inguinal hernias. [18] As the age of the patient increases, so does the incidence of acquired (direct) hernias. [17] Incisional and ventral hernias account for approximately 10% of all hernias. Hernias can develop along a congenital tract that fails to close (indirect inguinal hernia) or along a weakness in a muscular and fascial wall (direct inguinal hernia). This weakness may be due to aging and the accompanying loss of tissue elasticity, increased intra-abdominal pressure, or trauma to the wall itself. An abdominal wall hernia is defined as a protuberance of intra-abdominal contents through an abnormal opening in the wall.

CLASSIFICATION OF ABDOMINAL HERNIAS

A *reducible hernia* is one whose contents can be returned through the fascial defect back into the abdominal cavity.

An *incarcerated hernia* is one whose contents are not reducible back into the abdominal cavity. An associated swelling of the hernia sac contents may result.

A *strangulated hernia* is an incarcerated hernia whose blood supply to the herniated structures is compromised. Hernias with a small neck are more likely to strangulate. A strangulated hernia is a surgical emergency since gangrene will result if the vascular compromise is not relieved.

INGUINAL HERNIAS

Anatomy of the Inguinal Triangle

The inguinal (or Hesselbach's) triangle is formed by the inguinal ligament (on the inferior side), the inferior epigastric artery (on the supero-lateral side), and the lateral edge of the rectus abdominis muscle (on the medial side). There are two types of inguinal hernias (direct and indirect), both of which occur superior to the inguinal ligament. Femoral hernias are located inferior to the inguinal ligament.

Indirect Inguinal Hernia

When the hernia passes through the internal (deep) inguinal ring and into the inguinal canal, it is known as an indirect inguinal hernia (Fig. 45-1). It lies lateral to the inferior epigastric vessels. During fetal development the processus vaginalis allows for the descent of the testes into the scrotum. The processus vaginalis generally begins to close off shortly before birth. If it fails to be obliterated completely, a hernia or hydrocele may develop.

The indirect inguinal hernia is the most common hernia overall. Although there is a male to female ratio of 9:1, it is still the most frequently occurring hernia for either sex. It occurs more commonly in children and young adults. Approximately 3% to 5% of full-term infants and up to 30% of preterm infants will have an inguinal hernia.[11] [12] Of these, 80% to 90% occur in males. Incarceration occurs more commonly in the first 6 months of life, with an overall rate of 12%. [10] [22] Inguinal hernias that are successfully reduced should be considered for surgical repair within 24 to 48 hours. [2] [10] [14]

Direct Inguinal Hernia

A direct inguinal hernia is one that comes directly through the muscular and fascial wall of the abdomen. It is located within Hesselbach's triangle and therefore medial to the inferior epigastric vessels (Fig. 45-2). It can be differentiated from the indirect inguinal hernia because it does not travel along the inguinal canal.

The direct inguinal hernia is the second most common groin hernia. It is an acquired hernia and occurs later in life

Figure 45-1 Indirect inguinal hernia.

Figure 45-2 Direct inguinal hernia.

secondary to weakening of the fascial and muscular wall from aging and the repetitive stress of increased abdominal pressure. This hernia carries a minimal risk of incarceration because the neck of the hernial orifice is wide.

Pantaloon Hernia

The pantaloon hernia is a combination of a direct and indirect hernia, which resemble the two legs of a pair of pants. This hernia is difficult to diagnose in the ED and is often discovered during surgical exploration. Successful treatment depends upon correctly identifying the hernia followed by reduction of each hernia separately.

Femoral Hernia

A femoral hernia occurs inferior to the inguinal ligament through a defect in the transversalis fascia. The contents protrude into the potential space in the femoral canal located

Figure 45-3 Femoral hernia.

medial to the femoral vein and lateral to the lacunar ligament (Fig. 45-3). Due to the small fascial defect and constriction by the inguinal ligament, this hernia frequently becomes incarcerated. The femoral hernia is relatively rare, and occurs more commonly in women than in men.

Pelvic Floor Hernias

A pelvic floor hernia occurs in the peri-rectal area as a result of acquired weakness in the pelvic muscular sling. This hernia is noted to occur in approximately 3 to 6% of pelvic exenterations.[1] [19]

Ventral Hernia

A ventral hernia may be an incisional, umbilical, epigastric or a Spigelian hernia (Fig. 45-4). The ventral hernia occurs due to weakening of the diastases of the anterior abdominal wall.

Incisional Hernia

An incisional hernia commonly follows abdominal surgery in an area of postincisional weakness in the abdominal wall (see Fig. 45-4*A*). Poor wound healing (owing to

infection, for example) increases the likelihood of forming this type of hernia. An incisional hernia occurs in 2% to 10% of all abdominal surgeries and carries recurrence rates of 20% to 45%. As the lines of tension pull this hernia open, the size of the defect is usually sufficient to prevent incarceration.

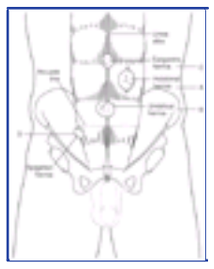

Figure 45-4 Ventral hernias. *A,* Incisional hernia. *B,* Umbilical hernia. *C,* Epigastric hernia. *D,* Spigelian hernia.

Umbilical Hernia

An umbilical hernia traverses the fibromuscular ring of the umbilicus (see Fig. 45-4*B*). This hernia is found commonly in infants, is congenital in origin, and usually resolves without treatment by age 2 years. If it persists beyond this age, is larger than 2 cm, or becomes incarcerated or strangulated, it may be repaired surgically. An acquired umbilical hernia may also be seen in an adult, particularly with increased abdominal pressure (such as in obesity, ascites, or pregnancy). An umbilical hernia is more prone to incarceration and strangulation in an adult than in a child.

Epigastric Hernia

This hernia occurs in the midline through the linea alba of the rectus sheath (see Fig. 45-4*C*). It is usually located in the epigastric region between the xiphoid and the umbilicus. Although previously considered rare in infants, one study found epigastric hernias in 4% of all pediatric patients seen for hernias. [6]

Spigelian Hernia

The Spigelian hernia is rare and courses through a defect at the lateral edge of the rectus muscle at the semilunar line (see Fig. 45-4*D*).

PATIENT PRESENTATION

An asymptomatic hernia may present as a mass that is found incidentally on physical exam. It requires no procedural intervention in the ED. A patient with a symptomatic hernia may describe swelling and/or pain. Many hernias, especially femoral hernias, present with abdominal pain. [25] The patient may report a history of heavy lifting. The clinician should inquire about signs of infection such as fever, chills, and malaise; and signs of bowel obstruction including nausea and vomiting. The patient's history should include a record of previous surgeries and hernia repairs (including the use of synthetic material).

The inguinal canal may be palpated in males by inverting the scrotal skin and passing a finger into the external ring. The Valsalva maneuver or coughing increases intraabdominal pressure and facilitates the detection of a hernia. The palpation of the external ring is more difficult in females because it is narrower.

An indirect inguinal hernia presents as a swelling in the area of the inguinal ligament or as a scrotal swelling. It is often painless and may be noted as an incidental finding. On examination, this hernia can be differentiated from a direct hernia in two distinct ways. First, it starts laterally to the inferior epigastric arteries. Second, on palpation of the inguinal canal, the contents of the hernia will strike the tip of the finger instead of the pad. This occurs as the hernia protrudes down the canal to meet the finger instead of across a fascial and muscular defect. This effect can be accentuated by applying pressure over the internal ring after hernia reduction. Bulging will reoccur with straining if the hernia is direct, but the pressure over the internal ring should block distention of the hernia into the inguinal canal. Similarly, a hernia that fills the scrotum is most likely an indirect hernia. The peritoneal contents may become incarcerated owing to swelling of the internal or external ring.

A child with an inguinal hernia may have a reducible inguinal or scrotal mass that occurs with straining or crying. A child may present with symptoms of vomiting, poor eating, lethargy, or irritability. The clinician must always consider incarcerated or strangulated hernias in the differential of such vague complaints.

Incarcerated Versus Strangulated

When one cannot reduce the contents of the hernia back into the abdominal cavity, the hernia is described as incarcerated. A patient with an incarcerated hernia usually presents with a mass that is now painful, discolored, enlarged, and no longer reducible. Associated symptoms may include nausea, vomiting, fever, scrotal pain, labial pain, and abdominal distention. Patients with incarcerated hernias do not necessarily have a bowel obstruction and those with a bowel obstruction are not necessarily incarcerated. A hernia may become incarcerated due to a small fascial defect. Constriction of the fascial defect by outside musculature or swelling of the defect or of the hernia contents may also lead to incarceration. Incarceration usually occurs with femoral hernias, small indirect inguinal hernias, or abdominal wall hernias.[3]

A strangulated hernia is one in which the vascular supply to the hernia is compromised, causing ischemia of the contents. Erythema, significant tenderness to palpation, purple or bluish discoloration, abdominal tenderness or peritoneal signs, or extra-luminal air (on x-ray) suggest ischemic injury to the bowel. [3] The patient may present with bowel obstruction, peritonitis, perforation, abscess, or even shock. A leukocytosis with a left shift is common but may be absent in the elderly.

It has long been suggested that strangulated hernias cannot be reduced. However, in rare instances, the hernia may inadvertently be reduced en masse to a pre-peritoneal location (Fig. 45-5), making the hernia sac and contents no longer palpable. [15] [16] [23] In this case, the hernia has not been reduced into the peritoneal cavity and the incarceration/ischemia has not been relieved. Because the clinician believes the hernia has been appropriately reduced, this can result in delay in the diagnosis of ischemic bowel. Fortunately, this is rare and occurs in less than 1% of hernias. [4]

Differential Diagnosis

The differential diagnosis for a groin mass is large. Table 45-1 lists a number of disease processes that may masquerade as a hernia.

Testicular torsion can be mistaken for a hernia, especially if there is an associated reactive hydrocele. The clinician must examine the testicle for tenderness, swelling, lie, and cremasteric reflex. If there is concern for a testicular torsion, urology should be notified immediately while simultaneous diagnostic studies are undertaken.

A hydrocele can be confused with a hernia because both can occupy the same anatomical space (Fig. 45-6). A hydrocele may transilluminate whereas a hernia generally does not.[21] Differentiation may be difficult and may require ultrasound to define the contents of the scrotum.

A retracted testis may be diagnosed by its absence in the scrotal sac. However, a mass felt in the inguinal canal may be mistaken for the testicle when it is actually a hernia.

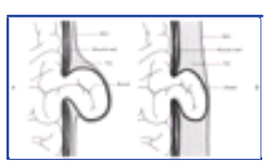

Figure 45-5 En masse reduction. *A,* When a hernia forms, it projects from the fascia into the subcutaneous fat. The object of reduction is to replace the hernia into the peritoneal cavity. *B,* If the hernia sac is partially reduced into the subcutaneous fat of an obese patient, it may appear reduced and may not be palpable owing to the patient's body habitus. However, the hernia is still susceptible to incarceration or ischemia, as it has not been returned to the peritoneal sac.

Disease processes remote to the inguinal canal can also cause a groin mass. There are reports of blood from a ruptured spleen [20] as well as appendicitis[5] presenting as a mass.

ABDOMINAL HERNIA REDUCTION

Indications and Contraindications

The indications for attempting to reduce a hernia are the presence of a hernia and the absence of strangulation. In some clinical practices, the surgeons prefer consultation before an attempt at reduction by the emergency clinician. Because many patients require sedation, it is ideal if the patient is sedated only once. This may be facilitated by discussing the

TABLE 45-1 -- Differential Diagnosis of Groin Masses

Hernia

Hematoma
Lipoma
Epidermal inclusion cyst
Tumor
Appendicitis
Tracking of intraperitoneal blood

treatment plan with the consultant prior to reduction. The emergency clinician should not make repetitive attempts at reducing the hernia as this may cause increased swelling and limit the chances of a non-operative reduction by the surgeon.

Figure 45-6 Hydrocele versus hernia. *A,* normal anatomy; *B,* noncommunicating hydrocele that may be confused with hernia; *C,* indirect hernia that can be palpated from inguinal ring to testicle.

Reduction of a strangulated hernia in the ED is contraindicated. In the case of a strangulated hernia, operative management is required. The presence of a bowel obstruction is a controversial contraindication for reduction in children younger than 2 years. [7]

The presence of a fever or an elevated white blood cell (WBC) count is a contraindication to reduction of a hernia; however, the absence of a fever or increased WBC count does not rule out the presence of ischemic bowel. [13]

When an undescended testis or ovary is trapped within an incarcerated hernia, it should be reduced surgically. Traumatic hernias also require surgical repair to allow for evaluation of the underlying organs.

PROCEDURE AND TECHNIQUE

An increase in intra-abdominal pressure will work in direct opposition to reducing a hernia. To limit this the patient should be positioned appropriately and steps should be taken to minimize patient discomfort. This in turn will decrease muscle guarding. The patient should be placed in a position so that gravity can work to pull the contents of the hernia sac back into the peritoneal cavity. For inguinal hernias, place the patient in the Trendelenburg position. For abdominal hernias place the patient in the supine position. Often, just leaving the patient in this position for 10 minutes will allow the hernia to reduce itself. In order to minimize tensing of the abdominal muscles, care must be taken not to hurt, tickle, startle, or chill the patient. To this end, using a slow approach with soft, ongoing dialogue and warm hands goes a long way.

Because swelling of the contents of the sac makes it more difficult to reduce, placing cool compresses on the hernia may help by producing vasoconstriction and by reducing the

Figure 45-7 Ballooning of contents. *A,* When reducing a hernia, the contents may ride up over the edge of the fascial defect. This leads to ballooning of the contents around the neck of the hernia, which hinders the reduction. *B,* By placing fingers along the edge of the hernia neck, one can direct the contents into instead of over the fascial defect.

volume of intraluminal bowel gas, thus decreasing the hernia sac swelling. Be sure to wrap the ice or ice water in a towel to prevent cold injury to the overlying skin. This should be done while the patient is positioned and preparations are being made to sedate the patient.

The patient should be relaxed and the pain of the procedure minimized. This can be accomplished by using sedation and analgesia before attempting reduction, not following a failed attempt. Although this author uses versed and fentanyl, other alternatives exist including etomidate and propofol. The techniques of analgesia and sedation are discussed in Chapter 34 .

To understand how to reduce a hernia, one must first consider its "parts." A hernia consists of a defect in the existing tissue (muscle and fascia) through which the visceral contents protrude. This defect makes up the neck of the hernia sac and it can be small or large. If it is small, the hernia will have a higher incidence of incarceration and strangulation. When attempting to reduce the hernia, care must be taken not to override the edge of the hernia orifice, since this will cause "ballooning" of the contents of the hernia sack around the hernia neck (Fig. 45-7). To prevent this, the examiner should attempt to find the edge of the hernia defect and position a hand or fingers opposite the reducing hand. After this preparation, the clinician may attempt to gently guide the hernia contents and sac back through the neck of the hernia. If the content of the hernia is small, gentle steady pressure will be all that is required. If the content of the hernia is large, a different approach may be needed. In this case gently guide the most proximal aspect of the hernia back through the neck. Reduce the hernia contents in the opposite order from which they protruded. Forcing the distal end of the hernia sac through the hernia opening causes the rest of the proximal contents to be displaced around the opening. This will

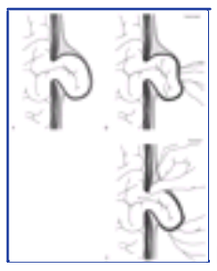

Figure 45-8 Guiding hernia into place. A, The hernia can be divided into several sections. The proximal portion is closest to the neck or fascial defect, through which the hernia protrudes. The distal portion is farthest from the neck. B, When attempting to reduce the hernia, be careful not to invaginate the distal portion first or the proximal portion may obstruct the opening as it is pushed over the sides. C, The last portion of the bowel that exits into the hernia sac should be the first returned to the peritoneal cavity.

obstruct the reduction of the more distal tissue. Gentle steady pressure on the tissue at the neck of the hernia (while preventing ballooning of the tissue over the edge of the hernia) will gradually reduce the hernia (Fig. 45-8 and Fig. 45-9).

With children, positioning is one of the most important aspects in the reduction of the inguinal hernia. For an inguinal hernia, the patient should be placed in a Trendelenburg position at about 20°. If spontaneous reduction does not occur, then manual reduction should be attempted. Spontaneous reduction has been reported in up to 80% of children with inguinal hernias over a 2-hour period without manipulation.

Secondly, place the patient in the "unilateral frog leg" position as described by Fraser (Fig. 45-10). [8] Stabilize the patient by grasping the anterior superior iliac spines to prevent lateral movement of the pelvis. Abduct the ipsilateral leg, externally rotate and flex the hip to obtain the classic "frog leg" position. The purpose of this position is to allow both the internal and external rings the greatest re-approximation. After achieving this position, use the fingers of one hand to prevent the hernia contents from overriding the external ring while the other hand provides steady but gentle pressure to the contents of the hernia sac. Repeated forceful attempts are not recommended.

COMPLICATIONS

Three major complications may occur during the reduction of hernias. The first is due to overzealous attempts at reduction by the clinician, thus causing injury to the underlying bowel. This may aggravate the swelling and make the hernia irreducible. Appropriate patient preparation, positioning,

Figure 45-9 *A,* This patient presented with signs and symptoms of a bowel obstruction. It was not until the surgery consultant removed the patient's pants that an inguinal hernia was found to be the cause of the obstruction. *B,* After intravenous analgesia/sedation, the inguinal ring is stabilized with the left hand. *C,* Slow gentle, yet persistent pressure is applied to reduce the hernia. It required 5 minutes. The hernia was reduced. Although this was a reducible hernia, because of the bowel obstruction this patient should be admitted to the hospital for observation and next day surgery.

sedation, and careful reduction can reduce the risk of this complication. The second and third major complications occur following reduction of ischemic bowel. Complications may occur when the clinician ignores or does not search for

Figure 45-10 Frog leg technique.

clues of ischemic tissue and inadvertently reduces ischemic bowel back into the peritoneal cavity. Finally, complications may occur when the tissue is reduced en masse into the pre-peritoneal position as described earlier.

CONCLUSION

The clinician must make sure that all the factors which aid in reduction are adequately in place before attempting the procedure. This includes positioning, sedation and pain control, and proper technique. Haphazard attempts may work in easily reducible hernias, but they seldom do more than cause pain and swelling in more difficult cases.

Acknowledgment

Chapter 46 - Anorectal Procedures

Christopher M. Strear
Wendy C. Coates

Patients with anorectal disorders frequently present to the emergency department (ED). In some cases, the condition is isolated, while in others, the anorectal complaint can be an outward manifestation of a more serious illness. A thorough history and physical examination must precede any procedure. Because of the nature of these complaints, extreme sensitivity and professionalism must be used during the care of the patients.

Patients may be quite anxious about an anorectal exam or associated procedure. Although sedation is rarely needed for a simple digital rectal exam (DRE), other anorectal procedures may be difficult, if not impossible, to perform without sedation, analgesia or both. Therefore, *the emergency clinician should consider the liberal use of analgesia and sedation with these anorectal procedures*. The use of a topical anesthetic on the anoscope is an effective lubricant, but provides inadequate analgesia in a patient with severe pain or anxiety. The use of parenteral analgesia and sedation is outlined in detail in Chapter 34 .

ANATOMY

The rectum and anus comprise the most distal portion of the gastrointestinal tract. The rectum is bounded by the sigmoid colon at the level of the third sacral vertebra and extends distally 12 to 15 cm. Here it joins the anal canal, which is the terminal 4 cm of the lower intestinal tract. Sensory innervation to the rectum is primarily visceral, while innervation to the anus is via cutaneous fibers. Therefore, patients are often unaware of rectal pathology since the pain associated with it is often vague or absent. By contrast, anal lesions are usually very painful and well localized by the patient. The dentate or pectinate line marks the transition from the anus to the rectum. At the line is a series of anal crypts where the openings of the submucosal anal glands lie. Infections of the anal glands are the likely etiology of many anorectal abscesses. The blood supply to the anorectum consists of superior, middle, and inferior hemorrhoidal arteries and veins. The venous system is formed by a series of plexi that are susceptible to overdistention and thrombosis [3] [18] [25] (Fig. 46-1).

DIGITAL RECTAL EXAMINATION

Indications and contraindications

The physical examination should take place in a private location and care should be taken to assure that the patient is completely draped and relaxed. Generally, a calm atmosphere and caring examiner should be sufficient. In some cases, analgesic or anxiolytic agents may be needed to facilitate a thorough examination. Some conditions, such as thrombosed or gangrenous hemorrhoids, produce so much pain that the examination may need to be postponed until the patient is anesthetized. A suspected sharp edged foreign body (e.g., metal blade or broken glass) warrants a preprocedure radiograph. If confirmed, the DRE should be deferred in favor of anoscopy or sigmoidoscopy under anesthesia.

Procedures

The patient is placed in the lateral decubitus position and the examiner's gloved finger is lubricated. Visual inspection of the perianal area may give important information regarding patient hygiene, trauma, or sexually transmitted diseases. The finger is placed firmly against the anal sphincter and the patient is asked to bear down. Prolapsing of hemorrhoids or rectal mucosa may be noted. The gloved finger is then inserted into the anus and a 360-degree sweep is performed to identify any irregularities. A prostate exam may be performed at the same time, if needed. After removing the finger from the anus, adherent stool or residual lubricating jelly can be applied to a stool guaiac card to examine for the presence of occult blood. [5]

Complications

Although DRE has been reported to cause a vasovagal response or cardiac dysrhythmias such as ventricular fibrillation, these complications are rare and do not negate the need for this examination.[23]

ANOSCOPY

Indications and Contraindications

Anoscopy may be used as an adjunct to the DRE when evaluating a patient for anal pathology. [25] Internal hemorrhoids, tears in the distal rectal mucosa, foreign bodies (FBs), and distal anorectal masses may be visualized. Imperforate anus is the only absolute contraindication to anoscopy; however, rectal pain, a common presenting complaint in the ED, may preclude awake anoscopic examination in the anxious patient.

Equipment and Setup

The anoscope is a clear plastic or stainless steel tube with a removable obturator inside. It may have an integrated light source or require an external light or head lamp. In addition, lubricant, an appropriate examination table, topical anesthetics, and gauze with forceps may be required (Fig. 46-2*A, B* and Fig. 46-3*A, B*).

Positioning

Ideally, the patient should be placed on a proctoscopic examination table or supine in the knee-chest position. The prone or lateral decubitus position with knees and hips flexed may also be adequate, and is sometimes better tolerated by the patient. In the decubitus position, the patient should be placed on the left side if the examiner is right-handed (Fig. 46-4).

Procedure

Although most patients do not require intravenous sedation and analgesia, these agents can be administered as needed to keep the patient relaxed and comfortable. A topical anesthetic

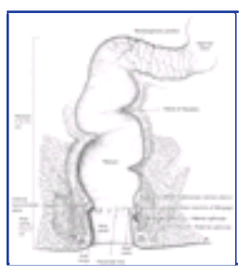

Figure 46-1 Anatomy of the terminal gastrointestinal tract. *(Redrawn from Abrahams PH, Webb PJ: Clinical Anatomy of Practical Procedures. London, Pitman, 1975.)*

such as 2% lidocaine jelly can be applied for painful conditions such as thrombosed hemorrhoids or anal fissures. Topical agents should be applied at least 10 minutes before anoscopy for optimal effect, although complete relief of pain should not be expected. Topical EMLA cream may serve as an alternative to lidocaine. Patients who do not tolerate anoscopy because of pain, or whose conditions are not limited to the anus, may be referred to a specialist for a more thorough examination (e.g., sigmoidoscopy, colonoscopy, examination under anesthesia).

Prior to anoscopy, a routine DRE should be performed to check for bleeding, identify a mass, or help localize pain. The axis of the anal canal should also be noted to properly direct the anoscope. After the DRE, the anoscope is introduced with the obturator inserted completely into the anoscope. The examiner gently advances the instrument while the patient bears down slightly. Gentle, constant pressure will overcome resistance from involuntary contraction of the external anal sphincter, as tonic contraction is exhausted after 2 minutes. The anoscope is passed gently into the anorectum while the examiner's thumb maintains the obturator in place. If the obturator falls back during insertion, the examiner must remove the anoscope completely and then replace the obturator. This will avoid pinching the anal mucosa. The instrument should be inserted until the outer flange impinges on the anal verge (Fig. 46-5).

Once the anoscope is fully inserted, the obturator is removed. The anal canal is then visualized as the anoscope is gradually withdrawn. Blood or debris can be swabbed to aid visualization, and discharge can be cultured. The anoscope should be withdrawn slowly as the entire circumference of mucosa is inspected. Near the last stage of withdrawal, reflex

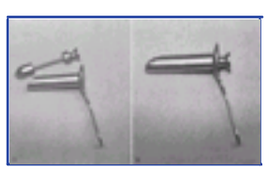

Figure 46-2 Stainless steel anoscope. *A,* Anoscope with obturator. *B,* Anoscope prepared for insertion.

spasm of the anal sphincters may cause the anoscope to be expelled quickly. Firm counterpressure may prevent such rapid expulsion, although it is not uncommon to need to repeat the procedure to obtain an adequate view of the anal verge.

Figure 46-3 Anoscope with integrated light source. *A,* Scope with obturator in place for insertion. *B,* Scope attached to light source, also with obturator in place. Generally the scope is inserted before attaching it to the light source.

Complications

Anoscopy is a safe procedure and complications are rare. Local mucosal irritation with subsequent bleeding is the most common complication. Transmission of infectious diseases

Figure 46-4 Positions for performing sigmoidoscopy or anoscopy. *(From Hill GJ II: Outpatient Surgery, 3rd ed. Philadelphia, WB Saunders, 1988.)*

is possible. Therefore, instruments must be disposed of or sterilized after each use.

MANAGEMENT OF HEMORRHOIDS

Hemorrhoids are a common affliction and have been described and treated for more than 4000 years. [18] Thrombosed hemorrhoids may have been responsible for Napoleon's defeat at Waterloo. [33] The refined, low-fiber diet

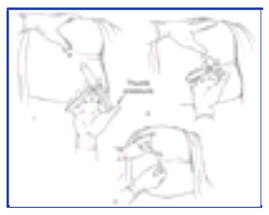

Figure 46-5 Anoscopy. Initially, with the thumb used to keep the obturator fully inserted during passage of the instruments, the anoscope is directed toward the umbilicus, and the obturator is not withdrawn until the scope has been passed to the hilt. Detailed examination is performed on withdrawal of the instrument. A penlight is used in this illustration for illumination of the deep anus.

of Western nations makes hemorrhoids extremely common in the United States [25] where 1 in 25 to 30 individuals are afflicted. [7] An estimated one third of these people, or 1 million patients annually, [2] have sought medical attention for their condition. [18] Many of these visits are to the ED.

The composition of hemorrhoidal tissue is thought to consist of vascular, mucosal, and muscular tissues. Although frequently attributed to varicosities, it is likely that all three elements comprise the hemorrhoid. [31] There are two types of hemorrhoids: internal and external. [18] [19] Internal hemorrhoids

originate above the dentate line. [3] [25] They are covered with mucosa and lack sensory innervation. [19] Internal hemorrhoidal prolapse is painless, [19] [25] and acutely thrombosed internal hemorrhoids may only be mildly tender. [3] Gangrenous, thrombosed internal hemorrhoids, however, may be exquisitely painful.

Internal hemorrhoids can be further classified as first through fourth degree. First-degree hemorrhoids do not prolapse but can be identified on anoscopic examination. Second-degree hemorrhoids prolapse upon straining, but reduce spontaneously. Third-degree internal hemorrhoids prolapse upon straining, and can be reduced manually, whereas fourth-degree internal hemorrhoids prolapse and are irreducible. Fourth-degree hemorrhoids are prone to thrombosis (Fig. 46-6). [18]

External hemorrhoids originate below the dentate line [3] [25] and are covered with squamous epithelium. They are innervated

Figure 46-6 *A*, Anatomic location of internal and external hemorrhoids. *B*, Large thrombosed external hemorrhoid. *C*, This thrombosed external hemorrhoid spontaneously ruptured. This demonstrates the concept that a thrombosed hemorrhoid is actually a hematoma into soft tissues. *D*, Thrombosed prolapsed internal hemorrhoids. These hemorrhoids cannot be reduced and are quite painful. They should not be incised in the ED, a formal hemorrhoidectomy is required if conservative measures are not successful. They are often mistaken for a partial "rectal prolapse". *(A from Hill GJ II: Outpatient Surgery. 2nd ed. Philadelphia, WB Saunders, 1980. Reproduced by permission.)*

by the inferior rectal nerve. [18] [19] A thrombosed external hemorrhoid appears as a bluish mass covered by epidermis. [19] [25] What is commonly referred to as a thrombosed external hemorrhoid often represents an actual rupture of one of the veins of the external hemorrhoidal plexus into the surrounding tissue. This condition is more accurately termed an anal hematoma or external anal thrombosis. Acute thrombosis occurs suddenly and is usually very painful, and pain is the presenting complaint of most patients with this condition. [3] [25] Many patients will feel a tender mass and state that it hurts to sit. Significant bleeding is uncommon but may occur if spontaneous rupture occurs. [25]

Increased pressures from straining or trauma from constipation or diarrhea may exacerbate external hemorrhoids. [3] [25] Distention and trauma predispose the hemorrhoidal venous plexus to stasis with ensuing clot formation and edema. [12] [26]

Indications and Contraindications

ED management of prolapsed internal hemorrhoids is conservative [2] and includes sitz baths, stool softeners, fiber supplement, and increased fluid intake. [25] A useful mnemonic for conservative therapy is WASH: *w*ater (increase fluid intake, sitz baths in water), *a*nalgesics, *s*tool softeners, *h*igh fiber diet. [5] Referral for outpatient surgical consultation can be considered. [19] An important historical question is whether the patient "must push the hemorrhoids back in after a bowel movement." An affirmative answer suggests that the patient has symptomatic third-degree internal hemorrhoids, which would benefit from elective surgical referral. This condition can be easily demonstrated by having the patient strain before the DRE. Surgical consultation should be obtained in the ED for very distressing and painful fourth-degree hemorrhoids [25] and for profuse bleeding that is hemodynamically significant.

Without treatment, thrombosed external hemorrhoids will resolve spontaneously over 1 to 3 weeks, [19] [26] usually without complication (except for an occasional skin tag). [25] Small hemorrhoids that present acutely with minimal discomfort may be managed conservatively. [14] This includes pain medication, sitz baths, stool softeners, and a dietary fiber supplement. [3] The pain is most severe within the first 48 hours, [25] and patients presenting within this time window are most likely to benefit from excision (not incision and drainage) of their thrombosed external hemorrhoid. Patients who present after this time are usually best managed with conservative treatment. [14] [19] Bleeding disorders, serious systemic illness, or hemodynamic instability are all relative contraindications to excision in the ED.

Procedure

The patient is placed in the prone or lateral decubitus position. [25] [28] The buttocks can be taped apart to aid in visualization (Fig. 46-7). Parenteral analgesia and sedation can be given as an adjunct to local anesthesia. Local infiltration with 0.5% bupivacaine or 1% lidocaine with epinephrine at 1:100,000 [3] may be administered just under the skin, above the hemorrhoid [19] (Fig. 46-8). The overlying skin should blanch, indicating that anesthesia has been introduced at the appropriate depth. This is usually all the anesthesia that is required. A

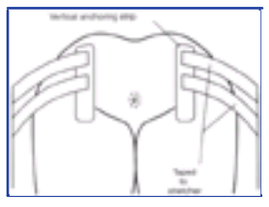

Figure 46-7 Taping the buttocks to gain exposure.

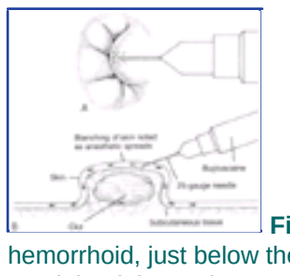

Figure 46-8 Very adequate anesthesia often can be obtained by a single injection of long-acting bupivacaine. *A,* A 25-ga needle is inserted in the middle of the swollen hemorrhoid, just below the skin surface. *B,* With the injection, the anesthetic spreads over the surface of the dome and into the surrounding tissue. A field block about the hemorrhoid can also be used, but it is much more painful, usually not required, and not advised as a first attempt at anesthesia.

field block may be necessary to anesthetize a larger area or multiple hemorrhoids but this is quite painful and rarely required. This can be accomplished by extending the injection circumferentially around the base of the hemorrhoid into the submucosal surface (Fig. 46-9).

The skin overlying the thrombosis is elevated with forceps. An elliptical incision is made around the clot and directed radially from the anal orifice (Fig. 46-10). The skin edges are then elevated with the forceps and excised to expose the underlying thrombosis. [19] The clot is removed with forceps[3] or by applying digital pressure (Fig. 46-11). Often multiple individual clots will be present. If any skin ulceration is noted over the hemorrhoid, it can be included in the excised portion. The wound is then packed loosely to prevent the skin edges from reapproximating prematurely. [3] Packing may be done with standard cotton gauze (e.g., NuGauze) or Gel-Foam.

For the trip home, a gauze pad can be placed between the buttocks and the buttocks taped together to hold it in place.

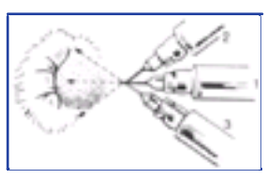

Figure 46-9 Subcutaneous injection of a long-acting local anesthetic using a field block will provide complete anesthesia during a procedure, but is rarely required.

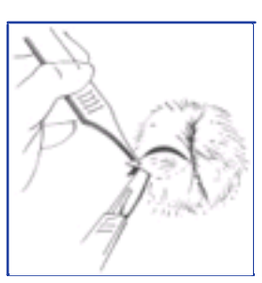

Figure 46-10 An unroofing technique uses an elliptic or triangular incision that removes a piece of the overlying skin. A simple linear incision should not be used.

The patient should be advised to avoid prolonged standing for the next few days. Sitz baths can be started as soon as the anesthetic has worn off. If the gauze has not fallen out, it can be removed by the patient after a sitz bath in 24–36 hours. Gelfoam packing avoids the need for this step, and is preferred as a packing agent. Minor bleeding can be expected, but it should be mimimal. After the packing has been removed, the patient may apply a soothing cream to the area for a few days (such as Preparation H, Anusol HC, lidocaine ointment). Routine stool softeners are unlikely to be of value for this episode, but may help prevent further episodes. Antibiotics are not indicated. Following a bowel movement the patient should avoid toilet paper for a few days and may wash the area with mild soap and water in the shower. Most patients with a straightforward case do not need a routine wound check and they should be relatively asymptomatic in 48 hours. If pain or bleeding persist, a wound check is necessary. If the clot has been removed a recurrence of this thrombosis is unlikely, but such patients are predisposed

Figure 46-11 Blood clots are removed with forceps *(A)* or expressed with the fingers *(B)*. Often multiple clots are present, and all should be removed. *C,* After the initial clot is removed, an assistant spreads the incision to expose the base of the hemorrhoid and allow other smaller clots to be removed individually with forceps or with a small hemostat.

to future episodes. Permanent skin tags may be felt after the area has healed.

Long-term therapy should be directed toward avoiding constipation by increasing dietary fiber and fluid intake. [25]

If an invasive procedure is not well-tolerated by the patient, alternate nonoperative treatments using topical nitrates [13] [19] or topical nifedipine have been proposed. [1] [26] Applied to the thrombosed hemorrhoid, these creams relax the anal sphincter, relieve pain, and promote healing. Systemic absorption is minimal and the application is usually well-tolerated.

Complications

While complications are rare, bleeding and infection do occur. [19] Bleeding is usually simple skin oozing and stops with direct pressure. [3] When a simple incision and drainage (I&D) is performed instead of an elliptical excision, or when the ellipse of skin is not completely removed, the skin edges can close prematurely and cause infection and a permanent perianal skin tag. [3] [25] [26] Premature closure can also result in an incomplete evacuation of a developing clot.

MANAGEMENT OF ANORECTAL ABSCESS AND PILONIDAL CYST/ABSCESS

These topics are covered in detail in chapter 38 .

MANAGEMENT OF RECTAL FOREIGN BODIES

The emergency clinician is often the primary care provider for patients presenting with rectal FBs. Many of these objects can be removed successfully in the ED. [34] By following some simple guidelines, outpatient treatment can be practical and cost-effective.

The etiology of rectal FBs includes autoeroticism (most common), [20] iatrogenic placement (e.g., thermometer, enema tip), assault, self-administered treatment (e.g., enema), accidental ingestion, and concealment (e.g., body packing). The myriad of objects that have been removed include vibrators, sex toy phalluses, aerosol cans, light bulbs, glass bottles, billiard balls, fruits and vegetables, and small animals. [8] [11] [20] [21] Most objects are cylindrical.

Although the early medical literature stressed inpatient treatment because of isolated complications from difficult retrievals, the most recent series show a high success rate for the outpatient management of rectal FBs, if proper guidelines for evaluation and treatment are followed. [20] [34]

Diagnosis of a rectal FB can usually be made from the history. The physical examination should, therefore, concentrate on excluding anorectal or intestinal perforation and determining which objects will be accessible in the ED. [34] DRE will identify objects that are low-lying or palpable. These are most likely to be removed successfully in the outpatient setting. [20] [34] Plain radiographs can supplement the examination by delineating the shape, position, and number of the object(s). [11] [20] If a FB with a sharp edge is suspected from the history, the clinician is advised to forego the DRE.

Indications and Contraindications

All rectal FBs should be removed when they are diagnosed. Although some objects may pass spontaneously, delayed removal may lead to obstipation, pain, and infection, with or without perforation. An algorithm for the removal of FBs in the ED has been outlined (Fig. 46-12).

FB removal in the ED is contraindicated in patients who have severe abdominal pain or signs of perforation, a

Figure 46-12 Emergency approach to the removal of rectal foreign bodies. Foreign bodies that are fragile or are associated with rectal spasm are generally managed with regional or general anesthesia. The use of supplemental analgesic, anxiolytic, and local anesthetic medications is highly recommended.

nonpalpable FB, or broken glass in the rectum. Other situations precluding ED removal include a FB that is unusually difficult to remove (a set time limit has elapsed or the patient cannot tolerate removal), or when there is insufficient experience or equipment to perform the procedure. [34] Patients who present under these conditions require surgical consultation and admission to the hospital.

Equipment

The specific equipment required will often depend on the nature of the FB. In general, the clinician will need anesthesia and analgesia as described earlier, a speculum with a light source, and an instrument to grasp the FB. The speculum can be an anoscope, a rigid sigmoidoscope, a vaginal speculum, or a retractor (Fig. 46-13). Instruments useful for grasping the FB include ring forceps, tenaculum forceps, or obstetric forceps. In some instances, a Foley catheter or endotracheal tube will be helpful. A suction dart, [9] vacuum extractor,[20] and plaster of Paris have also been used to aid in FB retrieval. Individual situations may lead to creative use of standard medical equipment, but one must ensure safety before using a device to remove a FB.

Procedure

The technique for removal depends on the size, location, orientation, and composition of the FB. The patient can lie prone in the knee-chest position, or in a lateral decubitus position. Alternatively, the patient can be placed in the lithotomy position where pressure can be placed on the abdomen to help maneuver the FB toward the distal rectum. Parenteral analgesia is often required to relieve pain from anal stretching and manipulation. Intravenous sedation is almost always

Figure 46-13 *A,* Parks retractor (unassembled). *B,* Assembled Parks retractor. *C,* A Parks retractor inserted into the anal canal to visualize the foreign body. *(C from Sohn N, Weinstein M: Office removal of foreign bodies in the rectum. Surg Gynecol Obstet 146:209, 1978.)*

required to calm the patient and facilitate relaxation of the anal sphincter. A perianal block will also allow greater dilation of the sphincter. Local infiltration with 0.5% bupivacaine or 1% lidocaine with epinephrine at 1:100,000 may be administered circumferentially around the anus in the submucosal tissue [34] (see Fig. 46-9).

After analgesia and sedation are administered, the clinician performs a DRE to gauge the position and orientation of the FB. Suprapubic pressure from above, the examiner's finger from below, and the patient performing a Valsalva maneuver may successfully deliver the object without instrumentation. [34] The FB is often lodged against the sacrum posteriorly[20] and may require gentle redirection. This can be accomplished by cradling the posterior aspect of the object between two fingers, directing the object slightly proximally and anteriorly, and having the patient bear down gently.

If this is unsuccessful, or if the DRE reveals that the object has an accessible edge or lip, the FB can be extracted under direct visualization using an instrument. An anoscope, rigid sigmoidoscope, vaginal speculum, or retractor is first inserted into the anus as described above (see section on anoscopy). If the object is visualized clearly, a blunt instrument can be used to secure it. Gentle traction is then applied to remove the object, the instrument, and the scope or speculum as a single unit. The object must be grasped under direct visualization to avoid pinching or tearing the mucosa. [34]

Rigid sigmoidoscopes offer a unique advantage as air can be insufflated into the rectum around the FB. This technique

can be particularly helpful when retrieving glass objects. Glass rectal FBs often create a vacuum in the segment of bowel just proximal to where they lie. This makes removal with simple traction almost impossible. The vacuum can be released by distending the rectal wall around the object with air. If a sigmoidoscope cannot be used to retrieve a glass object, one or two Foley catheters or an endotracheal tube can be passed beyond the FB and the balloon or cuff inflated, respectively. This may also release any vacuum. The object can then be removed using the inflated balloons with gentle traction (Fig. 46-14). Often specific equipment is not available to remove all foreign bodies, and the clinician must improvise based on the circumstances. Something as simple as 2 large spoons or an endotrachael tube may be used in lieu of complicated forceps and clamps (Fig. 46-15 (Figure Not Available)).

Besides creating a vacuum, glass objects are especially difficult to remove because they can break and cause a tear or perforation in the rectal wall. If forceps are used for retrieval of a glass object, the grasping edge should be coated in rubber [29] or plastic, or should be padded with gauze. Plaster of

Figure 46-14 Use of Foley catheters to remove a rectal foreign body made of glass. *(From Eftaiha M, Hambrick E, Abcarian H: Principles of management of colorectal foreign bodies. Arch Surg 112:693, 1977.)*

Paris has been used to remove a hollow glass object if the object has an open end facing distally. A hollow tube (e.g., an endotracheal tube or small chest tube) is inserted into the open end. The FB is filled with plaster using a large irrigation syringe to inject plaster through the hollow tube. The plaster then cools around the tube, which can be used as a handle to remove the object using gentle traction. Care must be taken with this technique to avoid leaking plaster onto the mucosa. Additionally, heat is released as the plaster hardens, and may cause the glass to crack or shatter. After removal, sigmoidoscopy is commonly recommended to evaluate for edema and possible perforation of the mucosa. [20] [34] Patients with normal postextraction examinations and no evidence of perforation may be safely released home after a period of observation.

Observation in the ED to allow small, high-lying or non-palpable FBs to pass into the lower rectum has occasionally been successful. [34] However, this may not be a feasible use of ED resources as there is no way to gauge how much time will be required or which cases will be successful. All cases of nonpalpable rectal FBs warrant surgical consultation in the ED. Enemas or cathartics should not be used, because they may increase the impaction of a FB or cause it to move higher into the colon.

Complications

Perhaps the most common complication of this procedure is failure to remove the rectal FB. This should prompt a surgical consultation in the ED. The most serious complication of rectal FB retrieval is perforation or deep mucosal tear. Both of these require hospitalization and may necessitate surgery. Cracking or shattering of glass may also require surgical exploration and retrieval. Mild mucosal edema and rectal bleeding are common complications of prolonged rectal FB placement and of retrieval. [11] These may not require any specific treatment. However, when post-extraction sigmoidoscopy is warranted and the emergency clinician is not skilled in this procedure or when other findings are present (e.g., post-procedural abdominal pain, fever, rectal bleeding, rectal discharge), surgical consultation is recommended.

MANAGEMENT OF RECTAL PROLAPSE

Rectal prolapse is the protrusion of some or all of the layers of the rectal wall through the anal orifice. [10] Prolapse is usually not an emergency, but manual reduction is usually easily accomplished in the ED. The most common presenting complaint is protrusion of a rectal "mass" or tissue. [6] Patients may also complain of "hemorrhoids," pain on defecation, itching, incomplete evacuation, incontinence, or bloody mucosal discharge. Rectal prolapse is diagnosed by visual inspection of the anus and DRE. The differential diagnosis includes hemorrhoids, polyps, cystocele, or carcinoma. [15]

There are three types of prolapse: (1) Complete prolapse, or procidentia, involves all layers of the rectum protruding through the anal orifice (Fig. 46-16 and Fig. 46-17). (2) Incomplete, or occult prolapse, describes internal prolapse that does not reach the orifice. This type is difficult to diagnose in the ED and requires no emergency intervention. (3) Mucosal prolapse is limited to mucosal protrusion through the anal opening. [10] [15] [32]

Figure 46-15 (Figure Not Available) *A*, Large spoons grasping a fragile foreign body in the rectum. *B*, Use of an endotracheal tube to remove a smooth foreign body made of glass. An advantage of this technique and the Foley catheter technique is that air is introduced above the obstruction to overcome the vacuum created by the foreign body. *(A, From Rosen P, Baker FJ, Barkin RM, et al (eds): Emergency Medicine: Concepts and Clinical Practice. St. Louis, CV Mosby, 1988. B, From Garber H, Rubin R, Eisenstat T: Removal of a glass foreign body from the rectum. Dis Colon Rectum 24:323, 1981. Reproduced by permission.)*

Complete and partial prolapse can be distinguished from each other by digital palpation. A thick muscular layer of tissue between the examiner's thumb and forefinger suggests complete prolapse. Partial or mucosal prolapse may demonstrate radial rectal folds protruding through the rectum and rarely extends more than 3 to 4 cm from the anus.[3] [6] Complete prolapse can extend 10 to 15 cm outside the anal verge.[3] [10]

Rectal prolapse can occur in children or adults. Prolapse in children is typically incomplete or mucosal. It usually affects children younger than age 3 years, and is often associated with

Figure 46-16 *A,* Type I procidentia (rectal prolapse). *B,* Intussusception of sigmoid colon beyond the anus. *(From Kratzer GL, Demarest RJ: Office Management of Colon and Rectal Disease. Philadelphia, WB Saunders, 1985, pp 221–333.)*

cystic fibrosis, parasitic infection, chronic diarrhea, malnutrition, or as a sequelae of chronic neurological disease. Prolapse is usually self-limited and outpatient management (after manual reduction) includes correcting constipation, [3] avoiding straining, and referring for testing to exclude cystic fibrosis. [15] [17] Rectal prolapse in adults occurs most often in older women. Nursing home patients may have recurrent prolapses. The etiology is poorly understood, but is associated with chronic constipation, chronic neurological conditions, or pudendal neuropathies that weaken the anal sphincter. [10] [17] [32]

Figure 46-17 *A,* Complete (recurrent) rectal prolapse in a nursing home patient. This can be very distressful and painful, or relatively asymptomatic. *B and C,* To reduce the prolapse, an assistant spreads the buttocks and the clinician's hands encircle the prolapse. The key to success is adequate sedation/analgesia and a slow steady gentle pressure. *D,* Successful reduction.

Indications for Reduction

Rectal prolapse may be reduced in the ED. If successful, outpatient surgical referral is appropriate. Definitive surgery may be attempted but occasional prolapses in debilitated patients are usually treated conservatively. [15] (Referral for outpatient proctoscopy should be made to search for a polyp or malignancy that may have acted as a lead point.[17] If the prolapse is incarcerated, a surgical consultation should be obtained in the ED. [15]

Procedure

Reduction of a mucosal prolapse can usually be accomplished easily with a few minutes of gentle, constant pressure on the mass. [15] In children, intravenous sedation may be necessary to allow reduction. Children are often more relaxed if they are allowed to remain in the parent's lap during the procedure. After reduction, the child is sent home with a pressure dressing and stool softeners. The parents are counseled on the use of dietary fiber and increased fluid intake to prevent constipation and straining.[15] The child is then referred for outpatient follow-up as described earlier. [16] [17] [24]

Reduction of a complete prolapse is accomplished with the patient in the prone or lateral decubitus position. Parenteral sedation may be required if the patient is anxious or is having difficulty relaxing the sphincteric muscles. The buttocks can be taped apart to aid in reduction (see Fig. 46-6). Constant, gentle circumferential pressure is applied to the prolapsed area, beginning with the portion closest to the lumen (the most distal segment). The examiner's thumbs are placed on either side of the lumen while the fingers grasp the exterior walls. The thumbs then apply pressure as the walls are rolled inward to force the prolapse back through the anus. [15] A DRE should be performed gently after reduction to search for a mass that may have acted as a lead point. [6]

Complications

Complications after a successful reduction are uncommon, but may include bleeding and ulceration. Failure to reduce a prolapse is a serious complication that requires surgical consultation. A persistently prolapsed rectum can result in ulceration, strangulation, and perforation of the bowel wall. [6] Moreover, the possibility of anal sphincter tone loss and

incontinence increases with delays in reduction of rectal prolapse. [15] [17]

CONCLUSION

Prompt attention and management of anorectal complaints in the ED may reduce delay in the diagnosis and management of diseases that involve this area. A caring clinician who is sensitive to the patient's concerns will facilitate treatment. Many conditions affecting the anorectum have associated medical or surgical issues, and a cooperative approach to their management will optimize patient care.

Section VIII - Musculoskeletal Procedures

Chapter 47 - Prehospital Splinting

Thomas A. Brabson
Brett S. Greenfield

SPINE IMMOBILIZATION

Despite a lack of data to show that it improves outcomes, spinal immobilization remains one of the most frequently performed prehospital procedures. [1] [2] Recommendations for spinal immobilization date back to 1971 when the American Academy of Orthopedic Surgeons [3] published the first set of guidelines for spinal immobilization following blunt trauma. In these guidelines, the presence of signs (e.g., weakness, paralysis) or symptoms (e.g., neck pain, paresthesias) of spine injury were the primary indications for spine immobilization. [3] Since then, recommendations for spine immobilization have evolved considerably. Today, indications for spine immobilization are based primarily on mechanism of injury, regardless of the presence or absence of symptoms or physical findings suggestive of a spine injury. [2] [4] This has resulted in routine prehospital spinal immobilization in all but the most trivial injuries.

While mechanism of injury is widely accepted as an indication for prehospital spine immobilization, recent focus on evidence-based medicine has led some investigators to question this practice. [4] [5] [6] The results of several trials support the use of clinical criteria for cervical spine clearance by prehospital care providers. [4] [7] [8] [9] [10] A few studies have found that unnecessary spine immobilization may be associated with increased morbidity and cost. [2] [11] [12] While large prospective studies will be needed before prehospital spine clearance gains widespread acceptance, studies to date have prompted several emergency medical service (EMS) systems across the country to establish specific clinical criteria for prehospital spine immobilization (Table 47-1). [2] [4] [9] [10] [13]

Despite the growing controversy regarding the practice of routine prehospital spine immobilization, mechanism of injury remains the primary indication for spine immobilization in the prehospital setting. This section outlines the techniques and equipment used by most prehospital care providers in the United States. All emergency care providers should be well trained on their use, limitations, and application.

TABLE 47-1 -- Clinical Criteria for Prehospital Spine Immobilization

Mechanism of injury
Spine pain or tenderness
Focal neurologic deficit
Unreliable patient examination (not awake, alert, oriented, calm, and cooperative)
Head injury (including severe head and facial trauma)
Altered mental status:
no available history;
found in the setting of possible trauma (e.g., lying at the bottom of a staircase); or
near drowning with a history or high probability of a diving injury
Distracting injury
Communication barriers
Extremes of age

CERVICAL SPINE

Trauma patients frequently sustain injuries to the cervical spine. These injuries are particularly devastating when associated with injury to the spinal cord. In the United States approximately 10,000 to 12,000 spinal cord injuries occur each year. [1] [14] Of these, more than half are in the cervical region, and most are a result of motor vehicle crashes.[14] The remainder are due to falls, recreational activities (e.g., diving, contact sports), and penetrating trauma. Therefore, it is critically important that the unstable cervical spine be immobilized early and effectively.

Because the minimum degree of motion required to cause spinal cord injury has not been defined, the goal of immobilization is to maintain the head in a neutral position with zero degrees of motion in all directions. [15] To immobilize the entire cervical spine, an orthotic device must fix the head, hold the occiput and mandible, and restrict motion at the cervicothoracic junction.[15A] This approach follows the basic orthopedic principle of immobilizing the joint above and below a suspected injury. In addition, to be useful in the prehospital setting, a cervical immobilization device must be portable and easy to apply, and must allow access to the upper airway.

At present, the standard technique of spinal immobilization involves early manual stabilization of the head and neck relative to the long axis of the body. Manual stabilization is usually followed by the application of a cervical collar. Although its use is controversial, a cervical collar has value as an early adjunct in the sometimes complex process of immobilization and extrication. It is extremely important to remember, however, that even the best-supporting collars *do not* provide adequate immobilization when used independently. For complete cervical spine immobilization, the patient must also be secured to an intermediate spine-immobilizing device (e.g., short spine board, KED) or a full-length spine board (e.g., backboard, scoop stretcher, full body splint), or both.

Complete cervical immobilization must also incorporate lateral stabilization of the head in the form of lightweight bulky objects such as foam blocks, towel rolls, blanket rolls, or cushions and tape. This can also be accomplished using factory-made devices such as the HeadBed (Laerdal Medical Corp., Wappingers Falls, NY) or Bashaw Cervical Immobilization Device (CID) (Bashaw Medical, Inc., Pensacola, FL).

Background

Since 1965, an entire industry aimed at prehospital preservation of life and limb has evolved. Specially manufactured spinal immobilizers were developed for field use during the late 1960s and early 1970s. Numerous variations of these early devices have been developed to solve specific prehospital problems and to meet the need for lightweight, durable, adaptable, and affordable equipment. Many of the latest designs have been possible by advances in composite

technology that have produced more versatile plastics and stronger adhesives.

It should be stressed that although there is widespread agreement about the basic steps of spinal immobilization, prehospital care is a difficult setting for individuals who cannot easily adapt. Because of the variety of circumstances that confront prehospital care providers on a daily basis, flexibility is mandatory.

In 1965, Louis Kossuth was the first clinician to support the need for extrication standards, including immobilization of the cervical spine. [16] J.D. Farrington, a pioneer in the use of the spine board for cervical immobilization, is credited with thrusting the concept of prehospital spinal immobilization into the venue of conventional medicine.[17] [18] Farrington emphasized that spinal fractures were frequently mishandled and made worse by rough or hasty movement at the scene. He outlined the use of a backboard, sandbags, and tape for the prehospital extrication and care of patients with suspected spinal injuries. He fashioned extrication collars using universal dressings held in place by soft roller bandages and advocated manual traction during the extrication phase. [18]

Manual *traction* is no longer recommended, because it may aggravate an underlying spinal injury. [19] In addition, although sandbags are effective devices for lateral immobilization, they may cause significant movement of the neck if the board is suddenly tilted (e.g., to decrease the risk of aspiration in a vomiting patient). As a result, sandbags have been replaced by more ergonomic and lighter weight devices such as foam blocks, the HeadBed, or Bashaw CID. Despite these modifications, the original Farrington method of splinting the head and torso to a rigid object remains the preferred technique for effective spinal immobilization.

Indications

An extrication collar should be used as a primary adjunct in cases involving trauma to the head and neck. In the absence of visible trauma, patients should be immobilized whenever the mechanism for a potential cervical spine injury exists. The most common mechanism of injury involves sudden deceleration of an automobile, resulting in hyperflexion and hyperextension forces. Patients under the influence of alcohol or drugs lack the self-awareness to recognize their own spinal injury and should be immobilized routinely. Likewise, every unconscious trauma patient should be immobilized to avoid aggravating an underlying spinal injury. Any awake and alert trauma patient who complains of spine pain, paresthesia, weakness, or absent movement should be immobilized carefully to avoid secondary injury to the spinal cord. Also, extremes of age and the presence of communication barriers (e.g., language, hearing impairment) may impact the ability to accurately assess the patient's perception and communication of pain, and should lower one's threshold for spinal immobilization. [2] [4]

It is not uncommon to encounter patients in the field who are both conscious and oriented but unaware of their own neck injuries. The sensory impact of having one's automobile forcibly disassembled by rescue personnel who are using modern tools that produce noise in excess of 80 dB may result in considerable distraction. In addition, the presence of other painful injuries or concern over other victims can easily mask the manifestations of an occult cervical spine injury.

Serious cervical cord injuries can also occur in the absence of demonstrable fractures. Spinal cord injury is common in elderly patients with cervical spondylosis, in whom an arthritic osteophyte may sever a portion of the cord as permanently as a fracture or dislocation. In such cases, there is often little or no subjective pain, and the mechanism of injury may appear seemingly minor.[20]

Therefore, a high index of suspicion for possible spinal injury must be maintained at all times. In all cases, the medical record must include documentation of the neurologic examination before and after spinal immobilization.

The purpose of an extrication collar is to assist in splinting the head and neck either therapeutically or prophylactically in a neutral position. [15A] The collar is useful for the following reasons:

1. It provides airway protection by limiting flexion in a patient whose unsupported jaw and neck position threatens patency.
2. It helps reduce cervical spine motion, especially flexion, but also rotation, lateral bending, and extension. In this regard, however, it serves only as an adjunct.
3. If properly chosen, it can support the weight of the head while the patient is sitting and help to maintain the alignment of the cervical spine once the patient has been moved to a supine position.
4. An equally important function is to serve as a reminder to the patient and rescuers that the integrity of the basilar skull and cervical spine are suspect because of the mechanism of injury.

The cervical collar does not provide complete immobilization of the head and neck. The collar was designed as an adjunct and was never intended to provide definitive immobilization in itself. Complete immobilization is not possible until the patient is properly secured to a long backboard-type device. Nonetheless, the collar should go on first and remain in place during the entire procedure.

Contraindications

There are few circumstances that preclude the use of an extrication collar. The presence of a surgical airway (i.e., cricothyroidotomy or tracheotomy) may require modification of the cervical immobilization technique.

In addition, cervical dislocation with fixed angulation or a preexisting anatomic abnormality may prevent effective application of factory-made collars. This situation is rarely encountered and can be managed with an improvised cervical immobilizer, such as a version of a horse collar or prolonged manual positioning without traction.[21]

A third circumstance that could preclude the use of a collar is massive cervical swelling (e.g., secondary to hemorrhage or tracheal injury). In these circumstances the compressive effect of a collar may impede air exchange, decrease cerebral perfusion, or increase intracranial pressure. [22] [23] [24] Finally, the presence of an impaled foreign body such as a knife, a piece of glass, or metal can also make cervical spine immobilization using extrication collars difficult.

Note that improvised cervical support may work better than a manufactured collar, depending on the size and shape of the patient. This is particularly true in the pediatric population, as collars come in limited sizes and may not be well tolerated. In such circumstances, prolonged manual in-line

stabilization is often necessary. Again, adaptability is a trait of the well-trained and experienced prehospital provider.

Equipment

There are three types of cervical collars: cervical, head-cervical, and head-cervical-thoracic. Traditionally, cervical collars have used a four-point support structure at the bottom of the collar: namely at the two trapezius muscles posteriorly and at the two clavicles anteriorly (Fig. 47-1). Most modern collars are modified rigid head-cervical-thoracic devices that use the sternum as a fifth support structure (Fig. 47-2). Current collar designs support the head with wing-like flaps on the collar's upper posterior edges. Anteriorly, the collar supports the mandible. The collar's flaring design generally prevents compression of the thyroid cartilage and cervical vessels, even when applied firmly.

Soft collars, although comfortable, have no role in spinal immobilization, because they provide minimal support and do not reduce cervical motion to any significant degree.[25] [26] However, the semirigid collar must be comfortable to ensure patient compliance. Dick and Land described the characteristics of an "ideal collar." [27] These features included the following:

1. It should support the weight of the head in a neutral position.
2. It should prevent lateral, rotational, and anteroposterior movement of the head.
3. It should be comfortable, translucent on radiographs, and compact.
4. It should be easy to apply.
5. Its price should be such that it can be carried in sufficient numbers in various sizes by any ambulance.
6. It should not interfere with the position or function of important airway structures, nor adversely affect cerebral circulation in any way.
7. Simplicity of design should permit its application by 2 rescuers in less than 60 seconds, in darkness, rain, or cold weather, without manipulation of the head or neck.
8. It should be available in the smallest number of sizes possible.

Figure 47-1 Philadelphia collar. This is a two-piece, high-type collar that comes in four sizes. The collar supports the head in a dish-shaped contour that is formed when the front and rear halves are joined by Velcro fasteners. When properly sized for a patient, this collar provides excellent support. When applied too tightly, it tends to force the mandible backward and can cause thyroid compression in some patients. It is extremely comfortable. *(Courtesy of Philadelphia Cervical Collar Company, Westville, NJ.)*

Figure 47-2 Stifneck collar. This collar is made of high-density polyethylene (a hard material) and padded with semiflexible foam margins. Note the low-reaching anterior panel, which contacts the sternum for additional support. *(Courtesy of Laerdal Medical Corporation, Wappingers Falls, NY.)*

Other investigators have attempted to evaluate cervical collars in an objective fashion. The accepted gold standard for comparison is the halo brace, which restricts motion to 4% flexion-extension, 1% rotation, and 4% lateral bending. [15A] Unfortunately, even the best cervical collars (when used independently) restrict flexion and extension by only 70% to 75%, and overall neck movement by less than or equal to 50%. [28] A number of studies have evaluated neck motion in volunteers immobilized supine on a backboard with various collars in place. [1] [25] [26] [29] [30] [31] [32] [33] [34] While these studies demonstrated small differences among some of the collars, overall they merely confirm the fact that cervical collars alone are inadequate to immobilize the cervical spine completely. Thus, it is important to keep in mind that for effective cervical spine

immobilization, differences among various types of cervical collars are less important than proper application, fit, and most importantly, use of adjunctive equipment.

Little information is available regarding the proper selection and application of spinal immobilization devices for children. Most of the available data were derived from studies of adults and may not be applicable to children. Half of the total growth in head circumference is achieved by the age of 18 months, giving children a disproportionately large head compared with the rest of the body. Prior to age 8, these anatomic and developmental differences result in a higher incidence of upper cervical spine injuries (C1–2). Because injuries in this area are frequently unstable, proper cervical immobilization in the *neutral* position is critically important. Schriger defined the "neutral" position as the normal position of the head, neck, and torso when the patient is upright and looking directly ahead. [35] In this position, the pediatric cervical spine is normally lordotic or extended. [24] However, because the head is large, positioning the child's body on a standard backboard may force the neck into flexion or a relative kyphosis. The clinical significance of this is currently unclear, but theoretically may be hazardous for young children. Therefore, the standard backboard should be modified to adapt to the child's larger head size. As a rough guide, the external auditory meatus should be on the same level as the mid-shoulder. Suggested modifications include a cutout in the backboard that accommodates the occiput or a pad under the back at the level of the chest (Fig. 47-3). If not modified, the standard backboard in conjunction with the disproportionately large head of a child may force the neck into hyperflexion, potentially aggravating an underlying cervical spine injury. [36] Nypaver and Treloar showed that all children required elevation of the back (mean height, 25.4 ± 6.7 mm) for correct neutral position on a spine board. Children younger than 4 years old required more elevation than those 4 years old or older. [37] It must be pointed out, however, that

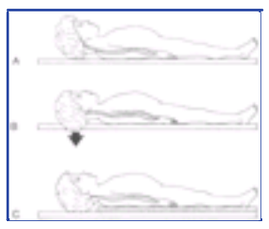

Figure 47-3 *A,* Young child immobilized on a standard backboard; note how the large head forces the neck into flexion. Backboards can be modified by an occiput cutout (*B*) or a double mattress pad (*C*) to raise the chest. *(Adapted from Herzenberg JE, Hensinger RN, Dedrick DK, et al: Emergency transport and positioning of young children who have an injury of the cervical spine. J Bone Joint Surg Am 71:15, 1989.)*

Figure 47-4 Pediatric high-cut extrication collar. *(Courtesy of Laerdal Medical Corporation, Wappingers Falls, NY.)*

there have been no published reports of a cord lesion resulting from the use of standard immobilization techniques and equipment in children. [24]

In a study addressing pediatric cervical spine immobilization, Huerta and coworkers evaluated the performance of infant and pediatric collars using a mannequin model.[38] They concluded that the high-cut collar in conjunction with a rigid backboard and lateral neck stabilizers provided the most effective spine immobilization (Fig. 47-4 and Fig. 47-5). In some children, these devices may provoke struggling because of fear, which has the potential to aggravate an underlying injury. In these situations, manual immobilization may be more effective and less frightening for the child. [39]

Procedure

Application of an extrication collar is a straightforward procedure (Fig. 47-6). A collar should be treated as a splint. The normal axiom in splinting is to immobilize the joint above and below the area of injury. Because no collar performs this function perfectly, a rescuer should be charged with maintaining manual in-line cervical stabilization in the neutral position during collar application and until the patient can be fully immobilized in an intermediate stage corset-type device or on a full backboard. The rescuer's intentions should be thoroughly explained to the patient throughout the procedure.

The neck should be examined before application of the collar for swelling, ecchymosis, deformity, or penetrating wounds. Once the collar is in place, a conscious patient should be cautioned repeatedly against movement of the head. Any persistent complaints of pain or dyspnea by the patient

Figure 47-5 LSP pediatric immobilization board with cervical collar. *(Courtesy of Allmed, St. Louis.)*

should be investigated by removal and possible replacement of the device while manual stabilization is maintained. The collar size should be determined using the manufacturer's suggested guidelines. For example, the Stifneck collar (Laerdal Medical Corp., Wappingers Falls, NY) is available in various sizes and uses the distance from the top of the shoulder to the chin to determine size (Fig. 47-7). The tallest collar that does not cause hyperextension should be used. For extremely short necks, a special extrication collar such as the No-Neck (Laerdal Medical Corp., Wappingers Falls, NY) is recommended (Fig. 47-8).

In cases in which an extrication collar of the proper size is not available, an improvised device should be made from available materials (Fig. 47-9). Once the patient is in the supine position and firmly secured to a backboard, lateral stabilization should be added, using foam blocks and tape or a factory-made lateral neck stabilizer (Fig. 47-10). Because immobilization on a flat backboard has been shown to place most adult patients into relative cervical extension, it is recommended that occipital padding (mean, 3.8 cm) be added to restore neutral position in adults. [35]

It should also be remembered that application of a cervical collar should not be attempted until the patient's head has been brought into a neutral position, and manual in-line stabilization has been applied. [28] If the patient experiences cervical muscle spasm, increased pain, neurologic complaints (e.g., paresthesia, weakness), or airway compromise, movement of the head and neck should be halted immediately. In these situations, patients should be immobilized in the position they are found using an alternative technique (e.g., blanket, towel roll).

Complications

Improper application of an extrication collar can occur if the wrong size is used or too little care is exercised during placement. The best means of preventing either error is strong clinician involvement in the training and continuing education of rescue crews, with vigorous feedback in cases of correct and incorrect application. In addition, adherence to the manufacturer's collar-specific recommendations for size and application should be emphasized.

A collar that is too small for a patient may be either too tight for the girth of the neck (with obvious complications) or too short to provide adequate immobilization. Too large a collar commonly results in hyperextension, which can exacerbate a preexisting spinal injury.

Improper or prolonged application of an extrication collar may impede venous return and raise intracranial pressure (ICP). [40] This is sometimes manifested by facial flushing and is more common with the short collar types.[22] While the clinical significance of increased ICP produced by cervical immobilization is still unknown, two studies have confirmed that the application of a rigid cervical collar causes a statistically significant and sustained rise in ICP. [41] [42] Kolb and coworkers reported a 24.8 cm H_2O increase in cerebrospinal fluid (CSF) pressure in 20 adult patients undergoing lumbar puncture. Hunt and associates reported a 4.6 mm Hg mean rise in ICP in 30 patients with severe traumatic brain injury. The largest rise in ICP was noted in patients with a baseline ICP greater than 15 mm Hg. The authors of these studies concluded that elevation of ICP produced by cervical immobilization might have deleterious effects in patients with acute or sustained intracranial hypertension.[41] [42]

The long-term use of the Philadelphia extrication collar as part of the treatment plan for an underlying cervical spine injury has been associated with pressure ulcers of the scalp.[43] Because some collars (e.g., Philadelphia [Philadelphia Cervical Collar Co., Westville, NJ] and Stifneck) have been shown to exert higher capillary closing pressures at contact points, it is suggested that collars with favorable skin pressure patterns and superior patient comfort (e.g., NECLOC [Jerome Medical, Moorestown, NJ]) be used in these settings.

One final complication should be mentioned. The patient who, for whatever reason, actively resists placement of an extrication collar or other splint should not be forced to wear it. Immobilization of the combative patient cannot be accomplished without considerable muscular exertion not only by rescuers but also by the patient.

If fractures do exist, it is possible that struggling can cause further damage. If the patient permits manual stabilization, this should be maintained as an alternative.

Conclusion

Cervical spine immobilization is an important skill for all emergency care providers. The use of a rigid cervical collar is an important first step in the immobilization of patients with potential cervical spine injuries. However, the use of a cervical collar alone does not provide complete immobilization. Proper cervical spine immobilization requires the use of a cervical collar, backboard, and lateral support device to ensure complete immobilization of the head and neck.

Figure 47-7 Method for predetermining the correct size for an extrication collar. *(Courtesy of Laerdal Medical Corporation, Wappingers Falls, NY.)*

Figure 47-8 No-Neck extrication collar. Designed for individuals with extremely short necks. *(Courtesy of Laerdal Medical Corporation, Wappingers Falls, NY.)*

Figure 47-9 Horse collar. Most extrication collars are available in three to five factory sizes. If a collar is not sized properly to fit a particular patient, it performs no function. Patients with extremely long necks or especially short ones can be immobilized by means of a horse collar fashioned from a bulky rescue blanket. The blanket is rolled to the thickness desired and slid under the patient's neck while a bystander applies manual stabilization; the ends of the blanket are then brought across the patient's anterior chest. The patient's forearms are fastened as shown to stabilize the "tails" of the collar. *(From Dick T: Tricks of the trade: Horse sense, immobilizing necks that don't fit collars. J Emerg Med Serv 7:23, 1982. Reproduced with permission.)*

THORACOLUMBAR SPINE

Adequate full-body thoracolumbar spine immobilization is best accomplished by means of a full-length spine board (also called a *backboard*). Full-body spinal immobilization includes early application of a cervical collar, lateral immobilization of the head and neck, and ample strapping of the entire body to the backboard. Proper strapping minimizes movement whenever the backboard is used to transport the patient over long distances. In addition, this will help limit spinal movement associated with backboard tilting, which may be necessary in the likelihood of emesis or during transport of pregnant females in the second or third trimester.

Transferring a victim from a location and position of origin to a backboard may require the use of an intermediate-stage immobilization device such as a short spine board or a corset-type device. Corset-type devices have extensions that engage the head and neck and are equipped with weight-bearing loops that allow easier handling of the patient. Intermediate immobilizers or extrication splints should be used when a patient must be removed from a confined environment or when circumstances require movement in or from a sitting position.

In some circumstances, a threatening environment (fire, hazardous material incident, extreme weather) or patient condition (compromised airway, shock) may necessitate *rapid extrication*. Rapid extrication is the process of patient removal and spinal immobilization using an abbreviated manual technique. [1] It is performed by first bringing the patient's head into the neutral position. A cervical collar is then applied and the patient is transferred to a backboard without using an intermediate-stage device. Manual in-line stabilization of the spine is maintained throughout the procedure.

When extrication is not required by a patient's location, position of origin, or route of egress, the patient is most often found lying at ground level. With an extrication collar in place and in-line manual cervical immobilization, the patient can be logrolled onto a backboard. [44] Visual inspection of the back should be carried out during the logrolling process while the body is kept in a single plane.

McGuire and colleagues evaluated the safety of the logroll maneuver in three different settings: a volunteer with a stable spine, a cadaver with a surgically created unstable thoracolumbar injury, and a patient with a T12–L1 fracture-dislocation. [45] Radiographic studies on the volunteer demonstrated mild lateral movement during logrolling. The cadaver demonstrated a 2.1-cm anteroposterior displacement and a 5-mm lateral displacement during the logroll. The injured patient demonstrated no anteroposterior displacement but did experience a 7-mm lateral displacement when logrolled onto the side. Suter and coworkers studied variations of the logroll maneuver in healthy volunteers to determine the effect of axial traction and subject arm positioning on thoracolumbar movement. [46] Their study demonstrated significant thoracolumbar movement during the logroll maneuver that was consistently minimized by positioning subjects with the arms extended at the sides and the palms resting on the thighs. These studies raise concerns about the safety of the logroll maneuver and suggest that extreme caution be used during transfer of patients with suspected spinal injuries. Despite these concerns, there have been no reports of neurologic deterioration following a logrolling maneuver. Consequently, logrolling remains a widely accepted method of transferring patients on the ground to a backboard.

An optional but effective means of moving a supine patient is provided by a type of stretcher that breaks apart longitudinally and can be slid beneath a victim without disturbing his or her position. The halves of this scoop stretcher are anatomically contoured to enhance comfort and limit lateral movement of the immobilized patient. Unfortunately, visual inspection of the back is not possible with the use of a scoop stretcher.

A third means of both immobilizing and moving a trauma victim consists of a specially designed full-body splint, complete with factory-made straps or harnesses. There are several such immobilizers, most of which are highly effective and provide good lateral stability as well as anatomic conformity. One such device that is popular in European countries is the vacuum stretcher. A full-body

Figure 47-11 The Evac-U-Splint mattress. *(Courtesy of Hartwell Medical, Carlsbad, CA.)*

splint marketed in the United States (Evac-U-Splint [Hartwell Medical, Carlsbad, CA]) offers fast, full-body immobilization that supports the entire patient without creating pressure points (Fig. 47-11). In general, the patient must either be logrolled or lifted, using a scoop stretcher or full backboard, onto one of these devices.

Background

Until 1965, the principle of "rapid transportation above all" held widespread acceptance among rescuers, who had little or no orthopedic training, and among clinicians whose emergency care experience, by modern standards, was just as limited. The most commonly agreed-on means of getting a sitting patient out of a wrecked automobile was to use some version of a chair-carry. If the patient originated in a position other than the sitting position, the patient was first placed into a sitting position and *then* moved by means of a chair-carry or simply dragged out of the vehicle.

Col. Louis Kossuth, commander of the U.S. Air Force's Medical Service School at Gunter Air Force Base in Alabama, made note of several automobile crashes in which he thought patients were handled roughly by bystanders who were trying to help. [16] Finding the medical literature lacking at that time, he made recommendations regarding how these victims should be handled. He experimented with a set of canvas splints reinforced with semirigid steel stays as slats, similar to the modern Kendrick extrication device (KED) (Ferno Model 125, Ferno-Washington, Inc., Wilmington, OH). In addition, Kossuth has been credited with developing the first modern-type spine board. [18]

In 1967 and 1968, Farrington wrote two classic articles that showed the use of an extrication collar, spinal traction, nine-foot webbing straps, and both short and long spine boards to remove people in every conceivable position from automobiles. [17] [18] Much of today's extrication theory is essentially identical to what was taught by Farrington.

In 1967, the Committee on Trauma of the American College of Surgeons listed the minimum amount and type of equipment that should be carried in ambulances. This list included both short and long spine boards with accessories. [47] A similar document published the following year by the National Academy of Science also listed medical requirements for ambulance equipment and recommended short and long spine boards. [48] Since then, the list of ambulance supplies and equipment has evolved greatly, but the requirement for both short and long spine boards (or their equivalent) has not changed. [49]

Indications and Contraindications

Any mechanism capable of causing injury to the cervical spine should prompt rescuers to immobilize not only the head and neck, but also the entire body. The motion of any one vertebral joint is impossible to isolate. For complete spinal immobilization, the head, neck, and torso must be fastened into a single common plane. Extrication devices (e.g., short spine boards) will accomplish this to some extent, although movement of nonimmobilized lower extremities can lead to secondary movement of the pelvis and lumbar spine. Movement of the lumbar spine may also induce thoracic movement to some extent. Considering the fact that the most

feasible position for transport is the supine position, full-body immobilization is best achieved using the long spine board with the extremities securely fastened to the board.

Mechanisms that arouse suspicion of injury to the thoracolumbar spine should also prompt full-body spinal immobilization. These include penetrating and blunt injuries to the thorax, abdomen, pelvis, and spine. Full-body immobilization should be considered whenever the mechanism for spinal injury exists, even in the absence of signs and symptoms. In such cases, the possibility of occult injury is best ruled out through clinical or radiographic examination, or both, at the hospital.

The only contraindication to full-body immobilization of a patient whose mechanism of injury suggests spinal injury is *the existence of a greater threat*. The threat to a patient's life may exceed the threat of *possible* spinal injury under the following circumstances:

- *Hazards on the scene.* Problems with traffic control in the direct vicinity of the patient's location such that the patient or rescuers are likely to be injured. Such hazardous situations include leaks of fuel or other flammable substances, fire, hostile crowds, partially collapsed structures, or unstable vehicles.
- *Ongoing gunfire at the scene.* Gunfire is always considered an indication for rescue personnel to stay away from a scene.
- *Overwhelming casualties.* Rescuers may have to improvise in cases in which casualties exceed available resources. In such cases, proper spinal immobilization may merit a lower priority than usual.
- *Weather extremes.* Under conditions of extremely adverse weather, the urgency to move the victim may supersede the priority of normal treatment, including immobilization.
- *Patient noncompliance.* A competent rescuer can do much to make an immobilization device comfortable by means of padding and reassurance. If this fails, immobilization that is applied by force may cause more harm than no immobilization at all.

Equipment

Cervical Extrication Splints

There is a large variety of short spine boards (Fig. 47-12) and intermediate-stage extrication devices available for prehospital use. Generally, these devices are manufactured using rigid lightweight materials. They have a narrow board design that permits easy application in small automobiles or confined spaces, and are constructed with multiple openings along the edges to allow for a variety of strapping options. Although these devices have not been compared scientifically, some useful and important features of cervical extrication splints have been identified.

The device should not produce unnecessary movement or change the position of the head, neck, shoulders, or torso during application. In conjunction with a good cervical collar, a properly applied cervical extrication splint should effectively limit flexion, extension, lateral, and rotational motion of the head, neck, and torso. A cervical extrication splint should be comfortable, since it may be left on a patient for prolonged periods. Simplicity of design should allow rapid placement of the device by two rescuers in any situation, without causing movement of the head, neck, or torso.

The cervical extrication splint should be compact enough to allow its use in many types of extrication situations. Cost should be reasonable so that at least one device can be carried in every ambulance. Ideally, the device should also be translucent so that radiographs can be readily obtained in the emergency department (ED). Lastly, the cervical extrication splint should be designed to allow for repeated use and easy cleanup.

One commonly used device that meets all of these criteria is the KED (Fig. 47-13). The KED was developed by Rick Kendrick, an emergency medical technician (EMT)-fire-fighter from El Cajon, CA, in response to frustrated rescuers who experienced difficulty when removing victims from wrecked racecars. The device consists of two layers of nylon mesh impregnated with plastic and sewn over plywood slats to provide rigidity. It has a nylon loop behind the patient's head that is continuous with the pelvic support straps for additional strength. Part of its anterior thoracic panels can be folded backward to fit the obese, pregnant, or pediatric

patient.[50] Properly applied, the KED is a snug-fitting, highly adaptable immobilizer that can be used under even the most adverse of circumstances.

Full-Body Spine Immobilizers

There are three basic classes of full-body spinal immobilizers, each with its own advantages and disadvantages. [27] It should be stressed that it is more important for a rescuer to achieve results (e.g., rapid, efficient, and complete spinal immobilization) than to be particular about using a specific piece of equipment.

Full-body spine boards (Backboards).

Backboards are made from wood or plastic composites, and can be either rectangular or tapered in shape (Fig. 47-14). Most rescuers prefer the tapered type because it takes up less horizontal room when angled into a narrow opening or doorway (such as that of an automobile). In addition, the slight narrowing of these boards on either end enhances the effectiveness of strapping.

Most backboards have strategically placed openings along the edges that can be used to secure head-stabilizing devices, strap the patient to the board, or lift. Many also feature runners, usually about 2.5 cm thick, on their undersides that serve both as stiffeners and as spacers. These raise the

Figure 47-14 The Bound Tree spine board. An example of a commercial plywood backboard. *(Courtesy of Bound Tree ALS Medical Products Corporation, Phoenix, AZ.)*

board slightly off the ground so that rescuers can get their fingers under the board during lifting. The runners, however, may make it more difficult to slide a patient onto the board.

Advantages of boards over full-body splints include their ease of storage, low cost, and extreme versatility. The backboard can be used to slide a victim out of an automobile or to protect a victim during removal of a windshield. Boards provide insulation against electrical hazards and can be used as improvised shelter in bad weather. Finally, they may be useful as ramps in muddy conditions.

Disadvantages of boards as immobilizers, although few, deserve mention. Board-like splints, as a class, are the least comfortable of all immobilizers. One prospective study demonstrated that standard spinal immobilization (hard backboard, rigid cervical collar, lateral immobilization device) of healthy volunteers was associated with a variety of symptoms, including headache, backache, and jaw pain.[11] In another study using EMT trainees, Cross and Bakerville found that the occiput, lower back, and sacrum are the three most common locations for pressure pain, and that pain in these areas is greater on a long backboard than with vacuum-type mattresses. [51] Pain in these areas may become severe as patients are frequently left immobilized on these boards for extended periods of time in the ED. [12] [52] [53] These findings may also have clinical implications, since pain generated by the application of a backboard can be difficult to separate from other sources of pain in the trauma patient, and may lead to unnecessary and costly radiographs.[4] Discomfort may be minimized by using padding at points of contact between a bony prominence and the board or the cervical collar. Alternatively, patient discomfort can be reduced, without compromising cervical spine immobilization, with the use of a pad (1.3 cm closed-cell foam padding) along the entire board. [54] This concept was reaffirmed by Hauswald and colleagues, who found that increasing the amount of padding on a backboard decreased the amount of ischemic pain caused by immobilization. [55]

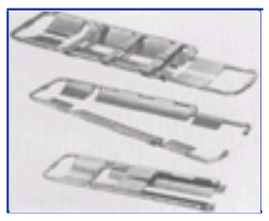

Figure 47-15 The Ferno-Washington model 65 orthopedic (scoop) stretcher. *(Courtesy of Ferno-Washington, Inc., Wilmington, OH.)*

Backboards have also been shown to produce higher sacral interface pressures and higher self-reported pain scale scores on the occiput, low back, and sacrum than a conforming support surface such as the vacuum-type splint.[51] [56] The duration and degree of contact pressure are considered important determinants of pressure necrosis in spinal cord injuries. [57] A further disadvantage of the backboard is its slippery surface, which makes it an unstable carrying device in rough terrain.

Scoop stretchers.

If a trauma victim has to be extricated from a tight location, a smooth backboard is probably the best immobilizer. If the victim is not in a tight location, the scoop stretcher is an ideal field immobilizer (Fig. 47-15). The scoop stretcher is designed to split into two or four pieces. It is comfortable, rigid, adaptable to patients of various lengths, and provides unobstructed radiographic transparency of the entire spine. If necessary, it can be almost instantly applied or removed without disturbing the position of the victim. The stretcher also provides good lateral stability due to the troughlike shape of its top surface, and it is stable enough to be used for carrying purposes. For optimal protection of a potential spinal injury, the spine should be completely immobilized (e.g., cervical collar, lateral supports, and secure strapping) and the scoop stretcher should be placed on a backboard before moving the patient. In addition, the scoop stretcher should be carefully reassembled to avoid trapping clothes, skin, or other objects between interlocking parts.

The scoop interferes slightly with the ischial section of a half-ring traction splint but works well with Sager-type devices. The scoop has no adverse effect on other immobilizers and does not interfere with cardiopulmonary resuscitation (CPR). The Ferno-Washington model 65 scoop (Ferno-Washington, Inc., Wilmington, OH) is the most widely used stretcher of this type. Newer devices such as the CombiCarrier (Hartwell Medical, Carlsbad, CA) and the Scoop EXL (Ferno-Washington, Inc., Wilmington, OH) offer lightweight polymer construction and additional spine support (Fig. 47-16 *A&B*).

Full-body splints.

Various devices take the concept of full-body immobilization one step further than the spine board. Los Angeles County Fire Department paramedic Larry Miller designed a narrow spine board shaped like the human body, with handles on both long edges and a system of harnesses to provide immobilization. The Miller body splint consists of a polyethylene shell injected with closed-cell foam that is radiographically translucent and provides buoyancy in water (Fig. 47-17). The full-body splint features a removable head harness, a thoracic harness, and pelvic as well as lower extremity belts. The space between its lower extremities facilitates wrapping with bandage material in the event of fractures. In addition, it is shaped so that it can easily fit into a basket-type rescue stretcher. Similar spine immobilization systems are now available for pediatric patients (e.g., Pedi-Pac [Ferno-Washington, Inc., Wilmington, OH]), making immobilization, extrication, and transport of traumatized children easier and safer for prehospital care providers.

Figure 47-17 The Miller body splint. *(Courtesy of Life Support Products, Inc., Irvine, CA.)*

An important innovation in the area of spine immobilization in the United States has been the vacuum mattress splint (e.g., EVAC-U-Splint [Hartwell Medical, Carlsbad, CA] and Immobile-VAC [MDI, Gurnee, IL]) (see Fig. 47-11). It consists of a vinyl-coated polyester envelope filled with thousands of 1.1 mm diameter polyester foam spheres. A manual or electric vacuum pump is used to evacuate the interior to a pressure of about one-fourth atmosphere. This reduction in internal pressure causes the mattress to conform to the contours of the patient's body. Vacuum splints are more comfortable, quicker to apply, and allow less slippage on lateral tilting than wooden spine boards. [58] [59] The vacuum splint has also been shown to produce lower sacral interface pressure and lower mean pain scores than traditional hard

Figure 47-18 The HeadBed, a cervical immobilization device made of a water-resistant corrugated board. *(Courtesy of Laerdal Medical Corporation, Wappingers Falls, NY.)*

backboards,[51] [56] and may provide better immobilization in patients with known spinal cord injuries. [60] [61] It should also be pointed out, however, that vacuum splints are larger and more cumbersome than backboards, making ambulance storage more difficult. In addition, cleaning, durability, and cost remain important concerns. [51]

Lateral neck stabilizers.

Sandbags, which were used as lateral neck stabilizers for years, are no longer recommended for use in the field. Lighter objects such as blocks (10 cm × 10 cm × 15 cm) made of medium-density foam rubber are commonly used. Foam blocks are lightweight, inexpensive, and disposable, and do not slip on the backboard. More recently, cardboard devices that have the same advantages as foam blocks have been developed to provide lateral stabilization (Fig. 47-18).

Another commercial device is the Bashaw CID. It is a lateral neck stabilizer designed to quickly and easily fasten the patient's head to a scoop stretcher or spine board (Fig. 47-19). The CID is made of a Herculite nylon and

Figure 47-19 The Bashaw cervical immobilization device (CID). *(Courtesy of Bashaw Medical, Inc., Pensacola, FL.)*

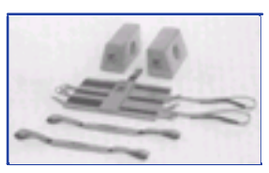

Figure 47-20 Ferno Universal Head Immobilizer. *(Courtesy of Ferno-Washington, Inc., Wilmington, OH.)*

polyethylene foam platform that is fastened to the stretcher, either by elastic belts or by nonelastic belts with buckled closures. Its pillows are then attached to the nylon platform by means of large Velcro interfaces. The Universal Head Immobilizer is a similar device manufactured by Ferno (Fig. 47-20).

Mosesso and colleagues compared six prehospital cervical immobilization devices and concluded that the devices were similar in their ability to immobilize the cervical spine, although the Bashaw CID was less effective than the other five devices in limiting rotational movement. [62]

Procedure

Despite the presence of a field cervical collar, manual in-line cervical stabilization should be continued until the patient is fully immobilized in either a cervical extrication splint or a full-body splint (e.g., a backboard or vacuum stretcher). The immobilization technique used will depend on the patient's position of origin.

Sitting Position

The extrication splint should be stored so that its straps are secured in their individual retainers, to reduce their likelihood of becoming entangled during application. At least two rescuers should be used to apply an extrication splint to a sitting patient.

When used, the device is opened, butterfly style, and gently slid behind the victim with a rocking motion. If necessary, the patient can be very carefully rocked forward a few degrees to facilitate placement of the splint.

Once behind the victim, the splint's pelvic support straps should be freed from their retainers and allowed to dangle at the patient's sides. Next, the lateral thoracic panels are brought around the chest just beneath the patient's shoulders. While grasping these panels, a rescuer *slides the splint upward until the top edges of the panels firmly engage the patient's axillae*.

Now the thoracic straps can be used to secure the splint, beginning with the middle strap, then the bottom strap, and finally the top strap. This procedure may need to be modified depending on injuries and preexisting conditions. For example, patients with pelvic fractures may not tolerate placement of the pelvic support and bottom straps, and the gravid abdomen of the pregnant patient may prevent placement of the middle strap. The straps should be fastened snugly but not so tightly as to interfere with respiration.

The pelvic support straps are fastened next. They can be slipped, one at a time, beneath the patient's lower extremities and *brought directly beneath the pelvis using a back-and-forth motion*. If the pelvic straps are not applied properly, they allow considerable slippage when the patient is lifted. The free end of each of these straps mates with a buckle located at the patient's hip on the outside of the splint. Once a strap is ready to be buckled, it can either be attached to the buckle on its own side or moved across the patient's lap and engaged with the opposite buckle. Most prehospital care providers prefer the latter method because it allows the patient's knees to remain together without discomfort to the patient. It is also a good idea to pad the groin area when placing the pelvic support straps as these may cause the patient considerable discomfort.

Next, the head is fastened. When using the KED, the head panels are wrapped snugly around the head and neck by one rescuer while another rescuer applies the diagonal head straps. It may be necessary to place padding behind the head to maintain a neutral position. The forehead can be used as a point of engagement for one strap, and the cervical collar itself can be used for the other.

Finally, all buckles should be tightened until the entire splint is firmly in place, while avoiding respiratory discomfort. The patient can now be moved (see Fig. 47-13). If the patient is to be lifted from a vehicle, the ambulance cot, with a spine board on it, should be brought as close as possible. While one rescuer supports the patient's knees, the other rescuer uses the handholds on the splint to lift the patient. The patient should be rotated and laid in a supine position onto a backboard.

The pelvic straps should then be loosened to allow the legs to be lowered onto the backboard. The legs can then be extended and secured to the backboard or left in the flexed position with a pillow placed under the knees for support.

Some type of lateral immobilizer should be applied for the head and neck, and the body should be belted into place on the board. Once the patient is on the board, the thoracic straps of the cervical extrication splint may need to be readjusted.

Recumbent Position

A patient who is found in a recumbent position should be placed in a supine position, if not already in one. If repositioning is necessary, the back should be examined in the process. Physical examination, spinal immobilization, airway management, and transport are easier to accomplish with the patient in the supine position.

Patients who are found supine do not require the use of a cervical extrication splint. They should, however, receive initial manual in-line cervical stabilization and an extrication collar. The patient should then be fastened to a full-body spinal immobilizer, such as a scoop stretcher, a backboard, or a full-body splint.

Scoop stretcher.

A patient who is in a supine position can be moved by means of a scoop stretcher. In the conscious patient, rescuers should explain that they are about to apply a

scoop-type stretcher, which may be cold to the touch, beneath the patient's body. An extrication collar is applied, and manual in-line cervical stabilization is maintained until the patient is completely secured to the stretcher. Another rescuer places the scoop on the ground next to the patient and opens the latches that regulate its length. The length should be adjusted

so that the scoop stretcher fits the full length of the patient's body. The latches that regulate the length of the device should then be engaged.

Next, the latches at each end should be released, allowing rescuers to separate the stretcher into two halves. Each half is then placed next to the patient. One rescuer then gently pushes half the stretcher under one side of the patient. In some cases it may be necessary to have another rescuer rock the patient to allow proper positioning. The same procedure takes place with the opposite half of the scoop until both halves are aligned beneath the patient. The latch at the head of the device should be engaged first. The lower end of the stretcher is then brought together, and the foot latch is engaged to complete the integrity of the stretcher. The patient's torso should be strapped into place and the head immobilized using a suitable lateral neck stabilizer. The patient can then be lifted onto another device (e.g., Stokes stretcher or backboard) for transport. After placement on another device, the scoop stretcher can be removed without disturbing the patient's position, if necessary.

Full-body spine boards (Backboards).

There are several ways of placing a patient onto a spine board. The precise technique used will depend on the space available and the position of the patient within that space.

For *lengthwise extrication*, as from an automobile seat, the patient can be slid, either feet first or head first, onto the backboard. It is important that the patient be moved as a unit during this process.

The end of the backboard should first be placed on the seat or doorsill of the automobile. One rescuer should then stabilize and maintain the backboard level at its opposite end, while other rescuers (at least two) lift and slide the body onto the board. Manual cervical in-line stabilization should be maintained throughout the procedure, and rescuers should avoid spinal compression or traction. Once the patient is completely on the board, the board can be slid out and placed on a waiting stretcher.

When space permits, *lateral extraction* is preferred. With the patient in the recumbent position, rescuers may logroll or slide the patient onto the board. As mentioned previously, extreme caution should be used with the logroll maneuver. [45] [46] The logroll maneuver requires the presence of at least three rescuers. One rescuer is positioned at the patient's head and applies manual in-line cervical stabilization. It will be this person's responsibility to oversee and direct body movement throughout the procedure. The backboard is then positioned next to the body. To minimize thoracolumbar movement, the patient's arms should be extended at the sides with the palms resting on the lateral thighs.[46] Some operators prefer to have the patient cross his/her arms across the thorax. If one arm is injured, the backboard should be placed against this side, so that the patient can be rolled onto the uninjured extremity. The other rescuers should be positioned on the side that the patient will be rolled *toward,* with one rescuer at the mid chest and the other at the legs. The rescuer at the chest should reach across the victim, taking hold of the shoulder and hips, while the other rescuer grasps the hips and lower legs. When everyone is ready, the rescuer at the head gives the command to roll the patient. The patient's back should be examined at this point. The backboard is then slid under the patient, and when everyone is ready, the rescuer at the head gives the command to lower the patient onto the board (Fig. 47-21). The patient should then be centered and securely strapped to the board. Alternatively,

Figure 47-21 Logroll maneuver. *(Courtesy of Albert Einstein Medical Center Emergency Medical Services Education, Philadelphia.)*

during lateral extraction, a recumbent patient can be slid sideways onto the spine board. This improvised technique also requires the presence of three or four rescuers, one of whom can maintain control of the patient's head and neck.

Various techniques can be used to secure a patient onto the backboard. Mazolewski and Manix evaluated the effectiveness of four different strapping techniques in reducing lateral motion of volunteers restrained on a backboard. [63] These investigators found that the addition of an abdominal strap significantly reduced lateral motion without compromising respiration. In addition, proper strap placement and firm contact between the straps and the patient are also important in limiting lateral motion.[64] Aside from this study, there is little scientific basis for the various strapping techniques, and in many cases the methods used are determined by local protocol.

After the body has been strapped to the board, the head can be secured. If necessary, padding should be placed under the occiput to maintain the head in neutral position. A lateral neck stabilizer (e.g., foam blocks or a Headbed device) is then applied and the head secured in place using tape or straps. Most taping techniques involve the use of one piece across the forehead and one piece across the cervical collar. Note that this method of securing a patient to a backboard is designed for horizontal lifting only.

Standing Position

The standing patient with a potential spine injury must be immobilized and placed in the supine position. One technique for placing these patients on a backboard that is quick, safe, and effective is presented here (Fig. 47-22).[65] The tallest rescuer should be positioned behind the patient to manually stabilize the head while a second rescuer applies an extrication collar. The first rescuer must maintain manual in-line cervical stabilization until the patient is completely secured to the board. The backboard should be centered behind the patient between the arms of the rescuer who is stabilizing the neck. Facing the patient, one rescuer on each side should each reach under the patient's arm and grab the backboard by a handhold at or above the patient's axillae. The patient's elbows are then brought closer to the body. If an additional rescuer is available, this rescuer should be positioned at the feet to prevent the board from sliding out, particularly on slippery surfaces.

Figure 47-22 Backboarding the standing patient. *A,* Step 1: Manual stabilization. *B,* Step 2: Apply a rigid collar. *C,* Step 3: Insert a long backboard. *D,* Step 4: Center the backboard. *E,* Step 5: Emergency medical technicians grasp the board, using a handle higher than the patient's armpit *(F)*. *G,* Step 6: Slowly lower the patient. *H,* Step 7: Fully immobilize the torso, then the head and neck. *(From Elling R, Politis J: Backboarding the standing patient. J Emerg Med Serv 12:9, 1987. Reproduced with permission.)*

The patient should be slowly tilted back by lowering the head of the backboard. The rescuer at the head should step back during this process while maintaining the patient's head and neck in neutral alignment. When the backboard is completely horizontal, the patient can be secured to the backboard in the normal fashion.

Complications

In general, complications are more likely to occur as a result of failure to immobilize spinal injuries before movement than from the technique of immobilization. When complications do arise, they may be related to improper choice or use of equipment. The variety of situations routinely encountered in the field call for a

common-sense approach to spinal immobilization.

Victims are generally belted in place on a spine board to prevent sliding during transport. If too few straps are used or if the straps are loosely applied, motion during transport can occur. Patients who are strapped too firmly in place may complain of extreme discomfort and even panic. Excessive strapping can interfere with respiratory function in both children and adults. [66] [67] [68] Totten and colleagues evaluated the effect of two spinal immobilization methods (wooden backboard and vacuum mattress) on eight respiratory function measurements in healthy volunteers. In comparing baselines for each method, six of the eight (FVC, FVC%, FEV_1, FEV_1 %, PEF, and FEF_{25} % to FEF_{75} %) measures showed respiratory

function to be restricted an average of 15%. [69] While this may not be a problem in healthy volunteers, the effects on patients with chest trauma or preexisting respiratory disease may be significant. [69]

Once strapped into place, an unresponsive patient who vomits should be protected from aspiration. The traditional means is to logroll the board and patient as a unit to the side. Although this procedure may be associated with some spinal movement, the airway takes higher priority.

Conclusion

The wide variety of circumstances in which a traumatized patient is likely to be involved mandates the need for many approaches to full-body spinal immobilization. The overall goal of rescuers is to immobilize the entire spine by fastening the victim to a board-like full-body immobilizer. After early application of an effective cervical *collar*, this process involves the following steps:

1. Application of a cervical *extrication splint* that serves to immobilize the cervical and thoracic spine. This sort of device is often used when the patient is first encountered in a confined environment, such as a wrecked automobile or bathtub.
2. Placement of the patient on a full-body spine board, a scoop stretcher, or a factory-designed full-body immobilizer.
3. Application of lateral immobilization support devices for the head.
4. Use of straps to fasten the patient securely to the backboard.
5. Placement of the immobilized patient into a rescue litter, such as a Stokes basket stretcher, if complex terrain must be traversed.

UPPER EXTREMITY SPLINTING

Fractures and dislocations of the upper extremity are extremely common injuries. Although upper extremity injuries are rarely life threatening, it is important to assess and manage these injuries properly. Splinting has constituted a fundamental component of orthopedic care since 2500 BC, when the Egyptians used palm fibers and reed bundles to immobilize injured extremities. [70] Appropriate splinting of a minor fracture or dislocation, in addition to decreasing pain, reduces the incidence of serious complications and the risk of permanent disability.

The rescuer must not let obvious injuries to the extremities be a distraction to the care of more life-threatening injuries. In some situations it may be necessary to rapidly secure the patient to a long backboard that supports and splints every bone and joint of the body in one efficient step. [44] Injuries to nerves or blood vessels are a frequent complication of upper extremity trauma. Circulation, motor function, and sensation distal to the injury must be assessed early and monitored closely.

The purpose of splinting is to prevent motion of broken or dislocated bone ends. Carefully applied splints decrease pain while minimizing further damage to muscles, nerves, and blood vessels. Splinting also reduces the risk of converting a closed injury to an open one. [71]

Indications and Contraindications

Indications for splinting an extremity are usually clear. Pain with or without deformity following trauma should arouse suspicion for underlying bone or joint injury. Other signs include swelling, discoloration, deformity, *crepitus*, or loss of neurovascular function. The absence of these findings does not always rule out an underlying fracture or dislocation. Whenever a musculoskeletal injury is suspected, a prophylactic splint should be applied and maintained. The old axiom, "if in doubt, splint," should be followed.

There are no contraindications to splinting suspected upper extremity fractures or dislocations. However, in the setting of multisystem trauma with life-threatening injuries, rapid transport may be more important than extremity splinting. Averting loss of life takes precedence over averting loss of limb.

Equipment

Various splints are currently available for immobilizing upper extremity injuries. They can be divided into two basic types: rigid and soft. [44]

Rigid splints are made of many different materials, including cardboard, plastic, aluminum, wire, and wood. These splints must be fastened to the injured extremity using tape, gauze, cravats, or Velcro straps. They are nonflexible and, when applied, immobilize the limb in a rigid fashion to maintain stability. Although some rigid splints are prepadded, many others require the use of some additional soft material to cushion the splint. When applying rigid splints, the fingertips should be left exposed so that distal circulation can be monitored.

Cardboard splints are excellent for long-bone fractures of the upper arm. They can be formed into any desired shape and are inexpensive. Plastic, aluminum, wire, and wood splints, although less malleable, are also good choices. An inexpensive aluminum splint that is popular in wilderness medical kits is the SAM splint (The Seaberg Company, Inc., South Beach, OR). The SAM splint is foam-padded for comfort, water-resistant, lightweight, radiolucent, and reusable. These characteristics also make it an ideal tool for disaster medicine. [72]

Vacuum splints (Fig. 47-23) are a special type of rigid splint in which the air is evacuated from a closed bag

Figure 47-23 Upper extremity vacuum splint. *(Courtesy of Hartwell Medical, Carlsbad, CA.)*

containing tiny foam beads. This compresses the contents into a solid mass, resulting in a rigid splint. Injuries can be encased and immobilized in the position in which they are found, thereby reducing patient discomfort. Flexibility of the splint before removal of air allows molding of the splint to conform to the patient's position. Vacuum splints are radiolucent and do not apply external pressure to the injured extremity.

Soft splints include air splints, pillows, slings, and swaths. Immobilization with pillows, slings, or swaths alone is usually inadequate because these splints allow significant flexibility and motion. Therefore, they are most effective when used with some form of a rigid device.

Air splints are soft splints that become rigid when inflated. Besides providing immobilization, they help compress underlying soft tissue to reduce local hemorrhage. These devices are sensitive to differences in atmospheric pressure and temperature. Therefore, their inflation must be constantly monitored to ensure that the underlying tissue is not subject to pressure-induced ischemia. One study suggests a maximum splint pressure of 15 mm Hg to reduce the risk of ischemia. [73] With long ambulance transports, the splint should be deflated for 5 minutes every 1.5 hours. [74] A significant disadvantage is that pulses can no longer be monitored once the air splint is in place. Air splints are designed to conform to a specific shape when inflated and should not be used on angulated fractures. In addition to being radiolucent, some types can be inflated with a refrigerant to provide concurrent cooling.

Pillow splints (Fig. 47-24) can be fashioned from any soft bulky material and are excellent choices for hand or wrist injuries. These splints are extremely comfortable and can be easily applied.

Slings and swaths are usually used in combination with a rigid or soft splint. When used alone, they can effectively immobilize injuries to the shoulder, clavicle, or humerus.

Procedures

To apply a splint properly to an injured extremity, several general rules must be followed. Communication is important to ensure that the patient understands what is being done at all times. If necessary, clothing should be removed to adequately visualize the injured extremity. Manual stabilization of the

Figure 47-24 Hand/wrist pillow splint.

TABLE 47-2 -- Management of Specific Upper Extremity Orthopedic Injuries

Site	Suggested Immobilization Techniques
Clavicle	Sling and swath
Shoulder	Sling and swath as it lies
Humerus	Cardboard or vacuum splint with sling and swath
Elbow	Cardboard or vacuum splint as it lies
Forearm	Cardboard, malleable metal, air, or vacuum splint with sling and swath
Wrist	Pillow, cardboard, malleable metal, or vacuum splint applied in position of presentation
Hand	Pillow, cardboard, or malleable metal splint in position of function
Finger	Tongue depressor or small malleable metal splint

fracture site helps limit unnecessary movement and prevent further injury. The neurovascular status (i.e., pulse, motor, and sensation) should be checked before and after the application of a splint. With a severely angulated extremity, traction not exceeding 10 lb of pressure may be applied to reduce the deformity. If resistance or pain is encountered, the extremity should be splinted in the position found. Open wounds should be covered with a sterile dressing before a splint is applied. The splint (Table 47-2) should be applied using the orthopedic principle of immobilizing the joint above and below a suspected fracture site. Cooling and elevation of the injured area may help reduce local swelling. Once the splint has been applied, the distal neurovascular status should be assessed frequently. Any deterioration requires immediate evaluation of the splint to determine if excess pressure is being applied.

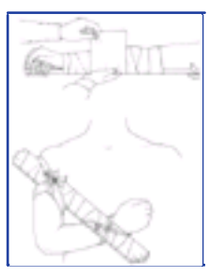

Figure 47-25 Examples of rigid splints.

Rigid Splints

To apply a rigid splint, an assistant should provide support and gentle traction above and below the injury. The splint is then applied on the side of the extremity away from any open wounds. The splint should be large enough to immobilize the joint above and below a fracture or the bone above and below a dislocation. The splint should be well padded to reduce the risk of pressure necrosis. The splint is then secured to the extremity using gauze or tape (Fig. 47-25).

Vacuum splints are applied in much the same manner as other rigid splints. While an assistant stabilizes the injured site and applies traction, the splint should be wrapped around the extremity and secured with the attached straps. The air is then evacuated from the splint by means of a hand pump until the splint becomes rigid.

Soft Splints

The application procedure for an air splint depends on whether the splint is equipped with a zipper. If the splint does not have a zipper, it must first be placed on the rescuer's arm until the bottom edge lies above the wrist. Next, the rescuer grasps the hand of the patient's injured extremity, while the free hand is used to provide support and gentle traction above the injury (Fig. 47-26*A*). An assistant should then slide the splint onto the patient's arm (see Fig. 47-26*B*). After making

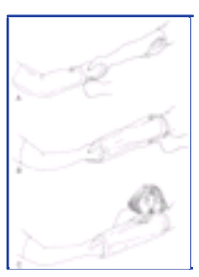

Figure 47-26 Application of an air splint. *A*, The rescuer supports the injured extremity with one hand and places the air splint on the other arm. *B*, An assistant slides the splint onto the patient's arm. *C*, The air splint is inflated until finger pressure makes a slight dent.

sure that the splint is not wrinkled, it should be inflated until finger pressure makes a slight dent (see Fig. 47-26*C*). Zippered air splints should be opened and placed around the injured area. The zipper should be closed and inflation accomplished as discussed previously. With air splints that completely enclose the hand, distal circulation must be assessed by checking capillary refill.

Pillow splints are applied by encasing the injury in the pillow and securing with tape, cravats, or gauze (see Fig. 47-24). If possible, the nailbeds should remain exposed to allow for assessment of circulation.

To apply a sling, an assistant should support the injured arm in a flexed position across the patient's chest. The long edge of the triangular bandage should then be placed lengthwise along the patient's side opposite the injury, with its tip over the uninjured shoulder (Fig. 47-27). The other tip is then brought over the injured shoulder to enclose the arm in the sling. The sling should be adjusted so that the arm rests comfortably with the hand higher than the elbow. The sling is then tied together at the side of the neck, and the knot is padded for patient comfort. The point of the sling at the elbow should be drawn around to the front and pinned. With the sling properly applied, the patient's arm rests comfortably against the chest with the fingertips exposed (Fig. 47-28).

To apply a swath, a cravat of sufficient length should be placed under the uninjured arm and over the injured arm at the level of the mid-humerus. This should then be fastened circumferentially around the thorax so that the injured extremity is secured snugly to the chest (Fig. 47-29). In adults, two

Figure 47-27 Stepwise application of a triangular bandage. 1, Place tip A over the uninjured shoulder. 2, Bring tip B over the injured shoulder to enclose the arm. 3, Draw tip C around the front and pin.

Figure 47-28 Completed triangular bandage.

cravats may have to be tied together in an end-to-end fashion to produce a swath of sufficient length.

Complications

Potential complications of upper extremity splinting include pressure necrosis, conversion of a closed injury into an open one, and loss of neurovascular function. With the use of air splints, there is the additional risk of pressure-induced tissue ischemia and compartment syndrome. [75]

Figure 47-29 Sling with swath.

Conclusion

Injuries to the upper extremities, although not life threatening, can have significant immediate or long-term effects. A high index of suspicion for underlying neurovascular injury should always be maintained. Neurovascular status must be checked before and after application of splints and monitored frequently throughout transport.

LOWER EXTREMITY SPLINTING

Many of the principles, techniques, and complications discussed with upper extremity splinting also apply to injuries of the lower extremity (Table 47-3); the pillow splint is one example (Fig. 47-30). In addition, the pneumatic anti-shock garment (PASG) can also be used as an effective splinting device for lower extremity injuries (see Pneumatic Anti-Shock

TABLE 47-3 -- Management of Specific Lower Extremity Orthopedic Injuries

Garment later in this chapter). Prolonged use of the PASG as a splinting device is discouraged, however, since it has been associated with an increased incidence of compartment syndrome.[75] The following discussion is limited to lower extremity traction splinting.

The use of traction and countertraction for the alignment and reduction of fractures dates from the time of Hippocrates. [76] In the late 1800s, Sir Hugh Owen Thomas developed the first full-ring traction splint for the definitive management of fractured femurs. [76] Since the Thomas full-ring splint was not an emergency treatment device, it was later modified by his nephew, Sir Robert Jones, and other surgeons to a half-ring splint that made it easier to apply in the field. During World War I, the modified splint was credited with reducing the mortality rate associated with fractured femurs from 80% to 15%. [77] Since then, several additional modifications that carry the name of their inventors (e.g., Glenn Hare, Joseph Sager, Allen Klippel) have furthered the development of lower extremity traction splints.

In the setting of a fractured femur, muscle spasm and fragment overlap may cause the thigh to lose its cylindrical shape and adopt a more spherical appearance. [76] The resultant decreased tissue pressure and increased volume may allow 1 to 2 L of blood to accumulate at the fracture site. Traction splints are designed to restore the cylindrical shape of the thigh, which in turn increases tissue pressure and inhibits further hemorrhage.

Indications and Contraindications

Application of a lower extremity traction splint is indicated whenever a fractured femur is suspected. This should be clinically suspected when there is shortening, angulation, crepitus, swelling, or ecchymosis of the thigh with pain. The use of a traction splint will help align the fracture fragments, relieve pain, prevent damage to neurovascular structures, and reduce blood loss.

Lower extremity traction splints should not be used to immobilize fractures or dislocations of the pelvis, hip, knee, and foreleg. [44] It is controversial whether traction should be applied to an open femur fracture. Concern has been expressed that the use of traction may allow contaminated bone fragments to retract into the wound. Should traction produce bony retraction into the wound, this information must be relayed to the receiving clinician. A workable compromise is to use the splint to apply sufficient traction to achieve stabilization without retraction. Alternatively, a vacuum splint or the PASG can be used to immobilize the bony fragments in the position of presentation. In any case, stabilization of the fracture site to prevent further hemorrhage, neurovascular damage, or soft tissue injury should take precedence over the theoretical risk of increased contamination.

Equipment

Currently, there are a variety of commercially available lower extremity traction splints (e.g., Hare Traction Splint, FernoTrac, Sager-type devices, Kendrick Traction Device), each with its own unique method of application. Despite the differences among these splints, each is designed to align and immobilize a fractured femur. Except for Sager-type devices, most traction splints produce flexion at the hip joint because of their half-ring design. This flexion of up to 30° does not allow complete fracture alignment, unless the patient is in a reclining position about 30° from horizontal or the injured extremity is elevated to create the same angle.

Procedure

Application of the FernoTrac Traction Splint (Ferno-Washington, Wilmington, OH) and the Sager Emergency Traction Splint (Minto Research and Development, Redding, CA) are illustrated in Figure 47-31 and Figure 47-32 Figure 47-32 Figure 47-32 , respectively.

When possible, the splinting procedure should be explained to the patient. There is always pain associated with the application of a traction splint, but the patient should be reassured that the resultant stabilization of the fracture site will help reduce subsequent discomfort. The area of injury should be exposed and the distal neurovascular status assessed before application. Open fractures should be managed as discussed previously. If the injured leg is markedly deformed, an assistant should first straighten it using manual traction and maintain that position until a splint has been applied. The amount of traction necessary to straighten a badly deformed extremity will vary, but rarely exceeds 15 lb. Also, keep in mind that the initial application of traction is often quite painful, but usually subsides quickly as the injured leg is aligned and stabilized. If the patient strongly resists while traction is being applied, the emergency care provider should stop and splint the limb in the position it was found.

If the splint has an adjustable bar, the noninjured extremity can be used for length adjustment. The splint should extend approximately 25 to 30 cm beyond the heel. With the extremity slightly elevated, the *traction-splint* (e.g., FernoTrac Traction Splint) is placed under the injured leg and brought to rest firmly against the ischial

tuberosity. The heel stand should be unfolded and locked in place to support the end of the splint. This will ensure that the injured extremity will remain elevated once manual traction has been released. *Sager-type devices* (e.g., Sager Emergency Traction Splint) should be placed either against the symphysis pubis or positioned laterally against the greater trochanter of the femur. When the padded end of a Sager-type device is placed in the groin, one should ensure that the genitalia are carefully protected. Once the splint is properly positioned, the thigh strap should be firmly secured.

A harness is then placed around the ankle immediately above the medial and lateral malleoli and attached to the distal end of the traction splint. Traction is then applied gradually to approximately 10% of body weight or a maximum of 22 to 25 lb (10 to 12 kg). The goal is to stabilize the fracture and maintain proper limb alignment; the least amount of force needed to accomplish this should be used. [78] For *Sager-type devices*, the inner shaft of the splint must be extended until the desired amount of traction is achieved, whereas the *FernoTrac Traction Splint* uses a ratchet mechanism to apply traction to the ankle strap.

Before movement, supportive straps are applied around the thigh, knee, and distal leg to vertically stabilize the extremity. After application of the splint, the distal neurovascular status should be rechecked. The patient and splint should be firmly secured on a backboard. Extra care should be taken while moving the patient and when closing the ambulance door to avoid any unnecessary movement. If the splint extends beyond the dimensions of the backboard or stretcher, additional support for the splint may be needed (e.g., short spine board) to ensure the injured extremity remains elevated

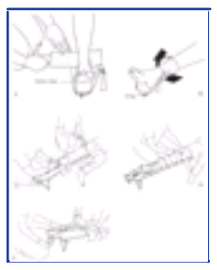

Figure 47-31 Application of the Ferno traction splint. *A–B*, Applying the ankle wrap. *C–E*, Applying the splint. *(Reproduced and modified with permission. Ferno-Washington, Inc., Wilmington, OH.)*

throughout transport. The loss of pulses with application of a traction splint requires that the position of straps and the amount of applied traction be reassessed immediately. Once the splint is applied, the position of the splint and the patient's neurovascular status should be rechecked following any patient movement. Removal of a traction splint should be done in reverse order of application.

Special Considerations

The traction splints in common use can be applied before application of the PASG. However, except for Sager-type devices, application of the PASG over a traction splint is awkward and associated with uneven pressure distribution. Sager-type devices are advantageous in that they can be

Figure 47-32a Application of the Sager emergency traction splint. *A–J*, Standard application.

applied *before* or *after* application of the PASG. In addition, the Sager splint can immobilize both legs using only one splint.

Unless the patient is found in an extremely cold environment, the shoe on the injured extremity should be removed before splinting to allow for assessment of neurovascular status. Furthermore, this facilitates monitoring of changes in color, temperature, or pulse distal to the injury en route to the hospital. The shoe can be removed by cutting the shoelace and pulling forward on the tongue of the shoe. The underlying sock can then be removed using scissors to prevent movement of the fracture site. Removal of the shoe and sock of the noninjured foot will allow comparison of the distal extremities.

The use of Sager-type devices is not recommended in the presence of an associated distal tibia-fibula or ankle fracture in the same extremity. In these circumstances, the amount of traction required to realign the fractured femur can distract the distal fracture site. Similarly, splints that incorporate part of the foot in their design may not be usable in the presence of an unstable foot fracture in the same extremity. A cardboard splint, pillow splint, or the PASG should be considered in these settings.

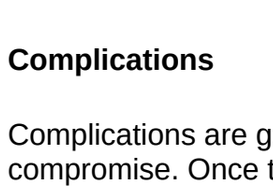

Figure 47-32b

Complications

Complications are generally the result of incorrect application and include ongoing hemorrhage, perineal injury, movement at the fracture site, or neurovascular compromise. Once the fracture site is stabilized, additional traction is unnecessary and potentially dangerous.

Conclusion

A properly applied traction splint will limit hemorrhage and movement associated with femur fractures. Careful monitoring of distal neurovascular status is imperative with the use of these splints.

PNEUMATIC ANTI-SHOCK GARMENT

The PASG, introduced earlier in this chapter, has been the source of much controversy since its introduction to medical practice. [79] In the late 1970s and 1980s, prehospital care providers and ED clinicians used the PASG routinely for patients with shock or hypotension from almost any cause. It was thought particularly useful in the management of blunt and penetrating trauma. However, the 1990s brought about a marked decline in use of the PASG as numerous studies failed to show improved outcome in patients with penetrating or blunt trauma. [80] [81] [82] [83] Today, the PASG is used primarily to stabilize fractured bone ends and control hemorrhage associated with fractures of the lower extremities and pelvis. [84]

Figure 47-33 Assembled pneumatic anti-shock garment and inflation pump. *(Courtesy of the American College of Surgeons, Committee on Trauma.)*

The PASG resembles a pair of high-waisted inflatable trousers. It is constructed from two layers of an opaque, air-tight fabric sewn into three independently inflatable chambers (Fig. 47-33 and Fig. 47-34). It is colored and labeled to signal the internal and external sides.

This device has been called many names. The most common are military anti-shock trousers (MAST), medical anti-shock trousers, pneumatic anti-shock garment (PASG), and G-suit. Because some of these names (e.g., MAST) are also registered commercial trademarks and because pneumatic anti-shock garment is the term adopted by the American College of Surgeons for its Advanced Trauma Life Support course, [84] PASG is used in this chapter to refer to the devices that are currently available.

Background

Regardless of the name, the device has changed little in its design or application since 1903, when Crile created a

Figure 47-34 Pneumatic anti-shock garment applied to a patient and inflated. *(Courtesy of the American College of Surgeons, Committee on Trauma.)*

"pneumatic suit" from a double layer of rubber. [85] One or both legs or the abdominal compartment could be inflated separately with a bicycle pump. He designed the device to manipulate blood pressure during head and neck surgery in the sitting position. The pneumatic suit was subsequently applied to the management of the trauma patient. [86] Leaks in the material, however, inhibited widespread use of the device. The principle of external counterpressure lay dormant until its rediscovery by the military (allegedly at Crile's suggestion) during World War II. [87] Reincarnated as the G-suit, the garment was used to provide momentary compression of up to 100 mm Hg to counteract the cerebral and retinal ischemia (with resultant loss of consciousness or vision) that occurred during certain maneuvers in high-speed aircraft. Medical interest was renewed with investigations performed by Gardner and Dohn. [88] They used a homemade G-suit in patients who were likely to experience postural hypotension. Their device subsequently became commercially available and consisted of a double-layered rectangular blanket wrapped completely around the patient from xiphoid to ankles. For the next decade or more, external counterpressure was used only in the hospital setting and usually as a last resort in cases of uncontrollable postoperative hemorrhage (Table 47-4).

The military G-suit experience during the Vietnam War was the first recorded routine use of the external counterpressure principle in the preoperative stabilization of trauma patients. [89] The Army continued to develop the device until the current pants-like form was achieved. [90] The inventor of the modern-era trousers, B. H. Kaplan, became the first to adapt them to their next area of extensive use: civilian prehospital application by paramedics and emergency medical technicians. [91]

Mechanism of Action

The PASG's mechanism of action has been the object of many experimental studies. Interpretation and comparison of results from these studies require attention to several factors: species of subjects, volume status, design of garment, inflation pressures, methods of hemodynamic measurements, and position of subjects (supine or tilted). The increase in blood pressure that results from application of the PASG is due to at least three effects: enhanced venous return (autotransfusion),

TABLE 47-4 -- Early Uses of the Pneumatic Anti-shock Garment Device

Retroperitoneal bleeding from massive pelvic trauma
Postoperative bleeding from coagulopathy
Postural hypotension
Spontaneous rupture of the liver
Postoperative hemorrhage after:
Abdominal procedures
Nephrectomy

Prostatectomy
Renal biopsy
Tubal ligation
Hysterectomy
Leaking and ruptured abdominal aortic aneurysms
Lower extremity fractures
Placenta previa
Gastrointestinal bleeding
Ruptured ectopic pregnancy

Direct pressure
Fracture stabilization
Effects on bleeding vessels
Decreased transmural pressure

increased total peripheral resistance, and reduced volume loss from control of hemorrhage (Table 47-5).

Enhanced Venous Return

The improvement in blood pressure seen during early PASG device studies was assumed to result from "autotransfusion" of blood from the venous system of the lower extremities and the splanchnic bed to circulation above the diaphragm. Increased central blood volume in humans after PASG application has been demonstrated by changes in thoracic radioactivity after ^{131}I-labeled albumin injection [92] and using a measurement of ^{99m}Tc-labeled albumin.[93] Attempts at quantification of "autotransfusion" in humans using nuclear scanning after radioactive red blood cell injection [94] have estimated that only 150 to 300 mL is actually autotransfused.

Increased Total Peripheral Resistance

Another explanation for the increase in blood pressure is an increase in total peripheral resistance after PASG application. This phenomenon has been well characterized in normovolemic and hypovolemic animal models.[95] [96] Using a hemorrhagic canine model, Niemann and colleagues demonstrated progressive increase in total peripheral resistance with inflation pressures of 40, 60, and 100 mm Hg. [96] Greater increases in total peripheral resistance occurred in the normovolemic group. Cardiac output increased only in the hemorrhagic hypovolemic group.

Control of Hemorrhage

The PASG can serve as a pressure dressing over otherwise uncontrollable internal and external bleeding sites. Acting as a pneumatic splint, the device prevents continued bleeding provoked by motion at fracture sites. This is particularly efficacious with lower extremity long-bone fractures and with retroperitoneal bleeding from pelvic fractures. In the management of hemorrhage associated with major pelvic fractures, the use of the PASG has been recommended as part of the initial management, followed by external fixation, surgery, or selective angiographic embolization. [97] [98] The application of the PASG in the prehospital setting is an efficacious means of initial tamponade and stabilization during the patient transport. One review of pelvic fractures has demonstrated radiographic realignment of an open-book, diastasis-type pelvic fracture after inflation of the PASG. [99] The prehospital application of the PASG, however, has the potential to mask an open-book pelvic fracture.[100] The PASG, combined with other nonsurgical therapy, has also been effective in controlling nontraumatic pelvic hemorrhage in obstetric and gynecologic patients.[101]

Indications

Today, the main indication for use of the PASG is fracture stabilization and hemorrhage control in patients with pelvic or

TABLE 47-6 -- Indications for Pneumatic Anti-shock Garment Application

Hypovolemic shock in selected trauma patients (*see text*)
Stabilization of fractures (pelvic and lower extremity)
"Prophylactic" uses (gastrointestinal bleeding, aortic aneurysm)
Compression of external bleeding
Non-traumatic pelvic hemorrhage

lower extremity fractures (Table 47-6). [84] [98] [99] [102] [103] [104] External pressure exerted by the PASG can improve pelvic alignment in open-book fractures, [95] [105] and provide prompt hemostasis in patients with severe hemorrhage from pelvic fractures. [106] It should be noted that the PASG could potentially cause a compartment syndrome.[105] [107] [108] [109] However, if used as a temporizing measure, the incidence appears to be very low, and most complications can be avoided.

PASG use has not been shown to improve outcome in victims of blunt or penetrating abdominal trauma (especially those with short transport times) and is no longer recommended in this setting.[80] [81] [83] Moreover, PASG use is contraindicated in patients with penetrating thoracic trauma as it has been shown to increase mortality.[82] [110]

While most prehospital providers have abandoned use of the PASG for trauma patients without pelvic or lower extremity fractures, there may be a few circumstances in which it is beneficial. A retrospective study of 142 patients who were severely hypotensive (systolic blood pressure [SBP] less than or equal to 50 mm Hg) as a result of both blunt and penetrating trauma found an improvement in survival with PASG use. [111] In another retrospective study comparing air and ground transport of patients with primarily blunt multi-organ trauma, Moylan and associates identified PASG use as one of several interventions in the air-transported group that were associated with improved survival.[112] Hence, PASG use may be considered for selected patients with blunt or penetrating abdominal trauma and severe hypotension who will require long transport times, especially when prehospital IV fluid therapy is not available.

"Prophylactic" application (with or without inflation) may be helpful in potentially hypovolemic or hypotensive patients. Examples are patients with gastrointestinal bleeding or those with leaking abdominal aortic aneurysms. Ali and associates examined outcomes in 18 patients with ruptured abdominal aortic aneurysms and SBPs

less than 80 mm Hg who were allocated to control and to PASG-treatment arms. The PASG group had a lower average SBP (54 mm Hg vs 76 mm Hg), but had increased survival to the operating room (88% vs 60%), and increased postoperative survival (75% vs 0%). Although the PASG-treatment group appeared more gravely ill, their outcomes were much improved.[113] In another study using a porcine model to study uncontrolled hemorrhage from the abdominal aorta, the group treated with the PASG survived longer than either the control group or the group treated with aggressive volumes of intravenous (IV) fluids. In addition, the use of the PASG was associated with a fourfold reduction in blood loss.[114] If definitive surgery is unavailable or delayed, PASG application may be indicated. In patients with leaking abdominal aortic aneurysms, one should maintain the SBP at approximately 100 mm Hg to avoid contributing to further hemorrhage.[114] [115]

Contraindications

Pulmonary edema, congestive heart failure, and penetrating thoracic trauma are the current absolute contraindications to the use of PASGs (Table 47-7). The increased venous return, decreased vital capacity, and elevation in pulmonary wedge pressure produced by these devices may aggravate preexisting pulmonary congestion.

External pressure applied below the diaphragm can increase the rate of blood loss from thoracic injuries. In a porcine model of thoracic aorta laceration, PASG inflation increased hemorrhage and mortality.[116] A retrospective review of 70 patients with penetrating cardiac wounds demonstrated a significantly lower survival rate in patients treated with PASG.[110] In addition, Mattox and colleagues, in a large clinical trial, found that PASG use coupled with aggressive fluid resuscitation in hypotensive patients with penetrating thoracic injury was deleterious.[82] There has also been a reported case of a traumatic diaphragmatic rupture that was exacerbated by the application of a PASG.[117] Therefore, PASG use in the setting of penetrating thoracic injury is contraindicated.

Other relative contraindications that have been proposed include pregnancy, evisceration of abdominal contents, a foreign body impaled in the abdomen, and lumbar spine injury. For these situations, the leg chambers may be inflated without additional risk, and the relative risks and benefits of inflation of the abdominal binder can then be assessed. Circumferential burns and other injuries that suggest lower extremity compartmental injury also represent significant relative contraindications. Application of external counterpressure elevates the limb compartment pressure and increases muscle ischemia.

Finally, advanced age represents a relative contraindication to PASG use. PASG application and inflation were associated with increased mean arterial pressure and total peripheral resistance in elderly patients without preexisting cardiac disease. Diminished left ventricular function, stroke volume, and cardiac output were observed and were greatest when higher inflation pressures were used and inflation times exceeded 10 to 15 minutes.[118] There are a number of situations in which PASG use has been discouraged by early authors (e.g., head injuries, cardiac tamponade, and tension pneumothorax). Although few data address these circumstances, some general review articles have discussed the judicious use of external counterpressure in these controversial settings.[119] [120] [121]

Equipment

PASGs are manufactured in two different sizes: adult and pediatric. Some features include x-ray transparency, perineal

TABLE 47-7 -- Proposed Contraindications to Pneumatic Anti-shock Garment Application

	Advanced age

opening, and the ability to fit over most and under some (e.g., Sager-type) traction splints. The trousers come with or without a gauge for monitoring air pressure. Advantages of using models with pressure gauges include the ability to (1) assess PASG inflation pressure during deflation for removal; (2) monitor garment pressure during air transport of the patient (in unpressurized aircraft); (3) evaluate PASG pressure in settings of extreme temperatures; and (4) detect damaged air chambers, tubing, and the like.

Procedure

Before PASG application, it is useful to inspect the device and to establish the proper orientation (Fig. 47-35). The device is labeled and color-coded to identify the inside and outside. If there is potential for a cervical spine injury, proper cervical spine stabilization should be maintained throughout the garment application process. The patient can be logrolled onto the opened garment. Alternatively, with one person standing on either side and elevating the patient's legs, the garment can be slid beneath to the buttocks. Then the patient's hips are elevated slightly, and the upper border of the garment is placed at the costal margin. The medial portion on each leg binder is brought between the legs, and the Velcro fasteners are closed over each leg and over the abdomen.

After device application, the foot pump hoses are attached to the stopcocks, and the foot pump is used to inflate the two leg compartments and then the abdomen. The operator can accomplish inflation faster if the compartments are initially filled by blowing into them. After resistance to filling is met, the pump becomes more efficient at increasing trouser pressures.[122] The compartments should be inflated until the SBP reaches 100 mm Hg, the pop-off valves engage, or the Velcro straps begin to snap. The pressure-relief valves are set at 104 mm Hg to prevent overinflation. Because the PASG is most often used to treat patients with pelvic fractures, all three compartments are typically inflated. In the rare event that it is used for hypotension, Hanke and associates found no difference in redistribution of blood volume between simultaneous and sequential inflation of the leg and abdominal compartments.[123] Jennings and coworkers similarly found no hemodynamic benefit to simultaneous device inflation.[124] Therefore, it seems prudent when using the device for hypotension to inflate the leg compartments first and then check the blood pressure. If an adequate blood pressure is obtained, the abdominal compartment does not need inflation. If the blood pressure is inadequate, the abdominal compartment is inflated. Blood pressure and pulse should be closely monitored during the procedure, and inflation should be stopped if the SBP exceeds 100 mm Hg.

The PASG alone can passively splint lower extremity fractures. Of the commonly available traction devices, only the Sager traction splint can be applied after the trousers are in place and inflated. The Sager splint can be used either inside or outside the device to splint one or both legs at the same time. The Ferno traction splint, Hare traction splint, and the Thomas splint are significantly more awkward to use with the PASG inflated. These traction splints also present some risk of damage to the trousers themselves and result in uneven application of circumferential pressure. It should be noted that the application of traction in combination with external counterpressure exacerbates compartmental pressures in the lower extremities.[125]

Figure 47-35 Pneumatic anti-shock garment application. *(Courtesy of the American College of Surgeons, Committee on Trauma.)*

Since PASGs are used primarily in patients with pelvic and lower extremity fractures, inflation is generally performed rapidly. Titrating the inflation pressure to achieve an SBP greater than 100 mm Hg is rarely necessary any longer. If the PASG is equipped with gauges, they should be checked periodically for accuracy. Most side effects and complications of these devices are proportional to the magnitude of PASG pressure and duration of pressure application. Most animal experiments and some clinical studies have suggested that hemorrhage control (presumably control of venous bleeding) in otherwise stable (often postoperative) patients is often accomplished with less than 40 mm Hg of inflation pressure.[126] The ultimate goal is to achieve fracture stabilization and hemorrhage control, or in selected hypotensive trauma patients, an SBP of approximately 100 mm Hg at the lowest inflation pressure possible.

For patients requiring pelvic stabilization, the PASG should only be deflated when a more definitive means of orthopedic stabilization becomes available. In other cases, deflation may be considered when the combination of PASG and other resuscitative measures (e.g., fluids, hemorrhage control) has resulted in restoration of satisfactory vital signs. The gradual deflation procedure outlined later in this section should be followed. The presence of any contraindications to continued use (e.g., congestive heart failure, renal disease, pulmonary disease) should also be considered. The presence of a coagulopathy may be a relative contraindication to removing the device.

If emergent surgical intervention is indicated, the operating room may be the best place to deflate the PASG. Once the anesthesiologist is prepared to monitor the patient and the surgeon is prepared to operate, the abdominal compartment can be slowly deflated. The leg compartments can remain inflated until any internal hemorrhage is controlled. In most situations, after adequate volume resuscitation and hemorrhage control, slow and systematic PASG deflation may be safely performed in the ED.

The PASG should be deflated gradually. Rapid deflation of the PASG in the hypovolemic patient can result in a

catastrophic drop in blood pressure. The hemodynamic changes seen during deflation result from a rapid reduction in left ventricular afterload followed by a decrease in preload.[127] This process may be exacerbated by the sudden release of lactic acid and other vasoactive chemicals pooled in the abdomen and the lower extremities.[128] Hence, deflation, particularly in the setting of prolonged PASG use, should be approached with caution.

The patient's hemodynamic status must be reassessed with each deflation attempt in order to identify any deterioration in the patient's condition. Deflation of the abdominal compartment should occur first. A small amount of air is released and the patient's blood pressure is then rechecked. If the SBP falls more than 5 mm Hg, deflation should be stopped immediately, and additional IV fluids should be infused until the SBP is restored. This process should be followed throughout the entire deflation procedure of the PASG. After the abdominal compartment is deflated, the same procedure should be followed for each individual leg compartment.

Complications and Disadvantages

A number of specific adverse effects have been noted in association with PASG use (Table 47-8). In addition, patients with penetrating abdominal and thoracic trauma whose management included PASG use in conjunction with vigorous prehospital fluid resuscitation reportedly had an increased mortality rate when compared with patients treated with fluid resuscitation alone in one urban prehospital setting. [80] [82] As noted previously, the use of PASG in patients with penetrating truncal injuries in the setting of rapid transport times or IV fluid therapy does not appear to be warranted.

Clinical experience has shown that the major life-threatening complication resulting from the use of the PASG in hypovolemic patients is sudden and severe hypotension resulting from precipitous removal of the device in the absence of adequate fluid resuscitation. [89] [129] Although ED

clinicians and emergency medical technicians are well aware of the problem, many consultants are not. The knowledgeable emergency clinician should prevent the consultants from making the potentially disastrous mistake of rapidly removing the PASG.

Abdominal binding invariably produces subjective effects on respiration; alert patients frequently complain of shortness of breath when the abdominal compartment is inflated. However, McCabe and colleagues found no changes in inspiratory and expiratory reserve volumes, maximum breathing capacity, or tidal volume in their volunteers.[130] Similarly, Batalden and coworkers found no pulmonary complications in 10 patients with external counterpressure garments who underwent positive-pressure ventilation for 24 to 48 hours. [131] However, Burdick and colleagues found atelectasis, pulmonary edema, or pneumonia in 14 of 28 similar patients.[132] Cogbill and coworkers demonstrated mild impairment of pulmonary function in healthy individuals and those with airflow obstruction when the PASG was inflated.[133] The impairment was restrictive rather than obstructive and was not clinically significant with inflation pressures less than 50 mm Hg. Some studies suggest

that impaired pulmonary function results from mechanical binding of the thorax and decreased excursion of the diaphragm. [130] [134] Newer designs of the device incorporate smaller abdominal compartments, which should not be applied at or above the costal margin, and have resulted in less restriction of vital capacity. [130] In general, investigators concerned about respiratory compromise have recommended careful attention to arterial blood gases combined with controlled positive-pressure ventilation in those patients requiring prolonged external counterpressure. [132] [135]

A number of case reports document some infrequent but serious complications with the application of the PASG.

Lower extremity compartment syndromes following use of PASG have been reviewed elsewhere.[136] Increased pressure within the limits of a fascial compartment results in impaired microcirculation. The compartment pressure under the PASG is dependent on the PASG inflation pressure, the mean arterial pressure, and the application of passive traction. [125] [137] During hypotension, with full PASG inflation, the compartment pressure may exceed the mean arterial pressure. [137] Many factors contribute to the development of a compartment syndrome, including prolonged shock, inflation pressure (and duration of inflation), reperfusion edema, and local tissue injury. [136] It is not completely understood which of the multiple factors are most significant in the compartment syndrome associated with PASG use. Some cases are related to a lower extremity fracture with prolonged application of PASG, [109] but other cases have occurred in the absence of lower extremity injury.[138] Improper deflation technique (i.e., leaving the abdominal compartment inflated after deflation of the extremity compartments) may facilitate the syndrome. [107] The overall frequency of this complication seems quite low. In their review of 1120 patients, Wayne and MacDonald reported no cases of compartment syndrome. [139] Mattox and associates found an incidence of anterior compartment syndrome in approximately 1% of their PASG patients and none of the patients without PASG. [81]

Skin breakdown at pressure points with prolonged use has prompted the suggestion to pad bony prominences.[131]

Diaphragmatic herniation has been reported following PASG inflation.[117] A sudden deterioration in blood pressure or respiratory status following PASG inflation should alert the clinician to this possibility. Using a porcine model of diaphragmatic injury, Ali and Qi demonstrated a significant increase in mortality rate after PASG as a result of cardiorespiratory deterioration caused by the increase in intra-abdominal pressure. [140] If significant herniation of abdominal contents into the thoracic space has occurred, deflation of the device may not fully resolve the clinical deterioration.

Metabolic acidosis may occur with prolonged use of the PASG. Close monitoring of the arterial blood gas and correction with IV fluids and bicarbonate as needed should correct the potential problem.

Environmental Influences on Device Pressures

With the current popularity and availability of helicopter ambulance transport, the role of Boyle's law (i.e., the volume of gas is inversely proportional to its pressure) must be reemphasized.[141] [142] As the helicopter rises, the air in the suit expands, increasing the trouser pressure. Decreasing altitude has the opposite effect. Similarly, as ambient temperature increases, trouser pressure rises, and vice versa. This is more of a concern with higher altitude fixed-wing airplane transports than with helicopter transports. Most helicopter transports occur at sufficiently low altitudes that the effects of altitude are not of concern, but when the "optimal" inflation pressure is determined at the scene of the injury, changes produced by movement into the controlled climate of the ambulance or hospital must be predicted and recognized.

An Alternative to the Pneumatic Anti-shock Garment for Stabilizing Pelvic Fractures

Based on some of the literature cited earlier, many prehospital and hospital emergency care providers have chosen to no longer have a PASG available. Thus, an alternative means of emergent pelvic stabilization is needed. A simple and cost-effective alternative is wrapping the pelvis with bed sheets (Fig. 47-36). In a recent study of hemodynamically compromised patients with a biomechanically unstable pelvic fracture, Biffl and associates demonstrated an immediate reduction of the pelvic volume by wrapping the pelvis with a sheet and binding the knees and ankles. [143] This simple maneuver can be performed quickly and easily in the ED, and is recommended for use by prehospital personnel to help stabilize patients for transport. [143]

Conclusion

The PASG is a useful adjunctive for temporary stabilization and hemorrhage control in patients with pelvic or lower fractures. When the garment is used, improvements in blood pressure, pulse, and pelvic fracture stabilization are often dramatic. If the PASG is not available, wrapping the pelvis with a sheet and binding the knees and ankles is a simple and inexpensive alternative. Although the PASG is not helpful in the management of urban trauma victims, it may be indicated

Figure 47-36 Stabilization of a pelvic fracture using a sheet.

for a select group of patients with blunt and penetrating abdominal trauma and severe hypotension who require long transport times, especially when prehospital IV fluid therapy is not available. It may also be helpful when surgery is unavailable or delayed in patients with a leaking abdominal aortic aneurysm.

HELMET REMOVAL

Although originally developed for protection of the head during combat, helmets are commonly worn by motorcyclists, athletes in many sports (e.g., football, hockey, lacrosse, motorsports), and individuals participating in a host of recreational activities (e.g., kayaking, rollerblading, skate-boarding). Hence, emergency care providers must be able to remove a helmet safely. The use of helmets has been shown to reduce the incidence and severity of head injuries associated with motorcycle crashes.[77] [144] [145] Most modern helmets consist of an inner layer of foam material covered by a hard plastic shell. Helmets may be modified with additional padding so that they conform tightly to the individual's head. Although earlier studies [77] [146] suggested that the use of motorcycle helmets might be associated with an increased incidence of cervical spine injury, this concern has not been substantiated. [145] [147] [148]

Helmet removal requires a careful, methodical approach to avoid compounding a suspected injury to the spinal cord. [149] Fluoroscopic studies have detected spinal motion even in the best of circumstances when removing hockey and football helmets. [150] [151] Prehospital care providers should understand that they can achieve proper cervical spine immobilization of an athlete wearing a well-fitted helmet and achieve adequate airway control by removing only the facemask. [152] A proper fitting helmet should hold

the head securely in a neutral position of alignment, minimizing any motion, provided that the athlete is wearing shoulder pads. Therefore, the first priority of field management is to stabilize the cervical spine and keep the helmet on, if possible.

Indications and Contraindications

When dealing with athletes and recreational helmet users, two schools of thought predominate with regard to helmet removal in the prehospital setting. One theory suggests that removal of helmets is rarely necessary, since the helmet itself provides for excellent spinal immobilization. The other philosophy recommends routine removal of the helmet so that the patient is completely exposed and the rescuer has full access to the head and neck for airway management, hemorrhage control, and cervical spine stabilization. This controversy prompted the formation of an Inter-Association Task Force for the "Appropriate Care of the Spine-Injured Athlete" in November 1999. The task force consensus guidelines recommend helmet removal only in the following situations [153] :

- If the helmet and chin strap fail to hold the head securely, such that immobilizing the helmet does not also adequately immobilize the head.
- If the helmet and chin strap design prevent adequate airway control, even after removal of the facemask.
- If the facemask cannot be removed after a reasonable amount of time.
- If the helmet prevents proper immobilization for transport.

If the helmet is not removed, cervical spine immobilization can usually be maintained with a properly fitting helmet by using tape, foam blocks, and a backboard. If it becomes necessary to remove the helmet, the shoulder pads (if present) should be removed at the same time to avoid hyperextension of the cervical spine. [150] [152] In the ED, stable patients typically undergo imaging studies of the cervical spine before helmet removal. However, a study by Davidson and coworkers found that the helmet and shoulder pads worn by football players interfere with cervical spine radiographic evaluation. They recommend incorporating procedures for controlled and cautious removal of equipment before initial radiographic evaluation. [154]

In contrast, motorcycle helmets often must be removed in the prehospital setting. [44] The motorcycle helmet with a full-face guard makes it very difficult to assess and manage the airway and to evaluate injuries to the head and neck. In addition, the helmet's large size and design may cause significant neck flexion if left in place when the patient is placed on a backboard.

The only absolute contraindication to helmet removal is neck pain or paresthesias associated with the procedure. Relative contraindications to helmet removal include unfamiliarity with the technique and lack of sufficient assistance. [147]

Procedure

In 1980, the American College of Surgeons endorsed the helmet removal technique discussed in this chapter. [155] Proper removal of a helmet requires at least two individuals along with manual stabilization of the cervical spine throughout the procedure. [147] [155] Although a one-person technique of helmet removal has been described, it is best for at least two rescuers (preferably three or four) to remove the helmet and shoulder pads, especially in the setting of an unconscious or uncooperative patient.

If applicable, the facemask should be removed and not retracted. Studies indicate more head and neck movement with this procedure than with complete facemask removal.[152] One rescuer establishes neutral position by placing his or her hands on each side of the helmet with the fingers on the victim's mandible (Fig. 47-37). The second rescuer then cuts or releases the chin strap and assumes manual in-line stabilization by placing one hand on the patient's mandible and the other hand on the occiput. The first rescuer then gently removes the helmet by grasping it at the base and expanding it laterally to clear the ears. Some helmets may need to be titled backward to allow the chin guard to clear the nose. The second rescuer must be prepared to assume the weight of the head as the helmet is removed. As soon as the helmet is removed, it is essential to place under the head a firm cushion or support thick enough to prevent hyperextension of the cervical spine. [149] The first rescuer then reassumes the responsibility for manual in-line stabilization and neutral positioning while the second rescuer applies a rigid extrication collar. Both rescuers should avoid in-line traction during helmet removal to reduce the risk of subluxation or distraction of an unstable cervical spine. [19]

In a volunteer study, Meyer and Daniel have shown limited motion of the cervical spine with this removal technique. [156] The addition of a folded sheet or jacket placed behind the patient's shoulders was also found to help limit any cervical motion associated with helmet removal. [156] In contrast, Aprahamian and colleagues demonstrated that manual helmet removal adversely affected a surgically created unstable cervical spine injury in a cadaver model. They recommended the use of a cast-cutter saw to divide the helmet into two pieces in the coronal plane and thereby facilitate removal. Following division of the helmet shell, the inner foam material may be cut with a scalpel or other sharp blade. Although this approach does provide an alternate method of removing the helmet, the intense vibrations produced during use of the cast cutter may exacerbate an underlying spinal injury. In addition, the technique would be slow and difficult with modern, well-fitting, high-quality helmets.[147] When necessary, removal of the full-face guard can be accomplished using a cast-cutter or other saw permitting rapid access to the airway without aggravating a possible cervical spine injury. This can then be followed by slow and careful removal of the entire helmet. [147] Donaldson and colleagues demonstrated in a cadaveric model that even in the best clinical setting there is a significant amount of motion during helmet and shoulder pad removal. [157] It is still unclear whether the results of any of these studies are applicable to patients with cervical spine injuries.

Complications

Underlying cervical spine injuries may be exacerbated by failure to adhere to proper helmet removal techniques. Although no controlled studies have demonstrated the safety of manual cervical stabilization, its efficacy during endotracheal intubation of the trauma patient suggests that minimal movement is likely during helmet removal.[158]

Conclusion

Airway management and cervical spine stabilization may be complicated by the presence of a helmet. If necessary,

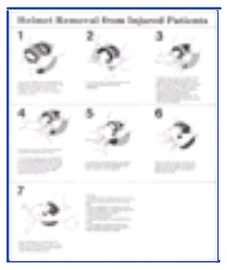

Figure 47-37 Helmet removal technique. *(Modified from McSwain N: Techniques of helmet removal from injured patients. Bull Am Coll Surg 65:20, 1980.)*

prehospital helmet removal can be accomplished in a safe and effective manner using a two-person technique. Current guidelines call for the removal of both the helmet and shoulder pads together in a controlled ED setting by qualified clinicians.

Chapter 48 - Management of Amputations

William C. Dalsey
Jeffrey Luk

"The first person caring for an injured hand will probably determine the ultimate stage of its usefulness." [1] Consequently, rapid and appropriate emergency care of a patient with an amputated part is crucial to the salvage and preservation of function. This chapter discusses the acute care of amputated parts before they are replanted and specifically addresses the management of distal digit amputations and dermal "slice" wounds.

Amputation may be partial or complete. Injuries with interconnecting tissue between the distal and proximal portions, even if there is only a small piece of bridging skin, technically are considered incomplete (or partial) amputations. Complete amputations are replanted, whereas partial amputations are revascularized. This distinction is arbitrary; for emergency clinicians, treatment for both injuries is very similar. The prognosis and outcome of both types of amputations are similar, although partial amputations often have better venous and lymphatic drainage, and functional recovery may be more complete if there is less anatomic damage.

The peak incidence of traumatic amputations occurs between the ages of 20 and 40 years, [2] [3] and men predominate over women at a ratio of 4:1. Local crush injuries are the most common mechanism of injury, and sharp guillotine amputations are the least common. [4] [5] [6] Partial amputations occur as often as total amputations. [7] Power saws and lawn mowers are frequently the instruments of destruction. [7] Proximal amputations are less common than distal amputations.

The media have exaggerated somewhat the success of replantation and have often generated unrealistic expectations from the public. The technical limitations of successful repair of vessels that are less than 0.3 mm in diameter usually preclude replantation of digits distal to the distal interphalangeal joint. [8] Successful revascularization of amputated parts often ensures viability, but neurologic, osseous, and tendinous healing are critical for ultimate function. If there is incomplete neurologic recovery, limited range of motion, and intolerance to cold, the replanted part may have little functional value for the patient. Rehabilitation from replantation surgery may be prolonged, often requiring more than 1 year and repeated surgical procedures. The emergency clinician should be aware of the limitations of replantation surgery and should not encourage unrealistic expectations in injured patients or their families.

BACKGROUND

The possibility of restoring viability and function to traumatically severed parts has fascinated clinicians for centuries. Clinicians have attempted to replant parts with little more than a few sutures and secure bandaging and occasionally have had spectacular results. One of the earliest medical reports was by Fiorvanti, who in 1570 reported the successful replantation of a soldier's nose, which was severed by a saber, after first cleansing it with urine and then carefully bandaging it. [9] [10] In 1814, Balfour reported the successful replantation of a finger, which was severed by a hatchet, [11] using only meticulous alignment and secure bandaging.

The ability to consistently replant amputated parts awaited the development of modern microvascular surgical techniques. The first reported successful upper limb replantation was by Malt and McKhann in 1962. [12] Later that year, a successful replantation of a hand and arm was reported by Chen and Pao. [13] Developments in microsurgical techniques, advanced optics, and microsurgical instruments have created the ability to consistently replant amputated parts with a high degree of success. Since 1965, when Kleinert and Kasdan [14] reported the first successful microvascular anastomosis of a digital vessel, there have been several large series of replantations, with success rates ranging from 70% to 90%. [6] [7] [15] [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] [27] To the original pioneers in replant surgery, survival of the replanted tissue was the criterion for success, but with further technological and surgical refinements, today's surgeons emphasize functional recovery as well as viability. The replantation of a part that is painful or useless or that interferes with function is a disservice to the patient and is less desirable than early restoration of function without replantation.

INDICATIONS

Preservation of the amputated part is generally indicated when replantation or revascularization is a potential therapeutic method for care of the injured part. Revascularization and reanastomosis of partially and completely amputated parts should be provided when there is hope of preservation or restoration of function. Aesthetic considerations, patient avocations, and occasional religious or social customs may also influence the decision to proceed with surgery. [16] [28] [29] Ultimately, the decision must be reached by both the operating microsurgical team and the patient after a rational explanation of potential results and successes.

Indications for replantation of fingers and hands have been proposed and are generally accepted, although they should not be applied rigidly to all circumstances. Successful functional recovery is more likely in distal than in proximal extremity amputations and more likely in multidigit amputations, single-digit thumb amputations, or transmetacarpal amputations.[30] [31] Generally these are indications for replantation (Table 48-1). Single digits that are both proximal to the distal interphalangeal joint and distal to the flexor digitorum superficialis may be replanted successfully, with good functional recovery.

Successful replantations have been reported in patients from the ages of 1 to 84. [32] [33] There are no fixed age limits for replantation, although particularly good results have been reported in children owing to their regenerative capacity and adaptability to rehabilitation. [2] [34] [35] [36] [37] [38] The decision to replant is made on a case-by-case basis by the microsurgical team, who must weigh all the factors involved.

CONTRAINDICATIONS

There is no contraindication to managing the amputated part and stump as though replantation were going to occur, even

TABLE 48-1 -- Replantation of the Amputated Extremity

Indications
Young stable patient
Thumb
Multiple digits injured
Sharp wounds with little associated damage
Upper extremity (children)
Absolute Contraindications
Associated life threats
Severe crush injuries
Inability to withstand prolonged surgery
Relative Contraindications*
Single digit, unless thumb
Avulsion injury
Prolonged warm ischemia (=12 hr)
Gross contamination
Prior injury or surgery to part
Emotionally unstable patients
Lower extremity

*If the victim is a child or if there are multiple losses, salvage replantations are attempted, and the relative contraindications are ignored.

when replantation is considered unlikely by the emergency clinician. In addition, the requirements of the amputated part and stump can often be handled by ancillary personnel during resuscitation and transportation of the patient. However, the care of the entire patient must take precedence over that of the amputated part. Contraindications to replantation are listed in Table 48-1 and are discussed in the following sections. Note that even when replantation is contraindicated, tissue (skin, bone, tendon) from the amputated part may be useful in restoring function to other damaged parts. *Never discard amputated tissue until all possible uses of the severed parts are considered.* For example, even though an amputated fingertip is not suitable for replantation, the skin may be an ideal donor source for a skin graft to the stump.

GENERAL CONSIDERATIONS

Mechanism of Injury

The potential for successful replantation in terms of survival as well as useful function is directly related to the mechanism of injury. Guillotine injuries, which are sharp, are the least common, but have the best prognosis owing to the limited area of destruction. Crush injuries, which are the most common, produce more tissue injury and therefore have a poorer prognosis. The avulsion injury has the worst prognosis because a significant amount of vessel, nerve, tendon, and soft tissue injury invariably occurs. [2] [5] [6] [7] [39]

Ischemia Time

The time that an amputated part can survive before replantation has not been determined. After 6 hours, additional delay may decrease the success rate of revascularization and lead to diminished function. Skin, bone, tendons, and ligaments tolerate ischemia much better than do muscle and connective tissue. Therefore, as a general rule, the more proximal the amputation, the less ischemia time the amputated part can tolerate. Attempts to extend viability during ischemia have shown that the most important controllable factor is the *temperature* of the amputated part. Warm ischemia may be tolerated for 6 to 8 hours. [40] When the part is cooled properly to 4°C, 12 to 24 hours of ischemia may be tolerated with distal amputations. [2] [5] [7] [15] [16] [17] [19] [20] [21] [22] [23] [24] [25] [26] [27] [39] [41] [42] There is a report of a successful digital replantation after 33 hours of cold ischemia. [42] It has been postulated that hypothermia may limit metabolic demand, thereby preserving intracellular energy. [43] [44] [45] [46] Other investigations suggest that the effect is due to the retardation in development of an acidotic pH. [47] Hypothermia may also prevent the no-reflow phenomenon that can follow low-flow states. [48]

Delay in the replantation of proximal arm and leg amputations containing significant amounts of muscle tissue can lead to the buildup of toxic products. In such cases, when blood supply is restored, the absorbed toxins have been reported to cause respiratory failure, renal failure, cardiovascular collapse, and even death. [29] [41] [49] [50] [51] [52] [53] [54]

Perfusion techniques such as those used in organ transplants to extend anoxic time have not yet been developed but are under investigation. In the past, surgical teams used intraoperative perfusion as a technique to help cool the amputated part. The benefits of intraoperative perfusion with cold hypertonic solutions are currently being investigated. Perfusion should not be attempted by emergency clinicians. The risk of damage to vessels as well as the potential delay in care and in rapid transport of the patient and the amputated part override the theoretic benefits of emergency department (ED) cold perfusion at this time. [52] [55]

ASSESSMENT OF THE PATIENT

The initial care and treatment of the patient who has had a body part amputated are the same as those for any trauma patient. The clinician must not be distracted by the amputated extremity or the excitement of others from assessing and stabilizing the patient's airway, breathing, and circulation. Amputations are generally not life-threatening injuries, and other potentially more serious injuries must first be assessed and treated. Hemorrhage from amputated limbs is often limited by the retraction and spasm of severed vessels. Therefore, partial amputations may result in more serious hemorrhage than if the vessels were totally severed. Usually hemorrhage can be controlled adequately with direct pressure and elevation. Vascular clamps and hemostats have no role in the ED management of these injuries and may cause additional injury that may make replantation impossible. A proximally placed blood pressure cuff inflated 30 mm Hg above systolic pressure can be used for short periods of time (<30 minutes) to control severe bleeding, if necessary.

After the initial primary assessment and treatment and subsequent stabilization of the patient, care of the stump and amputated part can be initiated safely. In addition to the general history obtained from all trauma patients, particular attention should be focused on the exact mechanism of injury, the time and duration of injury, handedness, allergies, medications, illness, prior injury to the affected part, care of the stump and amputated part before arrival in the ED, occupation, avocations, and tetanus history.

Tetanus prophylaxis and broad-spectrum systemic antibiotic therapy (e.g., cephalosporins) should be initiated; however, the role for routine prophylactic antibiotics has not been proven. Analgesic medications may be necessary, especially

with crushing injuries, for managing patient discomfort. The dose of IV opioids should be titrated to the clinical condition. In fingertip amputations, digital or regional nerve blocks are ideal for pain relief but may make functional and neurological evaluation by a consultant impossible. Some clinicians recommend the early use of aspirin, low-molecular-weight dextran, or both for amputation patients, but such attempts to maintain small vessel perfusion are controversial and have not proved efficacious in preoperative treatment.

Amputation patients often experience denial, shock, disbelief, and feelings of hopelessness about their injury; some have even become suicidal. Patients should be treated with supportive and realistic reassurance, but unrealistic medical promises should be avoided. It is important that the emergency clinician (or other non-replantation specialist) does not speculate on the specifics of the ultimate prognosis.

Examination of the stump may be brief and should primarily be an assessment of the degree of damage to the surrounding tissue. Gross contamination can be removed by irrigation with normal saline. Local antiseptics, especially hydrogen peroxide or alcohol, should *not* be used because they may damage viable tissues. Similarly, tissues should not be manipulated, clamped, tagged, or further traumatized in any way. It is important to assess the degree of contamination, the level of injury, and any concomitant injury, such as crushing or multiple levels of injury or amputation. The amputated part should also be examined for the degree of tissue injury, contamination, and possible distal injuries. Radiographs of the amputated part and proximal stump to the level of at least one joint proximal to an extremity injury should be obtained. Preoperative laboratory studies and IV access in an uninjured extremity should also be initiated.

The neurological status of the stump or distal extremity in partial amputations should be assessed by pinprick and two-point discrimination tests. The presence of sweat may indicate autonomic-neurologic functioning. Vascular competence can be assessed by noting the color, temperature, capillary refill, and presence of pulses. An Allen test at the wrist or a modified Allen test at each digit may aid in determining the existence of an arterial injury (see Chapter 20). The neurovascular status should be carefully and clearly documented in the medical record. Motor and tendon function should be evaluated immediately. The regional microvascular resource center should be contacted as soon as possible to arrange transportation and to provide adequate time for mobilization of the replantation team.

CARE OF THE STUMP AND AMPUTATED PART

The stump can be evaluated, and primary care can be rendered during the secondary assessment of the trauma victim (Table 48-2). If replantation is proposed, the goals of initial care include control of hemorrhage and prevention of further injury or contamination. All jewelry should be removed. The stump should be irrigated with normal saline to remove gross contamination. Debridement and dissection should be done by a specialist. Do not clamp arterial bleeders. The stump wound should then be covered with a *saline-moistened* sterile dressing to prevent further contamination and to limit damage from desiccation. The stump should be splinted for protection and for the prevention of further injury from concomitant

TABLE 48-2 -- Axioms for Care of Amputations

Do's	Dont's
Splint and elevate	Apply dry ice or freeze tissue
Apply pressure dressing	Place tags on tissue
Protect from further trauma or injury	Place sutures in tissue
	Sever skin bridges
Protect from further contamination	Initiate perfusion of amputated part
Provide analgesia	Place tissue in formalin or water
Supply tetanus prophylaxis and antibiotic therapy	
Obtain radiographs	

fractures or compromise of blood flow owing to change in position. Splinting and elevation may reduce the extent of edema and help control bleeding.

Care of the amputated part follows the same general guidelines as that for the stump. Gross contamination can be eliminated by irrigation with saline. All jewelry should be removed. The amputated part should be handled minimally to prevent further damage and should be wrapped in a salinemoistened sterile dressing. *Direct prolonged immersion in saline or hypotonic fluids should be avoided* because it may cause severe maceration of tissue and may make replantation more difficult technically. The amputated part should be cooled as soon as possible. The ideal temperature is 4°C. Care must be taken to prevent the freezing of tissues. Amputated parts *should not be placed directly on ice* because tissue that is in direct contact with the ice may freeze. Currently, the recommended method for cooling amputated parts is to place the part, which is wrapped in saline-moistened gauze, in a watertight plastic bag and immerse the bag in a container of ice water (Fig. 48-1). A guideline is to use half water and half ice; excessive ice should be avoided. Cooling coils and refrigeration devices have occasionally been used but are generally not available and offer no significant advantages. The tissue containers should be labeled with the patient's name, the amputated part contained within, the time of the original injury, and the time that cooling began.

Treatment for *partial amputations* with vascular compromise is the same as that just described. Clean the wound with normal saline irrigation. Place a saline-moistened sponge on the open tissue, and wrap the injury in a sterile dressing, incorporating a splint to protect it from further injury. Ice packs or commercial cold packs should be applied over the dressing to cool the devascularized area (Fig. 48-2).

SPECIAL CONSIDERATIONS

Hand Function

Hand function is often determined in part by pinch and grasp functions. If the index finger is removed, the pinching function of the index finger is adequately provided by the middle finger. Power in grasping and gripping is mainly considered an ulnar function of the fourth and fifth digits. An effective grip that provides the ability to hold a variety of objects is a central function of the ring and middle fingers. In addition to its function in pinching, the thumb is the major opposing

Figure 48-1 Evaluate the patient's condition to ensure that resuscitation is not necessary before transfer. *A,* The wound should be rinsed with saline solution. *Do not scrub or apply antiseptic solution to the wound.* Apply saline moistened sterile dressing, wrap in Kling or Kerlix for pressure, and elevate. *B,* The amputated part should be rinsed with saline. *Do not scrub or apply antiseptic solution to the amputated part.* Wrap it in moist sterile gauze or a towel, depending on its size, and place it in a plastic bag or plastic container. *Do not place the amputated part directly in saline. C,* The part is then put in a container, preferably Styrofoam, and cooled by separate plastic bags containing ice or in a container of ice water. Do not pack the bagged, injured part in ice, but it can be immersed in half water, half ice. *(From Hand Trauma: Emergency Care. Baltimore, MD, Emergency Services.)*

force for successful grip and grasp. The thumb is the most important digit for adequate hand function, and its loss results in 40 to 50% disability. Such disability requires aggressive attempts to replant amputated thumbs. If this is impossible or unsuccessful, secondary alternatives are pollicization of other digits or toe transfers.[56] [57] [58] [59] [60]

Lower Extremity Amputations

There are few reports of successful replantation of amputated parts of the lower extremity. [61] [62] Indications for replantation of amputated parts of the lower extremity are different from those for replantation of amputated parts of the upper extremity. The goal of all replantation is restored function. If this

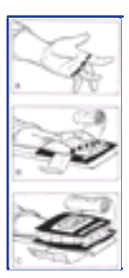

Figure 48-2 For a *partial amputation*, rinse with saline (*A*); then place part(s) in a functional position, apply a saline moistened sterile dressing, and splint and elevate *(B)*. Apply coolant bags to the *outside* of the dressing *(C)*. *Do not scrub or apply antiseptic solution to the wound.* Control any bleeding with pressure. If a tourniquet is necessary, place it close to the amputation site. *(From Hand Trauma: Emergency Care. Baltimore, MD, Emergency Services.)*

cannot be achieved, a patient is substantially better off with a prosthesis.

The lower extremity is primarily used for weight bearing and allows the individual to ambulate. Lower limb prostheses, especially those used below the knee, are well tolerated and functional. Prostheses provide a secure stance and permit locomotion. Lower extremity replantation generally requires skeletal shortening, and distal nerve regeneration is often imperfect. Both deficits may produce dysfunction. A patient with a replanted lower extremity with significant shortening and without sensation would function better with a prosthesis. This is not necessarily true of someone with an upper extremity replant. For these reasons, lower limbs are not generally replanted except under ideal circumstances, usually in children, although there have been documented cases of successful lower extremity replantation in adults. [61] [62] The final decision regarding replantation should be left to the replantation team.

Transplants of Upper Extremities

Advances in controlling tissue rejection have led to attempts at transplanting cadaveric hands in patients with complete amputations. This has been attempted in several patients with encouraging results. Many of the transplants have been

temporarily viable and those that have not been rejected have demonstrated both enervation and functional recovery. Patients must take immunosuppressive medications to prevent transplant rejection. These medications appear to facilitate reenervation and are being investigated as possible adjuncts for replantations.

Fingertip Amputations and Dermal "Slice" Wounds

Proper treatment of distal fingertip injuries is controversial. Fingertip amputations often heal by normal wound contracture, but occasionally this practice may result in the loss of functional ability to palpate. The basic goals of treatment are to provide tissue coverage, an acceptable cosmetic result, and an early functional recovery. In distal amputations in which the wound area is less than 10 mm^2 , this is not a problem (Fig. 48-3 (Figure Not Available)). Larger dorsal wounds also heal well by secondary intention. The challenging problem of fingertip injuries occurs when loss of skin and soft tissue from the fingerpad is significant. Volar skin is unique in its combination of toughness and sensitivity. Wounds with significant volar tissue loss frequently require additional treatment. Children, with their regenerative capacity, often progress very well when significant volar wounds are allowed to heal primarily. For older people and for amputations that involve a more significant amount of the distal digit, a wide variety of techniques for managing the injured fingertip have been advocated, including partial-thickness skin grafts; full-thickness skin grafts;

Figure 48-3 (Figure Not Available) Clinical classification of fingertip injuries and treatments for each type. *(From Newmeyer WL: Managing fingertip injuries on an outpatient basis. J Musculoskeletal Med 2:17, 1985.)*

V-Y, Kutler, Kleinert, and island advancement flaps; and various local and distal flap coverage techniques. These procedures are designed to preserve length and to provide soft tissue coverage of exposed bone and sensation to the fingerpad. Each of these procedures has its own indications, complications, and limitations. [63] [64] [65] [66] [67] [68] Discussion of these procedures is beyond the scope of this chapter. Most of these techniques are best performed by a specialist in the operating room as primary procedures under ideal circumstances or as delayed procedures when necessary.

In most complete fingertip amputations distal to the distal interphalangeal joint, the emergency clinician can provide adequate care initially with conservative wound management. Although thinking has changed significantly over the years, many hand surgeons still advise skin grafting to shorten the time for wound healing.

Although complete transverse amputations could be handled conservatively, wound healing may take several weeks, and these patients may benefit from operative treatments. Patients with complete transections should be referred for consultation to coordinate their initial care and subsequent follow-up. Regardless of the type of injury, definitive care is usually provided on a delayed basis, and ED intervention is conservative with subsequent consultation being considered standard.

Incomplete transections and small distal amputations without significant soft tissue loss may heal well with conservative therapy started by the emergency clinician. Nonoperative treatment in selected patients provides excellent functional and cosmetic results, minimizes recovery time, and

has few complications.[63] [66] [67] [69] [70] [71] [72] Children have excellent regenerative capacity and also respond extremely well to conservative treatment. Necrotic or grossly contaminated tissue should be debrided, and the wound should be irrigated thoroughly. If bone is left exposed without soft tissue coverage, the patient will need an operative procedure; alternatively, the bone may be rongeured (shortened) to allow soft tissue coverage and primary healing with better functional recovery. The nailbed tissues should be preserved, because the presence of a nail affects the cosmetic result. After cleansing and cautious debridement, an occlusive dressing is placed directly over the wound. Tetanus prophylaxis, wound dressings, and bandages, along with placement of a protective splint, complete the initial management of these injuries. Amputations that involve the distal phalanx are frequently treated as contaminated open fractures. IV antibiotics are often given initially, followed by a course of oral antibiotics, but the value of this intervention is unproved. [73] Wounds managed conservatively must have serial dressing changes and cleansing. Soaking wounds, cleansing, and replacement of dressings help provide superficial debridement, which may aid healing and minimize the chance of secondary infection. Wound contraction and healing usually result in acceptable cosmetic and functional recovery in 2 to 3 weeks. Patients should have appropriate follow-up to ensure adequate healing and recovery.

Partial fingertip amputations distal to the distal interphalangeal joint can also be managed successfully by the emergency clinician. These wounds are treated in a manner similar to that for complete amputations. However, when the amputation has substantial undamaged tissue connecting the fingertip, careful alignment and stabilization are provided by sutures or bandaging and protective splinting. Partially amputated fingertips, especially in children, may occasionally survive and regain vascularization and sensation. If the distal tissue becomes ischemic and necrotic, the amputation becomes complete.

Injury to the nailbed requires special attention to ensure proper alignment. If the nailbed tissues are not aligned properly, permanently disfigured nails may result. Removal of the nail helps provide adequate visualization for the placement of sutures and also minimizes the risk of wound contamination.

Dermal "slice" wounds (see type 1 in Fig. 48-3 (Figure Not Available)) are managed by gentle wound cleansing and application of an antibiotic ointment and a nonadherent dressing, followed by a pressure dressing (e.g., tube gauze). At a dressing change 48 to 72 hours after the initial treatment, the patient can be instructed on daily changes of nonadherent dressings for 10 to 14 days until functional epithelialization of the wound occurs. A protective finger splint or guard also minimizes the risk of further injury and pain from trauma to the sensitive wound area. Protection allows an earlier return to function and employment. Wounds larger than 10 mm^2 and those with deep loss of digit pulp tissue may be candidates for skin grafting.

Penis, Ear, and Nose Amputations

Replantation of the penis, ear, and nose generally results in better function and cosmesis than a prosthesis or reconstructive surgery. The amputated parts and wounds should be handled in the same manner as digital replantations.

Penile amputations are an uncommon problem. Most cases result from self-inflicted trauma in patients who are severely psychologically disturbed. Successful replantation has been reported using microsurgical techniques. Preservation or reconstruction of the urethra to maintain a competent urinary stream is critical for success.[74] [75] Ears and noses frequently are partially amputated and occasionally are totally amputated. Whenever possible, these body parts should be replanted unless they are severely traumatized and there is gross contamination. These wounds frequently heal well, and patients with such wounds have a high tissue survival rate and a low incidence of total necrosis. Replantation of these parts requires good suture technique and careful placement but does not necessarily require skill in microsurgical techniques. [75] [76] [77]

COMPLICATIONS

The care of amputated parts should not lead to avoidable complications if the aforementioned principles are followed. Improper management of the parts or stump with subsequent additional injury of the tissue from overzealous hemostasis or cleansing should be avoided. Furthermore, desiccation, maceration, or freezing of tissue from improper storage should not occur. The clinician must consider expediting the preoperative work-up of the patient and immediate notification of the replantation team as crucial factors in the patient's care.

Despite optimal initial care, replantation itself may be associated with acute or long-term complications. There is the usual risk of anesthesia and protracted surgery. Postoperative complications include vascular thrombosis, hemorrhage, infection, and reaction to accumulated toxins. It is not unusual for second and third emergency operations to be required to reestablish adequate blood flow. Patients are often placed on anticoagulants, which create an additional risk. Toxins accumulate in ischemic amputated parts, despite cooling. The amount of toxin is directly proportional to the amount of muscle mass and the duration of ischemia. Reports of significant pulmonary failure, electrolyte disturbance, and even death have been reported in replantation efforts.

Later complications include a significant percentage (60%) of patients with cold intolerance, limited function, anesthesia, pain, paresthesias, malunions, and nonunions. Repeated operative procedures may be required to obtain a functionally useful result. To minimize the morbidity from amputations, proper initial care is essential and may be the most important determining factor in the patient's eventual outcome.

COMMENTS

The emergency clinician will frequently encounter distal fingertip injuries that patients often expect will be replanted. These injuries heal well with conservative management and frequently the greatest clinical challenge is to reassure the patient or parents and convince them that replantation is not indicated and will not result in a better outcome. When a distal amputation has exposed bone, shortening can be easily accomplished with a rongeur so that healing will result in a better functional outcome. Bleeding from complete amputations is usually not life-threatening but partial amputations that don't allow retraction and spasm of blood vessels can bleed profusely. In such cases a proximally placed blood

pressure cuff inflated to 30 mm above the systolic blood pressure has been invaluable in initially controlling hemorrhage. Early notification of the transplant team is important to allow for timely referral and to ensure optimal outcomes. Consultation to determine the possibility of replantation also helps to communicate realistic expectations to the patient. Frequently, other ED personnel care for the amputated tissue. The emergency clinician should ensure that the tissue is appropriately cared for and not placed directly on ice, which might freeze tissue, or in saline, which will result in macerated tissue.

Chapter 49 - Extensor and Flexor Tendon Injuries in the Hand, Wrist, and Foot

Peter E. Sokolove

EXTENSOR TENDONS

Extensor tendons are quite superficial, covered only by skin and a thin layer of fascia, and are thus highly susceptible to injury. These injuries may result from lacerations, bites, or burns, but they also may be caused by closed injury with even seemingly superficial lacerations. While some extensor tendon injuries must be managed by a hand surgeon, others may be treated in the emergency department (ED). Extensor tendon injuries are not benign and must be managed with care. The emergency clinician must understand the anatomy,

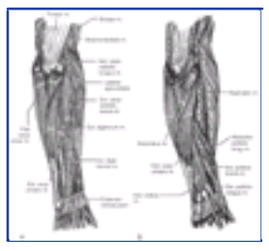

Figure 49-1 Extensor muscles and tendons of the RIGHT forearm and wrist. *A,* superficial layer. *B,* deep layer *(Modified from Pansky B: Upper extremity. In Review of Gross Anatomy, 4th ed. New York, Macmillan Publishing, 1979, pp 219 and 243.)*

principles of treatment, repair technique, and postrepair care of these injuries to ensure the best possible patient outcome.

FUNCTIONAL ANATOMY

There are 12 extrinsic extensors of the wrist and digits, all of which are innervated by the radial nerve. The muscles that give rise to these tendons originate in the forearm and elbow (Fig. 49-1). The extrinsic extensor tendons reach the hand and digits by passing through a fibro-osseous tendon sheath (retinaculum) located at the dorsal wrist. This synovium-lined sheath provides for smooth gliding of the tendons and prevents bowstringing when the wrist is extended. [19] The dorsal retinaculum contains six compartments or subdivisions (Fig. 49-2). These compartments are numbered from the radial to the ulnar side of the wrist.

The first compartment contains two tendons, abductor pollicis longus (APL) and extensor pollicis brevis (EPB). The APL tendon, the most radial of the extensor tendons, inserts on the base of the first metacarpal. It can be palpated just distal to the radial tubercle. The APL tendon causes thumb abduction and extension and some radial wrist deviation. The EPB travels with the APL through the first compartment but inserts at the base of the proximal phalanx of the thumb. The EPB tendon can be palpated over the dorsum of the first

Figure 49-2 *A,* The extensor mechanism at the wrist and dorsum of the right hand. The six extensor compartments at the wrist contain *(1)* the abductor pollicis longus (APL) and extensor pollicis brevis (EPB); *(2)* the extensor carpi radialis longus (ECRL) and brevis (ECRB); *(3)* the extensor pollicis longus (EPL); *(4)* the extensor digitorum communis (EDC) II–V and extensor indicis proprius (EIP); *(5)* the extensor digiti quinti (EDQ); and *(6)* the extensor carpi ulnaris (ECU). An important anatomic detail is the presence of a synovial sheath around each tendon unit within each fibro-osseous canal. *(From Thomas JS, Peimer CA: Extensor tendon injuries: Acute repair and late reconstruction. In Chapman MW [ed]: Operative Orthopaedics, 3rd ed. Philadelphia, JB Lippincott, 2001, p 1497.) B,* Cadaver model demonstrating the dorsal retinaculum of the left wrist with a probe passing through the fourth dorsal compartment. Note that the EDQ is also called the extensor digiti minimi (EDM) by some authors.

metacarpal when the thumb is extended against resistance. Both tendons can be tested by having the patient spread the fingers apart against resistance.

The second compartment also contains two tendons: the extensor carpi radialis brevis (ECRB) and the extensor carpi radialis longus (ECRL). These two tendons arise from the lateral epicondyle of the elbow. The ECRL inserts on the base of the second metacarpal, while the ECRB inserts on the base of the third metacarpal. Both tendons are powerful wrist extensors, and the ECRL also allows some radial wrist deviation. Wrist extension plays an especially important role in the mechanics of the hand, because hand grip strength is maximal only when the wrist is extended.

The third compartment contains only one extensor tendon: the extensor pollicis longus (EPL). This tendon crosses over the ECRB and ECRL and travels along the dorsum of the

thumb to insert on the distal phalanx. The EPL forms the top of the anatomic "snuff box," while the bottom is formed by the EPB. The EPL can be visualized when the thumb is extended, and its strength can be tested by having the patient hyperextend at the interphalangeal (IP) joint against resistance. The intrinsic extensor of the thumb can provide some degree of extension at the IP joint. Therefore, if EPL injury is suspected, it is important to compare extension at the IP joint with that of the unaffected thumb.

The fourth and fifth compartments contain the six tendons that extend the index through little fingers. Each finger has its own extensor digitorum communis (EDC) tendon. The index and little fingers have an additional independent extensor tendon—the extensor indicis proprius (EIP) for the index finger and the extensor digiti minimi (EDM) for the little finger. The fourth compartment contains the EIP and EDC tendons, while the fifth compartment contains only the EDM tendon. These six tendons can be seen over the dorsum of the hand, where they are poorly protected and prone to injury. In this region there are tendinous, ligamentous, and fascial connections between these tendons known as the *juncturae tendini. Because of these interconnections, a patient may be able to extend a digit, albeit weakly, even when there is a complete laceration of its EDC tendon.* To avoid missing a tendon injury on the dorsum of the hand, it is important that the examiner test for tendon *strength* and not just for active extension.

The course of the extensor tendons along the fingers is more complex, but a basic understanding of this anatomy is essential for the emergency clinician to evaluate and treat extensor tendon injuries (Fig. 49-3). The EIP tendon joins the EDC tendon at the level of the metacarpophalangeal (MCP) joint in the index finger. The EDM tendon parallels the course of the EDC tendon; the four EDC tendons eventually insert at the base of the proximal, middle, and distal phalanges. The most proximal insertion of the EDC tendon is at the level of

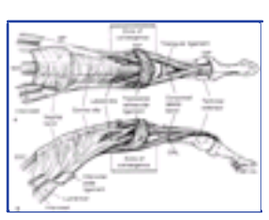

Figure 49-3 Digital extensor mechanism. *A,* Dorsal view. *B,* Lateral view. ORL, oblique retinacular ligament. See text and Figure 49-1 legend for other abbreviations. *(From Thomas JS, Peimer CA: Extensor tendon injuries: Acute repair and late reconstruction. In Chapman MW [ed]: Operative Orthopaedics, 3rd ed. Philadelphia, JB Lippincott, 2001, p 1498.)*

the base of the proximal phalanx. The tendon actually inserts in two ways. First, there is a loose dorsal insertion just distal to the MCP joint. In addition, the EDC tendon inserts into the volar plate via the sagittal bands. The sagittal bands are circumferential structures at the level of the metacarpal head that serve to keep the EDC tendon centered over the metacarpal head, as well as to provide a stable connection with the volar plate located on the palmar side of the hand. After its primary insertion at the level of the MCP joint, the EDC tendon then extends dorsally along the digit. The EDC trifurcates over the proximal phalanx (Fig. 49-4). Its major central slip inserts on the base of the middle phalanx (Fig. 49-5). The lateral branches of the EDC tendon join with the lateral bands from the interossei and lumbricals to form the co-joined lateral bands. The two co-joined lateral bands then fuse together over the middle phalanx to form the terminal extensor mechanism (TEM), which inserts into the base of the distal phalanx (Fig. 49-6). The triangular ligament is a connection between the two co-joined lateral bands that assists in keeping these structures on the dorsal aspect of the digit.

The sixth dorsal compartment of the wrist contains only one tendon: the extensor carpi ulnaris (ECU). This tendon originates at the lateral epicondyle of the elbow and inserts at the base of the fifth metacarpal. The ECU functions as a wrist extensor and ulnar deviator. It can be palpated just distal to the tip of the ulna, and its strength can be tested by forced ulnar deviation of the wrist.

GENERAL APPROACH TO EXTENSOR TENDON INJURIES

The key to detecting extensor tendon injuries in the ED is to perform a careful and thorough history and physical examination. Closed injuries may appear innocuous at first but may

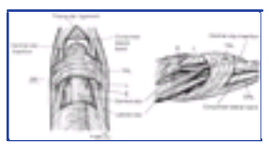

Figure 49-4 The zone of convergence of the digital extensor mechanism, which begins at about the midportion of the proximal phalanx and ends at the level of the central slip insertion into the dorsal base of the middle phalanx. Proximal to the zone of convergence, the extrinsic and intrinsic components of the extensor mechanism are separate: the central slip is extrinsic, whereas the lateral slips are intrinsic. Within the zone of convergence there is complete reciprocal crossover of fibers from the central slip and lateral slips. The products of the completed convergence are the central slip insertion and the conjoined lateral bands, both of which have dual muscular activity. PIP, proximal interphalangeal joint; TRL, transverse retinacular ligament; ORL, oblique retinacular ligament; E, extrinsic contribution to conjoined lateral bands; I, intrinsic contribution to central slip insertion. *(From Thomas JS, Peimer CA: Extensor tendon injuries: Acute repair and late reconstruction. In Chapman MW [ed]: Operative Orthopaedics, 3rd ed. Philadelphia, JB Lippincott, 2001, p 1500.)*

result in tendon injuries that often lead to severe deformities or dysfunction if undetected. Closed injuries are also commonly associated with fractures. A hand radiograph is recommended in closed hand injuries when a fracture is suspected or in open-hand injuries where fracture or a foreign body is suspected. It is generally accepted that all open injuries that result from glass should be radiographed. Plain radiographs have a sensitivity of approximately 98% for detecting radiopaque foreign bodies (e.g., gravel, glass, metal). [14]

Figure 49-5 The extensor mechanism on the dorsum of a finger. *Arrows* point to the radial and ulnar lateral band portions of the extensor mechanism, and the probe lifts the entire structure up off the phalanx.

Injuries to extensor tendons from lacerations are quite common, especially on the dorsum of the hand, where they are superficially located. *All dorsal wrist, hand, and digit lacerations should be assumed to have an underlying tendon laceration until proven otherwise* (Fig. 49-7). Digital extension, albeit it weak, can still occur with partial tendon lacerations of up to 90%, so visualization of the tendon and careful strength testing are required to definitively rule out a partial injury. In some cases, the specific diagnosis simply cannot be

Figure 49-6 The terminal extensor mechanism.

made on the first examination (see below). Complete lacerations of an EDC tendon on the dorsum of a hand can also still allow digital extension through the juncturae tendini.

After assessing the strength and neurovascular status of the injured hand, it is imperative that the emergency clinician visually inspect the wound thoroughly. Inspection should include an assessment of the degree of wound contamination,

Figure 49-7 Because of their superficial location, it is difficult to avoid at least partial injury to extensor tendons in even superficial lacerations of the dorsum of the wrist, hand, or fingers. In some cases *(A)* the injury is obvious. In other cases, a partial tendon laceration is not appreciated, but becomes obvious when complete rupture occurs *(B)*. In this case the patient seemingly had full tendon function during the initial ED evaluation, but the entire tendon could not be visualized due to an uncooperative patient. An unappreciated partial laceration progressed to complete rupture by the time of suture removal. The injury was diagnosed and an expeditious delayed primary repair resulted in a good outcome. Note: Inability to extend index finger is evident in both photos.

as well as a search for foreign bodies and occult tendon lacerations. It is often necessary to extend the skin laceration to aid in the visualization of a possible tendon injury. Because an extensor tendon is a mobile structure, it is imperative that if it is exposed, it is visualized in its entirety through a full range of motion. *It is especially important to examine the tendon in the position of injury, because the tendon injury frequently does not lie directly under the skin wound* (Fig. 49-8).

The definitive examination of any wound must occur under the best possible conditions—with a good light source, a bloodless field, adequate local anesthesia, and a cooperative patient (Fig. 49-9). It may be impossible to adequately assess some patients completely during the first ED visit. Final diagnosis must be delayed until the proper circumstances permit the required conditions. Occasionally, however, patient noncompliance thwarts even the most carefully planned follow-up. Often the patient's pain, swelling, anxiety, or degree of intoxication/altered sensorium limits the clinician's diagnostic ability; therefore, *it would not be considered standard of care to diagnose the presence of, or the full extent of, all extensor tendon injuries immediately*. Whenever logistically possible it is suggested that a specialist be consulted when an extensor tendon injury is suspected, either by mechanism or location of the wound, or tendon dysfunction. Under most circumstances, however, there is no value in obtaining an immediate onsite consultation with a hand surgeon/orthopedic surgeon, since the intrinsic scenario would similarly limit any clinician's diagnostic acumen.

If the examining clinician suspects, but is unable to locate, a tendon laceration, or if a patient is uncooperative with the examination and the circumstances prohibit ideal initial care, the patient should be referred for follow-up in 1 to 3 days for a repeat examination. Interim wound care with skin closure and splint application is advised. A delay of a few days for definitive diagnosis or surgical repair or both does not result in any significant alteration in final outcome. Delayed primary repair, without the need for tendon grafting or tendon transfer, is a well accepted technique. In fact, many

Figure 49-8 The location and depth of this laceration suggests an extensor tendon injury. On examination, the patient had full extension. Note that an intact tendon is visualized when the laceration is examined with the fingers in extension *(A)*. The injury occurred with a closed fist, and when the fingers were fully flexed, an 80% laceration of the extensor tendon could be viewed in the depths of the wound *(B)*. Note: Contrary to this figure, gloves should be worn by the examiner.

hand surgeons are reluctant to immediately repair even a complete extensor tendon laceration in a contused, potentially contaminated, wound. The exact time frame under which such delayed repair results in an outcome similar to immediate repair is not well defined and depends on the clinical scenario. Usually, delayed repair up to 7 to 10 days will ensure an outcome similar to an immediate repair, but this is variable depending on the injury. Inability to rule out a tendon injury in the ED and the mandate for follow-up, *with a specific following time frame indicated*, should be clearly documented on the medical record and discharge instructions.

Antibiotic Use

There are no data to support or refute the use of prophylactic antibiotics as a routine adjunct following tendon injury. In

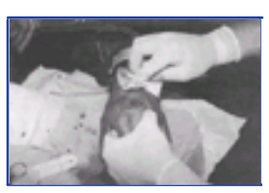

Figure 49-9 With this injury on the dorsum of the hand, the clinician should expect to find an extensor tendon injury. The proper way to examine this wound includes a bloodless field (often with the use of a blood pressure cuff tourniquet), good light, a cooperative patient, excellent anesthesia, and extending the skin laceration to visualize the depths of the laceration. Note that the tendon is visualized with the fingers manipulated from full extension to full flexion.

general, prophylactic antibiotics have not been demonstrated to reduce infection rates following soft tissue injury in the setting of proper wound cleaning. Neither have they been proven to reduce infection rates in the absence of gross contamination, retained foreign material, or extensive contusion, or after a delay in cleaning. Many clinicians opt for antibiotics with gram-positive (including antistaphylococcal) coverage if the tendon has been injured or sutured, but no universally accepted standard of care exists. An individualized approach is advocated. Prophylaxis is generally only used for 3 to 5 days post injury unless extenuating circumstances exist (such as immunocompromise, human bite, unusual source of contamination, or peripheral vascular disease). If there is doubt about the sterility of a wound, tendon repair should not be attempted.

PREPARATION FOR REPAIR

Prior to attempting repair of an open extensor tendon injury in the ED, it is essential that the treating clinician be prepared and has the proper equipment available. Patients should be placed supine on a gurney that ideally has an arm board attached. Bright overhead lighting is important for wound exploration so that the presence of tendon injuries and foreign bodies can be adequately assessed. Instruments should include, at a minimum, a needle holder; two skin hooks and retractors; sharp (i.e., "iris") and blunt-nosed scissors; several small hemostats; and one pair of small, single-toothed (i.e., Adson) forceps.

The choice of suture material depends on the location of the tendon injury. For the repair of *complete* tendon injuries on the dorsum of the hand, nonabsorbable, synthetic, braided sutures are preferred. [25] Polyester sutures, such as Ethibond or Mersilene, are recommended. Nylon sutures are acceptable but are less ideal, as colored nylon may be visible under the skin. Chromic and plain gut should be avoided because they will dissolve before adequate tendon healing has occurred. Silk is not desirable because of its reactivity. Most extensor tendons on the dorsum of the hand will accommodate 4-0 sutures, but 5-0 suture material may be needed for smaller

tendons. Small, "plastic repair," tapered needles should be used to avoid tearing the tendon. *Partial* tendon injuries of the digits are best repaired with fine, synthetic, absorbable sutures such as polyglactin (i.e., Vicryl).

It is imperative that the clinician use adequate anesthesia so that thorough wound exploration can occur. A field block or regional nerve block can be used on the dorsum of the hand, while local anesthesia or a digital nerve block can be used on the fingers (see Chapter 30 and Chapter 32). Many clinicians readily use lidocaine with epinephrine in the hand except in areas supplied by end arteries. It is important to liberally anesthetize the area around the wound, since many lacerations *must be extended to afford access to the surgical field*. It is a common error to neglect to extend a laceration and to attempt examination, cleaning, or repair through a small initial skin laceration.

Following the administration of anesthesia, a tourniquet may be placed on the involved limb if hemostasis is problematic. It is absolutely essential that adequate control of blood flow be obtained before attempting to repair a tendon laceration. It is very difficult to find the proximal end of a retracted tendon in a bloody field. Before application of a tourniquet, the patient's arm should be wrapped in several layers of cast padding as a comfort measure, and the arm should be elevated for at least 1 minute to allow blood to drain by gravity. A blood pressure cuff is placed on the mid to upper arm, wrapped in several more layers of cast padding, then inflated to 260 to 280 mm Hg. Once inflated, the tubes are clamped tightly using a hemostat. The use of cast padding during inflation helps avoid inadvertent unraveling of the cuff. The use of a hemostat to clamp the blood pressure cuff tubes helps avoid a slow leak in the cuff with resultant deflation. A blood pressure cuff tourniquet is generally well tolerated by patients for approximately 15 to 20 minutes. If tendon repair cannot be accomplished in this amount of time, it is likely that the injury is too complex for repair in the ED. When necessary, the use of parenteral sedation may allow the patient to tolerate a longer tourniquet time (see Chapter 34).

Atraumatic technique is essential for minimizing adhesions and scar tissue formation. Tendons should be handled delicately, avoiding crushing forces or excessive punctures with forceps and needles. Forceps should only be used on the exposed, cut end of the tendon whenever possible. [13]

PATTERNS OF INJURY AND MANAGEMENT

The treatment for extensor tendon injury depends primarily on whether the injury is open or closed, as well as the anatomic location of the injury. The most widely accepted classification system is that developed by Verdan, which divides the hand and wrist into eight anatomically based zones (Fig. 49-10).[26] It is quite useful for emergency clinicians to become familiar with this classification, because in many instances the zone of injury can help determine whether tendon repair should be attempted in the ED. One must keep in mind that repair of lacerated extensor tendons within 72 hours of injury is still considered primary closure. Therefore, while emergency clinicians may repair many extensor tendon injuries immediately, some injuries are best managed with delayed repair. In these cases, initial care in the ED should consist of sterile skin prep, copious wound irrigation and inspection for foreign bodies, skin closure, splint application,

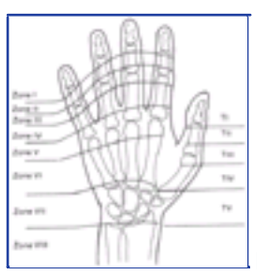

Figure 49-10 Dorsum of left hand. The injury classification system recommended by Verdan includes eight anatomically based zones. *(From Blair WF, Steyers CM: Extensor tendon injuries. Orthop Clin North Am 23:142, 1992.)*

and a referral to a hand specialist for further care in 1 to 5 days. A dorsal plaster/fiberglass splint, incorporating a metal foam finger splint, is an ideal way to totally immobilize a finger (Fig. 49-11). See an additional discussion in the previous section on the general approach to extensor tendon injuries.

Zone 7 and 8 Injuries

Zones 7 and 8 consist of the area over the wrist and dorsal forearm, respectively. [19] Extensor tendon lacerations in these regions can be quite complex and are therefore not repaired in the ED. Because of the close proximity of extensor tendons in the distal forearm, lacerations such as stab wounds may appear innocuous but often result in multiple tendon lacerations. At the wrist level, extensor tendons are covered by a retinaculum that is lined with synovium. While this tissue allows smooth gliding of tendons during normal activity, the presence of synovium increases the risk for adhesions following tendon repair. In addition, lacerated tendons in the wrist and distal forearm may retract away from the site of initial injury. This may make tendon retrieval and repair quite difficult and may necessitate incision of the retinaculum and exploration of 1 or more of the compartments.

As a result of the potential complexity of these injuries, all tendon lacerations in zones 7 and 8 require formal surgical exploration and repair. ED management of these patients includes local wound care (see Chapter 35) with primary repair of the skin (see Chapter 36) and placement of a volar splint with 35° of extension at the wrist and 10°–15° of flexion at the MCP joints (see Chapter 51). Many hand surgeons recommend prophylactic antibiotics for all open tendon lacerations, while others prescribe them selectively for patients with wounds where contamination is suspected or significant injury to the surrounding tissues is present. There are no prospective data proving or disproving the value of prophylactic antibiotics in either circumstance. These patients should

Figure 49-11 An effective way to fully immobilize a finger with a tendon laceration is to incorporate an aluminum foam splint into the middle of a standard dorsal plaster/fiberglass splint.

be promptly referred to a hand surgeon so that repair may be undertaken within 1 week of injury.

Zone 6 Injuries[7] [19] [25]

Zone 6 consists of the area over the dorsum of the hand. Extensor tendon injuries in this region frequently result from lacerations owing to broken glass or another sharp object. Common pitfalls in ED management of these injuries are usually related to failure to recognize that the tendon has been injured. It is important to remember that these tendons are superficially located, partial tendon lacerations may occur, and weak extension of a digit is possible in the presence of a complete tendon laceration because of transfer of extensor function through the juncturae tendini. Lacerations of the EIP or EDM tendons are evidenced by an inability to independently extend

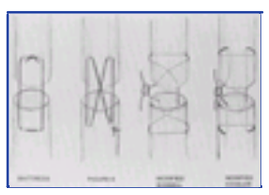

Figure 49-12 Suture techniques used in extensor tendon repair. *(From Newport ML, Williams CD: Biomechanical characteristics of extensor tendon suture techniques. J Hand Surg 17:1117, 1992.)*

the index or little fingers, respectively. All of these pitfalls can be avoided if a careful physical examination is performed, including a thorough wound exploration under sterile conditions using a tourniquet, adequate local anesthesia, and good lighting.

Extensor tendon injuries in zone 6 are usually appropriate for repair in the ED. Because of the juncturae tendini, extensor tendons in zone 6 are less likely to retract than those in zone 7 or 8; however, the severed tendon may retract when the injury is more proximal. The distal end of a severed tendon is usually easy to find by passively extending the patient's affected digit to bring the end into view. Retrieval of the proximal portion of a severed tendon is sometimes required and usually can be accomplished in the ED. Before searching for the proximal end of the tendon, the clinician should have a 4-0 nylon suture loaded onto a needle holder. When the proximal end is located, this suture should be placed as a holding suture as far proximal as possible so that the tendon is not lost again. It is often necessary to use a scalpel to extend the wound proximally in a direction parallel to the course of the injured tendon to obtain adequate exposure. One should then begin to search for the tendon by lifting up this overlying skin with a forceps and inspecting the proximal portion of the wound. Sometimes the blood-stained end of a tunnel can be seen; this may contain the proximal end of the tendon. By gently placing a small hemostat or toothed forceps up this tunnel, the tendon stump can often be pulled into view.

Once both ends of the injured tendon have been located, the technique used for repair is dependent on the size and shape of the tendon. While larger, round tendons can accommodate sutures that pass through the core of the tendon, smaller or flat tendons are difficult to repair using this technique. Most of the tendons in zone 6 can be repaired with either a modified Kessler or a modified Bunnell core suture technique, using 4-0 nonabsorbable suture (Fig. 49-12). Both of these techniques involve first placing a single suture into

one half of the cut tendon. The suture is placed into the tendon core by inserting the suture needle into the exposed, cut end, and then weaving the suture through the lateral tendon margins. Next, the same suture is placed through the core of the opposite half of the cut tendon. The suture ends are tied in a square knot in between the cut ends of the tendon, bringing the two halves together.

Smaller tendons may be repaired using a figure eight or horizontal mattress suture (see Fig. 49-12). Small, tapered needles should be used to avoid tearing the tendon. In a cadaver study comparing these multiple suture techniques, it was found that the modified Bunnell technique provided the strongest extensor tendon repair.[17] In addition, this technique produced no gaping between the repaired tendon ends and minimized the postrepair restriction of flexion at the MCP and proximal interphalangeal (PIP) joints. It is important to passively test the degree of flexion at the MCP joint after a zone 6 tendon repair to be certain that the tendon has not been excessively shortened.

To improve the tensile strength of the repair, a number of other suture techniques may be used. [13] One option is to increase the number of suture strands that cross the repair site (e.g., four strands rather than two). A cadaver study that compared various four-strand tendon repair techniques concluded that the MGH technique was more resistant to gap formation than either the Krackow-Thomas or four-strand modified Bunnell technique (Fig. 49-13).[9] Another way to improve tensile strength is to place a peripheral suture in addition to the core suture. A running suture can be placed circumferentially around the repair site using synthetic, absorbable

Figure 49-13 Four-strand suture techniques used in extensor tendon repair. *(Adapted from Howard RF, Ondrovic L, Greenwald DP: Biomechanical analysis of four-strand extensor tendon repair techniques. J Hand Surg 22:839, 1997.)*

material (e.g., polyglycolic acid, polyglactin, polydioxanone). Alternatively, sutures may be placed laterally along both sides of the tendon, starting at about 1 cm on either side of the repair site. The ultimate choice of repair technique will depend largely upon the treating clinician's familiarity with extensor tendon repair, as well as the size of the tendon.

The approach to partial extensor tendon lacerations is not well-defined, and no definitive standard of care exists. One evidence-based analysis identified 141 papers in its literature search, but none was relevant to the question of partial extensor tendon injury repair. [23] The authors concluded that there is no direct evidence to assist in answering this question. Given the lack of literature on the subject, a reasonable approach may be to extrapolate from data on flexor tendon injuries. It has been demonstrated that many partial *flexor* tendon lacerations do well without repair, [16] but disagreement still remains among hand surgeons concerning the need for repair of these injuries. In a survey of hand surgeons, 30% of respondents repaired *all* partial flexor tendon lacerations, while 45% of respondents repaired *only* lacerations with greater than 50% cross-sectional area involvement. [15] Except at the wrist level, extensor tendons are not covered with synovium and are less likely than flexor tendons to develop adhesions after repair. This encourages some authors to recommend repair of most partial extensor tendon lacerations. While the ideal approach to these injuries is not known, it is reasonable to consider repair of partial extensor tendon lacerations to be *optional* if less than 50% of the cross-sectional area is involved. However, such injuries must be splinted for 3 to 4 weeks to ensure that a partial laceration is not converted into a complete injury. Skin closure, splinting, and referral for follow-up is a standard approach to unsutured partial extensor tendon lacerations.

After repair of a lacerated EDC tendon in zone 6, a plaster or fiberglass volar splint should be applied (see Chapter 51) so that the wrist is in 45° of extension, the affected MCP joint is in neutral (0° of flexion), and the unaffected MCP joints are in 15° of flexion. The PIP and distal interphalangeal (DIP) joints should be allowed full range of motion. After 10 days, the MCP joints are allowed 20°–30° of flexion. If there is an isolated EIP or EDM tendon injury, then only the index or little finger must be included in this splint. Dynamic extension splinting may be used as early as 3 days after tendon repair, so close follow-up is recommended. [1]

Zone 5 Injuries[5] [22]

Zone 5 consists of the area over the MCP joint. Open injuries in this region should be considered secondary to a human tooth bite until proven otherwise. This is especially true if the injury occurs over the first or second MCP joint, as this is frequently the location of a clenched-fist ("fight-bite") injury. ED evaluation must begin with a careful and persistent history and physical examination, although patients' reluctance to admit to punching someone in the mouth is notorious. The wound should be inspected through its full range of motion, since the position of the EDC tendon changes with hand position. It is generally recommended that radiographs be obtained in all of these injuries to evaluate for metacarpal head fractures, air in the joint space, or presence of a foreign body, such as a tooth fragment [1] (Fig. 49-14).

If, after a thorough evaluation, it is determined that a human bite to this region has resulted in a superficial skin

Figure 49-14 *A,* Regardless of this patient's history, this wound is highly suggestive of a human bite injury. Human bites cause extensor tendon injuries, fractures, and joint capsule injuries, and can harbor foreign bodies. *B,* This patient stated that he cut his hand on a piece of metal at work (expecting a Workers Compensation claim), but was unable to explain the piece of tooth that was found in the wound on exploration.

laceration only, without injury to the underlying tendon or joint, outpatient management is appropriate. The wound should be copiously irrigated and left open. A volar splint is applied (see Chapter 51) with the wrist in 45° of extension, the MCP joints in the neutral position (0° of flexion), and the hand dressed with a bulky dressing. Most authors recommend that 3 to 5 days of prophylactic antibiotics be given to these patients, and patients should be seen in 24 to 36 hours for a repeat examination to evaluate for wound infection. As mentioned previously, there are inadequate prospective data to prove or disprove the value of prophylactic antibiotics for extensor tendon injuries, and no universally accepted standard of care exists. It would be prudent to err on the side of caution if doubt exists concerning the degree of contamination and potential for infection.

If a human bite results in tendon damage, including partial or complete laceration, some clinicians opt for admission and IV antibiotics. However, no specific standard of care exists. Outpatient therapy is acceptable in the reliable patient who has access to follow-up. Delayed closure with tendon evaluation/repair should be undertaken by a hand surgeon after 5 to 10 days of antibiotics. [1] [25] Primary closure of even seemingly clean and well-irrigated human bites in this region is not advisable because of the increased risk of wound infection, as well as the potential for septic destruction of the MCP joint if it is violated. If an *open joint* is noted by physical examination, a more aggressive approach is warranted. Such patients are generally admitted for IV antibiotics, following copious irrigation. [1] [25] However, after initial ED treatment (aggressive wound care and initial IV antibiotics), there may be a role for outpatient therapy in selected cases. If a patient suffers a zone 5 tendon injury, and it can be determined with complete certainty that it was caused by a relatively clean, sharp object rather than by a human bite, primary closure is appropriate. Referral of these injuries to a hand surgeon is a common practice, given the complexities of the injury and the sequelae. Careful repair of lacerations to both the EDC tendon and the sagittal bands is necessary to prevent subluxation of the EDC tendon away from the center of the metacarpal head. Initial ED management of non-human bite injuries is often limited to skin closure, splinting as described earlier, and referral to a hand surgeon within 1 to 5 days.

Closed extensor tendon injuries in zone 5 usually result from the acute or recurrent application of compressive forces to the MCP joint capsule. Closed injuries in this region are sometimes referred to as *boxer's knuckle*. Repetitive closed injury to the MCP joint region can produce small tears of the EDC tendon, the sagittal bands, or

the joint capsule. These patients tend to present with chronic and recurrent pain and swelling at the MCP joint region and usually have normal radiographs. Acute trauma may result in the same injuries or cause more severe damage to the extensor hood. Such patients may have complete disruption of the extensor mechanism, including damage to the central tendon and the sagittal bands. The MCP joint is swollen, has decreased mobility, and may exhibit an extensor lag. Traumatic subluxation of the EDC tendon may be present, and usually involves the middle finger with subluxation to the ulnar side (Fig. 49-15). The subluxation becomes more prominent with flexion at the MCP joint. There is controversy regarding the initial management of closed injuries to this region. While some authors prefer initial surgical repair,[22] others use an initial trial of extension splinting in some or all cases. [1] [5] [25] Splinting the MCP joint in neutral or slight flexion for 6 weeks has been recommended for dislocations presenting within 2 weeks of injury, with operative repair reserved for more delayed presentations. [1]

Zone 4 Injuries[5]

Zone 4 consists of the area over the dorsal aspect of the proximal phalanx between the MCP and PIP joints. The extensor tendon is a broad, flat structure in this region and is relatively easy to repair. Because the extensor tendon is flat and conforms to the roundness of the proximal phalanx, tendon injuries in this area usually result from a laceration and are almost always incomplete. As a result, extension at the PIP joint is usually not impaired. It is therefore imperative that all

Figure 49-15 Ulnar dislocation of the extensor tendon of metacarpophalangeal joint of the middle finger. *(From Leddy JP, Dennis TR: Tendon injuries. In Strickland JW, Rettic AC [eds]: Hand Injuries in Athletes. Philadelphia, WB Saunders, 1992, p 196.)*

of these wounds be explored carefully, remembering that the extensor tendon lies immediately beneath the thin overlying skin. Tendons tend not to retract in this area, so close inspection will usually result in location of the injured tendon.

A hand surgeon usually repairs central slip lacerations or any laceration that results in an extension lag at the PIP joint. The decision regarding whether to repair a partial tendon laceration and whether it should be repaired by the emergency clinician in this zone is best discussed with the consulting hand surgeon. In general, because of the duality of the extensor system in this region, lacerations of a single lateral slip can either be repaired with 5-0 nonabsorbable sutures or be left unrepaired and splinted. A running suture or simple interrupted sutures with buried knots are appropriate for this area. Postrepair splinting depends on the presence of tension at the repair site. Minor lacerations in zone 4 that do not result in tension on the repair site can be treated with a finger guard for 7 to 10 days and early range of motion. Larger lacerations or those that result in tension at the repair site are usually treated in a splint that extends from the forearm to the digit for 3 to 6 weeks. The splint should be applied so that the wrist is in 30° of extension, the MCP joints at 30° of flexion, and the PIP joint in neutral position. Fingers should be grouped so that either digits 2 and 3 or digits 3 through 5 are immobilized (see Chapter 51).

It is important to recognize that *complex partial* tendon lacerations (e.g., a laceration of a lateral slip resulting from a saw) in zone 4 may result in damage to the gliding layer located between the tendon and the bone. If the patient is still able to actively extend the digit at the PIP joint, then these *complex partial* tendon lacerations are best managed by debriding the frayed tendon ends and splinting the digit in extension rather than attempting to suture the damaged tendon. The splint should be worn for 10 days, followed by active range of motion.

Zone 3 Injuries[1] [19] [22]

Zone 3, the area over the PIP joint, is a common site of both closed and open injury. Open injury usually results from laceration with a sharp object. It is imperative that these wounds be carefully explored in the ED to rule out penetration of the joint capsule. Patients with wounds that are suspected of penetrating the joint are generally taken to the operating room for surgical exploration, irrigation, and treatment with IV antibiotics, but protocols vary.

Zone 3 tendon lacerations can result in long-term deformity if not carefully repaired, and patients with such injuries are commonly referred to a hand surgeon. Partial lacerations of the central slip or lateral bands are managed variably, and it is advisable to discuss these injuries with the consulting hand surgeon. Lacerations in this area may sometimes result in a complete central slip injury. This may present as an acute boutonnière ("buttonhole") deformity, where the PIP joint rests in 60° of flexion. The presentation may be subtler, however, and may only be noticeable by weakened extension at the PIP joint or incomplete extension by only a few degrees.

The boutonnière deformity develops when the central slip is ruptured by an open or closed mechanism, leading to unopposed action of the flexor digitorum superficialis tendon (Fig. 49-16). This results in flexion at the PIP joint, protrusion of the head of the proximal phalanx between the two lateral bands, and disruption of the triangular ligament. When this occurs, the lateral bands are displaced volar to the axis of motion of the PIP joint. The lateral bands then paradoxically become flexors of the PIP joint. In addition, the extensor hood mechanism is pulled more proximally, resulting in increased tension on the terminal extensor mechanism and hyperextension at the DIP joint. Thus, the boutonnière deformity consists of flexion of the PIP joint with hyperextension at the DIP joint.

Open central slip injuries are usually managed operatively, and complex injuries may require direct attachment of the tendon to bone or tendon reconstruction. If the consulting hand surgeon chooses not to repair the tendon injury immediately, the skin should be closed and a plaster splint applied in the same fashion as described for zone 4 injuries (see Chapter 51). Thermoplastic splints allow splinting of the hand without involvement of the wrist but are generally not available in the

Figure 49-16 Boutonnière deformity. This can be an open or closed injury. Note flexion of the PIP joint and extension of the DIP joint, from a laceration of the central slip mechanism.

ED setting. These patients should be promptly referred to a hand surgeon so that repair may be undertaken within 1 week of injury.

Patients with closed injuries to zone 3 present commonly to the ED. They may complain of a direct blow to the dorsal PIP joint, or they may complain of a "jammed" finger. This injury occurs when an object such as a ball delivers a sudden axial loading force with forced flexion of the PIP joint while it is extended. These patients commonly complain of a painful, swollen PIP joint, which often makes the examination difficult. Some of these injuries may represent PIP joint dislocations that were spontaneously or manually reduced before the patient's ED presentation (see Chapter 50). The tendon injury that is important to recognize in this setting is an occult isolated central slip rupture. Patients may have decreased extension at the PIP joint, but extension is usually normal because the lateral bands are the primary extenders of this joint. With forced extension against resistance, patients usually have pain and may have decreased strength. To eliminate pain as the cause of decreased mobility, it may be helpful to test PIP extension against resistance after performing a digital block. With acute central slip rupture, PIP joint extension may be particularly weak when the MCP and wrist joints are held in maximal flexion. In this position, a 15° or greater loss in active extension is highly suggestive of a central slip injury. [22] The Elson test may also help identify this injury [2] (Fig. 49-17 (Figure Not Available)).

The boutonnière deformity usually does not develop in patients with closed zone 3 injuries until 10 to 21 days after injury. The only way to prevent this deformity is to have a high index of suspicion for its presence and treat these patients conservatively. It is advisable that all patients with a swollen, tender PIP joint and pain with flexion or extension be splinted and referred for close follow-up. A dorsal splint should be applied overlying the PIP joint, keeping it in full extension. This can be

accomplished using an aluminum foam-backed splint or a Bunnell ("safety pin") splint, although the latter may not be available in the ED [1] (see Chapter 51). The MCP and DIP joints should be left free to have full, active range of motion (Fig. 49-18). If a central slip attachment fracture is present, orthopedic consultation is recommended, as these patients may require surgical internal fixation. [10]

Zone 1 and 2 Injuries[1] [19] [22] [25]

Zones 1 and 2 consist of the area over the DIP joint and the middle phalanx, respectively. In zone 2 the co-joined lateral bands come together to form the terminal extensor mechanism (TEM) and are held together, in part, by the triangular ligament. The TEM inserts on the base of the distal phalanx and allows extension at the DIP joint. Complete disruption of the TEM results in inability to extend at the DIP joint. Because of the unopposed action of the flexor digitorum profundus (FDP) tendon, the DIP joint rests in the flexed position. This is known as a mallet deformity of the finger (Fig. 49-19).

Tendon *lacerations* in zones 1 or 2 that result in a partial or complete mallet deformity generally warrant discussion with a hand surgeon. Management consists of repair of the lacerated tendon and post-repair immobilization. Some surgeons will use only an external splint, while others prefer placement of a K-wire through the distal phalanx into the

Figure 49-17 (Figure Not Available) *A,* Diagrammatic explanation of a boutonnière deformity. *(From Newmeyer WL: Primary Care of Hand Injuries. Philadelphia, Lea & Febiger, 1979.) B–E,* The Elson test for early diagnosis of an acute rupture of the central slip of the extensor digitorum communis tendon. Such rupture results in boutonnière deformity, in which the distal interphalangeal (DIP) joint is hyperextended, as shown. With the patient's finger flexed (over a straight edge) at the PIP joint, the examiner palpates the dorsal surface of the middle phalanx *(B)*. If the central slip is intact *(C),* PIP joint flexion causes the slip to tighten distally, thereby relaxing the lateral bands and leaving distal phalanx flail *(arrows)*. Thus, when the patient is asked to extend the digit, the examiner feels pressure that is necessarily being exerted by an intact central slip. If the central slip is disrupted, however, the examiner feels no pressure on the dorsum of the middle phalanx as the patient tries to extend the digit *(D)*. It is possible for the patient to extend the injured finger successfully only by hyperextending (by action of the lateral bands) *(arrows, D and E)*. *(From Connolly JF: What to do for a "jammed" finger. J Musculoskeletal Med 99, 1988 May.)*

middle phalanx to help stabilize the joint. One technique for tendon repair involves placement of a roll-type suture (dermatotenodesis), which incorporates the tendon and overlying skin into a single suture [1] [19] (Fig. 49-20). The DIP joint is then splinted in full extension for at least 6 weeks. Occult partial tendon lacerations are important to recognize to prevent development of a mallet deformity. If there is a partial tendon laceration in zone 1 or 2 that does not result in any extension lag, the approach to repair is variable, and it is advisable to discuss the repair with the consulting hand surgeon. In general, partial tendon lacerations of less than 50% of the tendon area that do not result in an extension lag may be splinted in extension for 7 to 10 days with or without repair of the tendon itself. [1] Partial tendon lacerations of more than

Figure 49-18 *A,* Boutonnière splint. *B,* This splint allows active flexion at the metacarpophalangeal and distal interphalangeal joints.

50% that do not result in an extension lag may be repaired by a hand surgeon or an emergency clinician who is experienced in the repair of these injuries. In either case, it is advisable to discuss whether tendon repair will occur in the ED or the operating room with the consultant hand surgeon.

If the zone 1 or 2 tendon laceration is repaired in the ED, it can be approximated using a combination of running and cross-stitch sutures, [1] using 5-0 nonabsorbable suture material (Fig. 49-21). It is important that the tendon ends be approximated but not pulled too tightly; otherwise joint stiffness and limitation of flexion will occur. After repair of a partial tendon laceration, the DIP joint should be splinted in extension for 6 weeks, followed by 2 to 4 weeks of night splinting

Figure 49-19 Mallet finger deformity. *(From Leddy JP, Dennis TR: Tendon injuries. In Strickland JW, Rettic AC [eds]: Hand Injuries in Athletes. Philadelphia, WB Saunders, 1992, p 180.)*

and active range-of-motion exercises. Patients should be warned after tendon repair that there is likely to be some residual loss of flexion at the DIP joint, even in the best case.

Closed injuries in zones 1 and 2 may result in a partial or complete mallet deformity depending on the injury pattern. These injuries are usually caused by an axial loading force with forced flexion of the DIP joint while it is being held in extension. A common ED presentation of this injury is a patient who complains of pain and swelling at the DIP joint after a ball strikes his or her fingertip.

Closed tendon injuries in this region can generally be classified into three types. In the first type of injury, there is a closed rupture of the TEM. The second type of injury is an avulsion fracture of the dorsal lip of the distal phalanx. This fracture is intra-articular, but there is no volar displacement of the remaining portion of the distal phalanx. Both type 1 and type 2 injuries can be treated by splinting in full extension for 6 weeks. The splint should hold the DIP joint in extension while allowing free range of motion of the PIP joint (Fig. 49-22). The splint can be constructed from an aluminum, foam-backed splint or from a prefabricated Stack splint (see Chapter 51).

The third type of closed injury is an intra-articular avulsion fracture of the dorsal lip of the distal phalanx *with* volar displacement of the remaining portion of the distal phalanx (Fig. 49-23). Normally the DIP collateral ligaments hold the distal phalanx in place; however, if there is a large enough fracture fragment (usually more than 50% of the articular surface), then the remaining distal phalanx fragment displaces in the volar direction secondary to unopposed action of the FDP tendon. When volar displacement of the distal phalanx occurs, this injury may require more aggressive treatment for an optimal outcome. [22] Operative repair usually involves placement of a K-wire and open reduction and internal fixation of the fracture. It is important to remember that it is the presence of volar subluxation, not the size of the avulsion fracture, that determines the need to consider operative management.

Any injury, whether open or closed, that results in a complete disruption of the TEM may result in a swan-neck deformity (Fig. 49-24). This deformity consists of flexion at the DIP (a mallet finger) and hyperextension at the PIP joint. This results from a dorsal and proximal displacement of the lateral bands causing increased extension forces on the middle phalanx. This complication often can be avoided if disruption of the TEM is diagnosed and treated correctly in the ED.

Figure 49-20 Dermatotenodesis technique for zone I extensor tendon repair. *A,* Fresh lacerations of the extensor mechanism over the distal joint with mallet finger deformity are

repaired by a running-type suture, which simultaneously approximates the skin and tendon *(B and C)*. A small dressing is applied along with a splint, which maintains the joint in full extension. The sutures are removed at 10 to 12 days, but the splint is continued for a total of 6 weeks. *(Adapted from Doyle JR: Extensor tendons: Acute injuries. In Green DP [ed]: Operative Hand Surgery, 4th ed. New York, Churchill Livingstone, 1999, p 1968.)*

COMPLICATIONS

All extensor tendon repairs are subject to the usual complications of wound infection and skin breakdown secondary to prolonged splinting. Tendon rupture is a rare complication following tendon repair and may result from inadequate suture technique or premature motion against resistance. It is important when extensor tendons are repaired for at least five throws to be used and a square knot to be tied. All extensor tendon repairs require some period of complete immobilization during tendon healing, and it is important for the emergency clinician to stress the necessity for patient compliance.

Extensor tendon injuries in zone 7 tend to have the worst prognosis. Because of the presence of a synovial lining, postrepair adhesions may occur. The adhesions may lead to decreased excursion of the extensor tendons with resultant decreased mobility at the wrist. There may also be limitation of finger flexion when the wrist is flexed, as well as finger extension when the wrist is extended. Because of the lack of synovium, the relatively simple anatomy, and the usual lack of associated injuries, zone 6 tendon injuries tend to have fewer complications than other areas of the hand. The tendons in zone 6, however, do have a tendency to shorten if the tendon ends are approximated too tightly. This may result in a restriction of PIP and MCP joint flexion.

Zone 5 injuries are particularly prone to infection, as injuries in this region commonly occur from a human bite. In addition, if the extensor hood covering the MCP joint is not carefully repaired, subluxation of the EDC tendon may occur. [7] If complex partial tendon lacerations in zone 4 are managed too aggressively, then tendon shortening and stiffness may result. As discussed previously, these injuries are often

Figure 49-21 Repair of zone II extensor tendon lacerations *(A)*. Zone II lacerations may be repaired with a running stitch *(B)* near the edge of the laceration, followed by the cross-stitch *(C)*. The extensor tendon in this zone is comparatively thin, and this dual-suture technique has sufficient grasping capability to restore and maintain the normal length of the extensor. The repair is protected by 6 weeks of DIP joint splinting, as for zone I injuries. *(Adapted from Doyle JR: Extensor tendons—Acute injuries. In Green DP [ed]: Operative Hand Surgery, 4th ed. New York, Churchill Livingstone, 1999, p 1971.)*

best managed with splinting alone. A common complication of zone 3 extensor tendon injuries is development of a boutonnière deformity. This usually results from failure to diagnose or adequately immobilize a central slip injury. Similarly, undiagnosed or improperly treated extensor tendon injuries in zones 1 and 2 may lead to either a swan-neck or chronic mallet deformity of the digit. DIP joint splinting itself may result in skin ulceration or tape allergy, usually presenting in the second week of treatment.[1] Skin breakdown may be encouraged if the DIP joint is splinted in hyperextension, because of decreased skin perfusion.

POSTREPAIR CARE AND REHABILITATION

Proper care after diagnosis and repair of an extensor tendon injury is extremely important for optimal patient outcome. Even the best initial tendon repair can have a poor result if subsequently treated improperly. The rehabilitation of tendon injuries has evolved since 1980 to include dynamic splinting and active range-of-motion exercises to obtain maximal motion of the affected digit.

Zone 1 and 2 injuries are usually treated with static splinting as described previously. After 6 weeks, active range-of-motion exercises should begin. Night splinting is recommended for an additional 2 weeks.[19] [22] Some authors also recommend wearing the splint during the day between exercises.[1] It is advisable to give the patient a number of extra splints so that the patient (or family) can change the splint

Figure 49-22 A proper mallet finger splint. Either a commercially available volar plastic splint (Stack mallet finger splint) *(A–C),* or a volar or dorsal aluminum foam splint may be used *(D and E)*. The splint should allow easy motion of the proximal interphalangeal joint. *(Adapted from Doyle JR: Extensor tendons—Acute injuries. In Green DP [ed]: Operative Hand Surgery, 4th ed. New York, Churchill Livingstone, 1999, p 1967.)*

frequently to avoid pressure injury. During splint changes, it is important that the DIP joint be held in full extension either by using the other hand or by placing the finger against a table. If an extension lag develops at any time, continuous splinting must be repeated. Closed injuries of the central slip (zone 3) are often treated with a boutonnière splint for 4 weeks, followed by 2 weeks of gradual flexion exercises and night splinting. During the initial 4 weeks, the patient should be instructed to passively flex the DIP joint every hour to maintain gliding and proper position of the lateral bands.

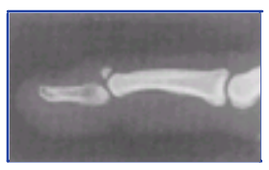

Figure 49-23 A mallet fracture with volar subluxation of the distal phalanx.

Figure 49-24 Swan neck deformity. *(Courtesy of Raymond G. Hart and Joseph E. Kutz.)*

Lacerations in zones 3 and 4 have traditionally been treated with static splinting from the forearm to digits. An alternative approach is to splint only the DIP and PIP joints in extension, and begin a "short-arc-motion" protocol within 1 to 2 days of repair.[3] This consists of active motion at the PIP joint progressing from 0° to 30° the first 2 weeks to 0° to 50° the fourth week. When compared to static splinting, this protocol may lead to better PIP and DIP joint flexion, without resulting in tendon rupture or boutonnière deformity. Dynamic extension splints are also proving to be useful for zone 3 and 4 tendon injury rehabilitation.[1] [3] [11]

Early motion following extensor tendon repair has been found to be most useful in zones 5 through 7. A dynamic extension splint is commonly used in which the wrist is extended 45°, and all finger joints rest in the neutral position (Fig. 49-25). A volar block allows 30° to 40° of MCP joint flexion, while a dynamic traction mechanism passively extends the digits. Dynamic splinting is started 1 to 3 days following repair. Active motion is added at 3 to 4 weeks, and resistance is added at 7 weeks. A short-arc-motion protocol with controlled active motion at the MCP joint has also been shown to be safe and effective when started 24 to 48 hours after repair.[3] One comparative trial reported that dynamic extension splinting and controlled active mobilization worked equally well for zones 5 and 6 tendon injuries.[12] Both protocols are most beneficial when managed closely by a skilled hand therapist. Patients must be reliable and motivated to take advantage of these techniques. It is best to refer patients to a hand surgeon or hand therapist as soon as possible following repair so that rehabilitation can begin in a timely manner.

EXTENSOR TENDON INJURIES OF THE FOOT

The extensor tendons of the foot are less commonly injured than the extensor tendons of the hand and wrist. The most important extensors of the foot and ankle that may be presented with injuries in the ED are the tibialis anterior, extensor hallucis longus, and extensor digitorum longus tendons.

The tibialis anterior muscle originates on the shaft of the tibia and interosseous membrane and inserts on the medial cuneiform and the base of the first metatarsal. The tibialis anterior extends the foot at the ankle joint and inverts the foot at the subtalar and transverse tarsal joints. Spontaneous rupture of the tibialis anterior tendon may be seen in both elderly and young patients who have been injured during athletic activity. Injury to this tendon commonly results from forceful attempted dorsiflexion of the ankle while it is held fixed in the

Figure 49-25 A dynamic extension splint allows for early motion following extensor tendon repair. Elastic retraction maintains the fingers in extension. Excursion of the repaired tendon is achieved by active flexion. *(Adapted from Doyle JR: Extensor tendons—Acute injuries. In Green DP [ed]: Operative Hand Surgery, 4th ed. New York, Churchill Livingstone, 1999, p 1957.)*

plantar-flexed position.[18] Patients generally present with decreased strength of foot dorsiflexion, because toe extensors are used to accomplish this motion. Ruptures or lacerations of the tibialis anterior tendon should be referred promptly to an orthopedic surgeon for consideration of formal operative repair.

The extensor digitorum longus (EDL) and extensor hallucis longus (EHL) tendons both originate from the shaft of the fibula and interosseous membrane. The EHL tendon inserts into the base of the distal phalanx of the great toe, while the EDL tendon divides into four branches that insert on toes 2 through 5 (Fig. 49-26). Both the EHL and EDL tendons primarily result in extension of the toes and dorsiflexion at the ankle. The extensor digitorum brevis (EDB) and extensor hallucis brevis (EHB) muscles originate from the upper part of the calcaneus. The EHB tendon joins the lateral aspect of the EHL tendon prior to inserting on the great toe. The EDB muscle gives rise to three tendons that join the lateral side of the EDL tendons going to toes 2 through 4 (see Fig. 49-26).

Injury to the EHL and EDL tendons may result from a sharp object lacerating the dorsum of the foot. Patients may present with weakness of, or an inability to extend, the involved toe. The examiner may be unable to palpate the injured tendon. Whether one should repair EHL or EDL tendon lacerations is controversial. However, many authors favor repair; failure to repair EDL tendons may result in a claw deformity of the adjacent toes. [4] Lacerations of EHL and EDL at the level of the ankle are usually repaired, while lacerations on the dorsum of the foot and the toe are managed variably. If the patient has significant pain or has any flexion deformity of the involved toe, one should probably repair the lacerated tendon. Repair is also favored when both tendon ends are easily visualized in the wound, and the patient is willing to undergo

Philadelphia, JB Lippincott, p 423.)*

prolonged postrepair immobilization.[20] Because management of these injuries is controversial, it is advisable to discuss the care of these patients with the consulting orthopedic surgeon. Extensor tendon repair of the foot is usually not performed in the ED setting. Superficial cutaneous nerves are easily injured on the dorsum of the foot during wound exploration, which

can lead to the formation of a chronic, painful neuroma. If the injury is repaired in the ED, the technique for repair is similar to that used for the dorsum of the hand (zone 6). A posterior splint that includes the toes should be applied following tendon repair. The ankle should be splinted at 90° with the toes in the neutral position (see Chapter 51).

FLEXOR TENDON INJURIES

Flexor tendon injuries are more difficult to diagnose and more challenging to treat than extensor tendon injuries. In general,

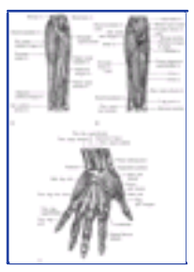

Figure 49-27 Flexor tendons of the right forearm, wrist, and hand. *A,* Superficial forearm layer. *B,* Deep forearm layer. *C,* Left wrist and palm. Proper function of the flexor tendons requires defect-free tendons and smooth tendon sheaths for easy gliding, and an intact pulley system; hence, flexor tendon lacerations are seldom repaired in the ED. *(Modified from Pansky B: Upper extremity. In Pansky B [ed]: Review of Gross Anatomy, 4th ed. New York, Macmillan Publishing, 1979, pp 219, 243.)*

ED repair of flexor tendons is not performed by emergency clinicians. Anatomic and biomechanic issues, the physiology of flexor tendons and tendon healing, and follow-up rehabilitation/physical therapy issues are complex and formidable. A satisfactory outcome of an injured flexor tendon is more difficult to achieve than is a similar degree of injury to an extensor tendon. Unlike extensor tendons, flexor tendons are influenced by a number of pulley mechanisms. The tendon must glide through delicate tendon sheaths, so even a minor defect in tendon integrity is physiologically magnified (Fig. 49-27). In addition, flexor tendon injuries are often associated with nerve and vascular injuries.

Figure 49-28 Deep puncture wounds of the palm may injure flexor tendons. The depth of this wound precludes extensive exploration to visualize the tendon. Partial tendon lacerations may still initially allow full function. Clues to a partial tendon laceration include weakness of flexion or pain with attempts at flexion against resistance, but many partial lacerations are clinically silent. Despite full function this wound's location and depth suggest the possibility of at least a partial tendon injury. The prudent course would include meticulous wound care, splinting, skin closure, and contact with a hand specialist to arrange re-examination in a few days, while cautioning the patient that further care may be required.

The main clinical mandates for emergency clinicians are to diagnose, or consider, flexor tendon injuries; provide initial proper wound care; and expedite appropriate consultation and follow-up. Unlike the more superficial extensor tendons, flexor tendons are often buried deep within the hand and forearm, and it is often not possible to readily visualize the tendon in the recesses of a wound. Puncture wounds of the palm often injure flexor tendons, but deep puncture wounds prohibit visualization of the injured structures (Fig. 49-28). Therefore, a partial flexor tendon injury may be totally

Figure 49-29 *A,* The flexor digitorum profundus tendon is examined by immobilizing the digit in question and asking the patient to flex the distal interphalangeal joint against resistance. *B,* The flexor digitorum superficialis tendon is examined by immobilizing the digits not being tested and asking the patient to flex the proximal interphalangeal joint against resistance. Pain and weakness associated with flexion against resistance may suggest a partial tendon laceration, but this is often a very subtle or inaccurate evaluation that must be repeated when pain and swelling have subsided.

clinically silent until rupture occurs days or weeks later. Delayed repair of undiagnosed flexor tendons may be complicated by tendon retraction or scar formation, and tendon transfer/grafting may be necessary.

It may not be possible for the emergency clinician to diagnose the presence of all flexor tendon injuries, nor the full extent of such injuries, on the initial visit. Help may be obtained from a specialist if logistically possible, but generally there is no mandate for such immediate on-site examination when there are questions about tendon integrity. While consultation is advised prior to definitive disposition, the same limitations in the examination would similarly confront a specialist. Individual scenarios and local protocols will guide the timing and degree of consultation in the ED.

Complete flexor tendon injuries are often readily apparent on physical examination, either by individual tendon testing or by the resting posture of the injured hand. Partial tendon lacerations are commonly clinically unappreciated since no functional deficit is evident. Clinical clues to a potential flexor tendon injury are weakness of flexor tendon function (difficult to evaluate in the acutely injured extremity), pain at the site of injury when performing active range of motion against resistance, or an abnormal resting posture of the hand (Fig. 49-29). However, the clinician may not ever be able to arrive at a complete or accurate diagnosis without surgical exploration. *It is counterproductive, and potentially harmful, to attempt extensive exploration of the deep recesses of the hand or forearm in the ED merely to visualize a suspected flexor tendon injury.*

Completely transected flexor tendons are surgically repaired by a consultant, usually on an elective basis. Most hand surgeons are reluctant to perform a primary repair of a flexor tendon injury on ED patients, and prefer to have the wound cleaned, the skin closed, and the patient schedule a subsequent definitive repair. The final outcome of flexor tendon surgery depends on multiple factors; however, surgical repair of most flexor tendons that is accomplished within 10 to 21 days of injury (delayed primary repair) generally

manifests final outcomes similar to immediate repair.[6] [21] [24] Therefore, if a partial tendon laceration is not diagnosed on the initial visit, and rupture is noted at the time of skin suture removal or wound check, immediate referral to a hand surgeon would be expected to produce a similar result as expected had the injury been diagnosed at the time of injury.

Partial flexor tendon lacerations, if appreciated, are usually treated by careful wound cleaning, skin closure, splinting, and referral for reevaluation in 1 to 5 days. The definitive treatment of partial lacerations remains quite controversial. Some surgeons will explore partial tendon lacerations. There is some experimental evidence that surgical repair of partially lacerated tendons results in weaker tendons than if the tendons were not surgically repaired. [28] To further complicate the issues, some authors suggest no suturing and early mobilization of lacerated tendons of 25 to 95% cross-sectional area. [27] As a guideline, tendon lacerations of greater than 50% cross-sectional area are often sutured with specific surgical techniques, 25 to 50% lacerations are repaired with simple or special sutures, and injuries of less than 25% are trimmed to promote normal gliding function.[24] All decisions concerning the type and timing of repair should be made in concert with a consultant. Some decisions concerning surgical repair of partial injuries cannot be made for weeks or months.

Following evaluation of a known or suspected flexor tendon injury, the skin is sutured and the hand splinted to protect the tendon and minimize retraction. Techniques vary, but splinting with the wrist in 30° of flexion, the MCP joints in 70° of flexion, and the interphalangeal joints flexed at 10 to 15% has been recommended. [8] There are no data to support or refute the value of prophylactic antibiotics in any soft tissue injury that has been properly cleaned. Although no definitive standard of care is promulgated, many clinicians prescribe 3 to 5 days of antibiotics effective against gram-positive organisms (including *Staphylococcus aureus*) if the tendon is injured.

Antibiotics are recommended if the degree of contamination is significant, there has been delay in cleaning, there are unusual sources of injury, or if the patient is immunocompromised. Specific written instructions, *with a definite follow-up time frame outlined,* and help with patient referral will likely improve final outcome, but flexor tendon injuries often produce life-long disability despite even ideal care in the ED.

Chapter 50 - Management of Common Dislocations

Jacob Ufberg
Robert McNamara

Joint dislocations are frequently encountered among patients presenting to the emergency department (ED). They can range from a simple finger injury to limb- or life-threatening consequences of high-energy trauma. Although the dislocated joint is most often clinically obvious, the presentation may be obscure or masked by other injuries. Emergency clinicians must be capable of detecting and managing these injuries; appropriate timely referral to a consultant is generally required for complex dislocation injuries.

This chapter addresses the diagnosis and management of joint dislocations. Keys to the clinical assessment and radiographic evaluation of these injuries are discussed along with methods of reduction. The emphasis of the chapter is on simple dislocations that should be diagnosed and generally managed in the ED. Fracture-dislocations that commonly require operative intervention and emergency orthopedic consultation are not discussed.

PREPARATION OF THE PATIENT

Although many authors claim their reduction method is well tolerated without premedication, they generally have not quantitatively measured the discomfort of their patients.[1] [2] [3] [4] [5] There are no rigid generally accepted guidelines for the use of pharmacologic adjuncts in the management of dislocations. Each patient and presentation is unique and the treating clinician must use judgment as to whether premedication is required, which agent or agents to use, and what dose to give. *In general, the editors suggest the judicious use of analgesia/sedation for the majority of reductions performed in the ED.* The calm, cooperative patient may tolerate gentle reduction attempts of a major joint such as the shoulder, but even the most stoic of patients may be quite uncomfortable with the manipulations necessary for reduction of a dislocated finger. A radial head dislocation in a child is usually easily accomplished without analgesia; however, the reduction of a hip dislocation is rarely successful without a significant amount of anesthesia/analgesia. Attempting any reduction technique in an extremely anxious patient without premedication will generally frustrate the operator and further upset the patient, and it may hinder a successful outcome. When multiple attempts are required, and significant force must be exerted due to muscle spasm or an uncooperative patient, there is additional chance of producing complications during the reduction.

Verbal techniques for alleviating anxiety and discomfort are not to be discounted as they can be of great assistance during joint reduction. In field settings, simple hypnosis techniques have been successfully used for major joint dislocations.[6] In the ED, verbal reassurance and distracting conversation are useful adjuncts.

In most circumstances, analgesia or sedation of some sort, or both, will be required; generally the intravenous (IV) route for drug administration is the method of choice, as it allows for rapid relief of patient discomfort and facilitates repetitive dosing for titration to the desired effect. Chapter 34 provides an in-depth discussion of procedural sedation and analgesia for a wide variety of ED procedures, including joint reduction. Alternatives to procedural sedation and analgesia include intra-articular injection of lidocaine, hematoma blocks (see Chapter 30), peripheral nerve blocks (see Chapter 32), and regional anesthesia (see Chapter 33).

GENERAL PRINCIPLES

The clinical assessment of the patient with a dislocation must include a search for other injuries, especially if the mechanism was of high energy. This is generally most important for hip, knee, and posterior sternoclavicular dislocations. For all dislocations, a detailed extremity neurovascular examination should be conducted and appropriately documented prior to focusing attention on the injured joint.

Although many dislocations are clinically obvious, some may escape detection for some time while other injuries or issues dominate the clinical picture. A knee dislocation may be quite obvious in a 170-pound man who displays a deformity of the knee, but in a 400-pound obese patient, the knee may look deceivingly normal on first glance. The history and mechanism of injury can be quite helpful in certain circumstances. For example, a painful shoulder joint in a seizure patient should prompt assessment for a posterior shoulder dislocation, whereas a history of the knee striking the dashboard will clue one to the potential for a hip dislocation. Some dislocations will have been reduced prior to clinician assessment. A careful history will uncover these injuries and prompt the necessary assessment of the ligamentous integrity of the joint and guide proper immobilization and follow-up care. A dislocated, then spontaneously reduced, knee has escaped detection by even the seasoned clinician's initial evaluation. Other dislocations that commonly present in a reduced state include finger dislocations, knee dislocations, patellar dislocations, and radial head subluxations.

Although the chance of a gentle reduction attempt causing a fracture or neurovascular injury is extremely low, *careful evaluations before and after reduction, as well as documentation of the neurovascular status, are prudent*. Often the initial pain of the dislocation is distracting, and paresthesias or a weak pulse may not be readily apparent until the joint has been replaced. When the integrity of the pulse is in question, the blood pressure at the wrist or foot may be compared to the uninjured extremity, or a pulse oximeter may be applied to the distal fingers (Fig. 50-1). *Prereduction radiographs of dislocated joints are generally recommended.* Reasons for this include the difficulty in distinguishing a fracture—dislocation by clinical examination and the potential for medicolegal problems if the fracture is not identified prior to reduction attempts. More important, certain associated fractures predict a poor outcome from closed reduction and make orthopedic consultation a consideration prior to such attempts. The obvious exceptions to this rule include suspected radial head subluxation in young children, clinical circumstances in which radiographs are not readily available (e.g., in the wilderness), minimally symptomatic patients with recurrent shoulder dislocations with a history of minor to no trauma, and clinical conditions (i.e., vascular compromise or

Figure 50-1 Significant vascular injuries from dislocations, such as the knee, are usually obvious, but some reduction in distal circulation may be subtle due to partial vascular compromise that heralds subsequent ischemia. The standard techniques to assess vascular injury are assessing the strength of the pulse and capillary refill, but other techniques may be helpful. While these procedures are neither well studied nor quantified, taking the blood pressure distal to the injury with a cuff and Doppler (shown here) or applying a pulse oximeter distal to the injury and comparing the results to the uninjured extremity may give some helpful clues to underlying vascular injuries. Calculating a brachial/ankle blood pressure index (see Chapter 1) is also more accurate than simple palpation.

threatened skin penetration) that dictate the need for immediate reduction. Some also question the need for prereduction films in certain patients with anterior shoulder dislocations.[7] [8] *The editors strongly suggest postreduction films in virtually all patients who have had a dislocation reduced in the ED.* Although postreduction radiographs are traditionally obtained, the need for this in a clinically obvious successful shoulder joint relocation also has been questioned. [8] [9] Although postreduction films are often not clinically useful and may not be cost-effective, they are recommended as prudent clinical practice and for medicolegal purposes.

Patients who have received sedatives and opioids may not remember the actual successful reduction or the immediate postreduction period. A reinjury after release from the ED without radiographic corroboration of a successful reduction can raise questions about the adequacy of the initial procedure. Occasionally a fracture is detected on postreduction radiographs that was not obvious on the initial films, or a previously noted minor fracture may be found to reside in an intra-articular location.

The proper terminology for dislocations describes the relationship of the distal (or displaced) segment relative to the proximal bone or the normal anatomic structure. The terms *anterior* and *posterior* are used in most dislocations. Therefore, if the head of the humerus lies anterior to the glenoid fossa, the injury is an *anterior shoulder dislocation*. Similarly, if the olecranon lies behind the distal end of the humerus, the injury is a *posterior elbow dislocation*. In the hand, wrist, and foot, one uses the terms *dorsal* and *volar. Palmar* and *plantar* are sometimes used in place of volar to describe the position of the dislocated part. Dislocations can be open or closed and may have associated fractures requiring separate description.

It is generally accepted that the sooner a dislocation is reduced, the better. This alleviates the patient's discomfort and corrects the distortion of surrounding soft tissue structures. In some studies the success rate of relocation (reduction) is higher when attempted closer to the time of injury. [2] However, there is no reason to forego an attempt at a closed reduction due to "old injuries" in the vast majority of dislocations. Chronic dislocations of several days, weeks, or more are often difficult to reduce in a closed manner, but such presentations are infrequent.

General points about the reduction itself include the need for patience on the operator's part and the avoidance of excessive or abrupt applications of force. Gentle and gradual application of the various reduction techniques lessen the risk of complications. The operator must clearly understand the technique to be applied, and one should not hesitate to review a description of the procedure on a regular basis. Review of the technique is most important for uncommon dislocations, but it is a good habit even for the more common dislocations performed by seasoned clinicians.

A certain percentage of all types of dislocations are not amenable to closed reduction. Inability to complete a closed reduction is generally a result of the interposition of soft tissue structures or fracture fragments and not necessarily due to improper technique. If one has achieved sedation/analgesia adequate to permit relaxation of the patient's muscle tone, reduction should be relatively straightforward. When reduction under adequate sedation/analgesia is unsuccessful, multiple attempts at closed reduction are inappropriate. Generally, orthopedic consultation should be considered after two failed attempts.

Once an attempt at reduction is completed, the operator should recheck the neurovascular status that was documented before the reduction was performed. For the elbow, hand, and forefoot joints, passive range of motion is performed to assess the stability of the reduction and to ensure a smoothly gliding joint that is free of intra-articular obstruction. In addition to close monitoring of the medicated patient, proper aftercare involves adequate immobilization of the injured joint for comfort and to prevent repeat dislocation. Recommendations for follow-up care are dependent on the injury and its severity.

Timing of Reductions

Questions often arise concerning the necessity of immediate reduction vs delayed reduction, with the clinician fearing disastrous neurovascular consequence if a dislocation is not manipulated immediately upon arrival. In reality, there is rarely an instance where some prereduction radiographs, even portable films, cannot be obtained prior to treatment. Even if the pulse is weak, or the fingers are numb, a few minutes' delay is usually acceptable in order to gain important radiographic information on the type of fracture and for documentation for the follow-up clinicians. Important clinical information may be difficult to obtain or the specific initial injury may be impossible to reconstruct once the joint has been reduced (Fig. 50-2). Of equal importance, dislocation with concomitant neurovascular injuries should be

reduced with the least amount of trauma possible, often requiring a

Figure 50-2 *A* and *B*, Because the distal pulse is weak and the toes are numb, it may be tempting to immediately reduce these obvious dislocations while the patient is still on the ambulance stretcher. Some clinicians prefer to first obtain proper analgesia/sedation to allow a less traumatic reduction. *C*, Prereduction radiographs (even limited-view portable films are acceptable) can be helpful since once the reduction is accomplished, the specific initial injury may be impossible to reconstruct from the physical examination alone. The few minutes required to properly prepare the patient for reduction and to document the initial injury should not result in a more adverse outcome than has been prognosticated by the initial injury. However, when the patient has sustained multiple trauma and extremity films are a low priority, early reduction without radiographs may be warranted.

few minutes for the induction of analgesia/sedation, a time during which radiographs can be obtained. *If a vascular or neurologic abnormality is documented prior to reduction, the joint should be reduced by the most timely and least traumatic procedure available.* Each case should be handled individually, considering the specific injury, available resources, and experience of the clinician. Although multiple unsuccessful or forceful attempts at reduction in the ED should be avoided with all dislocations, this is especially important if there is vascular or neurologic compromise. Occasionally, the more prudent course is reduction under general anesthesia, but this decision must be analyzed given the availability of consultation and other resources.

This chapter covers dislocations of the various joints with the exception of wrist dislocations, which are complex and require orthopedic consultation, and temporomandibular joint dislocations, which are discussed in Chapter 65 . Assessment and management principles, including reduction methods, are presented and aftercare is discussed.

SHOULDER DISLOCATIONS

The human shoulder joint is remarkable for its degree of possible motion. The anatomic features that allow for this mobility, however, contribute to its instability. The glenohumeral joint has the greatest range of motion of any joint in the body, largely due to the loose joint capsule and the shallow nature of the glenoid fossa. [10] Posterior dislocation is uncommon, largely due to the anatomic support of the scapula and the thick muscular support in this area. The anterior support is less pronounced, with the inferior glenohumeral ligament serving as the primary restraint to anterior dislocation. [11] The depth of the glenoid fossa is somewhat increased by the fibrocartilaginous glenoid labrum, which forms the rim of this structure.

Most shoulder dislocations are anterior (i.e., the humeral head becomes situated in front of the glenoid fossa). Posterior dislocations are the next most common, but they generally account for less than 4% of shoulder dislocations. [12]

Uncommon variations include inferior (luxatio erecta), superior, and intrathoracic dislocations. Dislocations of all types, including the shoulder, are less common in children due to the relative weakness of the epiphyseal plate as compared to the ligamentous support of the joint.

Anterior Shoulder Dislocations

Anterior dislocations of the shoulder are the most common major joint dislocation encountered in the ED. The usual mechanism of injury is indirect, with a combination of abduction, extension, and external rotation. [10] [11] Only rarely is the mechanism a direct blow to the posterior aspect of the shoulder. Occasionally, especially with recurrent dislocations, the mechanism is surprisingly minor, such as mere external rotation of the shoulder while rolling over in bed or raising the arm overhead. The occurrence of a first dislocation at a younger age is associated with a higher recurrence rate; 80% to 92% with a first dislocation before age 20 years vs 10% to 15% in patients with a first dislocation after age 40 years. [10] Rotator cuff injuries, however, occur more frequently in older patients with anterior shoulder dislocations. [13]

The 4 types of anterior dislocations are subcoracoid (accounting for >75% of anterior dislocations), subglenoid, and the uncommon subclavicular and intrathoracic. [10] These are classified according to where the humeral head comes to rest (Fig. 50-3).

Clinical Assessment

The presentation of anterior shoulder dislocation is usually obvious (Fig. 50-4). Posterior dislocations are more subtle on both clinical presentation and radiographic manifestations, and can be misdiagnosed as a severe contusion (Table 50-1). The patient supports the injured extremity and leans toward the injured side, holding the arm in *abduction* with slight external rotation. The patient cannot *adduct* or internally rotate the shoulder. Visual inspection reveals loss of the rounded appearance of the shoulder due to the absence of the humeral head beneath the deltoid region. The acromion is prominent and an abrupt drop-off below the acromion can be seen or palpated. An anterior fullness in the subclavicular region is visible in thinner individuals and is easily palpable in most others. Comparison to the uninjured side is a useful aid for both visual examination and palpation. Any attempt at internal rotation is quite painful and is resisted by the patient. The inability to place the palm from the injured extremity on the uninjured shoulder is consistent with anterior shoulder dislocation; postreduction, this maneuver should be possible.

A careful assessment of the neurovascular status of the affected extremity is essential. Injury to the axillary artery is rare, usually occurring in the elderly [13] and can be quickly assessed by palpation of the radial pulse or the presence of an expanding hematoma. It is important to assess the status of the axillary nerve, as this is the most common nerve lesion resulting from anterior dislocations. [14] The sensory component of the axillary nerve is assessed by testing for sensation over the lateral aspect of the upper arm (Fig. 50-5). The motor component of the axillary nerve would be tested by assessing the strength of the deltoid muscle, a difficult undertaking in the patient with a dislocated shoulder. Less commonly, the brachial plexus may be injured by a stretch injury, producing variable nerve deficits. The neurologic examination should include a complete assessment of all major nerves to the arm,

Figure 50-3 Types of anterior dislocations. These types of anterior dislocations should receive the same treatment. *A,* Subglenoid dislocation (rare type). *B,* Subcoracoid dislocation (most common type). *C,* Subclavicular dislocation (rare type). *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, p 617. Reproduced by permission.)*

as other nerve injuries such as to the ulnar and radial nerve may occur. [14] The presence of a neurologic deficit does not preclude closed reduction, *but in the presence of a nerve injury, multiple forceful attempts at reduction should be avoided*. Brachial plexus injuries require an especially atraumatic reduction. If generous sedation/analgesia does not permit an easy reduction in the ED, reduction of the dislocation with a nerve injury may be more prudently performed in the operating room under general anesthesia. Nerve injuries in this setting generally have a good prognosis, but the patient should be informed of the findings and the need for follow-up. Symptoms may require many months to resolve.

The rare vascular injuries, such as axillary artery disruption, are usually quite obvious, producing dysesthesias and coolness of the involved arm. An expanding axillary hematoma, pulse deficit, peripheral cyanosis, and pallor can be seen. Collateral circulation may produce a faint pulse in the extremity, so comparison blood pressure of the uninjured side may be helpful. Specific lesions include complete disruption, linear tears, or thrombus. Axillary artery injuries can occur in all ages, although they are more prominent in the

Figure 50-4 *A*, Typical presentation of an anterior right shoulder dislocation. The shoulder is very painful; thus, the patient resists movement. The outer round contour of the shoulder is flattened, and the displaced humeral head may be appreciated in the subcoracoid area. Often the patient abducts the arm slightly, bends the torso toward the injured side, and supports the flexed elbow on the injured side with the other hand. *B*, Another example of an obvious left shoulder dislocation. This chronic dislocation occurred frequently with minimal trauma, in this case from rolling over in bed.

elderly. The artery is at risk with anterior dislocations, and a dislocation-spontaneous reduction can produce the injury. Arteriography with surgical repair of the artery is required, occasionally with fasciotomy of the forearm if ischemia is longstanding. [15]

Some portion of the rotator cuff will be injured in many shoulder dislocations. Rotator cuff tears are easier to evaluate after reduction, often days later when pain and swelling have subsided.

Radiologic Examination

Associated fractures are detected in 15% to 35% of anterior shoulder dislocations, with fractures of the greater tuberosity being the most common. [10] The presence of a fracture of the greater tuberosity does not change the initial management of anterior shoulder dislocations, and these fractures usually heal well after closed reduction in the routine fashion. [10] The Hill-Sachs deformity, a sign of repeated dislocations, produces a groove in the posterolateral aspect of the humeral head and

TABLE 50-1 -- Comparison of Anterior and Posterior Shoulder Dislocations: Classified According to the Displacement of the Humeral Head

Type of Dislocation	Patient Presentation	Other Clinical Clues	Radiographs
Anterior	• Arm held in *abduction* and *slight external rotation* (abduction more prominent in subglenoid dislocation)	Seen from the front, shoulder appears "squared off"	*On AP view*: obvious dislocation
99% subcoracoid and subglenoid			
Humeral head is *anterior* to the glenoid		Distal acromion prominent from side view	*On lateral or "Y" view*: humeral head appears *anterior* to glenoid fossa
	• Patient cannot adduct or *internally* rotate shoulder		
Posterior	• Arm held in sling position, with adduction and internal rotation	Coracoid process prominent, glenoid fossa empty anteriorly and humeral head bulging posteriorly	*On AP view*: vacant glenoid sign, 6-mm sign, light bulb sign
95% subacromial			
5% subglenoid and subspinous			
Humeral head is *posterior* to the glenoid	• Attempts at *abduction* and *external rotation* cause extreme pain		*On lateral or "Y" view*: humeral head appears *posterior* to glenoid fossa

may be seen on prereduction or postreduction films (Fig. 50-6). It is caused by impaction of the humeral head against the glenoid rim after dislocation. It rarely has clinical significance, but may result in a loose body within the joint. [13] Impaction of the humeral head against the glenoid during dislocation may cause a disruption of the glenoid rim, known as a "Bankart lesion." This has been implicated as one cause of recurrent dislocations, but does not affect immediate ED management. [13]

Fractures of the humeral neck are frequently displaced with attempts at closed reduction, the result of which is often avascular necrosis of the humeral head. [16] The fact that humeral neck fractures are a known complication of shoulder relocation [10] suggests the value of prereduction radiographs in anterior shoulder dislocations. However, some argue that *clinically obvious recurrent dislocations and clinically obvious anterior dislocations without a blunt trauma injury mechanism* (information usually offered by the patient) can be reduced without prior radiographs, as fracture is quite unlikely in these situations. [7] [8]

Figure 50-5 Evaluation of the upper extremity with a shoulder dislocation. Axillary (circumflex) nerve palsy is the most common neurologic complication. The axillary nerve has a sensory and motor function. Test the integrity of the nerve by assessing sensation to pin prick (*1)* in its distribution over the "regimental badge" area. (The shoulder is usually too painful to allow assessment of deltoid activity with certainty.) Look for other (rare) involvement of the radial portion of the posterior cord (*2)* and involvement of the axillary artery (*3)*. *(From McRae R: Practical Fracture Treatment. Edinburgh, Churchill Livingstone, 1981, p 84. Reproduced by permission.)*

Anterior dislocations are not subtle on the routine anteroposterior (AP) radiograph, and this view detects the most important fracture to identify, that of the humeral neck. An adequate AP view, when combined with the typical clinical examination, allows for successful management of most anterior shoulder dislocations. The true AP view of the shoulder is taken at a right angle to the scapula, requiring rotation of the patient to 30 to 45° as shown in Figure 50-7 .

Figure 50-6 With repeated anterior shoulder dislocations, a Hill-Sachs lesion may form. During the dislocation the humeral head is damaged by the sharp anterior rim of the glenoid *(2)*. With repeated dislocation the lesion, called the "hatchet sign" develops *(3)*. On the reduction film the lesion is apparent *(4)*.

The typical lateral views obtained include the scapular Y view (Fig. 50-8), the transthoracic view, and the axillary view. These views rarely add to the AP in the obvious anterior dislocation, but they are of value in *posterior* dislocations. The usefulness of additional views in anterior shoulder dislocations is primarily to detect fractures, and the previously mentioned lateral views (especially the transthoracic view) are quite limited in this respect. [17] The apical oblique view has been found to be more valuable in acute shoulder trauma than the oblique scapular projection. [17] This view is obtained by angling the beam 45° caudad with the patient in a 45° oblique position (Fig. 50-9*A* and *B*).

Postreduction radiographs are obtained to document the success of the reduction. Occasionally they will reveal a fracture not detected on the prereduction radiographs.

Reduction Techniques

Hippocrates (450 B.C.) is generally credited with the first detailed description of reduction techniques, and it is believed that a drawing in the tomb of Upuy (1200 B.C.) is the earliest depiction of such a method. [10] The Hippocratic technique involves placement of the operator's foot in the axilla to effect countertraction. This technique is problematic and is not recommended by recent authors. [3] [11] Likewise, the Kocher method, which involves forceful leverage of the humerus, has an increased rate of complications and is generally discouraged in favor of other techniques. [10] [11]

This section discusses several methods of reduction that are well studied, proven to be safe, and easy to master. Regardless of the reduction technique used, gradual, gentle application of the technique is essential. Although all of the techniques discussed are generally acceptable and many authors state that their techniques are quite painless, [1] [2] [3] [4] [5] few studies have quantified the actual pain reported by patients. [18] McNamara found that scapular manipulation was generally well tolerated; 62% of patients not receiving premedication reported no or only mild pain during the reduction.

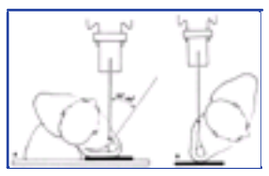

Figure 50-7 Trauma series includes two views of the shoulder made perpendicular and parallel to the scapular plane. This provides an anteroposterior (*A*) and a scapular Y (*B*) view. The advantage is that roentgenograms may be obtained without moving the patient or removing the arm from the sling. *(From Heppenstall RB: Fracture Treatment and Healing. Philadelphia, WB Saunders, 1980, p 374. Reproduced by permission.)*

Additionally, pain ratings were not lessened in the premedicated group. [18] As noted previously, intra-articular lidocaine also may be used to reduce the pain of reduction (Fig. 50-10). In studies by Matthews and Kosnick, the use of intra-articular lidocaine was found to offer significant pain relief during reduction of anterior shoulder dislocations, making it a useful alternative to procedural sedation and analgesia. [19] [20] Note that 10 to 20 mL of 1% lidocaine has been used with the intra-articular technique, and 15 to 20 minutes postinjection is

Figure 50-8 In the trauma series, a lateral view of the scapula (also called scapular Y view) demonstrates the head of the humerus displaced inferiorly and medially, the most common position for an anterior dislocation *(A)*. An anterior dislocation is shown on the anteroposterior projection *(B)*. A posterior dislocation: Transscapular projection showing the dislocated humeral head, posterior in relationship to the intersecting limbs of the Y *(C)*. *(A and B from Heppenstall RB: Fracture Treatment and Healing. Philadelphia, WB Saunders, 1980, p 392; C from Greenbaum E (ed): Radiology of the Emergency Patient. New York, John Wiley & Sons, 1982, p 512.)*

required to expect analgesia. Joint injection does not produce muscle relaxation, but it does obviate the need for intravenous access and prolonged observation. Operator judgment is an important part of the decision as to whether reduction should be attempted without premedication. The advantages of such an approach include the avoidance of potential complications from drug therapy, reduced staff requirements, and theoretically, a more rapid patient disposition. Certainly the patient who is markedly intoxicated may require little if any supplemental

Figure 50-9 *A,* Positioning for apical oblique view. The affected shoulder is placed at a 45° oblique position and the central ray is angled 45° caudad. The affected arm is adducted. *B,* Normal apical oblique view. *(A and B from Heppenstall RB: Fracture Treatment and Healing. Philadelphia, WB Saunders, 1980, p 392. Reproduced by permission.)*

sedative therapy. However, all patients who are more than mildly anxious or who are reluctant to cooperate with an attempt at reduction without medication, and those with a high degree of muscle spasm, should receive premedication. Generally, only one attempt is made and, if unsuccessful, reduction is attempted with the use of medication. When in doubt, it is best to use pharmacologic adjuncts (see Chapter 30 , Chapter 33 and Chapter 34).

Several factors will help decide which technique is best in each situation. One factor is whether the patient will tolerate a reduction attempt without sedation, as attempts without sedation should not use forceful techniques such as traction-countertraction. The comfort level of the clinician with a given technique is always a factor, as the greatest success rates will likely result from techniques with which the clinician is most familiar. The time and resources available to the clinician must be considered, as methods such as the Stimson maneuver require greater time and the availability of weights and straps. Additionally, certain reduction techniques can be performed without assistance, while others require an additional person to apply countertraction or to help with manipulation of the scapula or humeral head. Ideally, the emergency clinician should become familiar with a number of different techniques for reducing anterior dislocations of the shoulder, as no single method has a 100% success rate nor is any technique ideal in every situation.

Stimson maneuver.

The Stimson maneuver (Fig. 50-11) is a classic technique that offers the advantage of not requiring an assistant. The patient is placed prone on an elevated stretcher and about 2.5 to 5.0 kg (5 to 10 lb) of weight is suspended from the wrist. [10] [11] The weights can be strapped to the wrist, or a commercially available Velcro wrist splint can be placed and the weights hung from this with a hook. [21] The slow, steady traction of this method often permits reduction, but it may take 15 to 20 minutes. Reduction may be facilitated by gentle external rotation of the extended arm.

Variations of this method include the recommendation for flexion of the elbow to further relax the biceps tendon and the application of manual traction instead of weights. [22] [23] Rollinson allowed the arm to hang under its own weight after a supraclavicular block and reported a 91% success rate with usually no more than a gentle pull on the arm after 20 minutes in this position. [24] Each variation of the Stimson method can be used in combination with the scapular manipulation technique described later. Indeed, a success rate of 96% has been reported using the combined prone position, hanging weights, IV drug therapy, and scapular manipulation. [21]

Disadvantages of the Stimson method include the time required and the danger of patients slipping off the elevated bed. A "seatbelt" strap or bedsheet may be placed around the patient and stretcher to avoid patient movement off the stretcher. Additionally, a bed that elevates to a suitable height for the patient's arm length, a convenient method to hang the weights, the weights themselves, and adequate staff to monitor the patient are often difficult to locate and organize in a busy ED.

Scapular manipulation technique.

This method is popular due to its ease of performance, reported safety, and acceptability to patients. To date, no complications from this technique have been reported in the literature. [18] [21] [25] Shoulder reduction using this method focuses on repositioning the glenoid fossa rather than the humeral head, and it requires less force than other methods. [21] The success rate is high, generally > 90% in experienced hands. [21] [25]

The initial maneuver for scapular manipulation is traction on the arm as it is held in 90° of forward flexion. This may be performed with the patient prone and the arm hanging down as described in the Stimson method, with or without flexion of the elbow to 90° (Fig. 50-12*A*). Alternatively, this traction may be applied by the operator placing an outstretched arm over the seated patient's mid-clavicle while pulling the injured extremity with the other arm (Fig. 50-12*B*). Regardless of the

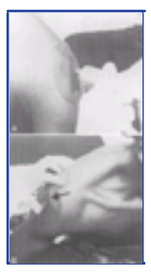

Figure 50-10 Intra-articular injection for the reduction of an acute anterior shoulder reduction. *A,* After aspirating blood from the joint, 10 to 20 mL of 1% plain lidocaine is slowly injected through the lateral sulcus, aiming slightly caudad. *B,* Anterior view. Allow 15 to 20 minutes for the lidocaine to take effect. *(From Matthews DE, Roberts T: Intraarticular lidocaine versus intravenous analgesic for reduction of acute anterior shoulder dislocations. Am J Sports Med 23:54, 1995. Reproduced by permission).*

means of arm traction, slight external rotation of the humerus may facilitate reduction by releasing the superior glenohumeral ligament and presenting a favorable

profile of the humeral head to the glenoid fossa. [26]

The prone patient position is recommended for those not familiar with the technique, as it facilitates identification of the scapula for manipulation (medial rotation of the tip). Nonetheless, the technique can be performed with the patient supine, given that the patient's shoulder is flexed to 90° and the scapula is exposed during gentle upward traction on the humerus. [27] Although seated scapular manipulation offers the advantage of not requiring the patient to go through the awkward and potentially uncomfortable assumption of the prone position, it is a technically more difficult variation of scapular manipulation. When placing the patient in the prone position it is important to place the injured shoulder over the edge of the bed to allow the arm to hang in a perpendicular manner for the application of traction. [25]

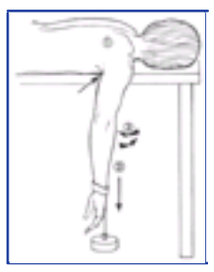

Figure 50-11 Stimson technique. This technique is often tried first, because it is the least traumatic if the patient can relax the shoulder muscles. *1,* The patient is lying prone on the edge of the table. One must be careful that the sedated or intoxicated patient does not fall off the table. Belts or sheets can be used to secure the patient to the stretcher. *2,* 5-kg weights are attached to the arm, and the patient maintains this position for 20 to 30 minutes, if necessary. *3,* Occasionally, gentle external and internal rotation of the shoulder with manual traction aids reduction. *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, p 618. Reproduced by permission.)*

After application of traction, the scapula is then manipulated to complete the reduction. Anderson and coworkers recommend manipulation of the scapula after the patient's arm is relaxed [25] ; however, success is possible with no delay in the performance of this second step. [16] Manipulation of the scapula is carried out by stabilizing the superior aspect of the scapula with one hand and pushing the inferior tip of the scapula medially toward the spine (see Fig. 50-12*A*). The thumb of the hand stabilizing the superior aspect of the scapula can be placed along the lateral border of the scapula and used to assist the pressure applied by the thumb of the other hand. A small degree of dorsal displacement of the scapular tip is recommended as it is being pushed as far as possible in the medial direction. [25]

When the patient is properly positioned, with the affected arm hanging in a perpendicular fashion, the lateral border of the scapula may be difficult to find in larger subjects. This border is generally located quite lateral with the patient in this position, and it must be properly located prior to any reduction attempt. The reduction itself is occasionally so subtle that it may be missed by both the patient and the operator. A minor shift of the arm may be the only clue to the successful reduction. Careful palpation of the subclavicular area prior to repositioning the patient may be used to determine the success of the reduction.

External rotation method.

This method offers the advantage of requiring only one person and no special equipment. The technique requires no strength or endurance on the part of the operator. Additionally, it has been reported to be well tolerated by patients. The actual pain experienced by patients with this technique has not been quantified, but

Figure 50-12 Scapular manipulation technique. *A,* The inferior tip of the scapula is pushed medially and dorsally with the thumbs while the superior aspect of the scapula is stabilized with the fingers of the superior hand. Weights may be attached to the hand to apply hanging traction. *B,* While the patient is seated, the operator applies traction with one hand and countertraction with the other, while an assistant rotates the scapula in the same manner as in *A*. *(From McNamara RM: Reduction of anterior shoulder dislocations by scapular manipulation. Ann Emerg Med 22:1140, 1995. Reproduced by permission.)*

Plummer and Clinton state it can be performed with "little, if any sedation." [3]

In this technique the basic maneuver is *slow, gentle* external rotation of the fully adducted arm. In 1957, Parvin described a self-reduction external rotation technique in which the patient sits on a swivel-top chair and grasps a fixed post at waist height and slowly turns the body to enact external rotation. Parvin reported that the reduction usually takes place at 70 to 110° of external rotation. [28]

Since Parvin's initial study, this method has been described with the patient supine and the affected arm adducted tightly to the side of the patient. [1] [29] The elbow is flexed to 90° and held in the adducted position with the operator's hand closest to the patient. The other hand holds the patient's wrist and guides the arm into slow and gentle external rotation (Fig. 50-13). The procedure may require several minutes, because each time the patient experiences pain, the procedure is momentarily halted. Although the report of Mirick and colleagues mentioned using the forearm as "a lever," [1] a later description clearly recommends allowing the forearm to "fall" under its own weight. [3] No additional force should be applied to the forearm and no traction is exerted on the arm.

The end point of the reduction may be difficult to identify, as reduction is frequently very subtle. It is therefore recommended to continue the external rotation until the forearm is near the coronal plane (lying on the bed, perpendicular to the body), a process that usually takes 5 to 10 minutes. [3] If the patient notes persistent dislocation with full external rotation, steady traction at the elbow may be added at this time. Reduction may occasionally be noted when the arm is rotated back internally. [29] The success rate of this technique in 3 series performed by emergency clinicians was around 80%. [1] [29] [30]

Milch technique.

Proponents of this method praise its gentle nature, high success rate, lack of complications, and tolerance by patients. [2] [5] It can be described as "reaching up to pull an apple from a tree." The basic steps of this technique are abduction, external rotation, and gentle traction of the affected arm. Finally, if needed, the humeral head is pushed into the glenoid fossa with the thumb or fingers (Fig. 50-14).

Milch, in describing this technique, wrote that the fully abducted arm was in a natural position in which there was little tension on the muscles of the shoulder girdle. [31] He postulated that this was related to our ancestral "arboreal brachiation" (swinging from trees). The primary step in this technique is to have the affected arm abducted to an overhead position. Russell and coworkers had their patients raise the arm and put the hand behind the head as a first step. [26] Although this seems odd, patients can usually do this quite readily with little assistance and be quite comfortable in this position. Alternatively, the operator may abduct the arm by grasping the patient's arm at the elbow or the wrist. Lacey and Crawford found that the prone position, with the patient's shoulder close to the end of the bed, facilitated this step. [32]

Once the arm is fully abducted, gentle longitudinal traction is applied with slight external rotation. If reduction does not occur quickly, the humeral head can be pushed upward into the glenoid fossa using the thumb or fingers of the other hand. Beattie and associates reported a success rate of 70% with the Milch technique, [2] but others report success rates of = 90%. [5] [26]

Traction-countertraction.

This method is commonly used in the ED, largely out of tradition, as it has a high rate of success and many emergency clinicians are most comfortable with it. Familiarity is an advantage of this technique, but it requires more than one operator, some degree of force, and, occasionally, endurance. This technique is usually quite uncomfortable for the patient, and premedication is recommended prior to any attempt.

With the patient supine, a sheet or strap is wrapped around the upper chest and under the axilla of the affected shoulder (Fig. 50-15). An assistant holds this sheet so as to apply the countertraction. The operator's foot should *not* be used in the axilla to provide countertraction. Traction may then be applied to the extended arm,

but this generally results in operator fatigue, especially if the operator relies on biceps

Figure 50-13 External rotation method. No traction is applied and a slow, gentle approach is essential. *A,* Arm is adducted to the patient's side. In one hand, the elbow is held flexed at 90° while the other hand grasps the wrist. *B,* Slowly and gently, the forearm is used as a lever to rotate the arm externally. *C,* Usually by the time the forearm has reached the coronal plane, the shoulder will have been reduced. *(From Mirick MJ, Clinton J, Ruiz E: External rotation method of shoulder dislocation reduction. JACEP 8:529, 1979. Reproduced by permission.)*

strength to provide continuous traction. Preferably, the elbow of the affected side is flexed to 90° and a sheet or strap is wrapped around the proximal forearm and then around the operator's back. The bed should be elevated to a point at which the sheet can sit at the level of the operator's ischial tuberosities. This allows the operator to comfortably lean back and use the body weight to supply the force of traction, eliminating the possibility of operator fatigue. The portion of the sheet that is positioned on the patient's forearm has a tendency to ride up; flexion of the elbow beyond 90° will minimize this problem. Alternatively, the operator merely leans backward with the arms fully extended, again using the continuous weight of the body rather than the strength of the biceps to provide constant traction.

Once traction is applied, the operator must be patient, as the procedure may take a number of minutes to be successful. Inadequate premedication is noted by the patient who resists the procedure or is notably uncomfortable during the reduction attempt. The operator should not hesitate to order supplementary medications. Gentle, limited external rotation is sometimes useful to speed reduction. [10] Applying traction to an arm that is slightly abducted from the patient's body is often successful, but some operators prefer to slowly bring the arm medial to the patient's midline while maintaining traction or to have an assistant apply a gentle lateral force to the mid-humerus to direct the humeral head laterally. Successful reduction is usually presaged by slight lengthening of the arm as relaxation occurs, and a noticeable "clunk" may occur at the point of reduction. A brief fasciculation wave in the deltoid may also be seen at the time of reduction.

Spaso technique.

This technique was first reported by Spaso Miljesic as a simple, single operator technique that requires minimal force. [33] One published series reported an 87.5% success rate among premedicated patients when performed by junior house officers. [34] The patient is placed in a supine position and the operator grasps the affected arm around the wrist or distal forearm. The affected arm is gently lifted vertically toward the ceiling, applying gentle vertical traction. While continuing to maintain traction, the arm is externally rotated (Fig. 50-16). Reduction may be subtle, but is generally signaled by hearing or feeling a "clunk." Completion of this technique may require several minutes of gentle traction, allowing the muscles of the patient's shoulder to relax. [34]

Figure 50-14 *A*, Milch technique. Slow, steady abduction with overhead-traction, external rotation (not shown), and direct pressure over the humeral head are the steps of the Milch technique. The procedure may take 3 to 4 minutes to complete, and the operator should avoid sudden, jerky manipulations. It may help to ask the patient to make a motion as if he or she is reaching up and picking an apple from a tree. *B*, The Milch method diagrammed: reduction of an anterior shoulder dislocation includes *(1)* abduction and external rotation, and *(2)* slow and steady gentle traction. When reduced, the arm is adducted *(3)*. Pressure to the humeral head with the operator's hand during traction *(4)* may aid the reduction.

Other methods.

Poulsen reported a method termed the *Eskimo technique*, which may be performed in field settings. In this technique, the patient lies on the unaffected side and is lifted a short distance off the ground by grasping the abducted arm of the injured side. The patient's body weight acts to effect the reduction. Poulsen's success rate was 74% in a series of 23 patients, all of whom were premedicated. [35] Poulsen also postulated that this technique could place undue stress on the brachial plexus or axillary vessels. Use of this technique, when other options are available, should probably be reserved until a larger experience is reported.

Noordeen and associates reported a simple method in which the patient sits sideways in a chair, with the affected arm draped over the backrest. The operator holds the arm with the wrist supinated, and the patient is instructed to stand up. The success rate was 72% in 32 patients treated in this manner. [36] A variation of the chair technique, which was successful in 97% of 188 anterior shoulder dislocations, involves operator-applied traction to the patient's flexed elbow by means of a cloth loop or stockinette. [37] While standing beside the patient, the operator supports the involved elbow, holding the cloth loop in 90° of flexion while stepping down on the cloth loop. The patient sits in the chair, and an assistant may help support the patient by applying countertraction under the involved arm.

Waldron described a technique, without detailing the success rate, which is essentially a reverse of the Stimson method. The patient is placed supine, the affected arm is forward flexed to 90° and upward traction is applied to the distal humerus with the support of the epicondyles. The elbow is allowed to flex passively, and gentle internal and external rotation is applied through an arc of 20° total. [38]

Postreduction Care

After an attempt at reduction, the neurovascular status of the affected extremity should be rechecked and the results documented on the patient record. Indirect evidence that the reduction has been successful includes an immediate reduction

Figure 50-15 Traction-countertraction method. This simple technique for reducing the dislocated shoulder applies gradual and steady traction along the axis of the dislocated limb. A bedsheet, wrapped around the supine patient's upper chest wall and over the unaffected shoulder, is either tied or held by an assistant and acts as a fixed counterforce. A second bedsheet is placed around the patient's flexed forearm, just distal to the flexed elbow, and securely tied behind the operator's back. Note that a significant skin avulsion or friction burn may occur if there is excessive motion of the sheets, especially in the elderly patient with thin, delicate skin. With the patient's forearm held in a neutral rotation and the hand in a vertical position, the operator applies traction by leaning back, rather than using the biceps to apply traction. *(From Respet PB: A practical technique for reducing shoulder dislocations. J Musculoskel Med 5:29, 1988.)*

in pain, restoration of the round shoulder contour, and increased passive mobility of the shoulder. No harm is done by putting the joint through a limited range of motion. If the patient can tolerate placement of the palm from the injured arm on the opposite shoulder, it is quite likely that the shoulder reduction was successful (Fig. 50-17).

Postreduction radiographs are often recommended, with a careful search for new fractures. Although most greater tuberosity fractures do not alter patient management, patients with greater tuberosity fractures displaced > 1 cm after closed reduction are almost always associated with a rotator cuff tear, [39] and should receive prompt orthopedic consultation, as they may require operative repair.

It is important to prevent further external rotation or abduction of the reduced shoulder; adequate immobilization can be obtained by a commercially available shoulder immobilizer or a sling and swath (see Chapter 51). Orthopedic follow-up is recommended for all anterior shoulder dislocations. The incidence of rotator cuff injury is as high as 38%[40] and may complicate restoration of normal function. Younger patients will generally be immobilized for approximately 3 weeks and can be instructed to follow up within 1 or 2 weeks of the event. The older the patient, the shorter the time of immobilization. [10] Those older than 60 years should have early follow-up (5 to 7 days) to allow for early mobilization and avoidance of shoulder joint stiffness.

It is appropriate to prescribe oral analgesics (either nonsteroidal antiinflammatory drugs or narcotics) appropriate for the amount of patient discomfort at the time of disposition and to instruct the patient to return for any worsening of the clinical condition. Periodically one may encounter a return visit from a successfully treated patient who is in severe pain from a hemarthrosis. Trimmings reported excellent relief of pain by aspiration of the hemarthrosis 24 to 48 hours

Figure 50-16 Spaso technique. While maintaining gentle vertical traction, the affected arm is externally rotated by grasping the wrist or forearm. Reduction may be subtle.

after shoulder reduction in a series of patients older than 60 years. [41] This can be accomplished using the technique of arthrocentesis described in Chapter 54 . In addition, intra-articular instillation of 10 to 20 mL of 1% lidocaine as has been recommended for shoulder reduction may be helpful for further pain relief.

Posterior Shoulder Dislocations

Posterior shoulder dislocations account for less than 4% of all shoulder dislocations. [12] Because they are so uncommon, posterior dislocations are easily overlooked and the emergency clinician must be knowledgeable about these injuries to avoid a misdiagnosis. Delays in diagnosis for weeks to months have been reported with posterior dislocations.[42] [43] This may lead

Figure 50-17 If a patient with a shoulder injury can place the palm of the injured arm on top of the contralateral shoulder, it is unlikely that a shoulder dislocation is present. Alternatively, completion of this maneuver after a reduction attempt provides strong evidence that the reduction was successful.

to increased rates of dislocation arthropathy and chronic pain. [13] The mechanism of injury is almost always indirect, with a combination of internal rotation, adduction, and flexion.[10] *Classic precipitating events include seizure, electrical shock, and falls.* The patient may also present at a point well past the original event. [43] Patients with seizures may not experience obvious problems in the immediate postictal period due to their altered mental status.

Clinical Assessment

While clinically less obvious than anterior dislocations, posterior shoulder dislocations do present in a typical, recognizable manner. Mistakes may be made if the clinician is overly reliant on the AP radiographs, which are potentially misleading, [43] and may result in misdiagnosing the injury as a soft tissue contusion or acromioclavicular (AC) strain. *The principal sign of posterior dislocation is an arm that is somewhat fixed in adduction and internal rotation.* Abduction and external rotation are limited, and attempts to perform these movements generally elicit pain (Fig. 50-18).[10] [12] Inspection and palpation reveal a loss of the normal anterior contour of the shoulder and a prominent coracoid and acromion. The shoulder is flattened anteriorly and rounded posteriorly, where the humeral head may be palpable.[10] [12]

Comparison to the opposite shoulder should be undertaken with the understanding that this injury may occasionally occur bilaterally. Neurovascular assessment is performed in the standard manner, although such complications are unusual with posterior dislocations.

Radiologic Examination

The key point regarding radiographs for posterior shoulder dislocations is the subtle nature of this dislocation on a single AP radiograph (Fig. 50-19*A and B*) and the diagnostic value of the scapular Y view (Fig. 50-19*C*) or the axillary view (Fig. 50-19*C*). The diagnosis of posterior shoulder dislocation using the axillary view is quite easy, whereas the routine AP and lateral views are difficult to interpret in around half of cases. [43] The axillary view is generally available in the radiology department and can be obtained with as little as 20–30° of abduction, with the plate placed on the shoulder. [43] In addition to easy visualization of the *posteriorly* situated humeral head, the axillary view often reveals an impression fracture of the humeral head (Fig. 50-19*D*). The humeral head is *anterior* to the glenoid.

Whereas the axillary view is diagnostic, clues to posterior dislocation do exist on the AP film. The internally rotated humeral head appears symmetrical on the AP film in the shape of a light bulb as opposed to the normal club-shaped appearance created by the greater tuberosity. [44] With posterior dislocation, the space between the articular surface of the humeral head and the anterior glenoid rim is widened, and there is a decrease in the half-moon-shaped overlap of the head and the fossa (Fig. 50-20 and Fig. 50-21). [42] [44] There may also be a compression fracture of the medial aspect of the humeral head, indicated by a dense line. This is known as the "trough" sign.[44] A fracture of the lesser tuberosity should always prompt a search for the presence of a posterior shoulder dislocation. [42]

Reduction Technique

An acute posterior dislocation may be reduced by traction on the internally rotated and adducted arm combined with posterior pressure on the humeral head (Fig. 50-22).[10] [43]

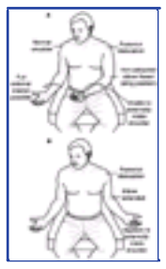

Figure 50-18 *A,* A clue to a posterior shoulder dislocation is the arm locked in adduction and internal rotation, with patient's inability to rotate the shoulder externally with the elbow flexed at 90°. *B,* Note that extension of the elbow with supination of the forearm may obscure loss of the external rotation.

Premedication is generally indicated (see Chapter 34) and countertraction may be applied with a sheet looped in the affected axilla much as described for anterior dislocations. Rockwood and Wirth recommend applying lateral traction on the upper humerus if the humeral head is locked on the posterior glenoid. [10] Hawkins and coworkers suggest that posterior dislocations with an impression defect of the humeral head that is greater than 20% of the articular surface require open reduction. [43] Posterior dislocations that have been diagnosed late are difficult to reduce in a closed manner, but an attempt with adequate premedication is generally indicated. [43]

Postreduction Care

As with anterior dislocations, a repeat neurovascular examination and radiographs are obtained after reduction attempts. As before, the patient's ability to place the palm of the injured arm on the opposite shoulder is suggestive of a successful reduction. Given the rarity of these injuries, orthopedic consultation is often sought early in the care of these patients. Certainly in a training environment, involvement of an orthopedic resident benefits his or her education and should be considered early on. After successful reduction, immobilization with application of a "hand-shake" cast in neutral rotation and slight extension is indicated (Fig. 50-23).[10] This relaxes the injured structures to allow healing.

Unusual Shoulder Dislocations

Inferior dislocations of the shoulder, known as *luxatio erecta*, are quite rare, but also quite obvious. The patient presents with the arm locked in marked abduction with the flexed forearm lying on or behind the head. [45] Occasionally, the humerus may have less abduction, thus potentially obscuring the diagnosis. [46] The humeral head can be palpated along the lateral chest wall. Neurovascular compression may be present, but this is usually reversed once reduction is accomplished. [10] Overhead traction (generally with the arm in full abduction) is applied in the longitudinal direction of the arm and cephalad pressure can be exerted over the humeral head much as in the Milch technique. [10] [46] Countertraction toward the patient's feet can be applied using a sheet placed over the injured shoulder. After reduction, the abducted arm is brought into adduction against the body and the forearm supinated. [47]

Scapular dislocation or "locked scapula" is a rare condition that presents with an obvious protrusion of the lateral border of the scapula and significant swelling of the medial border due to tearing of the musculature. [48] Reduction is accomplished by traction on the abducted arm and medial pressure on the scapula. [48]

ACROMIOCLAVICULAR SUBLUXATION AND DISLOCATIONS

The AC joint is a true diarthrodial joint with a synovial cavity surrounded by a relatively lax capsule and the weak AC ligament. This structure allows for the gliding motion necessary for shoulder movement. The major stability of the AC joint comes from the coracoclavicular ligament, which has posterior (conoid) and anterior (trapezoid) components. The mechanism of injury is generally from a direct force such as a fall on the point of the shoulder with the arm adducted. [49] There are six grades of injury to the AC joint; they are classified by degree or type (I through VI) (Fig. 50-24).

First degree (type I).

This injury consists of a minor tear in the AC ligament. The coracoclavicular ligament is intact. The clinical findings are limited to tenderness in the area of the AC joint. Radiographs show little if any change in the position of the clavicle in relation to the acromion. [39] The management of this condition consists of a sling for comfort, ice, and mild analgesics. Generally, symptoms subside with 7 to 10 days of rest. [10] Orthopedic referral is generally not necessary unless return to normal function is delayed beyond 2 weeks.

Second degree (type II).

In addition to a complete tear of the AC ligament, the coracoclavicular ligament is stretched or incompletely torn. [39] The patient generally supports the injured arm and has slight swelling and definite tenderness over the AC joint. Radiographs demonstrate a definite change in the relationship of the distal clavicle to the acromion.

Figure 50-19 *A,* This patient has a posterior dislocation of the humerus. Because the dislocation is directly posterior, there is no superior or inferior displacement of the humeral head. On superficial observation, the head of the humerus appears to maintain a normal relationship with the glenoid fossa and the acromion process. However, definite abnormalities exist in this film. The space between the humeral head and the glenoid fossa is abnormally wide, and because of the extreme internal rotation of the humerus, the head and neck are seen end on. In this projection, the humeral head resembles a light bulb. Compare this film with the same patient's normal opposite shoulder (note that the film is reversed for illustrative purposes) *(B). C,* The normal axillary view of the shoulder. The *asterisk* indicates the glenoid process. The *open arrow* indicates the coracoid process of the scapula and the *closed arrow* indicates the acromion process of the scapula. *D,* Axillary view of a posterior shoulder dislocation with an impression fracture of the humeral head. *(From Harris JH, Harris WH (eds): The Radiology of Emergency Medicine. Baltimore, Williams & Wilkins, 1971.)*

However, in type II injuries, the inferior edge of the clavicle should not be separated from the acromion by more than one-half its diameter, [39] and on radiographic examination, the coracoclavicular distance is the same as the uninjured side. [10] This injury can be treated in a closed fashion with a sling. [10] Orthopedic referral is recommended, and some will use a sling-strap device that elevates the arm and depresses the clavicle for these injuries. [39]

Third degree (type III).

In this injury, the distal end of the clavicle is essentially free floating, as both the AC and coracoclavicular ligament are completely disrupted. [39] The arm is supported by an uncomfortable patient and the distal clavicle is usually seen to be riding high above the acromion. The diagnosis is generally obvious, and radiographs are mainly used to rule out an associated fracture. Radiographic criteria for this degree of injury include an inferior border of the clavicle above the acromion, or a discrepancy in the coracoclavicular distance as compared with the normal side. [10] These injuries require orthopedic referral, and a fair bit of controversy exists regarding their subsequent management.[10] Larsen and colleagues conducted a prospective, randomized trial of conservative vs operative management for significant AC separations and concluded that conservative management was generally better, with possible exceptions made for patients with significant cosmetic deformity and for those who frequently keep the arm at 90° of abduction. [50] While optimal therapy is still unclear, a logical approach would include ED treatment with a sling and early orthopedic referral.

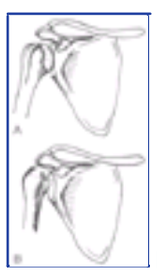

Figure 50-20 *A,* Note the normal elliptical pattern of overlap produced by the head of the humerus and the glenoid fossa. *B,* In the patient with a posterior dislocation, this pattern is lost, and internal rotation of the greater tuberosity is also noted. *(From Simon R, Koenigsknecht S: Orthopedics in Emergency Medicine. New York, Appleton-Century-Crofts, 1982, p 344. Reproduced by permission.)*

Fourth, fifth, and sixth degree (type IV to VI).

In type IV injury, the distal clavicle is free floating and posteriorly displaced into the mass of the trapezius muscle. Type V injury is characterized by inferior displacement of the scapula

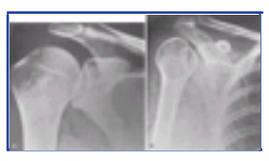

Figure 50-21 Posterior dislocation of the humeral head is a subtle, easily missed finding on the anteroposterior view. A key finding is an abnormal overlap of the humeral head with the glenoid fossa, but additional views are usually needed to confirm the dislocation. Comparison with the normal shoulder may also help. *A,* This AP film showing a posterior dislocation was initially read as normal, but the dislocation was obvious on an axillary view (see Fig. 50-19). *B,* "Light-bulb" appearance of the humeral head in a posterior dislocation. Posterior dislocation should be suspected in patients with significant pain and dysfunction after trauma, especially following seizures and electrical shock injuries. Occasionally the dislocations are bilateral. *(From Riddervold HO: Easily Missed Fractures and Corner Signs in Radiology. Mt Kisco, NY, Futura, 1991.)*

with a marked increase (two to three times normal) in the coracoclavicular interspace. [10] Type IV and V dislocations generally require surgery, and orthopedic referral is required. Type VI injury involves dislocation of the distal clavicle inferiorly. Because this is usually the result of major trauma, multiple other fractures are often seen.[10]

Radiographic Examination

The diagnosis is usually made clinically, with pain and local tenderness at the AC joint in the absence of other findings. Radiographs are generally indicated to rule out associated fractures and to aid in assessing the degree of injury. A single radiograph of the injured shoulder often suffices, but some clinicians prefer to obtain comparison views of the opposite shoulder. While their efficacy has never been proven, it has been traditionally recommended that "weighted" films be obtained in suspected type I or II injuries. Weighted films are generally performed after routine "unweighted" radiographs and are obtained by strapping about 4.5 to 7.0 kg (10 to 15 lb) of weight to the patient's wrists and repeating the radiographs. It is important that the patient keep the shoulders as relaxed as possible during this study, and the patient should not be asked to hold the weights (rather, they are strapped to the wrists). As expected, this study may cause significant discomfort for the patient. Weighted films are of questionable value in mild injuries, and superfluous in obvious type III to VI injuries.

The value of comparison views as well as weighted films may remain controversial by some authors, [51] but their use has been essentially abandoned in current day practice. Bossart and others examined the routine use of "weighted" studies of

Figure 50-22 Reduction of posterior shoulder dislocation—with countertraction being applied, traction on the internally rotated and adducted arm is combined with posterior pressure on the humeral head to effect reduction.

the AC joints and recommended abandoning their use in the ED. [52] In a prospective study of 70 type I or II injuries, the use of weights was associated with *less evident separation* in 7 cases, essentially producing a false-negative study compared to plain unweighted films. Only three injuries were re-categorized as type III after the performance of weighted films. [52] This yield is not necessarily inconsequential if subsequent management would entail a change in therapy for these three patients. However, Bossart and colleagues noted that surgery is often not recommended with type III injuries. [52] For the majority of cases, the editors consider weighted radiographs unnecessary, but they may be helpful for athletes or

Figure 50-23 Handshake cast—after successful reduction of an acute posterior shoulder dislocation, this cast is applied in neutral rotation, slight extension, and 15 to 20 degrees of abduction. *(From Rockwood CA, Wirth MA: Subluxations and Dislocations about the Glenohumeral Joint. In Rockwood CA, Green DP, Bucholz RW, et al (eds): Rockwood and Green's Fractures in Adults, vol 2, 4th ed. Philadelphia, Lippincott-Raven, 1996, p 1291. Reproduced by permission.)*

in other selected cases. When in doubt, consultation with the referring orthopedic surgeon is advised.

STERNOCLAVICULAR DISLOCATIONS

Despite the fact that the sternoclavicular joint is the least stable joint in the body, sternoclavicular dislocations are rare. [53] The primary supports of this joint are the sternoclavicular and costoclavicular ligaments. Anterior dislocations are much more common and are usually the result of an indirect mechanism involving a blow thrusting the shoulder forward, [39]

Figure 50-24 Grades I to III of acromioclavicular separation. (See text for description.) *(From Heppenstall RB: Fractures and dislocations of the distal clavicle. Orthop Clin North Am 6:480, 1975.)*

or they may be atraumatic due to ligamentous laxity in teens and young adults. [53] Posterior dislocations also usually result from a blow to the shoulder but can also be the result of a direct superior sternal or medial clavicular blow. [53] Posterior sternoclavicular dislocation (also known as retrosternal dislocation as the medial end of the clavicle dislocates both posteriorly and medially) is potentially life threatening, as injury to the great vessels or compression of the airway may occur. [53] Any suggestion of these complications should prompt immediate surgical consultation.

The presentation of these injuries is usually straightforward, with pain, swelling, tenderness, and deformity of the joint. Plain radiographs of this joint are difficult to interpret and generally include an apical lordotic-type view with the radiographic tube angled at 45° cephalad. Confirmation of the diagnosis is best made using a thoracic computed tomographic (CT) scan, which may also identify high rib fractures, pulmonary contusion, or pneumothorax. [53] [54] Children may have epiphyseal disruption with retrosternal displacement of the medial clavicle. [55]

Closed reduction of both types of sternoclavicular dislocation involves placing a rolled blanket or a sandbag between the scapula and applying traction to the 90° abducted arm in line with the clavicle. The clavicle can then be pushed (anterior) or lifted (posterior) back into position. [53] Posterior dislocations may be difficult to reduce and to maintain reduced in a closed manner. Therefore, some authors recommend reduction in an operating suite unless complications necessitate immediate reduction.[53] Given the rarity of this injury and the potential for major underlying complications, early consultation is recommended in suspected posterior sternoclavicular dislocations.

ELBOW DISLOCATIONS

The elbow is second only to the shoulder as a site for major joint dislocations in adults, and it is the most commonly dislocated joint in children. Anatomically, the principle articulation of the humerus and ulna is a stable hinge joint with the intercondylar groove of the distal humerus nestled in the olecranon fossa. Due to the stability of the elbow, any dislocation is expected to be accompanied by significant soft tissue damage, and associated fractures are common. Elbow dislocations are often simply divided into posterior and anterior dislocations (Fig. 50-25). However, there are actually several different types of elbow dislocations in addition to posterior and anterior. These include lateral, divergent, and isolated dislocations of the radius. [56] In the rare divergent dislocations, the radius and ulna are dislocated in opposite directions, either anterior and posterior or medial and lateral. [56]

The most serious complication of elbow dislocation is a brachial artery injury. This injury is possible with any type of

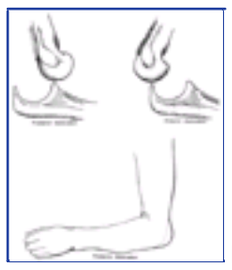

Figure 50-25 Classification of elbow dislocations. *(From Simon R, Koenigsknecht S: Orthopedics in Emergency Medicine. New York, Appleton-Century-Crofts, 1982, p 333. Reproduced by permission.)*

elbow dislocation and is a frequent occurrence in open dislocations. [56] Vascular compromise can be delayed in onset, resulting from either unsuspected arterial injury or progressive soft tissue swelling. The circulatory status of the arm must be carefully monitored even after successful reduction. [56] Although not absolute, patients with these injuries who manifest significant or immediate soft swelling, hematoma formation, or have questionable vascular integrity or neurologic findings are often admitted to the hospital or ED observation unit for observation. In most cases, orthopedic consultation should be sought prior to disposition.

Injury to the median and ulnar nerves may be the result of stretch, severance, or entrapment. It is difficult to clinically distinguish these etiologies, and management of nerve injuries is frequently expectant.[56] It is imperative to conduct a careful neurologic examination before and after reduction, as any increase in findings may indicate entrapment and the need for surgical intervention. [56] Myositis ossificans is also a potential complication of this injury, which underscores the advisability of orthopedic consultation early in the course of care.

Posterior Dislocations

Posterior dislocations make up the vast majority of elbow dislocations. [39] The usual mechanism is a fall on the outstretched hand, with the arm in extension. The clinical examination is usually diagnostic unless severe soft tissue swelling is present. The patient presents with a shortened forearm that is held in flexion, and the olecranon is prominent posteriorly (see Fig. 50-25). The normally tight triangular relationship of the olecranon and the epicondyles of the distal humerus is disturbed in a posterior dislocation. A defect may also be palpated above the prominence of the olecranon.

Radiologic Examination

Two radiographic views, an AP and a true lateral view, should be obtained. The diagnosis is obvious with proper radiographs. A

Figure 50-26 Manipulative reduction of posterior elbow dislocation. While an assistant holds the arm and makes steady countertraction *(1)*, grasp the wrist with one hand and apply steady traction on the forearm in the position in which it lies *(2)*. While traction is maintained, correct any lateral displacement with the other hand *(3)*. While traction is maintained *(4)*, gently flex the forearm *(5)*. Note that with reduction, a clunk is usually felt and heard as the olecranon engages the articular surface of the humerus. *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, pp 793 and 794. Reproduced by permission.)*

careful search for fractures of the distal humerus, radial head, and coronoid process must be undertaken, as they occur commonly in this injury. [56] In children younger than 14 years, the fracture is usually a medial epicondyle separation, as the epiphyseal plate gives way before the medial collateral ligament of the elbow. [56] Postreduction radiographs are also necessary to confirm reduction and to disclose any associated fractures. [57]

Reduction Techniques and Postreduction Care

Although, as with shoulder reduction, some authors claim that their method of reduction is virtually painless, [28] [58] this has not been objectively documented. In general, patients with posterior elbow dislocations are quite uncomfortable, and it is beneficial to administer IV analgesics early in the course of care, preferably prior to positioning for radiographs (see Chapter 34).

In addition to, or in lieu of parenteral sedation and analgesia, some clinicians inject the elbow joint with a local anesthetic (e.g., 3 to 5 mL of 2% plain lidocaine) prior to attempting reduction. Prior to injection, the joint should be aspirated to remove blood (see Chapter 54).

Traditional traction method.

The traditional method[59] of reducing a posterior dislocation is to place the patient in the supine position and have an assistant stabilize the humerus with both hands (Fig. 50-26). The operator then grasps the wrist and applies slow and steady in-line traction. The elbow is slightly flexed to keep the triceps mechanism loose, and the wrist is held supinated as traction is applied. Reduction is usually signified by a "clunk" that is heard or felt. If this method is not successful after a reasonable period of traction (10 minutes), the forearm may be gently flexed to try and effect reduction. Alternatively, downward pressure on the proximal volar surface of the forearm may help free up the coronoid process.

Alternatives.

Several authors have described variations of a prone method of reduction that are reportedly well tolerated by patients. [28] [58] [59] In the method described by Minford,

the patient is positioned with the arm hanging over the padded back of a chair or over the edge of the bed. The clinician then simply applies pressure to the prominent posterior aspect of the olecranon to achieve reduction. [56] Lavine applied traction with the elbow flexed over the edge of a chair by pulling down on the hand while

using the thumb to guide the olecranon into place (Fig. 50-27*A*).[59] Parvin positioned the patient as for the Stimson method of shoulder relocation and applied gentle downward traction to the wrist.[28] When the olecranon was felt to ride distally on the humerus, lifting the humerus completed the reduction.

Recommended initial approach.

A prone technique is advantageous, as patients tolerate this position quite well. The elbow is allowed to hang flexed over the edge of the bed, and an assistant is positioned with his or her back toward the patient such that the humerus can be encircled with both

Figure 50-27 *A,* Hanging method of elbow dislocation reduction. Downward traction is applied to the hand while the olecranon is guided into place. *(From Lavine LS: A simple method of reducing dislocations of the elbow joint. J Bone Joint Surg Am 35:785, 1953.) B,* Reduction of posterior elbow dislocation. An assistant encircles the distal humerus and applies pressure to the olecranon. Traction is applied with the elbow in slight flexion to relax the triceps. The reduction can be performed with the patient reclining *supine* as shown. Having the patient recline *prone* with the upper arm supported by the stretcher can often enhance muscle relaxation.

hands and pressure applied with the thumbs to the posterior aspect of the olecranon. This pressure on the olecranon is intended to lift it up and away from the humerus. The operator applies longitudinal traction to the arm with the elbow in slight flexion. If reduction is not succeeding, an attempt may be made to flex the elbow or the assistant can be instructed to lift the humerus (Fig. 50-27*B*). Reduction is generally noted by a definite "clunk."

Postreduction care.

Once reduction is achieved, the elbow should immediately be put through a gentle range of motion to ensure that the reduction is stable and that there is no mechanical block to movement.[56] An inability to move the elbow through a smooth range of motion after reduction is often caused by an entrapped medial epicondyle fracture fragment that requires operative intervention. [56] The elbow is generally immobilized in at least 90° of flexion with a long-arm posterior splint. A complete recheck of the neurovascular status is performed along with postreduction radiographs.

Following reduction, any signs of delayed vascular compromise are first addressed by loosening the splint and decreasing the degree of flexion. This may restore the pulse.[56] If not, immediate surgical consultation is necessary for emergent arteriogram or exploration of the brachial artery, or both. [57] The risk of vascular compromise is a reason to consider in-hospital observation. Alternatively, some clinicians observe the patient in the ED or ED Observation Unit for 2 to 3 hours postreduction, evaluating for delayed neurovascular compromise prior to discharge.

Anterior Dislocations

Anterior dislocations of the elbow are quite rare; they usually result from a direct posterior blow to the olecranon with the elbow flexed. [56] On physical examination, the arm is extended and there is anterior tenting of the proximal forearm with prominence of the distal humerus posteriorly. [56] These injuries are the result of a great deal of force; they are frequently open and accompanied by significant neurovascular injury. An avulsion of the triceps mechanism may also occur. [56]

Reduction of an anterior dislocation of the elbow involves in-line traction and backward pressure on the proximal forearm (Fig. 50-28). An assistant provides countertraction by grasping the humerus with both hands. Given the infrequent nature of anterior dislocations and the high probability of a severe associated injury, the emergency clinician should consider early orthopedic consultation in such dislocations.

Radial Head Subluxation (Nursemaid's Elbow)

Radial head subluxation is a common pediatric presentation generally occurring between the ages of 1 and 3 years. The mean age of presentation is just older than 2 years, but this entity has been reported in infants younger than 6 months [60] [61] and in older children up to the preteen years. [62] There is a slight predilection for this injury to occur in girls and in the left arm. [61] [63] The classic mechanism of injury is longitudinal traction on the arm with the wrist in pronation, as occurs when the child is lifted up by the wrist.[61] There is no support for the common assumption that a relatively small head of the radius as compared to the neck of the radius predisposes the young to this injury.[64] The pathologic lesion is generally a tear in the

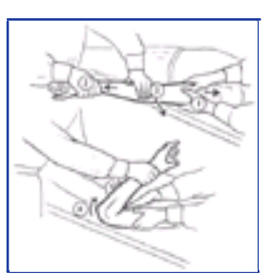

Figure 50-28 Manipulative reduction of anterior elbow dislocation. Reduction is performed with the patient under local or general anesthesia. *1*, An assistant grasps the arm and provides countertraction. *2*, The operator grasps the wrist with one hand and applies traction in the line of the arm, and with the other hand applies firm, steady pressure downward and backward on the upper end of the forearm *(3)*. A clunk usually indicates that reduction is achieved. *4*, The arm is flexed to 45° beyond a right angle. *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, p 796. Reproduced by permission.)*

attachment of the annular ligament to the periosteum of the radial neck, with the detached portion becoming trapped between the head of the radius and the capitellum. [64]

Clinical Assessment

The history offered by the caretaker may not be that of the classic pulling type mechanism. Schunk, in a series of 83 patients, reported that only 51% described such a mechanism, whereas 22% reported a fall.[61] In patients younger than 6 months, the mechanism in the majority is simply rolling over in bed. [60] It is important to remember this and not to proceed with a child abuse investigation unless other suggestive features are present. The typical patient with a nursemaid's elbow presents in no distress with the arm held slightly flexed and pronated at the side (Fig. 50-29). This has been termed the *nursemaid's position*. [65] The exact area of pain is often difficult to locate. The child will refuse to use the arm, and this may be the chief complaint. [62] The older child will usually point to the dorsal aspect of the distal forearm when asked where it hurts. This may mislead one to suspect a buckle fracture of the distal radius.

Although tenderness about the elbow has been reported occasionally, there is often little tenderness or swelling of the elbow region. [61] [62] In the cooperative child, the arm and shoulder are carefully palpated to discern any tenderness. Areas of focus on palpation should include the clavicle and the distal radius, as these are common sites of pediatric fractures. When patient anxiety interferes with a reliable assessment of tenderness in a child whose arm is in the classic nursemaid's position, the examiner can stand at a distance and have the parent or caretaker palpate the extremity to ascertain tenderness. This may also be done in the cooperative patient

Figure 50-29 Typical presentation of a child with a subluxation of the radial head (nursemaid's elbow). It may be difficult to determine exactly where the pathology exists, and often the wrist is thought to be the culprit. This child will not use the injured arm but has minimal discomfort as long as the elbow is not manipulated. *A*, The affected arm hangs down at the side, slightly flexed and pronated. *B*, Once reduced, full activity is generally regained in a matter of minutes.

to reassure the doubtful parent regarding the absence of a fracture. If no tenderness is noted by palpation, it is appropriate to attempt a reduction without prior radiographs. [66]

Although resistance to or pain with supination is a frequent finding in such patients, [61] one need not test for this finding until the time of reduction.

Radiographic Examination

Radiographs are generally not needed in a child presenting with an arm in the nursemaid's position that is nontender (or minimally tender in the radial head area) on palpation, regardless of the history. [66] In these cases, radiographs are generally normal, and if obtained, the positioning of the child's arm by the x-ray technician often effects reduction.[61] However, Frumkin described three cases of nursemaid's elbow in which a line drawn through the longitudinal axis of the radius did not normally bisect the capitellum on prereduction radiographs, but did so after reduction. [64] Radiographs are sometimes recommended if the child is not moving the arm normally 15 minutes after reduction.[65] However, this time frame may be too short, as reuse can be delayed for more than 30 minutes, particularly in children who present some time after the injury. Quan and Marcuse recommend an approach in which no radiographs are obtained on the first visit, including in those children released from the ED prior to full use of the arm. At the time of a 24-hour follow-up visit, radiographs are obtained only if repeat attempts at manipulation are not successful. [62]

While this condition does not generally require x-rays, they can be valuable if external signs of trauma are present (e.g., swelling, abrasions, ecchymoses), or if the child does not use the arm normally within 24 hours after the subluxation is considered reduced. Other less common conditions that can present with similar findings are fractures, joint infections, tumors, or osteomyelitis.

Reduction Technique

Supination method.

Reduction of a nursemaid's elbow (Fig. 50-30) is generally performed without premedication. If the subluxation has been present for hours, oral or nasal midazolam (see Chapter 34) can be a useful adjunct to overcome the child's anxiety related to manipulation. It is

Figure 50-30 Radial head subluxation. *A*, Anatomically, this injury represents interposition of the torn annular ligament between the radial head and the capitellum. *B*, The supination method of reduction is performed by grasping the arm about the wrist and placing the other hand about the elbow with the thumb over the radial head. The forearm is then supinated *(C)* and then the arm is flexed *(D)* in one continuous motion. *(From Fleisher GR, Ludwig S: Textbook of Pediatric Emergency Medicine. Baltimore, Williams & Wilkins, 1988, p 1322. Reproduced by permission).*

important to explain to the caretaker that the reduction will likely cause the child discomfort, but that this is transient and a clue to the diagnosis. The child is positioned seated on the lap of an assistant (often the parent) who stabilizes the arm by holding the humerus adducted to the side. The operator then grasps the elbow with one hand placing the thumb over the

region of the radial head. Although it has been stated that the thumb can apply pressure to the radial head, this positioning is mainly useful for palpation of the reduction "click." The other hand grasps the wrist and is then used to supinate the extended forearm in a steady, deliberate manner. Slight traction prior to supination is generally recommended, but it is unclear whether this increases the likelihood of successful reduction. Once supinated, the arm can be flexed or extended; however, flexion is the most common maneuver and may actually be somewhat more successful than extension.[61] An audible or palpable click signifies successful reduction, but it is not always noted. Once the reduction has been performed, the child usually cries for a few minutes. Generally the operator should leave the room and then return in 10 to 15 minutes to do a repeat examination. Full use of the arm should be evident (see Fig. 50-29B).

Pronation method.

This technique is performed with the child positioned as in the supination method. However, the forearm is not supinated. Instead, the forearm is rapidly hyper-pronated and flexed. A recent study by McDonald reported equal success rates using this technique as compared with the supination technique. [63]

After attempted reduction.

If a click is detected, the child will generally regain use of the arm quickly (almost always by 30 minutes). [62] Therefore, if a definite click is detected, it is reasonable to observe the child for up to 30 minutes prior to further intervention. If there is still no use at 30 minutes, the operator may try to determine if supination is still painful, which would suggest the need for a repeat attempt. In those in whom a click is not detected, the majority will not use the arm by 30 minutes. [62] In these children, a repeat attempt at reduction is recommended after 10 to 15 minutes of nonuse. Two or more attempts are required to produce the click in up to 30% of patients. [62]

If the child has not regained the use of the arm after a few attempts and a reasonable period of time, some authors recommend that radiographs be performed. [65] X-ray films also may help relieve parental anxiety. Alternatively, instructions should be given for 24-hour follow-up if normal function is not restored, with consideration for radiographs at the time of follow-up. [62] In 2 series of patients with nursemaid's elbow, of 10 patients released without normal arm use, 6 had spontaneous restoration of function, and the other 4 required remanipulation, which successfully restored function. [61] [62] The use of a posterior splint to protect the elbow of the child who refuses to use the arm after a presumed reduction is of uncertain value. However, some form of immobilization (e.g., splint, sling, or both) may be valuable in the child with significant residual discomfort following a prolonged period of subluxation or in whom recurrent subluxations have occurred. On occasion, a successful reduction painfully resubluxates with movement; in this case, immobilization and referral may be necessary. [64] If reduction has been achieved clinically and maintained in the ED, analgesics or a follow-up visit are unnecessary. Because other pathology can *rarely* mimic this condition (e.g., occult fractures, osteomyelitis, joint infection, tumors), full, unrestricted, and painless use of the arm must be evident by 24 hours. If not, further assessment is indicated.

HAND INJURIES

The hand is an extremely common site of injury due to the demands placed on it and the exposed nature of its region. Proper motion and function of the hand are intimately related to normal anatomic alignment.[67] The emergency clinician must therefore be skilled in the diagnosis and management of dislocations about the hand. An improperly managed hand injury can result in significant disability that the patient is reminded of on a daily basis.

Anatomically, the joints of the digits are quite similar and consist of a hinge joint with a tongue-in-groove type arrangement. [67] The soft tissue support includes 2 collateral ligaments that are attached to a volar plate (Fig. 50-31). The volar plate is dense fibrous connective tissue that is thickened at its distal attachment and thinner at its proximal attachment, to allow for folding with joint flexion. [67] [68] Dorsal dislocation of a digit requires failure of the volar plate, whereas lateral dislocation disrupts a collateral ligament and induces at least a partial tear in the volar plate (see Fig. 50-31).

Radiographic examination of all hand injuries is relatively straightforward, including at least two views (AP and lateral) of the injured area. The most important radiographic error in evaluating joint injuries of the hand is failing to get a true lateral view of the injured joint. [68] This may lead to missing a fracture or a loose body in the joint.

Anesthesia is generally required for the proper management of dislocations about the hand. This is most often accomplished by finger or wrist block, although a more proximal regional or Bier block may be used on occasion (see Chapter 32 and Chapter 33). Getting a secure grip on the digits may

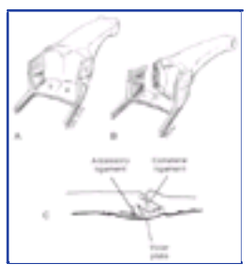

Figure 50-31 *A* and *B,* The collateral ligament-volar plate relationship. The metacarpophalangeal (MCP) and interphalangeal (IP) joints derive their strength from a combination of the two collateral ligaments and the volar plate. Dislocations of these joints require tearing of at least two parts of this three-part structure. *(From Carter P [ed]: Common Hand Injuries and Infections. Philadelphia, WB Saunders, 1983, p 114. Reproduced by permission.) C,* Lateral view demonstrating collateral ligament-volar plate relationship. *(Redrawn from Eaton RG: Joint Injuries of the Hand. Springfield, IL, Charles C Thomas, 1972.)*

be difficult and may complicate the reduction. Wearing rubber gloves or wrapping gauze around the fingers may be useful.

Thumb Dislocations

The opposable thumb is an essential structure for countless activities. Despite its strong ligamentous and capsular support, the exposed positioning of the thumb makes it a frequent site of dislocations and subluxations. The metacarpophalangeal (MCP) joint is similar to those of the fingers but has a stronger volar plate and collateral ligaments.[68]

Interphalangeal (IP) Joint Dislocation of the Thumb

The single interphalangeal (IP) joint of the thumb has strong cutaneous-periosteal attachments, and dislocations of this type are therefore frequently open. [68] Dislocations are generally dorsal and can be reduced in a manner similar to IP dislocations of the finger (Fig. 50-32). The mechanism of injury is recreated by longitudinal traction and hyperextension to distract the phalanges. Reduction is accomplished by flexing the IP joint with continued traction and by applying direct pressure to the base of the distal phalanx.[68]

Following reduction, the range of motion is tested and the stability of the reduction is ascertained. An adequate reduction that is documented on postreduction films is then splinted in slight flexion for 3 weeks.[68] Orthopedic referral is advisable.

Metacarpophalangeal Joint Injury of the Thumb

Dorsal dislocation.

The MCP joint of the thumb can be dorsally dislocated by a hyperextension injury. The proximal phalanx will come to rest in a position dorsal to the first metacarpal (Fig. 50-33). There are two basic types of MCP dislocations (this applies to the fingers also): simple and complex. In a complex MCP dislocation, the volar plate becomes entrapped dorsal to the metacarpal head (Fig. 50-34) with the flexor tendons and lumbricals acting to completely entrap the

Figure 50-32 *A–D,* Traction method of joint reduction. Complete anesthesia using a regional block should precede reduction attempts. *E–H,* Exaggeration of existing deformity method. First, exaggerate the deformity that is present. Then, in addition to steady traction, push the joint back into position. *(From Carter P [ed]: Common Hand Injuries and Infections. Philadelphia, WB Saunders, 1983, pp 109 and 110. Reproduced by permission.)*

metacarpal head.[68] The simple type is amenable to closed reduction, whereas the complex type requires operative reduction due to interposed soft tissue. [67] [68] A simple MCP dislocation can be converted into a complex one during reduction. [67]

Clinical features that suggest a complex MCP dislocation include a proximal phalanx that is less acutely angulated than with a simple dislocation (i.e., <60°). [68] There may also be dimpling noted over the thenar eminence due to pressure from the entrapped metacarpal head. [67] On radiographic studies of simple dislocations, the joint surfaces are in close contact, whereas they are separated in complex dislocations. The presence of a sesamoid bone in the joint space is diagnostic of a complex MCP dislocation (Fig. 50-35). [67]

Reduction of a simple MCP dislocation (Fig. 50-36) involves hyperextension of the joint as far as possible with the wrist in flexion to relax the tendons. Once maximal hyperextension is achieved, the base of the proximal phalanx is pushed distally while the joint is brought back into flexion. [67] Applying simple traction alone as an initial maneuver risks trapping the volar plate and creating a complex dislocation. [67] After reduction, stability of the joint is tested by putting the joint through a full range of motion. The integrity of the collateral ligaments is assessed with the MCP joint in flexion (see later). Simple MCP dislocation injuries generally require casting for 3 weeks with the joints in moderate flexion.[68]

Volar dislocation.

Volar dislocations are rare, and are generally associated with collateral ligament ruptures. They are commonly irreducible due to interposition of one or both extensor

tendons and the dorsal capsule.[67] Orthopedic consultation is required.

Ulnar collateral ligament rupture.

Also known as *gamekeeper's* or *skier's thumb,* this injury results from a laterally directed force at the thumb MCP joint causing a rupture of the ulnar collateral ligament (Fig. 50-37). The usual mechanisms include falling with a ski pole in hand or having the

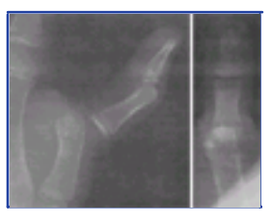

Figure 50-33 Complete dorsal dislocation at the metacarpophalangeal (MCP) joint of the thumb. There is neither associated fracture nor epiphyseal separation. *(From Harris JH Jr, Harris WH: Radiology of Emergency Medicine. 2nd ed. Baltimore, Williams & Wilkins, 1981, p 239. Reproduced by permission.)*

thumb alone draped over the steering wheel in an auto crash. These injuries most often present in the reduced state with just the complaint of pain in the area. Early recognition of this injury is essential in preventing further disability, as this ligament is important for the grasping function of the thumb.

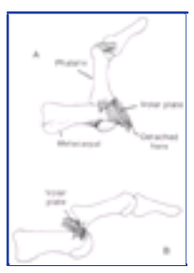

Figure 50-34 *A,* In a simple dorsal metacarpophalangeal (MCP) joint dislocation (note right angle between phalanx and metacarpal), the volar plate remains in front of the metacarpal head, although it is detached from its weaker metacarpal insertion. *B,* In a complex dislocation (note more parallel alignment between phalanx and metacarpal), the volar plate becomes entrapped in the joint and results in an irreducible reduction by closed methods. *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, p 1177. Reproduced by permission.)*

The diagnosis is generally made through stress testing of the MCP joint (Fig. 50-38). Radiographs occasionally demonstrate an avulsion-type fracture. The exact positioning of the thumb for stress testing is debatable, but the metacarpal should be stabilized with the thumb and index finger of one hand and stress applied with the other hand. Louis and coworkers recommend stressing the joint in full flexion, as virtually no lateral movement of the MCP joint should be noted in this position. Instability in full flexion of > 35° is indicative of complete rupture. [69] Hossfeld suggests testing the MCP joint in 20–30° of flexion to lessen the stabilizing effects of the volar plate; the results should be compared with stability on the other side. [68]

Partial injuries to the ulnar collateral ligament are generally casted for 3 weeks; complete rupture usually requires operative repair. [69] An associated nondisplaced fracture may be treated closed, while a displaced fracture is an indication for operative repair. [69]

Carpometacarpal Dislocations of the Thumb

Carpometacarpal dislocations of the thumb are uncommon; when present, they often occur with an associated fracture. Closed reduction is generally unstable, usually necessitating operative stabilization through the percutaneous placement of Kirschner wires. [68]

Finger Dislocations

The basic anatomic structure of the fingers is similar to that of the thumb with the exception that there is more lateral support of the MCP joints, making collateral ligament injury here much less common than in the thumb. The treatment principles are also similar. It is advisable to order radiographs for a specific finger (not just "hand" films). Complete views of the finger will include an AP view, a true lateral view, and an oblique view. The true lateral view is extremely important for detection of subtle dislocations or small avulsion fractures on the volar surface (Fig. 50-39*A* and *B*).

Figure 50-35 Irreducible metacarpophalangeal (MCP) joint dislocation of the thumb. Note the sesamoid bone *(arrow)*, indicating volar plate interposition between the two bone ends, which may prevent closed reduction. *(From Carter P [ed]: Common Hand Injuries and Infections. Philadelphia, WB Saunders, 1983, p 115. Reproduced by permission.)*

Proximal Interphalangeal Dislocations

The proximal interphalangeal (PIP) joint is extremely important, and any loss of motion in this joint may severely restrict normal function. [67] This joint is also prone to stiffness, so careful treatment of injuries to this area is essential. Injuries to the PIP joint are generally slow to heal and often result in an increase in joint size due to scar tissue formation.[67] Because of this propensity for a less-than-perfect outcome, it is advisable to refer PIP injuries after emergency care.

Figure 50-36 If a simple thumb metacarpophalangeal (MCP) dislocation is treated with traction alone, the forces will often interpose the volar plate and result in an irreducible complex dislocation. The proper technique for reduction includes *(1)* a good hold on the patient's distal thumb; *(2)* initial hyperextension of the dislocated phalanx; *(3)* pushing the base of the dislocated phalanx, rather than using traction alone; and *(4)* flexing the thumb. *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, p 1178. Reproduced by permission.)*

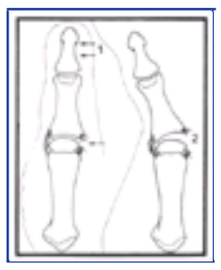

Figure 50-37 Rupture of the ulnar collateral ligament (gamekeeper's thumb). *1,* This injury is caused by forcible abduction. If unrecognized and untreated, progressive metacarpophalangeal (MCP) subluxation may occur *(2)* with interference during grasp, causing significant permanent disability. Suspect this injury when there is a complaint of pain in this region. Look for tenderness on the medial side of the MCP joint. *(From McRae R: Practical Fracture Treatment. Edinburgh, Churchill Livingstone, 1981, p 162. Reproduced by permission.)*

Proper examination of the PIP joint (Fig. 50-40) includes ulnar and radial stress to test the integrity of the collateral ligaments and hyperextension to determine the integrity of the volar plate. The inability to actively extend the flexed PIP joint against resistance suggests a central slip rupture, which may progress to a boutonniere deformity (see Chapter 49).[67] Such an examination should be carried out after any successful joint reduction. This examination should also be conducted in the painful PIP joint that is radiographically normal to detect soft tissue injury in a spontaneously or field-reduced

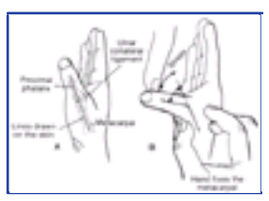

Figure 50-38 Stress testing of the ulnar collateral ligament of the thumb. This is done both clinically and with an anteroposterior radiograph. *A*, A line is drawn on the skin with a pen. The line is along the long axis of the metacarpal and the proximal phalanx. *B*, Deviation of the straight line during stress indicates instability. The metacarpal is fixed with the operator's other hand.

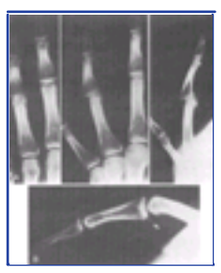

Figure 50-39 *A*, This fracture-dislocation is only fully appreciated on the true lateral film. *B*, A small fragment of bone was avulsed with the volar plate. This frequently is appreciated only with the postreduction film in a true lateral projection. *(From Carter P [ed]: Common Hand Injuries and Infections. Philadelphia, WB Saunders, 1983, p 113. Reproduced by permission.)*

dislocation. This is extremely important in athletes, as coaches often reduce these injuries. [67]

Dorsal PIP dislocations.

These are among the most common types of dislocations encountered in the ED. The

Figure 50-40 Postreduction stress of proximal interphalangeal dislocation. *A,* If the volar plate has been completely disrupted, the proximal interphalangeal joint will hyperextend with both passive and active motion. *B,* An inability to actively extend the proximal interphalangeal joint indicates a rupture of the central slip of the extensor tendon. *C,* Passive lateral stress is performed to check integrity of collateral ligaments. *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders 1970, pp 1203 and 1204. Reproduced by permission.)*

mechanism is usually a blow to the end of the finger, such as from a thrown ball, which creates an axial load and hyperextends the finger. [68] The middle phalanx comes to rest dorsal to the proximal phalanx (Fig. 50-41). There is always an associated disruption of the volar plate. [67] [68] The deformity is obvious on clinical examination, and radiographs clearly demonstrate the injury. An associated fracture of the volar lip may be detected. If this fracture affects > 33% of the joint surface, a closed reduction will be unstable and operative repair will be necessary, as the collateral ligament is attached to the bony fragment. [68]

A dorsal PIP dislocation can be reduced after a finger block. The usual method (see Fig. 50-32*E–H*) is to exaggerate the injury by slight traction and hyperextension, thereby distracting the middle phalanx. One can then apply pressure to the base of the middle phalanx as the finger is brought into flexion. These injuries usually reduce fairly easily, and failure of routine attempts should raise the suspicion of interposed soft tissue, for which an orthopedic consultation should be sought.

After reduction is completed, the joint should be placed through a range of motion to ensure stability of the reduction. If stable, the joint may be splinted in 20–30° of flexion for 3 weeks.[67] [68] Alternatively, buddy taping for 3 to 6 weeks allows early active motion and prevents hyperextension, which should be avoided. [67] As PIP injuries can be slow to heal and are complicated by stiffness, it is advisable to refer patients with these injuries for orthopedic follow-up.

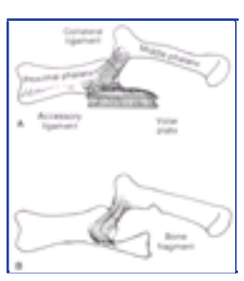

Figure 50-41 A dorsal proximal interphalangeal joint dislocation may involve rupture of the volar plate itself *(A)* or may involve an avulsion of varying amounts of bone from the middle phalanx *(B)*. If a large fragment of bone is avulsed from the base of the phalanx, the dislocation is unstable after reduction. The collateral ligaments will tear in varying degrees and should be assessed with stress testing following reduction.

Volar PIP dislocations.

These are uncommon injuries and virtually always are accompanied by an injury to the central slip of the extensor tendons. If the dislocation is reduced prior to the ED visit and there is no indication that the dislocation was volar, this injury may be incorrectly treated with splinting in mild flexion as if it were the more common dorsal dislocation. However, with disruption of the central slip of the extensor tendons, immobilization in flexion will lead to the development of a boutonniere deformity (see Chapter 49).[67] [70] Even when recognized and treated properly, some impairment of mobility may occur. [70] It is generally best to seek early orthopedic consultation for these injuries, as some require operative repair. If the emergency clinician accomplishes a closed reduction, postreduction films must demonstrate normal congruity of the joint surfaces and a central slip attachment fracture must be excluded. [70] If so, splinting of only the PIP joint in full extension should be undertaken for 3 weeks,

and early orthopedic follow-up ensured. [67]

Lateral PIP dislocations.

These injuries are fairly common and are often reduced in the field. The patient will often dramatically describe how the finger was pointing in an unnatural manner. The injury can be detected by ulnar and radial stress of the PIP joint. If still dislocated, reduction is usually easily accomplished by recreating the injury and applying longitudinal traction to the finger. Partial tears of the collateral ligaments can be treated by buddy taping the finger for 3 to 6 weeks. [67] The management of complete tears is controversial, with some using operative therapy for all such injuries, and others using varying durations of immobilization or buddy taping. [67] Referral is suggested for all but the mildest of PIP collateral ligament injuries.

Distal Interphalangeal Dislocations

As in the thumb, the distal phalanx is attached firmly to skin and subcutaneous tissue by osteocutaneous fibers. For this reason, dislocations of the distal interphalangeal (DIP) joint are frequently open. [67] A DIP dislocation is usually dorsal, and the mechanism is a blow to the end of the finger. Despite the dislocation, the DIP joint may retain some range of motion, so it is important not to overlook these injuries. [71] Lateral radiographs are diagnostic.

Management of the dorsal DIP dislocation involves reduction in a fashion similar to that described for other IP joint injuries. The injury is distracted by traction and hyperextension and relocated by pressure on the base of the distal phalanx during flexion. The joint should be checked for stability, and subsequent management involves application of a dorsal splint for 10 to 12 days of immobilization. [67]

An injury to the DIP joint that may be confused with a dislocation is the mallet finger (Fig. 50-42). This injury is often caused by blunt trauma to the end of the finger (e.g., struck by a baseball). The patient presents with an inability to extend the fingertip, but the joint appears normal on passive extension by the examiner. The injury is a rupture of the extensor tendon, with or without avulsion of a small piece of bone. Unless the injury is properly splinted or surgically immobilized, permanent deformity will occur (see Chapter 49 and Chapter 51).

Metacarpophalangeal Dislocations

The pathology and management of finger MCP dislocations are identical to those of the thumb, as discussed earlier. The same classification of simple and complex applies; the complex type requires operative repair. Dimpling on the palmar surface suggests the presence of a complex dislocation. It is important to remember that the application of traction alone for a simple MCP dislocation may convert it to a complex dislocation. For dorsal dislocations, the wrist is flexed to

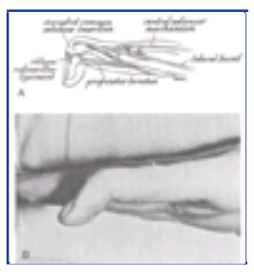

Figure 50-42 *A*, The mallet finger injury is not a dislocation; it is a rupture of the extensor tendon to the distal phalanx. *B*, This mallet deformity was caused by a baseball striking the fingertip end on, producing acute flexion of the joint.

relax the tendons. The next maneuver in reduction should be hyperextension as far as possible. This is followed by pressure on the base of the proximal phalanx to effect reduction.[67] After reduction of a simple dorsal MCP dislocation, buddy taping is generally sufficient to secure the reduction. [67] Volar dislocations are rare and require orthopedic consultation.

Carpometacarpal Dislocations

Carpometacarpal dislocations are rare injuries that are frequently misdiagnosed. The usual site of injury is the fifth carpometacarpal joint, which is dorsally dislocated.[68] The injury is usually the result of a high-energy mechanism, such as a motor vehicle crash or a fall. The diagnosis can be quite difficult, as it may be subtle even on the lateral radiograph. Associated fractures and other injuries are frequently present, and percutaneous fixation is usually required. [68]

HIP DISLOCATIONS

The hip is generally a stable ball-and-socket joint. The head of the femur is deeply situated in the acetabulum, and ligamentous and muscular support is very strong. Hip dislocations are therefore usually the result of significant forces, and a careful search for other limb- or life-threatening injuries must be undertaken. Common mechanisms of hip dislocation include motorcycle crashes, car crashes, and falls. [72]

Associated fractures are quite common with hip dislocations. In fact, up to 88% of hip dislocations present with an associated fracture. [73] When a fracture complicates the dislocation, orthopedic consultation is generally indicated. However, the emergency clinician should be able to reduce simple hip dislocations, which are dislocations without an associated fracture or with a very minor fracture. [74]

Hip dislocations may occasionally be missed in the setting of severe trauma, as other injuries garner more attention. A missed diagnosis can also occur when a femur fracture obscures the clinical picture of hip dislocation. [74] Common complications of hip dislocation include sciatic nerve injuries and avascular necrosis of the femoral head. Sciatic nerve injuries are seen in 10% to 14% of posterior hip dislocations. [74] Avascular necrosis of the femoral head is one of the more disabling complications associated with hip dislocation. Although it is generally stated that early reduction will reduce the frequency of this complication, evidence for this statement is hard to find. Dreinhofer and coworkers noted poor outcomes despite early (i.e., < 6 hours) reduction of type I hip dislocations. [73] Yang and colleagues found that reduction beyond 24 hours was associated with a worse prognosis, but they could not find a significant time factor for those reduced in < 24 hours. [72] However, it is still advisable to reduce hip dislocations as soon as feasible, to decrease soft tissue distortion. If evidence of nerve injury exists, the dislocation should be treated as an emergency and should be reduced as early as possible.

Radiographic Examination

Dislocation of the hip is generally obvious on the standard AP pelvic film that is often taken during trauma resuscitations. The use of a lateral or oblique view may help clarify the type of dislocation, but this can usually be deduced through clinical examination.

Analgesia and Anesthesia

Dislocation of a prosthetic hip can usually be managed with moderate amounts of IV premedication in the ED. Premedication recommendations for acute traumatic dislocations run the gamut from general anesthesia for all reductions [73] to IV sedation only.[75] Most clinicians would agree that some type of IV premedication is necessary, and patients often require deep sedation if the procedure is to be successful in the ED (see Chapter 34). One should not hesitate to opt for spinal or general anesthesia if a reasonable attempt at reduction fails in the ED.

Posterior Hip Dislocations

A posterior hip dislocation is most common and is usually the result of a blow to the flexed knee with the hip in varying degrees of flexion. The greater the amount of flexion of the hip at the time of the injury, the less the chance of an associated fracture. [74] The femoral head is forced out of the acetabulum and rests behind it (Fig. 50-43*A* and *B*). The sciatic nerve is located just behind the hip joint and may be injured with posterior hip dislocation. The clinical picture includes a shortened, internally rotated, and adducted leg.

Reduction Techniques

Several basic methods for hip reduction have been reported in the literature. In the prone or gravity method described by Stimson (Fig. 50-44 and Fig. 50-45), the patient is placed so that the distal pelvis overhangs the edge of the stretcher. The hip, knee, and ankle are all flexed to 90°, and downward pressure is applied to the proximal posterior tibia.[74] The hip can be gently internally and externally rotated to facilitate reduction, and if needed, direct downward pressure may be applied to the femoral head by an assistant. An alternative and more comfortable way to provide downward pressure on the tibia is for the operator to grasp the patient's ankle and place his or her own knee on the patient's calf, applying the body weight for pressure. [75] This method is believed to be the least traumatic; however, associated injuries or deep sedation may prevent the required prone position. [74]

Other techniques involve placing the patient in a supine position with downward stabilization of the pelvis performed by an assistant. In the Allis technique (Fig. 50-46), upward traction is exerted in line with the deformity, and the hip is flexed to 90°. The hip can be gently rotated internally and externally until it is reduced. [74] Howard suggests modifying this technique by applying lateral traction to the flexed upper femur to disengage the head of the femur from the outer lip of the acetabulum. [76]

A newer method known as the Whistler technique was described by Walden and Hamer. [77] The patient is placed in the supine position with both knees flexed to 130°. While an assistant stabilizes the pelvis, the operator stands beside the affected limb, placing an arm under the affected knee to grasp the unaffected knee. With the other hand, the operator anchors the ankle of the affected leg firmly against the stretcher (Fig. 50-47). Using the arm placed under the knee as a lever, the clinician raises the shoulder, elevating the affected knee. This allows the femoral head to move anteriorly around the acetabular rim to relocate. [77] Although there is only a limited experience with this technique, it appears to be a promising, gentle reduction method.

Once reduction is achieved, the legs are immobilized in slight abduction through the placement of pillows or another object between the knees. Reduction is confirmed by repeat radiographs, and the patient is admitted to the hospital.

Anterior Hip Dislocation

Anterior hip dislocation is a less common injury than posterior dislocation, constituting 10% to 15% of all hip dislocations. [74] There are three general types of anterior hip dislocations, which are defined by where the femoral head comes to rest (Fig. 50-48): the iliac or subspinous, the pubic,

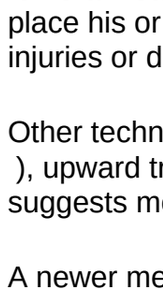

Figure 50-43 *A*, Posterior dislocation of the hip. *B,* In a severely injured patient, a hip dislocation may be initially missed while more pressing or obvious injuries are managed. In this posterior dislocation, the femur is adducted, internally rotated, and superiorly displaced, and an associated posterior acetabular fracture is present. A Malgaigne fracture of the pelvis is also present, with diastasis of the public symphysis and left sacroiliac joint. *(A from Simon R, Koenigsknecht S: Orthopedics in Emergency Medicine. New York, Appleton-Century-Crofts, 1982, p 366. B from Greenbaum E: Radiology of the Emergency Patient. New York, John Wiley & Sons, 1982, p 563. Reproduced by permission.)*

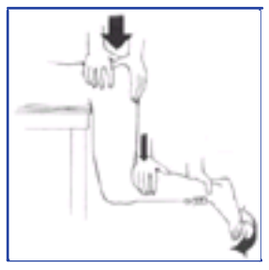

Figure 50-44 Stimson method of reduction for posterior dislocation of the hip (see text for description). *(From DeLee JC: Fractures and dislocations of the hip. In Rockwood CA, Green DP [eds]: Fractures in Adults, vol 2. Philadelphia, JB Lippincott, 1991, p 1588. Reproduced by permission.)*

and the inferior or obturator dislocation. Anterior hip dislocations generally result from a forced abduction of the thigh, which may occur in a fall or motor vehicle crash.[74] The clinical picture varies with the type of dislocation. With the obturator (inferior) type, the leg is abducted and externally rotated with varying degrees of flexion. In the other types, the hip is usually extended and externally rotated. [74]

Reduction Techniques

The Stimson gravity method may work for anterior hip dislocation, although it is not recommended for the pubic type. [74] Alternatively, the Allis maneuver is applied in a modified fashion (Fig. 50-49). The patient is placed in a supine position and an assistant stabilizes the pelvis and applies lateral countertraction to the thigh. Traction by the operator is applied in the long axis of the femur with the hip slightly flexed. The leg is then gently adducted and internally rotated to effect reduction. [74] This is the preferred method.[74]

In the reverse Bigelow technique, the hip is held in partial flexion and abduction. Traction is applied in the line of the deformity, and the hip is then adducted, sharply internally rotated, and extended. Caution should be exercised in using this technique, as the sharp internal rotation may result in femoral neck fracture in patients with osteoporotic bone.[74]

As with posterior dislocations, admission to the hospital is required for patients with these injuries.

Prosthetic Hip Dislocation

Prosthetic hip dislocations may occur with minimal trauma. The three major causes of prosthetic hip dislocations include: 1) the patient assumes a position that exceeds the stability of the prosthesis, 2) soft tissue imbalances, and 3) component malposition. [76] The clinical findings, radiography, and management of prosthetic hip dislocations are similar to those detailed earlier. Orthopedic consultation should be considered for patients with prosthetic hip dislocation.

Figure 50-45 Usually a hip dislocation is the result of significant trauma. *A*, An anterior dislocation of the hip occurred in this elderly patient with a hip prosthesis from minimal trauma (rolling over in bed). *B*, Note the position of the left leg, with the hip abducted, externally rotated, and extended. This is the same position assumed by a patient with an intertrochanteric hip fracture. The more common posterior dislocation positions the hip as adducted and internally rotated. *C* and *D*, Some clinicians prefer to climb on the bed to effect reduction. The assistant may lie over the pelvis or hold the pelvis for countertraction. Care must be taken not to disrupt the prosthesis by using excessive force. Also note that osteoporotic bones can fracture during a forceful reduction. *E*, Following relocation, a knee immobilizer usually prevents the motions required to produce a recurrent dislocation.

Dislocations of Hip Prostheses

The dislocation of a hip prosthesis is a separate issue (see Fig. 50-45). Unlike primary dislocations that require significant trauma, a prosthetic hip may dislocate with minimal force, such as rolling over in bed or trying to get out of a chair. Most dislocations occur in the first 3 to 4 months after surgery, but recurrent dislocation may occur much later. The majority of dislocations are posterior. Reduction techniques are similar to those described earlier; however, the urgency is not paramount since the problems with bone necrosis do not exist. *The clinician must be aware that forceful reduction of the dislocated hip prosthesis may dislodge the acetabular cup, fracture underlying osteoporotic bone, or loosen the prosthesis.*

KNEE (FEMUR/TIBIA) DISLOCATIONS

Although the knee is a simple hinge joint, dislocations are quite rare due to its strong ligamentous support. The major

Figure 50-46 Allis method of reducing posterior dislocation of the hip (see text for description). *(From DeLee JC: Fractures and dislocations of the hip. In Rockwood CA, Green DP [eds]: Fractures in Adults, vol 2. Philadelphia, JB Lippincott, 1991, p 1594. Reproduced by permission.)*

ligaments include the anterior and posterior cruciate and the collateral ligaments. The usual mechanism of a knee dislocation involves a great deal of force, such as a motor vehicle crash or a sporting injury. However, knee dislocation has been reported after minor mechanisms, such as stepping off a curb or into a hole, usually associated with a twisting action.[79] Obese patients may be more likely to dislocate a knee with surprisingly minor trauma, with stepping in a hole with a twisting mechanism being a common mechanism (Fig. 50-50). There are five general types of knee dislocations, including anterior, posterior, medial, lateral, and rotatory. The more common types are shown in Fig. 50-51 . Rotatory

Figure 50-47 Whistler technique of reducing posterior hip dislocation. The operator stabilizes the affected ankle with one hand while placing the other arm under the affected knee to grasp the unaffected knee. While an assistant stabilizes the pelvis, the operator raises the shoulder, elevating the knee to reduce the dislocation.

dislocations may be either posterolateral or posteromedial. Knee dislocations are described with respect to the position of the tibia in relation to the femur. [80]

Clinical Assessment

Knee dislocations are usually clinically obvious; however, dislocation may have been spontaneously reduced prior to ED evaluation, presenting only as a severe knee sprain/strain with hemarthrosis. It is the spontaneously reduced knee dislocation, often one that is associated with other major trauma, that thwarts initial diagnosis. Obese patients may exhibit a seemingly normal appearance to the knee (see Fig. 50-50), but an obvious deformity is often appreciated on initial examination. A grossly unstable knee is probably a reduced dislocation and carries the same risk of vascular and other complications as a dislocated knee. [81] The severely unstable knee can be defined as one that has > 30° of recurvatum (hyperextension) [81] or one that has gross instability after reduction. [80] Because of pain and muscle spasm that limit the physical examination for stability, a knee hemarthrosis, usually a large one with signs of posterior or calf hemorrhage, is a potential tipoff to a reduced dislocation.

An impressive effusion may not be present in knee dislocation, as the joint capsule is often disrupted and extravasation occurs into the surrounding tissue, usually posteriorly. The most important part of the clinical assessment is the vascular status of the extremity (see later). Nerve injury is less common, but peroneal nerve injury is a recognized complication, particularly of a posterolateral dislocation. [80] Posterolateral dislocations may be irreducible, as the medial femoral condyle buttonholes through the joint capsule. [80] A clue to this injury is the presence of a dimple sign at the medial joint line.

Vascular Injury

The most feared complication of a knee dislocation is severance or internal injury of the popliteal artery. Injury to the popliteal artery may complicate both anterior and posterior

Figure 50-48 Anterior dislocations of the hip: obturator, pubic, and iliac. *(From Simon R, Koenigsknecht S: Orthopedics in Emergency Medicine. New York, Appleton-Century-Crofts, 1982, p 367. Reproduced by permission.)*

knee dislocation, and occurs because the artery is relatively fixed both proximally and distally. [80] In addition, Varnell and others noted that vascular injury was as common in the severely unstable knee (e.g., field reduced) as in an acutely dislocated knee. [81] The incidence of popliteal artery injury in a dislocated knee is around 20% in most series.[81] [82] The seriousness of this complication is largely due to the fact that collateral circulation about the knee is poor, [39] and amputation may be the end result of popliteal artery (or vein) injury.

It has been previously stated that popliteal artery disruption can occur despite the presence of a normal pulse. [83] Such statements have led to recommendations to perform arteriography or exploration in all knee dislocations. [80] However, recent studies question that perspective. Varnell and coworkers reported a pulse deficit or absent pulse in all patients with

Figure 50-49 Modified Allis maneuver for reduction of anterior hip dislocation (see text for description). *(From DeLee JC: Fractures and dislocations of the hip. In Rockwood CA, Green DP (eds): Fractures in Adults, vol 2. Philadelphia, JB Lippincott, 1991, p 1588. Reproduced by permission.)*

vascular injury.[81] Kendall and colleagues also reported clear clinical evidence for all popliteal artery injuries in knee dislocations. [82] This group recommended exploration for obvious ischemia, angiography for those with ischemia who have pulse restoration after relocation, and observation for all others. [82] Dennis and colleagues reported that physical examination alone showed 100% accuracy in predicting the need for surgical intervention among patients with posterior knee dislocations. [84] Miranda et al.[85] reported that popliteal artery injury can be safely and reliably predicted by a physical examination that includes specific evaluation for active posterior hemorrhage, expanding hematoma, absent pulse, or the presence of a thrill/bruit. However, it is noted that the hard physical signs of arterial injury may be delayed for 24 to 48 hours. While the focused clinician examination may be quite accurate in the vast majority of cases, popliteal artery injury is subtle enough, or occasionally delayed, that any dislocated knee should prompt serious concern about the vascular integrity of the leg. Simple palpation of the artery may not be sensitive enough to detect a decreased pulse, so a brachial/ankle arterial pressure index, or comparison of the blood pressure at the ankle of the uninjured leg should be considered (see Fig. 50-1). Since all knee dislocations will require orthopedic evaluation, it is the dislocated/spontaneously reduced knee that is problematic for the emergency clinician to diagnose. Internal derangement with a knee hemarthrosis (often of the size noted with an anterior cruciate ligament tear) is a common first impression in the spontaneously reduced knee dislocation. Therefore, all knee injuries with significant swelling, hemarthrosis, or a dislocating mechanism of injury should be evaluated with a specific intent on ruling out vascular injury.

If vascular compromise is detected on clinical assessment, it is appropriate to reduce the knee dislocation without obtaining radiographs, although a few minutes to obtain portable x-rays and administer IV medication would probably rarely make a difference in final outcome. [80] Use of Doppler ultrasound for pulse checks and ankle-brachial pressure indices should also be considered in these injuries (see Chapter 1). Early consultation should be sought in knee dislocations due to the high incidence of complications and frequent need for operative intervention.

Figure 50-50 *A*, In an obese patient a dislocated knee may not be obvious on initial inspection. This patient stated that she stepped into a hole and twisted the knee (a classic mechanism for dislocation), causing the clinician to suspect only a sprain. *B*, An x-ray demonstrated the seriousness of this seemingly benign injury. *If a spontaneous reduction occurs prior to ED evaluation, this diagnosis may not even be considered. C*, The dislocation is usually readily reduced by traction-countertraction. Tibial manipulation concurrent with traction-countertraction is often helpful.

Figure 50-51 Types of knee dislocations. Anterior (*1*), posterior (*2*), and lateral (*3*). *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, p 1621. Reproduced by permission.)*

Reduction Technique

The need for IV sedation and analgesia is dependent on the clinical situation, but it should be considered whenever possible (see Chapter 34). The basic initial approach for all types of knee dislocations is to apply traction to the extremity (Fig. 50-52). This alone is often all that is required for reduction. [57] For anterior dislocations the distal femur is lifted to effect reduction. For posterior dislocations the proximal tibia is lifted to complete the reduction. [39] For medial, lateral, and rotatory dislocations, a similar approach is acceptable, with pressure being exerted as needed in the medial or lateral direction. Posterolateral rotatory dislocations may be irreducible, and will then require operative reduction. [39]

After reduction the extremity is splinted in 15° of flexion. The posterolateral dislocation may be irreducible, and operative intervention should be considered if reduction is not easily accomplished.

Postreduction Care

Appropriate aftercare for knee dislocations involves serial reassessment of the neurovascular status of the extremity. Postreduction radiographs are performed and the patient is

Figure 50-52 Manipulative reduction of a knee dislocation. *1,* An assistant fixes and provides countertraction on the thigh. *2,* Another assistant provides straight traction on the leg (this usually reduces the dislocation). *3,* The operator puts direct pressure over the displaced bones. *(From DePalma AF: Management of Fractures and Dislocations: An Atlas. Philadelphia, WB Saunders, 1970, p 1623. Reproduced by permission.)*

admitted to the hospital. The application of a knee immobilizer will provide stabilization and comfort. These injuries cause severe ligamentous and other derangements in the knee and generally require operative stabilization, with a long period of recovery and physical therapy.

DISLOCATIONS OF THE FIBULAR HEAD

The fibula can be dislocated at its proximal articulation in the knee joint. This is most commonly an anterolateral

Figure 50-53 Anterolateral fibular head dislocation compared to the normal knee. The interosseous distance is widened and the proximal fibula is displaced laterally. *A*, normal anteroposterior projection of knee. *B*, lateral displacement of proximal fibula. *C*, use of bilateral comparison views to highlight fibular displacement.

dislocation.[80] The fibular head is normally nestled in a stable manner behind the lateral tibial condyle with two supporting tibiofibular ligaments. [86] The tibiofibular joint has a separate synovial cavity, and therefore a typical knee joint effusion will not be seen with this dislocation. When the knee is flexed, the stability of this joint is decreased due to relaxation of the fibular collateral ligament. [86] The typical mechanism of injury is a fall on the flexed, adducted leg, often combined with ankle inversion. This mechanism is seen in sports and parachute landings. [86] Posterior dislocations can occur from a twisting mechanism or a direct blow to the area while the knee is flexed.[80]

Anterolateral dislocation is the most common type. It is accompanied by obvious prominence of the fibular head anteriorly; no associated neurovascular problems are noted. The less common posterior dislocation may be accompanied by peroneal nerve injury. [80] Patients present with varying degrees of disability, and some may walk on the leg with only mild discomfort. [86] On radiographic examination, the three cardinal signs of anterolateral dislocation are lateral displacement of the fibula on the AP film, a widened proximal interosseous space, and anterior displacement of the fibular head on the lateral view (Fig. 50-53).[86]

Reduction Technique

The position for reduction of an anterior fibular head dislocation is to place the patient supine and flex the knee to 90° in order to relax the biceps femoris tendon. Direct pressure is then applied to the fibular head and reduction is usually signified by a snap. [80] The method for a posterior dislocation is the same except that the direct pressure is applied in forward manner. Patients should not bear weight for 2 weeks and should receive orthopedic referral. Immobilization is probably unnecessary.[80]

PATELLAR DISLOCATION

Patellar dislocations are fairly common, especially among adolescents. The usual mechanism is a powerful quadriceps contraction combined with a strong valgus and external rotation component.[87] This may be seen in activities such as making a "cut" in sports or with dancing. The patella may

Figure 50-54 Various types of patellar dislocation. The lateral dislocation is the most common.

also dislocate from a direct blow to the flexed knee.[39] Predisposing factors to patellar dislocation include chronic patellofemoral abnormalities such as genu valgum and femoral anteversion.[87] The patellar dislocation is described by the relation of the patella to the knee joint. Lateral dislocations are the most common by far. Other types include superior, medial, and intra-articular (Fig. 50-54).

Figure 50-55 *A*, Lateral dislocation of the patella. *B*, To reduce a lateral dislocation, the knee is extended while the patella is directed medially using slight anteriorly directed elevation.

Clinical Assessment

Lateral dislocation of the patella is generally clinically obvious (Fig. 50-55). The knee is held in some degree of flexion and the patella can be easily seen and palpated on the lateral side of the knee. A tenting-type action of the patella is often detectable unless significant soft tissue swelling is present.

The patella may be spontaneously reduced in the field with simple leg straightening. The patient will report that the leg "went out" and may describe actually seeing the lateral deformity caused by the displaced patella. Clinical clues to the spontaneously reduced patella include the presence of a knee effusion and tenderness along the medial edge of the patella. Fairbank's test or the patellar "apprehension" sign is elicited when the patella is pushed laterally and the patient grabs for the knee, indicating the sensation of repeat injury.[39]

Radiographs

Prereduction films are difficult to obtain as the patient is usually in flexion. Some recommend prereduction films when possible in all patients [39] ; however, it is an easy matter to reduce these injuries prior to radiography. The diagnosis is usually obvious and there are no reports in the literature of complications from gentle reduction. Osteochondral fractures are detectable in about half of patients with patellar dislocations, but many of these are only visible on arthroscopy. [87] Postreduction radiographs are recommended, as are prereduction studies, when the diagnosis is uncertain. The clinical diagnosis of patellar dislocation in an older patient should be made with caution, as these are primarily injuries of the young.

Reduction Technique and Postreduction Care

Reduction of a lateral patellar dislocation is usually quite simple. Premedication is often not required if the patient can be verbally reassured. If the patient is anxious or in great discomfort, premedication should be considered (see Chapter 34). The two basic maneuvers for patellar relocation are extension of the knee and gentle medial pressure applied to the patella, lifting the most lateral edge of the patella over the femoral condyle (Fig. 50-56). [39]

The leg is then immobilized in extension. This may be done by casting or application of a commercially available knee immobilizer (see Chapter 51). Orthopedic follow-up is necessary because of the need for physical therapy and the high rate of persistent instability. [87] However, hospitalization is not required for routine lateral dislocations of the patella. Recurrent dislocation, and those associated with an osteochondral fracture, may require operative repair.

Patellar dislocations in other locations are often irreducible, and orthopedic consultation should be sought in these circumstances. Intracondylar and superior dislocations are extremely rare and require operative reduction. The rare horizontal dislocation may relocate with closed reduction but surgical reduction is often necessary.

ANKLE DISLOCATIONS

The ankle joint is a modified saddle joint in which the talus is nestled in the mortise formed by the distal tibia and fibula. [39]

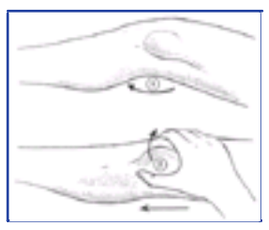

Figure 50-56 Manipulative reduction of a lateral patellar dislocation. Extend the knee gradually (*1*) while applying medially directed pressure on the patella *(2)*, pushing it over the lateral femoral condyle. *(From DePalma AF: Management of Fractures and Dislocations. Philadelphia, WB Saunders, 1970, p 1665. Reproduced by permission.)*

The ligamentous support of the ankle is quite strong, and pure dislocations are uncommon. Usually there are associated fractures of the ankle joint (Fig. 50-57). Ankle dislocations are described by the relation of the talus to the tibia. Posterior dislocations of the ankle are more common than are anterior dislocations, and they usually result from a fall on a plantar flexed foot. Patients with posterior dislocations often have an associated fracture of one or more of the malleoli (Fig. 50-58).[39] The clinical picture is usually one of significant deformity and disability.

Anterior dislocations generally result from forced dorsiflexion or a blow directed posteriorly to the distal tibia while the foot is fixed. The talus is prominent anteriorly and the dorsalis pedis pulse may be lost secondary to pressure from the talus. Superior dislocations are uncommon and result in diastasis of the tibiofibular joint. These injuries are usually the result of a significant axial force. Lateral dislocations of the

Figure 50-58 Isolated posterior tibial lip fracture *(open arrow),* seen after reduction of posterior ankle dislocation. *(From Harris JH Jr, Harris WH: Radiology of Emergency Medicine, 2nd ed. Baltimore, Williams & Wilkins, 1981, p 629. Reproduced by permission.)*

ankle are always associated with fractures of the malleoli or distal fibula.

Radiographic Examination

Because of the high rate of associated fractures and the clinical difficulty in assessing for the presence or the exact nature of a dislocation, it is recommended that prereduction radiographs be obtained in all suspected ankle dislocations. It is acceptable to reduce the dislocation without a radiograph if severe vascular compromise is present, but for the vast majority of cases, the few minutes taken to obtain bedside radiographs and administer IV medications rarely impact final outcome. It may be impossible to accurately determine the exact type of dislocation unless prereduction films are obtained. An AP and lateral view usually suffice for emergency management, and other views can be ordered if necessary after the joint is relocated.

Reduction Techniques

Unless a strong contraindication is present, it is advisable to administer IV sedation and analgesia to patients with ankle dislocation early in their care, preferably before conducting any manipulations or radiologic studies. Reduction is always painful in the awake patient, and sufficient premedication must be administered (see Chapter 34). For posterior dislocations, the patient is placed supine and the knee is flexed to relax the Achilles tendon. This can be done by an assistant, or

Figure 50-59 Manipulative reduction of a posterior ankle dislocation. *1,* The knee is flexed. *2,* The assistant provides countertraction on the leg. *3,* The forefoot is grasped with one hand and the heel with the other hand. *4,* The foot is slightly plantar flexed. *5,* Apply straight downward traction on the plantar flexed foot, then pull the foot forward *(6)* while a second assistant provides counterpressure on the front of the lower leg *(7). (From DePalma AF: Management of Fractures and Dislocations. Philadelphia, WB Saunders, 1970, pp 1916 and 1917. Reproduced by permission.)*

the patient can be brought to where the knee hangs over the end of the bed. The operator then grasps the foot with both hands, placing one hand on the heel and the other on the forefoot (Fig. 50-59). The foot is flexed slightly plantar, and traction is applied to the foot. A second assistant can then apply downward pressure on the distal tibia as the operator moves the heel anteriorly to effect reduction. [88]

For anterior dislocations, the initial steps and positioning are the same as for posterior dislocation (Fig. 50-60). However, instead of plantar flexion, the foot is dorsiflexed to free the talus. The second assistant applies upward pressure to the distal tibia while the operator applies traction and pushes the foot in a posterior direction. [39]

Lateral dislocations are really fracture-dislocations, and orthopedic consultation is generally required as part of the ED course. The emergency clinician will often need to reduce these injuries due to the extreme lateral deformity and the occasional compromise of the dorsalis pedis artery by stretch. Open dislocations (in the absence of vascular compromise) may be better handled by cleaning in the operating room prior to attempts at reduction. If a lateral fracture-dislocation is to be reduced in the ED, the approach is quite similar to that for posterior ankle dislocation. However, instead of pressure in the AP direction, the foot is moved medially

after application of traction. [39]

Postreduction Care

The ankle is splinted at 90° with a long-leg posterior splint; necessity for admission to the hospital must be determined in consultation with an orthopedic surgeon. Many patients with these injuries have associated fractures that necessitate surgical intervention.

DISLOCATIONS OF THE FOOT

The importance of the foot is recognized by anyone who has had to spend time ambulating with an injury to this area. For the purposes of discussion, injuries to the foot can be divided into those of the hindfoot and those of the forefoot.

Hindfoot Injuries

Injuries to this area are uncommon and usually require high-energy transfer. The major dislocations are the subtalar and talar dislocations, and midtarsal fracture-dislocations (Lisfranc injury). Lisfranc injury is complex and is always a fracture-dislocation because of the rigid nature of the region. These injuries require orthopedic management and are not discussed here.

Subtalar Dislocation

This uncommon injury generally occurs secondary to sports, falls from heights, or motor vehicle crashes. The calcaneus, navicular, and forefoot are displaced from the talus.[88] The primary mechanism is severe inversion causing a medial dislocation, or severe eversion resulting in a lateral dislocation. The medial type occurs so commonly during basketball that it has been termed *basketball foot*.[89] This is an injury usually seen in young adult males. Medial dislocations constitute the majority (85%) of these injuries, with lateral dislocations making up the rest. [89]

The diagnosis is usually obvious, as the talus is prominent and often tents the skin of the proximal foot. The medial type has been termed an "acquired clubfoot," whereas the lateral appears as an "acquired flatfoot." [89]

Some authors recommend spinal or general anesthesia for all such injuries [89] ; however, it is usually possible to reduce these injuries with IV premedication (see Chapter 34). The patient is positioned in a supine fashion and the hip and knee are flexed much as in posterior dislocation of the ankle. One hand is placed on the forefoot and the other grasps the heel. Firm longitudinal traction is required to effect reduction, and dangling the leg over the end of the bed allows the operator to use his or her body weight to assist in traction. Once traction is applied, the deformity is initially increased (inversion for medial; eversion for lateral) and then reversed to effect reduction.[89]

Dislocation of the Talus

In this extremely rare injury, the talus is essentially extruded from its normal position, coming to lie anteriorly. This injury is generally open, [89] is not amenable to closed reduction, and virtually always progresses to avascular necrosis. [90] Talectomy and arthrodesis are generally required, [89] and orthopedic referral should be emergently undertaken if vascular compromise of the foot is present.

Forefoot Dislocations

Much of what is pertinent to the diagnosis and management of forefoot dislocations has already been discussed in the

Figure 50-60 Manipulative reduction of anterior ankle dislocation. *1,* The knee is flexed. *2,* The operator grasps the forefoot with one hand and the heel with the other hand. *3,* Dorsiflexion of the foot is slightly increased (to disengage the talus). *4,* An assistant provides countertraction on the leg. *5,* Straight longitudinal traction is applied, then the foot is pushed directly backward *(6)* while a second assistant provides countertraction on the back of the lower leg *(7). (From DePalma AF: Management of Fractures and Dislocations. Philadelphia, WB Saunders, 1970, pp 1918 and 1919. Reproduced by permission.)*

management of dislocations of the fingers and hand MCP joints. Anatomically, the joints are quite similar.

Metatarsophalangeal (MTP) Dislocations

These uncommon injuries are generally the result of hyperextension resulting in a dorsal dislocation of the great toe MTP joint. [91] Among the lesser toe MTP joints, lateral or medial displacement of the digit on the metatarsal head is more common, and usually is the result of jamming the toe on a piece of furniture. [89] As with MCP dislocations, these can be simple or complex. Complex dislocations of the first toe can be suspected by the presence of sesamoid bones in the joint space in the prereduction radiographs. [89] Complex MTP dislocations are irreducible.

For simple MTP dislocations, reduction is accomplished by increasing the deformity through hyperextension and then applying traction while applying thumb pressure over the base of the dislocated proximal phalanx. Plantar flexion of the foot may be used to relax the flexor tendons. [88] Operative intervention is required after reduction if crepitus is present on motion, the joint is unstable, or an intra-articular loose body is noted on the postreduction radiographs. [89]

Interphalangeal Dislocations

In the foot, IP dislocations result from an axial load to the toe, such as from kicking a wall. These dislocations are generally dorsal and can be reduced as in the hand. Dislocations of the first toe interphalangeal joint are usually buddy taped to the second toe for 2 to 3 weeks, whereas those of lesser toes can be taped for 10 to 14 days.[89] As in the hand, complex dislocations may occur and require open reduction.

CONCLUSION

The following points are important regarding the assessment and management of dislocations:

1. A search for other more serious injuries should be undertaken when there is a high-energy mechanism of injury.
2. A neurovascular assessment should be performed early in the evaluation and appropriately documented.
3. Radiographs and IV premedication are generally indicated prior to reduction attempts.
4. Reduction attempts should involve the gentle, gradual application of forces and patience on the operator's part.
5. After completion of reduction, the operator should recheck the neurovascular status, request postreduction radiographs (except with radial head subluxations), and, in certain circumstances, assess the stability and the range of motion of the joint.
6. A definite percentage of dislocations are irreducible, and the need for multiple attempts should halt prolonged and forcefull attempts in the ED and prompt orthopedic consultation.
7. Reductions that present with neurologic injury should be reduced by the most expeditious and least traumatic method.

Chapter 51 - Splinting Techniques

Carl R. Chudnofsky
Stacie Byers

Splints are frequently used in the emergency department (ED) for temporary immobilization of fractures and dislocations and for definitive therapy of soft tissue injuries.[1] [2] Patients with acute gouty arthritis of the wrist acknowledge reduced pain with short-term use of a short arm splint while medical therapy is initiated.

Immobilization is the mainstay of fracture therapy, but it is difficult to find firm scientific data that support the use of splinting for soft tissue injuries. [3] [4] Although the general principle of immobilizing sprains and contusions is strongly supported by custom and personal preference, its exact influence on healing, number of complications, and ultimate return to normal activity is not known. In most studies of ankle sprains, for example, the function and pain of the injured joint are similar at 6 weeks' follow-up, regardless of whether treatment consisted of ad lib walking, a simple elastic bandage, a posterior splint, or a formal cast. [5] [6] A systematic review of 22 random clinical trials comparing various treatments for lateral acute ankle sprains (cast, splint, or early immobilization with support) found no favorable effect of immobilization. The current data support functional management for most cases of acute ankle sprains. [7] Similar concepts have evolved for acute cervical strain and low back strain. Although a strict standard of care cannot be promulgated, the use of short-term splinting in the ED for acutely painful conditions remains a common practice.

Most splinting techniques are handed down from house staff or experienced clinicians, but the procedure is often suboptimal and haphazard. [8] This chapter presents guidelines for the adequate immobilization of injuries that are commonly encountered by emergency clinicians.

Patients routinely present to the ED with injuries that are amenable to splinting to relieve pain and to augment healing (Table 51-1). Emergency clinicians have virtually abandoned the use of circumferential casts in favor of premade commercial immobilizing devices or splints made from plaster of Paris or fiberglass. The impetus for this change is primarily related to the complications occasionally associated with circumferential casts, liability issues, and ease of application

TABLE 51-1 -- Conditions That Benefit from Immobilization

Acute arthritis
Severe contusions and abrasions
Skin lacerations that cross joints
Tendon lacerations
Tenosynovitis
Puncture wounds to the hands, feet, and joints
Animal bites to the hands or feet
Deep space infections of the hands and feet
Joint infections
Fractures and sprains
Reduced joint dislocations

brought about by new technology. In most instances, properly applied splints provide short-term immobilization equal to that of casts, while allowing for continued swelling, thus reducing the risk of ischemic injury. Other obvious advantages of splints are that patients can take them off when immobilization is no longer needed or can remove them temporarily to bathe, exercise the injured part, or perform wound care.

INDICATIONS

Theoretically, immobilization facilitates the healing process by decreasing pain and protecting the extremity from further injury. Other benefits of splinting are specific to the particular injury or the problem that is being treated. For example, in the treatment of fractures, splinting helps maintain bony alignment. Splinting deep lacerations that cross joints reduces tension on the wound and helps prevent wound dehiscence. Immobilizing tendon lacerations may facilitate the healing process by relieving stress on the repaired tendon. The discomfort of inflammatory disorders such as tenosynovitis or acute gout is greatly reduced by immobilization. Deep space infections of the hands or feet as well as cellulitis over any joint should similarly be immobilized for comfort. Limiting early motion also may reduce edema and theoretically improve the immune system's ability to combat infection. Hence, select puncture wounds and mammalian bites of the hands and feet may be immobilized until the risk of infection has passed. Splinting large abrasions that cross joint surfaces prevents movement of the injured extremity and reduces the pain that is produced when the injured skin is stretched. Finally, patients with multiple trauma should have fractures and reduced dislocations adequately splinted while other diagnostic and therapeutic procedures (e.g., peritoneal lavage, computed tomography scan) are completed. Immobilization decreases blood loss, minimizes the potential for further neurovascular injury, decreases the need for opioid analgesia, and may decrease the risk of fat emboli from long bone fractures.

EQUIPMENT

Support Materials

Plaster of Paris

Plaster of Paris is the most widely used material for ED splinting. [9] Its name originated from the fact that it was first prepared from the gypsum of Paris, France. When gypsum is heated to approximately 128°C, most of the water of crystallization is driven off, leaving behind a fine white powder—plaster of Paris. When water is added to plaster, the reaction is reversed, and the plaster recrystallizes or sets by incorporating water molecules into the crystalline lattice of the calcium sulfate dehydrate molecules.

Today, plaster is impregnated into strips or rolls (2-, 3-, 4-, or 6-in widths) of a crinoline-type material. The crinoline allows for easy application, helps keep the plaster molded to the proper form during the setting process, and adds support to the finished splint. Plaster rolls and sheets are available in a variety of setting times and widths. The distinct advantage of plaster over commercially available, premade splints is that plaster can be more easily molded and tailored to the individual's anatomy, negating the "one-size-fits-all" approach. Also, plaster is generally less expensive than premade splints.

Prefabricated Splint Rolls

The use of plaster splints in the form of prefabricated splint rolls (e.g., OCL) are very popular among emergency clinicians. These splint rolls have 10 to 20 sheets of plaster enclosed between a thick layer of protective foam padding on one side, and a thin layer of cloth on the other side. Like custom-constructed splints, they are secured to the extremity with an elastic bandage. The major advantage of prefabricated splint rolls is that significant time is saved because the splint and padding come ready to apply. In addition, prefabricated splint rolls are ideal for intermittent splinting and can be removed and reapplied by the patient as needed. However, prefabricated plaster splint rolls are more expensive than simple plaster rolls, and they lack some of the versatility and custom-fit qualities of self-made plaster splints. The application of premade splints is shown in Figure 51-1 .

Prefabricated splint rolls using layers of fiberglass between polypropylene padding (e.g., Ortho-Glass, 3M) are now commonplace in many EDs (Fig. 51-2). Fiberglass splint rolls offer the same timesaving aspect of prefabricated plaster splint rolls, but require only 3 minutes to set, making application faster. In addition, splints made from prefabricated fiberglass rolls cure more rapidly (20 minutes), have no messy

Figure 51-1 Some clinicians prefer to use premade plaster splints for temporary immobilization (e.g., OCL, J-Splint). There is less latitude for custom fitting with these products compared with the technique demonstrated in Figure 51-3 . *A,* Measure the appropriate length. (Note that plain plaster slabs shrink several centimeters when wet. Cut the material slightly long, since the excess may be folded back on itself if necessary). *B,* Submerge the plaster until bubbling stops (do not oversoak). *C,* Roll and squeeze excess water from the premade splint. *Inset,* If using plain plaster slabs, allow the water to drip off. *D,* Smooth the sheets to remove wrinkles and mix the plaster throughout the layers. *E,* Apply the splint and secure it with an elastic bandage. *F,* Mold the splint to fit the contour of the extremity—an important step. *(Courtesy of Johnson & Johnson Products, Inc., New Brunswick, NJ.)*

residue (i.e., they can be hydrated using a conventional sink without a special trap), can be washed and reapplied, and are stronger and lighter than splints constructed from prefabricated plaster rolls. Another advantage is the polypropylene padding, which wicks moisture away from the skin better than polyester, nylon, or cotton padding. [10] Prefabricated fiberglass splint rolls are more expensive than both simple plaster rolls and prefabricated plaster splint rolls, and like prefabricated plaster splints, lack some of the versatility and custom-fit qualities of self-made plaster splints.

Protective and Miscellaneous Equipment

Stockinette

A single layer of stockinette is commonly used under circumferential casts and splints. It protects the skin and, when folded back over the ends of the plaster, creates a smooth, professional-looking, padded rim. Stockinette is available in 2-, 3-, 4-, 8-, 10-, and 12-in widths.

Padding

Padding under the splint protects the skin and bony prominences and allows for swelling of the injured extremity. Most

Figure 51-2 Premade fiberglass splints are also popular for temporary immobilization. Fiberglass splints set and cure more rapidly, have no messy residue (i.e., can be hydrated in a conventional sink without a special trap), can be washed and reapplied, and are lighter and stronger than plaster splints. *A*, Open the pouch and cut the splint to the desired length, stretching the padding to cover the exposed edge. Dip into cool water and squeeze three or four times (Note: Prefabricated fiberglass splints that do not contain water-repellant felt are hydrated in a different manner—Always follow the manufacturer's instructions). Remove the splint from the bucket and squeeze to remove any excess water (this allows a curing time of 3 to 4 minutes). *B*, Place the splint on an absorbent towel to remove excess water. *C,* Apply the splint and secure it with an elastic bandage. When applying the splint at a right angle (e.g., posterior ankle splint), pinch and fold over any extra splinting material). *(Adapted, courtesy of 3M Medical Division, 3M Health Care Markets, St. Paul, MN.)*

commercially available splints contain adequate padding in the premade product, but in some instances additional padding is prudent. In general, the older thin cotton padding known as sheet wadding has been replaced by newer materials such as Webril (Curity) or Specialist (Johnson & Johnson) cast padding. Webril is soft cotton with a much coarser weave than sheet wadding; consequently it has greater tensile strength, adheres better, and can be applied more evenly. Specialist padding uses micropleated cotton fibers that relax when moistened. This results in uniform, felt-like padding that conforms to the surface being wrapped. Felt (0.5-in thick) also may be used to pad bony prominences.

Elastic Bandages

Elastic bandages are used to secure the splint in place. Elastic bandages are available in 2-, 3-, 4-, and 6-in widths. Some bandages use metal clips. Others use a Velcro-type arrangement at the end of the roll.

Adhesive Tape

Adhesive tape is used to prevent slippage of the elastic bandages, to line the cut edges of a bivalved cast, and to "buddy tape" digits. Coban tape can be used in a similar manner and has the advantage of only adhering to itself.

Utility Knife, Scalpel, and Plaster Scissors

A utility knife, a No. 10 scalpel blade, or plaster scissors can be used to cut and shape dry plaster.

Bucket

A large bucket (preferably stainless steel) is used for wetting plaster. Plaster should not be prepared in the sink because the residue quickly clogs the drain. A special drain is required to accept plaster residue. A bucket is not required for the minimal amount of water used to soften fiberglass premade splints—they can be placed directly under the faucet.

Protective Gear

Gowns or sheets prevent soilage of both the patient's and the clinician's clothing. Gloves (vinyl or latex) and safety glasses are recommended to prevent skin or eye damage from plaster dust, wet plaster, or uncured fiberglass polymer. Wearing gloves also decreases clean-up time for the clinician.

GENERAL PROCEDURE OF CUSTOM SPLINT APPLICATION

The following section refers to the application of custom-made plaster splints (Fig. 51-3), unless otherwise stated. If periodic wound care is required, a more easily removable splint (e.g., OCL, Ortho-Glass, Velcro-type splint) should be applied in lieu of the standard splint to be described. The issue of removability should be addressed before the splint is applied. In addition, use of Webril (Curity) cast padding is described, but other suitable cast padding may be substituted.

Patient Preparation

If the clinical situation permits, the patient should be covered with a sheet or gown to protect clothing and the surrounding area from water and plaster. Nursing staff and housekeeping also appreciate this courtesy. The involved extremity should be inspected carefully before splinting. All skin lesions and soft tissue injuries should be examined and documented

Figure 51-3 Principles of custom splint application. *A*, Stockinette is applied to extend 2 or 3 in beyond the plaster. *B*, Two to three layers of Webril are evenly and smoothly applied over the area to be splinted. *C*, The plaster slab is positioned over the area to be immobilized and the stockinette and Webril are folded back to help secure the slab in place and to form smooth, rounded ends. *D*, The elastic bandage is applied to secure the splint. *E*, While still wet, the plaster is molded to conform to the shape of the extremity. This is an important step that is often overlooked.

clearly on the ED record. All wounds should be cleaned, repaired, and dressed in the usual manner. When immobilizing open fractures or joints, the soft tissue defect should be covered with saline-moistened sterile gauze.

Padding

When the splint involves the digits, padding must be placed between the fingers and toes to prevent maceration of the skin. This can be done with pieces of Webril or gauze cut to the appropriate length.

Following placement of padding between the fingers and toes, stockinette is often used as the next protective layer in self-made splints (see Fig. 51-3*A*). The stockinette should extend at least 10 to 15 cm beyond the area to be splinted at both ends of the extremity. Later, after plaster has been applied, the stockinette can be folded back over the ends of the splint to create smooth, padded rims. Folding back the stockinette can also help hold the splint in place when applying elastic bandages (see Fig. 51-3*C*). Care is needed to avoid pressure damage from pulling the stockinette too tightly over bony prominences, such as the heel. Wrinkling over flexion creases should also be avoided by slitting and overlapping the stockinette at bony prominences. One may also use two separate pieces of stockinette (one at each end of the splint) to produce the smooth padded rims. As a general rule, a 3-in-wide stockinette is used for the upper extremity, whereas a 4-in-wide one is used for the lower extremity.

After the stockinette has been properly positioned, Webril should be wrapped around the entire area that will be exposed to plaster. The Webril should be at least 2 to 3 layers thick and each turn should overlap the previous turn by 25% to 50% of its width (see Fig. 51-3*B*). In addition, the Webril should extend 2.5 to 5.0 cm beyond the ends of the splint so that it, too, can be folded back over the splint to help create smooth, well-padded edges (see Fig. 51-3*C*). Extra padding should be placed over areas of bony prominence, such as the radial condyle or the malleoli (Table 51-2). If significant swelling is anticipated, three to four layers of Webril should be applied as padding. Care should be taken to avoid wrinkling because it can result in significant skin pressure when a tight splint is used for a long period. Wrinkles can be eliminated by proportionately stretching or even tearing the side of the Webril that must wrap around the bigger portion of an extremity. Joints that must be immobilized in a 90° position, such as the ankle, make continuous Webril wrapping difficult. To avoid wrinkles in the area of the ankle, the joint should be placed in the proper position before padding. Webril is then wrapped around the malleolar and midtarsal regions first. The

TABLE 51-2 -- Areas of the Upper and Lower Extremity That Require Additional Padding

Medial and lateral malleoli

bare calcaneal region can then be covered with overlapping vertical and horizontal Webril strips until the entire heel region is evenly padded. The same approach can be used in similar areas such as the elbow. The width of Webril that should be used varies depending on the extremity to be splinted. In general, the 2-in width should be used for hands and feet, the 3- to 4-in width for the upper extremity, and the 4- to 6-in width for the lower extremity.

A final caveat when using Webril is to be aware of the potential for ischemic injury. This rare complication is most likely to occur in an extremity that continues to have significant swelling after the patient is released from the ED. Ischemia may result because the concentrically placed Webril can become a constricting band. If this situation is anticipated, it can be prevented easily by cutting through the Webril along the side of the extremity opposite to the plaster splint. The splint is then secured to the extremity in the usual manner. Alternatively, two to three layers of Webril (the same diameter as the plaster) are placed directly over the wet plaster (Fig. 51-4). The Webril-lined splint is then positioned over the area to be immobilized and secured with an elastic bandage.

Plaster Preparation

The choice of plaster setting time depends on the nature of the injury and the expertise of the clinician. Extra-fast-setting plaster is typically used when rapid hardening is desired to help maintain alignment of an acutely reduced fracture. However, for the majority of ED splints, plaster with slower setting times (e.g., Specialist fast-drying) is recommended.[11] Plaster that sets more slowly is easier for some clinicians to use because it affords more leeway in applying and molding

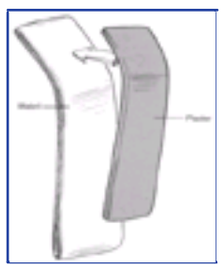

Figure 51-4 Alternative method of Webril application. If significant swelling is anticipated, Webril (the same diameter as the plaster) may be placed directly over the wet plaster, rather than wrapping it around the extremity. The Webril-lined splint is then positioned over the area to be immobilized and secured with an elastic bandage. Sandwiching the plaster strips with Webril will also minimize rigid adherence of the plaster to the elastic wrap.

TABLE 51-3 -- Setting Times of Fast- and Extra-Fast-Drying Plaster

Plaster	Setting Time (min)
Fast-drying	5–8
Extra-fast-drying	2–4

the splint. Furthermore, plaster with a longer setting time produces less heat, thus reducing both patient discomfort and the risk of serious burns. [12] Table 51-3 lists the setting times for commonly used plaster. These setting times are created by adding different substances to the plaster during the production process (Table 51-4). Given plaster with equal setting times, the most important variable affecting the rate of crystallization is water temperature. *Warm water hardens a splint faster than cold water* and should not be used when extra time is needed for splint application.

The ideal length and width of plaster depends on the body part to be splinted and the amount of immobilization required. The best way to estimate length is to lay the dry splint next to the area to be splinted. It is best to use a generous length because wet plaster shrinks slightly from its dry length. Also, if the wet splint is too long, the ends can be folded back easily. The plaster width varies according to the type of splint being made and the body part that is injured, but generally it should be slightly greater than the diameter of the limb to be splinted. Specific recommendations regarding splint length and width are made in sections describing individual splints.

The thickness of a splint depends on the size of the patient, the extremity that is injured, and the desired strength of the final product. An ankle splint may crack quickly and become useless if only eight layers are used, but this thickness may be ideal for a wrist splint. In general it is best to use the minimum number of layers that are necessary to achieve adequate strength. Thicker splints are heavier and more uncomfortable. It is also important to note that plaster thickness is a major determinant of the amount of heat given off during the setting process. With more than 12 sheets of plaster, there is an increased risk of significant burns, especially when using extra-fast-drying plaster, using dipping water with a temperature greater than 24°C, or placing a pillow under or around the extremity for support during the setting process (Table 51-5). For an average-sized adult, upper extremities should be splinted with 8 sheets of plaster, whereas lower extremity injuries generally require 12 to 15 sheets. This layering usually gives the strength necessary for adequate immobilization

TABLE 51-4 -- Effect of Water Temperature and Different Additives on Setting Time of Plaster

Accelerates Setting Time	Slows Setting Time
Reusing dip water	Cool dip water
Higher dip water temperature	Glue

TABLE 51-5 -- Variables That Increase Heat Production During Crystallization

Major	Minor
Increased splint thickness	High humidity
Setting time*	High ambient temperature
High dip water temperature†	Reusing dip water
Wrapping the extremity for support while drying	

*Faster setting times produce more heat.
†Dip water temperature has been a minor determinant of heat production in some studies.

while reducing the patient's discomfort and the risk of significant burns. In a 136 kg (300 lb) patient, however, up to 20 layers may be required to make a durable ankle splint.

The dipping water should be kept clean and fresh. The use of water that has been used previously for wetting plaster increases the amount of heat given off during crystallization and causes plaster to set more quickly. As a rule of thumb, the temperature of the water should be kept around 24°C. This temperature allows for a workable setting time and has not been associated with an increased risk of significant burns. As the temperature of the dipping water approaches 40°C, the potential for serious burns increases, even at splint thicknesses of less than 12 plies. It is interesting to note that water temperature has been shown to be only a minor consideration in heat production in some studies (see Table 51-5).

Splint Application

The dry splint should be completely submerged in the water until bubbling stops. The splint is removed and excess water is gently squeezed out until the plaster has a wet and sloppy consistency. The splint is placed on a hard table or countertop (a protective covering is recommended to prevent water or plaster damage) and

smoothed out to remove any wrinkles and to ensure uniform lamination of all layers. Lamination helps to increase the final strength of the splint. The splint is placed over the Webril and gently smoothed over the extremity. Plaster is usually somewhat adherent to Webril, but an assistant may be required to hold the splint in place. Once the splint has been properly positioned over the extremity, folding back the underlying stockinette and Webril also helps hold it in place. The splint is secured with an appropriately sized elastic bandage by wrapping in a distal to proximal direction. Finally, the extremity is placed in the desired position and the wet plaster is molded to the contour of the extremity using only the palms of the hand. Finger indentations may cause a ridge that will produce a pressure point.

Molding the wet splint to conform to the body's anatomy is probably the most important, yet the most frequently overlooked, step to ensure adequate immobilization (see Fig. 51-3*E*). The act of molding may cause some pain, and the patient should be forewarned. All manipulation of the wet plaster should be completed before it reaches a thick, creamy consistency. Any movement after this time, also known as the critical period, results in an imperfect crystalline network of calcium sulfate molecules and greatly weakens the ultimate strength of the splint. *While the plaster is setting*, a pillow or blanket should *NOT* be wrapped around the extremity for support. This leads to inadequate ventilation around the splint and greatly increases the amount of heat produced (see Table 51-5).

If an elastic bandage is applied directly over wet plaster, the elastic bandage may be incorporated into the drying plaster, making subsequent removal of the bandage difficult. To make it easier for patients to remove and reapply the splint, a single layer of Webril or roll gauze can be wrapped around the wet plaster loosely before application of the elastic bandage. This prevents the wet plaster from becoming stuck to the elastic bandage. Only one layer of Webril should be used over the plaster because multiple layers have been associated with high drying temperatures.

Before the patient is released from the ED, the splint should be checked for adequate immobilization, and the patient should be observed for any evidence of vascular compromise or significant discomfort. If either occurs, the elastic bandage should be loosened. If the discomfort persists, additional padding should be placed over the painful areas. If this measure, too, is unsuccessful, a new splint should be made, and special attention should be paid to proper molding so that the wet plaster does not become indented. By resting tender tissue, splinting usually relieves discomfort quickly, and patients generally say that they feel better immediately after the splint has been applied. Never release a patient who complains of *increased* pain after a splint has been placed.

After a proper-fitting, comfortable splint has been applied, one may place two strips of tape along each side of the splint to prevent the elastic bandage from slipping. Tape should always be applied over the metal fasteners used to secure the elastic bandages. Note that these objects can be easily swallowed or aspirated by infants and small children. Finally, a sling should be provided for upper extremity injuries, and, if required, crutches should be dispensed (and instructions given for their proper use) for lower extremity injuries.

Patient Instructions

Patients should receive both verbal and written instructions on splint care and precautions. The importance of elevation in helping to decrease pain and swelling should be stressed and demonstrated (most patients do not understand the medical definition of elevation). *At night* a pillow wrapped and secured around a hand or foot will help the patient keep the injured extremity satisfactorily elevated. If the injury is less than 24 hours old, the application of ice bags or cold packs also should be encouraged. It is useless to apply cold packs over plaster, but it can be beneficial if it is applied over Webril and an elastic bandage or directly over an injury if the splint is removed. In theory, cold therapy stiffens collagen and thus reduces the tendency for ligaments and tendons to deform. Cold therapy also decreases muscle spasm and excitability, decreases blood flow (thus limiting hemorrhage and edema), increases the pain threshold, and decreases inflammation. Because the thermal conductivity of subcutaneous tissue is poor, cold packs should be applied for at least 30 minutes at a time. This guideline is in contrast to the popular recommendation of "ice 20 minutes on, 20 minutes off," which does nothing more than cool the skin. Cold packs should not be applied for more than the first 24 to 48 hours because cold can interfere with long-term healing. The patient should be instructed not to stress the splint for at least 24 hours because plaster does not approach optimal strength until evaporation has reduced the water content of the plaster to approximately 21% of its initial hydrated level. This process of removing excess water by evaporation is called *curing* and it generally takes several days to be completed. However, by 24 hours the water content of the plaster has usually been reduced enough to produce a strong resilient splint. In addition, because the chemical process involved in the formation of plaster is reversible, the patient should avoid getting the splint wet. If the injury permits, the splint can be removed for showering and then reapplied. Alternatively, one or more plastic bags may be placed over a splint before showering.

Splints may crack, break, or disintegrate with wear, and such a useless splint should be removed or replaced. Patients should be given general guidelines for length of immobilization and appropriate follow-up care. Long-term immobilization, particularly in the elderly, can produce permanent disability.

It is extremely important for the patient to continue to check for signs of vascular compromise. If the patient experiences a significant increase in pain, any numbness or tingling of the digits, pallor of the distal extremity, decreased capillary refill, or weakness, he or she should be instructed to return to the ED or to see the primary clinician without delay. As with casting, increased pain after splinting is a warning sign that should prompt a return visit— *not telephone advice*. Strong opioids should be avoided during the first 2 to 3 days after splinting to allow pain to prompt a follow-up visit.

UPPER EXTREMITY SPLINTS

Long Arm Splints

Long Arm Posterior Splint

Indications.

The long arm posterior splint (Fig. 51-5) is used to immobilize injuries of the elbow and proximal forearm. It completely eliminates flexion and extension of the elbow, but it does not entirely prevent pronation and supination of the forearm. Therefore, it is not recommended for immobilization of complex or unstable distal forearm fractures unless used in conjunction with a long arm anterior splint. Alternatively, a double "sugar-tong" splint can be applied.

Construction.

The long arm posterior splint is constructed using 8 to 10 layers of 4- to 6-in wide plaster. The splint starts on the posterior aspect of the proximal arm. It runs down the arm to the elbow and then continues along the ulnar aspect of the forearm and hand to the level of the metacarpophalangeal joints. The anterior splint is constructed in the same manner. It mirrors the posterior splint by running down the anterior aspect of the arm to the antecubital fossa, where it continues along the radial aspect of the forearm to the distal radius. The anterior splint is never used alone, but rather is used as an adjunct to the long arm posterior splint to improve immobilization by increasing stability and preventing pronation and supination of the forearm.

Application.

Stockinette and Webril are applied as described previously. A hole should be cut in the stockinette to expose the thumb and extra padding should be placed over the olecranon to prevent pressure injury. The arm is positioned with the elbow flexed to 90°, the forearm neutral (thumb upward), and the wrist neutral or extended slightly (10°–20°). It is helpful to have an assistant hold the wet splint in place, particularly when applying both a posterior and anterior splint. Once the splint has been properly positioned, the ends of the stockinette and Webril are folded back and

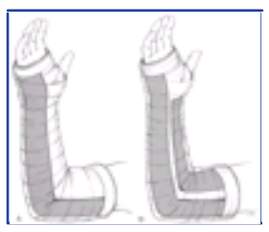

Figure 51-5 Application of a long arm posterior splint. *A*, The posterior portion of the splint begins on the posterior aspect of the proximal humerus. It runs down the arm to the elbow and then continues along the ulnar aspect of the forearm and hand to the distal metacarpals. The elbow is flexed at a 90° angle, the forearm is in the neutral (thumb up) position, and the wrist is in a neutral position or slightly (10°–20°) extended. *B*, Adding an anterior splint. The anterior splint mirrors the posterior splint by running down the anterior aspect of the arm to the antecubital fossa, where it continues along the radial aspect of the forearm and hand to the distal radius. The anterior splint is never used alone, but rather as an adjunct to the long arm posterior splint. It improves immobilization by increasing stability and preventing pronation and supination of the forearm.

the splint is secured in place using 2-, 3- to 4-in elastic bandages. Finally, the sides of the splint are folded up to create a gutter configuration and the splint is carefully molded using the palms of the hand. The fingers and thumb should remain free to prevent stiffness from unnecessary immobilization.

Double Sugar-Tong Splint

Indications.

Like the long arm posterior splint, the double sugar-tong splint (Fig. 51-6) is used to immobilize injuries of the elbow and forearm. However, because it prevents pronation and supination of the forearm, it is preferable for some fractures of the distal forearm and elbow.

Construction.

The splint consists of two separate pieces of plaster, a forearm splint and an arm splint. Each piece is constructed using 8 layers of 3- to 4-in plaster. The forearm portion of the splint runs from the metacarpal heads on the dorsum of the hand, along the dorsal surface of the forearm around the elbow. It continues along the volar surface of the forearm to the palm of the hand, stopping at the level of the metacarpophalangeal joints. The arm portion of the splint begins on the anterior aspect of the proximal humerus. It runs down the arm over the forearm splint and around the elbow. It then continues up the posterior aspect of the arm, once again going over the forearm splint, until it reaches the starting point.

Application.

Use of stockinette, Webril, and positioning are similar to those described for application of a long arm posterior splint. The two splints are secured in place using two 3- to 4-in elastic bandages starting at the forearm splint at the hand. Once secure, the arm portion of the splint is wrapped beginning at the proximal end. The fingers and thumb should remain free to avoid stiffness.

Forearm and Hand Splints

Volar Splint

Indications.

The volar splint (Fig. 51-7*A*) is used to immobilize a variety of soft tissue injuries of the hand and wrist. It is also used for temporary immobilization of triquetral fractures, lunate and perilunate dislocations, and second through fifth metacarpal head fractures. For these more serious injuries, some clinicians prefer to add a dorsal splint to create a more stable bivalve effect (Fig. 51-7*B*). Because the volar splint does not completely eliminate pronation and supination of the forearm, it may not be ideal for fractures of the distal radius and ulnar, although many clinicians use this splint for nondisplaced or minimally displaced distal ulnar and radial fractures.

Construction.

The splint is constructed using 8 to 10 layers of 3- to 4-in wide plaster. The splint begins in the palm at the metacarpal heads and extends along the volar surface of the forearm to just proximal to the elbow. If there is an injury to any of the fingers, the splint may be extended to incorporate the involved digit.

Application.

Stockinette and Webril should be applied as described previously. A hole should be cut in the stockinette to expose the thumb. In addition, Webril or gauze should be placed between any digits that are going to be immobilized. The forearm is placed in the neutral position (thumb upward) with the wrist extended slightly (10°–20°). Wrist flexion should be avoided. After the wet plaster has been properly positioned, the ends of the stockinette and Webril are folded back and a 3- or 4-in elastic bandage is used to hold the splint in place. The sides of the splint are folded up, creating a gutter effect, and the plaster is carefully molded to conform to the contours of the palm and wrist. Some

Figure 51-6 An alternative to the long arm posterior splint is a double sugar-tong splint. This splint immobilizes the elbow and prevents pronation and supination of the forearm. The splint consists of two separate pieces of 4-in plaster, a forearm splint, and an arm splint. The elbow is flexed at a 90° angle, the forearm is in the neutral (thumb up) position, and the wrist is in a neutral position or slightly (10°–20°) extended. The forearm portion of the splint is applied first. It runs from the metacarpal heads on the dorsum of the hand, along the dorsal surface of the forearm, and around the elbow. It continues along the volar surface of the forearm, stopping at the level of the metacarpophalangeal joints. The arm portion of this splint begins on the anterior aspect of the proximal arm. It runs down the arm over the forearm splint and around the elbow. It then continues up the posterior aspect of the arm, once again going over the forearm splint until it reaches the starting point. The fingers and thumb should remain free to avoid stiffness.

clinicians prefer to extend the splint to the fingertips and then fold the wet plaster back toward the palm, allowing the fingers to "grasp" the rounded distal end when at rest. In any event, the thumb and fingers should be free to move unless they are injured and are being intentionally immobilized by the splint.

Sugar-Tong Splint

Indications.

The sugar-tong splint (Fig. 51-8) is used for fractures of the distal radius and ulna. The advantage of this splint over the volar splint is prevention of pronation and supination of the forearm. In addition, it immobilizes the elbow, which is desirable for the first few days following a distal forearm fracture.

Construction and Application.

The splint is constructed and applied the same way as the forearm portion of the double sugar-tong splint, described earlier.

Figure 51-7 Application of a volar splint. *A*, The splint begins in the palm at the metacarpal heads and extends along the volar surface of the forearm to a point just proximal to the elbow. If any of the fingers are injured, the splint may be extended to incorporate the involved digits. The forearm is placed in the neutral position (thumb upward) with the wrist slightly (10°–20°) extended. Wrist flexion should be avoided. *B*, For more serious injuries, an additional dorsal slab may be used to create a bivalve splint.

Thumb Spica Splint

Indications.

The thumb spica splint (Fig. 51-9) is used to immobilize injuries to the scaphoid, lunate, and thumb and fractures of the first metacarpal. It is also used in the treatment of de Quervain tenosynovitis. Traditionally, a thumb spica splint or cast was thought to be a requirement to properly immobilize scaphoid fractures; however, there is no totally agreed-upon standard. Clay and coworkers state that the optimal method of casting scaphoid fractures has not been definitively established. They were unable to prove a difference in patient comfort, recovery of function, or incidence of nonunion between a Colles' cast and a traditional scaphoid cast that included the thumb.[13]

The incidence of nonunion of scaphoid fractures is about 10%, regardless of the type of immobilization in the ED, but it is greatest with unstable proximal pole fractures. Since some scaphoid fractures heal poorly under the best of circumstances, it seems prudent to provide thumb immobilization in the initial splinting. Failure to do so, such as when a "sprained wrist" is suspected, should not be construed as beneath the accepted standard of care. Most volar splints will at least partly immobilize the base of the thumb, so the discussion may be moot.

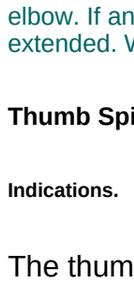

Figure 51-8 Application of a forearm sugar-tong splint. The splint runs from the metacarpal heads on the dorsum of the hand, along the dorsal surface of the forearm, and around the elbow. It continues along the volar surface of the forearm stopping at the level of the metacarpophalangeal joints. The elbow is flexed at a 90° angle, the forearm is in the neutral (thumb up) position, and the wrist is in a neutral position or slightly (10°–20°) extended. The advantage of this splint over the volar splint is immobilization of the elbow and prevention of pronation and supination of the forearm.

Construction.

The splint is constructed using 8 layers of 3-in wide plaster. The splint extends from just distal to the interphalangeal joint of the thumb to the mid-forearm.

Application.

The forearm is placed in the neutral position with the wrist extended 25° and the thumb in the wine glass position (Fig. 51-10). Stockinette and Webril are applied from the base of the palm to the mid-forearm. It may be difficult to place stockinette around the thumb. Instead, a hole can be cut in the stockinette to expose the thumb. The thumb is then padded with small vertical strips of Webril or wrapped with 2-in Webril. The dry plaster is then placed over the radial aspect of the forearm

from just beyond the thumb interphalangeal joint to the mid-forearm. Once in position, the location of the first metacarpophalangeal joint is marked and a small (1 to 2 cm) perpendicular cut is made 1 cm distal to the mark on each edge of the plaster (see Fig. 51-9 inset). If necessary the plaster distal to the notch may be tapered slightly. This will allow the splint to be molded around the thumb without creating a buckle in the plaster. The plaster is then dipped and secured in place with a 2- or 3-in elastic bandage. It is important to carefully mold the wet plaster around the thumb and palm and to maintain the thumb in the wine glass position while the plaster is drying.

Figure 51-9 Application of a thumb spica splint. The splint extends from just distal to the interphalangeal joint of the thumb to the mid-forearm. The forearm is placed in the neutral position with the wrist extended 25° and the thumb in the wine glass position (see Fig. 51-10). *Inset, A* small (1- to 2-cm) perpendicular cut is made 1 cm distal to the first metacarpophalangeal joint on each edge of the plaster to allow molding of the splint around the thumb without creating a buckle in the plaster.

Ulnar Gutter Splint

Indications.

The ulnar gutter splint (Fig. 51-11) is used to immobilize fractures and serious soft tissue injuries of the little and ring fingers and fractures of the neck, shaft, and base of the fourth and fifth metacarpals.

Construction.

The splint is made using 6 to 8 layers of 3- to 4-in plaster. It incorporates both the little and ring fingers. It runs along the ulnar aspect of the forearm from just beyond the distal interphalangeal joint of the little finger to the mid-forearm.

Application.

Stockinette and Webril are applied as usual. Additional Webril or gauze should be placed between the little and ring fingers to prevent maceration of the skin. The forearm is in the neutral position with the wrist in slight extension (10°–20°), the metacarpophalangeal joints in 50° of flexion, and the proximal and distal interphalangeal joints in slight (10°–15°) flexion. When immobilizing a metacarpal neck fracture (i.e., boxer's fracture), the metacarpophalangeal joint should be flexed to 90°. Once in the proper position, the sides of the splint are folded up to form a gutter. The ends of the stockinette and Webril are then folded back to help hold the splint while it is secured in place with a 2- or 3-in elastic bandage.

Figure 51-10 The wine glass position, which is a safe splint position for the hand. The wrist should allow alignment of the thumb with the forearm, the metacarpophalangeal joint should be moderately flexed, and the interphalangeal joints should be only slightly flexed. The thumb should be abdicted away from the palm.

Radial Gutter Splint

Indications.

The radial gutter splint (Fig. 51-12) is used to immobilize fractures and serious soft tissue injuries of the index and long fingers and fractures of the neck, shaft, and base of the second and third metacarpals.

Construction.

The splint is made using 6 to 8 layers of 3- to 4-in plaster. It runs along the radial aspect of the forearm from just beyond the distal interphalangeal joint of the index finger to the mid-forearm.

Application.

Stockinette (with a hole cut to expose the thumb) and Webril are applied as previously described. Additional Webril or gauze should be placed between the index and long fingers to prevent maceration of the skin. The forearm is in the neutral position with the wrist in slight extension (10°–20°), the metacarpophalangeal joints in 50° of flexion, and the proximal and distal interphalangeal joints in slight (10°–15°) flexion. When immobilizing a metacarpal neck fracture, the metacarpophalangeal joint should be flexed to 90°. The dry plaster is placed over the extremity and the location of the thumb is marked. A hole is cut in the dry plaster to expose the thumb. The plaster is then dipped and positioned over the extremity. The ends of the stockinette and Webril are folded back to help hold the splint while it is secured in place with a 2- or 3-in elastic bandage.

Figure 51-11 Application of an ulnar gutter splint. The ulnar gutter splint incorporates both the little and ring fingers. Webril or gauze should be placed between the digits to prevent maceration of the skin. The splint runs along the ulnar aspect of the forearm from just beyond the distal interphalangeal joint of the little finger to the mid-forearm. The forearm is in the neutral position with the wrist in slight extension (10°–20°), the metacarpophalangeal joint in 50° of flexion, and the proximal and distal interphalangeal joint in slight (10°–15°) flexion. When immobilizing a metacarpal neck fracture, the metacarpophalangeal joint should be flexed to 90°.

Finger Splints

Fingers are splinted following sprains, fractures, tendon repair, or infection. Minor finger sprains can often be managed with dynamic splinting (e.g., buddy taping) (Fig. 51-13) or a commercially available foam splint with aluminum backing (one-surface splint) (Fig. 51-14), but fractures, tendon repairs, and some soft tissue injuries benefit from formal splinting (e.g., thumb spica, ulnar and radial gutter splints). Specific conditions, such as mallet finger, require a specialized splint (Fig. 51-15). When complete immobilization of a finger is required (e.g., unstable phalangeal fractures), an "outrigger" finger splint that incorporates the wrist may be used (Fig. 51-16).

Sling, Swathe and Sling, Shoulder Immobilizer

Sling

The sling is used to maintain elevation and provide immobilization of the hand, forearm, and elbow. It is most often used in conjunction with a plaster splint or cast. There are a number of commercially available slings to choose from. Many of these are fairly economical and simple to use, while others are very expensive and do not allow the versatility of a simple, inexpensive triangular muslin bandage. When applying a sling, it is important to have adequate support of the wrist and hand (Fig. 51-17). A sling that is too short will allow the wrist and hand to hang down (ulnar deviate) and can result in ulnar nerve injury.

Swathe and Sling, Shoulder Immobilizer

The swathe and sling is the treatment of choice for most proximal humerus fractures and shoulder injuries, such as reduced dislocations. The sling supports the weight of the arm, and the swathe immobilizes the arm against the chest wall to minimize shoulder motion. In most EDs, the swathe and sling has been replaced by the commercially available shoulder immobilizer (Fig. 51-18). Its advantage is that it may be removed for showering and range-of-motion exercises and is easily reapplied by the patient (a desirable option in the care of a shoulder dislocation). If used for more than a few days the axilla should be padded to absorb moisture and decrease skin chafing.

Figure 51-12 Application of a radial gutter splint. The radial gutter splint incorporates both the index and long fingers. Webril or gauze should be placed between the digits to prevent maceration of the skin. The splint runs along the radial aspect of the forearm from just beyond the distal interphalangeal joint of the index finger to the mid-forearm. The forearm is in the neutral position with the wrist in slight extension (10°–20°), the metacarpophalangeal joint in 50° of flexion, and the proximal and distal interphalangeal joint in slight (10°–15°) flexion. When immobilizing a metacarpal neck fracture, the metacarpophalangeal joint should be flexed to 90°.

The Velpeau bandage is a sling and swathe device that positions the forearm diagonally rather than horizontally across the chest with the hand elevated to the level of the shoulder. This offers no particular advantage over a standard sling and swathe, is difficult to apply, cannot be removed easily, and is not well tolerated for prolonged immobilization.

Figure-of-8 Clavicle Strap

Clavicle fractures have been traditionally treated with an uncomfortable and complex figure-of-8 bandage. Despite its widespread use, this device has never been proved superior to a simple sling (in terms of cosmesis, functional outcome, or pain relief). [14] [15] Indeed, use of the figure-of-8 dressing should be discouraged because it may actually promote nonunion or increase the deformity at the fracture site; it is very uncomfortable; it prohibits bathing, often causing chafing and discomfort in the axilla; and it may predispose to axillary vein thrombosis. [4] Although some orthopedists continue to recommend the figure-of-8 bandage, a simple sling is sufficient to treat most clavicular fractures.

Figure 51-13 "Buddy tape" technique. Taping between the digital joints allows the normal adjacent finger to protect the collateral ligament of its injured neighbor. Webril should be placed between the digits to prevent maceration of the skin.

Pitfalls of Hand Dressings and Splints

The two most common problems with hand dressings are putting them on too tightly and leaving them on too long (Table 51-6). One must be especially careful to avoid wrapping elastic bandages too snugly. The patient should be instructed to loosen an elastic bandage if it feels too tight. The patient should always have access to emergency follow-up care. It is often advisable to start patients on a regimen of early protected motion. This means that the patient removes the splint for a specified period, does a prescribed exercise, and then replaces the splint. A splint is not an all-or-none device, and the patient is generally weaned slowly from it before it is discarded entirely. A stiff hand is a nonfunctional

Figure 51-14 Dorsal aluminum foam splint. The bone is subcutaneous dorsally, and splints here afford better immobilization of the digit. The dorsal splint also allows preservation and use of tactile sense, which encourages function and better splint acceptance on the part of the patient.

Figure 51-15 Splinting a mallet finger. The dorsal splint immobilizes only the distal interphalangeal joint. This allows use of the finger. Hyperextension of this joint predisposes to skin sloughing and should be avoided. The patient should be advised not to flex the joint during splint changes.

one, and stiffness is often a consequence of prolonged immobilization. It is important for the patient to be made aware of his or her responsibility for the injured hand.

LOWER EXTREMITY SPLINTS

Knee Splints

Knee Immobilizer

Indications.

The knee immobilizer (Fig. 51-19) is commonly used for mild to moderate ligamentous and soft tissue injuries of the knee. It is removable and extremely easy to apply, making it popular among patients and clinicians alike. In many EDs it has almost totally replaced the more bulky plaster splint. Its use should be restricted to injuries that do not require immediate surgical intervention, traction, or

Figure 51-16 "Outrigger" finger splint for complete immobilization of the finger. A padded aluminum splint is incorporated into the middle of a plaster splint, forming an outrigger configuration. The plaster splint is applied to the dorsum of the hand and wrist with an elastic bandage; the finger is then taped to the aluminum splint.

casting. For these injuries, in which temporary but more complete immobilization is needed, a plaster knee splint can be used because it provides better stabilization and costs much less than a knee immobilizer. The exact scientific benefit of the knee immobilizer is poorly studied and difficult to document. However, it clearly helps relieve pain and, at least theoretically, hastens healing.

Application.

The knee immobilizer is available in small, medium, large, and extra-large sizes. To choose the appropriate size, the knee immobilizer is placed next to the injured leg so that the tapered end lies distal to the patient's knee; if present, the cutout patellar area on the anterior aspect of the splint lies adjacent to the knee. In this position, the splint should extend distally to within a few inches of the malleoli and proximally to just below the buttocks crease. To apply the knee immobilizer, the open splint is slid under the injured extremity and firmly secured in place using the Velcro straps. The knee immobilizer can be applied directly over clothing, obviating the need to remove or cut the patient's pants.

Posterior Knee Splint

Indications.

In many EDs, the knee immobilizer has virtually replaced the plaster knee splint for mild to moderate injuries to the knee. However, the plaster knee splint can be particularly useful in patients whose extremities are too large for the knee immobilizer, in the treatment of angulated fractures, or for temporarily immobilizing other knee injuries that require immediate operative intervention or orthopedic referral. The posterior (gutter) knee splint (Fig. 51-20*A*) is the type most commonly applied, but as an alternative, two parallel splints can be placed along each side of the leg and foreleg, creating a bivalve effect (see Fig. 51-20*B*), or a long leg U-splint can be applied (see later). The bilateral knee splint is slightly more difficult to apply than the posterior knee splint, but it may provide better immobilization of the lateral and medial collateral ligaments and can be used for injuries to these structures.

Construction.

The knee splint is made with 12 to 15 layers of 6-in plaster. It should run from just below the buttocks crease to approximately 5–8 cm above the malleoli. The sides of the splint are folded upward to form a gutter configuration.

Application.

A stockinette should be placed in the usual manner, and the leg should be well padded with 4- to 6-in Webril. If available, an assistant can help elevate the leg and hold the splint in place while it is being secured with 4- or 6-in elastic bandages. If no aide is available, the patient can be placed in the prone position and the splint laid on the posterior surface of the extremity. The leg is then wrapped in the usual manner without the need for special support of the applied plaster. Also, while in the prone position, the patient's toes can elevate the lower part of the leg off the bed, allowing sufficient room to wrap the Webril and elastic bandages around the injured extremity.

Jones Compression Dressing

Indications.

A Jones compression dressing is commonly used for short-term immobilization of soft tissue injuries of the knee. It immobilizes and compresses the knee, reducing both pain and swelling. However, because it does allow slight flexion and extension of the knee, it should not be used for injuries that require strict immobilization. In addition, it is difficult to maintain the splint for more than a few days.

Figure 51-17 *A*, Step-wise application of a triangular muslin sling. (1) Place tip X over the uninjured shoulder. (2) Bring tip Y over the injured shoulder to enclose the arm. (3) Draw tip Z around the front and pin. *B*, Completed triangular muslin sling (Note: When applying a sling, it is important to have adequate support of the wrist and hand. A sling that is too short will allow the wrist and hand to hang down [ulnar deviate] and can result in ulnar nerve injury).

Figure 51-18 The shoulder immobilizer is used for most proximal humerus fractures and shoulder injuries. It may be removed for showering and range-of-motion exercises and is easily reapplied by the patient.

Construction.

A Jones dressing is made using 6-in Webril and elastic bandages.

Application.

To apply a Jones dressing, the patient is placed on a stretcher, lying supine. If available, an assistant can elevate the patient's leg to facilitate wrapping. If no help is available, a pillow placed under the patient's heel should suffice. Webril is then wrapped around the extremity from the groin to a few inches above the malleoli. Two or 3 layers of Webril can be used, and each turn should overlap the previous turn by 25% to 50%. The elastic bandage (two are usually required) is then wrapped around the Webril. If more support is required, the process can be repeated with another two to three layers of Webril held in place by additional elastic bandages.

Ankle Splints

Posterior Splint

Indications.

The posterior ankle splint (Fig. 51-21) is one of the most common splints applied in the ED. As noted in the introduction, the entire concept of splinting an acutely sprained ankle has been questioned, with no firm evidence to support a better outcome of any type of splinting or casting versus functional management (early mobilization with an external support). Nonetheless, an acutely sprained ankle is painful, and if nothing else, splinting for a few days will alleviate pain.

The posterior splint is used primarily to immobilize severe ankle sprains, fractures of the distal fibula and tibia, and reduced ankle dislocations. It can also be used for

TABLE 51-6 -- Useful Estimates of Splint Times for Various Hand Problems

Injury	Splint Type	Immobilization Time*
Mallet finger	FIN†	8 wk

§The diagnosis of a sprain should be made only after a thorough effort has been made to rule out a fracture or dislocation. This is particularly true in the wrist.

fractures of the tarsal and metatarsal bones or for other foot conditions that require immobilization. In particularly severe or unstable injuries, an additional anterior splint may be used to provide extra immobilization resembling that of a formal cast (Fig. 51-22). For severe lateral or bilateral ligamentous injuries, a U-splint or stirrup splint (see later) may be added to the posterior splint for increased immobilization. With minor soft tissue injuries, patients may have partial weight bearing on ankle splints after 24 hours. If the patient will be bearing weight, a cast shoe over the splint makes it easier to walk. In addition, a cast shoe increases the longevity of the splint because walking on an unprotected splint quickly destroys the device. Generally, walking on the splint is prohibited if immobilization for more than 2 or 3 days is desired.

Construction.

The posterior splint is made using 4- to 6-in-wide plaster strips. It should extend from the plantar surface of the great toe or metatarsal heads along the posterior surface of the foreleg to the level of the fibular head. If it hurts to move the toes, they should be incorporated into the splint (after padding is placed between the digits). It is a common mistake to apply a posterior splint that does not extend far enough to support the ball of the foot. Fifteen to 20 layers should be used if partial weight bearing is allowed because this splint frequently breaks or cracks when walked on. [16]

Application.

The easiest way to apply a posterior splint is to place the patient in the prone position with the knee and ankle flexed at a 90° angle. Failure to place the ankle in a 90° angle results in a plantar-flexed splint. The supine patient may help maintain the ankle in a 90° angle by pulling up on the foot with a wide stockinette stirrup. Flexing the knee to a 90° angle relaxes the gastrocnemius muscle and facilitates ankle motion. With the knee and ankle in the proper position, stockinette may be applied and the foot and leg padded with Webril as described earlier. Extra padding is used

Figure 51-19 The Velcro strap bulky knee immobilizer is easily removed and readily applied by the patient. It can be worn over clothes.

over bony prominences, particularly the malleoli. Again, Webril or gauze is placed between the toes if they are to be included in the splint. The wet plaster is then laid over the plantar surface of the foot and secured in place by folding back the ends of the stockinette and wrapping with one or two 4-in-wide elastic bandages. The wet plaster is carefully molded around the malleoli and instep to ensure maximum comfort and immobilization. The toes should be left partially exposed for later examination of color and capillary refill.

Anterior-Posterior Splint

Indications.

The anterior splint is never used by itself, but it can augment a posterior splint, creating a bivalve effect (see Fig. 51-22). It is used for serious fractures and soft tissue injuries of the ankle.

Construction.

A piece of plaster should be cut several centimeters shorter than the one used for the posterior splint, but because this splint does not bear weight, only 8 to 10 layers are required.

Application.

The patient should be positioned and padded as for the posterior splint. After the wet posterior splint has been applied, the anterior splint is placed over the anterior aspect of the ankle and foreleg parallel to the posterior splint. The two are then held in place with elastic bandages as described earlier for the posterior splint alone. An assistant is needed to apply the anterior-posterior splint because it is extremely difficult to hold both splints in place

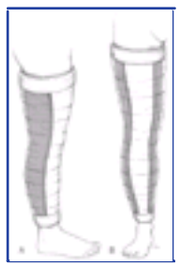

Figure 51-20 Application of a posterior knee splint. *A*, The posterior knee splint runs from just below the buttocks crease to approximately 2 to 3 cm above the malleoli. *B*, Alternatively, two parallel splints can be placed along each side of the leg and foreleg, creating a bivalve effect.

while wrapping the elastic bandages. Once secured, both splints are carefully molded over the instep and ankle joint.

U-Splint (Stirrup Splint)

Indications.

The U-splint or stirrup splint (Fig. 51-23) is used primarily for injuries to the ankle. It functions like the posterior splint, and either of the two provides satisfactory ankle immobilization. In one study that compared these splints in normal volunteers, the U-splint allowed less plantar flexion and broke less often with plantar flexion than the posterior splint.[16] Also, because it actually covers the malleoli, the U-splint may protect the medial and lateral ligamentous area from further injury better than the posterior splint.

Construction.

The U-splint is made using 4- or 6-in-wide plaster strips. The splint passes under the plantar surface of the foot from the calcaneus to the metatarsal heads and extends up the medial and lateral sides of the foreleg to just below the level of the fibular head.

Application.

The patient is positioned, and the extremity is padded as described for the posterior splint. If both posterior and U-splints are used, the posterior splint is applied first. The wet plaster is laid across the plantar surface of the foot between the calcaneus and metatarsal heads with the sides extending up the lateral and medial aspects of the foreleg. The plaster is secured in place with 4-in elastic bandages. The elastic bandage should be wrapped around the extremity starting at the metatarsal heads and continuing around the ankle using a figure-of-8 configuration. Once the ankle has been wrapped, another 4- or 6-in elastic bandage can be used to secure the remainder of the splint in place. The splint should be carefully molded around the malleoli. The plaster may overlap on the anterior aspect of the ankle; this overlap does not interfere with the splint's ability to accommodate further swelling.

Semirigid Orthosis

Indications.

In patients with sprains of the lateral ankle associated with a stable joint, the use of a functional brace with early mobilization is frequently more comfortable, and results in an earlier return to normal function than complete immobilization in a plaster splint or cast. [17] [18] [19] [20] [21] [22] [23] Consequently, functional bracing with early mobilization has become the standard of care. However, it should be pointed out that there is no documented difference in long-term outcome between the two methods of treatment.

Application.

Most functional ankle braces resemble a U-splint with air bladders (Aircast, Inc., Summit, NJ) or foam padding (DeRoyal Inc., Powell, TN) for cushioning the malleoli. The braces are secured about the ankle by Velcro straps. The device is worn within the patient's shoe over a sock and appears to eliminate ankle instability.

Hard Shoe (Cast or Reese Shoe)

Indications.

A hard shoe can help reduce the pain associated with ambulation in patients with fractures or soft tissue injuries to the foot. This device can also be used over a splint or cast to allow partial weight bearing.

Application.

If the cast shoe is going to be used by a patient with a fractured toe, the injured digit should first be "buddy taped" to the adjacent toe. After this is done, the patient merely slips on the hard shoe like a sandal. The shoe is then fastened with ties or Velcro straps.

Soft Cast

Indications.

A "soft cast" is basically a modified Jones compression dressing. It is useful for minor ligamentous and soft tissue injuries of the foot and ankle that do not require prolonged or complete immobilization. A soft cast can help reduce the pain and swelling often associated with mild ankle sprains and gives support for early weight bearing.

Construction.

A soft cast is made using 3- or 4-in Webril and elastic bandages.

Application.

A soft cast is as simple to apply as the Jones compression dressing. To begin, the patient is placed in a supine position with the foot and ankle extending off the end of the stretcher. Alternatively, the leg can be elevated by an assistant or by placing pillows under the knee and foreleg. The ankle and foot are then wrapped with two to three layers of Webril, starting at the metatarsal heads and continuing around the ankle in a figure-of-8 configuration. The Webril should extend 5 to 7 cm above the malleoli and, as discussed earlier, should overlap by 25% to 50% of its width. After the Webril is in place, an elastic bandage is wrapped around the foot and ankle in a similar fashion. Additional layers of Webril and elastic bandages are seldom required.

Unna Boot Dressing

Ligamentous injuries of the ankle may be treated with a cloth dressing impregnated with calamine gelatin-zinc oxide (Dome-Paste or Unna Boot) (Fig. 51-24).[24] This moist dressing is applied like that for a rolled cast in a figure-of-8

Figure 51-21 Posterior ankle pitfalls. *A*, Proper application of a posterior ankle splint. This splint extends from the plantar surface of the great toe (or metatarsal heads) along the posterior surface of the foreleg to the level of the fibular head. The ankle should be at a 90° angle. *B,* The most convenient way to apply an ankle splint is to have the patient lie prone and bend the knee to a 90° angle, thereby relaxing the calf muscles. The ankle should be at a 90° angle so that the foot is flat for partial weight bearing. *C, Incorrect splint application.* There are three things wrong with this posterior ankle splint: (1) It does not extend distally enough to support the entire foot. (2) The ankle is not maintained at a 90° angle. (3) The edges and ankle area are not molded. Overall the splint is sloppy and ineffective. *D*, The problem with this splint is that it was intended to be used for only a few days, but the patient wore it for 3 weeks. Note the resultant full-thickness skin loss. No padding was used under the premade splint. Skin grafting was eventually required.

design, from the metatarsal heads to the distal foreleg. This dressing remains moist for a few days (it should be covered with a gauze roll or an elastic bandage) and dries to a leathery consistency. It requires minimal maintenance or patient compliance, is lightweight, can be worn under a shoe, and is associated with few complications. It is cut off with scissors by the patient after 5 to 10 days, depending on symptoms. This dressing is nonyielding; hence, evaluation for ischemia is essential in the edema-prone extremity. The dressing (unna boot) is also useful for covering chronic stasis ulcers and averting patient manipulation of lower extremity wounds.

COMPLICATIONS OF SPLINTS

Ischemia

A compartment syndrome leading to ischemic injury and ultimately to a Volkmann ischemic contracture is the most worrisome complication of cylindrical casts. Although the risk of ischemia is drastically reduced with splinting, Webril or elastic bandages can cause significant constriction. To reduce the likelihood of this occurring, the elastic bandage should not be excessively tight. If the patient has a high-risk injury, the

Figure 51-22 Application of an anterior-posterior ankle splint. In particularly severe or unstable injuries, an anterior splint may be added to a posterior ankle splint to provide extra immobilization resembling that of a formal cast. The anterior splint is never used by itself, but it can augment a posterior splint, creating a bivalve effect. The ankle should be at a 90° angle.

Webril may be cut lengthwise before the plaster is applied. Elevation, no weight bearing, and application of cold packs should be stressed to each patient. Furthermore, signs and symptoms of vascular compromise should be explained carefully, and all patients whose injuries have the potential for significant swelling or loss of vascular integrity should receive follow-up in the first 24 to 48 hours. *Complaints of increasing pain under a splint should not be ignored by the clinician. Patients with splint-related discomfort should re-evaluated clinically and should not be treated with a telephone prescription for opioid analgesics.*

Heat Injury

Fiberglass splints produce minimal heat when drying, but plaster generates considerable heat as it hardens. Many clinicians are unaware of the potential for drying plaster to produce second-degree burns.[25] Thermal injury can occur with both cylindrical casts and plaster splints. Some clinicians have reported a higher incidence of burns with the use of plaster splints, although the reasons for this are unclear.[25] [26] Table 51-5 lists factors that can increase the amount of heat produced during plaster recrystallization. Their effects are additive, and this fact should be taken into account when applying a splint. For example, if 15 sheets of plaster are needed for strength in a particular splint, one should not increase the heat production further by using extra-fast-drying plaster or by reusing warm dip water. To avoid plaster burns, use only 8 to 12 sheets of plaster when possible, use fresh dip water with a

Figure 51-23 The U-splint (AKA sugar-tong or stirrup splint) is also used primarily for injuries to the ankle. The splint passes under the plantar surface of the foot, extending up the medial and lateral sides of the foreleg to just below the level of the fibular head. The ankle should be at a 90° angle. For immobilization of the knee, the sides of the splint may be extended proximally to the groin, creating a long leg splint.

temperature near 24°C, and never wrap the extremity in a sheet or pillow during the setting process. Peak temperatures usually occur between 5 and 15 minutes after plaster wetting.

The patient should be warned that the hardening process produces warmth. The heat of drying may produce pain in patients with hemophilia-related hemarthroses. Splinting these patients may require that the plaster splint only be placed long enough to verify proper fit; the splint is then reapplied after setting (and cooling) of the plaster. *If any patient complains of significant burning while the plaster is drying, do not ignore this complaint!* Immediately remove the splint, and promptly cool the area with cold packs or cool water. Patients with vascular insufficiency or sensory deficits (e.g., diabetic neuropathy, stroke) are at high risk for plaster burns and require close observation during the drying process.

Pressure Sores

Pressure sores are an uncommon complication of short-term splinting.[27] They can result from stockinette wrinkles, irregular wadding of Webril, incorrectly padded or unpadded bony prominences, irregular splint ends, plaster ridges, or indentations produced from using the fingers rather than the palms to smooth and mold the wet plaster. Attention to detail during padding and splinting reduces the incidence of pressure sores. However, whenever a patient complains of a persistent pain or burning sensation under any part of a splint, the splint should be removed and the symptomatic area inspected closely. The padding that is incorporated in premade plaster and fiberglass splints is generally all that is needed for safe short-term splinting. However, the life of a splint applied in the ED may be longer than intended by the clinician; therefore, it is

Figure 51-24 The Unna boot provides effective immobilization of an ankle soft tissue injury. It is applied from a semisolid paste roll. The wrap is then covered with gauze or an elastic bandage. The entire dressing can be cut off by the patient at home. For similar short-term immobilization without plaster, a modified Jones dressing can be used. Webril is wrapped around the ankle and it is covered with an elastic bandage.

prudent to err on the side of additional padding when putting splints on patients who will overuse the splint, such as those who will not use crutches, or for those who may not have ready access to follow-up.

Infection

Bacterial and fungal infections can occur under a splint.[28] [29] Infection is more common in the presence of an open wound but may occur with intact skin or develop in a skin lesion produced by prolonged splinting. The moist, warm, and dark environment created by the splint is an excellent nidus for infection. Toxic shock syndrome has been rarely reported from a staphylococcal skin infection that has clandestinely developed under a splint or cast. Also, it has been shown that bacteria can

multiply in slowly drying plaster. To avoid infection, all wounds should be cleaned and debrided before splint application, and clean, fresh tap water should be used for plaster wetting. In some instances, it is preferable to apply a removable splint that allows for periodic wound inspection or local wound care.

Dermatitis

Occasionally patients develop a rash under a plaster cast or splint. [30] [31] [32] [33] [34] Allergy to plaster is exceedingly rare, but there are several reports of contact dermatitis when formaldehyde and melamine resins are added to the plaster. [32] [33] The rash is usually pruritic, with weeping papular or vesicular lesions. Because these resins are unnecessary for ED splints, their use should be avoided whenever possible. Dermatitis has also been reported with the use of fiberglass splinting materials.[35]

Joint Stiffness

Some degree of joint stiffness is an invariable consequence of immobilization. It can range in severity from mild to incapacitating and can result in transient, prolonged, or, in some cases, permanent loss of function. Stiffness appears to be worse with prolonged periods of immobilization, in elderly

TABLE 51-7 -- Suggested Length of Immobilization for Conditions That Frequently Require Splinting

Condition	Length of Immobilization (Days)
Contusions	1–3
Abrasions	1–3
Soft tissue lacerations	5–7
Tendon lacerations	Variable*
Tendonitis	5–7
Puncture wounds and bites	3–4
Deep space infections and cellulitis	3–5
Mild sprains	5–7
Fractures and severe sprains	Variable†

*There is considerable controversy surrounding the length of immobilization for tendon lacerations, and duration therefore is best left to the orthopedic or plastic surgeon.
†Usually requires prolonged immobilization; best determined by an orthopedic surgeon.

patients, and in patients with preexisting joint diseases such as rheumatoid arthritis or osteoarthritis. Thus, splints should be left on only for that period of time necessary for adequate healing. Table 51-7 lists several injuries that commonly require splinting, along with some suggestions for length of immobilization. Fractures, dislocations, or other conditions that require prolonged immobilization (more than 7 days) should have orthopedic follow-up. Patients must be told that a splint is only a short-term device and that prolonged immobilization can be detrimental. For minor injuries, the clinician can suggest that the patient use his or her own judgment about when to remove the splint, but a definite end point should be set.

CAST PAIN

Cast-related pain is a common complaint that brings patients to the ED. Because of the potential for ischemia with circumferential casts, all complaints should be fully investigated, and vascular compromise must be ruled out. A detailed history and physical examination should be performed on all such patients. The nature and onset of the pain is of particular importance. A dull, nonspecific pain that has worsened gradually since the time of injury may be the only clue to an early compartment syndrome (see Chapter 55). The sudden onset of throbbing pain associated with swelling and redness suggests a possible deep venous thrombosis. In both these cases, rapid intervention is the key to decreasing morbidity and mortality. The physical examination should pay particular attention to the areas of tenderness and the effect of active and passive movement on the severity of pain.

With a *compartment syndrome*, tenderness over the involved compartment is a common finding; stretching or contracting ischemic muscle also elicits significant pain. The examination should also evaluate the presence and quality of distal pulses, amount of edema fluid present, distal sensation, capillary refill, and color and temperature of the digits. The finding of pain, pallor, paresthesias, paralysis, and pulselessness (the five Ps) are said to be pathognomonic for ischemia. Unfortunately, they seldom occur simultaneously, and their presence together is usually a late finding that carries a poor prognosis. Hence, the emergency clinician must maintain a high index of suspicion for possible ischemia and remove the

Figure 51-25 *A,* The cast saw vibrates; it does not rotate. The blade is controlled by placing the thumb on the splint and lowering the saw to the plaster. The blade is raised and lowered for each cut; it is *not* drawn across the plaster like a knife. *B,* This cast was too tight, and it was therefore bivalved from cast to forefoot with a cast saw. After separation of the edges of the cut cast, the anterior and posterior components were secured in place with an elastic bandage. Note that the underlying Webril padding was cut to relieve pressure but was not removed *(inset)*. A bivalved cast provides temporary immobilization equal to that of an intact cast.

cast if any possibility of vascular compromise exists. Almost any cast can be bivalved and reapplied after inspection without significant loss of short-term immobilization.

To loosen a cast, an oscillating cast saw is used to cut along the medial and lateral aspects of the cast (Fig. 51-25). This is called *bivalving* the cast, and it allows the halves to be spread and reapplied in a less constricting manner while still maintaining proper immobilization. To use the oscillating power saw, proceed in a series of downward cutting movements facilitated by wrist supination, removing the blade between cuts. The blade is removed between cuts to prevent it from getting hot enough to burn the skin. This is particularly important if synthetic materials have been used in the cast. Also, the blade should not be allowed to slide along the skin, and the saw should never be used on unpadded plaster. With an apprehensive patient, the clinician can demonstrate that the cast saw blade only vibrates (it does not turn) and that it does not cut the skin.

After completely cutting through the medial and lateral sides of the cast, the two halves are separated using a cast spreader, and the padding is cut lengthwise with scissors. This may be sufficient to relieve early ischemia if the problem is simple postinjury swelling, but both the padding and cast can be removed totally to inspect the injured area if necessary. If ischemia cannot be ruled out, compartment pressures should be measured (see Chapter 55), and an orthopedic consultation should be obtained.

If vascular integrity is established and no other problems are found, the bivalved cast can be replaced. First, the extremity should be padded in the usual manner using fresh Webril. The cut ends of the bivalved cast are then lined with white adhesive tape, and the cast is replaced around the extremity. Finally, the cast is secured in place using elastic bandages.

If plaster sores are causing the patient's discomfort, the clinician who placed the cast should be consulted. In some cases, additional padding is all that is needed, but in others a window should be cut out over the problem area. Because pressure sores can lead to significant tissue necrosis, the patient should receive follow-up care within 24 hours.

If the patient's problem is plaster (or more likely, resin) dermatitis, treatment generally consists of topical or oral steroids and antihistamines. Therapy should be done in concert with an orthopedic surgeon because the patient may require admission for other forms of immobilization until the cast can be replaced. With mild cases, changing the cast or splint and using antihistamines for symptomatic relief may suffice. All of these patients should receive close follow-up, and if the condition does not improve, the cast must be removed.

CONCLUSION

Splinting represents an important means of temporary fracture immobilization and provides protection and comfort for a variety of soft tissue injuries. The clinician should be aware of potential complications including ischemia, thermal injury, and pressure sores, which can occur with improper splint application. Proper technique should minimize the risk of these adverse outcomes. The emergency clinician also should be facile in the release of circumferential cast and splint materials when ischemia is suspected.

Chapter 52 - Podiatric Procedures

Douglas McGee

Patients with painful or infectious conditions of the feet often seek medical attention since normal daily activities cannot be easily accomplished without walking. This chapter focuses on procedures performed for common maladies of the foot. Other procedures of the foot are described elsewhere in this text, including anesthesia of the foot and ankle (see Chapter 30 and Chapter 32), management of nailbed injuries (see Chapter 36 and Chapter 38), incision and drainage of paronychia (see Chapter 38), joint fluid analysis (see Chapter 54) the management of common dislocations of the foot (see Chapter 50), and splinting (see Chapter 51).

COMMON NONTRAUMATIC CONDITIONS OF THE FOOT

Many painful conditions of the foot are chronic and usually do not require definitive treatment in the emergency department (ED); however, patients often present with common conditions that require evaluation and proper referral. To accomplish this, the clinician must be cognizant of basic podiatric issues. Typical conditions include painful lesions over bony prominences, heel pain, foot infections, and pain on the plantar surface of the foot.

Footpad Use

Footpads redistribute pressure over an inflamed, tender area of the foot. The particular type of footpad and its placement depend on the condition being treated (Fig. 52-1). Commercially available aperture footpads are recommended

Figure 52-1 Use of aperture pads to redistribute pressure from painful areas to surrounding structures. *(Courtesy of Kenneth R. Walker, DPM.)*

for temporary relief of warts, corns, hyperkeratoses, and bunions. Verruca virus introduced into the plantar surface of the foot may produce a painful hyperkeratotic lesion, commonly referred to as a "plantar wart," on the sole of the foot. Simple callus may be painful and result in the formation of a "hard corn" when formed over the bony prominence of a digit. Once recognized, and after other conditions are ruled out, definitive care of these lesions is rarely indicated in the ED.

When tenderness is elicited over more than one metatarsal head, the diagnosis is metatarsalgia. Pain that is progressively worse while walking but relieved by rest, often beneath the second or third metatarsal heads, is typical in this case. A pad placed under the first metatarsal head to raise the second and third metatarsals may provide some relief.

A bunion develops when unbalanced forces applied to the first metatarsal cause lateral displacement of the distal hallux. Bunions typically form in women wearing heeled shoes with narrow toe boxes. The patient may complain of numbness over the distal, medial aspect of the first toe owing to compression of the terminal branch of the medial dorsal cutaneous nerve. The mechanical forces that precipitate bunion formation may also cause other painful conditions including intermetatarsal neuroma, hammertoes, ingrown toenails, corns, and callus. Bursitis may develop over the medial bony prominence of the first metatarsal phalangeal (MTP) joint. Self-adherent bunion pads placed over the first MTP joint may provide temporary relief (Fig. 52-2). In the ED, treat patients suffering from these common disorders with analgesics and footpads followed by referral for definitive care. When appropriate, recommend that the patient avoid the offending shoes. Also, remember to consider gout when evaluating pain over the first MTP joint, particularly in the presence of other signs of inflammation (e.g., redness, swelling, warmth).

Heel Pain Syndromes

Bony spurs on the plantar surface of the calcaneus, retrocalcaneal bursitis, calcaneal apophysitis, and other conditions may cause heel pain. Treat most of these conditions with rest, nonsteroidal analgesics, modification of physical activities or shoewear, footpads, and orthoses. Some clinicians also include the injection of anesthetics or steroids for these conditions.

Figure 52-2 Use of a self-adherent bunion pad. *(Courtesy of Kenneth R. Walker, DPM.)*

Heel spur pain can be quite bothersome and chronic. This condition is not easily remedied in the ED, and after other conditions are ruled out, minimal intervention with podiatric referral is often the best course of action. Patients typically present with pain over the medial border of the plantar aspect of the calcaneus. The pain gradually worsens over months. A bony prominence that begins as periostitis extends from the medial aspect of the calcaneal tuberosity into the central plantar fascia and may be demonstrated on radiographs. Radiographs of the calcaneus that do not demonstrate a bony spur suggest plantar fascitis (see Painful Conditions on the Plantar Surface of the Foot later in this chapter).

Shoe supports using a heel pad or cup, or a donut-shaped orthosis often help reduce the discomfort by redistributing weight. Injection of the painful site is done with 10 to 20 mg of methylprednisolone injected from the medial aspect of the foot, avoiding the sensitive plantar surface. Few randomized controlled trials have evaluated steroid therapy; those that have do not provide substantial evidence supporting its long-term efficacy. [1] [2] Some evidence suggests that 25 mg prednisolone acetate injected into the medial heel provides partial pain relief at 1 month compared with lidocaine only, but no advantage can be detected at 3 months. [3] A short leg walking cast may be effective in some patients with recalcitrant heel pain. [4]

Retrocalcaneal Bursitis, Achilles Tendonitis, and Calcaneal Apophysitis

Although retrocalcaneal bursitis and Achilles tendonitis are anatomically distinct, the clinical presentation is similar. Pain at the insertion of the Achilles tendon is worsened with prolonged standing or walking and is aggravated by passive or active range of motion in both conditions. Directed palpation can distinguish one entity from the other but both are treated similarly. Tenderness of the Achilles tendon suggests tendonitis, whereas tenderness between the tendon and calcaneus suggests retrocalcaneal bursitis. Rest, elevation, ice, nonsteroidal anti-inflammatory medications, heel pads, and an open-back shoe provide relief in the majority of patients. A corticosteroid injection may provide some relief although its superiority to conservative measures is unproven. Repeated steroid injection is associated with Achilles tendon rupture. [5] Osteochondrosis of the posterior calcaneal apophysis may cause pain worsened by activity in the child between 7 and 10 years old. It is thought to represent an overuse syndrome in the athletically active child with a tender posterior heel. [5] [6] Treat this self-limited condition with rest, ice, and heel pads. Activity is resumed when the pain abates.

Painful Conditions of the Plantar Surface of the Foot

Plantar Fascitis

Repeated microtrauma to the plantar aponeurosis causes pain on the plantar surface of the foot. Plantar fascitis is typically unilateral and found in women who wear high-heeled shoes. The pain is maximally severe in the morning or after prolonged sitting and improves after walking. Some patients with plantar fascitis may also have a calcaneal heel spur. Pain is elicited with palpation, toe walking, or passive stretching of the plantar aponeurosis. Often this annoying condition resolves on its own, but resolution is slow. Conservative therapy, including rest, elevation, ice, and nonsteroidal anti-inflammatory medications, results in a satisfactory outcome after

6 to 8 weeks in 90% of patients.[7] Corticosteroid injection is used by some clinicians; the benefit remains unproven. Repeated injections with corticosteroids have been associated with rupture of the plantar fascia.[8]

Forefoot Neuroma

A forefoot neuroma, also know as a Morton neuroma, is a painful condition of the plantar surface of the foot. It most commonly affects women who wear high-heeled shoes. The neuroma forms after chronic irritation to the sensory nerve between the metatarsals. The neuroma frequently occurs in the third interspace but may be found in the second space. Patients report the sensation of a lump or cord in the interspace and describe paresthesia or numbness in the third or fourth toes. Rest, elevation, ice, and nonsteroidal anti-inflammatory medications may result in some improvement, but surgical excision is often required.[9] [10] Little data support the use of corticosteroid injections. In one study, less than 50% of patients with a foot neuroma had any benefit from injected corticosteroids.[9]

Ganglion Cyst of the Foot

A ganglion cyst is histologically similar to the synovial sheath and contains synovial fluid. The diagnosis is easy to make when the cyst is located over a tendon on the dorsum of the foot, but may be difficult when located among the compact structures of the plantar forefoot. The ganglion cyst usually causes edema located along the involved tendon sheath. The mass should roll under the examiner's finger; a painless, immovable mass suggests a soft tissue neoplasm. Painful ganglion cysts are treated with aspiration with or without the injection of corticosteroid (see Chapter 53). After local or regional anesthesia (see Chapter 30 and Chapter 32), insert a 20-ga needle into the cyst and withdraw yellow, thick, synovial fluid. Manually express any remaining synovial fluid after the needle is withdrawn. Corticosteroid injection is often advocated for ganglion cysts but recurrence is common after aspiration and corticosteroid injection—as high as 57% in one study.[11] Recurrence, chronic pain, neuritis, stiffness and infection are not uncommon even after surgical excision.[12]

TRAUMATIC CONDITIONS OF THE FOOT

Trauma to the feet and toes is common and covers a broad spectrum of injury. Lacerations, fractures, dislocations, compartment syndromes, and nailbed injuries are described in other chapters of this text. Two specific injuries, toe fractures and puncture wounds to the plantar surface of the foot, are discussed in detail here.

Toe Fractures and Fractures of the Sesamoid Bones

Many clinicians and laypersons shrug their shoulders at a toe fracture, believing nothing can be done. Something *can and should be done* to relieve the pain and encourage healing. As with any other fracture, pay attention to the possibility of disrupted joint cartilage, hypermobility of fracture segments, and malposition or malunion of the fracture fragments. Aggressive reduction is indicated for fractures of the proximal phalanx of the great toe, as it represents the main propulsive segment of the forefoot. A plaster cast alone without anatomic

reduction is insufficient treatment. Displacement suggests axial rotation or abnormal biomechanical interaction between the hallux and its own interphalangeal or MTP joint.

In the acute setting, a non-weight-bearing ankle splint that extends beyond the great toe (see Chapter 51) provides protection until the patient with a complicated great toe fracture obtains follow-up with a foot and ankle surgeon. Open fractures mandate immediate referral for debridement and antibiotic therapy. Fractures of the lesser toes usually result from jamming the toe into a nightstand or bedpost while barefoot. Radiographs of the lesser phalanges confirm the suspected fracture and may occasionally reveal an unsuspected interphalangeal or metatarsal phalangeal dislocation. However, x-rays are generally not required and the injured digit is easily reduced.

Treat closed, lesser phalangeal fractures with "immobilization" for 6 weeks. After the fracture is reduced, splint the injured toe against an adjacent noninjured toe. Place a soft corn pad or other suitable material between the toes to prevent skin maceration, and hold the toes together with adhesive tape or a self-adherent wrap like Coban (Fig. 52-3). Demonstrate the procedure to the patient or family and dispense or prescribe enough material so that the splint can be changed every 2 to 3 days at home. Put the patient in a less restrictive,

Figure 52-3 "Buddy taping" of a fractured lesser toe. *A,* a pad is placed between the injured toe and an adjacent toe. *B,* the toes are secured together with tape or self-adherent wrap. *(Courtesy of Kenneth R. Walker, DPM.)*

stiff-soled shoe. A postoperative shoe (or similar footwear) may be a comfortable alternative for the first several days.

Jumping from a height can result in a fracture of the first MTP joint sesamoid bone. The great toe sesamoid bones lie in grooves on the bottom of the metatarsal head. Each bone lies within the tendon of its respective flexor *hallucis brevis* muscle belly. There is localized pain on the plantar aspect of the first metatarsal head with a sesamoid bone fracture. Bipartite sesamoids (tibial more frequently than fibular) are common. Comparison radiographs clarify whether the radiographic abnormality represents a fracture.

For a tibial sesamoid injury, an aperture bunion-type pad, reinforced medially, of 0.5- to 0.75-cm-thick felt protects the sesamoid and transfers weight bearing to the surrounding structures (Fig. 52-4). A hard-soled shoe and nonsteroidal anti-inflammatory drugs are also helpful. Subsequent radiographs rarely show bony consolidation, but the fracture interface appears smoother.

Plantar Puncture Wounds

Plantar puncture wounds present a diagnostic and therapeutic challenge for the clinician (Fig. 52-5). Considerable controversy exists regarding the proper initial management of puncture wounds to the plantar surface of the foot, and no universally accepted standard of care exists. Treatment recommendations range from simple wound cleaning to aggressive débridement (see also Chapter 37 and Chapter 38). No single approach has been demonstrated to be superior. The editors support an initial conservative approach, but an aggressive one if the patient returns or presents with an infection, or if pain persists for more than a few days.

Although nails produce many such wounds, various other objects may cause them, too, including other metal objects,

Figure 52-4 Bunion shields redistribute pressure away from fractured sesamoid bones. *(Courtesy of Kenneth R. Walker, DPM.)*

Figure 52-5 *A,* An ingrown toenail of this degree requires removal of a portion of the nail and debridement of inflamed tissue. *B,* Two days later, there is marked improvement. *C,* To remove a toenail, small scissors are held parallel to the nail bed, advanced, and spread. This will produce the least damage to the nail bed.

wood, and glass. Patient response to the injury depends on the penetrating material, location and circumstances of the wound, depth of penetration, footwear, time from injury until presentation, and underlying health. Because superficial puncture wounds generally do well, depth of penetration may be a primary determinant of outcome. [13] Since one's reflexes are not fast enough to pull back when stepping on a sharp object, the clinician should assume that the entire length of a protruding nail has entered the foot (minus, of course, the thickness of footwear). Stepping on an unknown object in a field or while walking in a stream requires a more cautious approach than does a simple puncture from a known object, such as a protruding nail.

The vast majority of patients who "step on a nail" suffer nothing more than transient pain and never seek medical attention. Since most minor puncture wounds are not seen in the ED, the true risk of infection, in particular osteomyelitis, is unknown. Consequently, reported infection rates vastly overstate the actual incidence. One review of these wounds suggests that no more than 2% to 8% of puncture wounds become infected and only a small percentage of these develop osteomyelitis. [13] A prospective series suggests that only the presence of symptoms (e.g., redness, tenderness, increased swelling) at 48 hours was associated with the risk of infection or potential retained foreign body. [14] Retained foreign material (e.g., a portion of a tennis shoe sole) in the wound is an important factor in persistent infection. Since no single test detects all possible foreign bodies, tailor the evaluation of a suspected foreign body to the suspected object.

Evaluation

The approach to the patient is dependent on several factors, including the time from injury to presentation, the suspicion of a foreign body, and the presence of infection. The extent to which a foreign body is pursued depends on the history and physical findings. When the patient clearly states that a needle, pin, or nail was removed intact, radiograph or local wound exploration for a retained metallic foreign body are not needed. If there is any debate regarding a retained metallic object, plain radiographs readily demonstrate their presence. Plain radiographs also demonstrate other radiopaque objects such as glass, gravel, bone, and teeth. If the patient steps on an unknown object, a radiograph is usually indicated unless the entire depth of the wound can be ascertained and inspected. Ultrasonography is noninvasive and does not use radiation, making it potentially useful for radiolucent foreign bodies, but soft tissue air or calcifications may suggest a retained foreign body when there is not one (see Chapter 69). Computed tomography can demonstrate radiopaque and radiolucent objects but its expense, limited availability, and greater radiation exposure as compared to plain films make it unsuitable as a screening tool. Use CT scanning when other screening tools have failed to demonstrate a suspected foreign object, when infection is present, or when joint penetration is suspected. Magnetic resonance imaging provides no additional benefit and cannot be used when metallic objects are retained. General management of suspected foreign bodies is discussed in further detail in Chapter 37 .

Treatment

As a general rule, the plantar surface of the foot should be examined under good lighting and in a bloodless field. This is best accomplished with the patient in a prone position (Fig. 52-6 and Fig. 52-7). Plantar puncture wounds explored for persistent infection often have contained foreign material (Fig. 52-8). Since most patients do not develop persistent infection, initial deep exploration in the absence of evidence or strong suspicion for retained material cannot be advocated. [13] Routine initial deep wound exploration, including coring of the wound, is not supported by scientific research and is not recommended for simple, noninfected puncture wounds. [13]

However, select wounds may benefit from exploration to facilitate a search for foreign objects and to promote irrigation, cleansing, and drainage. When the wound is large and retained organic material is suspected, local wound exploration may be warranted. Patients wearing rubber-soled shoes

Figure 52-6 *A,* The best way to examine a puncture wound of the foot is to place the patient prone on a stretcher and obtain good lighting and a bloodless field (in this case, a blood pressure cuff was applied to the lower leg). *B,* When the overlying skin was unroofed, a small piece of rubber from the patient's sneaker was found imbedded in the wound. It was removed by a coring technique and packed.

during plantar puncture wounds may retain a portion of the shoe in the wound (Fig. 52-9). Exploration of the wound is most productive after local anesthesia or a regional anesthetic block (see Chapter 32) and excision of the epidermal flap. An incision may be required to facilitate foreign body removal, but extensive removal of surrounding tissue is not proven to increase successful removal of retained material. [13] Some clinicians favor a coring technique when a foreign body is found or suspected. Although this may be aggressive for many wounds, it is the best way to remove particulate matter as a block. To accomplish coring, a No. 11 blade is advanced to the hilt and a 2 to 3 mm core is excised. This tract can be packed with gauze for a few days or left open. Occasionally, blunt probes may facilitate wound exploration. It is generally impossible, and likely counterproductive, to attempt to probe or visualize the entire length of the puncture tract.

Patients presenting within 24 hours and *without* signs of infection generally require only simple wound care. Although irrigation of all exposed dermal tissue is recommended, high-pressure irrigation of deep tissues with distention of the soft tissues is unlikely to be helpful and not recommended. Schwab described a case series of uncomplicated puncture wounds in healthy individuals who had conservative treatment with cleansing and crutches. Radiographs were obtained at the discretion of the treating clinician; antibiotics were not given. [14] At their 6-month follow-ups, 88% of all patients had healed without complication. The remaining 12% developed

Figure 52-7 *A,* Patients who present with lymphangitis, obvious cellulitis, or both within a few days of stepping on a nail usually have a gram-positive soft tissue infection. *B,* In this case, the puncture wound was excised by a coring technique, yielding a few bits of foreign material. A pack was placed in the wound, oral antibiotics were given, and the patient did well.

complications including wound infection due to retained foreign body. No findings on initial presentation predicted a subsequent infection. Initial antibiotic therapy remains controversial, but there is no evidence to suggest that prophylactic antibiotics reduce the already low rate of infection.

Symptomatic patients who present later (24 hours or longer) have an increased risk for a retained foreign body, since delayed presentation is often due to the development of inflammation or infection. Local wound exploration is warranted unless the patient presents without infection or with a clearly superficial cellulitis expected to respond to simple oral antibiotics (see Fig. 52-7 and Fig. 52-8). Recurrent infection, deep soft tissue tenderness, and increasing soft tissue swelling suggest a retained foreign body or deep space infection, such as osteomyelitis. Such patients require prompt specialty referral or additional diagnostic studies in the ED.

Patients with obvious signs of infection within a few days of a puncture wound usually have a simple cellulitis (with or without a foreign body) with a gram-positive organism. In a patient with persistent pain or swelling days to weeks after a puncture wound, *the presence or absence of a deep soft tissue infection, or a low-grade osteomyelitis cannot be ruled in, or ruled out, by physical examination, plain radiographs, or laboratory tests (such as a sedimentation rate, complete blood count, or wound cultures)*. A high index of suspicion, coupled with additional investigation, is the prudent approach to the patient with minimal physical findings, normal laboratory

Figure 52-8 This 4-day-old inflamed puncture wound tract likely harbors a foreign body. Excision of a core of the tract found a few pieces of the patient's sock embedded in the wound.

tests, and continued pain or swelling following a seemingly simple puncture wound to the bottom of the foot. This usually entails a computed tomography scan, bone scan, or magnetic resonance imaging.

Plantar puncture wounds with *Pseudomonas* osteomyelitis and osteochondritis are clinically clandestine and particularly devastating, and have been described for nearly 40 years. Some investigators have cultured *Pseudomonas* from the sole of tennis shoes, suggesting that puncture wounds made through athletic footwear may be inoculated with *Pseudomonas*.[15] There is no evidence that prophylactic anti-*Pseudomonas* antibiotics prescribed on an initial evaluation of an uncomplicated wound will prevent infection among patients with subsequent deep

Figure 52-9 A patient stepped on a nail while wearing this shoe. An initial ED evaluation 3 weeks previous found no foreign body or infection. A week previous, the patient began taking antibiotics, but did not improve. The physical examination was quite benign, but the continued aching pain and minimal swelling suggested a deep infection. The complete blood count, sedimentation rate, and plain film were negative. A magnetic resonance imaging scan demonstrated osteomyelitis. *Pseudomonas* is often the offending organism in this scenario.

space or bone infections.[15] Some argue that prophylactic antibiotics, at the time of puncture, may select out resistant organisms. Surgical debridement and prolonged intravenous antibiotics are often required for established infections. In Figure 52-10 , an algorithm is offered to guide evaluation and management of plantar puncture wounds.

INGROWN TOENAIL

An "ingrown toenail" is characterized by progressive curving or excessive widening of the lateral margin of the toenail and impingement of the nail into the periungual soft tissue (see Fig. 52-5). The toenail normally grows distally in an unimpeded manner, allowing the nail to pass beyond the lateral nail fold. Nail deformity, tight fitting shoes, and rotational deformity of the toes increases the friction between the nail and nail fold. Toenails that have been trimmed in a curve increase the likelihood that the lateral nail margin will impinge on the lateral nail fold. The resulting soft tissue injury may lead to hyperkeratosis, edema, and erythema of the nail fold or frank infection (Fig. 52-11). Although an ingrown toenail can be found on any toe, the majority occur in the great toe.

Evaluation

The patient presents with pain, edema, and erythema of the lateral nail fold. Pressure over the nail margins increases the pain. Since intense pain often precipitates an early visit to the ED, most inflammatory or infectious responses are confined locally. Recurrent ingrown toenails or those in patients with circulatory dysfunction, neuropathy, or diabetes may have underlying osteomyelitis. Cleanse the toe gently to make visualization of periungual debris easier. When the free edge of the lateral nail can be easily visualized as separate from the lateral nail fold, consider other painful conditions of the toe like trauma, gout, paronychia, and cellulitis.

Treatment

Because the toe is exquisitely tender, additional treatment will usually require a digital block as described in Chapter 32 . The decision to treat and what course of action to take in the ED depends on the patient's degree of discomfort. Two general courses of action may be needed: removal of the offending nail spicule or removal of the spicule and some portion of the nail. Any degree of nail removal is usually followed with ablation of the nail bed. [16]

Removal of the Nail Spicule and Debridement of Hyperkeratosis

When the amount of inflammation and pain and the degree of nail deformity are both minimal, removal of the impacted nail spicule is indicated. After a digital block and thorough cleansing, remove an oblique segment of the nail about one third to one half of the way to the proximal nail fold (Fig. 52-12). The ideal instrument is an English anvil nail splitter designed to cut the nail while minimizing trauma to the underlying nail matrix (Fig. 52-13). Sharp, pointed scissors may be substituted if care is taken to minimize nailbed injury by maintaining upward pressure while cutting the nail. Some clinicians use a disposable electric cautery device to cut the nail after it has been softened by soaking in warm soapy water.

Figure 52-10 Plantar puncture wound management. *A,* Management within 24 hours of wounding. *B,* Management after 72 hours. *(From Chisolm CD, Schlesser JF: Plantar puncture wounds: Controversies and treatment recommendations. Ann Emerg Med 18:1352, 1989.)*

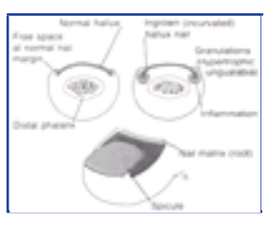

Figure 52-11 Pathology of an ingrown toenail. The normal free space at the nail margin is obliterated by inflammation and granulation tissue, which is caused by improper nail trimming, trauma to the matrix, and faulty footwear. *(From Hill GL II: Outpatient Surgery, 3rd ed. Philadelphia, WB Saunders, 1988. Reproduced by permission.)*

After cutting the nail spicule free from the bulk of the nail, grasp the free edge of the nail with forceps or hemostats and remove it. The nail fold typically contains impacted debris that must be removed after the nail fold has been gently retracted away from the nail. Remove debris until the epidermis or dermis is uncovered, taking care to avoid aggressive debridement that causes bleeding. Dress the area with antibiotic ointment and a nonadherent dressing. The wound should be reinspected for signs of infection at 48 hours and referral made for definitive podiatric care. Instruct patients to wear less constricting shoes and to trim the nail straight across. Like most foreign body reactions, removal of the nail spicule resolves the inflammation and infection. Antibiotics given without removal of the nail spicule will not ensure a satisfactory result or add benefit after spicule removal. [17] When the ingrown toenail is caused by nail deformity, a podiatrist or primary clinician can accomplish definitive removal during follow-up evaluation.

Toenail Removal

Toenail removal may be total or partial. Total nail removal is rarely needed but may be used when infection of both lateral

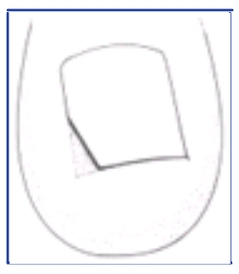

Figure 52-12 An oblique wedge of nail is trimmed from the lateral margin of the nail to free it from the hyperkeratotic area. *(Courtesy of Kenneth R. Walker, DPM.)*

Figure 52-13 English nail anvil used to divide the nail. *(Courtesy of Gill Podiatry Supply Company, Middleburg Heights, OH.)*

nail folds is present, particularly if the condition is present for more than a month. Consider partially removing the toenail when ingrown toenails are associated with chronic inflammation/infection or severe pain. Partial nail removal accomplishes two things: removal of the offending portion of nail and destruction of the underlying nail matrix to prevent nail regrowth. Phenol, the most commonly applied chemical, causes neurolysis of nerve endings and necrosis of the nail matrix in a procedure

called matrixectomy. After digital block, exsanguinate the toe by squeezing or wrapping, and apply a tourniquet at the base of the toe. A dry nail matrix after nail removal is needed prior to application of phenol.

Stabilize the toe in the nondominant hand and remove the lateral quarter of the nail by splitting the nail toward the cuticle. An English anvil nail splitter is desirable to begin the procedure, but sharp scissors, a No. 11 blade, or electric cautery device as described previously for removal of the nail spicule will work, too. When a nail splitter is used, divide the nail about one half to two thirds of the way back. Then divide the remainder of the nail using scissors or a scalpel. Take care to perform a controlled division along the longitudinal lines of the nail until resistance is no longer felt. The nail should be divided several millimeters past the proximal nail fold. Carefully separate the lateral portion of the nail from the underlying matrix and grasp it with a hemostat or forceps. Remove the free piece of nail by twisting it toward the remaining nail. Inspect the remnant to be certain that the entire piece of nail has been removed as desired. Curette the posterior and lateral nail grooves to remove any remaining hyperkeratotic debris. Take great care to avoid hemorrhage; a dry nailbed is mandatory before phenol application. Adjust the tourniquet if needed to achieve a bloodless field.

Apply a 70% to 90% solution of aqueous phenol to the nail matrix beneath the involved area of the lateral nail groove and proximal nail fold using cotton wound applicators. A 1% phenol solution can be prepared by diluting a 70% to 90% aqueous phenol solution in an 80:1 ratio (e.g., 8 mL distilled water to 0.1 mL phenol). Another alternative is to desiccate the exposed nailbed with silver nitrate sticks. Remove some of the cotton if the applicator is too bulky to concentrate the solution beneath the proximal nail fold and lateral nail groove. Apply thoroughly moistened (but not saturated) applicators, using three 30-second applications. Avoid forcing phenol under the remaining nail by rolling the applicator so that it rolls over the matrix and over the nail surface rather than against the split edge of the nail. Do not allow excess phenol to contact the exposed nail bed or surrounding healthy tissue. After the third application, the cauterized tissue appears

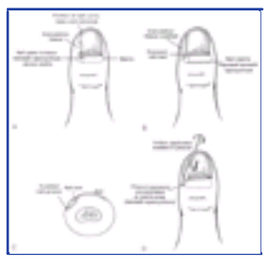

Figure 52-14 The nail ablation technique for treatment of an ingrown toenail. The lateral portion of the nail is cut and removed (*A*), exposing the nailbed. Granulation tissue is curetted (*B* and *C*) and the nail matrix is cauterized with absolute phenol (*D*) (see text).

brown tinged or gray. Alternatively, a 1% phenol solution can be applied for 5 minutes. Thoroughly irrigate the cauterized nailbed with water and rub the area with a gloved finger to remove traces of phenol. Snip away any remaining debris or dead skin with scissors. The technique is illustrated in Figure 52-14 .

Dress the wound with antibiotic ointment and a non-adherent dressing, followed by a dry sterile wrap. Do not forget to remove the tourniquet after the dressing has been applied. Instruct the patient to wash the wound twice daily followed by dry dressing changes. Antibiotics do not hasten wound healing and are not necessary in most cases.[17] The wound will heal in 2 to 4 weeks and may be accompanied by serous drainage for 2 weeks. The patient should be informed of this possibility. Complications include nail regrowth, infection, growth of an inclusion cyst, or delayed healing. The procedure successfully ablates the removed nail in more than 90% of cases.

CONCLUSION

Many common maladies of the foot can be treated in the ED with rest, analgesia, and supportive measures such as footpad use. Fractures of the lesser toes are easily treated with dynamic splinting, but the great toe may require definitive treatment by a foot and ankle surgeon. Most plantar puncture wounds can be treated like other soft tissue injuries but retained foreign bodies, deep space inoculation, and osteomyelitis can occur. Most ingrown toenails can be simply treated with removal of the offending nail spicule, although nail removal and ablation may be needed in severe or recurrent circumstances.

Chapter 53 - Injection Therapy of Bursitis and Tendinitis

Brenda Foley
Theodore A. Christopher

Bursitis and *tendinitis* are terms frequently used to describe a variety of regional musculoskeletal conditions that are characterized chiefly by pain and disability at the involved site. Bursitis of the shoulder may be considered the prototypical disorder. All too often, in cases of ill-defined regional soft tissue rheumatic problems, bursitis or tendinitis is used as a "wastebasket" diagnosis. The pain and dysfunction of tendinitis and bursitis are variable, and not always reproducible by each examination. In addition, many muscular, neurologic, and even infectious conditions present similarly to these syndromes. For purposes of this chapter, in consideration of the accurate diagnosis that is necessary to institute appropriate therapy, the terms are reserved for well-defined, specific clinical entities. The clinician must, however, appreciate the fact that these are largely clinical diagnoses that cannot be verified by objective data, radiographs, or laboratory parameters.

GENERAL ANATOMIC CONSIDERATIONS OF BURSAE AND TENDON SHEATHS

Bursae are potential spaces or sacs, subcutaneous or deep, that develop in relation to friction and facilitate the gliding motion of tendons and muscles. There are approximately 78 bursae on each side of the body. These were well described in the classic atlas of anatomy by Monro in 1788 [1] and were later elaborated in greater detail in the atlas of Spalteholz in 1932. [2]

The normal bursal wall is lined with a thin layer of synovial cells that appear to be similar to those of joint synovial membrane when examined by electron microscopy.[3] When a bursa becomes subacutely or chronically inflamed, the normally thin surface of sparse cells may thicken to 1 to 2 mm. *Bursitis* may be caused by trauma, infection, crystal deposition, chronic friction from overuse, or a systemic inflammatory arthropathy. In addition, so-called adventitial bursae may form in response to abnormal shearing stress at sites subjected to chronic pressure; an example is a bunion over the head of the metatarsal bone of the great toe.

Involvement of the synovial lining of bursae and tendon sheaths may also result from underlying systemic diseases, including rheumatoid arthritis, ankylosing spondylitis, psoriatic arthropathy, and gout. The most common bursal lesions in these systemic inflammatory arthropathies involve the olecranon at the elbow and the trochanter region of the hip. Smaller bursae, especially those around the Achilles tendon, also may be affected. *Tendinitis* and *tenosynovitis* are useful terms that describe inflammatory reactions in tendons and tendon sheaths. Tendon sheaths are relatively long and tubular, whereas bursae are round and flat. Except for their shape, however, the structures are similar. In fact, because of the adjacent location of bursae and tendons, an inflammatory process in one may also involve the other.[4] Common sites of tendinitis in the body are depicted in Figure 53-1 (Figure Not Available) .

Bursitis and tendinitis embrace a variety of conditions that may be grouped together on a regional basis for the sake of a simple and convenient classification (Table 53-1).

In rare cases, the etiologies of tendinitis/bursitis syndromes can be exotic, such as the tendinitis caused by quinolone antibiotics or the bursitis noted in dialysis patients.[5] Tendon rupture (especially of the Achilles tendon) has been associated with the use of fluoroquinolone antibiotics (especially ciprofloxacin), but this rare condition is not appreciated by most clinicians and usually goes undiagnosed. [6] Steroid injection may facilitate tendon rupture if fluoroquinolone tendonopathy is present. Gonorrheal tenosynovitis may mimic various forms of tendinitis and is not always associated with overt vaginitis or urethritis or other signs or symptoms of bacteremia.

RATIONALE FOR STEROID INJECTIONS

The management of pain and dysfunction resulting from bursitis and tendinitis may be greatly enhanced by the proper selection and administration of local injections. Successful application of local injection and intrasynovial (bursa and tendon sheath) therapy requires an understanding of the diagnosis, accurate localization of the pathologic condition, and the appropriate choice of suitable injection techniques. Not infrequently, injections of lidocaine or corticosteroid preparations provide the additional aid that, alone or as an important adjunct to the management program, overcomes the refractory pain. While steroid injections are universally administered, often with great success, there are no convincing prospective data to support or refute the specific therapeutic benefit of this

Figure 53-1 (Figure Not Available) Common sites of tendinitis. *(From Walker LG, Meals RM: Tendinitis: A practical approach to diagnosis and management. J Musculoskel Med 6:24, 1989. Reproduced with permission.)*

therapy. Many painful conditions wax and wane, there is a significant placebo effect from injections, and there is a natural regression of pain syndromes due to a variety of factors. Although the emergency clinician may administer a local injection with success, in some instances a short course of an oral steroid may produce statistically similar results. In fact, the primary goal of corticosteroid injection therapy is the relief of pain so that the patient can not only function but, more importantly, participate in a physical rehabilitation program. [7] In many cases, a single injection may be all that is required to ameliorate a painful condition. However, injection therapy is best viewed as an adjunct in the management of painful tendinitis/bursitis syndromes. It should not be viewed as a single quick fix, but more of a method of facilitation of other modalities.

The precise mechanism of the lasting analgesia and the beneficial therapeutic effects of local injection therapy have not been clarified. Few clinical trials have adequately measured the efficacy of corticosteroid therapy. Although steroids are known to reduce inflammation, it is unclear if the anti-inflammatory effect is responsible for the increased range of motion and relief of pain that the patient usually experiences. There are histological studies of chronic tenosynovitis lesions that demonstrate degeneration, but not inflammation. [7] It is therefore possible that the pain experienced with tendinitis or bursitis occurs from other mechanisms besides inflammation, such as mechanoreceptor stimulation by shearing or traction, or activation of nociceptive receptors by substance P and chondroitin sulphate. [7]

Injection therapy should be considered an adjunct to a variety of treatment modalities including pain control, physical therapy, occupational therapy, relative rest, immobilization, and exercise. Additional pain control can be achieved with such options as nonsteroidal anti-inflammatory agents, acupuncture, ultrasound, ice, heat, and electrical nerve stimulation. [7] [8] [9] Besides pain relief, early participation by the patient in rehabilitative activities and exercises can be an important aspect of patient recovery. Patients receiving only analgesics may have poor outcomes compared to those who also have exercise as part of their treatment. [4] Any factors that provoke the initial injury should also be identified, as failure to eliminate these provoking factors can contribute to the injury becoming chronic. [7]

Although there are differing opinions in the literature, we recommend that corticosteroid injections not be repeated in the same site unless there has been at least a partial clinical response. There should be at least 6 weeks between injections in the same site, and an injection should not be repeated more than once every 3 to 4 months. [7] [8] [9] [10] Although there is little data on the outcome of repeated procedures, these recommendations are generally accepted and may limit the risk of adverse effects.

INDICATIONS AND CONTRAINDICATIONS

Local injection therapy with corticosteroids or local anesthetics may be effective treatment and provide relief of symptoms in a variety of acute or subacute bursitides and other painful soft tissue conditions. The indications for steroid injection are twofold: therapy and diagnosis. Injection therapy not only offers pain relief, particularly when a local anesthetic is concurrently used, but also offers a medium to deliver therapeutic agents. In addition to relieving pain, injection therapy may aid with a diagnosis. When injecting a bursa, for example, bursal fluid is sometimes collected for laboratory analysis. Finally, the relief of pain helps differentiate a localized site of injury from referred or visceral pain. [9]

Absolute contraindications to local injection therapy are limited and include specific infections such as bacteremia, infectious arthritis, periarticular cellulitis or ulceration, or adjacent osteomyelitis (Table 53-2). The procedure is also contraindicated in patients with significant bleeding disorders. A history of hypersensitivity, either to the corticosteroid or to the vehicle by which it is delivered, is an absolute contraindication. Finally, corticosteroid injections should not be performed in a patient who has a documented osteochondral fracture. However, because stress fractures and nonvisualizing fractures may result from the same trauma or mechanisms that have been implicated in producing an inflammatory condition, it is inevitable that some bony injuries will inadvertently be diagnosed as tendinitis or bursitis.

Relative contraindications depend on both the practitioner's experience and the indication for the injection. A violation of the integrity of the skin or chronic foci of infection, either locally or in the vicinity of the site of involvement, is a

TABLE 53-2 -- Contraindications to Local Injection Therapy

Absolute
Infection (bacteremia, infectious arthritis, periarticular cellulitis/ulceration, adjacent osteomyelitis)
Uncontrolled bleeding disorder
Hypersensitivity to corticosteroid or vehicle
Osteochondral fracture
Relative
Anticoagulant therapy
Joint instability
Poorly controlled diabetes
Hemarthrosis
Decubitus ulcers
Joint prosthesis
Adjacent abraded skin
Chronic foci of infection
Internal joint derangement
Partial tendon rupture

relative contraindication. The procedure is also relatively contraindicated in patients on anticoagulants, with poorly controlled diabetes, and with internal joint derangements or hemarthrosis. The patient with a preexisting tendon injury may be subject to tendon rupture when the corticosteroid injection removes pain and full activity is resumed. Hence, partial tendon rupture is a relative contraindication.

AVAILABLE PREPARATIONS AND CHOICE OF COMPOUND

Hydrocortisone and a variety of available corticosteroid repository preparations are described in Table 53-3 . Local anesthetics, such as lidocaine or bupivacaine, can be mixed with the corticosteroid preparation in the same syringe. All corticosteroid suspensions, with the exception of cortisone and prednisone, can produce a significant and rapid anti-inflammatory effect (in synovial spaces). These preparations are categorized based on their solubility and on their relative potency. Solutions that are more soluble have a shorter duration of action, primarily because these soluble preparations are absorbed and dispersed more rapidly. The addition of tertiary butyl acetate (TBA) to the solution causes decreased solubility, and therefore a longer duration of action. For example, triamcinolone hexacetonide, the least soluble preparation, has the longest duration of action. [10] Because of this and its greater potential for subcutaneous atrophy, however, some authors use this preparation only for intra-articular injections. [9] [10]

There have been attempts to incorporate steroid esters into liposomes to create an even less soluble preparation. This has been shown in both human and animal studies to offer long-lasting relief with minimal drug absorption; however, further research is necessary before this method of delivery is fully developed. [8] [10] [11]

There is little consensus in the literature regarding which corticosteroid should be used and what dosage is most appropriate for a given s[7] [11] [12]

Centeno and Moore noted that the choice of injection agent seemed dependent on the institution where the clinician trained. [13] In 1995, a survey of 172 rheumatologists found differing opinions regarding almost every facet of soft tissue and intra-articular injection, including

TABLE 53-3 -- Injectable Corticosteroids

Intrasynovial Preparations	Potency*	Range of Usual Dosage	Solubility
Short-Acting			
Hydrocortisone acetate	1	12.5–75 mg	High
Cortisone	0.8	15–25 mg	High
Intermediate-Acting			
Prednisone	3.5	2.5–5 mg	Medium
Prednisolone acetate	4	5–30 mg	NA
Methylprednisolone acetate	5	5–40 mg	Medium
Long-Acting†			
Triamcinolone acetonide	5	5–40 mg	Low
Triamcinolone diacetate	5	4–40 mg	Low
Triamcinolone hexacetonide	5	4–25 mg	Low
Betamethasone acetate and disodium phosphatate	25	1.5–6 mg	Low
Dexamethasone acetate	25	0.8–6 mg	Low

*Hydrocortisone equivalents (per mg).
†Best used for intra-articular injection only.

patient preparation, choice of corticosteroid, and post-injection advice. [14] In general, it is recommended that for an acute or subacute diagnosis such as bursitis/tendinitis, it is prudent to use a short- or intermediate-acting agent, while longer-acting agents, such as triamcinolone, should be reserved for chronic and prolonged conditions, including arthritis. [8] [10] Some clinicians, however, advocate mixing both shorter- and longer-acting corticosteroids in the same syringe, with little consideration for the location or category of the condition. [9] [10] We recommend that longer-acting corticosteroids not be used for any soft-tissue injections, particularly because of the increased risk of associated atrophy [7] [9] including atrophy of surrounding structures, such as ligaments and fascia. [15] Methylprednisolone acetate (Depo-Medrol) is a reasonable first choice for most ED indications.

DOSAGE AND ADMINISTRATION

The dose of any corticosteroid suspension used for intrasynovial injection may be arbitrarily selected. Factors that influence the dosage and expected response include the size of the affected area, the presence or absence of synovial fluid or edema, the severity and extent of any synovitis, and the steroid preparation selected for injection.

A useful guideline for estimating dosage is as follows: For relatively large spaces such as subacromial, olecranon, and trochanteric bursae, 40–60 mg of methylprednisolone acetate or equivalent; for medium- or intermediate-sized bursae and ganglia formation at the wrists, knees, and heels, 10 to 20 mg; and for tendon sheaths, such as flexor tenosynovitis of digits and the abductor tendon of the thumb (de Quervain disease), 5 to 15 mg. Sometimes it may be necessary to give larger doses for optimal response. Intrabursal therapy of elbow (olecranon) or knee (prepatellar) bursae containing considerable fluid may require 30- to 40-mg doses. Doses greater than discussed will likely not be detrimental in the vast majority of patients.

Unlike intra-articular injections for synovitis in chronic joint disease, repeat infiltrations for soft tissue conditions such as bursitis and tendinitis are generally not recommended or required. However, if only a partial response occurs or if recurrence develops, a single repeat injection can be given as long as one waits at least 6 to 12 weeks between injections.[7] [8] [9] [10]

PREPARATION OF THE SITE

Preparation of the site before injection requires meticulous adherence to aseptic technique. Anatomic landmarks may be outlined with a black or red skin pencil. Tincture of iodine or thimerosal (Merthiolate) applied with a sterile swab can be used in place of the skin pencil. The point of entry is cleansed with povidone-iodine (Betadine) and alcohol. It is important that the injection site and needle tip remain sterile, using the "no touch" technique, although sterile drapes are not generally considered necessary.[7] [12] For operator protection, universal precautions should be followed, including the use of sterile examination gloves. [9]

TECHNIQUES

General Considerations

Radiographs are not required prior to injection if the diagnosis is clinically well supported. Radiographs may occasionally demonstrate calcium deposits, especially around the shoulder, but the often described spurs associated with olecranon bursitis are of questionable significance. If a patient has an atypical presentation or systemic symptoms (such as fever, chills, nausea), a history of cancer, soft tissue swelling, or suspected bone disease, a radiograph would be prudent. Also, if the patient has had previous unsuccessful injections, a radiograph of the area may be helpful in further clarifying the diagnosis. In the elderly, metastatic disease or fractures without significant trauma may mimic tendinitis/bursitis.

Before beginning the injection, the patient should be informed of the specific indication(s) for treatment. The practitioner should describe the details of the procedure, including risks and complications, and obtain informed consent. Subsequently, the details of the procedure should be documented in the medical record. Use of a written consent form is optional.

Materials that are required beyond the aseptic preparation technique include needles, syringes, a hemostat, culture and laboratory supplies, bandages, and sterile gauze. Disposable needles and syringes are convenient and adequate for emergency department (ED) use. Special trays may also be stocked for this purpose. The usual sizes of needles for injection sites are listed in Table 53-4 .

TABLE 53-4 -- A Guide for Needle Size and Dosage for Injection of Common Regional Disorders

Disorder or Injection Site	Needle Size	Usual Dosage of Methylprednisolone acetate*
Bicipital tendinitis	1.5–2 in., 22–25 ga	20–40 mg
Calcareous tendinitis	1.5–2 in., 22–25 ga	20–60 mg
Subacromial bursitis		
Radiohumeral bursitis	1.5 in., 22–25 ga	20–40 mg
Epicondylitis		
Olecranon bursitis	1–1.5 in., 20 ga	15–30 mg
Ganglia on wrist	1 in., 18–20 ga	10–15 mg
de Quervain disease	7/8 in., 22–25 ga	10–20 mg
Carpal tunnel syndrome	1–1.5 in., 22–25 ga	20–40 mg
Digital flexor tenosynovitis	7/8 in., 22–25 ga	00–05 mg
Trochanteric bursitis	1.5–2 in., 22–25 ga	20–40 mg
Prepatellar bursitis	1–1.5 in., 22–25 ga	15–20 mg
Anserine bursitis	1–1.5 in., 22–25 ga	20–40 mg
Bunion bursitis	1 in., 22–25 ga	5–10 mg
Calcaneal bursitis	1 in., 22–25 ga	10–20 mg

*Empiric dose. Larger or smaller dose may be used dependent upon clinical scenario.

Once the point of entry has been determined and the site is prepared, either a superficial skin wheal is made with 1% lidocaine (Xylocaine) or 0.25% bupivacaine (Marcaine, Sensorcaine) using a 25-ga needle. Some clinicians do not use a skin wheal when the steroid is mixed with a rapid-acting local anesthetic. Topical vapocoolants (e.g., Fluori-Methane) may be helpful in these circumstances. Ordinarily, procedural sedation and analgesia is not necessary, but occasionally, in highly nervous or agitated individuals, it may be advisable (see Chapter 34).

Local injections can be administered with corticosteroids and local anesthetics mixed together in the same syringe. This is commonly done with peritendinous injections using the *Z-tract technique*, which limits the risk of a fistulous tract in the soft tissue. Because the steroid may theoretically precipitate or layer in the barrel of the syringe during the injection, the syringe should be agitated immediately prior to use to optimize its distribution. In addition to minimizing the pain associated with the injection, mixing the anesthetic with the corticosteroid also produces a larger volume for delivery into the soft tissue. [7]

The local anesthetic can also be given alone, before the injection of the corticosteroid. This is commonly seen when injecting bursae using the *two-syringe* technique. After making a wheal, a needle is introduced into the bursa and approximately half of the anesthetic is injected as the needle is inserted. Once the needle reaches the target site, the syringes are changed. Then, as much fluid as possible is aspirated before instillation of the corticosteroid suspension to reduce the dilution factor and to collect bursal fluid for laboratory analysis. Upon changing syringes again, the steroid is introduced without anesthetic. Often syringes are changed once more, and the remaining anesthetic is used to flush out the needle, frequently causing injection and deposition of several milliliters of the local anesthetic. There is no evidence, however, that the injection of the anesthetic before the steroid provides a benefit, or that there is a difference in later outcome with the use of short-acting versus long-acting steroids. [7] [8]

The duration of action of lidocaine is approximately 100 minutes whereas bupivacaine may last several hours. The

patient should be cautioned that *the local anesthetic effect may "wear off" within a couple of hours* and that *the beneficial effects of the corticosteroid may be delayed*.

The most important aspect of a successful technique is accurate positioning of the needle. The needle must "hit the mark" or the results will be disappointing. Injecting an inflamed synovial space, such as a bursa-containing fluid, may be as simple as puncturing a balloon. Aspiration of the fluid confirms that the needle has correctly entered the sac. On the other hand, direct injection into a painful soft tissue lesion requires additional skill that can be acquired only with experience. Sometimes it is advisable to reaspirate and reinject several times within the barrel of the syringe, a procedure called *barbotage*, to obtain heterogeneous mixing and maximal dispersion of the steroid throughout the synovial cavity. Although it is desirable to inject directly into a bursa, direct injection into the tendon itself is best avoided. If the injection requires significant pressure, the needle may be in the tendon, and it should be withdrawn or advanced a few millimeters. The patient may commonly feel some myofascial radiating pain during the injection, but true paresthesias should not be elicited. "Electric shocks" felt with an injection may signal that the needle is in a nerve.

While an accurate injection is desirable, injections are largely blind procedures aimed at depositing the medications near or around inflamed structures. Using a generous volume of anesthetic (3 to 6 mL) to dilute and hence disperse the steroid can compensate for a less than perfect injection. As a general rule, one should

allow the patient to localize the area of maximum tenderness, and the injection should begin in that area. Asking the patient to use one finger to localize the area of maximum pain and tenderness is the best way to ensure the most accurate positioning of the needle. In general, if the patient cannot localize a specific area of tenderness, the diagnosis should be reconsidered or the expectations of success lowered. Diffuse pain, such as throughout the entire shoulder or knee, is probably not tendinitis or bursitis, and will not likely be cured with a local injection. In such instances where the diffuse pain is inflammatory in nature, an oral corticosteroid preparation may be more appropriate.

The development of ultrasound-guided therapy has led to improvement in the accuracy of corticosteroid injections. Used to evaluate musculoskeletal pathology since the 1970s, ultrasound is now steadily becoming an important tool for both diagnosis and therapy by identifying soft tissue structures such as bursae, tendons, and joint capsules.[16] [17] In addition, cartilage, muscles, nerves, and blood vessels can now be easily visualized using this technique. [16] Chapter 69 provides a detailed description of ultrasound-guided procedures.

Specific Regions and Clinical Entities

Shoulder Region

Pain associated with disability may result from any of the intrinsic shoulder disorders, including bicipital tendinitis, calcareous tendinitis, and subacromial bursitis (Fig. 53-2 (Figure Not Available)). These areas may be frequently injected because it is safe and easy to do so, and one gets a consistently good response to therapy. The danger of an untreated persistent inflammation is the development of a "frozen shoulder."

Bicipital tendinitis (Tenosynovitis).

This is a nonspecific low-grade inflammation of the biceps tendon or its sheath, or both, and is more common in those who repeatedly

Figure 53-2 (Figure Not Available) Pain in the shoulder is often caused by biceps tendinitis or subacromial bursitis. *(From Walker LG, Meals RM: Tendinitis: A practical approach to diagnosis and management. J Musculoskel Med 6:24, 1989. Reproduced with permission.)*

flex at the elbow against resistance, such as weightlifters and swimmers.[4] [18] The tendon courses through the joint and along the bicipital (intertubercular) groove, which can be appreciated as the elbow is held at 90° of flexion, and the arm is internally and externally rotated. [18] Patients may have restricted or normal range of motion and normal strength; however, they usually complain of tenderness to palpation over the bicipital groove. [4] Efforts to elevate the shoulder, reach the hip pocket, or pull a back zipper all aggravate the symptoms. Tenderness over the bicipital groove does not confirm the diagnosis; however, as the supraspinatus tendon is in such close proximity to the bicipital tendon insertion. [18] Other diagnostic clues include the Lipman test, in which "rolling" the bicipital tendon produces localized tenderness. The Yergason test elicits pain along the bicipital groove when the patient attempts supination of the forearm against resistance, holding the elbow flexed at a 90° angle against the side of the body (Fig. 53-3 (Figure Not Available)). Radiographs are normal and are not required if the clinical diagnosis is supported.

Approach.

The point of maximal tenderness of the bicipital tendon is located. Entry is made with a 22- or 25-ga, 3.9- to 5.0-cm needle through a lidocaine skin wheal (Fig. 53-4). It is wise to *avoid an actual intratendinous injection*, which may cause weakening of the tendon and predispose the patient to tendon rupture. The needle is brought in along the side of the tendon, aimed at one border of the bicipital groove to give a *peritendinous infiltration*. One third of the injection is administered at this point. The needle is then withdrawn slightly but is kept subcutaneous. It is redirected upward approximately 2.5 cm for another one third of the injection, withdrawn again, and redirected downward, touching the bicipital border gently; the remainder of the drug is deposited at this point. If the two-syringe technique is used, 1 to 1.5 mL of an intermediate-acting corticosteroid suspension, such as prednisolone tebutate, is usually instilled at the maximum area of tenderness. The anesthetic is injected along the upper and lower borders of the tendon.

Figure 53-3 (Figure Not Available) The Yergason test helps determine the stability of the long head of the biceps tendon in the bicipital groove. This test, which involves resisted supination of the forearm with the elbow flexed to 90°, may accurately reproduce symptoms of bicipital tendinitis. *(From Walker LG, Meals RM: Tendinitis: A practical approach to diagnosis and management. J Musculoskel Med 6:24, 1989. Reproduced with permission.)*

Calcareous tendinitis, supraspinatus tendinitis, and subacromial bursitis.

These inflammations are so clinically similar that their symptoms and signs are difficult to differentiate. The musculotendinous rotator cuff is composed of the supraspinatus, infraspinatus, teres minor, and subscapularis muscles, which insert as the conjoined tendon into the greater tuberosity of the humerus. The subacromial bursa lies just superior and lateral to the supraspinatus tendon (Fig. 53-5). Both the tendon and the bursa are located in the space between the acromion process and the head of the humerus, and are particularly prone to impingement in this "critical zone." Injections into either the bursa or tendon sheath area are commonly performed secondary to inflammation and overuse.

In *calcareous* (or calcific) tendinitis of the shoulder, there is a calcific deposit (hydroxyapatite) within the substance of one or more of the rotator cuff tendons (commonly the

Figure 53-4 *A,* Anatomic site for injection into the bicipital groove for treating bicipital tendinitis. The anesthetic is infiltrated around the biceps tendon sheath in a fan-wise distribution, avoiding intratendinous injection. *B,* Actual peritendon injection of bicipital tendinitis: The patient is seated with the forearm and hand resting in the lap and externally rotated.

supraspinatus).[19] These calcium crystals can occasionally rupture into the adjacent subacromial bursa, causing acute pain and tenderness in the deltoid area (Fig. 53-6). The bursae in relation to the greater tuberosity and the subdeltoid (subacromial) bursa are the most common sites of calcific deposits.

During the acute or hyperacute stage, the patient holds the arm in a protective fashion against the chest wall. Pain may be incapacitating, and all ranges of motion are disturbed, with internal rotation markedly limited. Tenderness is often diffuse over the perihumeral region. The patient may also complain of pain at night when lying on the affected side and with abduction of the arm. Constitutional symptoms are rare, but sometimes in the hyperacute form, actual swelling may be visible, and even fever and an accelerated sedimentation rate may develop. When shoulder radiographs demonstrate a calcific deposit, the shadow appears "hazy" with lightening of the periphery caused by the pressure of inflammatory edema. Night pain may be intolerable, requiring opioids for control.

Anterior approach.

In calcific tendinitis or supraspinatus tendinitis without calcification, the injection may be given by the anterior (subcoracoid) approach. The patient is asked to rest the extremity on the lap, and the arm is rotated externally about 15°. The point of insertion is over the depression that is palpable inferior and lateral to the coracoid process, and medial to the head of the humerus (Fig. 53-7).

Posterolateral approach.

With the patient sitting and the lower part of the extremity resting on the lap, a lidocaine skin wheal is made at the depression about 1 cm inferior to the posterolateral tip of the acromion, located between the head of the humerus and the acromion. A 3.9- to 5.0-cm, 22- or 25-ga needle is then directed toward the center of the head of the humerus and upward at an angle of approximately 10° (Fig. 53-8). After the site has been penetrated 2 to 3 cm, aspiration is carried out for any fluid or calcific material. The syringe is then removed, leaving the needle in position. Another syringe containing 20 to 40 mg of methylprednisolone suspension or equivalent intermediate-acting steroid is attached, and the medication is instilled. There should be little resistance when injecting the medication. If resistance is appreciated,

then the needle should be repositioned, as it may be in the tendon substance of the rotator cuff. This injection can be followed with 1 to 5 mL of 1% lidocaine (or a similar volume of 0.25% bupivacaine). Alternatively, local anesthetic can be given combined with the steroid in the same syringe. One should be generous with the volume of local anesthetic

Figure 53-5 The "critical zone." Note the close relationship of the supraspinatus tendon and subacromial bursa to the humeral head and acromion.

to ensure adequate dispersion of the steroid. A single treatment relieves the majority of acute disorders. An injection into the peritendinous space is similar to that described earlier, except that the needle is advanced deeper than with a subacromial bursal injection. [20]

If calcific tendinitis is suspected, some recommend attempting to aspirate the calcium deposits. After the bursa has been anesthetized, an 18-ga needle can be used to penetrate the calcium, often creating a "gritty" sensation. [19] In addition, the practitioner may consider the technique of barbotage to facilitate the cleavage of calcium deposits. Using this method as described previously, the steroid or anesthetic/steroid combination is aspirated and re-injected repeatedly. [19]

Sometimes a painful reaction may follow when the analgesic has worn off. To avoid severe pain, the patient should be warned about this possibility and given appropriate analgesia. A sling may provide additional relief, and short-term use of opioids is appropriate. While some authors claim that patients who do not also undergo physical therapy after corticosteroid injection have satisfactory results, there is evidence to support the importance of close patient follow-up, range-of-motion exercises, and physical therapy to total recovery. [18]

Acromioclavicular joint inflammation.

Pain arising in the acromioclavicular (AC) joint is frequently an aftermath of an acute injury, such as falling on an outstretched hand or weightlifting. With this injury, all ranges of motion of the shoulder cause pain, and the joint is tender but rarely swollen. The practitioner should be aware of an obvious deformity or mechanism of injury that may suggest an AC separation or dislocation. With AC joint inflammation, crepitus is not uncommon. [18] Adduction of the arm across the body with forward elevation to 90° (the cross arm test) may also exacerbate the pain, as the AC joint is compressed with such motion. [18]

Approach.

Entry is made through a cutaneous lidocaine wheal over the interosseous groove at the point of greatest tenderness. This is usually just at the AC joint, which is palpated as a small "V"-shaped depression posteriorly at the

Figure 53-6 Abnormal calcific deposits in calcareous tendinitis of the shoulder are usually demonstrated roentgenographically in the suprahumeral region or adjacent to the greater tuberosity. When bursal calcifications appear dense (as in this x-ray film), they are frequently asymptomatic, whereas lightening at the margins of the calcium deposit is compatible with the presence of inflammatory edema in the rotator cuff, which produces pain and tenderness in the shoulder region. The location of the calcific deposit in the radiograph may be a useful guide for the point of entry of aspiration and injection. The needle is directed to the calcareous deposit, aspiration is carried out, and a portion of the steroid medication is deposited there. The calcium may subsequently disappear. Not infrequently, it does so spontaneously, without a needling procedure.

most lateral aspect of the clavicle (Fig. 53-9).[19] The joint line is relatively superficial, and a 2.2- to 2.5-cm, 22- or 25-ga needle is usually only advanced approximately 5 mm. One to 2 mL of lidocaine and 5 to 10 mg of a methylprednisolone suspension are injected. It is not necessary to advance the needle beyond the proximal margin of the joint surface.

Elbow Region

The elbow is subject to frequently occurring, characteristic, extra-articular disorders. These include radiohumeral bursitis, lateral and medial epicondylitis ("tennis elbow" and "golfer's elbow"), and olecranon bursitis ("barfly's elbow").

Radiohumeral bursitis, lateral epicondylitis, and medial epicondylitis.

Radiohumeral bursitis occurs at the juncture of the radial head and the lateral epicondyle of the elbow. This condition is commonly found in combination with lateral epicondylitis ("tennis elbow"), which is an inflammation at the insertion of the *extensor carpi radialis* and *extensor digitorum* muscles. The symptoms of the two adjacent problems are indistinguishable, but tenderness in bursitis overlies the site of the radiohumeral groove, whereas

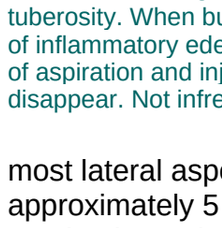

Figure 53-7 *A,* Anterior approach to the subacromial bursa or supraspinatus tendon. The needle is inserted into the depression located inferolateral to the coracoid process and medial to the humeral head.

tenderness in tennis elbow occurs chiefly at the lateral epicondyle (Fig. 53-10 (Figure Not Available)). There is often a history of repetitive motion, such as while golfing, gardening, or using tools. [4] A clinical sign supporting the diagnosis of tennis elbow is the provocation of pain when the patient attempts elevation of the middle finger against resistance, with the wrist and the elbow held in extension. Alternatively, pain is reproduced at the elbow when the patient is asked to extend the wrist against resistance (Fig. 53-11).

Medial epicondylitis ("golfer's elbow") is a similar condition, although it occurs on the opposite side as that of lateral epicondylitis and is much less common. [4] On physical examination, the patient will usually complain of pain when the wrist is *flexed* against resistance. Palpation of the medial epicondyle also elicits tenderness.

There is evidence to support the efficacy of corticosteroid injection for these conditions, particularly in the short term. In 1999 Hay and associates compared local corticosteroid injection, oral nonsteroidal anti-inflammatory medication, and other analgesics in 164 patients with lateral epicondylitis. [21] In 4 weeks, the injection group had the highest treatment success (defined as "better") rate (82%), versus the nonsteroidal

Figure 53-8 Posterolateral approach. *A,* The needle is inserted in the depression just inferior to the posterolateral tip of the acromion and superior to the head of the humerus. *B,* Injection using the posterolateral approach. The angle of entry should be approximately 15°.

anti-inflammatory (48%) and other analgesics group (50%). It should be noted, however, that after 1 year, the results were similar for all three groups (84% vs 85% vs 82%). Similarly, Stahl and colleagues studied 58 patients with medial epicondylitis who were first injected with methylprednisolone and then treated with both physical therapy and nonsteroidal anti-inflammatory agents. [22] In 6 weeks, the patients who received steroid injections reported significantly less pain compared to the placebo group. However, at 3 months and 1 year after the initial injection therapy, the two groups did not differ with regard to pain.

Approach.

With the elbow flexed at 90°, the radial head can be palpated as a bony protrusion just distal to the lateral epicondyle, and confirmed by rotation of the patient's forearm. The entry site is the point of maximal tenderness, usually found at a point slightly distal to the lateral epicondyle (Fig. 53-12). The injection is made through a skin wheal with a 3.9-cm, 22-ga needle, depositing 20 to 30 mg of methylprednisolone or equivalent intermediate-acting steroid mixed with anesthetic. Alternatively, the steroid is followed with 1 to 3 mL of local anesthetic. The injection should be infiltrated in a fan-like distribution, avoiding direct tendon injection. For radiohumeral bursitis, part of the repository preparation may be instilled into the radiohumeral bursa and part at the lateral epicondyle. In medial epicondylitis (golfer's elbow), a similar technique can be used, but it is important to remember to avoid the ulnar nerve, which lies in a groove behind the medial epicondyle. Damage to this nerve during steroid injection has been reported. [23]

Olecranon bursitis (Aseptic).

"Student's elbow," or "barfly elbow," is a common condition that is frequently idiopathic or provoked by minor trauma (Fig. 53-13*A* and *B*). [4] It is common for patients to present following some minor, often unrelated, trauma to the elbow region, and may also be seen in activities whereby the patient often leans on the elbow, such as gardening.[4] Acute trauma may result in a bursal hematoma from bleeding into the olecranon bursa, simulating acute bursitis. Although most cases of olecranon bursitis are sterile, the olecranon bursa is the most frequent site of septic bursitis. [24] The diagnosis of aseptic olecranon bursitis is obvious when the elbow is inspected and examined during flexion and extension. Radiographs are normal, but bony spurs (of questionable relationship) may be noted at the olecranon process, and amorphous calcific deposits may be seen. Occasionally in rheumatoid arthritis and gout, nodules, or tophi, may be readily palpated within the bursal sac. The olecranon bursa that is most commonly involved lies between the skin and the olecranon process. Motion at the elbow joint

Figure 53-9 Injection of the acromioclavicular joint. Entry is made at the "V"-shaped depression at the most lateral aspect of the clavicle.

remains complete and painless in aseptic bursitis. [4] In contrast, all motion is usually painful with septic arthritis.

Aseptic olecranon bursitis is cosmetically bothersome to the patient but does not cause discomfort and may resolve spontaneously unless there has been bleeding into the bursa or the effusion is extremely tense. When the bursa is large and subject to trauma or is tender and inflamed, provided that infection is excluded, aspiration and a steroid injection will expedite resolution. Smith and associates demonstrated the superiority of intrabursal methylprednisolone acetate over oral

Figure 53-10 (Figure Not Available) Lateral epicondylitis—commonly known as "tennis elbow"—is the result of microscopic rupture and incomplete tendinous repair of the *extensor carpi radialis brevis* origin on the lateral epicondyle of the humerus. Pain usually occurs over the lateral humeral epicondyle during work or recreation. *(From Walker LG, Meals RM: Tendinitis. A practical approach to diagnosis and management. J Musculoskel Med 6:24, 1989. Reproduced with permission.)*

naproxen or placebo at 6 months, noting faster resolution and less reaccumulation of fluid with the steroid injection. [25] The addition of a course of an oral nonsteroidal drug after steroid injection did not affect the outcome. Aspiration without injection is often followed by recurrence in a few days or weeks.

Septic bursitis.

Septic bursitis is most common in the olecranon and prepatellar bursae. [24] Infection of the other bursae is exceedingly rare. The infection is probably secondary to acute trauma or skin breakage resulting in direct penetration of the bursa by common skin pathogens, rather than by hematogenous spread. [26] [27] It would be impossible to clinically differentiate acute gouty olecranon bursitis from septic bursitis without laboratory analysis. Some unusual conditions that simulate bacterial septic olecranon bursitis include acute rheumatoid bursitis, aseptic bursitis secondary to oxalosis induced by dialysis, or infectious bursitis secondary to unusual organisms such as Mycobacterium, Serratia marcescens, or fungal organisms.

Septic bursitis is not associated with septic arthritis of the underlying joint, although, rarely, adjacent bone may become involved. [28] Many patients have an underlying predisposition to infection (e.g., diabetes mellitus, alcoholism, uremia, or gout). Rarely, an infection may follow an injection of corticosteroids into the bursa.

In most cases the diagnosis of septic bursitis is obvious (Fig. 53-14). The onset of pain and swelling may be quite rapid (over 8 to 24 hours), as compared with the more gradual onset of aseptic bursitis. The bursa is erythematous, tense, swollen, and very painful. Furthermore, the infected bursa is generally = 2.2°C warmer than the opposite elbow.[28A] The diagnosis of septic bursitis is confirmed by aspirating infected bursal fluid and culturing bacteria from the aspirate. Fluid is usually easily obtained from the tense bursa and (in the case of an established infection) is cloudy or grossly purulent.

The white blood cell count of the fluid in septic bursitis is usually 5000 to 100,000 cells/mm ^{3} or greater, and polymorphonuclear cells usually exceed 90%. Neither fever nor systemic leukocytosis are considered sensitive or specific for the disease. However, in immunocompromised patients (e.g., diabetes mellitus, alcoholism), the white blood cell count in the bursal fluid tends to be higher. [29] Because of some overlap in the leukocyte count of bursal fluid in septic versus nonseptic bursitis, it is important to remember that a low bursal white blood cell count does not exclude a septic etiology. Thus, Gram stain and culture are required in confusing cases. [24] Gram-positive organisms may be seen on Gram stain. The majority of septic bursitis cases are caused by penicillin-resistant *Staphylococcus aureus* (78%) in both immunocompromised and non-immunocompromised patients, followed by a small percentage of streptococcal organisms.[29]

Treatment of septic bursitis includes aspiration of the bursa and the use of antibiotics directed against penicillinase-producing *Staphylococcus*, splinting, hot soaks, and drainage of the bursa. Drainage may be adequately performed with one or more needle aspirations, but open incision and drainage may be required, particularly if the infection is recurrent or refractory. [26] *Corticosteroid injections should not be performed in infected tissue. They should also be withheld in the setting of high clinical suspicion for infection, pending negative bacteriology findings.* Outpatient therapy with oral antibiotics is generally acceptable, although this approach has been challenged for immunocompromised patients.[29]

Figure 53-11 Clinical test for lateral epicondylitis. The patient extends the wrist against resistance, while the examiner localizes the site of maximal tenderness at the lateral epicondyle.

Toxic-appearing, unreliable, or immunocompromised patients may be initially treated with intravenous antibiotics as inpatients, but no universally accepted standard exists. This decision is generally guided by the clinical appearance of the bursa, as well as associated comorbidities, compliance, and other factors regarding patient care. In general, the length of antibiotic therapy is often correlated with the length of time that the patient had symptoms before antibiotics were initiated. [29] Response to antibiotic therapy may be slow. Thus, it is important to initiate antimicrobial treatment once there is clinical suspicion for

Figure 53-12 *A,* Injection at lateral epicondyle for treatment of "tennis elbow." *(Redrawn from steinbrocker O, Neustadt DH: Aspiration and Injection Therapy in rthritis and Musculoskeletal Disorders: A Handbook on Technique and Management. septic bursitis. Additional treatment with oral nonsteroidal anti-inflammatory agents may also be effective. Standard gout medications will generally resolve acute gouty bursitis.

Approach.

A 2.5- to 3.9-cm, 20-ga needle is introduced at a dependent aspect of the bursal sac through a lidocaine skin wheal, or the skin may remain unanesthetized (Fig. 53-13C–E). If infected or inspissated fluid is anticipated, a 16- to 18-ga needle may be necessary for aspiration of the viscous contents. After as much fluid as possible is aspirated, 15 to 30 mg of methylprednisolone or an equivalent

Figure 53-13 *A,* Anatomy showing location of the olecranon bursa superficial to the ulnar olecranon. *B,* traumatic painless swelling over the posterior elbow is characteristic of nonseptic olecranon bursitis. The mass is soft, movable, and fluctuant and is usually filled with serosanguineous fluid. *C,* Using sterile preparation, a 20-ga needle on a 10-mL syringe is advanced parallel to the forearm, and the bursal fluid is completely aspirated. *D,* The aspirating syringe is changed while the needle remains in the bursal sac, and a long-acting steroid preparation (such as 40 mg of methylprednisolone) is injected. An elastic bandage provides compression for 12 hours. *E,* An alternative posterior approach to the bursa. *F,* An extreme case of tophaceous gout involving the olecranon bursa. Most cases of acute gout bursitis resemble septic bursitis.

intermediate-acting preparation is injected. In aseptic bursitis the aspirated fluid may be yellow and clear, but often it is mildly serosanguineous in appearance. There are no compelling reasons to routinely send aspirated fluid for laboratory analysis or culture. The leukocyte count of aspirated fluid of aseptic bursitis should be less than 1000/mm^3 . Counts above 2000 to 10,000/mm^3 are associated with a higher incidence of infection or acute gout. The elbow is wrapped with an elastic compression bandage for 5 to 7 days following aspiration and injection. *Again, if septic olecranon bursitis is suspected, corticosteroid injections should not be used.*

Wrist and Hand Region

Ganglion cysts of wrist or hand.

These are cystic swellings occurring frequently on the hands, especially on the dorsal aspect of the wrist. Ganglion cysts are common and make up approximately 60% of all soft tissue tumors affecting the wrist and hand. They usually develop spontaneously in

---

Figure 53-14 Fully developed septic olecranon bursitis is easily distinguished from nonseptic bursitis by clinical parameters. In the septic variety, there is diffuse swelling, as opposed to a discrete mass; the area is red, warm, and quite tender. In addition, bursal fluid leukocytosis is present.

adults between 20 and 50 years old, with a female-to-male ratio of 3:1. Ganglion cysts may also be seen on the foot and ankle, generally on the extensor surface.

The etiology of ganglia remains obscure. The word *ganglion* is derived from the Greek word meaning "cystic tumor." The mesothelium- or synovium-lined cystic structures are attached to or may arise from tendon sheaths or near the joint capsule and do not extend into the joint itself. [30] Attachment is often by a pedicle. The wall of the ganglia is smooth, fibrous, and of variable thickness. The cyst is filled with a clear, gelatinous, sticky, or mucoid fluid of great density. The viscous fluid in the cyst may sometimes represent almost pure hyaluronic acid.

The types of ganglia vary with their location. The most common ganglion is the dorsal wrist variety, which arises from the scapholunate joint and constitutes approximately 65% of ganglia. The volar wrist ganglion, which arises over

Figure 53-15 A typical volar ganglion cyst of the wrist (*A*) and dorsum of the foot (*B*).

the distal aspect of the radius, constitutes another approximately 20 to 25% of ganglia (Fig. 53-15). Flexor tendon sheath ganglia make up the remaining 10 to 15% found on the hand and wrist.

Most ganglia are of no great clinical significance and most do not require treatment. Spontaneous regression is common. However, if the appearance of the cyst is disturbing to the patient or if the ganglion is painful or tender (from soft tissue or nerve compression, or bone erosion), then simple aspiration with or without injection of a corticosteroid suspension is usually an effective approach. Up to three aspirations may be required before the technique is termed a failure. In one study, 69% of 116 patients required only a single aspiration for successful treatment. [31] Two or three aspirations were required for 19%, and only 12% of patients ultimately needed surgical excision. Aspiration with or without steroid injection is associated with considerable cost savings when compared with surgery. [25] The "old" treatment of attempting to rupture the ganglion with a heavy book is not advised due to the potential for local injury. In the event of failure of nonsurgical treatment, surgical

excision may be indicated. Reported recurrence rates after surgical removal range from 6 to 50%.

Approach.

Following instillation of 1% lidocaine for local anesthesia, a 2.5-cm, relatively large-bore needle (17- to 18-ga) is inserted into the center of the ganglion. The cyst is aspirated, with an attempt to achieve maximum evacuation of the contents. Usually 1 to 2 mL of mucinous fluid can be aspirated. Milking the contents of the cyst toward the aspiration needle can maximize the volume that is removed.[32] After localizing the cyst by aspiration, another smaller needle is used to simultaneously administer 10 to 15 mg of methylprednisolone (or equivalent intermediate-acting steroid). The use of steroids instilled into the cyst is a common procedure that has been proven to significantly augment the success of simple aspiration. [33] Following aspiration, a splint is usually not required, and activity need not be restricted. There is no proven role for routine nonsteroidal anti-inflammatory drugs or oral steroid therapy.

DeQuervain disease and intersection syndrome.

DeQuervain disease, a relatively common disorder, is a stenosing tenovaginitis of the short extensor tendon (*extensor pollicis brevis* [EPB]) and long abductor tendon (*abductor pollicis longus* [APL]) of the thumb. Although commonly referred to as a tenosynovitis, denoting inflammation of synovial sheaths of the tendons of the EPB and APL, this condition is more accurately described as a tenovaginitis. [34] Tenovaginitis refers to thickening of the fibrous sheath of the first extensor compartment. In 1912, deQuervain described "thickening of the dense fibrous connective tissues without any fresh sign of inflammation, neither round cell inflammation nor increase in numbers of cells".[34]

It is commonly thought that the disorder more often occurs following repetitive use of the wrists, especially with a wringing motion. The syndrome has been called "washerwoman's sprain," and often no specific etiology is apparent. However, a study by Kay and colleagues challenges the association

Figure 53-16 (Figure Not Available) *A,* de Quervain tenosynovitis occurs in the first dorsal compartment of the wrist secondary to tenosynovitis of the *abductor pollicis longus* and *extensor pollicis brevis* tendons. Symptoms, which include pain over the radial styloid, are generally caused by overuse. The Finkelstein test is positive when pain is reproduced by ulnar deviation of the wrist while the patient grasps the thumb with the fingers. *B,* Occasionally, crepitus may be palpated over the involved area. To elicit this sign, the examiner's fingers are placed over the painful area, and the patient's wrist is placed in ulnar deviation, which produces the characteristic sensation. *C,* Signs and symptoms of tenosynovitis of the wrist in a 25-year-old woman, which were initially thought to be de Quervain disease. The hemorrhagic papules found on the hand are classic for gonococcal bacteremia, and one aspect of this sexually transmitted disease is tenosynovitis. Cervical cultures were positive for *Neisseria gonorrhoeae*, despite the absence of vaginal symptoms. *(A from Walker LG, Meals RM: Tendinitis: A practical approach to diagnosis and management. J Musculoskel Med 6:24, 1989.)*

between repetitive motion and deQuervain disease. [34] In a retrospective study of 100 cases, there was not a strong correlation with occupation or history of repetitive activities in patients diagnosed with deQuervain disease. Thus, it may be possible that repetitive activities exacerbate the pain associated with a condition for which the etiology is unclear.

Tenderness and occasionally palpable crepitation is elicited just distal to the radial styloid process where both tendons come together in an osseofibrous tunnel. Patients usually present with wrist pain and often mistakenly attribute the discomfort to some distant, albeit irrelevant, trauma. The condition may be confused with first carpometacarpal arthrosis (osteoarthritis of the thumb) and intersection syndrome. Radiographs will be normal in deQuervain disease but may be appropriate to rule out other pathologic abnormalities. Rarely, gonococcal tenosynovitis may simulate this inflammatory condition.

A useful specific clinical maneuver that indicates deQuervain disease is the Finkelstein test (Fig. 53-16 *A* (Figure Not Available)),

---

performed by abducting the patient's thumb into the palm of the hand and folding the fingers over the thumb. Forcible ulnar deviation at the wrist is then carried out, with severe pain at the site of the affected tendon sheaths indicating a positive test. When performing the Finkelstein test, one should also evaluate the tender area for palpable crepitus (see Fig. 53-16 *B* (Figure Not Available)). If axial traction or compression (the "carpometacarpal grind test") and rotation of the thumb produce pain, the condition is most likely due to degenerative changes of the carpometacarpal joint of the thumb rather than from deQuervain disease. It should be noted that gonococcal tenosynovitis of the wrist may mimic deQuervain disease, and one should inquire about other symptoms (e.g., sore throat, penile or vaginal discharge, or fever) and carefully look for the characteristic rash of this sexually transmitted disease (see Fig. 53-16 *C* (Figure Not Available)).

In a study comparing steroid injection of deQuervain disease with a splint and oral nonsteroidal anti-inflammatory therapy alone, the latter traditionally accepted initial treatment was effective only in a small group of patients with minimal symptoms.[35] Steroid injection therapy was recommended as the initial treatment once the disease began to cause an interference with activities of daily living or if symptoms were more severe. Overall, there is increasing evidence supporting the effectiveness of local corticosteroid injection as the therapeutic preference for deQuervain tenovaginitis. In 1 report, 90% of 56 cases were effectively managed either with a single injection (58%) or with repeat injections (33%), with only 10% requiring surgical treatment. [20] These data support a previous report describing an 83% rate of successful response to injections in 63 wrists with deQuervain tenosynovitis. [36] The strikingly favorable response to local injection therapy suggests that surgery to release the tendon sheaths is seldom needed.

Accurate injection of the corticosteroid has been found to be an important aspect of the patient's response to treatment. [37] Using radiographic dye to verify correct corticosteroid placement, researchers have found that when the corticosteroid and anesthetic injection did not successfully reach either the EPB or APL compartment, the patient did not experience relief of pain. Conversely, when the medication was accurately injected, most patients reported an improvement of symptoms.

Intersection syndrome is a condition that may be easily confused with deQuervain disease. Because the treatment approach and clinical course of intersection syndrome differ from that of deQuervain tenovaginitis, it is important that the clinician is also familiar with this entity. First described in 1841 by Velpea, intersection syndrome describes a clinical entity approximately 4 to 8 cm proximal to the location of deQuervain disease. [38] Although the etiology is not yet clear, some authors believe it to be an inflammation of the second dorsal compartment of the wrist, which houses the *extensor carpi radialis longus* (ECRL) and *extensor carpi radialis brevis* (ECRB) tendons.[39] Others report that the primary site of pathology lies in the compression of the ECRL and ECRB muscles by the muscle bellies of the APL and EPB (Fig. 53-17). [40]

Intersection syndrome presents with pain, tenderness, edema, and occasional crepitus 4 to 8 cm proximal to the radial styloid (Fig. 53-18). Treatment includes rest, nonsteroidal anti-inflammatories, and immobilization with a thumb spica splint (see Chapter 51). Corticosteroid injection

Figure 53-17 *A,* Site of de Quervain disease at the *extensor pollicis brevis* (EPB) and *abductor pollicus longus* (APL) tendons. *B,* Site of intersection syndrome at the *extensor carpi radialis longus* (ECRL) and *extensor carpi radialis brevis* (ECRB) tendons.

therapy is recommended only after a 2 to 3 week trial of splinting. Approximately 60% of patients will respond with nonoperative treatment. [39] Surgery for this condition is reserved for refractory cases.[38] In contrast, steroid injection therapy is recommended earlier in the course of deQuervain disease. Some authors, in fact, recommend corticosteroid injection therapy on initial presentation of deQuervain disease. [38]

Approach.

For deQuervain disease, the hand is positioned with the ulnar side of the wrist on the table and the radial side facing upward. A 2.2-cm, 25-ga needle is introduced at the most tender point (about 1 cm distal to the radial styloid) through a skin wheal, and 10 to 20 mg of prednisolone or equivalent intermediate-acting steroid suspension mixed with 4 to 5 mL of lidocaine 1% are deposited adjacent and parallel to the tendon sheath (peritendinous infiltration) (Fig. 53-19*A* and *B*). The

injection should be under the edge of the first dorsal compartment retinaculum, within the first extensor compartment. If firm resistance is appreciated, the needle should be redirected to prevent intratendinous injection. Because there are many superficial vessels in this area, it is important to aspirate before injecting, to verify that the needle is not in a blood vessel. [37] One should be generous with the injection volume, since a common reason for failure is the inability to get medication into both tendon sheaths. This may

Figure 53-18 Photograph of a patient's wrist with intersection syndrome. Note that the swelling (arrow) is several centimeters *proximal* to the radial styloid, overlying the compartment of the common wrist extensors (*extensor carpi radialis longus* and *extensor carpi radialis brevis*). *(From Hanlon DP, Luellen JR: Intersection Syndrome: A case report and review of the literature. J Emerg Med 17:970, 1999. Reproduced with permission.)*

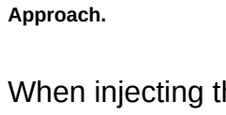

Figure 53-19 Injection of abductor tendon sheath (de Quervain disease). When giving an injection for de Quervain disease, it is desirable to avoid direct tendon injection and to instead aim for a peritendinous infiltration (*A*). If 3 to 4 mL of a local anesthetic is added to the steroid, generous infiltration over a diffuse area can compensate for a less than perfect localization (*B*). *(A from Steinbrocker O, Neustadt DH: Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders: A Handbook on Technique and Management. Hagerstown, MD, Harper & Row, 1972. B from Zingas C, Failla JM, Holsbeeck MV: Injection accuracy and clinical relief of de Quervain tendinitis. J Hand Surg 23a:89, 1998. Reproduced with permission.)*

be partially overcome by increasing the volume of steroid-lidocaine injected in a more diffuse area. Often, there is visible edema at the radial aspect of the first metacarpal base and at the thumb metacarpophalangeal joint dorsally after successful injection. [37] A lightweight thumb or wrist splint for wrist support and protection may be used at night for several weeks after the injection, but routine splinting following injection is not required. [38] Oral nonsteroidal anti-inflammatory agents may be prescribed for analgesia but will likely not effect a cure by themselves. There is no proven role for oral corticosteroids.

Injection for intersection syndrome is similar to that of deQuervain disease, except that the target site is at the point of maximal tenderness, which is usually 4 to 8 cm proximal to the radial styloid.

Carpal tunnel syndrome.

Carpal tunnel syndrome is a common nerve entrapment caused by median nerve compression in the fibro-osseous tunnel of the wrist. It is characterized by pain at the wrist that sometimes radiates upward into the forearm and is associated with tingling and paresthesias of the palmar side of the index and middle fingers and the radial half of the ring finger. Typically, the patient wakes during the night with burning or aching pain, numbness, and tingling. Occasionally the discomfort is extremely severe, causing the patient to seek emergency care. Clinical signs supporting the diagnosis include a positive Tinel sign, elicited by reproducing the tingling and paresthesias by tapping (with a reflex hammer) over the median nerve at the volar crease of the wrist. [41] In addition, one can perform the Phalen test, described as flexed wrists held against each other for several minutes in an effort to provoke the symptoms in the median nerve distribution. [41] Severe muscle atrophy of the thenar eminence may develop in advanced or neglected cases. In many cases the disturbance is idiopathic, without a recognizable underlying cause. Other causes of carpal tunnel syndrome include rheumatoid arthritis (sometimes as the presenting manifestation), pregnancy, hypothyroidism, diabetes, and acromegaly.

Approach.

When injecting the carpal canal, one should insert the needle through a skin wheal at a site just radial or ulnar to the *palmaris longus* tendon and proximal to the distal crease at the wrist. The *palmaris longus* tendon can be appreciated by having the patient oppose the thumb and fifth digit while flexing the wrist (Fig. 53-20).[42] Injecting medial (ulnar) to the *palmaris longus* is preferred because it avoids direct injection of the median nerve and superficial veins. A 2.5- to 3.9-cm, 25-ga needle is directed at an angle of approximately 60° to the skin surface, pointing toward the tip of the middle finger. The needle is advanced 1 to 2 cm, and 20 to 40 mg of methylprednisolone (or other intermediate-acting steroid equivalent) with or without lidocaine is injected along the track and into the tissue space. Up to 2 weeks may be required for paresthesias to abate significantly, although it usually only takes a few days for an improvement in nocturnal pain. [43] A lightweight wrist splint may hasten recovery. Repeat injections may be given, but if a response is not elicited or permanent after two or three injections, decompressive surgery should be considered. Surgery is reserved for medically recalcitrant cases, thenar atrophy, or patients with significant sensory loss. [10] [42] Nerve compression should be confirmed by nerve conduction studies before surgery. [37]

Digital flexor tenosynovitis ("Trigger finger").

A "trigger" or "snapping" finger is characterized by a stenosed tendon sheath on the palmar surface over the base of the metacarpal head. The area of stenosis leads to intermittent catching of the tendon. Locking occurs when the involved digit is in flexion and is especially troublesome when the patient awakens in the morning. This can occur in any finger but is seen most frequently in the ring and middle fingers.

Besides a thickening and stenosing of the tendon sheath, trigger finger may also be characterized by flexor tendon synovitis.

The tendon sheaths are long and tubular, and the walls are lined with a thin layer of synovial cells. Symptoms develop when the tendon becomes trapped and is unable to glide within the tendon sheath (Fig. 53-21 (Figure Not Available)). A nodule or fibrinous deposit may form at a site in the tendon sheath, usually over or just distal to the metacarpal head in trigger finger. Carpal tunnel syndrome commonly coexists with trigger finger and may be caused by tenosynovitis. The common causes of tenosynovitis include trauma, diabetes mellitus, and rheumatoid arthritis, although it may also be a primary and idiopathic disorder. [39]

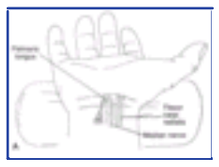

Figure 53-20 *A,* Injection of the median carpal tunnel with the wrist dorsiflexed over a rolled towel. To avoid direct injection of the median nerve, the needle is introduced just medial (ulnar) to the *palmaris longus* tendon. *B,* A palpable bulge at the distal edge of this ligament indicates correct placement of the injection. Direct injection into the median or ulnar nerve is to be avoided. *(A redrawn from Steinbrocker O, Neustadt DH: Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders: A Handbook on Technique and Management. Hagerstown, MD, Harper & Row, 1972. B from Dehaan MR, Wilson RL: Diagnosis and management of carpal tunnel syndrome. J Musculoskel Med 6:47, 1989. Reproduced with permission.)*

Conservative treatment, including local rest or splinting, application of moist heat, and non steroidal anti-inflammatory therapy is the usual initial therapeutic approach for symptomatic tenosynovitis. If these simple measures fail to control symptoms, then corticosteroid injection, appropriately administered to the involved tendon sheath, is indicated. One double-blind, placebo-controlled, randomized study of trigger finger demonstrated that steroid injection was significantly more effective than placebo.[44] At follow-up 3 weeks post treatment, 9 of the 14 patients receiving a combination lidocaine and steroid injection were asymptomatic, versus 2 of the 10 patients receiving lidocaine injections alone. A similar study

Figure 53-21 (Figure Not Available) Trigger finger (stenosing tenosynovitis) can affect any digit, including the thumb, as shown here, but it is most common in the ring and middle fingers. In advanced cases, inflammation at the proximal (A1) pulley of the flexor tendon sheath overlying the metacarpophalangeal joint may hold the digit in either a flexed or an extended position. Generally, the tendon becomes thickened either proximal or distal to the pulley, causing a snapping or a locking phenomenon with finger flexion or extension. Palpation of the flexor tendon sheath over the metacarpophalangeal joint often reproduces symptoms. *(From Walker LG, Meals RA: Tendinitis: A practical approach to diagnosis and management. J Musculoskel Med 6:41, 1989. Reproduced with permission.)*

showed improvement in 1 month in 60% of patients receiving a corticosteroid and lidocaine injection, compared with a 16% improvement rate in a control group that

received lidocaine alone.[45] Alternatively, there is evidence to suggest that the efficacy of steroid injections for trigger finger diminishes with each subsequent injection in the same site.[46] This suggests that surgery may be an acceptable alternative if the patient does not obtain relief of symptoms after the first injection. [46] In particular, patients with diabetes mellitus more commonly require surgical release for trigger finger compared with non-insulin-dependent diabetic patients. [47] Division of the first annular pulley, digital nerve injury, scarring, and recurrence are well-known complications of surgical release. [46]

Approach.

Preparation of the site before the injection requires meticulous adherence to aseptic technique. The technique for injecting flexor tenosynovitis includes placing the palm in an upward direction and locating the tendon point at the base of the finger flexion crease, which is located between the A1 and A2 tendon pulleys. Approximately 0.25 to 0.35 mL of an intermediate-acting corticosteroid suspension mixed with 1.5–3 mL of anesthetic is subcutaneously injected with a 2.2-cm, 25-ga needle angled slightly proximally into the involved tendon sheath (Fig 53-22). The needle enters the

Figure 53-22 Injection of flexor tendon sheath in digital tenosynovitis.

skin at an angle of approximately 30° and is inserted into the tendon sheath, parallel to the tendon fibers. If resistance is felt on needle insertion, this suggests an intratendinous location, and the needle should be slightly withdrawn prior to injection. This injection can be quite painful. Local epidermal and SQ lidocaine may make the more critical tendon sheath placement tolerable. Similar injections can be administered to the base of the thumb metacarpal for a "snapping" thumb. If relapses are frequent or the clinical response is not satisfactory, then surgical release is indicated.

Hip Region

Trochanteric bursitis.

Trochanteric bursitis is the second leading cause of lateral hip pain after osteoarthritis. [48] However, the condition can be confused with other conditions at or about the hip, such as sacro-lumbar disease, hip/femur pathology, and metastases. [28] [49] Patients with trochanteric bursitis, however, usually demonstrate discrete tenderness to deep palpation at or adjacent to the greater trochanter, and relief of symptoms with a proper corticosteroid injection can help confirm the diagnosis. [49]

The principal bursa lies between the gluteus maximus and the posterolateral prominence of the greater trochanter, although other bursae of the hip are also commonly affected (Fig. 53-23). Pain may be acute but is more often subacute or chronic; often patients have tried nonsteroidal anti-inflammatory agents without success and have been given a number of incorrect diagnoses. The chief locus of the pathologic condition is in the abductor mechanism of the hip. Pain occurs near the greater trochanter and may radiate down the lateral or posterolateral aspect of the thigh. Pain is described as deep, dull, and aching, and it often interferes with sleep.

Lying on the side of the hip, stepping from curbs, and descending steps provokes pain. Tenderness may be elicited over and adjacent to the greater trochanter. In contrast with true hip involvement, the Patrick *fabere* sign (*f*lexion, *ab*duction, *e*xternal *r*otation, and *e*xtension) may be negative, and complete passive range of motion is relatively painless. Active abduction when the patient lies on the opposite side typically intensifies the discomfort, and sharp external rotation may accentuate the symptoms. Internal rotation does not usually affect the level of pain. [49] Hip radiographs may demonstrate a

Figure 53-23 Trochanteric bursitis. The principal bursa lies between the gluteus maximus and the greater trochanter, although other bursae may also be involved.

calcific deposit adjacent to the trochanter; however, the incidence of this is low. [28]

Corticosteroid injection for trochanteric bursitis is often an effective therapy. [28] In one study 77% of patients reported improvement of their pain after an injection of betamethasone mixed with lidocaine.[50] In addition, 61% of patients reported improvement of pain 26 weeks after receiving the injection.

Approach.

Intrabursal injection uses the site of maximum tenderness for the entry point. A 3.9- to 5.0-cm, 20- or 21-ga needle is advanced until the needle tip reaches the trochanter. The needle is then withdrawn slightly, and the site is infiltrated fairly widely with 3 to 10 mL of lidocaine and 20 to 40 mg of methylprednisolone or the equivalent.

Ischiogluteal bursitis.

"Weaver's bottom" is a painful disorder characterized by pain over the center of the buttocks with radiation down the back of the leg. [28] This condition is rarely initially diagnosed, often being mistaken for lumbosacral strain, a herniated disk, or spinal cord tumor. When it is recognized, a skillful intrabursal injection, coupled with a few days' rest, usually relieves the extreme pain. The ischial or ischiogluteal bursa is adjacent to the ischial tuberosity and overlies the sciatic and posterior femoral cutaneous nerves. Sitting on hard surfaces, bending forward, and standing on tiptoe provokes pain. Tenderness is present over the ischial tuberosity.

Approach.

The usual technique for injection requires that the patient lie in a prone position. A 5.0-cm, 20- to 22-ga needle is inserted through a skin wheal and is advanced cautiously in an effort to avoid the sciatic nerve, which lies at a depth of approximately 6.5 to 7.5 cm. Paresthesias occur on striking the nerve, and if this occurs, the needle should be withdrawn from the nerve. Generally, 5 to 10 mL of lidocaine and 20 to 40 mg of methylprednisolone are introduced into the bursa.

Knee Region

Prepatellar bursitis.

"Housemaid's knee," or "nun's knee," is characterized by swelling with effusion of the superficial bursa overlying the lower pole of the patella (Fig. 53-24). Passive motion is fully preserved, and pain is

Figure 53-24 Prepatellar bursitis and *pes anserine* bursitis. The prepatellar bursa lies superior to the patella, while the *pes anserine* bursa lies deep to the insertion of the sartorius, gracilis, and semitendinosus tendons.

generally mild, except during extreme knee flexion or direct pressure. Although the disorder is usually caused by pressure from repetitive kneeling on a firm surface ("rug cutter's knee"), rarely it can develop after direct trauma, and occasionally it is a manifestation of rheumatoid arthritis. Although uncommon, the prepatellar bursa is one of the most common sites of septic bursitis.[4] The bursal aspirate should therefore always be sent for laboratory analysis, particularly if infection is suspected. [4]

Approach.

The patient should be in a supine position with the leg extended. The bursa is located superficially, between the skin and the patella, and can oftentimes be "milked" during the procedure to facilitate aspiration. This aspiration often yields a surprisingly scant amount of clear, serous fluid because the prepatellar bursa is a multilocular structure rather than the usual single cavity. Once aspiration is complete, the instillation of 1 to 2 mL of lidocaine with 15 to 20 mg of a prednisolone (or equivalent) suspension with a 2.5-cm, 20- to 21-ga needle is usually sufficient to cause the swelling to abate. In some cases the procedure may need to be repeated more than once (in 6- to 8-week intervals) to obtain a lasting result. The provocative activity should be discontinued.

Suprapatellar bursitis.

Suprapatellar bursitis usually is associated with synovitis of the knees. On occasion the bursa is largely separated from the synovial cavity with only a very minor communication, and the swelling and effusion are chiefly confined to the suprapatellar area. This may be traumatic in origin or an associated manifestation of an inflammatory arthropathy.

Approach.

The procedure for aspiration and injection of the suprapatellar area is similar to that for the knee (see Chapter 54).

Anserine bursitis.

"Cavalryman's disease" now mainly occurs in obese women with disproportionately large thighs in association with osteoarthritis of the knee, although this entity is also seen in athletes who are involved with running, baseball, and racquet sports. [28] The bursa is on the anteromedial side of the knee, inferior to the joint line at the site of the insertion of the conjoined tendons of the sartorius, semitendinous, and gracilis muscles and superficial to the medial collateral ligament (see Fig. 53-24). The entity is characterized by a relatively abrupt onset of knee pain, with localized tenderness and a puffy sensation in the vicinity of the anserine bursa about 4 to 5 cm below the medial aspect of the tibial plateau. Pain is exacerbated by flexion of the knee.

Approach.

The patient is positioned with the knee flexed at 90°. An injection of 2 to 4 mL of lidocaine, with or followed by approximately 20 to 40 mg of a corticosteroid suspension, is given using an anterior or medial approach with a 2.5- to 3.9-cm, 22-ga needle (Fig. 53-25). At the point of greatest tenderness, the needle is gently advanced until the tibia is reached, the needle is withdrawn 2 to 3 mm, and the steroid is then injected. Prompt symptomatic relief is frequently obtained, but the duration of benefit is variable and probably correlates with the patient's weight-bearing activities. It is important to avoid direct injection of the corticosteroid suspension into the nearby tendons.

Medial collateral ligament bursa.

This bursa is located anterior to the tibia and posterior to the medial collateral ligament (MCL). Injury to this bursa often occurs when the patient undergoes a twisting motion, with concurrent external rotation of the tibia. Tenderness may be appreciated along the anteroinferior aspect of the medial collateral ligament, and the pain is exacerbated with extension of the knee. This condition may sometimes be confused with a medial meniscus tear, and magnetic resonance imaging may be necessary to differentiate the two conditions. Treatment is usually successful with conservative measures, including relative rest, compression, and nonsteroidal anti-inflammatory agents.[28]

Popliteal cyst.

"Baker cysts" are herniated fluid-filled sacs of the articular synovial membrane that extend into the *popliteal fossa*, sometimes through the natural communication between the bursa of the posterior knee and the joint itself. These cysts may also be due to swelling of the medial gastrocnemius or semimembranosus bursae alone. Baker's cysts can occur secondary to trauma, although they are also seen in patients with rheumatoid arthritis, gout, and osteoarthritis. [28] The patient will often complain of *popliteal fossa* tenderness and swelling that may extend into the calf. Activities that involve active flexion of the knee, such as walking or jumping, will exacerbate the symptoms.

Figure 53-25 Injection of the anserine bursa of the knee. Note that the point of entry, which is the point of maximal tenderness, is inferior to the patella and medial to the tibial tuberosity.

The clinical presentation of Baker cysts can mimic that of a deep venous thrombosis (DVT), and it is important to take great care in differentiating the two. For this reason, symptomatic Baker cysts are also known as the pseudothrombophlebitis syndrome.[51] In most studies, 2% to 6% of patients suspected of having a DVT actually have a popliteal cyst as the cause of their knee/calf pain. Ultrasound is an important tool in this diagnosis.

Many cases of Baker cysts resolve spontaneously over a few weeks. However, treatment of Baker cysts may require surgery to correct any articular injury or to remove the cyst. Steroid injections are not usually performed because of the risk of neurovascular injury.

Patellar tendinitis.

The patellar tendon (also known as patellar ligament because it connects two bones) should not be injected in the ED since this weight-bearing tendon is subject to rupture with repeated injections. Referral to an appropriate specialist is recommended. Patellar tendinitis can be a manifestation of gout.

Quadriceps tendinitis.

The quadriceps tendon apparatus should not be injected in the ED since this weight-bearing structure is subject to spontaneous rupture and rupture secondary to repeated injections.

Ankle, Foot, and Heel Region

Ankle tendinitis.

This is a relatively uncommon condition. It may result from unusual repetitive activity or, rarely, from acute trauma. The disorder is differentiated from ankle joint involvement by the lack of pain or restricted motion during passive flexion and extension of the ankle. Active flexion and extension of the toes does produce pain. Local tenderness is elicited along the flexor and extensor tendons. Injection of the tendon sheaths is useful, producing considerable relief of symptoms. Tenosynovitis of the dorsum of the foot occurs in acute gout and can mimic acute tendinitis or cellulitis.

Approach.

A 2.5- to 3.9-cm, 22- or 25-ga needle is used. One makes a tangential entry to the enlarged tendon sheath, distending the sheath with approximately 2 to 4 mL of a mixture of corticosteroid (e.g., 20–40 mg of methylprednisolone) and lidocaine.

Bunion bursitis.

It is common for bunion bursitis to overlie the first metatarsophalangeal joint at its medial surface on the great toe. On occasion, tense swelling occurs, and decompression is required. Aspiration with culture of the fluid should be performed.

Approach.

If no infection is present, the bursa is injected with 5 to 10 mg of methylprednisolone with a 2.5-cm, 20-ga needle. Special shoes or an orthopedic correction will be needed if the swelling recurs.

Heel pain.

"Talalgia" has many different causes, including Achilles tendinitis, retrocalcaneal bursitis, or plantar fasciitis (Fig. 53-26). The bursae of clinical significance around the heel include the space between the skin and the Achilles tendon, the retrocalcaneal bursa, and the subcalcaneal bursa. Achilles tendinitis or bursitis may be traumatic in origin but is more apt to be part of a systemic disease, such as rheumatoid or gouty arthritis. Although the normal Achilles tendon is thick and strong, when affected by an inflammatory arthropathy, it is predisposed to degeneration, and since the Achilles tendon is not invested by a full synovial sheath, it is more vulnerable to intratendon instillation. Because of the potential hazard of tendon rupture after local steroid injection, it is wise to avoid infiltration of steroids into this area. In a double-blind, randomized, controlled trial, it was shown that the injection of methylprednisolone and Marcaine had no benefit over injecting Marcaine alone.[7] It is preferable to treat Achilles tendinitis with rest, splinting, and oral medication.

Retrocalcaneal bursitis is often seen in association with Haglund disease, which is a bony ridge on the posterosuperior aspect of the calcaneus. The bursa lies anterior to the Achilles tendon, and posterior to the calcaneus. Local swelling and tenderness at the posterior heel, proximal (and sometimes lateral) to the insertion of the Achilles tendon, characterize this bursitis. Treatment is focused on minimizing pressure on the bony ridge, which includes open heels (clogs), bare feet, sandals, or a heel lift. Conservative measures such as ice, nonsteroidal anti-inflammatory medications, and rest are other common treatment modalities. See Chapter 52 for more discussion of these conditions.

The condition in this region most amenable to injection therapy is plantar fasciitis, which is frequently associated with painful heel spurs ("policeman's heel" or "soldier's heel"). Plantar fasciitis involves collagen degeneration of the plantar fascial band at its origin at the medial aspect of the calcaneous. [52] The familiar signs of this condition include pain on the plantar medial aspect of the heel, which is often worse in the morning and after long periods of rest. The pain may be relieved with activity. Although patients may have a heel spur, many symptomatic patients do not. The pathology is thought to originate from microtears in the fascia, often due to

Figure 53-26 Heel pain. Talalgia may involve the tendons, bursa, or fascia around the heel.

overuse.[52] [53] Treatment begins with elimination of precipitating activity, relative rest, strength and stretching exercises, arch supports, and night splints. If these conservative measures are not effective, injection of the painful heel is sometimes beneficial. Studies have demonstrated a 70% success rate with steroid injections. [52] However, there is a risk of plantar fascia rupture and fat pad atrophy. [52] Since this tends to be a chronic or recurring condition, referral to the appropriate specialist is recommended following initial injection therapy. Orthotic devices in the shoes are often prescribed with good success.

Approach.

At the spot of maximal tenderness, a 2.5-cm, 22- to 24-ga needle enters the plantar surface at 90°, sliding into the space at the midpoint of the calcaneus. The tip of the needle lies in the aponeurosis of the attachment to the os calcis (Fig. 53-27). One milliliter of lidocaine and 10 to 20 mg of methylprednisolone are instilled.

HAZARDS AND COMPLICATIONS

Local anesthetics are often mixed with a corticosteroid preparation to increase volume, decrease postinjection pain, and assess the accuracy of the injection. Local anesthetics may also be used alone, before injection of the corticosteroid. The major hazards in the use of local anesthetics are hypersensitivity and accidental intravenous or intra-arterial introduction. Serious or fatal hypersensitivity to procaine and other regional anesthetic compounds is encountered very rarely; the possibility is usually suggested by a history of previous reactions. Lidocaine or one of the newer amide derivatives may be used to avoid sensitivity reactions to procaine (or other ester derivatives). Bupivacaine is an excellent choice because of its safety and long duration of action. When there is a definite history of sensitivity, the use of anesthetic agents during injection therapy is absolutely contraindicated.

In the event of accidental intravenous injection of an amide drug or if symptoms of hypersensitivity arise from these compounds, such as a significant slowing of the pulse rate or a seizure, a benzodiazepine or a rapidly acting barbiturate (e.g., sodium pentobarbital) should be given promptly in accordance with the reaction and response (see

Figure 53-27 Injection of calcaneal bursitis with heel spur. *(Redrawn from Steinbrocker O, Neustadt DH: Aspiration and Injection Therapy in Arthritis and Musculoskeletal Disorders: A Handbook on Technique and Management. Hagerstown, MD, Harper & Row, 1972.)*

Chapter 30). In addition, the patient should be placed on a cardiac monitor, oxygen should be administered, and a patent airway maintained. Severe reactions from accidental vascular injection of these drugs in the doses usually given are very rare.

No serious reaction to a depot corticosteroid preparation given intravenously has been reported. The possibility of an allergic reaction caused by corticosteroids is highly unlikely. However, an unusual skin rash following an intra-articular methylprednisolone injection, which appears to be consistent with a delayed type of hypersensitivity, has been reported. [11]

Minor reactions occasionally seen after injection of amide preparations include light-headedness or dizziness, pallor, weakness, sweating, nausea, and (rarely) fainting and tachycardia. These symptoms usually disappear within a few minutes after the injection and rarely require any treatment except reassurance and a cold compress to the forehead of the patient. Often it is difficult to decide whether the symptoms are the result of sensitivity to the drug or a fright (vasovagal) reaction. *The patient should always be in a supine, prone, or reclining position during the injection to minimize the effect of any vasovagal reaction.*

The obvious ways to prevent entering a blood vessel are an awareness of the local anatomy and aspiration after every 1 to 2 mL of solution are injected. Penetration into or striking a nerve may cause sharp pain or paresthesias, and the patient should be warned of this possibility in advance.

Corticosteroid injections have been found to be safe procedures with few complications (Table 53-5). [54] Although the possibility of introducing infection is one of the most serious potential complications, infections occurring as an aftermath of intrasynovial injections are extremely rare. In a study at the Mayo Clinic, no infections were reported for 3000 injections given in 1 year. [11] Others have found the infection risk to be 4.6 per 100,000 intra-articular injections. [55]

Although the problem of infection is usually avoided with meticulous attention to aseptic technique, the patient should be cautioned to report the development of any significant pain, redness, or swelling after any local injection. We do not recommend routine prophylactic antibiotic administration following corticosteroid injection.

Local undesirable reactions are usually minor and reversible. After steroid injection, about 2% of patients may experience an acute synovitis otherwise known as "post injection" flare. [10] [12] Characterized by an increase in pain and joint swelling, symptoms usually begin a few hours after steroid injection and can last as long as 3 days. Histologically, steroid

crystals within polymorphonuclear cells have been demonstrated, making them true synovitises. [10] This reaction may be difficult to differentiate from an infection, and infection must be ruled out if symptoms last greater than 48 hours or are associated with fever, warmth, or other suspicious signs of infection. The incidence of postinjection flare appears to be more likely with more soluble (shorter-acting) steroid solutions, and may be related to the carrier in which the steroid is manufactured. [8] [11] Usually, the reaction is mild and can be adequately controlled with application of ice or cold compresses and analgesics as needed.

Rarely following injections, "after pain" may occur up to several hours. Although the cause is obscure, this phenomenon may result from the trauma of needle insertion, penetration of inflamed tissue, or pressure on adjacent nerves from local swelling or bleeding. "After pain" is usually relieved by application of moist or dry heat and analgesics until the pain abates but is best prevented by mixing a long-acting anesthetic such as bupivacaine with the steroid preparation.

Occasional subcutaneous bleeding at the site of injection may occur with penetration of a venule, an arteriole, or a capillary. The patient should be warned that this may occur and should be reassured that the discoloration or hematoma will disappear spontaneously. Ice packs or cold compresses applied to the involved area for the first 24 hours are commonly advised.

Another relatively minor complication is localized subcutaneous or cutaneous atrophy at the site of the injection. [10] This problem is chiefly of cosmetic concern and is recognized as a small depression in the skin frequently associated with depigmentation, transparency, and occasionally the formation of telangiectasia. These

changes in the skin occur when injections are made near the surface and some of the injected steroid leaks back along the needle track. The skin depression usually recedes and the skin returns to normal with time, when the crystals of the steroid have been completely absorbed. These changes are usually evident 6 weeks to 3 months after the initial injection, and usually resolve within 6 months, although these changes can be permanent. [8] [10] The *two-syringe technique*, in which the anesthetic is first injected, the needle advanced to the bursa/peritendon area, and the syringe then exchanged for another in order to inject steroid, helps prevents this complication by avoiding any leaking of the steroid suspension to the skin surface. [12] A small amount of lidocaine or normal saline can be used to flush the needle of the suspension before removing it. The *Z-tract technique* is a method of creating an indirect route from puncture of skin to the ultimate site of steroid injection. [12] Using this method, the needle is introduced at a site 0.5 to 1.0 cm from the actual target site and is redirected when halfway through the fat tissue to the target site of injection. This is followed by injection of both anesthetic and corticosteroid. Injection site atrophy is more likely in preparations that are less soluble and thus longer-acting. [8]

One of the most serious complications following local steroid injection is tendon rupture. In general, the risk is very low (<1%) and appears to be dose-related. [8] [10] It is believed by some that steroids injected directly into the tendon lead to a decrease in the tendon tensile strength. [10] [11] [56] [57] However, Gray and coworkers noted no cases of tendon rupture after more than 300 tendon sheath injections. [10] We still advise being diligent about injection into the surrounding area of the tendon sheath and not into the tendon substance. Also, by using one size needle and syringe, the operator is more likely to appreciate the increase in resistance when injecting the needle directly into the tendon. We also suggest limiting the number of injections to no more than once every 3 to 4 months. [7] [8] [9] [10] Tendon rupture is especially more likely in major stress-bearing tendons, such as the Achilles tendon and the patellar tendons, in athletes. The injection of corticosteroids in these areas should be avoided. [12]

There have been reports of accidental nerve injury following corticosteroid injection, particularly of the ulnar nerve (in treating medial epicondylitis) and median nerve (in treating carpal tunnel syndrome). [22] Also, up to 42% of patients undergoing local steroid therapy develop pericapsular calcifications, although these are generally asymptomatic. [10] [12] Finally, within minutes to hours of injection, approximately 1% of patients may experience facial and neck flushing. This reaction may last a few days, but it is usually a benign and self-limited reaction. Facial flushing seems to be more common with triamcinolone preparations. [8] [10]

Systemic absorption of local corticosteroid injections does occur, although at a slower rate than with oral steroids. [9] As a result, patients are at a low risk for systemic complications, but they do occur. Specifically, intrasynovial injections of steroids have been shown to suppress the hypopituitary-adrenal axis for 2 to 7 days. [8] Corticosteroids can also exacerbate hyperglycemia in diabetes. [9] [12] Abnormal uterine bleeding has also been reported. [8] [9] [12]

CONCLUSION

Local injection therapy for painful nonarticular rheumatic disorders is a relatively simple, safe, and effective form of treatment. In association with other treatment measures, the patient may experience rapid relief of pain and swelling and on occasion may return to work and normal activity after a single injection. Additionally, steroid injections may allow the patient to participate more fully in a physical rehabilitation program. [7] Injection therapy may also avoid surgical intervention in some injuries.

The local introduction of a corticosteroid suspension is associated with side effects that should be considered with each patient. It is recommended that an injection should not be repeated more than once every 3 to 4 months, and injection about the Achilles and patellar tendons should be avoided. [7] [8] [9] [10] [12] However, local undesirable reactions are usually minor and reversible. In general, the injection of corticosteroids is a safe procedure with few complications. [54]

Chapter 54 - Arthrocentesis

Steven J. Parrillo
Jonathan Fisher

Arthrocentesis, the puncture and aspiration of a joint, is an acknowledged, useful procedure that is easily performed in the emergency department (ED). It has been established as both a diagnostic and a therapeutic tool for various clinical situations. Many clinicians are wary of joint fluid aspiration because of a lack of experience and because of the fear of introducing infection. When performed properly, however, the procedure offers a wealth of clinical information and is associated with few complications. In the ED it is difficult to make an accurate assessment of an acutely painful, hot, and swollen joint without performing arthrocentesis.

INDICATIONS AND CONTRAINDICATIONS

The indications for arthrocentesis include the following [1] :

1. Diagnosis of nontraumatic joint disease by synovial fluid analysis (septic joint or crystal-induced arthritis).
2. Diagnosis of ligamentous or bony injury by confirmation of the presence of blood in the joint. Arthrocentesis may be needed to differentiate a traumatic joint effusion from an inflammatory process.
3. Establishment of the existence of an intra-articular fracture by the presence of blood with fat globules in the joint.
4. Relief of the pain of an acute hemarthrosis or a tense effusion. Although a minor hemarthrosis need not be drained, arthrocentesis can reduce the pain associated with large effusions and examination of an injured joint.
5. Local instillation of medications in acute and chronic inflammatory arthritides. Instillation of lidocaine into an injured joint also makes the initial examination of a traumatic injury less painful.
6. Obtaining fluid for culture, Gram staining, immunologic studies, and cell count in cases of suspected joint infection.
7. Determining if a laceration communicates with the joint space.

Infection in the tissues overlying the site to be punctured (e.g., an abscess or a frank cellulitis) is generally considered an absolute contraindication to arthrocentesis. However, inflammation with warmth, swelling, and tenderness may overlie an acutely arthritic joint, and this condition may mimic a soft tissue infection. Once convinced that cellulitis does not exist, the clinician should not hesitate to obtain the necessary diagnostic joint fluid. Known bacteremia is a relative contraindication as a hematogenous spread of bacteria into the joint after arthrocentesis because, with or without hemorrhage, it may lead to infection.

Bleeding diatheses are rarely a relative contraindication, and arthrocentesis to relieve a tense hemarthrosis in bleeding disorders, such as hemophilia, is an accepted practice following infusion of the appropriate clotting factors. There is little data regarding the safety or dangers of arthrocentesis in a patient receiving anticoagulants or platelet inhibitors. One prospective trial of 32 patients on warfarin found no complications after arthrocentesis. [2] Hence, when necessary (e.g., to rule out infection), arthrocentesis should be performed in patients with a coagulopathy. The value of reversing a coagulopathy prior to the procedure with blood components is not proven, and clinical judgment should prevail. Prosthetic joints are at high risk for infection and arthrocentesis should be avoided whenever possible. However, if an infected prosthesis is suspected, arthrocentesis should be performed.

Articular versus Periarticular Disease

Periarticular diseases such as trauma, tendonitis, bursitis, contusion, cellulitis, or phlebitis may mimic articular disease and suggest the need for arthrocentesis. Therefore, administration of the correct therapy for acute joint disease requires that the clinician first determine whether the patient's constellation of signs and symptoms derives from the joint itself and not from some other musculoskeletal or periarticular structure. Such a distinction, however, may be difficult, if not impossible, to make. No specific test or physical finding has high specificity for solving this dilemma.

If swelling is secondary to joint effusion or inflammation, then the entire articular capsule will be inflamed and distended, and fluid can often be palpated within the joint. In the knee, this condition must be differentiated from effusion into the prepatellar bursa, where swelling distends the bursa that lies mainly over the lower portion of the patella, between it and the skin. Effusion into the joint occurs posterior to the patella, whereas bursal swelling occurs anterior to it (Fig. 54-1). When there is considerable articular effusion, the capsule of the joint is distended, and an inverted U-shaped swelling of the joint occurs. This characteristic shape occurs because the dense patellar ligament prevents distention of the capsule along its inferior border. Also, with the knee extended, a large effusion causes the patella to "float" or lift away from the femoral condyles. Complete extension and flexion are often impossible because of the joint tension produced by the effusion.

Joint effusion causes limited movement of the joint in all directions with active and passive motion producing pain. The pain arising from a pathologic condition involving a joint may be diffuse or clearly localized to the joint, or it may radiate. Hip pain, for example, frequently radiates into the groin or down the front of the thigh into the knee. Shoulder joint pain commonly radiates into the elbow or the neck. Therefore, complete examination of contiguous structures is essential for adequate diagnosis.

In contrast, pain from a periarticular process is often more localized, and tenderness can be elicited only with certain specific movements or at specific points around the joint. In periarticular inflammation, one can often passively lead a joint through a range of motion with minimal discomfort, yet pain is significant when the patient attempts active motion. Crepitus may be elicited in tendinitis, or the pain may be traced along the course of a specific tendon.

Septic Arthritis

Acute monoarticular arthritis is a common problem in emergency medicine. Although there are many causes of acute monoarticular arthritis, the one requiring most urgent diagnosis and treatment is septic arthritis. Infectious arthritis is still relatively frequent, and suspicion of a septic process in the

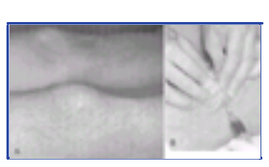

Figure 54-1 Periarticular problems may mimic an intra-articular process. *A*, This patient had trauma to the knee and presented with anterior soft tissue swelling and fluctuance, representing a hematoma of the prepatellar bursa. *B*, While an assistant (gloves should be worn) compresses the fluid, the bursa is aspirated of all blood.

joint is the first step in appropriate management; confirmation requires arthrocentesis and synovial fluid culture. Although repeated arthrocentesis may be needed when treating a septic joint, such therapy is usually performed on an inpatient basis.

Infection of a joint occurs by one of these mechanisms: 1) hematogenous spread, 2) spread from a contiguous source of infection, 3) direct implantation, or 4) postoperative contamination. The joint distribution of septic arthritis is typically monoarticular with a swollen, erythematous, and painful joint. The noninfectious differential diagnosis includes limited rheumatoid arthritis, gout, pseudogout, synovial osteochondromatosis, pigmented villonodular synovitis, and trauma. In many instances an acutely inflamed joint from gout or other arthritides simply cannot be clinically distinguished from infection. Early diagnosis is essential to prevent complications such as growth impairment, articular destruction with ankylosis, osteomyelitis, or soft tissue extension. [3]

Because an acutely swollen joint may be indicative of a number of disease entities, a thorough history and physical examination are the cornerstones of evaluation, followed by arthrocentesis (Fig. 54-2). Laboratory findings can be useful in diagnosis, as can response to therapy (e.g., response to penicillin in gonococcal arthritis is often the only criterion for diagnosis, as the organism is difficult to culture). Patients with malignancy (especially leukemia) or who are immunosuppressed or otherwise debilitated are at particular risk for a septic etiology. Infectious arthritis should be the first potential cause looked for in these patients, as well as in patients with such preexisting joint diseases as rheumatoid arthritis. In general, a swollen joint is usually not injected with corticosteroids until the possibility of infection has been eliminated. [4]

Neisseria gonorrhoeae, *Staphylococcus,* and *Streptococcus* are the most frequently identified etiologic agents. *N. gonorrhoeae* is the most common organism causing septic arthritis among adolescents and young adults. Patients older than 40 years and those with other medical illnesses are more likely to have *Staphylococcus* joint infections. In children, *Staphyloccus*, *Streptococcus, and Escherichia coli* predominate. *Haemophilus influenzae* was a common cause of septic arthritis in the past, but

widespread use of the conjugate vaccine has reduced *H. Influenzae* infection rates to near zero.[5] In neonates, *staphylococci, enterobacteriaceae*, *Group B Streptococcus*, and *N. gonorrhoeae* are the most likely organisms. Intravenous drug abusers commonly develop staphylococcal or *Pseudomonas* infections. *Salmonella* arthritis is seen in patients with sickle cell disease. Prosthetic joints or postoperative infections have high rates of *methicillin-resistant staph aureus*, *enterobacteriaceae*, and *Pseudomonas*.[6]

Although precise incidences for nongonococcal septic arthritis have not been established, predisposing factors have been described. These include chronic debilitating disease; prior antibiotic or immunosuppressive medications; a previous history of joint damage, such as from rheumatoid arthritis or degenerative joint disease; and prosthetic joints.[7] [8] [9] In a study by Sharp and coworkers, 22 of 113 patients (19%) with septic arthritis had other arthritides, the most common being rheumatoid arthritis.[3] Elderly patients with a debilitating arthritis and minor skin infections seem to be the most susceptible; the infection may be overlooked and the patient's findings thought to be an exacerbation of the rheumatoid arthritis. [10]

The simultaneous occurrence of gout and septic arthritis is possible, and one should not allow the establishment of a diagnosis of crystal-induced disease to stop a thorough search for infection.[11]

Because *N. gonorrhoeae* is the most common organism causing septic arthritis, gonococcal arthritis deserves special mention (Fig. 54-3). Disseminated gonococcal infection occurs in 0.5% to 3% of cases of mucosal infection. Gonococcal septic arthritis is more common in women, especially during pregnancy or after menstruation, because women are more likely to be asymptomatic. Time for local infection to disseminate can vary for several days to weeks. Patients will often experience systemic symptoms including fevers, chills, and malaise as well as migratory polyarthralgias. Tenosynovitis occurs in two thirds of patients. A dermatitis is also present in two thirds of patients (see Fig. 54-3). The most common rash is scattered painless, nonpruritic 0.5- to 0.75-cm macules or papules with necrotic or pustular centers distributed on the extremities and trunk. Eventually, the infection settles into one or two large joints, yielding a purulent arthritis. [12]

Whereas *N. gonorrhoeae*-infected joint fluid is usually "septic" in character, the yield of positive synovial fluid cultures has ranged from 25% to 50%. Blood cultures appear to be less helpful, being positive in only 20% to 30% of cases. However, cultures from the primary mucosal site are positive in up to 80% of infected patients.[12] A positive Gram stain is immediately diagnostic of septic arthritis. Gram staining is positive in only 65% of cases of septic arthritis, and therefore a negative Gram stain does not rule out an infectious process.

Figure 54-2 *A*, *B*, and *C*, Dramatic representation of tophaceous gout. These nodules are painless and full of uric acid crystals. An acutely swollen and painful joint in this patient is most likely acute gouty arthritis. *D*, This markedly swollen wrist is secondary to acute gouty arthritis. The patient had a fever and leukocytosis, and arthrocentesis with joint fluid analysis was the only way to differentiate gout from a septic joint.

A white blood cell (WBC) count and a synovial fluid glucose reduction may give confirmatory data. However, the synovial fluid WBC count in gonococcal arthritis is often <50,000 cells/mm^3 .[13] Although mild leukocytosis and elevated erythrocyte sedimentation rate (ESR) may occur, normal laboratory values do not exclude infection.[12] Counter-immunoelectrophoresis and latex agglutination have shown promise for early identification of infection. [14]

Hemarthrosis

Isolated nontraumatic hemarthrosis may occasionally be seen by the emergency clinician. An inflammatory reaction may follow an intracapsular bleed, and the proliferative reaction and the hyperplastic synovium formed may predispose the patient to recurrent hemorrhage in that joint, especially patients with bleeding diatheses. The knee is the most commonly affected joint (whether the cause is hemophilia or oral anticoagulants), followed by the foot and the ankle. [15]

The most common cause of intra-articular hemorrhage in the setting of no trauma or minor trauma is a hereditary clotting factor deficiency, as in hemophilia. Hemarthrosis is an infrequent complication of oral anticoagulant therapy but may occur even with prothrombin times within the normal range. [16] Chronic arthritis does not appear to be a long-term complication in patients with intra-articular bleeding from oral anticoagulant therapy. Hemarthrosis may also be a complication of sickle cell anemia, pseudogout, amyloidosis, pigmented villonodular synovitis, synovial hemangioma, rheumatoid arthritis, and infection. [15]

Management of acute hemarthrosis depends on the cause. Studies by Jaffer and Schmid and Wild and Zvaifler from the 1970s showed that the synovitis associated with oral anticoagulant therapy improves only after the oral anticoagulant is discontinued and the prothrombin time returns to normal. [16] [17] However, before stopping anticoagulation therapy, one must consider why the patient was anticoagulated, and weigh the risks and benefits of such a decision. Hemarthrosis following trauma is a frequent occurrence. It is most common in the knee and often denotes significant internal damage. A massively swollen knee after trauma is seen with knee dislocation (occasionally with spontaneous relocation) and a tear of the anterior cruciate ligament.

Distention of the joint by effusion or hemorrhage causes considerable pain and disability. If the exudate or the blood is not removed, it is partly absorbed, but part of it may undergo organization, resulting in formation of adhesions or bands in the joint. This is one argument for drainage of the joint. [18] Some believe that in an otherwise healthy joint that is subjected to a single traumatic event, even a relatively large hemarthrosis will be spontaneously reabsorbed without significant sequelae and therefore presents no pressing need to drain.[16] [17] Unfortunately, there is little literature to guide the best approach.

Figure 54-3 *A*, Skin lesions, ranging single or multiple petechiae to pustules may be seen in patients with acutely swollen joints infected with *Neisseria gonorrhoeae*. Skin lesions are usually found on the extremities, especially the feet and hands, and may be present before a large joint effusion accumulates, or with gonococcal tenosynovitis.

Nonetheless, a large, tense, traumatic effusion is quite painful, and its presence precludes proper evaluation of an injured joint. Therapeutic arthrocentesis to drain a symptomatic traumatic effusion is a well accepted practice.[19] The source of blood following trauma is frequently (1) a tear in a ligamentous structure, capsule, or synovium or (2) a fracture. Cruciate (especially anterior) ligament injury is the most common cause of significant hemarthrosis following trauma to the knee. [20] A joint effusion that develops 1 to 5 days following trauma may be secondary to a slow hemorrhage or a reinjury, but the swelling is often caused by a nonhemorrhagic irritative synovial effusion.

Occasionally one will diagnose an occult fracture by the presence of fat globules in the arthrocentesis blood. This may be appreciated when the bloody effusion is placed in a clear container (e.g., test tube or specimen jar) and held to the light. If the history of trauma is vague, arthrocentesis may be required to differentiate hemorrhage from other causes of joint effusion. Following therapeutic arthrocentesis for a hemarthrosis, it may be desirable to inject 2 to 15 mL of a local anesthetic, depending on joint size, into the joint to facilitate examination or provide temporary symptomatic relief. [19]

Intra-articular Corticosteroid Injections

In 1951 Hollander and coworkers first demonstrated that intra-articular corticosteroid injections were useful for symptomatic relief in patients with severe rheumatoid arthritis.[21] The use of steroids has proved to be a dependable method for providing rapid relief from pain and swelling of inflamed joints, although it is strictly local, usually temporary, and rarely curative.[22] [23] It is not commonly performed in the emergency setting.

Corticosteroid injections are most helpful when only a few of a patient's joints are actively inflamed. The most frequently used corticosteroids for intra-articular injection are shown in Table 54-1 .[24] Diminution of joint pain, swelling, effusion, and warmth is usually evident within 6 to 12 hours after injection.

Although very rare, the most serious complication of this practice is intra-articular infection. Therefore, steroids should not be injected into a joint if there is suspicion of a joint space infection. Repeated injections into one joint carry the risk of necrosis of juxta-articular bone with subsequent joint destruction and instability. Other complications include local soft tissue atrophy and calcification, tendon rupture, intra-articular bleeding, and transient nerve palsy. [23] Deposition of steroid crystals on the synovium may give rise to a transient, self-limited flare-up of a synovitis.[25]

It is always important to ascertain whether local corticosteroid therapy has been used previously, not only to consider the array of clinical conditions associated with steroid use, but also because crystalline corticosteroid material can hinder proper interpretation of crystals found in synovial fluid. [25]

TABLE 54-1 -- Intrasynovial Corticosteroid Preparations*

Preparation	Large-Joint Dose (mg)	Small-Joint Dose (mg)†
Triamcinolone hexacetonide	20	2–6
Triamcinolone acetonide	20	2–6
Prednisolone tebutate	25	2.5–7.5
Methylprednisolone acetate	40	3.5–10.5
Triamcinolone diacetate	20	2–6
Prednisolone acetate	30	3–9
Dexamethasone acetate	5	0.5–1.5

*Listed in approximate descending order of duration of action.
†Dose will depend on joint size, capsular distensibility, and degree of inflammation.

EQUIPMENT

Necessary materials for arthrocentesis include skin preparation solutions (usually povidone-iodine followed by alcohol), sterile gloves and drapes, local or topical anesthetics, a syringe, and various-sized needles (Table 54-2). Fluid for cell count should be collected in a lavender-topped tube with ethylenediaminetetraacetic acid (EDTA) anticoagulant; however, glucose and viscosity determinations do not require anticoagulants. Immediately examine fresh synovial fluid in its unadulterated form for crystals. Calcium oxalate and lithium heparin anticoagulants have been reported to introduce artifactual crystals into the fluid. Joint fluid to be analyzed for crystals should be collected in a green-topped tube containing sodium heparin. If culturing for *N. gonorrhoeae*, the fluid should be immediately placed on proper medium and stored in a low-oxygen environment in the ED.

GENERAL ARTHROCENTESIS TECHNIQUE

Joint fluid may be obtained even when there is little clinical evidence of an effusion. Although you may successfully

TABLE 54-2 -- Emergency Department Arthrocentesis Tray

Gloves
Surgical scrub or plain green soap
Povidone-iodine solution
Alcohol sponges
Sterile towel (with center perforation)
Vapor coolant (e.g., fluoromethane solution)
1% or 2% lidocaine
Sterile saline for injection
Sterile gauze dressings (2 in. × 2 in.)
Sterile syringes (2 mL, 10 mL, 20 mL) Luer-Lok
Needles (18, 20, 22, and 25 ga) or over-the-needle intravenous catheters
Hemostat
Three-way stopcock (optional)
Plastic adhesive bandages
Sterile basin
Plain test tubes
Test tubes with liquid anticoagulant
Microscope slides and coverslips
Clear nail polish (to seal coverslip over material)

aspirate where the joint bulges maximally, certain landmarks are important. The most crucial part of arthrocentesis is spending adequate time in defining the joint anatomy by palpating the bony landmarks as a guide. These are described in detail later in this chapter. A puncture site and an approach to the joint should be selected; tendons, major vessels, and major nerve branches should be avoided. In most instances, the approach is via the extensor surfaces of joints, because most major vessels and nerves are found in flexor surfaces. Also, the synovial pouch is usually more superficial on the extensor side of a joint. If available, the use of ultrasound to help guide needle placement can be very helpful in difficult cases. Ultrasound can also help locate small effusions (see Chapter 69).

Aseptic technique is essential to avoid infection. Only sterile instruments should be used. Arthrocentesis should not be attempted if the skin or subcutaneous tissue overlying the joint is infected. Sterile gloves should be worn for the remainder of the preparation. The skin is thoroughly scrubbed with a surgical scrub, such as povidone-iodine scrub, and the skin is painted with an iodinated solution, such as povidone-iodine (Betadine). This antiseptic solution should be allowed to dry for several minutes, because the bactericidal effects of iodine are both concentration- and time-dependent. The iodine solution is then removed with an alcohol sponge to prevent transference of iodine into the joint space with a resultant inflammatory process. Although the utility of draping is unproven, and may obscure the site, a sterile perforated drape may be placed over the joint.

With appropriate local anesthesia, arthrocentesis should be a relatively painless procedure; without anesthesia, it may be quite painful and distressing to the patient. The synovial membrane itself has pain fibers associated with blood vessels, and the articular capsule and bone periosteum are richly supplied with nerve fibers and are very sensitive. The articular cartilage has no intrinsic pain fibers. It is important to have the patient relax during the procedure. Tense muscles narrow the joint space and make the procedure more difficult, requiring repeated attempts at aspiration, or result in inadequate drainage. Distraction of the joint may enhance the target area, especially in areas such as the wrist and the finger joints. Traction not only increases the chance of entering the joint, it also lessens the chance of scoring the articular cartilage with the needle.

Anesthesia is best accomplished by infiltrating the skin down to the area of the joint capsule using a local anesthetic agent such as 1% or 2% lidocaine (Xylocaine) with a 25- to

27-ga needle. For extremely painful joints, a regional nerve block before the procedure (see Chapter 32) is often greatly appreciated by the patient.

The landmarks described under Specific Arthrocentesis Techniques later in this chapter should be used, and care should be taken not to bounce the needle off bony structures as a means of finding the joint space, because this may damage the cartilage. [13] An 18- to 22-ga needle or intravenous (IV) catheter and needle set of appropriate length attached to a syringe is inserted at the desired anatomic point through the skin and subcutaneous tissue into the joint space. The largest needle that is practical is used to avoid obstructing the lumen with debris or clot. In large joints such as the knee, which can accommodate large effusions, it is suggested that one use a 30- to 60-mL syringe, because it may be difficult to change a syringe when the needle is within the joint cavity (Fig. 54-4). A three-way stopcock placed between the needle and syringe is an option for draining large effusions. If the syringe must be changed during the procedure, the hub of the needle should be grasped with a hemostat and held tightly while the syringe is removed. If an IV catheter and needle set is used, the needle is removed, leaving the outer atraumatic plastic catheter in the joint space. The syringe is then attached to the catheter for aspiration. Now manipulation of the joint or catheter can occur with little threat of tissue injury.

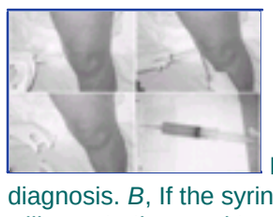

Figure 54-4 *A*, A chronic miniscus tear can produce a large effusion of clear yellow fluid. The miniscus has no blood supply, and a hemarthrosis suggests another or additional diagnosis. *B*, If the syringe is too small to accommodate all of the fluid, grasp the needle hub with a hemostat and remove the syringe without disturbing the correct position of the needle. A stopcock will negate the need to change the syringe. *C*, With the needle still held in place, use another syringe to instill a steroid when the aspirate is a clear yellow. *D*, Cloudy fluid such as this is from an inflammatory source, such as gout or a septic joint. Intra-articular steroids should not be administered in the setting of a cloudy aspirate.

Aspiration of synovial fluid and the easy injection and return of fluid indicate intra-articular placement of the needle tip. As a general rule, *one should try to remove as much fluid or blood as possible*. If the fluid stops flowing, this is a sign that the joint has been drained completely, the needle tip has become dislodged, or debris or clot is obstructing the needle. One should slightly advance or retract the tip of the needle, rotate the bevel, or ease up on the force of aspiration. Occasionally,

reinjecting a small amount of fluid back into the joint space confirms the needle placement and may clear the needle. If fluid flows freely back into the joint and is easily reaspirated, one has probably removed all the fluid. If resistance is met, the needle has probably been jarred from the joint space and is lodged in the soft tissue. In some instances, minor position changes produced by flexion or extension of the joint may allow the fluid to flow more freely. Scraping or shearing the articular cartilage with the needle should be avoided, since this may produce permanent cartilage damage. One should enter the joint in a straight line and avoid unnecessary side-to-side motion of the syringe. After aspiration is complete, the needle is removed, and a sterile dressing is applied over the puncture site.

Synovial fluid should be sent for studies as indicated by the clinical situation. Studies usually obtained include cell count with differential, crystal analysis, Gram staining,

---

bacterial culture and sensitivity analysis, and synovial fluid glucose measurement. Less frequently obtained studies include synovial fluid protein measurement, rheumatoid factor analysis, lupus erythematosus (LE) cell preparation, viscosity analysis, mucin clot, fibrin clot, fungal and acid-fast stains, lyme titer, fungal and tuberculous culture, and synovial fluid complement analysis. If the arthrocentesis is performed for the relief of a hemarthrosis, the fluid need not be sent for analysis. One should be selective in ordering tests. There is no need to order a large battery of tests routinely on all fluids. If the volume of fluid collected is low, culture and examination of the "wet prep" under regular and polarizing microscopy have the highest priority. To avoid misdiagnosing borderline inflammatory fluids, missing crystals that dissolve with time, or overinterpreting the findings because of new artifactual crystals that appear over a prolonged time, prompt examination of synovial fluid specimens should be performed.[26]

COMPLICATIONS

Significant complications are rare with arthrocentesis and include the following:

1. *Infection.* Skin bacteria may be introduced into the joint space during needle puncture. This is a rare occurrence. One can, of course, limit this complication by maintaining rigorous sterile technique and avoiding inserting the needle through obviously infected skin or subcutaneous tissue. The chance of introducing infection with arthrocentesis through a noninfected area is very minimal if proper attention is paid to technique. Various studies report the incidence of infection following routine arthrocentesis to be in the range of 1 per 10,000 aspirations. [27] Joint aspiration in the presence of a bacteremia has been discussed previously.
2. *Bleeding.* Bleeding with subsequent hemarthrosis is rarely a complication, except in the patient with a bleeding diathesis. If a patient has a bleeding diathesis, such as hemophilia, arthrocentesis should be delayed until clotting competence has been enhanced by the infusion of specific clotting factors. Occasionally, a small quantity of blood may be aspirated along with the synovial fluid. This happens most often when the joint is nearly emptied. A small amount of blood-tinged fluid is generally the result of nicking a small synovial blood vessel; this is usually inconsequential. A grossly bloody effusion must be investigated. [4]
3. *Allergic reaction.* Hypersensitivity to the local anesthetic that is used can usually be prevented by thorough history taking. Fainting during the procedure is not uncommon and is most often the result of vasovagal influences.
4. *Corticosteroid-induced complications.* See Intra-articular Corticosteroid Injections earlier in this chapter.

SPECIFIC ARTHROCENTESIS TECHNIQUES

Arthrocentesis of the hip is generally performed by an orthopedic surgeon under fluoroscopic guidance and will not be discussed here. If available, fluoroscopy or ultrasound can also be used to guide aspiration of other joints, but these imaging adjuncts are generally not required.

First Carpometacarpal Joint (Fig. 54-5)

Landmarks.

The radial aspect of the proximal end of the first metacarpal is the arthrocentesis landmark for this joint. The abductor pollicis longus tendon is located by active extension of the tendon.

Position.

The thumb is opposed against the little finger so that the proximal end of the first metacarpal is palpable. Traction is applied to the thumb in order to widen the joint space between the first metacarpal and the greater multangular bone.

Needle insertion.

A 22- to 23-ga needle is inserted at a point proximal to the prominence at the base of the first metacarpal, on the palmar side of the abductor pollicis longus tendon.

Comments.

Degenerative arthritis commonly affects this joint. Arthrocentesis is of moderate difficulty. The anatomic "snuff box" (located more proximally and on the dorsal side of the abductor pollicis longus tendon) should be avoided, because it contains the radial artery and superficial radial nerve. A more dorsal approach may also be used.

Interphalangeal and Metacarpophalangeal Joints (Fig. 54-6)

Landmarks.

The landmarks are on the dorsal surface—the prominence at the proximal end of the proximal phalanx for metacarpophalangeal joints and the prominence at the proximal end of the middle or distal phalanx for interphalangeal joints. The extensor tendon runs down the midline.

Position.

The fingers are flexed to approximately 15°–20° and traction is applied.

Needle insertion.

A 22- to 25-ga needle is inserted into the joint space dorsally, just medial or lateral to the central slip of the extensor tendon.

Comments.

Synovitis causes these joints to bulge dorsally. Normally, it is unusual to obtain fluid in the absence of a significant pathologic condition.

Radiocarpal Joint (Wrist) (Fig. 54-7)

Landmarks.

The dorsal radial tubercle (Lister tubercle) is an elevation found in the center of the dorsal aspect of the distal end of the radius. The extensor pollicis longus tendon runs in a groove on the radial side of the tubercle. The tendon can be palpated by active extension of the wrist and thumb.

Figure 54-5 Landmarks for arthrocentesis of first carpometacarpal joint (see text). *(From Akins CM: Aspiration and injection of joints, bursae, and tendons. In Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

Figure 54-6 Landmarks for arthrocentesis of interphalangeal and metacarpophalangeal joints (see text). *(From Akins CM: Aspiration and injection of joints, bursae, and tendons. In Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

Position.

The wrist should be positioned in approximately 20°–30° of flexion and accompanying ulnar deviation. Traction is applied to the hand.

Needle insertion.

A 22-ga needle is inserted dorsally, just distal to the dorsal tubercle and on the ulnar side of the extensor pollicis longus tendon. The anatomic snuff box, located more radially, should be avoided.

Radiohumeral Joint (Elbow) (Fig. 54-8)

Landmarks.

The lateral epicondyle of the humerus and the head of the radius are the arthrocentesis landmarks for the radiohumeral joint. With the elbow extended, the depression between the radial head and the lateral epicondyle of the humerus is palpated.

Position.

With the palpating finger still touching the radial head, the elbow is flexed to 90°. The forearm is pronated, and the palm is placed down flat on a table.

Needle insertion.

A 22-ga needle is inserted from the lateral aspect just distal to the lateral epicondyle and is directed medially.

Comments.

Elevation of the anterior fat pad, or the presence of a posterior fat pad, on a lateral soft tissue elbow

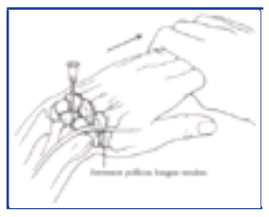

Figure 54-7 Landmarks for arthrocentesis of the radiocarpal joint (see text). Traction is applied with slight flexion. Contrary to the figure, *no* radial deviation is applied. *(From Akins CM: Aspiration and injection of joints, bursae, and tendons. In Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

radiograph signifies blood, pus, or fluid in the elbow joint (see Fig. 54-8*A*). Effusions in the elbow joint may bulge and be readily palpated (see Fig. 54-8*C*). Often the effusion appears inferior to the lateral epicondyle. The bulge can then be aspirated from a posterior approach on the lateral side (see Fig. 54-8*D*). A medial approach is not recommended, because the ulnar nerve and the superior ulnar collateral artery may be damaged. This is a common joint for gout or septic arthritis. The most common cause of an elbow hemarthrosis following trauma, with no obvious fracture, is a nondisplaced radial head fracture. A small hemarthrosis need not be aspirated, but removal of blood from a tense elbow joint will significantly hasten recovery and facilitate range of motion in patients with a radial head fracture.

Glenohumeral Joint (Shoulder), Anterior Approach (Fig. 54-9)

Landmarks.

The coracoid process medially and the proximal humerus laterally are palpated anteriorly.

Position.

The patient should sit upright with the arm at the side and his or her hand in the lap.

Needle insertion.

A 20-ga needle is inserted at a point inferior and lateral to the coracoid process and is directed posteriorly toward the glenoid rim.

Comments.

Arthrocentesis of this joint is of moderate difficulty. Other approaches have been suggested but are less well accepted. Ultrasound guidance may be helpful.

Knee Joint, Anteromedial Approach (Fig. 54-10*A*)

Landmarks.

The medial surface of the patella at the middle or superior portion of the patella is the landmark for the knee joint.

Position.

It is usually recommended that the knee be fully extended as far as possible. Alternatively, some practitioners prefer to flex the knee 15°–20° by placing a towel under the popliteal region in order to open up the joint space. Relaxation of the quadriceps muscle greatly facilitates needle placement. The foot is kept perpendicular to the floor.

Needle insertion.

An 18-ga needle or catheter and needle set is inserted at the midpoint or superior portion of the patella approximately 1 cm medial to the anteromedial patellar edge. The needle is directed between the posterior surface of the patella and the intercondylar femoral notch. The patella may be grasped with the hand and elevated to aid needle entry into the joint.

Comments.

If the patient is tense, contraction of the quadriceps will greatly hinder entering the joint. However, the knee is probably the easiest joint to enter and removal of a tense hemarthrosis will relieve pain and facilitate examination for ligamentous injury. If fluid stops flowing, the operator or assistant should squeeze the soft tissue area of the suprapatellar region to "milk" the suprapatellar pouch of fluid (see Fig. 54-10*B*). Alternatively, the patient's thigh can be wrapped with a 6-in elastic bandage from the groin to the suprapatellar area prior to beginning the procedure. The knee can easily accommodate 50 to 70 mL of fluid, and the clinician should therefore use a large syringe or be prepared to change syringes during the procedure, or both. Holding/securing the hub of the needle with a hemostat allows the clinician to remove the syringe without changing the position of the

Figure 54-8 *A*, On a lateral elbow radiograph, displacement of the anterior fat pad (arrows) or the presence of a posterior fat pad (arrows) indicate blood, pus, or fluid in the joint. *B*, Landmarks for arthrocentesis of the radiohumeral joint (see text). *(From Akins CM: Aspiration and injection of joints, bursae, and tendons. In Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.) C*, An effusion in the elbow joint can usually be readily palpated. The index finger is placed over the lateral epicondyle

and slid posteriorly toward the olecranon. Usually a depression is felt as the finger leaves the epicondyle, but a bulge is appreciated if there is a joint effusion. *D*, Removal of only a few milliliters of blood will reduce pain and hasten recovery of the range of motion. The most common pathology following trauma with an x-ray negative for fracture, but positive for a hemarthosis, is a nondisplaced radial head fracture.

intra-articular needle. Alternatively, a stopcock on the needle will allow for complete removal of fluid without changing the position of the needle. The knee is a common site for septic arthritis (especially gonococcal) and various inflammatory or degenerative diseases. An anterolateral approach can be accomplished in a similar manner if the patella is approached laterally.

Tibiotalar Joint (Ankle) (Fig. 54-11)

Landmarks.

The medial malleolar sulcus is bordered medially by the medial malleolus and laterally by the anterior tibial tendon. The tendon can be easily identified by active dorsiflexion of the foot.

Position.

With the patient lying supine on the table, the foot is plantar flexed.

Needle insertion.

A 20- to 22-ga needle is inserted at a point just medial to the anterior tibial tendon and directed into the hollow at the anterior edge of the medial malleolus. The needle must be inserted 2 to 3 cm to penetrate the joint space.

Comments.

If the joint bulges medially, one may use an approach that is more medial than anterior, entering at a point just anterior to the medial malleolus. The needle may have to be advanced 2 to 4 cm with this approach.

Metatarsophalangeal and Interphalangeal Joints (Fig. 54-12)

Landmarks.

For the first digit, landmarks are the distal metatarsal head and the proximal base of the first phalanx. For the other toes, the landmarks are the prominences at the proximal interphalangeal and distal interphalangeal joints. The extensor tendon of the great toe can be located by active extension of the toe.

Position.

With the patient supine on the table, the toes should be flexed 15°–20°. *Traction is then applied.*

Needle insertion.

A 22-ga needle is inserted on the dorsal surface at a point just medial or lateral to the central slip of the extensor tendon.

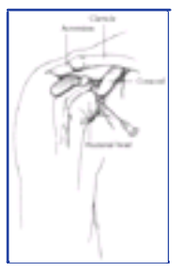

Figure 54-9 Landmarks for arthrocentesis of glenohumeral joint (see text). *(From Akins CM: Aspiration and injection of joints, bursae, and tendons. In Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

SYNOVIAL FLUID INTERPRETATION

Synovial fluid examination is essential for the diagnosis of septic arthritis, gout, and pseudogout. Inflammatory joint disease of previously unknown etiology can often be diagnosed

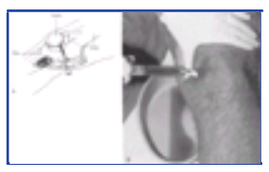

Figure 54-10 *A*, Landmarks for arthrocentesis of the knee joint, medial approach (see text). *B*, Note the use of a stopcock on the syringe to allow complete drainage without repositioning the needle. Compression of the suprapatellar region by the operator or an assistant will facilitate complete aspiration. For the knee, a 60 mL syringe should be used to drain large effusions. *(From Akins CM: Aspiration and injection of joints, bursae, and tendons. In Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

precisely by synovial fluid studies. Joint fluid is a dialysate of plasma that contains protein and hyaluronic acid. Normal fluid is clear enough to allow newsprint to be read through it, and it will not clot. Normal fluid is straw-colored and flows freely, with the consistency of machine oil. Normal fluid produces a good mucin clot and gives a positive "string sign" (see next section). The uric acid level of joint fluid approaches that of serum, and the glucose concentration is normally at least 80% that of serum. A normal joint contains only a few milliliters of fluid. Clarity of fluid reflects the leukocyte count. High leukocyte counts result in opacity, the degree of which generally correlates with the degree of elevated synovial fluid leukocytes.

String Sign

Viscosity correlates with the concentration of hyaluronate in the synovial fluid. Any inflammation degrades hyaluronate, characteristically resulting in low-viscosity synovial fluids. The string sign is a simple test for assessing viscosity. The practitioner measures the length of the "string" formed by a falling drop extruded from a syringe of synovial fluid. Normal joint fluid produces a string of 5 to 10 cm (Fig. 54-13). If viscosity is reduced, as in inflammatory conditions, the synovial fluid forms a shorter string or falls in drops.

Mucin Clot Test

The mucin clot test also corresponds to viscosity and inflammation. The greater the inflammatory response, the poorer the mucin clot and the lower the viscosity. The mucin clot test is rarely performed in emergency medical practice, and it is

Figure 54-11 Landmarks for arthrocentesis of the tibiotalar joint (see text). *(From Akins CM: Aspiration and injection of joints, bursae, and tendons. In Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

mentioned for completeness. This test may be useful to define the degree of polymerization of hyaluronate. Mucin clots are produced by mixing 1 part joint fluid with 4 parts 2% acetic acid. A good clot indicates a high degree of polymerization and correlates with normal high viscosity. In inflammatory synovial fluid, such as that seen in osteoarthritis and rheumatoid arthritis-related effusions, the mucin clot is poor. Many do not consider this test diagnostically useful. [28]

Cell Count and Glucose

A leukocytosis consisting predominantly of neutrophils is usually seen with inflammatory arthritides; a WBC count >50,000/mm ^{3} (i.e., >50,000/muL) is highly suggestive of a

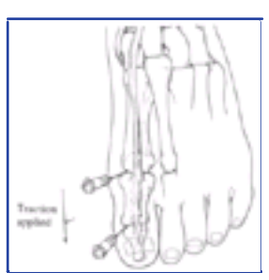

Figure 54-12 Landmarks for metatarsophalangeal and interphalangeal joints (see text). *(From Akins CM: Aspiration and injection of joints, bursae, and tendons. In Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

Figure 54-13 *A*, Ability of normal synovial fluid to form a long tenacious string. (Note: Gloves should be worn during procedure.) *B*, Bloody joint fluid from recent trauma forms a normal string sign.

septic joint. Joint fluid glucose usually decreases as inflammation increases, but a proper interpretation requires a simultaneous blood glucose evaluation. A joint fluid-to-serum glucose ratio of less than 50% suggests a septic joint. Shmerling and coworkers have found a WBC count of >2000/mm ^{3} to be 84% sensitive and 84% specific for *all* inflammatory arthritides. Of their septic arthritis patients, 37% had a total WBC count <50,000/mm ^{3} . However, 89% of their patients with a total WBC count >50,000/mm^3 had a septic joint.[29]

Serology

Although available, most of the serological tests are not likely to be useful in the emergency setting. The detection of

TABLE 54-3 -- Synovial Fluid Interpretation

Diagnosis	Appearance	WBCs/mm^3	Polymorphonuclear Leukocytes	Glucose: % Blood Level	Crystals Under Polarized Light	Culture
Normal	Clear	<200	<25	95–100	None	Negative
Degenerative joint disease	Clear	<4000	<25	95–100	None	Negative
Traumatic arthritis	Straw-colored, bloody, xanthochromic, occasionally with fat droplets	<4000	<25	95–100	None	Negative
Acute gout	Turbid	2000–50,000	>75	80–100	Negative birefringence;* needle-like crystals	Negative†
Pseudogout	Turbid	2000–50,000	>75	80–100	Positive birefringence;* rhomboid crystals	Negative
Septic arthritis	Purulent/turbid	5000–>50,000	>75	<50	None	Positive (usually)
Rheumatoid arthritis/seronegative arthritis (Reiter disease, psoriatic arthritis, ankylosing spondylitis, inflammatory bowel disease)	Turbid	2000–50,000	50–75	~75	None	Negative†

WBC, White blood cell.

*Negative birefringence means that crystals appear yellow when lying parallel to the axis of the slow vibration of light of the first-order red compensator. With the same orientation to the compensator, positive birefringence crystals appear blue. When the crystals lie perpendicular to the axis, the opposite is true—that is, negative birefringence crystals are blue, and positive ones are yellow. A polarizing microscope is necessary for this distinction to be made.
†May be coexisting infection.

succinic acid is helpful in identifying patients with septic arthritis who have received antibiotic treatment before arthrocentesis. [30] Gas-liquid chromatography, a rapid and sensitive method for the detection of short-chain fatty acids, may complement the currently available methods used to diagnose septic arthritis of synovial fluid. [31]

Counterimmunoelectrophoresis and latex agglutination also are useful and are available in some centers on an emergency basis. Other immunologic markers such as complement, rheumatoid factor, and antinuclear antibodies have little diagnostic value in the acute setting but may be useful to the clinician providing follow-up care when compared to serum levels.

Fluid Processing

Proper collection of the joint fluid is essential for examination and testing. Tests for viscosity, serology, and chemistries are done on fluid collected in a red-topped (clot) tube, whereas cytology samples are collected in tubes with an anticoagulant (purple top). One should always transfer the fluid for crystal examination into a tube with liquid heparin (green top), because undissolved heparin crystals from powdered anticoagulant tubes can be seen on microscopy. Early transfer of synovial fluid to this green-topped tube is essential to prevent clotting. Culture requirements for transport and processing should be accessed before the procedure to ensure appropriate processing or plating of specimens. A useful data form and summary of specimens developed by Alexander Trott, MD, of the University of Cincinnati is shown in Figure 54-14 .

Polarizing Microscope

No synovial fluid analysis is complete until the fluid has been examined under a polarizing light microscope for crystals. The polarizing microscope used for crystal identification differs from the ordinary light microscope because it contains two identical polarizing prisms or filters. One filter, called the *polarizer,* is positioned below the condenser. The other filter is called the *analyzer* and is inserted at some point above the objective. A detailed discussion of the technique is beyond the scope of this textbook and is described elsewhere. [32] [33] The procedure is generally performed by trained laboratory personnel.

Polarization Physics

The polarizer allows passage of light in only one specific orientation. The analyzer acts as a crossed filter, removing all light in the light path unless the material being examined rotates the beam from the polarizer into the plane of the analyzer. The compensator functions by imparting color of a certain wavelength (red at about 550 nm). Birefringent materials change the wavelength to blue or yellow, depending on the direction (negative or positive) of refringence.

Microscopic Analysis

When examining crystals under polarized microscopy, the technician orients crystals on a stage according to 2 axes referred to as X and Z. If the long axis of the crystals is blue when parallel to the Z axis and yellow when perpendicular to it, it is calcium pyrophosphate and is termed *positively birefringent*. If the long axis of the crystal is yellow when parallel to the Z axis and blue when perpendicular to it, it is monosodium urate and is termed *negatively birefringent*. Urate crystals are 2 to 10 µm and are usually needle-shaped. Calcium pyrophosphate crystals range from 10 µm down to tiny crystals that have to be examined with the oil objective; they appear as rods, rhomboids, plates, or needle-like forms and are weakly birefringent. Cholesterol crystals are sometimes seen and are large, very bright, square, or rectangular plates with broken corners. [32]

Items found in synovial fluid that can be confused with sodium urate (Fig. 54-15) or calcium pyrophosphate crystals (Fig. 54-16) include collagen fibrils, cartilage fragments (Fig. 54-17), cholesterol crystals (Fig. 54-18), metallic fragments from prosthetic arthroplasty, and corticosteroid esters. [31] One may also identify fat globules (Fig. 54-19 *A* and *B*). Note that rare cases of uric acid spherulites in gouty synovia have been reported. [34] The spherulites are birefringent and do not take up fat stains.

Table 54-3 summarizes synovial fluid features for the joint diseases commonly encountered and studies commonly performed in the ED.

CONCLUSION

When performed correctly, arthrocentesis is a relatively safe procedure that is used to obtain valuable diagnostic information as well as to provide therapy for acute joint disease. The key to success is strict adherence to sterile technique, observance of anatomic landmarks, and proper preparation of the synovial fluid for examination.

Chapter 55 - Compartment Syndrome Evaluation

Neal R. Frankel
L. Albert Villarin Jr.

Compartment syndrome, a condition of increased pressure within a limited space, results in compromised tissue perfusion and ultimate dysfunction of neural and muscular structures contained within that space.[1] Clinical hallmarks include burning, deep-seated pain, worsening of the pain with passive stretch of the involved muscles, paresthesias in the distribution of the involved nerves, paresis or paralysis of the involved limb, and palpable tenseness of the involved compartment. It should be stressed that severe pain, *out of proportion to the injury, may be the only early symptom of acute compartment syndrome* .[2] When pain is the only symptom, however, this diagnosis may be impossible to make on clinical grounds. Several theories have been proposed to account for the tissue ischemia associated with compartment syndrome. These include the "arteriovenous gradient,"[3] "critical closure,"[4] and "venous occlusion"[5] theories. The central theme in each of these is a significant rise in intracompartmental pressure, which results in reduced blood flow and muscle perfusion to a level below the metabolic demands of the tissue. The relationship between intracompartmental pressure and general circulatory status is one of the most important factors in the development of a compartment syndrome. Knowledge of this relationship is very important in determining the appropriate time to perform decompressive fasciotomy.[2] A high index of suspicion should be maintained, especially in the multi-trauma patient or obtunded patient, since prompt recognition and treatment are essential for optimal outcome.

Although compartment syndrome is relatively uncommon, recognition of this process has increased with greater clinician awareness of its clinical features. The lower leg and forearm are the most frequent locations of compartment syndrome; however, gluteal, hand, foot, upper arm, thigh, and back compartment syndromes are not uncommon.[1] Causes of compartment syndrome have been categorized into those that decrease compartment volume, increase compartment content, or create externally applied pressure.[1] If left untreated, compartment syndrome may result in permanent neurologic-muscular dysfunction and extremity deformity or lead to shock or renal failure if myonecrosis is extensive.[6]

The differential diagnosis of compartment syndrome includes neuropraxia, reflex sympathetic dystrophy (RSD), arterial injury, cellulitis, osteomyelitis, tenosynovitis, synovitis, and thrombophlebitis. Nerve and arterial injury may coexist with compartment syndrome. Differentiating compartment syndrome from these disease processes may be difficult even for the experienced clinician. Although compartment syndrome is a clinical diagnosis, objective measurement of compartment tissue pressure may help confirm the diagnosis and determine if operative treatment is required. This chapter discusses the indications, complications, and interpretation of compartment pressure monitoring. The equipment and techniques required to perform compartment pressure monitoring are described.

BACKGROUND

Postischemic myoneural dysfunction and contractures were first described in the 1870s by Von Volkmann. [7] In 1935, Henderson and associates developed an open-needle technique for measuring muscle "tonus." [8] Their method consisted of the three-way connection of a syringe, a manometer, and a needle placed into the muscle itself. In the 1960s, the technique was applied to muscle compartment pressure measurement. In 1975, Whitesides and colleagues refined the technique and described its ability to accurately reflect muscle compartment pressures. [9] They also related elevated pressures to a need for fasciotomy to relieve a compartment syndrome.

In an effort to improve the accuracy and reproducibility of intermittent pressure measurements, Matsen and coworkers modified the "simple needle" technique to include a constant infusion pump that allowed for prolonged, continuous monitoring. [10] While this proved more accurate than intermittent measurements, concerns were raised over injecting more fluid into an already compromised compartment. As a result, new methods were developed to continuously measure intracompartmental pressure without the risk of further pressures increases. One method used a biodegradable "wick" catheter attached to an extracorporeal transducer. [11] [12] Despite demonstrated accuracy, [12] [13] fears of catheter breakdown leading to measurement errors and retained foreign bodies resulted in development of the "slit" catheter. [14] Accuracy and reproducibility of the wick catheter and slit catheter have been similar. [13] [15] In the mid-1980s, a solid-state transducer intracompartmental (STIC) catheter was developed. This device, produced by Millar Instruments (Houston, TX), does not require saline-filled tubing to transmit the compartment pressure to an external transducer. [16] The Stryker intracompartmental pressure monitoring system (Kalamazoo, MI) is currently the most widely recognized solid-state handheld device used for temporary or continuous compartment pressure monitoring (Fig. 55-1). Arterial line transducer monitoring systems have also been used for acute monitoring of compartment pressure, although no study has been conducted to support the accuracy of this technique.

Noninfusion systems like the transducer-tipped fiberoptic system offer a distinct advantage over the conventional fluid-filled systems since they do not produce hydrostatic pressure

Figure 55-1 The Stryker 295 intracompartmental pressure monitor system. *(Courtesy of Stryker Instruments, Kalamazoo, MI.)*

artifacts or require injections of fluid for long-term measurement. However, the fiberoptic transducer is relatively large and must be attached to an intracath sheath (2.1 mm outer diameter), which may cause patient discomfort during compartment pressure measurement. [17] In the late 1990s the HANDY (Mammendorfer Institute for Physics and Medicine LTD. Munich, Germany), a noninfusion electronic transducer-tipped catheter system, was introduced. This system consists of a reusable probe attached to a separate portable, battery-powered handheld device (Fig. 55-2). The electronic transducer-tipped catheter system is self-calibrating, and except for sterilization of the reusable probe, requires minimal setup and maintenance. One study has shown that this system accurately measures intramuscular pressure and can be used for both acute and long-term monitoring. [17]

Development of miniature transducer-tipped catheters and noninvasive techniques are ongoing. Until recently, noninvasive technologies like near-infrared spectroscopy and magnetic resonance imaging have mainly been used for the diagnosis of chronic compartment syndrome. [18] [19] [20] Further investigation will determine the utility of these non-invasive technologies as diagnostic tools for acute compartment syndrome.

PATHOPHYSIOLOGY OF COMPARTMENT SYNDROME

Whitesides and Heckman report that the most common cause of compartment syndrome is muscle injury edema, which is usually proportional to tissue damage. [2] Because the extremities are composed of relatively nonyielding fascial compartments, circulatory impedance ultimately occurs as tissue pressure rises. [2] A "vicious cycle" involving hydrostatic and osmotic forces ensues. When vascular perfusion falls below the metabolic demands of the tissue, cellular disruption creates more interstitial edema, increasing compartment pressure and leading to progressive ischemia. [21] Other factors, such as associated hematoma formation (with or without fracture), which can occur at the time of injury, may further exacerbate an early or existing compartment syndrome. Coagulopathies may also aggravate an existing compartment syndrome and may require different approaches to treatment.[22]

Pressure studies clearly show a linear relationship between increased tissue pressure and decreased blood flow [1] ; however, the complex relationship between systemic and venous pressures is not completely understood and how capillary blood flow ultimately becomes compromised depends on a number of clinical variables.[23]

Heppenstall and colleagues used MRI analysis of muscle cell phosphorus metabolism to confirm the relationship between perfusion pressure and cellular ischemia. [24] That investigation was followed by another study comparing muscle tolerance to ischemia induced by tourniquet application to ischemia caused by acute high-pressure compartment syndrome.[25] This comparative study was initiated because previous discussions of ischemic injury in compartment syndrome frequently used the tourniquet technique as a pathophysiologic reference. However, there was no evidence that ischemia was the *only* cause of muscle injury in the acute compartment syndrome.[26] It was noted that during ischemia, cellular levels of phosphocreatine decreased equally between both groups. In contrast, the levels of adenosine triphosphate (ATP) diminished rapidly in the compartment syndrome group alone. Moreover, phosphocreatine, ATP, and pH normalized within 15 minutes of releasing the tourniquet, whereas these values remained depressed for a significant period of time, even after fasciotomy, in the compartment syndrome group. These results indicate that elevated tissue pressure acts synergistically with ischemia to produce more severe cellular deterioration than ischemia alone. [26]

Early in compartment syndrome, the dysfunction may be reversible if conditions are improved. Some evidence shows that skeletal muscle at body temperature can survive for as long as 4 hours without irreversible damage, whereas complete irreversible changes occur with total ischemia of 8 hours. [27] [28] Other investigators, however, have noted that muscle necrosis may occur as early as 2 hours post trauma.[29] This observation is important since *even the most expeditious diagnosis may not always result in a positive outcome.* Variable results occurred after 6 hours. Peripheral nerves experience similar susceptibility to ischemia but, while dose-responsive relationship effects have been observed in some studies, the critical values for pressure and duration with respect to nerve injury are unknown. [30] Interestingly, a study done on healthy volunteers that measured nerve function with carpal tunnel compression found the critical extraneural value above which nerve function was blocked was pressure 30 mm Hg below diastolic pressure. [31]

Although lowering or raising the systemic blood pressure may affect the level of direct compartment pressure that results in ischemic compromise, two points are stressed: (1) tissue that has been damaged by injury is more sensitive to ischemia and, therefore, the threshold for definitive intervention is lessened and (2) in severely traumatized limbs or clinical instances where the diagnosis is clear-cut, fasciotomy may be justified regardless of the tissue pressures documented. [2] [26]

CLINICAL PRESENTATION

Even experienced clinicians find it difficult to evaluate a potential compartment syndrome, and no specific standard of

care exists with regard to a time interval from injury to definitive treatment. In the unconscious patient, or for those with other life-threatening conditions that mandate other priorities, the clinical scenario simply does not allow for a diagnosis to be made in a timely fashion. In the nontrauma case, or for the patient unable to voice pain or cooperate with an examination, this diagnosis is often not considered, or the diagnosis is delayed. Delays in diagnosis occur because the time of onset is extremely variable and because of other clinical variables (especially altered mental status and the absence of known trauma). Matsen and Clawson have found the onset of symptoms to range from 2 hours to as long as 6 days after the insult.[32] The peak time seems to be 15 to 30 hours (Fig. 55-3). The difficulty in diagnosing an acute compartment syndrome is further emphasized in a report by Vaillancourt et al.[29] In a retrospective review of 76 patients who underwent fasciotomy at major university trauma centers/teaching hospitals, the interval from initial patient assessment to diagnosis of a compartment syndrome was up to 8 hours, being most prolonged in nontraumatic cases. The interval from the precipitating event to definitive surgery was up to 35 hours, reflecting the difficulty in suspecting this diagnosis and instituting definitive therapy.

The limiting envelope required to produce a compartment syndrome may include fascia, skin, casts, external dressings, or even epimysium alone.[1] General categories for the many sources of increased pressure within these envelopes include decreased compartment volume, increased compartment contents, and externally applied pressure. Table 55-1 lists the reported causes in each category. Because of the nature of the limiting envelopes and the acknowledged causes, compartment syndromes are most commonly seen in the extremities. The lower leg is at high risk because of its propensity for injury and the existence of several low-volume compartments. It is interesting to note that lumbar paraspinal

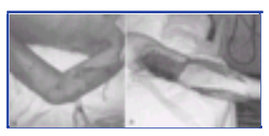

Figure 55-3 The diagnosis of a compartment syndrome is not always straightforward. This young man presented in coma from a drug overdose and had been lying on his arm for a number of hours. The entire arm was swollen and rhabdomyolysis was correctly suspected and treated *(A)*. Because of the coma he was unable to voice any complaint of pain. When he awakened 20 hours later the pain was severe, and compartment pressures demonstrated the need for fasciotomy *(B)*.

compartment syndrome may represent an unusual presentation of low back pain.[33]

Clinical history is the first step in the evaluation of an injury or condition that may produce a compartment syndrome, and it may reveal the etiology (see Table 55-1). Clinical examination confirms the diagnosis when there is clear evidence of increased tissue pressure, inadequate tissue perfusion, and loss of tissue function. The diagnosis is less certain when one or more of these factors are absent.[1]

Often the first symptom described by the patient is pain greater than expected for a given clinical situation. Pain often increases with the passive stretching of muscles in the involved compartment. The muscles also may be weak in comparison to normal. Hypesthesia may be present in the distribution of nerves and tenseness may be palpable in the involved compartment. Decreased vibratory sensation may be one of the earliest sensory findings.[34] [35] These findings usually progress during a period of observation. As a rule, *the presence or absence of arterial pulsation is not an accurate indicator of increased tissue pressure*; pulses may be present in a severely compromised extremity compartment.[2] When pulses are obliterated distally, irreversible damage has often occurred. Table 55-2 lists symptoms and signs of the respective compartments when compartment syndrome is suspected.

Patients who have an altered mental status and younger, uncooperative patients may make the interpretation of neuromuscular signs difficult. In addition, casts or bulky dressings may make careful examination impossible. Attributing the signs and symptoms to other pathologic entities is also a problem (Table 55-3). Primary nerve and muscle injuries can produce similar findings, but the deficit should be maximal initially and should not progress. Arterial injuries and subsequent ischemia may produce pain and dysfunction, although neurologic changes may be less pronounced unless secondary edema produces a compartment syndrome. The acute phase of

RSD may present similarly; however, a history of accidental trauma is typically more remote (days to months).[23] Thrombophlebitis[36] and cellulitis[32] must also be considered in the differential diagnosis. Pain out of proportion to obvious injury may raise the issue of drug-seeking behavior, but a focused evaluation for potential compartment syndrome should precede such a diagnosis.

INDICATIONS FOR INVASIVE (COMPARTMENT PRESSURE) MONITORING

The earliest manifestation of acute compartment syndrome is an elevated tissue pressure. Signs and symptoms occur after tissue pressure has been elevated beyond a critical time period. Measurement of this pressure allows earlier diagnosis and treatment. In some patients, the diagnosis of compartment syndrome is clinically obvious, and one can proceed directly to fasciotomy. However, when clinical findings are equivocal or difficult to interpret, tissue pressure measurement may help guide treatment (Fig. 55-4). Tissue pressure measurements may suggest a compartment syndrome, but equivocal measurements will still require clinical judgment. Three groups of patients for whom clinical findings are difficult to interpret, and who may benefit from compartment pressure measurement, are unresponsive patients, uncooperative patients (such as children or intoxicated patients), and patients with peripheral nerve deficits attributable to other causes (e.g., tibial fracture with peroneal nerve injury).

PATIENT PREPARATION

Patient preparation includes positioning the patient and extremity for optimal results, performing skin preparation at the site of needle introduction, local anesthesia, and procedural sedation when necessary. Because compartment pressure monitoring is an invasive procedure with potential complications and may require procedural sedation and possibly an operative procedure, informed consent should be obtained from the patient or guardian. Details of the consent should be subsequently documented by a procedural note and where appropriate using standard hospital forms. The patient's clinical status and lack of availability of family will often prohibit formal written consent. Such circumstances should be clearly documented in the emergency department (ED) record.

Patient and extremity position for compartment pressure measurement depends on the extremity being studied, the compartment being studied, and presence of coexisting injury. Patients should be comfortable, usually in the supine or prone position, and the compartment to be measured should be at the same level as the heart. The patient and extremity should be positioned to allow the needle to be introduced perpendicular to the muscular compartment being measured. Any obstructions to the needle entry point into the skin and all structures that may put pressure on the compartment and falsely elevate the pressure should be removed. That is, the extremity of the compartment being measured should be positioned so that no external pressure is applied to that compartment. This may require that an assistant hold the extremity slightly above the stretcher.

Once the location for needle placement has been identified, preparation of the skin should be conducted as for any sterile procedure. Care should be taken to avoid needle placement in areas in which the overlying skin is possibly infected, to avoid introduction of bacteria into deep tissues. If an overlying cast is present, it should be bivalved, and if necessary, a window overlying the desired area of needle penetration should be cut from the cast (see Chapter 51). The skin should be anesthetized with a small amount of local anesthetic, with care taken to avoid injection into muscle or fascia. Excessive,

deep infiltration may falsely elevate the compartment pressure reading.

Procedural sedation and analgesia should be considered in any patient who may be uncooperative and unable to hold the extremity still during the procedure (see Chapter 34). Any struggling or movement that requires restraint of the extremity may falsely elevate the compartment pressure. Caution should be taken as parenteral sedation and analgesia may blunt the pain and paresthesias that are paramount in the diagnosis of compartment syndrome. The benefits of accurate pressure measurement must be weighed against obliterating these clinical findings for the duration of sedation.

TISSUE PRESSURE MONITORING

The methods described in this chapter focus on the acute compartment pressure measurement with equipment commonly found in the ED or intensive care setting. These include the mercury manometer system,[37] arterial line system, and the Stryker 295 intracompartmental pressure monitor system (see Fig. 55-1). The described methods provide rapid

compartment pressure measurement with reasonable accuracy. Although the mercury manometer system is the least expensive and most readily available, it is also the least accurate and its results are the least reproducible. [1] Continuous monitoring of compartment pressures has been used to map out the changes in pressure over time, but this technique has not been widely accepted. [38] Note that *isolated, elevated tissue pressures do not mandate surgical intervention*. The entire clinical scenario must be cnsidered.

Needles commonly available for placement into the compartment for pressure measurement include a simple 18-ga needle, an 18-ga spinal needle (for deep compartments), and the side-port needle (Stryker Instruments, Kalamazoo, MI). The side-port needle and slit catheter have comparable efficacy when used for compartment pressure measurement, whereas a simple 18-ga needle is less precise.[39] The HANDY electronic transducer-tipped catheter system (Mammendorfer Institute for Physics and Medicine LTD) is a newer device, which may not be widely available (see Fig. 55-2). The wick catheter, slit catheter, and the STIC (described previously in the Background section) generally require specialized, cumbersome equipment that is not available in most EDs and are therefore not described.

Mercury Manometer System

Equipment

2 18-ga needles (or spinal needles)

2 plastic extension tubes

1 20-mL syringe

1 3-way stopcock

1 vial of sterile normal saline

1 mercury manometer

Setup and Procedure

1. The patient and extremity are prepared according to the guidelines described earlier.

2. The syringe, tubing, extension tubing, and needle are assembled as shown in Figure 55-5*A* .
3. The needle is inserted into a vented vial of sterile saline. A column of saline is aspirated into the tubing halfway to the stopcock; care should be taken to avoid bubble formation. The 3-way stopcock is turned to close off this tube to avoid losing saline during movement of the needle into the patient.
4. The needle is inserted into the muscle of the desired compartment (see Needle Placement Techniques later in this chapter for details).
5. The second extension tubing is attached to the monitor and to the third port of the 3-way stopcock. The stopcock is turned so that the syringe is open to both extension tubes (Fig. 55-5*B*). This closed system has equal pressure in both extension tubes.
6. The pressure in the system is increased gradually by *slowly* depressing the syringe plunger while simultaneously watching the column of saline. The mercury manometer will rise as the pressure in the system rises. When the pressure in the system exceeds the tissue pressure, saline is injected into the compartment, causing the saline column to move. The manometer is read at the time at which the saline moves. This reading corresponds to the tissue pressure in millimeters of mercury.
7. Completely remove the needle and repeat steps 4 to 6 to get a second measurement. A third measurement may be necessary to get two readings in agreement. The needle should be checked between readings for tissue plugs and blood clots.

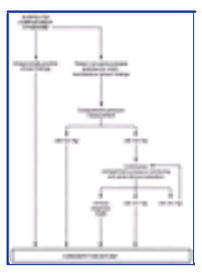

Figure 55-4 Algorithm for management of a patient with suspected compartment syndrome. Pressure thresholds (*) are based on published case series. *Clinical correlation is paramount to proper interpretation of compartment pressure measurements. (From Rorabeck CH: Compartment syndromes. In Browner BD, Jupiter JB, Levine AM, Trafton PG (eds): Skeletal Trauma: Fractures, Dislocations, Ligamentous Injuries, vol 1, 2nd ed. Philadelphia, WB Saunders, 1992, p 290.)*

Procedural Pearls

The most common error with this system is depressing the syringe plunger too quickly. Only when the saline is slowly injected into the compartment will the mercury column (which has greater inertia) accurately reflect the compartment pressure. Another source of error with this system is obstruction of the needle with a plug of tissue if the syringe plunger is pulled back. Finally, aneroid manometers are not calibrated at lower pressure ranges and should not be substituted for the more accurate mercury manometers.

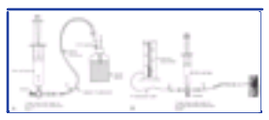

Figure 55-5 *A* and *B*, Mercury monitor technique for compartmental pressure monitoring. *(From Whitesides TE, Haney TC, Morimoto K, et al: Tissue pressure measurements as a determinant for the need of fasciotomy. Clin Orthop 113:43, 1975.)*

Arterial Line System

Equipment

Intracompartment needle

High-pressure tubing

Pressure transducer with cable

Pressure monitor/module

Sterile saline

Transducer stand that allows variable height

2 3-way stopcocks

1 20-mL syringe

Setup and Procedure

1. The patient and extremity are prepared according to the guidelines described earlier.
2. The transducer cable is connected to the pressure monitor/module.
3. The stopcocks, transducer, transducer cable, syringe, high-pressure tubing, and needle are assembled as in Figure 55-6 .
4. The syringe is filled with 15 mL of sterile saline and placed on 1 stopcock. The stopcocks are turned to allow filling of the transducer, high-pressure tubing, and needle. The stopcock to the high-pressure tubing is then closed.
5. The top stopcock is opened to air and the transducer placed at the height of the compartment to be measured. The transducer is calibrated to zero and the top stopcock closed.
6. The lower stopcock to the high-pressure tubing is opened and the needle is inserted into the muscle of the desired compartment (see Needle Placement Techniques later in this chapter for details). Digitally compressing the compartment or passively moving the muscles within the compartment should result in a pressure spike suggesting appropriate placement. The compartment is allowed to equilibrate for several seconds after this maneuver, and the *mean* pressure is measured.
7. Completely remove the needle and repeat steps 4 to 6 to get a second measurement. A third measurement may be necessary to get two readings in agreement. The needle should be checked between readings for tissue plugs and blood clots.

Stryker 295 Intracompartmental Pressure Monitor System

Equipment

Handheld pressure monitor

Stryker 295 quick-pressure monitor set (disposable pouch)

1 prefilled syringe with saline

1 side-port needle

1 diaphragm chamber

Setup and Procedure

1. The 295 quick-pressure monitor set (disposable) is opened, and contents are removed, maintaining appropriate system sterility.

2. The needle is placed firmly on the tapered chamber stem (Fig. 55-7*A*).
3. The blue cap on the prefilled syringe is removed and screwed onto the remaining chamber stem (see Fig. 55-7*A*). Care must be maintained to not contaminate the fluid pathway.
4. The cover of the monitor is opened. The chamber is placed in the device well (black surface down) and pushed gently until it seats (Fig. 55-7*B*).
5. The cover is snapped closed—*NOT FORCED*. The latch must have "snapped" in place.
6. The clear end cap is pulled off the syringe and the plunger rod is attached to the syringe.
7. The needle is held at approximately 45° up from horizontal while fluid is slowly forced through the disposable system to purge it of air. *Caution:* Saline *MUST NOT* roll down the needle into the transducer well.
8. The unit is turned on and should read between 0 and 9 mm Hg.
9. The intended angle of insertion of the needle into the skin is approximated while the "zero" button is pressed. The display should read "00" (Fig. 55-7*C*). *Note:* The display must read "00" before continuing. If it does not, troubleshooting using that section of the maintenance manual should be undertaken.
10. The needle is inserted into the compartment (see Needle Placement Techniques later in this chapter for details). <0.3 mL of saline should be slowly injected into the compartment for equilibration with interstitial fluids.
11. The pressure is read after the display reaches equilibrium.
12. *For additional measurements:* The unit is turned off and steps 8 to 11 are repeated. The unit must be recalibrated to zero before each measurement.

NEEDLE PLACEMENT TECHNIQUES

General Principles

Once the decision to perform compartment pressure measurement has been made, the approach for needle placement and confirmation of correct placement must be considered. In a prospective study of tibial fractures, Heckman and Whitesides found the highest tissue pressure was at the level, or within 5 centimeters, of the fracture.[40] The requirements for a useful approach include: (1) reliable placement in the compartment to be measured; (2) avoidance of important neurovascular structures; (3) simplicity and reproducibility; and (4) minimal discomfort to the patient. [41] Most compartments are superficial and are easily accessible. Only the deep posterior compartment of the lower leg and the gluteal compartment may require a spinal needle for deeper needle placement. Most approaches allow the needle to enter perpendicular to the skin. Figure 55-8 Figure 55-9 Figure 55-10 Figure 55-11 Figure 55-12 Figure 55-13 Figure 55-14 Figure 55-15 Figure 55-16 Figure 55-17 Figure 55-18 Figure 55-19 in conjunction with the text, provide landmarks for proper needle placement and passage to ensure proper compartment placement and avoidance of neurovascular structures.

Lower Leg

The lower leg traditionally has four compartments [1] : anterior, lateral, deep posterior, and superficial posterior (Fig. 55-8). Occasionally, the tibialis posterior muscle will reside in a separate fascial compartment. [26] The lower leg, especially the anterior compartment, is predisposed to compartment syndrome because of its high vulnerability to injury and the relatively limited compartment compliance. The anterior compartment is often mentioned as the most frequent site of compartment syndrome. [23]

The easiest cross-sectional level for needle placement for all four compartments is approximately 3 cm on either side of a transverse line drawn at the junction of the proximal and middle thirds of the lower leg (Fig. 55-9 Fig. 55-10 Fig. 55-11 Fig. 55-12). When measuring the leg compartment pressures, the patient should be placed in the supine position with the leg at heart level (however, when measuring the superficial posterior compartment, the patient should be prone). Patient preparation should be performed as described previously.

Anterior Compartment

With the patient supine, the anterior border of the tibia is palpated at the level of the junction of the proximal and middle thirds of the lower leg (see Fig. 55-9*A*). The needle entry point is 1 cm *lateral* to the anterior border of the tibia. The needle should be directed perpendicular to the skin to a depth of 1 to 3 cm (see Fig. 55-9*B*). Proper needle placement can be confirmed by seeing a rise in pressure during (1) digital compression of the anterior compartment just proximal or distal to the needle insertion site, (2) plantar flexion of the foot, and (3) dorsiflexion of the foot. These maneuvers should produce a several-fold rise in pressure on the monitor.

Deep Posterior Compartment

With the patient supine, the leg should be slightly elevated off the stretcher if the clinical situation permits. The medial border of the tibia is palpated at the level of the junction of the proximal and middle thirds of the lower leg. The needle entry point is just posterior to the medial border of the tibia (see Fig. 55-10*A*). The posterior border of the fibula should be

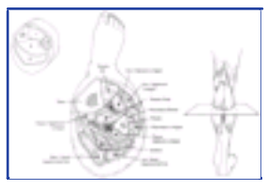

Figure 55-8 Fascial compartments of the lower leg with enclosed muscle groups (insert upper left): (1) anterior; (2) lateral; (3) superficial posterior; and (4) deep posterior compartments.

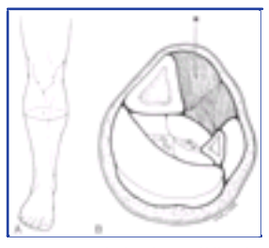

Figure 55-9 Anterior compartment syndrome of the lower leg. Suggested needle entry point is indicated by the small circle *(A)*. The needle should be inserted (*) to a depth of 1 to 3 cm *(B). (Modified with permission from Matsen FA (ed): Compartmental Syndromes. New York, Grune & Stratton, 1980, p 91.)*

palpated on the lateral aspect of the leg at the same level. The needle path should be perpendicular to the skin and directed toward the palpated posterior border of the fibula to a depth of 2 to 4 cm, depending on the amount of subcutaneous fat (see Fig. 55-10*B*). Proper needle placement can be confirmed by seeing a rise in pressure during (1) toe extension and (2) ankle eversion.

Lateral Compartment

With the patient supine, the leg should be slightly elevated off the stretcher if the clinical situation permits. The posterior border of the fibula is palpated at the level of the junction of the proximal and middle thirds of the lower leg. The needle entry point is just anterior to the posterior border of the fibula (see Fig. 55-11*A*). The needle path should be perpendicular to the skin and directed toward the fibula to a depth of 1 to 1.5 cm (see Fig. 55-11*B*). If the needle contacts bone, the needle should be retracted 0.5 cm. Proper needle placement can be confirmed by seeing a rise in pressure during (1) digital compression of the lateral compartment just inferior or superior to the needle entrance site and (2) inversion of the foot and ankle.

Superficial Posterior Compartment

With the patient prone and the leg at heart level, a transverse line at the level of the junction of the proximal and middle

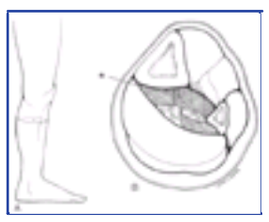

Figure 55-10 Deep posterior compartment syndrome of the lower leg. Suggested needle entry point indicated by the small circle *(A)*. The needle should be inserted (*) to a depth of 2 to 4 cm *(B)*. *(Modified with permission from Matsen FA (ed): Compartmental Syndromes. New York, Grune & Stratton, 1980, p 92.)*

thirds of the lower leg is identified. The needle entry point is at this level and 3 to 5 cm on either side of a vertical line drawn down the middle of the calf (see Fig. 55-12*A*). The needle path should be perpendicular to the skin and directed toward the center of the lower leg to a depth of 2 to 4 cm (see Fig. 55-12*B*). Proper needle placement can be confirmed by seeing a rise in pressure during (1) digital compression of the superficial posterior compartment just inferior or superior to the needle entrance site and (2) foot dorsiflexion.

Forearm

The forearm traditionally has two compartments,[1] volar and dorsal, which are divided by the interosseus membrane. However,

The needle should be inserted (*) to a depth of 2 to 4 cm *(B)*. *(Modified with permission from Matsen FA (ed): Compartmental Syndromes. New York, Grune & Stratton, 1980, p 92.)*

some authors place the extensor *carpi radialis longus*, extensor *carpi radialis brevis*, and *brachioradialis* muscles into their own compartment, called the "mobile wad."[42] The latter group of muscles is considered a separate compartment in this chapter. The forearm compartments are predisposed to compartment syndrome, especially the volar compartment, because of their use during vigorous exercise, accessibility for drug injection, and vulnerability to burns. [1]

The junction of the proximal and middle thirds of the forearm is the cross-sectional level for needle insertion (Fig. 55-13).[43] When measuring forearm compartment pressures, the patient should be placed in the supine position with the arm at heart level. Patient preparation should be performed as described previously.

Volar Compartment

The forearm should be held in supination. The *palmaris longus* tendon is identified and its course traced proximal to the level of the junction of the proximal and middle thirds of the forearm. The posterior border of the ulna is palpated. The needle entry point is just medial to the *palmaris longus* (Fig. 55-14*A*). The needle path should be perpendicular to the skin and directed toward the palpated posterior border of the ulna to a depth of 1 to 2 cm (Fig. 55-14*B*). Proper needle placement can be confirmed by seeing a rise in pressure during (1) digital compression of the volar compartment just proximal or distal to the needle entry point and (2) extension of the fingers or wrist.

Dorsal Compartment

The forearm should be held in supination with the elbow flexed, allowing the dorsum of the forearm to face downward. The posterior aspect of the ulna is palpated at the level of the junction of the proximal and middle thirds of the forearm. The needle entry point is 1 to 2 cm lateral to the posterior aspect of the ulna (Fig. 55-15*A*). The needle should be directed perpendicular to the skin to a depth of 1 to 2 cm (Fig. 55-15*B*). Proper needle placement can be confirmed by seeing a rise in

Figure 55-13 Level of needle insertion of the forearm *(A)* with cross section through the upper third of the forearm *(B)* demonstrating the three forearm compartments (volar, dorsal, mobile wad). *(With permission from Green DP (ed): Operative Hand Surgery. New York, Churchill Livingstone, 1982.)*

pressure during (1) digital compression of the dorsal compartment just proximal or distal to the needle entry point and (2) flexion of the fingers or wrist.

Mobile Wad

The forearm should be held in supination. The most lateral (radial) portion of the forearm is identified at the level of the junction of its proximal and middle thirds. The needle entry point is the muscle tissue lateral to the radius. The needle should be directed perpendicular to the skin (Fig. 55-16*A*) and inserted to a depth of 1 to 1.5 cm (Fig. 55-16*B*). Proper needle placement can be confirmed by seeing a rise in pressure during (1) digital compression of the mobile wad just proximal and distal to the needle entry point and (2) ulnar deviation of the wrist.

Gluteal Musculature

The gluteal musculature is enclosed by an enveloping fascia that splits into two layers and encases the muscle bellies of the *tensor fascia lata* anteriorly and gluteus maximus posteriorly. This

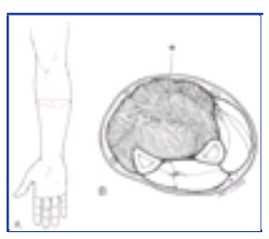

Figure 55-14 Volar compartment syndrome of the forearm. Suggested needle entry point indicated by the small circle on the volar forearm *(A)*. The needle should be inserted (*) to a depth of 1 to 2 cm *(B)*. *(Modified with permission from Matsen FA (ed): Compartmental Syndromes. New York, Grune & Stratton, 1980, p 93.)*

fascia divides the musculature into three distinct compartments: maximus, tensor, and medius/minimus (Fig. 55-17). The sciatic nerve is deep to the fascia but lies between the pelvis-external rotator complex and the gluteus maximus, making it susceptible to injury in compartment syndrome of the gluteus maximus. Most reported cases of gluteal compartment syndrome result from prolonged immobilization and local compression in association with drug or alcohol intoxication. [43] Gluteal

compartment syndrome is rare, making the diagnosis difficult, as local tenderness is often attributed to contusion or hematoma. Rhabdomyolysis should be considered in patients with gluteal compartment syndrome because of the large muscle mass that may be injured.

Gluteal Compartments

The patient should be placed in the prone position with the buttocks at heart level. Patient preparation should be performed as described previously. Cutaneous landmarks for the three compartments are not consistent from patient to patient. In all cases of suspected gluteal compartment syndrome, the needle insertion point can be at the point of maximal

Figure 55-15 Dorsal compartment syndrome of the forearm. Suggested needle entry point indicated by the small circle *(A)*. The needle should be inserted (*) to a depth of 1 to 2 cm *(B)*. *(Modified with permission from Matsen FA (ed): Compartmental Syndromes. New York, Grune & Stratton, 1980, p 93.)*

Figure 55-16 Mobile wad compartment syndrome of the forearm. Suggested needle entry point indicated by the small circle on lateral (radial) aspect of proximal fore arm *(A)*. The needle should be inserted (*) to a depth of 1 to 1.5 cm *(B)*. *(Modified with permission from Matsen FA (ed): Compartmental Syndromes. New York, Grune & Stratton, 1980, p 93.)*

tenderness.[43] An 18-ga spinal needle should be used. The needle should be directed perpendicularly to the skin toward the point of maximum tenderness to a depth of 4 to 8 cm. Proper needle placement is confirmed by seeing a rise in pressure during digital compression of the gluteal musculature.

Foot

Compartment syndrome of the foot is rare, but it is being reported with increasing frequency as clinicians become more aware of the disease process. The four compartments of the foot as seen from a coronal section at the base of the first metatarsal are the central, interosseous, medial, and lateral compartments (Fig. 55-18). The foot is vulnerable to isolated

Figure 55-17 Gluteal compartment syndrome. Suggested entry points are indicated by the small circles *(A)*. The needle should be inserted to a depth of 4 to 8 cm depending on which compartment is being measured. Needle tips (*) shown entering muscle compartments *(B)*. *(Modified with permission from Owen CA, Moody PR, Mubarak SJ, et al: Gluteal compartment syndromes. Clin Orthop 132:57, 1978.)*

extremity injury by virtue of its location. Most compartment syndromes in the foot are the result of crushing forces.

When measuring compartment pressures in the foot, the patient should be placed in a supine position with the foot at the level of the heart. [44] Patient preparation should be performed as described previously.

Medial Compartment

The medial compartment contains the *abductor hallucis* and *flexor hallucis brevis* muscles and is bounded medially and inferiorly by the extension of the plantar aponeurosis, laterally by an intermuscular septum, and dorsally by the first metatarsal (Fig. 55-19*A*). The medial aspect of the base of the first metatarsal is palpated. The needle entry point is the medial aspect of the foot just inferior to the base of the first metatarsal and into the *abductor hallucis* muscle.[45] The needle is advanced to a depth of 1 to 1.5 cm. Proper needle placement is confirmed by seeing a rise in pressure during digital compression of the medial compartment of the foot.

Central Compartment

The central compartment contains the *flexor digitorum brevis*, the *quadratus plantae*, the *lumbricals*, and the *abductor hallucis* muscles. Its boundaries are the plantar aponeurosis inferiorly, the osseofascial tarsometatarsal structures dorsally, and the intermuscular septa medially and laterally. The medial aspect of the base of the first metatarsal is palpated. The needle entry point is the medial aspect of the foot just inferior to the base of the first metatarsal and through the *abductor hallucis* muscle. The needle is advanced to a depth of 3 cm.[45] Proper needle placement is confirmed by seeing a rise in pressure during digital compression of the central compartment of the foot.

Lateral Compartment

The lateral compartment contains the abductor, flexor, and opponens muscles of the fifth toe. The boundaries are the fifth metatarsal dorsally, the plantar aponeurosis inferiorly and laterally, and an intermuscular septum medially. [46] The base of the fifth metatarsal is palpated. The needle entry point is just inferior to the base of the fifth metatarsal (Fig. 55-19*B*). The needle should be directed parallel to the plantar aspect of the

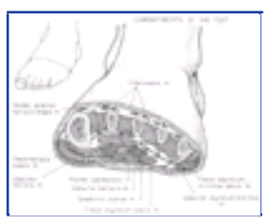

Figure 55-18 The compartments of the foot. *(From Mubarak SJ, Hargens AR: Compartment Syndromes and Volkmann's Contracture. Philadelphia, WB Saunders, 1981.)*

foot to a depth of 1 to 1.5 cm. Proper needle placement is confirmed by seeing a rise in pressure during digital compression of the lateral compartment of the foot.

Interosseous Compartment

The interosseous compartment contains the seven interossei muscles and is bounded by the metatarsals and the interosseous fascia. The dorsums of the bases of the metatarsals are palpated and the second and fourth web spaces are identified. The first web space is avoided to prevent inadvertent puncture of the *dorsalis pedis* or deep peroneal nerve.[45] The needle entry point is the dorsum of the second

Figure 55-19 Compartment syndromes of the foot. Suggested needle pathways (*) to measure intracompartmental pressures: *A,* Medial. *B,* Lateral. *C,* Interosseous compartments. The central compartment is surrounded by these compartments. *(Modified from Myerson M: Acute compartment syndromes of the foot. Bull Hosp Jt Dis 47:251, 1987.)*

and fourth web spaces at the metatarsal bases (Fig. 55-19*C*). The needle is directed perpendicularly to the skin to a depth of 1 cm. [45] Proper needle placement is confirmed by seeing a rise in pressure during digital compression of the interosseous compartment adjacent to the needle entry point.

COMPLICATIONS

All of the procedures described have a similar risk of infection, both local and systemic; exact risk figures are unavailable. Strict adherence to aseptic technique, careful sterilization of catheters, and use of sterile, disposable components whenever possible help to minimize this risk.

All monitoring procedures cause some pain. The pain associated with the actual insertion of needles and catheters may be reduced by local anesthesia. Caution is advised to avoid injections into the compartment, which might result in inaccurate readings or further increases in tissue pressure. Once inserted and secured, the needle or catheter should produce only minimal discomfort. However, the injection of saline into an already tense compartment may produce further discomfort. Reassurance and systemic analgesia may be required to gain the cooperation necessary for accurate readings. Technically, the injection of fluid may actually exacerbate a compartment syndrome. Whitesides and colleagues found an increase in compartment pressure of 1 mm Hg for each milliliter of saline infused into human anterior leg compartments.[9] It is difficult to assess the relevance of this problem, but recognition of the potential for its occurrence is important.

INTERPRETATION

When properly performed, each method has an acceptable accuracy in the clinical setting. Investigators report standard deviations from 2 to 6 mm Hg with any of the techniques.[1] [11] [12] [13] [14] It is generally agreed that the mercury manometer system is

the least accurate. The arterial line system used with a simple or side-port needle provides a high degree of accuracy for simple, episodic readings. The Stryker intracompartmental pressure monitor system provides consistent, accurate readings for episodic and extended monitoring situations. The electronic transducer-tipped catheter system is a promising new device, but not widely available.

Reports of normal human compartment pressures vary in the literature. In comparing several techniques, Shakespeare and associates found an average pressure of 8.5 mm Hg with slightly higher pressures in individuals who were physically fit. [13] Willy et al. found a mean of 13 mm Hg (+/- 8 mm Hg) using the electronic transducer-tipped probe in healthy volunteers.[17] Other investigators have found similar pressures with a range from 0 to 16 mm Hg. [1] [11] [36] Mubarak and Hargens previously stated that an absolute pressure measurement of 30 mm Hg in the compartment should be the "critical pressure" for recommending fasciotomy. [12] [47] [48] Despite the fact that this tissue pressure is abnormal and corresponds to the onset of pain and paresthesias, [12] it does not necessarily precipitate a compartment syndrome in the absence of other factors.

Some variability seems to exist among patients for tolerance of increased pressures. Matsen found that no patients with pressures of <45 mm Hg had symptoms of compartment syndrome, whereas all patients with pressures >60 mm Hg had symptoms.[1] Whitesides found that fasciotomy was required when the intracompartmental pressure approaches 20 mm Hg *below* the diastolic pressure,[9] whereas McQueen et al. recommend using a differential pressure (diastolic minus the compartment pressure) of <30 mm Hg as a criteria for fasciotomy.[49] Heppenstall concluded that consideration of either criteria will produce similar results. [26] He recommends using a ?P (MAP minus the compartment pressure) of 30 mm Hg or less in nontraumatized muscle as a guide to fasciotomy, whereas in traumatized muscle (in which metabolic demands are greater), the critical ?P is 40 mm Hg.[24] It is clear that factors other than compartment pressure alone may become important. Situations in which the mean arterial pressure is lowered (e.g., hypovolemia) may compromise a patient's ability to tolerate even mildly elevated compartment pressures. Duration of increased pressure is also important. There is continued debate over the effects of early versus late fasciotomy (generally regarded as < or >12 hours) in the management of compartment syndrome, especially in trauma. Authors relate varying outcome with regard to infection rate and limb function. [50] There is agreement that the limb may be salvageable for up to 10 to 12 hours, but with very high pressures, the time period may be as little as 4 to 6 hours. [51]

Compartment pressures must be interpreted within the context of the clinical picture. Inaccurate measurements are far worse than no measurement at all. Care must be taken to identify the area of high pressure and greatest tissue damage. [2] Falsely elevated pressures may be a result of needles placed into tendons or fascia, plugged catheters, or faulty electronic systems. Falsely low readings may result from bubbles in the lines or transducer, plugged catheters, or faulty electronic systems. One must carefully troubleshoot the system before making a decision to treat a presumed compartment syndrome.

Actual treatment consists of improving the perfusion pressure gradient. Support of arterial pressures in hypotensive patients can prevent ischemia in marginal compartments. If external pressure is at fault, removal of pneumatic anti-shock garments, casts, or dressings may be therapeutic. Interstitial edema may be a factor in increased tissue pressure as well. The use of diuretics, [52] mannitol,[53] intracompartmental injections of hyaluronidase, [54] and hyperbaric oxygenation[55] [56] have been described for both primary non-invasive therapy and adjunctive to surgical intervention. The latter remains the treatment of choice. If noninvasive therapies fail, fasciotomy, which involves opening the skin and muscle fascia at key points overlying the involved compartments, should be performed. The escape of enclosed muscles causes a decrease in compartment pressure, thereby improving blood flow to the tissues. This procedure is left to personnel who are experienced in the problem and who will subsequently manage the patient. Details of fasciotomy technique may be found in surgical or orthopedic texts. Escharotomy for release of circumferential burn injury may be required on an emergent basis (see Chapter 39).

CONCLUSION

A compartment syndrome, with its myriad potential causes, is a challenging problem for all clinicians. If untreated, the sequelae are devastating. Appropriate management requires rapid assessment and treatment. In the early stages of the syndrome, clinical examination findings may be equivocal. Pressure readings can be an objective aid to prompt recognition of this problem. All of the techniques outlined in this chapter are clinically acceptable. For more prolonged in-hospital monitoring or research, a technique with reliable serial measurement capability is needed. The complications from all of these procedures are negligible in comparison to delayed recognition of a compartment syndrome. Whether using an arterial line system, a mercury manometer system, or Stryker STIC technique, placement of a needle into the compartment for a pressure reading appears to be the technique best suited to episodic ED evaluation of acute compartment syndromes. It is essential to treat underlying factors like hypotension, coagulopathy, and vascular injury or artificially created external pressure, which will exacerbate the syndrome. The use of adjunctive therapies may be helpful, but should not be routinely used in place of definitive surgical intervention. Maintaining a high index of suspicion, especially in the multitrauma, unresponsive, or uncooperative patient is the best approach to maximize outcome.

Section IX - Genitourinary Procedures

Chapter 56 - Urologic Procedures

Robert E. Schneider

This chapter addresses urologic conditions that either are initially or eventually associated with an emergency procedure or may need to be performed in the absence of a urologic surgeon.

Paraphimosis and priapism are both urologic emergencies. Treatment options must be instituted as soon as they are encountered. Phimosis by itself is not an emergency unless it results in complete obstruction of the preputial opening (rare) or is transposed into paraphimosis.

Testicular torsion is an emergency that can be difficult to diagnose under the best of clinical conditions. While some argue that surgical exploration, rather than radionuclide scanning or color Doppler ultrasonography, is the diagnostic and therapeutic procedure of choice, most urologists prefer some study prior to surgical exploration. This chapter addresses bedside maneuvers including testicular detorsion for this entity in the setting of scrotal pain.

Access to and the subsequent evaluation of bladder urine is clinically important to every practicing clinician. Various approaches to urine sampling, including the techniques and complications of male and female urethral catheterization in various clinical situations, are addressed.

Finally, a discussion of radiographic imaging of the genitourinary system is provided, with an emphasis on assessing lower urinary tract injury. Although the timing of genitourinary radiologic examinations within the workup of the critically ill multiple trauma patient must be individualized, general guidelines are provided.

PHIMOSIS AND DORSAL SLIT

Background

Phimosis has been recognized since ancient times. Models of phimotic foreskin have been found near the altars of Hygeia and Aesendopius in ancient Greece. Orikosius (A.D. 325 to 403) was the first to describe the dorsal slit as definitive treatment for phimosis.

Following any injury or inflammatory event, the foreskin (prepuce) reacts by forming scar tissue. The normally soft pliable foreskin can develop sufficient distal scarring to make routine retraction of the tissue over the glans penis difficult or impossible. This is especially true if the end of the foreskin is injured, such as in zipper injuries, toilet seat trauma, or other crush injuries (known as the Tristram Shandy syndrome, after the well-known literary character who had a window sash fall on his penis while he was urinating out the window). A chronically irritated and infected foreskin often occurs in diabetic patients. [1] Rarely, a tight phimosis and accompanying poor hygiene may lead to abscesses of the foreskin, which can result in further contracture.

Asymptomatic phimosis does not ordinarily require any treatment. It may prevent or make easy urethral catheterization more difficult. In such situations, the phimotic opening may need to be dilated or crushed and formally incised (dorsal slit), using light sedation and local anesthesia to allow access to the urethral meatus. This minor operative procedure can be performed in the emergency department (ED) by any practicing clinician.

Indications and Contraindications

Dorsal slit of the foreskin is performed in any emergent situation either to gain access to the urethral meatus for urethral catheterization or as definitive treatment following simple foreskin reduction or phimotic ring incision and foreskin reduction in a patient with paraphimosis. Elective circumcision rather than dorsal slit of the foreskin is the definitive procedure of choice in nonemergent situations.

Procedure

The equipment needed to perform dorsal slit of the foreskin is listed in Table 56-1 . After cleansing and draping the penis with sterile towels, one infiltrates 1% plain lidocaine *without* epinephrine into the dorsal midline of the foreskin just beneath the superficial fascia throughout the course of the proposed incision, starting proximally at the level of the coronal sulcus and proceeding distally to the tip of the foreskin (Fig. 56-1). After 3 to 5 minutes, the foreskin is grasped with toothed forceps to test for anesthesia. The operator must be certain that the inner surface of the foreskin is also anesthetized. If this area is not numb, a dorsal nerve block or "ring block" at the base of the penis should be used (Fig. 56-2). [2] [3]

After achieving both adequate local anesthesia and light sedation, the operator takes a straight hemostat and carefully advances both jaws of the hemostat proximally to the area of the coronal sulcus between the inner layer of the foreskin and the smooth glans penis, carefully separating any existing preputial adhesions. Care must be taken that the meatus and urethra are visualized or palpated at all times so they are not inadvertently injured during this maneuver. Once release of adhesions is complete, the hemostat is then opened, and one jaw of the hemostat is placed in the recently developed plane between the glans penis and the superior overlying inner layer of foreskin; the hemostat is advanced to the level of the coronal sulcus and then closed, effectively crushing the interposed anesthetized foreskin (Fig. 56-3). The closed hemostat is left in place for 3 to 5 minutes, after which it is removed, and the resultant serrated, crushed foreskin is cut longitudinally with straight scissors throughout the extent of the crushed tissue. Normally, the incised, anatomically approximated skin edges bleed and ooze. Not infrequently, these skin edges may separate (Fig. 56-4*A* and *B*). Two absorbable chromic or Vicryl running hemostatic sutures may be placed, each beginning proximally at the apex of the dorsal slit and carried distally, reapproximating the two leaves of foreskin.

TABLE 56-1 -- Equipment Needed to Perform Dorsal Slit for the Emergency Treatment of Phimosis

1% lidocaine (Xylocaine) without epinephrine
5-mL syringe
27-ga needle
1 straight Crile clamp
1 straight scissors
1 needle holder
4-0 absorbable suture

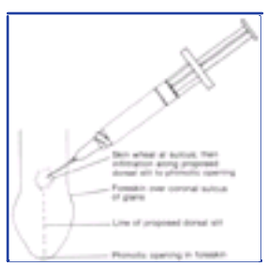

Figure 56-1 Technique for obtaining anesthesia before performing a dorsal slit.

After successful dorsal slit of the foreskin, the prepuce is easily retracted for cleansing of the glans penis or exposure of the urethral meatus. Postprocedural conscientious foreskin reduction to its normal anatomic position must be assured after any distal penile procedure, to avoid iatrogenic paraphimosis.

Ideally, a definitive elective circumcision is recommended following a dorsal slit. Some patients complain about the appearance of their incised foreskin ("dog ears") and the relative inconvenience during urination, whereas others are pleased they no longer have their phimosis and refuse further treatment (Fig. 56-4*C* and *D*).

Complications

Injury to the urethral meatus and the glans penis may occur if the hemostat or straight scissors are blindly and unknowingly introduced into the urethra. Bleeding may occur if the hemostat

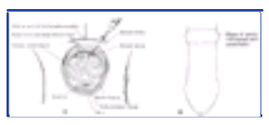

Figure 56-2 *A*, Dorsal nerve block at the base of the penis will provide anesthesia of only the dorsum of the penis. *B,* Circumferential subcutaneous lidocaine infiltration for a ("ring") field block at the base of the penis can provide anesthesia to the entire distal penis. *(A from Soliman MG, Tremblay NA: Nerve block of the penis for postoperative pain relief in children. Anesth*

Analg 57:495, 1978. Reproduced by permission.)

has not adequately crushed the foreskin or the scissor incision is made lateral to the serrated crushed tissue. The latter two problems are easily resolved with the previously described running hemostatic suture.

PARAPHIMOSIS AND FORESKIN REDUCTION

Background

Paraphimosis is a urologic emergency. By definition, it is the inability to reduce the proximally positioned foreskin over the glans penis back to its normal anatomic position. Paraphimosis is most often associated with phimosis. In the obtunded or demented patient, subjective pain may not be perceived or communicated. Today, the most common cause of paraphimosis is iatrogenic: the catheterist or examining health care provider forgets to reduce the foreskin after penile examination or urethral instrumentation. Paraphimosis can be quite subtle and may either be unrecognized or misdiagnosed by those unfamiliar with the condition as an allergic reaction, penile trauma, or an infection (Fig. 56-5*A*).

The coexisting phimotic ring initially interferes with venous and lymphatic drainage, precipitating foreskin swelling. Over time, the degree of swelling prevents manual reduction of the retracted foreskin. When left untreated, eventual arterial embarrassment leads to tissue anoxia, skin ulceration, and, ultimately, to infection or penile gangrene, or both.[4]

Emergent manual or surgical reduction of the edematous foreskin is mandatory to restore proper circulation, relieve discomfort, and permit resolution of potential serious sequelae: skin ulceration and gangrene. It must be done as soon as a paraphimosis is recognized. Once the foreskin is successfully reduced, dorsal slit as previously described is advised in those cases of potential patient noncompliance until definitive circumcision can be performed.

Indications and Contraindications

Emergent reduction of a paraphimotic foreskin is indicated whenever the condition exists. There are no contraindications.

Figure 56-3 Placement of hemostat for treatment of phimosis. The "tenting up" of the foreskin in this manner proves that the tip of the hemostat is *not* in the urethra or under the glans. Once properly placed between the glans and overlying foreskin, the instrument is closed to crush the area of the foreskin to be cut.

Procedure

The equipment needed for reduction of paraphimosis is listed in Table 56-2 .

Manual Reduction[4] [5]

A nonirritating topical anesthetic lubricant is applied to the inner surface of the foreskin (not to the shaft of the penis) and

Figure 56-4 Treatment of phimosis. *A,* Dorsal slit in phimotic foreskin. Exposed glans is shaded. A single (dorsal) lengthwise incision has been made through crushed tissue (a^1, outer layer of foreskin; *a,* inner layer of foreskin). *B*, Cut edges of foreskin drawn back around glans penis. First, a^1 is sutured to *a*, then the remainder of the cut edges are sewn together for hemostasis. *C,* Final "beagle-ear" deformity of ventral transposed foreskin after the dorsal slit procedure has been completed. *D*, Postoperative appearance of dorsal slit.

the glans to reduce friction and decrease the discomfort of the procedure. A previously described penile block may be performed if required. Light sedation is an excellent adjunct. The foreskin is then manually compressed for several minutes to reduce as much edema fluid as possible (Fig. 56-5*B*). Snugly wrapping the distal penis in a 5-cm piece of Elastoplast (or elastic bandage) for 10 minutes has also been described. [6] Injection of hyaluronidase[7] has been reported to reduce edema, but seems unnecessary. If the patient is catheterized, *the catheter may be removed and replaced later, but generally that is not necessary* . Reduction can be completed with the catheter in place.

The index and long fingers of both hands are placed in apposition just proximal to the phimotic ring. Both thumbs are aligned on the urethral meatus. Constant force is applied as the thumbs try to invert the glans penis proximally while the index and long fingers attempt to reduce the phimotic ring distally over the glans penis into its normal anatomic position (Fig. 56-5*C*). Successful reduction results in the appearance of an uncircumcised penis with a phimotic foreskin. Alternatively, the thumb may be used to push the glans through the foreskin that has been encircled by the entire palm—in a maneuver similar to taking off a rubber glove (Fig. 56-5*D* and *E*). The key to success in both of these maneuvers is the application of slow, steady pressure.

Assisted Manual Reduction ("Iced-Glove" Method or Babcock Clamp Method)

If the constricting phimotic ring cannot be brought down over the glans easily, additional measures may be used. In the "iced-glove" method, [8] cold compression is used to reduce foreskin swelling and to induce vasoconstriction in the glans penis. A large latex glove is half filled with crushed ice and water, and the cuff end is securely tied. The thumb of the glove is invaginated by the operator and then is drawn over the lubricated paraphimotic penis. The thumb of the glove is held securely in place over the penis for 5 to 10 minutes. The combination of cooling and compression usually decreases the edema sufficiently to permit manual reduction of the foreskin. If the constricting ring cannot be brought down over the glans after this maneuver, it may be necessary to use Babcock clamps. From six to eight Babcock clamps (*not* Allis clamps, which are serrated and intolerably painful for the patient) are

Figure 56-5 *A,* Paraphimosis, pictured here, may be mistaken for penile trauma, angioedema, or infection. The cause of paraphimosis in this case was failure to replace the foreskin following a catheter change in a demented nursing home patient. Prior to reduction, the catheter is usually removed. When the edema is minimal, the catheter may be left in place during reduction. *B,*

Manual compression of the foreskin, or wrapping the penis with an elastic bandage for a few minutes, may reduce edema before a reduction of the paraphimosis is attempted. *C,* Technique for reduction of paraphimosis. Gentle, steady pressure is placed on the glans with the tips of the thumbs while gentle traction is applied to the foreskin. In this line drawing, the catheter is left in place during reduction. *D,* In a manner reminiscent of removing a rubber glove, the thumb forces the glans through the foreskin that is encircled by the entire palm to achieve final reduction *(E). (C from Neuwirth H, et al: Genitourinary imaging and procedures by the emergency clinician. Emerg Med Clin North Am 7:1, 1989.)*

used to grasp the phimotic ring circumferentially.[9] The clamps are then slowly pulled distally over the glans. With gentle, slow traction, the phimotic ring can hopefully be reduced over the glans penis (Fig. 56-6).

Phimotic Ring Incision

This procedure is indicated when other methods fail or when skin ulceration, infection, or gangrene is present. [10] [11] [12] Although it is usually recommended that this procedure be performed in the operating room, it may be undertaken in the ED using local anesthesia and light sedation.

The penis is cleansed and draped with sterile towels. Using a 1% solution of lidocaine *without epinephrine*, one infiltrates the phimotic ring on the dorsum or 12 o'clock position (when facing the patient), making sure to infiltrate proximally and distally as well as into the constricting ring (Fig. 56-7*A*).

The skin, the edematous subcutaneous tissue, and the constricting ring are then slowly incised perpendicular to the

phimotic ring. You must incise directly on the ring so as not to injure the penile shaft. When the constricting ring is completely incised, it will spring open, and the foreskin edges will relax laterally and produce a diamond-shaped defect (Fig. 56-7*B*). At this point, successful foreskin reduction can be accomplished quite easily and an immediate dorsal slit incision carried out by extension of the wound, if recurring paraphimosis or patient compliance is a concern. Definitive circumcision, as always, is elective, and should be delayed 7 to 10 days until edema, inflammation, and ulceration have resolved.

Complications

Penile shaft laceration or simple tearing of compromised penile skin may occur during manual or surgical paraphimotic reduction. Simple suturing will resolve most injuries.

PRIAPISM AND PENILE INJECTION/ASPIRATION

Priapism is manifested by a persistent, usually painful, penile erection, unrelated to sexual stimulation and not relieved by ejaculation. Most often priapism is a urologic emergency that is associated with a high incidence of impotence, regardless of treatment. It is characterized clinically by a soft glans penis and spongy urethra in the presence of two erect penile bodies or corpora cavernosa. Although reported in most age groups, the condition is most common between the ages of 30 and 50 years.

The pathophysiology of priapism is complex, and is likely the combination of the sympathetic and parasympathetic

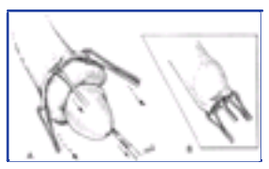

Figure 56-6 *A,* Application of Babcock clamps to reduce paraphimosis. *B,* Foreskin reduced. *(From Skoglund RW, Chapman WH: Reduction of paraphimosis. J Urol 104:137, 1970. Reproduced by permission. © Williams & Wilkins, 1970.)*

nervous system and local factors. The pharmacologic basis for treatment is based on manipulating blood flow via the a and ß receptors. As an overall mechanism, increased arterial inflow of blood into the corpora cavernosa secondary to dilation of the cavernosal arteries with relaxation of the cavernosal tissue and secondary compression of the emissary veins leads to engorgement of both corpora cavernosa during an erection. When the cavernosal pressure approaches the arterial pressure, blood flow is markedly reduced. Ischemic or low-flow priapism results after several hours of continuous painful erection, leading to intracavernosal acidosis and sludging of blood with subsequent thrombosis of the cavernosal arteries, fibrosis of the corporal tissue, and irreversible impotence. This urologic emergency may be treated by the emergency clinician, although in some settings this pathology is best referred.

High-flow priapism is less common than low-flow priapism and usually results from traumatic production of an arteriocavernosal fistula. It is not associated with intracavernosal ischemia or acidosis and therefore is painless and may be treated electively rather than emergently.

In the past, priapism was most often encountered as a complication of a number of medical (e.g., hematologic, neoplastic, and drug-related) conditions (Table 56-3). Today many cases are idiopathic or iatrogenic, resulting from the current practice of using vasoactive substances (e.g., papaverine and phentolamine) to induce penile erections in impotent men. Sickle cell disease is the leading cause of priapism in some settings. Sickle cell patients may experience such a high rate of recurrence that home self-injection of vasoactive drugs

into the penis has been advocated. Cocaine use is one etiology that is likely underreported. [13] A drug screen may unravel some discrepancies between clinical findings and history. As an end result, vasoactive drugs promote engorgement of the corpora cavernosa and reduction in venous outflow, which may result in low-flow or ischemic priapism.[14] [15] [16] Prostaglandin E_1 (PGE_1) is currently the only FDA-approved drug for impotence. PGE_1 produces increased penile blood flow by enhancing smooth muscle relaxation, and the incidence of priapism with this medication is quite low. Penile rigidity due to a nondeflating penile prosthesis (pseudopriapism) or malignant replacement of the corpora in patients with bladder or prostate cancer should not be confused with true priapism.

Indications and Contraindications for Priapism Procedures

The emergency clinician should attempt to identify reversible causes for low-flow priapism and, in conjunction with a urologist, initiate specific corrective therapy as soon as possible. Almost 66% of cases of low-flow priapism in children and young adults are due to sickle cell disease, and such cases may respond to noninvasive standard anti-sickling measures (including exchange transfusion).

Regardless of the etiology, this distressing condition is first treated with adequate analgesia, often consisting of parenteral opiates and benzodiazepines. Empiric terbutaline, 0.25 to 0.5 mg given subcutaneously (SQ), is recommended for every patient presenting with low-flow priapism as soon as the diagnosis is made; this treatment may be repeated, when needed, in 15 to 20 minutes. If a patient with previous low-flow priapism calls from home and has the appropriate supplies, he should be instructed to inject himself with terbutaline (as described earlier) or take a 5 mg terbutaline tablet by mouth, if available, before coming to the ED. The pharmacotherapeutic action of terbutaline for priapism is not well elucidated. Oral pseudoephedrine (60 to 120 mg) also has been suggested as a noninvasive initial therapy for low-flow priapism secondary to intracavernosal agents, but its efficacy has not been well studied. [18] While terbutaline and other oral or parenteral medications have been advocated for the treatment of priapism, it is the editors' experience that such interventions are only rarely successful, and many cases will require more aggressive procedures. Table 56-4 lists the reversible causes of low-flow priapism with their respective therapies.

TABLE 56-4 -- Treatment of Low-Flow Priapism Based on Etiology

A. Terbutaline 0.25 to 0.5 mg subcutaneously (SQ) in the deltoid muscle area or thigh for all patients with priapism (may be repeated in 15–20 min); alternatively, 5 mg terbutaline *per os* (PO) may be used (1 dose)
B. Reversible causes
1. Sickle cell anemia
a. Packed red blood cell (RBC) transfusion
b. Hyperbaric oxygenation (investigational)
2. Iatrogenic injection of PGE_1, papaverine, or phentolamine for impotence
a. Corporal aspiration of 30–60 mL of blood, followed by observation
1) Detumescence: no further treatment
2) Persistent erection: inject an equal volume of a-agonist (e.g., phenylephrine, 10 mg in 500 mL of normal saline)
3. Leukemic infiltration
a. Specific chemotherapy
4. Medication (phenothiazines, trazodone)
a. Corporeal aspiration, observation
b. a-Agonist instillation, observation
c. Heparin irrigation of corporeal bodies, observation
d. Corpus cavernosum-spongiosum shunt
C. Nonreversible causes
1. Idiopathic
2. High spinal cord lesion

In the majority of patients, no reversible cause will be disclosed. When detumescence does not occur with SQ terbutaline, the condition necessitates corporal aspiration/injection alone or corporal aspiration and irrigation with an a-agonist (epinephrine or phenylephrine [Neo-Synephrine]). Conservative measures, such as sedation and analgesia, oral estrogens, ice-water enemas, transurethral diathermy, spinal/epidural/general anesthesia, and local anesthetic injections have not

proven to be of value and should not be used in lieu of definitive intracavernosal therapy. [18]

Should initial medical and corporal aspiration and irrigation fail, Lue and associates recommend that further therapy be guided by cavernosal blood gas and pressure measurements.[19] If one elects to use blood gas analysis of aspirated corporal blood to help guide therapy, the initial results will reflect the degree of ischemia present in the priapismic penis. Sequential blood gas analyses that fail to show an improvement in the initial acidosis (pH remaining at =7.10) despite corporal aspiration or irrigation, or both, suggest that a more aggressive definitive corpus cavernosum-spongiosum shunt may be indicated, and urgent urologic intervention should be sought. Although not usually performed, the aspirating or irrigating corporal needle may also be used for measurement of intracorporal pressures similar to the approach outlined for muscular compartmental pressures.[20]

A variety of regimens and protocols have been suggested for the treatment of priapism. No single intervention has known superior efficacy. The mainstay of therapy for advanced priapism is aspiration of the corpora cavernosa combined with saline irrigation, usually coupled with the intracavernosal injection of a-adrenergic agents. When urologic consultation is unavailable or delayed, the emergency clinician can initiate therapeutic corporal aspiration. Because prolonged priapism increases the risk of subsequent erectile dysfunction, an aggressive management strategy is advised. Impotence rates of up to 35% to 60% have been reported when priapism persists for 5 to 10 days, respectively.[18] If present for more than 24 hours, priapism often does not respond to aspiration techniques. Recurrence is not uncommon and some patients require multiple procedures on a frequent basis. Shunting procedures may be required if the measures described earlier are not successful.

Equipment

The equipment needed for aspiration and irrigation of the corpus cavernosum is listed in Table 56-5 .

Procedure

(Simple intracorporal injection): While the aspiration/irrigation technique is often recommended, some clinicians have had success with the simple injection of vasoactive solutions into the corpus cavernosum. This negates the more complicated irrigation procedure and may be attempted as an initial approach to the uncomplicated case. This is the technique used by outpatients as a self-injection technique for recurrent priapism. With this technique a 25- to 27-ga needle is used to inject vasoactive substances into the corpus at the base of the penis, with the aim of pharmacologically reversing the priapism process. Often this can be done without anesthesia. Specific protocols are not established, but one option is to draw up 0.5 mg of phenylephrine into a 3-mL syringe, and add 2 mL of saline diluent. The needle punctures the corpus

TABLE 56-5 -- Equipment Needed for Aspiration of Corpus Cavernosum for Low-Flow Priapism

27-ga needle (for penile block)
12-mL syringe (for local anesthetic)
1% lidocaine without epinephrine (for penile block)
Sterile drapes
Gauze sponges
Povidone-iodine (or alternative) preparation solution
19-ga butterfly needles (for aspiration)
Two 30-mL syringes (for aspiration and injection)
Sterile basin for aspirated blood
Blood gas syringe with cap
Injection fluid (1 of the following vasoactive agents* is diluted with 500 mL of normal saline and up to 20 to 30 mL is administered; 5000 units of heparin added to solution is optional; see text)
Phenylephrine, 10 mg/500 mL of saline
Norepinephrine, 1 mg/500 mL of saline
Epinephrine, 0.5 mg/500 mL of saline

*Systemic absorption of vasoactive agents may occur with adverse cardiovascular effects.

at the 10 o'clock or 2 o'clock position at the base of the penis, blood is aspirated to confirm position, and the solution is injected. If not successful in 30 minutes, a repeat injection can be given, up to a total of 3 injections (Fig. 56-8). In one small

Figure 56-8 As an initial approach to priapism, and as an alternative to aspiration/irrigation, the intracorporeal injection of vasoactive drugs such as phenylephrine may be used. A small gauge needle is used to inject the corpus at 10 o'clock or 2 o'clock, at the base of the penis. Repeat injection may be required.

study, successful detumescence was achieved in eight of nine patients by simple intracorporal injection of phenylephrine with this regimen, with three or fewer injections being required.[21] Alternatively, 0.1 mg of epinephrine (0.1 mL of 1:1000) diluted with 2 mL of saline may be used.

(Aspiration and irrigation): This procedure entails drainage of blood from the erect penis, irrigation of the corpus cavernosum, and the instillation of a vasoactive medication. As an alternative intervention, simple injection is also described. The patient is placed in the supine position (Fig. 56-9*A to D*). Parenteral analgesia and sedation are suggested. Local anesthesia is also recommended for this procedure. An injection of 1% plain lidocaine placed at the base of the penis for a dorsal penile nerve block or placement of a circumferential penile block can be done (see Fig. 56-2). A local anesthetic injection at the site of aspiration is also commonly performed. The penis is sterilely prepared and draped. When standing to the

Figure 56-9 *A,* This patient experienced 18 hours of priapism after penile self-injection of papaverine as therapy for impotence. *B,* A penile dorsal nerve block is performed. *C,* A 19-ga butterfly needle is inserted into the corpus via the penile shaft at either the 2 o'clock or 10 o'clock position, and aspiration is performed. Slow steady suction will be most successful, while excessive suction may halt the aspiration. Do not puncture the corpus via the glans (see text). *D,* After detumescence with aspiration or with irrigation and injection of a vasoactive medication (see

text), the penis is wrapped with an elastic bandage to discourage re-engorgement and to compress the puncture site.

right of the patient, the clinician grasps the shaft of the penis with the left hand using the thumb and index finger. An engorged corpus cavernosum is palpated laterally and a 21- to 19-ga butterfly needle is inserted into *one of the corpora cavernosa*.[20] Alternatively, a 20-ga intravenous (IV) catheter may be used, but the butterfly needle catheter is preferred. If palpation failsto demonstrate the corpus, inserting the needle at either 10 o'clock or 2 o'clock will usually readily gain access to this large vascular structure. Since there is communication of blood flow between both sides, the operator needs access to only one of the corpora. Either side may be punctured. The site of needle placement is one of personal preference, and locations from the base to the distal shaft of the penis have been suggested. The editors suggest using the midshaft for irrigation, and the base for simple injection. *The glans should not be used as a puncture site.* The needle is advanced in a 45° angle, using constant suction. Blood is usually readily

aspirated, and once it is obtained, the needle is not advanced. Deep penetration is to be avoided to minimize the risk of injury to the cavernosal artery during this procedure.

An initial 20 to 30 mL of corporal blood is aspirated while the operator milks the corpus with the left hand. *Excessive suction should not be applied since this often halts the aspiration.* A common error is to use too much suction with a 60-mL syringe. Using a 10-mL syringe, and changing it if it fills with blood, is preferable. If a butterfly is used, there is no danger in dislodging the needle when changing syringes. This initial aspiration is continued until the original egress of dark blood ceases and bright red arterial blood is obtained, or complete detumescence is obtained. Because multiple anastomoses exist between the two corpora cavernosa, bilateral aspiration is not required.

If detumescence is achieved after initial aspiration, no further treatment may be required. However, if this is successful, the editors advise injecting an aliquot of vasoactive substance. Simple aspiration is most likely to be successful if the priapism has been present for less than 24 hours. If retumescence occurs, then repeated aspiration, followed by irrigation with an equal exchange of an a-agonist solution for aspirated corporal blood, should be performed. A number of irrigating solutions have been suggested, but none has proven superiority. Some suggest 20 to 30 mL of a phenylephrine/normal saline solution (10 mg of phenylephrine in 500 mL of normal saline) as the exchange for 20 to 30 mL of aspirated corporal blood. Some clinicians add 2500 to 5000 units of heparin to the solution, but the value of heparin is unproven. The use of ß-agonists for corporal injection or irrigation also has been reported, and the advantage of pure a-agonists over ß-agonists is a subject of debate. O'Brien and associates recommend a 1:100,000 solution of epinephrine (1 mg/100 mL of saline), irrigating with 2 to 3 mL at a time to a maximum dose of 0.1 mg (10 mL).[20] Alternatively, 1 mg of epinephrine can be added to 1 L of saline, with irrigation performed using 20 to 30 mL aliquots. A norepinephrine solution also may be used (see Table 56-5). Note that the corpus cavernosum has ready access to systemic circulation and injecting a drug into it is essentially the same as an IV injection. When detumescence occurs, the unmetabolized drug enters the venous system; therefore, vasoactive drug dosages should be monitored. Some clinicians wrap the penis snugly in an elastic wrap with the needle securely in place following aspiration to discourage retumescence and to decrease hematoma formation of the penile shaft.

Complications

Although hematoma and infection can occur with properly performed aspiration, these complications are infrequent. Both phenylephrine and epinephrine can be absorbed systemically, with the potential for toxic effects.[19] Therefore, the intracavernosal use of vasoactive agents is contraindicated in patients with conditions sensitive to these agents (e.g., severe hypertension, dysrhythmias, monoamine oxidase inhibitor use). Blood pressure and cardiac rhythm should be monitored throughout the procedure if the patient is at risk. Supplemental O_2 should be considered in any patient undergoing conscious sedation. Failure to aspirate blood is a potential complication, usually because of a misplaced needle, applying excessive suction, or if blood has clotted. Because impotence is a well-recognized complication following priapism, regardless of the cause or the promptness of therapeutic intervention, the patient must be advised both verbally and in writing of this potential complication.

ADJUNCTIVE TESTING IN ACUTE SCROTAL PAIN

Establishing a diagnosis in the patient with acute scrotal pain creates significant clinician anxiety. The condition most easily confused with torsion of the testicle is acute epididymitis. The prompt diagnosis of testicular torsion and differentiation of this condition from epididymitis can be quite difficult, but it is obviously crucial to the patient's care. The treatment of acute epididymitis requires appropriate antimicrobial and supportive therapy. The treatment of testicular torsion requires emergent operative intervention, not excessive adjunctive testing. [22] Although all clinicians recognize the need for expeditious surgery in the setting of known torsion, not all consultants will agree on surgery in the absence of some adjunctive testing.

Torsion of the testicle is the most frequent cause of acute testicular pain in celibate men younger than 20 years. One pediatric series of patients presenting with a painful scrotum reported a 6% incidence of epididymitis vs a 42% incidence of testicular torsion and a 32% incidence of torsion of the appendix testis and epididymis. [23] It is interesting to note that pyuria was seen in 10% of the patients with testicular torsion and in 80% of the children with epididymitis. In men 20 years or older, testicular torsion is less common, but it must always be considered in the differential diagnosis as it may occur well into the seventh decade of life. [24]

In contrast, epididymitis is an *uncommon* condition in young celibate boys unless a congenital lower urinary tract abnormality is present, promoting urinary tract infection with subsequent epididymitis.

As with all difficult diagnostic dilemmas, the patient's history is of paramount importance in establishing the correct diagnosis. The evaluation of acute scrotal pain is no different. In considering epididymitis, detailed and often probing questions must be asked regarding the patient's work habits and his sexual experiences. The pathophysiology of epididymitis emanates from the generation of increased pressure in the prostatic urethra as a result of either heavy lifting (e.g., in roofers or construction workers), detrusor external sphincter dyssynergia (e.g., in patients with neurogenic bladder dysfunction), or iatrogenic promotion of a Valsalva maneuver for whatever reason. These mechanisms force sterile or infected urine out through the ejaculatory ducts into the vas deferens (urethrovasal reflux), then retrograde down the vas into the tail of the epididymis (globus minor). Initially, this may cause nonspecific lower quadrant abdominal pain or inguinal canal pain (vasitis) before it causes scrotal or testicular pain, and vasitis should be included in the initial differential diagnosis in any male presenting with lower abdominal pain.

Sexually transmitted diseases with subsequent epididymitis are quite common in sexually active young men, usually associated with chlamydial or gonococcal urethritis. Signs and symptoms of infection may be minimal when the patient is first examined. [25] The presence of genitourinary infection, a history of previous sexually transmitted diseases, or a history of multiple sexual partners and the absence of penile protection during intercourse may all be important clues to the diagnosis of epididymitis. In older men, epididymitis is usually due

to urinary tract infection secondary to outlet obstruction or urethral stricture disease. In such cases, enteric gram-negative bacilli and *Pseudomonas* species are the predominant organisms. If one cannot be certain after taking a careful history and examining the patient that epididymitis or torsion of the appendix testis or epididymis is the correct diagnosis, then urologic consultation to exclude testicular torsion is required. A clinical diagnosis of epididymitis should be based on the focal finding of epididymal induration and tenderness (the vas deferens also may be involved) in the proper patient population. The site of tenderness is best discerned when examining the patient in the relaxed supine position. Although testicular tenderness can develop with advanced epididymo-orchitis, the time course is generally gradual and on an order of days. However, marked testicular tenderness in a patient with advanced epididymo-orchitis may reflect secondary testicular ischemia and also warrants urologic consultation. [26]

The "gold standard" for the diagnosis of testicular torsion is scrotal exploration. [27] However, some clinicians incorporate radionuclide testicular scanning or color Doppler ultrasound examination in their diagnostic work-up. [28] Unfortunately, these studies are time-, technician-, and reader-dependent examinations in a clinical situation in which time is essential. The quintessential point in testicular torsion is that no markers, signs, or symptoms will distinguish incomplete from complete testicular ischemia. One minute there may be total absence of blood flow to the involved testis; the next minute sufficient spontaneous detorsion may have occurred to provide temporary testicular perfusion. This is the dilemma. Scrotal exploration, detorsion, and orchiopexy or orchiectomy of the involved testis and orchiopexy of the contralateral testis is a relatively benign, straightforward operative procedure.

Intravaginal testicular torsion is a congenital bilateral abnormality. The ischemic testis must be detorsed and pexed with nonabsorbable (e.g., nylon, polypropylene), rather than absorbable (e.g., chromic, Vicryl), suture. The torsed testis that is pexed with absorbable suture remains at risk for subsequent postoperative torsion. Orchiopexy of the nonischemic contralateral testis is mandatory to ensure prevention of future torsion.

Once the diagnosis of testicular torsion is suspected, a call should be placed immediately to notify a urologist of the suspected diagnosis, the perceived need for surgical exploration, and the fact that you will be attempting testicular detorsion while awaiting patient transport to the operating room. At some point before the patient leaves the ED, meticulous charting to document time, suspected diagnosis, notification of the urologist, and any manipulation of the affected testis must be done. All efforts are then focused on attempting testicular detorsion.

Doppler Assessment of Testicular Perfusion

Indications and Contraindications

The most important nonoperative adjunctive procedure in suspected testicular torsion is testicular *detorsion*. This can be carried out with or without the aid of a Doppler stethoscope. Using the Doppler stethoscope alone to make a diagnosis of testicular torsion or successful detorsion is *not* recommended. Nonetheless, the Doppler device may be used to support one's clinical assessment in cases strongly suggestive of epididymitis or to monitor the response to detorsion efforts.

Equipment

In circumstances in which one wishes to use the Doppler, the directional Doppler operating on a 10-MHz transducer is recommended. See Chapter 69 for further discussion of Doppler ultrasound physics. A pencil transducer is the most appropriate (e.g., the Model 806 directional 10-MHz Doppler, Park Electronics Laboratory, Beaverton, OR). The Doppler response may be transmitted over a loudspeaker, copied on a measuring device, or transmitted through a stethoscope to the clinician. The higher the frequency of the transducer, the narrower the beam and the less the distance of transmission through the tissues. In this respect, a 10-MHz transducer is preferred over a lower-frequency transducer for examination of the testicle.

Technique

Because scrotal tenderness often precludes adequate examination, anesthesia may be needed. A cord block using 1% lidocaine may be applied at the external ring (see discussion of this block under Testicular Detorsion later in this section). The area of maximum testicular swelling is determined. An aqueous transmission gel is then placed over the scrotum. Holding the testicle in one hand and the Doppler probe in the other, one displaces as much of the scrotal wall as possible between the skin and the underlying testicle. The Doppler probe should be placed in the center of the testicle, pointing slightly caudally so that pulsations in the cord are not detected (Fig. 56-10). (Firm probe pressure "focuses" the ultrasound waves deep to the scrotum into the testis.) The pulsation in the tender, ipsilateral testicle is then compared with that in the contralateral testicle. Decreased or absent flow to the ipsilateral testicle is most surely a result of torsion. Increased flow to the ipsilateral testicle may be a result of epididymitis, inflamed scrotal tissue, a false signal from either the cord or the examiner's fingers, or a false comparison with a contralateral partial torsion of the testis. [29]

The *funicular compression test* should be performed to confirm that flow signals are related to perfusion to the testicle. If the increased signal lessens on compression

of the patient's spermatic cord, then the signal is most probably coming from the patient's testicle and not from inflamed scrotal tissues. If there is no change in the signal on adequate cord compression, the increased flow may be originating in inflamed scrotal tissue, and torsion should still be suspected.

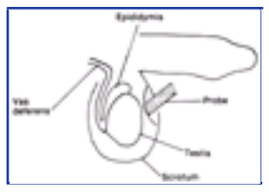

Figure 56-10 Proper position of the Doppler probe in the examination of the acute scrotum. Note caudal orientation of the probe (drawing is a lateral projection).

Complications

Absolute proficiency with the Doppler stethoscope is difficult to achieve, and examination findings are subject to misinterpretation. The greatest risk comes in those cases that represent a later stage of testicular torsion. Although the testes may not be necrotic, a secondary inflammatory response may develop as a result of the underlying ischemia. Any perceived Doppler signal in the hyperemic surrounding scrotum may be misinterpreted by an inexperienced examiner as epididymitis rather than late torsion with an associated inflammatory response, the result of which may be inappropriate treatment. Obviously, the affected testis would remain ischemic, but more important, the contralateral testis would remain at risk for later torsion.

Failure to perform the funicular compression test may lead to the mistaking of scrotal blood flow for testicular blood flow. The Doppler signal should fade and then promptly return as the spermatic cord is first compressed and then released. With an incomplete torsion, one may also hear an attenuated arterial pulse in the testicle. For these reasons, it should be evident that one cannot rely entirely on the Doppler ultrasound examination. [30]

Manual Detorison and Spermatic Cord Anesthesia

Manual detorsion is performed in the following manner. Advise the patient that the procedure will be uncomfortable and painful and offer light sedation if it seems appropriate. The rationale for not using spermatic cord anesthesia with attempted detorsion is that the anesthesia takes away an important subjective end point (i.e., relief of the patient's pain after manipulation of the testis). However, many authors do advocate spermatic cord anesthesia prior to detorsion, and if anesthesia of the spermatic cord is elected, it can be done in the following manner.

Spermatic Cord Anesthesia

Local anesthesia of the spermatic cord using 1% plain lidocaine is usually done at the external inguinal ring. [31] The skin is first prepared with an iodophor solution. The cord can usually be grasped between the thumb and index finger, and 10 mL of 1% plain lidocaine can be directly injected into the cord. If the cord is swollen, as it often is in testicular torsion, or if the testicle is lying very high in the hemiscrotum as a result of spermatic cord torsion (so as to preclude grasping), the cord may be palpated at the pubic tubercle as it passes over the pubis and the lidocaine injected at this landmark. Lee and colleagues [32] were able to perform manual detorsion with local spermatic cord anesthesia in 70% of their adult cases of torsion. Kresling and associates [33] had success in 15 of 16 patients and noted a fair amount of associated cremasteric muscle spasm, which must also be relieved. In their experience, torsion usually resulted from an initial lateral-to-medial rotation (Fig. 56-11), with an occasional caudal-to-cranial component.

Manual Detorsion

The goal of manual detorsion is to reestablish or increase blood flow to a previously ischemic testis. This should be done in conjunction with preparation of the operating suite. *It should never delay operative intervention.*

Before initiating detorsion, one must ensure that the patient is as comfortable as possible in a reclining or supine position. Lithotomy position gives the examiner the most

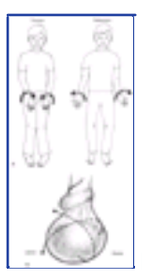

Figure 56-11 *A,* Testicular torsion usually occurs in a medial direction. Detorsion should be attempted initially by rotating the testis outward toward the thigh. This is most successful if attempted within the first few hours of torsion, before the onset of significant scrotal swelling. Intravenous narcotics (such as fentanyl) or a cord block can be administered before attempting detorsion. *B,* Detorsion of the testicle may require testicular rotation through two planes. To release the cremasteric muscle, the testis is rotated in a caudal to cranial direction simultaneously with medial to lateral rotation. The right testis is shown. *(B from Freeman S, et al: Urologic procedures. Emerg Med Clin North Am 4:543, 1986.)*

access to the patient's genitalia and prevents the patient from retreating during the procedure. If light analgesia/sedation are selected, they should be implemented at this time.

Manual detorsion begins with the clinician standing comfortably at the side of the bed or stretcher, preferably on the patient's right side if the clinician is right handed, or vice versa. Detorsion is begun just as one would open a book

(i.e., an initial 180° detorsion of the patient's right testis is done in a counterclockwise fashion. The patient's left testis is detorsed 180° in a clockwise fashion (see Fig. 56-11). Pain relief and an increase in the Doppler signal are the objective end points. If one rotation relieves some but not all of the pain, continue with another rotation. If the initial detorsion is mechanically difficult (which it will be if you are detorsing in the wrong direction) or makes the pain worse, detorse the testis in the opposite direction and observe your result. The objective success or failure of any testicular manipulation can be substantiated by an increase in Doppler signal and the patient's relief of pain.

With successful detorsion, the testicle returns to its normal anatomic position. Resolution of induration and swelling of the spermatic cord, testis, and epididymis will depend on the degree and duration of ischemia. Thus, the more severe the torsion and the longer it has been present, the longer it will take for the edema and induration to resolve. With significant ischemia, the entire epididymis often becomes enlarged like a link sausage (uncommon in epididymitis except in severe cases or those that are initially misdiagnosed or seen late in their clinical course), and the testis becomes quite firm, simulating a testicular tumor. In the author's experience, both of these reversible changes usually resolve over 3 to 4 hours. Occasionally the testis will torse in the opposite direction (medial to lateral) or have multiple twists. This may become apparent as the clinician assesses the results of the detorsion procedure by palpation, relief of edema, and return or increase of the Doppler signal. Even though manual detorsion will save an ischemic testicle, *it should not be substituted for definitive scrotal exploration*.

URETHRAL CATHETERIZATION

Alternatives to Catheterization

The merits of alternative approaches to urine specimen collection over patient catheterization are dependent on the patient's age and clinical setting.

In children, the collection technique reported by Amir and coworkers consists of placing the young child on his or her back. [34] In very young children, collection and analysis of spontaneously voided urine specimens following penile cleansing or suprapubic "finger tap" showed identical urine culture results to those specimens obtained by suprapubic aspiration. [34] The applicability of this to a busy ED is questionable. Often, it is possible to collect a spontaneously voided midstream specimen in a child if ED personnel are prepared in advance. The problem is that the voiding events tend to occur as the child is undergoing venipuncture, spinal tap, or attempted urethral catheterization. And more important, if the first specimen is missed or inadequate, how long are we willing to wait for another chance? Urethral catheterization is quick, definitive, and routinely used.

In adult men without anatomic lesions, first-voided specimens can define the presence or absence of culture-proven bacteriuria. [35] This certainly represents a user-friendly approach to urine collection in a busy ED and needs to be carefully considered.

In adult women, collection of clean-catch midstream specimens has been found to be as reliable bacteriologically as catheterized specimens. [36] A few caveats are worth mentioning: Patients must sit backward on the toilet when collecting the specimen (i.e., facing the wall, which theoretically promotes labial spreading). Of more concern is the fact that these studies excluded patients with vaginitis, urologic abnormalities, pregnancy, and vaginal bleeding. These are the clinical circumstances for which urine is commonly examined in young women visiting the ED. In this "at-risk" population, catheterized urine specimens are preferred.

Urethral catheterization seems a simple task—insertion of one tube into a larger tube. Nonetheless, many difficulties may arise. Patients often remember catheterization as either painful or uneventful and reflective of the operator's expertise, confidence, and gentleness.

Patients are often apprehensive about catheterization. If the clinician shows concern regarding position and exposure, the patient will be reassured. A moment should be spent in making sure a patient is positioned comfortably and appropriately for the procedure. Although adequate exposure may be obtained from a frog-legged position, the use of a table with stirrups (lithotomy position) is ideal, especially for female catheterization.

Anticipation and preparation of all materials necessary for urethral catheterization beforehand is reassuring to the patient. It is frustrating for the health care provider and upsetting to the patient when he or she is told "not to move or touch anything" while a search is made for additional equipment. Most catheterizations are performed using a standard catheterization tray. Often, these trays contain more equipment than is truly needed. This necessitates opening the tray and establishing a sterile field at the bedside, selecting those items that will be needed, and discarding the rest of the equipment. Once the penis or labia has been touched in preparation for the procedure, the touching hand is contaminated and ideally should not be handling any of the sterile equipment. When a standard catheterization tray is not used or is not available, catheterists should go through the anticipated procedure mentally to secure all of the appropriate equipment before actually starting the procedure.

Indications and Contraindications

Urinary catheterization and instrumentation are rarely a primary cause of urinary infection in otherwise healthy patients who urinate normally and carry small amounts of post-void residual urine. As with any procedure, catheterization needs to be limited to those clinical situations in which the benefits outweigh the risks. The following are considered to be indications for urethral catheterization:

1. Acute urinary retention.
2. Urethral or prostatic obstruction leading to compromised renal function.
3. Urine output monitoring in any critically ill or injured patient.
4. Collection of a sterile urine specimen for diagnostic purposes.
5. Intermittent bladder catheterization in patients with neurogenic bladder dysfunction.
6. Urologic study of the lower urinary tract.

Urethral catheterization should be avoided when other less invasive procedures will be as informative. The only absolute contraindication to urethral catheterization is the trauma patient with suspected urethral injury as evidenced by blood at the urethral meatus; an abnormal-feeling or high-riding prostate on rectal examination; or penile, scrotal, or perineal hematoma. These findings dictate the need for

retrograde urethrography to define the integrity of the urethra prior to any attempted urethral catheterization. [37]

Equipment

The equipment listed in Table 56-6 is included in most standard catheterization trays and must be at hand before attempting urethral catheterization. The catheterist should check the list of contents *before* opening the tray, as some trays do not include certain items. For most routine adult in-and-out catheterizations, a 14 Fr red rubber catheter or Foley balloon catheter is adequate. In infants or neonates, a 2 or 5 Fr feeding tube taped in place produces the least amount of urethral trauma. In older boys, a 5 to 12 Fr red rubber catheter or Foley balloon catheter may be used. Table 56-7 lists appropriate-sized catheters and feeding tubes for all ages. A 14 to 18 Fr coudé catheter should be considered after unsuccessful passage of a straight Foley balloon catheter or in any male patient with known enlargement of the prostatic median lobe. If a coudé catheter is not available, a larger 18 to 22 Fr Foley balloon catheter can be tried. In a male patient with a urethral stricture in whom attempts at catheterization with a straight Foley or coudé catheter have failed, passage of filiforms and followers is the next logical step. This requires special

TABLE 56-6 -- Sterile Equipment Required for Urethral and Suprapubic Catheterization

Urethral Catheterization
Foley catheter of appropriate size
Water-soluble lubricant for catheter
10-mL syringe of sterile water for Foley balloon
Sterile drainage bag with tubing
Sterile drapes
Sterile gloves
Povidone-iodine
Sterile gauze pads or cotton balls
Sterile specimen cup with lid

Cloth, paper, or plastic tape (to secure catheter to trunk or leg)
Benzoin (for increasing tape adherence)
Forceps
Suprapubic Catheterization
Foley catheter of appropriate size*
Sterile gloves
Sterile drapes
Sterile drainage bag with tubing
Sterile specimen cup with lid
Cloth, paper, or plastic tape (to secure catheter to trunk or leg)
Benzoin (for increasing tape adherence)
Materials in Cook "Peel-Away" Catheter Set
10-mL syringe
25-ga needle
22-ga needle
1% plain lidocaine
Povidone-iodine swab-sticks
Fenestrated drape
Gauze sponges
Disposable scalpel
Suture with needle
Introducer needle
Curved J-tipped wire guide
Peel-away sheath
Introducer

*Select the sheath size (in catheter set) based on the Foley catheter size. Generally, the sheath is 1 to 2 Fr sizes larger than the catheter (e.g., use an 18 Fr peel-away sheath with a 16 Fr Foley).

TABLE 56-7 -- Pediatric Urethral Catheter Size

Age Group	Pediatric Catheter Size*
Infants	8 Fr feeding tube
1–3 yr	10 Fr feeding tube
4–6 yr	10–12 Fr red rubber catheter (Robinson)
7–12 yr	>12 yr
5–8 Fr feeding tube	14 Fr red rubber catheter (Robinson)

*6 Fr is the smallest balloon catheter and is quite flimsy; would recommend 8 Fr in most cases; 12 Fr is the smallest coudé catheter.

expertise, but it can be learned quickly. If immediate bladder access is required in this circumstance or in any emergency, suprapubic placement of a peel-away sheath and Foley balloon catheter using the Seldinger technique will be needed. [38]

Anatomic Considerations

Female Catheterization

The female urethra is a short (approximately 4 cm), straight tube, usually of wide caliber, lying on top of the vagina. It must be approached between double labia, and the urethral meatus is occasionally hidden and not obvious (in contradistinction to that of most males, except those with hypospadias). If the female patient nervously adducts her legs, successful catheterization is most uncertain.

The female urethral meatus is an anteroposterior slit with rather prominent margins that is situated directly superior to the opening of the vagina and approximately 2.5 cm inferior to the glans clitoris (Fig. 56-12).[39] It is the first of three orifices encountered when examining any female genitalia cephalad to caudad in the lithotomy position. The urethral meatus may be especially difficult to find in the very young infant and the older postmenopausal woman. Anticipation of this and knowledge of the anatomic variances will help to modify any patient discomfort associated with needless catheter tip probing, which is an unsettling experience for both the patient and the catheterist.

Occasionally, the urethral meatus recedes superiorly into the vagina and is not immediately visible, because of either prior surgical procedures or atrophic postmenopausal changes. Anticipation of such cases will allow the examiner to gently advance an index finger into the vagina in the superior midline. The urethral meatus can usually be palpated and often visualized as a soft mound surrounded by a firmer ring of supporting periurethral tissue. Rarely, the meatus will have receded so far superiorly that it cannot be visualized at all, and catheterization must be carried out by palpation alone. From the meatus (if the patient assumes a supine position), the urethra proceeds straight back to slightly downward as it advances into the bladder just behind the symphysis pubis (Fig. 56-13*A*).

In women with a *urethrocele or cystourethrocele,* in whom the urethra or the bladder falls into the vagina, the "normal" urethral course may be more significantly posterior (Fig. 56-13*B* and *C*). The normal anatomic relationships in these situations may be recreated by spreading the index and long fingers and placing them along the superior vaginal wall and gently applying upward support (Fig. 56-13*D* and *E*). This reconstitutes the normal anatomic relationships and permits straight, rapid urethral catheterization.

Because the female urethra is so short, only half the total length of the catheter has to be inserted before it is safe to inflate the Foley balloon.

Figure 56-12 *A,* Anatomy of the female external genitalia. *B,* Uncomplicated catheterization in the female. *(A from Flocks RH, Culp DA: Surgical Urology: A Handbook of Operative Surgery, 4th ed. Chicago, Year Book Medical Publishers, 1975, p 357. B from Brunner LS, Suddarth DS: Lippincott Manual of Nursing Practice. Philadelphia, JB Lippincott, 1974, p 465. Reproduced by permission.)*

Male Catheterization

Because the urethral meatus is usually evident in most males, it may seem a simple matter to insert a urethral catheter. [40] Yet catheterization can be quite difficult. The normal male urethra is approximately 20 cm long from the external urethral meatus to the bladder neck (Fig. 56-14). The posterior prostatic urethra is approximately 3.5 cm long, and the contiguous external sphincter or urogenital diaphragm that encompasses the membranous urethra is 4 cm from the bladder neck. In males, any catheter must be fully inserted to the balloon-inflating side-arm channel before it is safe to inflate the balloon (Fig. 56-15). At the first egress of urine from the catheter, the balloon is just passing through the membranous urethra. The catheter still has greater than or equal to 3 cm to go before clearing the bladder neck. Inflation of the Foley balloon at any point other than full insertion of the catheter may result in iatrogenic urethral injury.

The male urethra is relatively fixed at the level of the urogenital diaphragm and symphysis pubis; traction downward on the penis kinks and promotes urethral folding at the level of the penile suspensory ligament (Fig. 56-16*A*). This creates a level of spurious obstruction. For this reason, the penis should always be held taut and upright during any urethral instrumentation including catheterization (Fig. 56-16*B*). The catheter then needs to make only a single curve rather than a complex S curve as it traverses into the bladder.

General Procedure

As stated previously, urethral catheterization must be done using sterile technique. Both male and female patients have special urethral meatal considerations. In the male, absolute total control of the penile foreskin is paramount to ensuring success. This is true for any male patient, but it is especially important in uncircumcised patients. Prior to establishing a sterile field, the foreskin should be retracted to its fullest extent proximal to the glans penis (Fig. 56-17*A*). A standard 4 × 4 gauze pad is unfolded, then refolded in its longest dimension, and carefully wrapped around the retracted foreskin at the level of the coronal sulcus (Fig. 56-17*B*). This will prevent the tendency for normal anatomic foreskin reduction during catheterization and provide a continuously dry and sterile field. The folded 4 × 4 gauze surrounding the foreskin is secured between the nondominant long and ring fingers when beginning the procedure and is not released until the procedure is completed (Fig. 56-18). This position leaves the nondominant index finger and thumb available for manipulating the catheter. Following catheterization, removal of the 4 × 4 pad and reduction of the penile foreskin to its normal anatomic position will prevent the development of iatrogenic paraphimosis.

In the female patient, the catheterist's nondominant thumb and index finger are used to separate the labia and create exposure of the urethral meatus. Once meatal visualization is achieved, the nondominant hand should not be removed (see Fig. 56-12*B*). This underscores the importance of proper equipment preparation. Access to antiseptic solution, viscous lubricating jelly, the appropriate catheter, and the urinary collection device should be prepared in advance to permit single-handed sterile use.

Following exposure of the urethral meatus in the female and the glans penis and urethral meatus in the male, an antiseptic solution (e.g., povidone-iodine) soaked into cotton balls or oversized cotton-tipped applicators is used to cleanse the exposed meatus and surrounding tissues. This is best done by hand but can also be done using the plastic forceps in the catheterization tray. The cleansing circular motion should begin on the urethral meatus and proceed outward, intentionally moving any debris toward the periphery and thus creating a sterile field.

An appropriately sized catheter (10 Fr is adequate for small children, whereas 14 to 16 Fr is commonly used in adults) that has been lubricated with viscous rather than inspissated lubricating jelly is gently passed by hand, or with the aid of a hemostat or plastic forceps, into the urethra and upward into the bladder. Injection of the male urethra with 5 mL of 2% viscous lidocaine (Anestacon) or a similar anesthetic lubricant administered through a syringe can be helpful for urethral distention and topical anesthesia. Regardless, the

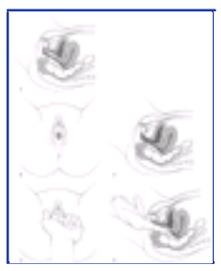

Figure 56-13 Female urethra. *A,* Sagittal view showing normal urethral course into the bladder. *B* and *C,* Cystourethrocele with loss of anterior support (frontal and sagittal views). *D* and *E,* Intravaginal re-creation of normal anatomic relationships with nondominant index and long fingers (frontal and sagittal views).

Figure 56-14 Anatomy of the male urethra. *(From Flocks RH, Culp DA: Surgical Urology: A Handbook of Operative Surgery, 4th ed. Chicago, Year Book Medical Publishers, 1975, p 359. Reproduced by permission.)*

patient should be advised of mild urethral discomfort and the potential urge to void. During slow, gentle passage of the catheter, one should be aware of the anatomic considerations discussed previously. A catheter that inadvertently enters the vagina should be discarded.

After passing the catheter "to the hilt" in all male patients, the balloon should be slowly inflated with 10 mL of air or tap water. Sterile water or saline is not required. Most 5-mL balloons will easily accommodate up to 30 to 50 mL of air or water without bursting. Obvious resistance or patient discomfort on balloon inflation should signal potential erroneous urethral positioning and mandates

Figure 56-15 Foley catheter placement. Foley catheter is inserted fully (i.e., to the balloon port) before air or water is injected to inflate the balloon.

reevaluation. If this occurs, the Foley balloon should be immediately deflated and the catheter repositioned or withdrawn slightly, then passed "to the hilt" again prior

to balloon reinflation. If this is unsuccessful a second time, catheter removal and urethral evaluation for a potential obstructive problem or false passage using retrograde urethrography is recommended (see Retrograde Urethrogram later in this chapter).

Following successful catheter passage and Foley balloon inflation, the catheter should be slowly withdrawn until the approximation of the balloon with the bladder neck precludes further withdrawal. The catheter is then connected to either a sterile leg bag or closed-system bedside drainage bag. If the patient will be released with an indwelling Foley catheter, it can be initially connected to a leg bag, which is then comfortably fastened to the lower thigh and upper calf. The patient and family must be instructed regarding proper care of the catheter and drainage device. In most other cases, the catheter may be secured either to the thigh or the lower abdomen (preferred with males) with adhesive tape or simply placed under the knee and left to drain dependently into the bedside drainage bag.

The use of antibiotics before simple catheterization is not warranted. However, patients with known valvular heart disease, suspected urinary tract bacteremia, chronic urinary tract infection, urethral stricture disease, or outlet obstruction associated with infection are considered to be at risk for procedure-induced bacteremia. In these patients, any urinary instrumentation, especially urethral dilation, requires early prophylactic parenteral gram-negative antibiotic coverage before any instrumentation is begun. These patients must also be released with appropriate antibiotic coverage and be scheduled for early urologic follow-up within 1 to 2 days. [41]

Difficulties in Male Catheterization

Phimosis

Physiologic adhesions between the foreskin (prepuce) and glans penis with associated inability to retract the foreskin are normal in children. This condition must be distinguished from phimosis, which is the inability to retract the foreskin proximally over the glans penis due to recurrent inflammation or trauma, which results in gradual scarring of the preputial opening. [42] It is not essential to retract the foreskin in uncircumcised boys at the time of catheterization if the urethral meatus can be visualized. At birth, the foreskin is fully retractable in only 4% of boys. Sufficient foreskin retraction to visualize the urethral meatus is possible in only half of newborn boys. Although the foreskin can be retracted completely in only 20% of 6-month-old boys, 90% of 3-year-old boys have a fully retractable prepuce. By 17 years of age, the foreskin should be physiologically separated and fully retractable in all males unless they have experienced secondary infections or repeated preputial trauma. [43]

The foreskin, especially in diabetics, is susceptible to recurrent infections and inflammation. A scarred, contracted, difficult-to-retract preputial opening may result, leading to phimosis. Phimosis precludes optimal hygiene of the glans penis and coronal sulcus, resulting in an increased risk of bacterial infection, transmission of sexually transmitted diseases (especially human immunodeficiency virus), and the development of penile malignancies. Occasionally the

Figure 56-16 Foley catheter placement. *A,* Holding penis taut and upright prevents urethral folding, lessens external sphincter spasm, and promotes unobstructed catheterization. *B,* Proper uncomplicated male catheterization with upward traction on the penis. *(From Brunner LS, Suddarth DS: Lippincott Manual of Nursing Practice. Philadelphia, JB Lippincott, 1974, p 465. Reproduced by permission.)*

phimotic opening becomes so tight that the meatus cannot be visualized or palpated, even for nonsterile catheterization. If the patient requires catheterization, it will be necessary either to perform a dorsal slit of the foreskin to expose the glans and urethral meatus sufficiently for cleansing and catheterization or to dilate the phimotic opening sufficiently to identify the urethral meatus and blindly pass the catheter. These procedures are discussed at the beginning of the chapter.

Edema of the Foreskin

Patients with penile trauma, paraphimosis, anasarca, or significant lymphatic obstruction from irradiation or cancer may have marked edema of the foreskin, subsequently burying the

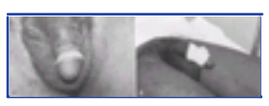

Figure 56-17 Foley catheter placement. It is important to fully retract the foreskin *(A),* especially in the uncircumcised male, so that a folded 4 × 4 gauze sponge can be wrapped around the coronal sulcus *(B)* and prevent foreskin reduction during the procedure. Once the procedure is terminated, the foreskin must be reduced to its normal anatomic position.

urethral meatus and glans penis in several centimeters of boggy foreskin (Fig. 56-19). Because the latter group of patients often require careful fluid monitoring, they may need an indwelling catheter. The clinician's first responsibility is to disclose the proper etiology for the foreskin edema. This will require enough foreskin manipulation to identify the glans penis, coronal sulcus, and urethral meatus, as well as the relationship of the prepuce and preputial opening to these structures, to ensure the absence of foreign body strangulation or paraphimosis (Fig. 56-20).

Two separate methods of visualizing the glans penis and urethral meatus are available to the clinician. [44] The simplest method is to manually compress the swollen foreskin by hand

Figure 56-18 Penile stabilization. To optimize manual dexterity during urethral instrumentation, the prepared penis should be grasped between the nondominant long and ring fingers. This leaves the index finger and thumb available to stabilize the catheter or glans.

or between opposing cold packs in an attempt to reduce the edema fluid (see Fig. 56-5*C* and *D*). Snugly wrapping the distal penis with Elastoplast for 10 minutes may also be helpful. In most mild cases, manual compression is often successful, and no further maneuvers are required. In more severe cases, the foreskin may be 6 cm thick in diameter. In such cases, the least traumatic but unfortunately most cumbersome way to visualize the glans penis and urethral meatus is to use a pediatric-sized vaginal speculum. The outer surfaces of the speculum are lightly lubricated, and the speculum is inserted into the opening of the edematous foreskin. The operator then opens the speculum gently and visualizes the glans penis, similar to viewing the cervix. Commonly, the 2 leaves of the speculum will slip out of the foreskin, making adequate visualization quite difficult. Subsequent meatal cleansing and catheterization performed with plastic instruments is cumbersome and is not recommended. It is much easier to palpate the urethral meatus with the index finger of the nondominant hand, then use the same index finger as a guide to blindly insert the Foley or coudé catheter into the urethra and upward into the bladder.

Figure 56-19 Paraphimosis. Tremendous foreskin edema from paraphimosis can make this diagnosis difficult unless the examiner searches diligently for the constricting band.

Meatal Stenosis

The urethral meatus may be either congenitally or secondarily narrowed by scarring, resulting in meatal stenosis. The stenosis may prevent admission of a normal-sized catheter. If the meatus admits a small-caliber tube (i.e., 5 Fr pediatric feeding tube or larger), this may be all that is required for the short term. It should be remembered that the inner diameter of the feeding tube or catheter is the important diameter for urinary drainage. A smaller, single-lumen tube may provide better drainage than a larger, double-lumen Foley balloon catheter.

If a larger-caliber catheter or a Foley balloon catheter is required, meatal dilation or meatotomy may be necessary. Meatal dilation is accomplished by repeatedly inserting larger meatal dilators to a certain end point. This procedure is painful and should be performed with topical meatal anesthesia in conjunction with light IV sedation.

On occasion, a ventral meatotomy may be required in men in whom repeated instrumentation or long-term catheterization has resulted in severe meatal stenosis. Using a 25- or 27-ga needle, infiltration of the ventral midline of the glans from the coronal sulcus to the distal tip of the meatus is performed with 1% plain lidocaine. A straight hemostatic clamp is then gently applied to the anesthetized area, with one jaw inside the meatus and the other on the anesthetized ventral midline of the glans. After the hemostat has been closed and left in place for 3 to 5 minutes, it is opened and removed. The crushed tissue is then cut with straight scissors. Some clinicians place a running hemostatic 4-0 chromic suture through the apex of the meatal incision and carry it out distally on both sides of the incision to prevent restenosis of the meatus. A 16 or 18 Fr Foley catheter left indwelling for 3 to 4 days may serve the same purpose. This procedure is best performed by a urologist.

Urethral Stricture

Urethral obstruction encountered in the anterior or bulbous urethra during catheterization is usually the result of urethral stricture disease. [45] Urethral strictures develop as a result of trauma, infection (especially sexually transmitted diseases), lower urinary tract instrumentation, or long-term indwelling catheter drainage. Strictures may remain asymptomatic for a period of time, but eventually most become symptomatic and cause urethral voiding symptoms, hematuria, or bloody urethral discharge that may or may not be associated with infection. *Manual force should not be used to negotiate or to dilate urethral strictures.* Force merely promotes a vicious cycle of false passages, bleeding, and eventual increased scarring, which makes catheterization more difficult. Inability to negotiate a urethral stricture with a simple straight Foley catheter or coudé catheter leads to consideration of urethral dilation using filiforms and followers.

Filiforms are very narrow, flexible, solid catheters, usually not exceeding 4 Fr in caliber. They are not dilators. Their sole function is to locate and successfully negotiate a strictured urethral segment. Each filiform has a straight or pigtailed (curved) distal end and a proximal female-threaded coupling into which the distal male end of a follower may be threaded. Following generous topical anesthesia with 2% lidocaine (Anestacon), the previously prepared penis is grasped between the nondominant long and ring fingers and stretched upward. The filiform is slowly passed down the urethra in an attempt to negotiate the strictured iris or

Figure 56-20 Paraphimosis. The appearance of this penis *(A)* could easily be mistaken as being normal. Proximal foreskin retraction reveals a normal coronal sulcus *(B)*. Distal foreskin manipulation *(C)* reveals a phimotic band causing paraphimosis.

narrowed segment of involved urethra (Fig. 56-21*A*). This is all done by "feel" and experience and may require several attempts. It is always best to advance the filiform with the gentlest of pressure.

Filiforms should never be forced through the urethra. Any encountered resistance represents the potential edge of the strictured urethra or fold of urethral mucosa. Undue force applied to the filiform at this point may result in perforation of the urethral mucosa and creation of a false passage along the urethral body or inferiorly into the perineum. If the filiform meets resistance, it should be partially withdrawn, rotated 90°–180°, then gently reinserted. If resistance is met again at the same location, the first filiform may be left in place (to fill up that particular obstructing site) and a second filiform advanced alongside it. A third and fourth filiform may be necessary before one of them successfully navigates the narrowed aperture of the stricture and advances upward through the normal proximal urethra and into the bladder (Fig. 56-21*B–D*). The sine qua non of success is the effortless passage of the filiform through the strictured area without spontaneous discharge of the filiform when it is released. Any amount of filiform return should alert the catheterist that the filiform has not negotiated the stricture and requires replacement. Pigtail filiforms (with a corkscrew-shaped tip) (Fig. 56-21*E*), rather than straight-tipped filiforms, are often easier to advance over an abrupt urethral edge and through the smallest of strictured openings. Once through the stricture, the filiform is advanced until the threaded coupling is near the urethral meatus (Fig. 56-21*F*).

Because filiforms are very pliable, they must be grasped securely. This is ensured by stabilizing the retracted foreskin and penis just proximal to the glans between the long and ring fingers of the nondominant hand as described previously (see Fig. 56-18) and holding the filiform between the nondominant

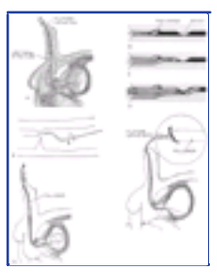

Figure 56-21 *A,* Passage of the filiform past the urethral stricture. *B,* Sequential passage of filiforms, with entry of the first catheter into the false passage. *C,* Advancement of the second filiform to the stricture site. *D,* Passage of the third filiform past the stricture. Following passage of the filiform into the bladder, redundant catheters are removed. *E,* Pigtail filiform passing through the stricture. *F,* Attachment of a follower to the filiform. *G,* Dilation of the stricture with a follower. *(E from Blandy J: Operative Urology. index finger and thumb. This allows controlled attachment and subsequent detachment of graduated followers as serial dilation is performed (Fig. 56-21*G*).

A follower of the smallest caliber (usually 8 Fr) should always be selected first; it should be copiously lubricated and threaded onto the filiform. When it has been threaded completely (no threads showing), it is gently advanced without pressure through the upwardly stretched penis and urethra into the bladder (see Fig. 56-21*G*). Stretching the penis upward discourages telescoping of the urethra and subsequent kinking of the filiform and follower (see Fig. 56-16*B*). The follower is advanced into the bladder until there is spontaneous egress of

urine from the follower, guaranteeing successful passage. Note that the side drainage holes of the 8 and 10 Fr followers are quite small and frequently become occluded with lubricating jelly. This may prevent spontaneous urinary drainage from the follower even though it has successfully negotiated the stricture and passed into the bladder. In this circumstance, easy passage of the 8 Fr follower into the bladder and the lack of gross blood or bloody drainage at the filiform-follower coupling when changing follower sizes are indicative of successful passage and dilation rather than creation of a false passage.

Absolute certainty of location of the 8 or 10 Fr follower can be established at any time by irrigating the follower with sterile saline, much like irrigating a Foley catheter. The irrigating fluid will dislodge any obstructing lubricating jelly from the side holes of the follower and will allow egress of urine from the follower. The entire dilating procedure is repeated with sequentially larger followers until one size larger than the proposed retention catheter is successfully introduced. Following completed dilation, the coupled filiform and follower are removed intact, the urethra is relubricated with topical lidocaine (Anestacon) anesthesia, and the previously selected 14 to 16 Fr balloon Foley or coudé catheter is passed to its fullest extent into the bladder. After return of urine from the Foley ensures proper placement, the Foley balloon is inflated and the catheter is withdrawn and left to drain as described previously.

Occasionally, a urethral stricture is so dense and irregular that a filiform and 8 Fr follower may pass successfully, but the density and length of the stricture prevent further dilation. In this circumstance, the indwelling filiform and follower may be taped to the penile shaft for 1 to 2 days to provide adequate bladder drainage and probable softening of the stricture.

The following procedure is used to *tape the follower to the penis*. After wiping excess lubricant from the follower and from the penile glans and shaft, a small amount of tincture of benzoin is applied to the follower and to the unbroken skin of the penile shaft (*not to the glans*). After the benzoin has dried, strips of paper tape 1.25 cm in width are placed longitudinally down the penile shaft without overlapping. The distal ends of each strip of tape are wrapped around the follower much like taping a nasogastric tube to the nose. These longitudinal strips will keep the follower in place. *It is important not to circumferentially wrap these strips around the penis.* If the tape were applied circumferentially, the tape might constrict venous and lymphatic return sufficiently to produce a relative paraphimosis.

Urethral dilation with filiforms and followers should be neither bloody nor excessively uncomfortable for the patient. If the procedure is bloody or uncomfortable or if no urine is returned despite advancement of the follower for at least 24 cm, the clinician should consider that the filiform may not be in the urethra, but instead has created a false passage. In such a situation, retrograde urethrography will define the urethral anatomy. In cases in which urethral instrumentation is unsuccessful for whatever reason, it may be necessary to place a suprapubic peel-away sheath cystostomy tube rather than persist with unsuccessful urethral dilation.

Spasm of the External Urethral Sphincter

The male patient may voluntarily or involuntarily contract the urogenital diaphragm (external sphincter), the striated urethral sphincter at the apex of the prostate. (This is especially true of trauma patients and men with neurogenic bladder dysfunction and pelvic floor spasms.) This produces spurious urethral resistance at approximately 16 cm from the meatus. Because increased abdominal pressure or voluntary perineal contraction causes reflex contraction of the external sphincter, the patient in these situations should be encouraged to lie supine and take slow, deep breaths, consciously trying to relax the perineum and rectum. Plantar flexion of the toes and ankles also aids in relaxation of the pelvic floor. Because the external sphincter is composed of striated muscle and fatigues within a few minutes, gentle but steady pressure exerted on the syringe or the catheter while the previously mentioned maneuvers are undertaken usually results in successful catheterization. If these maneuvers do not result in successful passage of the catheter, the catheterist may be encountering an anatomic abnormality that will require definitive retrograde urethrography before instrumentation.

High Bladder Neck

Occasionally, a patient may have an enlarged intravesical portion of the prostate with a secondary high-riding bladder neck. The tip of the standard Foley catheter may encounter this intravesical portion of the prostate and may not readily pass above it into the bladder. Resistance is usually encountered after the catheter has been passed 16 to 20 cm into the urethra. Slow instillation or injection of 20 to 30 mL of sterile lubricating jelly into the urethra may allow the catheter to slip over the prostate and into the bladder. If this fails, a coudé catheter may be inserted. This catheter has a bend in the tip, and one will almost always be able to maneuver it gently into the bladder (Fig. 56-22*A* and *B*). Passage of the coudé catheter often may be enhanced by having an assistant exert digital compression and flattening of the elongated prostate using a gloved finger in the patient's rectum (Fig. 56-22*C*).

Use of a catheter guide or stylet is *best reserved for the urologist,* as such techniques encourage creation of a urethral false passage (Fig. 56-22*D*). If the coudé catheter cannot be advanced on its own or with the added help of an assistant, a scarred, fixed bladder neck contracture, usually the result of transurethral surgery, may be present. Such a contracture is often very difficult to blindly negotiate. An attempt with filiforms and followers may be warranted. Direct cystoscopic visualization and incision of the bladder neck obstruction by a urologist is usually required.

Catheterization in the Patient with Pelvic Trauma

The patient with pelvic trauma or a straddle injury presents special problems in urinary management. The patient may be in shock from associated injuries. Accurate minute-to-minute monitoring of urinary output requiring bladder catheterization may be required in the initial resuscitation. Furthermore, radiographic evaluation to define the extent of lower urinary tract injury may require a retrograde cystogram, which necessitates urethral catheterization. Prior to urethral catheterization in all trauma patients, the penis should be examined for evidence of blood at the urethral meatus, the absolute marker of urethral injury. [37] Blood at the urethral meatus, a "high-riding" or abnormal feeling prostate on rectal examination, and penile, scrotal, or perineal ecchymoses are all hallmarks of potential urethral injury and represent contraindications to empiric urethral catheterization without an antecedent normal retrograde urethrogram. [37]

The hazard of injudicious urethral catheterization in the pelvic trauma patient is the potential worsening of an already

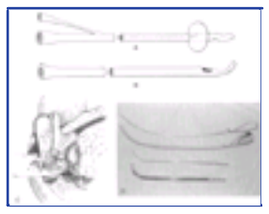

Figure 56-22 *A,* Self-retaining Foley-type catheter. *B,* Coudé catheter (also available in a non-self-retaining model). *C,* Superior pressure on the prostate may facilitate catheter passage. *D*, Catheter guide or stylet should be used only by a urologist.

existing, less serious urethral injury that is often associated with such trauma. Pelvic fractures most often impart injury to the prostatomembranous urethra just above the urogenital diaphragm. The shearing pelvic fracture fragments transect the urethra and puboprostatic ligaments, thereby displacing the prostate superiorly from its normal anatomic attachment to the posterior surface of the public bone. A partial or complete urethral injury may occur. An appropriately recognized and treated partial urethral disruption may heal with little or no scarring. However, a complete urethral disruption requires surgical repair and usually results in some degree of postoperative urethral stricture and, occasionally, urinary incontinence and impotence, all of which portend significant morbidity. The danger of injudicious urethral catheterization in this situation is the potential conversion of a partial injury into a complete urethral injury, with its associated complications. Retrograde urethrography is the diagnostic procedure of choice in any suspected urethral injury (see Retrograde Urethrogram later in this chapter).

In the event that contrast material flows easily from the urethra into the bladder without extravasation, complete urethral integrity is ensured, and an attempt to pass a 14 or 16 Fr Foley catheter should be made. If *any* urethral resistance is encountered other than that normally expected at the voluntary external sphincter (urogenital diaphragm) in a conscious, anxious patient, the catheterization should be immediately aborted and a urologist consulted. If passage is successful, the catheter balloon should be inflated and the catheter withdrawn until it approximates the bladder neck. At this point, it is left to dependent drainage, and very careful attention is

paid to the initial bladder effluent. Any colored urine other than clear or yellow is considered gross hematuria and mandates evaluation of the bladder and upper urinary tract to disclose the source.

If the retrograde urethrogram shows urethral extravasation *AND* passage of contrast into the bladder, a partial urethral injury has been identified. One gentle attempt at passage of a 12 to 14 Fr Foley or coudé catheter may be attempted, depending on the experience and confidence of the catheterist. Once again, any degree of resistance dictates termination of the procedure and urologic consultation.

In the patient without external sphincter spasm in whom the retrograde urethrogram shows evidence of urethral extravasation without any contrast filling the bladder, a complete urethral injury has been identified. Upon identification, immediate urologic consultation is indicated for placement of a suprapubic catheter and subsequent surgical repair of the complete urethral injury. One caveat: if more than 50 to 60 mL of contrast is used at any time for urethrography and more than gentle pressure is exerted during urethral contrast instillation, it is possible to create objective penile venous intravasation of contrast, which is benign. This intravasation of contrast may simulate urethral extravasation and produce a spurious examination result similar to urethral injury. The distinguishing feature with intravasation is that any subsequent film (i.e., post-void film) will disclose immediate clearing of the iatrogenic penile venogram, whereas urethral extravasation will persist indefinitely.

Suprapubic placement of a peel-away sheath and Foley catheter as an alternative to urethral catheterization for the trauma patient is covered elsewhere in this chapter.

Complications of Urethral Catheterization

Although urethral catheterization performed by skilled personnel in appropriate circumstances has an acceptable complication rate, untoward sequelae of catheterization are not unusual.

The frequency of bacteriuria after a single catheterization in a healthy outpatient population is probably less than 1%. [41] However, in hospitalized, elderly, debilitated, or postpartum patients, the rate may be considerably higher. Urinary catheterization is the leading cause of nosocomial urinary tract infections. The mortality in patients with nosocomial urinary tract infection is approximately three times that in patients not acquiring infection. [46] Of patients catheterized with a closed system for 2 to 7 days, 8% to 10% will have significant bacteriuria once the catheter is removed. [47] Patients with catheters indwelling more than 10 days almost always acquire an infection. Infection from the urethra and the bladder may disseminate to cause epididymitis, pyelonephritis, and bacteremia. Although the use of a povidone-iodine lubricating gel has been shown to reduce the inoculation of bacteria into the bladder at the time of catheterization, [48] further study will be needed to determine if this antiseptic lubricant actually reduces infectious sequelae.

With long-term catheterization, bacteriuria is inevitable. Although episodes of high temperature (=38.8°C) due to urinary tract infection in patients with long-term catheterizations are rare (2 per 1000 patient-days), these episodes can be associated with bacteremia and death. [49] Use of a condom catheter, adult diapers, and intermittent self-catheterization [50] represent noninvasive alternatives to long-term Foley catheterization in nonambulatory incontinent men and women. Other rare complications of long-term indwelling urethral catheterization include bladder stones, recurring bladder spasm, periurethral abscesses, bladder perforation, [51] and urethral erosion. [52]

In addition, complications may occur during the act of catheterization. False passages may be established in any area of the urethra when force is exerted on the catheter. In an uncircumcised patient, negligence in reducing the retracted foreskin to its normal anatomic position after urethral catheterization or instrumentation may lead to painful paraphimosis and associated complications.

Leaving a catheter indwelling too long or using a larger catheter than is needed promotes poor drainage of the periurethral glands, urethritis, and periurethral abscesses, all of which may lead to urethral stricture disease. Likewise, concretions may form around the catheter balloon and lead to the formation of bladder stones, many of which require operative removal.

The use of silicone rather than latex catheters for postoperative urinary drainage in adult males undergoing cardiac surgery has been shown to reduce the incidence of subsequent urethral stricture formation. [53] Although patients with indwelling latex catheters were catheterized less than 48 hours, a 2% incidence of urethral stricture was still noted at 1 year and a 5% incidence at 2 years. None of the patients with indwelling silicone catheters developed a stricture.

Hematuria has long been considered to be common immediately following even atraumatic catheterization. Although Sklar and colleagues found a small increase in urinary red blood cell (RBC) count with catheterization, only 1 in 47 patients had an increase of >4 RBCs per high-power field (HPF) attributable to the procedure. [54] They suggest that >4 RBCs per HPF following catheterization is unlikely to be due to the procedure and is, in fact, evidence of preexisting hematuria, which must be explained.

Undesirably retained urethral catheters are an uncommon but frustrating problem. Catheters may be retained because of balloons that do not deflate (see following section) or very rarely because of a knot that has spontaneously developed in the catheter (very rare). Catheter knotting has been associated with the insertion of a highly flexible catheter far into the bladder. [55] A guide wire passed up the catheter may be successful to manipulate some knots free, but urethral dilation with progressively larger catheters adjacent to the retained catheter may be needed to permit urethral passage of the knot.

REMOVING THE NON-DEFLATING CATHETER

The self-retaining Foley balloon-type catheter obviates the need for cumbersome taping or suturing of the catheter to keep it in place. Occasionally, however, an indwelling catheter balloon does not deflate. Needless to say, this problem has challenged and frustrated many clinicians and has produced a number of solutions. The usual cause of the nondeflating catheter balloon is the malfunction of the flap-type valve in the balloon lumen of the catheter, which normally allows fluid to enter the balloon of the catheter but prevents passive egress (Fig. 56-23).[56] The ideal solution is one that resolves the problem—deflating the balloon—without creating another problem (i.e., unnecessary bladder irritation or balloon fragmentation). Of the methods recommended to decompress nondeflating catheter balloons, the only technique that approaches the ideal directly attacks this flap valve deformity. Other methods of deflation are effective but require more creativity and dexterity on the part of the catheterist.

Techniques

One method of balloon deflation consists of simply overstretching the balloon with air or water to the point of rupture. Up to 200 mL of fluid can be injected before a 5-mL balloon will rupture.[56] [57] Adding volume to the empty bladder may not be a problem. Unfortunately, this technique may produce unacceptably painful bladder distention for the patient whose catheter is blocked and whose bladder is either secondarily

Figure 56-23 A flap-like defect in the inflating channel of a balloon catheter that is being raised by a wire stylet passed down the inflating channel to deflate the balloon. *(From Eichenberg HA, Amin M, Clark J: Nondeflating Foley catheters. Int Urol Nephrol 8:171, 1976. Reproduced by permission.)*

contracted due to chronic infection or neurogenic bladder dysfunction or distended to the point of maximum filling. An even more compelling reason not to use this technique is the disconcerting frequency of balloon fragmentation and subsequent foreign-body bladder stone formation. In an experimental study of 100 catheters (50 of which were overdistended with water and 50 of which were overdistended with air), all 100 catheter balloons ruptured into fragments. [56] Cystoscopic inspection of the bladder and removal of any fragments will be required to prevent bladder stone formation if this method of balloon deflation is selected.

A second method of balloon deflation involves injecting an erosive substance into the balloon port. This causes the balloon to deflate after part of the balloon wall has been eroded. Organic compounds that attack the latex polymers are often used. Ether, acetone, mineral oil, and even petrolatum ointment have been used. In general, the more volatile the substance, the more rapidly it ruptures the balloon. Rupture of the balloon may be partly a result of the rapid expansion that some of these volatile substances—especially ether—undergo at body temperature. Ether was reported to rupture 58 of 60 catheter balloons within 2 minutes of injection into the balloon port. Unfortunately, in 56 of the catheters, a free fragment of the balloon was created. Mineral oil, which works more slowly, was associated with fragment production in 95 of 100 catheters tested.[56] When released into the bladder, organic substances often produce a symptomatic chemical cystitis. Use of these substances is discouraged.

A third method of deflating the balloon is to puncture it with a needle. With gentle traction, the balloon is located in the urethra or drawn against the bladder neck and is punctured with a thin 25- or 27-ga spinal needle. This needle may be directed suprapubically (transvesically), transvaginally, transperineally, or transrectally. The procedure may be done either blindly[58] or with the aid of ultrasound. In women, a spinal needle may be gently introduced transurethrally alongside the catheter. Fragmentation during puncture can occur, but it is much rarer than in the two techniques described previously.

The easiest way to deflate a nondeflating balloon is to attack the inflate-deflate channel that normally prevents the passive egress of inflating fluid. Patients may be sent to the ED in the late evening or early morning hours after their catheters have been progressively shortened by ingenious health care providers during the day. Cutting the catheter may result in rapid deflation if the valve-flap defect happens to be present in the part of the catheter that is cut off. This is an uncommon occurrence. A shorter catheter with a more proximal valve-flap defect can often be left for 24 hours with ongoing slow balloon deflation, but this maneuver leaves the problem of managing an unconnected catheter and an incontinent patient. Devising a waterproof and aseptic method of collecting urine from the shortened Foley catheter may require use of a ureteral catheter drainage bag or other ingenious approaches.

When presented with this situation, it is often best to insert a thin, rigid wire into the balloon-port lumen in an effort to deflate the valve-flap defect sufficiently and promote the escape of fluid from the balloon. A stainless steel wire suture of 3-0 or 4-0 gauge is the thinnest suitable material. The wire stylet from an angiographic catheter, guide wires from ureteral catheters, and very small, well-lubricated ureteral catheters themselves have all been reported to be successful. When a ureteral catheter guide wire was used in one series, 34 of 39 balloons were deflated without fragmentation. In the five unsuccessful cases, needle puncture of the balloon was required and was successful.[58]

One approach is to use a stepwise series of maneuvers. If the balloon does not deflate, remove the syringe adapter plug from the balloon-inflating channel. This rules out a malfunction of the adapter. If the balloon water does not escape, next insert an angiographic catheter stylet into the balloon-inflating channel and rotate it. Usually, the water from the balloon flows out along the wire. If it does not, place the catheter on traction and attempt to locate the balloon by palpation either perineally, transvaginally, or transrectally. If this is successful, a 25- to 27-ga spinal needle under local anesthesia is used to blindly puncture the balloon and then remove the catheter. If localization is unsuccessful, multiple blind passes with the 27-ga needle can be attempted; this is usually successful in decompressing the balloon and removing the catheter.[59] If the patient requires a permanent indwelling catheter, one may be replaced immediately. Concomitant inadvertent needle punctures of the rectum are usually of no clinical significance.

Once a malfunctioning balloon has been deflated, it is mandatory to carefully inspect the balloon itself for missing fragments. If a piece of the balloon is missing, it is necessary to arrange for subsequent cystoscopy to look for and remove the fragment. Unfortunately, pretesting Foley catheter balloons by trial inflation and deflation before insertion does not eliminate the potential for a nondeflating Foley catheter balloon.

SUPRAPUBIC ASPIRATION OF THE BLADDER

One problem of interpreting voided urine samples is that the urine from the bladder passes through a progressively more contaminated urethral conduit. In the female, the perineum is a culture medium where bacteria are seemingly eager to be swept along into the sterile collection cup and onto the agar plate. To avoid the dilemma of interpretation, clinicians have devised maneuvers to minimize the presence of contaminating organisms. Male patients are instructed to retract the foreskin, cleanse the meatus, discard the first portion of urine, and catch the midstream part of the voided specimen. Female patients are asked to perform even more difficult maneuvers to avoid bacterial contamination: sit backward on the commode facing the wall, hold the labia apart with one hand, cleanse the periurethral skin blindly with the other, then reach for the cup, initiate voiding, and catch the midstream urine—all while holding the labia apart and maintaining the precarious position on the commode. Some experts[60] have women void in the lithotomy position after an assistant retracts the labia, cleanses the perineum, and then catches the midstream urine.

In standard transurethral bladder catheterization, even under ideal circumstances, the procedure is often uncomfortable. The catheter must traverse the distal contaminated urethra and may infrequently introduce contaminating bacteria into the specimen and into the bladder of the patient, resulting in infection, primarily in patients who don't empty their bladder with normal voiding.

Suprapubic aspiration of the bladder, first reported as a method of collecting urine for bacteriologic study in 1956, [61] offers the clinician a relatively simple means of obtaining uncontaminated bladder urine. Urethral contamination is successfully avoided, and positive results always represent

true bacteriuria. The one caveat is that the bladder must be full to avoid multiple painful needle sticks, a clinical situation that may be difficult to discern in a sick child.

Indications

In the neonate or the young child, suprapubic aspiration or urethral catheterization can provide the clinician with a sample that is reliable for bacteriologic interpretation.[61] [62] [63] Although disconcerting to some parents (they may wish to leave the room or look away during the procedure), suprapubic aspiration is not a dangerous procedure, and the sensitivity of urinalysis of this urine for bacteriuria approaches 100%. However, for children 2 years or older, urine can generally be more easily collected by urethral catheterization.

For adult patients, the indications for suprapubic aspiration are more limited, because these patients usually can cooperate with the clinician. Men with condom catheters or phimosis, however, may require suprapubic aspiration to minimize urethral contamination. Aspirated cultures, rather than catheterized specimens, may help rule out contamination in patients with asymptomatic bacteriuria on routine urine collection. In infections caused by organisms that in other circumstances are often discounted as contaminants (e.g., *Staphylococcus epidermidis* or *Candida albicans*), suprapubic aspiration or a catheterized specimen is required to confirm the presence of such pathogens.

In patients in whom the possibility of infravesical infection is a concern (e.g., patients with chronic infections of the urethra or the periurethral glands), suprapubic aspiration may help localize a bladder from a urethral source.

Figure 56-24 *A,* For a suprapubic bladder tap, the infant is restrained and placed in a frog-legged position. *B,* A 22-ga needle punctures the abdominal wall in the midline approximately 1 to 2 cm cephalad to the superior border of the pubic bone. The syringe is perpendicular to the plane of the abdominal wall (usually 10°–20° from the true vertical). The bladder is an abdominal organ in infants, and placing the needle too close to the pubic bone or angling toward the feet may cause the needle to miss the bladder. Localizing the bladder with bedside ultrasound facilitates this procedure.

Procedure

The clinician must first locate the bladder. A full, palpable, or percussible bladder should be readily apparent, but this can be difficult to discern in all but the thinnest patients. If there is any question about the location or the amount of bladder urine, a quick ultrasound examination is informative. The point of entry in the skin should be 1 to 2 cm above the superior edge of the symphysis pubis. The syringe and needle are passed perpendicular to the abdominal wall toward the bladder, usually a 10° to 20° angle from the true vertical, somewhat *cephalad* in *children* (Fig. 56-24) and somewhat *caudad* in *adults* (Fig. 56-25). Note that the bladder of a newborn is an abdominal organ and that it will be missed if the needle is inserted too close to the pubis or is angled toward the feet.

The child is placed supine and is restrained with the legs in a frog-legged position. Once the prepared skin has been draped and the point of entry has been chosen, a skin wheal of local anesthesia is raised to reduce discomfort. When the skin has been anesthetized, a longer, larger-caliber needle (usually 22-ga, 3.75 to 8.75 cm in length) is advanced in the midline through the skin and quickly into the bladder. The editors prefer to advance the needle attached to a syringe, with active aspiration during advancement. As soon as the bladder is entered, urine appears in the syringe. A short needle is adequate for virtually all pediatric patients. After the urine is collected, the syringe and needle are withdrawn. Microscopic hematuria always follows the procedure but gross hematuria is uncommon. A bandage may be placed over the puncture site. If urine is not obtained, the needle is not removed but withdrawn to a subcutaneous position and redirected at a

Figure 56-25 The peritoneum is pushed cephalad by the filled bladder during suprapubic aspiration in an adult. The needle is directed slightly caudad.

different angle. Often a child may spontaneously start to void following any type of invasive stimulus (e.g., bladder irritation by a probing needle, venipuncture, or lumbar puncture). Hence, preparation to collect a spontaneously voided specimen is recommended, should that option arise. This should be anticipated before beginning blood or spinal fluid collection during the bacteremic workup of the febrile neonate.

In most patients, an acceptable urine sample can be obtained with the first needle pass. If the needle points too caudad in an effort to avoid entering the peritoneum, it is possible to enter the retropubic space, skimming the bladder muscle and never penetrating the bladder mucosa.

Complications

Stamey has performed several thousand aspirations without complications. [63] Bacteremia does not result from this procedure. [64] Bowel penetration has occurred in children with distended abdomens from gastrointestinal disturbances. [65] The combination of gaseous bowel distention and relative hypovolemia may displace and flatten the relatively empty bladder against the pelvic floor. Even when the large bowel has been penetrated, patients recover uneventfully. Simple penetration of the bowel with a needle is considered an innocuous event and requires no specific treatment.

PERCUTANEOUS SUPRAPUBIC CYSTOSTOMY

Background

Although suprapubic cystostomy was described as early as 4 centuries ago, the safety of the procedure was first demonstrated by Garson and Peterson in 1888. The first modern method was the Campbell trocar set, described in 1951. [66] [67] Campbell used a sharp trocar passing through a sheath. The sheath had one longitudinal portion of its wall missing to permit a balloon-type Foley catheter to be passed into the bladder. The Campbell trocar is a large-diameter instrument, accepting up to a 20 Fr catheter. Newer technologies have made its use obsolete in the ED.

The development of punch thoracostomy tube sets suggested their use as modified cystostomy tubes. This led to the invention of medium-caliber cystostomy tubes, which were easier to insert than the Campbell trocar but provided more satisfactory drainage than adaptations of IV infusion sets. [68] [69] [70] Ingram's trocar catheter is perhaps the best known of these tubes. It has three lumina: one for inflating the retention balloon and the other two for drainage or irrigation. The Ingram catheter is available in a 12 or 16 Fr size. The Stamey suprapubic catheter is another variation of this type, but it uses a four-wing Malecot-type retention device rather than a preferred user-friendly inflatable balloon.

Perhaps the most widely known and frequently used trocar-type cystostomy tube is the Cystocath. [71] It is available in 8 and 12 Fr sizes. The latter is more commonly used for adult patients. The Cystocath is packaged as a self-contained set supplying virtually everything needed for insertion. The device is easy to insert and may be satisfactory for relatively long periods of trouble-free use if the patient is given conscientious nursing care.

The major difficulty with cystostomy tubes of all designs has been securing them to the patient's skin. Those with retention balloons, such as the regular Foley urethral catheter or the Ingram catheter, are most secure and only need tape to secure them to the anterior abdominal wall. Virtually all other systems depend on tape or skin adhesive to hold either the tube or the appliance in place. They become an annoyance to both the patient and the care provider.

The most user-friendly device for suprapubic bladder access is the Cook peel-away sheath unit. [38] It uses the Seldinger (guide wire) technique to gain bladder access and allows suprapubic placement of a Foley balloon catheter for definitive bladder drainage. This device is recommended for ED use over other suprapubic bladder access approaches and is discussed in this section.

Indications

In general, any patient who would require a urethral catheter but in whom a catheter cannot be passed is a candidate for a suprapubic cystostomy tube. In emergency situations, the majority of these patients are men with urethral stricture or complex prostatic disease and trauma patients with urethral disruption. Depending on the experience of the catheterist, dilation can usually be performed in patients with urethral strictures using filiforms and followers. If there is any difficulty with urethral instrumentation, a suprapubic cystostomy tube is prudent and prevents further urethral injury. Complete urethral transection associated with a pelvic fracture is an absolute indication for emergent suprapubic cystostomy. Many affected patients need laparotomy because of associated injuries, and a large suprapubic catheter can be placed intraoperatively. However, if the patient does not require laparotomy, a percutaneously placed Foley catheter allows urologic surgery to be done electively after the patient's condition has stabilized clinically.

Patients with lower genitourinary infection deserve special care before instituting any type of urethral instrumentation. The risk of inciting an episode of gram-negative bacteremia with urethral dilation must be considered, and

appropriate IV gram-negative antibiotic coverage started before the patient is instrumented. Foley catheter drainage is the first choice and suprapubic drainage is an option in patients with acute prostatitis or epididymitis who require bladder drainage. Ideally, a suprapubic catheter allows both bladder drainage and unobstructed drainage of prostatic, seminal vesicle, and urethral secretions but requires an invasive procedure with its associated risks.

Neurologically disabled patients (e.g., quadriplegics or paraplegics) or patients with any type of neurogenic bladder dysfunction who have been successfully maintained on a program of intermittent self-catheterization occasionally have difficulty with urethral catheterization. In these patients, especially those with high spinal cord lesions, suprapubic needle aspiration or suprapubic cystostomy can be a rapidly effective method of relieving autonomic hyperreflexia associated with acute bladder distention. Bladder decompression in the dysreflexic, profusely perspiring, hypertensive quadriplegic in sympathetic crisis provides dramatic symptom resolution, whether by suprapubic bladder decompression or Foley catheter placement.

Suprapubic catheterization is *not* recommended as first-line treatment for the patient who is voiding poorly from lower urinary tract prostatic obstruction. Such patients, although symptomatic, are better off with intermittent self-catheterization or an indwelling Foley catheter if they are in retention or have chronically infected urine. Young women with psychosocial or emotional neurogenic bladder dysfunction are best managed by intermittent self-catheterization. In all such cases, clinical judgment will dictate the most appropriate form of treatment and whether concomitant antibiotic therapy is required.

Contraindications

Because placement of a suprapubic tube involves some risk, patient selection is important. The procedure should not be performed in a patient whose bladder is not definable. Although no absolute reported minimum bladder volume has ever been established, there must be enough urine in the bladder to allow the needle to fully penetrate the bladder dome without immediately exiting through the base. There must also be enough urine in the bladder to displace the bowel away from the anterosuperior surface of the bladder and the entrance of the needle. Ultrasound may be helpful in defining bladder anatomy.

Individuals who have a history of previous lower abdominal surgery, intraperitoneal surgery, or irradiation may have developed adhesions or adherence of the bowel to the anterior bladder wall. They are potentially at greater risk for bowel injury during percutaneous suprapubic cystostomy tube placement than those without previous abdominal surgery. Blind suprapubic cystostomy tube placement in these patients should be avoided. The absence of any of these risk factors does not totally exclude the risks of bowel or intraperitoneal injury, but it reduces them significantly.

Patients with bleeding diatheses are at greater risk for postinsertion bleeding, either into the bladder or into the retropubic space, than their normal counterparts.

Equipment

The items of equipment needed for Cook's peel-away sheath placement are listed in Table 56-6 .

Procedure

The following comments describe the placement of the Cook peel-away sheath. With modifications, these guidelines are adaptable for any type of suprapubic catheter placement.

Preparing the Patient

If necessary, the lower abdomen is shaved. Povidone-iodine skin preparation or another suitable bactericide is used to cleanse the area. The extra liquid is removed, and the skin is allowed to dry. A 6-mL syringe is filled with 1% lidocaine, and a 22-ga, 7.75-cm spinal needle is attached. A skin wheal is raised in the proposed site (approximately 2 to 3 cm above the pubic symphysis), and the subcutaneous tissue and rectus abdominis muscle fascia is infiltrated at a 10°–20° angle toward the pelvis.

The bladder is located by advancing the needle in the prescribed direction while aspirating the syringe. Urine is easily aspirated when the bladder is entered (Fig. 56-26*A*).

Placing the Tube

Once the bladder has been located, the syringe is removed from the needle and a guide wire is advanced through the needle into the bladder (Fig. 56-26*B*). The needle is withdrawn, leaving only the guide wire traversing the anterior abdominal wall and positioned inside the bladder. A No. 15 scalpel blade is used to make a stab incision directly posterior to the wire through the skin, subcutaneous tissue, and superficial anterior abdominal wall fascia. The peel-away sheath and indwelling fascial dilator are then passed together over the wire into the bladder (Fig. 56-26*C*). The guide wire and fascial dilator are removed, leaving only the peel-away sheath inside the bladder (Fig. 56-26*D*). A preselected Foley balloon catheter is then passed through the indwelling intravesical sheath into the bladder (Fig. 56-26*E*). Urine is aspirated to confirm proper placement. The Foley balloon is inflated with a minimum of 10 mL of air, water, or saline (Fig. 56-26*F*). The peel-away sheath is withdrawn from the bladder and anterior abdominal wall and is literally peeled away from the catheter, leaving only the indwelling suprapubic Foley catheter (Fig. 56-26*G*). The catheter is withdrawn slowly until the inflated balloon approximates the cystostomy site (Fig. 56-26*H*). The catheter is connected to a drainage bag, and the wound is dressed with 4 × 4 gauze pads to complete the procedure.

Complications

A wide variety of complications specific to each procedure have been reported, which serve as reminders that suprapubic cystostomy is not innocuous. Occasionally, despite the best intentions, the suprapubic tube or catheter cannot be positioned or maintained successfully without untoward sequelae (Table 56-8).

The most serious complications involve perforation of the peritoneum or the intraperitoneal contents. Any condition that might fix the anterior peritoneum so that the filled bladder cannot lift the peritoneum cephalad may result in either transperitoneal bladder puncture or possible perforation of small or large bowel. [73] [74] [75] Although finding the bladder using a small-gauge scout needle may help reduce bowel injury, even in the most apparently successful of bladder punctures, a complication may result.

Figure 56-26 Suprapubic cystostomy with the Cook peel-away sheath introducer. *A,* Bladder is entered with a syringe and needle. Location is confirmed by the aspiration of urine. *B,* Syringe is removed and the guide wire is passed through the needle into the bladder. *C,* The needle is removed, then the dilator and peel-away sheath are passed over the wire into the bladder. A small stab wound in the anterior abdominal fascia may be required to accommodate the dilator and sheath. *D,* The dilator and wire are removed, leaving only the sheath inside the bladder. *E,* The preselected Foley balloon catheter is passed through the sheath into the bladder. Urine is aspirated to confirm location. *F,* The balloon is inflated with a minimum of 10 mL of air, saline, or water. A 5-mL balloon will accommodate 10 mL easily and make accidental catheter distraction less likely. *G,* The sheath is removed from the bladder, anterior abdominal wall, and cutaneous entry site, and is then literally peeled away from the indwelling catheter. *H,* The catheter is withdrawn until a snug fit is ensured at the cystostomy site.

TABLE 56-8 -- Reported Complications of Suprapubic Cystostomy

Bowel perforation
Intraperitoneal extravasation (without a prior history of surgery)
Extraperitoneal extravasation
Infection of space of Retzius
Ureteral catheterization
Obstruction of tubing by blood, mucus, or kinking
Tubing comes out
Hematuria

The cystostomy tube or catheter that merely traverses the peritoneum may produce a mild ileus, serve as a route for peritoneal infection, or drain the bladder contents into the peritoneal cavity. The last situation would be expected if a Cystocath, rather than a peel-away sheath, were used, and one of the extra holes of the Cystocath tubing opened into the peritoneal cavity. Through-and-through bladder penetration with associated rectal, vaginal, or uterine injury has been reported, although the consistent use of small-gauge bladder locator needles and the judicious advancement of fascial dilators should reduce the incidence.

Occasionally the clinician is tempted to proceed with suprapubic cystostomy when the bladder is not palpable and has not been located with a syringe and needle. Injury of adjacent organs is much more frequent in these circumstances. If clinicians remind themselves that the bladder eventually refills, they will find waiting much more tolerable. If faced with an emergency, *ultrasound guidance may be helpful for determining bladder size and location*.

Infection may occur at the suprapubic cystostomy skin site or anywhere along the course of the catheter. [76] Use of antimicrobial ointment daily after cleaning the catheter entry site may reduce purulence around the tube. However, topical care does not prevent eventual deep space or bladder infection from the presence of a foreign body. Deeper tissue infections may result from extravasated infected urine or from a superficial infection spreading along the tube to a hematoma at the bladder or fascial level. Parenteral antibiotics may be required. Open drainage is rarely needed unless a loculated abscess has formed.

Hematuria is rarely more than a transient problem. [77] After suprapubic Foley catheter insertion, bladder irrigation may occasionally be required to clear the hematuria. Transient Toomey syringe aspiration may be needed to evacuate clots.

EMERGENCY LOWER GENITOURINARY RADIOLOGIC PROCEDURES

Trauma to the urinary tract accounts for about 10% of all injuries seen in EDs. Although the signs of genitourinary trauma in general can be quite subtle, lower urinary tract injury can often be quickly identified and thoroughly evaluated radiographically in the ED. Radiologic imaging of the upper urinary tract is generally a less urgent matter and can usually be done in the radiology suite or, when important for emergency operative decision-making, as a single shot intravenous pyelogram (IVP) in the operating room. Hence, this section does not discuss the role or technique of IVP in detail. Note that the timing of any radiologic evaluation can be challenging to the emergency clinician, especially when faced with a critically ill multiple trauma patient. The priority and extent of such an evaluation, of course, must be determined by the trauma team of clinicians involved in each resuscitation.

Indications for Evaluation

The urinary tract includes the kidneys, ureters, bladder, urethra, and external genitalia. Approximately 8% to 10% of *blunt* abdominal trauma is associated with injuries to the urinary tract.[78] In one large series,[79] 7% of gunshot wounds and 6% of stab wounds to the abdomen resulted in *penetrating* wounds to the kidney. For injury identification purposes, the genitourinary system is best divided into lower urinary tract (i.e., urethra and bladder), upper urinary tract (i.e., kidneys and ureter), and external genitalia (i.e., penis, scrotum, and testes or vagina, labia majora, and labia minora). Each of these subdivisions has its own markers for potential injury. These markers are addressed during the resuscitation phase of trauma care and during secondary injury survey when the abdomen, pelvis, external genitalia, vaginal vault, and rectum are systematically examined.

The markers for lower urinary tract injury are blood at the urethral meatus, abnormal position of the prostate on rectal examination (in men), and gross hematuria. [80] Perineal ecchymosis and scrotal hematoma also represent potential lower urinary tract injury, but these findings are usually seen later in the patient's course rather than acutely in the ED. Gross hematuria or microscopic hematuria (=3 to 5 RBCs per HPF-spun specimen) *in conjunction with any history of shock* (systolic blood pressure =90 mm Hg) *in the field or in the ED following blunt trauma* are markers of potential upper urinary tract injury in any adult. [81] In children, a meta analysis has defined 50 RBC/hpf as the quantity below which imaging may be omitted and no significant injuries missed. [82]

In genitourinary trauma, the lower urinary tract is always evaluated before the upper urinary tract. Retrograde urethrography and retrograde cystography are the diagnostic procedures of choice to evaluate potential injury to the lower urinary tract. These studies must be carried out in the proper sequence and in a retrograde fashion to avoid missing potential injuries. *Retrograde* refers to the technique of instilling contrast retrograde through the urethra or by gravity filling of the bladder. It must be distinguished from antegrade filling, in which IV contrast for IVP or abdominal computed tomography (CT) is excreted from the kidneys and allowed to fill the bladder passively over time.

Contrast-enhanced CT is the diagnostic examination of choice for suspected renal trauma. It provides greater resolution and sensitivity than bolus infusion IVP with nephrotomography and has the advantage of evaluating other intra-abdominal structures as well. [83] However, it is expensive, and in some hospitals it is not readily available on a 24-hour basis. A reasonable course of action under these circumstances would be to initiate the upper urinary tract investigation with bolus-infusion IVP with nephrotomography and to investigate further with contrast-enhanced CT if an ill-defined or poorly visualizing kidney is the result of the initial study. Contrast-enhanced CT should be performed initially if thoracic or intra-abdominal injuries are present or suspected, or if there is concern about renal pedicle injury.

Gross Hematuria

Gross hematuria is indicated by any color of urine other than clear or yellow. It is an *absolute* marker for urinary tract injury and an indication for diagnostic evaluation. The resuscitating clinician must be responsible for observing the initial bladder effluent following Foley catheter insertion. Vigorous fluid resuscitation may quickly clear initial gross hematuria and eliminate the only marker for potential injury. When gross hematuria is encountered as an injury marker, the bladder and kidneys are thought of as potential sources for the hematuria. In most cases, gross hematuria in association with a pelvic fracture will implicate the bladder as the most likely source of injury. In the absence of a pelvic fracture and with a history of upper abdominal or chest trauma, the kidneys are the most likely source of the hematuria. In urologic trauma, the lower urinary tract must always be studied before the upper urinary tract (i.e., study the urethra before the bladder, study the bladder before the kidneys). The specific diagnostic studies must always be done in a retrograde fashion. This allows the responsible clinician to directly control the amount of contrast used to investigate potential urethral or bladder injuries. Whenever any doubt exists about the mechanism of injury, the patient's physical examination, or the source of gross hematuria, the resuscitating clinician is always advised to begin with an evaluation of the lower urinary tract before evaluating the upper urinary tract.

Evidence of Lower Urinary Tract Injury

In the resuscitation of any trauma patient, placement of a Foley catheter has become the standard method of monitoring urinary output. Blood at the urethral meatus, however, indicates a potential partial or complete urethral disruption and dictates the need for a retrograde urethrogram to delineate urethral integrity. This study can be done by the resuscitating clinician in the ED or on the operating room table by the trauma surgeon or urologist if the patient requires immediate surgical intervention for life-threatening injuries.

The male posterior urethra, which includes the membranous and prostatic urethra, is injured more frequently than the anterior urethra. The urogenital diaphragm encloses and fixes the membranous urethra; the prostate and prostatic

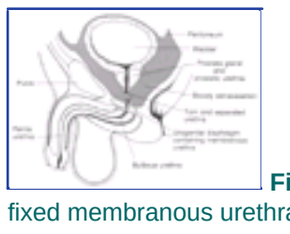

Figure 56-27 A common posterior urethral injury is a disruption of the membranous urethra. In this case, a distended bladder and attached prostate gland are sheared from the fixed membranous urethra. Note the development of a perivesical hematoma and the presence of a "high-riding" prostate gland.

urethra are firmly attached to the posterior surface of the symphysis pubis by the puboprostatic ligaments. Blunt trauma and pelvic fractures, especially in the presence of a full bladder, may result in shearing forces that partially or completely avulse portions of the firmly attached posterior urethra. Usually the bladder and prostate gland are sheared from the membranous urethra, resulting in a complete urethral disruption (Fig. 56-27). The female urethra, in contrast, is short and relatively mobile and generally escapes injury in blunt trauma. Occasionally, a significant pelvic fracture will result in a laceration or avulsion of the female urethra at the bladder neck. Direct injuries to the female urethra may also occur secondary to penetrating trauma to the vagina or perineum. These injuries often are disclosed by blood at the introitus or an abnormal vaginal examination in the female pelvic fracture patient. [84]

Contusions or lacerations of the male anterior urethra occur when the bulbous urethra is compressed against the inferior surface of the symphysis pubis. This happens most commonly as a result of straddle injuries in males but may result from any blunt perineal trauma. Significant trauma to the penile urethra is rare without penetrating injuries or urethral instrumentation. *Anterior urethral injuries* may result in extravasation of blood or urine into the penis, scrotum, or perineum, or along the anterior abdominal wall, depending on whether or not Buck fascia has been violated (Fig. 56-28).[37] This is in contrast to *posterior urethral injuries*, in which blood and urine extravasate into the pelvis.

The rectal examination is highly specific in the evaluation of a posterior urethral disruption. If the prostate is not clearly defined (it should have the consistency of the examiner's thenar eminence), is high-riding rather than in its normal anatomic location, or if a pelvic hematoma can be palpated (see Fig. 56-27), one should be

suspicious of a posterior urethral injury, and a retrograde urethrogram should be performed before attempting urethral catheterization. However, a normal rectal examination, by itself, *should not be considered definitive evidence of an intact urethra* if other clinical signs raise suspicion for urethral injury. Retrograde urethrography is a quick, technically easy study to perform and should be part of every emergency clinician's armamentarium.

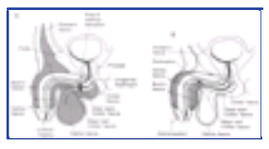

Figure 56-28 *A,* Disruption of the anterior urethra (bulbous urethra) occurs with straddle-type injuries in the male. Extravasation of urine and blood may occur in the perineum or scrotum, or along the anterior abdominal wall. Note that in this diagram, Buck fascia has been penetrated. *B,* Anterior urethral injury in which Buck fascia remains intact. In this situation, extravasation is confirmed and results in a swollen and ecchymotic penis. Such an injury usually results from instrumentation of the anterior urethra.

Pelvic Fracture

Pelvic fractures occur commonly in patients with urethral or bladder injury. The incidence of lower tract injuries in males with pelvic fractures ranges from 7% to 25%. Conversely, approximately 80% of all posterior urethral and bladder injuries are associated with pelvic fractures. [80] Because of the severity of late complications, especially urethral strictures, which most often require difficult surgical repair, it is paramount that these injuries not be missed. Again, in any female patient with a pelvic fracture, it is most important to examine the introitus and vaginal vault for blood, which may be indicative of urethral, bladder neck, or vaginal wall lacerations. In male patients, rectal examination of the prostate to assess its position will be most helpful in assessing the posterior urethra. A pelvic fracture in association with gross hematuria is an absolute indication for retrograde cystography. In a review of 234 patients with traumatic pelvic fractures, no major lower urinary tract injuries were found in the absence of gross hematuria. [80]

Radiographic Contrast Material

Radiographic contrast material is used to fill vessels and other structures to render them diagnostically radiopaque. To evaluate the urethra and bladder, contrast is injected or instilled into these structures in a retrograde manner. To evaluate the kidneys and ureters, a bolus of contrast material is injected into the venous system, opacifying the renal parenchyma and collecting system as it is excreted unchanged in the urine. Three types of contrast material are currently available (Table 56-9). All contain iodine, and all are hyperosmolar with respect to blood. Conventional agents, such as Hypaque and Renografin (diatrizoate), are triiodinated water-soluble agents (ionic monoacetic monomers) that completely dissociate into anion and cation moieties on intravascular injection. Osmolality is quite high, ranging from 1200 to 2000 mOsm/kg. Many of the side effects of contrast agents have been attributed to their osmolarity. Although iodine concentrations do determine the quality of the radiographic image, iodine itself is not thought to play a major role in the typical anaphylactoid side effects. [85]

Two new classes of contrast agents are ioxaglate (Hexabrix), an ionic monoacetic dimer, and nonionic (nondissociating) agents, such as iopamidol (Isovue) and iohexol (Omnipaque). The newer agents have twice as many iodine atoms per particle in solution as conventional agents and therefore provide significantly higher urinary iodine concentration, offering better diagnostic imaging. The osmolality of the newer agents is markedly lower, ranging from 600 to 700 mOsm/kg. The lower osmolality and improved chemical structure may be associated with fewer adverse side effects. [86] [87] Although these new agents are promising for intravascular use, there is still some skepticism that they will truly limit major or clinically significant contrast reactions. [88] The lower-osmolarity nonionic agents have not been associated with a lower incidence of contrast-induced nephropathy. Furthermore, there is no indication for using these more expensive products in the retrograde evaluation of the injured lower urinary tract.

Radiographic Techniques

Kidneys, Ureters, and Bladder

The plain film, scout film, or KUB (for kidneys, ureters, and bladder) film of the abdomen, as this view is variously referenced, includes the kidneys, ureters, bladder, and full pelvis. It is essential as the initial diagnostic film because it serves as a reference for all subsequent films after injection or instillation of contrast material. Incidental nondiagnostic findings on initial KUB that may alert the clinician to the possibility of

TABLE 56-9 -- Clinical Use of Radiographic Contrast Material (RCM) for Intravenous Pyelogram (IVP) and Retrograde Studies

Use of RCM for IVP	Iodine Content (mg/mL of Solution)	Osmolality (mOsm/kg) (H_2O)	Average Volume for IVP
Conventional ionic RMC	288	1511	Adult: 100 mL over 30–60 sec*
Renografin-60 (diatrizoate sodium)			Child: 1.5 mL/kg†
Hypaque (50%) (diatrizoate sodium)	300	1500	Adult: 100 mL over 30–60 sec*
			Child: 1.5 mL/kg†
Conray (methyl glucamine iothalamate)	282	1217	Adult: 100 mL over 30–60 sec*
			Child: 1.5 mL/kg†
New nonionic RMC	300	616	Adult: 50 mL over 30–60 sec‡
Isovue (iopamidol)			Child: 1–1.5 mL/kg†
Omnipaque 300 (iohexol)	300	672	Adult: 50 mL over 30–60 sec‡
			Child: 1–1.5 mL/kg†

Use of RCM for Retrograde Studies	Use	Procedure
Renografin-60 or Hypaque (50%)	Dilute stock solutions with saline 1:10 (10% solution)	Urethrogram: 10–15 mL of dilute solution injected slowly through urethral meatus. Children: 0.2 mL/kg Cystogram: after plain film and with Foley catheter in place, fill bladder of adult with 400 mL of dilute contrast material, introduced under gravity. Children: 5 mL/kg

*Average dose of iodine for IVP with ionic RCM: 350–400 mg/kg or 1.5 mL/kg
Adult: Low dose: 10 g
Intermediate dose: 30 g
High dose: 60 g
†Do not exceed 3 mL/kg total dose.
‡Because the ratio of iodine atoms to dissolved particles is 1.5 with conventional ionic agents and 3.0 with the nonionic agents, less volume is required with the new agents. Average dose is 200–350 mg/kg.

Figure 56-29 Retrograde urethrogram. The foreskin is fully retracted and an unwrapped 4 × 4 gauze sponge is folded in half longitudinally and wrapped around the penis proximal to the coronal sulcus, to prevent foreskin reduction. *A,* The penis is held between the long and ring fingers of the nondominant hand. The thumb and index finger ensure a snug fit of the syringe in the urethra. *B,* Equipment needed for retrograde urethrography and cystography. *C,* Alternative technique for securing the "irrigation-tip" syringe in the urethra.

urinary tract injury include the following:

1. Loss of one or both psoas shadows secondary to blood in the retroperitoneum.
2. Spinal curvature secondary to splinting—usually concave to the side of the injury.
3. Lower rib or transverse process fractures, both of which may be associated with upper urinary tract injury.
4. Pelvic fracture.

The KUB must always precede the injection or instillation of contrast material, because radiopaque shadows seen on the plain film must be differentiated from extravasation on the postevacuation film.

Retrograde Urethrogram

Retrograde urethrography is indicated whenever there is uncertainty about the integrity of the urethra. In cases associated with pelvic fracture, the patient should remain supine throughout the entire radiographic examination. This is important to ensure stability of any possible retropubic hematoma that may result from extensive venous bleeding associated with the initial pelvic fracture. In cases of suspected urethral injury not associated with pelvic fracture, it is acceptable to obtain oblique films during the study that may complement the examination findings. Perpendicular stretching of the penis across the thigh or oblique films may be needed to ensure urethral unfolding and a high-quality urethrogram.

Although several techniques have been promoted for retrograde urethrography, one is emphasized in this section. The choice of technique is not as important as attention to detail. Solutions of either full-strength Hypaque (50%), Cystografin or Renografin-60, or the same agents diluted to a less than 10% solution using sterile saline as the diluent, are frequently used (see Table 56-9). First, a plain film (KUB) of reference must be taken before injection of any contrast material. [81] The penile foreskin must be retracted and secured with a folded 4 × 4 gauze sponge. Second, the penis should be held between the long and ring fingers of the nondominant hand to allow the thumb and index finger of the nondominant

Figure 56-30 Normal retrograde urethrogram. The patient is supine on the examination table. The penis is stretched perpendicularly across the patient's right thigh to allow urethral unfolding and complete urethral visualization.

hand (see Fig. 56-18) a snug fit of the contrast-filled syringe inside the urethra (Fig. 56-29*A*).

After sterile penile preparation, a catheter-tipped Toomey irrigating syringe or a regular 60-mL syringe with an attached Christmas-tree adapter (Fig. 56-29*B*) is gently advanced inside the urethral meatus until a snug fit is ensured (Fig. 56-29*C*). Third, approximately 50 to 60 mL of full- or half-strength contrast material is then injected *slowly* under constant pressure into the urethra. Prior to the injection of contrast, the penis should be stretched perpendicularly across the patient's thigh to prevent urethral folding (i.e., the double image of the proximal penile and bulbous urethra superimposed on one another) (Fig. 56-30). Overly forceful injection of contrast material may cause intravasation of contrast material into the venous plexus of the urethra (Fig. 56-31). Finally, during the injection of the last 10 mL of contrast, a film (the urethrogram) is taken.

Figure 56-31 Venous intravasation (*arrows*) during a forceful retrograde urethrogram. This may mimic urethral extravasation, but it clears immediately, as opposed to actual extravasation, which remains indefinitely. The presence of intravasation is benign. *(From Richter MW, Lytton B, Myerson D, Grnja V: Radiology of genitourinary trauma. Radiol Clin North Am 11(3):626, 1973.)*

The alternative to this technique, which is discussed in most standard textbooks, is to insert a Foley catheter just inside the urethral meatus, inflate the balloon to ensure a snug fit in the fossa navicularis, and then inject contrast through the catheter (Fig. 56-32). If not done carefully, this technique often results in the spillage and deposition of contrast outside the urethra and onto the patient and the examination table, thus yielding a spurious result.

The extravasation of contrast material from a urethral disruption usually appears as a flame-like density outside the urethral contour (Fig. 56-33*A–C*). If any contrast material is seen within the bladder in conjunction with urethral extravasation, a partial rather than complete urethral disruption is more likely. In a complete urethral disruption, urethral extravasation will be present without evidence of contrast within the bladder. The examiner needs to be certain that the lack of bladder contrast is not secondary to voluntary contraction of the external sphincter. Occasionally, as mentioned previously, intravasated contrast material is seen in the periurethral penile venous

Figure 56-32 Retrograde urethrogram using a Foley catheter (8 Fr). Slowly inflate the balloon with 2 mL of air, tap water, or sterile saline to create a snug fit; then slowly inject 60 mL of a 10% solution of contrast material through the catheter lumen (see text).

Figure 56-33 *A,* Retrograde urethrogram. Urethrogram in case of supramembranous urethral rupture. Contrast extravasation is typical of that seen with this type of injury. *B,* A

rupture at the proximal bulbous urethra into the scrotum (*arrows*). *C,* Residual contrast material within perineum and scrotum. *(A from Morehouse DD, MacKinnon KJ: Posterior urethral injury: Etiology, diagnosis, initial management. Urol Clin North Am 4:74, 1977. C from Richter MW, Lytton B, Myerson D, Grnja V: Radiology of genitourinary trauma. Radiol Clin North Am 11:627, 1973.)*

plexus (see Fig. 56-31). It is of no clinical significance and should not be mistaken for urethral extravasation. As expected, penile venous intravasation (venous plexus opacification) is seen to clear spontaneously on any post-void films, as compared with urethral extravasation, which remains indefinitely.

If a Foley catheter has been successfully placed into the bladder and a partial urethral injury is suspected later, such an injury can be easily demonstrated without removing the catheter. The lubricated end of a pediatric feeding tube is placed into the penile urethra alongside the existing Foley catheter (Fig. 56-34). A seal can be obtained by compressing the glans penis with the nondominant thumb and index finger and gently injecting contrast material via a Luer-Lock syringe with the dominant hand. In this way, extravasation can be demonstrated. It should be noted, however, that successful placement of the Foley catheter obviates the need for further treatment of a partial urethral tear in the emergency setting, because an indwelling catheter alone is appropriate initial management for this type of injury. The finding of an associated urethral injury must be conveyed to a urologist, as it will dictate the duration of definitive Foley catheter drainage.

Retrograde Cystogram

A retrograde cystogram is performed any time a bladder injury is suspected. It assumes the urethra is normal prior to passing the Foley catheter. A preliminary KUB is obtained that will serve as the reference film for the entire examination. Next, the bladder is filled under direct operator supervision by *gravity instillation of contrast material*. After the central piston is removed from a 60-mL catheter-tip syringe, the catheter-tipped end of the syringe is attached to the Foley catheter and held above the level of the patient's bladder. The contrast material is poured into the syringe

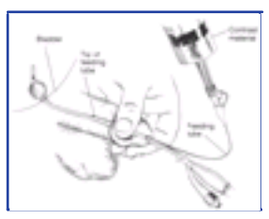

Figure 56-34 Evaluation of a urethral injury with a Foley catheter in place. A lubricated pediatric feeding tube has been advanced into the urethra beside the indwelling Foley catheter.

and allowed to fill the bladder by gravity instillation to 1 of 3 end points: (1) 100 mL with evidence of gross extravasation on fluoroscopy or on plain film, (if the examiner elects to check at this point); (2) 400 mL in an adult or any child 11 years or older. In children younger than 11 years, bladder capacity, and therefore appropriate contrast volumes, are estimated based on the formula "(age in years + 2) × 30"; or (3) to the point of initiating a bladder contraction (see later), then adding an additional 50 mL by hand injection under pressure.

Anteroposterior (AP) and complementary oblique projections are obtained so long as there is no evidence of a

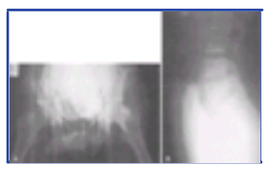

Figure 56-35 Retrograde cystogram. *A,* In patients with pelvic fracture, retrograde cystography should be done with the patient supine throughout the examination. Here, gross extravasation is evident, but its superior extent is not well defined. *B,* A lateral film may help define the extent of any extravasation. This film shows no intraperitoneal extension, so the extravasation must be totally extraperitoneal.

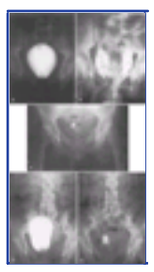

Figure 56-36 Retrograde cystogram. *A,* Anteroposterior (AP) filled-bladder film. *B,* AP postevacuation film of same patient showing extensive extravasation not seen on the AP filled-bladder film. Balloon of catheter is identified by *arrows*. *C,* "KUB" (kidneys, ureters, and bladder) showing bullet in the area of pelvis. *D,* AP filled-bladder film of same patient showing bladder displacement to right, presumably from a pelvic hematoma. No extravasation is visible with the bladder full of contrast. *E,* AP postevacuation film of same patient, showing subtle contrast extravasation in area of bullet that could easily be missed without a high-quality preliminary KUB and post-evacuation film.

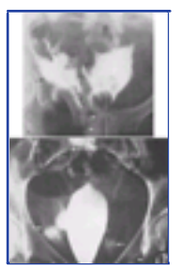

Figure 56-37 Examples of extraperitoneal bladder rupture. *A,* Note the amorphous extravasation of contrast material within the perivesical space (*arrows*) in a patient with a right pelvic fracture (*arrowheads*). *B,* A second patient with a pelvic fracture (*arrowhead*) and perivesical hematoma shows the teardrop shape of a deformed bladder and extraperitoneal extravasation (*arrows*). *(From Richter MW, Lytton B, Myerson D, Grnja V: Radiology of genitourinary trauma. Radiol Clin North Am 11:623, 1973.)*

pelvic fracture. In the presence of a pelvic fracture, all films are obtained with the patient in the supine position for the same reasons that were elucidated for retrograde urethrography. A lateral film may be informative when oblique films are not possible (Fig. 56-35). An AP postevacuation film must be obtained in all cases following bladder drainage. This will disclose posterior perforation in select cases, especially those associated with penetrating trauma (Fig. 56-36*A–E*). Again, a *dilute solution of contrast material* (see Table 56-9) may be used, rather than full-strength contrast. Some authors recommend a dilute solution of contrast material (=10%) because extravasation into periurethral or perivesical tissues may cause considerable inflammatory reaction at higher concentrations. The dilute solutions do not appear to compromise the quality of the study, but this must be a consideration. *Retrograde cystography done by any technique other than hand-poured gravity instillation is subject to inadequate bladder filling or connector tubing-catheter disconnection.* Both conditions will result in spurious examination results, which may adversely impact important patient management decisions.

It must be stressed that in the absence of initial gross extravasation, the bladder must be filled to 400 mL in an

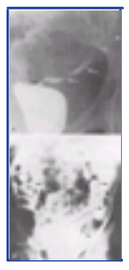

Figure 56-38 Intraperitoneal bladder rupture. *A,* A 22-year-old pedestrian hit by an automobile. Note extravasation of contrast material beginning at the dome and tracking up the left paracolic gutter (*arrows*). *B,* This 57-year-old man had fulguration of a bladder tumor at the bladder dome and sustained perforation. A cystogram dramatically demonstrates the extravasation of contrast material that outlines the bowel loops (*arrows*) and the paracolic gutters. *(Courtesy of Morton A, Bosniak MD, New York.) (From Richter MW, Lytton B, Myerson D, Grnja V: Radiology of genitourinary trauma. Radiol Clin North Am 11:623, 1973.)*

adult, and to an appropriate capacity in a child, and the catheter clamped with a Kelly clamp. Volumes less than 400 mL have been associated with false-negative findings, especially in penetrating bladder injuries. [89] At times, the patient may have difficulty cooperating with bladder filling because of a head injury or associated pain; and in the case of severe injury, the patient may have involuntary bladder contractions, causing contrast material to back up into the Toomey syringe. If this occurs, refill the bladder to the point of initiating a bladder contraction, clamp the Foley, remove the initial syringe, and replace it with a 60-mL contrast-filled syringe, unclamp the catheter, hand-inject the additional 50 mL under pressure, and reclamp the catheter. The goal is to overdistend the bladder. Once the filled-bladder films have been obtained and reviewed, the Foley catheter is unclamped and the contrast material is allowed to drain into a bedside drainage bag. The AP postevacuation film is then obtained to visualize any posterior extravasation that may have been hidden by the distended bladder during the AP filled-bladder film. Once again, care must be taken to ensure that contrast material is not spilled onto the patient or the examination table during the procedure. Spilled contrast can lead to spurious examination results.

Extravasation from an injured bladder may be intraperitoneal, extraperitoneal, or both. Extraperitoneal extravasation is usually seen as flame-like areas of contrast material confined to the pelvis and projecting lateral to the bladder (Fig. 56-37). If the contrast material extravasates intraperitoneally, it tends to fill the paracolic gutters and outline intraperitoneal structures, particularly the bowel, spleen, or liver (Fig. 56-38). It is important to distinguish extraperitoneal from intraperitoneal injury, as the treatment options are totally different (i.e., surgical repair for all intraperitoneal injuries and for extraperitoneal injuries that extend into or primarily involve the bladder neck, especially in women). Most other extraperitoneal injuries can be managed confidently by Foley catheter drainage alone.

Retrograde cystography may be done in conjunction with contrast-enhanced abdominal CT scanning. The bladder must be filled just as if a conventional retrograde cystogram were being obtained. The catheter is clamped, and evidence for contrast ascites is sought on the CT scan (Fig. 56-39). When this is encountered, bladder injury with extravasation must be looked for with selective images of the pelvis.

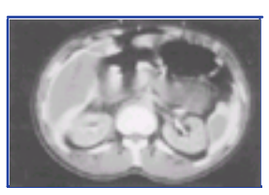

Figure 56-39 Retrograde cystogram and abdominal computed tomography (CT) scan. These two procedures can be done concomitantly. The bladder is filled in the standard retrograde fashion and the catheter is clamped. Intravenous and oral contrast can then be administered and CT scanning performed. This film demonstrates contrast ascites, which is consistent with intraperitoneal bladder rupture and extravasation.

Contrast Medium Reactions and Toxic Effects

In the lower genitourinary tract radiologic procedures that are described in this section, the contrast material is administered within the urinary collecting and drainage system. Hence, the patient is at low risk for systemic absorption and allergic reaction. Even with IV infusion, contrast medium reactions are rare; the incidence of significant reactions (i.e., of sufficient severity to require medical intervention) with IV administration is between 1 in 1000 and 1 in 10,000 uses.

Although IV use of contrast medium is outside the scope of this text, volumes and administration information are outlined in Table 56-9 . The ED use of contrast agents is often necessary and justified despite the small possibility of untoward reactions. At times, the patient's past history may not be known, underlying renal function cannot be rapidly assessed, or alternative imaging techniques (e.g., ultrasonography) are unavailable. In such circumstances, the risks vs the benefits of emergent imaging using IV contrast must be carefully weighed. Often the potential information gain of contrast-enhanced imaging in the unstable patient far outweighs the small associated additional risk.

Section X - Obstetric and Gynecologic Procedures

Chapter 57 - Emergency Childbirth

Lynnette Doan-Wiggins

The past century has witnessed a marked improvement in prenatal and obstetric care in the United States and with that a marked reduction in infant and maternal mortality. At the beginning of the 20th century, for every 1000 live births in the United States, six to nine women died of pregnancy-related complications and approximately 100 infants died before 1 year of age. [2] From 1900 through 1997, the maternal mortality rate declined almost 99% to less than 0.1 reported deaths per 1000 live births. Similarly from 1915 to 1997 the infant mortality rate declined 93%, to 7.2 per 1000 live births. [2] Environmental interventions, improvements in nutrition, access to health care, and medical advances (such as better management of pregnancy-related hypertension) and an increase in the number of in-hospital deliveries have all contributed to this remarkable decline. [2] [36]

The degree to which the emergency clinician interacts in the process of labor and delivery varies among institutions, depending on the availability and readiness of inpatient obstetric services. The role of the emergency clinician may be only to determine that the patient is indeed in active labor and to order transport directly to the labor and delivery area. In a hospital with little or no obstetric services, the emergency clinician may alternatively be called on to manage a complicated delivery and neonatal resuscitation until transfer to another hospital is possible.

To this end, the emergency clinician should be able to assess the stage and timing of labor, aid the mother in delivery of the infant, and provide initial stabilization of the newborn.

LABOR

Labor is defined as the coordinated sequence of involuntary uterine contractions that result in progressive effacement and dilation of the cervix. This, coupled with the voluntary bearing-down efforts of the mother, terminates in delivery, the actual expulsion of the products of conception.

Labor is normally divided into three stages. The first stage begins when uterine contractions reach sufficient force to cause cervical effacement and dilation and ends when the cervix is completely dilated. Although the average duration of the first stage of labor is about 4 hours in parous patients and 7 hours in nulliparous patients, there is marked individual variation. [22] The second stage of labor begins when dilation of the cervix is complete and ends with delivery of the infant. The duration of this stage is also highly variable, with a median of 50 minutes in nulliparas and 20 minutes in multiparas. [22] In general, if the second stage lasts more than 2 hours, abnormal labor has developed. [22] The third stage of labor begins after delivery of the infant and ends after delivery of the placenta. Infrequently, a fourth stage of labor is described as the hour immediately following delivery and is the period in which postpartum hemorrhage due to uterine atony is most likely to occur. [22]

IDENTIFICATION OF LABOR

True versus False Labor

Before the establishment of true or effective labor, women may experience so-called false labor. Quite common in late pregnancy, false labor is characterized by irregular, brief contractions of the uterus, usually with discomfort confined to the lower abdomen and groin. These contractions, commonly referred to as *Braxton-Hicks contractions,* are typically irregular in timing and strength, and there is no change in the cervix and no descent of the fetus.

True labor is characterized by a regular sequence of uterine contractions, with progressively increasing intensity and decreasing intervals between contractions. The discomfort produced by the uterine contractions of true labor begins in the fundal region and radiates over the uterus into the lower back. The uterine contractions of true labor are accompanied by effacement and dilation of the cervix, with descent of the presenting part of the fetus.

False labor is most common in late pregnancy and in parous women. Although false labor usually stops spontaneously, it may convert rapidly to the effective contractions of true labor. Therefore, a period of observation may be necessary. The interval between true labor contractions gradually diminishes from 10 minutes at the onset of the first stage of labor to as short as 1 minute or less in the second stage. [22]

Show

A rather common and dependable sign of the approach of labor is the "show" or "bloody show." A rather late sign of labor, show consists of a small amount of blood-tinged mucus discharged from the vagina and indicates that labor is already in progress or will likely occur during the next several hours to few days. Show represents extrusion of the mucus plug that filled the cervical canal during pregnancy and is evidence of cervical effacement and dilation. Normally, only a few drops of blood escape with the mucus plug.[22] More substantial bleeding during labor suggests an abnormal cause such as abruption of placenta or placenta previa, and vaginal examination is generally *contraindicated*. [22]

Rupture of the Membranes

Spontaneous rupture of the membranes usually occurs during the course of active labor. Typically, rupture is evident by a sudden gush of a variable amount of clear or slightly turbid fluid. Rupture of the membranes before the onset of labor at any stage of gestation is referred to as *premature rupture of the membranes* (PROM).

Rupture occurring at term, but before the onset of labor, is called *term premature rupture of the membranes* and complicates approximately 8% of pregnancies.[7] Term PROM is followed by the onset of labor and delivery within 5 hours in approximately 95% of cases. [7] The most significant maternal risk of term PROM is intrauterine infection. Fetal risks associated with PROM include umbilical cord compression and ascending infection. [7]

Membrane rupture occurring before 37 weeks of gestation is called *preterm premature rupture of the membranes* (pPROM). Delivery within 1 week of pPROM occurs in approximately 75% of patients regardless of management or clinical presentation. [7] The most significant maternal risk of pPROM is intrauterine infection, although with appropriate management, serious maternal sequelae are uncommon. [7] The most significant risks to the fetus are complications of prematurity such as respiratory distress, necrotizing enterocolitis, and intraventricular hemorrhage. [7] Definitive treatment of

PROM at any stage of gestation is left to the clinician and is dependent on multiple factors including the presentation, status and gestational age of the fetus, and maternal factors, such as suspected infection and placental location. Treatment options include the induction of labor, operative delivery, the use of prophylactic antibiotics, and the use of antenatal corticosteroids to promote fetal lung maturity. [7] [48] [52]

Although membrane rupture during labor is typically manifested by a sudden gush of fluid, presentation, particularly that of PROM, may be more subtle. Because accurate diagnosis is crucial to management, symptoms suggestive of PROM should be confirmed. Examination should be performed in a manner that minimizes the risk of introducing infection. Therefore digital cervical examinations, which increase this risk, should be avoided unless prompt labor and delivery is anticipated. When obstetric facilities are not immediately available, a sterile speculum examination can be performed. Rupture of the membranes is verified if amniotic fluid is seen extruding from the cervical os or pooling in the posterior fornix. [7] [22]

Differentiation of amniotic fluid from vaginal fluid may be made by testing the pH of a drop of the fluid with Nitrazine paper. Amniotic fluid has a pH of 7.0 to 7.5 and turns the paper blue-green to deep blue. In the presence of vaginal secretions only, with a pH of 4.5 to 5.5, Nitrazine paper remains yellow. [2] [7] [12] [22] Abe[2] found the Nitrazine test to be positive in 98.9% of women with known rupture of the membranes and negative in 96.2% of women with intact membranes. In clinical practice, however, the test is less reliable because it is frequently used in cases of questionable rupture in which the amount of amniotic fluid is small and, therefore, more subject to pH changes from admixed blood and vaginal secretions. False positive tests may occur with blood, semen, or bacterial vaginosis and false-negative tests with minimal fluid.[2] [7] [12] [22]

A less frequently used method to test for amniotic fluid is *fern*ing. A drop of fluid from the cervical os or vaginal fornix is placed on a clean glass slide. Owing to the high sodium chloride content of amniotic fluid, a fern pattern is seen through the microscope as amniotic fluid dries. [7] [29] When the clinical history or physical examination is unclear, ultrasound examination may be useful to document oligohydramnios that, in the absence of fetal abnormalities, is suggestive of membrane rupture. Although outside the scope of the emergency clinician, membrane rupture can be diagnosed unequivocally with ultrasonographically guided transabdominal instillation of indigo carmine dye with subsequent passage of blue fluid from the vagina. [7] If rupture of the membranes is documented in the emergency department (ED), the patient's clinician should be notified and hospital admission of the patient considered.

Evaluation of Labor

When a woman presents in labor, the general condition of the fetus and mother must be quickly ascertained by means of the patient history and physical examination. Inquiry is made as to the onset and frequency of contractions, the presence or absence of bleeding, the possible loss of amniotic fluid, and the prenatal care and condition of the mother and fetus. In the absence of active vaginal bleeding, the position, presentation, and lie of the fetus may be determined by abdominal palpation and sterile vaginal examination. Staging of labor is assessed by vaginal examination. Fetal well-being is monitored by auscultation of fetal heart tones, particularly immediately after a uterine contraction.

Lie, Presentation, and Position

In the latter months of pregnancy, the fetus assumes a characteristic posture within the uterus, usually forming an ovoid mass that corresponds roughly to the shape of the uterine cavity. Typically, the fetus becomes folded or bent on itself in such a way that the back becomes markedly convex, with the head, thighs, and knees sharply flexed. Usually the arms are crossed over the thorax and are parallel to the sides of the body. The umbilical cord lies in the space between the arms and the lower extremities. This characteristic posture is due in part to the mode of growth of the fetus and is also a result of accommodation to the uterine cavity.

Lie refers to the relation of the long axis of the fetus to that of the mother. Lie is either longitudinal or transverse (Fig. 57-1 (Figure Not Available)). Longitudinal lies occur in greater than 99% of pregnancies at term. [22]

The *presentation*, or presenting part, refers to that portion of the body of the fetus that is nearest to, or foremost in, the birth canal. The presenting part is felt through

the cervix on sterile vaginal examination. In longitudinal lies, the presenting part is either the fetal head, the buttocks, or the feet. In *transverse lie*, the shoulder is the presenting part.

Cephalic presentations are classified by the relation of the fetal head to the body of the fetus (Fig. 57-2 (Figure Not Available)). Ordinarily, the head is sharply flexed so that the occipital fontanel is the presenting part. This is referred to as the *vertex* or *occiput presentation*. Less commonly, the neck is fully extended and the face is foremost in the birth canal; this is termed *face presentation*. Occasionally, the fetal head assumes a partially flexed or partially extended position, resulting in *sinciput* and *brow presentations*, respectively. Sinciput and brow presentations, associated with preterm infants, are almost always unstable and convert to either the occiput or face presentation as labor progresses.

Breech presentations are classified as frank, complete, and footling or incomplete (Fig. 57-3 (Figure Not Available)). When the fetus presents with the hips flexed and the legs extended over the anterior surfaces of the body, this is termed *frank breech*. Flexion of the fetal hips and knees results in *complete breech* presentation. When one or both of the feet or knees are lowermost in the canal, an *incomplete* or *footling breech* results.

Figure 57-1 (Figure Not Available) *A,* Transverse lie with shoulder presentation. *B,* Longitudinal lie with vertex presentation. *(From Romney S, Gray MK, Little AB, et al [eds]: Gynecology and Obstetrics: The Health Care of Women. New York, McGraw-Hill, 1975.)*

Figure 57-2 (Figure Not Available) Cephalic presentations-deflexion attitude of fetal head. *A,* Vertex. *B,* Sinciput. *C,* Brow. *D,* Face. Diameter of the presenting fetal head is shown for each of the attitudes. *(From Romney S, Gray MK, Little AB, et al [eds]: Gynecology and Obstetrics: The Health Care of Women. New York, McGraw-Hill, 1975.)*

At or near term, the incidence of the various presentations is approximately 96% for vertex, 3.5% for breech, 0.3% for face, and 0.4% for shoulder. [22]

Position refers to the relation of the presenting part to the birth canal and may be either left or right. The occiput, chin, and sacrum are the determining parts in vertex, face, and breech presentations, respectively. The presentation and position of the fetus are initially determined by abdominal palpation using Leopold maneuvers.

Abdominal palpation (Leopold maneuvers).

Although abdominal ultrasonography has largely replaced abdominal palpation for determination of fetal lie, these maneuvers may be helpful when ultrasound evaluation is unavailable. They can be performed throughout the latter months of pregnancy and during labor in the intervals between contractions. The findings from abdominal palpation provide information about the presentation and position of the fetus and the extent to which the presenting part has descended into the pelvis (Fig. 57-4 (Figure Not Available)). The mother should be placed on a firm bed or examining table with her abdomen bared. For the first three of the four maneuvers, the examiner stands at the side of the bed facing the patient. During the first maneuver (see Fig. 57-4 *A* (Figure Not Available)), the upper abdomen is gently palpated with the fingertips of both hands to determine which fetal pole is present in the uterine fundus. The fetal breech gives the sensation of a large, nodular body, whereas the fetal head is hard, round, and freely movable.

During the second maneuver, the examiner places his or her hands on either side of the abdomen, exerting deep, gentle pressure (see Fig. 57-4 *B* (Figure Not Available)). On one side, the hard, resistant back is felt; on the other side, the fetal extremities or small parts are felt. By noting whether the back is directed anteriorly,

Figure 57-3 (Figure Not Available) Fetal attitude in breech presentations. *A,* Frank. *B,* Complete. *C,* Single footling—incomplete. *D,* Double footling—incomplete. *(From Romney S, Gray MK, Little AB, et al [eds]: Gynecology and Obstetrics: The Health Care of Women. New York, McGraw-Hill, 1975.)*

posteriorly, or transversely, fetal orientation or lie is determined.

The third maneuver is performed by grasping the lower portion of the maternal abdomen just above the symphysis pubis with the thumb and forefinger of one hand (see Fig. 57-4*C* (Figure Not Available)). If the presenting part is not engaged, the position of the head in relation to the back and extremities is ascertained. If the cephalic prominence is palpated on the same side as the small parts, the head must be flexed and therefore a vertex or occiput presentation exists. If the cephalic prominence is on the same side as the back, the head must be extended. If the presenting part is deeply engaged in the pelvis, the findings from this maneuver indicate that the lower pole of the fetus is fixed in the pelvis. The details of presentation and position are then defined by the fourth maneuver.

To perform the fourth maneuver, the examiner changes position and faces the mother's feet. With the tips of the first three fingers of each hand, the examiner exerts deep, gentle pressure in the direction of the axis of the pelvic inlet (see Fig. 57-4 *D* (Figure Not Available)). When the head is the presenting part, one examining hand will be stopped sooner than the other by a rounded body, the cephalic prominence, while the other hand continues more deeply into the pelvis. The cephalic prominence is felt on the same side as the small parts in vertex presentations and on the same side as the back in face presentations. In breech presentations, the information obtained from this maneuver is less precise. [22]

Vaginal examination.

Unless there has been bleeding in excess of a bloody show, a manual (not speculum) vaginal examination should be performed to identify fetal presentation and position and to assess the progress of labor.

Figure 57-4 (Figure Not Available) Abdominal palpation (four maneuvers of Leopold). *A,* Determination of the fetal part occupying the uterine fundus. *B,* Palpation of fetal small parts and back. *C,* Determination of the part occupying the lower uterine segment. *D,* Determination of the cephalic prominence. *(From Romney S, Gray MK, Little AB, et al [eds]: Gynecology and Obstetrics: The Health Care of Women. New York, McGraw-Hill, 1975.)*

The vulva and perineal area are prepared with an antiseptic solution such as povidone-iodine. The woman is placed on a bedpan with her legs widely separated. Scrubbing is directed from anterior to posterior and away from the vaginal introitus; each sponge should be discarded after it passes over the anal region. A dry sponge placed on the introitus prevents contaminated solution from running into the vagina.

After preparation of the vulvar and perineal regions, the examiner uses the thumb and forefinger of a sterile-gloved hand to widely separate the labia to expose the vaginal opening; this prevents the examining fingers from coming into contact with the inner surfaces of the labia. The index and second fingers of the other hand are then introduced into the vagina to perform the examination. Cervical effacement, dilation, and fetal station are assessed. Fetal presentation and position are confirmed.[22]

Cervical effacement refers to the process of cervical thinning that occurs before and during the first stage of labor as the cervical canal shortens from a length of about 2 cm to a circular opening with almost paper-thin edges (Fig. 57-5 (Figure Not Available)). The degree of cervical effacement is assessed by palpation and is determined by the palpated length of the cervical canal compared with that of the uneffaced, or normal, cervical canal. Effacement is expressed as a percentage from 0%, or totally uneffaced, to 100%, or completely effaced.

Cervical dilation is determined by estimating the average diameter of the cervical os. The examining finger is swept

Figure 57-5 (Figure Not Available) Effacement of the cervix. *A,* None. *B,* Partial. *C,* Complete. *(From Romney S, Gray MK, Little AB, et al [eds]: Gynecology and Obstetrics: The Health Care of Women. New York, McGraw-Hill, 1975.)*

from the cervical margin on one side across the cervical os to the opposite margin. The transverse diameter is expressed in centimeters. Ten centimeters constitutes full cervical dilation. A diameter of <6 cm can be measured directly. For a diameter >6 cm, it is frequently easier to determine the width of the remaining cervical rim

and subtract twice that measurement from 10 cm. For example, if a 1 cm rim is felt, dilation is 8 cm.

Station refers to the level of the presenting fetal part in the birth canal relative to the ischial spines which lie halfway between the pelvic inlet and the pelvic outlet (Fig. 57-6). Zero station is used to denote that the presenting part is at the level of the ischial spines. The birth canal above and below the spines is divided into fifths. When the presenting part lies above the spines the distances are stated in negative figures (-5, -4, -3, -2, and -1). Below the ischial spines the presenting fetal part passes +1, +2, +3, +4, and +5 stations to delivery. Determination is made by simple palpation. [22]

Position and presentation of the fetus may be inconclusive before labor, because the presenting parts must be palpated through the lower uterine segment. After dilation and effacement of the cervix, however, further delineation of presentation and position of the fetus may be made by vaginal examination.

After the perineal area has been appropriately prepared, as described previously, 3 maneuvers are used to determine fetal presentation and position. In the first maneuver, 2 fingers of the examiner's gloved hand are introduced into the vagina and advanced to the presenting part, differentiating face, vertex, and breech presentations. In vertex presentations, the examiner's

Figure 57-6 Station of the fetal head. As a reference point, the level of the ischial spines is zero station. *(From Benson RC [ed]: Current Obstetric and Gynecologic Diagnosis and Treatment, 3rd ed. Los Altos, Calif., Lange Medical Publications, 1980.)*

fingers are carried up behind the symphysis pubis and then swept posteriorly over the fetal head toward the maternal sacrum, identifying the course of the sagittal suture. The positions of the two fontanels, located at opposite ends of the sagittal sutures, are then defined by palpation. The anterior fontanel is diamond shaped; the posterior fontanel is triangular.

In face and breech presentations, the various parts are more readily distinguished. In breech presentations, the fetal sacrum is the point of reference; in face presentations, the easily identifiable fetal chin is used.

Fetal Well-Being

Auscultation.

Auscultation of fetal heart tones is necessary to determine fetal well-being. The heart rate of the fetus can be identified with a stethoscope, a fetoscope, or preferably a Doppler ultrasound device placed firmly on the maternal abdominal wall overlying the fetal thorax and repositioned until fetal heart tones are heard. When a Doppler device is used, a conducting gel should be applied to the abdominal wall, interfacing with the Doppler receiver. The region of the abdomen in which fetal heart sounds are heard most clearly varies with fetal presentation and the degree to which the presenting part has descended. In cephalic presentations, fetal heart sounds are heard best midway between the maternal umbilicus and the anterior superior spine of the maternal ilium. [22] To avoid confusion of maternal and fetal heart sounds, the maternal pulse should be palpated as the fetal heart rate is auscultated.

Normal baseline fetal heart rate is 120 to 160 bpm with heart rate varying considerably from beat to beat. [5] [22] Rates above or below this range may indicate fetal distress. Fetal tachycardia occurs when fetal heart rate is >160 beats/min. [22] Brief accelerations in fetal heart rate (i.e., those lasting <20 seconds) occur commonly during labor and are probably a physiologic response to fetal movement. [5] [22] [63] In contrast, persistent fetal tachycardia occurs most commonly in response to maternal fever or amnionitis but may also indicate fetal compromise. [5] [22]

Fetal bradycardia occurs when fetal heart rate falls below 120 beats/min. [22] Like brief accelerations in fetal heart rate, decreases in rate, which reach their nadir with the peak of a contraction and end with or slightly after the end of a contraction (early decelerations), are physiologic and are probably the result of vagal nerve stimulation due to compression of the fetal head. [5] [22] In contrast, decelerations that occur independently of uterine contractions (variable decelerations) and those that persist significantly after a contraction (late decelerations) are ominous and may represent cord compression and uteroplacental insufficiency, respectively. [5] [22] [63]

Changes in the fetal heart rate indicating fetal distress are usually evident immediately after a uterine contraction and, therefore, fetal heart rate is optimally assessed at this time. If prolonged monitoring of labor is necessary in the ED, fetal heart sounds should be assessed at 15-minute intervals during the first stage of labor and at 5-minute intervals during the second stage in the pregnancy at risk. In the absence of risk factors, intervals of 30 minutes and 15 minutes respectively, are probably sufficient.[5] [22] If trained personnel and equipment are available, external tocography provides a noninvasive method for continuous assessment of fetal heart rate and maternal uterine contractions.

Management of fetal distress.

If fetal distress is suspected on the basis of resting fetal heart rate or changes after contractions, changing maternal position, typically into the left lateral decubitus position, may be beneficial. Maternal O_2 should be administered to improve fetal oxygenation. In the absence of bleeding, a vaginal examination should be performed to rule out the possibility of prolapse of the umbilical cord. [5] [29] If immediate obstetric services are not available, consideration should be given to tocolytic therapy to improve fetoplacental blood flow until delivery can be accomplished. By stopping uterine contractions, a more sustained placental blood flow is maintained and, in the case of cord prolapse, intermittent pressure on a compromised umbilical cord may be averted. [5] [63] The definitive therapy for fetal distress is delivery of the infant, either vaginally or by cesarean section. [5] [22]

Cord prolapse usually occurs at the same time as rupture of the membranes and is diagnosed by palpation of the umbilical cord on vaginal examination or by visualization of the cord protruding through the introitus. The incidence of cord prolapse in labor is approximately 0.2% and most often occurs when the fetal presenting part does not completely fill the lower uterine segment during labor or when there is unusual mobility of the cord. [20] [54] [59] Cord prolapse is frequently encountered with breech presentation, multiple pregnancies, and prematurity. [20] [54] [59]

The management of cord prolapse is directed at sustaining fetal life until delivery is accomplished. Unless immediate delivery is feasible or the fetus is known to be dead, preparations should be made for an emergency cesarean section. If immediate obstetric services are not available, tocolytic therapy may be instituted to decrease uterine contractions and improve fetoplacental perfusion. [13] [39] Compression of the umbilical cord should be minimized by exerting manual pressure through the vagina to lift and maintain the presenting part away from the prolapsed cord. The patient should be placed in the knee-chest or deep Trendelenburg position, and this position maintained until delivery is accomplished. [13] [29] [59] Some clinicians recommend that after manual elevation of the presenting part, 500 to 700 mL of saline be instilled into the

bladder to maintain cord decompression. Once the bladder is filled, the vaginal hand may be removed. [13] [39]

With cord prolapse, the fetal prognosis is dependent on presentation, gestation, and the timing of diagnosis and management. Partial cord compression for <5 minutes may not be harmful. Complete occlusion for the same period or partial occlusion for a longer time is likely to cause death or severe central nervous system

damage to the fetus. The perinatal mortality rate from umbilical cord prolapse has fallen and ranges from 3.6 to 16.2%. [55] The cause of death for infants born after cord prolapse now seems to be related more to complications of prematurity and low birth weight than to intrapartum asphyxia per se. [59]

Inhibition of Labor

Tocolytic therapy may be indicated in the ED to prevent the progression of labor when fetal distress is noted, particularly that due to cord compression, and to treat preterm labor.

Preterm Labor

Preterm labor is defined as labor occurring prior to the completion of 37 weeks of gestation. It is a major cause of preterm delivery, a complication that affects approximately 1 in 10 births in the United States and one that continues to be a significant cause of neonatal morbidity and mortality. [6] Although a wide variety of treatments for the inhibition of labor have been advocated, including bedrest, intravenous (IV) fluids, ß-agonist agents such as terbutaline and ritodrine, magnesium sulfate ($MgSO_4$), prostaglandin inhibitors, calcium-channel blockers, and oxytocin receptor antagonists, there has been little improvement in neonatal outcome since the early 1980s.[6] [65] In addition, the efficacy of each of these regimens has been difficult to establish, owing in part to inconsistencies in establishing an accurate diagnosis of preterm labor and the lack of consensus as to what constitutes successful treatment or failure. [6]

The criteria for defining preterm labor vary among investigators. A presumptive diagnosis of premature labor may be made in the woman who is between 20 and 37 weeks of gestation in the presence of regular uterine contractions occurring at intervals of 5 to 8 minutes or less that are accompanied by one or more of the following: (1) progressive cervical effacement and dilation, (2) cervical dilation of >1cm, or (3) cervical effacement of 80% or more. [22] External monitoring devices, when available, are helpful by providing objective evidence of the character of uterine contractions, as well as the condition of the fetus.

Ideally, when preterm labor is suspected, obstetric consultation should be obtained and the patient transferred immediately to the labor and delivery area for monitoring and determination of fetal maturity. When appropriate obstetric facilities are not available, attempts to arrest labor may be initiated in the ED.

Tocolytic Therapy

Basic maneuvers to improve uterine and fetal status should be initiated before instituting pharmacologic tocolytic therapy when either preterm labor or fetal distress is suspected (Table 57-1). Because uterine hypoxia may induce uterine contractions, supplemental O_2, IV infusion of 500 mL of crystalloid, and assumption of the left lateral decubitus position should initially be attempted to improve uterine perfusion. [6] [22] [29] Because uterine, cervical, or urinary tract infections account for 20% to 40% of cases of preterm labor, a specific cause should be sought and treated as appropriate. [29] [52] [68] If contractions persist and cervical changes are documented, despite these basic interventions, pharmacologic therapy may be indicated. [6] [22] [29] Although tocolytic agents are commonly used and have been shown to prolong pregnancy by several days, there are little data to suggest that tocolysis improves long-term perinatal or neonatal outcome. [6] [22] [32] Therefore the principal benefit of pharmacologic therapy may be only to prolong pregnancy to allow maternal transfer to a tertiary care facility or delay delivery sufficiently to improve fetal maturation with corticosteroids.[6] [22] [40] [52] [68] Contraindications to tocolytic therapy include uncorrected fetal distress or fetal death, fetal maturity, chorioamnionitis, and complications requiring early delivery such as severe pregnancy-induced hypertension or antepartum vaginal bleeding. [8] [40] Tocolysis is probably most beneficial to infants between 24 and 28 weeks of gestation when even a short time gained in utero may substantially improve neonatal survival. [22] [40] In contrast, delivery of infants born before 24 weeks of gestation results in serious morbidity or mortality in almost 90%. [15] Similarly, prolonging gestation beyond 34 weeks provides little additional benefit to the nearly mature fetus.[6] [22] [40] Therefore, tocolytic therapy in these latter two groups should be considered carefully.

The most commonly used tocolytic agents in the United States are magnesium sulfate and the $ß_2$-receptor agonists ritodrine and terbutaline. Other agents such as calcium channel blockers, the prostaglandin inhibitor, indomethacin, and the oxytocin receptor antagonist, atosiban, have shown varying efficacy in clinical trials. [6] [22] [32] [40] [52]

TABLE 57-1 -- Drugs for the Emergency Management of Preterm Labor

$ß_2$-Receptor Agonists	
Ritodrine	
Dose	50 to 100 µg/min IV infusion ? 50 µg/min q 10 to 20 min
Endpoint	Cessation of uterine contractions
	Intolerable maternal side effects
	Maximum dose 350 µg/min
Terbutaline	
Dose	0.25 mg SC
	May repeat q 20 to 60 min
Endpoint	Cessation of uterine contractions
	Intolerable maternal side effects
Magnesium sulfate	
Dose	4 to 6 g IV over 20 min ? 2 to 4 g/hr IV infusion
Endpoint	Cessation of uterine contractions
	Signs of magnesium toxicity (e.g., respiratory depression, hypotension, somnolence)
Nifedipine*	
Dose	10 mg PO
	May repeat q 15 to 20 min
Endpoint	Cessation of uterine contractions
	Harmful maternal side effects, e.g., hypotension
	Maximum dose of 40 mg

PO, by mouth; SC, subcutaneously.

Sublinqual dose may cause excessive hypotension. It is best to avoid SL route.

*Variable doses have been used. Data on effects, particularly uteroplacental blood flow, is limited.

$ß_2$-Receptor agonists.

The traditional mainstays of pharmacologic tocolytic agents are the selective $ß_2$-adrenergic agents ritodrine (Yutopar) and terbutaline (Brethine, Bricanyl). Ritodrine

was approved by the U.S. Food and Drug Administration (FDA) for the inhibition of preterm labor in 1980 and is the only agent approved for tocolysis in the United States. Terbutaline has also been used extensively as a tocolytic agent and is frequently more readily available to the emergency clinician. [6] [22]

The ß-adrenergic agents prevent contraction of the myometrium through activation of the enzyme, adenyl cyclase. Adenyl cyclase enhances the conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (AMP), which, in turn, initiates a number of reactions that reduce the intracellular concentration of ionized calcium, thereby preventing activation of contractile proteins. [22] Although both ritodrine and terbutaline stimulate $ß_2$ -receptors primarily, both have some $ß_1$ activity that is responsible for their cardiovascular side effects.

Ritodrine is given as an IV infusion prepared by mixing 150 mg ritodrine in 500 mL fluid, preferably with 5% dextrose solution, yielding a final concentration of 0.3 mg/mL (i.e., 300 µg/mL). The initial infusion rate of ritodrine is 50 µg/min (i.e., 10 mL/hr), which is increased by 50 µg/min (i.e., by 10 mL/hr) every 10 to 20 minutes until uterine contractions cease, intolerable maternal side effects develop, or a maximal dose of 350 µg/min (i.e., 70 mL/hr) is reached. [52] [69] If labor is successfully arrested, IV therapy is continued for 12 to 24 hours after contractions cease. [69] A controlled infusion device is required. Ritodrine is contraindicated in patients with cardiac disease, pulmonary hypertension, hyperthyroidism, or uncontrolled diabetes. It should be used cautiously in patients on other sympathomimetic amines. [69]

The usual clinical side effects of ritodrine are related to its inherent activity as a ß mimetic drug. Maternal cardiovascular effects include a dose-related increase in heart rate, an increase in systolic pressure, and a decrease in diastolic blood pressure. Fetal heart rate also increases slightly. About one third of patients experience palpitations, and up to 15% have tremor, nausea, vomiting, headache, or erythema. Cardiac symptoms including chest pain or tightness, and arrhythmias are reported in less than 3% of patients. [69] Pulmonary edema resulting in maternal death has also been reported. [22] Side effects are usually self-limited and resolve with dosage reduction or discontinuation of the drug. Treatment of the majority of side effects is supportive; severe cardiovascular effects may be treated with ß-blocking agents. [69]

Although not approved for use by the FDA as a tocolytic agent, terbutaline is commonly used in the treatment of preterm labor. [22] [31] [52] When given subcutaneously, terbutaline is administered as a 0.25 mg dose, which may be repeated every 20 to 60 minutes until contractions cease or intolerable maternal side effects occur. [29] [72] Terbutaline is occasionally administered as an IV infusion. Terbutaline should be used with caution in patients with cardiovascular disease, hypertension, hyperthyroidism, diabetes, or seizures and in those on other sympathomimetic amines. [69] Side effects associated with the parenteral use of terbutaline are similar to those of ritodrine. [69]

Magnesium sulfate.

Magnesium sulfate ($MgSO_4$) is not approved in the United States for use as a tocolytic agent. Nevertheless, some perinatal centers prefer $MgSO_4$ over the ß-mimetic agents because of its lower incidence of side effects. [26] [29] [73] Although its mechanism of action is not fully understood, magnesium probably decreases myometrial contractility through its role as a calcium antagonist. [22]

When used as a tocolytic agent, 4 to 6 g of $MgSO_4$ is given IV over 20 to 30 minutes, followed by a maintenance IV infusion beginning at 2 to 4 g/hour. [26] [29] Because studies have questioned the efficacy of magnesium in prolonging labor, some authors have suggested increasing the maintenance infusion to 5 g/hr. [52] [73] Infusion of $MgSO_4$ typically produces sweating, warmth, and flushing. Rapid parenteral administration may cause transient nausea, vomiting, headache, or palpitations. [26] [52] Infrequently, pulmonary edema or chest pain has necessitated stopping the drug. [26] The major side effect of magnesium therapy is related to impairment of the muscles of respiration with subsequent respiratory arrest, an effect usually not seen until the serum magnesium level exceeds 10 mEq/L. The first sign of magnesium toxicity, decrease of the patellar reflex, typically occurs as serum magnesium levels exceed 4 mEq/L, with loss of the reflex as levels approach 10 mEq/L. Therefore, the patellar reflex should be monitored throughout therapy. Respiratory depression typically occurs when serum magnesium levels exceed 10 mEq/L. At levels of 12 mEq/L or greater, respiratory arrest may occur. [69]

Because magnesium is almost totally excreted by the kidney, it is contraindicated in the presence of renal failure and urinary output, and renal function should be monitored throughout therapy. If respiratory depression develops, 10 mL of a 10% solution of calcium gluconate or calcium chloride injected over 3 minutes is an effective antidote. For severe respiratory depression and arrest, prompt endotracheal intubation may be life saving.

Calcium channel blockers.

Smooth muscle activity, including that of the myometrium, is directly related to free calcium within the cytoplasm, and a reduction in calcium concentration inhibits contraction. Therefore, calcium channel blockers have become promising agents in the treatment of preterm labor. Studies comparing oral or sublingual nifedipine (Procardia, Adalat) with ritodrine indicate that nifedipine is more effective in suppressing preterm labor and is associated with significantly fewer neonatal intensive care (NICU) admissions, a lower incidence of neonatal morbidity, especially respiratory distress syndrome, and a lower incidence of maternal side effects. [57] [60] Although dosing regimens vary, nifedipine is frequently given as an initial dose of 10 mg orally or sublingually, repeated every 15 minutes until tocolysis is achieved or a maximum of 40 mg is reached. [57] [60] Oral nicardipine (Cardene), which has been shown to be a more potent inhibitor of muscle contraction in vitro, has also been shown to be an effective and safe tocolytic agent. [45] Because data on these agents are limited, some authors caution that more research is needed to clarify their potential maternal or fetal dangers, particularly the effect of calcium channel blocker-induced decreased vascular resistance, maternal hypotension, and thus decreased uteroplacental perfusion. [22] [52]

Prostaglandin inhibitors.

A number of prostaglandin synthesis inhibitors have been evaluated for their efficacy as tocolytic agents. Indomethacin is the most widely studied and has been demonstrated to offer short- and long-term benefits regarding pregnancy prolongation. Indomethacin is usually given as an initial rectal dose of 100 mg, followed by 25 mg

orally every 6 hours for up to 48 hours. Although it appears that indomethacin is an effective tocolytic agent, its administration is not without significant potential risk to the fetus, including premature closure of the ductus arteriosus, necrotizing enterocolitis, and intracranial hemorrhage. [22] [52]

Oxytocin antagonists.

Oxytocin is a potent stimulator of myometrial contractility. Atosiban is a selective oxytocin-vasopressin receptor antagonist capable of inhibiting oxytocin-induced uterine contractions in both animals and women with preterm labor. Several clinical trials have found atosiban to be an effective tocolytic agent without significant adverse maternal effects. [53] [67] [74] Further study is needed, including that of atosiban's effect on the fetus and newborn, before atosiban can be recommended for ED use. [22]

VAGINAL BLEEDING DURING THE THIRD TRIMESTER

Bleeding during the third trimester should always be considered an emergency. Profound shock secondary to exsanguinating hemorrhage may occur within minutes. Although bleeding may result from local vaginal and cervical lesions, genital lacerations, circumvallate placenta, vasa previa, or rupture of the uterus, the more typical causes are those due to placenta previa and placental abruption. *Placenta previa* refers to implantation of the placenta in the lower uterine segment with varying degrees of encroachment on the cervical os. Complicating approximately 1 in 180 to 1 in 390 deliveries, [22] placenta previa is classically characterized by vaginal bleeding with little or no abdominal or pelvic pain. Premature separation of the placenta, or *abruptio placentae,* refers to separation of the placenta from its site of implantation in the uterus before delivery of the fetus. Placental abruption occurs in about 1 in 200 deliveries and has a perinatal mortality of approximately 25%. [22] Although the clinical signs and symptoms with placental abruption can vary considerably, abruptio placentae is typically associated with varying degrees of abdominal pain and uterine irritability. [22]

As noted previously, third-trimester vaginal bleeding should always be considered an emergency. Stabilization should be initiated with large-bore IV access. Routine blood work should include a complete blood count with platelets and a type and crossmatch. If abruption is suspected, clotting studies including a fibrinogen level, and a toxicology screen for cocaine may be indicated because of the association of abruption with disseminated intravascular coagulation and cocaine abuse, respectively. Until the diagnosis of placenta previa is excluded digital vaginal examination is *contraindicated* because of the possibility of tearing or dislodging a placenta previa, which may result in profuse, potentially fatal hemorrhage. [22] The patient should be immediately transferred to the care of her clinician for further evaluation. The simplest and most precise method of placental localization is by transabdominal ultrasound, which has an accuracy of locating a placenta previa of about 96%.[22] In contrast, ultrasonography has limited sensitivity in detecting abruptio placenta with a reported negative predictive value of between 63% and 88% [22] ; therefore, negative findings on ultrasound should not be used to exclude placental abruption.

DELIVERY

Full dilation of the cervix signifies the second stage of labor, heralding delivery of the infant. Typically, the patient begins to bear down and, with descent of the presenting part, develops the urge to defecate. Uterine contractions may last 1.5 minutes and recur after a myometrial resting phase of less than 1 minute.

The mechanism of labor in vertex and breech presentations consists of engagement of the presenting part, flexion, descent, internal rotation, extension, external rotation or restitution, and expulsion (Fig. 57-7 (Figure Not Available)). The mechanism of labor is determined by the pelvic dimensions and configuration, the size of the fetus, and the strength of uterine contractions. Essentially, the fetus will follow the path of least resistance by adaptation of the smallest achievable diameters of the presenting part to the most favorable dimensions and contours of the birth canal.

The sequence of movements in vertex presentations is as follows:

1. *Engagement.* Usually occurring in the last 2 weeks of pregnancy in the primiparous patient and at the onset of labor in the multiparous patient, engagement refers to the mechanism by which the greatest transverse diameter of the head, the biparietal diameter in occiput presentations, passes through the pelvic inlet.
2. *Flexion.* Flexion of the head is necessary to minimize the presenting cross-sectional diameter of the head during passage through the smallest diameter of the bony pelvis. In most cases, flexion is necessary for both engagement and descent.
3. *Descent.* Descent is gradually progressive and is affected by uterine and abdominal contractions as well as by straightening and extension of the fetal body.
4. *Internal rotation.* Internal rotation occurs with descent and is necessary for the head or presenting part to traverse the ischial spines. This movement is essentially a turning of the head such that the occiput gradually moves from its original, more transverse position, anteriorly toward the symphysis pubis or, less commonly, posteriorly toward the hollow of the sacrum.
5. *Extension.* After internal rotation, the sharply flexed head reaches the anteriorly directed vulvar outlet, undergoing extension. With increasing distention of the perineum and vaginal opening, an increasingly larger portion of the occiput appears gradually. The head is born by further extensions as the occiput, bregma, forehead, nose, mouth, and finally chin pass successively over the anterior margin of the perineum. Immediately after its birth, the head drops downward such that the chin lies over the maternal anal region.
6. *External rotation.* External rotation or restitution follows delivery of the head as it rotates to the transverse position that it occupied at engagement. After this movement, the shoulders descend in a path similar to that traced by the head, rotating anteroposteriorly for delivery. First, the anterior shoulder is delivered beneath the symphysis pubis, followed by the posterior shoulder across the perineum. Expulsion of the remainder of the fetal body occurs with ease.

Traction is to be minimized. *(Adapted from Romney S, Gray MK, Little AB, et al [eds]: Gynecology and Obstetrics: The Health Care of Women. New York, McGraw-Hill, 1975.)*

The mechanism of the labor for breech presentations varies (Fig. 57-8). Usually the hips engage in one of the oblique diameters of the pelvic inlet. As descent occurs, the anterior hip generally descends more rapidly than the posterior hip. Internal rotation occurs as the bitrochanteric diameter assumes the anteroposterior position. Lateral flexion occurs as the anterior hip catches beneath the symphysis pubis, allowing the posterior hip to be born first. The infant's body then rotates, allowing engagement of the shoulders in an oblique orientation. There is gradual descent, with the anterior shoulder rotating to bring the shoulders into the anteroposterior diameter of the outlet. The anterior shoulder follows lateral flexion to appear beneath the symphysis, with the posterior shoulder delivered first as the body is supported. The head tends to engage in the same diameter as the shoulders. Subsequent flexion, descent, and rotation of the head occurs, bringing the posterior portion of the neck under the symphysis pubis. The head is then born in flexion.

Los Altos, Calif., Lange Medical Publications, 1980.)*

Delivery of the vertex-presenting infant usually occurs spontaneously. The role of the clinician or attendant is principally to provide control of the birth process, preventing forceful, sudden expulsion or extraction of the infant with resultant fetal and maternal injury.

Equipment for Delivery

Prepackaged "precip trays" are available from several medical supply companies, although the majority of equipment can generally be assembled from existing emergency department stock and may be financially more practical.[50]

Essential equipment includes the following:

1 pair of scissors

2 medium Kelly clamps

1 bulb syringe

Sterile towels and blankets

Gauze sponges

Sterile gloves

Gown, mask, and protective eyewear

Optional equipment includes the following:

1 plastic umbilical cord clamp

1 large basin (for placenta)

1 ring forceps

Syringe and tubes for collection of cord blood

In addition, neonatal resuscitation supplies should be available in the ED as described subsequently.

Technique for Uncomplicated Delivery

Although complete sterility is not a priority, when time permits sterile technique should be used. Sterile gloves, a gown, mask and eye protection should be worn for protection of both the mother and the clinician. The perineum and vulva should be cleansed as described for vaginal examination and may be draped with sterile towels such that only the immediate area about the vulva is exposed. Care should be taken to avoid fecal contamination of the infant. Equipment in the obstetric pack should be sterile.

Ideally the patient should be placed on a delivery table in the dorsal lithotomy position to increase the diameter of the pelvic outlet. Alternatively, the patient may be positioned on a stretcher with her hips and knees partially flexed, her thighs abducted, and the soles of her feet placed firmly on the stretcher. The delivery position may be enhanced by placing the patient's buttocks on the underside of a sterile bedpan, which will provide additional space between the bed and the perineum.

Vertex Delivery

Spontaneous delivery of the vertex-presenting infant is divided into three phases: delivery of the head, delivery of the shoulders, and delivery of the body and legs.

Delivery should be anticipated when the presenting part reaches the pelvic floor. With each contraction, the perineum bulges increasingly and the vulvovaginal opening becomes more and more dilated by the fetal head. Just before delivery, "crowning" occurs; the head is visible at the vaginal introitus, and the widest portion, or biparietal diameter, of the head distends the vulva.

Gentle, gradual, controlled delivery is desirable and explosive delivery of the head should be avoided. Once the fetal head distends the vaginal introitus to 5 cm or more during a contraction, one palm of the clinician's hand is placed over the occipital area, providing gentle pressure to control delivery of the head. The other hand, preferably draped with a sterile towel to protect it from the anus, may exert forward pressure on the chin of the fetus through the perineum just in front of the coccyx in a modified Ritgen maneuver (Fig. 57-9). This maneuver extends the neck at the proper time, such that the smallest diameters of the head pass through the introitus and over the perineum, thereby protecting the maternal perineal musculature.

The head is gently supported during subsequent delivery of the forehead, face, chin, and neck.

After the head has been delivered, the infant's face and mouth should be quickly wiped and the oral cavity and nose suctioned with a bulb syringe. This minimizes the chance of aspiration of amniotic fluid, debris, and blood, which may occur with inspiration during delivery of the thorax. If meconium stained amniotic fluid is detected during delivery, use of wall suction with a large-bore (12 or 14 Fr) suction catheter or wall-mounted DeLee suction trap is preferable to a bulb syringe. [18] [61] [62]

With delivery of the neck, a finger should be passed around the neck to determine whether it is encircled by one or more coils of the umbilical cord (Fig. 57-10). If a cord is felt, it should cautiously be loosened and gently slipped over the infant's head. If this cannot be done easily, the cord should be doubly clamped and cut and the infant delivered promptly. In approximately 25% of deliveries, the umbilical cord is around

Figure 57-9 Modified Ritgen maneuver. *(From Pritchard JA, MacDonald PC: Williams Obstetrics, 16th ed. New York, Appleton-Century-Crofts, 1980.)*

the infant's neck but is rarely tight enough to cause fetal hypoxia. [22] [23]

Just before external rotation, the head usually falls posteriorly, bringing it almost into contact with the mother's anus. As rotation occurs, the head assumes a transverse position and the transverse diameter of the thorax or bisacromial diameter rotates into the anteroposterior diameter of the pelvis. In most cases the shoulders are born spontaneously. Delivery may be aided by grasping the sides of the head and exerting *gentle* downward (posterior) traction until the anterior shoulder appears beneath the symphysis pubis. The head is then *gently* lifted upward to aid the delivery of the posterior shoulder (see Fig. 57-7 (Figure Not Available)). The remainder of the body usually follows without difficulty.

If delivery of the body is delayed after the shoulders have been freed, delivery may be assisted by *moderate* traction on the fetal head accompanied by *moderate* pressure on the uterine fundus. Hooking the fingers in the axilla during delivery may result in brachial plexus injury and therefore should be avoided. Traction should always be exerted in the direction of the long axis of the infant. If applied obliquely, traction may

Figure 57-10 Checking for the cord around the infant's neck.

cause bending of the neck and excessive stretching of the brachial plexus. [22] [23]

Immediately after delivery the infant's airway should be thoroughly suctioned. Although some controversy exists as to the optimal timing and position of the infant in relation to the mother during this stage, most authorities recommend that the infant be placed at or slightly below the level of the vaginal introitus during suctioning, that is for approximately 30 seconds, before the cord is clamped. [22] [23] [79]

The umbilical cord is cut with scissors between two Kelly clamps placed 4 to 5 cm from the infant's abdomen. Later, an umbilical cord clamp is applied 2 to 3 cm from the infant's abdomen. Blood samples from the placental end of the cord can be collected for infant serology, including Rh determination. [22] [23]

Immediately after cutting the umbilical cord, the infant should be briefly evaluated and, if necessary, resuscitation should be initiated. Because of the relatively large surface area of the newborn, attention should be directed toward maintaining body temperature by drying the newborn and placing the baby in a heated isolette, under a radiant warmer, or in warm blankets. [18] [22] [23] [61]

Meconium-stained amniotic fluid (MSAF) occurs in approximately 8% to 17% of all deliveries and results in meconium aspiration syndrome in 2% to 6% of these

neonates. Meconium aspiration syndrome is associated with significant neonatal morbidity including respiratory failure. [51] [55] [62] To minimize the risk of aspiration, all infants with MSAF should have the nose, mouth and posterior pharynx thoroughly suctioned after delivery of the head but before delivery of the shoulders and the first thoracic expansion. If possible suctioning should be accomplished using wall suction and a large-bore (12 or 14 Fr) suction catheter or a wall mounted DeLee suction trap.[18] [61] [62] The traditional approaches to MSAF have included direct visualization and suctioning of all infants born through meconium-stained fluid and visualization and suctioning based on the thickness of the meconium. Evidence indicates, however, that tracheal suctioning of the vigorous newborn with MSAF does not improve outcome and may cause complications. [55] [61] [78] Therefore, immediately after delivery the infant should be evaluated for heart rate, respiratory effort, and muscle tone. If the infant has absent or depressed respirations, decreased muscle tone, or a heart rate less than 100 bpm, direct laryngoscopy should be immediately performed. Residual meconium is then suctioned from the hypopharynx under direct vision and intubation and suctioning of the trachea subsequently performed. [55] [61] [78] Initially vigorous neonates exposed to MSAF who later experience apnea or respiratory distress should also receive tracheal suctioning before positive-pressure ventilation is instituted.[55] [61] [78]

Delivery of the Placenta

Placental separation usually occurs within 5 minutes after delivery of the infant and may be recognized by the following signs:

1. The uterus becomes globular and firmer as it contracts.
2. There is a sudden gush of blood.
3. The uterine fundus rises in the abdomen as the separated placenta passes into the lower uterine segment and vagina, pushing the uterus upward.
4. The umbilical cord protrudes farther out of the vagina, indicating placental descent.

The placenta usually delivers spontaneously within 20 to 30 minutes. [29] Intra-abdominal pressure produced by the mother's bearing-down efforts may be enough to effect complete expulsion of the placenta. If maternal force alone is insufficient, delivery of the placenta may be aided by the clinician. After ensuring that the uterus is firmly contracted and placental separation has occurred, the clinician uses one hand to exert gentle pressure through the abdominal wall to lift the uterine fundus cephalad while keeping the umbilical cord slightly taut with the other hand. This is repeated until the placenta reaches the introitus, at which time uterine pressure is stopped and the placenta is gently lifted upward out of the vagina (Fig. 57-11). Membranes that are adherent to the uterine lining should be grasped with a clamp or ring forceps and removed by gentle traction. Placental expression should never be forced before placental separation nor should traction ever be used to pull the placenta out of the uterus. Both traction and premature placental expression may result in uterine inversion with catastrophic hemodynamic consequences. The placenta should be examined for completeness and saved for later evaluation by the clinician. [22] [23] [29]

The vulva, vagina, and cervix should be examined to assess for traumatic lacerations. Cervical lacerations most typically occur at the 9- or 3-o'clock position; vaginal lacerations typically occur at the point of the ischial spines. If found, these injuries are best repaired in the operating room or delivery suite. [29]

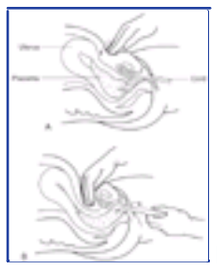

Figure 57-11 Delivery of the placenta. Gentle pressure is exerted through the abdominal wall to lift the uterine fundus upward while keeping the umbilical cord slightly taught. This maneuver is repeated until the placenta reaches the introitus.

After delivery of the placenta, the primary mechanism by which hemostasis is achieved at the placental site is through myometrial contraction. Agents such as oxytocin, methylergonovine and ergonovine may be used to stimulate myometrial contraction. Oxytocin (Pitocin, Syntocinon) is the most commonly used oxytocic drug and is usually given by IV infusion. Twenty units of oxytocin is added to 1 L of normal saline and is given at a rate of 10 mL/min for several minutes until the uterus remains firmly contracted and bleeding is controlled. The infusion rate is then reduced to 1 to 2 mL/min. [22] [23] [29] Alternatively, ergot derivatives such as methylergonovine maleate (Methergine), 0.2 mg, or ergonovine maleate (Ergotrate) 0.2 mg, may be given intramuscularly (IM). [22] [29] Because of their vasoconstrictive properties, ergot preparations are relatively contraindicated in patients with hypertension, including pregnancy-associated hypertension or preeclampsia. [22] Oxytocic agents should not be used before delivery of the placenta because the resultant uterine contraction may entrap the placenta or an undiagnosed twin within the uterus, the latter of which may prove fatal to the entrapped fetus.[22] [23]

Even when oxytocics are administered, the hour after delivery of the placenta is the time during which postpartum hemorrhage owing to uterine atony is the most likely to occur. Therefore, the uterus should be palpated frequently to ensure that it is well contracted. A normally contracted uterus will be firm with its upper margin just below the maternal umbilicus. If bleeding occurs from a flaccid uterus, gentle uterine massage through the abdominal wall should be performed. Occasionally, the placenta may fail to separate completely, resulting in a retained placenta or placental fragments, with persistent uterine bleeding. Manual removal of the placenta, exploration of the uterine cavity for retained products and, occasionally, hysterectomy are indicated. These procedures are beyond the scope of ED care and should be left to the admitting clinician. The patient should be supported with IV fluids and blood transfusion as indicated until definitive therapy is available. Constant firm uterine massage can lessen hemorrhage and may be life saving.

Complex Deliveries

Shoulder Dystocia

The term *shoulder dystocia* refers to impaction of the fetal shoulders in the pelvic outlet occurring after delivery of the head in vertex presentations. The reported incidence of shoulder dystocia ranges from 0.2% to slightly more than 4%. [9] [14] [28] Differences in reported rates of occurrence are due partly to the clinical variation in describing shoulder dystocia as well as the difficulty in retrospective retrieval of information from medical records. [9] [14] Shoulder dystocia is associated with several risk factors including fetal macrosomia, maternal diabetes or obesity, multiparity, and post-term pregnancy. These risk factors, however, are absent in up to 50% of cases, making antenatal identification of fetuses at risk difficult. [14]

Impaction of the fetal shoulders and thorax in the maternal pelvis prohibits adequate respiration, whereas compression of the umbilical cord frequently compromises fetal circulation, making shoulder dystocia a serious, and at times fatal, complication of delivery. [14] [23] Postpartum hemorrhage, usually from uterine atony, is the most common maternal complication. [22] Fetal complications include brachial plexus injuries, clavicular fractures, humeral fractures, and, infrequently, death. [9] [14] [28]

Management.

General anesthesia is desirable but is seldom available in the ED. A wide episiotomy may be used to reduce the incidence of major perineal lacerations and provide additional space for manipulation. Because the techniques used to treat shoulder dystocia frequently require an assistant, and delivery can result in fetal injury or hypoxia, assistance of specialist clinicians should be emergently sought. [14] [22] [64] Although reduction in the interval of time from delivery of the head to delivery of the body is of great importance to infant survival, overly vigorous traction on the fetal head or neck or excessive rotation of the body may seriously damage the infant. [9] [22]

Although a variety of techniques have been described to free the anterior shoulder from its impacted position beneath the symphysis pubis, most cases of shoulder dystocia can be resolved with 1 of 2 simple maneuvers. In the McRoberts maneuver, the mother is placed in the extreme lithotomy position with her hips completely flexed, thereby allowing her knees to rest on her chest. This causes a flattening of the lumbar lordosis and rotation of the maternal pelvis cephalad which frequently frees the impacted anterior fetal shoulder (Fig. 57-12).[9] [14] [22] [27] [30] If the McRoberts maneuver fails to effect delivery, moderate suprapubic pressure applied to the maternal abdomen by an assistant may be added while gentle downward traction is exerted on the fetal head. [14] [28] The "all-fours" or Gaskin maneuver has been described and consists of placing the mother on her hands and knees to effect delivery without the aid of additional maneuvers. [14] [17]

If these simple maneuvers fail to effect delivery, several other techniques exist, the choice of which will depend on clinician preference and experience. In the first maneuver, the clinician places two fingers in the vagina and exerts pressure on the fetal scapula, rotating the posterior shoulder 180° in a corkscrew fashion (reverse Wood's screw or Rubin maneuver). This may cause the impacted anterior shoulder to be released and delivery to progress (Fig. 57-13).[14] [64] Alternatively, delivery of the posterior arm may be attempted. Here, the clinician's hand is inserted along the hollow of the maternal sacrum to the level of the fetus' posterior elbow. By exerting pressure at the antecubital fossa the posterior forearm is flexed, the hand or forearm grasped, and the posterior arm of the fetus then carefully swept across its chest to effect delivery of the posterior arm and shoulder. The shoulder girdle is then rotated into one of the oblique diameters of the pelvis with subsequent delivery of the anterior shoulder (Fig. 57-14).[14] [22] If all of these strategies fail, controlled destructive procedures, such as fracture of the fetal clavicle or cephalic replacement (Zavanelli maneuver) with subsequent cesarean delivery, may be necessary. [22] [23]

Breech Delivery

When compared with cephalic presentations, the breech delivery is associated with a greater incidence of prematurity, prolapsed cord, low implantation of the placenta, uterine and congenital abnormalities, multiple pregnancies, and increased perinatal morbidity and mortality rates. [16] [21] [22] [65] The incidence of breech presentation varies inversely with gestational age and weight. At term, the incidence of breech presentation

Figure 57-12 McRoberts maneuver for shoulder dystocia. The maternal hips are completely flexed, allowing the knees to rest on the abdomen. This causes cephalad rotation of the maternal pelvis and flattening of the lumbar lordosis resulting in an increase in the useful size of the pelvic outlet.

is 3% to 4%; from 28 to 38 weeks' gestation, 17%; and at less than 28 weeks' gestation, 40%. [35]

Increased rates of prematurity and congenital anomalies associated with breech presentation account for much of the perinatal loss. [16] [19] [34] In addition, fetal distress also occurs more frequently. Whereas umbilical cord prolapse occurs in approximately 0.4% of cephalic presentations, the rate increases in breech presentation, particularly when the fetus is small or there is a non-frank breech. Occurring in 0% to 2% of frank breech presentations, the incidence of cord prolapse rises to 5% to 10.5% with complete breech presentation and to 8% to 28.5% with footling presentations. [19]

The increased use of cesarean section has greatly decreased the morbidity and mortality associated with breech delivery. Although cesarean section has been traditionally

Figure 57-13 Rubin or reverse Wood's screw maneuver for shoulder dystocia. *A,* Rotation of the posterior shoulder. *B,* Delivery of the rotated shoulder.

considered the standard of care, vaginal delivery may be the method of choice in carefully selected cases. [16] [25] [34] The emergency clinician seldom is called on to make the decision as to the most appropriate means of delivery, but rather could be faced with the imminent vaginal delivery of the breech infant. Breech delivery is most appropriately performed with both a clinician and an assistant present and preferably with specialist clinicians as well.

Types.

There are three types of vaginal breech delivery. Spontaneous breech is a breech delivery in which the infant is delivered spontaneously without any manipulation or traction other than supporting the infant. Although this form of delivery is rare with term infants, there is little associated traumatic morbidity. Partial breech extraction is when the infant is delivered spontaneously as far as the umbilicus

Figure 57-14 Delivery of the posterior arm for shoulder dystocia. *A,* Flexion of the posterior arm. *B,* delivery of the posterior arm to permit delivery of the anterior shoulder.

and the remainder of the body is extracted. Total breech extraction is when the entire body of the infant is extracted by the clinician.

Delivery is easier and perinatal morbidity and mortality are reduced when the breech is born spontaneously to the level of the umbilicus. [22] Similar to vertex presentations, the role of the clinician is to assist the mother in the birthing process, allowing maternal expulsive efforts to effect delivery of the infant. Premature or aggressive assistance or traction can significantly increase fetal and maternal morbidity.

To perform any vaginal breech delivery, the birth canal must be sufficiently large to allow passage of the fetus without trauma and the cervix must be completely effaced and dilated. If these conditions do not exist, a cesarean section is indicated. To ensure full cervical dilation in the footling or complete breech, it is important that the feet, legs, and buttocks advance through the introitus to the level of the fetal umbilicus before the clinician intervenes and further delivery is attempted. The mere appearance of the feet through the vulva is not in itself an indication to proceed with delivery. This may be a footling presentation through a cervix that is not completely dilated. In this case there may be time to transfer the patient to the labor and delivery suite, preferably in the knee-chest position to minimize the risk of cord compression.[23] Similarly, if the breech is frank, cervical dilatation and outcome is improved if the infant is allowed to deliver to the level of the umbilicus. Prior to this, as with complete and footling presentations, there may be time to effect safe transfer to the labor and delivery area, if available. [23] Tocolytics such as subcutaneous terbutaline may be used to inhibit labor until such patients can be safely transferred. [23]

Technique.

If assisted delivery of the frank breech becomes necessary in the ED, an episiotomy should be performed unless there is considerable perineal relaxation. As the breech progressively distends the perineum, the posterior hip will deliver, usually from the 6-o'clock position. The anterior hip then delivers, followed by external rotation to the sacrum anterior position (see Fig. 57-8). Continued descent of the fetus will allow delivery of the legs, which may be aided by splinting the medial thighs of the fetus with the fingers positioned parallel to the femur and exerting pressure laterally to sweep the legs away from the midline (Fig. 57-15). Following delivery of the legs, the fetal bony pelvis is grasped using both hands with the fingers resting on the anterior superior iliac crests and the thumbs on the sacrum (Fig. 57-16). Because the fetal body is slippery and difficult to hold, it may be wrapped in a towel to assist delivery. Maternal expulsive efforts are used in conjunction with continued gentle downward traction and rotation of the fetal pelvis to bring the fetal sacrum into the transverse position to effect delivery of the scapulae (Fig. 57-17).

Two methods of shoulder delivery are commonly used. In the first method, with the scapulae visible, the trunk is rotated such that the anterior arm and shoulder appear at the vulva and can be easily released and delivered. The body of the fetus is then rotated in the reverse direction to deliver the other shoulder and arm beneath the symphysis pubis. In the second method, if trunk rotation is unsuccessful, the posterior shoulder must be delivered first. The feet are grasped in one hand and drawn upward over the mother's groin. In this manner, leverage is exerted on the posterior shoulder, which slides out over the perineal margin, usually followed

by the arm and hand. The anterior shoulder, arm, and hand are then delivered beneath the symphysis pubis by downward traction on the fetal body (Fig. 57-18).

Occasionally, spontaneous delivery of the arm and hand does not follow delivery of the shoulder. If this occurs, upward traction of the fetal body should be continued after delivery of the posterior shoulder. Two fingers of the clinician are then passed along the fetal humerus until the fetal elbow

Figure 57-15 Assisted breech delivery. Once the breech has delivered to the level of the umbilicus, delivery of the legs may be aided by placing the fingers parallel to the medial thigh and sweeping the legs laterally away from the midline.

Figure 57-16 Assisted breech delivery. The clinician's hands are placed over the infant's sacrum to deliver the body. *(From Taylor ES: Obstetrics and Fetal Medicine, 2nd ed. Baltimore, Williams & Wilkins, 1977.)*

Figure 57-17 Assisted breech delivery. Rotation occurs as the scapulae emerge. *(From Taylor ES: Obstetrics and Fetal Medicine, 2nd ed. Baltimore, Williams & Wilkins, 1977.)*

is reached. The fingers are used to splint the fetal arm, which is then swept downward and delivered. The anterior arm may then be delivered by depression of the fetal body alone. In some cases it may be necessary to sweep the anterior arm down over the thorax using two fingers as a splint.

After the shoulders appear, the head usually occupies one of the oblique diameters of the pelvis, with the chin directed posteriorly. The head may then be extracted using the Mauriceau maneuver. With the fetal body resting on the clinician's palm and forearm, the index and middle finger of the hand are placed over the infant's maxilla, flexing the fetal head. Two fingers of the other hand are hooked over the fetal neck, and, grasping the shoulders, the clinician applies downward traction until the suboccipital region appears under the symphysis pubis (Fig. 57-19). As the body of the fetus is then elevated toward the mother's abdomen, the fetal mouth, nose, brow, and eventually occiput successively emerge over the perineum. Suprapubic pressure applied by an assistant is helpful in delivery of the head. If delivery of the head is not effected by the Mauriceau maneuver, forceps delivery may be necessary. Forceps application is beyond the scope of this text.

Rarely *breech extraction* of the infant becomes necessary and is indicated only if there is a definite diagnosis of fetal distress unresponsive to routine maneuvers, obstetric services are unavailable, and cesarean section cannot be performed promptly.

If extraction of the incomplete or complete breech is deemed necessary, the clinician's hand is introduced into the vagina and both feet of the fetus are grasped, with the index finger placed between the fetal ankles. Gentle traction is applied until the feet are pulled through the vulva (Fig. 57-20). Gentle downward traction is continued as successively higher portions of both legs and thighs are grasped (Fig. 57-21). When the breech appears at the vulva, gentle traction is applied until the hips are delivered. As the buttocks emerge, the fetal back usually rotates anteriorly. The thumbs

Figure 57-18 Assisted breech delivery. *A,* Delivery of the posterior shoulder by upward traction on the fetal body. *B,* Delivery of the anterior shoulder beneath the symphysis by downward traction. *(From Taylor ES: Obstetrics and Fetal Medicine, 2nd ed. Baltimore, Williams & Wilkins, 1977.)*

are then placed over the sacrum and the fingers over the hips and the remainder of the breech is delivered as described earlier (see Fig. 57-16 Fig. 57-17 Fig. 57-18 Fig. 57-19). At times, delivery of a frank breech may be necessary. Facilitated by an episiotomy, the breech should be allowed to deliver spontaneously as far as possible. Moderate traction may then be exerted by a finger placed in each fetal groin (Fig. 57-22). Once the knees appear outside the birth canal, the legs may be slowly flexed to assist delivery and delivery is accomplished as described earlier.

Complications.

The prognosis for the fetus in breech presentation is considerably worse than that in vertex presentations and is inversely related to the height of the presenting part at the beginning of breech extraction.[22] The major contributors to perinatal loss are preterm delivery, congenital anomalies, and birth trauma, with a high incidence of respiratory distress syndrome, high-grade intraventricular hemorrhage, and neurologic damage.[16] [19] [22] [34] Maternal morbidity is also increased as manipulations within the birth canal increase the risk of maternal infection, lacerations of the cervix, and uterine rupture.[22]

EPISIOTOMY

An episiotomy is an incision of the posterior vaginal wall and a portion of the pudenda, which is made to enlarge the vaginal introitus to permit easier passage of the fetus and, theoretically, to prevent perineal lacerations of the mother, preserving the structure and function of the vaginal introitus. Before the early 1990s, more than 60% of women in the United States received an episiotomy during childbirth, most as a routine procedure. [47] [70] Its use was justified by the theoretic prevention of severe perineal tears, better future sexual function, and a reduced incidence of urinary and fecal incontinence. [33] [47] Studies in the 1990s, however, determined that the routine use of episiotomy resulted in an equal or greater incidence of third- and fourth-degree perineal lacerations, postpartum

Figure 57-19 Mauriceau maneuver: delivery of the aftercoming head. While suprapubic pressure is applied by an assistant, the head is gently flexed by pressure on the maxilla. *(From Taylor ES: Obstetrics and Fetal Medicine, 2nd ed. Baltimore, Williams & Wilkins, 1977.)*

perineal pain, urinary incontinence, and dyspareunia. [10] [33] [41] [47] Therefore, the routine use of episiotomy has been abandoned for a more selective approach. Indications for selective episiotomy include breech delivery, shoulder dystocia, occiput posterior presentations, and imminent perineal tear. [22] [33]

Two types of episiotomy are used: the median or midline episiotomy and the mediolateral episiotomy (Fig. 57-23). The median incision is the easiest type of episiotomy to perform and repair, results in the least amount of blood loss, heals rapidly with minimal discomfort, and is generally preferred in the United States. [22] [23] The major disadvantage to the median

Figure 57-20 Breech extraction. Traction of the feet and ankles. Note that the index finger is placed between the ankles. *(From Pritchard JA, MacDonald PC: Williams Obstetrics, 16th ed. New York, Appleton-Century-Crofts, 1980.)*

incision is accidental extension of the incision into the anal sphincter or rectum, resulting in third- and fourth-degree lacerations, respectively. [22] [23] [42] [70] Although a mediolateral episiotomy seldom results in extension through the anal sphincter, blood loss is generally greater, repair is more difficult, and painful healing may result. [22] [23]

Equipment

The following equipment is required for episiotomy and repair:

- Tissue scissors
- 3-0 or 2-0 absorbable suture on atraumatic needle (e.g., chromic catgut, polyglycolic acid)
- Needle holder
- Suture scissors
- Gauze
- Local anesthesia and injection equipment

Technique

The episiotomy should be timed so that it precedes trauma to the maternal tissues and fetus but avoids excessive maternal blood loss before delivery. With vertex presentations, the

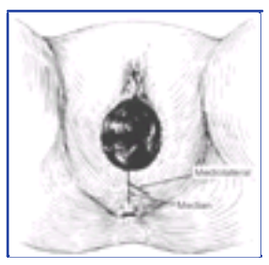

Figure 57-23 Types of episiotomy. The median episiotomy is the easiest to perform and repair.

episiotomy should be performed when the fetal head begins to distend the perineum and the caput becomes visible to a diameter of 3 to 4 cm during a contraction. [22] Anesthesia for episiotomy in the ED is usually limited to local infiltration of the perineum with 1% or 2% lidocaine.

The episiotomy is a simple incision that extends through the skin and subcutaneous tissues, the vaginal mucosa, the urogenital septum, and the superior fascia of the pelvic diaphragm, and if the episiotomy is mediolateral and deep, through the lowermost fibers of the puborectalis portion of the levator ani muscles. As the head crowns the clinician's index and second fingers are placed inside the vaginal introitus to expose the mucosa, posterior fourchette, and perineal body. Scissors are then used to incise the median raphe of the perineum almost to the anal sphincter (Fig. 57-24). For the mediolateral episiotomy, the incision is directed downward and outward in the direction of the lateral margin of the anal sphincter and may be either to the right or to the left (see Fig. 57-23).

After delivery of the infant and placenta, the episiotomy is repaired. The goals of episiotomy repair are to restore anatomy and achieve adequate hemostasis with a minimum of suture material. It is preferable to perform the closure after delivery of the placenta and after inspection and repair of the cervix and upper vaginal canal. The same principles of repair are followed for both the median (Fig. 57-25) and mediolateral episiotomies.

Because there is minimal tension on the closed wound, most authorities recommend the use of 2-0 or preferably 3-0 absorbable suture such as chromic catgut or polyglycolic acid on a large, atraumatic needle. The first step is to close the vaginal mucosa using a continuous suture from just above the apex of the incision to the mucocutaneous junction, reapproximating the margins of the hymenal ring. Burying the closing knot in the incision minimizes the amount of scar tissue and prevents tenderness and dyspareunia. Large actively bleeding vessels may require ligation during closure with separate

Figure 57-24 Midline (median) episiotomy.

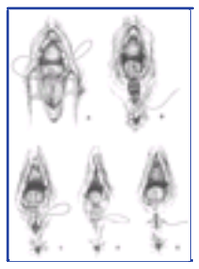

Figure 57-25 Closure of median episiotomy. *A,* Closure of mucosa and hymenal ring with continuous suture. *B,* Approximation of perineal musculature with interrupted sutures. *C,* Continuous suture to unite superficial fascia. *D,* Completion of repair by carrying continuous suture upward as a subcuticular stitch. *E,* Alternatively, closure of the superficial fascia and skin (*C* and *D*) may be accomplished by a series of loosely tied interrupted sutures. *(From Pritchard JA, MacDonald PC: Williams Obstetrics, 16th ed. New York, Appleton-Century-Crofts, 1980.)*

absorbable suture ligatures. Next, the perineal musculature is reapproximated with three or four interrupted sutures. Closure of the superficial layers may be accomplished by 1 of 2 methods. In the first method, a continuous suture is used to close the superficial fascia from the mucocutaneous junction outward and is then continued upward as a subcuticular skin closure, returning to and ending at the mucocutaneous junction. Alternatively, several interrupted sutures may be placed through the skin and subcutaneous fascia and loosely tied. This last method of skin closure avoids burying two layers of suture in the more superficial layers of the perineum.[22] [23]

The most common complication of episiotomy is hematoma formation, owing to inadequate hemostasis. A hematoma is treated by evacuation and drainage. Occasionally, large bleeding vessels will require delayed ligation. Postpartum episiotomy pain can usually be controlled by analgesics and local heat or sitz baths. Infection is an infrequent complication and it usually responds readily to sitz baths, good hygiene, and antibiotic therapy. Although most infections are not serious, examination is important to rule out deeper infection and necrotizing fasciitis. [37]

IMMEDIATE POSTPARTUM HEMORRHAGE

Postpartum hemorrhage is traditionally defined as maternal blood loss greater than 500 mL after delivery. Although this is the classic definition, ample evidence indicates that normal blood loss after vaginal delivery is frequently equal to or greater than 500 mL. [4] [22] [37] [66] Therefore, in clinical practice the diagnosis of postpartum hemorrhage is usually made when the amount of bleeding exceeds the clinician's estimate of "normal." The most common cause of serious obstetric hemorrhage, postpartum hemorrhage accounts for a significant proportion of maternal deaths. [4] Postpartum hemorrhage is conventionally divided into immediate hemorrhage occurring within 24 hours of delivery and delayed hemorrhage occurring nore than 24 hours after delivery.

Postpartum hemorrhage is frequently characterized by steady, moderate bleeding that persists until serious hypovolemia develops, rather than by sudden massive hemorrhage. Because of the relative hypervolemia that occurs during normal pregnancy, these cases of postpartum hemorrhage may remain unrecognized until a large volume loss has occurred.[66] Careful observation for blood loss, including evaluation of uterine size and consistency, is therefore needed during the early postpartum period.

The most common cause of immediate postpartum hemorrhage is uterine atony. Less common causes include lacerations of the vagina and cervix, retained placenta or placental fragments, coagulation disorders, uterine rupture, and uterine inversion. [4] [22] [37] [66]

Management

Management of postpartum hemorrhage consists of replacement of intravascular volume with crystalloid and blood products as needed, as well as therapy directed toward the cause of hemorrhage. The diagnosis of uterine atony, the most common cause of bleeding, is made when uterine palpation reveals a soft boggy uterine corpus. Although the diagnosis may be suspected on the basis of abdominal examination alone, bimanual pelvic examination is frequently necessary to confirm the diagnosis.

Uterine atony is initially managed with firm manual massage of the uterine fundus through the abdominal wall in conjunction with the administration of oxytocic agents (Table 57-2). If bleeding persists, bimanual uterine compression is indicated (Fig. 57-26). One hand of the clinician is used to compress and massage the posterior aspect of the uterus through the abdominal wall while the fist of the other hand is used to gently massage the anterior aspect of the uterus through the vaginal wall. Care must be taken to avoid vigorous downward massage, which can result in acute uterine inversion.

Oxytocics

Oxytocin is ideally administered as an IV infusion, which is prepared by adding 20 to 40 units of oxytocin to 1 L of crystalloid and infused at a rate of 200 to 500 mL/hour, titrated to sustain uterine contractions and control uterine hemorrhage. Oxytocin should not be administered as an IV bolus because profound hypotension and myocardial arrhythmias may occur.[22] If IV access is unavailable, 10 units of oxytocin may be given IM. [69] Because the onset of action of IV oxytocin is rapid, uterine contractions and therefore

slowing of hemorrhage should be observed within minutes of administration. If bleeding persists and the uterus remains boggy despite oxytocin therapy, an ergot derivative such as methylergonovine or a prostaglandin may be used. If methylergonovine (Methergine) is chosen to help stimulate uterine contractions, it is given as a 0.2 mg dose IM. Typically, uterine contractions occur within 2 to 5 minutes of administration and last for several hours. [69] Because of their tendency to cause vasoconstriction and severe hypertension in some patients, ergot preparations should be avoided in women with

Figure 57-26 Uterine massage. One hand is used to massage the posterior aspect of the uterus through the abdominal wall. The other hand, inserted in the vagina, compresses the anterior uterus. *(From Pritchard JA, MacDonald PC: Williams Obstetrics, 16th ed. New York, Appleton-Century-Crofts, 1980.)*

hypertensive disease, including preeclampsia. [4] [69] Alternatively, 15-methyl prostaglandin F_{2a} (carboprost tromethamine [Hemabate]) may be used to stimulate uterine contractions and is preferred over methylergonovine by some authors. [4] [37] Approved for use in the control of uterine atony by the FDA in the mid-1980s, carboprost is administered in a dose of 0.25 mg IM, which may be repeated at 15 minute intervals as determined by the clinical course. The total dose should not exceed 2 mg. [66] [69] The rate of successful control of uterine hemorrhage with carboprost exceeds 85%. [58] Because nausea, vomiting, and diarrhea occur frequently in patients receiving prostaglandins, concurrent administration of antiemetic and antidiarrheal agents is recommended. [69] Misoprostol (Cytotec), an orally administered prostaglandin E_1 analogue approved for use in the treatment of gastric ulcers due to non-steroidal anti-inflammatory agents, has been found to effectively control postpartum hemorrhage in over 88% of women when administered rectally in a dose of 1000 µg. [1] [56]

Procedures

If vaginal bleeding persists despite uterine massage and a firmly contracted uterus, a cause other than uterine atony should be suspected. The labia, vagina, and cervix should be carefully inspected for lacerations. Bleeding from lacerations may be controlled by direct pressure or, in the case of cervical lacerations, by gentle application of ring forceps to the bleeding point. Absorbable sutures may be used to control bleeding from easily accessible lacerations. Because adequate visualization of the cervix and upper vagina is difficult and repair of extensive lacerations frequently requires general anesthesia, repair of these lacerations is often better left to the obstetrician.

Although rare, occurring in approximately 1 in 1700 to 6400 deliveries, *uterine inversion* is frequently thought to be the result of traction on the umbilical cord during the third stage of labor.[22] [66] [75] Other factors associated with the disorder include manual removal of the placenta, an increase in intra-abdominal pressure, placental abnormalities such as placenta accreta, and congenital weakness of the uterine wall or cervix. [4] [76] The principal signs and symptoms of the disorder are lancinating and, often violent pelvic pain, and excessive postpartum hemorrhage with up to 40% of patients developing shock. [4] [43] [75] [76] Diagnosis is made by visualization or palpation of the soft purplish-red mass of the uterus filling the vaginal vault or protruding through the introitus. On abdominal examination, no mass representing the uterus may be palpated or, when palpable, the uterus may have a cup-like dimpling of the fundus. [4] [43] [66] [76] Treatment is aimed at maintaining cardiovascular stability through the use of IV fluids and immediate repositioning of the uterine corpus. Conscious sedation is indicated and general anesthesia is often necessary, especially if the cervix has contracted. Tocolytic agents such as terbutaline or magnesium sulfate have been used successfully for uterine relaxation and repositioning. [4] [22] [76] Oxytocics should not be given until after the uterus is repositioned. [43] [66] There is controversy over management when the placenta is still attached to the uterus. Some advocate removal of the placenta before replacement of the uterus to decrease uterine bulk and allow for easier repositioning through the cervical ring. Others suggest that early placental removal increases uterine bleeding and may increase the risk of septic complications. [22] [43] [75] [76]

Repositioning of the uterus may be accomplished by inserting one hand into the vagina with the tips of the fingers at the uterocervical junction and the uterine fundus firmly held in the palm of the hand. Gentle pressure exerted with the fingers on the edges of the uterus closest to the cervix in the direction of the umbilicus is followed by gradual replacement of the corpus (Fig. 57-27). Pressure should not initially be exerted centrally on the fundus, because this will cause the uterus to be compressed, forcing more "layers" of the uterus to simultaneously lie within the relatively tight cervical ring. [43] [75] [76] Although replacement of the inverted uterus can usually be accomplished by vaginal manipulation, occasionally a dense cervical contraction ring is present, preventing repositioning. General anesthesia and laparotomy may be necessary for uterine repositioning.

PERIMORTEM CESAREAN SECTION

Perimortem cesarean section, one of the oldest and most dramatic surgical procedures known, has long been used as an attempt to preserve the life of the fetus. [46] Earliest records trace its origin back to 715 BC, when the legendary king of Rome, Numa Pompilious, decreed that the child be excised from the womb of any woman who died late in pregnancy. Under the emperors of Rome, the *caesars*, this law became known as the "lex caesare," and hence the name cesarean operation. [77]

From 1879 until 1986, there were 188 reports of perimortem cesarean section resulting in the delivery of a live infant. [38] Since that time, only isolated cases of long-term fetal survival have been reported. [44] [49] Because most of the literature on perimortem cesarean section involves only small numbers of cases with emphasis on those that are successful, accurate survival statistics are difficult to ascertain. When reported, infant survival rates range from 11% to 70%. [11] [38] [77] Because the potential for survival of a normal infant exists, cesarean delivery must be considered in any woman who suffers a cardiac arrest after 24 weeks' gestation and is unresponsive to brief resuscitation. [38] [44] Although the procedure is rare, the decision and its performance may fall to the emergency clinician.

Indications

Survival of the infant is directly related to the elapsed time from death of the mother to delivery, the maturity of the fetus, the performance of cardiopulmonary resuscitation (CPR) on the mother, and, in certain circumstances, the availability of neonatal intensive care facilities. [38] [44] [77] Although the lower limit of fetal viability varies among institutions, in general, performance of the procedure before the point of fetal viability at approximately 24 weeks is not indicated. [29] If the duration of gestation is not known from the history, fetal maturity may be quickly estimated by calculating gestational age on the basis of the date of the patient's last normal menstrual period or by measuring the height of the uterine fundus. Between 18 and 30 weeks' gestation, the age of the fetus in weeks will correspond to the distance in centimeters from the uterine fundus to the symphysis pubis (e.g., at 28 weeks' gestation the fundus is approximately 28 cm above the symphysis pubis or halfway between the umbilicus and the costal margin). [71] Criteria for intervention should be established prospectively at each institution and be in accordance with the institution's general neonatal policies. [29] [71]

Figure 57-27 Replacement of the inverted uterus.

The potential for infant survival decreases and the chance of neurologic damage increases as the time from maternal death (cessation of circulation) to cesarean section rises (Table 57-3). When cesarean section is performed within 5 minutes of death of the mother, neonatal outcome is generally considered excellent; from 5 to 10 minutes, good; from 10 to 15 minutes, fair; and from 15 to 20 minutes, poor. Because even under optimal conditions CPR results in a cardiac output of 30% to 40% of normal and placental perfusion may be severely compromised, every attempt should be made to begin cesarean delivery within 4 minutes of the cardiopulmonary arrest, completing the procedure within 5 minutes of arrest. [29] [38] [44] [71] Fetal prognosis is generally better after the sudden death of a previously healthy mother than after the death of a mother with a prolonged and debilitating illness. [38] [71] [77]

CPR should, of course, be initiated immediately on cardiac arrest of the mother and be continued until after delivery of the infant. The pregnant state produces certain physiologic

TABLE 57-3 -- Outcome of 61 Infants Who Survived Postmortem Cesarean Section from 1900 to 1985 as a Function of Time from Death to Delivery

Time (min)	No. of Patients (%)	Normal	Neurologic Sequelae
0– 5	42 (69)	42	0
6–10	8 (13)	7	1 (mild)
11–15	7 (11)	6	1 (severe)
16–20	1 (2)	0	1 (severe)
21–25	3 (5)	1	2 (severe)

From Katz VL, Dotters DJ, Droegemueller W: Perimortem cesarean delivery. Obstet Gynecol 68:571, 1986.

changes that adversely affect the adequacy of standard CPR. Vena caval occlusion by the gravid uterus hampers venous return and thus compromises maternal cardiac output. A decreased functional residual capacity of the lungs may impede ventilation. Manual displacement of the uterus away from the inferior vena cava may be attempted by an assistant. However, perimortem cesarean delivery in itself may represent the most important variable for a successful maternal resuscitation. [24] [38] [77]

Legal and Ethical Considerations

No clinician has been found liable for performing a perimortem cesarean section. Indeed, it is thought that the clinician has the legal right and responsibility to provide the fetus with every possible chance of survival when there is no hope of survival of the mother. [38] [71] Verbal permission for the operation should be obtained from the family when possible but not at the expense of delaying the procedure. Failure to obtain permission should not preclude cesarean section. [38] [71]

There is no standard of care relating to emergency clinicians performing a perimortem cesarean delivery. Each case must be individualized. Limited resources often place the clinician in the difficult situation of deciding whether to continue efforts to resuscitate the mother or to attempt to deliver the fetus in a difficult situation under less than ideal conditions. In the absence of obstetric backup immediately at hand, it is reasonable for the emergency clinician to proceed with delivery of the child if the mother cannot be resuscitated. Prolonged attempts to resuscitate the mother are unlikely to benefit either the mother or the fetus.

Equipment

The following equipment is needed for a perimortem cesarean section:

- Scalpel with a no. 10 blade
- Bandage scissors
- Bladder retractor

Large retractors (2)

Forceps

Lap or gauze sponges

Hemostats (curved and straight)

Suction

Obstetric pack (as described earlier for vaginal delivery)

Because of the rarity of this procedure in the ED, it is unlikely that a specific instrument pack will be available. Minimally, a scalpel with a large blade and an obstetric pack are necessary.

Technique

Perimortem cesarean section should be performed by the most experienced person present, preferably an obstetrician. When possible, a neonatologist should be in attendance. Their arrival, however, should not delay onset of the procedure. CPR should be initiated for the mother at the time of cardiac arrest and continued throughout the procedure. Although it is helpful if fetal heart tones are present premortem, time should not be wasted searching for them or attempting to evaluate fetal viability with abdominal ultrasonography.

Rapid extraction of the infant while avoiding fetal and maternal injury is the goal of the procedure. Hence, time should not be wasted preparing a sterile operating field or transporting the patient to an operating suite outside the ED. Using a large (e.g., no. 10) scalpel, a midline vertical incision is made through the abdominal wall extending from the symphysis pubis to the umbilicus and carried through all abdominal layers to the peritoneal cavity (Fig. 57-28). In most gravid women, the hyperpigmented "linea nigra" is apparent and may serve as a guide for the incision. If available, retractors are placed in the abdominal wound and drawn laterally to expose the anterior surface of the uterus. The bladder is reflected inferiorly; if it is full, it may be aspirated to evacuate it and permit better access to the uterus (Fig. 57-29). While avoiding injury to fetal parts, a small (approximately 5 cm) vertical incision is made through the lower uterine segment until amniotic fluid is obtained or until the uterine cavity is clearly entered (Fig. 57-30*A*). The index and long fingers are then inserted into the incision and used to lift the uterine wall away from the fetus. Bandage scissors are used to extend the incision vertically to the fundus until a wide exposure is obtained (Fig. 57-30*B*). The infant is then gently delivered, the mouth and nose suctioned, and the cord clamped and cut (Fig. 57-31). Because the incision is relatively high in the uterus, the infant's head may not be readily accessible to the clinician, in which case the infant's feet are grasped and the infant delivered through maneuvers similar to those of a breech delivery. Neonatal resuscitation should be carried out as necessary.

Because, in rare instances, relief of vena caval compression by the uterus improves maternal hemodynamics such

Figure 57-28 Cesarean delivery. A vertical incision is made through the abdominal wall from the level of the uterine fundus to the symphysis pubis.

Figure 57-29 Cesarean delivery. If available, retractors are used to expose the anterior surface of the uterus, and the bladder is retracted inferiorly.

that survival of the mother is possible, maternal pulses should be checked and CPR continued after delivery of the infant.

Conclusion

Perimortem cesarean section is a rarely performed but potentially life-saving procedure that should be considered in any woman in the third trimester of pregnancy who suffers irreversible cardiopulmonary arrest. Because neonatal survival is enhanced as the time from maternal death to delivery decreases (while the irreversible nature of maternal cardiac arrest becomes more apparent as resuscitative efforts progress), the decision to perform this procedure may be one of the most difficult that the emergency clinician makes. Once the decision is made to perform a cesarean section, it should be done as quickly as possible by the most experienced person present. CPR should be continued until after delivery of the infant. Although rare, maternal survival has been reported after perimortem cesarean section.

THE NEWBORN

Approximately 5% to 10% of newborns require some degree of active resuscitation at birth (e.g., stimulation to breathe) and approximately 1% to 10% of those born in hospitals require assisted ventilation. [61] Evaluation of the newborn begins before delivery with assessment of maternal well-being and gestational age, and with the recognition of fetal distress, as evidenced by meconium staining of the amniotic fluid, fetal bradycardia, or evidence of cord prolapse. Care of the newborn begins with delivery of the head when the nose and mouth are suctioned.

Newborn resuscitation can be divided into four categories of action: (1) basic steps including assessment and initial stabilization, (2) ventilation including bag-valve-mask or bag-tube ventilation, (3) chest compressions, and (4) administration of

Figure 57-30 Cesarean delivery. *A,* Small vertical incision is made with a scalpel through the lower uterine segment. *B,* Bandage scissors are used to extend the incision vertically to the fundus.

medications or fluids. Although most newborns require only basic steps such as suctioning, drying, stimulation, and perhaps supplemental oxygen, some require further intervention, the most crucial action of which is the establishment of adequate ventilation. [61]

Evaluation

Traditionally, the *Apgar scoring system*, applied at 1 and 5 minutes after birth, has been the standard of newborn evaluation (Table 57-4).[18] [22] In general, the higher the score, the better the condition of the infant. Although traditionally the 1-minute Apgar score has been used to indicate the need for immediate resuscitation, the decision to begin resuscitation should not be delayed until an Apgar score is obtained. Rather, resuscitation decisions are based on the clinical triad of respiration, heart rate, and color. [18] [61]

Figure 57-31 Cesarean delivery. The infant is delivered, the nose and mouth suctioned, and the cord clamped and cut.

Respiration.

Normally, the newborn begins to breath and cry almost immediately after birth. [22] After initial respiratory efforts, the newborn should be able to establish regular respirations sufficient to improve color and maintain a heart rate of more than 100 bpm. Gasping and apnea are signs indicating the need for assisted ventilation. [61] If initial respirations are shallow or slow, a brief period of stimulation may be attempted while 100% oxygen is administered. [18] [61] Establishing adequate ventilation and oxygenation will restore vital signs in the vast majority of newborns. [61]

Heart rate.

Heart rate may be determined by auscultation or by palpation of the pulse at the base of the umbilical cord. Heart rate should be consistently >100 bpm in an uncompromised newborn. If heart rate is <100 bpm, positive pressure ventilation with 100% oxygen should be initiated. If the heart rate is <60 bpm, despite adequate ventilation with 100% oxygen for 30 seconds, chest compressions should be initiated. [61] Because chest compressions may diminish the effectiveness of ventilation, they should not

TABLE 57-4 -- Apgar Scoring System

Sign	0	1	2
Heart rate	Absent	Slow (<100)	>100
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Flaccid	Some flexion of extremities	Active motion
Reflex irritability	No response	Grimace	Vigorous cry
Color	Blue, pale	Body pink, extremities blue	Completely pink

be initiated until lung inflation and ventilation have been established. [61]

Color.

An uncompromised newborn will be able to maintain a pink color of the mucous membranes without supplemental oxygenation. Central cyanosis is determined by examining the face, trunk, and mucous membranes and, if present, should be treated with supplemental oxygen. Acrocyanosis is usually a normal finding in the newborn and not a reliable indicator of hypoxemia. It may, however, indicate other conditions such as cold stress. [18] [61]

Equipment for Infant Stabilization

The following equipment is recommended for infant stabilization:

Bulb syringe or DeLee suction trap

Suction catheters (size 5 or 6 Fr, 8 Fr, and 10 or 12 Fr)

Endotracheal tubes (size 2.5 mm, 3.0 mm, 3.5 mm, and 4.0 mm)

Endotracheal tube stylet (optional)

Face masks (premature and newborn)

Feeding tubes (8 Fr) with 20 mL syringe

Heat source (radiant warmer or heating lamps)

Interosseous infusion needles

Laryngoscope handle

Laryngoscope blades (straight; sizes 0 and 1)

Laryngeal mask airway (optional)

Neonatal resuscitation bag with pressure-release valve or manometer

Oropharyngeal airways

Oxygen with flow meter

Umbilical vessel catheterization tray

Umbilical catheters (3.5 Fr and 5 Fr)

Wall suction with manometer

Warmed blankets

Stabilization Technique

Following delivery of the infant and cutting of the umbilical cord, the newborn should be placed on his or her side with the neck in a neutral or slightly extended position.[61] A rolled blanket or towel placed under the back and shoulders of the supine infant, thus elevating the torso 2 to 2.5 cm, may help in maintaining head position.[18] [61] Preventing heat loss in the newborn is vital because cold stress can increase oxygen consumption and impede effective resuscitation. [61] Hyperthermia, however, should be avoided because it is associated with perinatal respiratory depression. [55] [61] Placing the infant under a radiant warmer, rapidly drying the skin, and wrapping the infant in warmed blankets will reduce heat loss. [18] [61] Alternatively the mother's body may be used as a heat source.

If initial evaluation indicates the infant is stable, the infant may be dried and placed skin to skin on the mother's chest or abdomen and both covered with blankets. [18] [61]

Healthy vigorous newborns generally do not require suctioning after delivery. If suctioning is necessary secretions should be cleared first from the mouth and then the nose with a bulb syringe or suction catheter (8 Fr or 10 Fr). Because aggressive pharyngeal suctioning can cause laryngeal spasm and vagal bradycardia, mechanical suctioning should be limited in depth and duration, and negative pressures should not exceed 100 mm Hg. [61] Generally drying and suctioning are enough to stimulate effective respirations in the newborn. If effective spontaneous respirations are not established after drying with a towel or gentle rubbing of the back, flicking the soles of the feet may initiate spontaneous respiration. [61] If these maneuvers do not initiate spontaneous respirations, positive-pressure ventilation will be required. [18] [61]

Meconium aspiration is a significant cause of morbidity and mortality in newborns. Careful suctioning of the nose and mouth should be performed in all infants born through meconium-stained amniotic fluid. Intubation and tracheal suctioning is indicated for depressed infants as discussed earlier. [55] [61] [78]

Most newborns who require positive ventilation can be adequately ventilated with a bag and mask. Indications for positive-pressure ventilation include apnea or gasping respirations, heart rate <100 bpm, and persistent central cyanosis despite 100% oxygen. [18] [61] Assisted ventilations are performed at a rate of 40 to 60 per minute (30 breaths per minute if mechanical compressions are being performed). Typically higher inflation pressures (30 to 40 cm H_2O or greater) and longer inflation times are required for the first several breaths than for subsequent breaths. Visible chest expansion is probably a more reliable indicator of appropriate inflation pressures than any specific manometer reading. [18] [61] Because bag-valve-mask ventilation can produce gastric distention, which impedes respiration, an orogastric tube (8 Fr) should be inserted in infants undergoing prolonged positive pressure ventilation. [61]

Endotracheal intubation may be indicated when bag-valve-mask ventilation is ineffective, when tracheal suctioning

TABLE 57-5 -- Medications Commonly Used in Neonatal Resuscitations[61]

Drug	Dose	Indications	Comments
Epinephrine*	0.01–0.03 mg/kg (0.1–0.3 mL/kg of 1:10,000 solution)	Bradycardia, asystole	May be repeated every 3 to 5 minutes as indicated;
			Data regarding high-dose epinephrine in newborns inadequate to support routine use
Naloxone*	0.1 mg/kg (0.25 mL/kg of a 0.4 mg/mL solution or 0.1 mL/kg of a 1 mg/mL solution)	Respiratory depression induced by maternal narcotics during delivery	May be repeated every 2 to 3 minutes as needed
			May be given IM or SC if perfusion adequate
			May induce narcotic withdrawal in the newborn chronically exposed to narcotics and therefore relatively contraindicated
Volume expanders (normal saline or Ringer's solution)	10 mL/kg IV over 5 to 10 minutes	Suspected hypovolemia, shock or blood loss	May be repeated after determination of clinical response;
			Higher initial dose not recommended and may result in volume overload
Bicarbonate	1–2 mEq/kg of a 0.5 mEq/mL solution given over at least 2 minutes	Prolonged arrests unresponsive to other therapy	Not indicated during brief periods of CPR;
			Should be used only after adequate ventilation and perfusion have been established

CPR, cardiopulmonary resuscitation; IV, intravenously; SC, subcutaneously.
*May also be given via endotracheal tube.

for meconium is required, when chest compressions are performed, or when prolonged positive-pressure ventilation is required. [18] [61] Alternatively, the neonatal laryngeal mask airway may provide effective airway management, especially in the case of ineffective bag-valve-mask ventilation or failed endotracheal intubation. [61] Use of the laryngeal mask airway, however, has not been adequately studied in preterm infants and those with deliveries complicated by meconium-stained fluid. Its use, therefore, cannot be recommended in these situations. [61]

The heart rate should be monitored during the course of neonatal evaluation and stabilization with either direct auscultation over the chest or palpation of the pulse at the base of the umbilical cord. A readily discernible heartbeat of greater than or equal to 100 bpm is acceptable. If the heart rate is <60 bpm, despite adequate ventilation with 100% oxygen for 30 seconds, chest compressions should be instituted while ventilation is continued. [61] Chest compressions should be delivered on the lower one third of the sternum and not over the xiphoid to avoid damage to the liver. [18] There are two techniques for performing chest compression in the newborn. In the preferred method, two thumbs of the resuscitator's hands are positioned side by side over the lower one third of the sternum just below the nipple line. If the infant is large or the resuscitator's hands are too small to encircle the chest, two finger compressions using the ring and middle fingers may be used. [18] [61] The depth of compression should be approximately one third to one half of the anterior-posterior diameter of the newborn's chest, such that a palpable pulse is generated. [61] Compressions and ventilations should be coordinated to avoid simultaneous delivery, which may compromise the efficacy of ventilation. The compression to ventilation ratio should be 3:1 with 90 compressions and 30 breaths to achieve approximately 120 respirations per minute. [61] If the heart rate remains <60 bpm, despite these interventions, [61] an umbilical or IV line should be established and appropriate drug therapy initiated. Alternatively, intraosseous access can be used but may not be as effective in the preterm infant. [61] The medications most commonly used in neonatal resuscitation are listed in Table 57-5 .

Chapter 58 - Culdocentesis

G. Richard Braen

A number of conditions require sampling of the intraperitoneal fluid to confirm a diagnosis or to obtain material for microbial culturing. This fluid can be obtained from the peritoneal cavity in a number of ways. Culdocentesis involves the introduction of a hollow needle through the vaginal wall into the peritoneal space. Culdocentesis is a simple, rapid, and safe procedure. The technique has several indications, but it is used primarily for diagnosing ruptured ectopic pregnancies and ruptured ovarian cysts and for obtaining fluid to aid in the culture diagnosis of pelvic inflammatory disease (PID). As beta subunit human chorionic gonadotropin (ß-hCG) assays have improved, and as the resolution of transvaginal ultrasonography has increased, the use of culdocentesis to diagnose ectopic pregnancies has decreased. In present practice, culdocentesis is used in situations where a ruptured ectopic pregnancy is suspected but a sonographic examination cannot be obtained.[15]

ANATOMY

Before culdocentesis is attempted, the clinician must be familiar with the anatomy of the vaginal and rectouterine pouch (pouch of Douglas). In the adult female, the vagina is approximately 9 cm long. From its inferior to its superior aspect, the posterior wall of the vagina is related to the anal canal by way of the perineal body, the rectum, and the peritoneum of the rectouterine pouch.[10] The rectouterine pouch and the posterior wall of the vagina are adjacent only at the upper quarter (approximately 2 cm) of the posterior vaginal wall. The vaginal wall in this area is <5 mm thick. The uterus lies nearly at a right angle to the vagina.

The blood supply of the upper vagina comes from the uterine and vaginal arteries, which are branches of the internal iliac artery. The area is drained by a vaginal venous plexus that communicates with the uterine and vesical plexuses. The vagina has its greatest sensation near the introitus and little sensation in the area adjacent to the rectouterine pouch.

The rectouterine pouch is formed by reflections of the peritoneum, and it is the most dependent intraperitoneal space in both the upright and the supine positions. Blood, pus, and other free fluids in the peritoneal cavity pool in the pouch because of its dependent location. This pouch separates the upper portion of the rectum from the uterus and the upper part of the vagina. The pouch often contains small intestine and, normally, a small amount of peritoneal fluid.

INDICATIONS

Culdocentesis is indicated in any adult female when fluid aspirated from the rectouterine pouch will help to confirm a clinical diagnosis. Ultrasound examination has largely replaced culdocentesis in the diagnosis of ruptured ectopic pregnancy and ruptured ovarian cysts, but the procedure still has an important role in emergency medicine. If ultrasound examination is not readily available in the emergency department (ED), or if the patient is too hemodynamically unstable to be transported to an off-site location for ultrasound, culdocentesis may be the fastest and most accurate diagnostic technique available to the emergency physician. [23] Analysis of peritoneal fluid is also a reliable method of differentiating inflammatory from hemorrhagic pelvic pathologic conditions. Conditions in which culdocentesis may be of diagnostic value include a ruptured viscus (particularly an ectopic pregnancy or a corpus luteum cyst), PID, and other intra-abdominal infections (particularly appendicitis with rupture or diverticulitis with perforation), intra-abdominal injuries to the liver or the spleen, and ruptured aortic aneurysms. [7]

Ectopic Pregnancy

Ectopic pregnancy is often one of the most difficult gynecologic lesions to diagnose. [14] The incidence of ectopic pregnancy is on the rise, accounting for 1.6% of all pregnancies. Ectopic pregnancy is the most common obstetrical cause of maternal death in the first trimester. [14] In a series of 300 consecutive cases of ectopic pregnancy, 50% of patients received medical consultation at least two times before the correct diagnosis was made. [3] In 11% of the patients in this series, the diagnosis was not made until the third medical visit. Because of the severe consequences of a ruptured ectopic pregnancy, an early, accurate diagnosis is desired.

The clinical picture of ectopic pregnancy may include vascular collapse, pelvic pain, amenorrhea or abnormal menses, shoulder pain, syncope, cervical or adnexal tenderness, adnexal mass, anemia, and leukocytosis. There is often a history of salpingitis, use of an intrauterine contraceptive device, or tubal ligation; however, no combination of these signs, symptoms, or historical data is diagnostic for an ectopic pregnancy. To confuse the diagnosis further, a normal menstrual history is reported in approximately 50% of patients with ectopic pregnancy and the *urine* pregnancy test is occasionally negative. [17] Although rarely seen, the combination of a uterine decidual cast (Fig. 58-1) and a positive pregnancy test are virtually pathognomonic of an ectopic pregnancy. A uterine cast is decidua that has been hormonally stimulated by the ectopic pregnancy but is passed vaginally when the tissue can no longer be supported. The cast is an outline of the uterine cavity, but it can be mistaken for products of conception if not inspected carefully. Therefore, all tissue passed vaginally should be carefully inspected before it is sent to the laboratory for analysis for products of conception.

The greater sensitivity of the serum and urine ß-hCG radioreceptor assay, coupled with the proliferation of trans-vaginal ultrasound and laparoscopy, have greatly increased the chances for early diagnosis of unruptured and ruptured ectopic pregnancy. [6] A sensitive and specific ß-hCG test must be used. The newer urinary ß-hCG tests (enzyme-linked or solid-phase immunoassay) provide sensitivity to 20 to 50 mIU/mL. Quantification of the serum test adds additional information being sensitive to 5 mIU/mL. Therefore, a negative *urine* ß-hCG test rules out pregnancy in greater than 98% of cases, and pregnancy in any site can be ruled out in virtually all patients with a negative *serum* ß-hCG test. [1] A single quantitative ß-hCG is a poor predictor of size of the pregnancy or the risk of ectopic pregnancy, but serial testing is quite helpful. It is expected that the quantitative serum ß-hCG level should double approximately every two days in the first trimester. Serum progesterone determinations

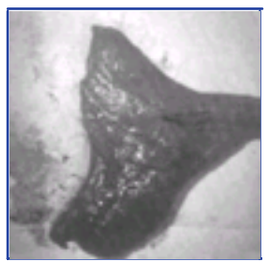

Figure 58-1 This decidual cast, a perfect outline of the uterine cavity, was initially thought to be products of conception when found in the vaginal vault of a pregnant woman treated for abdominal pain and vaginal bleeding. The initial diagnosis was a spontaneous abortion, but this cast is virtually diagnostic of an ectopic pregnancy. The woman later developed hypotension and was found to have a ruptured tubal pregnancy.

may also help to identify a normal or abnormal pregnancy. Although not infallible, a serum progesterone level of <10 ng/mL is usually associated with a nonviable intrauterine pregnancy or ectopic pregnancy, and a level >25 ng/mL is usually associated with a viable intrauterine pregnancy.

To increase the accuracy of diagnosis, it is helpful to combine quantitative ß-hCG testing with ultrasound examination. An empty uterus by transvaginal or abdominal ultrasound combined with certain quantitative serum ß-hCG results can be quite helpful to the clinician. The quantitative range in which the ultrasonographer should detect an intrauterine pregnancy varies, but an intrauterine pregnancy should be detected if the serum ß-hCG level is in the range of 1200 to 1500 mIU/mL when using a transvaginal probe, and if the level is >6500 mIU/mL when using a transabdominal probe. Endovaginal ultrasonic scanning consistently identifies 4-week gestational sacs if the ß-hCG levels =2000 mIU/mL. The presence of a fetal pole and cardiac activity are detectable with endovaginal ultrasound scanning at approximately 6 and 7 weeks, respectively. [8] It is important to note that the absence of an intrauterine pregnancy by ultrasound when the ß-hCG level is below the discriminatory zone is nondiagnostic and could represent an early viable normal pregnancy, a nonviable intrauterine pregnancy, or an ectopic pregnancy. When no intrauterine pregnancy is detected by ultrasound and the serum ß-hCG exceeds the discriminatory zone, the chance of an ectopic pregnancy ranges from 86% to 100%.[2]

Culdocentesis, for some patients, may play an important role in the diagnosis of ectopic pregnancy. The test has an accuracy rate of 85% to 95%. [3] [16] [26] Romero et al reported that an ectopic pregnancy was found in 99% of cases when a positive pregnancy test and a positive culdocentesis were present. [21] Although culdocentesis is most often positive in the presence of a frankly ruptured ectopic pregnancy, it may be diagnostic even in the nonruptured case when bleeding has been slow or intermittent. It is useful to note that many ectopic pregnancies leak varying amounts of blood for days or weeks before rupture. It is important that hemoperitoneum has been noted to occur in 45% to 60% of cases of *unruptured* ectopic pregnancy proved at surgery. [4] [24]

Hence, culdocentesis may be helpful in the stable patient whose ultrasound examination does not demonstrate an intrauterine pregnancy, despite a quantitative serum ß-hCG level in the appropriate range. Although some clinicians opt for outpatient monitoring of serial ß-hCG levels in this setting, patients for whom the clinician has a high suspicion for ectopic pregnancy (e.g., the patient who has or had significant discomfort) or for whom close follow-up cannot be ensured, are candidates for culdocentesis. [23] Although a negative culdocentesis does not rule out an early ectopic pregnancy, patients with a nondiagnostic ultrasound and a negative culdocentesis generally represent patients at lower risk for "rupture" of an ectopic pregnancy during outpatient serum ß-hCG monitoring. Patients with a nondiagnostic ultrasound examination and a serum ß-hCG level below the threshold at which an intrauterine pregnancy should be visible on the ultrasound examination also must be individualized. Those patients with significant pain, an unexplained low hematocrit reading, or postural vital sign changes (or near syncope) are candidates for culdocentesis.

Pelvic Infection

Acute PID has a polymicrobial etiology. [12] [19] [22] It has been common practice to define the etiology of PID by isolation of pathogens from the endocervix. The etiology is probably better defined by examination of the tubal flora. In fact, there is little correlation between cul-de-sac cultures and cervical cultures in PID. [5] Some medical centers routinely use aspirates obtained through culdocentesis to aid in determining the causative microbial agents for PID. [11] As the microbiology of PID becomes more complex and as the causative organisms develop resistance to antimicrobial agents, culdocentesis may evolve as one of the prime methods of obtaining meaningful microbiologic cultures that will dictate appropriate therapy.

Blunt Abdominal Trauma

Although diagnostic peritoneal lavage, computed tomographic (CT) scanning, and ultrasound examination are popular and valuable techniques to detect hemoperitoneum, the use of culdocentesis also has been advocated. [7] [13] Because small amounts of blood tend to collect in the rectouterine pouch, the aspiration of clear peritoneal fluid is of great potential value in *excluding* a diagnosis of hemoperitoneum. The procedure may be more advantageous than peritoneal lavage in some instances because there is less risk of urinary bladder perforation or bowel injury. In addition, previous abdominal surgery is not a relative contraindication to culdocentesis, as it is with peritoneal lavage. [20]

CONTRAINDICATIONS

The contraindications to culdocentesis are relatively few and include an uncooperative patient, a pelvic mass detected on bimanual pelvic examination, a nonmobile retroverted uterus,

TABLE 58-1 -- Correlation Between the Results of Culdocenteses Performed on 77 Patients with Ectopic Gestation and Various Clinical Parameters

Classic Triad	*Bleeding*	*Pain*	*Adnexal Mass*	Peritoneal Signs	Pulse =100/min	Blood Pressure <90/40 mmHg	Mean Hematocrit (%)	Hemoperitoneum =100 ml	Ruptured Tube	Total
Positive	37	54	10	26	19	9	35	52	30	54
Negative	8	8	3	1	1	0	39	0	0	8
Inadequate	13	15	6	5	4	1	38	13	7	15
Total patients	58	77	19	32	24	10	65	37	77	

Note: There is a lack of correlation between positive culdocentesis and peritoneal signs and changes in vital signs. Patients are grouped by culdocentesis result (i.e., positive, negative, or inadequate). Note that only 10 patients were hypotensive and only 24 experienced tachycardia.

From Cartwright PS, Vaughn B, Tuttle D: Culdocentesis and ectopic pregnancy. J Reprod Med 29:88, 1984. Reproduced by permission.

and coagulopathies. Pelvic masses may include tubo-ovarian abscesses, appendiceal abscesses, ovarian masses, and pelvic kidneys. It has been suggested that the only major risk with the procedure is that of rupturing an unsuspected tubo-ovarian abscess into the peritoneal cavity. This can be avoided by careful bimanual pelvic examination to exclude patients with large masses in the cul-de-sac.[5] Although there are no data to guide the age at which culdocentesis may be safely performed, the procedure is generally limited to patients who are beyond puberty. This limitation is suggested on the basis of anatomy and with the consideration that the procedure is difficult to perform through a small, prepubertal vagina.

One should not forgo culdocentesis due to the absence of classic signs anticipated with ectopic pregnancy. It is important to note that a positive culdocentesis does not consistently correlate with peritoneal irritation, blood pressure, pulse rate, or the actual volume of hemoperitoneum.[4] In fact, bradycardia in the presence of significant intraperitoneal bleeding from a ruptured ectopic pregnancy is not unusual (Table 58-1 and Table 58-2).

EQUIPMENT

The equipment required for culdocentesis is listed in Table 58-3 . Either an 18-ga spinal needle or a 19-ga butterfly needle held by ring forceps is acceptable. It may be helpful to anesthetize the posterior vaginal wall at the site of the puncture with 1% to 2% lidocaine with epinephrine administered through a 27- or 25-ga needle. Some physicians use a cocaine-soaked cotton ball to anesthetize the mucosa before infiltration with a local anesthetic. Although local anesthesia is often unnecessary (because *puncture of the posterior vaginal wall at the upper one fourth of the vagina is generally no more painful than a venipuncture*), there is some advantage to use

TABLE 58-2 -- Correlation Between Tubal Status and Hypotension, Tachycardia, Hematocrit, Signs of Peritoneal Irritation, and Hemoperitoneum in 77 Patients with Ectopic Gestation

Culdocentesis	Culdocentesis Positive	Peritoneal Signs	Blood Pressure <90/40 mm Hg	Pulse =100/min	Hemoperitoneum =100 mL	Average Hematocrit (%)
Ruptured (n = 37)	30	25	8	19	37	33.6
Intact (n = 40)	24	7	2	5	28	37.3
Total patients	54	32	10	24	65	

Note: Culdocentesis is frequently positive in the absence of rupture. Patients are grouped by the presence (i.e., "ruptured") or absence (i.e., "intact") of hemoperitoneum. Note that only about one half of patients with "ruptured" status had tachycardia.

From Cartwright PS, Vaughn B, Tuttle D: Culdocentesis and ectopic pregnancy. J Reprod Med 29:88, 1984. Reproduced by permission.

of a local anesthetic if multiple attempts at culdocentesis are required, as is sometimes the case. In addition, the epinephrine may produce vasoconstriction and may reduce bleeding associated with the needle puncture. Culdocentesis is often stressful to the patient, and all attempts should be made to render the procedure as painless as possible. Consideration of parenteral analgesia and sedation (see Chapter 34) should also be made when the patient is uncomfortable or anxious.

TECHNIQUE

Preparation

Culdocentesis is an invasive procedure that, in some hospitals, requires a written, witnessed, and signed consent form from the patient, parent, or guardian when the patient's condition permits. If verbal consent is obtained, this action should be witnessed and a notation in the medical record made documenting that the procedure was described, complications were discussed, and any alternatives (e.g., sonography, immediate laparoscopy) were offered when appropriate.

Once written or verbal consent is obtained, the patient is placed in a lithotomy position with the head of the table slightly elevated (reverse Trendelenburg position) so that intraperitoneal fluid gravitates into the rectouterine pouch. The patient's feet are placed in stirrups. In selected patients, some physicians premedicate with intravenous (IV) opioids or sedatives. The administration of nitrous oxide analgesia also is an accepted practice. When nitrous oxide is used during this procedure, it is important to document the presence of a chaperone, as some patients may develop sexual delusions under this agent. Although pain associated with culdocentesis needle passage is generally minor, the judicious use of analgesia and sedation makes the procedure easier for both physician and patient.

TABLE 58-3 -- Equipment for Culdocentesis

Bivalve vaginal speculum
Uterine cervical tenaculum
19-ga butterfly needle or 18-ga spinal needle
27- or 25-ga needle (for local anesthetic infiltration)
Ring sponge forceps
Syringes (20 mL)
Surgical preparation (iodinated, such as povidone-iodine)
Sterile water, cotton balls, 4 × 4 gauze sponges
Cocaine (10% solution) or benzocaine (20% solution)
Lidocaine (1%) with epinephrine
Culture media or test tube without anticoagulant

Radiographs, when indicated in the *stable* patient, are taken *prior* to culdocentesis, to avoid possible confusion if a pneumoperitoneum is detected following the procedure.

Exposure

A bimanual pelvic examination must be performed before culdocentesis to rule out a fixed pelvic mass and to assess the position of the uterus. Palpation of an adnexal mass is possible if the mass exceeds 3 cm in diameter. The examiner then inserts the bivalve vaginal speculum and opens it widely by adjusting both the height and the angle thumbscrews. The *posterior* lip of the cervix is grasped with the toothed uterine cervical tenaculum, and the cervix is elevated (Fig. 58-2). Grasping the cervix may produce minor discomfort, and the patient should be warned in advance of a possible sharp pain during this part of the examination. Bleeding from the tenaculum puncture site or culdocentesis site, or both, may produce postprocedure spotting, and the patient should similarly be informed.

Use of the tenaculum elevates a retroverted uterus from the pouch, exposes the puncture site, and stabilizes the posterior wall during the needle puncture. Some physicians prefer to use longitudinal traction on the cervix to produce the same result. The vaginal wall adjacent to the rectouterine pouch will be tightened somewhat between the inferior blade of the bivalve speculum and the elevated posterior lip of the cervix. This tightening of the vaginal wall exposes the puncture site and keeps it from moving away from the needle when the wall is punctured.

After the tenaculum is applied and the posterior lip of the cervix is elevated or traction is applied, the vaginal wall in the area of the rectouterine pouch should be swabbed with surgical preparation followed by a small amount of sterile water. Local anesthesia (1% lidocaine with epinephrine) may be administered at this point. Anesthesia may be injected with a separate 27- or 25-ga needle or by the spinal needle to be used for the culdocentesis. A cotton ball soaked in cocaine or benzocaine solution can be used for topical anesthesia of the posterior vaginal wall before infiltration with a local anesthetic. The needles used for both the local anesthetic and the puncture should be attached to a 20-mL syringe. A smaller syringe may not be long enough to allow adequate control of the needle, and the physician's hand may block the view of the puncture site if a smaller syringe is used.

Aspiration

Following local anesthesia, the syringe and the spinal needle to be used for the culdocentesis, are advanced parallel to the lower blade of the speculum. It is helpful to fill the syringe with 2 to 3 mL of saline (nonbacteriostatic) before puncture. Following needle puncture, the free flow of the fluid from the syringe expels tissue that may have clogged the needle and confirms that the needle tip is in the proper position and is not lodged in the uterine wall or the intestinal wall. Saline (rather than air) is preferred, because if air is used, one must be careful in interpreting the presence of free peritoneal air on subsequent radiographs. To avoid the need to change the syringe during the procedure, 1% lidocaine may be used for both anesthesia and confirmation of proper needle placement, but the bacteriostatic property of this agent precludes its use if the procedure is performed to obtain fluid for culture.

The vaginal wall should be penetrated in the midline 1 to 1.5 cm posteriorly (inferiorly) to the point at which the vaginal wall joins the cervix (Fig. 58-3).[25] The needle should penetrate a total of 2 to 2.5 cm.[18] [25] Gentle suction is then applied with the syringe while the needle is slowly withdrawn. It is important for the physician to avoid aspirating any blood that has accumulated in the vagina from previous needle punctures or from cervical bleeding because this may give the false impression of a positive tap. Bleeding from the puncture site in the vaginal wall is minimized if epinephrine is added to the local anesthetic.

Blood or fluid may be obtained immediately but may also be obtained just before the needle is withdrawn from the peritoneal cavity. Therefore, it is important to aspirate throughout the gradual withdrawal procedure. If no fluid is aspirated, the needle should be reintroduced and directed only slightly to the left or right of the midline. Directing the needle too far laterally may result in puncture of mesenteric or pelvic vessels. It is important to note that *if no fluid is obtained on the first attempt, the procedure should be repeated*.

Some physicians prefer the use of a 19-ga butterfly needle held with a ring forceps (Fig. 58-4). [25] This technique offers a built-in guide to needle depth and allows for good control of the needle during puncture. An assistant must aspirate the tubing while the physician controls positioning and withdrawal of the needle.

Fluid that is aspirated may be old, nonclotting blood; bright red blood; pus; exudate; or a straw-colored serous liquid. Any fluid that is not blood should be submitted for Gram staining, aerobic and anaerobic culture, and cell counts. Blood should be observed for clotting. Blood should also be sent for a hematocrit determination.

INTERPRETATION OF RESULTS

An interpretation of the results of culdocentesis depends primarily on whether any fluid was obtained. In the absence of a pathologic condition, one will often aspirate 2 to 3 mL of clear, yellowish peritoneal fluid. When there is no return of fluid of any type (a so-called dry tap), the procedure has *no diagnostic value*. Because a dry tap is nondiagnostic, it should not be equated with normal peritoneal fluid. In addition, when less than 2 mL of clotting blood is obtained, this is also considered to be a nondiagnostic tap, because the source of this small amount of blood may be the puncture site on the vaginal wall. Such blood will usually clot. More than 2 mL of *nonclotting blood* is certainly suggestive of hemoperitoneum. However, some researchers interpret as little as 0.3 mL of *nonclotting* blood as a positive tap.[4] There is no particular

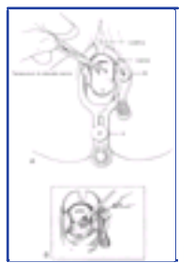

Figure 58-2 *A,* Preparation for culdocentesis. Note that one opens the speculum widely by using both the height *(A)* and the angle *(B)* adjustments. The cervix is grasped on the posterior lip with a toothed tenaculum. X marks the site for puncture of the vaginal wall. *B,* The use of a butterfly needle for culdocentesis. The needle is inserted 1 cm posterior to the point at which the vaginal wall joins the cervix. *(A, From Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. B, From Webb MJ: Culdocentesis. JACEP 7:452, 1978.)*

significance to larger amounts of blood, because absolute volume may be related to the needle position or the rate of bleeding. Brenner and coworkers [3] reported no blood from culdocentesis in 5% of patients with proven ectopic pregnancies, even when rupture had occurred. In the series of 61 patients with surgically proven ectopic pregnancy reported by Cartwright and colleagues, culdocentesis performed within 4 hours of surgery was positive in 70%, negative in 10%, and inadequate in 20%.[4] "Positive" in their series was defined as obtaining at least 0.3 mL of nonclotting blood with a hematocrit of greater than 3%. "Negative" was defined as obtaining 0.3 mL of fluid with a hematocrit of less than 3%. An "inadequate" tap was one in which no fluid was obtained. In the 252 surgically proven ectopic pregnancy patients having culdocentesis reported by Vermesh and others, 83% had a positive tap. [24] They defined a positive tap as nonclotting blood with a hematocrit of > 15%.

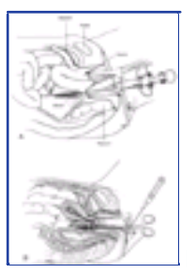

Figure 58-3 The needle is advanced parallel to the lower blade of the speculum. Aspiration is continued throughout the gradual withdrawal of the needle. *A,* The use of a spinal needle. *B,* the use of a butterfly needle and ringed forceps. *(A, from Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. B, from Webb MJ: Culdocentesis. JACEP 7:452, 1978.)*

Because culdocentesis is usually used to diagnose an ectopic pregnancy, a "negative tap" is one that yields pus or clear, straw-colored peritoneal or cystic fluid. A large amount of clear fluid (> 10 mL) indicates a probable ruptured ovarian cyst, aspiration of an intact corpus luteal cyst, ascites, or possibly, carcinoma. The significance of these fluids and the interpretation of results are outlined in Table 58-4 and Table 58-5 . Elliot and associates[9] cautioned that obtaining greater than 10 mL of clear fluid should not automatically rule out an ectopic pregnancy because the latter may coexist with other pathologic conditions.

A "positive tap" is one in which nonclotting blood is obtained, although the presence of nonclotted blood does not confirm a tubal pregnancy. Intraperitoneal blood from any source (ectopic pregnancy, ovarian cyst, ruptured spleen) may remain unclotted after aspiration for days in the syringe as a result of the defibrination activity of the peritoneum. The return of a serosanguineous fluid also suggests a ruptured ovarian cyst. The hematocrit of blood from active intraperitoneal

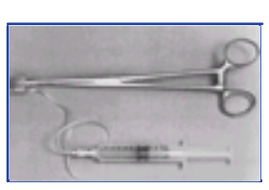

Figure 58-4 Culdocentesis may be performed with a 19-ga butterfly needle held with ring forceps. The ringed forceps grasp the wings of the butterfly needle to direct its placement. An assistant aspirates for fluid through the proximal end of the tubing. *(From Webb MJ: Culdocentesis. JACEP 7:451, 1978.)*

bleeding is greater than 10%. In one series, the hematocrit of blood from a ruptured ectopic pregnancy was =15% in 97% of cases. [3]

It should be emphasized that a positive culdocentesis in the presence of a positive pregnancy test does not always prove an ectopic pregnancy. [24] A ruptured corpus luteum cyst in the presence of an intrauterine pregnancy test is probably the most common cause of a false-positive scenario. When possible, ultrasound may help corroborate the culdocentesis findings.

TABLE 58-4 -- Interpretation of Culdocentesis Fluid

Aspirated Fluid	Condition and Suggested Differential Diagnosis
Clear, serous, straw-colored (usually only a few milliliters)	Normal peritoneal fluid
Large amount of clear fluid	Ruptured or large ovarian cyst (fluid may be serosanguineous); pregnancy may be coexistent
	Ascites
	Carcinoma
Exudate with polymorphonuclear leukocytes	Pelvic inflammatory disease
	Gonococcal salpingitis
	Chronic salpingitis
Purulent fluid	Bacterial infection

	Tubo-ovarian abscess with rupture
	Appendicitis with rupture
	Diverticulitis with perforation
Bright red blood*	Ruptured viscus or vascular injury
	Recently bleeding ectopic pregnancy* (ruptured or unruptured)
	Bleeding corpus luteum
	Intra-abdominal injury
	Liver
	Spleen
	Other organs
	Ruptured aortic aneurysm
Old, brown, nonclotting blood	Ruptured viscus
	Ectopic pregnancy with intraperitoneal bleeding over a few days or weeks
	Old (days) intra-abdominal injury (e.g., delayed splenic rupture)

*Note: The hematocrit of blood from a ruptured ectopic pregnancy is usually =15% (97.5% of cases), but some authors use >3% as positive.

COMPLICATIONS

Culdocentesis is one of the safest procedures performed in the emergency setting, and there are probably fewer complications with this technique than with peripheral venous cannulation. Complications have been reported, the most serious being rupture of an unsuspected tubo-ovarian abscess. [25] Other complications include perforation of the bowel, perforation of a pelvic kidney, and bleeding from the puncture site in patients with clotting disorders. Because the most common

TABLE 58-5 -- Interpretation of Culdocentesis

Positive
>0.5 mL nonclotting, bloody fluid (hematocrit >12%)
Indicates hemoperitoneum
When ß-hCG also positive, ectopic pregnancy found in >95%
Nonspecific—can occur in intrauterine pregnancies and nonpregnant women (e.g., ruptured cyst, retrograde bleeding)
Does not necessarily indicate tubal rupture
50%–62% of ectopic pregnancies with peritoneal blood may be unruptured
Negative
Serous fluid
Excludes hemoperitoneum and tubal rupture
False negative in 10%–15% of ectopic pregnancies (generally unruptured)
Nondiagnostic
Dry tap or clotting blood
Excludes neither ectopic pregnancy nor hemoperitoneum
15% of procedures are nondiagnostic
16% of ectopic pregnancies have nondiagnostic study results

From Brennan DF: Ectopic pregnancy: II. Diagnostic procedures and imaging. Acad Emerg Med 2:1090, 1995.

complications result from the puncture of a pelvic mass, careful bimanual examination of the patient should help prevent this problem. Puncture of the bowel and the uterine wall occurs relatively frequently, but this occurrence does not generally result in serious morbidity. Obviously, penetration of the gravid uterus has greater potential for harm. Occasionally, one will aspirate air or fecal matter, confirming inadvertent puncture of the rectum. Although this may be disconcerting, it is seldom of serious clinical concern and requires no immediate change in therapy.

CONCLUSION

In the emergency setting, culdocentesis can be a helpful diagnostic procedure. In an unstable patient with a strong clinical scenario for a ruptured ectopic pregnancy, the procedure may facilitate life-saving surgery by confirming the diagnosis without the need for time-consuming ultrasound examinations. Although the procedure is mainly used in the evaluation of ectopic pregnancy, culdocentesis should also be considered as a diagnostic aid in the evaluation of PID and in abdominal trauma. This is a safe, simple procedure that every physician who deals with the emergency evaluation of women, *particularly women of childbearing age*, should know and use. It may be the most rapid way to confirm hemoperitoneum in the unstable patient with suspected ectopic pregnancy.

Chapter 59 - Examination of the Sexual Assault Victim

Carolyn Sachs
Malinda Waddell

Despite a decrease in violent crime overall, sexual assault remains a significant societal problem that affects hundreds of thousands of women and men yearly. [1] Our best estimate of the true incidence of sexual assault in the United States comes from the National Crime Victimization Survey, a national telephone survey that collects data on nonfatal violent crimes against persons older than 12 years. [1] According to this survey that includes data from the year 2000, over 261,000 sexual assaults occurred with females sustaining 20 times the number of assaults as males. [1] Encouraging news found not only a decline in the incidence of sexual assault, but also an increase in reporting of the crime to police. [1] The majority of victims still do not report the assault to anyone, however. It is estimated that over the last decade victims have reported an average of one third of sexual assaults to law enforcement. After reporting to law enforcement, sexual assault victims may be transported to the emergency department (ED) for evaluation, examination, and treatment. Sexual assault victims may also present to the ED for treatment without prior contact with law enforcement. Victims are usually willing to cooperate with police investigation, but they may not be. Most states have laws requiring medical personnel treating sexual assault victims to report the assault to local law enforcement. Clinicians must know their own state laws regarding this.

DEFINITIONS

Although many use the term synonymously with rape, *sexual assault* more accurately refers to any sexual contact of one person with another without appropriate legal consent.[2] Physical force may be used to overcome the victim's lack of consent, but this is not mandatory to prove assault. Lack of consent for sexual contact by intimidation, threats, or fear equals sexual assault. State law differs slightly on the description of exact acts that constitute sexual contact and on which populations are unable to give legal consent. In general those under the influence of drugs or alcohol, those who are minors, and those who are mentally incapacitated are deemed unable to give consent for sexual contact.

Clinicians who treat sexual assault victims have a professional, ethical, and moral responsibility to provide the best medical and psychological care possible. At the same time, they must collect and preserve the proper medicolegal evidence that is unique to the evaluation of sexual assault cases.

Many hospitals and jurisdictions are affiliated with designated sexual assault examination teams that provide specialized evaluation and treatment for victims. The sexual assault response teams (SARTs) provide clear advantages. These are outlined toward the end of the chapter. However, victims may be brought to an ED that does not routinely provide specialized care for sexual assault. This chapter is designed to aid clinicians in such a general care location. Prepared emergency personnel can help attenuate the psychological and physical impact of sexual assault. Through proper care of the victim and careful acquisition of evidence, ED staff can help the victim to recover from the assault and can aid society in improving the prosecution and conviction of sexual predators.

MANAGEMENT OF THE ADULT FEMALE SEXUAL ASSAULT VICTIM

In most places, local jurisdictions or hospitals provide clinicians with detailed forms and instructions for the examination and documentation of sexual assault. This chapter is meant to supplement these instructions and forms. Clinicians should familiarize themselves with local forms and instructions prior to performing a sexual assault exam. Careful step-by-step planning using written protocols to guide the way in which a victim is handled in the ED and in follow-up helps both to ensure the best care for the victim and to aid in the prosecution and conviction of assailants.

Major provisions in the ED protocol include patient privacy and the designation of a separate area for the care of the victims. If medically and logistically possible, the victim should be interviewed in a private room that is separate from the examination room. EDs often have such an area often called the "grieving room" or the "family room." Many legal jurisdictions provide examination kits for the collection of forensic evidence from the victims (Fig. 59-1). These kits should be available in the ED, and the staff should be familiar with them. If such kits are not provided by local jurisdiction, hospital staff may need to assemble their own kits from materials found in most EDs. Alternatively, private companies assemble and sell such kits (The Lynn Peavey Company, PO Box 14100, Lenexa, Kansas 66285-4100). Prepared kits save a tremendous amount of nursing and clinician time when a victim comes to the ED. A checklist for local requirements for sexual assault examinations should be included in the kits and serves as a reminder for all of the medicolegal procedures to be completed.

Although this chapter is primarily devoted to the evaluation of the adult female sexual assault victim, guidelines for the evaluation of the adult male sexual assault victim, the female child victim, the male child victim, and the accused assailant are provided in separate sections of this chapter. The same examiners designated to perform adult female examinations may easily perform male victim and assailant examinations; however, the examination of the child sexual assault victim often requires considerable expertise and training. When possible, medical staff with extra training in the examination of the child sexual assault victim should perform these examinations. If this is not possible, the special section of this chapter should provide emergency medical personnel with a framework to perform an initial examination.

Consent

Consent for the treatment of a sexual assault victim is mandatory. The victim has undergone an experience in which her right to grant or deny consent was taken from her, and obtaining consent for medical treatment and for the gathering of evidence has important psychological and legal implications. The victim has the right to decline medicolegal examination and even

Figure 59-1 Sexual assault examination kit used in Los Angeles County.

medical treatment. Witnessed, written, informed consent must therefore be obtained before beginning evaluation and treatment. In most cases the standard ED "consent to treat" section will suffice. Although most states mandate that medical personnel report sexual assaults to law enforcement, victims may decline to discuss the event with police. However, victims may need to cooperate with police and give consent for evidence collection to have the examination paid for by law enforcement (California and Oregon law). If the victim cannot give consent for a forensic examination owing to a reversible process (e.g., intoxication, an acute psychological reaction), clinicians may wait several hours for the victim's mental status to improve to a reasonable level for consent to be obtained. When victims cannot give consent due to minor status or developmental disability, the person authorized to give medical consent for the patient may consent for the examination unless he or she is a suspect in the assault. Many states allow an adolescent victim of a certain age (e.g., older than 12 to 14 years) to consent to an examination for conditions related to STDs, sexual assault, and pregnancy. State laws also differ in examiners' requirements to make an attempt to contact the legal guardian (unless he or she is a suspected perpetrator). Clearly, emergency personnel must be informed regarding their local laws concerning these requirements.

History

The history of the event should include only those elements necessary for the clinician to complete required forms, to perform a focused physical examination, and to collect evidence. Questions beyond this, such as the details leading up to the assault, should be left to the police investigators. The clinician should avoid the urge to "help" the alleged victim by unduly embellishing or detailing uncorroborated or nonmedical information that is supplied during the examination. Limiting the history not only shortens the evaluation in the ED, but it also helps to prevent discrepancies between the ED history and the official police investigation report, which could weaken the victim's case in court. Documentation of pertinent medical history includes last menstrual period, current contraception, recent anal-genital injuries or surgeries, and pre-existing injuries.

The history of the event required by protocol usually includes the time, date, and place of the alleged assault and a description of the use of force, threats of force, and the type of assault. Elements of force may include the type of violence used, threats of violence, the use of restraints, the number of assailants, the use of alcohol or drugs (forcibly or willingly) by the victim, and any loss of consciousness experienced by the victim. Elements of the type of assault include fondling; vaginal, oral, or anal penetration or attempted penetration; ejaculation on or in the body; the use of a condom; and the insertion of foreign bodies into the vagina or the anus. The use of physical force or violence is partly a police matter, but from a medical standpoint it is desirable to correlate positive findings on the physical examination (abrasions, ecchymosis, scratches) with a description of any force, restraint, or violence.

A gynecologic history should be obtained in preparation for injury documentation and treatment plans. From a medicolegal standpoint examiners must question victims about any recent gynecologic surgical procedures or unintentional genital trauma that might alter the expected normal genital appearance. The history should also include the use of any method of birth control before the attack (with information regarding any missed birth control pills), last normal menstrual period, last voluntary intercourse, gravidity and parity, and recent sexually transmitted diseases.

The medical history should include current medications, tetanus immunization status, and allergies. Documentation of post-assault activity commonly requested by forms includes douching, bathing, urinating, defecating, gargling, or brushing teeth. These can alter the recovery of seminal specimens and other sexual assault evidence. In addition, examiners need to question victims about potential injuries from any preassault bodily trauma.

Elements of the victim history should lead examiners in deciding which potential samples to collect. For example, sperm may be recovered after intercourse from the *cervix* for up to 12 days and from the *vagina* for five days.[3] For example, if the victim had voluntary intercourse 48 hours

before examination and was sexually assaulted 3 hours before examination, the clinician should obtain samples from both the vagina and the cervix, keeping the two specimens separate. By taking a careful history, the clinician is able to perform an appropriate examination given these two separate events. In general, cervical swabs should be collected in addition to the usual vaginal swabs if the time between assault and examination is >48 hours.

While taking the history, the examiner should observe the patient's ability to understand and respond appropriately to questions. Victims of sexual assault may not

possess the capacity to consent to intercourse because of developmental disability, young age, or intoxication with drugs or alcohol. Clinicians must consider obtaining blood or urine, or both, and testing for drugs or alcohol when the history suggests lapses of (or impaired) consciousness. Most often victims who lack consenting capacity owing to developmental disability will have sufficient prior documentation of the condition. In the rare instance when an examiner suspects previously undocumented developmental disability, formal examination of the patient's mental capacity can be assessed at a later time by request of the district attorney.

Physical Examination

The physical examination of the sexual assault victim differs from most other ED examinations because examiners are not only caring for a patient's physical and mental well being, but they are also investigating a crime scene and collecting specific evidence. Examiners must remember to explain every step of the examination to victims. Victims need to be reminded to communicate any discomfort or questions to the examiner and to ask for a break from the examination if needed. Additionally, they need to be reminded of their right to decline any portion of the examination and the ability to stop at any point. Victims should have the opportunity to have a family member, friend, or victim advocate, or both, in the room during all parts of the examination. In some jurisdictions, state law mandates that victims be informed of this right (California Penal Code 679.04, Victim of Sexual Assault; Right to Advocate and Support Person).

Collection of Clothing

If not already collected by law enforcement, the clothes that the victim wore during the assault need to be collected for potential evidence. Victims should disrobe by dropping clothes onto a clean sheet. Using gloved hands examiners can then place each clothing item in a separate paper bag. All collected material needs to be meticulously labeled and its collection noted and described in the chart. The sheet and any material that might have fallen during the victim's disrobing should be bundled and placed in a separate paper bag. When a victim's clothing must be collected, the ED assumes the responsibility of providing suitable dress for the victim to wear after release from the ED.

General Body Examination

After she disrobes, the patient's body should be examined for signs of trauma and foreign material. Important areas for evaluation are the back, the thighs, the breasts, the wrists, and the ankles (particularly if restraints were used). Even in the absence of ecchymosis, tender areas should be noted. Leaves, grass, sand, and other materials can occasionally be found in the hair or on the skin and should be retained as evidence. Areas of trauma should be documented and further evaluated (e.g., with radiographs) as indicated by the type and extent of injury. Approximately 10% to 67% of sexual assault victims display bodily injuries. [4] Documentation of these bodily injuries correlates significantly with successful perpetrator prosecution. [5] Bodily evidence may range from abrasions to major blunt and penetrating trauma. If the victim has not bathed, bodily evidence in the form of dried semen stains may be visible on the hair or the skin of the victim. In a darkened room, dried semen (and many other substances) on skin may fluoresce under examination with short wave light, such as that produced by a Wood's lamp or an alternative light source (ALS) (Fig. 59-2).[6] The ALS may perform better than the Wood's lamp for this function. [7] Furthermore, the possibility of finding seminal fluid with the Wood's lamp is negligible after 24 hours. [8] Potential dried secretions may be collected with moistened swabs; the swabs are then air-dried and preserved as evidence. In addition to the skin, the fingernails can contain hidden bits of evidence. Rape victims may have fragments of the assailant's skin, blood, facial hair, or other foreign material from the rape site beneath their fingernails. Fingernail scrapings are obtained by cleaning under a victim's nails with a toothpick or cutting the nails closely over a clean paper. The toothpick and debris are then folded into the paper, placed in an envelope, and packaged with the other specimens.

Photographs can be a valuable addition to the documentation of bodily injury. Some institutions employ professional quality photographic equipment; others use police photographers. Most institutions require patient consent for photographs taken by hospital personnel. Optimally, institutions should arrange a prior plan to handle film according to a written "chain of custody." Alternatively, self-developing film (Polaroid) that can be permanently labeled (e.g., subject, date, details of pictured injury) may be used. The photographs should be labeled immediately and may be added to the legal evidence. In some jurisdictions, photographs of physical injuries will be taken and retained by an accompanying law officer. These photographs may serve as evidence or may simply refresh the examiner's memory at the time of the trial.

Oral Evaluation

If indicated by history, the oral cavity must be closely inspected for signs of trauma and evidence collected. Potential mouth injuries from forced oral copulation include lacerations of labial or lingual frenulum and mucosal lacerations and abrasions (often produced by the victim's own teeth as her lips are forced inward with the perpetrator's penis). Potential injuries to the posterior pharyngeal wall and soft palate include petechiae, contusions, and lacerations. Clinicians need to document these injuries at the time of initial examination as mucosal injuries heal quickly and may not be present hours or days later. Potential evidence should be collected using swabs rubbed between the teeth and the buccal mucosa on both upper and lower gingival surfaces bilaterally. Spermatozoa have been identified in oral smears up to 6 hours after the attack despite tooth brushing, using mouthwash, or drinking various fluids and may show valuable evidence up to 12 hours after examination. [9] Any foreign material (e.g., hair) should be collected and included as potential evidence. The old practice of collecting saliva for blood group antigen secretor testing as a reference sample has mostly been abandoned in favor of more specific DNA testing by most crime laboratories.

Figure 59-2 Alternative light source.

Genital Examination

Once in the lithotomy position examiners should inspect the victim's thighs and perineum for signs of trauma and for foreign materials, such as seminal stains. An ultraviolet light may again be used to look at suspicious dried secretions. Many jurisdictions recommend routine collection of swabs from the external genital area owing to the high likelihood of evidence being present and the inconsistent fluorescence of seminal fluid with the Wood's lamp.

Pubic Hair Samples

The victim's pubic hair can be combed for foreign material (particularly public hair belonging to the assailant) before the pelvic examination. This is done by placing a clean paper below the victim's buttocks with the victim in the lithotomy position and combing the public hair onto the paper. These hairs and comb are then folded into the paper and placed directly into a large paper envelope to be given to law enforcement. Foreign pubic hairs can often provide enough cellular DNA material from the root to enable the crime laboratory to perform DNA analysis. Additionally, specialized laboratories posses the capability of performing mitochondrial DNA analysis from the hair shaft in many cases.

Unfortunately, significant hair transfer occurs in less than 5% of assaults. [10] In the minority of cases when foreign suspect hairs must be compared with victim hairs, a pulled victim sample may be desired. Although the routine pulling of the patient's hair from the roots may provide the best sample, the act of pulling the victim's hair may be considered insensitive and unnecessary during the initial evaluation. Additionally, these hairs will rarely be needed, as the vast majority of cases do not concern this evidence. A victim can provide the hairs at a later time if needed, and often the victim is willing to pluck the hairs herself at that time.

The genital examination of the sexual assault victim differs considerably from most ED pelvic examinations. Examiners must first perform a careful evaluation of the vulva and the introitus for signs of trauma. The techniques of separation and traction move the tissues most likely to suffer injury into view. If the examiner fails to perform these maneuvers, he or she will miss traumatic genital injuries. Examiners must be familiar with genital anatomy including all terms used to describe these areas (Fig. 59-3 and Fig. 59-4). Although most novice examiners concern themselves with detecting injuries to the hymen, the majority of sexual assault-related

vaginal injuries occur to the posterior fourchette. [11] In fact, hymeneal injuries are rare in sexually active adult women and are more commonly observed in sexually inexperienced adolescents.[12] More uncommon injuries to the vaginal walls and cervix may be discovered during the speculum examination. Reported rates of genital injury among forensically examined victims range from 6% to 53% without colposcopy[4] [13] to 53% to 87% with colposcopy.[11] [13] Most importantly examiners must be cognizant of the fact that a completely normal genital examination is consistent with forced sexual assault. In fact, a study of more than 1000 sexual assault victims found that almost one half of all victims with crime laboratory evidence positive for sperm had no genital injury. [4]

Colposcopy

Teixeira[14] first described the use of colposcopy for documentation in sexual assault in 1981. Although it is not the standard of care, and not readily available in most ED evaluations, the use of colposcopy has revolutionized the documentation of injury. The colposcope provides magnification, a bright light source, and usually permanent documentation of injuries in

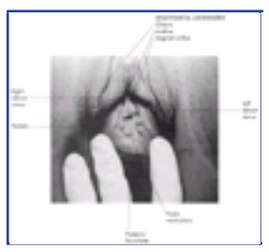

Figure 59-3 Female anatomy. *(From Girardin BW, Faugno DK, Seneski PC, et al: Color Atlas of Sexual Assault. St. Louis, Mosby-Year Book, 1997. Originally from Seidel HM, et al: Mosby's Guide to Physical Examination, 3rd ed. St. Louis, Mosby, 1995.)*

the form of slides, pictures, or video (Fig. 59-5). In one small study the colposcope increased the rate of genital injury detection from 6% to 53%. [13] Colposcopes with photo or video attachments provide excellent photographic documentation for court and allow for expert practitioner review for court testimony without subjecting the victim to re-examination. Although colposcopically visible injuries have also been described in women following consensual intercourse, these so called injuries consist only of increased vascularity and microabrasions, but no lacerations. [15]

Conversely, a totally normal genital examination by colposcopy is often found following sexual assault. Even in sexually inexperienced adolescents, forced penetration can occur without leaving discernible genital injury. [16] Although prior victim sexual experience decreases the likelihood of finding genital injury, experts cannot fully explain the reasons that some rape victims sustain measurable genital injury (Fig. 59-6), when others do not.

Forensic Evidence Collection

Protocols for evidence collection vary in different jurisdictions. Many rape evaluation centers have abandoned the cumbersome rape kits that have been used in the past, substituting simple collection methods that concentrate on important and usable legal evidence. The following discussion is patterned after the model protocol suggested by the state of California and the ACEP manual. [2]

During inspection of the external genitalia, rectum, vagina, and cervix, standard forensic specimens should be obtained. Experts recommend lubrication of the speculum with warm water rather than lubricant owing to the potential spermicidal activity of lubricants; however, the potential for corruption of DNA evidence should be negligible.[17] Generally, the specimens collected will be determined by victim history and local protocol, but they may include any of the items listed in Table 59-1 . Although not a standard examination by the emergency clinician, a wet mount of one swab from the vaginal pool may reveal motile sperm. From 13% to 26% of wet mounts provide evidence of sperm.[4] [18] Because of rapid cell death, studies have shown a negligible chance of finding motile sperm from a vaginal wet mount more than 8 hours after intercourse.[19] Several swabs from the vaginal pool (including the one used to make the wet mount) and the external genitalia are run over clean slides for a dry mount. All swabs and slides must be air dried, labeled, and packaged in

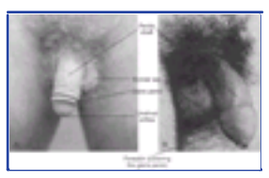

Figure 59-4 Male anatomy. *(From Girardin, et al: Color Atlas of Sexual Assault. St. Louis, Mosby-Year Book, 1997.)*

paper envelopes for the local crime laboratory. Equipment to aid the drying of specimens is shown in Figure 59-7 . Many crime laboratories also request collection of vaginal washing in which 5 mL of sterile (but not bacteriostatic) water or saline is inserted into the vagina and removed. The washing can be placed in a sealed container for later examination for evidence. Additionally, collection of cervical swabs may be indicated if the time from assault to examination (the postcoital interval) is greater than 48 hours, or if there is a history of recent consensual intercourse as well. The crime laboratory may recover sperm from cervical specimens up to 12 days after coitus.[3]

Swabbing the rectum must be performed if anal penetration is stated or suspected. Many experts also recommend routine collection of rectal swabs, because many victims may be unsure or embarrassed about rectal penetration.

Figure 59-5 Video colposcope with real time visualization on monitor shown. Image is eye of teddy bear at 15× magnification.

The CDC guidelines suggest considering a (cervical, rectal, or oral) culture or polymerase chain reaction (PCR) specimen, or both, for chlamydia and for *Neisseria gonorrhoeae*. However, the majority of SART programs in the United States do not routinely perform these tests. [20] Sexually transmitted disease (STD) testing during sexual assault examination can only detect pre-assault infection and provides no meaningful information for the crime laboratory. Additionally, the routine prophylactic treatment with antibiotics effective against *Neisseria gonorrhoeae* and chlamydia makes detection of these pre-existing infections superfluous; however, clinicians may want to consider obtaining cultures on child victims in whom the presence of an STD would be indicative of previous abuse.

Each sample should be labeled separately. The label should include mention of the area from which the specimen was collected and collection should be recorded in the chart.

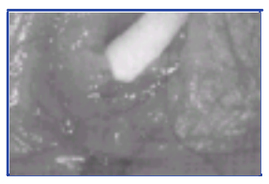

Figure 59-6 Hymenal injury at the 6-o'clock position in adolescent female.

Perineal Toluidine Blue Dye Staining

Toluidine blue dye is a nuclear stain that adheres to areas of injury (subepithelial nucleated cells) but not to intact epithelialized cells. Although it is not a uniform standard of care, the dye can enhance the examiner's ability to visualize genital injuries (Fig. 59-8). Genital lacerations may provide corroborating evidence of non-consensual intercourse. To outline injuries a 1% aqueous solution of toluidine blue dye is applied to the perineum and excess dye is wiped off with a cotton ball moistened with lubricating jelly. Some examiners use acetic acid to remove the excess; however, acetic acid may produce pain when it contacts injured tissues. After the excess dye is removed, any remaining linear areas that retain the stain signify injury. Folds of the area must be separated and carefully examined to avoid missing injuries. Ideally the dye should be applied before speculum examination to eliminate the possibility of iatrogenic injury. The procedure is shown in Figure 59-9 . In one study the use of toluidine blue dye increased the injury detection rate from 16% to 40% and up to 70% in nulliparous women without the use of colposcopy [21] ; however, injuries detected with the aid of toluidine blue dye are not 100% specific for sexual assault

TABLE 59-1 -- Potential Evidence Collected

Clothing (list and describe all clothing collected on chart and checklist form)
Debris
Dried secretions, swabs, and slides
External genital swabs and slides
Pubic hair combings
Oral mucosal swab and slide
Rectal swabs and slides
Vaginal pool swabs and slides
Vaginal lavage fluid in test tube or urine container
Tampon or condom present in vagina (dried or frozen)
Urine or blood toxicology sample (timed collection)
Reference blood, buccal mucosa, and/or hair sample
Collect all evidence using gloved hands to avoid DNA contamination
Change gloves when necessary to avoid inter-location contamination

because injuries have also been found following consensual intercourse, especially in adolescents. [22]

If seminal stains are noted on the perineum, samples should be collected before toluidine blue application. Contrary to earlier thinking, the use of toluidine blue dye does not interfere with recovery of DNA evidence [23] and has proven safe for mucosal application. [24]

Anal Evaluation

The anal exam follows the genital exam in most cases. Because of a reluctance of some victims to admit to anal penetration, some clinicians recommend an anal examination in all cases. Documentation of anal penetration holds significant value as it is a separate crime in addition to vaginal penetration and can add years to the sentence of the alleged perpetrator. Anal swabs are inserted approximately 2 cm into the anus, gently moved in a circular motion, removed, and used to make slides, which are air dried and included in evidence sent to the crime laboratory. In some jurisdictions additional evidence in the form of rectal washings may be requested. This is done by injecting 5 to 10 mL of normal saline with a syringe and a small plastic IV catheter, aspirating and preserving the fluid as evidence. Visualization of injury is increased by the use of toluidine blue dye as described earlier (Fig. 59-10). Anoscopy is not a routine part of the examination but it may be a useful adjunct in the documentation of rectal injuries. Examiners perform this procedure in the same manner as diagnostic anoscopy used to evaluate other anal or rectal emergencies in the ED (Fig. 59-11). In one retrospective observational study of male victims, the use of anoscopy and colposcopy provided superior documentation of injuries over colposcopy alone. [25] The location of anoscopically detected injuries may be recorded geographically.

Reference Samples

Crime laboratories often request reference samples taken from various locations on the victim's body to use in comparison testing with potential perpetrator evidence. These reference samples include blind swabs on the victim's skin in a complementary location to suspicious skin samples. For example, if a suspicious discharge is swabbed from the victim's right shoulder, a control swab may be taken from the victim's left shoulder. Crime laboratories may also request other control samples for victim DNA reference, such as blood, buccal mucosa cells, head hairs, or pubic hairs. The need for such samples will be determined by local protocol.

Blood Tests

Some crime laboratories request blood samples for DNA reference or toxicology analysis, or both. These samples must be included in the materials sent with law enforcement and not to the hospital laboratory unless a firm procedural "chain of custody" has been established for this purpose. When collecting blood for toxicology testing, the exact time of collection must be recorded on the specimen so that the criminologist may estimate dose and timing of substances used to perpetrate the assault.

Urine Tests

Bedside urine ß-hCG testing should be performed on all women victims of childbearing age to exclude pre-existing

Figure 59-7 Device used to hold swabs and slides to speed drying.

pregnancy before consideration of pregnancy and sexually transmitted disease prophylaxis. Additionally, urine may be requested by local crime laboratories for toxicology testing. Crime laboratories request the victim's first available voided urine to optimize recovery of potential evidence.

Spermatozoa, Semen, and DNA Testing

Motile and immotile sperm may be found microscopically in wet mounts of vaginal aspirates and in vaginal, oral, and rectal swabs. Some examiners microscopically

evaluate the slide immediately after the physical examination. These examiners find sperm in 13% to 26% of vaginal wet mount specimens. [4] [16] Early discovery of sperm may be helpful to law enforcement investigation. However, most ED examiners lack formal training in this process, and crime laboratories possess much higher sensitivity for sperm detection, making a negative initial wet mount unhelpful. For these reasons, many examiners do not routinely perform the wet mount examination.[4] After consensual intercourse with normal ejaculate, laboratory testing of vaginal secretions will likely be able to identify

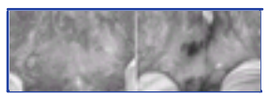

Figure 59-8 Posterior fourchette injuries. *A,* Viewed through the colposcope without the use of toluidine blue dye. *B,* Same posterior fourchette injuries outlined with toluidine blue dye.

sperm after 3 days and in 50% of cases at 4 days.[26] However, despite penile penetration during sexual assault, the crime laboratories may fail to identify sperm. Reasons for this failure include inadequate specimen collection, degradation of ejaculate, azoospermia, failure of the perpetrator to ejaculate, perpetrator vasectomy, or condom use.

A crime laboratory investigator initially looks for semen in a given sample by searching microscopically for sperm on a concentrated specimen and by testing for other components found in semen. Such seminal plasma components include P30 and acid phosphatase. P30 is a glycoprotein specific to the prostate [27] and is regarded as conclusive evidence of semen (i.e., ejaculation within 48 hours), whereas acid phosphatase is only presumptive evidence because it can occur in other body fluids, such as vaginal secretions. Although a main component of crime laboratory investigation in the past, many laboratories have abandoned the acid phosphatase test in favor of the more sensitive P30 test.[27] [28] Despite negative testing for seminal plasma components, laboratories may be able to detect valuable DNA evidence from persistent sperm cells or perpetrator epithelial cells. [29] [30] As DNA testing

Figure 59-9 Toluidine blue application procedure. *(From McCauley J, Guzinski G, Welch R, et al: Toluidine blue in the corroboration of rape in the adult victim. Am J Emerg Med 5:106, 1987.)*

technology rapidly changes, crime laboratory ability to perform a specific forensic test varies by location and over time. Most crime laboratories use PCR (polymerase chain reaction) testing, which requires minimal material.

Chain of Custody

Samples and other evidence must be given to the police, a crime laboratory, or a forensic pathologist. Each sample must be labeled with the patient's name, hospital number, date, time of collection, the area from which the specimen was collected, and the collector's name. These specimens should then be packaged according to local crime laboratory specifications and transferred to the next appropriate official

Figure 59-10 Anal injury is best seen with separation of perianal tissues. *A,* Without toluidine blue dye. *B,* Visualized after toluidine blue dye.

(police officer, pathologist, or other individual) along with a written chain of custody, which includes a list of the specimens, the signature of each person who provided them, and the signature of each person who received them. If this chain is broken, important evidence may be deemed inadmissible in court.

TREATMENT

Sexually Transmitted Disease Prophylaxis

The factors of sexually transmitted disease (STD), pregnancy, psychological distress, and follow-up should be considered in

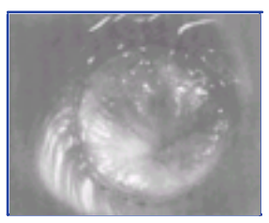

Figure 59-11 Rectal injury visualized with anoscopy.

the treatment of a sexual assault victim. Because pre-assault infection rates are not known, the risk of contracting a sexually transmitted disease (STD) as a consequence of a sexual assault has been difficult to determine, and estimates are tentative or nonexistent. One report of post-assault STDs found a 3% chance of development of gonorrhea and a 0.1% chance of development of syphilis. Other investigations suggest that the risk for these STDs may be as high as 12% and 3%, respectively. [32] Jenny and colleagues[33] found the post-assault incidence of STDs to be 2% for chlamydia and 4% for gonorrhea. The reported rates of 12% for *Trichomonas* and 19% for bacterial vaginosis may reflect a pre-exposure infection since male transmission of these organisms is rare. Glaser and others [34] found similar STD infection rates. The risk of developing herpes, hepatitis B, or human immunodeficiency virus (HIV) infection from being sexually assaulted has not been determined. However, HIV transmission has been noted.[35]

Although the chance of contracting an STD is small, examiners may choose to treat a victim prophylactically for gonorrhea, syphilis, and chlamydia; alternatively, examiners may choose to rely on follow-up cultures. The need for routine prophylaxis against Trichomonas is unclear and many clinicians do not recommend it as a routine intervention. Gonorrhea resulting from a sexual assault may possible be culturable within hours of the attack, but is almost always culturable at a 2-week follow-up visit. Because of the omnipresent fear of contracting a sexually transmitted disease from a sexual assault, it is reasonable to routinely offer prophylaxis to all victims. Because victims tend to have a relatively low compliance with keeping follow-up visits, most examiners offer, at the least, gonorrhea and chlamydia prophylaxis at the time of the initial examination.[20]

With the increasing prevalence of *Neisseria gonorrhoeae* strains resistant to penicillin and tetracycline, ceftriaxone has become the antibiotic of choice in treating gonorrhea. Ceftriaxone also treats incubating syphilis. Spectinomycin (2 g IM) and oral quinolones are single-dose alternatives for penicillin- and cephalosporin-allergic patients, but neither of these has been shown to be effective against incubating syphilis. No single-dose regimen for gonorrhea is effective against coexisting *Chlamydia trachomatis* infection. Therefore, patients also should be given either a single dose of azithromycin (1 g PO) or a seven-day course of doxycycline (100 mg PO BID) or tetracycline (500 mg PO QID). A negative pregnancy test is a prerequisite for using either of the latter two antibiotics. Erythromycin

TABLE 59-2 -- Single-Dose Therapy for Preventing Sexually Transmitted Disease after Sexual Assault

Metronidazole*	2000 mg

IM, intramuscularly; PO, by mouth.

*Not for use in pregnancy. In pregnant cephalosporin-allergic patients, use Spectinomycin 2 mg IM for prevention of GC.
†Also treats incubating syphilis.

is a second alternative for Chlamydia prophylaxis in the pregnant patient. Some examiners administer prophylaxis for *Trichomonas* with a single 2 g oral dose of metronidazole; although effective and recommended by the CDC[36] this dose of metronidazole may cause significant nausea, vomiting, or diarrhea, or both, which can interfere with the efficacy of pregnancy prophylaxis. Table 59-2 provides one example of a completely oral STD prophylaxis regimen.

Hepatitis B Prevention

Current CDC treatment guidelines in the setting of a high-risk exposure recommend hepatitis B vaccination only, *without* hepatitis B immune globulin (HBIG), at the time of examination, followed by two more vaccines at 1 to 2 months and 4 to 6 months.[36] Interestingly, the same CDC publication recommends the use of HBIG plus vaccination for nonimmune sexual contacts of infected individuals, stating that it is 75% effective in preventing the non-immune individual from contraction of hepatitis B. Clearly, the vaccine alone would be less protective than the vaccine plus HBIG against sexual transmission of hepatitis B. Potential reasons that the CDC may have settled for this less effective prophylactic regimen include the following: HBIG is very expensive, the majority of sexual assaults do not involve an infected perpetrator and a non-immune victim, infant immunization has been standard for the last 7 or 8 years, and the vaccine alone provides some protection. Clinicians may still want to consider administering HBIG to nonimmune victims with a high-risk exposure.

HIV Prevention

In the non-assault scenario, the risk of transmission of HIV from one episode of unprotected consensual receptive vaginal intercourse with an infected individual is approximately 1 in 1000. The incidence with unprotected receptive anal intercourse is significantly higher, at 8 to 32 in 1000. [37] However, sexual assault victims often

sustain tissue injury owing to the violent nature of the act which may increase the transmission rate of the virus. Although treatment of parenteral occupational

exposure to infected body fluids (i.e., needle stick) is believed to be effective based upon case control studies, there is no proof that treatment of human sexual exposure prevents the transmission of the virus.[38] Furthermore, victims of sexual assault frequently present for treatment much later than those who have occupational exposures.

However, 40% of sexual assault victims fear contracting HIV post assault and should, at a minimum, receive counseling and some argue, the option of taking anti-HIV medicines because they may be effective.[39] [40] San Francisco investigators have described a large-scale feasibility trial of AZT/3TC for 28 days post sexual assault, and this regimen seems to be a logical choice in balancing side effects and possible efficacy. [41] In this trial, 32% of those offered prophylaxis accepted the regimen, and one third of those came back in a week to obtain the remainder of the oral prophylactic course. In a Canadian descriptive trial, 28% of sexual assault victims accepted HIV prophylaxis and 40% of those returned after 5 days for the remaining medication. [42] Unfortunately, immediate testing of the perpetrator remains a remote option owing to physical unavailability of the majority of perpetrators and the fact that only a minority of states provide for legal preconviction HIV testing of alleged perpetrators.[39] Given the extreme negative outcome of HIV infection, at least two states have written empiric policies to guide examiners with this complex issue. One such policy is shown in Table 59-3 . However, the antiviral agents are expensive and potentially toxic. Currently, no standard of care based upon objective outcome data exists regarding HIV prophylactic therapy.

Pregnancy Prophylaxis

Pregnancy occurs in up to 4.7% of sexual assault victims.[43] An estimated 22,000 annual rape-related pregnancies could be avoided if all victims sought and received pregnancy prophylaxis within 72 hours.[44] Victims should provide urine for a pregnancy test before administration of postcoital contraception. Modern urine pregnancy tests possess a detection threshold approaching 20 to 25 mIU/mL and usually will be positive 1 to 2 weeks after conception, and often before a menstrual period is missed.

Sexual assault victims must be offered pregnancy prevention using available oral postcoital contraception (Table 59-4). In 1997, the FDA published a list of available oral contraceptives that could be used to provide postcoital contraception.[45] Most of these pills are a combination of ethinyl estradiol and a progestin, known as the Yuzpe regimen. This method prevents approximately 75% of pregnancies that would have otherwise occurred.[46] Alternatively, an FDA-approved progestin regimen used as postcoital contraception prevents 89% of pregnancies that would have otherwise occurred and causes fewer side effects, but may be unavailable. [47] Both regimens involve two doses of the medication taken 12 hours apart within 72 hours of intercourse. Adverse side effects include nausea, vomiting, and breast tenderness. If the patient vomits within 1 hour of taking a dose, it should be repeated. Some routinely offer prophylactic antiemetic therapy; others reserve such treatment for patients who vomit. Two kits containing the needed pills along with an antiemetic (Preven and Plan B) are FDA approved and commercially available. These regimens are also available at pharmacies by prescription. Because of their extreme safety and importance, some states have already made these kits available without a prescription. All available evidence demonstrates no untoward effects on the fetus should pregnancy occur despite postcoital contraception. [48] The common practice of obtaining written patient consent for these medications seems unwarranted.

Unfortunately, religious preferences may deter some hospital EDs from providing postcoital contraception.[49] In these instances, the Web site and number listed in this paragraph provide practitioner referral for easy access to postcoital contraception. Additionally, given the ever-increasing availability of new methods and drugs for postcoital contraception, examiners will want to obtain up-to-date information from these sources (Web site: www.not-2-late.com; telephone: 1-800-not-2-late).

Psychological Support

Sexual assault precipitates a psychological crisis for the patient, and psychological care should begin when the patient first arrives in the ED. [50] [51] Examiners must reassure the victim that she will be in control of the examination, that she may ask questions at any point, and that she should notify the examiner if anything hurts or if she needs a break. Giving the victim control over her body and the examination is the first step toward psychological support. Unfortunately, if this is not made a priority, victims may experience "secondary victimization" and be further traumatized by the forensic examination.[52] Sexual assault victims often develop posttraumatic stress disorder (PTSD), manifested by numbed responsiveness to the external world, sleep disturbances, guilt feelings, memory impairment, avoidance of activities, and other symptoms.[50] *Rape trauma syndrome* is the specific label for PTSD in this population.[50] The victim is particularly vulnerable to this stress disorder because of the following characteristics of sexual assault: (1) it is sudden, and the victim is unable to develop adequate defenses; (2) it involves intentional cruelty or inhumanity; (3) it makes the victim feel trapped and unable to fight back; and (4) it often involves physical injury. Attention to the initial psychological care of the rape victim in the ED is fundamental and can reduce distress during forensic examination.[53] Many areas have a local sexual assault crisis agency that can dispatch an advocate to be with victims during the interview and examination. This same agency may then provide the follow-up psychological support that must be offered to all victims. It is critical that all examiners maintain current contact information with these agencies and use their services when at all possible. The importance of this contact is emphasized in some areas by the fact that state law dictates that medical personnel contact a local sexual assault crisis agency when a victim presents for examination (California penal code 264.2, Notification of a Counseling Center). In the absence of immediate local crisis services, a hospital social worker may fill this role.

Postexamination Follow-Up

Medical and psychological follow-up for sexual assault victims is essential. Unfortunately, less than one third of the victims complete follow-up medical care. [54] Many protocols recommend a 2-week follow-up to re-examine any injuries and to repeat testing for STDs and pregnancy. The timing of this follow-up seems less important given the widespread use of prophylactic medication to prevent STDs and pregnancy. However, given the measurable failure rate of postcoital contraception, repeat pregnancy testing is critical for a victim

TABLE 59-3 -- Empiric Guide to Offering HIV Post-Exposure Prophylaxis

Has less than 72 hours passed since the assault occurred?
If no, do not offer PEP but recommend or refer for baseline and follow-up HIV antibody testing.
If yes, continue risk analysis.
Is survivor 12 years of age or older?
If yes, continue risk analysis.
If no, consult pediatric HIV specialist (To operationalize this guide, this consultant must be identified in advance).
What is the risk of HIV transmission from the assault?
Was the assault one with measurable risk of HIV transmission, such as an assault with anal penetration, vaginal penetration, or injection?
Was the assault one with possible risk of HIV transmission, such as oral penetration with ejaculation, an assault involving other mucous membranes (e.g., eyes), an unknown assault, an assault in which the victim bit the assailant, or the assailant (with a bloody mouth) bit the victim?
Was the assault one with no risk of HIV transmission, such as kissing, object or digital penetration, ejaculation on intact skin, or an assault in which a condom was used?
What other risk factors were present in the assault, including presence of blood, survivor or perpetrator with STD, significant trauma to survivor; ejaculation by assailant, or multiple penetrations of the survivor?
Is the assailant's HIV status known?

If known HIV negative, *do not offer* PEP.

If known HIV positive:

Recommend PEP if assault with measurable risk of HIV transmission has occurred.

Recommend PEP if assault with possible risk of HIV transmission has occurred and at least one additional risk cofactor was present in assault.

Offer PEP if assault with possible risk of HIV transmission has occurred with no additional risk cofactors present.

Do not offer PEP for exposures carrying no risk.

Does the assailant engage in behaviors that put him/her at risk for contracting HIV?

High risk groups include men who have sex with men, past or present injection drug users, commercial sex workers, individuals with multiple sex partners, individuals with prior convictions for sexual assault, and individuals with a history of prison incarceration.

If known or suspected risk factors exist:

Recommend PEP if assault with measurable risk of HIV transmission has occurred.

Recommend PEP if assault with possible risk of HIV transmission has occurred and more than one additional risk cofactor was present in assault.

Recommend or offer PEP if assault with possible risk of HIV has occurred and only one additional risk cofactor was present in assault.

Offer PEP if assault with possible risk of HIV transmission has occurred with no additional risk cofactors present.

Do not offer PEP for exposures carrying no risk.

If assailant is not known and/or if assailant's risk factors are unknown:

Offer PEP if assault with measurable risk of HIV transmission has occurred.

Offer PEP if assault with possible risk of HIV transmission has occurred and more than one additional risk cofactor was present in assault.

Offer PEP if assault with possible risk of HIV transmission has occurred and only one additional risk cofactor was present in assault.

Offer or do not offer PEP if assault with possible risk of HIV transmission has occurred with no additional risk cofactors present.

Do not offer PEP for exposures carrying no risk.

Offering PEP after sexual assault

PEP, post-exposure prophylaxis.

†Acts with possible risk of HIV transmission, including oral penetration with ejaculation, unknown act, contact with other mucous membrane, victim biting assailant, and assailant with bloody mouth biting victim.
*Acts with measurable risk of HIV transmission, including anal penetration, vaginal penetration, and injection with a contaminated needle.
‡Acts with no risk of HIV transmission, including kissing, digital or object penetration of vagina, mouth, or anus, and ejaculation on intact skin.

who does not experience an expected menses. Further follow-up evaluations may be performed at 4 or 6 weeks and 4 to 6 months to repeat serologic tests for HIV, hepatitis B, hepatitis C, and syphilis. In addition, local volunteer support groups can be of immense assistance to a sexual assault victim, and contact with such a group should be offered to each victim.

SPECIFIC POPULATIONS

Male Evidentiary Examinations

Male evidentiary examinations include all of the same forensic evidence collection as female victims except vaginal specimens.

TABLE 59-4 -- Emergency Contraception

Brand	Manufacturer	Pills
Combined Emergency Contraception Oral Therapy		
Preven	Gynétics	2 blue pills immediately and in 12 hours
Ovral	Wyeth-Ayerst	2 white pills immediately and in 12 hours

Ovrette	Wyeth-Ayerst	2 yellow pills immediately and 1 in 12 hours
Plan B	WCC	1 white pill immediately and 1 in 12 hours

Note: Some regimens cause nausea and an antiemetic may be used. If vomiting occurs, repeat the dose of antiemetic.

The forensic examination is guided by the history of events related by the victim. Most male victims suffer from anal penetration, or sodomy, by their perpetrator. In addition to rape trauma syndrome, heterosexual male victims may suffer psychological trauma, wondering if the assault now means that they "are gay." Examiners should inform such victims that the act of forced sodomy in and of itself does not indicate homosexuality. The increased risk of HIV transmission with anal intercourse is noted (see section on HIV prevention). Because of the extreme emotional reaction men often feel after a sexual assault, they report the crime even more infrequently than do female victims.[55] [56] The male victim deserves the same unhurried, nonjudgmental manner that the female victim deserves. Penile samples from the shaft, glans, corona, and scrotum may be obtained if there is oral or anal contact with the perpetrator.

Child Sexual Assault Examinations

The care and treatment of the pediatric sexual assault patient requires expert knowledge and experience. The presence of obvious genital injury and trauma speaks for itself, based on the history provided. The subtle variations of developmental changes and congenital anomalies leave many clinicians ill-equipped to render an opinion concerning the validity of sexual assault injury. The lives of children and families may be disrupted or severely affected, depending on the practitioner's opinion on the presence of genital penetration-type findings.

A well-known study by Adams et al.[57] demonstrates that the majority of children reporting sexual abuse have normal or nonspecific genital findings. With child sexual assault, it is "normal to be normal." In spite of expert physical examination, the vast majority of sexually abused children cannot be differentiated from nonabused children.[58] The discovery of one of the rare examination markers of injury should be confirmed with experts, and a discussion of these findings, although beyond the scope of this chapter, is covered extensively in other resources. [59] The potential sexual assault history provided by the child or caretaker should, therefore, remain the primary indicator that inappropriate genital contact has occurred. At the very least, the history warrants an investigation of the possibility of sexual abuse.

It cannot be emphasized enough that the examiners' responsibility to the care of the child victim of sexual abuse remains within the realm of experts. However, in EDs without available local experts, careful inspection of the genitalia in a non-hurried, child-friendly manner must be completed. For the very young child with small genital orifices, the aid of the otoscope for magnification may be extremely helpful. Often a parent may assist in the calming, reassurance, and positioning of the child for careful inspection. However, when the parent is a suspect, the practitioner must exclude that parent from the examination. Other than basic lithotomy position for the older, more mature child or adolescent patient, alternative positioning of the pediatric female patient is essential to inspection. The frog-leg position using labial separation and traction is often most beneficial (Fig. 59-12). Care must be taken to gently separate the labia to avoid superficial examiner-induced injuries. Genital findings that are deemed definitive of sexual abuse, penetration, or are nonspecific are included in Table 59-5 . Many normal hymeneal differences exist, however, from one child to the next and the definitive diagnosis of "abnormal" is often difficult for experts. When any doubt exists, ED examiners need merely describe the findings and refer the child for a later examination by experts. The availability of a colposcope or alternative photographic equipment with magnification clearly aids in documentation of any injuries that may heal before a time when an expert examination can be performed.

When disclosure or genital injuries confirm possible penetration of the child, specimens must be collected for the presence of potential evidence. These specimens may be collected without the insertion of a pediatric speculum; in fact, many child abuse experts strongly advocate that no speculum examination be conducted on any prepubescent child.[59] Cases involving severe vaginal trauma or suspected internal genital injury warrant examination under general anesthesia. External anal and vulvar swabs are usually collected without difficulty on a child of any age. Vaginal samples on very young children usually are difficult to obtain

Figure 59-12 Recommended "frog leg" position to examine children.

and should remain the very last evidence collected. Vaginal aspirates using a feeding tube or plastic angiocatheters are alternatives to vaginal swabs.

Specimens for screening of sexually transmitted diseases remains a controversial issue in the realm of child abuse experts. For *Neisseria gonorrheae*, at least, the literature supports the notion that all infected children will display an abnormal discharge. [60] With very young children, the practitioner may have only one opportunity to collect vaginal specimens without subsequently restraining or sedating the child. The practitioner will need to decide at which point specimen collection becomes a second assault on the child. Because the child presents for possible sexual abuse, the primary specimens collected should be for forensic DNA analysis. STD detection and treatment can be performed at a later time. Clinicians must consult local child abuse centers for protocols regarding

TABLE 59-5 -- Genital Findings Possibly Related to Sexual Assault in Prepubertal Children *

Clear Evidence
Local areas of hymenal absence in knee-chest position
Hymenal transection
Anal laceration
Suspicious or Suggestive
Extremely narrow hymen (<1mm)
Acute abrasions or lacerations of labia or vagina external to hymen
Excessive anal dilatation (<15mm without stool in rectum)
Nonspecific
Redness
Increased vascularity
Labial adhesions

immediate STD specimen collection, referrals, and follow-up services.

Suspect Examinations

As forensic evidence collection in the form of DNA retrieval continues to evolve, EDs may see more requests from local law enforcement for evidence collection from alleged suspects. EDs should be familiar with local and state protocols, especially regarding consent. Some jurisdictions require that no voluntary consent be obtained from the alleged suspect, given imminent degradation of potential biologic evidence. Other jurisdictions require that alleged perpetrators give consent, or at the very least, that police obtain a search warrant from the court. The sooner a suspect is apprehended and brought in for a medical-forensic examination, the better the quality of forensic biologic evidence.

Performing a medical-forensic examination on an alleged suspect can give important corroborating information for the investigation of a crime. It can also help to exonerate the innocent. Law enforcement should always be in attendance during any suspect examination to address safety issues for the examiner. Furthermore, the suspect and victim should never encounter one another in the hospital setting during the examination period and care should be taken to examine the victim and suspect in separate locations within the ED. It is extremely beneficial to conduct the victim examination and history prior to the suspect's examination so that physical findings on the suspect may help to corroborate the victim's history. For example, if, during the victim's history, she relates that she scratched the suspect's left shoulder in defense, the examiner can be certain to examine, document, and preferably photograph the presence (or absence) of the injury on the suspect's left shoulder. However, having the same practitioner examine both victim and suspect can be controversial in some jurisdictions. Concerns have been raised regarding examiner bias against the suspect and potential evidentiary contamination.

The physical and evidentiary examination for the alleged suspect is similar to the victim examination. The primary differences lie in history taking, reference samples, and more "blind" samples (those that are presumed, not evident). During suspect examinations, law enforcement rather than the suspect, provides the history of the event. Reference samples of head and pubic hairs are routinely collected as well as blood, saliva, and urine, if possible. Special attention must also be applied not only to nail scrapings but also to swabbing all of the fingers for possible vaginal epithelial cells from digital penetration. Penile swabs include collecting from the shaft and corona of the glans, then separately collecting swabs from the scrotum for vaginal secretions. From an unwashed penis, swabs almost uniformly show evidence of female cells up to 24 hours after coitus. [29]

Suspect examinations require the same amount of professional sensitivity and respect that any patient receives within the ED. It is not within the realm of the clinician's expertise to determine whether or not the alleged suspect is guilty or innocent.

The Unconscious Victim and "Date Rape"

Alcohol and other drugs play an important role in many sexual assaults. One half of all sexual assaults involve drug or

alcohol ingestion. [61] In many cases it is unclear if a drug was taken voluntarily or if it was surreptitiously given to the assaulted victim.

The media has highlighted increasing awareness of drugs used to facilitate sexual assault under the term *date rape drugs* (Table 59-6). [62] The drugs most commonly associated with drug-facilitated sexual assault are ethanol, marijuana, cocaine, and benzodiazepines. Often more than one drug is found. Although any type of sedative or hypnotic drug, or combination of both, may be used to facilitate sexual assault, the most notable drugs include flunitrazepam (Rohypnol) and gamma hydroxybutyrate (GHB). [63] Despite their reputation in the lay press, flunitrazepam and gamma hydroxybutyrate are associated with drug-facilitated sexual assault in less than 5% of cases. [63] Flunitrazepam is a benzodiazepine unavailable in the United States but available in Mexico. It can be detected in the urine up to 3 weeks post ingestion. [64] Gamma hydroxybutyrate is a federally banned central nervous system depressant not available for legal purchase in the United States but easily manufactured illegally by users. It can be detected in drinking material residue by crime laboratories as well in the victim's urine up to 4 hours post-ingestion.

Drugs similar to GHB are 1,4 butanediol (BD) and gamma butyrolactone (GBL). Often the victim's last memory is of using drugs or alcohol and then passing out. Some may remember short segments of activity that may indicate some type of sexual acts. Some victims may have no memory at all but desire to be "checked" for intercourse. A comprehensive forensic-medical examination should be conducted on

these individuals. All orifices (oral, vaginal, and anal) should have standard sexual assault evidence collected and an evaluation conducted for injuries. Without a history from the victim, samples must be collected from even potential oral or genital contact including neck, breasts, and vulva. Toxicology samples (including ethanol) should be obtained from both blood and urine, if possible, with exact times of collection documented. Because of the wide spectrum of date rape drugs available, the standard hospital's drug screen may be inadequate and a reference laboratory is best consulted. Some forensic laboratories offer a "date rape panel" that tests for a variety of commonly used substances. Obviously a positive drug test does not prove date rape and it may be impossible to distinguish self-administration to clandestine ingestion.

Extreme sensitivity must be used for discussing positive genital findings with a victim who has no memory of any sexual activity. Many times the imagined sexual acts can create just as severe a traumatic response as an actual remembered sexual assault. For the unconscious victim, there is no memory of events to fill in the blanks, only her terrifying imagination of what could have happened.

Legal Issues

It is not uncommon for the examiner to be called to court to testify in cases of sexual assault. A well-documented chart often negates the need for a clinician's appearance in court. When required for this task it is best for the examiner to work with the prosecuting attorney to prepare testimony. As is the case for all ED patients, chart notes should be written with the expectation that the ED evaluation and evidence collection will have to be explained and defended in court. In some jurisdictions it is possible to minimize the time spent away from work by arranging to be called to the courtroom just before the time of testimony or by giving a deposition before the court date. Once on the witness stand, remember that one is called as the examining clinician and not necessarily as an expert witness. The law requires that one testify only to one's best recollection and to what is indicated in the chart. Factual information in answer to questions should be given only if one knows the facts, and assumptions should be avoided. One should not be afraid to acknowledge the limits of one's knowledge or expertise. Statements such as "there were marks on the body that were consistent with bite marks" are preferable to statements such as "there were bite marks." It is the court's decision whether or not a person was sexually assaulted, and the clinician is there to give information about the patient's presentation, statements, what was found, and what was done for treatment.

Sexual Assault Response Team

Traditionally the responsibility of emergency clinicians, since the early 1990s nurses or nurse clinicians have been performing an increasing number of sexual assault examinations. Called SANE (sexual assault nurse examiners), these nurses are the core members of the sexual assault response teams (SARTs). Other members of the SARTs include law enforcement individuals, victim advocates, prosecutors, and forensic laboratory personnel.

Most examinations still take place in the ED but may be done in a space near the ED or an affiliated clinic. To establish SARTs, extra funding by government or charitable organization

is needed because most local police jurisdictions do not reimburse adequately for the evidentiary examination to support a program. Nurse examiners have formed The International Association of Forensic Nurses (IAFN). This group has drafted standards of practice for sexual assault examiners' education and the exams themselves. Advantages of SART using SANEs include

1. The practitioner performing the examination is specifically dedicated to treating the victim, not tending to multiple patients in a busy ED.
2. The clinician has usually completed more extensive training on sexual assault examination (mean of 80 hours) [20] and evidence collection and, as such, may perform a more comprehensive examination with better evidence collection. [65]

3. Many involved feel that designated clinicians consider the emotional needs of the victim more fully because of their extra time in training.

Useful guidelines and resources for establishing SANE programs are currently available. [2] [6]

Chapter 60 - Drugs and Radiation In Pregnancy

Denis J. Dollard

Pregnant women are frequently evaluated in emergency departments (EDs) with varied complaints that may require medication or diagnostic imaging. Their chief complaint may be pregnancy-related, an acute illness/injury, or related to a chronic condition diagnosed before pregnancy. The potential teratogenic effects of some medications are well documented, but adverse effects to the developing fetus from diagnostic radiation and radionuclide procedures are more perceived than real. Since fetal safety is a major concern, it is important for clinicians to have a clear understanding of the actual risk and benefits associated with prescribing medication and radiographic imaging during pregnancy.

RADIATION IN PREGNANCY

Radiological tests are ordered every day in a busy ED. The current actual number is unknown, but approximately 40 million x-ray examinations were done on female patients in the childbearing age group, 15 to 44 years old, in 1980. [1] With such a high volume of imaging studies, there is a high likelihood of caring for a patient who requires an imaging study and has an early unknown or known pregnancy.

In utero radiation exposure of the embryo or fetus generally causes great, but largely unnecessary, anxiety among the parents, their families, and clinician. Much of this anxiety is secondary to a general misconception that any radiation exposure is harmful and will result in an anomalous fetus. More often than not, clinicians themselves add to the confusion and fear by providing exposed women with erroneous information. Many clinicians, nurses, and even radiology technicians are ignorant of the qualitative and quantitative effects of ionizing radiation. [2] This misinformation could lead to inappropriate abortions and litigation. For example, in Greece, following the Chernobyl disaster, 23% of pregnancies were terminated due to unsubstantiated fears of teratogenicity. [3] A better understanding of the true risk estimates will help alleviate this fear.

It is widely held and published that *concerns about possible effects of ionizing radiation exposure should not prevent medically indicated diagnostic procedures from being performed on the mother*. It is not standard of care to withold necessary radiologic studies because of fear of fetal injury from diagnostic studies. According to the American College of Radiology, "No single diagnostic x-ray procedure results in radiation exposure to the degree that would threaten the well being of the preembryo, embryo, or fetus".[4] This remarkable statement helps put the effects of diagnostic radiation exposure on pregnancy in perspective. Standard diagnostic radiological procedures performed in the ED are not associated with significant proven fetal risks. A clear understanding of these risks enables the clinician to make an informed decision and knowingly counsel patients in order to provide more benefit than harm.

Evaluation of radiation exposure on a pregnant patient should involve consideration of the type of radiation, types of examinations performed, gestational age, and radiation dose in order to determine risk estimation. The radiation dose of interest is the dose absorbed by the embryo or fetus, and not by the mother. The main goal of this chapter is to review the basic issues of pregnancy and radiation exposure and provide a practical approach for clinicians in counseling the patient who has or will receive an emergent diagnostic procedure.

Types of Radiation

All imaging techniques involve radiation or transmission of energy from one body or source to another. Imaging modalities used for diagnosis during pregnancy can be subdivided into ionization techniques (x-rays, computed tomography [CT] scans, nuclear imaging) and nonionization techniques (magnetic resonance imaging [MRI] and ultrasonography [US]). The nonionization techniques have insufficient energy to ionize target cells. It is the ionization process and sequelae that induce health-related fetal effects.

Ionizing Radiation

Ionization is the transfer of energy to a medium by either electromagnetic or particulate radiation that is sufficient to overcome the binding energy of an electron. The electron may be ejected from the atom. Both electromagnetic waves consisting of uncharged particles (x-rays and gamma rays) and charged particles (alpha and beta) can produce radiation. Indirect ionization modalities such as x-rays release an electron from a source that interacts with the target. Direct ionization refers to charged particles, alpha and beta, that strike the target directly.

Units of Radiation

The units used to measure the effects of x-rays can be confusing. Descriptive terms include the *rad* and *rem*, along with the modern International System of Units (SI) of Gray and Sievert. In terms of *radiation protection*, the significant radiation quantity is the absorbed dose. The unit of *absorbed radiation* is the rad or the Gray (Gy) (1 Gy = 100 rad). Any risk associated with radiation is related to the amount of energy absorbed.

The dose equivalent expressed in *rem* or Sievert (Sv) is used to quantify the degree of biological effect (1 Sv = 100 rem). This unit reflects the biological response and can be used to compare effects of different types of radiation. The dose equivalent is the product of the absorbed dose times a quality factor. The quality factor is dependent upon the mass and charge of the radiated particle. The quality factor is approximately 20 for an alpha particle, and equal to 1 for x-rays and gamma rays. Therefore, for diagnostic x-rays, CT scans, and Tc^{99} nuclear studies, the absorbed dose is equal to the dose equivalent; that is, an absorbed dose of 1 rad yields a dose equivalent of 1 rem (1 Gy = 1 Sv) (Table 60-1). All reference data was converted into rads for uniformity and comparison throughout the chapter.

Timing of Radiation During Pregnancy and its Effects

The effects of exposure to radiation on the conceptus depend on the gestational age and the amount of absorbed dose.

TABLE 60-1 -- Units of Radiation

Quantity	Unit	SI Unit	Relationship between Units
Absorbed dose	rad	Gray (Gy)	1 Gy = 100 rad
			100 mGy = 10 rad
			10 mGy = 1 rad
			1 mGy = 100 mrad
Equivalent dose	rem	Sievert (Sv)	1 Sv = 100 rem
			100 mSv = 10 rem
			10 mSv = 1 rem
			1 mSv = 100 mrem

Absorbed dose (Gy) × quality factor = equivalent dose (Sv).

The quality factor for x-rays = 1. Therefore, 1 rad = 1 rem, 1 Gy = 1 Sv.

The relationship between radiation-induced effects and stage of pregnancy is shown in Figure 60-1 .[1] The harmful effects of ionizing radiation have the following principal biological effects: intrauterine death, organ malformations, mental impairment, fetal growth retardation, cancer, and genetic mutation. [2]

Radiation-induced health effects are divided into two broad categories, stochastic and nonstochastic effects (Table 60-2). Stochastic effects, such as cancer or genetic mutation, can result from alterations produced in a single cell and are presumed to exist even at low exposure. [2] The probability of such an effect occurring increases with dose and there is no identifiable threshold dose below which the chance is known to be zero. However, at low doses of radiation, the risks are far

below the spontaneous incidence of carcinogenesis [6] or mutagenesis.[7]

The remaining harmful biological effects mentioned earlier are nonstochastic effects. Nonstochastic effects require multicellular injury and have a threshold dose below which deleterious effects do not occur.[2] It is important to emphasize that the vast majority of embryopathologic effects are believed to be threshold phenomenon; therefore, a dose of ionizing radiation below the threshold will not produce these effects.

Stages of Fetal Development

Development of the unborn child is expressed as post-conception age and can be divided approximately into three major phases. These include 1) the preimplantation/implantation phase, (0 to 2 weeks), from conception to implantation, 2) the phase of major organogenesis, which extends from the 3rd to approximately the 8th week post-conception, and 3) the phase of fetal development lasting from 9 weeks until birth.

TABLE 60-2 -- Stochastic and Nonstochastic (Threshold) Comparison

Phenomenon	Pathology	Diseases	Risk	Definition
Stochastic	Damage to a single cell may result in disease	Cancer, germ cell mutation	Some risk exists at all dosages; at low doses, risk may be less than spontaneous risk	The incidence of the disease increases but the severity and nature of the disease remain the same
Nonstochastic (Threshold)	Multicellular injury	Intrauterine death, organ malformations, mental impairment, growth retardation	No increased risk below the threshold dose	Both the severity and incidence of the disease increase with dose

Modified from Brent RL: Utilization of developmental basic science principles: The evaluation of reproductive risks from pre- and postconception environmental radiation exposures. Teratology 54:182, 1999.

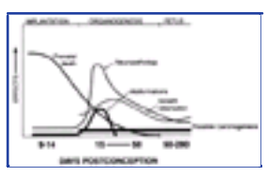

Figure 60-1 Schematic presentation of the various adverse effects associated with radiation and their relative incidence at different stages of gestation. *(Adapted from Mettler FA Jr, Upton A: Medical Effects of Ionizing Radiation, 2nd ed, Chapter 8, WB Saunders, 1995.)*

Preimplantation/Implantation

During the preimplantation and implantation phase the principal radiation-induced health effect is abortion. [8] When the number of cells in the conceptus is small and their nature not yet specialized, the effect of damage to these cells is most likely to take the form of failure to implant or an undeterminable death of the conceptus. [6] The *no effect threshold* of absorbed dose is quite high, estimated at 10 to 15 rad,[8] and not likely to be even distantly approached by diagnostic ED radiographs or radionuclide testing. By the time the pregnancy is at term, the threshold to cause intrauterine mortality has risen to about 100 rad. [8] These estimates have been extrapolated from animal data. This period has been referred to as the "all or none period" since radiation is more likely to kill the embryo than result in a live malformed newborn.

There are few human epidemiological data available for this period of gestation. Since many women are certainly unknowingly exposed to diagnostic radiation during this period, the lack of such data suggests a nonassociation between diagnostic radiation exposure and embryo death. Data from the Japanese atomic bomb experience have been cited for reference, but such a correlation is difficult to justify scientifically. Nonetheless, these data show a decrease in the number of offspring who retrospectively would have been 0 to 3 weeks postconception at the time of this significant radiation exposure, suggesting increased fetal loss caused by irradiation

TABLE 60-3 -- Risks and Threshold Doses of the Main Effects of Prenatal Irradiation

Gestational Age	Stage	Potential Biological Effect	Threshold	Risk
0–2 weeks	Preimplantation/Implantation	Abortion	>10 rad[2] [8]	
3–7 weeks	Organogenesis	Organ Malformation	>5[8] ; >10[2] [9] rad	
		Growth Retardation	>10 rad[2] [9]	
8–25 weeks	Fetal	Growth Retardation	>10 rad[2] [9]	
		Mental Impairment	>10 rad[9] [8]	
Whole Pregnancy		Carcinogenesis	None	6×10^{-4} per rad
		Mutagenesis	None	1×10^{-2} per rad

Modified from Fattibene P, Mazzei F, Nuccetelli C, Risica S: Prenatal exposure to ionizing radiation: Sources, effects, and regulatory aspects. Acta Paediatr 88:693, 1999.

during preimplantation.[9] This decrease in birth rate is likely multifactorial since stress, disease, and malnutrition were coexistent during this traumatic time. Importantly, fetal loss from exposure to an atomic bomb cannot be scientifically extrapolated to exposure to diagnostic radiation.

Any discussion concerning the potential adverse effects from diagnostic radiation must consider the natural incidence of spontaneous abortion. Since the main effect of radiation exposure during the first few weeks postfertilization is abortion due to embryo death, it is paramount to note that the normal incidence of spontaneous abortion in humans not exposed to radiation is in the 30% to 50% range. [2] *Exposure to <10 rad yields no statistical change in the rate of preimplantation/early postimplantation spontaneous abortion from the expected baseline (Table 60-3).*

Organogenesis

Very high-dose radiation exposure, far greater than could be delivered by even aggressive diagnostic radiographs/radionuclide procedures, has been reported to result in teratogenesis. Such information is gleaned from women who received therapeutic radiation (in the range of 250 rad) during early pregnancy for conditions such as pelvic malignancies. Organ malformations are the main consequence of radiation exposure during the organogenesis period (3 to 8 weeks). Abnormalities result from cell killing during the active phase of proliferation and differentiation. Since the embryo is unable to completely replace damaged cells, malformations occur. The most common effects of exposure during organogenesis are malformations caused in the organs under development at the time of exposure and the reduction of skeletal development. *Growth retardation and microcephaly are the predominant effects.* [6] [8] [9] These effects have a reported threshold dose range of 5 to 20 rads or higher, but are not generally observed unless the exposure is several orders of magnitude or higher. [6] [8] This dose range is significantly higher than what is reached in diagnostic radiology or diagnostic nuclear medicine procedures. While ocular abnormalities, developmental facial abnormalities, genital abnormalities, and physical deformities of the extremities have been reported after very high-dose embryonic exposure, such abnormalities are not linked to the amount of radiation that would be delivered from even multiple diagnostic radiographic procedures. Importantly, there are no reports of external radiation inducing morphologic malformations in humans unless offspring also exhibited either growth retardation or a central nervous system (CNS) abnormality. Simply stated, a fetus exposed to radiation will not

develop isolated structural abnormalities. The fear of extra toes, cleft palate, or heart or kidney malformations from diagnostic radiation during pregnancy is simply unfounded, yet often believed by the general public.

Temporary growth retardation is likely with doses in the range of 10 to 25 rad. [9] Infants with low birth weights and lengths may recover fully, attaining normal adult stature. The *natural incidence* of a live birth having a developmental anomaly is 2% to 4% [1] and intrauterine growth retardation is 2% to 3%. [1] Again, it is important to emphasize that exposure to less than 5 rad yields no change in the risk of occurrence of organ malformations or growth retardation [9] (see Table 60-3).

Fetal Period

The predominant observable effects of radiation exposure during this period are growth retardation, microencephaly, and severe mental retardation (SMR). The fetal stage has been subdivided into early fetal (8 to 15 weeks), mid fetal (16 to 25 weeks), and late fetal (26 weeks to term) because of identifiable periods of risk to the developing CNS.

Mental impairment.

From the 8th to the 15th week, there is a rapid increase in the number of neurons that migrate to their ultimate sites and lose their capacity to divide. At 15 to 25 weeks there is more differentiation and architectural definition. [1] These embryological changes make the fetus susceptible to CNS damage during the early and mid fetal periods.

The in utero atomic bomb survivor data indicates that the risk of SMR per rad was higher if exposed during the early fetal versus the mid fetal period. [9] In children receiving greater than 50 rad between 8 and 15 weeks postconception, a drop in IQ score of 0.3 points per rad was estimated. [9] There is no documented increased risk of mental retardation in humans at gestation age less than 8 weeks or greater than 25 weeks evaluated with doses of less than 50 rads. [10] The highest risk for SMR occurs during the early fetal period with fetal doses in the range of 100 rad. All the clinical observations on significant IQ reductions and SMR relate to fetal doses of about 50 rad and higher. [6] This dose range greatly exceeds the dosages utilized for diagnostic imaging.

It is important to relate the magnitude of radiation effects to those abnormalities that occur spontaneously in the population. There are multiple causes of mental retardation that have been identified, including malnutrition, lead poisoning, rubella infections during pregnancy, and maternal alcoholism. Current prevalence figures indicate that the normal incidence of a person with an IQ below 70 is approximately 3%. [6] At fetal doses of 10 rad, the spontaneous incidence of mental retardation is much larger than any potential radiation effect on IQ reduction. [6] Regardless of the time of gestation, IQ

---

reduction cannot be clinically identified at fetal doses of <10 rad (see Table 60-3). [6]

Growth retardation.

The human data for Hiroshima and Nagasaki reveal the major congenital anomaly observed was microencephaly. [9] Studies have demonstrated no increased risk for microencephaly in the population exposed to <150 rad in Nagasaki; however, an increased risk in the Hiroshima population exposed to doses as low as 10 to 19 rad has been reported. [11] It is possible that the difference between the two cities is secondary to other causes (trauma, stress, malnutrition) than radiation. In experimental animal data, a dose of 10 to 20 rad does not increase the incidence of microencephaly. [11] A dose threshold for microencephaly, as well as other congenital anomalies, is generally accepted to be in the range of a few rad. Permanent growth retardation isn't typically seen unless doses exceed 50 rad. [9] Irradiation of the human fetus at doses below 10 rad has not been observed to cause congenital malformations or growth retardation (see Table 60-3). [1] [2] [4]

Carcinogenesis

The magnitude of risk for carcinogenesis following low dose radiation exposure and whether the risk changes throughout gestation has been the subject of many publications, [12] [13] [14] yet interpretation of the data remains open to date. Numerous studies [15] [16] [17] [18] indicate a 1.3- to 3.0-fold higher incidence of leukemia in children exposed to diagnostic radiation in utero, although some studies fail to substantiate the association. [11] [19] Excess cancer as a result of in utero exposure has not been clearly demonstrated among Japanese atomic bomb survivor studies even though the population has been followed for about 50 years, but the number exposed is not large. [6] Identification and control of confounding factors make interpretation of radiation carcinogenesis studies difficult, if not impossible, to interpret. Brent notes most investigators agree that low doses of radiation present a carcinogenic risk to the embryo; however, findings of an increased cancer risk among children exposed in utero to low-dose diagnostic radiation must be reconciled with the fact that high-dose animal and human studies have not found marked increase in cancer incidence. [11]

Risk can be expressed in several ways, including as *relative risk* or *absolute risk*. Relative risk indicates the risk as a function of the "background" cancer risk. A relative risk of 1.0 indicates that there is no effect of irradiation, whereas a relative risk of 1.5 for a given dose indicates that the radiation is associated with a 50% increase in cancer above background rates. The absolute risk estimate simply indicates the excess number of cancer cases expected in a population due to a certain radiation dose. [6]

The International Commission on Radiological Protection Publication 84 [6] notes a recent analysis of many of the epidemiologic studies conducted on prenatal x-ray and childhood cancer are consistent with a relative risk of 1.4 (a 40% increase over the background risk) following a fetal dose of about 1 rad. The best methodological studies, however, suggest that the risk is probably lower than this. Even if the relative risk were as high as 1.4, the individual probability of childhood cancer after in utero irradiation would be very low (about 0.3% to 0.4%) since the background incidence of childhood cancer is so low (about 0.2% to 0.3%). Absolute risk estimates for cancer risk from ages 0 to 15 after in utero irradiation have been estimated to be in the range of 600 per 10,000 persons each exposed to 100 rad, or 0.06% per rad. [6] [8] If a fetus is exposed to 0.1 rad, the increased risk for carcinogenesis is 0.006% or 3/50,000, compared to the background incidence of 0.2% to 0.3% or 100 to 150/50,000. The increased carcinogenic risk from 0.1 rad exposure is approximately 50 times smaller than the already low natural incidence of cancer.

Mutagenesis

Investigating possible radiation-induced alteration to human genome is exceedingly difficult. The geneticists who studied the radiated populations in Japan are convinced that there were radiation-induced mutations. However, the calculated and demonstrated risks were so small that the investigators were unable to demonstrate statistically significant genetic effects. [5]

The risk of radiation-induced hereditary disease in humans is reported to be around 1% per 100 rad. [9] [20] If a fetus is exposed to 0.1 rad, then the increased risk is approximately 0.001% or 1/100,000. The natural frequency of genetic disease manifesting at birth is approximately 3% [7] or 3000/100,000. For 0.1 rad, the increased genetic risk is minute compared to the natural incidence of genetic disease.

In order to put all risks into proper perspective, the range of fetal absorbed doses for diagnostic imaging must be reviewed. The vast majority of diagnostic radiographic studies are markedly <5 rad. A comparison of fetal absorbed doses for the more common ED radiographic procedures follows.

Radiation Exposure from Diagnostic Radiographs

Estimated fetal exposure for various diagnostic imaging modalities is presented in Table 60-4 . [21] The number of examinations required to reach a cumulative dose of 5 rads is calculated in the second column to underscore the order-of-magnitude difference between the dose considered to have negligible risk (5 rad) and the actual exposed fetal dose. For example, one would require 5000 x-rays of an upper or lower extremity, 125 pelvic x-rays, or an impressive 70,000 2-view chest x-rays before the 5 rad limit is reached.

Radiation Exposure from Computed Tomography Scans

Many variables affect the calculation of fetal radiation dose from CT scans, especially slice thickness, number of cuts, distance of target organ from fetus, and gestational age. Estimated maximal fetal doses from CT scans are summarized in Table 60-4 . It should be noted that a CT of the lumbar spine delivers radiation to the fetus that approaches the safe cutoff range. A CT scan of the abdomen exposes the fetus to less radiation than the 5 rad cutoff, but alternative methods of investigation such as US should be considered in early pregnancy if the clinical condition warrants.

The most commonly requested CT scan in pregnancy is the head CT. The expected fetal absorbed dose is less than 50 millirad (mrad), which is 100 times less than the dose with negligible risk. The estimated radiation dose to the fetus for CT of the chest is <0.100 rad. Spiral CT is becoming commonplace in radiology departments and is gaining

TABLE 60-4 -- Estimated Fetal Exposure for Various Diagnostic Imaging Methods

Examination Type	Estimated Fetal Dose per Examination (rad)	Number of Examinations Required for Cumulative 5-rad Dose
Plain Films		
Skull	0.004	1250
Dental	0.0001	50,000
Cervical spine	0.002	2500
Upper or lower extremity	0.001	5000
Chest (two views)	0.00007	71,429
Mammogram	0.020	250
Abdominal (multiple views)	0.245	20
Thoracic spine	0.009	555
Lumbosacral spine	0.359	13
Intravenous pyelogram	1.398	3
Pelvis	0.040	125
Hip (single view)	0.213	23
CT Scans (Slice Thickness: 10 mm)		
Head (10 slices)	<0.050	>100
Chest (10 slices)	<0.100	>50
Abdomen (10 slices)	2.600	1–2
Lumbar spine (multiple views)	3.500	1–2
Pelvimetry (1 slice with scout film)	0.250	20
Fluoroscopic Studies	0.056	89
Upper GI series	0.006	833
Barium swallow	3.986	1
Barium enema		
Nuclear Medicine Studies		
Most studies using technetium (^{99m} Tc)	<0.500	>10
Hepatobiliary technetium HIDA scan	0.150	33
Ventilation-perfusion scan (total)	0.215	23
Perfusion portion: technetium	0.175	28
Ventilation portion: xenon (^{133} Xe)	0.040	125
Iodine (^{131} I), at fetal thyroid tissue	590.000	
Environmental Sources (for comparison)		
Environmental background radiation (cumulative dose over nine months)	0.100	N/A

HIDA, hepatobiliary iminodiacetic acid; rad, the unit of absorbed radiation.

Reproduced from Toppenberg KS, Hill DA, Miller DP: Safety of radiographic imaging during pregnancy. Am Fam Physician 59:1813, 1999.

popularity as a diagnostic tool in suspected pulmonary embolism (PE) in the pregnant patient. The dose for a spiral CT of the chest is less because the duration of the procedure is much shorter.[22] CT pelvimetry exposes the fetus to approximately half of the radiation delivered from conventional plain film pelvimetry.

Iodinated contrast material that is injected intravenously for CT scans does not emit radiation and is classified *pregnancy category B*. It is not known to be teratogenic. The product insert for barium sulfate suspension used as oral contrast for an abdominal CT scan (e.g., Redicat) notes no adverse fetal reactions under the heading "Usage in Pregnancy." Barium preparations do not emit radiation.

Nuclear Medicine Studies

The most common nuclear medicine procedure ordered from the ED is the ventilation perfusion (V/Q) scan. The perfusion portion of the scan is performed by injecting a radioisotope intravenously. The isotope emits radiation and is detected by sensitive cameras. This requires that a radioisotope (e.g., Tc^{99}) be tagged to a substrate, most commonly albumin. The albumin-technetium aggregate is temporarily trapped in the arterioles and capillaries in the lung and its distribution can be identified. The principle photon that is useful for detection and imaging with technetium studies is the gamma ray.[23] When the radio-tagged substrate is excreted into the maternal bladder, the fetus will receive additional radiation exposure based on the proximity of the maternal bladder. Patient hydration and frequent voiding or bladder catheterization post V/Q scan will lessen the radiation exposure to the fetus. The measurement of radioactive substances is based on its decay, and the units are the Curie (Ci) or the Becquerel (Bq). Doses are usually expressed in milliCurie (mCi). The usual dose of technetium for the lung perfusion portion of the scan is 1 to 5 mCi of Tc^{99} . Reduced doses, as low as 1 mCi, are often used in pregnancy.

Depending on the radioisotope and substrate employed, the average fetal exposures can be calculated. Commonly used radiopharmaceuticals and estimated fetal doses for V/Q scans, and other radionuclide studies are given in Table 60-5 .[10] A 5 mCi Tc^{99} albumin scan results in 175 mrad fetal exposure. Reducing the dose to 2

mCi results in a 70 mrad fetal exposure. Technetium Tc^{99} albumin is contraindicated in patients with severe pulmonary hypertension and is *pregnancy category C*.

Ten mCi of $Xenon^{133}$ are used for the ventilation portion of the V/Q scan. $Xenon^{133}$ has a short half-life and results in 40 mrad fetal exposure. Normal findings on the perfusion scan may obviate the need for the ventilation scan, and some centers routinely perform only the perfusion portion since most pregnant women have normal ventilation.

Pulmonary Embolism Diagnosis

The reported incidence of PE associated with pregnancy varies widely from 1 in 2700 deliveries to less than 1 in 7000 deliveries. [24] The radiological modalities of choice for definitive diagnosis are V/Q scan, thoracic CT scan with contrast, or angiography. A positive US for deep vein thrombosis of the legs, coupled with a clinical scenario consistent with PE, may suggest a diagnosis and guide therapy. However, since many pulmonary emboli, especially those occurring during pregnancy, are from pelvic veins, this approach clearly has limitations in establishing the presence or absence of PE. [24]

V/Q scans are widely recognized as extremely useful diagnostic tools in the evaluation of PE; however, many clinicians are reluctant to order this test in pregnant patients. The main concern is uncertainty, or essentially misinformation,

TABLE 60-5 -- Radiopharmaceuticals Used in Nuclear Medicine Studies

Examination	Estimated Activity Administered per Examination (mCi)	Dose to Uterus/Embryo per Pharmaceutical (mrad)
Brain	20 mCi ^{99m}Tc DTPA	700
	20 mCi ^{99m}Tc O_4	960
Hepatobiliary	5 mCi ^{99m}Tc sulfur colloid	55

over actual fetal radiation exposure and the long-term effect on the fetus. The mortality rate of untreated acute PE is about 30% compared to 3% in treated patients. [24] Therefore, the potential morbidity of PE and the attendant risk of anticoagulant therapy in pregnant patients necessitate definitive diagnosis. The calculated radiation exposure to the fetus from both V/Q scanning and CT of the chest confers minimal, and essentially only theoretical, fetal risk. [22] Fetal exposure from CT of the chest is less than 0.100 rad. A 5 mCi Tc^{99} perfusion scan and 10 mCi Xe^{133} ventilation scan summates to 0.225 rad. [21] The dose of fetal radiation from the perfusion scan can be altered, and is often lowered in the evaluation of pregnant patients (Table 60-6). Lowering the dose by 60%, a level that will usually produce a suitable study, results in lowering fetal exposure to 0.110 mrad. Pulmonary angiography results in an estimated fetal exposure of 0.22 to 0.37 rad when done via the femoral route but can be lowered to less than 0.05 rad by using the brachial route. [22]

The role of D-dimer levels in the diagnosis of PE is evolving. [25] [26] During pregnancy, D-dimer levels increase and should be considered physiological. D-dimer levels are similar to nonpregnant patients up to around 20 weeks, then noted to increase throughout pregnancy to 3 times higher than the mean of a healthy nonpregnant patient. [27]

Diagnosis of Pregnancy and Consent

If exposure <5 rad does not measurably affect the exposed embryo, then why should the clinician determine the pregnancy status of the patient? Brent reports sound reasoning for diagnosis of pregnancy prior to radiographic study. [2] First, the diagnosis of pregnancy may be in the differential diagnosis for the patient's presenting problem and may change or obviate any further need for imaging. Second, it is beneficial to have the patient informed of pregnancy status prior to the imaging, if possible. An informative discussion about the

TABLE 60-6 -- The Technique of Ventilation/Perfusion (V/Q) Scanning

This test uses both intravenous ([IV] perfusion) and aerosolized (ventilation) agents.
Perfusion
1. Prior to injection, the IV technetium (Tc) must be prepared. Sodium pertechnetate Tc-99m is mixed with macroaggregated human albumin (MAA), forming Tc-99m MAA, the substance that is injected intravenously to investigate blood flow in the lungs. If the preparation is not used within 8 hrs, it is discarded.
2. The usual dose is 1–5 millicurie (mCi). Doses as low as 1 mCi are used in pregnancy.
3. Within 5 min of injection, more than 90% of the Tc albumin aggregate is trapped in the arterioles and capillaries of the lung. The particle size determines where the Tc-99m will be localized in the body.
4. The accumulation in the lung is temporary, and fragile albumin aggregate quickly breaks down, allowing the Tc to enter the general circulation.
5. Once in the body, the half-life of Tc-99m is 6 hrs.
6. The majority of the Tc-99m is excreted in the urine. If it remains in the urinary bladder, it is in close proximity to the fetus.
7. Tc in the bladder also exposes the fetus to small amounts of radiation.
8. Frequent voiding or bladder catheterization after the study will lessen radiation exposure to the fetus.
9. Tc is relatively contraindicated in patients with severe pulmonary hypertension (since the Tc-99m MAA temporarily blocks blood flow in the lungs).
10. Allergic reactions to Tc and human serum albumin are extremely rare.
11. The radiation exposure to the total body from 4 mCi is extremely low: less than 0.1 rad.
Ventilation
1. Some radiologists forgo the ventilation portion of the V/Q scan in pregnancy to limit the total radiation exposure.
2. Most hospitals use xenon 133 for the ventilation portion of the V/Q scan.

3. The fetal radiation from xenon is extremely low, and the 5 rad cutoff is not reached until more than 125 scans have been performed.
4. The estimated dose to the fetus of a standard 10 mCi of xenon used in a V/Q scan is 0.04 rad.
5. If Tc based aerosol is the marker used for the ventilation portion, fetal exposure is higher than with xenon aerosol.

risk/benefit aspects of the test *prior to the study* conveys a concern for the patient and fetus. Discussing the risk/benefit aspects of imaging *after the study* may be misconstrued as "back stepping" and make the patient upset. Many lawsuits are stimulated by the factor of surprise. A frank discussion prior to the imaging may prevent misguided litigation.

Amenorrhea and physical changes in size and shape of the uterus may be consistent with pregnancy. However, menstrual history by itself may not be totally reliable in the determination of pregnancy. A history of recent menstruation, intrauterine device, tubal ligation, no coitus, or the proper use of birth control pills will result in the suggestion of pregnancy more than 90% of the time, but these parameters are not 100% accurate. If the diagnosis of pregnancy is in the differential or imaging is ordered, or both, the definitive determination of

the patient's pregnancy status should be strongly considered if the clinical scenario is reasonable. It is not standard of care to order a pregnancy test on all women of childbearing age prior to obtaining routine diagnostic radiographs. However, a menstrual history and other information should be obtained whenever possible. Urine pregnancy tests to detect early pregnancy are quite sensitive and reliable, and it is not necessary to routinely order a quantitative serum test. Theoretically, there will be a few days' window between fertilization and implantation when no method will exist to confirm the presence or absence of early pregnancy.

The pregnant patient has the right to know the magnitude and type of risks that might result from in utero exposure. The Annals of the International Commission on Radiological Protection Publication 84 [6] summarized the need for informed consent as follows: "The need and degree of disclosure is usually measured by what a reasonable person believes is material to the mother's decision to be exposed to radiation. The level and degree of disclosure should be related to the level of risk. For low-dose procedures, such as chest x-rays, <100 mrad, the only information that may be needed is a verbal assurance that the risk is judged to be extremely low. When fetal doses are >100 mrad, usually a more detailed explanation is given. The information should include potential radiation risks and potential alternative modalities as well as the risk of harm from not having the medical procedure. The degree of documentation of such explanations and consent is variable but many clinicians will include a note of any such counseling or consent in the record of the patient."

Patient Counseling

When a pregnant patient requires an imaging study, one should be prepared to discuss the risk associated with the test. Counseling can be accomplished after attempting to estimate the dose to the conceptus from the procedure and comparing the radiation risk with other risks of pregnancy. It is important to use terminology that is easily understood by the patient. Figure 60-2 depicts three different strategies to inform the patient about the level of exposure from her study compared to established limits. Table 60-7 compares the level of exposure to established background risks.

The main bar graph (*A*) in Figure 60-2 compares the fetal exposure level for various radiographic studies to the maximum accepted fetal dose during pregnancy (5 rad). A patient's particular study may be plotted on this graph, showing the clear margin of safety that exists for all single diagnostic tests.

The upper graph (*B*) equates the exposure from the low-level diagnostic studies to the number of hours needed to accumulate a similar exposure dose from background terrestrial radiation. One of the most commonly ordered studies in pregnancy is a chest x-ray. The potential risk to the fetus can be put into perspective for the patient by comparing the absorbed dose for the chest x-ray to the natural background radiation exposure. The environmental background radiation over 9 months has a cumulative dose of 100 mrad, [28] or 0.015 mrad per hour. The fetal dose exposure for a chest x-ray (2 views) is estimated at 0.07 mrad. Therefore, the exposure dose to the fetus from a chest x-ray is equivalent to the same amount of naturally occurring background radiation to which the patient was exposed in the previous 5 hours.

The lower graph (*C*) depicts the Nuclear Regulatory Commission's (NRC) upper limit for cumulative gestational dose compared to various diagnostic studies. The NRC has established occupational radiation dose limits for pregnancy. Its recommendation is that the dose to the fetus not be allowed to exceed 0.5 rem during gestation. Brent notes that this factor-of-10 lowering of the widely accepted threshold is "extremely conservative." [2] One can explain to the patient that the level of exposure from her x-ray is below the conservative cumulative acceptable dose for a pregnant employee at a nuclear facility in the United States.

Another useful approach is to indicate to the patient the probability of *not* having a child with either a malformation or cancer, and how that probability is affected by radiation. Table 60-7 depicts the probability of bearing healthy children as a function of radiation dose. This discussion should be coupled with the fact that the nonexposed fetus has a baseline incidence of spontaneous abortion, multiple developmental abnormalities, and subsequent childhood cancer.

Numerous organizations have declared fetal exposure to <5 rad as safe. Table 60-8 presents various conclusions from key organizations on use of radiation and pregnancy. *The International Commission on Radiological Protection concludes that fetal doses below 10 rad should not be considered a reason for terminating a pregnancy.* [6] If a patient still has considerable concern or has possibly received >5 rad, referral of the patient to a radiation physicist or genetic specialist for further counseling is reasonable.

Nonionizing Radiation: Magnetic Resonance Imaging and Ultrasonography

The term radiation describes the transmission of energy from one body or source to another. Nonionizing radiation includes the portion of the electromagnetic spectrum where the energy of emitted photons is insufficient to ionize atoms and molecules. MRI and US are forms of nonionizing radiation.

Magnetic Resonance Imaging

MRI is currently not approved by the U.S. Food and Drug Administration (FDA) for use in pregnant patients. [29] However, a body of data in this population is developing. MRI is becoming a valuable complement to US when additional information is needed to make treatment decisions during pregnancy. [30] [31] Recent advances in fast MRI techniques have helped to eliminate prior obstacles of slow imaging times and fetal movement. Possible indications for MRI use in a pregnant patient include further evaluation of adnexal masses, placental evaluation, hydronephrosis, pelvic vein thrombosis, and small bowel obstruction. [32]

The most common reason for emergent MRI scans from the ED is evaluation of neurological emergencies (e.g., spinal cord compression). In light of the serious sequelae of spinal cord compression along with a lack of data supporting adverse fetal effects, a pregnant patient exhibiting symptoms of a cord compression should have a magnetic resonance image taken to establish a diagnosis.

The Safety Committee of the Society for Magnetic Resonance Imaging states that MRI procedures are indicated for use in pregnant women when other nonionizing diagnostic imaging methods are inadequate or when the examination will provide important information that would otherwise require exposure to ionizing radiation. [33] It is required to inform pregnant patients that, although to date there is no

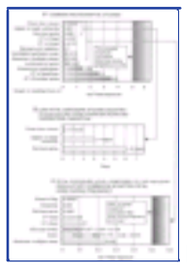

Figure 60-2 *Graph A*: Comparison of common radiographic studies with the accepted 5 rad cumulative fetal exposure limit. *Graph B:* Low fetal exposure studies equated to equivalent dose from background terrestrial radiation. *Graph C*: Fetal exposure level compared to the Nuclear Regulatory Commission's accepted fetal dose during pregnancy.

Modified from International Commission on Radiological Protection Publication 84: Pregnancy and medical radiation. Ann ICRP 30:iii, 1, 2000.

*Rounded values. Radiation risk for genetic mutation assumed at 0.01% per rad fetal dose and a linear dose response relationship. Background rate for genetic mutation estimated at 3%. From Osie IK: Fetal doses from radiological examinations. Br J Radiol 72:773, 1999.

†Rounded values. Radiation risk for fatal cancer assumed to be 0.06% per rad fetal dose and a linear dose response relationship. Many epidemiological studies suggest that the risk may be lower than that assumed here. Background risk of childhood cancer calculated from NCI-SEER: Surveillance, Epidemiology and End Results Cancer Statistics Review 1973–1991: Tables and Graphs. Bethesda, MD, National Cancer Institute, 1994.

TABLE 60-8 -- Key Statements on Diagnostic Imaging Modalities During Pregnancy

X-ray Imaging
"No single diagnostic procedure results in a radiation dose that threatens the well-being of the developing embryo and fetus." *(American College of Radiology) From Hall EJ: Scientific view of low-level radiation risks. Radiographics 11:509, 1991.)*
"[Fetal] risk is considered to be negligible at 5 rad or less when compared to the other risks of pregnancy, and the risk of malformations is significantly increased above control levels only at doses above 15 rad." *(National Council on Radiation Protection and Measurements) From NCRPM: Medical Radiation Exposure of Pregnant and Potentially Pregnant Women. NCRPM Report no. 54. Bethesda, MD, NCRPM, 1977.)*
"Women should be counseled that x-ray exposure from a single diagnostic procedure does not result in harmful fetal effects. Specifically, exposure to less than 5 rad has not been associated with an increase in fetal anomalies or pregnancy loss." *(American College of Obstetricians and Gynecologists [ACOG], Committee on Obstetric Practice) From ACOG: Guidelines for Diagnostic Imaging During Pregnancy. ACOG Committee Opinion No. 158. ACOG, Washington, DC, 1995.*
Magnetic Resonance Imaging
"Although there have been no documented adverse fetal effects reported, the National Radiological Protection Board arbitrarily advises against its use in the first trimester." *(American College of Obstetricians and Gynecologists [ACOG], Committee on Obstetric Practice) From ACOG: Guidelines for Diagnostic Imaging During Pregnancy. ACOG Committee Opinion No. 158. ACOG, Washington, DC, 1995.*
Ultrasound Imaging
"There have been no reports of documented adverse fetal effects for diagnostic ultrasound procedures, including duplex Doppler imaging." "There are no contraindications to ultrasound procedures during pregnancy, and this modality has largely replaced x-ray as the primary method of fetal imaging during pregnancy." *(American College of Obstetricians and Gynecologists [ACOG], Committee on Obstetric Practice) From ACOG: Guidelines for Diagnostic Imaging During Pregnancy. ACOG Committee Opinion No. 158. ACOG, Washington, DC, 1995.*
Reproduced from Toppenberg KS, Hill DA, Miller DP: Safety of radiographic imaging during pregnancy. Am Fam Physician 59:1813, 1999.

indication that the use of clinical MRI procedures during pregnancy produces deleterious effects, according to the FDA, the safety of MRI procedures during pregnancy has not been definitively proved. It is advisable to obtain informed consent for MRI of a pregnant patient. Also, because of limited data, most facilities avoid imaging patients in their first trimester. With an inadvertent exposure in a wanted pregnancy, however, the present accumulated data would not warrant an interruption of the pregnancy (Table 60-9).

Gadolinium-based contrast material is not recommended for use in pregnant patients. [32] Gadolinium-based contrast material has been shown to cross the placenta and appear within the fetal bladder moments after intravenous administration. [34] It is then excreted into the amniotic fluid and potentially reabsorbed from the gastrointestinal tract. [34] Because of this reabsorption, the half-life of gadolinium-based contrast material in the fetal circulation is not known.

TABLE 60-9 -- Summary of Magnetic Resonance Imaging (MRI) During Pregnancy

1. MRI involves no ionizing radiation.
2. There are no known biologic risks associated with MRI and no specific fetal abnormalities have been linked with standard low-intensity MRI scanning.
3. Most obstetrical problems can be adequately evaluated with ultrasound.
4. Contrast material is often avoided in conjunction with MRI scanning during pregnancy.
5. Both maternal and fetal anatomy, including the fetal central nervous system, can be evaluated with MRI.
6. The FDA requires documented informed consent and cautions that the full effects of MRI during pregnancy have not yet been determined.
7. MRI is usually eschewed during the first trimester unless there is a clear risk-to-benefit indication, such as possible spinal cord compression.
8. Claustrophobia and the pregnant woman's inability to tolerate prolonged lying on the back can occasionally be problematic.

9. Fetal movement limits information on the fetus unless sedation is provided or ultrafast scans are available.

Ultrasonography

US continues to be the screening modality of choice for the evaluation of the maternal pelvis and the fetus because of its safety profile, relatively low cost, and real-time capability. Obstetric and gynecological US account for more than half of the US imaging volume in the United States. [35] Human data accumulated over 25 years has revealed no consistent adverse effects from prenatal diagnostic US examinations. [36] [37] US in pregnancy is considered a safe procedure.

The American College of Obstetricians and Gynecologists has reviewed the effects of x-rays, US, and MRI exposure during pregnancy and suggested guidelines for radiographic examination during pregnancy (Table 60-10).[4]

Summary

In summary, the threshold dose for the non-stochastic effects throughout the gestational period is >5 rad. Prenatal doses of <5 rad present no measurable increased risk of prenatal death, malformations, growth retardation, or impairment of mental development over the background incidence of these entities. The risk for stochastic effects, carcinogenesis or mutagenesis, is related to the fetal absorbed dose and is very small compared to the natural background incidence of childhood cancer and genetic disease for most diagnostic procedures.

The vast majority of radiographic imaging obtained in the ED exposes the fetus to 100 times less than the threshold for adverse effects. The 5 rad threshold for onset of concern for adverse fetal effects is quite conservative, and any statistically significant change in fetal outcome probably requires at least several times this dose. Utilization of one of the methods put forth in this chapter to counsel pregnant patients in need of diagnostic imaging, and for women inadvertently exposed to radiation prior to the recognition of pregnancy, should help to educate patients and alleviate their fear.

TABLE 60-10 -- Guidelines for Emergency Department Diagnostic Imaging During Pregnancy

1. Women should be counseled that x-ray exposure from a single diagnostic procedure does not result in harmful fetal effects. Specifically, exposure to <5 rad has not been associated with an increase in fetal anomalies or pregnancy loss.
2. Concern about possible effects of high-dose ionizing radiation exposure should not prevent medically indicated diagnostic x-ray procedures from being performed on the mother. During pregnancy, other imaging procedures not associated with ionizing radiation, such as ultrasonography and magnetic resonance imaging, should be considered instead of x-rays when possible.
3. Ultrasonography and magnetic resonance imaging are not associated with known adverse fetal effects. However, until more information is available, magnetic resonance imaging is not recommended during the first trimester.
4. Consultation with a radiologist may be helpful in calculating estimated fetal dose when multiple diagnostic x-rays are performed on a pregnant patient.
5. The use of radioactive isotopes of iodine is contraindicated for therapeutic use during pregnancy.

Reproduced from American College of Obstetricians and Gynecologists (ACOG), Committee on Obstetric Practice: Guidelines for Diagnostic Imaging During Pregnancy. ACOG Committee Opinion No. 158. ACOG, Washington, DC, 1995.

DRUGS IN PREGNANCY

Hundreds of medications are prescribed in EDs across the nation every day. Emergency clinicians routinely inquire about pregnancy status before prescribing medication because of concern about potential adverse fetal effects. Concerns about drug effects on fetal development were heightened in the 1950s and '60s because several prescription medications fueled consumer outrage and provided the impetus for more efficient drug safety profiling. Thalidomide, diethylstilbestrol (DES), and to a lesser extent, Bendectin, sensitized the international health care community to controversy regarding drug use during pregnancy. For decades it was believed that the placenta served as a barrier that protected the fetus from the adverse effects of drugs. The thalidomide disaster drastically changed this perception by demonstrating that fetal exposure to a drug during critical periods of development resulted in fetal anomalies.

Thalidomide was prescribed to pregnant women in the 1950s and '60s because of its antiemetic and sedative effects. Many fetuses of women who took thalidomide developed phocomelia: the absence or malformation of either upper or lower limbs. It is estimated that 7000 deformed infants worldwide resulted from fetal exposure to thalidomide.[36] The majority of the exposed infants occurred in Europe. Less than 1% of Thalidomide-associated embryopathy occurred in the United States. [38] The low incidence of thalidomide babies born in the United States is directly attributable to the FDA, which did not want to distribute the drug without more rigorous safety testing.

DES was promoted as a miracle drug for women thought to be at risk for pregnancy-related problems. Before it was finally banned in 1971, an estimated 3 million pregnant women had been treated with DES-type drugs.[38] Physical consequences of in utero exposure to DES for female offspring include a rare form of vaginal and uterine cancer known as clear cell carcinoma; structural defects of sex organs; dysplasia of cervix; infertility; and adverse pregnancy outcomes. [38] Male offspring exposed to DES in utero have reportedly been at increased risk for anatomical abnormalities of the penis and testicles and increased risk for reproductive dysfunction.[38] The women who ingested the drug are also being followed to detect late adverse consequences, notably an increased risk of breast cancer.

Bendectin, a combination of an antihistamine (doxylamine) and pyridoxine, was the most widely used and only FDA-approved medication for nausea and vomiting associated with pregnancy. During the 1970s, however, many lawsuits claiming that Bendectin was teratogenic were filed against the manufacturer. It is estimated that more than 30 million pregnant women used the drug before it was removed in 1983.[38] The drug was withdrawn despite a substantial body of evidence that the rate of major malformation among the children of women who had received Bendectin during pregnancy did not differ from the rate in the general population. [39] However, comparisons of Bendectin to thalidomide eroded consumer confidence and fueled litigation. Although the potential teratogenicity of Bendectin was never substantiated and was statistically exonerated, the manufacturer withdrew Bendectin because it believed it would be more costly to fight the lawsuits than to settle them.

In 1979, drug safety and fetal well-being concerns prompted the FDA to develop a drug classification "Use in Pregnancy" ratings system (Table 60-11).[39] This system was developed to provide therapeutic guidance to clinicians as they consider the potential maternal/fetal risks and benefits of using a drug during pregnancy.[40] The ratings are written in such a manner that discourages nonessential use of medications during pregnancy. This can be alarming to a clinician or pregnant woman who is concerned about a pregnancy in

TABLE 60-11 -- Use-in-Pregnancy Ratings (U. S. Food and Drug Administration, 1979)

Category	Interpretation
A	Controlled studies show no risk. Adequate, well-controlled studies in pregnant women have failed to demonstrate risk to the fetus.
B	No evidence of risk in humans. Either animal findings show risk (but human findings do not) or, if no adequate human studies have been done, animal findings are negative.
C	Risk cannot be ruled out. Human studies are lacking, and animal studies are either positive for fetal risk or lacking as well. However, potential benefits may justify the potential risk.
D	Positive evidence of risk. Investigational or post-marketing data show risk to the fetus. Nevertheless, potential benefits may outweigh the potential risk.
X	Contraindicated in pregnancy. Studies in animals/humans or investigational/post-marketing reports have shown fetal risk that clearly outweighs any possible benefit to the patient.

Reproduced from FDA: Classification of Drugs for Teratogenic Risk. Teratology 49:446, 1994.

TABLE 60-12 -- Drugs with Proven Teratogenic Effects in Humans*

Drug	Teratogenic Effect
Methotrexate	CNS and limb malformations
Angiotensin-converting-enzyme inhibitors	Prolonged renal failure in neonates, decreased skull ossification, renal tubular dysgenesis
Anticholinergic drugs	Neonatal meconium ileus
Antithyroid drugs (propylthiouracil and Methimazole)	Fetal and neonatal goiter and hypothyroidism, aplasia cutis (with Methimazole)
Carbamazepine	Neural-tube defects
Cyclophosphamide	CNS malformations, secondary cancer
Danazol and other androgenic drugs	Masculinization of female fetuses
Diethylstilbestrol	Vaginal carcinoma and other genitourinary defects in female and male offspring
Hypoglycemic drugs	Neonatal hypoglycemia
Lithium	Ebstein anomaly
Misoprostol	Moebius sequence
Nonsteroidal anti-inflammatory drugs	Constriction of the *ductus arteriosus* necrotizing enterocolitis
Paramethadione	Facial and CNS defects
Phenytoin	Growth retardation, CNS deficits
Psychoactive drugs (e.g., barbiturates, opioids, and benzodiazepines)	Neonatal withdrawal syndrome when drug is taken in late pregnancy
Systemic retinoids (isotretinoin and etretinate)	CNS, craniofacial, cardiovascular, and other defects
Tetracycline	Anomalies of teeth and bone
Thalidomide	Limb-shortening defects, internal-organ defects
Trimethadione	Facial and CNS defects

Valproic acid	Neural-tube defects
Warfarin	Skeletal and CNS defects, Dandy-Walker syndrome

CNS, central nervous system

Reproduced from Koren G, Pastuszak A, Ito S: Drugs in pregnancy. N Engl J Med 338:1128, 1998.

*Only drugs that are teratogenic when used at clinically recommended doses are listed. The list includes all drugs proved to affect neonatal morphology or brain development and some of the toxic manifestations predicted on the basis of the pharmacologic actions of the drugs.

which medication is indicated or use has already occurred. Clinicians often inappropriately use this system as the basis for decisions regarding the continuation or termination of pregnancy in women who have received a medication.[40]

Although very few drugs are recognized as human teratogens, the 1992 Physicians' Desk Reference carried an FDA rating of category X on 7% of 1033 drugs listed (Category A, 0.7%; Category B, 19%; Category C, 66%; Category D, 7%). [40] Use of letters A, B, C, D, and X in the FDA system implies a gradation of risk, but the classification of agents does not consistently follow such a gradation. The vast majority of drugs are in category C. The default assignment of category C is misleading to many clinicians who consider this rating to indicate some degree of risk rather than just a lack of information. The Teratology Society has

TABLE 60-13 -- Common Drugs Initially Thought Teratogenic but Subsequently Proved Safe

Drug	Initial Evidence of Risk	Subsequent Evidence of Safety
Diazepam*	Oral clefts	No increase in risk in large cohort and case-control studies
Oral contraceptives	Birth defects involving the vertebrae, anus, heart, trachea, esophagus kidney, and limbs; masculinizing effects on female fetuses resulting in pseudohermaphroditism	No association between first-trimester exposure to oral contraceptives and malformations in general or external genital malformations in two meta-analyses
Spermicides	Limb defects, tumors, Down syndrome; and hypospadias	No increase in risk in a meta-analysis
Salicylates	Cleft palate and congenital heart disease	No increase in risk in large cohort studies
Bendectin (doxylamine plus pyridoxine)	Cardiac and limb defects	No increase in risk in two meta-analyses

Reproduced from Koren G, Pastuszak A, Ito S: Drugs in pregnancy. N Engl J Med 338:1128, 1998.

*Diazepam taken near term may cause the neonatal withdrawal syndrome or cardiorespiratory instability.

proposed that the FDA abandon the current classification system in favor of more meaningful, evidence-based, narrative statements. [40] This proposal has received public support.[41]

A fetus is subject to the dangers of teratogens carried by the placenta throughout all phases of growth. The organogenesis phase (3 to 8 weeks) is most critical because it encompasses organ development. Surprisingly, the number of drugs or medications that are strongly suspected or proven human teratogens is small. Forty years after the recognition of thalidomide-associated embryopathy, fewer than 30 drugs have been proven to be teratogenic in humans when used in clinically effective doses (Table 60-12). [41] Many other commonly used drugs, including oral contraceptives and diazepam, were once thought to be teratogenic, but have been shown to be safe in subsequent studies (Table 60-13).[41]

TABLE 60-14 -- Select Drugs for Safe Use During Pregnancy, According to Condition

Condition	Drugs of Choice	Alternative Drugs	Comments
Acne	Topical: erythromycin, clindamycin, benzoyl peroxide	Systemic: erythromycin, topical tretinoin (vitamin A acid)	Isotretinoin is contraindicated
Allergic rhinitis	Topical: glucocorticoids, cromolyn, decongestants, xylometazoline, oxymetazoline, naphazoline, phenylephrine; systemic: diphenhydramine, dimenhydrinate, tripelennamine, astemizole		
Constipation	Docusate sodium, calcium, glycerin, sorbitol, lactulose, mineral oil, magnesium hydroxide	Bisacodyl, phenolphthalein	
Cough	Diphenhydramine, codeine, dextromethorphan		
Depression	Tricyclic antidepressant drugs, fluoxetine	Lithium	When lithium is used in first trimester, fetal echocardiography and ultrasonography are recommended because of small risk of cardiovascular defects
Diabetes	Insulin (human)	Insulin (beef or pork)	Hypoglycemic drugs should be avoided
Headache			
Tension	Acetaminophen	Aspirin and nonsteroidal anti-inflammatory drugs, benzodiazepines ß-adrenergic-receptor antagonists and tricyclic antidepressant drugs (for prophylaxis)	Aspirin and nonsteroidal anti-inflammatory drugs should be avoided in third trimester
Migraine	Acetaminophen, codeine, dimenhydrinate		Limited experience with ergotamine has not revealed evidence of teratogenicity, but there is concern about potent vasoconstriction and uterine contraction
Hypertension	Labetalol, methyldopa	ß-adrenergic-receptor antagonists, prazosin, hydralazine	Angiotensin-converting-enzyme inhibitors should be avoided because of risk of severe neonatal renal insufficiency
Hyperthyroidism	Propylthiouracil, methimazole	ß-adrenergic-receptor antagonists (for symptoms)	Surgery may be required; radioactive iodine should be avoided

Mania (and bipolar affective disorder)	Lithium, chlorpromazine, haloperidol	For depressive episodes: tricyclic antidepressant drugs, fluoxetine, valproic acid	If lithium is used in first trimester, fetal echocardio graphy and ultrasonography are recommended because of small risk of cardiac anomalies; valproic acid may be given after neuraltube closure is complete
Nausea, vomiting, motion sickness	Diclectin (doxylamine plus pyridoxine)	Chlorpromazine, metoclopramide (in third trimester), diphenhydramine, dimenhydrinate, meclizine, cyclizine	
Peptic ulcer disease	Antacids, magnesium hydroxide, aluminum hydroxide, calcium carbonate, ranitidine	Sucralfate, bismuth subsalicylate	
Pruritus	Topical: moisturizing creams or lotions, aluminum acetate, zinc oxide cream or ointment, calamine lotion, glucocorticoids; systemic: hydroxyzine, diphenhydramine, glucocorticoids, astemizole	Topical: local anesthetics	
Thrombophlebitis, deep-vein thrombosis	Heparin, antifibrinolytic drugs, streptokinase		Streptokinase is associated with a risk of bleeding; warfarin should be avoided

Reproduced from Koren G, Pastuszak A, Ito S: Drugs in pregnancy. N Engl J Med 338:1128, 1998.

TABLE 60-15 -- Classification of Some Commonly Used Drugs in Emergency Department

ANALGESICS	
Aspirin	D
Acetaminophen	B
NSAIDS	
Celecoxib	C (3rd)
Ibuprofen	B (3rd)
Ketorolac	C (3rd)

Quinolones (1st–4th)	C
Tetracyclines	D
Carbapenems	B/C
Macrolides	B/C

Sulfonamides	C
OTHER ANTIMICROBIALS	
Clindamycin	B
Metronidazole	B (1st)
Nitrofurantoin	B
Rifampin	C
Vancomycin	C
ANTIVIRALS	
Anti-Cytomegalovirus	C
Anti-Herpetic	B
Anti-Human immunodeficiency virus	
Non-Nucleoside reverse transcriptase inhibitors	C
Nucleoside reverse transcriptase inhibitors	B/C
Protease Inhibitor	B/C
ANTIFUNGALS	
Amphotericin	B/C
Clotrimazole	C
Fluconazole	C
Griseofulvin	C
Itraconazole	C
Nystatin	B
Terbinafine	B
ANTIPARASITICS	
Mebendazole	C
Pentamidine	C
Pyrimethamine	C
Permethrin	B
RID	C
1st Prohibited usage during first trimester	
3rd Prohibited usage during third trimester	
(1st–4th) First through fourth generations	

Since fetal safety is a major concern, effective drugs that have been in use for long periods are preferable to newer alternatives. If drugs are required for certain conditions, the safest drugs at the lowest effective dose should be used. Table 60-14 lists selected drugs considered to be safe for common conditions afflicting pregnant women. Table 60-15 lists the classification of commonly used drugs in the ED. [42]

To receive up-to-date, evidence-based information on the safety and risk of drugs during pregnancy, clinicians can consult a teratogen information service. Table 60-16 lists

Section XI - Neurologic Procedures

Chapter 61 - Management of Increased Intracranial Pressure and Intracranial Shunts

Khosrow Tabbassi
Cecile G. Silvestre

Headache and head injuries are diagnoses commonly encountered in emergency departments (EDs). If either headache or head injury are accompanied by vomiting, decreased level of consciousness, and abnormal vital signs, the possibility of increased intracranial pressure (ICP) must be considered. Accompanying clinical symptoms can often be vague or subtle, making the diagnosis of possible central nervous system (CNS) pathology difficult. Therefore, the clinician must rely on the physical examination, diagnostic studies, and a high index of suspicion to diagnose increased ICP. Increased ICP is a neurological emergency that must be managed quickly before further brain damage ensues. Therefore, it is important to understand the pathophysiology of ICP. Although many emergency clinicians have knowledge of, and expertis in, the management of intracranial shunts, the shunt-related techniques described here should not be considered standard of care.

PATHOPHYSIOLOGY OF INTRACRANIAL PRESSURE

Alexander Monro, an anatomist in the 18th century, defined the intracranial contents as a fixed volume. The fixed-volume theory was supported by George Kellie a few years later and became known as the Monro-Kellie doctrine. This doctrine has guided over understanding of intracranial dynamics and the principles of autoregulation.

The components of the calvaria are the brain, cerebrospinal fluid (CSF), the venous blood supply, and the arterial blood supply (Fig. 61-1). The CSF and the venous blood supply have the greatest ability to change their volume to compensate for increases due to other reasons.

Figure 61-1 Intracranial contents and their volumes for healthy adults.

These dynamic changes in relative cranial content proportions may not impact the patient if the ICP is not excessive. If a pathologic process overwhelms the compensating mechanisms, the result will be an increase in ICP. Unfortunately, ICP increases nearly exponentially as the brain volume increases, despite compensating mechanisms (Fig. 61-2).

Normal supine ICP usually ranges from 5 to 15 mm Hg relative to foramen of Monro. Transient increases of ICP as high as 80 to 100 mm Hg can be noted with coughing or straining. Other factors that can transiently increase ICP are movement, pain, and fever. A space-occupying lesion such as a tumor, hematoma, pus, or foreign body can also raise ICP. Figure 61-3 demonstrates that the area and the etiology of increased ICP will determine where the brain shift occurs to produce herniation.

Brain.

The brain volume can be increased by edema, benign intracranial hypertension, tumor, or bleeding. There are two types of edema, vasogenic and cytotoxic. Vasogenic edema is due to increased permeability of the capillaries leading to the passage of excess fluid into the extracellular space. Cytotoxic edema is due to brain tissue (neurons and glia) accumulation of intracellular fluid due to dysfunction of the adenosinetriphosphatase (ATPase) pump.

Benign intracranial hypertension (BIH) is also known as pseudotumor cerebri. It is increased CSF pressure that is not due to a tumor, edema, or hydrocephalus. Its exact pathophysiology remains a mystery. Common conditions associated with it are listed in Table 61-1 (Table Not Available) . This is a diagnosis of exclusion. It is usually self-limited without alteration of level of consciousness or severe brain dysfunction. Pseudotumor cerebri can present with clinical symptoms similar to conditions causing increased ICP. In general, patients with BIH have a normal neurological examination except for the occasional papilledema. Severe cases can lead to permanent vision loss (see Chapter 62).

Brain tumors encompass neoplasms that originate in the brain itself (primary brain tumors) or involve the brain as a metastatic site (secondary brain tumors).

Primary brain tumors include tumors of the brain parenchyma, meninges, cranial nerves, and other intracranial structures (the pituitary and pineal glands). Primary CNS lymphoma refers to non-Hodgkin's lymphoma confined to the CNS. The site of origin of this type of tumor remains unknown.

Secondary brain tumors, which originate elsewhere in the body and metastasize to the intracranial compartment, are the most common types of brain tumors.

Philadelphia, FA Davis, 1972. Reproduced by permission.)*

Bleeding in the brain can occur spontaneously (as in the case of subarachnoid hemorrhage [SAH]) or can be a result of trauma. Spontaneous SAH is often the result of a ruptured berry aneurysm. Traumatic injury to the brain can often result in increased ICP by causing either epidural hematomas, subdural hematomas, or intraparenchymal hemorrhage. Diffuse

TABLE 61-1 -- Clinical Conditions and Factors Associated with Pseudotumor Cerebri

(Not Available)

axonal injury (DAI) may occur in isolation or conjuction with intracerebral bleeding. With DAI, it is believed that the axons are not actually torn, but instead suffer significant injury (shearing effect) that may lead to swelling (shearing effect). [1]

CSF.

The CSF is produced by the choroid plexus at a daily rate of 500 mL. It flows freely from the lateral ventricles into the cisterns and the subarachnoid space and is drained by the arachnoid villi of the dural sinuses to maintain a volume of 100 to 150 mL. Blockage of this flow at any point can cause hydrocephalus proximal to the obstruction. The two types of hydrocephalus are obstructive and communicating. *Obstructive hydrocephalus* occurs when the blockage occurs at the ventricular system by a tumor, colloid cyst, or primary stenosis. Communicating hydrocephalus is due to blockage outside of the ventricular system by either impedance of flow through the basal cisterns or lack of absorption by the arachnoid villi. Communicating hydrocephalus is often due to infection or subarachnoid hemorrhage (Fig. 61-4).

Blood.

Up to a certain range, cerebral blood flow (CBF) is maintained by an autoregulatory mechanism despite fluctuations in cerebral perfusion pressure (CPP) (Fig. 61-5). This autoregulatory zone is CPP of 60 to 160 mm Hg.

Once the CPP is out of the autoregulatory zone, CBF is linearly related to CPP. CPP less than 60 mm Hg can lead to ischemia whereas that above 160 mm Hg can cause hypertensive encephalopathy.

CLINICAL PRESENTATION

The neurological examination can be normal in someone with a mild increase in ICP due to the brain's compensatory mechanisms. Patients who present with a complaint of headache or

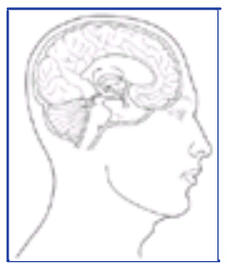

Figure 61-4 Cerebrospinal fluid production and flow *(From Rengachary and Wilkins: Principles of Neurosurgery. Philadelphia, Mosby, 1994).*

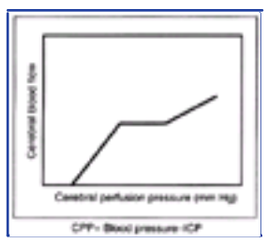

Figure 61-5 Cerebral autoregulation.

head injury may not initially manifest the more dramatic and worrisome symptoms of increased ICP such as vomiting, syncope, altered mentation, or Cushing's triad. (This triad consists of bradycardia, increased blood pressure with wide pulse pressure, and irregular respirations.) ICP correlates poorly with the degree of clinical examination depending on how gradual the increase in ICP is. Early clinical signs are decreased venous pulsations in the funduscopic examination, but this can be difficult to detect in the uncooperative individual. Initially, head computed tomography (CT) scan findings may not correlate well with the patient's neurologic insult. However,

Figure 61-6 (Figure Not Available) The basic tripartite ventricular shunt system is composed of ventricular catheter, valve mechanism, and distal tubing. A slit valve may be used in the far end of the distal tubing instead of a more proximally placed valve as shown in the figure. *(Adapted from Wilkins RH, Rengachary SS: Neurosurgery, 2nd ed. New York, McGraw-Hill, Health Professions Division, 1996, p 3648.)*

as compensatory mechanisms fail, head CT findings as well as clinical symptoms will become more obvious.

Signs and symptoms of severe ICP increases include the following: Glasgow coma scale (GCS) score of 8 or less, decreased level of consciousness, papilledema, cranial nerve findings, or CT scans showing compression of the third ventricle or midline shift. When any of these findings are noted, urgent intervention is warranted, including neurosurgical consultation, because invasive ICP reductionand monitoring may be warranted. The risk of such invasive intervention should be weighed carefully and should be performed by a neurosurgeon. There are less invasive interventions, which are listed as follows.

MEDICAL TREATMENT OF INCREASED ICP

Medical management of increased ICP often can be a useful adjunct pending definitive neurosurgical intervention.

Oxygenation.

In any trauma or medical patient, managing the airway deserves primary attention. If the patient is hypoxic, supportive oxygenation is necessary to prevent further ischemia. Once the patient's GCS is =9 or if any impending sign of inadequate respiratory status is observed, rapid sequence intubation should be considered to protect the airway, control the P_{CO_2} level, and optimize the P_{O_2} level based on the entire clinical scenario.

Sedation and paralytics.

(See also Chapter 5) Care must be given to the sequence and types of medications administered to avoid further increases in ICP while facilitating rapid intubation. Also, rapid assessment of the patient's neurological examination must be done prior to giving sedation and paralytics in order to determine any changes in the patient's status. If time allows, the patient should be premedicated 3 minutes prior to intubation with lidocaine at 1 to 1.5 mg/kg while preoxygenating the patient. Lidocaine has been reported to blunt the rise in ICP associated with laryngoscopy, and may protect against some hypoxia-related dysrhythmias. Atropine (0.02 mg/kg) should also be included in this premedication if the patient is younger than 10 years old since succinylcholine can be associated with bradycardia. This regimen should be followed by sedation with drugs that block the rise in ICP, such as etomidate (at 0.3 mg/kg) or thiopental (50 to 100 mg intravenously [IV] or 3 to 5 mg/kg). Etomidate is preferred over thiopental if the patient has an unstable hemodynamic status. It has two significant benefits—it has a minimal effect on systemic blood pressure and does not appear to increase ICP.[2] [3] A paralytic of choice is succinylcholine at 1.5 mg/kg (2 mg/kg in pediatric patients). Sedation and paralytics should be short-acting in order to follow the patient's neurological examination. Fentanyl (3 µg/kg) is an excellent drug for pain control, which, if untreated, can lead to increased ICP. This should be given during the pretreatment phase if time allows.

Hyperventilation.

Once the patient's airway has been secured, he or she should be maintained on adequate oxygenation, starting at 100%, and titrating to lower levels after transport to ICU settings.[1] In the past, aggressive hyperventilation was widely used to maintain $Paco_2$ at 25 mm Hg in order to reduce ICP. However, aggressive hyperventilation is no longer recommended because P_{CO_2} levels of 25 mm Hg can cause cerebral vasoconstriction resulting in decreased CBF. [1] The most recent recommendations state that in the short term,

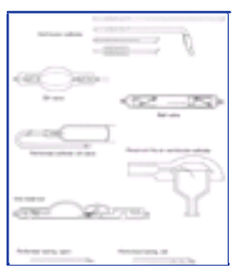

Figure 61-7 Shunt components *(From Rengachary and Wilkins: Principles of Neurosurgery. Philadelphia, Mosby, 1994).*

the target goal for ventilation is now 35 to 40 mm Hg.[4] The long-term recommendation is to avoid hyperventilation because it may cause prolonged vasoconstriction leading to ischemia and worse long-term outcome.[5] The role of hyperventilation in the rapidly deteriorating patient with elevated ICP remains controversial.

Head position.

If shock is not present, there is literature to support head elevation to about 30° in order to decrease ICP. According to Feldman and Kanter, elevation of the head to 30° significantly reduces ICP in a majority of patients without impairing CBF, CPP, and cerebral metabolic rate of oxygenation. [6] This position allows drainage of cerebral veins. Raising the head in a patient with hypotension would further decrease the patient's mean arterial pressure (MAP) and hence lower CPP. If head elevation is to be used, MAP must be maintained above 90 mm Hg.[7] It is also important to avoid neck rotation, flexion, or any intervention that could result in jugular compression. If jugular veins are compressed, venous outflow from the head can be further compromised.

Fluid management.

The goal in fluid management is to maintain euvolemia. Patients with increased ICP are often dehydrated due to profuse vomiting or are in shock due to loss of vasomotor sympathetic tone. The traditional practice of fluid restriction for patients with increased ICP is no longer in favor. Head-injured patients with hypotension have twice the mortality risk. Cardiac pressors, in addition to fluids, are often used to maintain CPP >70 mm Hg and MAP >90 mm Hg.

Diuresis.

Mannitol has been shown to be effective in reducing ICP. If increased ICP causes further deterioration in the patient's status, mannitol can be given at 0.5 to 1.0 g/kg infused every 2 to 6 hours. Current recommendations suggest bolus therapy over continuous infusion. This is a bridging effort while awaiting definitive therapy such as craniotomy.

Mannitol has two properties—it initially acts as a volume expander and then serves as an osmotic agent. Upon administration of mannitol, intravascular volume expands and blood viscosity decreases, resulting in augmentation of CBF. This is the reason the bolus should be administered as rapidly as possible. Once volume expansion has occurred, an osmotic movement of fluid from the cellular compartment to the intravascular compartment begins resulting in a decrease in ICP. The osmotic effect usually occurs within 15 minutes, resulting in decreased ICP. The half-life of mannitol ranges from 90 minutes to 6 hours. Patients who benefit most

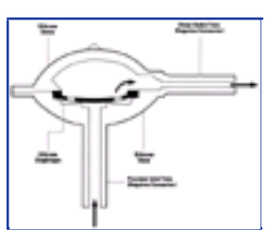

Figure 61-8 Cross section of a Pudenz flushing valve (American Heyer-Schulte, Santa Barbara, CA) illustrating the diaphragm valve. The proximal inlet tube and silicone base are placed in the burr hole so that only the reservoir (silicon dome) protrudes above the skull *(Courtesy of PS Medical, Goleta, CA).*

from the effects of mannitol are those with intact cerebral autoregulation. [8] If the patient's serum osmolality is above 320 mOsm/L, little benefit is obtained with the use of mannitol. Careful monitoring is necessary to maintain the osmolarity between 310 to 320 mOsm/L. [7] Higher levels of osmolality can lead to renal damage. In addition to serum osmolality, electrolytes, pH, and pulmonary status must be monitored closely to avoid the complications associated with these drugs. Hypertonic saline has been suggested as an alternative to mannitol. [9] Mannitol should not be used prophylactically, but instead, reserved for those patients with impending transtentorial herniation.

Seizure prophylaxis.

Controlling seizure activity is important to avoid elevation of ICP and possible herniation. Rapid-acting benzodiazepines such as lorazepam and diazepam are first-line therapy, followed by antiepileptic agents such as pentobarbital or phenytoin. Fosphenytoin has the advantage of rapid administration compared to phenytoin, which can only be given at a maximum rate of 50 mg/minute. Phenytoin can induce hypotension and lower CPP, even at rates <50 mg/minute. Some physicians give patients with severe head injury prophylactic phenytoin or fosphenytoin. The value of this practice for reducing seizure risk is unknown.

Patients who are paralyzed, either chemically or by their neurological disease, are hard to monitor for seizure unless electroencephalogram (EEG) monitoring is available. These patients manifest seizures by elevation in their heart rate or blood pressure or spikes in their ICP monitor. If seizure control is not obtained with benzodiazepines or phenytoin, or both, paralysis and the inducement of a pentobarbital coma should follow. Pentobarbital has been used to treat uncontrolled increased ICP if medical and surgical management have failed. It decreases cerebral blood flow, metabolism, oxygen consumption, and cerebral edema, and it also scavenges free radicals.[10] Pentobarbital is given at a loading dose of 10 mg/kg over 30 minutes followed by infusion of 3 mg/kg per hour with an EEG monitor available for burst suppression. Intensive monitoring of the patient's hemodynamic status is necessary due to pentobarbital's hypotensive effect. Similarly intubation and controlled ventilation is needed for patients receiving this much barbiturate.

Steroids.

Steroids have been shown to be beneficial in patients with vasogenic edema—edema that is associated with brain tumors. Its benefit has been noted to decrease CSF production, stabilize membranes, and restore normal membrane permeability. [11] [12] [13] Dexamethasone is usually given at 10 to 20 mg IV loading dose followed by 4 to 10 mg every 6 hours. No studies support the use of steroids in head-injured patients.

Glucose control.

Head-injured patients tend to be hyperglycemic as a response to stress or steroid administration. Optimization of blood glucose levels is important in order to avoid cellular edema of brain tissue. Hypoglycemic states should be avoided.

Hypothermia.

Lower body temperatures have been associated with a decrease in blood flow, ICP, and metabolism. The prior method of keeping core temperatures to less than 30°C has been abandoned. It fell out of favor due to complications of cardiac arrhythmias and difficulty maintaining this level. One study [14] has shown a statistically significant benefit in terms of survival and decreased ICP with mild

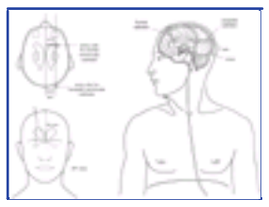

Figure 61-9 Ventriculoperitoneal shunt and alternative occipital placement *(From Rengachary and Wilkins: Principles of Neurosurgery. Philadelphia, Mosby, 1994, Fig. 7-6).*

hypothermia (32° to 34°C). It is important to avoid hyperthermia. A 1° rise in body temperature results in several mm Hg of rise in ICP. Acetaminophen is effective in fever control.

Operative management.

Operative management is the definitive treatment if ICP cannot be adequately managed by the previously discussed measures. This entails craniotomy to relieve the compressive edema, hematoma or tumor, or ventriculostomy with drainage of the increased blood or CSF fluid.

INTRACRANIAL SHUNTS

Intracranial shunts are used for the long-term management of increased ICP. A recurrent elevation in ICP due to shunt malfunction can occur days to years following shunt placement.

Intracranial shunt malfunctions are often diagnosed in the ED. In many cases, it is the patient's significant other or caretaker who provide the subtle clues to diagnose a shunt malfunction. Depending on the age of the patient, recurrent symptoms of increased ICP include changes in behavior, headache, nausea, vomiting, or visual disturbances. In children, lethargy, poor feeding, vomiting, ataxia, decreased or increased activity level, fever, diaphoresis, and fussiness can be indications of shunt malfunction. Failure to gaze upward is another sensitive sign of non-acute shunt malfunction (sunset eyes). Cranial nerves and visual field examination should be routine in the assessment of older, cooperative patients with intracranial shunts.

The essential elements of any shunt system include the proximal and distal catheters, a valve, and a reservoir. A wide array of valves, catheters, and other devices is available for use in shunt systems. Most of them are more or less satisfactory and the selection of a particular one is more subjective than scientific. The valve allows unidirectional flow, incorporates a pumping chamber, and regulates the pressure at which flow will occur by responding to the pressure difference across it. The reservoir is usually located between two valves. The proximal valve allows flow from the ventricles to the reservoir, while the distal valve allows flow from the reservoir to the distal portion of the catheter (Fig. 61-6 (Figure Not Available)). There are many different types of shunt systems incorporating a variety of designs (Fig. 61-7). Some have one valve or unique characteristics such as a double dome, or an absence of valves altogether.

In most cases, the reservoir gives successful access to the system for pressure measurement, patency testing, fluid sampling, and injection of medication or contrast material. In more rare cases, there is other equipment available that can be incorporated into the shunt system under special circumstances and for specific needs, including the on-off switch device, the telemetric pressure sensor, and the anti-siphon device.

In the basic shunt system, the ventricular catheter is usually placed in the right frontal horn of the lateral ventricle

Figure 61-10 A standard shunt series includes an anteroposterior (AP) skull, lateral skull, and chest radiograph and kidney, ureters, bladder (KUB) series. This intact shunt is a Rickham reservoir over the burr hole, with a cylindrical Holter valve a few centimeters distal. This AP skull radiograph reveals the proximal intracranial portion of the shunt and a Rickham reservoir over the burr hole.

(nondominant brain) to connect to a subcutaneous valve (Fig. 61-8) traversing the temporal side. This valve is then connected to a distal catheter threaded subcutaneously into the neck and finally into the peritoneum or some other defined body compartment. Ventricular catheters can either be straight or angled, with the latter having the option of a reservoir component attachment. Valves usually come in four different types (ball, diaphragm, miter, slit), each with its unique flow characteristics. The distal catheter is either a closed or open

Figure 61-11 Lateral skull radiograph of patient in Figure 61-10 . This view better reveals a cylindrical Holter valve situated a few centimeters distal to the Rickham reservoir.

Figure 61-12 Anteroposterior chest and abdominal radiograph of patient in Figure 61-10 . This radiograph reveals the distal portion of the shunt. Note the length of the catheter to allow for patient growth.

Figure 61-13 Lateral chest and radiograph of the patient in Figure 61-10 .

end. Identifying the type of shunt in place is often difficult unless the patient has that information available. The skin overlying the subcutaneous part at the temples can often scar, thus disabling the palpation of the shunt type.

The principle of any extra-cranial shunting technique is to divert CSF into a body cavity from which it can readily be eliminated and drained. Ventricular peritoneal (VP) shunts are presently the mainstay of hydrocephalus treatment in infants and children because of their ease of insertion and reliable long-term function (Fig. 61-9). Other types of extra-cranial shunts include ventriculovenous (VV), ventriculoatrial (VA), ventriculopleural (VPl), and lumboperitoneal. These other shunts are usually reserved for circumstances in which VP shunting has failed because of complications or if there is a history of multiple abdominal surgeries or peritoneal infections.

Shunt Assessment

The usual cause of shunt malfunction is catheter obstruction. Proximal blockage may be due to tissue debris or choroid plexus within the ventricular catheter. Distal obstruction of venous shunts may result from thrombus or venous occlusion (such as in the ventriculoatrial shunt). Peritoneal shunts may be associated with infection (peritonitis) or mechanical obstruction (e.g., omentum blockade). There is also evidence to suggest that delayed hypersensitivity to shunt material is an occasional cause of obstruction. Symptoms of shunt malfunction may be difficult to interpret, particularly if the symptoms are atypical or nonspecific or if the symptoms occur in young children. Likewise, asymptomatic shunt obstruction can take place in children who have developed shunt independence. The clinical evaluation of a child may not always be diagnostic of a shunt malfunction.

The characteristics of valve pumping may be useful in shunt malfunction diagnosis in only about 5% of cases. [15] Partial shunt valve compression should be done since full depression and release may lead to choroid plexus suction. If the CT scan shows narrow (slit) ventricles, indicating overdrainage, further valve compression may cause blockage of the shunt by suction of the choroid plexus. When palpating the shunt, a normal refill time of 15 to 30 seconds should be seen. If the valve fills slowly but can be compressed easily, the obstruction is proximal to the valve. If the valve is not compressible, blockage is either at the valve or distal to it. Proximal obstruction is more common than distal. Other sources of proximal blockage are blood clots or debris related to the surgical procedure. Sources of distal occlusion include malposition, infection, shunt disconnection, and pseudocyst formation. The entire shunt tract and surgical incisions should be examined for signs of wound infection, disruption of the tubing, or CSF leakage around the tract. Definitive treatment usually requires shunt revision.

Infection is often due to skin organisms overlying the valve that may ulcerate and colonize the shunt. [16] The typical organisms are *Staphylococcus Epidermidis* or *Aureus*. Approximately 70% of these infections are seen within 2 months of shunt placement. Other risk factors associated with shunt infection include perioperative infection or any subsequent dental or urological instrumentation. The VA shunt has been largely avoided because of chronic bacteremia associated with it. Two studies have shown that approximately 8% of neurosurgical patients with implanted shunts acquire infections. [17] [18] Treatment is often replacement of the system.

CT scan is likewise an unreliable method of assessing shunt function when there is a question of obstruction, although obliteration of the perimesencephalic cisterns may be a sign of life-threatening shunt failure. The finding of large ventricles on CT reveals little about shunt function *unless serial scans show progressive ventricular expansion*. Shunt devices should include a tapping reservoir proximal to the distal valve to allow percutaneous testing of the proximal shunt patency. Although this is useful in most instances, it can be difficult to assess the rate of inflow or runoff adequately with a small bore needle, particularly if the patient is a child or uncooperative. The potential for infection is a disadvantage of percutaneous tapping. Other invasive techniques include injection of either radionuclide or contrast material into the shunt as a marker of flow. If ventricular fluid pressure is low, there may be little evidence of flow, giving a false indication of shunt malfunction. Various non-invasive techniques have been devised for assessing shunt function. Visual evoked potential (VEP) changes associated with elevated intracranial pressure have been suggested as a means of determining function. Thermographic and Doppler detection of shunt flow is also possible. Using MRI technology, it is possible to assess CSF flow and shunt patency.

Assessing shunt malfunction can be done most efficiently by obtaining radiologic shunt series, which consist of anteroposterior (AP) and lateral skull, AP chest, and AP abdominal x-rays (Fig. 61-10 Fig. 61-11 Fig. 61-12 Fig. 61-13 Fig. 61-14 Fig. 61-15 Fig. 61-16 Fig. 61-17 Fig. 61-18). This may reveal kinkingor brealage of the catheter or its disconnection from the shunt. If the x-ray is nondiagnostic, head CT scan without contrast should follow. As stated earlier, prior CT scans should be obtained for comparison of the ventricular size and for the placement of the catheter (Fig. 61-19 , Fig. 61-20). If distal catheter obstruction is suspected, abdominal ultrasound can be used to determine abnormal fluid collection. Finally, CSF analysis is important whenever an assessment of infection or shunt function is undertaken.

Shunt Tapping

The scalp hairs should be clipped over and around the reservoir, then prepared with a surgical scrub brush for 10 minutes, followed by povidone-iodine solution which is allowed to fully dry. After appropriate draping, the skin is infiltrated using 1% plain lidocaine to a level of adequate local anesthesia. A 25-ga butterfly needle with tubing is used to enter the reservoir percutaneously at a 20° to 30° angle. Lack of CSF flow from the reservoir would indicate a proximal obstruction unless the ventricles are completely deflated (slit ventricles syndrome). Even so, a small amount of CSF should be obtained within the tubing, thus assuring that entry into the lumen of the reservoir has been accomplished. If the ventricles are deflated and only a small amount of CSF is aspirated, the end of the tubing can be held 5 to 10 cm below the level of the reservoir to see if CSF will fill the tubing and eventually begin to drip at the rate of 2 to 3 drops per minute. If the CSF readily aspirates from the reservoir, the tubing is held vertically to give an indication of the intraventricular pressure (Fig. 61-21). This pressure reading, as well as the ease with which CSF is aspirated, will give some indication of proximal obstruction. To assess the runoff or distal end patency, one

Figure 61-14 Connector discontinuity of a ventricular peritoneal shunt, at the level of the clavicle, is illustrated in this chest radiograph from a shunt series.

should apply pressure to the tubing proximal to the reservoir, and then deflate the reservoir without any resistance. If any resistance is encountered when deflating the reservoir, a distal obstruction should be suspected.

It is imperative to send any aspirated CSF for the relevant studies including cells, differentials, protein, and most all gram stains and cultures in evaluation of possible infection (see Chapter 62).

Special Consideration—Postoperative Complications of Shunts

Major complications after shunting for high-pressure hydrocephalus are infrequent. The most common are shunt malfunction, seizures, and infection.

Hemorrhage: Bleeding can also occur after the placement of the shunt. Both intracerebral and subdural hemorrhages have been noted. Intracerebral hemorrhage is due to trauma to the brain parenchyma as the catheter is passed through the ventricles. Subdural hematoma is due to sudden decompression of the ventricles that leads to tearing of the bridging veins as the brain pulls away from the dura. An acute or chronic subdural bleed is also encountered in shunts with overdrainage problems.

Shunt malfunction: If shunt malfunction is suspected, the first step is to perform head CT scan and shunt series imaging to visualize ventricular size and anatomical alignment of the tubes and devices. The ventricles usually begin to diminish in size within a week post shunt placement in high-pressure hydrocephalus, so continued enlargement suggests shunt malfunction. The shunt series images confirm the continuity of a drainage system from the insertion site through the proximal catheter, reservoir, distal catheter, to the receiving draining cavity, mostly and commonly peritoneum. It is important to know that in normal pressure hydrocephalus, the ventricles may remain large despite good functional shunting. The timing and indications of shunt placement are imperative to know when assessing the urgency of the management, especially when consulting a neurosurgeon.

Seizures: These are an infrequent complication of the shunt placement and occur in about 5% of patients.

Figure 61-21 A 25-ga butterfly needle puncture of a reservoir. To avoid damage to the reservoir, the angle should be approximately 20° to 30°. Note that the dome reservoir is under the skin. Prior to passage of the butterfly needle, the skin is anesthetized, sterilized with povidone-iodine, and nicked with a number 11 scalpal or larger needle. Fluid is not aspirated but is allowed to drain passively.

Technically occipital catheter placement may lessen the incidence of seizures because their location is far from the motor cortex. In patients thought to be at risk for a seizure, antiepileptic medication may be indicated.

Shunt infection—treatment and prevention: Of all the potential complications associated with shunting procedures, infection is the most notorious, occurring in 2% to 10% of the operated cases.[15] Most shunt infections appear within the first 2 months after surgery. The diagnosis may be obvious with variable systematic signs, wound infection, meningitis, peritonitis, or septicemia. It is also possible the shunt may harbor an indolent infection without symptoms or signs. CSF culture obtained from a shunt tap may be negative, even when the shunt is ultimately shown to be infected. [19] [20]

Most shunt infections are caused by otherwise nonvirulent bacteria such as *staphylococcus epidermidis*. In the presence of the shunt, these organisms exhibit unusual virulence. This reflects a variety of factors, including the ability to adhere to shunt surfaces, as well as production of mucoid substances that protect the bacteria from host defenses. The silastic shunt material itself has an adverse effect on the immune system. Specifically, leukocytes cannot adhere to such surfaces as well as bacteria. This situation allows phagocyted bacteria to remain viable within the cell. Controversy exists over the need for shunt removal in the context of treatment of infection. Although the systemic antibiotics alone are of unpredictable benefit, the addition of intraventricular drugs has allowed more success in treating without removal of a functioning shunt. Having said this, many neurosurgeons still recommend ultimately replacing the entire shunt after the infection is eradicated. The most important single factor in preventing shunt infection is obviously aseptic operative and postoperative shunt handling for diagnostic procedures technique. The role of prophylactic preoperative antibiotic treatment remains equivocal. Consultation with neurosurgeons and infectious disease specialists is recommended when deciding to administer antibiotics directly into the CSF either via the shunt or a lumbar puncture. Among the antibiotic options, oxacillin, nafcillin, and vancomycin are good empiric choices. If a shunt infection is suspected, systemic antibiotics may be given, and as with any serious infectious process, the earlier the administration, the better for the patient.

CONCLUSION

ICP is difficult to assess without obvious clinical and radiological findings. Because of compensatory mechanisms, the degree of increased ICP does not correlate with the degree of clinical and radiological abnormalities. It is therefore important to recognize by history, examination, and other ancillary tests how to detect early neurologic findings that may indicate elevations of ICP before further damage occurs. Understanding intracranial shunts and their complications is also necessary to assess patients with possible shunt malfunction.

Chapter 62 - Spinal Puncture and Cerebrospinal Fluid Examination

Brian Euerle

Cerebrospinal fluid (CSF) examination is performed in an emergency department (ED) for the purpose of obtaining information relevant to the diagnosis and treatment of specific disease entities. Many urgent and life-threatening conditions require immediate and accurate knowledge of the nature of the CSF. However, on rare occasion certain harmful consequences may result from a spinal puncture. The procedure should follow a careful neurologic examination with thought given to the risks and merits of the procedure in each given situation.

In 1885, Corning punctured the subarachnoid space to introduce cocaine anesthesia into a living patient. [21] Quincke (1891) first removed CSF in a diagnostic study and introduced the use of a stylet. [96] He studied cellular contents and measured protein and glucose levels. Quincke was also the first to record pressure with a manometer. Subsequently, increasingly sophisticated bacteriologic, biochemical, cytologic, and serologic techniques were introduced. In 1918, Dandy replaced CSF with air to determine normal brain anatomy and changes that would indicate disease. [22] Water-soluble contrast media have been used to delineate the spinal subarachnoid space and cerebral cisterns. Other uses of the spinal puncture include injection of anesthetic agents, chemotherapeutic agents, and antibiotics and drainage of fluids.

ANATOMY OF CSF FORMATION AND CIRCULATION

In the adult, CSF occupies approximately 140 mL of the spinal and cranial cavities, with approximately 30 mL in the spinal canal. This volume is the result of a balance between continuous secretion (primarily by the ventricular choroid plexus) and absorption into the venous system (mainly by way of the arachnoid villi). After formation, the fluid passes out of the ventricles by way of the midline dorsal foramen of Luschka and the lateral ventral foramina of Magendie. The fluid then flows into the spinal subarachnoid space, the basilar cisterns, and the cerebral subarachnoid space. Production is approximately 0.35 mL/min, and CSF ventricular production is such that there is a net flow out of the ventricles of 50 to 100 mL/day. Thus the usual volume of CSF removed at lumbar puncture is commonly regenerated in about 1 hour.

Cerebrospinal fluid may have an embryologic nutritive function; at maturity the CSF most likely acts as a mechanical barrier between the soft brain and the rigid fibro-osseous dura, skull, and vertebral column. It also appears to support the weight of the brain. [130] When buoyed by CSF, the functional brain weight is reduced from 1400 to 50 g. Contraction and expansion of the CSF may accommodate changes in brain volume. Additional functions, including intracerebral transport and maintenance of a stable chemical environment of the central nervous system (CNS), have been reviewed by Fishman. [39]

INDICATIONS FOR SPINAL PUNCTURE

General Indications

The indications for spinal puncture have been reduced with the introduction of noninvasive diagnostic procedures—magnetic resonance imaging (MRI) and computed tomography (CT). A few clinical situations require an early, or even an emergent, spinal puncture. The primary indication for an emergent spinal tap is the possibility of CNS infection, with the exception of suspected brain abscess or a parameningeal process. The need for early detection of meningitis results in performance of many more lumbar punctures than ultimate diagnoses of infection.[4] No other method can be used to completely exclude the diagnosis of meningitis.

The mere presence of a fever does not mandate lumbar puncture. However, CSF generally should be examined for evidence of an infection in patients with a fever of unknown origin, especially if an alteration of consciousness or impaired immune system is present, even in the absence of meningeal irritation. *Meningeal signs may not be present in patients who are old, debilitated, immunosuppressed, or receiving anti-inflammatory drugs or who have had partial treatment with antibiotics.* [82] [103] In a newborn, even a fever is not a dependable sign; temperatures may be normal or even subnormal. For infants under age 1 year, a high index of suspicion is required to make the diagnosis of meningitis. Approximately 25% of infants with meningitis will not have nuchal rigidity, but most will usually appear toxic or moribund. A tense and bulging fontanel is somewhat more reliable, although this sign may be absent in a dehydrated child. Neonatal meningitis occurs in 25% of sepsis cases. In addition, 15% to 20% of infants with meningitis will have negative blood cultures. [8] [137]

In a child between the ages of 1 month and 3 years, fever, irritability, and vomiting are the most common symptoms of meningitis. Typically, handling is painful for the child, and the child cannot be comforted. In addition, the older child may complain of a headache. In all ages, the patient generally looks unusually ill and appears drowsy with a dulled sensorium.

Physical signs become more useful in diagnosing meningitis in children older than age 3 years. [139] These include nuchal rigidity, Kernig's sign (efforts to extend the knee are resisted), and Brudzinski's sign (passive flexion of one hip causes the other leg to rise, and efforts to flex the neck make the knees come up). A useful aid in distinguishing neck rigidity of meningeal origin from that caused by primary pain in the cervical muscles and the soft tissues is the usual preservation of lateral movement in meningeal irritation. A petechial rash in a febrile child should also raise the possibility of *Neisseria* meningitis.[44] Prior use of antimicrobial agents may modify the clinical presentation and alter CSF findings; partially treated children are less likely to be febrile or exhibit an altered mental status. In addition, patients in the early stages of meningitis may lack the classic features associated with advanced disease.

The second indication for an emergent spinal puncture is a suspected spontaneous subarachnoid hemorrhage. The diagnosis will usually be made by head CT scan or by the

finding of blood in the CSF.[53] CT sensitivity drops in patients presenting later than 24 hours after the event to 76% after 48 hours. From 20% to 60% of aneurysmal subarachnoid hemorrhage will have "sentinel thunderclap" or "warning leak" headache before a major hemorrhage. This consists of an unusual sudden headache without nuchal rigidity caused by a "minor" leak of blood from the aneurysm and may precede major rupture by 10 to 320 days. [60] [72] Surgical treatment before a major hemorrhage is the goal of early clinical recognition. After a "warning leak," the head CT scan is usually negative, giving added importance to the performance of a lumbar puncture. Migraine or "vascular" headache is a common misdiagnosis in patients with a subarachnoid hemorrhage who have an initially negative head CT scan.

The usual clinical picture of a subarachnoid hemorrhage is a severe and instantaneous excruciating headache. Patients will usually recall the exact moment the headache occurred. The location of the headache is variable and does not give a clue as to the site of hemorrhage. Nausea, vomiting, and prostration are common symptoms, with approximately one third of patients becoming unconscious at the onset. Examination shows an acutely ill patient with irritability or overt altered mental status. Meningeal signs are commonly present at the time of the initial examination and usually develop in all cases within 2 to 3 days. Meningeal signs may become more severe during the first week after hemorrhage and correspond to the breakdown of blood in the CSF. During the first week, many patients are febrile, reflecting a chemical hemic meningitis.[124] Failure to detect blood radiographically in an awake patient may indicate a small hemorrhage or a predominant basal accumulation of blood. If a patient is seen several days after the hemorrhage, the blood may have become isodense with brain and may no longer be visible on a CT scan. The proper diagnosis would then require spinal puncture. Because 2 to 10% of acute subarachnoid hemorrhages will not be detected by the initial CT scan (even with modern third generation scanners), a lumbar puncture is appropriate to rule out the diagnosis with certainty. [3] [106] [119] [131] In theory, a small subarachnoid hemorrhage may take several hours to reach the lumbar region. Thus, it is possible that such a patient might have normal lumbar CSF if examined soon after rupture. A second, delayed lumbar puncture may occasionally be required for diagnosis in such a situation. If the neurologic picture demonstrates localizing findings, the presence of a large intracranial hematoma should be suspected, and spinal puncture is contraindicated until CT (or arteriography) delineates the nature of the lesion.

The emergency clinician also may be called on to perform a therapeutic lumbar puncture in the patient with known pseudotumor cerebri (also known as benign intracranial hypertension or idiopathic intracranial hypertension). The patient has elevated intracranial pressure (ICP) for unknown reasons and often has headaches and papilledema. The headache worsens with maneuvers that increase the ICP (e.g., Valsalva, squatting, bending, coughing). See the following section for details.

Other nonemergent reasons for CSF examination include evaluation of CNS syphilis, unexplained seizures, instillation of chemotherapy and positive contrast agents, evaluation of suspected demyelinating or inflammatory CNS process, and treatment of headache from subarachnoid hemorrhage or benign intracranial hypertension. [26] Carcinomatous meningitis and suspected spinal cord compression from metastatic disease may require spinal puncture for myelography and cytologic examination. The availability of MRI is a suitable alternative for identifying compressive myelopathies.

Pseudotumor Cerebri

Pseudotumor cerebri, more commonly known as idiopathic intracranial hypertension (IIH) is a rare condition that may present to the ED. [43] IIH is an elevation of intracranial pressure (usually to 250–450 cm H_2O) without hydrocephalus or mass lesions, in the setting of *normal CSF* composition. This is a diagnosis of exclusion. Most patients have headache, papilledema, and minimal or absent focal findings, with a normal CT or MRI scan. Most patients appear otherwise well, but some complain of tinnitus, nausea, or blurred vision. IIH has been related to hypervitaminosis A, tetracycline, estrogen therapy, and a plethora of other conditions, such as sarcoidosis, tuberculosis and carcinomatosis (see Table 61-1 (Table Not Available)). Most cases are idiopathic. IIH is most common in obese adolescent girls and young women, but it can occur in childhood and in men. The mechanism of increased CSF pressure is unclear, but the brain appears normal. One proposed mechanism is decreased CSF outflow.

IIH may regress spontaneously after a few months. The major concern is visual loss, which may be permanent. The diagnosis can only be made by lumbar puncture, performed after neuroimaging. *This condition underscores the need to measure opening pressure during lumbar puncture whenever possible.* Many cases can be controlled with medication, but occasionally lumbar puncture is required to lower ICP, measured in the lateral decubitus position, to 200 mm H_2O. One way to lower ICP in the ED is to drain CSF via lumbar puncture by removing 5–10 mL aliquots of CSF and check ICP after each removal. Herniation does not occur despite elevated pressures. Since spinal fluid is regenerated rapidly, the procedure may need to be performed every few days to keep CSF pressure at this level. Analysis of the CSF is normal in all parameters. Drug therapy, in the form of acetazolamide, glycerol, diuretics, corticosteroids and others have been advocated and may negate the need for repeated lumbar puncture. Resistant cases may require shunting procedures.

CONTRAINDICATIONS FOR SPINAL PUNCTURE

Spinal puncture is absolutely contraindicated in the presence of infection in the tissues near the puncture site. [39] [130] Spinal puncture is relatively contraindicated in the presence of increased ICP from a space-occupying lesion. Caution is particularly advised when lateralizing signs (hemiparesis) or signs of uncal herniation (unilateral third nerve palsy with altered level of consciousness) are present. In such cases, a tentorial or cerebellar pressure cone may be precipitated or aggravated by the spinal puncture. Cardiorespiratory collapse, stupor, seizures, and sudden death may occur when pressure is reduced in the spinal canal. [26]

The risk of herniation seems to be particularly pronounced in patients with brain abscess. [13] [107] Brain abscesses frequently occur as expanding intracranial lesions with headache, mental disturbances, and focal neurologic signs rather than as infectious processes with signs of meningeal irritation. In 75% of cases, a primary source of chronic suppuration is present. Common predisposing causes of brain abscess include

craniofacial trauma, craniocerebral trauma, penetrating injuries with bone fragments in brain, transmitted foreign objects or large animal bites of infant skulls, postneurosurgical procedures, cardiovascular disorders with right to left shunts, bacterial endocarditis, gram-negative sepsis in neonates, dental infections, chronic sinusitis, otitis, mastoiditis, chronic abdominal pulmonary or pelvic infections, bacterial meningitis, and immunosuppression. Infarcted brain tissue may develop abscesses in the presence of sepsis because of a compromised blood-brain barrier. [114] Although the CSF is usually abnormal (elevated pressure, elevated white blood cell count, and elevated protein concentration), spinal puncture in patients with a known, or highly probable, abscess is contraindicated in most cases. In one study by Samson and Clark, 5 of 22 patients exhibited signs of midbrain compression within 2 hours of lumbar puncture. [107] Evidence of herniation markedly reduces the patient's chances for survival.

Brain abscess may spontaneously rupture into the ventricular system producing ventriculitis and meningitis. If the history suggests possible brain abscess, CT can rapidly diagnose and localize the lesion. [144] Because the appearance of brain abscesses on CT is similar to that of neoplastic and vascular lesions, false-positive reports of brain abscess may be encountered. [102]

Lumbar puncture can cause trauma to the dural or arachnoid vessels, which may result in minor hemorrhage into the CSF. This generally is of little consequence. However, the number of patients with hemophilia and human immunodeficiency virus (HIV) infection who require lumbar puncture has increased in the past decade. Spinal epidural hematomas may occur in some subpopulations of patients undergoing lumbar puncture. Individuals most at risk are those with some sort of bleeding diathesis, including those on anticoagulant therapy or those with abnormal clotting mechanisms, especially thrombocytopenia. Edelson and colleagues reviewed more than 100 cases of spinal epidural hematoma; approximately one third were associated with anticoagulant therapy. [29] Most articles describe isolated cases. [29] [71] [104] [112] Spinal subdural hematomas after lumbar puncture are even more rare than epidural hematomas. [25] [30]

When a patient is anticoagulated or has a coagulopathy, the tap should be performed by experienced clinicians, who are less likely to traumatize the dura. The patient should be carefully followed for progressive back pain, lower extremity motor and sensory deficits, and sphincter impairment after the procedure. *Complaints of motor weakness, sensory loss, or incontinence after lumbar puncture should be thoroughly investigated.* Lumbar puncture may be performed in the presence of a coagulation defect if the procedure is expected to provide essential information, such as in the diagnosis of meningitis. In cases of severe thrombocytopenia, the infusion of platelets before the lumbar puncture may be desirable.

The infusion of clotting factors in the hemophiliac patient and normalization of the prothrombin time with fresh frozen plasma in the anticoagulated patient are desirable if the clinical situation permits such delay before performing a lumbar puncture. Because as many as 90% of patients with severe hemophilia are seropositive for HIV, the issue of performing a lumbar puncture in patients with coagulopathies is an increasingly common phenomenon. Silverman and colleagues have demonstrated the safety of lumbar puncture in patients with hemophilia A or B who had their deficit clotting factor replaced before the procedure. In their series of 33 patients (30 with <1% normal factor level) who underwent a total of 52 spinal taps after specific factor replacement, no serious procedure-related complications were identified.[120] Their protocol was to attain an immediate postinfusion factor level between 5% and 100%. Use of additional factor replacement after lumbar puncture is of unknown value.

Howard and colleagues reported on 5223 lumbar punctures done in 958 children with newly diagnosed acute lymphoblastic leukemia. [56] Of these lumbar punctures, 29 were performed with platelet counts of 10×10^9 /L or less, 170 with platelet counts of $11–20 \times 10^9$ /L, and 742 with platelet counts of $21–50 \times 10^9$ /L. No serious complications were reported. The overall rate of traumatic taps was 10.5%, but these were not associated with adverse sequelae. They concluded that in children with acute lymphoblastic leukemia, prophylactic platelet transfusion for lumbar puncture is not required if the platelet count is greater than 10×10^9 /L. The number of patients with platelet counts of 10×10^9 /L or less was too small to reach any conclusion about this group of patients.

If the history and physical examination suggest a treatable illness, such as meningitis or subarachnoid hemorrhage, the clinician may perform a spinal puncture after careful consideration of the entire clinical picture. In all cases, the study should be undertaken after careful thought regarding how the results will assist in patient evaluation and treatment. It is unlikely that the spinal puncture will beneficially alter management in the presence of a neoplasm, a cranial hematoma, an abscess, a completed nonembolic infarction, or cranial trauma.

EQUIPMENT

The standard equipment for a spinal puncture should be assembled prior to beginning the procedure and placed where the operator can easily access it during the procedure. Standard equipment includes several spinal needles; three-way stopcock; manometer; and connecting tubing (optional, to connect needle with stopcock and manometer); at least four specimen tubes; local anesthetic; syringes and needles for local anesthesia (appropriate for both skin and subcutaneous tissue infiltration); sterile drapes, gauze, sponges, and gloves; and an antiseptic solution for skin preparation (e.g., 0.5% chlorhexidine in alcohol, 1% povidone-iodine). [42]

Some operators prefer to use an "atraumatic standard Sprotte needle" (Havel's, Inc, Cincinnati, OH) or Whitacre needle (Becton Dickinson and Co, Rutherford, NJ) to minimize the dural injury associated with needle passage. These styletted needles have a side port for fluid withdrawal and theoretically are more likely to *separate* rather than cut the dural tissue.

Although commercial kits provide most of the items (Fig. 62-1), it is important for the operator to bring additional supplies, including supplemental spinal needles and specimen tubes, gauze and antiseptic solution, additional local anesthesia and needles/syringes, and extra sterile gloves of the appropriate size. Following this advice will minimize procedural interruptions when material in the commercial kit must be supplemented.

TECHNIQUE

Lumbar puncture is commonly carried out with the patient in the lateral recumbent position. A line connecting the

Figure 62-1 Standard lumbar puncture tray. Separate equipment is available for infants, children, and adults. *(Image courtesy of the American Pharmaseal Company, Glendale, CA.)*

posterior-superior iliac crests will intersect the midline at approximately the L4 spinous process (Fig. 62-2 (Figure Not Available)). Spinal needles entering the subarachnoid space at this point are well below the termination of the spinal cord, and the only important neurologic structure is the cauda equina. Generally, the needle will push isolated nerves to the side during advancement. The adjacent interspace above or below may be used, depending on which area appears to be most open to palpation. The space between lumbar vertebrae is relatively wide. In the thoracic region, the spinous processes overlap and are directed caudad, and therefore there is no midline area free of overlying bone. In the adult, the spinal cord extends to the lower level of L1 or the body of L2 in 31% of persons, thus eliminating higher levels as sites for puncture. The puncture in adults and in older children may be performed from the L2 to L3 interspace to the L5 to S1 interspace.

Developmentally, the spinal canal and the spinal cord are of equal length in the fetus. Growth of the cord does not keep pace with longitudinal growth of the spinal canal. At birth, the cord ends at the level of the L3 vertebra. The needle in infants should be placed at the L4 to L5 or L5 to S1 interspaces. The subarachnoid space extends to an S2 vertebral level; however, the overlying bony mass prevents entry into this lowermost portion of the subarachnoid space.

When performed with parenteral sedation and proper local anesthesia, a spinal tap is neither overly distressing nor very painful to most patients. Almost all patients are afraid of a spinal puncture because they have heard stories of severe complications. Explaining the procedure in advance and discussing each step during the course of the test aids in reducing patient anxiety and helps the clinician. The clinician should inquire about history of allergies to local anesthetic agents and topical antiseptics. Use of a written informed consent is optional. However, a detailed procedural note is recommended to document the process of patient/guardian education regarding the indications, procedural techniques, risks/benefits and alternatives to the procedure, and the patient/guardian's assent to the procedure. This step may need to be abridged when the patient is critically ill or eliminated when the patient is mentally incapacitated and no guardian is present. In anxious patients, a benzodiazepine agent given parenterally (e.g., midazolam, 0.05 to 0.075 mg/kg IV) will facilitate the procedure and is recommended.

The next important step is positioning of the patient. Generally the procedure is performed in the lateral decubitus position in older children and adults. The patient is given a pillow to keep the head in the same plane as the vertebral axis. The shoulders and the hips are positioned perpendicular with the table. A firm table or bed is desirable whenever possible. Flexion of the neck does *not* facilitate the procedure to any great extent; and because severe flexion may add to the patient's discomfort, this step may be omitted. The patient's lower back should be arched toward the clinician by having the patient's knees drawn toward the chest.

Some clinicians place the patient in an upright sitting position, because the midline is more easily identified when the patient is sitting. The higher CSF hydrostatic pressure in a sitting, dehydrated patient may aid CSF flow. Caution regarding orthostatic blood pressure changes and airway maintenance must be observed when the patient is sitting for the procedure. Generally the sitting patient is allowed to lean onto a bedside stand using a pillow to rest the head and arms. An assistant also must help support the patient during the procedure. Radiographic studies by Fisher and colleagues [38] have shown the advantages of hip flexion when the sitting position is used. This can be accomplished by having seated patients pull their knees up to their chest, as is generally done when the lateral decubitus position is used. This will increase the

Figure 62-2 (Figure Not Available) When the patient has been correctly positioned for the lumbar tap *(left),* an imaginary line connecting the iliac crests will be exactly perpendicular to the bed. Insertion sites are marked by *x;* the operative field is draped. The needle should be inserted perpendicularly (or nearly so) to the plane of the back, with the forefingers of both hands guiding it in *(right)*. *(From Cole M: Pitfalls in cerebrospinal fluid examination. Hosp Pract 4:47, 1969. Illustration by Carol Donner. Reproduced by permission.)*

lumbar interspinous width, which may increase the success or ease of needle passage.

Although introgenic infection following lumbar puncture is extremely rare, sterile gloves are customary. The use of face masks by medical personnel who are performing a lumbar puncture is controversial. [5] [10] [142] Although definitive supporting data do not exist, some authors recommend use of a face mask while performing a lumbar puncture as an infection control practice. The examiner should wash the patient's back with an antiseptic solution applied in a circular motion. The circumference of the cleansed area should increase with each motion. A povidone-iodine solution will decrease skin flora to a bacterial count of 0 to 2 bacteria/in ^{2} .[59] Friction during skin preparation helps remove loose debris. The patient should be warned that the solution will be cold. The povidone-iodine must be allowed to dry completely. This can be hastened by removing excess fluid with a dry sterile gauze pad. A sterile towel or drape is placed between the patient's hip and the bed. Commercial trays have a second sterile drape with a hole that may be centered over the site selected for the tap.

The skin and deeper subcutaneous tissue are infiltrated with local anesthetic (1% lidocaine). Buffered or warmed lidocaine is preferred (see Chapter 30). The patient should be warned about transient discomfort from the anesthetic. Anesthetizing the deeper subcutaneous tissue significantly reduces the procedural discomfort. *Merely raising a skin wheal is insufficient anesthesia.* Some operators not only anesthetize the interspinous ligament but also apply local anesthesia in a vertically fanning distribution on both sides of the spinous processes near the lamina. This field block on each side of the spinous processes anesthetizes the recurrent spinal nerves that innervate the interspinous ligaments and muscles.

While waiting for the anesthetic to take effect, the clinician should attach the stopcock and manometer and see that the valve is working. Commonly, a 3.5-in, 20-ga needle is used in adults, and a 2.5-in, 22-ga needle is used in children (a 1.5-in, 22-ga needle is available for infants). A needle of this size has enough rigidity to allow the procedure to be accomplished easily but makes less of a dural tear than do larger needles. The patient should be told to report any pain and should be informed that he or she will feel some pressure.

The needle is placed into the skin in the midline parallel to the bed. The needle is held between both thumbs and index fingers. After the subcutaneous tissue has been penetrated, the needle is angled toward the umbilicus. The bevel of the needle should be facing straight up toward the ceiling, assuming that the patient is in the lateral decubitus position. It has been speculated that pointing the bevel parallel to the longitudinal axis of the spine may allow the needle to separate the fibers of the dura rather than cut through them, allowing for less CSF leakage after the needle has been withdrawn.

The supraspinal ligament connects the spinous process; the interspinal ligaments join the inferior and superior borders of adjacent spinous processes. The ligamentum flavum is a strong, elastic, yellow membrane that may reach a thickness of 1 cm in the lumbar region. The ligamentum flavum covers the interlaminar space between the vertebrae and functions to assist the paraspinous muscles in maintaining an upright posture (Fig. 62-3 (Figure Not Available)). The ligaments are stretched in a flexed position and are more easily crossed by the needle. The ligaments offer resistance to the needle, and a "pop" is often felt as they are penetrated.

One should remove the stylet frequently to see if the subarachnoid space has been reached. The pop is occasionally not felt with the very sharp needles contained in disposable trays.

If bone is encountered, the needle must be partially withdrawn to the subcutaneous tissue. The clinician should repalpate the back and ascertain that the needle is in the midline. Directing the needle tip toward the navel often enhances navigation of the interspinal space. If bone is again encountered, the needle should be slightly withdrawn and re-angled, with the point placed so that it angles more sharply cephalad. This should avoid hitting the inferior spinous process.

Clear fluid will flow from the needle when the subarachnoid space has been penetrated. In normal patients the dura will be penetrated when the needle is advanced about ½ to ¾ of its length. In obese patients the entire needle length may required to reach the subdural space (Fig. 62-4).

The clinician should attach the manometer and record the opening pressure. Although commonly omitted in critical patients, whenever feasible, this step should be preformed. In the struggling patient, pressure readings may be inaccurate. Pressure readings are only valid if taken with the patient in the lateral decubitus position and not the sitting position. A three-way stopcock is supplied in disposable trays; this allows both collection and pressure to be measured by a single needle (Fig. 62-5 (Figure Not Available)). Positioning of the manometer is often more convenient if an extension tube (provided with most disposable trays) connects the needle hub to the stopcock, which is in

Figure 62-3 (Figure Not Available) Midsagittal section through lumbar spinal column with spinal puncture needle in place between spinous processes of L3 and L4. Note the slightly ascending direction of the needle. The needle has pierced three ligaments and the dura/arachnoid and is in the subarachnoid space. *(From Lachman E: Anatomy as applied to clinical medicine. New Physician 17:145, 1968.)*

turn attached to the manometer. The manometer should be positioned so that the "zero" mark is at the level of the spinal needle. The patient is then asked to relax. Extending the legs after needle placement does not meaningfully decreased the opening CSF pressure. [2] The fluid column is observed for phasic changes with respirations and arterial pulsations. This ensures needle placement in the subarachnoid space. If the needle is against a nerve root or is only partially within the dura, the pressure may be falsely low, and respiratory excursions will not be seen in the manometer. Minor rotation of the needle may solve these problems. Hyperventilation to relax the patient should not be attempted, because this will reduce the pressure readings owing to hypocapnia and resultant cerebral vasoconstriction.

Figure 62-4 The spinal needle is usually advanced ½ to ¾ of its length before the spinal canal is reached. In this obese patient the needle was advanced all the way to the hub of the needle before spinal fluid was returned.

After measuring the pressure, the clinician should turn the stopcock and collect enough fluid to perform all desired studies. Even if the pressure is elevated, sufficient fluid should be removed for performance of all indicated studies, because the risk of the procedure involves the dural rent and not the amount of fluid initially removed. Presumably, more fluid will be lost subsequently through the hole in the dura. After cleaning off the povodine-iodine from the patient's back using a wash cloth moistened with warm tap water, a clean dressing is placed over the puncture site. Commercial trays supply four specimen tubes. Generally, tube 1 is used for determining protein and glucose levels and for electrophoretic studies, tube 2 is used for microbiologic and cytologic studies, and tube 3 is for cell counts and serologic tests for syphilis. In the presence of bloody CSF, cell counts should be performed in tubes 1 and 3 to help differentiate traumatic taps. One may compare water placed in tube 4 with CSF in tube 3 to detect cloudiness or discoloration. Alternatively, tube 4 can be stored under refrigeration in the laboratory for subsequent studies.

Traumatic taps are common and usually clinically inconsequential but they can be minimized by proper patient and needle positioning. A traumatic tap most commonly occurs when the subarachnoid space is transfixed at the entrance of the ventral epidural space, where the venous plexus is heavier. A plexus of veins forms a ring around the cord, and these veins may be entered if the needle is advanced too far ventrally or is directed laterally (Fig. 62-6 (Figure Not Available)). If blood is encountered and the fluid does not clear, the procedure should be repeated at a higher interspace with a fresh needle. A traumatic tap, per se, is not a particularly dangerous problem in the patient with normal coagulation, and no specific precautions are needed if blood-tinged fluid is obtained. However, observation for signs of cord or spinal nerve compression from a developing hematoma within the first several hours should be routine for these patients.

Figure 62-5 (Figure Not Available) Whenever feasible, opening pressure should be measured, not estimated, by means of an air-water manometer affixed to the needle by a three-way stopcock, thus allowing pressure to be taken and fluid withdrawn through a single needle, normal pressure is 70 to 180 mm H_2O. *(From Cole M: Pitfalls in cerebrospinal fluid examination. Hosp Pract 4:47, 1969. Illustration by Carol Donner. Reproduced by permission.)*

Lateral Approach in Lumbar Puncture

The supraspinal ligament may be calcified in older persons, making a midline perforation difficult. A calcified ligament may deflect the needle. In this case, a slightly lateral approach may be used. As the lower lamina rises upward from the midline, the needle is directed slightly cephalad to miss the lamina and slightly medially to compensate for the lateral approach. The needle passes through the skin, superficial fascia, fat, the dense posterior layer of thoracolumbar fascia, and the erector spinae muscles. The needle then penetrates the ligamentum flavum (bypassing the supraspinal and interspinal ligaments), the epidural space, and the dura before CSF is obtained (Fig. 62-7 (Figure Not Available)).

Cisternal Puncture

In situations in which lumbar puncture is contraindicated (such as local infection or acute trauma to the lumbar spine),

Figure 62-6 (Figure Not Available) Spinal contents at L4 and L5 show the relationship of a lumbar puncture needle to the major vessels at this level. The major radiculomedullary vein, shown accompanying the L5 nerve root, is situated far laterally to a needle correctly positioned in the midline of the dural sac. Note the avascular subdural space. *(From Edelson RN, Chernik IVL, Rosner JB: Spinal subdural hematomas. Arch Neurol 31:134, 1974. Illustration by Lynn McDowell. Reproduced by permission. Copyright 1974, American Medical Association.)*

cisternal, or suboccipital, puncture is the usual alternative. Technical problems, such as morbid obesity, cord tumor, arachnoiditis, bony deformities, or prior spinal surgery (fusion), may make lumbar puncture impossible. Contrast material may be injected into the cisterna magna to identify the rostral extent of an obstructing lesion identified by lumbar myelography.

The patient is cleaned and anesthetized in a manner similar to that for a lumbar puncture after the neck has been shaved from the external occipital protuberance to the mastoid process laterally. The patient is preferably placed in a lateral decubitus position, but a sitting position can be used. A pillow is placed under the head to keep the neck and the vertebral axis in the same plane. The patient's neck is flexed to the chest. The spinal needle is placed in the midline halfway between the spinous process of C2 and the inferior occiput. The needle is angled cephalad through the subcutaneous tissue until it comes in contact with the bony occiput. The needle is then withdrawn and subsequently advanced at a less acute angle with the horizontal plane of the cervical

Figure 62-7 (Figure Not Available) Horizontal section through the body of L3. Note the two puncture needles in the subarachnoid space. The medial one is in the midline, corresponding to the position

in Figure 62-3 (Figure Not Available) . The lateral one exemplifies the lateral approach, which avoids the occasionally calcified supraspinal ligament. Note the lateral needle piercing the intrinsic musculature of the back and only one ligament, the ligamentum flavum. *(From Lachman E: Anatomy as applied to clinical medicine. New Physician 17:145, 1968.)*

spine. This is repeated until the dural pop is felt. As in the lumbar region, the stylet should be removed frequently so that the dura is not punctured unknowingly. Fluid is removed in the usual manner. Dural veins are less extensive, and bloody taps are less common. Low-pressure headaches are less common, presumably because the subarachnoid pressure is lower and the dural tear can heal faster.

Lateral Cervical Puncture

The patient is placed in a supine position and fully sterilized and anesthetized. A 20-ga lumbar puncture needle is inserted perpendicular to the neck and parallel to the bed. The landmark for insertion is a point 1 cm inferior and 1 cm dorsal to the mastoid process. The clinician frequently removes the stylet to check for fluid return and, as at other sites, advances the needle slowly. If the needle goes too deeply and encounters paraspinous muscles, it is probably too deep posteriorly and should be repositioned more anteriorly. If bone is encountered, more dorsal placement is needed. Pressure and fluid samples are collected, as in other sites. [146]

The contraindications to cisternal and cervical punctures are the same as those to lumbar puncture. Both techniques are easily mastered, but prior demonstration of the procedure by an experienced operator is advised. When lumbar puncture cannot be performed for technical reasons and meningitis is suspected, placement of the needle under fluoroscopy may help obtain CSF.

Lumbar Puncture in Infants

Lumbar puncture in infants is usually performed to exclude meningitis. The sitting position may allow the midline to be more easily identified. Some authors use a nonstyleted needle in small infants, because this device allows the pressure to be estimated as the needle punctures the dura. [50] However, the failure to use a stylet may be the source of later development of an intraspinal epidermoid tumor. [83] A technique of lumbar puncture in the neonate using a butterfly infusion set needle has been described as a simplified procedure that may be useful in the squirming or hyperactive patient. [50] In general, the stylet is recommended primarily at the time of skin penetration and upon needle withdrawal. Although many operators use the stylet during any advancement of the needle, frequent stylet placement and withdrawal after skin penetration has occurred is optional.

If the child's neck is very tightly flexed, CSF may not be obtained. However, if the head is held in midflexion, CSF usually flows briskly. Prolonged severe flexion of the neck in an infant should be avoided because it may produce dangerous airway obstruction; the airway should be checked if the infant suddenly stops crying. [37] Incorrect positioning usually results in multiple punctures and a bloody tap. If CSF fails to flow, gentle suction with a 1.0-mL syringe may be used to exclude a low-pressure syndrome. Pressure readings are inaccurate in the struggling child and hence not commonly measured in infants or young children. Positioning is very important in the infant and is best accomplished by an assistant, who maintains the spine maximally flexed by partially overlying the child using the holder's chest and body weight to immobilize the thorax and hips, while holding the child behind the shoulders and the knees. The infant has poor neck control; hence, the assistant must also ensure that the child maintains an open airway.

Newborn and preterm infants may experience significant hypoxia during lumbar puncture with clinical deterioration; a sitting position appears preferable. [140] Lumbar puncture in infants with respiratory distress syndrome may cause greater risk than benefit. [31] This is a problem primarily in neonates but may occur in younger infants with sepsis. Gleason and coworkers[45] demonstrated that performing a lumbar puncture in the ill preterm infant using the traditional lateral recumbent position with full neck flexion resulted in significant respiratory abnormalities, presumably owing to a ventilation-perfusion mismatch. All infants with serious cardiopulmonary disease should be closely monitored during the procedure. Preoxygenation with or without oxygen saturation monitoring may be used as a precaution. Particular attention should be given to avoiding marked neck and trunk flexion.

Although local anesthesia or sedation has not been a routine practice during lumbar puncture in the infant or child, it is being reconsidered. Pain is perceived in the neonate, and local anesthesia neither produces physiologic instability nor makes the procedure more difficult. [91] [93] Sedation in the anxious child may be considered as an adjunct as for the adult, although these agents are relatively contraindicated in the obtunded infant or child without a protected airway or in the setting of hemodynamic instability.

Coley and colleagues advocate ultrasound evaluation in cases of failed lumbar puncture in neonates and infants. [20] Ultrasound was able to provide information concerning the presence or absence of CSF, the cause of the failed lumbar puncture, and whether to proceed with further attempts.

COMPLICATIONS

Implantation of Epidermoid Tumors

An epidermoid tumor or cyst is a mass of desquamated cells containing keratin within a capsule of well-differentiated stratified squamous epithelium. Congenital lesions are rare and arise from epithelial tissue that becomes sequestered at the time of closure of the neural groove between the third and fifth weeks of embryonic life. Acquired intraspinal epidermoid tumors result from implantation of epidermoid tissue into the spinal canal at the time of lumbar puncture performed with needles without stylets or with ill-fitting stylets. [83] The clinical syndrome consists of pain in the back and the lower extremities developing years after spinal puncture. Failure to use a stylet upon needle withdrawal may also result in aspiration of a nerve root into the epidural space.

Headache after Lumbar Puncture

A number of complications from lumbar puncture have been reported. By far the most common is the post-lumbar puncture headache. This occurs after 5% to 40% of spinal taps.[35] [39] [74] [133] The syndrome starts up to 48 hours after the procedure and usually lasts for 1 to 2 days and occasionally up to 14 days. Exceptional cases lasting months have been described. The headache usually begins within minutes after the patient arises and characteristically ceases as soon as he or she assumes a recumbent position. The pain is mild to incapacitating and is usually cervical and suboccipital but may involve the shoulders and the entire cranium. Exceptional cases include nausea, vomiting, vertigo, blurred vision, ear pressure, tinnitus, and stiff neck. The headache may improve and change to a positional backache or neckache. The headache appears in the first 1 to 3 days and may last for weeks or rarely months to years. The syndrome is thought to be caused by leakage of fluid through the dural puncture site. This results in an absolute reduction of CSF volume below the cisterna magna and a downward movement of brain tissue with displacement and stretching of pain-sensitive structures, such as meninges and vessels, which, in turn, causes a traction headache. Past puncture cerebral vasodilation is another proposed mechanism. In the recumbent position there is relief, because the weight of the brain is shifted cephalad. Dural leakage has been confirmed at surgery for disk disease and by at least one isotope myelographic study. [77] [129]

The incidence of headache in normal volunteers has been found to be one case per nine subjects with the use of a 26-ga needle and one case per three subjects with a 22-ga needle.[129] The headache was reported to be milder when the smaller needle was used. Technically, a 26-ga needle is difficult to place and to manipulate into a position in which it does not become intermittently obstructed by nerve roots. In addition, a syringe is needed to withdraw fluid, and pressure cannot be easily recorded. Theoretically, the incidence of headache is greater with an 18-ga needle.

Other factors claimed to influence the incidence of postspinal headache have been reviewed by Fishman and Lin. [79] The incidence is higher in young patients than in older patients and is also increased in females and individuals with a prior headache history. *Psychologic factors, quantity and rapidity of CSF removal, forced bedrest, immediate ambutation, postlumbar puncture hydration, and position during lumbar puncture have not been found to be relevant in the incidence of headache.*[70] Such common and strictly applied rituals have been termed mythical by some authors. [79] Some reports suggest a lower incidence with the lateral approach resulting from the production of holes in the dura and the arachnoid that do not overlap.

The influence of activity on postspinal puncture headache has been studied with contradictory results, including worsening of, improvement in, and no effect on the incidence of headaches when patients were mobilized. [14] Brocker studied 1094 patients and reported a reduction of headache from 36.5% to 0.5% by having the patients lie prone instead of supine for 3 hours after puncture with an 18-ga needle. He concluded that the prone position caused hyperextension of the spine and disrupted alignment of the holes in the dura and the arachnoid, making a leak less likely. Others have failed to show a decrease in duration, severity, or incidence of spinal headache with 24 hours of bedrest. [16] Interestingly, Vilming and colleagues [135] noted a slight reduction in postlumbar puncture headache if immediate mobilization was undertaken.

Much medical literature has commented on the incidence and severity of postdural puncture headache as related to spinal needle bevel orientation [41] [143] and type/size.[1] [17] [33] [40] [65] [78] [113] [127] [134] Concerning bevel orientation, it is clear that the incidence of postdural puncture headache is lower when the bevel of the needle is oriented parallel to the longitudinal axis of the spine. Until relatively recently, the explanation for this was that the parallel oriented bevel would separate rather than cut the longitudinally oriented dural fibers and thus result in a smaller dural hole and less CSF leakage. However, it is now known that the dural fibers are not oriented longitudinally but rather randomly. [99] Even with random fiber orientation, it is more likely that a longitudinal dural hole will be pulled closed during back flexion than a horizontal dural hole.

There are two basic types of spinal needles: cutting [96] and non-cutting or pencil-point (Sprotte and Whitacre). The non-cutting needles cause a lower incidence of postdural puncture headache. This may be because the tip of the non-cutting needle tends to separate rather than cut dural fibers. It has traditionally been thought that the dural hole resulting from non-cutting needle puncture is smaller than with cutting needle puncture; however, this may not be true. The important difference may be that the cutting needle causes a clean-cut opening in the dura while the non-cutting needle produces a jagged opening with rough edges. [98] The jagged opening may produce more intense inflammatory response, resulting in edema and more complete hole closure. The use of atraumatic spinal needles is not routine amongst all specialists. Perhaps as more spinal kit manufacturers include them in their kits their use will increase. [9] In thick-skinned individuals, passage of a thin, non-cutting needle may be technically difficult. The initial pass of a thicker cutting needle to the level of the interspinal ligament, followed by removal and advancement of the noncutting needle in the same soft tissue tract, can be helpful.

A smaller diameter needle will cause a smaller incidence of postdural puncture headache because it causes a smaller dural hole. However, a needle must have adequate CSF flow rates in order to allow timely CSF collection and pressure measurement. When these characteristics are considered, the 20-ga atraumatic needle may be the best overall choice for diagnostic lumbar puncture. [17]

Many medications have been advocated for treatment of post-lumbar puncture headache: barbiturates, codeine,

neostigmine, ergots, diphenhydramine (Benadryl), dimenhydrinate (Dramamine), amphetamine sulfate (Benzedrine), ephedrine, intravenous fluids (normal saline, Ringers lactate), magnesium sulfate, and vitamins.[19] [35] [136] Sechzer and Abel[111] in a double-blind demand method, found caffeine sodium benzoate (500 mg in 2 mL normal saline given by IV push) to be effective in 75% of patients. Additional patients responded to a second injection 1 to 2 hours later. Other clinicians prefer to put 500 mg of caffeine sodium benzoate in 1 L of saline and infuse the fluid over 1 hour. [58] This approach is contraindicated in the patient at risk for xanthine toxicity (e.g., supratherapeutic theophylline level, history of cardiac dysrhythmias). Aminophylline, 5 to 6 mg/kg by IV infusion over 20 minutes, is also reported to be useful.

Most clinicians generally follow the practice of using a styleted needle that is as small as possible. A 20- to 22-ga needle is often used for adults because of its stiffness and ease of fluid flow. Multiple punctures should be avoided. There is no certainty about activity and position immediately after the procedure. Most postspinal puncture headaches can be managed with bedrest with the head in the horizontal position. Dehydration should be avoided, because it lowers CSF pressure and might aggravate the headache. Although simple analgesics are commonly prescribed, they have no apparent advantage over bedrest and fluid intake. In the absence of a postural headache it is not necessary to stress immobilization or bedrest after lumbar puncture. [24] A patient with a prolonged headache after spinal puncture should be reassessed to rule out other structural causes of headaches. If the headache is not postural, other causes should be sought.

In cases in which a prolonged low-pressure headache exists, the placing of an epidural blood patch by experienced operators is highly successful. [15] [64] [88] [132] An epidural tap is performed at the level of the prior lumbar puncture. The loss-of-resistance technique using sterile saline can be used to locate the epidural space. [105] Ten to 20 mL of autologous blood is then drawn aseptically into a syringe and slowly injected (1 to 2 mL every 10 seconds) into the epidural space at the site of the

dural puncture. The injection is slowed or discontinued if back pain or paresthesias develop. The patient is kept supine for 1 hour while receiving intravenous hydration. Relief usually occurs within 20 to 30 minutes of the procedure. However, epidural patches are less likely to be effective if symptoms have been present for more than 2 weeks. Pain relief is due to the blood patch forming a gelatinous tamponade, hence stopping the CSF leak and providing an immediate elevation of CSF pressure. Patch failures (15% to 20%) are believed to be due to improper needle placement, injection of an inadequate quantity of blood, or an incorrect diagnosis. A second patch is often successful.

Complications reported after an epidural patch include back stiffness (15%), paresthesias, radicular pain, subdural hematoma, adhesive arachnoiditis, and bacterial meningitis.[15] [88] The procedure should be used in patients with refractory headaches who fail to respond to conservative therapy and should be performed by clinicians trained in the procedure.

Infection

Spinal puncture is absolutely contraindicated in the presence of local infection at the puncture site (cellulitis, suspected epidural abscess, or furunculosis) because of the danger of inducing meningitis.

Several laboratory and clinical investigators have examined the relationship between performance of a lumbar puncture during bacteremia and the later development of meningitis.[90] [126] A large concentration of bacteria in the bloodstream at the time of CSF examination is associated with meningitis. The meningitis could be coincidental ("spontaneous meningitis") or could result from leakage of blood containing bacteria into the subarachnoid space after lumbar puncture ("lumbar puncture-induced meningitis"). Eng and Seligman [32] reported that 14% of 165 cases of bacteremia caused by *Streptococcus pneumoniae, Haemophilus influenzae,* and *Neisseria meningitidis* had evidence of meningitis at the time of initial lumbar puncture. They argue that one cannot easily differentiate spontaneous meningitis from lumbar puncture-induced meningitis with these organisms because of their ability to invade the meninges spontaneously. It is likely that many of these rare cases of lumbar puncture-induced meningitis occur when the cautious clinician performs a lumbar puncture early in the course of meningitis, that is, before the infection has had time to be reflected in the CSF.

Teele and coworkers,[126] however, reported that 7 of 46 children developed meningitis after an initial normal lumbar puncture in the presence of bacteremia. *S. pneumoniae, H. influenzae,* and *N. meningitidis* were recovered in all cases. All cases of lumbar puncture-induced meningitis occurred in children younger than 1 year who received no antimicrobial therapy at the time of initial cultures. Empirical treatment for bacteremia despite a clear CSF is recommended by Teele and associates [126] in the child younger than 1 year if a high fever and leukocytosis are present.

Other studies suggest that the development of meningitis in children with occult bacteremia is more strongly associated with *S. pneumoniae, H. influenzae* type B, or *N. meningitidis* species of bacteria and *not* with the performance of lumbar puncture.[115] Suspected bacteremia is not a contraindication for performing a lumbar puncture; delay in diagnosis because of concern regarding the risks of a lumbar puncture is more serious than the risk of causing meningitis with the procedure. [36] [67]

Herniation Syndromes after Lumbar Puncture

Lumbar puncture is of value in confirming a diagnosis of meningitis and subarachnoid hemorrhage. Generally, when the patient has symptoms consistent with bacterial meningitis, lumbar puncture is performed before a head CT scan. Some have suggested that a lumbar puncture may be the best initial procedure to diagnose sybarachnoid hemorrhage, thus reducing the need for routine CT scanning in certain low risk patients with acute sudden headache. [110] However, in patients with a suspected intracranial mass lesion, a CT scan is generally performed before the lumbar puncture. Antibiotics are best administered *after* blood cultures are obtained and *before* the CT scan when meningitis remains on the differential diagnosis list.

Particularly with supratentorial mass lesions, there may be large pressure gradients between the cranial and lumbar compartments. When brain volume is increased because of a mass lesion or edema, rostrocaudal displacement may occur after lumbar puncture if the skull is intact. Techniques for management of increased ICP are discussed elsewhere (see Chapter 61).

The specific question whether or not lumbar puncture causes brain herniation to occur, when otherwise herniation

would not have occurred spontaneously, cannot be answered with certainty. Lowering the lumbar spinal canal pressure by removing CSF may increase the gradient between cranial and lumbar compartments, theoretically promoting both transtentorial and foramen magnum herniation. The frequency with which a lumbar puncture causes or accelerates transtentorial herniation is unknown, because a seriously ill patient might have developed herniation spontaneously without the procedure. Duffy reported experience with 30 patients referred to a neurosurgical service with post-lumbar puncture herniation syndromes; in this selected population of adverse outcomes, he noted that complications occurred in the first 12 hours after the procedure. [26] Half of these referred patients lost consciousness immediately after the puncture. In half of these patients, the lumbar pressure was normal. Only one third had papilledema.

With the availability of CT scanning, patients at risk of herniation should be less likely to undergo lumbar puncture. However, the literature from both the pre- and post-CT eras suggests a risk of herniation after lumbar puncture to be in the range of 2% to 3%. [66] Baker and colleagues noted that CT scans at their institution were poorly correlated with CSF pressures. [6] Among 13 patients with a CSF pressure of 210 mm H_2O or higher, 6 had normal CT scans and 3 had generalized atrophy. Only four had evidence of an intracranial mass, midline shift, or hydrocephalus. Of note, no patient demonstrated herniation over the subsequent 48 hours. Similarly, Zisfein and Tuchman[145] observed 38 patients with CT scan-documented intracranial mass lesions who underwent lumbar puncture. They noted that only one patient (who had fixed, dilated pupils and absent caloric reflexes before the lumbar puncture) died. All other patients were neurologically stable or had improved within 48 hours. Hence, with the current use of small-caliber spinal needles and aggressive concurrent use of ICP-lowering agents, herniation appears extremely rare and is not fully predictable by CT scan or opening CSF pressure readings.

Horowitz and coworkers[54] reported herniation in 18 of 302 infants with bacterial meningitis, all of whom experienced deterioration within 8 hours of lumbar puncture. Patients with meningitis who have localizing neurologic signs may have a coexisting brain abscess or infarction from arterial or venous thrombosis. Obstructive hydrocephalus and generalized cerebral edema may complicate meningitis with a secondary increase in ICP.

A careful neurologic examination should precede all spinal punctures. When there is a history of headache with progressive mental changes and the development of *localizing* neurologic signs, then spinal puncture should *not* be performed as the initial diagnostic procedure. A study by Gopal and colleagues [46] identified three statistically significant predictors of new intracranial masses: papilledema, focal neurologic examination, and altered mental status. Hasbun et al [51] demonstrated that in adults with suspected meningitis, clinical features could identify patients who were *likely* to have abnormal CT findings. Thus, the *absence* of the findings would suggest that the patient is a good candidate for immediate lumbar puncture since they have a low risk of brain herniation as a result of the procedure (Table 62-1). When these findings are present and meningitis is still clinically suspected, an initial dose of antibiotic should be administered empirically while awaiting results of CT or MRI to help assess the safety of a subsequent lumbar puncture. Appropriate cultures of blood and other body fluid should be obtained before

*This category includes patients with human immunodeficiency virus infection or acquired immunodeficiency syndrome, patients who were receiving immunosuppressive therapy, and patients who had undergone transplantation.
†The CNS disease consisted of mass lesion, stroke, and focal infection.
‡The abnormalities consisted of aphasia, dysarthria, and extinction.

antibiotic administration. Blood cultures are positive in 80% of infants with meningitis. Measures to lower ICP before spinal puncture can also be instituted.

A CT scan should identify hemorrhagic lesions and most neoplasms. The CT scan should aid in the decision regarding the need for and the risk involved with spinal puncture. Head CT may help identify patients with unequal pressures between intracranial compartments who are at greater risk for cerebral herniation. CT findings that suggest unequal pressure between intracranial compartments include (1) lateral shift of midline structures, (2) loss of suprachiasmatic and circummesencephalic cisterns, (3) shift or obliteration of the fourth ventricle, and (4) failure to visualize the superior cerebellar and quadrigeminal plate cisterns with sparing of the ambient cisterns.[47] The presence of a posterior fossa mass would be a strong contraindication to a lumbar puncture. Because of bone and motion artifact, the posterior fossa unfortunately may be a difficult area to visualize on CT.

In summary, with regard to CT scan prior to lumbar puncture, there is no totally agreed upon standard of care that mandates when a lumber puncture should, or should not, be performed. A reasonable and logical approach is to avoid initial lumbar puncture, and first perform a CT scan when a mass lesion is suspected or if the patient has signs and symptoms of increased intracranial pressure as outlined in Table 62-1 . This approach correlates with the 2002 clinical policy promulgated by the American College of Emergency Physicians.[121]

Recognition of Herniation Syndromes

Herniation syndromes are the result of downward displacement of the hemispheres and the basal ganglia, which compress and displace the diencephalon and the midbrain rostrocaudally through the tentorial notch. Etiologic features and pathogenesis are detailed in the monograph by Plum and Posner. [92] Herniations have the potential to initiate vascular and obstructive complications that aggravate the original

expanding lesion and can create an irreversible pathologic process. The anterior cerebral artery may be compressed against the falx and may increase ischemia and edema of the herniating hemisphere. Midline displacement posteriorly compresses the deep great cerebral vein and raises pressure in its area of drainage. Compression of the posterior cerebral artery at the tentorial notch can produce occipital infarction and swelling. In addition, kinking of the aqueduct may interfere with CSF circulation. This blockage may produce a normal spinal CSF pressure. Transtentorial herniation displaces the brainstem downward, stretching medial perforating branches of the basilar artery, as the artery is tethered to the circle of Willis. This produces brainstem ischemia and hemorrhages.

In general, pathologic changes with supratentorial mass lesions spread through the hemisphere and move rostrad and caudad in a progressive manner, with progressive dysfunction of the hemisphere and, subsequently, succeeding levels of the brainstem. The infrequent exceptions are seen in patients with acute cerebral-intraventricular hemorrhage and in patients with hemispheric mass lesions with incipient herniation who undergo lumbar puncture. Such conditions may rapidly progress from hemispheric dysfunction to sudden medullary failure.

Central (Transtentorial) Herniation

This condition occurs in response to lesions of the frontal, parietal, and occipital lobes and the extracerebral lesions lying toward the vertex or the fronto-occipital lobes (Fig. 62-8 (Figure Not Available)). Frequently, patients are subacutely or chronically ill with bilateral disease, and the diagnosis may be uncertain. Initially, subjects exhibit a change in alertness or behavior. If the supratentorial lesion enlarges, compressing the diencephalon, stupor and then coma develop. At this point, monitoring of respiratory, ocular, and motor signs helps in diagnosing a supratentorial lesion and in determining the rostrocaudal direction of the disease process. Respirations at this time may be interrupted by deep sighs or yawns and periodic breathing of the Cheyne-Stokes type (periods of hyperpnea regularly alternating with apnea). Pupils are small but react briskly. Eye movements may be conjugate or slightly divergent with roving eye movements. Caloric testing with cold water produces a conjugate slow tonic movement to the side of irrigation. Many individuals have a hemiparesis before herniation. As the diencephalic stage of the central syndrome evolves, the contralateral hemiplegia may worsen, with the homolateral limbs developing a paratonic resistance to movement, but the individual continues to respond to noxious stimuli appropriately. At this stage both plantar responses are extensor. Decorticate responses appear and consist of flexor muscle hypertonus in the upper extremity with predominantly extensor hypertonus in the leg. Recognition of a diencephalic stage of herniation is important in that it gives warning that a potentially reversible lesion may become irreversible.

Once midbrain signs develop, infarction has likely occurred rather than reversible ischemia and compression. The chances of successfully removing or alleviating a supratentorial mass are small once the midbrain stage is reached.

Patients who develop midbrain and upper pons failure exhibit a sustained tachypnea; pupils dilate to a fixed midposition (3 to 5 mm), and oculovestibular reflexes become difficult to obtain, requiring side-to-side head movements and cold caloric irrigation. Disconjugate eye movements appear with failure to adduct (internuclear ophthalmoplegia). Motor responses give way to extensor hypertonus in all limbs (decerebrate rigidity). Midbrain damage results from ischemia and infarction, and few patients recover.

As the brainstem becomes more ischemic, the pupils maintain a fixed position, eye movements are lost, and decerebration gives way to flaccidity. The medullary stage consists of irregular respirations with long periods of apnea. The pupils dilate and the blood pressure falls, with death being inevitable.

Uncal Herniation

Uncal herniation occurs when expanding lesions in the temporal fossa shift the medial temporal lobe (uncus) and the hippocampal gyrus medially over the incisural edge of the tentorium. This flattens the midbrain, pushing it against the contralateral incisura. The third nerve and the posterior cerebral artery on the side of the lesion are caught between the swollen uncus and the free edge of the tentorium (Fig. 62-9 (Figure Not Available) and Fig. 62-10 (Figure Not Available)). The earliest sign is a unilaterally sluggish or slightly dilated pupil. Because the diencephalon may not be the first structure encroached on, impaired consciousness is not consistently present as an early sign of uncal herniation. Other respiratory, ocular, and motor findings may not be appreciably changed from earlier examinations. Pupillary dilation may persist for several hours, but once the patient progresses beyond this stage there is a tendency for midbrain dysfunction to occur rapidly. Ipsilateral external ophthalmoplegia soon follows pupillary dilation along with stupor and coma. Oculovestibular reflexes disappear as ischemia spreads to the midbrain. As the opposite cerebral peduncle is compressed against the tentorial edge, hemiplegia may appear ipsilaterally to the expanding supratentorial lesion (Kernohan's notch). Decerebrate posturing develops, with the opposite pupil becoming dilated and fixed. Progression then proceeds as described for the central syndrome. As with transtentorial herniation, once midbrain failure occurs, survival is much less likely.

Backache and Radicular Symptoms

Minor backache occurs with a frequency of 90% from the trauma of the spinal needle. Frank disk herniation has been reported from the passing of the needle beyond the subarachnoid space into the annulus fibrosis. Transient sensory symptoms from irritation of the cauda equina are also common.

Other reported complications include transient unilateral or bilateral sixth nerve palsies caused by stretching or displacement of the abducens nerve as it crosses the petrous ridge of the temporal bone, subarachnoid hemorrhage, subdural and epidural hematoma, anaphylactoid reactions to local anesthetics, settling of cord tumors, and retroperitoneal abscess produced by dural laceration in patients with meningitis. [75] [128] Most of these are rare and seldom encountered.

Most of the complications of lateral cervical and cisternal puncture are similar to those encountered with a lumbar puncture. In addition, perforation of a large vessel with resultant cisterna magna hematoma or obstruction of vertebral artery flow has been described. Puncture of the medulla oblongata may cause vomiting or apnea, and puncture of the cord may be associated with pain. Long-lasting side effects of cord puncture are probably minor. [146] In addition, traumatic tap and post-spinal puncture headache may occur with lateral cervical and cisternal puncture.

Figure 62-8 (Figure Not Available) Intracranial shifts from supratentorial lesions. *A,* The relationships of the various supratentorial and infratentorial compartments are seen in a coronal section. *B,* Central transtentorial herniation. A patient with carcinoma of the lung and multiple cerebral metastases (none is apparent in this section) died after developing signs and symptoms of the central syndrome of rostral-caudal deterioration. The brain is swollen, the diencephalon is compressed and elongated, and the mammillary bodies lie far caudad to those in the normal brain. Neither the cingulated gyrus nor the uncus is herniated. *C,* Uncal and transtentorial herniation. A patient developed a massive hemorrhagic infarction and died after developing the syndrome of uncal herniation. The cingulated gyrus is herniated after the falx; there is hemorrhagic infarction of the opposite cerebral peduncle and marked swelling and grooving of the uncus on the side of the lesion. Central downward displacement is also present but is less marked than in *B*. *(From Plum F, Posner J: The Diagnosis of Stupor and Coma. Philadelphia, FA Davis, 1980.)*

INTERPRETATION

Pressure

The pressure of the CSF is of great clinical importance. Although, it will occasionally be logistically impossible to obtain, it should be accurately measured whenever feasible. Accurate measurement is dependent on patient cooperation and in the struggling or agitated patient, measurements may be inaccurate. In such cases, sedation may provide more accurate readings. Elevated pressures are abnormal. Opening pressure is taken promptly, avoiding falsely low values due to leakage through and around the needle. Normal pressure is between 70 and 180 mm H_2O. Herniating cerebellar tonsils may occlude the foramen magnum and prevent increased ICP from being reflected in the lumbar pressure reading. Increased ICP can result from expansion of the brain (edema, hemorrhage, or neoplasm), overproduction of CSF (choroid plexus papilloma), a defect in absorption, or obstruction of flow of CSF through the ventricles. Cerebral edema may be associated with meningitis, CO_2 retention, subarachnoid hemorrhage, anoxia, congestive heart failure, or superior vena cava obstruction. Pressure may be falsely elevated in a tense patient, when the head is elevated above the plane of the needle, and, possibly, with marked obesity or muscle contraction. [39] Pressure is not usually measured in the neonate, because a struggling or crying child will have a falsely elevated pressure. The upper limits of normal are 50 mm H_2O in neonates and 85 mm H_2O in infants and young children. [80] Although the manometer reading is falsely elevated in the sitting position, the level should not rise above the foramen magnum in the child.

Low pressure should suggest obstruction of the needle by meninges. Low pressure can also be seen with spinal block. Rarely, a primary low-pressure syndrome occurs in a setting

Figure 62-9 (Figure Not Available) The floor of the anterior and middle fossae, illustrating the tentorial notch and the way in which the third nerve (Oculomoter N.) passes between the posterior cerebral and superior cerebellar arteries over the petroclinoid ligaments. *(From Plum F, Posner J: The Diagnosis of Stupor and Coma. Philadelphia, FA Davis, 1980.)*

of trauma, following neurosurgical procedures, secondary to subdural hematomas in elderly patients, with barbiturate intoxication, and in cases of CSF leakage through holes in the arachnoid. [97] [116]

The Queckenstedt test is useful for demonstrating the presence of obstruction in the spinal subarachnoid space. [39] [130] The test is seldom performed today, because myelographic techniques have been refined and the availability of MRI has reduced the number of myelograms and associated lumbar puncture studies. With the patient in the lateral recumbent position, jugular vein compression causes decreased venous return to the heart. This distends cerebral veins and causes a rise of ICP, which is transmitted throughout the system and is measured in the manometer. After 10 seconds of bilateral compression, CSF pressure usually rises to 150 mm H_2O over the initial reading and returns to the baseline in 10 to 20 seconds after release. If there is no change in the lumbar pressure or if the rise and fall are delayed, it should be concluded that the spinal subarachnoid space does not communicate with the cranial subarachnoid space. In this situation, Pantopaque should be injected before needle removal to facilitate subsequent performance of a myelogram. This is necessary because the lumbar dural sac may collapse, making it impossible to reenter the canal. If cervical cord disease is suspected, the test should be repeated with the neck in the neutral position, hyperextended, and flexed. When lateral sinus obstruction is suspected, unilateral jugular venous compression may be used (Tobey-Ayer test).

Appearance

If the CSF is not crystal clear, a pathologic condition of the CNS should be suspected. The examiner should compare the fluid with water, viewing down the long axis of the tube or holding both tubes against a white background. A glass tube is preferred, because plastic tubes are frequently not clear. The fluid may be clear with as many as 400 RBCs/µL and 200 WBCs/µL. [39]

Xanthochromia is a yellow-orange discoloration of the supernate of centrifuged CSF. Xanthochromia is generally considered to be the result of subarachnoid hemorrhage of at least a few hours duration and has been used to differentiate prior bleeding from a traumatic tap. A traumatic tap usually does not exhibit xanthochromia (see traumatic tap). Xanthochromia is produced by red cell lysis and is caused by one or more of the following pigments: oxyhemoglobin, bilirubin, and methemoglobin. Oxyhemoglobin causes red coloration; bilirubin, yellow; and methemoglobin, brown. Oxyhemoglobin is seen within 2 hours of subarachnoid bleeding and red cell lysis. Formation reaches a maximum in 24 to 48 hours after hemorrhage and disappears in 3 to 30 days. [130] The appearance of bilirubin in the CSF involves the conversion of oxyhemoglobin by the enzyme heme oxygenase. The enzyme is found in the choroid plexus, the arachnoid, and the meninges. Enzyme activity appears approximately 12 hours after the hemorrhage. [130] Bilirubin may persist for 2 to 4 weeks. Bilirubin in CSF caused by hepatic or hemolytic disease does not appear until a serum level of 10 to 15 mg total bilirubin per 100 mL is reached, unless underlying disease associated with a high CSF protein is present. Xanthochromia may be seen with CSF protein values above 150 mg/dL. CSF may clot with complete spinal block and very high CSF protein.

Oxyhemoglobin and bilirubin may be measured chemically or by spectrophotometric analysis. Demonstration of these compounds in CSF may help in the distinction between recent intracranial hemorrhage and a traumatic tap. Oxyhemoglobin may form as a result of red cell lysis if the tube has been allowed to stand for more than 1 hour before testing. Groves and Sidman noted that an RBC concentration of 5,000/µL created by addition of RBCs to a cellular CSF fluid will produce spectrophotometrically evident xanthochromia by 2 hours. [48] The addition of RBCs to form RBC concentrations of 20,000/µL and 30,000/µL will produce xanthochromia by 1 hour or immediately, respectively.

Figure 62-10 (Figure Not Available) The undersurface of the forebrain in transtentorial herniation. Compare the positioning of cranial nerve *III* and the adjacent posterior cerebral artery as well as the shape of the midbrain with those in Figure 62-8 (Figure Not Available) . Large arrows point to the edge where the hippocampus herniated through the tentorium. *Small arrows* and the *dotted line* indicate the lateral shift of the mesencephalon, which produces a hemorrhagic Kernohan's notch at point *K*. *(From Plum F, Posner J: The Diagnosis of Stupor and Coma. Philadelphia, FA Davis, 1980. Reproduced by permission.)*

Methemoglobin is a reduction product of oxyhemoglobin characteristically found in encapsulated subdural hematomas or in old intracerebral hematomas.

Cells

The technique involved in cell counts is reviewed elsewhere. [39] WBC counts over 5 cells/µL should be taken to indicate the presence of a pathologic condition. In a study of 135 normal university students, Tourtellotte and Shorr reported almost exclusively lymphocytes and monocytes, and the presence of one to five lymphocytes in the CSF may be normal. [130] On the other hand, neonatal CSF may show up to 32 WBCs/µL with prominent neutrophils, while infants 4 to 8 weeks old may have 22 WBCs/µL. [12] It has been stated that polymorphonuclear leukocytes are never seen in normal adults. However, with the use of the cytocentrifuge, an occasional specimen may show a neutrophil in an otherwise normal individual. [52] Such a finding should routinely prompt culture of the CSF, because the presence of a neutrophilic pleocytosis is commonly associated with bacterial infections or the early stages of viral infections, tuberculosis, meningitis, hematogenous meningitis, and chemical meningitis due to foreign bodies.

As many as 30% of patients may exhibit CSF pleocytosis after a generalized or focal seizure. In a review of 102 patients without CNS infection who had lumbar puncture within 48 hours of a seizure, Prokesch et al [94] reported an average of 72 cells/mm^3 , noting the presence of both polymorphonuclear and mononuclear cells. Although these patients did not have CNS infection, many did have serious intracranial pathologic processes (subdural hematoma, subarachnoid hemorrhage, or stroke). This finding should prompt a search for infection and assessment of the seizure as being possibly secondary to an underlying neurologic disorder.

Small lymphocytes may be seen in normal individuals. Small and large immunocompetent cells are found with a variety of bacterial, fungal, viral, granulomatous, and spirochetal diseases as well as with the presence of foreign substances.

Eosinophils are always abnormal and most commonly represent a parasitic infestation of the CNS. They may also be seen after myelography and pneumoencephalography and, to a minor degree, in other inflammatory diseases, including tuberculous meningitis and neurosyphilis. CSF eosinophilia has also been reported in cases of subarachnoid hemorrhage, lymphoma, Hodgkin's disease, brucellosis, fungal meningitis, *Mycoplasma pneumoniae* infection, measles, lymphocytic choriomeningitis, rickettsial infections, leukemia, demyelinating diseases, sarcoidosis, acute inflammatory demyelinating polyneuropathy, allergic reactions, and idiopathic eosinophilic meningitis. [69]

Normal CSF RBCs are <10/µL. Counts up to 100/µL that are otherwise unexplained may be due to a traumatic tap. Herpes simplex virus encephalitis may elevate the CSF RBC count in many patients. Myeloid and RBC precursors may contaminate CSF with bone marrow cells from an adjacent vertebral body. [68]

Glucose

Glucose enters the CSF by way of the choroid plexus as well as by transcapillary movement into the extracellular space of the brain and the cord by carrier-mediated transport. It then equilibrates freely with the CSF subarachnoid space. Fishman [39] concluded that a low CSF glucose concentration indicates increased glucose use in the brain and the spinal cord and, to a lesser degree, by polymorphonuclear leukocytes, bacteria, and inhibition of membrane carrier systems. Once in the CSF, glucose undergoes glycolysis and there is an invariable rise in CSF lactate levels. Glucose levels remain subnormal for 1 to 2 weeks after the effective treatment of meningitis.

The normal range of CSF glucose is between 50 and 80 mg/dL, which is 60% to 70% of the glucose concentration in the blood. Ventricular fluid glucose levels are 6 to 8 mg/dL higher than in lumbar fluid. A ratio of CSF to blood of <0.5 or CSF levels <40 mg/dL are invariably abnormal. The ratio is higher in infants for whom a ratio of <0.6 is considered abnormal. Hyperglycemia may mask a depressed CSF glucose level, and the CSF to blood glucose ratio should be measured routinely. With extreme hyperglycemia a ratio of 0.3 has been suggested as being abnormal. [49] Between 90 and 120 minutes is required before the CSF glucose reaches a steady state with blood glucose changes (e.g., after the intravenous injection of glucose). When CSF glucose is of diagnostic importance, CSF and blood samples ideally should be obtained after a 4-hour fast.

Low CSF glucose levels may be found in several diseases of the nervous system (Table 62-2). Only low concentrations of glucose are of diagnostic value, and elevated CSF

glucose levels generally have no significance; elevation usually reflects hyperglycemia. A rapid estimate of the CSF glucose level can be obtained by using bedside reagent strip testing with a commercial autoanalyzer. However, formal laboratory testing is recommended for confirmation of bedside levels.

Protein

The normal range of the lumbar CSF protein level is 15 to 45 mg/dL. Infants normally have a lower level than adults, and protein levels may drop after a lumbar puncture. The concentration is lower in the ventricles (5 to 15 mg/dL) and the basilar cisterns (10 to 25 mg/dL), reflecting a gradient in the permeability of capillary endothelial cells to proteins in the blood. Levels of CSF protein in premature infants and full-term neonates is higher than in adults with a mean of 90 mg/dL; protein levels decline by age 8 weeks, reflecting maturation of the blood-brain barrier. Most of the proteins in CSF normally come from the blood, which normally has a protein concentration of up to 8000 mg/dL. Protein entry is determined by its molecular size and the relative impermeability of the blood-CSF barrier. A full range of serum proteins are found in CSF at several hundred-fold dilution. Faulty reabsorption of protein by arachnoid villi may also elevate protein levels. Increases in CSF total protein levels are a nonspecific abnormality associated with many disease states. Levels higher than 500 mg/dL are uncommon and are seen mainly in meningitis, in subarachnoid bleeding, and with spinal tumors. The high levels seen with cord tumors result from an increase in local capillary permeability. With high levels (generally 1000 mg/dL), CSF may clot (Froin's syndrome).

Hemorrhage into the CSF or the introduction of blood by a traumatic tap increases CSF protein levels. If the serum protein is normal, the CSF protein should theoretically rise by 1 mg/dL for every 1000 red cells, but this is variable. The inflammatory effect of hemolyzed RBCs may also significantly increase CSF protein.

Selective measurement of immunoglobulin fractions in CSF has proved to be of diagnostic value in suspected cases of multiple sclerosis. Elevated CSF immunoglobulin levels may reflect blood-brain barrier disruption or local antibody response to a CNS immune response. [141] Stimuli may be infectious or antigenic, producing an inflammatory response. Immunoglobulin elevation has been found in many chronic inflammatory conditions, including syphilis, viral encephalitis including HIV infection, subacute sclerosing panencephalitis, progressive rubella encephalitis, tuberculous meningitis, sarcoidosis, cysticercosis, and acute inflammatory demyelinating polyneuropathy (Guillain-Barré syndrome).

The Traumatic Tap

The incidence of a traumatic tap is 10–15%, depending on the cut off of RBCs used to define the condition. A cutoff of 400 RBCs/µL is commonly used. It is often possible to distinguish between subarachnoid bleeding and bloodshed by the spinal needle if certain steps are taken *at the time of the initial puncture*. In traumatic punctures the fluid generally clears between the first and third tubes as the needle is washed by CSF. Decreasing cell counts on the first and third tubes help confirm this. In a recent hemorrhage, however, a declining cell count may represent layering of cells in a recumbent patient. The fluid should then be centrifuged. With moderately blood-stained fluid, the supernatant should be clear if the RBCs have been present for =2 hours (traumatic tap). Red cells undergo hemolysis in the CSF after a few hours to produce xanthochromia. Xanthochromia persists for up to 4 weeks, depending on the number of RBCs that were originally present. An early CSF examination may show clear fluid before the development of hemolysis, even after spontaneous subarachnoid bleeding. However, xanthochromia may be measured

immediately after a traumatic tap if the RBC count exceeds 30,000/µL. [48] The presence of a clot in one of the tubes strongly favors a traumatic tap.

In subarachnoid hemorrhage, clotting does not occur because blood is defibrinated at the site of the hemorrhage. Any lumbar puncture performed several days after a traumatic tap may yield stained fluid. An immediate repeat puncture at a higher interspace yielding clear CSF may also help distinguish a traumatic tap. The fluid from a traumatic tap should contain about 1 WBC per 700 RBCs if the complete blood cell count is normal, but this ratio is highly variable. Formulas to assess the contribution of total CSF cell count and protein values from traumatic taps have been proposed but do not have uniform support. [85] [86] Indeed, Bonadio and colleagues[11] suggested that children with meningitis and traumatic taps (i.e., RBC count =1000/µL) generally have other features of meningitis besides an observed-to-predicted WBC ratio of 10 or more (e.g., predominance of neutrophils, low CSF-to-serum-glucose ratio, positive Gram stain). All blood-contaminated CSF should be cultured, especially from uncooperative infants and children being evaluated for sepsis.

Lang and colleagues suggest the use of a D-dimer test on CSF to identify subarachnoid hemorrhage. [73] Although identifying local fibrinolysis, other conditions such as disseminated intravascular coagulation, a previous traumatic tap, or prior thrombolytic therapy may produce false-positive test results. Eskey and Ogilvy [34] have suggested that the routine use of fluoroscopy-guided lumbar puncture in patients with suspected subarachnoid hemorrhage and negative CT scan would reduce the frequency of traumatic punctures.

CSF Analysis with Infections

Bacterial Infections

The CSF findings are essential in establishing a provisional diagnosis of acute bacterial meningitis. CSF analysis establishes the diagnosis, the causative organism, and the choice of antibiotics. CSF must be transported to the laboratory immediately and examined at once. CSF cells begin to lyse within 1 hour of collection, but this may be slowed by refrigeration. In cases of meningococcal infection, a delay in processing may cause the diagnosis to be missed, because the organism

tends to autolyze rapidly. Speed is only slightly less important with other organisms, because early initiation of antibiotic therapy is crucial.

The Gram stain is of great importance, because this often dictates the initial choice of antibiotic therapy. Gram-negative intracellular or extracellular diplococci are indicative of *Neisseria meningitidis*. Small gram-negative bacilli may indicate *Haemophilus influenzae*, especially in children. The presence of gram-positive cocci indicates *Streptococcus pneumoniae*, other *Streptococcus* species, or *Staphylococcus*. Twenty percent of Gram stains may be falsely negative because too few organisms are present. The Gram stain smear is more likely to be positive in patients who have not received prior antibiotic therapy. Acridine orange stain may improve the yield in bacterial infections with negative Gram stains. [62]

For culture, blood and chocolate agar are required. *N. meningitidis* and *H. influenzae* grow best on chocolate agar. The plates are incubated under 10% CO_2. Thioglycolate medium is used for possible anaerobic organisms. Cultures are examined at 24 and 48 hours, but plates should be kept for at least 7 days. Large volumes of CSF may improve yields.[117]

While the culture is pending, one may suspect a bacterial infection in the presence of an elevated opening pressure and a marked pleocytosis ranging between 500 and 20,000 WBCs/µL.[22] The differential count with bacterial infections is usually composed chiefly of neutrophils. A count of more than 1000 cells/µL seldom occurs in viral infections. Occasionally, acellular fluid may be found in the severely immunosuppressed patient or others with appropriate presentations. Repeat lumbar puncture may be required in febrile patients in whom the clinical features remain compatible with meningitis. [49] [100] [138]

CSF glucose levels =40 mg/dL or less than 50% of a simultaneous blood glucose level should raise the question of bacterial meningitis, even in the presence of a negative Gram stain and a low cell count. Glucose levels with bacterial meningitis are occasionally below 10 mg/dL; levels are normal in 9% of bacterial meningitis. [49]

The CSF protein content in bacterial meningitis ranges from 500 to 1500 mg/dL and usually returns to normal by the end of therapy. CSF protein values above 220 mg/dL virtually ensure an acute meningitis of being bacterial. Of note, prior antibiotic therapy may adversely affect the sensitivity of cultures and Gram stains for bacterial meningitis but does not significantly affect WBC counts, CSF to blood glucose ratios, or CSF protein values. [118] Spanos and colleagues[123] have developed a useful nomogram to help distinguish bacterial from viral infections (Fig. 62-11 (Figure Not Available)).

A useful test that can be performed in nearly all laboratories is the measurement of CSF lactate dehydrogenase (LDH) levels. In bacterial and fungal meningitis, LDH levels are increased.[7] The LDH level may be elevated even in patients who have received antibiotics for 1 or 2 days. The LDH levels in viral infections tend to be normal, whereas values in bacterial meningitis are usually two to four times greater than the normal concentration of approximately 1.6 mEq/L.

A study by Durack and Spanos questions the use of repeat spinal taps as a test of meningitis cure. [27] Their review of 165 meningitis cases revealed 13 instances in which the repeat tap led to unnecessary intervention and 2 others in which treatment failure was *not* detected by the repeat spinal tap.

Microbial Antigens and Polymerase Chain Reaction

Several tests other than CSF culture and Gram stain are available to establish a bacterial etiology of meningitis. These include blood cultures, CSF counterimmunoelectrophoresis (CIE), CSF latex agglutination (LA), and coagglutination counterimmunoelectrophoresis. [82] All of the ancillary tests have a low sensitivity for bacterial meningitis, thus limiting their use. In 50 to 80% of bacterial meningitis cases, blood cultures are positive for the etiologic agent. [125]

CIE uses wells in two rows of agarose gel. A different antiserum is placed in each well. A current is passed through the gel with the reactants then moving toward each other by electrophoretic mobilization of the antigen. A line of precipitation visualized in 1 to 4 hours represents positive reaction between antiserum and antigen.[28] Commercial kits are available to detect *S. pneumoniae; Listeria monocytogenes; H. influenzae; N. meningitidis* A, B, and C and W135; group B *Streptococcus*; K1 strains of *Escherichia coli; Klebsiella*; and *Pseudomonas* species.[63]

Particle agglutination involves staphylococcal coagglutination and latex agglutination. Antibody on the surface of a colloid combines with antigen-binding sites to cross-link the colloid-forming antigen bridges. A matrix forms and appears as a macroscopic agglutination. Agglutination tests can detect approximately 10 times less antigen than CIE. False-positive tests can occur in the presence of rheumatoid factor, serum complement components, and possibly other serum proteins. The technique may be used in infections due to *H. influenzae, S. pneumoniae, N. meningitidis*, and group B *Streptococcus*.

Another technique having some potential use is the enzyme-linked immunosorbent assay. This technique may detect 100 to 1000 times less antigen than agglutination tests but is technically more difficult and requires 4 hours to perform.

A positive CSF antigen test may be expected in 70% to 90% of patients with *Neisseria* meningitis. This compares with a positive Gram stain in approximately 70% of patients. Positive latex antigen tests have been reported in approximately 60% of *S. pneumoniae* meningitis cases, with a positive Gram stain in 80%. A positive latex test and Gram stain are reported in approximately 85% of *H. influenzae* meningitis cases.[28] [125] Group B *Streptococcus* can be detected with a 60 to 90% sensitivity. The Gram stain may be difficult to assess after antibiotic therapy has been initiated. Bacterial antigens may persist in the CSF for several days after antibiotic therapy. Twenty-five percent to 33% of positive tests are lost per day in the setting of appropriate antimicrobial therapy. A negative test, however, does not rule out bacterial meningitis.[63] In addition, blood and urine should be examined for antigen. Often, antigen may be found only in the urine. Urine needs to be concentrated and may have the disadvantage of reflecting urinary tract infections. The particle agglutination test for *H. influenzae* type B may be positive for up to 10 days after children have received *H. influenzae* polysaccharide vaccine. Antigen tests are not useful in diagnosing gram-negative bacillary, staphylococcal, and *Listeria* meningitis. In addition, although antigen tests may identify the bacterial pathogen, they do not provide information about the antibiotic susceptibility of the organism.

Future use of polymerase chain reaction (PCR) will aid the rapid diagnosis of CNS infection when results of current techniques are suboptimal. PCR is a method for amplifying target nucleic acid in CSF by use of repeated cycles of DNA

Figure 62-11 (Figure Not Available) Nomogram for estimating the probability of bacterial (ABM) versus viral (AVM) meningitis in immunocompetent host. Step 1: Place the ruler on reading lines for the patient's age and month of presentation, and mark the intersection with line A. Step 2: Place the ruler on the values for the glucose ratio and total polymorphonuclear leukocyte (PMN) count in cerebrospinal fluid, and mark the intersection with line B. Step 3: Use the ruler to join the marks on lines A and B, and then read off the probability of ABM versus AVM. *(From Spanos A, Harrell FE Jr, Durack DT: Diagnosis of acute meningitis: An analysis of the predictive value of initial observations. JAMA 262:2700, 1989. Copyright 1989, American Medical Association. Reprinted by permission.)*

synthesis. PCR requires use of flanking DNA sequences at the opposite ends of the target DNA. Synthetic primers anneal to their respective recognition sequences at the opposite end of the target sequence; they serve as primers for new DNA synthesis. PCR allows detection of and quantification of organisms whose genetic material is DNA or messenger RNA. PCR permits the diagnosis of infectious disease with a high degree of sensitivity and specificity and allows rapid reliable detection of microbes present in small numbers. Laboratory false-negative and false-positive results may occur. PCR is only available at limited centers, although this seems likely to change in the near future.[89]

Empirical Antibiotic Use Before Lumbar Puncture

Many patients are transported to a referral center or within a facility for a CT scan to rule out an intracranial mass after a clinical concern for meningitis is raised. In such instances, CSF examination may not be performed before transport. This may be due to technical problems (uncooperative or large patient) or concerns regarding safety of lumbar puncture in an obtunded patient with possible increased ICP. [49] [80] The initial clinician may have to decide whether to initiate empirical antibiotic therapy. Prior antibiotic administration could obscure the bacterial etiology, whereas a delay in initiating therapy may increase the morbidity and mortality of the illness. It may be difficult to identify individuals at risk for a fulminant course, and the diagnosis of bacterial meningitis cannot always be made with confidence; some cases may be misdiagnosed as subarachnoid hemorrhage or metabolic encephalopathy.

Talan and associates[125] noted that parenteral antibiotic treatment decreases the percentage of positive CSF cultures by 4 to 33% and of positive CSF Gram stains by 7 to 41%. A minimum window of 2 to 3 hours exists after giving parenteral antibiotics when CSF cultures are not adversely affected. After 24 hours post treatment, as many as 38% of meningitis patients may still have positive CSF cultures. Kanegaye et al [61] demonstrated that CSF sterilization may be dependent on the infecting organism. They reported CSF sterilization post antibiotics within the following time frame for various organisms: Meningococcal (<2 hrs), pneumococcal (<4.3 hrs) and Group B streptococcal (>8 hrs).

When CSF is cultured more than several hours after parenteral antibiotics are administered, antigen tests may be of help. Of course, blood cultures should be obtained immediately before antibiotic administrations whenever possible. Occasionally, patients may develop a lymphocytic pleocytosis with antibiotic therapy; but in most cases, cell count, differential, glucose, and protein concentrations are not changed in the first 2 to 3 days of antibiotic therapy. [49] Although there are no data to confidently address the potential advantages or disadvantages of antibiotic therapy before lumbar puncture, it is reasonable to initiate therapy on the premise that a delay may be deleterious. If a lumbar puncture cannot be done, consultation with clinicians at the referral center would seem appropriate. If a lumbar puncture is performed before a transfer, a portion of the CSF (chilled on ice) should be sent with the patient or held in the referring hospital laboratory.

Bacterial meningitis occurring in children younger than 10 years of age historically has been often due to *H. influenzae*. Fortunately, *H. influenzae* appears to be easier

to grow from early postantibiotic cultures and is more likely to be associated with positive blood cultures and antigen tests. In the pediatric population a single dose of antibiotic before transport is unlikely to prevent bacterial identification. In neonates, adults, and immunosuppressed patients, the sensitivity of blood cultures and immunologic tests is less reliable. CSF examination before antibiotic administration or *early* in the course of treatment is preferred.

For suspected or confirmed cases of acute bacterial meningitis, antimicrobial therapy can be started based on the most likely causative organism based on age of the subject, associated diseases, and renal function.

For immunocompromised and postneurosurgical patients, a third-generation cephalosporin (cefotaxime, ceftizoxime, ceftazidime, or ceftriaxone) plus ampicillin and vancomycin should be used for coverage against staphylococci, *L. monocytogenes*, and gram-negative organisms.[82] Table 62-3 Table 62-4 Table 62-5 offers guidelines for emergency antibiotic therapy. The third-generation cephalosporins are efficacious in many empirical regimens or situations where the organism is known. To rely on third-generation cephalosporins alone for all cases of bacterial meningitis would result in treatment failures of all *Listeria* species and increasing numbers of *Enterobacter, Serratia*, and *Pseudomonas* groups. Treatment with older agents may be as or more effective in bacteria demonstrating appropriate sensitivity.

Dexamethasone Therapy in Bacterial Meningitis

Studies have suggested benefit from adjunctive dexamethasone therapy in reducing neurologic sequelae, especially hearing loss, in children with *H. influenzae* meningitis and for a lower mortality and a better overall outcome in adults with acute bacterial meningitis. [23] There appears to be no adverse sequelae from steroid therapy. The adjunctive benefit of corticosteroids during treatment of meningitis caused by other organisms is unknown.

In acute bacterial meningitis, bacterial cell wall components including lipopolysaccharides and teichoic acid initiate

TABLE 62-3 -- Empirical Therapy for Purulent Meningitis*

Predisposing Factor	Antimicrobial Therapy‡
Age	
0–4 wk	Ampicillin plus cefotaxime; or ampicillin plus an aminoglycoside
4–12 wk	Ampicillin plus a third-generation cephalosporin†
3 mo to 18 yr	Third-generation cephalosporin† ; or ampicillin plus chloramphenicol
18–50 yr	Third-generation cephalosporin† §
> 50 yr	Ampicillin plus a third-generation cephalosporin†
Immunocompromised state	Vancomycin plus ampicillin plus ceftazidime
Basilar skull fracture	Third-generation cephalosporin†
Head trauma; postneurosurgery	Vancomycin plus ceftazidime
Cerebrospinal fluid shunt	Vancomycin plus ceftazidime

*Consider corticosteroids prior to antibiotic administration (see text).
‡Vancomycin should be added to all empirical therapeutic regimens when highly penicillin- or cephalosporin-resistant strains of *Streptococcus pneumoniae* are suspected.
†Cefotaxime or Ceftriaxone.
§Add ampicillin if meningitis caused by *Listeria monocytogenes* is suspected.

TABLE 62-4 -- Recommended Dosages of Antimicrobial Agents for Meningitis in Adults with Normal Renal and Hepatic Function

Antimicrobial Agent	Total Daily Dose (IV)	Dosing Interval (hours)
Ampicillin	12 g	4
Cefotaxime	8–12 g	4–6
Ceftazidime	6 g	8
Ceftriaxone	4 g	12–24
Chloramphenicol*	4–6 g	6
Gentamicin†	3–5 mg/kg	8
Tobramycin†	3–5 mg/kg	8
Vancomycin†	2–3 g	8–12

*High dose recommended for pneumococcal meningitis.
†Need to monitor peak and trough serum concentrations.

and exacerbate the host response. These stimulate the production of cytokines, including interleukin-1 and tumor necrosis factor, from macrophages and monocytes. Cytokines may injure vessels, diminish cerebral perfusion, and stimulate cerebral swelling. [80] The dosage of dexamethasone is 0.15 mg/kg (10 mg IV in adults) every 6 hours for 4 days. When used, it is recommended that the corticosteroid *be given before antibiotic use*. Benefit in adults is less certain but experimental data in children would seem to support corticosteroid use, with caution being exercised in immunocompromised or leukopenic patients. A moderate inflammatory response in the meninges is required for penetration of the CNS by many antibiotics. Reducing meningeal inflammation will reduce the concentration of antibiotics in the CSF. Corticosteroids should be discontinued after approximately 4 days of treatment, at which time meningeal inflammation has been reduced by antibiotics. [87] [95]

Although an intriguing concept, the actual benefit from adjunctive corticosteroids is controversial. Current data do not allow for definitive recommendations regarding the use of corticosteroids in bacterial meningitis. With the increasing use of *H. influenzae* and *S. pneumoniae* vaccines, the role of corticosteroids in bacterial meningitis becomes less clear.

Neurosyphilis

The true incidence of this disease is unknown. Approximately 5000 new cases of neurosyphilis are estimated to occur in the United States each year. [55] The natural history and clinical manifestations have been modified in the antibiotic era. The widespread use of oral antibiotics has changed neurosyphilis into a chronic partially treated meningitis. Partial therapy may clear peripheral infection and attenuate the immune response. Therapy may be sufficient to mininimize symptoms but insufficient to eradicate organisms in the CNS and eye, which may then multiply. In the preantibiotic era, seizures were considered to complicate general paresis only late in the course of the illness. Previously, seizures were reported as an early manifestation in less than 5% of symptomatic neurosyphilis cases. More current reports indicate seizures occur in 25% of symptomatic cases and may, on occasion, be the sole manifestation of neurosyphilis. [55] Seizures are usually partial (focal), with one third of patients having no interictal clinical findings. A treponemal serologic test should be obtained in every adult with acquired partial seizures.

Ophthalmologic findings are frequently present in syphilis. These include a slowly progressive optic atrophy, an acute optic neuritis, cranial oculomotor neuropathy, and a

TABLE 62-5 -- Recommended Dosages of Antimicrobial Agents for Meningitis in Neonates, Infants, and Children with Normal Renal and Hepatic Function

	Total Daily Dose IV (Dosing Interval in Hours)		
Antimicrobial Agent	***Neonates (0–7 d)****	***Neonates (8–28 d)****	***Infants and Children***

*Smaller dosages and longer intervals of administration may be advisable for very low birth weight neonates (<2000 g).
†Need to monitor peak and trough serum concentrations.

chorioretinitis. A more specific sign is a dissociated pupillary response to light and convergence with loss of the light reflex (Argyll Robertson pupil).

Meningovascular neurosyphilis involves infection of both the meninges and the cerebral vasculature. The clinical picture is that of a cerebral infarction or an acute meningoencephalitis. Meningovascular syphilis also may present as headache, nausea, vomiting, confusion, stiff neck, and cranial nerve palsies. Arteritis may affect small, medium, or large vessels, producing infarction or ischemia of brain or spinal cord. The peak incidence is 5 to 7 years after initial infection. Tabes dorsalis, general paresis, and gummas occur 10 to 20 years after initial infection.

CSF findings suggestive of neurosyphilis include >5 WBCs/µL, elevated protein concentration, elevated ?-globulin concentration, and a positive serologic test for syphilis. The glucose concentration is usually normal. Higher cell and protein values are seen in early as opposed to late neurosyphilis.

Diagnostic certainty remains difficult. The diagnostic criterion standard is darkfield microscopy to identify morphology and flexing "corkscrew" motility of spirochetes. Serologic tests for syphilis are either treponemal or nontreponemal. Nontreponemal tests detect a nonspecific globulin complex called reagin. Reagin tests, such as the Venereal Disease Research Laboratory (VDRL) flocculation test, lack sensitivity and should not be used to exclude the diagnosis of neurosyphilis. One third to one half of patients with neurosyphilis have a negative VDRL test in the serum, and more than one third have a negative VDRL test in the CSF. [55] CSF VDRL is quite specific with false-positive results seen primarily with traumatic taps.

Treponemal tests provide evidence of a specific immune response to *Treponema pallidum*. These include the serum fluorescent treponemal antibody adsorption (FTA-ABS), microhemagglutination tests for *T. pallidum* (MHA-TP), and the *T. pallidum* hemagglutination assay (TPHA). These assays are believed to remain positive for life. The FTA-ABS and MHA-TP tests may revert to negative in 13 to 24% of patients after therapy for early (primary) syphilis. There is no evidence that these tests revert to negative in untreated disease. [101] The serum FTA-ABS test is the test of choice to confirm the diagnosis of neurosyphilis. The serum FTA-ABS test is reactive in 95 to 100% of cases of neurosyphilis. A negative serum FTA-ABS test makes CSF examination unnecessary. Its false-positive rate is less than 1%, but the incidence of biologic false-positive tests may increase in the presence of collagen vascular disorders.

A positive serum treponemal test indicates past infection with syphilis and may be reactive indefinitely, even after treatment. Therefore, CSF is used as a guide to the

presence and the activity of neurosyphilis. The VDRL test is the test of choice in CSF and, when positive, is strong evidence for neurosyphilis. False-positive CSF VDRL tests are rare. The FTA-ABS test is not used in CSF; the false-positive rate is between 4 and 6% and is believed possibly to represent antibodies that have passively entered from serum.[57] The FTA-ABS test measures IgG antibody and cannot differentiate active from past infection. The CSF VDRL either may be reactive by contamination with seropositive blood (traumatic tap, subarachnoid hemorrhage) or may occur with entry of serum reagin into CSF during meningitis.

There is some concern that today many patients with parenchymal neurosyphilis have normal CSF. This finding leads to the recommendation that a patient with signs of progressive neurosyphilis and a positive treponemal serologic test be treated with antibiotics regardless of the CSF findings. A CSF pleocytosis may be provoked after 1 week of therapy and may supply supportive evidence for a diagnosis of neurosyphilis. PCR may have future applications for diagnosis of neurosyphilis (see the section on neurosyphilis and HIV infection later in this chapter).

Viral Meningitis

The organisms most commonly isolated in viral meningitis are the enteroviruses (coxsackieviruses, echoviruses) and mumps virus. Enteroviruses are most commonly seen in the summer and fall, and mumps appears most frequently in the winter and spring. Viral cultures in most hospitals are not available and play little role in acute decisions regarding diagnosis and treatment. A serial rise in CSF antibody titers may be helpful but may be difficult to obtain in patients who have clinically recovered. Intrathecal production of organ-specific antibodies (IgM, IgG, and IgA isotopes) may be diagnostic of neurologic infection if there is no prior history of infections. This measurement of both serum and CSF antibody titers must be done in a specialized laboratory. Viral meningitis is diagnosed when bacterial culture and Gram stain are negative. A tentative diagnosis may be based on analysis of the CSF.

The WBC count in viral meningitis and encephalitis characteristically shows 10 to 1000 cells/µL. The differential cell count is predominantly lymphocytic and mononuclear in type. In the early stages of meningoencephalitis, however, polymorphonuclear cells may predominate, making the distinction between viral and bacterial infections difficult. In such cases, a repeat tap in 12 to 24 hours will assist in

clarifying the diagnosis. Protein levels are usually mildly elevated, but normal levels may be seen. Antibiotic coverage pending culture results may be reasonably initiated if the diagnosis of viral meningitis is in doubt. [49] The CSF glucose is characteristically normal; however, notable exceptions include some cases of mumps meningoencephalitis and herpes simplex encephalitis. CSF pleocytosis and elevated protein levels have also been found in asymptomatic HIV-seropositive individuals.[18]

If the CSF cannot be delivered to the viral laboratory in 24 to 48 hours, it should be refrigerated at 4°C. Members of the enterovirus group are occasionally isolated from CSF. Herpes viruses and arboviruses are rarely found in CSF. In known viral CNS disease, the stool is more rewarding (85% positive) than CSF (10% positive).[108] Because CSF is normally sterile, any isolate is significant, whereas a stool isolate does not necessarily indicate that the agent is responsible for CNS disease.[117] The PCR is the diagnostic test of choice for herpes simplex meningoencephalitis and PCR will be increasingly applied to the diagnosis of other CNS viral infections.

CSF Analysis in Immunocompromised Patients

The number of immunocompromised individuals is increasing because of the HIV epidemic and the increased survival of patients with cancer and autoimmune disorders. The nervous system is a major target of the HIV virus, with 40 to 60% of infected individuals developing neurologic disease during their lifetime. One third of HIV infected patients will present with neurologic complaints as the initial manifestations of the acquired immune deficiency syndrome (AIDS), and an even higher incidence of nervous system involvement is found at autopsy. [76] Risk of CNS infection depends on the underlying disease, treatment, duration, and type of immune abnormality. Abnormalities include defects in T-lymphocyte and macrophage cellular immune function, defects in humoral immunity, defects in number and function of neutrophils, and loss of splenic function with inability to remove encapsulated bacteria. [109] A summary of the major neurologic manifestations of HIV infection including their clinical characteristics is presented in Table 62-6 .

Patients with defects of their cell-mediated immunity include those with lymphoma, organ transplant recipients, daily corticosteroid therapy, and patients with AIDS. These individuals are vulnerable to infections with microorganisms that are intracellular parasites. The most common source of acute bacterial meningitis in such patients is *L. monocytogenes*. The clinical presentation includes fever, headache, seizures, focal neurologic deficits, and a brainstem encephalitis.

Patients with defective humoral immunity include those with chronic lymphocytic leukemia, multiple myeloma, and Hodgkin's disease after radiotherapy or chemotherapy. These patients have difficulty controlling infection by encapsulated bacteria. They may develop a fulminant meningitis due to *S. pneumoniae, H. influenzae* type b, and *N. meningitidis*. Patients after splenectomy are at risk for the development of meningitis for the same reason. Neutropenic patients are at risk for meningitis due to *P. aeruginosa* and the Enterobacteriaceae.

Establishing a specific diagnosis in HIV and organ transplant patients may be difficult to impossible because of overlapping clinical and radiographic presentations, the presence of simultaneous infections with more than one organism, and CSF changes that may be nonspecific. The immune response may be altered with the absence of signs of meningeal irritation; patients may present with a diffuse encephalopathy or with focal neurologic deficits. CSF is abnormal in 60% of asymptomatic HIV-infected individuals, complicating CSF/clinical correlation. [76]

Neurosyphilis in Patients with HIV Infection

Both syphilis and HIV infection are sexually transmitted diseases, and patients with syphilis are at increased risk of HIV infection. CNS invasion is probably no more common in HIV-infected and HIV-noninfected patients.[81] Both diseases may have elevations in CSF WBC counts, protein levels, and ?-globulin levels. Early CNS infection may be more common in patients with HIV infection. Reports also have noted an increased incidence of syphilitic meningitis, meningovascular syphilis, and ocular syphilis, which has been uncommon in the past. Studies suggest HIV patients treated for syphilis may have viable organisms in CSF after therapy or have persistent CSF VDRL titers. Treatment failures are more likely to occur with single-dose benzathine penicillin therapy.

Diagnosis of neurosyphilis may also be more difficult in HIV-infected patients. A small number of patients with secondary or ocular syphilis have been described with negative serum reagin tests. Positive treponemal tests may revert to nonreactivity after treatment, particularly in individuals with advanced symptomatic HIV disease and a low VDRL titer at the time of diagnosis. CSF pleocytosis and increased ?-globulin levels may not help distinguish between HIV infection and CNS syphilis.

HIV-infected patients should have serum treponemal and nontreponemal tests early in their illness to minimize a false-negative result. [81] Infected patients should undergo a CSF examination. Previously treated patients without a CSF examination at the time of initial syphilis treatment should have a lumbar puncture because of a probable increased risk of neurosyphilis even with a decline in serum nontreponemal titers. Asymptomatic patients with neurosyphilis should be treated to prevent CNS relapse.

Cryptococcal Meningitis

The most common CNS fungal infection is due to *Cryptococcus neoformans*. Approximately 5% of AIDS patients will develop infection with this common fungus. Clinical presentation in AIDS and non-AIDS patients include nonspecific symptoms of headache and altered mental status with or without meningeal signs. Most patients have increased ICP. Immunocompetent patients show a lymphocytic pleocytosis with CSF WBC counts under 500/µL. Glucose levels are depressed with elevation of CSF protein. India ink preparations are positive in 50% of cases. The CSF is less likely to have abnormal cell counts and chemistries in HIV infection. However, CSF cultures and cryptococcal polysaccharide capsular antigens are almost always positive. False-positive antigen tests are rare but may be seen in the presence of rheumatoid factor. Blood cultures are frequently positive in AIDS patients. Cisternal puncture for fluid analysis may be helpful in undiagnosed cases of lymphocytic meningitis in which multiple lumbar punctures have not established a diagnosis. [76]

Toxoplasmosis

Toxoplasma gondii, an intracellular protozoan, is associated with CNS infection in up to 30% of AIDS patients who have

TABLE 62-6 -- Major Neurologic Manifestations of HIV Infection

Diagnosis	CD4+ Count (cells/mm^3)	Presenting Symptoms	Neurologic Signs	Diagnostic Studies	Therapy
HIV dementia	<200	Memory loss, gait disorder, behavioral change	Dementia, spasticity, psychosis	CT/MRI: brain atrophy, white matter abnormalities; CSF: increased $ß_2$ microglobulin	High-dose zidovudine, clinical trial
Toxoplasma encephalitis	<200	Headache, fever, confusion, lethargy, seizures	Dementia, ataxia, hemiparesis	Serum *Toxoplasma* antibodies; CT/MRI: multiple enhancing lesions, edema	Pyrimethamine, sulfadiazine, clindamycin
CNS lymphoma	<100	Headache, confusion, lethargy, memory loss, seizures	Dementia, hemiparesis, aphasia	CT/MRI: enhancing lesions (especially if single); stereotactic biopsy	Radiotherapy
Progressive multifocal leukoencephalopathy	<100	Lethargy, confusion, weakness	Hemiparesis, ataxia, visual disturbance	CT/MRI: multiple hypodense, nonenhancing white matter lesions, stereotactic biopsy	High-dose zidovudine, Ara-C (IV, IT); clinical trial
CMV encephalitis	<50	Rapidly progressive confusion, apathy, weakness	Dementia, cranial neuropathies, spasticity	CT/MRI: periventricular and meningeal abnormalities; CSF: CMV culture, PCR; electrolyte abnormalities	Ganciclovir, foscarnet
Vacuolar myelopathy	<200	Gait dysfunction, lower extremity weakness and stiffness, urinary dysfunction	Spastic paraparesis, Babinski signs, sensory abnormalities	MRI/CSF: normal or nonspecific abnormalities	Baclofen, physical therapy
Cryptococcus neoformans meningitis	<200	Fever, headache, neck stiffness, memory loss	Lethargy, confusion, meningeal signs, cranial nerve palsies	CSF India ink, serum and CSF *Cryptococcus neoformans* antigen and culture	Amphotericin B (plus or minus flucytosine), fluconazole
Neurosyphilis	Any	Headache, memory loss, visual disturbances	Dementia, stroke, meningeal or myelopathic signs, cranial nerve palsies	CSF: increased leukocyte count, increased protein, serum and CSF VDRL	IV penicillin (plus probenecid)
Distal symmetrical polyneuropathy	<200	Distal numbness, parasthesias, pain	Stocking-glove sensory loss, decreased ankle reflexes	EMG: distal axonopathy	Neurotoxin withdrawal, analgesics, tricyclic antidepressants, anticonvulsants, capsaicin
Inflammatory demyelinating polyneuropathy	>500, =50	Progressive weakness, paresthesias	Weakness, areflexia, mild sensory loss	CSF: increased leukocyte count, elevated protein; EMG: demyelination	Early (increased CD4 count): plasmapheresis, IV Ig, steroids. Late (decreased CD4 count): ganciclovir
Manoneuropathy multiplex	>500, =50	Facial weakness, footdrop, wristdrop	Multifocal cranial and peripheral neuropathies	EMG: multifocal axonal neuropathy; nerve biopsy: inflammation, vasculitis, CMV inclusions	Early: none Late: ganciclovir
Progressive polyradiculopathy	<50	Lower extremity weakness, paresthesias, urinary dysfunction	Flaccid paraparesis, saddle anesthesia, decreased reflexes, urinary retention	CSF: increased leukocytes (PMNs), CMV culture, PCR; EMG: polyradiculopathy	Ganciclovir, foscarnet
Myopathy	Any	Muscle weakness, myalgia, weight loss	Proximal muscle weakness	Increased creatine kinase; EMG: irritative myopathy; muscle biopsy: myofiber degeneration, inflammation, inclusions	Zidovudine reduction or withdrawal, corticosteroids

CMV, cytomegalovirus; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; EMG, electromyography; IT, intrathecal; IV, intravenous; IV Ig, intravenous immunoglobulin; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; PMN, polymorphonuclear leukocytes.

From Simpson DM, Tagliati M: Neurologic manifestations of HIV infection. Ann Intern Med 121:770, 1994.

antibodies to *T. gondii*. Most adults have antibodies; infection is believed to represent reactivation of latent primary infection. *Toxoplasma* encephalitis usually develops within the first 2 years after the diagnosis of AIDS. Cerebral toxoplasmosis usually presents with the acute/subacute appearance of focal disease including seizures. MRI or CT scanning often reveals multiple abscesses that may represent multiple pathogens. The distinction between toxoplasmosis and lymphoma may be difficult clinically. Less commonly, the presentation is of a chronic meningitis with confusion, memory loss, and lethargy similar to the AIDS-dementia complex. CSF in these patients is nonspecific with increased protein, mononuclear pleocytosis (<100 cells/µL) and, rarely, reduced glucose concentration. Serum and CSF serologies may be either positive or negative and do not help make a diagnosis, although most patients with encephalitis have detectable IgG antibodies. Diagnosis is usually made based on clinical and imaging responses to antibiotics (pyrimethamine or sulfadiazine) or brain biopsy. Treatment failures with relapse occur in 50% of AIDS patients and 15% to 25% of non-AIDS patients, necessitating lifelong treatment.

Mycobacterial Tuberculosis

CNS mycobacteria infection is almost always the result of infection with *Mycobacterium tuberculosis*. Infection occurs in the setting of disseminated tuberculosis. Atypical *Mycobacterium* infection occurring in HIV-infected individuals uncommonly affects the CNS. Clinical presentation is that of meningitis (particularly involving the basal cistern), encephalitis, or abscess formation. If tuberculosis is suspected, a large volume of CSF (10 mL) is required for adequate culture. The cell count varies from 100 to 400 cells/µL, with a lymphocytic predominance; 30% may show predominantly neutrophils early in the course of infection. Protein levels are elevated (100–500 mg/dL); CSF glucose level may be depressed. Acid-fast stains should be examined by experienced technicians. Fluid is inoculated onto Löwenstein-Jensen medium, and the absence of visible growth on the medium should not be considered negative for 8 weeks. CSF cultures are more sensitive than stains. Many of the current tests for mycobacteria are likely to be replaced by PCR tests. [109]

Primary CNS Lymphoma

The risk of developing CNS lymphoma in an AIDS patient is 2%. Presentation is that of a diffuse encephalopathy, although occasionally focal neurologic deficits occur. Leptomeningeal spread of malignancy is reflected in a modest lymphocytic pleocytosis with slightly elevated protein and decreased glucose. Cytologic yield is

improved by repeat lumbar punctures and submitting large quantities of CSF or sampling fluid by cisternal puncture. [76]

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy is an uncommon disorder in individuals with impaired cell-mediated immunity and is caused by reactivation of the JC papovavirus in the kidney. Progressive demyelination presents as combinations of dementia, blindness, aphasia, hemiparesis, and seizures that progress until death. MRI and CT demonstrate nonenhancing white matter lesions without mass effect. Definitive diagnosis is made by brain biopsy, but CSF may show the presence of myelin basic protein, increased IgG, with acellular or a mild CSF pleocytosis (<50 WBCs/µL). Average survival is 4 months. [109]

Brain Abscess

Brain abscesses also occur in the immune-deficient host. Diverse causes have been described as well as multiple pathogens. Lesions may be difficult to detect by CT with contrast enhancement, particularly if a patient is undergoing corticosteroid therapy and has a diminished host inflammatory response. Organisms reported include *T. gondii, Nocardia asteroides, Cryptococcus neoformans, Mycobacterium* species, aerobic gram-negative bacteria, *Aspergillus* species, *Candida* species, and Zygomycetes.

Cytomegalovirus Infection

Cytomegalovirus may be detected in 30% of brains of HIV-infected persons who come to autopsy. A distinct CNS disorder has not been defined. CSF pleocytosis may be minimal. Retinitis and painful polyradiculopathies are recognized with a prominent CSF pleocytosis in the later condition. [76]

CONCLUSION

A spinal tap should only be performed when the treating clinician believes the CSF specimen or specimens will be of diagnostic or therapeutic value, as in the case of patients with symptomatic pseudotumor cerebri. The procedure is often indicated in the diagnosis of meningitis or subarachnoid hemorrhage. Complications are uncommon, and risks are usually outweighed by the benefit of the procedure. Most contraindications are relative and not absolute, particularly if infection is an overriding consideration.

Chapter 63 - Special Neurologic Tests and Procedures

J. Stephen Huff

Neuro-otologic tests and procedures are used in a variety of clinical scenarios ranging from evaluation of the dizzy patient to diagnosing brain death. Many of these have been replaced by neuroimaging or other tests but there is still utility in bedside testing in selected patients. In addition to caloric testing, the Dix-Hallpike maneuver for diagnosing benign paroxysmal positional vertigo is described and techniques of canalith repositioning are summarized. A new discussion of brain death aimed at the emergency clinician follows, and a brief synopsis of emergency department (ED) testing for myasthenia gravis completes the section.

CALORIC TESTING

An accurate assessment of the comatose patient requires a thorough neurologic examination including careful evaluation of the patient's responses to a variety of external stimuli. In a comatose individual with normal brainstem and cranial nerve function, stimulation of the vestibular labyrinth results in well-described and reproducible extraocular movements. This response is known as *the vestibulo-ocular reflex* and forms the physiologic basis for caloric testing. Caloric testing involves delivering a thermal stimulus to the external auditory canal to activate the labyrinth. Pathologic conditions involving either the vestibular or oculomotor reflex pathways will alter or abolish the usual response to caloric stimulation.

Caloric tests may be performed in both conscious and unconscious patients, depending on the diagnostic circumstances. Quantitative caloric examination is conducted in the awake ambulatory patient for evaluation of possible vestibular dysfunction. This type of testing requires precisely controlled irrigation temperatures and specialized recording devices and is best undertaken in a properly equipped laboratory under the supervision of an experienced neuro-otologist. However, the neurologist, neurosurgeon, or emergency clinician may perform *qualitative* caloric testing in the comatose patient to detect gross disruption of vestibulo-ocular reflex pathways that may indicate structural lesions or metabolic abnormalities affecting the labyrinth, vestibulocochlear nerve, or brainstem. In this clinical setting, ice water is used to provide maximal stimulation of the vestibular system. Such testing needs no special expertise and can be done at the bedside using equipment readily available in the ED. This simple procedure can provide valuable diagnostic and prognostic information necessary for management of the comatose patient.

Background

Brown-Séquard first described the effects of introducing cold water into the ear canal in the mid-19th century. [11] The clinical importance of the phenomenon was first realized in 1906 by Bárány, [3] who developed a caloric procedure using an ice water stimulus. He postulated, correctly, that caloric stimulation of the auditory canal induced the formation of convection currents within the semicircular canals of the vestibular labyrinth.

Standardization of the procedure awaited the introduction of the Fitzgerald-Hallpike technique in 1942. This technique used both warm and cool water stimuli under rigidly specified conditions permitting quantification of normal and abnormal caloric responses. Today, most formal caloric testing of conscious patients is based on variations of the original Fitzgerald-Hallpike procedure. [27]

The value of caloric testing in the assessment of the comatose patient was emphasized by the work of Klingon [49] and Bender and associates.[5] Vaernet[91] and Ethelberg[23] studied the changes in caloric reactions during transtentorial herniation of the brainstem. Blegvad [7] reported the effects of barbiturate intoxication on the vestibulo-ocular reflex.

More recent advances include the development of electronystagmography (ENG), which provides a graphic record of reflex eye movements and permits precise determination of the intensity of the caloric response. [4] Some authorities now advocate performing caloric testing at a single temperature (monothermal calorics) as an equally sensitive and less time-consuming alternative to standard bithermal calorics. [44] Others have investigated the use of heated air as an alternative to traditional water caloric tests.[98]

Physiology and Functional Anatomy

Proper performance and interpretation of the caloric test require a basic understanding of the structure and function of both the vestibular and oculomotor systems. The anatomic pathways underlying the vestibulo-ocular reflex begin in the posterior portion of the labyrinth of the inner ear. The peripheral vestibular apparatus is located within the temporal bone and consists of the utricle, the saccule, and the lateral, anterior, and posterior semicircular canals. Because of its proximity to the external ear canal, the lateral or horizontal canal is of principal interest in caloric testing. The lateral canal is oriented at a 30° angle to the horizontal. Deflections of the cupula due to movement of endolymphatic fluid within the canal result in polarization changes in the underlying hair cell, which in turn are relayed to the afferent limb of the primary vestibular neuron.

Impulses of the primary neuron travel via Scarpa's ganglion and cranial nerve (CN) VIII to the brainstem to synapse with secondary vestibular neurons in the superior and medial vestibular nuclei of the upper medulla and lower pons (Fig. 63-1). Although the connections between the vestibular and oculomotor nuclei in the brainstem are quite complex, two main pathways exist. The direct projection runs from the vestibular complex to the nuclei of CN III and VI via the medial longitudinal fasciculus (MLF) and involves only three neurons: (1) primary vestibular, (2) secondary vestibular, and (3) oculomotor. [89] The indirect projection between these nuclei occurs over multisynaptic circuits in the tegmental reticular formation. [64] Another brainstem structure that contributes to the vestibulo-ocular interaction is the parapontine reticular formation (PPRF), a poorly characterized group of pontine neurons that coordinates both voluntary and involuntary lateral gaze. The PPRF receives multiple inputs, including projections from the vestibular system and the contralateral frontal cortex, and sends output to oculomotor neurons through both

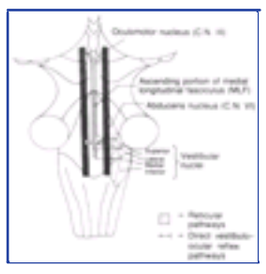

Figure 63-1 Schematic drawing of the brainstem, showing the major elements of the vestibulo-ocular reflex (VOR) pathway. The *solid line* indicates the direct projection between the vestibular nuclei and the third and sixth nuclei. The *stippled area* represents the indirect projections between the nuclei. *(Modified from Barr ML, Kiernan JA: The Human Nervous System—An Anatomical Viewpoint, 5th ed. Philadelphia, JB Lippincott, 1988, p 330.)*

the direct and indirect pathways. Excitatory impulses originating in the lateral canal finally travel via the oculomotor and abducens nerves to the ipsilateral medial rectus and contralateral lateral rectus muscles.

Rotation of the head generates flow of endolymphatic fluid within the semicircular canals. The firing rate of the primary vestibular neuron is dependent on the direction of flow. For example, in the lateral canal, flow toward the ampulla (ampullopetal) increases the firing rate, whereas flow away from the ampulla (ampullofugal) decreases the firing rate.[2] Increased firing on one side results in conjugate deviation of the eyes toward the opposite side, whereas decreased firing causes deviation to the same side. This principle forms the physiologic basis of caloric testing. When the lateral canal is placed in the vertical position and ice water is infused into the ear, the endolymph nearest the canal cools and sinks, resulting in ampullofugal flow (Fig. 63-2 (Figure Not Available)). As the firing rate decreases, the eyes deviate conjugately toward the side of irrigation. If warm water were used in the same position or if the canal were inverted 180° the opposite would occur.

Eye movements induced by caloric stimulation in conscious, neurologically normal individuals are more complex. Ice water infusions induce a rhythmic jerking of the eyes that includes a slow deviation toward the irrigated side followed by a quick compensatory saccade toward the midline. This is known as *caloric nystagmus*. By convention, *caloric nystagmus is named for the fast component,* thus the popular mnemonic "fast COWS" (*C*old irrigation—*O*pposite beating nystagmus; *W*arm irrigation—*S*ame-sided beating nystagmus). Most sources attribute the slow phase of nystagmus to vestibular activity transmitted over the direct pathway, whereas the fast phase is believed to be generated by the PPRF in conjunction with cortical activity and carried over indirect pathways within the reticular formation. Numerous factors, including physiologic, pharmacologic, and pathologic factors, can alter caloric-induced eye movements.

Indications and Contraindications

Caloric testing of the comatose patient is indicated when the clinician needs information regarding the functional integrity of the brainstem. When the cause of the coma is initially unknown, qualitative caloric testing at the bedside may assist in differentiation among structural, metabolic, and psychogenic causes for unresponsiveness. Even when the cause is clear, caloric testing may provide an indication of the depth of coma and the prognosis for eventual recovery.

In conscious patients who complain of vertigo, quantitative caloric testing may be indicated for the nonemergency evaluation of possible vestibular disorders. Ice water produces maximal stimulation of the labyrinth. This can be quite uncomfortable and may induce nausea and vomiting in awake, susceptible individuals. These patients are best referred to a qualified neuro-otologist or audiologist, who may conduct more accurate testing in the ENG laboratory with less discomfort to the patient.

There are few contraindications to caloric testing in the unresponsive patient. An absolute contraindication is the presence of a basilar skull fracture, either documented radiologically or suspected by clinical signs, because of the risk of introducing infection into the central nervous system (CNS) through an associated dural tear. If a basilar skull fracture is discovered to be unilateral, testing of the intact ear with warm then cold water will yield results similar to those of the standard bilateral examination with cold water stimulation.

Relative contraindications to water caloric testing include perforations of the tympanic membrane (those not due to temporal fractures), otitis media and externa, and the presence of previous otologic surgery (e.g., mastoidectomy). Although the risk of causing otitis media is probably small, carrying out the caloric test in the comatose patient under these conditions remains a matter of clinical judgment. When available, auditory evoked potentials may provide an alternative source of information when caloric testing is contraindicated.

Equipment

The equipment needed for performance of the caloric test is minimal and is readily available in the ED or hospital ward. Although almost any size syringe will suffice, a 30- or 50-mL plastic syringe is ideal for irrigation. The syringe may be used as is, or a short length of soft plastic tubing may be attached. A good source of tubing is a butterfly catheter with the needle cut or pulled off. At least 100 mL of ice water should be available, although larger quantities of cool tap water (<25°C) can be used with similar results if ice is unavailable. Sterile or bacteriostatic saline may be used, although no advantage over tap water has been demonstrated. A small, curved, plastic emesis basin is useful to collect water as it drains from the ear canal. Additional required equipment includes an otoscope, several sizes of ear speculums, and equipment for removal of cerumen. Towels and a thermometer that reads from 0° to 50°C may be helpful.

Figure 63-2 (Figure Not Available) The effects of ice water irrigation on the lateral semicircular canal. The cooler endolymph sinks, resulting in ampullofugal flow and decreased neural firing of the primary vestibular neuron. Actual temperature changes within the endolymphatic fluid are on the order of 1° to 2°C. *(Modified from Baloh RW, Honrubia V: Clinical Neurophysiology of the Vestibular System. Philadelphia, FA Davis, 1979, p 133.)*

Procedure

Vestibulo-ocular reflex testing should be deferred until the patient's condition has been stabilized with attention to the airway and evaluation of the cervical spine in trauma patients. A thorough neurologic assessment should be performed prior to caloric testing, with special attention given to the ocular examination. Pupillary responses, spontaneous ocular movements, and resting eye position should be accurately recorded. The ears should be inspected before insertion of the otoscope. If active bleeding or CSF otorrhea or rhinorrhea is noted in the trauma victim, caloric testing and further otoscopic examination should be deferred and the patient should be treated for a probable basilar skull fracture. If the external ear canal appears normal, the otoscopic examination should be completed. Signs of active ear infection or perforation of the tympanic membrane are contraindications to caloric testing. Tympanic rupture, hemotympanum, and step deformities of the canal may indicate fracture of the temporal bone; caloric testing in this situation is contraindicated. Excess cerumen and foreign material must be removed, and the tympanic membrane should be clearly visualized. The ear speculum may be left in the canal as a guide for irrigation.

Though the test is commonly performed with the patient supine, ideally the head or upper body should be raised 30° (two pillows will provide the appropriate angle). The elevation places the lateral canal in the vertical position and ensures a maximal response. The patient should be draped with a towel, and a small basin should be positioned below the ear to collect the water outflow. A container should be filled with ice water and placed near the bedside.

The syringe and catheter system (*minus the needle*) should be filled with 10 mL of ice water, and the irrigation stream should be directed at the tympanic membrane. Because the goal of the qualitative caloric test is to induce a maximum response, the amount and rate of infusion are not critical. As a general guide, 5 to 10 mL of ice water should be initially infused over a period of 5 to 10 seconds; amounts less than 5 mL may be advisable in suspected cases of light coma or psychogenic unresponsiveness. If no response is noted within a moment, at least 100 mL should be infused before declaring that there is no response. Testing of the contralateral ear may begin 5 or 10 minutes after the eyes have returned to their original position. At the conclusion of the testing, the otoscopic examination may be repeated to check for blanching of the tympanic membrane, a sign that the irrigation stream was properly directed.

Observation of eye deviation is easier when an assistant holds the patient's eyelids open. Movement usually occurs after a latency of 10 to 40 seconds, with persistence of the response for as long as 4 to 5 minutes. Small deviations may be detected by focusing on a small scleral vessel. Alternatively, a dermographic pencil may be used to mark the initial position of the pupil with respect to the eyelid.

Variations of the caloric technique may be useful in certain situations. Warm water caloric testing may be performed if no response to bilateral ice water caloric testing is obtained or in cases in which only one ear can be tested. Water temperature should be kept below 50°C. The response elicited will be the opposite of that obtained with ice water. In patients who fail to respond to ice water caloric testing alone, additional stimulation may be obtained by combining irrigation with repeated head turning away from the irrigated side *(doll's-eye maneuver). Obviously, cervical injury must be excluded before using this technique*. This combination of techniques may produce eye movements in patients who do not respond to caloric testing alone.[26] Eviatar and Goodhill[24] have described a technique for caloric testing in tympanic perforations using a small latex finger cot placed in the ear canal to prevent water from entering the middle ear.

Complications

The few complications that are possible with caloric testing can be avoided by carefully selecting both the patients to be tested and the equipment and technique to be used. Using needles or other sharp objects to irrigate the ear may result in laceration or perforation of the tympanic membrane or canal wall if the patient moves unexpectedly. The use of plastic syringes and soft catheter tubing aids in reducing such occurrences.

Other potential complications of caloric testing include otitis media, meningitis, and the induction of vomiting and subsequent aspiration. Ice water irrigation in the presence of tympanic membrane perforation increases the chance of middle ear infection; however, the incidence of this complication following caloric testing has not been reported. Meningitis may follow basilar skull fractures with meningeal tears; the additional risk of calorics in such situations is not known. Therefore, caloric testing should be omitted in the head-injured patient if there is any suspicion of temporal fracture. Although ice water irrigation may produce nausea and even emesis in a few awake patients, vomiting with aspiration has not been reported as a complication of caloric testing in the comatose patient. Nevertheless, some operators prefer to delay testing until the patient's airway is protected.

Interpretation

First phase of interpretation.

Analysis of initial eye position and spontaneous movements should be made before irrigation. The eyes of comatose patients with intact oculomotor pathways are usually directed straight ahead or are slightly divergent. Unilateral destructive lesions of the cerebral hemisphere can cause conjugate deviation of the eyes toward the side of the lesion, whereas irritative foci, as might be seen in status epilepticus, can cause conjugate deviation away from the affected side. Deviations of this type can usually be overcome by caloric stimulation, although combined irrigation and head turning may be required in the first hours following the insult. Lesions in or near the PPRF in the brainstem cause conjugate deviation away from the side of the lesion that usually cannot be overcome by calorics. Conjugate downward deviation can be seen with structural lesions of the brainstem or in the deeper phases of metabolic coma. Dysconjugate gaze may indicate damage at the level of the oculomotor nuclei or below or reflect disruption of the ocular muscles themselves. [61] Dysconjugate gaze is also seen in drug-induced coma in the presence of a structurally intact brainstem pathway. In the very late stages of brainstem dysfunction, the eyes usually return to the central position. Spontaneous roving movements of the eyes, either conjugate or dysconjugate, may be seen in supratentorial insults, but these, too, disappear with brainstem involvement. [26] Ocular "bobbing" is an intermittent, spontaneous downward jerking of the eyes that may occur with massive pontine lesions. Paralysis of both voluntary and reflex lateral gaze occurs, and caloric stimulation may increase the rate of bobbing without causing lateral deviation of the eyes. [87] Ocular "dipping" is a more prolonged, downward conjugate deviation of the eyes and has been reported in cases of severe anoxic encephalopathy (e.g., carbon monoxide poisoning). [68] The pathophysiologic basis of these eye movements is poorly understood.[69]

The second phase of interpretation.

After irrigation, the ocular movements should be observed for any response to the stimulus. Again, typically there is a latency of response of 10 to 40 seconds. Reactions to ice water irrigation may be divided into four categories: (1) caloric nystagmus, (2) conjugate deviation, (3) dysconjugate deviation, and (4) absent responses (Fig. 63-3*A, B* (Figure Not Available)). The first reaction, caloric nystagmus with the fast component beating away from the side of ice water irrigation, is seen in normal, alert individuals; in cases of psychogenic unresponsiveness; and in those who have very mild organic disturbances of consciousness. The intensity of nystagmus is highly variable in conscious subjects and depends on the degree of visual fixation and the level of mental alertness. The response is present in more than 90% of children by age 6 months and declines in magnitude only after the seventh decade of life. [12] Corneal reflexes and responses to facial pinprick may be abolished by hypnotic suggestion in susceptible individuals; however, caloric nystagmus appears to be immune to similar manipulation. [13]

Caloric-induced nystagmus following cold water irritation in the apparently comatose individual usually results from testing individuals with psychogenic unresponsiveness due to catatonia, conversion reactions, schizophrenia, or feigned coma. Hyperactive caloric responses may result from testing in the presence of tympanic perforation or mastoid disease. Hypoactive caloric responses are recorded in a wide variety of vestibular and neurologic disorders.

Hypoactive or abnormal caloric responses may be further evaluated with quantitative caloric testing and ENG. Caloric nystagmus may be *inverted* (beating to the wrong side) or *perverted* (beating in the wrong plane); both responses are seen in brainstem lesions. *Pseudocaloric nystagmus* is a pre-existing latent nystagmus that is brought out by the general arousal of ice water irrigation; it can be distinguished from true nystagmus by its failure to reverse direction with warm water irrigation.

As the level of coma deepens, the fast phase of nystagmus becomes intermittent and then disappears, probably as a result of decreased activity in the cerebral cortex.

In the second type of response to cold caloric stimulation, the eyes deviate conjugately toward the side of ice water stimulation (they "look" toward the source of irritation). When present, this reaction indicates intact brainstem function as well as intact afferent and efferent limbs of the reflex. This is seen during general anesthesia, in supratentorial lesions *without brainstem compression*, and in many metabolic and drug-induced comas. In such situations, bilateral simultaneous irrigation with ice water may result in conjugate downward deviation, implying that brainstem centers for vertical gaze are functional.

Dysconjugate reactions constitute the third type of caloric response to ice water stimuli. The most common dysconjugate reaction is internuclear ophthalmoplegia, in which a lesion of the MLF causes weakness or paralysis of the *adducting* eye following caloric irrigation. Internuclear ophthalmoplegia may be due to acute damage to the rostral pons or may be seen as a manifestation of multiple sclerosis or stroke.

In acute supratentorial lesions, the development of dysconjugate caloric responses is a significant sign that may indicate compression of the brainstem and impending herniation. Caloric responses of this type are less common with metabolic and drug-induced coma, and when present in metabolic coma, their significance is less ominous. Reversible internuclear ophthalmoplegia has been reported in hepatic coma and may occur during toxic response to phenytoin, barbiturate, or amitriptyline. Forced downward deviation of the eyes, either conjugate or dysconjugate, may be seen in sedative-hypnotic drug-induced coma when unilateral caloric testing is performed. [81]

Palsies of the oculomotor nerves are another cause of dysconjugate reactions, although most should be apparent before irrigation. Causes include diabetic neuropathy (especially CN VI), increased intracranial pressure, and Wernicke's

---

Figure 63-3 (Figure Not Available) *A,* The four types of caloric responses seen with unilateral and bilateral irrigations: *1,* Normal nystagmus; *2,* Conjugate deviation; *3,* Dysconjugate deviation. The most common type, internuclear ophthalmoplegia, is shown here. Vertical eye movements usually remain intact in this lesion; *4,* Absent caloric responses. Philadelphia, FA Davis, 1980, p 55. B, From Smith M, Bleck T: Techniques for evaluating the cause of coma. J Crit Illness 2:51, 1987.)*

---

encephalopathy. Finally, Plum and Posner[61] reported that unusual and poorly characterized caloric responses may be obtained from the testing of comatose patients with long-standing severe brain injury.

Absent caloric response is the fourth category of reactions to ice water stimuli. As a general rule, the oculovestibular response is preserved longer than other brainstem reflexes; however, the oculocephalic or doll's eye response may persist in the absence of caloric responses due to bilateral labyrinthine disease because of additional input from proprioceptive receptors in the neck. Loss of caloric responses in comatose patients with structural lesions is usually a sign of brainstem damage. In supratentorial lesions, progressive loss of caloric responses may be seen in the final stages of transtentorial herniation. The oculovestibular reflex may also be transiently absent or decreased on the side opposite massive supratentorial damage during the first hours following injury. [62] Absent caloric responses may occur in any subtentorial lesion that affects vestibular reflex pathways, including pontine hemorrhage, basilar artery occlusion, cerebellar hemorrhage, or infarction with encroachment on the brainstem, and in any expanding mass lesion within the posterior fossa. Calorics may disappear in deep coma resulting from subarachnoid hemorrhage, perhaps owing to pressure on the brainstem.

The vestibulo-ocular reflex is usually retained until the late stages of metabolic coma. Disappearance of the reflex, as in the case of hepatic coma, is frequently a preterminal event.[32] Nevertheless, caloric responses may be transiently absent in certain types of drug-induced coma, with the *eventual complete recovery of the patient*. The vestibulo-ocular reflex seems particularly sensitive to the effects of sedative-hypnotic drugs (e.g., barbiturates, glutethimide), antidepressants (e.g., amitriptyline, doxepin), and anticonvulsants (e.g., phenytoin, carbamazepine). [7] [84] [85] Obviously, neuromuscular blocking agents (e.g., succinylcholine) will abolish caloric-induced ocular movements.

Finally, the caloric response may be absent for reasons other than the neurologic causes responsible for the coma. Inadequate irrigation owing to excess cerumen or poor technique and unilateral or bilateral dysfunction of the peripheral vestibular apparatus must be considered. Bilateral loss of caloric response (areflexia vestibularis) is uncommon in conscious patients, constituting 1.7% and 0.2%, respectively, of the ENG clinical population in two large series of patients. [85] [86] Some of the causes of unilateral and bilateral loss of oculovestibular reflexes in conscious patients are listed in Table 63-1 .

The vestibulo-ocular reflex has prognostic as well as diagnostic significance in the comatose patient. In a study of 100 patients who were comatose from head trauma, absence of calorics at 1 to 3 days after injury was associated with extremely high mortality. [63] Testing in the immediate posttraumatic period may yield inconsistent responses and is of considerably less prognostic value. Levy and coworkers studied 500 cases of nontraumatic, non-drug-induced coma in a large multicenter effort. Absence of the vestibulo-ocular reflex correlated with less than a 5% chance of achieving functional recovery within 1 year when tested within 6 to 24 hours of coma onset. [43] In one study of comatose patients, the combination of absent vestibulo-ocular reflex and absent pupillary light reflex at 24 hours was associated with 100% mortality. [51] Complete loss of caloric responses is part of the

criteria for the diagnosis of brain death and correlates with the irreversible cessation of cerebral function at least as well as an isoelectric electroencephalogram (EEG). [34] Excessive reliance on a single clinical sign must be avoided in the consideration of brain death, and decisions regarding neurologic prognosis and future therapy should be based on complete consideration of all evidence available. The topic clinical diagnosis of brain death is discussed in detail subsequently.

Summary

Caloric testing is a simple, easily performed bedside procedure that may enhance the neurologic assessment of the comatose patient. When reliably interpreted, caloric testing may furnish valuable diagnostic and prognostic information. Even if the cause of the coma is known, the test may provide a baseline for the evaluation of changes in the patient's status. In the emergency patient, this test should be reserved for the stable patient undergoing secondary assessment. The examination requires minimal equipment and can be conducted in a few minutes while awaiting laboratory results or during preparation for computed tomographic scanning. Complications are few if patients are properly selected and correct technique is used.

DIX-HALLPIKE TEST IN DIAGNOSIS OF POSITIONAL VERTIGO

Vertigo occurring only and repeatedly with position change is probably benign paroxysmal positional vertigo (BPPV); the head-hanging positioning maneuver (Dix-Hallpike test, sometimes referred to as the Nylèn-Bárány maneuver) is useful in confirming the clinical suspicion of BPPV since the provoked abnormal nystagmus is characteristic of the disorder. [18] [28] Evolving pathophysiologic theory is that calcium crystal material displaced from the vestibule floats within the endolymph of the posterior semicircular canal and head movement induces bidirectional forces in the fluid acting on the cupula, triggering the BPPV attack. [9] [10] [21] [59] [73] The

posterior semicircular canal is most commonly affected, [28] [59] but at times the horizontal canal is thought to be involved, leading to variants of typical BPPV. [15] [49] [93]

Background

BPPV is a common mechanical disorder of the inner ear in which vertigo is precipitated by certain head movements; nystagmus and autonomic symptoms such as nausea commonly accompany the vertigo. Syndromes of positional vertigo and provocative maneuvers have been described by clinicians for more than 100 years; the description of BPPV has been attributed to Adler, Bárány, Nylèn, Bruns, Borries, Dix, and Hallpike. [42] Current consensus is that Dix and Hallpike most fully defined the disorder and that the provocative technique they described is superior and most accurately should bear the eponymic Dix-Hallpike positioning test or the Dix-Hallpike test. [28] [42]

Indications and Contraindications

The Dix-Hallpike test may be a useful diagnostic test in confirming BPPV by provoking a specific type of nystagmus and in selecting patients suitable for positional therapy (discussed later). The maneuver should not be performed in patients with severe cervical spine disease, unstable spinal injury, high-grade carotid stenosis, or unstable heart disease. [25] Patient discomfort or physical infirmity are relative contraindications; some elderly patients or patients with ongoing nausea or vertigo may not tolerate the body position changes necessary for performance of the procedure. If nystagmus is present at rest without any provocation or if associated neurologic signs or symptoms exist, the diagnosis of BPPV is likely excluded and the maneuver is not clinically indicated.

Procedure

The Dix-Hallpike maneuver is illustrated in Figure 63-4 (Figure Not Available) . The seated patient, whose head is turned 45° to one side, is quickly laid back to a head-hanging position and the eyes are observed for any induced nystagmus. [28]

Interpretation

The Dix-Hallpike head-hanging positioning maneuver produces vertigo only in patients with positional vertigo that is most commonly characterized as BPPV. The stereotypic positive response in BPPV is provoked vertigo developing after a brief delay (1 to 10 seconds), lasting less than a minute, and with direction-fixed rotary or vertical nystagmus. Nausea or other systemic symptoms are often present. [18] [28] The eye movements are mixed torsional and vertical nystagmus of both eyes with the upper pole of the eye beating toward the dependent ear and the vertical nystagmus beating toward the forehead. The side of the ear in the downward position during the Dix-Hallpike test that elicits the greater nystagmus likely identifies the affected ear. After the patient is returned to the sitting position, the nystagmus may again be transiently observed in a reversed direction. If the positional nystagmus is atypical or if the maneuver fails to elicit nystagmus in a patient with ongoing symptoms of vertigo, another diagnostic possibility should be considered. [25] [28]

Complications

The maneuver may precipitate brief vertigo and nausea in patients with BPPV.

Summary

The Dix-Hallpike test may be useful in confirming the diagnosis of BPPV in patients when there is doubt and in localizing the abnormality to one ear. Accurate identification of BPPV is of interest because of the possibility of interventional therapies as described subsequently.

CANALITH-REPOSITIONING MANEUVERS

If the clinical evaluation of the patient with vertigo is consistent with the diagnosis of BPPV and the Dix-Hallpike test is supportive of the diagnosis and lateralizes to one ear, the patient may be a candidate for attempted canalith repositioning maneuvers. These techniques have largely been described in the otologic and neurologic literature and have not been studied in the emergency patient population or as performed by emergency clinicians. Success rates of 44% to 100% are reported. [28] The success in the ED population as performed by emergency clinicians is unknown.

Background

With theory suggesting that stray material in the posterior semicircular canal is causative of the symptoms of BPPV, maneuvers were designed using sequential head movements to reposition the debris to the vestibule. [8] [21] [28] [75] The manipulation of head position theoretically allows the debris ("canaliths") to sequentially fall from the problematic location in the semicircular canal to the vestibule of the labyrinth where they presumably adhere. The currently recommended maneuver was introduced by Epley. [21] Other maneuvers are described but require repeated trials or are more difficult to perform and perhaps more uncomfortable for the patient. [8] [28] [41] [75] The Semont maneuver will also be described because it may be performed at the bedside. In theory, the Semont maneuver would be effective primarily in patients in whom the displaced canaliths were adhering to the cupola of the posterior semicircular canal (Schuknecht cupolith theory) though it might be effective as well when the debris are free floating in the long arm of the semicircular canal; the Epley maneuver would be effective only in patients with debris floating in the long arm of the posterior semicircular canal (canalith theory). [33] In one small trial comparing the efficacy of either the Semont or Epley maneuvers in a carefully selected outpatient otolaryngology population, the maneuvers were found to be of roughly the same effectiveness (90%) in relieving or improving symptoms of BPPV. [33]

Indications and Contraindications

The indication for any canal-clearing or "liberatory" procedure is the clinical diagnosis of BPPV as confirmed by history and physical examination including the Dix-Hallpike maneuver. Careful patient selection is likely a key point in success of any of these maneuvers as well as correct identification of the impaired ear, which will govern the initial position and

---

Figure 63-4 (Figure Not Available) The Dix-Hallpike test of a patient with benign paroxysmal positional vertigo (BPPV) affecting the right ear. *A,* The examiner stands at the patient's head 45° to the right to align the right posterior semicircular canal with the sagittal plane of the body. *B,* The examiner moves the patient, whose eyes are open, from the seated to the supine right ear-down position and then extends the patient's neck slightly so that the chin is pointed slightly upward. The latency, duration, and direction of the nystagmus, if present, and the latency and duration of vertigo, if present, should be noted. The arrows over the eyes in the insert depict the direction of nystagmus in patients with typical BPPV. The presumed location in the labyrinth of the free-floating debris thought to cause the disorder is also shown. *(From Furman C: Benign paroxysmal positional vertigo. New Engl J Med 341:1590, 1999.)*

movement of the patient. Contraindications are the same as for the Dix-Hallpike maneuver as noted earlier.

Procedure

The Epley procedure has several variations. Please refer to Figure 63-5 (Figure Not Available) and the caption for details. Briefly, with the patient sitting, the head is turned 45° toward the affected side; the patient is then moved to the head-hanging orientation as in the Dix-Hallpike procedure. After 20 seconds or after any symptoms subside, the patient's head is then rotated to face the opposite shoulder remaining in a head-hanging orientation. Then the patient is rolled further onto his or her side while the head is rotated further into a face-down position. Again, after 20 seconds or after any symptoms subside, the patient is returned to a seated position. [10] [25] [41] Some authors suggest keeping the patient's head in each position long enough for any provoked symptoms of nystagmus or vertigo to resolve. [28] Others suggest a period of 4 minutes after the head is placed in the hanging position and again after rotation of the head

---

Figure 63-5 (Figure Not Available) Bedside maneuver for the treatment of a patient with benign paroxysmal positional vertigo affecting the right ear. The presumed position of the debris within the labyrinth during the maneuver is shown in each panel. The maneuver is a three-step procedure. First, a Dix-Hallpike test is performed with the patient's head rotated 45° toward the right ear and the neck slightly extended with the chin pointed slightly upward. This position results in the patient's head hanging to the right *(A)*. Once the vertigo and nystagmus provoked by the Dix-Hallpike test cease, the patient's head is rotated about the rostral-caudal body axis until the left ear is down *(B)*. Then the head and body are further rotated until the head is face down *(C)*. The vertex of the head is kept tilted downward throughout rotation. The maneuver usually provokes brief vertigo. The patient should be kept in the final, face-down position for about 10 to 15 seconds. With the head kept turned toward the left shoulder, the patient is brought into the seated position *(D)*. Once the patient is upright, the head is tilted so that the chin is pointed slightly downward. *(From Furman C: Benign paroxysmal positional vertigo. New Engl J Med 341:1590, 1999.)*

("modified Epley maneuver"). [33] The maneuver may be repeated after the first sequence to determine if positional symptoms have subsided. The maneuver may be repeated a few times until some improvement in symptoms occurs though this is not typically described in the literature. [33] Usually it is recommended after a successful procedure that the patient remain in a head-upright position for 24 hours.

The Semont maneuver involves larger and more abrupt body movements. The affected ear is identified by the Dix-Hallpike maneuver. With the patient seated on the side of an examination table or bed, the head is turned toward the unaffected side. The patient is then quickly moved to a sidelying position (Fig. 63-6 (Figure Not Available)) and kept there until symptoms subside. The patient is then moved abruptly through the sitting position to the opposite sidelying position and kept there until symptoms subside. He or she is then returned to the upright position. [33] [41] Again, typically it is recommended after a successful procedure that the patient remain in a head-upright position for 24 hours.

Complications

Exacerbation of vertigo occurs occasionally and is thought to result from displacement or the dislodgment of the canal debris. Repeating the procedure is recommended for relief. Similar symptoms may occur in up to 50% of patients with up to 20% in the first 2 weeks. [10]

Summary

In most patients with correctly identified BPPV, canalith-repositioning techniques may be useful and may bring immediate relief or improvement of symptoms. Experience in an emergency patient population with treatment by emergency clinicians has not been reported, though with careful patient selection some success should be achieved.

BRAIN DEATH TESTING

In a textbook of emergency medicine from 1988, the author wrote that because emergency medicine was a life-supporting-moriented specialty, the determination of brain death was outside

Figure 63-6 (Figure Not Available) Semont's maneuver. The patient is moved quickly into the position that provokes the vertigo and remains in that position for 4 minutes. The patient is then turned rapidly to the opposite side, ear down, and remains in this second position for 4 minutes before slowly sitting up (for detailed description of the technique, see text). The insets represent the right labyrinth as it would be viewed from the front of the patient. The orientation of the labyrinth is shown for when the patient is sitting *(A),* lying on the affected side *(B),* and lying on the opposite side *(C)*. The solid black arrow indicates the location of the relative position of free-floating debris with the canal during the different stages of this maneuver. *(From Herdman SJ, et al: Single treatment approaches to benign paroxysmal positional vertigo. Arch Otolaryngol Head Neck Surg 119:450, 1993.)*

the practice of the emergency clinician.[35] The date of publication reflects practice at that time; neuroimaging was not often performed while patients were in the ED and delays for inpatient bed availability were unusual. With increased use of neuroimaging in the ED and general trends to increased ED length of stay, the occasion may arise for emergency clinicians to be involved in assessment of brain death. The duty to identify potential organ and tissue donors is another consideration in identifying patients with irreversible loss of brain function. Local practices, policies, regulations, and laws differ and these remarks are general; the clinician is urged to be familiar with local practices and administrative policies regarding the issue of brain death.

For purposes of this discussion, brain death is defined as irreversible loss of functioning of the cerebral hemispheres and brainstem consistent with definitions in the literature.[1] [6] [16] [94] [95] The cause of the brain injury should be known or identified since some toxicologic syndromes, notably barbiturate toxicity, exactly duplicate the clinical syndrome of brain death. In keeping with the theme of this book, this chapter focuses on clinical procedures commonly used to delineate brain death. Radiologic and other tests will be mentioned only in passing. This chapter is not a historical summary of the complex legal and ethical issues surrounding this topic or a guide to approaching the family of a severely injured or impaired patient. Frequently in current practice, if a cause for coma or neurologic injury is identified and prognosis is shared with family, the option of withholding or withdrawing advanced life support is considered and implemented. This is entirely within the realm of patient, family, and clinician interactions and any discussion of brain death does not surface in those circumstances.

Background

With the advancement of intensive care techniques, patients were identified with continuing spontaneous cardiovascular function while on ventilatory support but without evidence of central nervous system activity. Observation of these patients showed that cardiovascular function would eventually fail though rare prolonged survival has been reported.[14] [75] Efforts to reliably identify these patients were sought for improved resource allocation, optimal family counseling, and also to identify possible organ donors. Part of the impetus for reliably establishing clinical brain death was to allow the medical and legal pronouncement of death and allow discontinuation of advanced life support without fear of legal consequences. Death had long been defined as cessation of cardiac function; these deeply comatose patients with persistent cardiac activity but without demonstrable brain function challenged the traditional definition of death. The concept of brain death has been entangled in ethical, legal, and policy discussions roughly since the advent of clinical application of mechanical ventilation in the 1960s. [1] [88] [96] Current medical practice in the United States allows withdrawal of life-sustaining therapies when they are considered futile. In most patients, formal declaration of brain death is not necessary before withdrawing support.

Indications and Contraindications

Assessment of brain function is part of the ongoing care of every patient. Evaluation for brain death implies that severe CNS dysfunction has been identified, that the cause of CNS dysfunction is known, and that reversible causes of profound coma have been confidently excluded. [6] [16] [95] Formal brain death assessment is in preparation for pronouncement of death to allow organ harvest or in uncommon cases of disparate family or caregiver convictions regarding patient prognosis. Complex medical issues that may confound the assessment

and should be considered and ruled out include: severe electrolyte disturbances, hypothermia (defined as core temperature <32°C), hypotension, drug intoxication or poisoning, and pharmacologic neuromuscular blockade.[95] Any neuroimaging studies should be reviewed.

Procedure

By definition, the patient under evaluation will be in coma without spontaneous respirations. Certain examination techniques are used to establish loss of function of the cerebral cortex and brainstem; the clinical neurologic examination remains the standard for determination of brain death. [95] These typically involve assessment for cortical function and brainstem reflexes including respiratory drive. Should any cerebral or brainstem function be discovered, the patient is not brain dead by definition in spite of what may be severe brain injury. Some institutions may require evaluation by two clinicians of particular specialty training, or local practice patterns may require ancillary testing with EEG, nuclear angiography, or other techniques. Again, the clinician must be familiar with local practices and policies. Brain death in the pediatric population is more complex with varying recommendations of repeat examinations and ancillary tests; that discussion is outside the scope of this chapter but is summarized elsewhere. [95]

Establishment of coma and cortical assessment.

By definition, patients undergoing assessment for possible brain death will be in an unresponsive state. However, loud verbal commands such as "Look up!" are given while holding the patient's eyes open to assess for any voluntary eye movements as has been described in the patient with locked-in syndrome. Additionally, a strong painful stimulus should be delivered by forcefully pressing on brow, sternum, or nail bed; any response including abnormal posturing excludes the diagnosis of brain death.

Brainstem Reflex Testing

Pupillary response.

The pupils in brain dead patients are unreactive and mid-position to dilated. Brain death assessment involves shining a bright light stimulus into the pupil and observing the reaction; there will be none in the brain dead patient. Should any reactivity be noted, the patient is not brain dead.

Auditory reflex.

A loud handclap is delivered in each ear; any observed eye blink or other reaction establishes that some brainstem function remains and excludes brain death.

Caloric testing.

Cold-water irrigation of the external auditory canals should be performed with large volumes (100 mL or more) to elicit any eye movements through the oculovestibular

reflexes (described in detail earlier in this chapter). In the brain dead patient, there will be no movement of the eyes in response to irrigation. Any eye movement excludes brain death.

Corneal reflex.

Stimulation of the cornea is performed with a cotton wisp or applicator; any observed eye closure indicates that the V–VII reflex arc remains intact and excludes the diagnosis of brain death.

Cough reflex.

Suctioning with stimulation of the trachea or mainstem bronchi is performed to assess for cough response; there should be no cough or other reaction.

Apneic oxygenation test.

CNS control of respiratory drive resides in the medulla. Establishing apnea is necessary to confirm medullary failure. Mechanical hyperventilation may artificially depress respiratory effort. Recall that it is hypercapnia, not hypoxia, that triggers respiratory effort. Simply disconnecting the ventilator to allow development of hypercapnia for apnea testing may lead to hypoxia.[46] A variety of techniques have been described that allow adequate hypercapnia for medullary stimulation to develop but ensure that oxygenation is adequate during the test. The most commonly described technique is to disconnect the patient from the ventilator and deliver oxygen at 10 to 15 L/min through a catheter inserted into the trachea and then observe for respiratory efforts for 8 minutes. Any observed excursion of the abdomen or chest sufficient to produce a tidal volume suggests that brain death is not present. If there are no observed respiratory excursions, arterial blood gas analysis is obtained and the patient is reconnected to the ventilator pending results. An arterial pCO_2 =60 mm Hg and the absence of respiratory excursions are the criteria for a positive apnea test.[94] Others suggest that a possibly safer technique is to simply set the ventilator rate to zero while allowing continuous oxygen flow to continue and maintaining any necessary continuous positive pressure through the ventilator.[66]

Declaration of Death

If the criteria for brain death are satisfied, the family and all clinicians involved in patient care should be informed to allow further management decisions. At some institutions, the patient is declared dead at the time criteria are met and further care is assumed by transplant services if that is the anticipated course. Per institutional protocol a two-person confirmation of brain death may be required. Families are generally given the option of being present at the bedside while mechanical ventilation is discontinued, though some advise against this because spontaneous reflex movements such as the Lazarus sign (discussed later) may occur and disturb the family.[66] Again, for patients age 18 years or younger, particularly infants, repeated examinations and confirmatory tests are generally recommended.[95] [96]

Complications

Carefully following the physical examination protocol reliably identifies the majority of patients with irreversible loss of brain function. Two basic areas of error are possible; either erroneously declaring a patient brain dead when in fact some CNS function is retained, or failing to correctly identify brain death.

Profound barbiturate intoxication may simulate the picture of brain death at times. To guard against the error of failing to detect surreptitious pharmacologic coma, some protocols include toxicologic screening tests for barbiturates as part of the process of assessment for brain death. Ancillary techniques for assessing intracranial blood flow would also prevent this error. Two examinations both confirming brain death performed several hours apart have been part of some protocols with the idea that toxicologic coma might improve during this period of observation. Again, familiarity with local practices is necessary.

A variety of movements have been observed in brain dead patients; at times these spinal-level-mediated reflexes may be dramatic and erroneously lead observers to believe that the brain dead patient is demonstrating voluntary movements or brain-mediated reflex movements. Finger jerks and facial myokymia (spontaneous, fine fascicular muscular

contractions) have been reported to be spontaneously present in brain dead patients. Decerebrate-like extensor posturing, the Lazarus sign (flexion of the arms at the elbow, shoulder adduction, lifting arms, dystonic posturing of the hands with crossing of the hands), undulating toe flexion, triple flexion response in the lower extremities, and flexion of the trunk (giving the appearance of sitting up) are among the signs described during apnea testing and following the termination of ventilation, or triggered by tactile stimuli.[37] [38] [45] [47] [68] [72]

Summary

The emergency clinician may become involved in assessment of patients for brain death in the course of current practice. The screening physical examination for assessing brain death is described earlier. Again, the cause of irreversible coma should be known. The clinician is urged to be familiar with local practices and regulations in this sometimes complex medicolegal process.

MYASTHENIA GRAVIS TESTING

Background

Myasthenia gravis is the most common disease of neuromuscular transmission but still the incidence is only 1 in 20,000 in the general population. Patients with myasthenia may be grouped into two major categories. The first group shows weakness in proximal muscles, which increases with activity and improves with rest. The other group presents with ocular complaints of diplopia or ptosis. Patients in the ocular weakness group may or may not have generalized symptoms as well. Fatigue is the hallmark of the disease; symptoms typically wax and wane. Patients often see a number of clinicians before a correct diagnosis is made. [20] [78]

Myasthenia gravis results from an immune-mediated destruction of postsynaptic acetylcholine (ACh) receptors, with variable failure of neuromuscular transmission. [19] [20] [52] [78] ACh is the transmitter at the neuromuscular junction. When the nerve terminal is stimulated, ACh is released in a quantity far in excess of that needed for effective activation of the ACh receptor. ACh diffuses across the synaptic cleft to transiently interact with the ACh receptor, and an electrical potential is generated at the myoneural end plate. If it is of sufficient magnitude, the end plate potential initiates an action potential that is propagated along the muscle membrane and muscle fiber contraction follows. The ACh is rapidly hydrolized by acetylcholinesterase in the synaptic cleft. Figure 63-7 summarizes neurotransmitter action at the neuromuscular junction. Of the millions of receptors at each myoneural junction, only a fraction must depolarize to stimulate muscle fiber contraction. Any factor that decreases interactions of ACh with ACh receptors decreases the probability of an action potential being generated and may lead to failure of neuromuscular transmission with resulting weakness. Acetylcholinesterase inhibitors (anticholinesterases) have been the mainstay of therapy for myasthenia gravis for years, but they have been supplemented by immunosuppressive regimens and thymectomy. Failure of neuromuscular transmission may also occur with excessive acetylcholinesterase inhibition; the persistence of ACh in the synaptic cleft leads to continuous depolarization of the receptor.

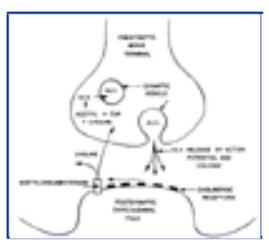

Figure 63-7 Neurotransmitter action at a neuromuscular junction. Acetylcholine *(Ach)* is formed and stored in the nerve terminal. It is released by nerve terminal depolarization in the presence of calcium and binds with receptors on the postsynaptic membrane. After producing an ionic conductance charge, it is hydrolyzed by acetylcholinesterase. *(From Daube JR, Reagen TJ, Sandok BA, Westmoreland BF: Medical Neurosciences: An Approach to Anatomy, Pathology and Physiology, and Physiology by Systems and Levels. Boston, Little, Brown, 1986, p 278.)*

Bedside diagnostic testing for myasthenia gravis has been described in patients presenting to the ED with two different clinical pictures. The first presentation involves a known patient with myasthenia gravis on cholinesterase inhibitor therapy with increased weakness; pharmacologic testing in this setting is controversial. The second presentation involves a previously undiagnosed patient in whom the diagnosis of myasthenia gravis is suspected with ptosis, diplopia, or fluctuating muscular weakness; bedside testing may be helpful in select patients in this group.

A battery of tests can be used in the assessment of the patient with suspected myasthenia gravis, but only a few are available to the emergency clinician. ACh receptor antibody assay is positive in more than 80% of patients with myasthenia but has a turnaround time of several days. [35] [83] Repetitive nerve stimulation and single-fiber electromyography tests are available in the electrophysiology laboratory. [60] Several pharmacologic tests have been used to aid in the diagnosis of suspected myasthenia gravis including parenteral administration of edrophonium chloride (Tensilon), neostigmine, or curare. Edrophonium chloride administration for diagnosis of myasthenia gravis (Tensilon test) is described in detail because of the drug's rapid onset, short duration of action, and widespread acceptance for this diagnostic challenge; the emergency clinician may find occasion to use this test. The ice-pack test is discussed because of favorable reports of its utility and the noninvasive nature of the test.[22] [76] The use of curare has been described to aid in diagnosis of myasthenia gravis by both systemic and regional administration. A technique is described for administration into an ischemic arm; this modification is known as the *regional curare test*.[60] The

use of curare in this setting is outside the realm of practice of the emergency clinician.

Edrophonium (Tensilon) Test

Background

Edrophonium chloride (Tensilon) is an acetylcholinesterase inhibitor that has been used in the diagnosis of myasthenia gravis since the 1960s. The short duration of action of edrophonium that made it unsatisfactory as a therapeutic agent for myasthenia gravis makes it useful as a diagnostic agent. The drug's onset of action is rapid, and the duration of maximal effect is short, usually <2 minutes. Any effect resolves within 5 to 10 minutes. [56]

Edrophonium administration has also been recommended in the past to monitor acetylcholinesterase inhibitor therapy. [57] [58] However, edrophonium administration is not sufficiently reliable for titrating the effect of anticholinesterase medication. [71] The use of the Tensilon test in a patient with known myasthenia gravis is controversial and should be done only in consultation or in the presence of the treating neurologist, if at all.

Myasthenic crisis may be loosely defined as respiratory distress in a patient with myasthenia gravis. Earlier concepts included "myasthenic" crisis from insufficient drug administration, "cholinergic" crisis from cholinesterase inhibitor overdosage, and the "brittle" patient with rapidly changing drug requirements, [30] [90] but terminology in this setting remains controversial. [31] Even the clinical existence of the different types of crisis has been debated. [71] Certainly, in the myasthenic patient with respiratory distress, airway management and assisted ventilation are top priorities. Edrophonium administration should not be viewed as a possible alternative to intubation and mechanical ventilation. Several authorities advocate withdrawing all cholinesterase inhibitors in this setting because most patients show increased responsiveness to cholinesterase inhibitors after several days without taking the drug. [31] [71] Others advocate a trial of edrophonium chloride at reduced dosage (1 to 2 mg) only after respiratory support is achieved. [30] [74]

Indications and Contraindications

The bedside Tensilon test is indicated for diagnosis of patients with suspected myasthenia gravis when there is clinical need to make that diagnosis immediately. If other bedside tests such as the ice pack test (discussed later) are conclusive, or if eyelid fatigue on prolonged upgaze can be demonstrated, there is no need to administer Tensilon.[55] If the tempo of the clinical scenario is such that consultation or admission and obtaining specialized EMG or serologies is feasible, then deferring the Tensilon test in the ED may be the preferred strategy, realizing that serologies and neurophysiologic testing will not be completed for some days.

Administration of edrophonium is commonly performed in office settings by neuro-ophthalmologists with occasional complications of bradycardia that at times may be symptomatic with hypotension and loss of consciousness.[36] [92] One study reports the complication rate in office settings as 0.16%. [36] A history of asthma or cardiac dysrhythmias is a relative contraindication to administration of cholinesterase inhibitors. Complications reported in the literature from Tensilon testing largely date from the era when it was used in cardiology to differentiate supraventricular rhythms. [55] Reported complications include cardiac rhythm disturbances and even death; several of these patients were taking digoxin or beta-blockers. [29] [48] [70] [97] One report notes transient asystole following Tensilon administration in a patient with suspected myasthenia; the patient was critically ill and had been receiving intravenous labetalol. [55] Hence, caution is advised in Tensilon administration in patients receiving beta-blocking agents, digoxin, or other drugs with atrioventricular-blocking properties.

Administration of edrophonium to a patient with myasthenia gravis being treated with cholinesterase inhibitors is controversial. Many investigators consider myasthenic crisis to be a contraindication to edrophonium administration, though a series of patients with myasthenic crisis continue to report its use in the clinical setting.[30] [74]

A muscle that is clearly weak must be identified to monitor during Tensilon testing; ptosis is a commonly monitored sign. If a specific muscle cannot be isolated for objective testing, edrophonium administration should be deferred and other approaches to diagnosis pursued.

Equipment

The following materials are needed for testing an adult. Intravenous access should be secured with D_5W at a keep-open rate or with a saline lock. Ten milligrams of edrophonium chloride should be drawn up in a tuberculin syringe. Edrophonium chloride is supplied in 1- and 10-mL vials at a concentration of 10 mg/mL. A second syringe of normal saline should be available to administer as a placebo, although some clinicians have recommended nicotine, calcium chloride, or atropine for this purpose.[58] Atropine and other cardiovascular drugs and resuscitative equipment should be readily available. Cardiac monitoring is generally recommended. Photographic recording equipment is desirable to objectively document any improvement in motor function.

Procedure

Again, a muscle that is clearly weak must be identified. A clinically evident extraocular muscle weakness or the presence of ptosis allows direct observation of a single weak muscle becoming stronger in response to the drug. Simple grip dynamometry does not aid in evaluation; a repetitive measure of grip strength (ergogram) is necessary. Ideally, one person is available to administer the edrophonium or placebo and a second person is free to observe the effect of medication on the patient. It is best if both the observer and the patient do not know which syringe contains edrophonium and which contains saline, thus creating a double-blind testing situation.

The paretic muscle to be tested is identified. Again, ptosis is an easily testable sign and is generally used if present. The principles involved with assessing the effect of edrophonium on ptosis may be extended to testing other muscles. The patient is instructed to look upward for several moments in an attempt to fatigue the levator muscles. The degree of ptosis is noted and documented by measurements or photographs. After a moment's rest, with the patient looking straight ahead, 0.2 mL of the test substance in one syringe is injected (2 mg of edrophonium or saline). If there is no response within 1 minute, another 0.3 mL is injected (3 mg of edrophonium or saline). If there is still no response, the remainder of the syringe is injected 3 minutes later. Any increase in strength reflected by an increase in palpebral fissure size is noted. The procedure may then be repeated with the other test substance.

Complications

A small percentage of individuals are hypersensitive to even the initial small dose of edrophonium and show cholinergic side effects of salivation, lacrimation, and miosis. These effects are transient. Atropine, 0.5 mg, may be given IV if necessary to counteract these symptoms. A smaller number of patients may experience symptomatic bradycardia that responds to atropine. As described earlier, rare cardiac arrhythmias and death have been reported, usually in patients taking digoxin or beta-blockers.

Interpretation

The key to the procedure is its interpretation. If a clearly paretic muscle has been identified, objective signs of improvement in the strength of that muscle within a moment of administration of edrophonium and the fading of that improvement over the next 5 minutes are criteria for a positive test result. Up to 90% of patients with myasthenia have a positive test result under ideal circumstances. [57] [58] False-negative results do occur consistently.

For evaluating the effect of edrophonium on ptosis, a positive test consists of the patient having increased ability to elevate the eyelids after administration of 5 to 10 mg of edrophonium. The ptosis returns within 5 minutes. Subjective increases in general strength or relief of fatigue do not constitute a positive test. Fasciculations, brief twitches of muscles, are not usually observed in the patient with myasthenia who has received edrophonium, in contrast to normal subjects. The Tensilon test may be repeated in 30 minutes if desired.

Normal subjects have no change in muscle strength. They may transiently experience the side effects of salivation, lacrimation, and diaphoresis. Perioral, periocular, or lingual fasciculations are almost always noted in the normal patient following edrophonium administration.

The reproducible and unequivocal reversal of weakness in a specific muscle is extremely specific for myasthenia. [53] [54] False-positive test results have been reported in patients with Eaton-Lambert syndrome and rarely in patients with intracranial lesions. [17] [50] [65] Other rare reports of positive test results involve patients with amyotrophic lateral sclerosis. A "perverse" reaction has been noted rarely, in which a paretic extraocular muscle weak from other causes becomes even weaker with edrophonium administration.[77]

Ice Pack Test

Background

It has been observed clinically that myasthenic patients have exacerbations of weakness with environmental heat and improvement in strength with cold temperatures. A simple bedside test uses these observations to evaluate ptosis. [22] [76] Ice placed in a surgical glove or wrapped in a towel is placed lightly over the eyelid of a patient. Cooling of the eyelid below 29°C is accomplished within 2 minutes. The ptosis has been noted to improve in 80% or more of patients tested and may be more sensitive than the edrophonium test in detecting ocular myasthenia gravis. Although the reported number of patients evaluated by this method continues to be small, the test is included here because of its potential application in the ED, its lack of side effects, and its noninvasive nature.

Indications

Unilateral or bilateral ptosis of uncertain etiology in which myasthenia is a diagnostic possibility is the sole indication for this test.

Procedure

Ice and a surgical glove or towel are the only materials required. A camera to record any response is optional. The degree of ptosis of the patient is noted and, ideally, photographed. Momentary upward gaze may be used to provoke the ptosis. If bilateral ptosis is present, the more affected eye should be tested. Eyelid cooling is accomplished by lightly holding the wrapped ice to the patient's eyelid for 2 minutes or until patient discomfort limits the application. The width of the palpebral fissure is immediately compared with the pretest width (Fig. 63-8).

Complications

Patient discomfort from the ice pack application may limit the cold exposure time to less than 2 minutes but may still allow a successful test.

Interpretation

A clear improvement of ptosis in the cooled eye is the criterion for a positive test. The effect should be reproducible. In small clinical studies, the ice pack test is at least as sensitive as edrophonium administration in improving ptosis in patients with ocular myasthenia. False-negative results do occur, probably at about the same frequency as those in Tensilon testing. One individual has been reported to have had a negative ice pack test result with a positive Tensilon test result. Negative or

equivocal Tensilon tests have been reported in other individuals who had clearly positive ice pack test results. Normal individuals showed no change in palpebral fissure width after the cold exposure. There are no reports of false-positive results. [22] [76]

Summary

The bedside Tensilon test has a long history of utility in diagnosing myasthenia gravis, but it has been largely replaced by

Figure 63-8 *A,* Before ice pack placement. *B,* After ice pack placement, improvement is noted in ptosis of the right eye. *(From Sethi KD, Rivner MH, Swift TR: Ice pack test for myasthenia gravis. Neurology 37:1383, 1987.)*

acetylcholinesterase receptor assay and electrodiagnostic studies in the ambulatory setting. [39] [54] [55] [60] On occasion when rapid diagnosis is desired or myasthenia gravis is suspected in the presence of a normal ACh receptor titer, a carefully performed Tensilon test is still clinically valuable. The use of the Tensilon test in the setting of myasthenic crisis is controversial and is discouraged.

The ice pack test is so simple and noninvasive that it should become the initial procedure of choice in the ED for evaluating the possibility of ocular myasthenia. A positive ice pack test result strongly suggests ocular myasthenia gravis and alleviates any need for the Tensilon test. False-negative results do occur, and additional testing should be performed if the clinical suspicion of myasthenia gravis is strong.

It is often the case with neuromuscular diseases, given the broad diagnostic possibilities, that the emergency clinician is unable to establish a confident diagnosis at a single patient encounter. [82] Appropriate consultation and referral are necessary.

Acknowledgments

The author would like to thank Paul B. Baker, MD, for his contributions to this chapter in earlier editions of this work and would also like to thank the section editor, Cathy Custalow, MD, PhD, for her seemingly infinite patience.

Section XII - Ophthalmologic, Otolarynologic, and Dental Procedures

Chapter 64 - Ophthalmologic Procedures

Kevin J. Knoop
William R. Dennis
Jerris R. Hedges *

The following discussion focuses on procedures performed by emergency clinicians during the evaluation and treatment of injuries and diseases of the eye. The emphasis is on the practical application of the techniques, and cautions to be heeded by the emergency clinician are included.

VISUAL ACUITY ASSESSMENT

Visual acuity may initially be eschewed in simple, obvious, or straightforward cases, such as a stye, periorbital laceration, or minor eye irritation; however, visual acuity assessment should be the first procedure performed in the majority of patients who present to the emergency department (ED) with an eye complaint. While it may be initially deferred in the triage or trauma room setting, or under other relevant scenarios, it is incumbent upon the emergency clinician to ensure that visual acuity or function is ultimately adequately assessed.

Indications

Visual acuity should be done as soon as practicable and before the patient is examined with bright lights. In the event of blepharospasm from an injury (e.g. abrasion, chemical exposure), a topical anesthetic may facilitate the examination. Patients often present in the context of an eye complaint saying that they "can't see." In these instances, emergent visual acuity assessment should first be performed beginning with the assessment of light perception, then hand motion, and finally counting fingers at 3 feet (Fig. 64-1). If the patient succeeds in performing these assessments, a near vision card may then be used, or distant visual acuity assessed. Under emergent circumstances, detailed formal vision testing is not essential; however, some form of visual acuity assessment is needed. In this situation, the ability to count fingers or read newsprint gives some indication of gross visual function. Formal visual acuity testing should never delay important therapeutic interventions such as eye irrigation.[1]

Distant Visual Acuity Procedure

For formal vision testing, the patient faces a well-lit standard Snellen or similar eye chart from a premeasured distance of 20 feet. A card or the palm of the hand is used to occlude one eye at a time. If possible, all patients should be examined while wearing their current lens correction in order to obtain the best corrected distant visual acuity. If this is not available, measure visual acuity first without correction, then with a pinhole device and note any improvement in visual acuity. This device functions as a corrective lens by reducing corneal refractive error. In general, visual acuity should be improved with the pinhole device. Decreased visual acuity that is not improved with this device suggests that corneal refractive error is not the cause. A pinhole device can be made by punching several holes in the center of a card (3" × 5" index card) with an 18-gauge (ga) needle. Devices with one or more pinholes drilled into an eye cover are available commercially (Fig. 64-2). A visual activity chart for visual acuity testing while the patient is on a stretcher or in a chair is depicted in Figure 64-2*C* . The chart can be used directly from this text if it is held 14 inches from the eye. Begin by testing the affected eye or the one presumed to have the worst visual acuity. First, instruct the patient to read the smallest letters on the chart that can easily be seen. Then, ask the patient to read letters that can just barely be made out (i.e., they do not have to be clear). If the patient is unable to read the largest letter on the chart, move the patient to one half the distance from the chart (10 feet) or move the figure 7 inches closer to the edge and repeat the procedure. Record the results reflecting the change in distance (e.g., 10/200). The numerator in the vision ratio is the distance of the patient from the chart and the denominator is the distance at which a patient with normal vision can read the line of letters. For the patient who still cannot read the letters on the chart, test vision progressively as follows: ability to count fingers, detect hand motion, perceive light (with or without projection and ability to perceive the direction of light), and finally note the inability to perceive light. [2]

Near Visual Acuity Procedure

Near visual acuity is performed in the ED at the bedside or at triage. A pocket near vision card (Figure 54-2*C*) or any printed material is held at a distance of approximately 14" in good light in front of the patient as each eye is alternately occluded as described earlier. When using available printed material in lieu of a near vision card, the size of the letters discerned by the patient should be measured. These can be compared with the letter size on the near vision card to deduce the actual visual acuity at a later time. When near vision is decreased, it is usually from either loss of visual function or as a result of poor accommodation from advancing age

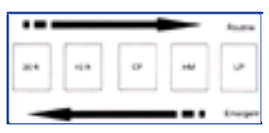

Figure 64-1 The "routine" progression of visual acuity assessment is reversed in the emergent presentation. Assessing an intact visual pathway begins with quickly discerning if the patient has light perception (LP), can see hand motion (HM), and count fingers at 3 feet (CF). Subsequent progression to assess vision at 10, then 20, feet from a standard eye chart ensues.

*This article represents the views of the authors and is not to be interpreted as official, or representing the U.S. Navy or the Bureau of Medicine.

Figure 64-2 A commercial pinhole device reveals refractive error caused by corneal aberration (excess tearing or nearsightedness). *A*, First measure visual acuity without the device. *B*, Then measure with the pinhole cover lowered. Acuity with and without the pinhole device should be documented. *C*, If the patient cannot stand or a formal eye chart is not available, ask the patient to read this "distance equivalent" chart by holding this figure 14 inches away from the patient.

(presbyopia). Less commonly it is caused by traumatic mydriasis. Thus, patients with presbyopia should be examined with their reading correction in place to obtain the best corrected near visual acuity.

For patients who cannot communicate or in whom factitious blindness or malingering is suspected, checking for optokinetic nystagmus (OKN) will determine if there is an intact visual pathway. OKN is induced by the passage of a regularly sequenced pattern in front of the eyes. This is usually tested with the rotation of a striped drum in front of the patient (Fig. 64-3). This is not available in many EDs, though. A printed piece of paper such as newsprint (without photographs or large areas with no print) or a standard tape measure can be substituted. It should be passed in front of the eye at reading distance while instructing the patient to look at it as it moves by rapidly. Tracking is demonstrated by nystagmus-like eye movements seen when the test object is moved from side to side in front of the patient and indicates an intact visual pathway. Finally, another effective method is to hold a mirror in front of the patient and slowly rotate the mirror to either side of the patient. The patient with an intact visual pathway will maintain eye contact with himself or herself as demonstrated by eye movement as the mirror is moved. A large mirror that reflects the patient's entire face is most effective for this purpose.

All patients with decreased visual acuity from their baseline require routine referral for further ophthalmologic follow-up; however, those patients with moderately or severely decreased visual acuity not explained by refractive error require ophthalmologic consultation in the ED.

Figure 64-3 Optokinetic Nystagmus (OKN) testing will determine if there is an intact visual pathway. OKN is induced by the passage of a regularly sequenced pattern in front of the eye such as this commercially available drum. The patient is directed to look at the drum that is held in front of the patient and rotated slowly. Alternatively, a tape measure can be drawn across the line of sight while asking the patient to look directly at it as it passes.

DILATING THE EYE

Dilating the eye is useful for both diagnostic and therapeutic purposes. Clinicians should be advised, however, that on various occasions, an attack of narrow-angle (angle-closure) glaucoma may be precipitated by dilating the pupil. The most common form of glaucoma, however, is open-angle glaucoma and this type is not precipitated by dilating the pupil. Some patients may have a "mixed-mechanism" glaucoma with both open-angle and narrow-angle components. Systemic reactions, such as bradycardia from beta blocker eye drops, can be produced by mucosal absorption of dilating medications. To minimize complications, the correct agent must be chosen and the proper technique used.

There are two types of dilators: sympathomimetic agents, which stimulate the dilator muscle of the iris, and cycloplegic agents, which block the parasympathetic stimulus that constricts the iris sphincter. Cycloplegic agents also block the contraction of the ciliary muscles, which control the focusing of the lens of the eye. This second effect of cycloplegic agents is of great importance in the therapeutic use of dilators for iritis.

Cycloplegic agents were used cosmetically as early as Galen's time. Beginning in the early 1800s, extracts from the plants *Hyoscyamus* and belladonna were used in ophthalmology. Atropine was first isolated in 1833. Epinephrine was used on eyes in 1900 as the first sympathomimetic agent. [3]

Indications and Contraindications

There are diagnostic and therapeutic indications for dilating the pupil. Dilation is indicated for *diagnosis* when the fundus cannot be examined adequately through an undilated pupil. The elderly patient with miotic pupils and cataracts is an example of a patient in whom dilation may facilitate fundoscopic examination. Dilation is *therapeutically* useful for many ophthalmic conditions, including inflammation in the eye. In the emergency setting, corneal injury with a secondary traumatic iritis is a common example. Dilation helps the inflamed eye in two ways. First, it may hinder adhesions (synechiae) from forming between the iris and other ocular structures. Such adhesions eventually limit the movement of the pupil and may precipitate glaucoma. Second, cycloplegic dilating agents relax the ciliary muscle spasm that often accompanies an inflamed eye and thus may reduce the pain associated with inflammation. While traditionally used for these purposes, both benefits are largely theoretical, with little formal evidence to support or refute their use in the ED.

Dilation is discouraged in the patient with head injury at risk for herriation, when monitoring pupil findings can be helpful prior to obtaining a head computed tomography (CT) scan. Dilation is contraindicated in the presence of narrow anterior chamber angles. Patients who are predisposed to having narrow angles may be unaware of this condition. The clinician should evaluate the depth of the anterior chamber before this procedure and the pupil should not be dilated if there is any question of a narrow angle. The depth of the anterior chamber can be estimated by shining a penlight in tangentially from the lateral side of the eye. When the depth of the anterior chamber is normal, a uniform illumination of the iris is seen. However, when there is a forward convexity of the iris in the case of a narrow anterior chamber, only a sector of iris is illuminated and there will be a shadow on the medial (nasal) side of the iris (Fig. 64-4). With a slit lamp, the depth of the anterior chamber angle can be assessed directly. The definitive test for assessing the anterior chamber angle is gonioscopy, in which the anterior chamber angle structures are viewed directly by means of a special mirrored contact lens and the slit lamp. Gonioscopy is not a technique normally performed by emergency clinicians.

Systemic effects can develop after the application of eyedrops. [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] The reader should review the following sections on agents and complications before using these drugs in patients with compromised cardiovascular function.

Agents

Only two dilating agents are really needed in the ED. Phenylephrine (Neo-Synephrine) 2.5% is used for diagnostic dilation of the pupil for visualization of the fundus. The drug is short-acting, and because accommodation is not affected, the patient's vision is not altered. Phenylephrine 10% should not be used routinely because it can be absorbed systemically and in rare cases has caused hypertensive crisis, myocardial infarction, and death. [17] [18]

For therapeutic cycloplegia in iritis, homatropine 5% works well. Although Table 64-1 indicates a maximum duration of 3 days, 24 hours is a more common duration. Therefore, homatropine 5% is a useful therapeutic agent for traumatic iritis. Atropine should not be used for traumatic iritis because the undesirable effects of pupillary dilation and blurred vision persist for a week or longer after healing of associated corneal abrasions. Atropine drops may be prescribed as part of the therapy for nontraumatic iritis after appropriate ophthalmologic consultation. Individuals with lightly pigmented irides tend to have a greater sensitivity to the cycloplegic agents than do individuals with greater pigmentation; the cycloplegic effect may therefore be more prolonged in people with light eyes. It may be difficult to dilate some patients with deeply pigmented irides, and numerous applications of drops may be required.

Figure 64-4 Anterior chamber depth and transillumination test. *A,* Normal anterior chamber with negative transillumination test. Note that the entire iris is illuminated. *B,* Shallow anterior chamber with positive transillumination test. Note the shadow on the outer half of the iris. *C,* Shallow anterior chamber with correctly placed light source yielding a true-positive test result in the presence of a shallow anterior chamber. *D,* Shallow anterior chamber with incorrectly placed light source giving a false-negative test result. *E,* Clinical use of the penlight examination to assess the depth of the anterior chamber. The examiner sits face-to-face with the patient to ensure that the light source is perfectly perpendicular to the line of vision. *F*, Note the shadow cast on the nasal portion of the iris, indicating a very narrow anterior chamber in this patient with acute angle closure glaucoma. *(A–D from Bresler MJ, Hoffman RS: Prevention of iatrogenic acute narrow-angle glaucoma. Ann Emerg Med 10:535, 1981. Reproduced by permission.)*

Malingerers may use mydriatic agents to dilate a pupil unilaterally for the purpose of feigning neurologic disease. Normally, a pupillary dilation caused by intracranial third cranial nerve compression will constrict with 2% pilocarpine eyedrops. The mydriatic-treated eye can be identified by full motor function of the third cranial nerve and the absence of

TABLE 64-1 -- Mydriatic Agents

Agent	Maximum Mydriasis	Duration of Mydriasis[§]	Common Trade Name
Sympathomimetics			
Phenylephrine[*] , 2.5%[†]	20 min	3 hr	Neo-Synephrine
Cocaine, 5% or 4%	20 min	2 hr	—
Parasympatholytics (Cycloplegics)			
Atropine, 1%	40 min	12 days	—
Scopolamine, 0.25%	30 min	7 days	—
Homatropine, 5%[‡]	30 min	1–3 days	—
Cyclopentolate, 1%	30 min	6–24 hr	Cyclogyl
Tropicamide, 1%	30 min	4 hr	Mydriacyl

§The duration of effect shows considerable individual variation. These are general estimates.
*Preferred for funduscopic examination.
†A 10% solution may produce cardiovascular reaction and hence should not be used.
‡Preferred for iritis or corneal abrasion therapy.

miosis after pilocarpine instillation. A fixed and dilated pupil in an awake and alert patient cannot be secondary to brain herniation. Although other neurologic problems may be present, in the normal-appearing patient with a fixed and dilated pupil, a pharmacologic cause is highly likely. It should be noted that legitimate patients may not recall the name of an

Figure 64-5 *A*, After neosynephrine drops were instilled in the nose to facilitate tube passage, this comatose patient was nasotracheally intubated for his drug overdose. *B*, On a subsequent examination a unilateral fixed and dilated pupil was noted. The pupil dilation was from neosynephrine nose drops that were snorted from the nose into the eye during intubation, simulating cerebral herniation. Other unusual causes of a fixed and dilated pupil are endotracheal epinephrine expelled from the lungs and splashed in the eye during cardiopulmonary resuscitation and inadvertant contamination of the eye following application of a scopolamine patch behind the ear.

eye medicine that they used but will usually recall whether the bottle had a red cap, as is found on all cycloplegic solutions. An unexpected mydriasis in a trusted patient may be the result of such an agent. Medications that constrict the pupil, such as pilocarpine, have a green cap. Pressure-lowering drops for glaucoma may be yellow- or blue-topped (ß-blockers), purple-topped (adrenergic agents) or orange-topped (topical carbonic anhydrase inhibitors).

A fixed and dilated pupil from a pharmacologic cause may be encountered following both nasotracheal and orotracheal intubation (Fig. 64-5). In such ill or injured patients, cerebral herniation must be considered. When neosynephrine is used to constrict the nasal mucosa prior to nasal intubation (endotrachial tube, nasogastric tube), the inadvertant contamination of the eye will cause a fixed and dilated pupil. The same scenario may occur after endotracheal epinephrine has been instilled into the lungs during resuscitation, and cardiopulmonary resuscitation has expelled epinephrine into the eye. Under such scenarios, the affected pupil will not constrict following intraocular pilocarpine administration. Finally, a fixed and dilated pupil may occur from inadvertent contamination of the eye with scopolamine following application of a scopolamine patch.

Procedure

The instillation of mydriatic agents is similar to the administration of other eye solutions. For medicolegal purposes, visual acuity should be noted before the instillation of the medicine. This documents that any decreased vision is not the result of the mydriatic agent. Whenever dilation is performed, it is important to note on the patient's chart the dose and time that agents have been given to avoid confusion during subsequent neurologic evaluation.

The patient is placed in a supine or a comfortable semirecumbent position. The patient is then instructed to gaze at an object (such as a fixture on the ceiling) in the upper visual field. The clinician gently depresses the lower lid using a finger on the epidermis (Fig. 64-6). A *single* drop of the solution is instilled into the lower lid fornix, and the patient is permitted to blink and to spread the medication. More than a single drop is not recommended because it produces reflex tearing and reduces the concentration in contact with the conjunctiva. The patient should be forewarned that the medication is uncomfortable and that the closed eye can be blotted but *not*

Figure 64-6 *A*, Administration of eyedrops. The patient should lie in a supine position or with the head tilted back. The patient's gaze should be directed upward. The lower lid is pulled downward and a single drop of medicine is instilled in the lower conjunctival fornix. The patient should be instructed to close the eyelids for 1 minute to increase the contact of the medicine with the globe and to decrease the medication outflow down the tear duct and over the lid margin. *B*, If one is administering large amounts of eye drops that have systemic effects, such as beta blocker drops, the operator's index finger is placed under the inferior eyelid along the nasal borders of the eye, firmly compressing the nasolacrimal duct against the globe for a few minutes, thereby preventing migration of the drops into the nose and reducing systemic absorption.

rubbed with a tissue after the medicine is used. If the desired effect is not noted in 15 to 20 minutes, a repeat dose may be used, but this is seldom required.

Complications

As mentioned in the section on contraindications, any dilator can precipitate an attack of angle-closure glaucoma in susceptible patients. [19] In a case of angle-closure glaucoma, it may take several hours before symptoms become evident. The patient often complains of smoky vision with "halos" around lights as well as an aching pain that is sometimes severe. There may be nausea and vomiting. The affected eye becomes injected in association with a hazy cornea, elevated pressure on tonometry, and an oval, fixed pupil. Immediate consultation with an ophthalmologist should be obtained. The treatment usually includes osmotic agents, carbonic anhydrase inhibitors, beta-blocker drugs, pilocarpine, and, later, definitive laser or surgical procedures (Table 64-2).

The practitioner should be aware that the use of eye medications may introduce infections. Most solutions contain bactericidal ingredients, although contamination of the tips of the droppers can still occur. [20] Only newly opened bottles of eye medication should be used if the practitioner suspects a deep corneal injury or if the patient has recently had eye surgery. Out-of-date drops and drops in which crust or other material is found around the nozzle should be discarded promptly.

Any cycloplegic (in contrast to a sympathomimetic) blurs a patient's near vision. Patients should be forewarned of this effect. Vision will be less blurred in adults older than 45 years of age, who generally have a reduced ability to focus for near vision. Although most adults will be able to drive safely, even with both eyes affected, it is advisable to have someone else drive whenever feasible. Light sensitivity caused by pupillary dilation may also be bothersome; sunglasses are sufficient for this problem.

Systemic reactions can be produced by sympathomimetic and cycloplegic eyedrops. [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] In one report of 33 cases of adverse reactions associated with 10% phenylephrine, there were 15 myocardial infarctions (11 deaths), 7 cases of precipitation of angle-closure glaucoma, and a variety of systemic cardiovascular or neurologic reactions. [18]

After instillation of eyedrops into the conjunctival sac, systemic absorption can occur through the conjunctival capillaries as well as by way of the nasal mucosa, the oral pharynx, and the gastrointestinal tract after passage through the lacrimal drainage system. Mucosal hyperemia enhances absorption. Symptoms can often be avoided by maintaining digital pressure on the nasal canthus, thus occluding the puncta, for several minutes after administration. [4]

TABLE 64-2 -- Treatment Options for Acute Angle-Closure Glaucoma

1. Pilocarpine 4%: 2 drops every 15 min for 1–2 hr*
2. Glycerol: 1 mL/kg by mouth (as 50% solution in citrus juice)

3. Mannitol: 1.5–3 g/kg intravenously over 20 min (as 20% solution)[*]
4. Acetazolamide: 500 mg intravenously[*]
5. Beta-blocker drugs (e.g., timolol 0.5%) 1 drop every 30 minutes for 2 doses[*, †]
6. Alpha-2-agonist (apraclonidine [Iopidine] 0.5%) 1 drop[†]

*First line therapy
†May cause cardiovascular effects

THE FLUORESCEIN EXAMINATION

Fluorescein staining of the eye should be part of the evaluation of all cases of eye trauma and infection. It is a quick and easy technique that is crucial for the proper diagnosis and management of common eye emergencies. The fluorescein-stained cornea and conjunctiva should be viewed under a "blue" light and ideally in conjunction with slit lamp magnification (see Slit Lamp Examination later in this chapter).

Sodium fluorescein is a water-soluble chemical that fluoresces—it absorbs light in the blue wavelengths and emits the energy in the longer green wavelengths (Fig. 64-7). It fluoresces in an alkaline environment (such as in the Bowman membrane, which is located below the corneal epithelium) but not in an acidic environment (such as in the tear film over an intact corneal epithelium). [21] Thus, it is useful in revealing even minute abrasions on the cornea.

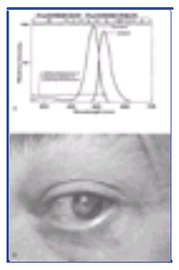

Figure 64-7 *A*, Sodium fluorescein absorbs light in the blue wavelengths and emits the energy in the longer green wavelengths. *B*, This large corneal abrasion is readily seen without the slit lamp when fluorescein is instilled into the eye. Smaller abrasions, or corneal injuries produced by keratitis or welder's arc flash injuries, require slit lamp evaluation to identify minor corneal defects. Even minor traumatic abrasions will escape detection with only a blue light examination by the naked eye.

Fluorescein was first used in ophthalmology in the 1880s. [22] It was first used as a drop, but when the danger of contamination by bacteria (especially *Pseudomonas*) was recognized in the 1950s, [23] paper strips impregnated with fluorescein were developed. These are now supplied in individual sterile wrappers and should be used instead of the premixed solution.

Indications and Contraindications

Fluorescein staining is indicated for evaluation of suspected abrasions, foreign bodies, and infections of the eye. [24] This includes "simple" cases of conjunctivitis, which may actually be herpetic keratitis. Pepper spray exposure to the face has been associated with corneal abrasions and these patients should be stained with fluorescein and evaluated with slit lamp or Wood's lamp. [25] Corneal defects may be seen after unprotected viewing of a welder's arc flame.

Fluorescein permanently stains soft contact lenses. Therefore, when fluorescein is used, soft contact lenses should first be removed and the patient cautioned not to put the lenses back into the eye for several hours. Topically administered fluorescein is considered nontoxic, [26] although reactions to a fluorescein-containing *solution* (not impregnated strips) have been described. These reports consisting of vagal reactions [27] and generalized convulsions [28] are rare, not rigorously supported, and are believed to be caused by agents other than fluorescein in the solution. The practitioner who chooses to use one of the fluorescein-containing solutions rather than the fluorescein-impregnated strips should be aware of these potential, yet scientifically suspect, idiosyncratic reactions.

The clinician should also be aware that fluorescein dye may enter the anterior chamber of the eye in the presence of deep corneal defects. This form of intraocular fluorescein accumulation is also nontoxic. When the anterior chamber is viewed under the blue filter of the slit lamp, a fluorescein "flare" is visible and should not be confused with the flare reaction noted with iritis.

Procedure

Theoretically, one should not use topical anesthetics before fluorescein staining, because some patients may develop a superficial punctate keratitis from the anesthetic, [21] which can confuse the diagnosis. However, with patients who are tearing profusely and who are squeezing their eyes shut from an abrasion or a foreign body (FB), the examination often is impossible if a topical anesthetic is not first used. Theoretical downsides notwithstanding, it is common practice to instill fluorescein after the application of a local anesthetic.

The fluorescein strip is grasped by the non-orange end, and the orange end is wetted with 1 drop of saline (most conveniently available as a small bottle of artificial tears, or a 5 mL "bullet" or "fish" of normal saline usually used for nebulizer treatments) or dextrose solution. Some clinicians will wet the strip with tap water or the recently used local anesthetic drops. The moistened strip is then placed gently onto the inside of the patient's lower lid (Fig. 64-8). The strip is withdrawn, and the patient is instructed to blink. The patient's blinking spreads the fluorescein over the surface of the eye. The key to a good examination is a *thin* layer of fluorescein over the corneal and conjunctival surfaces. If the strip is heavily moistened before application in the lower fornix, the eye may become flooded with the solution, thus making evaluation

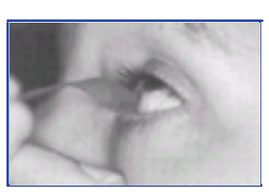

Figure 64-8 The fluorescein strip has been moistened with 1 drop of saline or tap water. The lower lid is depressed and a wetted strip is then placed gently onto the inside of the patient's lower lid so that only the smallest amount is instilled. Excess fluorescein may obscure subtle findings and thus should be avoided. Fluorescein will permanently stain contact lenses not removed (as seen in this model).

difficult. On the other hand, use of a dry strip in the unanesthetized eye may be irritating. If too much dye accumulates, the patient can remove the excess by blotting the closed eye with a tissue. The clinician uses a Wood's lamp, the blue filter of a slit lamp, or simply a penlight with a blue filter to examine the eye in a darkened room, checking for areas of bright green fluorescence on the corneal and conjunctival surfaces. Small defects may not be seen with the naked eye; ideally, a slit lamp should be used to examine the stained cornea before ruling out a pathologic process. After completion of the fluorescein examination, excess dye should be irrigated from the eye to minimize damage to the patient's clothing from dye-stained tears.

The *Seidel* test [29] uses fluorescein to detect perforation of the eye. To perform this test, the clinician instills a large amount of fluorescein onto the eye by profusely wetting the strip. The eye is then examined for a small stream of fluid leaking from the globe (Fig. 64-9 (Figure Not Available)). This stream will fluoresce blue or green in contrast to the orange appearance of the rest of the globe flooded with fluorescein. [21]

Interpretation

Fluorescein is mainly used for evaluation of corneal injuries. Although conjunctival abrasions pick up the stain, most of the staining on the conjunctiva represents patches of mucus rather than a real pathologic condition. Corneal staining is more specific for injury, and the pattern of injury often reflects the original insult.

Corneal staining patterns are illustrated in Figure 64-10 . Abrasions usually occur in the central cornea because of the limited protection of the patient's closing eyelids. The margins of the abrasions are usually sharp and linear if seen in the first 24 hours. Circular defects are seen about embedded FBs and may persist for up

to 48 hours after removal of a superficial foreign object. Deeply embedded objects may be associated with defects persisting for longer than 48 hours. Objects under the upper lid (including some chalazia) often produce *vertical linear lesions* on the upper surface of the cornea. When vertical lesions are noted, a *diligent search for a retained FB under the upper lid should be made*. Hard contact

Figure 64-9 (Figure Not Available) Positive Seidel test showing aqueous leaking through a full-thickness corneal wound. Aqueous will turn fluorescein lime-green under cobalt-blue light as it oozes through the wound while being observed at the slit lamp. *(From Mitchell JD: Ocular Emergencies. In Tintinalli JE, Kelen GD, Stapcynski JS (eds): Emergency Medicine—A Comprehensive Study Guide, 5th ed. New York, McGraw-Hill, 2000. Reproduced by permission.)*

lens overuse diminishes the nutrient supply to the cornea. The central cornea receives the most injury and thus fluoresces brightly when stained. Ultraviolet light exposure from sunlamp abuse, snow blindness, or welding flash produces a superficial punctate keratitis, which in its mildest form may not be visible without a slit lamp. The central cornea is the least protected by the lids, and a central horizontal band-like keratitis can result. Herpetic lesions may develop anywhere on the cornea. Classically, these lesions are dendritic, although ulcers may also be punctate or stellate. [30] [31]

Any area of corneal staining with an infiltrate or opacification beneath or around the lesion should alert the practitioner to the possibility of a viral, [30] [31] bacterial,[32] or fungal[33] *keratitis*. Urgent ophthalmologic consultation should be obtained so that cultures of the possible etiologic agents can be procured and appropriate treatment initiated.

Many *Pseudomonas* organisms fluoresce when exposed to ultraviolet light [34] ; therefore, presence of fluorescence before the instillation of fluorescein in the red eye should suggest the possibility of a pseudomonal infection.

Summary

Fluorescein staining is a quick, easy diagnostic procedure that should be part of every eye evaluation. The extra minute that the examination takes provides a wealth of diagnostic information for patients with eye trauma or infection. With the exception of the reactions noted with fluorescein solution, the potential discoloration of soft contact lenses, and the potential for infection when premixed solutions rather than fluorescein-impregnated paper strips are used, no complications are associated with the procedure.

EYE IRRIGATION

Eye irrigation is the crucial first step in the treatment of chemical injuries to the eye. Irrigation should be clinically appropriate to the exposure and severity of the injury. Serious chemical injury to the eye requires irrigation at the site of injury, *before* the patient is brought to the ED.[24] Corneal injury can occur within seconds of contact with an alkaline substance. Eye irrigation must often be continued in the ED.

This section discusses methods of irrigation. Although it is best to irrigate liberally, copious irrigation is not needed when the patient has gotten a small amount of a noncaustic, nonalkaline compound in the eye.

Indications and Contraindications

Irrigation is indicated for all acute chemical injuries to the eyes. Irrigation may also be therapeutic for patients having an FB sensation with no visible FB. Small, unseen foreign material in the conjunctival tissues may be flushed out with irrigation. There is no contraindication to eye irrigation, but if there is also a possible perforating injury to the eye, the irrigation must be performed especially gently and carefully.

Equipment

The following equipment is necessary for eye irrigation:

- Topical anesthetic, such as proparacaine 0.5%
- Sterile irrigating solution (warmed intravenous saline or lactated Ringer's [LR] solution in a bag with tubing) *
- A basin to catch the fluid
- Cotton-tipped applicators
- Gauze pads to help hold the patient's lids open
- Lid retractors
- Irrigating device (e.g., Morgan Therapeutic Lens, modified central venous catheter, or Eye Irrigator) for prolonged irrigation

Procedure

Basic Technique

Topical anesthetic is first instilled in the eye. Any particulate matter should be swept out of the conjunctival fornices with

*A balanced salt solution designed for eye irrigation is preferred by some (when available) and may produce less corneal edema with chemical injuries.

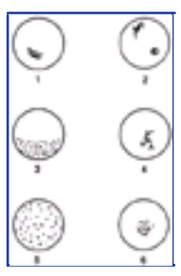

Figure 64-10 Patterns of acute corneal injury.

1. Traumatic abrasion: usually with linear features and sharp borders when seen early (< 24 hours). Occurs more in the central cornea.
2. Abrasion from foreign body (FB): vertical abrasions on the upper cornea seen when an FB is embedded in the upper lid. Also shown is a rust ring with a metallic FB.
3. Exposure pattern: seen with prolonged exposure to ultraviolet (e.g., welding flash, sunlamp exposure); produces bandlike keratitis over lower half of the cornea. Squinting in the setting of the bright light protected the upper corneal surface.
4. Herpes simplex keratitis: classic dendritic pattern.
5. Adenovirus keratitis: Diffuse minute corneal staining seen in epidemic keratoconjunctivitis about 7 days after symptoms.
6. Contact lens overuse: Central punctate staining.

moistened cotton-tipped applicators.[24] This requires eversion of the upper lid (see Ocular Foreign Body Removal later in this chapter and Fig. 64-11). During actual irrigation, the lids must be held open. It is easiest to use the gauze pads to get a

Figure 64-11 Double eversion of upper lid using a lid retractor. From Fogle JA, Spyker DA: Management of chemical and drug injury to the eye. *(In Haddad LM, Winchester JF (eds): Clinical Management of Poisoning and Drug Overdose, 2nd ed. Philadelphia, WB Saunders, 1990 Reproduced by permission.)*

grip on the wet, slippery lids. At times the patient has blepharospasm to such a degree that lid retractors (Desmarres or paper clip retractors; Fig. 64-12) may be necessary (Fig. 64-13). When lid retractors are used, the practitioner must be certain that the eye is well anesthetized, that the retractors do not injure the globe or the lids, and that chemicals are not harbored under the retractors. Retractors fashioned from metal paper clips (especially those that are nickel-plated and shiny) may have surface chipping, which can create an ocular FB.[35] Caution is needed to avert ocular injury when using such a makeshift retractor.

Deutsch and Feller recommend an ipsilateral facial nerve block for severe blepharospasm (Fig. 64-14).[24] To avoid swelling of the periorbital tissue, the facial nerve is blocked just anterior to the condyloid process of the ipsilateral mandible. A line of anesthesia (2% lidocaine) is placed subcutaneously to temporarily paralyze the *orbicularis* muscle.

The saline or LR solution exiting from the intravenous tubing is directed over the globe and into the upper and lower fornices. The choice of fluid initially is less important than the rapidity of irrigation initiation. Tap water should be readily available at the scene of the injury, and copious immediate irrigation should be encouraged before patient transport to the hospital. Out-of-hospital care providers should be taught to irrigate all acid injuries of the eye for at least 5 minutes at the scene and to irrigate all alkali injuries for at least 15 minutes.[36] [37] LR solution or normal saline are preferred over tap water or D_5W for eye irrigation, because they are isotonic and do not contain dextrose. Dextrose can be quite sticky if spilled and may serve as a nutrient for an opportunistic bacterial infection. Although one

clinical trial found a balanced salt solution less painful in patients with a chemical eye injury, [38A] another volunteer study on *uninjured* eyes found LR solution is better tolerated than normal saline and balanced saline solution when used with a morgan lens. [38B] Warmed fluids are also better tolerated than fluids at room temperature.[39] Warmed LR solution should be considered when both it and normal saline are available for eye irrigation.

Care should be taken to direct the irrigating stream onto the conjunctiva and then across the cornea without letting the stream splash directly onto the cornea, because the mechanical injury of the solution striking the eye can of itself be harmful. Direct irrigation of the cornea can result in the development of a superficial punctate epithelial keratopathy.

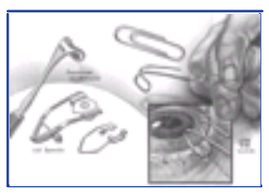

Figure 64-12 Devices for separating eyelids. A Desmarres retractor and a retractor improvised from a paper clip allow active manipulation of lids. Freestanding specula may require a seventh nerve block to reduce blepharospasm. *(From Fogle JA, Spyker DA: Management of chemical and drug injury to the eye. In Haddad LM, Winchester JF (eds): Clinical Management of Poisoning and Drug Overdose, 2nd ed. Philadelphia, WB Saunders, 1990. Reproduced by permission.)*

Duration of Irrigation

Although Deutsch and Feller recommend that a full liter of irrigating solution be used in every case of caustic injury, [24] the duration of the irrigation is best determined by the extent of exposure and the causative agent. Acids are quickly neutralized by the proteins of the eye surface tissues and, once irrigated out, cause no further damage. The only exceptions are hydrofluoric and heavy metal acids, which can penetrate through the cornea. Alkalis can penetrate rapidly and, if not removed (because of the slow dissociation of the cation from combination with proteins), will continue to produce damage for days. [24] Therefore, prolonged irrigation is indicated; at least 2 L of solution should be used. Although rapid flushing with the first 500 mL is prudent, slow continuous irrigation as discussed below at a rate sufficient to generate a continuous trickle is often more effective, and better tolerated than continued high volume flushing. If the nature of the offending agent is in doubt, prolonged irrigation should be used.

Ophthalmologic consultation should be obtained for all alkaline, hydrofluoric acid, and heavy metal acid injuries. Irrigation on an inpatient basis may be required for a period of 24 hours or more. This is especially likely when the cornea is hazy or obviously thickened. It should be noted that the magnesium contained in sparklers combines with water from tears to produce magnesium hydroxide. [40] Such fireworks injuries should be treated as alkaline injuries rather than thermal injuries. Eye damage from hair straighteners, [41] phosphate-free detergents,[42] and automobile airbags[43] must also be treated as alkaline injuries.

A good method of checking the effectiveness of irrigation is to measure the pH of the conjunctival fornices with a pH paper strip. The pH indicator on urine multi-indicator sticks can also be used. The pH indicator on urine dipsticks is conveniently closest to the handle; all the distal indicator squares can be cut off with scissors. The normal tear film pH is 7.4. The non-injured eye may be used as a control if the results are equivocal. If the pH measured in the conjunctival fornices after the initial irrigation is still abnormal, irrigation is to be continued. If the pH is normal after irrigation, *one should check it again in 20 minutes to make sure that it remains normal, especially in the presence of an alkaline contamination*.

Delayed pH changes are usually the result of incomplete irrigation and inadequate swabbing of the fornices. In anticipation of this deficiency, one should measure the pH deep in the fornices. Often, double-lid eversion with a lid elevator is required to expose the upper fornix for swabbing, irrigation, and pH testing (see Fig. 64-11).

Prolonged Irrigation

Prolonged irrigation may be required with alkaline burns. Ophthalmologic consultation is essential in such situations. One technique for prolonged irrigation uses a contact lens-type irrigation device (e.g., Morgan therapeutic lens), which allows for slow continuous irrigation once the more vigorous irrigation described earlier has been used. During use, the device is set on the anesthetized eye, and the lids are allowed to close around the intravenous tubing adaptor (Fig. 64-15). Continuous flow through the device onto the cornea and into

---

Figure 64-13 Irrigation technique using a Desmarres retractor for lid separation Irrigation is performed with saline or lactated Ringer's solution. For alkaline injuries the pH of the eye should be checked with pH paper to assess the adequacy of irrigation (normal pH = 7.4). Since a rebound may occur with alkaline products, the pH should be rechecked 20 to 30 minutes *after irrigation* to assure complete removal. *(From Fogle JA, Spyker DA: Management of chemical and drug injury to the eye. In Haddad LM, Winchester JF: Clinical Management of Poisoning and Drug Overdose, 2nd ed. Philadelphia, WB Saunders, 1990. Reproduced by permission.)*

the fornices occurs. This contact lens device can become uncomfortable as local anesthetic agents are washed out during the irrigation process; the anesthetic agent must be reapplied frequently during irrigation for patient comfort. Such short-term use of local anesthetics will not inhibit healing of the cornea.

Another irrigation device can be made for the prolonged irrigation of the fornices by modification of a small-caliber central venous catheter. Multiple perforations are made with a scissors or a scalpel in the distal portion of the catheter. This perforated section is placed in the inferior fornix of the anesthetized eye beginning at the lateral canthus and is then looped back in the upper lid fornix (Fig. 64-16). The patient is instructed to tilt the head toward the side of the tubing to permit drainage into a laterally placed basin. After loosely applying an eye patch, one attaches the catheter to an intravenous setup for continuous irrigation. An anesthetic agent is also needed with this technique, albeit less frequently than with the contact lens-type device.

Yet another irrigation device, the Eye Irrigator, is designed to slide up easily under the upper lid (Fig. 64-17). This device is marketed for use at the injury site as part of the initial first aid to supplement flushing at the eyewash station.

Lippas described the successful treatment of two alkaline burns using a similar but more invasive continuous irrigation technique for prolonged irrigation after immediate copious irrigation.[44] Continuous irrigation of an alkaline injury with a 10% or 20% acetylcysteine (Mucomyst) solution to inhibit collagenase [45] and topical (1%) calcium gluconate eye drops[46] have been recommended, although these recommendations are controversial and poorly researched, and one should await ophthalmologic consultation before using these methods.

Complications

The only complication from irrigation is abrasion of the cornea or the conjunctiva. This can be a mechanical injury from trying to keep the lids open in an uncooperative patient, a small corneal epithelial defect from a Morgan irrigating lens or other irrigation device, or a fine punctate keratitis from the irrigation itself. [47] It is for this reason that the stream should not be directed onto the cornea. If a superficial corneal defect occurs, it is treated in the usual manner. Deep or penetrating corneal injuries are likely to be the result of the caustic chemical and require emergency ophthalmologic consultation. They should receive slow continuous irrigation pending ophthalmologic consultation. There is some experimental evidence that massive parenteral or oral ascorbic acid supplementation may prevent the development of deep corneal injury, [48] although this treatment has not gained universal acceptance.

Summary

Eye irrigation is easy, and complications associated with the technique are minimal. At times, the clinician may be unsure whether a chemical injury is toxic enough to warrant

Figure 64-14 Injection points for facial and orbital anesthesia and akinesia. *A,* Van Lint technique of orbicularis infiltration. *B,* Retrobulbar injection site. *C,* O'Brien facial nerve block. *C',* Alternative facial nerve block by tympanomastoid fissure injection. *D,* Infraorbital sensory block. *E,* Supraorbital sensory block. Injection of orbicularis *(A)* or facial nerve *(C* or *C')* permits examination and treatment of the eye in the setting of severe blepharospasm. irrigation. One should irrigate the eye if any doubt exists rather than omit this vital procedure and permit the progression of eye injury.

OCULAR FOREIGN BODY REMOVAL

Patients with an external FB in the eye are frequently seen in EDs. They are often in pain and desperate for help. A high degree of suspicion for FB injuries and perforations of the eye is necessary, because such injuries may be occult and not readily detected. Not all FB injuries are associated with pain; glass embedded in the cornea may be particularly difficult to detect. This section is a review of the procedures for locating and removing extraocular FBs. A brief discussion covering evaluation for perforation of the globe and for an intraocular FB is provided. Care of the patient after removal of an extraocular FB is presented.

Indications and Contraindications

Removal of extraocular FBs is always indicated. The timing of removal and the technique that is required vary according to the patient's clinical status and the type of injury. For the most part, the emergency clinician can proceed directly to removal of the object using the techniques described in this section. When the patient is extremely uncooperative (e.g., intoxicated, a mentally deficient individual or a young child) or when the injury is complicated (e.g., deeply embedded object, multiple foreign objects from a blast injury, or possible globe penetration), immediate ophthalmologic consultation is

Figure 64-16 Continuous irrigation device. A central venous catheter (after perforation by the clinician) is looped in the fornices of the anesthetized eye, beginning from the temporal border of the eyelids. The eye is lightly patched after catheter placement.

indicated. *Any patient presenting with a suspected FB or abrasion after exposure to a projectile (grinding wheel, hammering, metal objects colliding) should be rigorously evaluated for the presence of a deep intraocular FB.* See further discussion later in this chapter. A penetrating injury to the cornea is particularly troublesome in that iris tissue may prolapse and may appear to represent a corneal FB (Fig. 64-18). Hence, in addition to the history of projectile exposure, an irregular pupil, especially a pear-shaped pupil, should alert the clinician that a penetrating injury may have occurred.

Globe Protection

In the evaluation of a patient where a penetrating injury to the globe is suspected, a careful expeditious examination of the eye is indicated, preferably with a slit lamp. Care should be taken to avoid any pressure on the eye or rapid eye movements. If perforation is obvious (teardrop pupil, flaccid globe, flat anterior chamber, prolapsed iris) or confirmed by slit lamp (Seidel test positive—see Fig. 64-9 (Figure Not Available)), no procedures (save perhaps irrigation) should be attempted, and early ophthalmologic consultation is warranted for definitive diagnosis and care. Pending evaluation by the consultant, the eye should be protected from further harm by keeping the patient quiet,

Figure 64-17 The Eye Irrigator is designed to slide up under the upper lid as shown. Irrigation is accomplished by connecting the device to an intravenous bag containing the desired irrigation fluid. It is used primarily at the injury site to supplement flushing at the eyewash station. *(Courtesy of the Eye Irrigator, American Health and Safety, Inc.)*

elevating the head of the bed, and placing a protective shield over the eye. Commercial shields are available for this purpose. When a metal shield is not available, a makeshift shield can be fashioned with available materials (paper, plastic, or Styrofoam cups) (Fig. 64-19). The protective shield functions to avoid pressure on the globe and overlying tissues to avoid extrusion of vitreous and other ocular contents. The shield edges should extend to or beyond the bony orbital rim for this purpose. Adhesive tape is applied from forehead to cheek over the shield to secure the shield in position.

Patients with globe perforation should be treated with systemic antibiotics (a combination of cefazolin and gentamycin is a good initial choice), texnus toxoid, and antiemetics in doses aggressive enough to halt vomiting.

Equipment

The following equipment is necessary for extraocular FB removal:

- Topical anesthetic, such as proparacaine 0.5%
- Sterile cotton-tipped applicators
- Fluorescein strips
- Magnification: loupes plus a Wood's lamp or a slit lamp
- Eye spud or 25-ga needle attached to a 1- or 3-mL syringe or to the tip of a cotton-tipped applicator
- Dilator drops, such as homatropine 5%
- Antibiotic ointment, such as erythromycin

Consideration of Intraocular Foreign Body

The emergency clinician should always remain cognizant of the potential for an *intraorbital* or *intraocular* FB when examining the patient with a "FB" sensation. Penetrating injuries represent a greater threat of visual loss than extraocular FBs and can be disastrous if overlooked. *Intraocular FB, can be deceptively subtle on intial presentation.*

The clinical presentation is most helpful in the determination of which patients are at risk for a penetrating injury to the globe. An individual who complains of an FB sensation in the *absence* of trauma or one whose history is simply that something "fell" or "blew" into the eye is at *low* risk for a globe perforation. On the other hand, there is a greater probability of globe penetration in the individual who has sustained a high-velocity wound to the eye (e.g., drilling, hammering, grinding metal, blasting rock). The presence of any of the following physical findings should alert the clinician to a probable *intra*ocular FB: irregular pupil, shallow anterior chamber on slit lamp examination, prolapsed iris, positive Seidel test (see Fluorescein Examination), focal conjunctival swelling and hemorrhage, hyphema, lens opacification, and reduced intraocular pressure (IOP). Tonometry should not be performed in the presence of other physical findings suggesting penetration of the globe. One should be aware that a penetrating injury may *not* be associated with eye pain. Strong historical evidence and physical findings supporting a diagnosis of penetration

of the globe should prompt emergent ophthalmologic consultation.

Often, *intraocular* FBs are not visible on direct ophthalmoscopy. Although orbital radiography for radiopaque objects and ultrasonography of the globe have been used for indirect FB localization, [24] computed tomography of the orbit is now considered the most useful technique. [49] [50] When plain orbital radiography is performed looking for intraocular FBs,

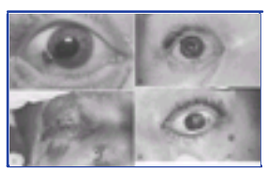

Figure 64-18 *A*, Corneal laceration with prolapse of the iris. The extruded iris is dark, mimicking a corneal foreign body. Often the only clue is an abnormal pupil and the extruded iris may not be appreciated as intraocular tissue. The pupil is irregular (often pear- or teardrop-shaped), pointing toward the laceration (photo courtesy of Lawrence B. Stack, MD). *B*, A pear-shaped pupil without protrusion of the lens is a more subtle, yet characteristic, indication of a perforated globe. *C*, Another indication of a penetrating globe injury is periorbital fat protruding from an upper eyelid laceration. This patient was stabbed by a knife. *D*, This patient has an obviously cloudy lens soon after trauma. A projectile entered the temporal portion of the globe and produced a seemingly minor scleral hemorrhage. Patients with penetrating injuries to the globe should be treated with systemic antibiotics (such as cefazolin/gentamycin combination), tetanus toxoid if indicated, and antiemetics to control vomiting (which raises intraocular pressure).

one must be aware that an eyelid FB may mimic an intraocular FB.[51] Patients with a suspected metallic FB should *not* undergo magnetic resonance imaging if the FB may be *intra*ocular. Therapy for intraocular and intraorbital FBs must be individualized. Often, an ophthalmologist can localize an intraocular FB (if the vitreous is clear) using indirect ophthalmoscopy. The role of the emergency clinician is to suspect the diagnosis, to protect the eye from further harm, and to obtain ophthalmologic consultation. The remainder of this section addresses the problem of extraocular FBs.

Procedure

Foreign Body Location

The first step is to locate the FB. A drop of both topical anesthetic and fluorescein is applied to the inside of the lower lid (see Fluorescein Examination Figure 64-8 , Figure 64-17 earlier in this chapter). Vertical corneal abrasions from FBs under the lids are helpful for localizing these hidden foreign objects (see Fig. 64-10*C*). One should use a penlight and loupes or a slit lamp to examine the bulbar conjunctiva by having the patient look in all directions. The clinician examines the inside of the lower lid by pulling it down with the thumb while the patient looks up. One everts the upper lid by having the patient look down as the end of an applicator stick is pressed against the superior edge of the tarsal plate of the upper lid. Meanwhile, the clinician grasps the lashes and pulls down, out, and then up to flip the lid over (Fig. 64-20).

Minute FBs under the lid will be missed with simple visual inspection. Ideally, the everted lid should be examined under magnification with loupes or a slit lamp. With simple lid eversion it is still not possible to see the far recesses of the upper conjunctival fornix. Although double eversion of the upper lid (see Fig. 64-11) is helpful, the best way to rule out an FB in the upper fornix is to sweep the anesthetized fornix with a moistened applicator as the upper lid is held everted. The applicator tip should be examined for removed foreign material. Small conjunctival FBs not hidden by the lids are often best removed with a moistened nasopharyngeal swab (e.g., nasopharyngeal Calgiswab).

The cornea is then reexamined. Most corneal FBs have an area of fluorescein staining around them. A slit lamp makes the examination easier. If the clinician is limited to loupes and a penlight, the light is shined diagonally on the cornea. One then finds an FB directly or indirectly by noting a shadow on the cornea or the iris (Fig. 64-21).

With a history of a high-speed projectile hitting the eye, one must rule out an intraocular FB. In the case of a blast injury, multiple FBs may penetrate the eye. If an FB cannot be found

Figure 64-19 When a penetrating globe injury is suspected and a metal shield is not available in the emergency department or prehospital setting, a makeshift shield can be fashioned with available materials. A paper cup was used to fashion this shield.

on the surface despite a suggestive history, the eye should be examined for physical evidence of penetration as discussed earlier. The pupil is dilated, and the fundus is examined. If in doubt regarding an intraocular FB, one should consider computed tomography and ophthalmologic consultation.

Foreign Body Removal

Once an extraocular FB is located, the technique of removal depends on whether it is embedded. If the FB is lying on the

Figure 64-20 Single upper lid eversion. *A,* The patient is instructed to look downward, and the end of a cotton-tipped applicator is placed above the tarsal plate while the lashes and the lid margin are pulled down, out and up. *B,* One everts the lid and holds it by pressing the lashes against the superior orbital rim. If the foreign body is seen on the lid, it can usually be removed by touching it with a moistened cotton-tipped applicator. *(From Pavan-Langston D: Manual of Ocular Diagnosis and Therapy, 3rd ed. Boston, Little, Brown & Co, 1991. Reproduced by permission.)* *C*, This patient presented with a swollen and tender upper eyelid thought to be secondary to a stye. *D*, With lid eversion a small pustule was found under the upper eyelid. *E*, With a 27-gauge needle the pustule was incised and a drop of pus was expressed, and she made a rapid and uneventful recovery.

surface, a stream of water ejected from a syringe through a plastic catheter usually washes the object onto the bulbar conjunctiva. Once the FB is on the inner lid or bulbar conjunctiva, a wetted cotton-tipped applicator can be gently touched to the conjunctiva and the object will adhere to the applicator tip. Overzealous use of an applicator for corneal FB removal can lead to extensive corneal epithelial injury. A spud device is required for removal of objects that cannot be irrigated off the cornea.

Embedded corneal FBs (Fig. 64-22) are best removed with a commercial spud device, a Burr drill, a short 25- or 27-ga needle on a small-diameter syringe (e.g., insulin or "TB" syringe), or a cotton-tipped applicator (Fig. 64-23*A* and *B*). The applicator or the syringe serves as a handle for the attached needle. Contrary to what one might expect, it is difficult to penetrate the sclera or the cornea with a needle, especially when it is applied tangentially to the cornea. [39] As with removal of conjunctival FBs, the eye must be well anesthetized. The patient should be positioned so that the head is well secured (preferably in a slit lamp frame). At this point a simple explanation of the procedure usually ensures excellent compliance on the part of the patient. The examiner's hand rests on the patient's cheek so that unexpected movements on the part of the patient will not result in large movements of the removal device. The patient must be instructed to gaze at an object in the distance (e.g., the practitioner's ear when a slit lamp is used) to stabilize the eye further. The removal device is brought close to the eye *under direct vision*; then, while it is in focus, the device is manipulated under the slit lamp to remove the FB. The device is held *tangentially* to the globe, and the foreign object is picked or

scooped out. If a Burr drill

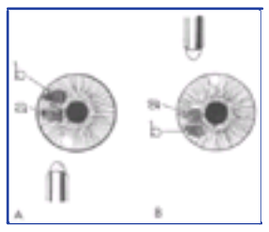

Figure 64-21 An "invisible" corneal abrasion casts an obvious shadow on the iris. The relative positions of *(a)* the corneal abrasion and *(b)* the iris shadow depend on the direction of the incident light (as in *A* and *B*). *(From Paton D, Goldberg MF: Management of Ocular Injuries. Philadelphia, WB Saunders, 1976. Reproduced by permission.)*

is used, the side of the drill is pressed against the FB until removal is accomplished (Fig. 64-23*C*).

During removal, the clinician should brace his or her hand against the patient's face. It also may be helpful to brace the elbow with a pad or half-full tissue box to provide further support to the arm as the FB is removed. The right-handed clinician should place the lower hand against the left maxillary bone when removing a foreign object from the patient's left eye and against the bridge of the patient's nose or infranasal area when removing an object from the right eye. These positions should be reversed by the left-handed clinician. The use of loupes or a slit lamp for magnification is highly recommended to minimize further injury during removal. In particular, corneal contact with the spud device is more readily discerned when magnification is used. Only topical anesthesia is required to remove FBs from the cornea. Although the patient may feel pressure during FB removal, pain should not be felt after the eye is anesthetized.

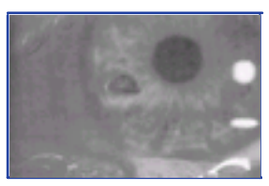

Figure 64-22 This embedded corneal foreign body is readily seen under slit lamp examination. A removal device (needle, spud, or burr drill) should be used for careful removal.

Rust Rings

A common problem with metallic FBs is the development of rust rings (Fig. 64-24). These can develop within hours because of oxidation of the iron in the FB. There are two preferred techniques for removal of a rust ring. The most direct method is to remove it at the same time as the FB, either with repeated picking away with a spud device or with a rotating burr. The second approach is to let the iron of the rust ring oxidize and kill the surrounding epithelial cells during a 24- to 48-hour patching period. At that time, the rust ring will be soft and often comes out in one solid plug. [52] Generally, a small rust ring produces little visual difficulty unless it is directly in the line of sight. The rust ring, if large, may delay corneal healing. Close follow-up is important to ensure healing of the cornea and total removal of the rust ring and FB.

Multiple Foreign Bodies

The patient with multiple FBs in the eye, such as from an explosion, should be referred to an ophthalmologist. A technique that may be chosen by the ophthalmologist is to denude the entire epithelium with alcohol and remove the superficial FBs. The deeper ones gradually work their way to the surface, sometimes years later.

Aftercare

After removing the FB, an antibiotic ointment is frequently instilled. Although commonly used, the value of the ointment for *superficial* corneal defects after FB removal is unproven, and no specific standard of care is supported by scientific evidence. *Conjunctival* and corneal abrasions do not need patching, but if the eye is patched, the patient should be reexamined in 24 hours. Data suggest that eye patching offers no benefit in healing small, uncomplicated corneal abrasions secondary to FBs.[53] If the patient sustains a *superficial* injury from the FB, the clinician may wish to instruct him or her to return only if the eye does *not* feel completely normal *or* if there is any blurred vision. The majority of superficial injuries heal without difficulty. The patient should be warned that the FB sensation may return temporarily when the anesthetic agent has worn off. One animal study with direct ocular exposure to *Clostridium tetani* organisms suggests that nonpenetrating ocular injuries are unlikely to lead to tetanus.[54] Tetanus prophylaxis after a corneal FB removal is not standard, but it may be considered. However, tetanus prophylaxis appears essential for injuries that penetrate through the cornea or sclera.

Use of Ophthalmic Anesthetic Agents

Application of topical anesthetic agents can be both diagnostic and therapeutic. Relief of discomfort with topical anesthetic use often suggests, but does not ensure, a conjunctival or corneal injury. An ocular irritant may also be masked by the use of these agents. Classic teaching is that the anesthetic preparations should not be self-administered by patients. The absence of protective reflexes while the patient is under the effect of the medicine may encourage the patient to use the eye while an FB or a corneal infection inflicts further corneal injury.

Bartfield and coworkers found that the pain of instillation of 0.5% proparacaine was significantly less than that of 0.5% tetracaine. [55] As evident from Table 64-3 , the anesthetic

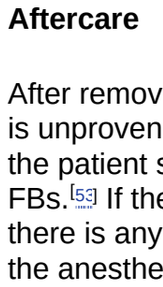

Figure 64-23 It is preferable to remove the corneal foreign body (FB) under the slit lamp. A topical anesthetic is applied and the operator uses a small syringe with a short 25- to 27-ga needle (such as a tuberculin syringe). Be certain that the needle is firmly attached to the syringe. *A*, *Under direct vision*, the syringe is brought close to the eye and the operator rests the hand on the patient's cheek. Be sure that the patient's forehead maintains continual contact with the cross bar on the slit lamp. *B,* While looking through the slit lamp, the needle is brought to the cornea and the FB is removed. *C,* The side of the instrument (drill bit or beveled edge of the needle) should be held tangential to the cornea. Arrows indicate the direction of device in order to remove the FB. *(From Knoop K, Trott A: Ophthalmologic procedures in the emergency department—Part III: Slit lamp use and foreign bodies. Acad Emerg Med 2:224, 1995. Reproduced by permission.)*

solutions that are commonly used have a duration of action of <20 minutes. The patient with a large corneal lesion may need a more extended period of pain relief. The discomfort associated with a large healing corneal lesion is usually made tolerable by bedrest, opioid analgesics, and appropriate sedatives. Even in the absence of infection or a retained FB, the long-term *repeated* use of ophthalmic anesthetic ointments may be detrimental to corneal healing. [56]

A final word of caution should be added regarding the use of ophthalmic solutions. Guaiac solutions are commonly supplied in dropper bottles similar in size and appearance to those containing ophthalmic solutions. Well-intentioned ED personnel may store the guaiac reagent bottles with the ophthalmic bottles. One should encourage both color-coding of the bottles and examination of them and their labels before each use to avoid corneal injury from inadvertently instilling guaiac

reagent in the eye.

Complications

Complications associated with ocular FB removal are rare. The most frequent problem is incomplete removal of the FB. In such cases the epithelium has difficulty healing over the affected area, and thus the eye stays inflamed. Eventually, the diseased epithelium either sloughs off and heals, or heals over the FB remnants, which are gradually absorbed. In either case, the adverse effects on the eye are minimal; a minute scar on the cornea, even directly in the center, will rarely affect the vision. Nonetheless, incomplete removal of a corneal foreign object warrants ophthalmologic follow-up.

Figure 64-24 A typical rust ring is seen at 8 o'clock on the cornea. A burr drill can be used for attempted removal, which if unsuccessful, can be reattempted in 24 hours. *(From Knoop KJ, Stack LB, Storrow AB (eds). Atlas of Emergency Medicine, 2nd ed. New York, McGraw-Hill, 2002. Reproduced by permission.)*

Conjunctivitis may develop after removal of an extraocular FB. In most cases, the bacteria producing the infection are introduced by the patient through rubbing of the irritated eye.

Although perforation of the globe by the clinician's spud device is theoretically possible, this complication is exceedingly rare. Treatment of this type of corneal puncture wound consists of antibiotics, eye shield placement, and ophthalmologic consultation. In the absence of resultant endophthalmitis, permanent sequelae are unlikely to develop.

Epithelial injury can occur when cotton-tipped applicators are vigorously used to remove corneal FBs. Indeed, the use of cotton-tipped applicators for embedded *corneal* FB removal is condemned.

Summary

Ocular FBs are one of the most common eye emergencies. Searching for and removing the FB is usually straightforward. The only real trap is missing an intraocular FB. This must be ruled out if there is a history of a high-speed projectile hitting the eye or if physical findings suggestive of globe penetration are present.

Use of Ophthalmic Nonsteroidal Anti-Inflammatory Drugs

Ophthalmic nonsteroidal anti-inflammatory drugs (NSAIDs) have been evaluated for their effectiveness in the treatment of

TABLE 64-3 -- Ophthalmic Anesthetic Agents

Generic name	Tetracaine	Proparacaine	Benoxinate
Trade name	Pontocaine	Ophthaine, Ophthetic	Dorsacaine
Concentration	0.5 to 1.0%	0.5%	0.4%
Onset of anesthesia	< 1 min	< 20 sec	1–2 min
Duration of anesthesia	15–20 min	10–15 min	10–15 min
Comments	Marked stinging; also available in ointment	Least irritating; no cross-sensitization with other agents	Only anesthetic compatible with fluorescein in solution

traumatic corneal abrasions. Examples include ketorolac tromethamine, diclofenac, and flurbiprofen. These agents are safe to use and effective for the relief of pain associated with corneal abrasions. [57] [58] [59] [60]

EYE PATCHING

Patching the lids shut has traditionally been the last step in treatment of a number of common eye emergencies; however, multiple studies have shown that eye patching may offer no benefit in pain relief or healing rates with conjuctival or corneal abrasions. [53] [61] [62] [63] Many clinicians have only a vague idea of what the purpose of patching is, how to do it, and how to follow up. Even this simple procedure can be performed incorrectly.

Patching may be used for several goals. A simple patch may be used to protect the dilated eye from bright light. Pressure patching as discussed in this section is the use of a patch to hold the eyelid closed to possibly facilitate healing of a large corneal defect by limiting eyelid movement over an injured area.

It has been suggested in some studies that small, simple corneal abrasions do not require patching to aid healing or for reduction of pain. [64] [65] [66] A recent meta-analysis has elaborated on whether patching or not patching influences healing times or pain perception in corneal abrasions. The conclusion was that "eye patching was not found to improve healing rates or reduce pain in patients with corneal abrasions." [63] Collectively these studies support the treatment of small corneal defects without a pressure patch. The value of pressure patch application for large defects remains unclear. The patch may be of value until a bandage, soft-contact lens, or collagen corneal shield can be obtained at follow-up (see later sections on recurrent corneal erosions).

Indications and Contraindications

Patching was indicated in the recent past whenever the surface of the cornea had been injured; however, as mentioned earlier, there is little evidence to support its routine use. Nonetheless, practitioners may elect to patch an injured eye since the procedure has little downside. Injury can occur after a mechanical abrasion, such as a fingernail scratch, or after the removal of an FB. Chemical damage, damage from prolonged *hard* contact lens use, and ultraviolet light injuries are also commonly seen in the ED. With each of these forms of injury, if a patch is used, the purpose is to keep the lids from moving over the cornea and to keep light out. After patching, the patient may immediately experience less pain and tearing.

Patching is contraindicated when the corneal epithelial loss results from an active infection—such as a corneal ulcer—rather than from an abrasion. The first consideration in the differentiation between ulcer and abrasion is the history of the injury (how recently it occurred and how clean the offending object was). The second determining factor is the appearance of the cornea (i.e., an ulcer will have an infiltrate of white cells beneath the area of epithelial loss and will be accompanied by a purulent discharge). Generally, abrasions associated with *soft* contact lens use should be considered infected and patching avoided until ophthalmologic evaluation. [67] Of particular concern is the rapid development of *Pseudomonas* keratitis, an unusual but serious infection associated with corneal abrasions from soft contact lenses. A pressure patch should never be applied to an eye with a penetrating injury. A protective cup is the preferred covering in such cases pending ophthalmologic consultation.

Equipment

The following equipment is necessary for patching the eye:

- Gauze eye patches (2)
- Tape (e.g., 1-in. paper tape, preferably nonallergenic)
- Antibiotic ointment (e.g., sulfacetamide 10%)
- Dilator eyedrops (cyclopentolate [Cyclogyl] 1% or homatropine 5%)

The tape should be precut into 4- to 6-in. strips and should be kept within reach. Commercial patching products are also available and are discussed later.

Procedure

Before patching a corneal abrasion, one may apply both a dilator drop and an antibiotic ointment. While commonly used, there are no data to support or refute efficacy of routine pupillary dilation. The dilator must be a cycloplegic to relax the ciliary muscle spasm that accompanies corneal abrasions. Both cyclopentolate 1% and homatropine 5% last approximately 24 hours. The patient should be checked for a narrow

Figure 64-25 Application of eye patch. *A,* Vertically folded first patch in orbital recess. *B,* Horizontally oriented second patch with forehead to cheek taping. The contralateral eye should be kept closed throughout patching.

anterior chamber before the drop is instilled (see Fig. 64-4). Antibiotic ointment may be used prophylactically, although there are no data to support or refute efficacy. It is rare for abrasions to become infected. [68] In the past it was thought that the ointment vehicle would slow epithelial healing, but the vehicles that are currently used do not have this effect. [69] [70]

An effective patch must be put on tightly enough to keep the lids shut. The clinician should have the patient shut both eyes and should remind him or her to keep them shut throughout the entire procedure. Two patches are used. The vertically positioned first patch is doubly folded and placed over the closed lids. The unfolded second patch is then put horizontally over the first (Fig. 64-25). The tape strips are stretched diagonally from the center of the forehead to the cheekbone. The clinician can pull up the skin of the cheek; when he or she lets go, the tape will be even tighter. If the tape completely covers the patch, slippage of the patch and resultant eye movement are avoided (Fig. 64-26). The tape should not extend onto the angle of the mandible, because mastication loosens the tape in such a situation. Some clinicians paint the skin about the eye with tincture of benzoin to help secure the tape. Care must be taken not to introduce the benzoin into the eye. The presence of extensive facial hairs may prevent tight taping of the patch. An adjustable elastic strap pressure patch (e.g., Presspatch II, Precision Therapeutics, Inc, Las Vegas, NV) may be useful in this setting (Fig. 64-27). The patient must be carefully instructed in the use of this commercial patch, and avoidance of excessive globe pressure from the elastic straps must be confirmed.

It is imprudent to leave a pressure patch on for >24 hours. When repatching is required, a clean patch should be applied within each 24 hours. Repatching prevents a patch from becoming moist and serving as a nidus for the development of infection.

The Donaldson Eyepatch (Keeler Instruments, Inc, Broomall, PA) is a commercial product used for enforced eyelid closure that avoids the bulkiness of pressure patching (Fig. 64-28). The device has two components: one adheres to the upper lid, and the other is a circle that adheres to the

Figure 64-26 Final appearance of pressure eye patch.

ipsilateral cheek. A tab on the upper component connects by Velcro to the lower component. This patch may be advantageous in some settings, but its design may encourage some individuals to release the lid closure prematurely.

Because of conjugate eye movement, patching only one eye does not totally immobilize the globe. When all movement must be stopped, bilateral eye patches should be applied. The use of bilateral patches may not be accepted by all patients, and one must seek both patient understanding and family support for patient home activities if dual eye patching is to be successful.

Complications

There are few complications involved in patching. It is possible to patch the patient's lashes in between the lids so that they abrade the cornea. This can occur if the patient partially

Figure 64-27 Use of the adjustable elastic strap pressure patch, Presspatch II. The clinician should ensure that the elastic straps for the patch are adjusted to avoid excessive globe pressure. *(Courtesy of Precision Therapeutics, Inc, Las Vegas, NV.)*

Figure 64-28 Donaldson eye patch (Keeler Instruments, Inc, Broomall, PA). *Inset* shows the means by which the patch can be released for eye inspection or medication administration.

opens the eye during the procedure. This can be avoided by insisting that both eyes stay closed during the entire patching.

Most problems develop when the eye is not securely patched and excessive lid motion occurs. In this situation the corneal epithelial cells are not permitted to migrate over and close the epithelial defect. This leads to increased pain and delayed healing. Some corneal defects are extensive and may require 3 to 5 days for healing. Patients with extensive injuries should be observed frequently and treated with cycloplegic agents, pain medication, and (if clinically indicated) sedatives for sleep. The practitioner should document the size of the corneal defect at each visit. If healing does not occur in a progressive fashion, ophthalmologic consultation should be obtained. As mentioned earlier, patching is contraindicated when a corneal ulcer is present, the possibility of infection is high, or there has been soft contact use. A corneal "abrasion" that does not heal could very well be a herpetic ulcer.

Recurrent Corneal Erosions

Patients whose eyes have been patched for a corneal abrasion may experience *recurrent corneal erosions* in the future as a complication of the original injury. The original abrasion may appear to have healed perfectly, but days, weeks, or even months later a small area of corneal epithelium can come off, re-creating the symptoms of the original abrasion in the absence of new trauma. This usually occurs in the mornings as the patient opens the eyes, presumably due to adherence of the weaker, recently healed corneal epithelium to the upper lid during sleep. These erosions may heal before the patient is reexamined and can be very puzzling. The cause is

a failure of bonding of the corneal epithelium to its basement membrane. [71] Patients who develop this syndrome are given 5% sodium chloride ointment to use nightly to prevent the erosions; some require bandage soft (collagen) contact lenses. [72]

Summary

Patching is generally not necessary in the treatment of corneal epithelial defects, but if performed, should be an easy, straightforward procedure. A common problem is the lack of follow-up instructions given to the patient after the patching. Too often, the patient is given a bottle of antibiotic drops to be used every 4 hours and only vague recommendations for a follow-up check. When patients remove the patch to put in an antibiotic drop, they are never able to replace the patch properly again and may actually deter any healing that has already taken place. Instead, they should be told to keep the patch on for 24 hours and to return to have their abrasion checked by a clinician after that time. Generally a large abrasion will take several days to heal. Serial assessment is valuable for patient reassurance and assuring that complications do not develop.

The patient with an eye patch should be instructed to rest the uninjured eye. Reading should be discouraged, because involuntary movement of the patched eye will result. Watching television from a distance of 10 feet or more promotes eye fixation and is acceptable. Distant vision is unaffected by patching, although a small degree of peripheral vision is lost on the patched side. Although the visual field is minimally affected, driving after a patch is placed is not advisable. Preferably, the patient should be driven home from the hospital to minimize the potential for patient injury. An elderly patient may require assistance with routine ambulation after eye patching. Use of collagen shields applied directly to the cornea may offer an attractive alternative to eye patches. [72] These devices have yet to be introduced into ED practice.

CONTACT LENS PROCEDURES

An estimated 24 million Americans wear a form of contact lenses. [73] Removal of these lenses in the ED may be required to permit further evaluation of the eye or to prevent injury from prolonged wear. Emergency clinicians also evaluate patients for "lost" contact lenses, which may be trapped under the upper lid. At times, the patient may request that the clinician remove a lens that he or she has failed to extract from the cornea. Corneal ulcers may occur in patients who wear contact lenses and may require prompt treatment. This section on contact lens procedures addresses these concerns and discusses injuries associated with removal attempts, the mechanism of injury from prolonged wear, and instructions to be given to patients at discharge.

The first contact lenses were scleral lenses made of glass. These lenses, covering the cornea as well as much of the surrounding sclera, are reported to have been in use from 1888 to 1948.[74] Glass corneal lenses (sitting entirely on the cornea) made by the Carl Zeiss Optical Works of Jena were first described in 1912. A practical synthetic scleral lens using methyl methacrylate rather than glass was discussed by Obrig and Mullen in 1938. [75] [76] In 1947, Tuohy redeveloped the corneal lens using methyl methacrylate. This was the forerunner of the current hard contact lens. [77] The development in Czechoslovakia of lenses made of soft gas-permeable polymers was reported in 1960.[78] These hydrogel (hydrophilic gelatinous-like) lenses have evolved into today's soft contact lenses. Soft contact lenses now come in a variety of types including extended and daily wear. Some extended-wear lenses are disposable. All lenses should be removed at least once a week.

Mechanism of Corneal Injury from Contact Lens Wear

Hard Contact Lenses

The oxygenation of the cornea is dependent on movement of oxygen-rich tears under the hard contact lens during blinking. During the "adaptation" phase of early wear, the wearer of hard contact lenses produces hypotonic tears as a result of mechanical irritation from the lens. [74] This results in corneal edema, which reduces subsequent tear flow under the lens during blinking. Overwearing a lens at this time leads to corneal ischemia, with superficial epithelial defects predominantly in the central corneal area (see Fig. 64-10*D*), where the least tear flow occurs. With adaptation, the tears become isotonic and the blinking rate normalizes, permitting increased wear time. During early adaptation blinking is more rapid than normal and then slows to a subnormal rate during late adaptation. Mucus delivery to the cornea in the tear film may also play an important role in maintaining corneal lubrication. Tight-fitting contact lenses may never permit good tear flow despite an adaptation phase; individuals with tightly fitted lenses may never be able to wear their original contact lenses for longer than 6 to 8 hours. Lenses that are excessively loose can also cause irritation by moving during blinking. Rough or cracked edges can cause corneal abrasions.

In the ED, the patient who presents with irritation caused by prolonged wear may be either a new or an adapted wearer. The adapted wearer may have been exposed to chemical irritants (e.g., smoke), which reduce the tonicity of tears and lead to corneal edema and decreased tear flow. Alternatively, the adapted wearer with irritation may have ingested sedatives (e.g., alcohol) or may have fallen asleep wearing the contact lenses, thus decreasing blinking and tear flow. Another possibility is that the patient may actually be wearing tight-fitting contact lenses that have never allowed true adaptation despite many months of wear.

The patient with the overwear syndrome usually awakens a few hours after removing the lenses. The patient experiences intense pain and tearing similar to that caused by an FB. The delay in the onset of symptoms until after removal of the lenses is caused by a temporary corneal anesthesia produced by the anoxic metabolic by-products that build up during extended lens wear. [79] A second factor is the slow passage of microcysts of edema, which are pushed up to the corneal surface by mitosis of the underlying cells. When the cysts break open on the surface, the corneal nerve endings are exposed. [80]

Most patients with the overwear syndrome can be managed with reassurance, frequent administration of artificial tears, oral analgesics, and advice to "wait it out" in a darkened room. Some patients require patching for comfort. A patient who has experienced no problems with contact lenses before an overwear episode can return to using the lenses after 2 or 3 days of wearing glasses but should be

advised to build up wearing time gradually. A patient who was having chronic problems with lens comfort before the episode should check with an ophthalmologist before using the contact lenses again.

Soft Contact Lenses

Although there is also oxygenation of the cornea by way of the tear film with soft contact lenses, only approximately one tenth of the flow behind the lens that occurs with a hard lens is present during soft contact wear. [74] The high degree of lens gas permeability permits the majority of oxygenation to occur directly through the lens. The hydrogel lens is more comfortable than the hard contact lens because lid motion over the lens is smooth. The minimization of lid and corneal irritation allows a more rapid adaptation phase because the initial reflex-induced tearing and blinking changes are reduced. Nonetheless, the lenses may still lead to corneal edema and secondary hypoxic epithelial changes if worn for an excessive period when blinking is inhibited. Some individuals can tolerate the lenses for extended periods and may on occasion sleep with the contact lenses in place, although this practice is not encouraged. Newer extended-wear hydrogel lenses (e.g., Permalens) permit wear for several days without injury. These lenses are not discernible from standard soft lenses on examination.

Although the acute overwear syndrome that occurs with hard contact lenses can also occur with soft lenses, it is infrequent. More commonly, ocular damage from soft contact lenses falls into one of the three following categories:

1. *Corneal neovascularization.* Often the patient is asymptomatic, but on slit lamp examination fine vessels are seen invading the peripheral cornea. The treatment is to have an ophthalmologist refit the patient with looser or thinner lenses or with contact lenses that are more gas permeable.
2. *Giant papillary conjunctivitis.*[81] The patient notes decreased lens tolerance and increased mucus production. On examination of the tarsal conjunctiva (best seen on eversion of the upper lid), large papillae are seen. These grossly appear as a cobblestoned surface. The treatment is to discontinue wearing the lenses until the process reverses and then have the lenses refitted.
3. *A sensitivity reaction to the contact lens solutions* (usually thimerosol or chlorhexidine). [82] [83] There is diffuse conjunctival injection and sometimes a superficial keratitis. The treatment is to switch to preservative-free saline with the use of heat sterilization. Often, the contact lenses will need to be replaced before lens wear can be resumed.

All of these problems with soft lenses have bilateral, subacute onsets and do not require emergency treatment. The only form of ocular damage associated with soft contact lenses that is a true emergency is a bacterial (often *Pseudomonas* or *Acanthamoeba* with soft contact lenses) or fungal corneal ulcer. [84] [85] [86] Because the nature of soft contact lenses is to absorb water, they can also absorb pathogens, which then can invade the cornea. This is especially true if the soft lens is worn continuously for extended periods of time. The patient presents with a painful, red eye with associated discharge and a white infiltrate on the cornea. Immediate ophthalmologic consultation is required for appropriate culturing and antimicrobial treatment. These infections can permanently affect the patient's visual acuity.

Indications for Removal

Removal of a contact lens is recommended in the following situations:

1. *Contact lens wearer with an altered state of consciousness.* The emergency clinician should always be aware that the patient with a depressed or acutely agitated sensorium may be unable to express the need to have his or her contact lenses removed. Furthermore, it is likely that patients with a depressed sensorium will have decreased lid motion. During the secondary survey of these patients, the emergency clinician should identify the presence of the lenses and should arrange for their removal and storage to prevent harm from excessive wear or possible accidental dislodgment at a later time. Without magnification, soft

contact lenses may be difficult to see. Examination with an obliquely directed penlight should reveal the edge of the soft lens 1 to 2 mm from the limbus on the bulbar conjunctiva.

2. *Eye trauma with lens in place.* After measurement of visual acuity with the patient's lenses in place, the lenses should be removed to permit more detailed examination of the cornea. Fluorescein may discolor hydrogel lenses; when possible, extended-wear lenses should be removed before the use of this chemical. After the dye is instilled, the eyes should be flushed with normal saline; at least 1 hour should pass before reinsertion. [74] The availability of single-use droppers of 0.35% fluorexon (Fluresoft) has permitted the safe staining of eyes when soft lenses are to be worn immediately after the examination. A limited eye irrigation after the use of fluorexon drops is still recommended before the reinsertion of soft contact lenses.
3. *Inability of the patient to remove the contact lens.* A patient may present with a hard contact lens that cannot be removed because of corneal edema from prolonged wear. Alternatively, the patient may present with a "lost" contact lens that is believed to be behind the upper lid. There is no urgency for contact removal in the out-of-hospital setting; hence, removal can wait until the patient has been evaluated by a clinician.

Contraindication to Removal

The only major problem with contact lens removal occurs when the cornea may have been perforated. In this case, the suction cup technique of removal described later is preferred.

Procedure

Hard Contact Lens Removal

A number of maneuvers have been devised for removal of the corneal lens. One technique is to first lean the patient's face over a table or a collecting cloth. The clinician pulls the lids temporally from the lateral palpebral margin to lock the lids against the contact lens edges. The patient should look toward the nose and then downward toward the chin. This movement works the lower eyelid under the lower lens edge and flips the lens off the eye. The technique requires a cooperative patient because the clinician must pull the patient's lids tightly against the edge of the contact lens. The movement of the patient's eye then flips the contact free.

In the unresponsive patient, a modification of the technique can be used while the patient is supine. The clinician

takes a more active role in lid movement using the following procedure: one thumb is placed on the upper eyelid and the other on the lower eyelid near the margin of each lid. With the lens centered over the cornea, the eyelids are opened until the lid margins are beyond the edges of the lens (Fig. 64-29*A*). The clinician then presses both eyelids gently but firmly on the globe of the eye and moves the lids so that they are barely touching the edges of the lens (Fig. 64-29*B*). One presses slightly harder on the lower lid to move it under the bottom edge of the lens. As the lower edge of the lens begins to tip away from the eye, the lids are moved together, allowing the lens to slide out to where it can be grasped (Fig. 64-29*C*). The clinician should remember to use clean hands (and preferably wear examination gloves that have been rinsed in tap water or saline) when removing the lens.

Alternatively, one can move the lens gently off the cornea using a cotton-tipped applicator to guide the lens onto the sclera, where the applicator tip can be forced under an edge of the lens to flip the contact loose. Topical anesthesia is indicated when using an applicator and the patient is awake. Care must be taken with this technique to avoid contact of the applicator with the cornea when the lens is moved off the eye. Perhaps the easiest technique is to use a moistened suction-tipped device and simply lift the lens off the cornea (Fig. 64-30).

Several lenses (those hard contact lenses that cover both the cornea and an amount of the sclera) can be removed by an exaggeration of the manual technique described earlier (Fig. 64-31). Elevation of the lens with a cotton-tipped applicator or a suction-tipped device is also an effective technique. Soft

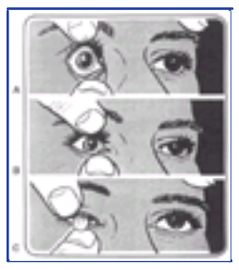

Figure 64-29 Manual technique for removing a hard contact lens. *A,* Separation of lids. *B,* Entrapment of lens edges with lids. *C,* Expulsion of lens by forcing of lower lid under inferior edge of lens. *(From Grant HD, Murray RH, Bergeron JF: Brady Emergency Care, 5th ed. Figure 64-30 Use of a moistened suction cup to remove a hard contact lens. *(From Grant HD, Murray RH, Bergeron JF: Brady Emergency Care, 5th ed. Englewood Cliffs, NJ, Prentice Hall, 1990, p 338. Reproduced by permission.)*

contact lenses should not be removed with a suction-tipped device because tearing or splitting of the lens may occur.

Soft Contact Lens Removal

With clean hands (preferably using gloves rinsed in saline or tap water), the clinician pulls down the lower eyelid using the middle finger. The tip of the index finger is placed on the lower edge of the lens. The lens is slid down onto the sclera and is compressed slightly between the thumb and the index finger. This pinching motion folds the lens and allows its removal from the eye (Fig. 64-32).

Englewood Cliffs, NJ, Prentice Hall, 1990, p 338. Reproduced by permission.)*

Lens Storage

After a contact lens is removed, it should be stored in sterile normal saline solution. It is best to use the patient's own storage container and, if available, the patient's lens solution. A variety of alternative sterile containers are available for use in the ED. One should be certain that right and left lenses are kept separate and in appropriately labeled containers. The containers should be kept with the patient until a friend or family member can procure them, or they should be locked with the patient's valuables.

Evaluation of the "Lost Contact"

A patient may present with a request to be examined for a "lost" contact lens. The patient may be unsure if the lens is hidden under a lid, remains on the cornea, or is truly outside the eye. The evaluation of the patient with a "lost" contact should begin, as should all eye examinations, with the measurement of visual acuity. Visual acuity is preferably measured using a 20-foot eye chart. A diminished visual acuity in the eye in which a patient just cannot seem to "take out" a soft contact lens may be the most convincing evidence that the lens is missing. Although transparent, soft contact lenses in proper position are usually seen easily when viewed closely with loupes or on slit lamp examination. The lens forms a fine line where it ends on the sclera several millimeters peripherally to the limbus. Hard contact lenses are even more evident as they change in position on the cornea.

If the contact is not evident on initial inspection, the lids are everted as discussed in the section on FB removal (double eversion of the upper lid). If the lens is still not visible, a drop of topical anesthetic is placed in the eye. The upper fornix is gently swept with a moistened cotton-tipped applicator while the patient looks toward the chin. If the lens is still not evident even though the patient remains insistent that it is in the eye, one may perform a fluorescein examination after explaining that the dye will color the lens (permanently). The upper lid should again be doubly everted and visualized using an ultraviolet light source.

If the lens remains elusive, the patient should be reassured that a thorough examination was performed and that no object was located under the eyelids or on the cornea. The cornea should then be examined for defects that warrant antibiotic ointment and a pressure patch placed over the eye (as discussed in the section on patching). Follow-up with the patient's eye specialist for a replacement lens and further reassurance is encouraged. One also should ask the patient to retrace movements at the time the contact began to give trouble or was missed and to check the clothing being worn for the presence of the lens. A final possibility is that the patient may have accidentally placed the two lenses together in the same side of the carrying case, causing them to stick together. In fact, patients have inadvertently placed one contact lens over the other—both in the same eye. One should note that hard contact lenses have been found embedded in conjunctival tissue under the upper lid (Fig. 64-33) after more than a year.[87] [88] Hence, a methodical approach, as outlined earlier, should be taken to ensure that no lens remains hidden in the eye.

Complications of Lens Removal

Unless care is used during lens removal, a corneal abrasion can occur. It is difficult at times to determine whether the injury was produced by the patient or was a result of the clinician's technique. Fortunately, the corneal injury is usually of a superficial nature and responds well to eye patching, or other symptomatic care.

Summary

Contact lens removal is seldom a difficult task. More challenging situations are the identification of emergency patients at risk for corneal injury due to overuse, the evaluation of patients who cannot locate a soft lens, and the instruction of patients with contact lens-related problems concerning aftercare.

INFECTIOUS KERATITIS

Infectious keratitis with corneal ulceration can have a variety of causes, including the overwear of contact lenses. Diagnosis of a corneal ulcer requires the use of a slit lamp and an accurate determination of the patient's history. Infectious keratitis is a frequent problem in ophthalmic practice. Herpes simplex is a common corneal pathogen. *Acanthamoeba* is another pathogen that is particularly associated with contact lens use and exposure to organism-tainted environments. Patients presenting with a corneal ulcer require prompt referral to an ophthalmologist. When immediate referral to an ophthalmologist is not possible, telephone guidance from the ophthalmologist and therapy needs to be initiated with ophthalmology follow-up in 24 hours or less.

Patients with herpes simplex keratitis often give a history of prior episodes of the disease. Patients who undergo almost any form of corneal stress may sustain an activation of preexisting corneal disease. Herpes simplex keratitis is classically recognized by its dendritic pattern on fluorescein staining.

Acanthamoeba keratitis is a disease with potentially devastating consequence. Its frequency seems to be increasing, particularly in contact lens wearers, and its pathophysiology is not completely understood. Patients often present with a red eye in which initial bacterial culture results are negative.

Bacterial keratitis occurs in a variety of settings. Organisms range from the relatively common *Staphylococcus* or *Streptococcus* to *Mycobacterium,* which can be difficult to identify. A variety of antibiotics are used against bacterial agents. Ciprofloxacin is a quinolone that has demonstrated efficacy against most of the common causative agents. Bacterial organisms in the cornea can develop resistance to any antibiotic and resistance to fluoroquinolones has been observed. [85] Ideally, treatment follows culturing of the ulcer.

In instances in which a cellular infiltrate is seen on slit lamp examination and in which there will be a delay of hours before an ophthalmologic consultant can culture the patient, it is prudent to initiate therapy with topical ciprofloxacin. In such circumstances, the emergency clinician may consider corneal cultures if suggested under the telephone guidance of the consultant before administering the antibiotic. One approach is to lightly touch a culture-moistened cotton-tipped swab against the ulcer and then streak standard culture media. If the ulcer is chronic or the patient is immunocompromised, fungal organisms may be culprit. Finally, a saline-moistened cotton-tipped swab may be used to obtain a Gram stain of the ulcer. Initiation of therapy before obtaining specimens for culture makes the subsequent identification of an organism difficult. For this reason the immediate initiation of treatment depends on the circumstances of the individual case.

TONOMETRY

Tonometry is the estimation of IOP obtained by measurement of the resistance of the eyeball to indentation of an applied force. Prolonged elevated IOP is associated with visual field loss and blindness. Sudden elevation of IOP can follow trauma or occur with primary angle-closure glaucoma. Often, patients with primary angle-closure glaucoma come to the ED with systemic complaints that include nausea, vomiting, and headache. The emergency clinician must determine the IOP and its relationship to the systemic symptoms. Occasionally, such patients are surprisingly free of pain in or about the eye.

Ophthalmologists depended on tactile estimation of eye pressure until the 1860s when von Graefe developed the first mechanical tonometer. [3] [22] Applanation tonometry was introduced in 1885 by Maklakoff[90] but was not popularized until Goldmann [91] improved the instrument in the 1930s. Schiotz developed an impression tonometer in 1905 and modified it in the 1920s; this form is still in use today. [92] Aside from modifications in configuration, current tonometers closely resemble the devices popularized by Schiotz and Goldmann. The most dramatic variations are the Mackay-Marg tonometer, [93] which permits a continuous tonographic recording, and the noncontact tonometer, which is a pneumatic applanation tonometer.[94] Pocket-sized tonometers using the MacKay-Marg tonometer principle are available. One such device is the Tono-Pen XL (Mentor O & O, Inc, Norwell, MA).[95] These devices are portable, lightweight, and relatively accurate, with built-in provisions for calibration. They have the advantage of a one-time-use replaceable cover that eliminates concern about the possible transmission of an infectious agent. While numerous devices are available, the Schiotz tonometer is the standard way for emergency clinicians to measure IOP.

Tonometric Techniques

Three tonometric techniques are reliable and clinically useful for estimating IOP:

1. The impression method uses a plunger (3 mm in diameter) to deform the cornea and the "indentation" is then measured. This technique was popularized by Schiotz and commonly bears his name.
2. The MacKay-Marg method is a refined version of the impression technique in which smaller amounts of cornea are indented.
3. In the applanation method a planar surface is pressed against the cornea.

One can either measure the pressure necessary to flatten a defined area or measure the size of a flattened area produced by the defined pressure. These tonometric techniques are based on the Imbert-Fick law, which states that if a plane surface is applied with force (F) to a thin, spheric membrane within which a pressure (P_t) exists, at equilibrium the expression $P_t = F/A$ is valid if A is the area of the applied surface (Fig. 64-34). The Schiotz tonometer (Fig. 64-35) actually measures the total IOP (initial pressure plus the pressure added by the weight of the tonometer and the plunger). Friedenwald empirically found that a "rigidity coefficient" could be introduced to allow an estimation of the true intraocular eye pressure. [96] One must be aware, however, that calculated conversion tables for Schiotz tonometers use an average estimate of the rigidity coefficient and hence are not accurate when eye rigidity is altered (e.g., after scleral buckle procedures for retinal detachment or with extreme myopia). Although the applanation tonometer (Fig. 64-36) also increases the IOP during measurement, the applied pressure is much smaller and is partially countered by the surface tension of the eye tear film. Emergency clinicians usually do not have experience or availability of this technique, but studies have shown applanation tonometer measurements to be within 2% of the true IOP.[97]

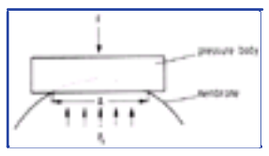

Figure 64-34 Principle of tonometry. At equilibrium: $P_t = F/A$. *(From Draeger J, Jessen K: Tonometry and tonography. In Bellows JG (ed): Glaucoma: Contemporary International Concepts. New York, Masson Publishing USA, 1979. Reproduced by permission.)*

The noncontact tonometer is a pneumatic applanation tonometer that permits IOP measurement without eye contact. A pulsed air jet is used to deform the cornea. The technique is also dependent on ocular rigidity. Although readings taken by different examiners correlate well, the measurements are altered by the use of local anesthetics and show a wide standard deviation of measurement in patients with pathologic elevation of ocular pressure (when standard applanation tonometry is used as a reference).[98] Furthermore, the technique is not useful with corneal surface irregularities (e.g., corneal edema, keratoconus, corneal perforation) or when medications in viscous preparations have been used. The use of this type of tonometer is not recommended when accurate determination of the IOP is required. This type of device is primarily useful for glaucoma screening.

Indications for Tonometry

Measurement of IOP in the ED by tonometry is a technique available to most emergency clinicians. Tonometry is not a standard procedure for many eye-related complaints, but special situations in which tonometry may be particularly helpful are as follows:

Confirmation of a clinical diagnosis of acute angle-closure glaucoma. The middle-aged or elderly patient who presents with acute aching pain in one eye, blurred vision (including "halos" around lights), and a red eye with a smoky cornea and a fixed midposition pupil obviously needs a pressure reading. Sometimes the findings are less dramatic, and

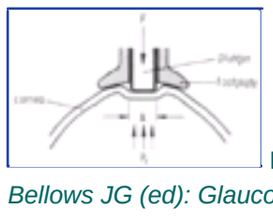

Figure 64-35 Principle of impression tonometry. In reality, P_t is increased slightly by the weight of the instrument. *(From Draeger J, Jessen K: Tonometry and tonography. In Bellows JG (ed): Glaucoma: Contemporary International Concepts. New York, Masson Publishing USA, 1979. Reproduced by permission.)*

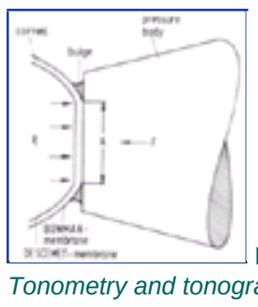

Figure 64-36 Principle of applanation tonometry. The effect of surface tension counters the pressure rise produced by application of the instrument. *(From Draeger J, Jessen K: Tonometry and tonography. In Bellows JG (ed): Glaucoma: Contemporary International Concepts. New York, Masson Publishing USA, 1979. Reproduced by permission.)*

sometimes the patient complains mostly of nausea and vomiting that suggest a "flu" rather than an eye disorder.

Determination of a baseline ocular pressure after blunt ocular injury. Patients with hyphema often have acute rises in IOP because of blood obstructing the trabecular meshwork.[99] Later, angle recession can cause a permanent form of open-angle glaucoma. Arts and coworkers suggest that an IOP >22 mm Hg or a

difference of 3 mm Hg or greater between eyes is a good marker for "ocular injury" in the setting of an orbital fracture. [100]

Tonometry may also be considered under the following scenarios:

Determination of a baseline ocular pressure in a patient with iritis. Patients with iritis can develop both open- and closed-angle glaucoma as well as corticosteroid-induced glaucoma. Since most cases of iritis are referred, tonometry may also be deferred unless there are signs of increased IOP.

Documentation of ocular pressure in the patient at risk for open-angle glaucoma. All patients older than 40 years with a familial history of open-angle glaucoma, optic disc changes, visual field defects, and pressures =21 mm Hg should be referred to an ophthalmologist for further work-up. Referral should also be made for those patients with suspiciously cupped discs who have normal pressures; some of these patients may have "low pressure" glaucoma associated with visual field defects. This is usually part of an ophthalmologist's examination.

Contraindications to Tonometry

Tonometry is relatively contraindicated in eyes that are infected unless one is using a device such as the Tono-Pen XL, which uses a sterilized cover. [2] One should sterilize a tonometer before and after applying it to a potentially infected eye. Infected eyes are preferably measured with either a noncontact tonometer or a device with a covered tip (e.g., Tono-Pen). The contact portions of any device should be swabbed with alcohol and allowed to dry before use on another eye. Not all viruses are destroyed by alcohol cleansing. Hydrogen peroxide is effective for deactivating the human immunodeficiency virus responsible for the acquired immunodeficiency syndrome (AIDS). Ultraviolet sterilization, cold-sterilizer

bathing of the footplate and plunger, and ethylene oxide sterilization have been advocated as alternatives to sterilize the Schiötz tonometer tip. The Schiötz tonometer is also used with sterile disposable coverings (marketed as Tonofilm). Nonetheless, measurement of IOP in an obviously infected eye can be deferred until a subsequent visit to the ED or private clinician unless the red eye demands an immediate determination of IOP.

Examples of indications for immediate tonometry in the setting of a red eye are suspected angle-closure glaucoma (acute onset of redness and pain in the eye with smoky vision, a cloudy cornea, and a fixed pupil in mid-dilation) and iritis (ciliary injection with photophobia), in which secondary angle-closure or corticosteroid-induced pressure changes may occur. Reported cases of conjunctivitis spread by tonometry predominantly tend to be viral infections. Particular efforts should be made to avoid use of the instrument on patients with active facial or ocular herpetic lesions or on patients who may have AIDS.

The presence of corneal defects also represents a relative contraindication to tonometry. [3] [22] The use of a tonometer on an abraded cornea may lead to further injury and is commonly deferred until a subsequent visit. Patients who cannot maintain a relaxed position (e.g., because of significant apprehension, blepharospasm, uncontrolled coughing, nystagmus, or uncontrolled singultus) are unlikely to permit an adequate examination and can receive corneal injury when sudden movements occur during an examination. Furthermore, tonometric examination, with the exception of the palpation technique (through the lids) and the noncontact method, should not be performed on a cornea without complete anesthesia.

Tonometry should *not* be performed with a suspected penetrating ocular injury. [2] Globe perforation may be exacerbated by pressure on the globe with resultant extrusion of intraocular contents. Slit lamp examination can be used for detection of a possible perforation.

Procedure

Palpation Technique

All forms of tonometry are essentially ways of determining the ease of deforming the eye; an eye that is easily deformed has a low pressure. The most direct way to do this is simply to press on the sclera through the lids and grossly compare one eye with the other. One can easily distinguish the rock-hard eye of acute glaucoma from the normal opposite eye by this method. The patient is directed to look down but without closing the lids. The examiner rests both hands upon the patient's forehead and alternately applies just enough digital pressure on the globe to indent it slightly with one index finger while feeling the compliance of the globe with the other (Fig. 64-37). [101] An experienced examiner is able to estimate the IOP within 3 to 5 mm Hg of the actual IOP with the palpation technique, but most emergency clinicians do not have enough experience to trust this method. [39]

Another method is to anesthetize the eyes topically and press a wetted applicator on the sclera of each eye. Again, eye deformation is inversely related to ocular pressure. Rigidity of the globe also is a factor in this crude method of tonometry.

Impression (Schiötz) Technique

Use of the Schiotz tonometer requires relaxation on the part of the patient and steadiness on the part of the clinician. The

Figure 64-37 The relatively unskilled examiner can detect very high intraocular pressure of acute angle closure glaucoma with tactile tonometry. The examiner rests both hands upon the patient's forehead and alternately applies just enough digital pressure on the globe to indent it slightly with one index finger while feeling the compliance of the globe with the other.

patient is placed in either a supine or a semirecumbent position and is instructed to gaze at a spot directly above the eyes. A spot on the ceiling should suffice; alternatively, the patient can stretch the arm up over the head and gaze at the thumb. A drop of topical anesthetic is placed in each eye. After the irritation of the drop passes, the patient is allowed to blink while the clinician blots the tears away with a tissue. Rubbing the eyes lowers IOP. The patient is reassured that further discomfort during the procedure will not occur.

The patient *keeps both eyes wide open and fixed on an object*, and the clinician separates the eyelids on the side to which he or she is standing. Care must be taken to direct pressure onto the orbital rims rather than into the orbit, because pressure directed into the orbit falsely raises the reading (Fig. 64-38). The tonometer is momentarily held over the open eye, and the patient is informed that the instrument will block vision in the one eye. The patient is instructed to continue to gaze at the fixation point as though the instrument were not there. After the patient relaxes the involuntary muscle contraction that occurs when the instrument is first placed in the line of sight, the instrument is gently lowered onto the middle portion of the cornea. This is a painless experience for the patient with an anesthetized cornea. The instrument is vertically aligned with the footplate resting on the cornea; the reading should be in mid-scale. Should the reading be on the low end of the scale (<5 units), additional weight should be added to the plunger after the instrument has been removed. The process is repeated as before with the additional weight.

The opposite eye is measured in the same fashion. A converted scale reading giving an IOP of =21 mm Hg requires ophthalmologic referral (Table 64-4). Patients with elevations of IOP =30 mm Hg require more urgent consultation and initiation of therapy. Associated symptoms or signs of angle-closure glaucoma (primary or secondary) represent an ophthalmologic emergency. [102]

Figure 64-38 One technique of lid separation and Schiotz tonometer placement. Lid separation pressure is applied to the bony orbital rims. An assistant may separate the lids while the operator concentrates on proper placement of the tonometer. The tonometer is held vertically during use, and the clinician's hand is established against the patient's facial bones. After instillation of anesthetic drops, the patient will not experience any pain from this procedure. It is important to have a relaxed patient, since squinting and blepharospasm may interfere with the reading. *(From Keeney AH: Ocular Examination, 2nd ed. St Louis, CV Mosby, 1976. Reproduced by permission.)*

Errors with impression tonometry.

Inaccurate readings occur with the Schiötz tonometer for a variety of reasons. If the plunger is sticky, falsely low readings may be obtained. Plunger motion and the zero point of the tonometer should be checked on a firm test button before use. A sticky plunger can be cleaned with isopropyl alcohol and dried with a tissue. When

TABLE 64-4 -- Schiötz Tonometry

	Tonometer Weights (g)		
Tonometer Scale Reading (Units)	***5.5 (mm Hg)***	***7.5 (mm Hg)***	***10 (mm Hg)***
2.50	27	39	55
3.00	24	36	51
3.50	22	33	47
4.00	21	30	43
4.50	19	28	40
5.00	17	26	37
5.50	16	24	34
6.00	15	22	32

9.50	8	12	18
10.00	7	11	16

The table provides estimates of the intraocular pressure to the nearest mm Hg for the different weight of the Schiötz tonometer. Accuracy is most dependable with scale readings larger than 5. If the scale reading is less than 5, use the next highest weight that will give a reading of 5 or more.

the lids are held open, pressure directed into the orbit elevates the IOP and provides a falsely elevated reading. The following eye movements have been found to elevate the IOP: closure of the lids (increase by 5 mm Hg), blinking (increase by 5 to 10 mm Hg), accommodation (increase by 2 mm Hg), and looking toward the nose (increase by 5 to 10 mm Hg).[103] Repeated measurements or prolonged measurements have been found to lower the IOP approximately 2 mm Hg and may also lower the pressure in the opposite eye.[104] As mentioned in the introduction to this section, the calibration of the Schiötz tonometer is based on a mean rigidity coefficient. Factors that produce a reduction in ocular rigidity falsely lower the measured pressure. These factors include high myopia, anticholinesterase drugs, overhydration (e.g., four large cups of coffee or six cans of beer), and scleral buckle operations. [103] [105]

Ocular pressure measurements can vary with ocular perfusion. When measured after a premature ventricular contraction, the IOP may be reduced as much as 8 mm Hg.[106] Similarly, decreased venous return as produced by breath holding, the Valsalva maneuver, or a tight collar can increase the IOP. [103]

Impression (Tono-Pen XL) Technique

When using this device (Fig. 64-39), the preparations for testing are similar to those for the Schiötz device. The patient is encouraged to relax, and a topical anesthetic is used to numb the cornea. The patient should be encouraged to stare with both eyes at a distant object during testing. As noted previously, the operator can help separate the eyelids, but any pressure on the globe itself should be avoided. One major advantage to the use of the Tono-Pen XL is that the patient may be evaluated in any position as long as the device is applied perpendicular to the corneal surface. Another advantage is that the device can be used in cases of irregular or high corneal astigmatism.

Although ideally the complete instructions that are provided with the device kit should be consulted prior to each use, the following synoposis is provided to help in circumstances in which instructions are unavailable. It is assumed that the previously mentioned preparations for testing have been made before the device is used.

The probe tip is first sprayed with compressed gas to clean the mechanism and ensure its free movement. An Ocu-Film (latex) cover is placed snugly (but without tension) over the probe tip.

Calibration is performed before use at least once each day. The *activation* switch is momentarily depressed and released. The liquid crystal display (LCD) should show "—." If the device beeps and "====" appears on the LCD, the activation switch should be pushed again so that the

Figure 64-39 Bedside tonometry is easily accomplished with the Tono-Pen XL. The battery-powered device averages four consecutive readings and reports statistical reliability.

"—" reappears. If the prior calibration was "bAd" (on LCD), a long beep sounds, followed by "CAL" (on LCD). A short beep follows and then the desired "—" is displayed.

Once the "—" is displayed, the probe is held vertically with the tip pointing straight down. The activation switch is then pressed and released twice in rapid succession. Two beeps will then sound, and "CAL" will appear (on LCD). The probe is held in this position (up to 20 seconds) until a beep sounds and "-UP-" appears (on LCD). The probe is then immediately turned 180° so that the tip points straight up. In a few seconds, another beep occurs, and the LCD changes. If the LCD reads "Good,"

the calibration was successful. If the LCD reads "bAd," the calibration was unsuccessful.

With an unsuccessful calibration, repeat the calibration steps described earlier until two consecutive "Good" readings are obtained. If further attempts are unsuccessful, loosen the Ocu-Film tip cover and repeat the calibration process. If attempts are still unsuccessful, press the RESET button and repeat the process. If still unsuccessful, use compressed air to clean the probe tip and repeat the process. If still unsuccessful, the battery should be replaced and the process repeated. Continued failure warrants a call to the MENTOR Technical Service Group at 800-992-7557 or 617-871-6950.

Measurement occurs once the device is calibrated and the patient is prepared as outlined earlier. The activation switch is again depressed and released to obtain "====" (on LCD). A beep will occur with this change. If the switch is not depressed long enough, the LCD will be blank. If a blank screen is seen, again use the activation switch to obtain "====" (on LCD). The probe is held like a pen and briefly and lightly touched to the cornea (Fig. 64-40). This is done four times. A click will sound and a reading will appear on the LCD each time a valid reading is obtained. After four valid readings, a final beep will sound and the averaged measurement will appear on the LCD. The number represents the IOP in millimeters of mercury. The associated bar reflects the statistical reliability (a reading of > 20% reflects an unreliable measurement, which should be repeated).

If four dashes ("----") appear on the LCD after the final beep, too few valid readings were obtained. In such a case, the probe can be reactivated (without recalibration) and the

Figure 64-40 After topical anesthesia, the Tono-Pen XL is touched lightly and briefly to the cornea with a tapping motion, then withdrawn. Disposable tip covers are used to minimize any cross contamination.

measurement procedure repeated. If the probe is not reactivated within 20 seconds, the LCD will clear, but the device can be activated as noted previously without recalibration.

The values are interpreted as outlined earlier for the Schiötz device. Readings may be affected by the same features noted as causes of errors with impression tonometry via the Schiötz device. The device should be stored with an unused Ocu-Film cover protecting the probe tip.

Applanation Technique

One can perform this technique using a slit lamp attachment for an applanation tonometer with the patient's head stabilized in the headrest of the slit lamp (see the following section on the slit lamp examination) (Fig. 64-41).[107] [108] A portable device also is available and is similar in principle. The portable device is not discussed specifically.

The patient must be comfortable and relaxed. The clinician should anesthetize the eye as discussed previously, avoiding ocular pressure, which can lower the subsequent measurements. Fluorescein should be applied to each eye. Excess fluorescein should be blotted from the eye. The patient's head should be in the slit lamp with the forehead firmly against the headrest, and the clinician should direct the patient to gaze straight ahead. One can use a light for fixation or can ask the patient to focus on the clinician's ear on the side opposite the eye being examined.

The cobalt blue light filter is placed in the light beam, and the slit diaphragm is opened fully. The light arm is angulated to shine on the applanation prism in the region of the encircling black line near the anterior prism tip at an angle of 45°–60° to the line of observation. The voltage is turned to the maximum setting, and the low-power microscopic system is focused through the plastic prism so that the front face is

Figure 64-41 Goldmann applanation tonometer with the biprism aligned with the patient's right cornea.

clearly seen through the chosen eyepiece. The pressure knob of the tonometer is turned to 1 g (10 mm Hg), bringing the prism arm to its forward stop. Thus, when corneal contact is made, the prism will be exerting only light pressure. The room lights are dimmed.

The patient's eye that is being examined and the applanation prism are watched from the side (or with the operator's eye not sighting through the microscope) as the instrument is brought forward by the joystick control until gentle contact is made between the prism face and the corneal center. Contact is evidenced by an immediate bluish glow throughout the limbus. The patient's lids must be wide open and unblinking. Contact with the lid margins produces reflex blinking, and the lids may require separation by the clinician's fingers. Pressure during lid separation must be exerted only against the orbital rims. Through the microscope, the clinician sees two blue semicircles (surrounding the flattened area of cornea). Each semicircle is bordered by an arc of green light and pulses synchronously with the cardiac rate (Fig. 64-42).

The semicircles should be of equal size; their width should be approximately one tenth the diameter of the flattened surface contained within each arc. If the semicircles are grossly widened, either excessive tears are present or the prism was probably wet before contact. A wet prism must be withdrawn, dried, and reapplied. If the semicircles are grossly narrowed, the tear film has dried excessively. In this case, the prism must be withdrawn and the patient instructed to blink several times before contact with the cornea is attempted again. If the semicircles are so broad that they extend beyond the illuminate field, there is excessive flattening and the slit lamp must be drawn back. If the semicircles suddenly shrink, either the patient has moved back or the instrument has been backed away from the eye. The semicircles should be of equal extent above and below a horizontal dividing line. If the dividing line is not horizontal, the applanation prism assembly should be rotated on its holder until the line is horizontal. If the semicircles are not equally divided above and below the line, vertical adjustments of the slit lamp should be made.

Readings should be taken at approximately the midpoint between systole and diastole, when the inner (concave) boundaries of each semicircle rhythmically glide past each

Figure 64-42 Schematic representation of semicircles seen through the contact applanation prism of the Goldmann tonometer. *A,* Semicircles are too wide, suggesting excessive moistening of the prism or cornea. The prism must be withdrawn and dried. *B,* Semicircles are too narrow, suggesting that the lacrimal fluid has dried out, as during a prolonged measurement. The prism must be withdrawn so that the patient may blink a few times. The measurement is then repeated. *C,* Semicircles are of appropriate width, and their inner borders just touch. Cardiac pulsations transmitted through the globe cause rhythmic or pulsating movement of the semicircles over each other through a small amplitude. *D,* Semicircles are slightly separated, indicating applied pressure below that of the eye. The measuring drum must be turned to increase applanation pressure until the end point is reached. *(From Keeney AH: Ocular Examination, 2nd ed. St Louis, CV Mosby, 1976. Reproduced by permission.)*

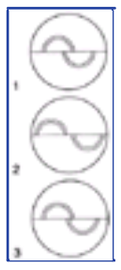

Figure 64-43 Appearance of the semicircles in applanation tonometry. Rotate the pressure knob to align the innermost concave margins of the two semicircles. IOP = intraocular pressure. (1) Pressure on the tonometer head is too high—rotate the knob to decrease reading. (2) Pressure on the tonometer head is too low—rotate the knob to increase reading. (3) Pressure on the tonometer head is equal to IOP—the dial reading equals IOP. *(From Knoop K, Trott A: Ophthalmologic procedures in the emergency department—Part III: Slit lamp use and foreign bodies. Acad Emerg Med 2:224, 1995. Reproduced by permission.)*

other through excursions of equal distance (see Fig. 64-42*C*). One finalizes adjustments to the end point of properly located and sized semicircles by rotating the pressure knob back and forth. When applanation pressure exceeds IOP, the semicircles are too small to intersect (Fig. 64-43).

At the end point is a flattened disc area 3.06 mm in diameter within the 7-mm diameter of the prism face. Here the attractive surface tension of the tears toward the prism is counterbalanced by the elasticity, or springiness, of the cornea; at this point the grams of force applied through the prism (indicated on the pressure knob) are directly convertible (when multiplied by 10 into mmHg) to express IOP. With an

applanation tonometer, the average IOP in a seated adult is 14 to 17 mm Hg.

After use, the tonometer should be wiped dry and removed for storage if used infrequently in the ED. One should verify the pressure adjustment periodically using the test weight or metal balance bar supplied with the instrument.

Potential sources of error with the applanation tonometer are similar to those mentioned for the impression tonometer, with the exception that ocular rigidity is not a factor. Inaccuracies primarily result from ocular motion or tensing of the lids.

Complications

When tonometric instruments are used properly and reasonable precautions are taken, complications are unusual. The eye with preexisting corneal injury should be spared the additional trauma of tonometer placement. Corneal abrasions can be produced by ocular movement during testing. In particular, patients with uncontrollable nystagmus, singultus, or coughing or those who are extremely apprehensive should not be subjected to tonometry. Infection can be transmitted by the use of the instrument. Careful cleansing of the device and avoidance of tonometry in patients with obvious conjunctivitis, corneal ulcers, or active herpetic lesions should minimize the risk of spreading the infection to the unaffected eye or to subsequent patients. Although protective coverings can be placed over the tonometer contact, tonometry can usually be postponed in the aforementioned individuals until the risk of infection is minimal. Extrusion of ocular contents with penetrating injuries is a potential but rare complication.

Summary

Tonometry is an easily learned technique that should be used by the emergency clinician for the detection of elevated IOP. An elevated IOP in conjunction with physical findings suggestive of acute angle-closure glaucoma is an indication for therapy and consultation with an ophthalmologist. The baseline measurement of IOP will aid the ophthalmologist in subsequent evaluation of a referred patient. In addition, the emergency clinician can serve as a referral source for patients with elevated IOP who are suspected of having open-angle glaucoma. In particular, future drug therapy for systemic hypertension may be altered by the presence of concomitant intraocular hypertension. The emergency clinician who aggressively manages patients with hypertensive crises must also be aware of potential visual field defects when systemic blood pressure is vigorously lowered without concurrent lowering of IOP.

SLIT LAMP EXAMINATION

The slit lamp is an extremely useful instrument; it makes the examination of the anterior segment of the eye a pleasure. The instrument can reveal pathologic conditions that would otherwise be invisible. The slit lamp permits detailed evaluation of external eye injury and is the definitive tool for diagnosing anterior chamber hemorrhage and inflammation.

Since the 1800s, clinicians have searched for a better way both to magnify and to illuminate the anterior segment of the eye. In 1891, Aubert developed the first true binocular stereoscopic microscope. Then, in 1911, Gullstrand introduced a slit illuminator device. The microscope and the illuminator were combined by Henker in 1916; the result was the first true slit lamp. Goldmann improved the mechanical supports for the microscope and the illuminator and in 1937 marketed a slit lamp that closely resembles the device used today.[109]

Indications and Contraindications

The slit lamp can be used in the majority of eye examinations. It is especially useful in the ED for the diagnosis of corneal abrasions, FBs, and iritis. [39] The slit lamp facilitates FB removal and is also used in conjunction with most applanation tonometers. Although portable slit lamp instruments exist, emergency clinicians generally have access only to a stationary, upright device. Therefore, in the absence of a portable device, a slit lamp examination is contraindicated in patients who cannot tolerate an upright sitting position (e.g., those with orthostatic syncope).

Equipment

The slit lamp has three essential components: a binocular microscope mounted horizontally, a light source that can create a beam of variable width, and a mechanical assembly to immobilize the patient's head and to manipulate the microscope and the light source. The location and arrangement of the knobs that control these components vary in devices made by different manufacturers. Usually, by simply turning each knob and watching the results, one can quickly master a new machine. Figure 64-44 illustrates the location of the functional controls on one particular instrument.

The first knob that one should locate is the on/off switch for the entire machine. Often this switch incorporates or is adjacent to a rheostat that provides two or three different power settings. The lowest setting is adequate for routine examination and will preserve bulb life. One can use a high-intensity setting when examining the anterior chamber with a narrow slit beam. Often, these controls are located on a transformer placed beneath the table to which the slit lamp has been attached. The second knob that one should find is the locking nut for the mechanical assembly. This must be loosened for the assembly to be moved.

The patient should be comfortable while sitting with the head in the device. The patient's forehead should be firmly against the headrest, and the chin should be in the chinrest. By varying the table height and height of the chinrest, one should be able to maximize the comfort of the patient's neck and back. The chinrest should be adjusted to align the patient's eye level with the mark on the headrest support rods.

The binocular microscope has a control for varying the magnification. Usually low powers, such as 10× or 16×, are the most useful. A higher power is helpful when the anterior chamber is examined for cells and flare and when the cornea is examined in minute detail. The binocular interpupillary distance should be adjusted to match that of the examiner. One can focus the eyepieces by moving the instrument forward and backward until the narrowed vertical beam is sharpest on the patient's cornea when viewed with the unaided eye. Then, while viewing through each eyepiece individually, the clinician adjusts the focus of each to produce a sharp image of the anterior cornea.

The light source is mounted on a swinging arm. There are knobs to vary the width and the height of the light beam. There are also filters that can be "clicked" in; only white and blue filters are usually needed. The angle of the slit beam can be varied from vertical to horizontal. The vertical alignment is preferred for routine examinations in the ED.

Both the microscope and the light source are mounted on swivel arms, linked at their base to a movable table. One can change the position of this table by pushing on any part of it. For finer movements, the clinician uses a joystick. One can vary the height of the microscope and the light source by twisting either the joystick or a separate knob at the base, depending on the design of the instrument.

Procedure

There are 3 setups that every slit lamp operator must know.[107] [110] The first is for an overall screening of the anterior segment of the eye. For examination of the patient's right eye, the light source is swung to the examiner's left at a 45° angle while the microscope is directly in front of the eye. The slit beam is set at the maximum height and the minimum width using the white light. To scan across the patient's cornea, one first focuses the beam on the cornea by moving the entire base of the slit lamp forward and backward. One then moves the whole base left and right to scan across. The 45° angle between the microscope and the light source should be the default position. The most common mistake is to try to scan by swinging the arm of the light source in an arc; this does not work because the light beam will remain centered on the same point of the patient's eye. The examiner scans across at the level of the conjunctiva and the cornea and then pushes slightly forward on the base or joystick and scans at the level of the iris. The depth of the anterior chamber is easily appreciated with this low magnification setup (Fig. 64-45). When the depth of the anterior chamber is reduced, one should suspect a corneal perforation or a predisposition to angle-closure glaucoma.

Figure 64-45 Slit lamp photograph of a normal right eye under low power. The curved slit of light on the left is reflected off the cornea while the slit on the right is reflected off the iris. The depth of the anterior chamber can easily be appreciated under this low magnification setup. *(Courtesy of D. Price.)*

This basic setup can also be used to examine the conjunctiva for traumatic lesions, inflammation, and FBs. The lids can be examined for hordeolum, blepharitis, or trichiasis. Complete lid eversion (as described earlier in the section on FB removal) can be performed in conjunction with the slit lamp examination to permit evaluation of the undersurface of the upper lid for FB retention.

Corneal FB removal can be enhanced by use of the slit lamp. In particular, the instrument allows stabilization of the patient's head. Magnification also minimizes corneal injury during FB or rust ring removal. The upper eyelid may be immobilized by a cotton-tipped applicator, as discussed previously. The clinician's hand can be steadied against the patient's nose, cheek, or forehead or against the support rods of the headrest. The patient should be instructed to stare straight ahead at a fixed light or at the clinician's ear during removal of the FB.
