Percutaneous Technique for Arterial Cannulation

Direct Over-the-Needle Catheter Cannulation

Placement of an angio-catheter directly into an arterial lumen in a manner similar to placement of an intravenous catheter is the most practiced and simplest method—when it works. The only routine site for this technique is the radial artery. Although other sites, namely the femoral artery, may be attempted, use of a catheter over a guidewire is strongly advised at most other sites.

The operator should always remember to take time for proper alignment of the desired site. Delays, complications, and inability to successfully cannulate an artery often occur due to failure to properly prepare the desired site and involved limb. An important preparatory step is ensuring that the target limb is secured flat and not rotated; any rotation could result in the desired artery being shifted from the expected anatomical position, making it more difficult to cannulate. For example, to adequately prepare the radial artery, the wrist and hand should be immobilized in mild, dorsiflexion with some padding for support underneath the wrist. As usual, sterile skin prep and local anesthetic injection using a 25-ga or smaller needle with sufficient infiltration to assure a painless procedure can then be performed. The subcutaneous infiltration of lidocaine or similar anesthetic may reduce vessel spasm at the time of arterial puncture.

The catheter assembly should be checked for proper movement and function. Alternatively, a 3-mL syringe with the plunger removed could be used as a blood reservoir. The catheter is advanced toward the palpated artery at a comfortable angle for the operator, generally 30 to 45° from the skin. Making a small nick with a No. 11 scalpel or a larger bore needle will eliminate the problem of catheter damage from kinking on the skin. The needle tip is often perceived to pierce the artery, but successful puncture is confirmed by identifying a "flash" of arterial blood flow into the needle hub and reservoir. As the needle-catheter assembly advances through the

Figure 20-4 Arterial puncture: The syringe-needle is held at a 30 to 45° angle and should enter with the bevel up and advanced slowly. The landmark is best located by palpating the pulse using the index and middle fingers placed immediately proximal to the needle entry site. The needle should *not* be passed between the fingers due to risk of operator self-injury. *(Picture courtesy of JMM, with permission.)*

skin toward the artery, the initial flash of arterial blood is obtained by the needle alone, which protrudes beyond the catheter. For this reason, the needle-catheter should be lowered and advanced 2 mm forward to ensure that the catheter tip has cannulated the vessel, along with the needle. Confirmation of the catheter within the vessel lumen will be continued arterial blood return. The catheter alone can now be advanced over the needle with care into the artery. If the catheter fails to thread, it has not properly entered the vessel lumen and should not be forced to advance without active blood return confirming placement.

When blood flow into the needle-catheter has ceased, it is likely to have pierced the back side of the artery wall. This double-puncture method is useful for cannulating small vessels, yet it is not recommended to the inexperienced clinician

Figure 20-5 Removal of air bubbles from the syringe. Air bubbles are finger-tapped to the top of the syringe. An alcohol swab is placed over the top of the needle. The plunger is advanced to expel air while drops of blood are collected on the alcohol swab. After removal of the bubbles, the syringe is capped and sent to the laboratory.

as a routine procedure.[5] If double puncture has occurred and blood has ceased to flow into the collection reservoir, the entire needle-catheter assembly should not be removed. Instead, simply retract the needle slightly to determine if blood flow can be re-established into the catheter. If blood flow occurs, gently advance the catheter. If not, the catheter should be slowly withdrawn until pulsatile blood flow reappears and then the catheter can be advanced into the artery. The important point is for the clinician to be aware whether the needle tip or the catheter is the leading edge within the vessel. [5]

Once the catheter is fully advanced into the vessel lumen, occlusive pressure is held transiently on the proximal artery to limit blood loss, and the needle is removed. A narrow bore, low compliance pressure tubing is then fastened to the catheter. An appropriate sterile dressing should be applied after the apparatus has been securely sutured to the wrist.

Occasionally one will encounter difficulty advancing the catheter into the lumen. The "liquid stylet" method may aid further passage of the catheter. [31] A 10-mL syringe should be filled with about 5-mL of sterile normal saline. The syringe is then attached to the catheter hub, and 1 to 2 mL of blood should be easily aspirated to confirm intraluminal position. The fluid from the syringe is then slowly injected, and the catheter is advanced behind the fluid wave. Alternatively, a more popular method is to use a guidewire that easily passes into the vessel lumen. [32] [33] This modified Seldinger technique is discussed fully in the next section.

The number of repeat attempts with additional arterial punctures increases the size of the developing hematoma and real risk of vessel wall damage, thrombosis, and even loss of arterial flow through the vessel. Despite the added trauma, there is no reported increase in complications when both walls, rather than one, are punctured from a single cannulation attempt.[34] [35] [36]

Guidewire Techniques for Arterial Cannulation

Using a "modified" Seldinger technique can often rescue a failed over-the-needle catheter, direct cannulation attempt. If the catheter has been placed in the arterial lumen with blood return, a proper sized guidewire may be gently passed through

---

the catheter into the artery. The catheter should then be advanced fully into the vessel over the guidewire. The clinician is cautioned that stiffer guidewires, unlike most prepackaged ones, do not have a softer tip and the vessel wall may be damaged, even perforated with excessive force. Alternatively, catheter sets are available with a wire stylet that permits a modified Seldinger technique for catheter placement. The over-the-needle catheter follows the self-contained guidewire during cannulation. Numerous commercially available sets feature differing styles of guidewire and reservoir attachments to an over-the-needle catheter assembly. One readily available device of this type is the Arrow arterial catheterization system (Arrow International, Inc., Reading, PA) (Fig. 20-6). These kits are extremely practical for smaller vessels, especially radial, brachial, and axillary arteries and have excellent success rates at first-time placement. Although some authors have suggested that guidewire-based techniques will improve arterial cannulation success rates in some patients, [33] it appears that success is more a function of operator experience and personal preference. [37]

Figure 20-6 Step-by-step arterial cannulation, using the guidewire technique (Arrow arterial catheterization kit). *(Courtesy of Arrow International, Inc., Reading, PA.)*

Seldinger Technique

An alternate to placing an indwelling cannula is the Seldinger technique, [32] which is described in detail for venipuncture in Chapter 22 . Overall success rates with the Seldinger, guidewire-directed technique are superior compared to direct arterial cannulation. [37] There are a few available kits designed specifically for arterial cannulation (Fig. 20-7), but single lumen venous catheters with guidewires may be used if catheter size and length are appropriate for specific arteries (see following section for guidelines). Guidewire technique should be used initially for critical patients.

A needle is percutaneously placed into the arterial lumen, as described previously. A guidewire is then placed through the needle into the vessel lumen, and the needle is removed. A catheter is then threaded over the wire, and the wire is pulled out. Although most kits have vessel dilators, especially with larger catheter sizes, caution is advised. Only the tract should be dilated, not the artery, to avoid unnecessary blood loss and excessive arterial injury.

Figure 20-7 Femoral vessel cannulation kit. (Arrow International, Inc., Reading, PA.) A 16-ga single lumen vessel with a guidewire for Seldinger placement includes entire

procedural needs with local anesthetic, subcutaneous puncture syringe, needle, scalpel, and suture material.

Cutdown Technique for Arterial Cannulation

The cutdown technique is rarely practiced, but in certain circumstances it may be used to obtain arterial access by the most experienced personnel. Cannulation is performed after direct visualization of the vessel. A cutdown can be performed on any artery but is most commonly reserved for distal lower limb arteries and, rarely, the brachial. After a site has been selected, the overlying skin should be surgically prepared with an iodophor solution. Using sterile technique, local anesthetic solution is injected subcutaneously in a horizontal line 2 to 3 cm long and perpendicular to the artery. This step may be omitted if the patient is unconscious or otherwise anesthetic at the cutdown site.

Using a scalpel with a No. 10 or 15 blade, the skin is incised along the anesthetic wheal. Underlying tissues are spread parallel to the artery with a mosquito hemostat. The pulse is palpated repeatedly throughout the procedure to ensure proper positioning. Once the surrounding soft tissue has been removed, and after exposing the artery approximately 1 cm, the artery should be isolated by passing 2 silk sutures underneath it, using the hemostat. Strip away only enough perivascular tissue to expose the artery. Perivascular tissue will help limit bleeding at the time of catheter removal. An over-the-needle catheter device, such as that used in the percutaneous method, is then introduced through the skin just distal to the incision and advanced into the surgical site (Fig. 20-8).[31] Alternatively, a modified Seldinger guidewire setup may be used to catheterize the artery. The arterial wall is punctured with the needle tip, and the catheter is threaded into the vessel lumen. When this has been accomplished, the 2 silk sutures, which have been used only to control the vessel, are removed, and the skin incision is closed. *The artery is not tied off as the vessel would be during a venous cutdown.* Firm pressure, as used following arterial puncture, should be applied over the cutdown site. The separation of the soft tissue during the procedure may allow considerable hemorrhage into the tissue if pressure is not applied.

Catheter and Site Care

Once the catheter has been placed successfully, it should be advanced until the hub is in contact with the skin. The catheter is then secured by fastening it to the skin with suture material. Silk (2-0) or nylon (5-0) sutures provide the best anchoring. To accomplish this, a moderate bite of skin is taken with the needle, and a knot is tied in the suture leaving both tails of the suture long. Take care to avoid pinching the skin too tightly. The loose ends of the suture should then be tied around the catheter at its hub. Then, after laying two ties, a second set of knots should be placed on the back portion without occluding the lumen by constriction (Fig. 20-9).

After tying the catheter in place, a drop of antibiotic ointment is applied to the puncture site, [38] and a self-adhesive dressing is applied over the area. The catheter and its connecting tubing are further secured with sterile sponges and adhesive tape. All tubing connections must be tight and secure. If the tubing becomes disconnected inadvertently, the patient may exsanguinate rapidly.

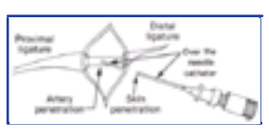

Figure 20-8 Placement of an arterial line using the cutdown technique. Note that the catheter enters the surgical wound percutaneously to minimize bacterial entry into the healing wound and permit better stabilization of the catheter. Catheter entry of the vessel is more parallel to the vessel than is illustrated. Ligatures are used only to *temporarily* isolate the artery and to control bleeding. *The artery should not be tied off.* The catheter is secured by suturing the hub to the skin (see Fig. 20-9).

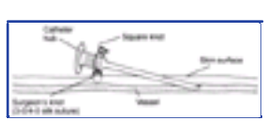

Figure 20-9 Illustration of a technique for securing a vascular catheter to adjacent skin.

Fluid-Pressurized Systems

When successful arterial cannulation has been performed, the catheter should be attached to a pressurized fluid-filled system. A three-way stopcock is commonly interposed between the patient and the transducer for blood gas sampling and to allow flushing of the system. Flushing can be periodic or continuous at a rate of 3 to 4 mL/hr through a continuous flow device (Fig. 20-10). Many institutions have begun using normal saline in place of heparinized solution to maintain patency. There is no significant difference for patency; however, heparinized flush solution in pressurized arterial lines results in greater long-term accuracy of pressure monitoring, but no real difference in catheter blockage has been reported. [39]

Literature review supports the use of normal saline solution for maintaining patency of intermittent vascular catheters. In one study, a change to normal saline solution as an alternative to heparinized saline solutions (2 mL 1:1000 heparin/L of saline) to maintain arterial line patency resulted in elimination of heparin-associated risks such as drug incompatibilities, thrombosis, local tissue damage, and hemorrhage. Additionally, decreased potential for infections, substantial money savings, and decreased nursing time make it an attractive alternative. There are, however, some studies that found the use of saline as a continuous flush for radial artery catheters are associated with an increased frequency of catheter occlusion and malfunctions compared with solutions containing heparin. [40] [41] For

Figure 20-10 Pressure transducer fluid monitoring set; a pressurized saline (heparinized solution may be substituted) connected to an intravascular line and arterial catheter, which is then fixed to a three-way stopcock. The fluid wave is directly monitored by the electormechanical transducer, which records pressure cycles and displays multiple hemodynamic values.

short-term setups as in the ED, saline is sufficient. Change to heparinized flush is an option depending on prevailing practice within the ICUs of the institution.

Procurement of a blood sample from the arterial catheter system is easily performed. A syringe is attached to the three-way stopcock, and blood is aspirated and discarded to clear the line. Studies examining the necessary discard volume of flush-blood solution have found considerable variation dependent on the volume of the system.[42] [43] Short lengths of tubing between the catheter and aspiration port minimize the discard volume. For a tubing length of 91 cm (36 in.), 4 to 5 mL should be aspirated[43] ; for a tubing length of 213 cm (84 in.), 8 mL should be aspirated. [42] A second syringe, which has been heparinized, is then attached, and 3 mL of blood are aspirated and sent for blood gas analysis. If the blood is to be used for other tests, the second syringe does not need to be heparinized. The stopcock and line should be flushed after sampling to avoid clotting.

SELECTION OF ARTERIES FOR CANNULATION

Radial and Ulnar

The artery most frequently used for prolonged cannulation is the radial artery. Widespread collateral flow exists in the wrist due to two major palmar anastomoses known as *arches* (Fig. 20-11). The superficial palmar arch lies between the aponeurosis palmaris and the tendons of the flexor digitorum sublimis. The arch is formed mainly by the terminal ulnar artery and the superficial palmar branch of the radial artery. The other major communication of these two vessels, the deep palmar arch, is formed by connections of the terminal radial artery with the deep palmar branches of the ulnar artery. [44] Some collateral flow is almost always present at the wrist, with the deep arch alone being complete in 97% of 650 hand dissections at autopsy. [45] Despite these findings, Friedman noted the absence of palpable ulnar pulses in 10 of 290 (3.4%) healthy children and young adults. [46] Interestingly,

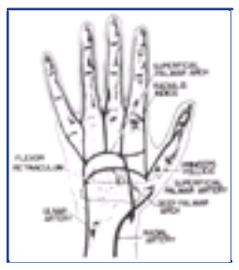

Figure 20-11 Arterial anatomy of the hand and wrist. *(From Ramanathan S, Chalon J, Turndorf H: Determining patency of palmar arches by retrograde radial pulsation. Anesthesiology 42:758, 1975. Reproduced by permission.)*

this was always a bilateral finding. Radial pulses were present in all subjects.

Before attempting radial artery cannulation, assess the adequacy of collateral flow to the hand by performing a bedside examination. This examination was originally described by E.V. Allen in 1929[47] and used to assess arterial stenosis in the hands of patients with thromboangiitis obliterans. The Allen test is performed to identify patients with increased risk for ischemic complications from radial artery catheterization. The procedure has seen many modifications [48] [49] since originally being described in a cooperative patient. The basic Allen test is performed as follows: The examiner occludes both the radial and ulnar arteries with digital pressure, and the patient is asked to tightly clench the fist repetitively to exsanguinate the hand. The hand is then opened, and the examiner releases the occlusion of the ulnar artery (Fig. 20-12). After 2 minutes, the test is repeated with release of the radial artery. Rubor should return rapidly to the hand with release of pressure from either vessel.

An abnormal (positive) Allen test, suggestive of inadequate collateralization, is defined as the continued presence of pallor 5 to 15 seconds after release of the artery.[15] [32] [49] [50] If the return of color takes >5 to 10 seconds, radial artery puncture should not be performed. Be careful to avoid overextension of the hand with wide separation of the digits, because this may compress the palmar arches between fascial planes and give a false-positive result. [51] Barber and associates[47] reported a modified Allen test that is useful in unconscious or anesthetized patients who cannot clench their fists. An Esmarch bandage is used to exsanguinate the hand, and the test is performed as previously described. Time permitting, performance of some variation of the Allen test is desirable before ulnar or radial puncture for cannulation or blood gas sampling.

The true predictive value of the Allen test is still questioned, as there are numerous reports of permanent ischemic sequelae, post-cannulation, following a normal Allen test.[49] [52] [53] Notably,

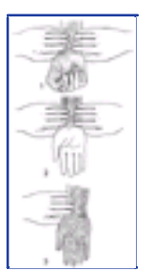

Figure 20-12 Allen test. Before puncturing the radial artery it is important to identify a competent ulnar artery. This can be done as follows: (*1*) The examiner compresses both arteries, and the patient repeatedly makes a tight fist to squeeze all the blood out of the hand. (*2*) The patient then extends the fingers, and the examiner observes the blanched hand. (*3*) Compression of the ulnar artery is released, and the examiner observes the hand filled with blood. If filling does not occur within 5 to 10 seconds, radial artery puncture should not be done. If brisk filling occurs, the test is then repeated with release of the radial artery to assess radial artery patency. If both radial and ulnar arteries demonstrate patency, the wrist may be used for arterial puncture. *(From Schwartz GR [ed]: Principles and Practice of Emergency Medicine. Philadelphia, WB Saunders, 1978, p 354. Reproduced by permission.)*

other studies have found no ischemic complications following radial artery catheterizations after abnormal Allen tests. [35] [54] Although there are no guarantees against digital ischemia following radial artery cannulation, [55] the finding of an abnormal Allen test should result in the search for an alternative site. If available, this alternative arterial site should be used and the abnormal Allen test documented for medicolegal reasons.

Once adequate collateral flow has been ascertained, arterial puncture may be performed. At the wrist, the radial artery rests on the flexor digitorum superficialis, flexor pollicis longus, and pronator quadratus, and against the radius. [45] The pulsation of the artery should be isolated on the palmar surface of the wrist. The radial artery is more superficial closer to the wrist and provides a more consistent cannulation due to fixation and less mobility. Dorsiflexing the wrist at about a 60° angle over a towel or sandbag, preferably

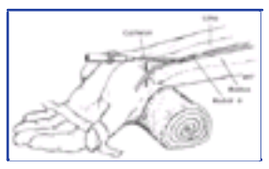

Figure 20-13 Percutaneous arterial cannulation at the wrist. The catheter unit is advanced 1 to 2 mm into the vessel lumen after blood first appears in the flash chamber. While the needle is fixed, the catheter is threaded over the needle. *(From Beal JM [ed]: Critical Care for Surgical Patients. New York, Macmillan, 1982. Reproduced by permission.)*

fixing the wrist to an arm board, will also significantly help isolate the artery. This degree of preparation should be considered standard when time for setup is allowable (Fig. 20-13). [34] [35]

Antegrade radial artery cannulation may be accomplished in infants and children when radial arteries are obstructed and retrograde blood flow is observed during a failed cut down attempt at standard retrograde arterial cannulation. [56] Additionally, displacement of perivascular interstitial fluid in neonates and bright light makes the course of the artery visible so that under direct vision, cannulation of the artery becomes as easy as venous cannulation. [57] Doppler ultrasound use on select patients with poor peripheral pulses may facilitate percutaneous radial artery cannulations and minimize the number of punctures needed for placement. [27]

The ulnar artery is seldom used because its smaller size makes it more difficult to puncture than the radial artery. At the wrist, the ulnar artery runs along the palmar margin of the flexor carpi ulnaris in the space between it and the flexor digitorum sublimes. [45] Caution is necessary because the artery runs next to the ulnar nerve as both pass into the hand just radial to the pisiform bone. The ulnar artery can also be made more accessible with dorsiflexion of the wrist.

Brachial

The brachial artery appears safe for arterial puncture, but it does not have the anatomic benefit of the collateral circulation found in the wrist. The brachial artery begins as the continuation of the axillary artery and ends at the head of the radius, where it splits into the ulnar and radial arteries. The preferred puncture site of the brachial artery is in or just proximal to the antecubital fossa. In this region the artery lies on top of the brachialis muscle and enters the *fossa* underneath the bicipital aponeurosis with the median nerve occupying the medial side of the artery (Fig. 20-14). Both the radial and axillary arteries are preferred upper extremity sites to the brachial artery. There is an increased ischemic complication risk from reduced collateral circulation as well as the necessity of maintaining the arm in extension for puncture or prolonged cannulation. Despite all of these theoretical possibilities, the safe cannulation of the brachial artery has been demonstrated by some investigators.[58] Bazaral et al. found only one minor thrombotic occurrence in more than 3000 brachial artery

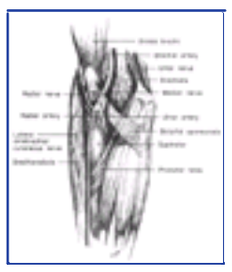

Figure 20-14 The right brachial artery and its branches. *(From Christensen JB, Telford IR: Synopsis of Gross Anatomy. New York, Harper & Row, 1966. Reproduced by permission.)*

catheterizations over 3 years in cardiac surgery patients. [59] A longer catheter (10-cm) is required for the brachial artery so that sufficient length is available to traverse the elbow joint.

Axillary

Axillary artery cannulation as described by Adler and coworkers [60] is also a safe means of monitoring arterial blood pressure for a long time. The left axillary artery is preferred in order to decrease the possibility of cerebral embolization of flush solution or thrombus. The path from the left subclavian to the left carotid artery is less direct than on the right side, whereas the vertebral arteries are equally vulnerable.

To cannulate the axillary artery, the arm is placed in 90° abduction. The axillary pulse is then palpated high in the axilla between the insertion of the pectoralis major and the deltoid muscles. The artery may then be cannulated percutaneously, and a Seldinger guidewire technique with a longer catheter (18-ga, 10-cm) is strongly recommended. This site is seldom used and is unfamiliar to many clinicians. Due to positioning and extra time for setup, this site should be avoided in the ED. There are few reported complications from catheter placement in the axillary artery. [61]

Dorsalis Pedis

The dorsalis pedis artery continues from the anterior tibial artery and runs from approximately midway between the malleoli to the posterior end of the first metatarsal space, where it forms the dorsal metatarsal and deep plantar arteries. The lateral plantar artery, a branch of the posterior tibial,

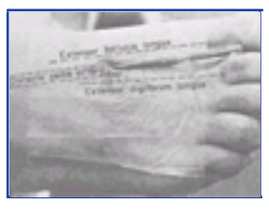

Figure 20-15 A 20-ga catheter in the dorsalis pedis artery, illustrating the relationship to surrounding tendons. The catheter is secured with Steri-Drape. Splinting is not needed. *(From Johnstone RE, Greenhow DE: Catheterization of the dorsalis pedis artery. Anesthesiology 39:655, 1973. Reproduced by permission.)*

passes obliquely across the foot to the base of the fifth metatarsal. The plantar arch is completed where the lateral plantar artery joins the deep plantar artery between the first and second metatarsals. On the dorsum of the foot, the dorsalis pedis artery lies in the subcutaneous tissue parallel to the extensor hallucis longus tendon, and between it and the extensor digitorum longus (Fig. 20-15).[62]

The artery should be cannulated in the mid-foot region. Although this vessel is amenable to cutdown, the vascular anatomy of the foot is quite variable. This is of no consequence if a pulse can be palpated, but Huber, in his dissection of 200 feet, noted the dorsalis pedis artery was absent in 12% of patients. [63] In 16% of patients, the dorsalis pedis artery provides the main blood supply to the toes. [64] Although the dorsal pedis and posterior tibial arteries form similar collateral foot circulation as in the hand, the nature of advancing vascular disease makes this a more difficult cannulation, with increased complication compared to the wrist. Nevertheless, this site has its major utility in pediatric monitoring cases. Attempts to predetermine collateral flow with a modified Allen test using the posterior tibial and dorsalis pedis arteries is not as easily performed in the foot as in the hand, nor is there good data to prove its validity. Monitoring problems also exist with this artery. The pressure wave obtained with an electronic transducer attached to the dorsalis pedis artery will be 5 to 20 mm Hg higher than that of the radial artery and, in addition, will be delayed by about one tenth of a second. [62]

Femoral

The femoral artery is the second most commonly used vessel for prolonged arterial cannulation. Based on its ease of cannulation and low record of complication, it has been called the vessel of choice for arterial access. [61] [65] [66] Along with the axillary artery, the femoral artery more closely resembles aortic pressure waveforms than those from any other peripheral site.[5] The femoral artery is the direct continuation of the iliac artery and enters the thigh after passing below the inguinal ligament. Arterial puncture must always occur distal to the ligament to prevent uncontrolled hemorrhage into the pelvis or peritoneum. [67] The artery may be easily palpable midway between the public symphysis and the anterior superior iliac spine. One can also place the thumb and fifth finger on the aforementioned distal sites and locate the artery underneath the middle knuckle. When puncturing this vessel, care must be taken to avoid the femoral nerve and vein, which create the lateral and medial borders, respectively (Fig. 20-16).

A longer, larger diameter catheter is required for accurate monitoring of the femoral artery due to the relatively greater depth at which it lies and greater vessel size. Only the Seldinger technique is recommended for this site, enabling placement of a 15- to 20-cm plastic catheter for prolonged monitoring. Use of catheter-through-the-needle or over-the-needle catheter devices should be avoided because cannulating the vessel is difficult due to its distance beneath the skin. Leakage around the catheter can occur with catheter-through-the-needle or over-the-needle catheter devices due to high arterial pressures and loose fit of the cannula in the hole in the vessel wall. Regardless of the device used, the needle should enter the skin at an angle of about 45° instead of the usual 15 to 20°.

The extremely large ratio of arterial diameter to catheter diameter is thought to beneficially reduce the incidence of thrombosis, particularly total occlusion. However, occlusions have been reported with femoral cannulation for monitoring purposes. [68] A commonly postulated disadvantage of this site is the possibility of increased bacterial contamination because of its proximity to the warm, moist groin and perineum; however, no studies confirm this hypothesis. [69] The femoral area is inconvenient for any patient who is awake and mobile, or if the patient is able to sit in a chair. If the patient is that mobile, then risk/benefit from invasive monitoring should be reconsidered. Despite theoretic difficulties, some large hospitals use femoral arterial lines almost exclusively, and the intensive care nursing staff is often

more comfortable caring for these lines than those at other sites.

Umbilical and Temporal

In the neonate, arterial access can be accomplished through the umbilical artery for a short time. After this artery closes, the temporal artery provides a safe alternative. Prian described the use of the temporal artery, noting its accessibility and the lack of clinical sequelae if it undergoes thrombosis. [70] The cutdown method should be used with a 22-ga catheter after the artery's course has been traced with an ultrasonic flow detector. Because of the increasing accuracy of ear oximeters and the use of capillary blood gases for pH determination, prolonged arterial cannulation will become less frequent during infant care. Further discussion of infant arterial cannulation is provided in Chapter 19 .

COMPLICATIONS

Long-term arterial cannulation is safe if care is taken to avoid complications. Almost all difficulties one may encounter can be avoided or their incidence markedly decreased by adhering to a few simple principles. Reported clinical sequelae of arterial puncture and cannulation range from simple hematomas to life-threatening infections and exsanguination. Other potential complications include ischemia, arteriovenous fistula, and pseudoaneurysm formation. The incidence of complications varies with the site selection, method of

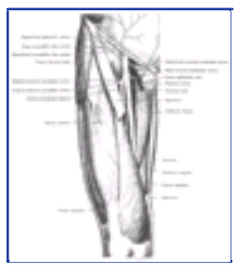

Figure 20-16 The right femoral vessels and some of their branches. The femoral nerve (not shown) lies lateral to the artery and may be deep to the artery. *(From Warwick R, Williams PL [eds]: Gray's Anatomy, 35th ed. Edinburgh, Churchill Livingstone, 1973, p 676. Reproduced by permission.)*

cannulation, and clinician's procedural skill and experience. Early detection of complications is greatly aided by enhanced vigilance and concern of the patient's clinicians and nurses. It is difficult to compare complication rates at various sites, because most published studies have primarily used the radial artery.

No studies have compared the approach and complication rates of arterial catheters in the ED compared to ICU or to OR uses. Over 24 months, 2119 ICU patients had an arterial catheter placed at admission: 52% at the radial site and 45% at the femoral site. The most common complication was vascular insufficiency (4%), followed by bleeding (2.1%) and infection (0.6%). There was no difference reported for infection rates for femoral vs radial sites. [71] There are reports of complications from arterial puncture for procedures unrelated to long-term cannulation such as arteriography or simple arterial puncture for blood sampling as routinely performed in the ED. In a study of 2400 consecutive cardiac catheterizations over a 12-month period, complications occurred in 1.6% of patients including 17 needing vascular repair and 28 needing transfusion. [72]

A commonly encountered problem is hematoma formation at the puncture site. Zorab[22] reported this complication in 50% of catheterizations. The bruising was of minimal clinical significance in Zorab's study, but leakage, when it occurs around the catheter or from the puncture site after the catheter's removal, can be dangerous. Compression neuropathy secondary to bleeding has been reported after brachial artery puncture in anticoagulated patients; in some cases, surgical decompression has been necessary.[9] The large amount of soft tissue surrounding the femoral artery makes bleeding in this area difficult to control. Large hematomas are

not uncommon after femoral artery catheterization; indeed, Soderstrom and associates [65] reported two cases of bleeding that required transfusion after femoral puncture. More commonly, hematomas are painful, slow to resolve, and prone to infection. Multiple-site punctures and inadequate pressure applied for sufficient time account for most hematomas. Furthermore, hematomas may make further procedures in the groin difficult to complete.

Thrombotic occlusion after radial arterial cannulation occurs in nearly 50% of infants and small children; however, ischemia from occlusion is rare because of collateral blood supply from the ulnar artery. [73] Insertion sites closest to the bend of the wrist increase the chances of maintaining patency. Nonpatency is 4 times more likely with insertion in sites =3 cm above the bend in the wrist. [74] Slogoff et al.[54] described 1700 cardiovascular surgical patients who underwent radial artery cannulation without any long-term, ischemic complications, despite evidence of radial artery occlusion after de-cannulation in more than 25% of patients. Serious complications after radial artery cannulation are extremely rare in the absence of contributing factors, such as preexisting vasospastic arterial disease, previous arterial injury, protracted shock, high-dose vasopressor administration, prolonged cannulation, or infection. [53] [75]

Prevention of bleeding complications may be accomplished with frequent careful inspection of the puncture site and with the use of prolonged compression after removal of the catheter or needle. Firm pressure should be maintained for =10 minutes after removal of a peripheral artery catheter and longer after femoral cannulation or if the patient is anticoagulated. Five minutes of pressure is sufficient after puncture for a blood gas sample in an individual with normal coagulation. Exsanguination, a related complication, may occur if the arterial line apparatus becomes disconnected. This is more common in the obtunded or combative patient, and restraints are often required for patients with indwelling arterial cannulas. Exsanguination should not occur if tight connections are maintained throughout the system and if frequent, careful inspections of both the circuit and the patient are made.

Meticulous attention to aseptic technique is necessary during insertion and catheter maintenance to minimize the risk of catheter-related infection. [76] [77] Serious infections rarely complicate arterial cannulation. Most simple interventions can reduce the risk for serious catheter-related infection. The strongest supportive evidence is from usage of full barrier precautions during catheter insertion, specialized nursing care, and newer generation catheters with antiseptic hubs or antimicrobial agent impregnated catheters.[76] The incidence of catheter-related infections increases with prolonged cannulation. [69] Catheters placed with sterile technique have an extremely low rate of infection up to 96 hours. Catheters changed over a guidewire every 96 hours have an infection rate of about 10% at the radial and femoral sites.[66]

Most infections begin locally at the puncture site and remain localized, although systemic sepsis has been reported. [75] Radial and femoral sites have a similar incidence of complications, but axillary cannulations seem to have a much higher incidence of infection (although no large studies of cannulation at this site exist). [70] [78] Arterial cannulas are more prone to infectious complications than other vascular catheters. Many mechanisms have been proposed for this occurrence. [77] [79] The arterial pressure monitoring system usually consists of a long column of fairly stagnant fluid and is subject to frequent manipulation. Stamm and colleagues [78] found that patients were at greater risk for systemic infection if they had an arterial line and required frequent blood gas determinations than if they had the cannula alone. The sampling stopcock is a site of frequent bacterial contamination.

The risk of infection also increases as the duration of cannulation is prolonged. Older studies recommend that catheters be changed after 4 days if continued monitoring is necessary.[78] [79] In addition, Makai and Hassemer[79] recommend changing the entire fluid-filled system, including transducer chamber-domes and continuous flow devices, every 48 hours. However, other risks for noninfectious concerns increase with more frequent catheter and site changes when based solely on length of catheterization of a site. Therefore, daily evaluation of the site is advised and catheter change should not be mandatory until 7 to 8 days, if the site remains clean.

Shinozaki and coworkers[80] demonstrated a marked reduction in equipment contamination when the continuous flush device was located just distal to the transducer, as opposed to closer to the three-way stopcock used for sampling. This setup reduces the length of the static column of fluid between the sampling stopcock and the transducer. As mentioned previously, a drop of iodophor or antibiotic ointment applied to the puncture site decreases the incidence of local wound infection. [39] This technique has drawn a great deal of criticism, however. The current standard is a clean, dry dressing, not an occlusive type. An antibiotic or silver impregnated catheter is always recommended for long-term placements.

Thrombosis of the vessel in which the cannula is placed is another frequently encountered problem. The incidence with which this occurs varies with the method used

to determine the presence of the clot. Bedford and Wollman [14] found a >40% occlusion rate when radial artery catheters were left in place for >20 hours. All of these occluded vessels eventually re-cannulized. Angiographic studies show deposition of fibrin on 100% of the catheters left in place for >1 day, although clinical evidence of ischemia secondary to occlusion with thrombus present occurs in <1% in most studies. Most reports of nonangiographic catheterizations that mention thrombosis are studies of the radial artery. Therefore, it is difficult to compare the incidence of thrombosis at other sites, although during the 176 femoral catheterizations of Soderstrom and coworkers and Ersoz and associates,[65] [81] *dorsalis pedis* pulses were decreased in only 2 patients, and no clinical signs of ischemia were noted. Larger catheter sizes, trauma during cannulation, and the presence of atherosclerosis have all been postulated to increase the incidence of thrombosis; however, conflicting studies abound. Downs and colleagues associated tapered catheters with an increased incidence of thrombosis. [16]

Arterial spasm after puncture (usually following multiple attempts) can predispose to thrombus formation and can even lead to ischemic changes without fibrin deposition. Successful reversal of spasm after intra-arterial lidocaine, reserpine, and phentolamine has been reported, but no reliable studies of efficacy in this situation have been published. [82] Thrombosis can be minimized by decreasing the duration of catheterization, by proper flushing, and by using larger arteries. Surgical embolectomy or thrombectomy is rarely required because the smaller vessels that are most likely to occlude usually have good collateral circulation. A normal (negative) result on an Allen test or a similar test suggests but does not ensure adequate collateral flow. [49] [55] The larger femoral artery,

which has poor collateralization, rarely occludes with catheterization when used for monitoring purposes.

Another complication of thrombosis is occlusion of the catheter. Time until occlusion of radial and femoral artery catheters has been compared. Radial cannulas became occluded at an average of 3.8 days, whereas femoral cannulas occluded after 7.3 days. [66] The importance of this comparison is minimal if the clinician follows infection prophylaxis guidelines and changes arterial catheters after 4 days.

A few less common complications are easily prevented. One that occurs only with the percutaneous catheter-through-the-needle method is catheter embolization. Once the catheter has been placed through the needle, it should never be pulled back, because the end of the catheter may be sheared off by the sharp needle bevel. If this occurs, surgical removal of the catheter tip is necessary.

Skin necrosis is a complication of radial artery cannulation involving an area of the volar forearm proximal to the cannula. [83] [84] Wyatt and colleagues [83] believe this is secondary to the poor blood supply of this area and state that taking the precautionary steps described previously prevents or decreases the incidence of necrosis. One feared complication of indwelling radial and brachial arterial catheters is the occurrence of a cerebrovascular accident secondary to embolization from flushing of the catheters.[16] [85] As little as 3 to 12 mL of flush solution has shown reflux to the junction of subclavian and vertebral arteries. [65] A fatality due to air embolism from a radial artery catheter has been reported and was re-created in a primate model. [86] Although these animals are much smaller (7 kg) than an adult human, as little as 2.5 mL of air introduced at a relatively low flush rate was found to embolize in a retrograde fashion to the brain. Cerebral embolization can be prevented with the use of continuous flush systems (3 mL/hour) and by ensuring the integrity of the tubing and transducer systems to prevent air entry. In addition, small volumes (<2 mL) of intermittent flush solution should be used.

Complication rates also vary according to the method of arterial cannulation. Mortensen [87] studied the three main techniques (discussed earlier in Techniques), but unfortunately, most of his arterial cannulations were for angiographic purposes. The complications associated with prolonged cannulation time are therefore underrepresented. For Mortensen's series, cutdown arteriotomy exhibited the lowest incidence of complications (7.7%), whereas the Seldinger technique had a complication incidence of 17.7%. Complications of percutaneous cannulation were 11.3%. Apparently, false passage of the guidewire, the catheter, or both were associated with increased intimal damage and complications. *It is imperative that the wire or catheter be advanced only if no resistance is met!*

In actuality, arterial puncture and cannulation are safe procedures when care is taken and basic principles are kept in mind. The operator should be skilled and should seek an atraumatic insertion. Once the monitoring system is set up, it should be manipulated as little as possible. Any handling should be performed with a flawless aseptic technique. The tubing and other fluid-filled devices should be changed every 48 hours, and catheters should be inserted into a vessel that provides a vessel-to-catheter ratio as great as possible without compromising other needs. If these principles are followed and the patient and system are carefully inspected at frequent intervals, complications of arterial puncture and cannulation can be minimized.

INTERPRETATION

An indwelling arterial cannula can provide valuable information about the hemodynamic status of a patient (through continuous pressure monitoring) and about the patient's respiratory and metabolic status (through intermittent sampling for blood gas analysis and other blood tests). The partial pressure of carbon dioxide and pH of the blood can be used to define four major groups of metabolic derangement: respiratory acidosis or alkalosis, and metabolic acidosis or alkalosis. Rarely will a disorder be strictly classified into one of these groups; however, a simple chart such as that shown in the appendix helps determine the relative effects of metabolic and respiratory influence on the blood pH. (See also the discussion in the Appendix .)

A rough estimate of the contribution of respiratory factors may be made by assuming that for every 10 torr (mm Hg) that the pCO_2 varies from 40, the pH will inversely vary 0.08 pH units from 7.4. Adequacy of blood oxygenation can be determined from the measured pO_2 of the arterial blood and from the known concentration of oxygen that the patient is inspiring. To avoid iatrogenic complications of intensive care, one must be absolutely certain that the data are from an arterial sample that has been properly analyzed before basing one's treatment decisions on the numbers obtained. Not uncommonly, one may accidentally puncture a vein when attempting to obtain an arterial blood sample. Furthermore, false readings may result if the sample is not free of air bubbles, not promptly chilled, and not analyzed within 20 to 30 minutes. Although still controversial, blood gas values that are *uncorrected* for body temperature appear more appropriate for guiding therapy in hypothermic patients.[88] [89]

An indwelling arterial catheter also provides continuous blood pressure monitoring. The trend of a patient's pressure helps one assess the effect of various therapeutic interventions. The absolute systolic and diastolic pressures measured will vary at different catheter sites, with higher peak systolic pressures measured at the periphery; the pressures will also be higher when measured in the distal lower limb. [17] [65] A wide variance between direct arterial pressure and pressure measured with a standard pneumatic cuff will always exist in some patients. Data averaged over a population group, however, compare fairly well. [17] For this reason, the cuff pressure and that displayed on the monitor should be compared regularly. A change in their relationship may be the first indication of difficulties with the direct measuring system. Auscultatory methods usually give a slightly lower value than direct measuring systems.

Waveform analysis may also provide an early indication of thrombosis in the arterial catheter. Many variables affect the waveform, including cardiac valvular disease, arteriosclerosis, and other peculiarities of an individual's cardiovascular system that may contribute to pulse wave reflections. [90] Waveforms may vary tremendously among patients, but after an adequate monitoring system has been established, a change in an individual's pressure wave is usually indicative of thrombosis or other malfunction in the monitoring system. A change in waveform may also indicate a change in the patient's cardiovascular status, such as a papillary muscle rupture. Once again, before making a therapeutic decision based on an electronically generated number, the patient should be rechecked with a pneumatic cuff; this device is less fallible than the electromechanical system.

Radial systolic arterial pressures poorly estimate the actual ascending aortic pressure, with >50% of cases reporting a difference in values by 10 to 35 mm Hg. Mean arterial pressures or even diastolic pressures were found to be highly accurate with >90% of the values being within 3 mm Hg of aortic values. [91] Longer catheters have also been successfully used from radial sites to more accurately reflect central aortic pressure for cardiac surgery patients. [92]

CONCLUSION

As intensive care knowledge and technology grow and develop, cannulation of the arterial system may decrease in frequency. Oximeters can determine the quality of blood oxygenation percutaneously and are becoming more accurate and sophisticated (see Chapter 2). Electronic sphygmomanometers are being refined for continuous indirect blood pressure monitoring. As these devices improve and noninvasive sampling methods for clinically relevant electrolytes and physiologic markers are refined, the indwelling arterial cannula may in time become considered overly invasive. At the time of publication, the current need for frequent blood sampling for chemical and hematologic analysis remains a strong indication for its use in the most critically ill patients. Overzealous blood gas analysis may lead to iatrogenic anemia in the ICU. Multiple reports document the advantages to limiting frequent blood sampling (and its associate waste). [93]

Arterial puncture and cannulation are invaluable aids to the emergency and critical care clinician. Long-term catheterization is a safe procedure when the catheter is placed, maintained, and removed with care. The radial artery is the most favored location for puncture, but as more experience is gained and reported with femoral artery catheterization, the latter may become a more frequently used site. Selection of either site is associated with a low complication rate and should be determined by the skill of the clinician and the nursing team and the relative convenience and comfort of the patient.

Chapter 21 - Peripheral Intravenous Access

Shan W. Liu
Richard Zane

Intravenous (IV) access is a mainstay of modern medicine. IV cannulation is a procedure performed by nearly all involved in the health care profession—clinicians, nurses, clinician assistants, phlebotomists, and emergency medical technicians. In the United States, more than 25 million patients have peripheral IV catheters placed per year, allowing access for medication administration, fluids and nutrition, and blood sampling for laboratory analysis. IV access can usually be accomplished in 2 to 5 minutes, although in small children it may take considerably longer. [1] [2] [3] [4] Despite their growing number, dedicated IV teams are very costly and not always cost effective, making it paramount for clinicians to continue to master IV cannulation. [3] [5]

Bloodletting, or bleeding, has been a long-established medical practice dating back to the time of Hippocrates. The most common ancient technique for bleeding was to tie a bandage around the arm so the veins of the forearm would distend. The vein was then opened with a sharp knife and the blood collected in a bowl or basin. By the Middle Ages, this was usually done by barber-surgeons. In 1656, Sir Christopher Wren injected opium intravenously into dogs using a quill and bladder, thereby becoming the father of modern IV therapy.[6] Blood transfusions also date back to the mid-1600s. French physician Jean Denis successfully transfused lamb's blood to a 15-year-old boy in 1667. [7] [8]

Originally, 16- to 18-gauge (ga) steel needles were used for infusions. However, in the 1950s, with the introduction of the Rochester needle (a resinous catheter on the outside of a steel introducer needle), IV plastic catheters soon replaced indwelling metal needles and increased comfort and mobility. [6] [9] Today, plastic catheters are the mainstay of IV access.

INDICATIONS AND CONTRAINDICATIONS

Obtaining timely and adequate access is a major priority during a cardiac arrest and major trauma. In normal perfusion, differences in delivery times for injections centrally vs. peripherally are minimal essentially a matter of seconds. [10] Canine studies show that 90% of peripheral IV fluid reaches central circulation beneath inflated pneumatic anti-shock garments. [11] During cardiopulmonary resuscitation, medications have been shown to reach the central circulation faster with central access than with peripheral venous access. [12] However, peripheral IV cannulation is still the procedure of choice even during cardiopulmonary resuscitation (CPR) because of the usual speed, ease, and safety with which it can be accomplished. [13]

Saline locks, commonly known as heparin locks because of prior use with heparin flushes, are preferable when IV medications are needed and there are limited foreseeable fluid requirements. Saline locks cost much less than a full IV fluid and tubing assembly; therefore, saline locks have largely replaced the time-honored method of maintaining access by a slow, constant infusion. [13a] Such locks are especially helpful when prompt vascular access may be suddenly needed. Their disadvantage is that irrigating the catheter requires a separate syringe and flush. [13]

In terms of contraindications to IV placement, with the risk of extravasation of irritating or tissue-injuring solutions (colchicine, phenytoin, vasoconstrictors, and others) or suboptimal volume flow, peripheral IVs should not be placed in extremities with massive edema, burns, sclerosis, phlebitis, or thrombosis. Furthermore, extremities on the side of radical mastectomies or dialysis grafts should also be avoided, although they should be used when an urgent condition exists and other peripheral access is not possible. Veins that drain from an area of neck trauma or into an affected traumatic extremity or the side of a chest or abdominal trauma are also suboptimal. The patency and flow of the vessels and fluid or medications may not be delivered to the circulatory system. Cannulation at sites of cellulitis should be avoided as it may cause bacteremia. Also avoid extremities with shunts or fistulas to minimize shunt infections or thrombosis. Similarly, IV access in feet and ankles are suboptimal for long-term use, but may suffice in the emergency department.

Blood samples for laboratory analysis are usually drawn before IV cannulation to avoid contamination with IV fluid or medication. However, several studies have shown that accurate basic electrolytes and hematologic values can be drawn from peripheral IV lines when infusions are shut off at least 2 minutes, at least 5 mL of blood are wasted, and all tubes are filled to the top to avoid inaccurate bicarbonate readings. [14] [15] [16] By adopting this technique, one can reduce the number of peripheral needle sticks, minimizing trauma and sclerosis of the vein and improving patient satisfaction.

PERIPHERAL INTRAVENOUS CENTRAL CATHETERS

In this modern age of multiple types of IV access devices, familiarity with peripheral devices is necessary to ensure proper selection. A common option is the *PICC line*, or peripheral IV central catheter. It is a relatively recent addition to the IV access armamentarium and shares attributes of both central and peripheral venous access. A PICC line is composed of a thin tube of biocompatible material and an attachment hub that is inserted percutaneously into peripheral veins and advanced into a large central vein with radiographic confirmation of placement. PICC lines are suitable for long-term vascular access for blood sampling and infusion of hyperosmolar solutions such as those used for total parenteral nutrition. These lines should be inserted as soon as intermediate-term access is anticipated. [17]

ANATOMY

Success of cannulation depends on familiarity with the vascular anatomy of the extremities. In the upper extremity, the veins of the hands are drained by the metacarpal and dorsal veins, which connect and form the dorsal venous arch and are excellent sites for IV therapy. These veins can easily accommodate 22- and 20-ga catheters. The wrist and forearm's venous supply is the basilic vein, which courses along the ulnar portion of

the posterior forearm; it is often ignored because of its location, but can be easily accessed if the patient's forearm is flexed and the cannulator stands at the head of the patient.[18] On the radial side of the forearm, the cephalic is best known as the "intern vein." Easily accessed, this vein can accommodate 22- to 16-ga catheters. The median veins of the forearm course through the mid-forearm. Accessory cephalic veins at the top radial aspect of the forearm are easily stabilized and accessible.

The antecubital veins consist of the medial cubital, basilic, and cephalic veins and are often selected for midline catheters or blood draws. IV placement here is easy, but mobility of the arm is often subsequently restricted. The larger veins above the antecubital space, the cephalic and basilic veins, are often more difficult to see, but can be accessed if necessary without difficulty (Fig. 21-1).

The relevant lower extremity venous anatomy starts with the dorsal digital veins, which become the dorsal metatarsal veins and then form the dorsal venous arch. The arch ultimately splits into (1) the greater saphenous vein, which travels up the medial aspect of the ankle, and (2) the lesser saphenous vein, which courses laterally up the opposite side. These are the vascular structures most accessible for IV therapy.

The external jugular vein is formed below the ear and behind the angle of the mandible. It then passes downward and obliquely across the sternocleidomastoid, then under the

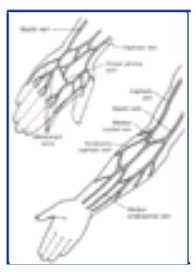

Figure 21-1 Anatomy of veins in hands and arms for intravenous cannulation. *(Adapted from Millam DA: How to insert an IV. Am J Nurs 79:1268, 1979.)*

middle of the clavicle to join the subclavian vein. This vein is often cannulated in adults and children who have venous access problems, but it usually only provides access for a short time (Fig. 21-2). It is important to note the presence of valves in the external jugular, notably about 4 cm above the clavicle, as they can significantly impede IV function.[13] Flow is commonly dependent on the position of the neck.

PREPARATION

Safety.

In the era of HIV and hepatitis, safety in placing IVs cannot be overemphasized. Universal precautions must be applied to all patients, especially in emergency care settings where risk of blood exposure is increased and infection status of patients is largely unknown. [19] One study showed that 11% of all hospital IV catheter injuries to health care workers occurred in the emergency department (ED). [20] Newer catheter devices have emerged to prevent inadvertent needle injuries. The Protectiv IV Catheter Safety System (Johnson & Johnson, Inc., Arlington, TX), Insyte Antoguard Shielded IV catheter (Becton-Dickinson, Franklin Lakes, NJ), Saf-T-Intima IV Catheter Safety System (Becton-Dickinson, Franklin Lakes, NJ), Vacutainer Brand Safety-Lok (Becton-Dickinson, Franklin Lakes, NJ), Shamrock Safety Blood Collection Set (Winfield Industries, San Diego, CA) has a protective sleeve that encases the sharp stylet as it is retracted from the catheter. The Insyte Autoguard Shielded IV Catheter's needle is instantly encased inside a tamper-resistant safety barrel by pressing the activation button. The Saf-T-Intima IV catheter, puncture-guard winged set, Vacutainer Brand Safety-Lok, and

Figure 21-2 The external jugular vein may be cannulated in the same manner as any other peripheral vein, which often negates the need for central venous catheterization. This site is especially useful to obtain blood and to infuse fluids and medication in obese adults, infants, and IV drug users. The major disadvantages are that flow is very dependent on the position of the neck (a significant problem in children and obtunded or restless adults), and valves may abut against the tip of the catheter. Air embolism from a disconnected catheter is another potential hazard with this access route.

Shamrock safety winged needle are all types of winged safety devices that have shields which advance over the needle to prevent needle exposures. [6]

Choosing catheter gauge.

The catheter gauge will depend on the clinical scenario. The smallest, shortest catheter is a 22-ga, which is sufficient for routine maintenance fluids and routine antibiotics. A 20-ga or 18-ga is necessary for blood product administration and a 16-ga needle is suggested for resuscitating patients. [18]

Appropriate site.

Site selection will depend largely on the expected duration of IV therapy, patient's activity level, and condition of the extremities. When choosing a place to initiate IV therapy, the best starting place is the hand. Then advance cephalad as necessary. Hand veins are appropriate for 22-ga IV catheters. Cephalic, accessory, or basilic veins are ideal for larger bore IVs. Avoid veins that are not resilient and feel hard and cordlike, as they are often thrombosed. [6] Deep, percutaneous antecubital venipuncture or external jugular vein cannulation are also options in the patient with difficult veins or those that may need IV access in a hurry. [21]

In patients who have undergone radical mastectomy, avoid the arm on the same side as the surgery because circulation may be impaired, affecting flow, causing edema and other complications like thrombosis. [6] [18] Furthermore, while lower extremity veins can be useful locations for IV access, especially in children, they are often easily traumatized and may lead to deep vein thrombosis. [6]

Anesthesia for IV placement.

Prospective studies continue to demonstrate that local anesthesia, such as buffered or plain lidocaine or benzyl alcohol, significantly decrease perceived patient pain before IV cannulation. [22] [23] [24] Although somewhat time-consuming and impractical, and sometimes as painful as cannulation itself, anesthesizing at the site of cannulation should be at least considered as part of routine IV care. Similarly, in the pediatric population, 2.5 g of EMLA (eutectic mixture of local anesthetics) can also be applied to the vein to ensure local anesthesia. [6] The main disadvantage of using EMLA is that one must wait up to an hour for anethestic onset before cannulation. [25] In one study regarding the use of 4% liposomal lidocaine (ELA-Max) in children, the authors reported that a 30-minute application was as safe and effective as EMLA for reducing pain during venipuncture (see Chapter 30). [26]

IV assembly.

Collecting the proper supplies before inspecting the patient's veins and performing cannulation is imperative. Listed in Table 21-1 are the necessary materials. They are shown in Figure 21-3 .

IV fluids and lines should be prepared as well, if needed. The cap should be removed from the IV line and the tab

Figure 21-3 Materials for intravenous insertion. *A* and *B*, Tape for securement. *C*, Gloves as part of universal health precautions. *D*, Saline lock. *E*, Saline. *F*, Tape roll. *G*, Gauze. *H*, Tegaderm. *I*, Alcohol swabs. *J*, Butterfly needle, if needed. *K*, Intravenous tubing. *L*, Iodine swabs. *M*, Syringe for phlebotomy. *N*, Angiocatheter. *O*, Prepped saline flush. *P*, Tourniquet.

removed from the IV bag. The IV tubing should be clamped shut and the spiked end inserted into the IV bag (Fig. 21-4). The drip chamber should be pinched and filled halfway (Fig. 21-5). The clamp should then be opened slightly to flush the IV tubing (Fig. 21-6). If saline locks are being used, the locks should similarly be flushed before cannulation. This can be accomplished by attaching the lock to a saline-filled syringe and flushed (Fig. 21-7).

Inspection and positioning.

After collecting supplies and making appropriate preparations, palpation is the next crucial step in successful cannulization. Position the patient comfortably on a flat surface. Place a 1-in wide tourniquet on the patient's upper arm or forearm sufficiently tight enough to impede venous flow but not to the extent arterial flow is compromised. Start by placing the tourniquet under the arm (Fig. 21-8). Fold both ends of the tourniquet above the arm and cross the ends (Fig. 21-9). Pull the overlying end taut and tuck the middle portion below the underlying end, creating a loop (Fig. 21-10 and Fig. 21-11). After tourniquet placement, palpate with the index and middle fingers of one's nondominant hand—veins are soft, elastic, resilient, and pulseless. [18]

Cannulation.

Wash hands, put gloves on, and clean the site with iodine or alcohol, or both. Studies suggest that iodine is better as an antiseptic than alcohol in terms of fewer infections.[27] Most skin preparations require drying to optimize surface antibacterial activity (Fig. 21-12). Stabilize the vein without contaminating the prepared site. One method is to position one's thumb alongside the vein and pull down and then place the index finger more cephalad and push upward (Fig. 21-13). Take the angiocatheter between the thumb and forefinger of the dominant hand with the bevel up, angled 10 to 30° between angiocath and vein, aligned parallel to the vein. Puncture the vein (Fig. 21-14). Once a flash is seen,

Figure 21-4 Insertion of spiked end of IV tubing into IV bag.

advance the catheter several millimeters more to ensure it has entered the vein and not just the wall. Avoid advancing too far and puncturing the posterior wall; loosen the stylet and advance only the catheter (Fig. 21-15). Take the fingers anchoring the vein and occlude the vein at the tip of the catheter to prevent extravasation of blood from the angiocatheter. Remove the needle and connect the saline lock, IV

lining, or syringe for phlebotomy and release the tourniquet (Fig. 21-16 and Fig. 21-17). [18]

External jugular vein cannulation deserves a special note. In the patient with otherwise little peripheral access, cannulate as follows: Place patient in the Trendelenburg position to fill the external jugular. See Fig. 19-5 in the Pediatric Vascular Access chapter. Rotate the head to the opposite side.

Figure 21-19 Crossing ends of tape over top of hub.

Figure 21-20 Transparent polyurethane dressing.

Prep the area as described earlier. Align the cannula in the direction of the vein with the point aimed toward the ipsilateral shoulder. Puncture midway between the angle of the jaw and midclavicular line, lightly compressing the vein with a free finger above the clavicle. Proceed as previously described for cannulation. [13]

Anchoring the device.

After the IV has been connected to the saline lock or IV tubing, anchoring the device is essential. Use a ½-in wide strip of tape, adhesive up, under the hub of the catheter and fold it over like a bow (Fig. 21-18 and Fig. 21-19). This will secure the cathether and prevent lateral movement. Clear polyurethane dressings can also be used with or instead of tape (Fig. 21-20). Saline locks can be connected to needleless hubs to prevent accidental needle injury (Fig. 21-21). Then secure the loose saline lock or IV tubing with tape to prevent accidental dislodgement (Fig. 21-22). IV tubing can be similarly connected to the angiocatheter and anchored (Fig. 21-23). Commercially available securement devices can also be used. Dressings should then be signed and dated to assure timely dressing changes. [6] Topical antibiotics

Figure 21-21 Attachment of IV saline lock to angiocatheter. This can be used for IV fluids or medications.

Figure 21-22 Securing the saline lock.

or iodophor ointment should be applied to the insertion site to prevent infection. [28]

Maintaining patency.

An important component of IV care is maintaining patency with frequent flushing. Until recently, heparin solutions had been used to flush catheters and maintain patency but have been shown to cause problems such as hemorrhage. Saline flushes are as effective as heparin in maintaining patency and preventing phlebitis in peripheral devices. In a meta-analysis comparing saline and heparin flushes, there was no statistical difference between the incidence of clotting, phlebitis, and duration of IV patency. With the advantage of decreased costs and avoiding complications such as bleeding and heparin-induced thrombocytopenia, heparin flushes should be replaced with saline flushes. [29] [30] [31]

Dressing.

It is not cost-effective to continually redress peripheral venous catheters at periodic intervals. Sterile gauze or transparent, semipermeable, polyurethane dressings can be used and left on until removal of the catheter without increasing infection as long as the site is regularly evaluated. [32] There is emerging evidence that the type of securement

Figure 21-23 Attaching the IV tubing for infusion.

techniques (e.g., the StatLock IV, a sterile, adhesive-backed dressing and proprietary distal male luer-tip extension set) can decrease mobility and the risk of dislodgement. [33]

Adjuncts.

Often, patients have nonvisible and nonpalpable veins. Several adjuncts can increase the likelihood of successful cannulation.

Nitroglycerin ointment applied to the hands of patients with small caliber veins has been shown to increase vein diameter size two to six times the original diameter and increase the rate of successful first-attempt cannulation without complications. Once the tourniquet is applied to the wrist, 0.5 to 1 cm of 2% nitroglycerin is applied to a 2.5 cm square area, left on for 2 minutes, and then rubbed off. [34] Nitroglycerin is useful and safe in the pediatric population, as well. [35]

In the late 1980s, several small studies demonstrated the potential uses of a venous distention device—a cardboard mailing tube placed over the forearm with a sealed bulb at one end that would cause a vacuum within the tube. Ninety percent of the patients predetermined to be difficult to access were cannulated using this device. There were few reported complications, such as petechiae and discomfort. [36] [37] Another useful, common method of increasing venous distention is simply to ask the patient to open and close his or her fist. This causes increased blood flow into the arm or hand and distends the veins. Light tapping can also increase venous distention, although heavy tapping may cause the vein to spasm. Lowering the arm below the level of the heart can also increase venous distention. If these methods are inadequate, heat packs can be applied for 10 to 20 minutes to increase venous engorgement. This is particularly useful in the pediatric population. [6]

Percutaneous brachial vein cannulation.

Brachial vein cannulation is an option when attempts at peripheral IV access have failed or are contraindicated and may obviate the need for central venous access or surgical cutdown. Complications include brachial artery puncture, hematoma, and transitory paresthesias.

Figure 21-24 *A*, Anatomy of the vessels of the arm. *B*, Corresponding ultrasound image obtained with an Aloka 7.5-MHz ultrasound probe on the right arm. BA, brachial artery; BAV, basilic vein; DBV, deep brachial vein. *(From Keyes LE, et al: Ultrasound-guided brachial and basilic vein cannulation in emergency department patients with difficult intravenous access. Ann*

Emerg Med 34:711, 1999.)

To cannulate the brachial vein, the brachial artery must be palpated in the antecubital fossa. Prepare the site in the usual manner and apply a tourniquet above the antecubital space. At a point immediately medial or lateral to the pulse, an angiocatheter with an attached syringe is inserted and advanced at a 45° angle, maintaining suction on the syringe. After entering the vein, continue 2 to 3 mm more to ensure cannulation. Advance the catheter and remove the needle as usual. [21] [38]

Ultrasound-guided deep brachial vein cannulation has been reported in the literature. [39] In this study, a 7.5 MHz probe was used to identify the more laterally and superficially situated basilic vein, as well as the noncompressible brachial artery and brachial vein. After identification of the appropriate vessels using ultrasound, a second operator inserted a 1.8- to 2-in, 18- to 20-ga IV catheter successfully in a majority of patients (Fig. 21-24).

COMPLICATIONS

Though IV placement is a common procedure, it is not without complications. Phlebitis, infiltration, infection, nerve damage, air embolism, bruising, and thrombosis are the most common complications and rarely cause significant morbidity or fatality.

Phlebitis.

Phlebitis is a common complication after IV cannulation and administration of medication, especially vancomycin, potassium, and any hyperosmolar solution or cytotoxic agents.[40] [41] IV devices facilitate infection by damaging epithelial and mucosal barriers to infection and provide microorganisms direct access to the bloodstream.[42] The most common infectious complication of peripheral IV access is a self-limited cellulitis. Bacteremia and sepsis occur rarely. Phlebitis is described as the presence of a palpable cord accompanied by warmth, erythema, tenderness, and induration. Phlebitis will usually manifest as discomfort for the patient and necessitates removal of the catheter and replacement on

another extremity. The occurrence of phlebitis can be minimized by reducing trauma to the venous wall. Not placing IVs in the lower extremities or across joint sites, when possible, also decreases the incidence of IV-related phlebitis, as trauma, motion, and stagnant blood in varicose veins will be minimized. [6] In one study, phlebitis occurred in 15% of patients receiving IV infusions. Of these patients, 6.5% had local staphylococcus epidermidis colonization of the catheter. Interestingly, this study also demonstrated that an increased incidence of phlebitis was not related to duration of the IV but rather to patients with higher hemoglobin levels, for unclear reasons.[43] In another study, bacteremia developed from peripherally inserted lines 0.4% of the time. [44] With such low levels of clinically significant bacteremia, some argue routine replacement of catheters is now no longer needed. [43] The only large, prospective study investigating the incidence of phlebitis associated with peripheral IVs required replacement of the IVs every 72 hours. [32] Therefore, it is still standard practice to change IV lines every 72 hours.

The role of in-line filters to prevent phlebitis is controversial. It is thought that particulates from reconstituted medications, degradation products, precipitates, glass from vials, and other foreign debris all may play a part in postinfusion phlebitis. In-line filters may therefore play a role in preventing phlebitis, but given their cost, risk of clogging, and paucity of evidence that they improve outcomes, they have not become standard of care. [45]

Occasionally patients recently discharged from the hospital or ED will return with concern about a lump or cord at an IV site, often convinced that a piece of the catheter is still in the arm. This is a manifestation of vein injury from IV cannulation, and it may not be painful or show erythema or redness. Resolution is often quite slow (weeks) but no specific intervention is helpful or required.

Extravasation.

Usually, infiltration of a vein is a relatively minor and common complication of IV therapy. This often occurs when the catheter is dislodged from the vein during infusion. However, if the infusions are hypertonic, vasopressors, or chemotherapies, there is a significant risk of skin sloughing when infiltration and extravasation occur (Table 21-2). *Pain at the infusion site or the alarm sounding on an infusion pump device requires inspection of the infusion site for extravasation.* In extreme cases, skin slough with grafting may be required (Fig. 21-25).[6] If dopamine or norepinephrine extravasates, phentolamine may be used as an antidote to prevent ischemia to the local area. The reversal of ischemia with phentolamine is a common technique, but its ability to reverse or prevent a skin slough is not certain and not well documented. However, if infiltration of these vasopressors occurs, the editors suggest that it be routinely used. To inject phentolamine, 5 mL of a standard phentolamine solution is diluted with equal parts of saline. Using a 25- to 27-ga needle or a TB syringe, the entire area of skin blanching is injected with multiple small aliquots of the solution. Hyaluronidase was suggested in the past to ameliorate some effects of extravasation of other solutions. Although it was a common suggestion, its efficacy was not well established. Now this solution is not commercially available.

Infection.

Infection can be a costly and potentially devastating complication of IV therapy. Although rare with peripheral IVs, intravascular device-related bloodstream infections are often the least recognized cause of nosocomial infection. Peripheral IV catheters are most often associated

Many medications and IV solutions will cause pain and occasionally skin slough if significant amounts extravasate into soft tissues. Therefore, any complaint of pain during infusion or signs of tissue swelling should prompt an investigation for extravasation. Most extravasations have no specific therapy, so prevention is the only option. Phentolamine, injected subcutaneously to reverse vasoconstriction, is the most common technique, but its efficacy has not been well studied.

**Use a maximum concentration of 1 mg/mL of saline or phosphenytoin solution to minimize this risk.

with *Staphylococci epidermidis*, *Staphylococcus aureus*, and *candida* infections.[46] Infectious complications can be significantly reduced by handwashing, wearing gloves, site preparation with iodine, and monitoring site for signs of infection. [6]

Nerve injury.

Another rare complication of IV cannulation is nerve injury. Any peripheral nerve is potentially vulnerable to a needle-induced injury and sequelae can range from minor motor or sensory abnormality to complete paralysis. Nerve damage may come from needle damage, intraneural microvascular damage from hematomas, or toxic effects of the agent injected.[47] The first symptoms are often pain, numbness, or paresthesia. Pain may persist for years and can be debilitating. Fortunately, most simple procedures do not result in nerve injury as nerves often roll or slide away from the needle. Like all procedures, knowledge of relevant anatomy is essential. Should a patient complain of numbness or severe pain after needle puncture, injection into that site should immediately stop. [48] [49]

Air embolism.

Air embolism is another significant, although exceedingly rare, complication of peripheral IV

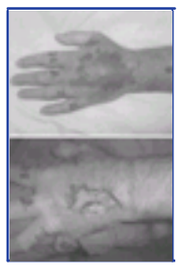

Figure 21-25 Extravasation of phenytoin. Pain at the infusion site or the alarm of an infusion pump requires inspection of the IV site for extravasation when irritating solutions are infused. In this case, an unconscious patient received a concentrated phenytoin infusion for status epilepticus, but his comatose state did not allow him to complain of pain. Over a few days, a skin slough occurred, requiring many weeks to resolve. This could have been avoided with the use of a more dilute solution (i.e., <1 mg/mL phenytoin to saline solution) or a central vein. The top panel shows the site one day after the phenytoin extravasation. The bottom panel was taken on follow up approximately a month later. *(Pictures courtesy of Dr. Mahesh Shrestha.)*

access. The symptoms are chest pain, shortness of breath, sudden vascular collapse, cyanosis, and hypotension. If air embolism is suspected, the patient must be placed in the left lateral position, ideally with the head and chest tilted downward. Such near fatal complications can be prevented by eliminating air from IV tubing before initiating therapy and not letting IVs run dry. [6] If the air bubbles are present near the top of the IV line, tap the tubing while holding it taut so they escape to the top. Similarly, curling the tubing around a pen or syringe can accomplish the same goal. If the air is near the Y connector, one can use a needle and syringe to directly remove it. If all else fails and the air is between the Y connector and the patient, the tubing will likely have to be disconnected and flushed. [50]

Other complications.

Bruising is a common complication of IV therapy. This is an inconsequential and common sequela of blood sampling or IV access, although it is often distressing to patients. Contrary to popular belief, flexing the elbow after venipuncture does not prevent bruising in the antecubital site. [51] Applying direct pressure immediately after decannulation is the most useful technique to prevent bruising.

Suppurative thrombophlebitis is another extremely rare complication of peripheral IV therapy. This is not an issue in ED patients—it most frequently occurs in patients with thermal injury, long-term cannulation with a plastic catheter, or lower extremity cannulation. [42] Local signs of inflammation or suppuration are often absent and can occur 2 to 10 days after catheter removal.[52] Treatment may include surgical excision of the entire length of involved vein and involved tributaries. As with all the infectious complications of IV therapy, it can be prevented by meticulous aseptic cannulation technique. [53]

Thrombosis and subsequent pulmonary embolism is a rare complication of peripheral IV access and is more commonly associated with centrally placed IV catheters and central lines.[6] Although rare, thrombosis and pulmonary embolism may occur in peripheral IV lines if saline locks are not flushed or fluids are allowed to run out. Should this occur, aspirate the line. If the return appears bloody, discard the syringe, gently flush the saline lock, and resume infusion. If there is no bloody aspirate, use 2 to 3 mL of saline to gently flush the line. If there is resistance, stop flushing immediately as there is a risk of an embolism developing. Recannulization at another site is then recommended. [54]

The Centers for Disease Control recommendations for IV care are:

1. Record and date the time of the catheter insertion in an obvious location near the insertion site.
2. Do not palpate the insertion site after the skin has been cleansed with antiseptic.
3. Palpate the insertion site for tenderness daily through an intact dressing.
4. Visually inspect the site if the patient reports tenderness.
5. Wash hands before and after palpating, inserting, replacing, or dressing any intravascular access site.
6. Replace dressings when they are damp, loose, or soiled.[44]

SPECIAL SITUATIONS

One of the greatest challenges in IV cannulation is establishing access in small children and infants (see Chapter 19). Some clinicians recommend a technique similar to the Seldinger technique, placing a guidewire into the angiocatheter once a flashback is obtained and then advancing the angiocatheter over the wire. [55] In establishing peripheral IV access in small children and infants, the technique is similar to that used in adults, but dorsal veins of the hands and feet are often the preferred site, while trying to reserve the antecubitals for PICC lines. In neonates, superficial scalp veins are convenient access sites as well. [17]

In children younger than 6 years who are critically ill, the intraosseous (IO) route is excellent (chapter 26) if peripheral IV access is difficult. It is possible because of the presence of noncollapsable veins that drain the medullary sinuses of the marrow. Such conduits drain into the central venous circulation via nutrient and emissary veins and allow administration of drugs, crystalloid, and blood products intraosseously with nearly immediate systemic absorption. [56] The recommended location for IO placement is the anteromedial tibia, 1 to 2 cm

below the tibial tuberosity. A 14- to 20-ga IO needle with stylus is recommended. This needle is placed at a 90° angle to the bone and advanced using a twisting motion through the skin and bone cortex, in a slightly caudal direction away from the growth plate to a depth of 1 cm. Placement is confirmed by feeling the pop of the needle and then aspirating bone marrow. IV fluids, medications, and blood can be delivered via this route. The overall complication rate for the IO route is low, although infiltration and osteomyelitis have been reported. These infusions must be delivered using a pressure pump because the viscosity of the marrow can be up to 10 mL/min. The needle must be secured well to avoid displacement. [57] [58] Recent swine experimental data and pediatric oncology data have demonstrated that lab values obtained from bone marrow aspirates may be reliable for blood gas and chemistry values, with the exception of potassium and ionized calcium and oxygenation levels. [59] [60] Laboratory porcine data have shown promise for the possible use of IO blood gas values in the setting of hypothermia. [61] While rare, there have been several case reports of compartment syndrome requiring amputation following IO infusion. To prevent such complications, IO placement of a catheter must be definitively confirmed by visualization of bone marrow, secured, and then carefully observed for early signs of compartment syndrome. [62]

IO infusions into adults are under research. Even though adults have a much less active bone marrow than young children, they still have patent sinusoidal vascularity. Of several commercially available IO kits for adults, the most promising one involves placing the IO needle device in the manubrium of the sternum. One study examined emergent bone marrow infusion into adult patients in whom IV access could not be established within a reasonable time frame. The success rate of adequate insertion was 100% and all patients' cardiovascular and general conditions improved or permitted additional IV lines to be placed. Despite a small sample size, the study offered IO injection as a rapid and safe alternative method for emergently accessing the vascular system for administration of fluids, medications, and blood products. [63] Further research is needed to address the optimal site of injection, instrument used, and insertion technique of adult bone marrow infusion.

CONCLUSION

Peripheral IV access is a necessary skill in the armamentarium of health care providers. It is quickly and easily performed and often life saving. Knowledge of anatomy and sterile technique is essential to successful cannulation and is a skill that can be mastered with minimal training.

Chapter 22 - Central Venous Catheterization and Central Venous Pressure Monitoring

Marc Mickiewicz
Steven C. Dronen
John G. Younger

CENTRAL VENOUS CATHETERIZATION

The use of central venous access in the emergency department (ED) and intensive care settings has increased in conjunction with new technologies and more invasive approaches to patient care. Advanced monitoring techniques, transvenous pacemakers, and parenteral nutrition all require rapid, reliable methods of central venous access. Select central venous catheterization has also gained acceptance in resuscitation and treatment of the critically ill child (see Chapter 19). Peripheral venous sites can be used for some of these procedures, but use of peripheral sites requires long catheters that must be threaded accurately into the superior vena cava (SVC) or inferior vena cava (IVC). Peripheral veins may be collapsed, thrombosed, buried in subcutaneous (SQ) tissue, or otherwise difficult to locate. Several large central veins, including the subclavian, jugular, and femoral, have predictable relationships to easily identified landmarks and can be cannulated within minutes. Consequently, cannulation of these vessels has become a common practice in a variety of clinical settings, and it is a skill required of all clinicians involved in the care of acutely ill patients.

Even in the most experienced hands, all routes and techniques described in this chapter are associated with complications and some degree of failure. Given the invasive nature of blindly catheterizing the central circulation, considering the close proximity of other organs and structure, and recognizing the less than ideal circumstances under which catheters must be placed, some complications are unavoidable. While knowledge of the anatomy is critical, and attention to technique is paramount, some complications of central venous catheterization are simply inevitable. It is desirable to limit complications, but their occurrence cannot naively be viewed as evidence of faulty technique or substandard care.

Numerous authors have reported success rates and complication rates from central vein catheterization. While data vary widely, and clinical experience portends better results, the 10% to 20% failure rate, the 5% to 10% complication rate, and the 4% malposition rate reported by Sznajder et al. [1] with percutaneous subclavian, anterior jugular, and posterior jugular catheterization are representative of the significant clinical issues surrounding these procedures.

BACKGROUND

Subclavian venipuncture was first described by Aubaniac in 1952, and its use was promptly adopted by others. [2] [3] [4] Subsequently the role of central venous pressure (CVP) monitoring in the maintenance of optimal blood volume was described and helped popularize subclavian venipuncture in the United States. [5]

Numerous reports of clinical experience with the infraclavicular (IC) subclavian technique followed. These stressed the clinical usefulness of the procedure, the ease with which it is performed, and its low complication rate. Subclavian venipuncture was described as useful in the management of hypovolemia, burns, cardiac arrest, chronic IV therapy, and septic shock. [6] [7] [8] [9] [10]

Early enthusiasm for IC subclavian venipuncture was eventually tempered by a growing awareness of serious and occasionally fatal complications. [11] These complications suggested the need for a safer method. In 1965, the supraclavicular (SC) approach was described, with advantages of a more direct approach to the subclavian vein and a potentially lower complication rate. [12] Later these two approaches were compared during the performance of cardiopulmonary resuscitation (CPR). The SC approach offered a significant decrease in catheter tip malposition and CPR interruption. [13]

An early mention of the internal jugular (IJ) approach appeared in a pediatric handbook in 1963. [14] An IJ approach in the adult (with what later became known as the *central approach*) was described in 1966. [15] Subsequently a variety of approaches were described, ultimately to be grouped into the anterior, central, and posterior approaches. [16]

All of these techniques, as well as the femoral and cephalic-basilic approaches, have inherent advantages and disadvantages, but each has a place in the practice of emergency medicine. Often the choice of a particular approach is determined solely by the individual clinician's prior experience with that approach. In general, success rates are higher and complications less frequent when these techniques are used by more experienced technicians. [17] Although every clinician has a preferred method for achieving central venous access, any clinician caring for critically ill patients should master several of these techniques.

INDICATIONS

There are several commonly encountered clinical situations in which central venous access is indicated. If necessary, any central venous approach could be used in each of these situations. However, experience suggests that certain approaches offer advantages over others in most clinical settings. Advantages and disadvantages of each technique are outlined in Table 22-1 and discussed in detail after the general indications.

Central Venous Pressure Monitoring

Although supplanted to a great extent by more sophisticated and accurate methods, particularly right heart catheterization with a balloon-tipped pulmonary artery catheter, CVP measurement may be useful in select hypovolemic patients.

Volume Loading

Subclavian venipuncture has been widely used as a vehicle for rapid volume resuscitation. Unfortunately, it is often misused in this regard. The flow rate of saline through a peripheral 5-cm, 14-ga catheter is roughly twice that through a 20-cm, 16-ga central venous catheter, with equivalent pressure heads. [18] The difference in flow is even greater for blood

TABLE 22-1 -- Advantages and Disadvantages of Central Venous Access Techniques

Technique	Advantages	Disadvantages
Basilic (peripheral) puncture	Low incidence of major complications	Greater incidence of minor complications of infection, phlebitis, and thrombosis
	Performed under direct visualization of the vein	
	Allows large quantities of fluid to be given rapidly	Hinders free movement of arms
		More difficult to place catheter in correct position for central venous pressure monitoring
Internal jugular puncture	Good external landmarks	"Blind" procedure
	Less risk of pneumothorax than with subclavian puncture	Has a slightly higher incidence of failures than subclavian approach
	Bleeding can be recognized and controlled	More difficult and inconvenient to secure
	Malposition of catheter is rare	
	Almost a straight course to the superior vena cava on the right side	
	Carotid artery easily identified	
	Useful alternative approach to cutdown in children younger than 2 years of age	
Femoral puncture	Good external landmarks	Difficult to secure in potentially ambulatory patients
	Useful alternative to other supradiaphragmatic approaches in patients with coagulopathies, superior vena caval trauma, or patients undergoing CPR	"Dirty" site
Infraclavicular subclavian approach	Good external landmarks	Higher incidence of complications, especially in hypovolemic shock
		"Blind" procedure
		Should not be attempted in children younger than 2 years of age
Supraclavicular subclavian approach	Good landmarks	"Blind" procedure
	Less risk of pneumothorax	
	Most practical method of inserting a central line in cardiorespiratory arrest	
	Malposition of catheter is uncommon	

From Knopp R, Dailey RH: Central venous cannulation and pressure monitoring. JACEP 6:358, 1977.

products because their higher viscosity further slows their passage through small-gauge catheters. [19] Consequently, the placement of peripheral large-bore catheters is the preferred method of rapid volume loading, unless time would be lost searching for a venipuncture site or unusually large volumes need to be infused.

Use of a large-bore (8 Fr) introducer catheter overcomes the impairment of flow seen with small-gauge central venous catheters. Flow rates through introducers alone can exceed those of common IV tubing.[20] In trained hands placement of an introducer device is a useful method of fluid resuscitation when very rapid flow rates are required. The benefit of increased flow rate is potentially limited by catheter kinking. [21] This problem is more common when long introducer catheters are placed via the IC route. A significant risk of introducer insertion is catheter misplacement, which may result in rapid infusion of fluid or blood into the chest cavity or mediastinum.

Emergency Venous Access

The predictable anatomic locations of the subclavian and femoral veins, and the speed with which they can be cannulated (often within 30 seconds) have prompted their use in cardiac arrest and other emergency situations. The need for a central line during CPR is controversial. Although there is not a universal standard of care, some clinicians advocate use of a central line routinely in cardiac arrest. It has been suggested that therapeutic drug levels are reached more rapidly if given centrally.[22] [23] However, the clinical importance of this observation remains theoretical. When easily obtained, central venous cannulation is preferred over peripheral venous access, because it provides a rapid and reliable route for the administration of drugs to the central circulation of the patient in cardiac arrest.

Routine Venous Access

Patients with a history of IV drug abuse, major burns, or obesity and those requiring long-term care may have inadequate peripheral IV sites. Central venous cannulation may be indicated as a means of venous access in these patients even under nonemergent conditions.

Routine Blood Drawing

The potential complications of central venous cannulation do not justify its use in routine blood sampling. Lines already in place may be used for this purpose if they

are properly cleared of IV fluid. A 20-cm, 16-ga catheter contains 0.3 mL of fluid, so at least this much must be withdrawn to avoid dilution of blood samples. Further, to avoid aspiration of crystalloid diluted blood from the peripheral vein, it is advised that the IV be turned off for 2 to 3 minutes prior to using the catheter for a blood draw. Because of the increased risk of infectious complications, air embolus, and venous backbleeding, the IV

tubing should not be repeatedly disconnected from the catheter hub. Interposition of a three-way stopcock in the IV tubing simplifies access and is an acceptable method of blood sampling in the intensive care setting, regardless of the IV site.

Infusion of Hyperalimentation and Other Concentrated Solutions

Hyperalimentation by way of the subclavian vein is safe and reliable. [24] Use of the IC technique frees the patient's extremities and neck; this procedure is therefore well suited to long-term applications. However, strict aseptic technique is necessary to minimize infectious complications. [25] Hyperosmolar or irritating solutions that have the potential to cause thrombophlebitis if given through small peripheral vessels are frequently infused by way of the subclavian vein. Examples are potassium chloride (>40 mmol/L), hyperosmolar saline, 10% dextrose infusions, chemotherapeutic agents, and acidifying solutions such as ammonium chloride. Some clinicians prefer to obtain central access because of the potential harm of extravasation of vasoactive substances (dopamine, norepinephrine), which may result in soft tissue necrosis.

Other Indications

Other indications for central venous access include placement of a pulmonary artery catheter or transvenous pacemaker, performance of cardiac catheterization and pulmonary angiography, and hemodialysis. Catheters such as the Uldall or Quinton device can be inserted within minutes, permitting use of the subclavian vein for emergency or short-term hemodialysis.[26]

Relative Indications for Different Approaches

Subclavian approaches.

Subclavian venipuncture is the most frequently used means of central venous access. The IC approach was the first popular means of central venous access and has been widely taught during residency training for more than 30 years. It is effective, useful in many clinical situations, and relatively easy to learn. Although generally safe in experienced hands, the IC approach is associated with significant complications, most notably pneumothorax. The SC approach is an important alternative to IC venipuncture. The SC approach may be preferable during CPR because it minimizes physical interference with the functions of chest compression and airway management. The IC approach requires deep penetration of a moving chest wall and frequently demands an interruption of chest compression. An SC subclavian venipuncture can be performed without cessation of CPR and involves superficial penetration of the relatively motionless neck. [13] The SC approach also avoids interference with airway management, which commonly occurs when the internal jugular vein is cannulated. [27] When a true central venous location is required, the SC approach is superior to the IC approach and long peripheral line insertion techniques because of the low incidence of catheter tip malposition with the SC approach. [28] In addition, the SC technique has been performed in the sitting position in patients with severe orthopnea. Placement of a central line with the patient in a sitting position is virtually impossible with other central venous access routes. [29] Finally, the low complication rate reported for SC subclavian venipuncture makes it a more attractive alternative, especially in the seriously ill patient. [27] [28] [29]

Internal jugular approach.

As is true of the SC subclavian approach, the IJ technique is useful for routine central venous access and for emergency venous access during CPR, since the site is removed from the area of chest compressions.[30] Comparison of IJ and subclavian cannulation has found a significantly greater incidence of proper venipuncture and catheter passage with the IC subclavian approach as compared with the posterior IJ method (98% vs 84%). [31] A 20% rate of catheter malposition was noted with each method. In 1 retrospective study, only 0.4% of 248 IJ cannulations resulted in clinically significant morbidity, compared with 4.2% of 298 subclavian insertions, even though the overall complication rate was similar. [32] Although there may be a slight difference in complications between the two routes, in the absence of specific contraindications, the clinician should use the technique with which he or she is most familiar. The IJ route is slightly more technically difficult than the subclavian route but is faster and easier than a venous cutdown. Bedside ultrasound guidance offers the potential to allow safer catheterization of the internal jugular vein (see Chapter 69).

Femoral approach.

The cannulation of the femoral vein for central venous access has become increasingly popular, especially for venous access, infusion ports, and the passage of transvenous pacemakers and pressure measurement catheters in critically ill patients. [33] Some investigators recommend femoral vein cannulation for hypotensive trauma patients with an 8.5 Fr catheter connected to genitourinary irrigation tubing immediately after 2 peripheral catheters are established. [34] Other indications for urgent femoral cannulation include emergency cardiopulmonary bypass for resuscitation purposes, charcoal hemoperfusion for severe drug overdoses, and dialysis access.[35] Advantages of the femoral site over other central venous access sites are that the femoral area is less congested with monitoring and airway equipment than the head and neck area and that the conscious patient, who is still bedridden, may turn the head and use the arms without movement of the central line. The femoral site is contraindicated in the ambulatory patient who requires central access.

Other approaches.

When other methods of central venous catheterization are not possible, central venous access may be obtained via the external jugular (EJ) vein or basilic-cephalic vein.[36] [37] Although generally accessible for peripheral IV access, the valves and tortuousity of these veins often preclude or delay placement of standard central venous catheters. Successful cannulation of the central venous circulation is generally possible by these routes only with the use of guidewires. When time is available for a careful, deliberate attempt, these methods avoid the complications of pneumothorax, carotid or subclavian artery puncture, and hidden hemorrhage associated with other methods of central venous cannulation.

The EJ approach can be used in both children and adults, but success is more common in adults. [37] [38] The EJ vein must be visible to the eye or via ultrasound for percutaneous cannulation to be successful (see Fig. 21-2). This route is used primarily as a peripheral venous action site. Central venous catheterization by the EJ route is technically more difficult than IJ cannulation, but it is successful 70% to 100% of the time in adults. [39] While use of a straight guidewire has been described, the use of a J wire is more reliable and is the preferred method. [38] The J wire is more easily advanced

because its round tip deflects off vessel walls and navigates sharp angulations in the vessel course more easily.

When rapid access to the central venous circulation is not important, the basilic-cephalic route may be considered. This route has the lowest incidence of complications since the basilic and cephalic veins are located far away from vital organs and major arteries. When the patient is upright, the basilic vein is preferred over the cephalic vein because of a higher incidence of successful central catheter passage, although the overall success rate of SVC cannulation is similar for both techniques in the supine patient. [40] Nonetheless, both veins have valves, which may impede catheter advancement. [41]

CONTRAINDICATIONS

Contraindications to the various techniques of central venous access are shown in Table 22-2 . Most listed contraindications must be considered relative, with clinical use of these techniques based on clinical conditions and available options for vascular access. Each technique is contraindicated in patients with distorted local anatomy or landmarks. Skin lesions such as local cellulitis, burns, abrasions, or severe dermatitis are relative contraindications to any access routes. Other relative contraindications include those conditions predisposing to sclerosis or thrombosis of the central veins, such as vasculitis, prior long-term cannulation, or illicit IV drug use via any of the deep venous systems. Mumatz and colleagues reviewed the placement of central venous catheters in patients with disorders of hemostasis. They found that even in patients with low platelet counts (i.e., <50 × 10^9 /L), bleeding complications are uncommon and generally easily managed, in the absence of arterial puncture.[42] The incidence of bleeding complications (other than bleeding requiring digital pressure)

TABLE 22-2 -- Relative Contraindications to Specific Central Venous Access Routes *

General
Distorted local anatomy†
Extremes of weight
Vasculitis
Prior long-term venous cannulation
Prior injection of sclerosis agents

§May use standard (short) large-bore IV catheters.

in patients with abnormal hemostasis in their study was only 3%, and no benefit could be found from correcting an abnormal international normalized ratio (INR) or platelet count prior to the procedure. This conclusion challenges prior anecdotal recommendations that patients with a coagulopathy receive blood component therapy to correct a coagulopathy prior to percutaneous central venous catheterization.

Subclavian Approach

Patients in whom subclavian access is contraindicated include those who have undergone previous surgery or trauma involving the clavicle, the first rib, or the subclavian vessels; patients who have undergone previous radiation therapy to the clavicular area; patients with significant chest wall deformities; and those with marked cachexia or obesity. However, clinicians in burn centers routinely place central catheters through burned areas. Patients with unilateral deformities not associated with pneumothorax (e.g., fractured clavicle) should be catheterized on the opposite side.

Subclavian venipuncture is not contraindicated in patients who have penetrating thoracic wounds unless the injuries are suspected or known to involve the subclavian vessels or SVC. Generally, *the vein on the same side of the chest wound should be cannulated* to avoid the possibility of bilateral pneumothoraces. When subclavian vessel injury is suspected, cannulation should occur on the opposite side. [43] With penetrating wounds that may involve the SVC, neither subclavian vessel should be cannulated, and venous access below the diaphragm should be sought. Use of the subclavian approach in patients with coagulation disorders or in those receiving heparin therapy is contraindicated. A more visible and accessible site should be chosen (preferably percutaneous cannulation of a peripheral vein), because it is impossible to apply direct pressure to a bleeding subclavian vessel. The procedure should not be performed in combative patients because of the greater possibility of pneumothorax, vessel laceration, air embolism, and septic complications. Although subclavian venipuncture has been used successfully in children younger than 2 years of age,[44] it is not generally recommended for use in small children. [45]

Internal Jugular Approach

Cervical trauma with swelling or anatomic distortion at the intended site of IJ venipuncture is the most important contraindication to the IJ approach. Neck motion is limited when the IJ line is in place, and this limitation represents a relative contraindication in conscious patients. Although bleeding disorders are relative contraindications to central venous cannulation, the IJ approach is preferred over the subclavian route, as the IJ site is compressible. In the setting of severe bleeding diatheses, the femoral approach should be considered. Carotid arterial disease (obstruction or atherosclerotic plaques) is a relative contraindication to IJ cannulation, since inadvertent puncture or manipulation of the artery may dislodge a plaque. In addition, prolonged compression of the artery to control bleeding may impair cerebral circulation if collateral blood flow is compromised. If a preceding subclavian catheterization has been unsuccessful, the ipsilateral IJ route is generally preferred for a subsequent attempt. In this manner, bilateral iatrogenic complications are avoided.

External Jugular Approach

The greatest disadvantage of the EJ approach for central venous access is the time required to successfully pass a J wire and catheter into appropriate position. [46] However, the ease and relative safety of this approach make the EJ vein an excellent site of simple IV cannulation for fluid or drug administration, especially during an emergency when peripheral veins cannot be cannulated.

Femoral Vein Approach

Contraindications to femoral cannulation include known or suspected injury to the groin, iliac vessels, or IVC. Percutaneous femoral line placement is not recommended in a patient who is in cardiac arrest or has an absent femoral pulse, unless other alternatives have been exhausted. [47] In a

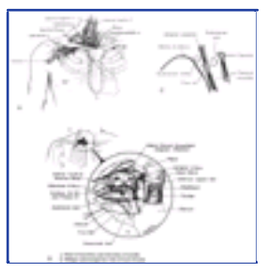

Figure 22-1 *A* and *B,* Subclavian vein and local anatomy. *C,* Subclavian area, sagittal section. *(A from Linos D, Mucha P, von Heerden J: The subclavian vein: A golden route. canine model of cardiac arrest, palpable pulsations in the groin were found to be venous rather than arterial in origin 50% of the time. [48]

ANATOMY

Subclavian System

The subclavian vein begins as a continuation of the axillary vein at the outer edge of the first rib (Fig. 22-1). It joins the IJ vein to become the innominate vein 3 to 4 cm proximally. The subclavian has a diameter of 10 to 20 mm and is valveless. After crossing the first rib, the vein lies posterior to the medial third of the clavicle. It is only in this area that there is an intimate association between the clavicle and the subclavian vein. The costoclavicular ligament lies anterior and inferior to

the subclavian vein, and the fascia contiguous to this ligament invests the vessel. Posterior to the vein, separating it from the subclavian artery, lies the anterior scalene muscle, which has a thickness of 10 to 15 mm. The phrenic nerve passes over the anterior surface of the scalene muscle and runs immediately behind the junction of the subclavian and IJ jugular veins. The thoracic duct (on the left) and the lymphatic duct (on the right) pass over the anterior scalene muscle and enter the subclavian vein near its junction with the IJ vein. Superior and posterior to the subclavian artery lies the brachial plexus. The dome of the left lung may extend above the first rib, but the right lung rarely extends this high.

Jugular System

The anatomy of the IJ vein is relatively constant, regardless of body habitus. The vein drains the cranium, beginning as the superior jugular bulb, which is separated from the floor of the middle ear by a delicate bony plate. The IJ vein emerges deep to the posterior belly of the digastric muscle. At its origin the IJ vein courses adjacent to the spinal accessory, vagus, and hypoglossal nerves, as well as the internal carotid artery. Several

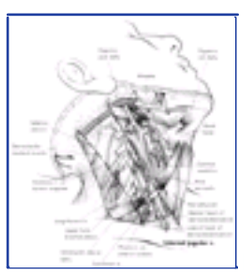

Figure 22-2 Structures in a dissection of the neck. The superficial veins and the sternocleidomastoid muscle have been removed, as have the submandibular gland and a segment of the facial vein. The cutaneous nerves have been cut down to short stumps arising from the second, third, and fourth cervical nerves. The internal jugular vein is drawn somewhat more medial in this illustration than is commonly found. *(From Hollinshead WH: Textbook of Anatomy, 3rd ed. New York, Harper & Row, 1974, p 765. Reproduced by permission.)*

tributary veins enter the IJ vein at the level of the hyoid bone. The IJ vein, the internal (and, later, the common) carotid artery, and the vagus nerve course together in the carotid sheath, with the IJ vein occupying the anterior lateral position. [49] The only structure that maintains a fixed anatomic relationship with the IJ vein is the carotid artery. The vein invariably lies lateral and slightly anterior to the carotid artery, and the course of the artery serves as a guide to venous cannulation. At the level of the thyroid cartilage, the IJ vein can be found just deep of the sternocleidomastoid muscle (Fig. 22-2).

The IJ vein emerges from under the apex of the triangle of the two heads of the sternocleidomastoid muscle and joins the subclavian vein behind the clavicle. As the vein approaches its supraclavicular junction with the subclavian vein, it assumes a more medial position in the triangle formed by the two heads of the sternocleidomastoid muscles, following the anterior border of the lateral head. In this lower cervical region, the common carotid artery assumes a deep paratracheal location. The brachial plexus is separated from the IJ vein by the scalenus anterior muscle. The phrenic nerve is anterior to the scalenus anterior muscle. Although quite deep, the stellate ganglion lies anterior to the lower brachial plexus.

Unlike the subclavian vein, the IJ vein is quite distensible. The vessel diameter is increased with performance of a Valsalva maneuver and the assumption of the head-down (Trendelenburg) tilt position. Prolonged palpation of the carotid pulse will decrease the diameter of the IJ vein. [49] Rotating the head 90 degrees toward the opposite side or extending the neck will not change the size of the IJ vessel significantly. Severe rotation of the head will bring the sterno-cleidomastoid muscle anterior or medial to the IJ vein and may make cannulation impossible without first traversing the carotid artery. The diameter of the IJ vessel is largest below the cricoid ring, where it may reach 2 to 2.5 cm.[49]

Femoral System

The femoral vein is most easily cannulated percutaneously in patients with a palpable femoral pulse. The femoral vein lies

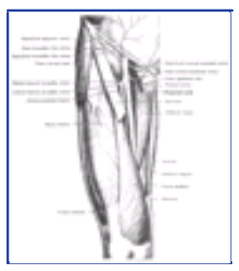

Figure 22-3 The right femoral vessels and some of their branches. The femoral nerve (not shown) lies lateral to the artery and may be deep to the artery. *(From Warwick R, Williams PL [eds]: Gray's Anatomy, 35th ed. Edinburgh, Churchill Livingstone, 1973, p 676. Reproduced by permission.)*

just medial to the artery in the femoral canal below the inguinal ligament. Beneath the femoral vessels lie the psoas muscle and the hip (Fig. 22-3). As the femoral vein progresses distally in the leg, it becomes closer, and almost posterior, to the femoral artery. When cannulating this vessel distally to the inguinal ligament, ultrasound guidance can be helpful to avoid arterial puncture.

Basilic and Cephalic System

Considerable variation is present in the venous vasculature of the upper extremities. Nonetheless, the cephalic and basilic veins can usually be located in the volar antecubital region (Fig. 22-4). The interconnecting median antecubital vein is often the most prominent, thus making it a popular site for venipuncture during blood sampling. The basilic vein merges proximally with the brachial vein to form the axillary vein,

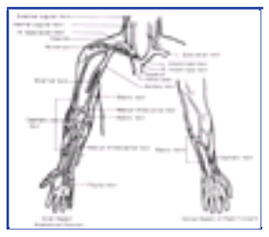

Figure 22-4 Major veins of the upper half of the body. *(From Hedges JR: Vascular access. Curr Top Emerg Med 2:1, 1981. Reproduced by permission.)*

which subsequently meets the cephalic vein to form the subclavian vein near the distal clavicle. The IJ and EJ veins join the subclavian vein to form the innominate vein bilaterally. Many venous valves exist in the peripheral vessels. Vascular anastomoses may permit aberrant advancement of a long line from the upper extremity. In particular, lines threaded up the cephalic vein may dead-end in a venous plexus or enter the EJ vein. Furthermore, lines passed through the basilic vein may easily enter the IJ vein.

TECHNIQUE AND EQUIPMENT

Some clinicians prefer to first locate the position of a central vein with a small exploratory or "finder" needle, rather than directly cannulating the vein with only the larger needle that will accommodate a guidewire or catheter. While this may be desirable in some circumstances, and can minimize trauma and complications of a larger needle, no specific standard exists. In clinical practice, this exploratory needle is seldom used in an emergency situation. The smaller introducing needles used with the Seldinger technique have largely supplanted the need for this exploratory procedure.

Seldinger and Other Techniques

The most commonly used means of central venous cannulation is the Seldinger (guidewire) technique, by which a thin-walled needle is used to introduce a guidewire into the vessel lumen. Seldinger originally described this in 1953 as a method for catheter placement in percutaneous arteriography. [50] To obtain vascular access, a small needle is used to enter the intended vessel. Once the introducing needle is positioned within the vessel lumen, a wire is threaded through the needle, and the needle is removed. The wire, now within the vessel, serves as a guide over which the selected catheter is placed. Although the Seldinger technique involves several steps, it may be performed quickly once mastered. More important, this technique broadens the application of central vein cannulation, permitting the insertion of standard infusion catheters,

TABLE 22-3 -- Materials for Central Venous Cannulation

1% lidocaine
26-ga needle
2-mL Luer-Lok syringe (for anesthetic)
10-mL non-Luer-Lok syringe (for catheter placement)
Swabs
Preparation solution
Gloves
Drapes
Catheter device
Intravenous tubing
Intravenous solution
Needle holder
4-0 silk (or nylon) sutures
Suture scissors
Antibiotic ointment
Gauze pads
Tincture of benzoin
Cloth tape

multi-lumen catheters, large-bore rapid infusion systems, introducer devices, and even peripheral cardiopulmonary bypass cannulae. Given this degree of flexibility, the use of Seldinger-type systems is advantageous, despite greater cost.

The basic materials required for central venous cannulation are listed in Table 22-3 . The catheter may be a component in a guidewire system, or of the over-the-needle variety (the other widely used method of catheter placement). To obtain central access from the basilic-cephalic system (and occasionally from the femoral vein), a through-the-needle catheter passage technique is used. This is detailed in a special section after discussion of these more commonly used approaches.

Needle

Virtually any needle or catheter can be used to introduce a guidewire into a vessel, but there are advantages to using needles specifically designed for passage of a guidewire. These needles must be large enough to accommodate the desired wire, yet as small as possible to minimize bleeding complications. The needles provided with central vein catheters or introducer devices are usually thin walled, thereby maximizing lumen size relative to overall needle diameter. If a needle that is not thin walled is used, a size that is 1 ga smaller (larger bore) than that listed in Table 22-4 should be used.

Standard needles may have a uniformly straight-bore lumen throughout their length. A wire passing into a straight needle may encounter an obstacle at the proximal end. The proximal end of a Seldinger needle incorporates a funnel-shaped taper that guides the wire directly into the needle (Fig. 22-5).

TABLE 22-4 -- Needle Sizes for Venous and Arterial Catheters*

Standard Full-Length Coil Guidewire Catheter Size (Fr)	Needle Gauge†
3	21-
4 to 4.5	20-
5 to 6.0	20- to 19-
6 to 8.5	19- to 18-

*Any sized catheter from 3.0 to 8.5 Fr may be introduced using a 22-ga needle if a solid wire (Cor-Flex, Cook Critical Care) is used.
†All needle gauges are for thin-walled needles only.

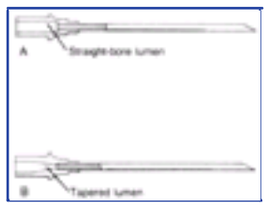

Figure 22-5 Introducing needles. *A,* Ordinary needle with a straight-bore lumen. *B,* Seldinger needle with a tapered lumen, allowing easy entry of the guidewire.

It is advisable to use a non-Luer-Lok or slip tip type, as the added twisting that is required to remove a Luer-Lok syringe from the introducer needle may dislodge a tenuously placed needle. Systems now exist that permit passage of the wire without removal of the aspirating syringe.

Guidewire

Two basic types of guidewires are used: straight or J-shaped. The straight wires are for use in vessels with a linear configuration, whereas the J wires are for use in tortuous vessels. Both wires have essentially the same internal design (Fig. 22-6*A*). The flexibility of the wire is a result of a stainless steel coil or helix that forms the bulk of the guidewire. Within the central lumen of the helix is a straight central core wire, called a mandrel, which adds rigidity to the steel coil. The mandrel is usually fixed at one end of the helix and terminates 0.5 and 3.0 cm from the other end, creating a flexible or floppy tip. Wires are also available with two flexible ends, one straight and the other J-shaped. The flexible end of the guidewire allows the wire to flex on contact with the wall of a vessel. If the contact is tangential, as in an infraclavicular approach to the subclavian vein, a straight wire is generally

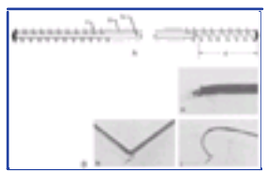

Figure 22-6 *A*, Guidewire internal structure: safety wire (a), core wire (mandrel) (b), coiled wire (c), flexible tip (d). *B*, Flexible end of a straight-spring guidewire knotted on a vessel dilator (a), bent junction of the rigid and flexible portions of a straight-spring guidewire with protrusion of the central core (arrow) (b), partially fractured tip (arrow) of a J-spring guidewire (c). *(From Schwartz AJ, Horrow JL, Jobes DR, Ellison N: Guide wires—A caution. Crit Care Med 9:348, 1981. ©1981 Williams & Wilkins, Baltimore. Reproduced by permission.)*

preferred. If the angle is more acute, as in an external jugular approach to the subclavian vein, or if the vessel is particularly tortuous or valves must be traversed, a J-shaped wire is used. The more rounded leading edge of the J wire provides a broader surface to manipulate within the vessel and decreases the risk of perforation. This is especially advantageous when attempting to thread a wire through a vessel with valves. Many guidewires also contain a straight safety wire that runs parallel to the mandrel to keep the wire from kinking or shearing.

The standard size for guidewires is from 0.025 to 0.035 in. (0.064 to 0.089 cm) in diameter, permitting introduction through an 18-ga thin-walled needle. A modification of this standard wire uses a bare mandrel with the flexible coil soldered to its end. This construction provides a wire with a diameter of only 0.018 in. (0.047 cm) but with the same rigidity as the larger wires. The manufacturer states that such a wire can be introduced through a 22-gauge thin-walled needle, yet still guide an 8.5 Fr catheter (Micropuncture Introducer Sets and Trays with Cor-Flex Wire Guides, Cook Critical Care Inc., Bloomington, IN).

It is important to emphasize that guidewires are delicate and may bend, kink, or unwind. A force of 4 to 6 lb may cause rupture of a wire. Wires should thread easily and smoothly and should never be forced. Embolization of portions of the guidewire is possible, and sharp defects in the wire may perforate vessel walls (Fig. 22-6*B*). Wires should be inspected for defects such as kinks, sharp ends, or spurs before use.

Catheters

A number of different catheter and introducer devices have been developed and the method of passage into the vessel varies accordingly. Single-, double-, and triple-lumen catheters generally are placed by sliding the catheter directly over the guidewire into the intended vessel. Larger catheters or nonlumen devices are generally introduced with a sheath-introducer system. Over-the-needle catheters are simply placed over the needle once intravascular placement is attained.

The Desilets-Hoffman type sheath introducer became available in 1965 to aid in arteriography procedures that required many catheter changes. [51] The sheath-introducer unit includes two catheters, an inner dilator and an outer sheath

Figure 22-7 Desilets-Hoffman sheath introducer. *A*, Guidewire. *B*, Sheath-introducer. *C*, Dilator. *D*, Assembled device.

(Fig. 22-7). The dilator is rigid with a narrow lumen to accommodate the guidewire. It is longer and thinner than its sheath and has a tapered end that dilates the SQ tissue and the vessel defect formed by the needle. The sheath (or introducer catheter when used as a cannula for introducing Swan-Ganz catheters, transvenous pacemakers, or other devices), has a blunt end and is simply a large diameter catheter.

Many modifications of the sheath exist, with side arms and diaphragms to aid in placement of nonlumen devices. Care must be taken in the use of side-arm sets for rapid fluid administration, because some catheters may be 8.5 Fr in diameter but may have only a 5 Fr side arm. This problem can be addressed by introducing a short segment of an 8 Fr feeding tube through the diaphragm at the catheter hub for rapid fluid administration.

Special catheters have been developed to prevent bacterial contamination and line sepsis. These catheters are impregnated either with antiseptics (silver sulfadiazine and chlorhexidine) or antibiotics (minocycline, rifampin, or cefazolin) to reduce bacterial colonization and microbe growth. Also, heparin-coated catheters are available that prevent fibronectin binding, thereby inhibiting the formation of bacterial biofilms on the catheter's surface. Whether these in vivo effects lead to decreased nosocomial infection rates and cases of line sepsis remains controversial. Few published studies demonstrate a statistically significant reduction in the infection rate when compared to traditional catheters.[52] [53] However, the overall risk of infection is generally low, thus small differences are difficult to detect. Two meta-analyses independently found that the use of antimicrobial and heparin bonded catheters reduced the risk of infection from about 5% to 3%. [52] [53] An impregnated catheter costs $25 to $40 more than a comparable standard device. This compares favorably to the estimated $6000 to $10,000 in additional medical costs associated with a case of line sepsis. Additionally, a catheter-related bloodstream infection may increase mortality by 15% to 35%. Convincing data do not exist to recommend one catheter type over another, though the silver sulfadiazine- and chlorhexidine-impregnated catheters are the most widely used and offer only modest additional expense. It is important to ensure that no known hypersensitivity to the impregnating-agent exists before insertion of these catheters.

Guidewire Placement

An introducing needle large enough to accommodate the guidewire is attached to a small syringe (Fig. 22-8). The needle and syringe are introduced together, and the selected vessel is entered with the needle tip (technique for specific veins and approaches is detailed later). Once a free return of blood is obtained, the syringe is removed, and the needle hub is stabilized to prevent needle movement and displacement of the tip from the vessel. At times detachment of the syringe from the thin-walled needle may lead to loss of the needle's intravascular position. The need to detach the syringe can be eliminated by use of the Arrow Safety Syringe. This device incorporates a hollow syringe through which the guidewire can be passed directly into the thin-walled needle without detachment. This also reduces the risk of air embolism, which can occur when the needle is open to the air. If the needle is removed from the syringe, the needle hub is capped with a thumb before passing the guidewire to minimize the potential for air embolism.

Next, the flexible end of the guidewire is threaded through the needle. The straight wire is easily introduced by threading its flexible end into the hub of the needle. Introduction of the J wire is accomplished by advancing a plastic sleeve contained in the kit to the floppy end of the wire, straightening out the J shape. This

straightened end is then introduced into the needle hub. Once the J wire has been advanced, the sleeve is removed and set aside (Fig. 22-9). It is important not to accidentally discard this sleeve as it will make insertion of the J wire very difficult.

The wire should thread smoothly into the vein without resistance. The wire should not be forced if resistance is met, but it should be removed from the needle and the syringe reattached to confirm intravascular placement. It is extremely important for the wire to slip easily from the needle during removal. If any resistance to removal of the wire is felt, the wire and the needle should be removed as a single unit to prevent shearing of the wire and resultant wire embolism. It has been recommended by some that no wire should ever be withdrawn through the introducing needle. [54] While there are no data to support this recommendation and newer wires are stronger and more resistant to shearing, it represents the

Figure 22-8 Procedure for placement of Seldinger-type guidewire catheter. *A*, The selected vessel is cannulated with a thin-walled needle, or an existing IV catheter is chosen to be changed with the wire technique. *B*, The guidewire is threaded through the vessel, with the flexible end first, into the lumen of the vessel. If a J wire is used, a sleeve will facilitate entry into the needle (see Fig. 22-9). *C*, The needle is removed so that only the wire now exits from the vessel. *D*, The skin entry site is enlarged with a No. 11 scalpel. *E*, The catheter sheath and the dilator are threaded over the wire and advanced to the skin. The wire must be visible through the back of the device. *F*, If the proximal wire is not visible, it is pulled from the skin through the catheter until it appears at the back of the catheter. *G*, The sheath and the dilator are advanced as a unit into the skin with a twisting motion. It is best to grasp the unit at the junction of sheath and dilator to prevent bunching up of the sheath. The wire (at the back of the catheter) must be held while the sheath and dilator are advanced as a unit. *H*, Once the sheath and the dilator are well within the vessel, the guidewire and the dilator are removed. Contrary to the illustration, latex gloves should be worn.

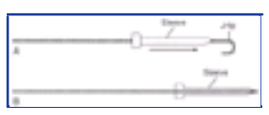

Figure 22-9 J wire. *A*, Plastic sleeve in retracted position, demonstrating the J tip. *B*, Plastic sleeve is advanced to straighten the curve to allow easy introduction into the needle hub. In an emergency, care must be taken to not misplace or throw away the sleeve. Without it, placing the J wire into the hub of the needle is very difficult.

safest course of action (Fig. 22-10). The recommendation to remove the needle and the wire as a unit is sometimes disregarded because of reluctance to abandon a potentially successful venipuncture. The clinician performing the procedure must use both caution and good judgment to determine the best course of action, but should not withdraw the guidewire against resistance. Manipulation of the wire within an introducer needle should be done only with standard coil guidewires. Solid wires (such as Cor-Flex Wire Guides from Cook Critical Care) have a small lip at the point the flexible coil is soldered to the wire. This lip can become caught on the edge of the needle tip, shearing off the coil portion of the wire. Solid wires must thread freely on the first attempt or the entire wire and needle assembly must be removed.

Occasionally, a wire must be teased into the vessel; rotating the wire or needle often helps in difficult placements. If the wire does not thread easily, another helpful maneuver is to pull back slightly on the needle itself just before advancing the wire. This helps if the opening of the needle is abutting the vessel's inner wall, blocking the wire's entry, or if the vein is compressed by introduction of the needle. Changing wire tips from a straight to a J wire or vice versa also may solve an advancement problem. If the inner lumen of a vessel is smaller than the diameter of the J, it will prevent the wire from reforming its natural shape, causing the spring in the coil to generate resistance. Any advantages of a J wire will be negated if the wire fails to regain its intended shape. In this instance, a straight tip should be introducible without problem. Alternatively, if the angle of entry of the needle and the vessel is more acute than was suspected, the straight wire may not be able to bend appropriately as it encounters the vessel's far wall. A J-tipped wire may be used and threaded in such a manner that the wire resumes its J shape away from the far wall. All of these maneuvers are performed with gentle free motions of the wire within the needle. If at any time the wire cannot be advanced freely, improper placement must be suspected and the attempt reevaluated.

If it is threading easily, the guidewire should be advanced until at least one quarter of the wire is within the vessel. The further into the vessel the wire extends, the more stable its location when the catheter is introduced. However, advancing the guidewire too far may result in ventricular ectopy secondary to endocardial irritation, myocardial puncture leading to tamponade, or entanglement in a previously placed pacemaker, internal defibrillator, or IVC filter. In both left and right IJ and IC approaches, fluoroscopic study during guidewire passage has determined the mean distance from

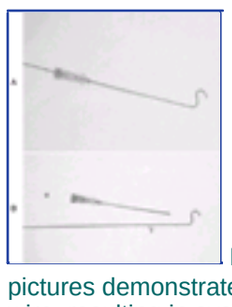

Figure 22-10 Although newer guidewires are more resistant to shearing, if a guidewire will not advance, it is best to withdraw both the needle and wire in one motion. These pictures demonstrate a permanently deformed guidewire that could not be advanced. Withdrawing the wire with the indwelling introducer needle in place within a vessel may shear off a portion of the wire, resulting in systemic embolization.

skin to SVC-atrial junction to be 18 cm. [55] This distance has been recommended as the greatest depth of guidewire insertion for these approaches. (It should be noted that 18 cm is not necessarily the appropriate final depth for the catheter being placed—see later discussion).

Cardiac monitoring is recommended for all central line insertions. Any increase in premature ventricular contractions or new ventricular dysrhythmia should be interpreted as evidence the guidewire is inserted too far, and should be remedied by withdrawing the wire until the rhythm reverts to baseline. Usually after a moment the procedure can be continued, with care taken not to re-advance the wire. Persistent ventricular dysrhythmias require standard Advanced Cardiac Life Support (ACLS) treatment and consideration of a new vascular approach.

Occasionally a wire threads easily past the tip of the needle and then suddenly will not advance farther. If the introducer needle demonstrated free blood return at the time of wire entry and the initial advancement of the wire met no resistance, the wire is most likely located properly in the vessel and can serve as a guide for the catheter. If further confirmation is needed, the needle may be removed, the wire fixed in place with a sterile hemostat, and a radiograph taken to confirm the position of the wire. [56] This confirmation may be advisable if the location of a wire is suspect and the introduction of a large-sized sheath is planned. A freely advancing wire may suddenly stop once it is well within a vessel if the vessel makes an

unsuspected bend or is being compressed or deviated by another structure, such as a rib or muscle.

Sheath Unit and Catheter Placement

Once the wire is placed into the vessel, the needle is removed in preparation for passage of the catheter (see Fig. 22-8). A small skin incision is then made at the site

of the wire. The incision should be approximately the width of the catheter to be introduced and should extend completely through the dermis. The guidewire is stabilized at the point of the skin incision and the dilator/sheath assembly is threaded over the wire to a point 1 cm from the surface of the skin. Once the dilator/sheath is advanced over the wire and before it enters the skin, the wire must protrude from the proximal end of the dilator. It is essential that the wire be grasped as the dilator/sheath is advanced to avoid farther advancement into the circulation and potential loss of the wire. If the wire is not protruding from the proximal end of the dilator, the wire should be withdrawn at the skin entry point until it protrudes a sufficient amount to be grasped. The wire must always be visible protruding from the end of the dilator at all times during dilator advancement.

The dilator/sheath assembly is threaded into the skin with a twisting motion until it is well within the vessel. When using a sheath/dilator, it is best to grasp the unit at the junction of the sheath and dilator. This prevents the thinner sheath from kinking or bending at the tip or from bunching up at the coupler end. If a rigid-walled sheath is used, the dilator need only be advanced a few centimeters into the vessel and the sheath slid off and advanced to its hub. If a thin-walled sheath is used, the introducer-sheath unit is kept intact and advanced through the skin to the hub. This adds rigidity to the sheath and prevents it from kinking before being fully seated in the vessel. When placing right-sided subclavian catheters, it is sometimes helpful to make a banana-like bend in the dilator before introduction to facilitate proper location in the SVC. [57] After the sheath is in place, the wire and dilator are removed together. The sheath hub must be covered at this point and until attachment of the infusion tubing or cap to avoid air embolism.

If a single-lumen catheter is used instead of a sheath/dilator, the catheter itself is passed over the wire to its desired depth and the wire is removed. When a soft catheter is used, a tract from the skin to the vessel must be created before the catheter can be introduced. This is accomplished by passing and then withdrawing a separate dilator over the guidewire, after the needle is removed but before the catheter is placed. After the dilator is removed the soft catheter is threaded into the position over the wire. Occasionally, it is easier to advance the soft catheter over the wire up to the skin edge and then to advance the catheter and wire together as a unit into the vessel. It is imperative that the guidewire protrudes from the catheter hub and be firmly grasped as the wire and catheter are advanced. Once the catheter is placed, the wire is gently removed with care taken to maintain the desired catheter insertion length. When removing the wire from a catheter it must slip out easily. If any resistance is met, both the wire and catheter must be removed as a single unit and the procedure reattempted. A common cause of a "stuck wire" is a small piece of adipose tissue wedged between the wire and the lumen of the catheter. This problem can be avoided by creating a deep enough skin nick and adequate dilation of the tract before insertion of the catheter.

Placement of multiple lumen catheters requires identification of the distal lumen and its corresponding hub. The distal lumen is found at the very tip of the catheter. The corresponding hub is usually labeled "distal" by the manufacturer. If there is any confusion, a small amount of sterile saline can be injected through each hub until it is observed exiting the distal lumen. Once the distal hub is identified, its cover cap is removed to allow passage of the guidewire (remember to replace this or immediately begin infusing saline upon completion of placement). The catheter is placed by threading the guidewire into the distal lumen and advancing it until it protrudes from the hub. At this point the device is placed in the same manner as a single-lumen catheter. If a soft multiple-lumen device is placed, a separate dilator is used to create a tract over the guidewire prior to placing the catheter. An alternate method of placing multiple-lumen catheters is to thread the catheter through a standard Desilets-Hoffman sheath introducer system. Any lumen in a multiple-lumen device that is not immediately used for an infusion must be flushed with a heparin solution. Saline solutions alone should not be used as flushes for central catheters.

The depth of catheter insertion is an important consideration. The SVC begins at the level of the manubriosternal junction and terminates in the right atrium, approximately 5 cm lower. For lines placed in the subclavian, jugular, basilic, and cephalic systems, the proper position of the catheter is in the SVC, not the right atrium or ventricle. Therefore, the catheter should be threaded approximately 2 cm below the manubriosternal junction. Many commonly used catheters are long enough to reach the atrium or ventricle. For example, the standard catheters marketed for subclavian venipuncture are often 20 to 30 cm long. Twenty cm from the skin insertion site is more than sufficient to reach the SVC for a subclavian catheter placed in the average adult male. Catheters 15 to 16 cm in length are recommended to avoid unintended placement to an excessive depth. The proper distance to advance the catheter can be estimated by placing the catheter parallel to the chest wall before insertion. Alternatively, formulas have been developed to determine optimal insertion length based on patient's height. One set (Table 22-5) was found to yield accurate placement in the SVC on 95% of 228 attempts. [58] Proper placement should always be confirmed by a postprocedure chest radiograph.

Many different catheters are currently manufactured. Although this leads to great flexibility in choice and cost, it often leads to confusion when a clinician is handed an unfamiliar catheter during an emergency. It is best to use one

TABLE 22-5 -- Formulas for Catheter Insertion Length Based on Patient Height (in cm) and Approach

Site	Formula	In SVC, %	In RA, %
RSC	(Hgt/10)-2 cm	96	4
LSC	(Hgt/10) +2 cm	97	2
RIJ	Hgt/10	90	10
LIJ	(Hgt/10) + 4 cm	94	5

Hgt = Patient height

SVC = Superior Vena Cava

RA = Right Atrium

RSC = Right Subclavian

LSC = Left Subclavian

brand routinely and to ensure that all medical personnel are thoroughly schooled in its use.

Replacement of Existing Catheters

In addition to placing new catheters, the guidewire technique can be used to change existing devices. Central veins are often cannulated in seriously ill patients who will require subsequent pulmonary artery wedge pressure monitoring, transvenous pacemaker placement, or placement of a different catheter. Any CVP catheter that is initially inserted should have a lumen large enough to accept a guidewire, facilitating conversion to a different catheter. The guidewire technique can also be used to change single-lumen central venous catheters to triple-lumen or sheath-introducer sets. Not all commercially available CVP catheters will accept a guidewire.

Replacement of an existing catheter begins with selection of a guidewire longer than either of the devices to be exchanged. Using sterile technique, the guidewire is inserted into the existing central venous catheter until a few centimeters are protruding and from the proximal end. With one hand holding the wire securely, the catheter and wire are removed as a single unit until the tip of the catheter just clears the patient's skin. The wire is grasped at the point at which it exits the skin, and only then is the other end of the wire released. The catheter is then slid off the wire, and the new device is inserted in the normal fashion. Caution must be exercised with this technique because catheter embolization can occur if a catheter is cut to allow use of a shorter guidewire for the exchange. [54] In patients without evidence of sepsis, the technique of guidewire exchange does not increase the incidence of catheter-related infections. However, in septic patients this maneuver does appear to increase infections related to central catheters. [59]

Over-the-Needle Technique

An optional method for cannulation uses percutaneous placement of an over-the-needle catheter. Over-the-needle devices (such as the Angiocath) use a tapered plastic catheter that passes through the vessel wall into the lumen using the needle tip as a guide. There are advantages to this system. The catheter does not pass

through a sharp needle, and the risk of shearing with resultant catheter embolization is thus decreased. Also, the hole made by the needle in the vessel wall is smaller than the catheter, producing a tighter seal. The internal jugular and subclavian vein via the SC approach are the most popular and appropriate targets for this approach. These devices are used primarily when rapid central venous access is required (e.g., during a cardiac arrest). The catheters are not suitable for high-volume fluid resuscitation, and they are too small for passage of a pacemaker lead. Once the clinical situation stabilizes, they may be exchanged for a larger central catheter via the Seldinger technique.

Insertion is straightforward, and should be preceded by quickly sterilizing the patient's skin (see later in this section). Longer peripheral-type catheters (such as a 16-ga 5 ¼-in. Angiocath) are required in adults. Smaller diameter devices, such as 20-ga catheters, may be easier to pass but also provide lower infusion rates. The needle is attached to a syringe, and very slowly advanced into the vein with steady negative pressure applied to the syringe. This may be difficult due to the longer length of the needle relative to the catheter. With over-the-needle catheters, the needle extends a few millimeters past the tip of the catheter. Blood return will be obtained when the tip of the needle is in the vein, while the catheter may actually be outside the lumen. If the needle is withdrawn before the catheter is advanced, the catheter tip will remain outside the vein. So, after the venous flash, the needle should be advanced a few millimeters and then held steady while the catheter is easily advanced into the vein. The catheter should then be secured and placement verified as detailed later in this chapter.

SPECIFIC VESSEL ACCESS TECHNIQUES

Strict adherence to the principles of sterile technique, including antiseptic skin preparation, sterile gloves and sterile procedural fields, is believed to reduce septic complications. Violation of these principles for the sake of speed is seldom justified. The few extra seconds required to put on gloves and to swab and drape the field will rarely make a critical difference in patient survival outside of the cardiac-arrest resuscitation scenario. It is recognized that the ideal practice of aseptic technique often cannot take place during resuscitation scenarios. For this reason, all central lines placed in an unsterile setting should be replaced at the earliest possible opportunity.

The area of the needle puncture should be widely prepared with povidone-iodine solution. In iodine-allergic patients, pHisoHex or Hibiclens are acceptable alternatives. If subclavian or IJ approaches are planned, the prepared area should include puncture sites for the IC and SC subclavian and IJ approaches. This permits the clinician to change the site following an unsuccessful attempt without repeating the preparation. In this circumstance, a standard preparation should include the ipsilateral anterior neck, the supraclavicular fossa, and the anterior chest 3 to 5 cm past the midline and the same distance above the nipple line. Preparation for femoral access includes shaving the groin or trimming groin hairs (preferred) as needed, followed by application of povidone-iodine solution to cover an area the breadth of, and extending 10 cm above and below, the inguinal ligament.

A significant decrease in the rate of catheter contamination has been observed by inserting the catheter through a previously placed iodophor-impregnated sterile film after the usual sterile preparation and draping. [60] However, there is little evidence that aggressive aseptic techniques offer additional benefit. In one prospective trial, 137 patients received standard antiseptic skin preparation and were then randomized to one of two groups. Clinicians in the aseptic group prepared as for surgery, with a 5-minute scrub and full gown, hat, mask, and gloves, whereas the "nonsterile" clinicians did not necessarily even wash their hands or use sterile gloves. No difference in rate of contamination was seen, and the contaminating organism in 87.1% of the overall cases was *Staphylococcus epidermidis*.[61] The need to perform an operating suite-style preparation in patients receiving hyperalimentation is also unproved. In a study of 63 patients with long-term subclavian catheterization for hyperalimentation, a simple iodophor spray preparation was associated with only 1 infection. [25]

Each approach to central venous cannulation is described separately in the following section. It is assumed that proper sterile procedure and any needed local anesthesia will be

provided. As in any invasive task, the procedure should be described briefly to awake patients, and each step should be restated as it is about to be performed. After the following descriptions of the common approaches to the central veins, puncture site care, placement verification, and other adjuncts to the procedure will be summarized.

Subclavian Vein, Infraclavicular Approach

Descriptions of subclavian venipuncture often unduly focus on angles and landmarks and overstate the effects of patient positioning. The most important factors governing success or failure are knowledge of anatomy and meticulous attention to the details of the procedure. [62]

Positioning.

The patient is placed in the supine position with the head in a neutral position and the arm abducted. Placing the patient in the Trendelenburg position (10 to 15 degrees) decreases the risk of air embolism. The claim that this position distends the vein is controversial. [63] Venographic studies show no change in the diameter of the subclavian vein associated with the Trendelenburg position, although these observations were limited to normovolemic patients. [64] Further, the vessel is hemmed by the semirigid costoclavicular ligament on its anteroinferior aspect and therefore will not distend in a direction that facilitates IC venipuncture. [12] Magnetic resonance imaging clearly demonstrates that the caliber of the subclavian vein is determined by its attachment to adjacent structures and is not affected by the CVP, although another study did detect mild dilation of the subclavian vein on B-mode ultrasound of normal subjects during Trendelenburg positioning. [65] [66]

Abduction of the arm has been recommended to flatten the deltoid bulge.[67] This is sometimes a helpful maneuver in muscular individuals but is not generally necessary. Abduction moves medially the point at which the subclavian vein passes beneath the clavicle. [64] Turning the head to the opposite side has no effect on the vessel size or on the relative positions of the vessel and the clavicle. [64] [68] This maneuver does change the relative positions of the subclavian and IJ vein and has been postulated to cause an increased incidence of catheter malposition in the jugular vein. [65] Placing a pillow under the back is commonly recommended to make the clavicle more prominent, but as the shoulder falls backward, the space between the clavicle and first rib narrows, making the subclavian vein less accessible. [65] Significant compression of the subclavian vessels between these bony structures occurs as the shoulders retract. [65] Based on the findings of seven cadaver dissections, Tan and colleagues recommend that the shoulders be in a neutral position with mild shoulder retraction. [69] The clinical case series of Boyd et al. also suggest that a small "bump" between the shoulder blades may enhance IC subclavian cannulation. [70]

Venipuncture site.

The right subclavian vein is usually cannulated because of the lower pleural dome on the right and because of the need to avoid the left-sided thoracic duct. The anatomically more direct route between the left subclavian vein and the SVC is a theoretic advantage of left-sided over right-sided subclavian venipuncture. However, it has not been proved that there is a higher incidence of catheter malposition when the right IC approach is used.

In the conscious patient, the point of needle entry is anesthetized with 1% lidocaine. SQ infiltration of the periosteum of the clavicle will make the procedure less painful but is not always necessary. Opinions vary as to the best point of needle entry. The junction of the middle and medial thirds of the clavicle is the standard site. There the vein lies just posterior to the clavicle and just above the first rib, which acts as a barrier to penetration of the pleura. This protective effect is lost when a more lateral location is chosen. Approaches include entry just laterally and inferiorly to the junction of the clavicle and the first rib, with the needle aiming at this junction, and entry at the site of a small tubercle in the medial aspect of the deltopectoral groove. [71] [72] In our opinion, the point of entry is less important than the direction taken by the needle after entry. Points lateral to the mid-clavicle should be avoided, because this location requires a deeper puncture and potentially increases the risk of pneumothorax.

Needle orientation.

The *needle bevel should be oriented inferomedially* for the IC approach to direct the catheter toward the innominate vein rather than toward the opposite vessel wall or up the IJ vein (Fig. 22-11). Alignment of the needle bevel with markings on the barrel of the syringe permits awareness of bevel orientation after skin puncture. Some investigators advise puncturing the skin with a No. 11 scalpel blade to avoid skin plugs in the needle. Others suggest filling the syringe with 2 to 3 mL of 1% plain lidocaine to both anesthetize the SQ tissue and flush the needle.

Before insertion of the needle, the left index finger is placed in the suprasternal notch and the thumb is positioned at the costoclavicular junction (Fig. 22-12). These serve as reference points for the direction of needle travel. The needle is aimed immediately above and posteriorly to the index finger. Vessel entry, signaled by a flashback of dark venous blood, usually occurs at a depth of 3 to 4 cm. If the needle tip is truly intraluminal, there will be free flow of blood. The return of pulsatile flow signifies arterial puncture. A single arterial puncture without laceration rarely causes serious harm. Use of this technique eliminates the need to measure angles, to "walk" the clavicle, or to concentrate excessively on maintaining the needle parallel to the chest wall. All of these techniques are based on fear of complications rather than knowledge of anatomy.[68] One should avoid any sweeping motions of the needle tip to prevent unseen injuries. In patients who are being ventilated with positive pressure, it is advisable to halt ventilation for a moment as the needle penetrates the chest wall. Interruptions should be kept to a minimum and should not exceed the

30-second standard.[73]

Unsuccessful attempts.

Cannulation of the subclavian vein may not be successful on the first attempt. It is reasonable to try again, but after three or four unsuccessful attempts, it is best to try another approach or allow a colleague to attempt the procedure. One must use a new setup each time blood is obtained, because clots and tissue will clog the needle and mislead the clinician even if subsequent procedures are performed correctly. If several attempts are made, the admitting clinician or anesthesiologist must be informed so that proper precautions are taken to identify subsequent complications. It is advisable to obtain radiographs of the chest even after unsuccessful attempts. If the initial puncture site was properly placed, then for aesthetic reasons, one should use the same needle hole for subsequent attempts (i.e., one should avoid an embarrassing pincushion appearance of the upper chest). If the subclavian route is unsuccessful on one side, it is best to attempt an IJ catheterization on the same side rather than attempt a subclavian cannulation on the opposite side. In this manner, bilateral complications are avoided.

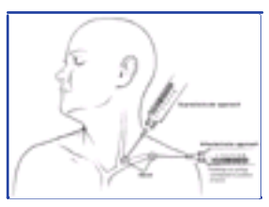

Figure 22-11 Needle bevel orientation using supraclavicular and infraclavicular venipuncture. The orientation of the needle bevel may help in positioning the catheter properly by guiding the direction of the catheter during advancement. If the bevel is aligned with the markings on the syringe, the orientation of the bevel is always certain.

Subclavian Vein, Supraclavicular Approach

Positioning.

The goal of the SC technique is to puncture the subclavian vein in its superior aspect just as it joins the IJ vein. The needle is inserted above and behind the clavicle, lateral to the sternocleidomastoid muscle. It advances in an avascular plane, away from the subclavian artery and the dome of the pleura. The right side is preferred because of the lower pleural dome, because it is the direct route to the SVC, and because the thoracic duct is on the left side. The Trendelenburg position may be helpful for distending the vein, because the

Figure 22-12 Hand position during subclavian venipuncture. Note that surgical gloves should be worn during this procedure, in contrast to the illustration. *(From Linos D, Mucha P, von Heerden J: Subclavian vein: A golden route. Mayo Clin Proc 55:318, 1980. Reproduced by permission.)*

subclavian vein is not bound by fasciae on its superior aspect. [28] The patient's head may be turned to the opposite side to help identify the landmarks. However, Jung and colleagues found that tilting the head toward the catheterization site during catheter passage reduced catheter malposition in children. [74]

Needle orientation.

After the area of the supraclavicular fossa has been prepared and draped, a point is identified 1 cm lateral to the clavicular head of the sternocleidomastoid and 1 cm posterior to the clavicle (Fig. 22-13). Alternatively, the junction of the middle and medial thirds of the clavicle has been used as the landmark for needle entry with good success in a cadaveric study.[75] In either case, the area is anesthetized with 1% lidocaine. If a 3-cm-long needle is used for anesthesia, it may also be used to locate the vessel in a relatively atraumatic manner. The subclavian vein can almost always be located with this needle because of the vein's superficial location and the absence of bony structures in the path of the needle. A 14-ga needle (or 18-ga thin-walled needle) is then advanced, following the path of the scout needle; gentle negative pressure is applied using an attached syringe.

When seeking the subclavian vein, the needle is aimed so as to bisect the clavicosternomastoid angle, with the tip pointing just caudal to the contralateral nipple. The *bevel is oriented medially* to prevent catheter trapping against the inferior vessel wall. The tip of the needle is pointed 10 degrees above the horizontal. Successful vessel puncture generally occurs at a depth of 2 to 3 cm.

Internal Jugular Approach

Positioning.

In preparation for all 3 IJ approaches, the patient is tilted 15 to 30 degrees in the Trendelenburg position and the head is turned slightly away from the side of venipuncture. The IJ vein is distensible, and tilting the patient increases the diameter of the vessel. If the patient is awake, he or she should be instructed to perform a Valsalva maneuver during

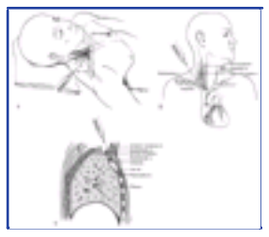

Figure 22-13 *A* and *B*, For the supraclavicular approach, the needle is inserted above and behind the clavicle, bisecting the angle made by the clavicle and the lateral border of the sternocleidomastoid muscle (clavisternomastoid angle). The point of entry is 1 cm lateral to the clavicular head of the muscle and 1 cm posterior to the clavicle. The needle traverses an avascular plane, puncturing the junction of the subclavian and internal jugular vein behind the sternoclavicular joint. The right side is preferred because of a direct route to the superior vena cava and the absence of the thoracic duct. The needle is directed 45° from the sagittal plane and 10° to 15° upward from the horizontal plane, aiming toward the contralateral nipple. Note that the vein is just posterior to the clavicle at this juncture. *C*, Sagittal view of the supraclavicular area. As the subclavian vein passes over (and somewhat anterior to) the first rib, it is separated from the subclavian artery by the anterior scalene muscle. The dome of the pleura is posterolateral to the confluence of the great veins.

vessel cannulation. In the unconscious patient, abdominal compression by an assistant can be used to help distend the vein.

Venipuncture site.

Familiarity with the anatomy of the neck is important to increase the probability of successful cannulation and to minimize complications. Most authors favor cannulation of the right side of the neck, which provides a more direct route to the SVC and avoids the thoracic duct. Although it is probably clinically insignificant, the cupola of the pleura is also slightly lower on the right side. The left IJ approach is more circuitous and, when used with a stiff Teflon catheter, may result in a major

venous puncture leading to hydrothorax, hydromediastinum, or even pericardial tamponade. [76] [77] [78] [79]

Central route.

This approach is favored by some, who believe that the incidence of cannulation of the carotid artery is decreased and the cupola of the lung is avoided with this method.[80] The triangle formed by the clavicle and the sternal and clavicular heads of the sternocleidomastoid is first palpated and identified. A local anesthetic skin wheal or a marking pen can mark the lateral border of the carotid pulse, and all subsequent needle punctures can be performed laterally to that point.

Some practitioners prefer to attempt cannulation with the catheter apparatus initially. Others use a small-gauge "locator" or scout needle to identify the vein. The smaller needle allows

one to ascertain the location of the vein and minimizes injury to deep structures by an incorrectly placed larger needle. Use of a locator needle can be time consuming in a cardiac arrest situation.

When using the scout needle technique, a 22-ga, 3-cm needle attached to a 5- to 10-mL syringe is introduced near the apex of the triangle and is directed caudally at an angle 30° to 40° to the skin. The needle should initially be directed parallel and slightly laterally to the course of the carotid artery (Fig. 22-14). If three fingers are lightly placed over the course of the carotid artery, the parallel course of the IJ vein can be estimated. The vein consistently lies just lateral to the carotid artery. Prolonged deep palpation of the carotid artery may decrease the size of the vein, and the three-finger technique should be used only long enough to identify the course of the artery.

Negative pressure should be maintained on the syringe at all times as the needle is advanced or retracted. The vein is more superficial than might be expected, and deep probing with the needle should be avoided; the vein is usually encountered at a depth of 1.0 to 1.5 cm. If the IJ vein is not entered at a depth of 3 to 5 cm, the needle should be withdrawn to just below the skin surface and directed toward the ipsilateral

Figure 22-14 Internal jugular vein approaches. *A*, Central approach. *B*, Posterior approach. *C*, Anterior approach. Note that contrary to the photographs, gloves should be worn during the procedure.

nipple underneath the medial border of the lateral (clavicular) head of the sternocleidomastoid. *During any type of central venous cannulation, a needle should always be withdrawn to the surface before being redirected to avoid lacerating or otherwise damaging important nerves, vessels, or other structures.*

The vein should be entered at 1 to 3 cm, and dark blood should be easily aspirated (bright red blood indicates carotid artery penetration and the need for needle repositioning). After locating the IJ vein, the locator needle is withdrawn and replaced with a 14-ga, 5-cm needle attached to a syringe. A drop of blood from the locator needle can be placed at the edge of the sterile field in line with the point of vessel entry, thus serving as a guide to recannulation. The larger needle is advanced through the skin along the path determined by the smaller needle until blood is aspirated. Care must be taken to cover the needle hub with a gloved thumb whenever the needle lumen is exposed to air. This practice will prevent an air embolus when the patient inspires.

The central approach has been used in children with good success [37] [81] (see Chapter 19). However, success is greater with larger infants (>10 kg) and those with higher CVPs (>10 cm H_2O). With infants and children, needle puncture

occurs at the apex of the triangle bordered by the two heads of the sternocleidomastoid muscle and the clavicle. Similar to the approach for adults, one passes a 22-ga needle attached to a 2- to 5-mL non-Luer-Lok syringe into the skin at a 45-degree angle and directs it caudally and laterally toward the ipsilateral nipple. The vessel is usually entered at a depth of 1 to 2 cm. The locator needle is then withdrawn, and a 17- to 19-ga needle is inserted into the skin until the IJ vein is penetrated.

Posterior and anterior routes.

For the *posterior approach*, the skin is entered at the lateral edge of the sternocleidomastoid muscle one third of the way from the clavicle to the mastoid process (see Fig. 22-14). The locator needle is directed caudally and medially toward the sternal notch until blood is aspirated.

To perform the *anterior approach,* the course of the carotid is identified and marked by the index and middle fingers (see Fig. 22-14).[82] The small needle should then enter the skin at the midpoint of the medial aspect of the sternocleidomastoid muscle. The needle is directed at an angle of 30 to 45 degrees to the coronal plane caudally toward the ipsilateral nipple. The proximity of the carotid artery in the anterior approach may prohibit venous cannulation without carotid puncture. [49] Doppler ultrasound can facilitate difficult IJ cannulation, a matter discussed in more detail later and in Chapter 69 .[83]

External Jugular Vein Approach

Positioning.

With the patient in the Trendelenburg position, the EJ vein is distended by instructing the patient to perform a Valsalva maneuver and then tamponading the vein just cephalad to the clavicle with a finger.

Venipuncture.

The vein is approached from the side while slight traction is placed on the vein to stabilize it. The needle is advanced at a small angle from the skin plane (about 10 degrees) until the operator feels it "pop" into the lumen of the vein. The needle or catheter should be advanced slightly after feeling the pop to ensure intraluminal placement. As discussed later, use of the EJ vein as a site for central vein access requires the use of a guidewire.

Femoral Vein Approach

Positioning and needle orientation.

The patient must be supine. The femoral pulse is identified and the scout needle (at least 4.4 cm length) is inserted at 45 degrees to the skin in a cephalic direction just medial to the femoral pulsation. Because CPR can produce *venous pulsations,* unsuccessful venous aspiration medial to the pulsations should be followed by an attempt directly over the pulsations.

Venipuncture.

During needle advancement, negative pressure is maintained within the syringe at all times while the needle is under the skin. The needle is directed posteriorly and advanced until the vein is entered, as identified by a flash of dark, nonpulsating blood. If the vessel is penetrated when the syringe is not being aspirated, the blood flash may be seen only as the needle is being withdrawn. The femoral vein lies just medial to the femoral artery at the level of the inguinal ligament. It is closer to the artery than many clinicians appreciate. As the vein progresses distally in the leg, it runs closer to, and almost behind, the femoral artery (see Fig. 22-3). This anatomical fact should be considered if the cannulating needle is introduced more than a few centimeters distal to the inguinal ligament.

Basilic and Cephalic Approach

Venipuncture.

The basilic and cephalic venous systems are entered through the large veins in the antecubital fossa (see Fig. 22-4). Tourniquet placement aids venous distention and initial venous puncture. When veins are not visible, they may be reached with a cutdown procedure, as described in Chapter 23 . The basilic vein, located on the medial aspect of the antecubital fossa, is generally larger than the radially located cephalic vein. Furthermore, the basilic vein generally provides a more direct route for passage into the axillary vein, subclavian vein, and SVC.

CATHETER PASSAGE TECHNIQUE

Once there is a venous flashback into the syringe, it is detached from the needle, and a catheter is passed either via the Seldinger technique or, alternatively, over or through the needle. Removing the syringe must be done with care to avoid dislodging the needle tip from the lumen of the vein. If the syringe is tightly attached to the needle, a hemostat may be used to grasp and secure the needle hub during removal of the syringe. Needle tip displacement may also occur if blood specimens are drawn at this time. Hence, it is best to delay blood sampling until the catheter has been advanced. The needle hub should be occluded with the thumb to avoid air embolism.

SPECIAL CONSIDERATIONS FOR THE FEMORAL AND SMALLER VESSELS

Femoral Vein Approach

Once in the femoral vein, the needle is stabilized; often, a hemostat is helpful for holding the needle during removal of the syringe. A premeasured section of a 90-cm catheter may then be inserted using a through-the-needle system. One determines the appropriate length by holding the catheter over the patient's body and estimating the distance from the skin puncture site to the right atrium. Contamination of the catheter must be avoided while this maneuver is performed. Once the catheter is placed, it is secured with sutures and dressed in the same manner as other central lines.

In situations requiring rapid volume infusion, in the absence of intra-abdominal trauma, the femoral vein may be cannulated with a sheath introduced via the guidewire technique. The introducer will allow rapid transfusion of large volumes of blood or crystalloid solution for fluid resuscitation. The femoral vessels may also be cannulated under direct visualization using a cutdown technique (see Chapter 23).

External Jugular Vein Approach

Central venous catheterization via the EJ vein is time consuming and often difficult. Use of the EJ vein for achieving

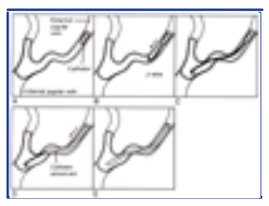

Figure 22-15 Insertion of a catheter over a wire via the external jugular vein. Successful passage may require many attempts and manipulations of the J wire to navigate turns and valves. *(From Blitt CD, Wright WA, Petty WC: Central venous catheterization via the external jugular vein, a technique employing the J-wire. JAMA 229:817, 1974. Reproduced by permission.)*

central venous access requires use of a guidewire. After cannulation of the vein and intraluminal placement of the guidewire, the guidewire is advanced into the thorax by rotating and manipulating the tip into the central venous circulation (Fig. 22-15). Guidewire advancement is the most difficult and time-consuming portion of the procedure, and this time constraint limits the usefulness of the technique in an emergency. A small-radius J-tipped wire, a distended vessel lumen, and exaggeration of patient head tilt, coupled with skin traction, may facilitate successful guidewire passage. Partially withdrawing the wire and twisting it 180° before readvancing the tip may also be helpful.

Basilic and Cephalic Approach

Passage of a catheter into the central circulation is difficult using the basilic and cephalic routes and failure is common. The cephalic vein may terminate inches above the antecubital fossa or bifurcate before entering the axillary vein, sending a branch to the EJ vein. The cephalic vein may also enter the axillary vein at right angles, defeating any attempt to pass the catheter centrally. Furthermore, both the basilic and cephalic systems contain valves that may impede catheterization. Abduction of the shoulder may help to advance the catheter if resistance near the axillary vein occurs. The incidence of failure to place the catheter in the SVC ranges from a high of 40% to a low of 2%.[40] [84] The greatest success rate (98%) reported was obtained with slow catheter advancement with the patient in a 45° to 90° upright position. [40] Flexible catheters were introduced into the basilic vein until the tip was judged to be proximal to the junction of the cephalic and basilic veins and distal to the junction of the IJ vein with the innominate vein. The wire stylet was withdrawn 18 cm, and the catheters were advanced slowly 1 cm at a time, with 2 seconds allowed between each 1-cm insertion. The natural flexibility of the Bard catheters contributed to negotiation into the SVC when the patient was upright. This time-consuming technique is contraindicated when the patient cannot tolerate an upright position.

ASSESSING LINE PLACEMENT

Once the catheter has been passed, it must be carefully secured. All tubing and connections should first be checked for tightness to prevent air embolism, fluid loss, or bleeding. The technique for securing a catheter depends on the type of equipment and the site of puncture. In general, all catheters should be secured with sutures (or skin staples[85]) and a sterile dressing placed. Most systems have some type of anchoring device to simplify securing of the catheter. Since dressings are inspected and changed periodically, it is prudent to place a simple dressing, avoiding excessive amounts of gauze and tape. An effective method for securing an IJ catheter is shown in Figure 22-16 . Care is taken to protect the skin against maceration. Transparent dressings made of polyurethane are popular and simple. They also yielded a lower rate of catheter colonization than newer hydrocolloid dressings in a prospective, randomized, controlled trial. [86]

Before the infusion of fluids, the IV fluid reservoir should be lowered below the level of the patient's right atrium and the line checked for backflow of blood. The free backflow of blood is suggestive, but not diagnostic, of intravascular placement. However, backflow may occur with a hematoma or a hemothorax if the catheter is free in the pleural space. A pulsatile blood column may be noted if the catheter has been inadvertently placed into an artery. Less pronounced pulsations may also occur if the catheter is advanced too far and reaches the right atrium or ventricle. Pulsations also may be noted with changes in intrathoracic pressure due to respirations, although these pulsations should be at a much slower rate than the arterial pulse. A final method of checking intravascular placement is to attach a syringe directly to the catheter hub and aspirate venous blood. It is also advisable to

Figure 22-16 Internal jugular line secured by looping around the ear. *(From Boulanger M, et al: Une nouvelle voie d'abord de la veine jugulaire interne. Can Anaesth Soc J 23:609, 1976. Reproduced by permission.)*

ensure that the catheter is easily flushed with a heparin solution, if no heparin sensitivity on the part of the patient exists. This carries the additional benefit of removing air from the system. Radiographs are also always indicated to verify catheter location and assess for potential complications, except for routine femoral line placements.

In an awake patient, infusing fluids via a catheter tip positioned in the internal jugular vein may produce an audible gurgling sound or flowing sound in the patient's ear.[87]

Radiographs

Following placement of lines involving puncture of the neck or thorax, the lungs should be auscultated to detect an inequality of lung sounds suggestive of a pneumo- or hemothorax. A chest film should be obtained as soon as possible, checking for hemothorax, pneumothorax, and catheter tip position. Because small amounts of fluid or air may layer out parallel to the x-ray plate with the patient in the supine position, the film should be taken in the upright or semi-upright position whenever possible. Proper catheter tip position is shown in Figure 22-17 . Misplaced catheters should be repositioned. In ill patients, a rotated or oblique projection on a chest radiograph may be obtained, and the clinician may be confused as to the proper position of the catheter (Fig. 22-18). In such cases, a repeat radiograph is necessary. A misplaced catheter tip is usually obvious on a properly positioned standard posteroanterior (PA) chest radiograph, but occasionally the injection of contrast material may be required. For example, a catheter in one of the internal thoracic veins may simply appear more lateral than expected, but because of the close proximity of these veins and the superior vena cava, malposition may not be appreciated by this subtle finding.

Postprocedure radiographs are not always warranted for routine *replacement* of catheters over guidewires. If such patients

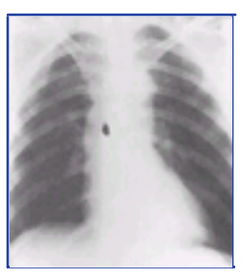

Figure 22-17 A chest film showing the proper catheter tip placement in the superior vena cava *(arrow)*. The tip should not lie within the right atrium or the right ventricle.

are stable and hemodynamically monitored, radiography may be safely deferred in the absence of apparent complications or clinical suspicion of malposition. [88] It is not standard to perform a radiograph following femoral line placement.

Redirection of Misplaced Catheters

Improper catheter tip position occurs commonly. It has been reported that only 71% of subclavian catheters are located in the SVC on the initial chest film. [122] Complications of improper positioning include hydrothorax, hemothorax, ascites, [123] chest wall abscesses,[124] embolization to the pleural space, [125] and chest pain.[126] More commonly, improper location yields inaccurate measurements of the CVP or is associated with poor flow caused by kinking. [127] An unusual complication caused by improper tip position is cerebral infarction, which can occur following inadvertent cannulation of the subclavian artery. [128]

Misdirection or inappropriate positioning of the tip of a central venous catheter is not uncommon. These events if promptly recognized and corrected represent inconsequential complications. Loop formation, lodging in small neck veins, tips directed caudally, and innominate vein position are common problems. Misplaced catheters should be repositioned as soon as logistically possible. If the catheter is being used for fluid resuscitation, the malposition may be tolerated for some time. If vasopressors or medications are infused, it is more critical to properly position the catheter tip. A number of options are available to remedy malpositioning. One strategy is to insert a 2 Fr Fogarty catheter through the lumen of the central line, advancing it 3 cm beyond the tip. The entire assembly is withdrawn until only the Fogarty catheter is in the subclavian vein. One milliliter of air is injected into the balloon, and the Fogarty catheter is advanced. It is hoped that the

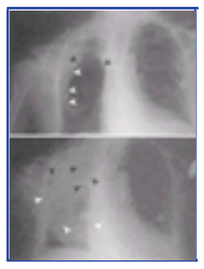

Figure 22-18 A chest radiograph should be routinely taken to assess position of a central catheter introduced via the chest or neck. *A*, In this case a poorly positioned patient produced a rotated and oblique film, and the catheter (black arrow) appeared, at first glance, to be in the correct position in the right subclavian vein. The supine position of the patient did not allow identification of an early hydrothorax (white arrow). *B*, A repeat radiograph shows the obvious intrapleural position of the catheter, and a large hydrothorax after infusion of 2 liters of saline.

blood flow will direct the assembly into the SVC. The balloon is deflated and the central line is advanced over the Fogarty catheter, which is then withdrawn. [89]

One anecdotal strategy is to withdraw the catheter until only the distal tip remains in the cannulated vessel. This measurement is best appreciated by comparing the indwelling catheter length with another unused catheter. The clinician then simply readvances the catheter, hoping that it becomes properly positioned. Other manipulations with guidewires have been suggested, but often reinsertion with another puncture is required for the misplaced catheter to be positioned properly.

ULTRASOUND-GUIDED CENTRAL VENOUS ACCESS

In maximizing the success and minimizing the complications of central venous access, there is no substitute for experience. However, some patients will present challenges to even the most seasoned clinician. Anatomic (skeletal or vascular) abnormalities, whether congenital or acquired, may be encountered and can thwart successful cannulation. When time permits, difficult cases may be simplified by using a Doppler ultrasound device to identify the location of major veins. The course of these vessels can be marked on the skin surface and used as an anatomic guide during needle placement. Alternatively, more sophisticated ultrasound imaging systems have been adopted for guiding venous cannulation.

The most commonly described imaging tool is a handheld 7.5 MHz real-time mechanical sector transducer with an attached needle guide. The device is coupled with a small video display (Fig. 22-19). To use the instrument, the nonsterile transducer is covered with acoustic coupling gel and placed inside a sterile sheath. Additional sterile gel is placed on the skin over the site being imaged, and the unit is used to determine the location, orientation, and diameter of the target vessel. When accessing the jugular or femoral systems, this is done by placing the transducer according to traditional puncture site landmarks. Imaging the subclavian vein from the IC approach is more difficult, but can be attempted by identifying the axillary vessels at their most proximal position under the distal clavicle and then following the vessels medially as they course beneath the clavicle. [90] Once the vessel is identified, the overlying skin may be marked for later venipuncture or a needle and syringe secured to the transducer for immediate cannulation. Under ultrasound guidance, the needle is advanced through the skin and SQ tissue toward the target vessel. Once the needle is in close proximity to the vessel, one will see compression of the vein. Once the vessel wall has been penetrated, the vein will refill with blood and assume its original shape. The transducer can then be detached and cannulation proceeds.

Most prospective analyses of the device have examined IJ vein cannulations [91] [92] [93] and have uniformly suggested advantages to the technique. Ultrasound-guided attempts demonstrated greater overall success, as well as an increased rate of successful first punctures. Clinically significant complications were too infrequent to definitely conclude greater patient safety with the ultrasound technique; studies specifically examining complications demonstrated less frequent hematoma formation and inadvertent arterial puncture. [90] [91] Ultrasound guidance may assume greater prominence in central venous access in the future. However, given the generally favorable success rate and low complication rate of traditional access techniques, the relative infrequency of central venous cannulation in many EDs, and the considerable cost of the device, the routine role of ultrasound imaging guidance remains uncertain.

COMPLICATIONS

The medical literature is replete with reports of the complications of large vein venipuncture. Some are minor and inconsequential, such as hematoma formation, while others are serious and life-threatening, such as hemothorax. *No clinician can expect to routinely perform these procedures and be complication-free.* Common complications for the different approaches are summarized in Table 22-6 and Table 22-7 . Key injuries categorized by organ system and by approach are discussed in the sections that follow. The FDA has released a three-volume video entitled "CVC Complications," which was sent to all hospitals where such catheters are placed. It is also commercially available from the Internet (at www.fda.gov).

Published rates vary widely and complication rates depend on one's definition. One 3-year retrospective review

Figure 22-19 *A*, Surface ultrasound-directed central vein identification. A handheld transducer allows noninvasive localization of veins, in this case the subclavian. The device shown includes a needle guide, which allows simultaneous visualization and penetration of a targeted vessel. *B,* Surface ultrasound image of the subclavian artery (left) and vein (right). *(Courtesy of Irene R. Skolnick, Dymax Corp, Pittsburgh.)*

of all central catheters placed in the ED (SC, IJ, and femoral lines) reported a mechanical complication rate of 3.5%, or 22 of 643 lines placed. [94] Complication was defined as pneumothorax, hematoma, line misplacement, hemothorax, or any issue with the CVC (excluding infection or thrombosis) that required an inpatient consultation. In general, failure and complication rates increase as the number of percutaneous punctures increase.

Pulmonary Complications

Pulmonary complications of subclavian and internal jugular venipuncture include pneumothorax, hemothorax, hydrothorax, hemomediastinum, hydromediastinum, tracheal perforation, and endotracheal cuff perforation. Pneumothorax is the most frequently reported complication, occurring in up to 6% of subclavian venipunctures. [95] Initially the importance of this complication was minimized, but reports of fatalities caused by tension pneumothorax, bilateral pneumothorax, and combined hemopneumothorax followed. [96] [97] One would expect a higher incidence of pneumothorax if the procedure were performed during CPR or positive-pressure ventilation. A small pneumothorax can quickly become a life-threatening tension pneumothorax under positive-pressure ventilation.

The treatment of a catheter-induced pneumothorax is controversial, but certainly not all patients will require a formal tube thoracostomy. [98] Some authors conclude that many stable outpatients exhibiting a pneumothorax following central venous catheter insertion can often be successfully managed with observation alone (60% in their series) or catheter (pigtail/Heimlich valve) aspiration, reserving large tube thoracostomy for refractory cases or emergent settings (Fig. 22-20). Critically ill patients, or those on mechanical ventilation will likely require invasive treatment of a catheter-induced pneumothorax.

Hemothorax may occur following subclavian vein or artery laceration, pulmonary artery puncture, or intrathoracic infusion of blood. Hydrothorax occurs as a result of infusion of IV fluid into the pleural space. Hydromediastinum is an uncommonly reported complication that is potentially fatal. [99]

Vascular/Bleeding Complications

The most common vascular complication is inadvertant artery puncture. This is usually easily recognized and controlled with simple compression. Rarely an artery is lacerated to an extent that bleeding is significant and arterial repair is necessary. In cardiac arrest, low flow, or shock states, arterial puncture may not be obvious, and arterial cannulation and the intra-arterial administration of medications has occurred. When the systolic blood pressure rises, arterial pulsations become more obvious. In critically ill patients, however, this complication may escape detection for some time. The subsequent development of ischemia or thrombosis of an artery that has been cannulated or injected with detrimental medication reflects the blind nature of this procedure in an emergency.

Air embolism is a very rare, but potentially serious complication from any central venous cannulation. Undoubtedly, minor and clinically inconsequential amounts of air enter the venous circulation during many cannulation procedures. Maintaining constant occlusion (with the operator's finger) of all needles that are located in central veins will minimize this occurrence. A 14-ga needle can transmit 100 mL of air per second with a 5-cm H_2O pressure difference across the needle. [100] Air embolism may occur if the line is open to air during catheterization or if it subsequently becomes disconnected. The recommended treatment is to place the patient in the left lateral decubitus position to relieve air bubble occlusion of the right ventricular outflow tract. [101] If this is unsuccessful, aspiration with the catheter advanced into the right ventricle has been

advocated.[102] Emergent cardiothoracic surgical consultation may also be warranted.

Catheter embolization resulting from shearing of a through-the-needle catheter by the needle tip is a serious and generally avoidable complication. Embolization can occur when the catheter is withdrawn through the needle or if the guard is not properly secured. Because through-the-needle catheters are less commonly need, this problem is rare. However, when present, subsequent adverse events occur frequently following embolization and include arrhythmias, venous thrombosis, endocarditis, myocardial perforation, and pulmonary embolus.[54] The mortality rate in patients who did not have these catheters removed has been reported to be as high as 60%.[103] Transvenous retrieval techniques are usually attempted and followed by surgery if they are unsuccessful. [104] Entire guidewires may also embolize to the general circulation if the tip is not always secured by the operator.

Perforation or laceration of vascular structures may cause hemothorax, hemomediastinum, and volume depletion. These are rarely serious complications, but fatalities have been reported. Surgical repair is occasionally required. [105] Arteriovenous fistula formation has also been reported. [106]

Delayed perforation of the myocardium is a rare but generally fatal complication of central venous catheterization by any route. [107] [108] The presumed mechanism is prolonged contact of the rigid catheter with the beating myocardium.[109] The catheter perforates the myocardial wall and causes tamponade either by bleeding from the involved chamber or infusion of IV fluid into the pericardium. The right atrium is involved more commonly than the right ventricle. [76] All who insert such catheters or care for such patients, or both, should be aware of this deadly complication, which results in profound deterioration with hypotension, shortness of breath, and shock. Emergent echocardiography, pericardiocentesis, and operative intervention by a chest surgeon all may be required for patient salvage. This can also occur with misplacement of the central venous line in the pericardiophrenic vein.[110] Fortunately this complication is preventable by using a postinsertion chest film to confirm catheter tip position and repositioning any catheter if the tip is within the cardiac silhouette.

Catheter knotting or kinking may occur if the catheter is forced or repositioned or if an excessively long catheter is used. [111] The most common result of kinking is poor flow of IV fluids, although rare complications as severe as SVC obstruction caused by a kinked catheter have been seen. [112]

Thrombosis and thrombophlebitis occur rarely because of the large caliber and high flow rates of the vessels involved. [68] It is important to determine that the catheter tip rests in the SVC, especially during the infusion of irritating or hypertonic solutions. [112] Thrombi may also form secondary to prolonged catheter contact against the vascular endothelium. One autopsy study found a 29% incidence of mural thrombi in the innominate vein, SVC, and right ventricle of patients who had central lines in place an average of 8 days before death.[113] However, no complications were directly attributable to these small, firmly adherent thrombi.

Thoracic duct laceration is a frequently discussed complication of left-sided subclavian venipuncture; however, it is extremely uncommon, and has been reported only as a complication of internal jugular, but not subclavian, cannulation. [95]

Although poorly studied, it has been promulgated that patients with a coagulopathy may experience significant bleeding from central catheter placement, especially if arterial puncture/laceration has occurred. Traditionally, prophylactic blood component therapy (fresh frozen plasma, platelet infusions) has been suggested in patients with a coagulopathy prior to percutaneous placement of a central venous catheter. While intuitively reasonable, this concept has no support in the literature. Mumtaz et al. have challenged this concept as unproven and unnecessary, citing a 3% bleeding rate in coagulopathic patients who experienced only minor bleeding that could be controlled with digital pressure. Although central venous access may be safely performed in patients with underlying disorders of hemostasis, without correction of the coagulopathy, caution is urged. It would be prudent to target central access in patients with coagulopathies to areas of arterial compression. [42]

Infectious Complications

Infectious complications include local cellulitis, thrombophlebitis, generalized septicemia, osteomyelitis, and septic arthritis. [95] The incidence of septic complications varies from 0% to 25%.[114] [115] The frequency with which infectious complications are seen is directly related to the attention given to

TABLE 22-7 -- Anatomic Structures That Can Be Injured by Central Venous Cannulation

Structure	Anatomic Relation to Vein	Error in Procedure	Injury
Subclavian Vein Cannulation			
Subclavian artery	Posterior and slightly superior, separated by scalenus anterior—10 to 15 mm in adults, 5 to 8 mm in children	Insertion too deep or lateral	Hemorrhage, hematoma, possible hemothorax

Brachial plexus	Posterior to and separated from the subclavian vein by the scalenus anterior and the subclavian artery (20 mm)	Same as with subclavian artery	Possible motor or sensory deficits of hand, arm, or shoulder
Parietal pleura	Contact with posteroinferior side of the subclavian vein, medial to the attachment of the anterior scalenus muscle to the first rib	Needle penetrates beneath or through both walls of the subclavian vein	Pneumothorax
Phrenic nerve	Same as with parietal pleura	Placement of needle above or behind the vein or by penetration of both its walls	Paralysis of the ipsilateral hemidiaphragm
Thoracic duct	Cross the scalenus anterior and enter the superior margin of the subclavian vein near the internal jugular junction	Same as with phrenic nerve	Soft tissue lymphedema or chylothorax on left
Internal Jugular Vein Cannulation			
Carotid artery	Passes with jugular vein in carotid sheath, consistently medial and deep to the vein	Insertion site too medial or needle course not directed at ipsilateral nipple	Hematoma, possible cerebral thromboembolism or airway obstruction
Phrenic nerve	Passes along anterior surface of scalenus anterior, behind the vein	Insertion too deep	Paralysis of the ipsilateral hemidiaphragm
Brachial plexus	Separated from the internal jugular by the scalenus anterior	Insertion too deep or too lateral	Possible motor or sensory deficits of hand, arm, or shoulder
Femoral Vein Cannulation			
Femoral artery	Lies lateral to the vein in the femoral triangle	Needle passed too laterally	Hematoma
Psoas muscle	Directly posterior to the artery and vein	Needle passed too deep	Hematoma, psoas abscess
Bowel	Proximal and deep to femoral vein	Needle passed too deep and above inguinal ligament	Enterotomy, peritonitis
Synovial capsule of hip	Deep to the psoas muscle	Needle passed too deep, particularly in small children	Arthritis

From Knopp R, Dailey RH: Central venous cannulation and pressure monitoring. JACEP 6:358, 1977.

aseptic technique in insertion and aftercare of the catheter. One study suggested a higher incidence of contamination with triple-lumen catheters [116] ; for the most part, however, an acceptably low incidence of bacteremia and sepsis (3.1%) using these devices has been encountered. [117] Femoral venous catheterization may be related to a greater risk of infection than subclavian catheterization. Merrer et al. reported overall infectious complications from femoral vs subclavian catheters to be 19.8% and 4.5% respectively. The most common organisms recovered from colonized femoral catheters, or involved with infectious complications from femoral catheters, were coagulase-negative staphylococci, Enterobacteriaceae, Enterococcus species, and *Pseudomonas aeruginosa*. [118]

Neurologic Complications

Neurologic complications are extremely rare and are presumably caused by direct trauma from the needle during venipuncture. Brachial plexus palsy and phrenic nerve injury with paralysis of the hemidiaphragm have been reported. [119] [120] Infusing medications into the internal jugular vein via a malpositioned catheter may result in a variety of neurologic complications from retrograde perfusion of intracranial vessels. [121]

Subclavian Approaches

Although both approaches to the subclavian are relatively safe (Fig. 22-21), the IC approach is more likely to be associated with complications. In a randomized prospective comparison of SC and IC venipuncture in 500 ED patients, complication rates were 2.0% and 5.1%, respectively. [129] The most significant complications have been pneumothorax and subclavian artery puncture; the highest incidence of pneumothorax is 2.4%. [29] Adherence to recommended techniques for SC subclavian venipuncture decreases the risk of these complications because the needle is directed away from the pleural dome and subclavian artery. [12] The relatively superficial location of the vein when approached from above the clavicle (1.5 to 3.5 cm) lessens the risk of puncture or laceration of deep structures.

Figure 22-20 *A,* A femoral vein catheter is more prone to deep vein thrombosis and infection than a subclavian/internal jugular line, but it is a standard access route in the emergency department. Strict attention to sterile procedure and limiting use for a few days will negate most of the negatives of this approach. *A*, Significant hemorrhage can occur after puncture of the femoral artery, but this area is readily compressed. The femoral route may be the route of choice in the patient with a coagulopathy who requires a central line. The femoral vein will accept: (*B*) a triple-lumen catheter or (*C*) a large sheath introducer.

Catheter tip malposition should be expected with some frequency, as high as 27.6% in one study examining the IC technique. [130] Because of the more direct path to the SVC, the SC approach may be advantageous in this regard. For those SC series in which malposition has been reported, the overall rate is 1.1%. [13] [28] [29] The highest incidence of malposition using the SC technique, 7%, occurred during the performance of CPR. [13]

The incidence of failure to establish a functioning SC line ranges from 0% to 5%, [12] [28] [29] [131] with an overall rate of 4%. The failure rate reported for the IC technique ranges from 2.5% to 8%.[68] A recent case series of 178 SC attempts, often in patients with difficult anatomy, supports the high placement success (97.8%) and low significant complication rate (0.56%). [132]

IJ Approach

Many complications of IJ cannulation are similar to those of subclavian access. Infection, catheter malposition, thrombosis, and damage to surrounding structures are complications common to all puncture sites for central venous cannulation. The reported rates of thrombosis for internal jugular vein catheterizations range from a report of no significant thrombosis in 1 study to a high of 66% of patients exhibiting some thrombosis in a study of 33 medical intensive care unit patients. [133] No reports of significant pulmonary embolus directly attributable to an IJ catheter were found. Such wide variation in the reported incidence of complications is common, in part because of the different methods of detecting and reporting complications, variable experience with the different techniques, and the different patient populations.

The number of complications increases, especially those due to thrombosis and infection, with longer duration of catheterization and increasing severity of the patient's illness. [17] Complications also seem to be higher with the use of the left IJ vein as opposed to the right. [49] [76] [77] Reported complications thought to be due at

least in part to the use of the left-sided approach include mediastinal migration of the catheters and at least one instance of fatal pericardial tamponade.

One fairly common complication unique to the IJ approach is a hematoma in the neck. [33] With the IJ approach, pressure can be maintained easily on the area of swelling, and most hematomas will resolve spontaneously. If carotid arterial puncture is recognized and treated with compression, it rarely causes significant morbidity in the absence of marked

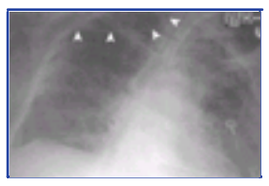

Figure 22-21 A subclavian line can easily be advanced into the neck (internal or external jugular vein). Malpositioned catheters should be discovered and replaced as soon as possible. Infusing saline into this catheter is not harmful, but hyperosmotic and vasoactive medications should not be given through this catheter for prolonged periods of time.

atherosclerotic disease, although arteriovenous fistulas have been reported after IJ puncture. [134] Several neurologic complications unique to the IJ site of venipuncture have also been reported as a result of hematomas or of direct injury. [135] [136] These complications include damage to the phrenic nerves, an iatrogenic Horner syndrome, trauma to the brachial plexus, and even an instance of the passage of a catheter into the thecal space of the spinal canal. [137] [138] [139] [140] If the carotid artery is punctured, one may again attempt IJ or subclavian cannulation on the same side after appropriate, prolonged (15 to 20 minutes) compression. The IJ vein valve is frequently damaged when cannulated, often resulting in its incompetence. The clinical significance of this, if any, is unknown. [141]

Arterial puncture is a contraindication to attempting the IJ route on the opposite side, because bilateral hemorrhage may occur with resultant airway compromise. The clinician should be prepared to rapidly intubate should this occur. Even in the face of a coagulopathy, however, the IJ approach has been found to be successful (up to 99.3% of cases) and safe (<1% complication rate). [142]

Femoral Approach

Femoral lines are generally associated with less severe complications than are IJ or subclavian approaches because of the avoidance of thoracic trauma. The most common complications of femoral venipuncture are inadvertent arterial and venous perforation. As mentioned in the Indications section, arterial puncture is more common in the patient who is in a low- or no-flow circulatory state; during cardiac arrest, the success rate for femoral catheterization may be as low as 77%, compared with 94% for subclavian vein catheterization. [143] Prolonged (>15 minutes) pressure should stop any arterial hemorrhage in a patient with normal clotting mechanisms. Prolonged arterial bleeding in patients, particularly those receiving thrombolytic or antiplatelet therapy, may warrant evaluation by a vascular surgeon or duplex imaging to evaluate for pseudoaneuyrsm formation, or both. A large study of military casualties found a 1.6% incidence of major hematomas, but these were mostly young, previously healthy patients. [144]

The peritoneum can also be violated, with possible resulting perforation of the bowel. Bowel penetration is especially likely if the patient has a femoral hernia. Injury to the bowel is usually minimal and is unlikely to require specific treatment. Nonetheless, the potential bacterial contamination of the femoral puncture site may pose a significant problem. Aspiration of air on placement of a femoral line necessitates removal of the catheter and reinsertion at another site. A case has been reported in which a patient developed clinical signs of peritonitis that were found to be due to infiltration of IV fluids into the anterior abdominal wall from a femoral catheter. [145]

A psoas abscess may result from penetration posteriorly of the underlying psoas fascia. The bladder, when distended, can also be punctured during femoral cannulation, although bladder puncture is unlikely to require therapy beyond removal of the aberrantly placed catheter. Strict aseptic technique should be maintained to prevent septic arthritis in the unlikely event that the hip capsule is punctured. This complication has been reported in infants. [146]

The femoral nerve can also be injured by an errant needle puncture. [142] [145] Complications can be minimized if the patient has a pulse and the femoral vein is approached medial to the femoral pulsations. A helpful mnemonic is NAVEL, which describes the anatomy of the region from lateral to medial: *n*erve, *a*rtery, *v*ein, *e*mpty space, and inguinal *l*igament.

A controlled trial by Merrer and colleagues identified significantly increased risks of infectious and thrombotic complications with the femoral vs the subclavian approach. [118] Deep venous thrombosis (DVT) may also occur in or near cannulated lower extremity veins, and propagate to the IVC. Several prospective studies followed cohorts of patients with femoral lines, and found iliofemoral DVT in frequencies ranging from 6.6% to 10%. [147] [148] Most were clinically silent, without leg swelling or suspicion for pulmonary embolism. The relevance of long-term complication cannot be extrapolated to the short-term value of this procedure in the ED setting. However, such DVTs definitely pose embolic risk, and may lead to fatal pulmonary emboli. [149] IJ or subclavian cannulation may result in comparable rates of upper extremity DVT. [150] The true incidence of clinical sequelae from upper extremity DVT remains unclear, and lower extremity DVT is felt to be more often responsible for large or fatal pulmonary embolism. Therefore, some authors believe that the additional risk of lower extremity DVT in patients receiving longer-term femoral catheterization (perhaps sixfold above baseline) is not justified given the existence of alternative approaches. [147] Others disagree, stating that femoral vein catheterization is a standard intervention and a valuable, generally safe technique in the ED setting.

Basilic-Cephalic Approaches

Cannulation of the central venous system through the arm veins has the lowest major complication rate of all the approaches. Superficial local infections are common (10% to 20% incidence) and rarely lead to more serious problems, including sepsis. Catheter malposition is common, and studies have shown this to occur in 10% to 40% of placements. [84] [151] Cannulation of these veins requires immobilization of the entire extremity and shoulder to prevent catheter movement

and kinking. Immobilization may be independently associated with complications.

CONCLUSION

Cannulation of the central venous circulation is a necessary skill for emergency clinicians. Safe application of the various techniques available requires detailed knowledge of anatomy and operative technique, as well as a healthy respect for potential complications. Inexperienced clinicians should not undertake these techniques without supervision, although even in experienced hands, complications should be expected. While the IC subclavian approach is most commonly encountered in clinical practice, familiarity with the SC, IJ, femoral, and basiliccephalic approaches will provide the emergency clinician with a full complement of techniques for gaining access to the central venous circulation under a variety of clinical demands.

CENTRAL VENOUS PRESSURE MEASUREMENT

Although described by Forssman in 1931, it was not until the early 1960s that measurement of CVP became commonplace as a means of assessing cardiac performance and guiding fluid therapy.[5] CVP measurements are most frequently used as a guide for determination of a patient's volume status and fluid requirements and for investigation of tamponade.[152] [153] Critical commentaries have been written by some researchers who regard CVP monitoring as ineffective, outmoded, and unreliable. [154] The astute clinician, however, can maximize the usefulness of this diagnostic tool by careful consideration of its indications and limitations. CVP is one of many variables that must be correlated in the development of an overall management plan for the care of critically ill patients.

Physiology

Simply stated, the CVP is the pressure exerted by the blood against the walls of the intrathoracic venae cava. Because the pressure in the great veins of the thorax is generally within 1 mm Hg of right atrial pressure, the CVP reflects the pressure under which blood is returned to the right atrium. [155] The pressure in the central veins has two significant hemodynamic effects. First, the pressure promotes filling of the heart during diastole, a factor that helps determine cardiac output. Second, the CVP is also the backpressure of the systemic circulation, opposing the return of blood from the peripheral blood vessels into the heart. [156] The CVP therefore affects both the ability of the heart to pump blood and the tendency for blood to flow from the peripheral veins. [27] [155] The CVP reading is determined by a complex interaction of intravascular volume, right atrial and ventricular function, venomotor tone, and intrathoracic pressure. [155]

One can measure CVP accurately by placing the tip of a pressure monitoring catheter into any of the great systemic veins of the thorax or into the right atrium. [156] Because the risks of catheter placement in the atrium include atrial perforation and cardiac dysrhythmias, any large vein within the thorax is preferred. [157] The catheter is commonly connected to an electronic pressure transducer interfaced with a monitoring system capable of calculating a mean pressure value and displaying pressure waveforms.

Indications and Contraindications for CVP Measurement

The four major indications for CVP monitoring are as follows:

1. Acute circulatory failure
2. Anticipated massive blood transfusion for fluid replacement therapy
3. Cautious fluid replacement in patients with compromised cardiovascular status
4. Suspected cardiac tamponade

The procedure is contraindicated when other resuscitation therapeutic and diagnostic interventions take priority over central venous access and CVP transducer setup and calibration.

A common misconception is that CVP consistently reflects pressures found in the left side of the heart. The measurement that best reflects left ventricular pressure changes and reserve is the left atrial pressure, or the nearly equivalent pulmonary capillary wedge pressure (PCWP). The development of the flow-directed pulmonary artery catheter has allowed repeated measurements of PCWP, thus permitting reliable estimation of the left atrial pressure.

The CVP is most helpful in patients without significant preexisting cardiopulmonary disease. Numerous studies highlight the apparent unreliability of right-sided hemodynamic monitoring in patients with underlying coronary artery or other cardiac disease or pulmonary disease. [131] [158] [159] [160] Ultimately, however, the differences noted are not a failure of CVP monitoring to reflect central hemodynamics. Rather, the disagreements noted by previous authors simply highlight the complexity of the relationship between ventricular and vascular compliance, blood volume, and filling pressures in all but very healthy patients. As when making pulmonary arterial and pulmonary arterial occlusion pressure measurements, the clinician is cautioned to be fully aware of the assumptions that such measurements make and to recognize the scenarios in which these assumptions do not hold true.

Procedure

Although CVP may be determined with a manometry column assembled at the bedside (Fig. 22-22), the most common technique in practice is measurement with an electronic transducer interfaced to a monitoring system (Fig. 22-23). Typical transducers include a nipple valve attached to a pressurized bag of saline to allow easy flushing of the system. To use these manometers, the transducer is attached to the patient's central line with a length of flexible yet fairly rigid-walled tubing filled with saline. A three-way stopcock is placed between the patient and the transducer to simplify line flushing and calibration.

All air bubbles are flushed from the system by opening the stopcock to air and flushing saline through the line. Air bubbles should not be flushed into the patient. Even tiny bubbles left in the tubing will dampen the CVP wave and potentially cause underestimation of venous pressure.

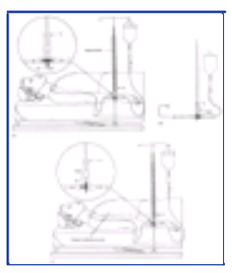

Figure 22-22 *A*, Simple manometry column used to measure CVP at the bedside. The stopcock is turned to direct the flow to the patient, bypassing the manometer. This is the position that is maintained to keep the catheter patent. The tubing is always flushed before connecting it to the patient's central venous pressure catheter. *B*, The stopcock is turned to fill the manometer to 25 cm H_2O. *C*, The stopcock is opened to the patient, and the column of water in the manometer is allowed to fall and stabilize before a reading is taken. Note that the zero mark is horizontally aligned with the tricuspid valve (midaxillary line in a supine patient).

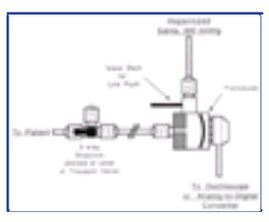

Figure 22-23 General configuration of an intravascular pressure transducer. A working understanding of these devices, particularly regarding proper setup, zeroing, and line debubbling, will maximize their effectiveness and accuracy.

After the system has been flushed, the stopcock (with the transducer still open to air) is placed at the level of the patient's tricuspid valve. The monitor detecting the transducer's signal is then "zeroed," or calibrated. The transducer is calibrated at the level of the tricuspid valve, which can be approximated on the skin surface as a

point at the midaxillary line and fourth intercostal space. [155] Finally, the stopcock is set so that the transducer is in continuity with the patient's venous catheter.

In spontaneously breathing patients, readings should be taken at the end of a normal inspiration. If the patient is receiving positive-pressure ventilation, the CVP changes during the respiratory cycle are reversed, rising with inspiration and decreasing with expiration. In these patients, readings should be taken near the end of expiration.[161] Thus, during both normal and mechanical ventilation, the lowest reading is a useful estimate of the mean CVP.

A reading may be taken after proper assembly of the equipment and after accurate placement of the tip of the catheter has been established. To ensure optimal measurement, the patient should be in the supine position. Whenever the patient is repositioned, care must be taken to ensure that the transducer has been recalibrated to reflect the new position of the patient.

Errors in CVP Measurement

A number of extrinsic factors may alter the accuracy of the CVP reading (Table 22-8).[27] In addition to the position of the patient, these include changes in intrathoracic pressure,[162] catheter tip malposition, obstruction of the catheter, and failure to calibrate or zero the line. Activities that increase intrathoracic pressure, such as coughing or straining, may cause spuriously high measurements. The patient should be relaxed at the time of the measurement and breathing normally. In mechanically ventilated patients, the CVP will be elevated to an extent directly proportional to the ventilatory pressures being delivered and inversely proportional to the mechanical

TABLE 22-8 -- Faulty Central Venous Pressure Readings

compliance of the lung. Care should be exercised in interpreting filling pressures in this circumstance, as ventilator-induced elevations in CVP are not artifactual, but represent changes in the hemodynamic physiology of the patient. As in spontaneously breathing patients, CVP measurements are only meaningful in a relaxed, sedated, or sedated and paralyzed subject.

Another reason for faulty readings is malposition of the catheter tip. If the catheter tip has not passed far enough into the central venous system, peripheral venous spasm or venous valves may yield pressure readings that are inconsistent with the true CVP. [27]

If the catheter tip is passed into the right ventricle, a falsely high CVP is obtained. Recognition of a characteristic right ventricular pressure waveform on the patient's monitor should hopefully preclude this error. Such fluctuations may occasionally be seen in appropriately positioned CVP lines when significant tricuspid regurgitation or atrioventricular dissociation (cannon a waves) is present.

Inaccurate low venous pressure readings are seen when a valve-like obstruction at the catheter tip occurs either by clot formation or by contact against a vein wall. As mentioned earlier, wave damping due to air bubbles in the transducer or tubing also leads to faulty readings.

Using poorly zeroed lines may result in inaccurate measurements that may be interpreted as a change in the patient's status when none has actually occurred. The transducer should be zeroed to the same level for every measurement.

Some investigators mention a falsely elevated CVP in patients who are receiving vasopressors, but controlled data on this aberration are lacking. One animal study suggests that fluid can be infused into one lumen of a multilumen catheter without affecting the CVP reading at another lumen. [163]

Interpretation of the CVP measurement

Because determination of the CVP can aid the clinician in assessment of the critically ill patient, it is paramount that the clinician knows the normal values and the variables that may affect these values and can recognize the pathologic conditions that correlate with abnormal values. Although various ranges for normal have been reported,[153] [164] [165] a summary of these values is as follows:

Low: <6 cm H_2O

Normal: 6 to 12 cm H_2O

High: >12 cm H_2O

In the late stages of pregnancy (30 to 42 weeks), the CVP is physiologically elevated, and normal readings are 5 to 8 cm H_2O higher in pregnant women.

A CVP reading <6 cm H_2O is consistent with low right atrial pressure and reflects a decrease in the return of blood volume to the right heart. This may indicate that the patient requires additional fluid or blood. A low CVP reading is also obtained when vasomotor tone is decreased, as in sepsis, spinal cord injury, or other forms of sympathetic interruption.[153] [164] [165]

A CVP reading falling within a normal range is viewed in relationship to the clinical situation. A reading >12 cm H_2O indicates that the heart is not effectively circulating the volume presented to it. This situation may occur in the case of either a normovolemic patient with underlying cardiac disease such as left ventricular hypertrophy (with associated poor ventricular compliance) or a patient with a normal heart who is over-hydrated and over-transfused. A high CVP is also related to variables other than pump failure, which include pericardial tamponade, restrictive pericarditis, pulmonary stenosis, and pulmonary embolus. [164]

Changes in blood volume, vessel tone, and cardiac function may occur alone or in combination with one another; therefore, it is possible to have a normal or high CVP in the presence of normovolemia, hypovolemia, and hypervolemia. One must interpret the specific CVP values with respect to the entire clinical picture. The response of the CVP to an infusion is more important than the initial reading.

Fluid Challenge

Monitoring of the CVP may be helpful as a practical guide for fluid therapy. [152] [153] Serial CVP measurements provide a fairly reliable indication of the capability of the right heart to accept an additional fluid load. Although the PCWP is a more sensitive index of left heart fluid needs (and in some clinical situations, PCWP measurement is essential), serial measurement of CVP can provide significant information.

A fluid challenge can help assess both volume deficits and pump failure. Although a fluid challenge can be used with either PCWP monitoring or CVP monitoring, only the fluid challenge for CVP monitoring is discussed here. Slight variations in methodology of fluid challenge are reported in the literature. Generally, aliquots of 50 to 200 mL of crystalloid are sequentially administered, and measurements of CVP levels are obtained after 10 minutes. [131] [164]

The fluid challenge is generally carried out in the following manner [153] : Fluid is administered by a route other than that used for monitoring. An initial CVP reading is taken, and fluid is infused at a rate of 20 mL/min over a 10-minute period. The infused volume is allowed to equilibrate for 10 minutes, and a reading is taken. If the CVP is >5 cm of H_2O over the initial measurement, the fluid challenge is discontinued, and one assumes that the right ventricle is unable to handle an additional fluid load. Increases of between 3 and 5 cm H_2O over the initial CVP value are equivocal, and additional measurements are taken over the next 30 minutes if this reading is obtained. An increase of <2 cm H_2O over the original reading is indicative of volume depletion. The fluid challenge is repeated until measurements indicate that adequate volume expansion has occurred. The fluid challenge is discontinued as soon as hemodynamic signs of shock are reversed or signs of cardiac incompetence are evident.

Cardiac Tamponade

In cardiac tamponade, pericardial pressure rises to equal right ventricular end-diastolic pressure. The pericardial pressure encountered in pericardial tamponade characteristically produces an elevated CVP. The degree of CVP elevation is variable, and one must interpret measurements cautiously; CVP readings in the range of 16 to 18 cm H_2O are typically seen in acute tamponade, [153] [166] but elevations of up to 30 cm H_2O may be encountered. The exact CVP reading is often lower than one might intuitively expect, and it is not uncommon to encounter tamponade with a CVP of 10 to 12 cm H_2O. A normal, or even low, CVP reading may be seen if the tamponade is associated with significant hypovolemia. An excessive rise in CVP following fluid challenge may be more important than a single reading in the diagnosis of pericardial tamponade.

Excessive straining, agitation, pneumatic antishock garment inflation, positive-pressure ventilation, or tension pneumothorax may increase intrathoracic pressure, producing a high CVP reading, and may erroneously suggest the diagnosis of pericardial tamponade. Increases in vascular tone, as seen with the use of dopamine or other vasopressors, may also elevate the CVP, mimicking tamponade and complicating volume estimation.

CONCLUSION

CVP monitoring provides useful hemodynamic monitoring information in those individuals with a relatively normal cardiopulmonary system who do not otherwise warrant PCWP monitoring.

Chapter 23 - Venous Cutdown

Steven C. Dronen
Patricia Lanter

"The standard cutdown is well known to all trauma surgeons and needs no description." [1] Were this a true statement, the remainder of this chapter would be superfluous; however, clinician training in the technique of venous cutdown has been largely informal. For 5 decades, the mechanics of venous cutdown have been handed down from house officer to house officer as one of the rites of internship. There are, in fact, few detailed descriptions of the procedure in the medical literature, and the scientific data documenting its usefulness or complication rate are sparse.

An early description of venous cutdown technique was provided in 1940 by Keeley, who offered the procedure as an alternative to venipuncture in patients who were in shock or had small, thin veins. [2] In 1945 Kirkham gave the first detailed description of the saphenous vein cutdown at the ankle. [3] The procedure changed little until 1990, when Shockley developed a modified cutdown technique. In 1997 Klofas adapted the Shockley method for the distal saphenous vein and developed a model on which to teach it.

The most significant changes over the past 5 decades have involved not the technique itself, but the cannulas that are used. Keeley and Kirkham used metal needles. With the advent of plastic cannulas in the mid-1940s, the cutdown became more popular as a means of providing long-term intravenous (IV) infusion. Clinicians have used IV tubing, feeding tubes, and even nasogastric tubes as cannulas in the management of hypovolemic patients. Currently, large-bore catheters (10-ga, 8 Fr) are often inserted by cutdown in the management of hypovolemic shock. [4]

The frequency of performing venous cutdowns is impossible to estimate. The popularity of central venous cannulation by the internal jugular, subclavian, and femoral routes has markedly decreased the frequency of venesection. In the Advanced Trauma and Life Support (ATLS) provider course, venous cutdown is no longer a mandatory procedure. Rather, it is optional, to be taught at the director's discretion. [5] Nevertheless, the cutdown remains an excellent method of obtaining venous access in several emergent clinical situations. Although a cutdown is mechanically simple to perform, ease of performance does not guarantee that the procedure will be performed efficiently and without complications. Performance of a rapid, effective cutdown can be achieved only by thorough knowledge of the anatomy and the procedure and attention to its many details.

INDICATIONS

There are no absolute indications for venous cutdown, simply because several options for venous access usually exist. The indications for use of the procedure are relative, depending to a great extent on clinician experience and preference. There are several clinical situations in which the venous cutdown may be used.

Venous Access in Infants

Small children present a unique challenge to the clinician who does not perform pediatric venipuncture regularly (see Chapter 19). The challenge is greater still if the procedure must be performed rapidly in a child or infant in shock or in a child in whom few, if any, veins are visible. Other options frequently used include intraosseous infusion or cannulation of the femoral, subclavian, or internal jugular veins. In selected circumstances (e.g., *status epilepticus*), the rectal route of administration, with mucosal absorption, is an effective alternative to cutdown.

A venous cutdown may be performed when all accessible peripheral sites, including scalp veins, have been exhausted. The distal saphenous vein is large enough to cannulate in most children and has a predictable anatomic location. Therefore, venous cutdown at the ankle is commonly used for both emergent management and long-term venous access.[6] [7]

Hypovolemic Shock

Rapid percutaneous insertion of large-bore (14-ga) catheters is appropriate in most cases of hypovolemic shock. Unfortunately, peripheral vessels frequently collapse in hypovolemia or have been rendered useless by IV drug abuse or previous venous catheterization. The venous cutdown is an acceptable alternative in these instances, although percutaneous insertion of a large-bore introducer device into a central vein can usually be performed more rapidly. [8] When the cutdown can be performed quickly, it offers the advantage of direct visualization of the vessel during cannulation.

Use of the cutdown as a vehicle for the insertion of IV extension tubing and rapid transfusion was popularized during the Vietnam War. [9] The technique also has been found useful in civilian practice for the resuscitation of patients with profound hypovolemia. [10] The flow rate for saline through a standard IV extension set (3 mm inside diameter) cut to a length of 28 cm (12 in.) and inserted directly into the vein is >15% to 30% than that through a 5-cm, 14-ga catheter. The difference is greater if pressure is applied to the system. The improvement in flow rate through large-bore lines is greater for blood than for crystalloid solutions, because the viscous characteristics of blood greatly impede its passage through small-bore tubing. [10] A unit of blood can be transfused in 3 minutes using IV extension tubing inserted into the vein. Consequently, large-bore lines placed by venous cutdown are an excellent mechanism for the treatment of severe hypovolemia. High-flow infusion techniques are discussed elsewhere (see Chapter 24).

CONTRAINDICATIONS

Venous cutdown is contraindicated when less invasive alternatives exist or when excessive delay would be required for the procedure to be performed. [12] Although highly skilled operators may perform a cutdown in <60 seconds, [13] studies by Rhee and colleagues, [14] Iserson and Criss, [15] and Westfall and Price [8] have shown that, on average, the procedure requires at least 5 to 6 minutes to complete. The modified guidewire method described both by Shockley and Klofas may decrease that time by 22%. [16] [17] Percutaneous insertion of large-bore catheters is the preferred method of rapid fluid infusion unless high flow rates are required or peripheral vessels have collapsed. Another method of rapid fluid infusion

that is technically easier and faster than venesection is the percutaneous insertion of large-bore introducer devices into the subclavian, internal jugular, or femoral veins (see Chapter 22). These devices typically use 8 Fr catheters with flow rates comparable to those obtained with IV tubing. The use of the subclavian and internal jugular vessels also is preferable to the cutdown for long-term venous access.

Other contraindications are relative. In the presence of coagulation disorders, impaired healing, or compromised host-defense mechanisms, the need to perform a cutdown should be weighed carefully against the potential complications. Cutdowns should be avoided when there is an infection over the site and in extremities with injuries proximal to the cutdown site.

ANATOMY

Detailed knowledge of anatomy is imperative to the success of this procedure. Veins in both the upper and lower extremities may be used. The choice of a particular vein should be governed by its accessibility and size and by the clinician's experience and training. The anatomy of individual vessels and their relative merits as cutdown sites are described as follows.

The Greater Saphenous Vein

The greater saphenous vein is the longest vein and runs subcutaneously throughout much of its course (Fig. 23-1). It is most easily accessible at the ankle but may also be cannulated below the knee and below the femoral triangle. The greater saphenous vein begins at the ankle, where it is the continuation of the medial marginal vein of the foot. The vein crosses 1 cm anterior to the medial malleolus and continues up the anteromedial aspect of the leg. [18] At the level of the malleolus, the vein lies adjacent to the periosteum and is accompanied by the relatively insignificant saphenous nerve, which, if transected, causes sensory loss in a small area along the medial aspect of the foot. At the ankle, the vessel can be exposed with minimal blunt dissection. The vein's superficial, predictable, and isolated location has made the distal saphenous vein the classic pediatric cutdown site. [19]

The saphenous vein lies superficially on the medial aspect of the knee. A cutdown performed 1 to 4 cm below the knee and immediately posterior to the tibia has been described in the pediatric literature. [6] This site is distal enough to avoid interference with the performance of other resuscitative procedures, yet proximal enough to allow the passage of a long line into the central circulation. [20] However, it is seldom used for venous cutdown. Disadvantages of this site include kinking of the line as the knee is flexed and the risk of injury to the saphenous branch of the genicular artery and the saphenous nerve. [21]

In the thigh, the saphenous vein begins on the medial aspect of the knee and crosses anterolaterally as it ascends toward the femoral triangle. Proximally, it enters the fossa ovalis and joins the femoral vein. Three to 4 cm distal to the inguinal ligament, the saphenous vein is of large caliber (4 to 5 mm outside diameter) and is easily isolated from the surrounding fat. Also lying anteromedially in the thigh is the lateral femoral cutaneous vein, which has a smaller diameter (2 to 3 mm) and lies lateral to the greater saphenous vein. [22] [23] The accessibility and large diameter of the greater saphenous

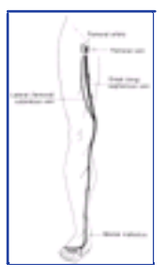

Figure 23-1 Superficial veins of the lower limb.

vein in the thigh make its use an option in the treatment of profound hypovolemia. [10]

The Basilic Vein

The basilic vein is a preferred site for venous cutdown in the upper extremity. Veins of the dorsal venous network of the hand unite to form the cephalic and basilic veins, which travel along the radial and ulnar sides of the forearm, respectively (Fig. 23-2). At the level of the mid-forearm, the basilic vein crosses anterolaterally and is consistently found 1 to 2 cm lateral to the medial epicondyle on the anterior surface of the upper arm. The medial cubital vein crosses over from the radial side of the arm to join the basilic vein just above the medial epicondyle. The basilic vein then continues proximally, occupying a superficial position between the biceps and pronator teres muscles. In this segment it lies in close association with the medial cutaneous nerve, which supplies sensation to the ulnar side of the forearm. The vein penetrates the brachial fascia in the distal third of the upper arm and then occupies a deeper position. [24]

The basilic vein is generally cannulated at the antecubital fossa 2 cm above and 2 to 3 cm lateral to the medial epicondyle. It is exposed through a transverse incision on the medial aspect of the proximal antecubital fossa. The size of this vein enables it to be located easily, even in the hypotensive or hypovolemic patient; large catheters can be passed without difficulty under most circumstances. The median

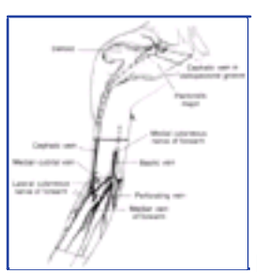

Figure 23-2 Veins of the upper limb.

cubital vein is accessible through the same incision. Superficially at this level, there are no important associated structures, but the brachial artery and the median nerve are found deep to the basilic vein.

A more proximal insertion site has been recommended by Simon and colleagues[25] to avoid the network of interconnecting veins at the level of the antecubital fossa. However, in the distal third of the upper arm, there is a closer association between the basilic vein and the medial cutaneous nerve. Transection of this nerve produces sensory loss on the ulnar side of the forearm.

The Cephalic Vein

This vessel begins on the radial aspect of the wrist and crosses anteromedially, ascending toward the antecubital fossa. In the forearm it lies in close association with the lateral cutaneous nerve, which supplies sensory innervation to the radial aspect of the forearm (see Fig. 23-2). In the antecubital fossa it lies subcutaneously, just lateral to the midline, and then ascends in the upper arm, overlying the lateral aspect of the biceps muscle. At the shoulder the cephalic vein lies in the deltopectoral groove. Just below the clavicle, it passes deep to end in the axillary vein. [24]

Venesection is easily performed on the cephalic vein because of its large diameter and superficial location. In the forearm it is important to avoid the lateral cutaneous nerve. A good location is in the antecubital fossa at the distal flexor crease. Cutdown on the cephalic vein at the wrist has also been reported, but the thin skin overlying the vein at this level usually permits simple percutaneous cannulation when the vein is available for cannulation. [26] The cephalic vein may also be entered in the deltopectoral groove. The slightly deeper position and physical interference with the performance of other procedures make this approach more difficult.

The Brachial Veins

The brachial veins are small, paired vessels lying on either side of the brachial artery. In contrast to the vessels described earlier, these are not superficial and will not

accommodate large cannulas. Their most superficial location is 1 to 2 cm above the antecubital fossa just medial to the biceps muscle. Palpation of the brachial pulse serves as a useful landmark. Because of its proximity, the brachial artery may be inadvertently cannulated in the pulseless patient. In addition, there is the risk of injury to the closely associated median nerve. Time-consuming blunt dissection is usually required because of the vessels' greater depth. For these reasons, brachial vein cutdown is *not recommended* as an emergency venous access route and should be used only in the absence of a suitable alternative. [12] This site may be acceptable when time and vessel size are not critical factors, but it is difficult to justify the deep dissection and associated risks that are involved.

The External Jugular Vein

The external jugular vein begins below the angle of the mandible and is formed by confluence of the posterior auricular and retromandibular veins. It descends posterolaterally across the surface of the sternocleidomastoid muscle and then pierces the fascia to join the subclavian vein deep to the clavicular head of this muscle. The greater auricular nerve, which supplies sensation to the external ear, travels parallel to the external jugular vein. [18] A venous cutdown may be performed on the external jugular vein at its superficial location on the sternocleidomastoid muscle. This is not recommended as a first-line venesection site for the following reasons: (1) Performance of a cutdown may cause physical interference with airway management and central venous cannulation. (2) There is risk of injury to the greater auricular nerve. (3) It is difficult to immobilize the area adequately. (4) Cervical spine immobilization frequently prohibits access to the area. (5) It is potentially a hazardous procedure in the uncooperative patient. [12]

As a general rule, cutdown on the external jugular vein should be performed only when other means of venous access are exhausted. The external jugular vein is an acceptable site for emergency *percutaneous* venous cannulation, especially in children.

EQUIPMENT

The materials required to perform a formal venous cutdown are listed in Table 23-1 . All necessary instruments should be available on a sterile tray before the procedure is begun. The standard cutdown tray is shown in Figure 23-3 . A time-consuming search for the proper instrument can be avoided if only necessary instruments are included on standardized trays. Pediatric patients also require both a warming table or radiant warmer and a padded extremity board.

Catheter choice depends on the desired function of the venous line. When central venous pressure (CVP) monitoring is needed, the catheter chosen must be long enough to reach the superior vena cava. The average distance from the antecubital fossa to the superior vena cava is 54 cm in the adult male. This distance can be approximated by aligning the catheter over the chest with the tip at the level of the manubrial-sternal

junction. Lumen size is relatively unimportant when the line is inserted for monitoring the CVP or to infuse drugs, but it is a critical factor in the treatment of hypovolemia. Short, large-bore catheters are preferred when fluid must be delivered rapidly. Silastic catheters, IV plastic tubing, or 5 or 8 Fr pediatric feeding tubes may be used as infusion catheters in older children and adults.

Table 23-2 Table 23-3 Table 23-4 list the flow rate of various fluids through some commonly used catheter systems. Knowledge of relative flow rates is essential if maximal benefit is to be obtained from the time spent performing the cutdown. Excellent flow rates can be achieved by threading IV tubing (sterile tubing may be cut to the appropriate

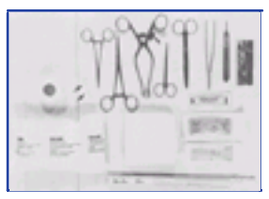

Figure 23-3 Venous cutdown tray. Note the small plastic vein dilator-lifter *(arrows)*, which is especially useful in children.

length—leaving a slight bevel on the end will facilitate cannulation of the opened vein) directly into the vein or by using a 5-cm, 10-ga IV catheter. [4] [13]

TECHNIQUE

The technique of venous cutdown is essentially the same regardless of the vessel cannulated (Fig. 23-4 Fig. 23-5 Fig. 23-6 Fig. 23-7 Fig. 23-8 Fig. 23-9 Fig. 23-10 Fig. 23-11 Fig. 23-12 Fig. 23-13). Detailed knowledge of the local anatomy is important if the procedure is to be performed rapidly without injury to associated structures. For children, adequate immobilization of the lower leg or elbow (depending upon cutdown site) on a padded board should be accomplished before beginning the procedure (see Fig. 23-13). Even in emergency situations, reasonable precautions should be taken to avoid infection. The area of the skin incision should be widely prepared with an antiseptic solution and then draped. A tourniquet placed proximal to the cutdown site helps in the visualization of the vein.

In the conscious patient, the site is infiltrated with 1% lidocaine. A skin incision is made transverse to the course of the vessel (see Fig. 23-4). A longitudinal incision decreases the risk of transecting neurovascular structures but may not provide sufficient exposure. A transverse incision involving all layers of the skin is the best approach. Subcutaneous (SQ) fat should bulge from the incision. The clinician bluntly dissects SQ tissue by spreading the tissue gently with a curved hemostat *in a direction parallel to the course of the vein with the tips downward*. Bleeding is usually minimal unless the vein is nicked. A tissue spreader or a self-retaining retractor may be used to provide a wider field. The vein is

then isolated from the adjacent tissue and mobilized for 1 to 3 cm (see Fig. 23-5).

For the standard venous cutdown technique, after the vein is mobilized, a hemostat can be used to pass proximal and distal silk ties placed under the vein for stabilization. An alternative approach is to simply use the hemostat tips (with no ligatures) in a "spread" position to elevate and stabilize the exposed vein during incision and cannulation. The hemostat is placed as in Fig. 23-7 , only without taking the time to pass ligatures.

If ligatures are passed before cannulation, the distal ligature may or may not be tied after initial placement. If the distal ligature is tied, it should not be cut because the proximal tie is useful in controlling the vein (see Fig. 23-6 and Fig. 23-7). Using a hemostat, the vessel is elevated and stretched flat. This provides good visualization and control of the vessel and limits bleeding when the vessel is incised. Alternatively, placing gentle traction on the proximal tie will control oozing around the puncture site. The vessel is incised at a 45° angle, through one third to one half of its diameter (see Fig. 23-7). A No. 11 blade (as illustrated) or a pair of iris scissors may be used to incise the vessel. Too small an incision may cause threading of the catheter into a false channel in the adventitia; conversely, the vessel may be torn completely and may retract

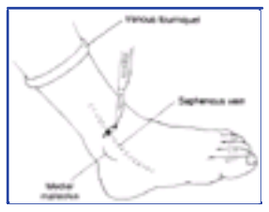

Figure 23-4 A skin incision is made perpendicular to the course of the vein.

from the field if the incision is too large. [27] A longitudinal incision is sometimes made to avoid transecting the vessel, but the lumen is more difficult to identify with this technique. *The vessel incision must enter the actual lumen of the vein*, although some bleeding will occur after the vein has merely been nicked. Incision of the vessel is unnecessary when an IV catheter with an introducing needle is used. The vessel is simply punctured, as in percutaneous venous cannulation (see Mini-cutdown later in this chapter).

Before being introduced into the vessel, the cannula is beveled at a 45° angle unless a cannula with a tapered tip is used. A short bevel is preferred, and a sharply pointed tip is to be avoided because it may pierce the posterior wall or otherwise damage the vein. The rounded tip of a feeding tube may be more difficult to introduce, but it may be advanced less traumatically. If using an IV cannula, the cannula may be introduced directly through the skin incision or through a separate stab wound. The latter method, using an Intracath device, is illustrated in Figure 23-8 and Figure 23-9 . Theoretically, the percutaneous approach reduces the risk of infection. [28] Threading the catheter into the vein is often the most difficult and time-consuming portion of the procedure.

Difficulty in threading may be encountered for several reasons. The lumen may have been incorrectly identified, or a false passage may have been created. This frequently occurs and may be difficult to recognize because the catheter can easily advance between layers of the vessel wall. Other causes of difficult threading are penetration of the posterior vessel wall, the presence of venous valves, or use of a catheter that is too large for the vessel being cannulated. Identification of the vessel lumen may be facilitated through use of a plastic venous dilator or elevator. The small, pointed tip of the device is threaded into the vessel to expose the lumen in advance of

the catheter (see Fig. 23-10). A sterile 20-ga needle bent at a 90° angle may also serve as a vein elevator. A vein dilator is useful in pediatric cutdowns but is generally unnecessary in adults. The clinician can facilitate the threading of large catheters in adults by grasping the proximal surgical edge of the vessel with small forceps or a mosquito hemostat. Countertraction is applied as the catheter is advanced (see Fig. 23-11). At no time should one force a catheter that will not advance.

Once the catheter is advanced into the lumen, air is back-bled from the cannula, and the cannula is connected to

Figure 23-6 Proximal and distal ties are passed under the vein. If the vein is to be sacrificed, the distal suture is tied to prevent bleeding, and the ends are left long to help stabilize the vein during cannulation. The proximal tie is not tied at this point, but traction on it will control back-bleeding. *(From Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

IV tubing. The proximal ligature is tied around the vessel wall and the intraluminal cannula. The tourniquet is now removed, the catheter is affixed to the skin, and the incision is closed (see Fig. 23-12). An antibiotic ointment is applied where the catheter passes through the skin, and the wound is dressed. In an emergent situation, skin closure can be delayed and the wound simply wrapped with a sterile dressing (e.g., Kerlix) (see Fig. 23-13). The IV tubing should be looped under the outer layers of the dressing to minimize the risk of inadvertent removal of the cannula should the external IV line be tugged.

Mini-Cutdown

An alternative method designed to preserve the vein and bypass the time-consuming step of placing a catheter into the vessel has been described. [29] A skin incision and blunt dissection are used to locate the vessel. Once identified, the vein is punctured under direct vision with a standard percutaneous venous catheter. The needle may be introduced through a separate stab incision or through the skin incision. If an over-the-needle device (e.g., Angiocath, Medicut) is used, the

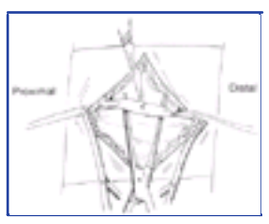

Figure 23-7 The vein is stretched flat and incised at a 45° angle. Approximately one third of the lumen must be exposed. Traction on the proximal tie will control back-bleeding. *(From Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

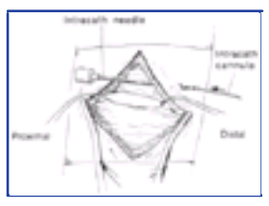

Figure 23-8 Use of the Intracath needle to produce a separate stab incision. The cannula is introduced into the wound by retrograde passage through the introducing needle. *(From Vander Salm TJ, Cutler BS, Wheeler HB: Atlas of Bedside Procedures. Boston, Little, Brown, 1979. Reproduced by permission.)*

needle is withdrawn and discarded. With a through-the-needle device, the cannula is threaded into the vein, and the needle is withdrawn to the skin surface (Fig. 23-14). A guard is placed on the needle tip, the catheter device is fixed to the skin, and the incision is closed. This method eliminates the need for tying or cutting the vein, thereby permitting repeated catheterization. Venipuncture is easier and uses the same equipment as for percutaneous venous cannulation. The mini-cutdown is therefore used in the treatment of chronically ill patients who require long-term IV therapy or in children who have limited accessible veins. A simple skin incision may also permit direct visualization of veins in the obese patient and may facilitate standard percutaneous venipuncture.

Hansbrough and coworkers[4] described the mini-cutdown procedure with a 10-ga IV catheter (Deseret 10-ga Angiocath). The flow rates of blood and saline with this catheter are equal to the rates obtained when IV extension tubing is placed in a vein using the more time-consuming standard venous cutdown technique. This catheter allows one to infuse a unit of whole blood in 2 to 3 minutes if pressure and oversized IV tubing (e.g., urology irrigation tubing) are used.

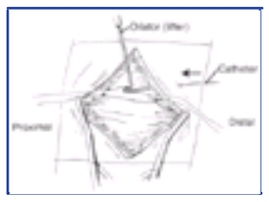

Figure 23-10 Threading the catheter with the aid of a venous dilator (lifter). This is technically the most difficult part of the procedure. The lifter is especially helpful in small veins.

MODIFIED CUTDOWN TECHNIQUE

Shockley and Butzier[16] describe a further modification whereby a guidewire, dilator, and sheath system are inserted following standard cutdown and venotomy. The guidewire, dilator, and sheath system should be set up before making the skin incision. Once the vessel has been incised, the end of the guidewire is inserted, followed by the dilator and sheath. The wire and dilator are then removed, leaving the sheath. They found that ligatures were not usually needed with this technique, and there was increased vessel salvage in the event of transection. In addition, they found this technique to save more than 2 minutes' time over the standard technique when performed by novices. Klofas[17] used a similar technique at the distal saphenous vein. In addition, he developed a model for teaching the modified technique using wood, gauze, cast padding, and tape.

Removal of catheters inserted by cutdown requires only cutting of the skin stitches holding the catheter in place, followed by withdrawal of the catheter. Backbleeding from

Figure 23-11 In larger veins, a mosquito hemostat can facilitate the placement of the cannula by opening the lumen and providing countertraction.

Figure 23-12 The incision is closed, and the catheter is sutured in place.

the proximal venous end is controlled by a simple pressure dressing and is generally not a significant problem.

COMPLICATIONS

The complications of venous cutdown include local hematoma and infection, sepsis, phlebitis, embolization, wound dehiscence, and injury to associated structures. An indirect but significant complication is deterioration of an unstable patient during a time-consuming cutdown attempt. Documentation of complications and their frequency has been sparse. Bogen[30] reported a 15% complication rate in 234 cases. Infection and phlebitis each occurred at a rate of 4%. Infectious complications may result from the introduction of pathogens during line placement, transcutaneous invasion along the course of the cannula, or deposition of blood-borne organisms on the catheter tip.[31] A clear correlation exists between the incidence of infectious complications and the length of time that a catheter is left in place. Moran and associates[32] found that the infection rate rose from 50% to 78% when a catheter was left in place for more than 48 hours. Druskin and Siegel, [31] studying a mixed population of patients who had undergone cutdowns and others who had catheters percutaneously inserted, found that the incidence of culture-positive catheter tips rose from 0 to 52% after 48 hours.[31] In the study by Moran and colleagues,[32] *Staphylococcus albus* was the predominant organism that was isolated, but organisms more commonly thought of as pathogenic (*S. aureus, Enterococcus* spp., and *Proteus* spp.) were isolated with

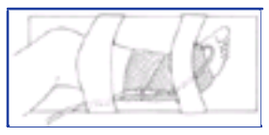

Figure 23-13 The cutdown site is securely dressed and splinted.

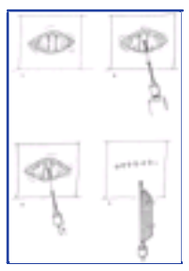

Figure 23-14 The mini-cutdown technique is an alternative to the venous cutdown method. The vein is cannulated under direct vision using standard percutaneous catheters. A separate entry site (shown) may be used, or the vein can be cannulated through the skin incision. Note that the vein is not tied off with this technique. A standard Angiocath IV set also may be used instead of the through-the-needle catheter shown here.

greater frequency from cutdowns that had been in place for long periods. Rhee and colleagues [14] reported a 1.4% infection rate (one episode of cellulitis) following 73 cutdown attempts. All catheters were removed within 24 hours.

There is some evidence that the rate of infectious complications decreases when a broad-spectrum antibiotic ointment is applied to the cutdown site. Moran and coworkers[32] found a rate of infectious complications of 18% when topical polymyxin B-neomycin-bacitracin (Neosporin) was used, compared with a 78% rate in a placebo-treated group. In this study, it was also shown that topical antibiotic use results in only a moderate decrease in the incidence of phlebitis (from 53% to 37%) but a significant decrease in the incidence of phlebitis associated with positive cultures (from 86% to 14%). This suggests that phlebitis is primarily a chemical or an irritative process rather than the result of infection. Whatever the cause, the incidence of phlebitis is clearly related to the duration of catheterization. [9] [30] [33] Early catheter removal is a key factor in the prevention of both phlebitis and the infectious complications of venous cutdown. This is especially true of lines inserted during emergency resuscitative treatment. Such lines should be removed as soon as the patient's condition stabilizes and alternative routes exist. [10] [12]

Proper attention to the details of surgical technique will limit the occurrence of minor complications, such as local hematoma, abscess, and wound dehiscence. One can avoid injury to associated structures by selecting a site in which the vein is isolated and specifically avoiding brachial vein cutdown.

CONCLUSION

The venous cutdown is a time-honored, simple surgical technique that is useful in the management of seriously ill patients. It is an excellent means of venous access in children and in markedly hypovolemic patients. Complications are potentially serious but can be controlled by good surgical technique and prompt removal of the catheter following clinical improvement.

Chapter 24 - High-Flow Infusion Techniques

Benjamin D. Vanlandingham
Kenneth V. Iserson

High-flow infusion techniques date back to the Vietnam War era. During that period, surgeons placed intravenous (IV) tubing directly into veins to facilitate rapid high-volume infusions. Rapid isotonic volume resuscitation following hemorrhage has been promoted as a means to minimize shock-related organ injury and death. [1] Since the early 1990s, laboratory [2] [3] and clinical investigations [4] have raised concerns that overzealous volume resuscitation of patients with penetrating trauma before definitive control of hemorrhage may increase hemorrhage volume and mortality. However, similar laboratory studies have demonstrated that delayed volume resuscitation is associated with increased metabolic acidosis. [5] Regardless of the optimal timing for fluid resuscitation (i.e., either "as soon as possible" or "after control of hemorrhage"), high-volume techniques remain an important therapeutic intervention for patients with significant volume deficits.

A difficulty in describing high-flow techniques is due to a progressive increase in flow rates described as "high-flow." Whereas 1L/hour of isotonic fluid was once considered a rapid infusion, isotonic fluids can now be placed through peripheral IV lines into normovolemic adults with commercially available equipment at rates exceeding 800 mL/min.[6] "High-volume" infusion of crystalloids may be set arbitrarily at >500 mL/min. Massive transfusion of blood has been traditionally defined as transfusion of an amount at least equal to the recipient's blood volume within a 24-hour period. [7] However, with commercially available equipment, the in vitro flow rate of admixed erythrocytes can exceed 800 mL/min through one line.[8] In one case, a patient survived after receiving more than 12 units of blood product per hour for 30 hours.[9]

IMPORTANCE OF TECHNIQUE

Several acute traumatic and nontraumatic conditions (e.g., gastrointestinal bleeding, septic shock, anaphylaxis) require prompt restoration of circulating blood volume. Hypovolemic shock also results in an increase in intravascular capacity, requiring much more IV fluid to be infused than the volume of blood lost. [10] During resuscitation, sufficient intravascular volume (preferably with adequate oxygen-carrying capacity) to supply nutrients for cellular metabolism must be restored. Placement of one or more small bore peripheral IVs may not be adequate when truly rapid volume replacement is required. In addition, it can be difficult and time-consuming to place more than one IV line (e.g., in patients with severe shock, a history of IV drug abuse, fragile veins, massive swelling, or obesity). [11] In these settings rapid high-volume infusion techniques facilitate maximal crystalloid or blood product infusion, or both, through a minimum number of infusion sites.

ROLE OF HIGH-FLOW INFUSION

High-flow infusion may be used by all clinicians, paramedical personnel, and nurses who treat critically ill patients. Trauma patients, patients with gastrointestinal bleeding, and those in septic or anaphylactic shock are prime candidates. The techniques involved are relatively easy to learn, and the equipment is inexpensive and similar enough to that already used for standard IV fluid therapy that no major barriers should exist to using high-flow techniques when indicated.

Some techniques, especially those using the automated external pressurization devices, reduce the time needed for personnel to infuse fluid by conventional IV techniques.[12] Large peripheral IV catheters (i.e., 12- or 10-ga) are not much more difficult to place than the 14- or 16-ga catheters that are routinely recommended. In the pediatric population, a venous cutdown, whether to directly insert IV tubing or catheters, requires a significant amount of time and skill. [13] Although venous cutdown lines (see Chapter 19 and Chapter 23) can be used in conjunction with high-flow infusion systems, cutdowns are not addressed further in this chapter.

INDICATIONS AND CONTRAINDICATIONS

The primary indication for high-volume infusion is hypovolemic shock. Although the infusion may be needed only for a short period until vital signs stabilize, preparations are often made for the necessary equipment to be available "on standby" in case the patient's condition deteriorates again.

Often it is unclear initially whether the patient requires high-volume resuscitation. Despite historical evidence suggesting massive volume loss, patients may be hypotensive for other reasons or may arrive in a volume-resuscitated condition after a prolonged transport with associated volume administration. If any doubt exists regarding the need for high-volume infusion, short, rapid boluses (10 to 20 mL/kg) of fluid can be given and the patient repeatedly reassessed.

The goals of shock resuscitation are to minimize further volume loss and to maintain organ perfusion until the shock-induced pathophysiologic state can be reversed. In hemorrhagic shock, control of ongoing blood loss is essential. When the blood loss is internal, excessive volume resuscitation accompanied by elevation of blood pressure may exacerbate the blood loss preoperatively: The classic clinical example of this phenomenon is the patient with a leaking aortic aneurysm. Hence volume resuscitation must be closely monitored.

Success with rapid IV infusion techniques is often fleeting. Often the goal is to buy enough time to institute definitive operative intervention. Interpretation of the adequacy of fluid resuscitation, at least at the present time, is largely clinical. Evaluation of the entire clinical picture, including vital signs, urine output, peripheral perfusion, and mentation, is necessary to determine the success of infusion therapy. Occasionally, of course, when a thoracotomy has been performed, direct observation of the central circulation allows an accurate determination of the state of vascular filling.

With rapid infusion consisting primarily of crystalloid solutions, patients sometimes have enough blood loss to leak "water" from bleeding sites. This is essentially a visual manifestation of an extremely low hematocrit and indicates a nearly hopeless prognosis. Otherwise, hematocrit measurements are virtually useless in assessing the intravascular status of unstable patients. Some patients, especially younger ones, continue to have enough vascular tone that they appear to stabilize after an initial large bolus of fluid. These patients must be carefully observed and evaluated, because their condition can deteriorate again without warning.

Rapid high-volume infusion is relatively contraindicated in cases of neurogenic shock following trauma. Because the hypotension of neurogenic shock is not due to hypovolemia, hemodynamics do not improve with administration of large amounts of fluid. Rather, the fluid often collects extravascularly and may lead to pulmonary edema. Patients with hypotension secondary to pericardial tamponade may benefit from administration of small, rapid boluses of fluid until a pericardiocentesis or definitive repair is performed, but large volumes of fluid do not appear to be beneficial. Patients whose hypotension is not due to hypovolemia (e.g., those with pump failure or impaired venous return) can be harmed by the fluid overload that would accompany a rapid, high-volume infusion.

EQUIPMENT FOR HIGH-FLOW INFUSION

The key to performing effective rapid infusion therapy and to obtaining the proper equipment is to consider the entire infusion system, rather than individual parts. Each part of the infusion system must be able to meet the desired flow and time requirements. Based on Poiseuille's law, it is the internal diameter (ID) of the system that primarily determines flow rate. The ID affects flow rates to the fourth power, whereas all other elements—length, viscosity, pressure gradient—affect flow only to the first power. Therefore, to obtain a maximal flow rate, the goal is to optimize the ID of all parts of the system. For example, more rapid infusion can occur by increasing the diameter of a small-gauge IV catheter than by starting a second line with another small-ID catheter. [14]

Although some very large experimental catheters, exceeding 4.5 mm (14 French [Fr]) ID, have been developed and used successfully for infusion in humans, [15] [16] large, commercially available percutaneous IV catheters have a maximum ID of 2.16 mm (12-ga, Vygon Mosquito 123) or 3 mm (9 Fr). [17] Theoretically, an IV catheter for rapid fluid replacement should have its maximum ID maintained throughout its length. This means not only that the main portion of the catheter should have a maximum ID consistent with structural stability, but also that the reduction in ID from narrowing at the catheter tip should be minimal. Some catheters lose more than 36% of their ID in this taper. [17]

Poiseuille's law applies to IV tubing as well as to indwelling catheters. Most standard IV tubing for blood transfusions has an ID of 3 mm. [6] [18] Larger tubing is now available, some with an ID of 3.66 (11 Fr) to 4.0 mm. Using even the 3.66-mm tubing can increase flow rate of saline from 70% (12-ga catheter, pressurized) to 126% (8 Fr catheter, no pressure) over rates with the 3-mm tubing. [6] A comparable difference would be expected with blood products.

Even if large-diameter tubing is used, adding small ID extension tubing can negate the benefit of the other system components. If large-ID IV tubing is used, it is essential that similarly sized extension tubing also be available.

In setting up a high-flow infusion system for either crystalloid fluid or blood, all IV tubing must be of the "Y"-type (i.e., there must be at least two attachments for IV bags). This feature allows one bag to be changed while the other is infusing. At the flow rates achieved by rapid high-flow systems, not having Y-type tubing will normally cut the overall system infusion rate by at least half. Y-type tubing is also necessary to admix blood with warmed saline, as described in the following section.

External Pressure Devices

Pressurizing the fluid being infused increases the fluid flow rate dramatically. [6] [11] This can be accomplished by manually squeezing the bags or using commercial pressure devices. [10] The most practical means of adding pressure to a high-flow IV system is with external pressure devices (Fig. 24-1). The standard maximal external pressure exerted by these units is 300 mm Hg. Most centers use pneumatic pressurization with three-way stopcocks. Although easy to use, they do not maintain a constant pressure on the fluid while the bag empties. Other, more elaborate external pressure devices have been advocated, including blood pumps attached to a constant air-pressure source. [19] More recently, these pressurization devices have not only been powered by wall air, but have also been contained in a rigid metal or plastic container for safety, more rapid access, and extremely rapid pressurization and depressurization (Infuser-1 and Alton Dean Infuser, North Salt Lake City, UT). These devices have the advantage of maintaining constant pressure on the fluid bag during emptying. Using the air-pressure devices dramatically decreases the time needed for changing bags, thus enhancing the effective flow rate (Table 24-1). [12] [20]

Blood Warmers

In nearly all high-volume infusions, blood products are administered. Rapid infusion of cold blood (which is stored at 4°C) may be associated with significant complications including ventricular fibrillation and cardiac arrest. [21] [22] Hypothermia is a major, yet often unappreciated problem during the resuscitation of seriously ill patients, particularly those who require multiple blood transfusions. [23] Blood warmers heat blood either before the infusion (prewarming) or during the infusion (in-line). Most commonly available warmers are the in-line type, and most of them significantly slow the flow rates of high-flow systems. [23] [24] [25] Some blood warmers have more rapid flow rates. [26]

Prewarming the blood is cost-effective and simple, requiring less setup time for resuscitation and no special training beyond standard nursing skills. One proposed method for keeping flow rates high while warming blood to approximately body temperature is to dilute the blood with an equivalent volume of 70°C saline. [2] [3] [4] The rapid equilibration of temperatures between the two mixing fluids prevents damage to the erythrocytes. [27] [28] [29] The warmed saline-blood mixture (approximately 37°C) must then be infused rapidly to prevent cooling to room temperature. *All personnel using this technique should be cautioned that the 70°C saline must never be used for direct infusion* (Fig. 24-2).

Figure 24-1 Three types of external pressure devices. *A*, Infuser-1. *(As modified in Iserson KV, Reeter A, Woods W, Criss E: Pressurization of IV bags: A new configuration and evaluation for use. J Emerg Med 3:89, 1985.) B*, Infusable *(Biomedical Dynamics Corp., Minneapolis, MN). C*, Alton Dean infuser *(North Salt Lake City, UT)*.

Unlike commercially available systems, this system permits multiple patients and multiple IV lines in each patient to be infused with warmed blood simultaneously. The only cost is for the single warming oven and the minimal cost of the "Plasma Transfer Sets", i.e., the IV tubes used for each unit (see later).

When transfusing cellular blood products rapidly, it is essential not only to warm the fluid but also to dilute it adequately to reduce the incidence of erythrocyte hemolysis. Cellular destruction in blood flow systems is directly proportional to the magnitude of shear stress and cellular-solid surface interactions. As hematocrit and plasma protein

concentration decrease with dilution, so does the risk of hemolysis. [30] [31]

PROCEDURE

Usually the most difficult part of initiating a rapid, high-volume fluid system is ensuring adequate preparation through in-service training of clinicians and nurses, stocking essential components, and setting up the components to be used. The equipment should be located conveniently close to the patient and within reach of the practitioners.

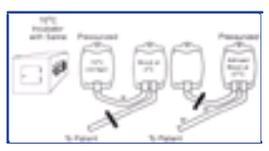

Figure 24-2 (1) During all handling of blood, standard universal precaution procedures should be followed. (2) Remove a 250-mL bag of normal (N) saline from the 70°C incubator. Check the bag for clarity, discoloration, particulate matter, obvious decreased volume, and cracking of the outer wrapper. Do not use if problems are found. (3) Check the incubator thermometer to ensure that its temperature is between 65° and 75°C. Do not use if above 75°C. (4) "Spike" the packed red blood cell (PRBC) unit from the blood bank with one end of a Fenwal plasma transfer set (No. 4C2243). Spike the other end of the transfer set into the 70°C, 250-mL N saline bag. Open the clamp, raise the saline bag above the level of the PRBC bag, and manually squeeze the saline (or use external pressure bag or other external pressure device) into the PRBC bag. (5) A towel or potholder-type kitchen glove may be used to squeeze the 70°C saline bag, if desired. (6) After all of the 70°C saline is transferred into the PRBC bag, tightly close the clamp on the transfer set tubing. (7) Do not remove the transfer set tubing spike from the PRBC bag (to prevent contamination). The now-empty saline bag may be removed from the other end of the transfer set and discarded, or simply left in place. (8) On the patient's side, spike the unused part of the PRBC bag (now admixed with 70°C saline) with one limb of the Y-type blood set already attached to the patient. The admixture temperature will be approximately 37°C. (9) Close the clamp on the other limb of the Y set, which has been infusing standard warm or room-temperature normal saline into the patient. (10) If the blood is to be rapidly infused, pressurize the external pressure bag or device. (11) Open the clamp on the PRBC admixture bag to begin infusion of 37°C PRBC unit into the patient. (12) Additional units of warm-admixed PRBC may be prepared using the same technique. Close the Y set clamp, remove the empty admixed PRBC bag, and replace it with the second unit. Open the clamp and begin infusing the second unit. (13) Infuse the blood into the patient as rapidly as necessary. (14) For each unit of warm-admixed PRBC infused, document in the patient's record that the patient received "1 unit of PRBC admixed with 250 mL of N saline at an infusion temperature of approximately 37°C." Include start/stop times of infusion and the name of the person preparing and administering the infusion. *(From Iserson KV, Knaut MA, Anhalt D: Rapid admixture blood warming: Technical advances. Crit Care Med 18:1138, 1990. © 1990, Williams & Wilkins, Baltimore.)* Following admixture, the infused blood will be between 35° and 40°C. *Cautions:* (1) Keep the blood bag hanging when adding saline. (2) If the blood is admixed, it must be infused or discarded to avoid contamination. (3) Do not mix the blood manually or shake the bag. (4) *Do not* infuse 70°C saline *directly* into patients!

Although new equipment items continue to be developed to assist in high-volume infusion, all items are limited by the same essential principle—the minimum ID of the system must be as large as possible.[15] [16] Equipment that only offers increased pressure, decreased setup and takedown time, or decreased system tubing length should be accompanied by an appropriately large system ID.

Given appropriate preparation, the next challenge is establishing IV access with a large-bore catheter. Catheter placement should proceed with the largest size catheter that can be quickly placed. Even if only a small-bore catheter can be placed initially, it can often be replaced by a larger catheter using the Seldinger technique (see Chapter 22). Furthermore, alternative sites can be sought for a larger-bore catheter as volume resuscitation begins through a smaller-bore catheter. Ideally, a 10- or 12-ga, 9 Fr or larger diameter catheter is placed in either a peripheral or, for central access, femoral vein. Central veins about the neck should be avoided, if possible, because extravasation with rapid flow rates may lead to a large hematoma and possible airway obstruction.

Once one or more catheters are in place, large-bore Y-type tubing, no smaller than 3.66 mm ID, should be attached. If an extension tube is needed, it must have at least as large an ID as the rest of the tubing. Prewarmed 1-L bags of crystalloid solutions (ideally at 37°C) should be initially hung in an external pressure device.

When erythroctye units are available, they can be diluted 1:1 with 70°C preheated 0.9 normal saline. (*Note*: Do not use lactated Ringer's solution, since the calcium causes clotting.) When performing this procedure, use a special system (e.g., Fenwal plasma transfer set, No. 4C2243, Fenwal Laboratories, Deerfield, IL) to guarantee that the hot saline will not be directly infused into the patient (Fig. 24-2).[29] [30] Many types of laboratory incubators can be used for preheating the saline. A constant temperature monitor should be available to ensure adequate heating. According to tests by the manufacturer, bacterial growth within the unopened heated saline units should not occur for at least 2 weeks if the units are left in their overwrap packaging. [28] When the 1:1 dilution is used, the admixed blood is then at approximately 37°C and ready for rapid infusion. Mistakes may be minimized by preheating only one particular-sized bag (250 mL is usually the right amount for diluting the erythrocyte unit) and premarking the bags for dilution with bright orange or yellow tape. Heated saline bags should be discarded if not used after 2 weeks to avoid chemical leaching from prolonged heating. [32]

If a rapid-infusion system is used in one part of an institution, it is essential that other interactive units (e.g., the operating room and intensive care unit) be made aware of it. In addition, any equipment that the other units use in managing critical care patients must be compatible with that used for rapid infusion in the emergency department.

COMPLICATIONS OF HIGH-FLOW INFUSION

The complications of high-volume infusion include all those related to IV access and fluid infusion. Complications specifically associated with high-volume infusion include:

1. The catheter may be misplaced, resulting in large-volume infusion into a closed space, such as the chest or pericardium. Rather than being resuscitated by the rapid fluid infusion, the patient may deteriorate as a result of, and in proportion to, the amount of fluid infused.
2. Excessive fluid may be inadvertently infused. Unfortunately, there is no totally satisfactory way to monitor intravascular volume in the acute setting, and excessive fluid resuscitation is surprisingly easy. Close attention to vital signs, pulmonary status, and urine

output is important. When available, central venous pressure monitoring or, preferably, Swan-Ganz catheter monitoring may be used, but these are generally not available in the acute resuscitation setting.
3. Problems related to massive blood transfusion may occur. The major and most immediate problems include hypothermia (with resultant dysrhythmia) and coagulopathies. These may be ameliorated with the use of warmed blood and the timely use of fresh frozen plasma (see Chapter 29).

The complication rate for high-volume fluid therapy in patients with severe hypovolemia is unknown. Candidates for rapid infusion generally have conditions associated with poor outcomes. Limited information on massive, rapid fluid boluses in otherwise healthy animals suggests that there are few problems that do not resolve once the infusion is stopped.[33] However, in the injured patient, cellular changes accompanying injury (e.g., pulmonary, neurologic) may not allow reversal of fluid-induced changes as easily. Further, concerns have been raised that over-resuscitation may exacerbate hemorrhage through various mechanisms.[2] [3] [4]

If a patient is believed to be overloaded with fluid, normal techniques to reduce the amount of fluid (e.g., stopping the infusion, using diuretics, and appropriately using cardiovascular or respiratory support) should be instituted.

CONCLUSION

Rapid infusion of IV fluids is a common occurrence in the management of acutely ill or injured patients. While enthusiasm for rapid infusion has been tempered by the lack of proven benefits on outcome in hemorrhagic shock studies, its skillful performance remains a requirement of all who treat critically ill patients. Correct performance of rapid IV infusion requires stocking the proper equipment; regularly training personnel; and, perhaps most important, understanding by all involved that flow rate is most affected by the minimum ID component in the system.

Chapter 25 - Indwelling Vascular Devices: Emergency Access and Management

Diann M. Krywko
Pino D. Colone

The use of indwelling vascular lines is becoming an increasingly important component of modern medical care. These lines provide routes for short- and long-term infusion of hyperalimentation fluids, chemotherapeutic agents, antibiotics, blood products, and anesthetic agents. [1] In addition, they provide access for such life-saving procedures as hemodialysis (HD) and plasmapheresis. The increasing complexity of medical care, coupled with an emphasis on outpatient care delivery, has resulted in an increased use of indwelling lines as well an increased likelihood that patients will present to the emergency department (ED) with one of these devices in place. It is estimated that more than 5 million central venous catheters (CVCs) and approximately 386,000 tunneled, cuffed CVCs were inserted in the United States[2] [3] during 1993. Other totally implantable devices are routinely seen in the ED. For the purpose of this chapter all implanted devices or intermediate- to long-term catheters for vascular access will be considered vascular access devices (VADs). Arteriovenous (AV) fistulas and AV grafts will also be discussed due to their similarities to the VADs. It is important that all emergency physicians are familiar with the devices in common use, the best methods to access them in an emergency, and their complications.

HISTORICAL PERSPECTIVE

A major advance, which would ultimately lead to the development of several types of indwelling catheters, was the introduction of Silastic (silicone rubber). This biocompatible material is an ideal substrate for an intravenous catheter as it is chemically inert, antithrombogenic, rigid at room temperature, and pliable at body temperature. In 1973, Broviac and colleagues used this material to develop a 90 cm × 0.22 mm indwelling right atrial catheter for total parenteral nutrition (TPN). [4] This prototype catheter was widely used for hyperalimentation and served as a template for catheters designed for other uses. In 1979, Hickman reported experience with a 0.32 mm catheter that could be used for blood products and drug therapy for recipients of bone marrow transplants. [5] Further modification resulted in the double-lumen Hickman, a fusion of the Broviac catheter [internal diameter (ID) 1.0 mm, external diameter (ED) 2.2 mm], and the Hickman (ID 1.6 mm, ED 3.2 mm). The increased diameter requires cannulation of a large vein, but it allows concomitant infusion of TPN through one port and IV drugs and blood products through the other. Another major advance was the development of totally implantable devices, first described by Fortner in 1972. [6] Since that time they have become a mainstay of treatment in oncology patients. Totally implantable devices allow less painful intravenous access, and improve quality of life by permitting unrestricted mobility.

In addition to their many uses for administration of drugs and blood products, indwelling vascular lines have been used for short- and long-term HD. Temporary access for HD via an external AV shunt was pioneered by both Quinton and colleagues [7] and Scribner and associates [8] in 1960. This original shunt was composed of a loop of tubing lying on the volar forearm connecting the radial artery to a wrist vein. Although it provided effective dialysis, it was associated with a high rate of infection, thrombosis, and restriction of patient activity. Brescia and coworkers [9] then introduced the peripheral subcutaneous (SQ) autogenous AV fistula in 1966. This Brescia-Cimino internal fistula used a side-to-side anastomosis (the current procedure of choice for long-term HD, connecting the radial artery to the cephalic vein in the nondominant hand). Several catheters have been developed for short-term dialysis. Erben and colleagues [10] described routine use of percutaneous cannulation of the subclavian vein for HD in 1969 and in 1979 Uldall and associates [11] reported development of a single-needle, subclavian, HD catheter.

INDWELLING VENOUS ACCESS DEVICES (VADS)

VADs are typically chosen based on the least invasive, smallest catheter with lowest complication risk that will last the length of therapy anticipated. [12] Length of therapy is often the major consideration when choosing a device. Long-term VADs consist of cuffed, tunneled right atrial catheters and implantable ports. Medium-term VADs include midline catheters (lasting weeks), peripherally inserted central catheter (PICC) lines (lasting months), and Silastic subclavian/jugular catheters. Short-term devices (not reviewed in this chapter) include short peripherals, SQ (butterfly), subclavian and jugular catheters, and temporary epidurals. Additional vascular access devices include those used for dialysis, as well as AV fistulas and grafts.

Cuffed, Tunneled, Right-Atrial Catheters (Broviac, Hickman, Hemocath, Leonard, Raaf)

There are several cuffed, tunneled, right-atrial (RA) catheters, each with differences tailored to specific applications. The **Broviac** (Fig. 25-1) is an all-Silastic (polymerized silicone rubber) single-lumen catheter with a 1.0 mm ID. It is 90 cm with a thin intravascular segment (55 cm). The **Hickman**, also a Silastic single-lumen catheter, has a 1.6 mm ID lumen. This allows for more frequent blood sampling without jeopardizing luminal patency. [13] A double-lumen variation of the Hickman also includes a small-bore lumen permitting drug infusion through the smaller lumen while the larger lumen is used for blood sampling and transfusions. [14]

Hemocath/Permacath (Fig. 25-2) has the largest bore of the RA catheters, 2.2 mm ID. Quinton Instrument Co. manufactures it for HD, plasmapheresis, long-term nutritional support, and pain control. Although some clinicians consider cuffed double-lumen HD catheters an alternative to AV shunts and fistulas for long-term HD, [15] the Dialysis Outcomes Quality Initiative (DOQI) panel concluded that the mean technique life span for cuffed tunneled catheters was 1 to 1.5 years. Thus, they should be reserved for bridge access only and discouraged from use as a permanent access. [16]

Figure 25-1 Broviac pediatric single-lumen catheter (4.2 Fr) with Dacron cuff.

Insertion of the RA catheters is typically done in an operating or interventional radiology suite. The device is introduced via the upper anterior abdominal wall and tunneled subcutaneously to enter the superior vena system via the cephalic, subclavian, internal or external jugular veins. The distal tip of the flexible catheter is advanced to the distal superior vena cava (SVC) or into the mid-RA area. The SQ tunnel isolates the venous puncture site from the skin and decreases the potential for bacterial contamination. The Dacron cuffs (one near the venous entrance site and one near the skin exit site) anchor the catheter and are also believed to inhibit colonization of the CVC by skin organisms. [17]

The advantages of an RA catheter include ease of insertion and use, minimal interference with patient activity, low incidence of major complications or unintended dislodgment, ease of removal, and potential repair via a kit. Disadvantages include the need for regular maintenance and the fact that some patients find it cosmetically unacceptable.

Totally Implantable Venous Access Devices (TIVADs)/Ports (Port-A-Cath, Infuse-A-Port, Mediport)

Since 1983, implanted ports have become the mainstay of treatment for long-term cancer therapy. TIVADs are tunneled RA catheters, but differ from Broviac-Hickman catheters in that they have a SQ portal with a self-sealing septum (Fig. 25-3 Fig. 25-4 Fig. 25-5) that may be accessed by needle puncture through intact skin. They require less manipulation and have lower complication rates than other Silastic catheters. [18] Cosmetically, they are superior to external tunneled catheters, require less maintenance, and afford patients greater freedom of movement. Ports are often used when prolonged access is necessary.

TIVADs may be inserted on an outpatient basis under local anesthesia using a SQ tunnel or an open cutdown. Many physicians believe that the cutdown technique offers speed (mean placement time 15 minutes), safety (negligible risk for pneumothorax), and low cost, with avoidance of early and late complications. [19] Placement is typically in the nondominant arm unless there is vein occlusion or planned radiation therapy on the contralateral side. Once inserted, the ideal position of the catheter tip is the junction between the right atrium and the SVC. As with any catheter, incorrect positioning increases the potential for complications, including deep vein thrombosis. [20]

Disadvantages of this type of device include the need for a specific access needle and special training for users of the device, the small gauge (20–22) of the access needle—which limits fluid infusion rates—and the potential for SQ extravasation. [15]

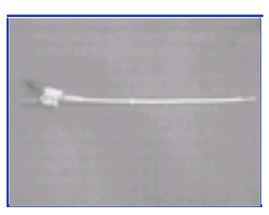

Figure 25-2 Permacath (Quinton Instrument Co.) double-lumen catheter (13.5 Fr).

Peripherally Inserted Central Catheters (PICCs) (Nontunneled, Noncuffed)

PICCs were first described in the 1970s. Their popularity grew immensely in the 1980s. Originally they were developed for the neonatal population, given their small size and minimal invasiveness. [21] Subsequently their use expanded into the adult arena and currently includes prolonged antibiotic therapy, intravenous fluids (IVFs), chemotherapy, TPN, and delivery of medications that are irritating to the peripheral vessels.

PICCs (Fig. 25-6) are made of two substances, either polyurethane (Intracath) or silicone (Intrasil), and are radiopaque, measuring 50 to 60 cm in length with an outside diameter of 2 to 7 French (Fr). The catheter may be single- or double-lumen configuration, and can be open- or close-ended or valved (e.g., Groshong). An open-ended PICC cannot prevent feedback of blood into the catheter and therefore must be flushed one or more times daily with heparinized saline. The Groshong three-way valve reduces blood backup into the catheter and therefore requires flushing as little as once a week. The most common type of PICC line in use today is the 5-Fr, double-lumen, closed-ended catheter.

The device selected should be based on the number of lumens necessary for therapy, recognizing that the potential for infection increases with lumen number. An access site is chosen based on many factors including the suitability of target vessels, the patient's body habitus, handedness, ability to manage self-care, comorbid conditions, the desired infusion rate, the number and compatibility of concurrent infusions, the infusate characteristics, and the estimated duration of therapy. Infusate that is hyperosmolar (TPN) or vesicant requires rapid dilution. As such, the tip must be in the SVC, where the estimated flow is 2000 mL/minute. PICC lines are most frequently placed in the superficial veins proximal to the antecubital fossa (usually the basilic or the cephalic). However, they may also be placed translumbar or

transhepatically when the SVC is thrombosed or occluded.[22]

PICC line advantages include usefulness in a wide variety of clinical situations, and ease of placement, use and maintenance. It is an excellent vehicle for medium-term intravenous therapy.

Midline Peripheral Catheters

Midline catheters are often confused with PICC lines. They are also placed peripherally in the superficial veins of the antecubital fossa or upper forearm. Midlines are typically 20 cm in length, with the tip terminating near the axillary vein. They are designed for short-term use; however, they last longer than a peripheral IV. Since it does not enter the central

Figure 25-3 Norport System single-lumen catheter and specially tapered Huber needle.

circulation with high flow, the delivery of medication types is limited. Differentiating between these two catheters in situ may be difficult, because the outward appearance is similar. Obtaining an x-ray film to determine tip placement will differentiate between the two types of catheters.

Hemodialysis Catheters

Vascular access has been referred to as the Achilles heel of the renal patient. Clinical practice guidelines of the National Kidney Foundation-Dialysis Outcomes Quality Initiative (NKF-DOQI) recommend early AV fistula construction and avoidance of catheters for permanent or prolonged vascular access. [23] However, in a recent study it was demonstrated that more than half of the patients began dialysis using a central catheter because a well-developed AV fistula was not available. [24] The risk of requiring three or more vascular accesses is almost double among patients who start HD using a central catheter. These patients are more likely to present to the ED for problems related to vascular access.

AV Fistula

An autogenous AV fistula is constructed by connecting an artery (usually the radial) to a nearby vein. The radial-cephalic (Brescia-Comino forearm) fistula is the most common choice for initial fistula placement. A secondary choice is the brachial-cephalic—if that is unsuitable, the proximal thigh is a consideration. Over time, the venous portion of the shunt is subjected to high pressure and flow becomes arterialized (hypertrophied and dilated), rendering it suitable for repeated vascular access. Full epithelialization of the shunt does not occur for 3 to 6 months.

An AV fistula is the preferred means of vascular access for HD, yet national data show that only 23% of patients used an AV fistula in 1997. [23] There is a general consensus that the use of the autogenous fistula for vascular access is associated with the longest period of graft patency and with relative freedom from thrombotic and infectious complications. In one study, the mean length of patency was 3.1 years for wrist fistula versus 2.6 years for forearm, with the overall mean length of patency for autogenous AV fistulas being 2.85 years. [24]

AV Graft

If a forearm Brescia-Comino fistula cannot be constructed or has failed, an AV bridge graft using a donor vein or synthetic material is a well-accepted alternative. A standard graft is 6 to 8mm in diameter and usually positioned in a U-shaped SQ tunnel in the forearm. The graft is attached by end-to-side

Figure 25-4 Port-A-Cath double-lumen catheter segment.

anastomoses to the brachial artery and antecubital vein. If no suitable antecubital vein is available, a straight bridge graft between the brachial artery and either the axillary or basilic vein is often used.

Compared with AV fistulas, AV grafts have a significantly higher incidence of thrombosis, infection, pseudoaneurysm formation, and limb loss with a significantly lower mean length of patency.[25] However, they have a low incidence of aneurysm formation and are comparatively easy to revise.

Several synthetic materials are used for grafts with polytetrafluoroethylene (PTFE) being the most common. The estimated life span of a PTFE graft is 3 to 5 years, [26] but in clinical practice is often less than 2 years. [24]

ACCESSING VADS IN THE EMERGENCY DEPARTMENT

In general, when IV access is required in patients with VADs, standard methods of peripheral access should be attempted first in order to preserve the lifespan of the VAD and avoid complications. However, VADs and even AV fistulas and shunts may be accessed in emergency situations for phlebotomy and infusion of medications and fluids. Because of the previously discussed complications of infection and catheter malfunction, dislodgment and fracture, only personnel with the requisite knowledge and skill should access VADs. When VADs are accessed, povidone-iodine and alcohol are acceptable cleansing agents.

The need to administer parenteral medications to patients lacking other means of vascular access is the most common reason to access a VAD in the ED. Assuming that proper access methods are used to prevent infection (described later), the greatest risk associated with medication administration is sludging in the catheter with resultant occlusion. Medications should always be followed by a saline flush both to clear the catheter and to ensure that the medication reaches the circulation. Medications that are known to be incompatible when mixed (e.g., calcium and bicarbonate) should not be administered concurrently, even through separate lumen of multilumen catheters. Taylor and Taylor[27] state that diazepam and phenytoin crystallize irreversibly on contact with the silicone catheter walls of long-term venous access catheters and TIVADs, thereby necessitating catheter replacement. In contrast, the manufacturers of these devices (Evermed, Pharmacia) hold that crystallization does not occur and that the silicone catheter wall absorbs these drugs without damage or the need for removal.

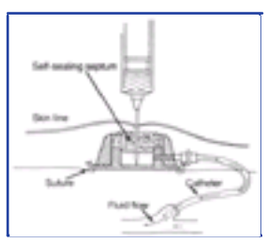

Figure 25-5 Port-A-Cath system (Deltec, Inc., St. Paul, MN). The Port-A-Cath system is accessed by inserting a Huber needle through the skin and portal septum.

Blood specimens including cultures can also be obtained in the ED assuming appropriate access technique is used. Phlebotomy requires stopping infusions, removing fluid occupying dead space in the catheter, and following the blood draw with a flush of heparinized saline.

Accessing Long-Term Venous Access Catheters

The catheter (with the exception of Groshong catheters) is first clamped to prevent air embolism. Patients usually carry their own clamps; however, a hemostat without teeth will suffice. In an emergency, sterile tape or tubing wrapped around the teeth of a hemostat also protects the catheter. The cap is removed, and a 10-mL syringe of sterile water or normal saline is attached. Three to 5 mL of solution are injected and then withdrawn to ensure patency. More pronounced aspiration might be necessary to ensure patency of Groshong catheters. This procedure is done slowly with a syringe at least 10 mL in volume to avoid damage to the cap area. [27]

Phlebotomy is accomplished by withdrawing dead space solution, reclamping, and using a separate syringe to remove the desired amount of blood. [27] Bolus medications are then injected and IV solutions infused through the catheter, which is clamped whenever unattached. A 5-mL normal saline flush should be delivered between medications. On completion, 3 to 5 mL of heparin (100 U/mL) are injected, the line is clamped, and the cap is repositioned. [27] [28] Groshong catheters should not be flushed with heparin but instead should be flushed briskly with 5 to 20 mL of saline.

Accessing Implantable VADS

The procedure for accessing totally implantable VADs is unique, because these devices are not external. Instead, a circular reservoir (cylinder) lies subcutaneously on the anterior chest wall. The cylinder is first palpated, and the overlying skin is prepared with povidone-iodine solution. A 10-mL syringe filled with sterile water or normal saline is attached to connecting tubing, which in turn is applied to a 19- to 22-gauge, 90-degree tapered (Huber) needle. The Huber needle is a specialized needle designed for use with the TIVAD to prevent damage to the portal septum. It has a 90-degree bend with a slightly curved tip, opening on the side rather than on the end. Most importantly, the Huber is a noncoring needle. This avoids damage to the Silastic septum, allowing up to 2000 punctures. The TIVAD should never be accessed with a standard 19-gauge needle unless in a code situation when the Huber is not available immediately. A clamp should be applied to the connecting tubing whenever the system is open. Air is expelled, and the Huber needle is inserted through the reservoir septum. The needle is inserted slowly and steadily through the diaphragm to the back of the reservoir, approximately 1.25 cm (or 0.5 inch) through the dome. [29] Although incomplete perforation of the septum will block flow, substantial pressure also may damage the back of the device and bend the needle tip. The clamp is removed slowly, and 5 mL of solution is injected to ensure patency. If patency is not easily demonstrated, the same measures described under Accessing Long-Term Venous Access Catheters may be used, including positioning, Valsalva maneuver, heparin flush, and low-dose thrombolytic therapy. [27] [28]

Once the solution has been injected, gentle negative pressure is applied to demonstrate the backflow of blood. The Huber needle is then stabilized by building 4 × 4-inch gauze about the needle and further reinforcing with 2.54 cm (1-inch) silk tape. Phlebotomy is performed through the extension tubing after first removing 8 to 9 mL of blood with a separate syringe. IV solutions may also be delivered through extension tubing, although the rate of flow will be limited by the Huber needle's radius. A 5-mL normal saline flush should be delivered between medications. The procedure is completed with a 3- to 5-mL heparin (1000 U/mL) flush [27] and with removal of the Huber needle.

Accessing Percutaneous Multilumen Catheters

Percutaneous multilumen central catheters are used infrequently by outpatients. They are usually placed in the subclavian vein to facilitate patient comfort. One port is available for each lumen, and after povidone-iodine preparation is completed, access is gained by either inserting a needle or syringe into the protective cap or removing the cap entirely. A 5-mL normal saline or sterile water flush and verification of backflow precede all subsequent procedures. Phlebotomy is performed through the proximal 18-gauge lumen to prevent mixture with medications being delivered through the other two ports. The proximal lumen port of the Arrow multilumen catheter is white and is the longest of the three tails. Tails attached to the more distal lumina are blue and brown. IV infusions are delivered in similar fashion, and a normal saline flush is injected between medications. The procedure is terminated with a 3- to 5-mL heparin (100 U/mL) flush.

Accessing Arteriovenous Fistulas, Shunts, and Catheters

AV fistulas, shunts, and Uldall and Manhurkar catheters are placed in patients who require hemodialysis and represent the sole access for that purpose. Consequently, routine use of

Figure 25-6 Double-lumen peripherally inserted central catheter (5.0 Fr, 18 ga).

these sites for phlebotomy and fluid administration is strongly discouraged. In fact, venipuncture in the same extremity as a patent AV fistula is not recommended, except for the veins in the dorsum of the ipsilateral hand. When standard IV access cannot be obtained under emergency circumstances, however, fistulas, shunts, and catheters may all be used to administer IV solutions and medications. If possible, fistula patency should first be ascertained by noting a bruit and palpable thrill, although these signs may not be appreciable if the patient is in extremis.

Prepare the area overlying the fistula with povidoneiodine solution and access the fistula with the smallest gauge needle appropriate to the task. [30] Puncture 1 to 2 cm from the anastomosis ends nearest the venous side, and avoid aneurysmal sites. [30] When complete, monitor the area for hemorrhage, and apply local pressure to avoid significant bleeding. AV shunts are accessed similarly by placing the smallest needle possible into the catheter, bridging arterial and venous circulations. Local pressure should be applied for 5 minutes after completing the procedure. Uldall and Manhurkar catheters are used in much the same way that multilumen central catheters are accessed. The retaining cap on each arm may be either removed or injected. Up to 5000 U of heparin are present within the two lumen, and so it is imperative that aspiration be performed before administering fluid or medications. After use, flush each catheter arm with 10 mL of normal saline and instill 1.5 mL of heparin solution (1000 U/mL) into each catheter arm.

COMPLICATIONS OF VADS

The use of VADs is now sufficiently commonplace to ensure that patients with these devices will present to the ED on a regular basis. Given a complication rate of 4% to 10%,[31] it is essential that emergency clinicians be aware of these complications and their management. Fifty-two percent of reported complications are associated with health care practitioner technique; 12% are associated with device failure; 6% are related to actions taken by the patient, as well as pathophysiologic events (such as thrombosis); and 30% have an unidentified cause. [32]

Complications of VADs include (1) infection, (2) clotting abnormalities, (3) malfunction, and (4) miscellaneous problems (Table 25-1).

Infection

Infection is the most common complication leading to CVC removal and potentially the most serious. Once the organisms

TABLE 25-1 -- Complications of Indwelling Vascular Access Devices

Infection	Coagulopathy	Malfunction	Miscellaneous
Skin/exit site	Bleeding	Occlusion	Embolism
Reservoir/pocket	Local puncture site	Medication delivery failure	Air
Tunnel	Arterial bleeding	Precipitants	Thrombus
Catheter tip/lumen	Over-heparinization	Thrombosis	Catheter
Sepsis	Heparin rebound	Failure to infuse/withdraw	Fragment
	Thrombosis	Pinch off syndrome	Arrhythmias
	DVT	Steal syndrome	Cutaneous dacron
	Fibrin sheath	Malposition	Cuff erosion
			Catheter dislodgment

DVT, deep venous thrombosis

spread beyond the confines of the device itself, the danger to the patient increases significantly, with an estimated case fatality rate of 10% to 20%. [24] With each access there is potential for local, device, or generalized infection with subsequent line failure. The definitions of CVC-related infections are not uniform, making it difficult to compare results of various investigations. However, it is generally agreed that risk factors for infection include site of insertion; hospital size; duration of catheter placement; type of catheter; and patient factors. Most studies show a lower incidence of infection for completely implanted CVCs than for external systems, presumably due to lack of direct access of cutaneous organisms with TIVADs. The rates of CVC infection tend to be highest in the first 3 months following insertion, with skin flora being most common.[31] [33] The rate of infection decreases significantly, reaching a plateau after 5 to 6 months. [33] The most common infecting organisms are listed in Table 25-2 .

Clinical findings are unreliable in the diagnosis of infection secondary to VADs. Fever, rigors, and elevated white blood cell count may be sensitive but not specific, whereas purulent drainage at the insertion site may be specific but not sensitive. Therefore, evaluation beyond physical examination alone is essential when infection is suspected, including blood cultures, possibly catheter segment culture, and transesophageal echocardiography if valvular vegetations are suspected (*Staphylococcus aureus*, persistent bacteremia or fungemia post-catheter removal, or lack of clinical improvement).

TABLE 25-2 -- Microorganisms Causing Indwelling Catheter Infection

Bacterial	
Gram-positive cocci	*Staphylococcus aureus, Staphylococcus epidermidis, Streptococcus faecalis, Streptococcus bovis,* group C streptococci, and viridans streptococcus
Gram-negative bacilli	*Pseudomonas aeruginosa, Klebsiella* sp., *Acinetobacter* sp., *Serratia* sp.
Gram-positive bacilli	*Bacillus cereus, Bacillus laterosporus, Corynebacterium* sp.
Atypical	*Mycobacterium neoaurum, Mycobacterium fortuitum, Mycobacterium chelonae*
Mycotic	*Malassezia furfur, Malassezia pachydermatis, Aspergillus fumigatus, Aspergillus flavus, Candida albicans*

Two sets of blood cultures are typically drawn, one set through the catheter itself and one from a peripheral site. Positive blood cultures for *S. aureus*, coagulase-negative staphylococci, or *Candida* species, in the appropriate patient setting and in the absence of another identifiable source of infection, should increase the suspicion for catheter-related bloodstream infection. [31] When blood obtained from a CVC yields a colony count at least 5- to 10-fold greater than that for blood obtained from a peripheral site, this suggests a catheter-related source of infection. [34] Similarly, catheter infection should be assumed if the peripherally derived blood culture are negative and the CVC-derived cultures are positive. [33] Not only is blood drawn from the catheter more likely to yield a positive culture, this may occur earlier in the course of infection. One study demonstrated 16 of 17 patients with CVC-related infections had positive blood culture results at least 2 hours earlier from the CVC than from peripheral blood cultures. [35]

Infusate-related bloodstream infection is uncommon and is defined as the isolation of the same organism from both infusate and separate percutaneous blood cultures, with no other source of infection. When this diagnosis is suggested, cultures of the infusate should be obtained in addition to catheter and peripheral cultures.[31]

Although it has been common practice to immediately remove a CVC in the setting of acute infection, the need for removal has been called into question. [35] The CVC should be removed and cultured if the patient is immunocompromised or severely ill (e.g., sepsis, shock) or if there is purulent discharge or erythema of the catheter exit site. The CVC should also be removed in a patient with sepsis and without other source of infection. If blood cultures are positive, or if the CVC is changed over a guidewire and has significant colonization, the catheter should be removed and cultured, and a new catheter should be placed at a new site. Without evidence of persistent bloodstream infection, or if the infecting organism is coagulase-negative *Staphylococcus* and there is no suspicion of local or metastatic complications, the CVC may be left in place.[31]

If a CVC is removed, it should be cultured to determine the offending organism. The most widely used laboratory technique for the clinical diagnosis of catheter-related infection is the semiquantitative method, in which the catheter segment is rolled across the surface of an agar plate and colony-forming units (CFUs)

are counted after overnight incubation. Quantitative culture of the catheter segment requires either flushing the segment with broth, or vortexing in broth, followed by serial dilutions and surface plating on blood agar. A yield of 15 CFUs or more from a catheter, by

semiquantitative culture, or a yield of 10[2] or more from a catheter by quantitative culture, with accompanying signs of local or systemic infection, is indicative of catheter-related infection.[31]

HD catheters deserve special consideration. The process of HD requires several connections to the graft, thereby increasing the risk of infection. The rate of bacteremia in HD patients attributed to the graft varies from 48% to 73%. The incidence is highest when central venous dialysis catheters are used. Native AV fistulas carry the lowest risk of infection. Unfortunately, prosthetic AV fistulas (i.e., prosthetic grafts) are more commonly used in the United States. [36] As with other CVCs, empirical antibiotic therapy should be initiated based on epidemiologic and patient factors, followed by narrowed spectrum after isolation and determination of sensitivities. The most common infecting organism is *S. aureus*. There has been an association between nasal carriage of *S. aureus* in hemodialysis patients and catheter infection. Reduction of carriage rates has resulted in a decreased incidence of bloodstream infections. [31]

Antimicrobial Therapy

Pending culture results, the initial choice of an antibiotic is empirical and depends on the clinical setting, the site of infection, type of device, host factors (e.g., immunocompromised state), severity of illness, and whether or not the device is removed. There are not compelling data to support either the choice of a specific empirical antibiotic or duration of therapy for device-related infections. [31] If *coagulase-negative* staphylococcus is the suspected organism, empirical vancomycin should be initiated, followed by semisynthetic penicillin or other appropriate antibiotics as guided by sensitivity studies. When *S. aureus* is the suspected organism, b-lactam antibiotics (e.g., penicillins, cephalosporins, carbapenems, and monobactams) should be first-line therapy. In penicillin-allergic patients or those with methicillin-resistant *S. aureus* (MRSA), vancomycin is the drug of choice. Vancomycin is typically recommended in areas of significant rates of MRSA, followed by a semisynthetic penicillin. In absence of significant rates of MRSA, penicillinase-resistant penicillins, such as nafcillin or oxacillin, should be used. Additional coverage should be initiated in immunocompromised or severely debilitated patients. This should include coverage for enteric organisms as well as *Pseudomonas aeruginosa*, with a third- or fourth-generation cephalosporin (e.g., cefoperazone, ceftazidime, cefepime) or an aminoglycoside. With infections involving gram-negative bacilli, quinolones with or without rifampin should be instituted for 14 days. If fungemia is suspected or confirmed, initiation of antifungal and catheter removal is imperative. Parenteral amphotericin B should be initiated for patients who are hemodynamically unstable or who have received prolonged fluconazole. Fluconazole should be initiated when patients are hemodynamically stable and have not had recent therapy with fluconazole, or those with a fluconazole-susceptible organism. Duration of therapy should continue for 14 days following the last positive blood culture and evidence of clinical improvement. [31] [33] [36] [37] [38]

There are variable recommendations regarding exit site/tunnel/pocket infections. [31] [33] Jones recommends aggressive local care in the early stages and use of topical antibiotic ointment for short-term treatment, adding that long-term treatment should be avoided due to the risk of *Candida* colonization.[33] Mermel and coworkers, however, recommend that in patients with complicated infections, such as tunnel infection or port abscess, catheter removal is required and antibiotics should be initiated for 7 to 10 days.[31] There are not sufficient data to make strong recommendations regarding a strict duration of antibiotic treatment; however, there are generally agreed upon ranges of therapy. [31] [33] [37] Patients who are not immunocompromised and in whom there is no evidence of complication (e.g., endocarditis, septic thrombosis/emboli, osteomyelitis) should receive antibiotics for 5 to 7 days if the catheter is removed, and 10 to 14 days if the CVC is retained. Those with persistent bacteremia or fungemia after catheter removal should be treated for 4 to 6 weeks. Those who develop complications should be treated for 6 to 8 weeks. [31] If the CVC is retained, antibiotic lock therapy (ALT) should be considered.

ALT is a promising area of research in CVC-related infections. Most infections in tunneled catheters originate in the hub and spread to the catheter lumen. This, combined with the deposition of fibrin, makes eradication of organisms difficult. ALT involves filling the catheter hub and lumen with a higher concentration of antibiotics and leaving them in place for extended periods of time. Studies have suggested that ALT alone may be as effective as parenteral antibiotics followed by ALT. The duration of ALT is most often 2 weeks.[31] Some recommend the use of prophylactic vancomycin lock solutions as a beneficial and cost-effective method of preventing infection in long-term tunneled and cuffed CVCs.[39]

Thrombolytics (e.g., streptokinase, urokinase) were initially considered promising in conjunction with antibiotic therapy for intraluminal catheter-related infections due to fibrin deposits that develop over time and provide a nidus of infection. These have not been shown to be beneficial, however. [40] [41]

Prophylactic Measures

Antibiotic prophylaxis during initial line insertion.

Prophylaxis with vancomycin or teicoplanin during central line insertion has not consistently demonstrated reduced incidence of catheter-related bloodstream infection. Based on the limited available data, the Centers for Disease Control and Prevention guidelines currently recommend against prophylactic use of vancomycin because it is an independent risk factor for the acquisition of *Vancomycin-Resistant Enterococcus (VRE)*,[39] and more recently, staphylococci with reduced susceptibility to glycopeptides. One study showed a reduced infection rate when vancomycin was used to flush solutions or TPN, [42] although this beneficial effect was not demonstrated in a subsequent study.[43] Rather than use antibiotic prophylaxis, it is recommended that efforts focus on interventions that are not likely to encourage the emergence of antimicrobial resistance, such as maximal barrier precautions.[43]

Impregnated catheters.

The use of antimicrobial or antiseptic impregnated catheters or silver impregnated collagen cuffs may be an effective intervention to reduce CVC-related bloodstream infection. Hanley and colleagues reported beneficial results with triple-lumen catheters in an intensive care setting. [44] These findings may be applicable to long-term tunneled or nontunneled catheters, as well as AV fistulas, but further studies are necessary. Nonetheless, the Hospital Infection Control Practices Advisory Committee of the CDC has made use of these devices a category II recommendation.[44]

Routine line changing.

Despite the incidence of infection and the potential complications, routine changing of CVCs is not recommended. [45] Cobb and coworkers found that

replacement of CVCs every 3 days did not prevent infection, and, in fact, doing so over a guidewire increased the risk of bloodstream infection. [45]

Coagulopathy

Bleeding may be seen with any indwelling CVC or AV fistula, but is more commonly seen with nontunneled CVCs or temporary dialysis catheters. It is often related to preexisting or transient thrombocytopenia, drug- or uremia-induced platelet dysfunction, trauma, infection, heparinization, or heparin rebound. [46] Treatment includes direct pressure for 5 to 10 minutes, supportive measures, and correction of the underlying cause. If bleeding stops, the patient should be observed for 2 hours for evidence of rebleeding and to detect graft thrombosis. If bleeding cannot be controlled by direct pressure or with thrombogenic agents (e.g., Surgicel, Oxycel), consider IV protamine. The dose of protamine is 0.01 mg per unit (U) of heparin, or 10 to 20 mg for 1000 to 2000 U of heparin. Laboratory studies should include hemoglobin, platelet count, prothrombin time/partial thromboplastin time (PT/PTT), and blood urea nitrogen. If uremic platelet dysfunction is present, consider desmopressin or cryoprecipitate.[30] If possible, consult with the patient's nephrologist or vascular surgeon, given the potential for thrombus formation with the administration of protamine and the need for close follow-up.

There are conflicting data in the literature regarding a bleeding phenomenon know as "heparin rebound." It is unclear whether this occurs after a single administration of heparin or whether it requires repeated exposures to heparin as in dialysis patients. It may account for episodes of post-dialysis bleeding that are seen in the ED.

Heparin rebound is most likely to occur in dialysis patients, who, because of being at high risk for bleeding, have heparin continuously infused into the dialyzer inlet line and protamine sulfate into the outlet line. Thus, only the blood in the extracorporeal circuit is anticoagulated. When the inactive heparin-protamine complexes are metabolized during the hours post dialysis, active heparin may be released into the patient's circulation. This rebound effect may be seen up to 10 hours post dialysis.[46] Experts explain it as an increase in thrombin activity following a discontinuation of heparin [45] [47] or as a reappearance of anticoagulant activity after adequate neutralization of heparin with protamine. [27] [48] [49] [50]

Thrombus Formation

It has been estimated that from 2% to 42% of CVCs are associated with deep venous thrombosis (DVT). [20] Numerous risk factors have been established for catheter-related DVT, including the composition, diameter and position of the CVC, elevated intraluminal pressure, turbulent blood flow, vascular calcification, endothelial injury, and increased levels of fibronectin. [20] [51] Polyurethane and silicone catheters have a lower rate of CVC-related DVT than polyethylene or Teflon-coated catheters. An external diameter of less than 2.8 mm is also associated with a lower incidence of DVT. Incorrect placement of the CVC in the SVC, as opposed to the junction of the SVC and the right atrium, results in a higher incidence of catheter-related DVT. [20]

DVTs may be asymptomatic or may not be recognized due to the underlying condition of the patient. Luciani and associates found that upper-extremity DVT was relatively common, occurring in 11.7% of their patient population, the vast majority of whom (76%) were asymptomatic. [20] They recommend routine Doppler screening for at least the first 3 months after catheter placement. Pulmonary embolism can occur with the catheter in place as well as days to weeks after its removal. [52]

Most HD access failure (80% to 85%) is related to thrombosis, with 85% to 90% of these thromboses associated with venous outflow stenosis. [16] Histologically, hyperplasia of the endothelium and fibromuscular vessel wall also occurs. Over time, fibrin deposits build up on the tip of the CVC. This may continue to the point of occlusion, preventing infusion or aspiration from the CVC. Oftentimes, early detection may be enhanced by a high index of suspicion, noting prolonged bleeding post cannula withdrawal or a change in the bruit over the device, or both. Prompt consultation with a nephrologist and vascular surgeon is indicated. Systemic heparin or local thrombolytic agents, such as urokinase (both in bolus fashion, and in continuous infusion), may be tried. The clinician should be familiar with local institutional recommendations for thrombolysis in the setting of recent CVC occlusion attributed to a fibrin plug. Atkinson and colleagues reported good response with urokinase and follow-up tissue plasminogen activator (t-PA) when urokinase failed. [53] The initial treatment was 2 to 3 mL of urokinase (5,000 U/mL). Catheters remaining occluded received 2 mL of t-PA (1 mg/mL). The t-PA was repeated once if needed.

Embolization

A serious but comparatively uncommon complication of CVC use is embolization with either air, catheter fragment, or thrombotic emboli. [54] [55] [56] Air emboli develop when the catheter lumen is left open to air or the catheter is fractured, perforated, or cut. Care must be taken to maintain a closed system by clamping the catheter appropriately to prevent the delivery of air into the venous circulation. The externalized portion of a right atrial catheter may be accidentally cut [37] or perforated during clamping, especially if an improper clamp is used. [57] Should this occur, an appropriate clamp must immediately be placed between the damaged portion and the skin (except for Groshong catheters). [27] Air embolism is suggested by an open or damaged catheter in association with tachypnea and hypotension. [58] The patient must be placed in a left lateral decubitus and Trendelenburg position (to reduce ventricular outflow obstruction by air pockets), and supportive measures including high-flow oxygen should be initiated. Attempt at catheter repair may be made if a repair kit is available and the operator is familiar with the technique (Fig. 25-7). Repair kits that contain silicone adhesive, plastic clamps, injection caps, and a 12 Fr catheter replacement segment (e.g., Evermed) are available for externalized catheters.

Embolization of catheter thrombi may occur during flushing and injection of solutions. Anderson and colleagues [59] prospectively evaluated the size and frequency of catheter thrombi in 43 patients by aspirating after a urokinase flush. Clots were noted in 40 of 43 subjects and 153 of 508 total specimens. Thrombi varied in size from small fragments to 5 cm in length. Haimov[28] reported no clinical pulmonary emboli after heparin flushes in 70 patients; however, Zureikat and associates reported 1 case of pulmonary embolus associated with Broviac catheterization in a 2-month-old. [52]

Embolization of a catheter fragment is a potentially life-threatening complication causing acute dyspnea, palpitations,

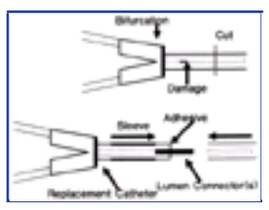

Figure 25-7 Catheter repair. A hollow lumen connector and outer sleeve are placed to splice a replacement catheter to the remaining catheter segment.

atypical chest pain, hypoxia, and atrial fibrillation. Sequelae of catheter fragment embolization include sepsis, lung abscess, dysrhythmias, vascular or cardiac perforation, and sudden death. [55] Catheter fragments are identified radiographically, and may be removed either surgically or using intravascular retrieval methods. Neumann and colleagues reported aid of transesophageal echocardiography to visualize the catheter. [60]

Catheter Displacement

Catheter displacement may occur accidentally secondary to patient movement or iatrogenically, or both. Harvey and colleagues [49] reported two cases of Hickman catheters being withdrawn accidentally by patients. Chardavoyne and coworkers [50] described a similar case in which a TIVAD (Infuse-A-Port) spontaneously withdrew from the central circulation after documented placement. Care must be taken when handling both long-term venous access catheters and TIVADs, especially in active patients.

Catheter Occlusion

Catheter occlusion or low flow may be caused by improper positioning, kinking or compression of the catheter, intraluminal thrombi, extraluminal thrombi, or fibrin deposits at the catheter tip, and by intraluminal precipitation of infusate. "Pinch off syndrome" occurs when the line (most often a PICC) is compressed between the clavicle and the first rib. [36] Maneuvers to facilitate flow include the Valsalva maneuver, the reverse Trendelenburg position, slight tension on the catheter, IV hydration, and extension of the arms above the head. [27] [61] Overzealous withdrawal on the syringe will collapse the catheter and make demonstration of patency difficult. If these measures are unsuccessful, instilling 3 to 5 mL of heparin followed several minutes later by gentle aspiration is often successful in dislodging a clot. Use of urokinase is a reasonable next step. One milliliter of urokinase (5000 U) may be injected and aspiration attempted after a 10-minute interval. A urokinase flush has been reported to successfully open lines in 95% of cases. [28] Atkinson and colleagues have advocated an initial treatment with 2 to 3 mL of urokinase (5000 U/mL). [53] If the urokinase failed to resolve the occlusion, they administered 2 mL of t-PA (1 mg/mL). The t-PA was repeated once if needed.

Catheter Fracture

Fracture of a VAD can occur either subcutaneously or in the externalized portion. [29] Subcutaneous fractures cause localized pain and swelling and require line removal. Fractures in the externalized portion may be repaired using commercially available kits (see Fig. 25-7).

Subclavian Steal

"Vascular steal syndrome" is an uncommon (1% to 3% incidence) but serious complication of AV fistulas that is difficult to predict and often leads to graft failure. It occurs because of a preferential flow through the low-resistance fistula at the expense of the distal circulation. The syndrome is manifested by pain, pallor, numbness, motor weakness, and diminished or absent pulses distal to the fistula [62] and may also manifest as intermittent claudication. [63] Symptoms may be precipitated by dialysis owing to lowered systolic blood pressure or P_{O_2} . [64] They must be differentiated from the nonspecific complaints of diabetic or uremic neuropathy as they may lead to the development of irreversible neuromuscular dysfunction and tissue necrosis. The recognition and prompt correction of hand ischemia would lead to increased salvage and utilization of functioning fistulas. There is no reliable method to predict the development of steal syndrome after construction of a fistula. [62]

Severe cases of steal syndrome require ligation or removal of the vascular access device.

AFTERCARE INSTRUCTIONS

Before release from the ED, each patient should be instructed regarding proper catheter care to prevent complications and prolong the device's lifetime. [27] Patients may bathe and swim normally; they should avoid direct pressure on the reservoir and report local bruising or bleeding immediately.

Long-term venous access catheters and multilumen catheters should be dressed in sterile fashion and observed daily for bleeding and signs of infection, which include fever, pain, redness, swelling, and purulent drainage. VADs should be gently flushed on a routine basis. [27] Heparin flushes are essential to prevent thrombosis. Tunneled (e.g., Hickman) and nontunneled (e.g., PICC) catheters require flushing twice weekly with 5 mL of heparin (10 U/mL). TIVADs require heparin flushing every 4 weeks. Generally, Groshong catheters are flushed with 5 mL of saline once weekly. Manhurkar and Uldall catheters are "flushed" during dialysis. Manhurkar catheters also are used for phoresis, in which case they are treated three times a week with normal saline and heparin, as outlined earlier. Signs of infection and any inability to flush any indwelling catheter should be reported immediately to a physician.

SUMMARY

Numerous vascular access devices are currently available for long-term patient care, including tunneled, cuffed, right-atrial

catheters, PICC lines, midline catheters, and AV fistulas and grafts. These devices potentially provide the emergency clinician with circulatory access to a large, high-risk patient population in a relatively safe and painless manner. However, many life-threatening risks, including hemorrhage, thrombosis, and sepsis are inherent in accessing these devices. A thorough knowledge of the various access devices and the potential complications will adequately equip the provider to minimize these risks, ensuring decreased patient and catheter morbidity and mortality.

Chapter 26 - Intraosseous Infusion

Rachel Stanley

Establishing vascular access in a critically ill or injured pediatric patient can be one of the most difficult and frustrating procedures a clinician has to perform. From a procedural or logistical standpoint, it is simply not possible to rapidly establish adequate vascular access for all ill children. In a review of intravascular access in pediatric cardiac arrest, the mean (± SD) time needed to establish venous access was a disappointing 7.9 ± 4.2 minutes. [1] Although peripheral percutaneous venous access was the fastest method noted in the review (mean time, 3.0 minutes), it was successful in only 17% of cases. Success rate was highest for an intraosseous (IO) infusion (83%), followed by surgical cutdown (81%), and central venous catheterization (77%). The mean time required to obtain a functioning IO line was 4.7 minutes, followed by 8.4 minutes for a central line, and 12.7 minutes for a cutdown. Another study of emergency department (ED) pediatric arrests demonstrated failure to gain intravenous (IV) access entirely in 6% of the patients. [2] Clearly, in the real world these times will vary according to institution, clinical scenario, and experience of the operator.

Small peripheral vessels in children often collapse during shock, and the child's increased body fat makes peripheral cannulation time-consuming and at times impossible. Central venous cannulation can be equally difficult and carries the risk of pneumothorax or arterial injury. Alternative routes for drug administration, such as the endotracheal and rectal routes, may not provide rapid, reliable drug absorption during cardiac arrest. For example, epinephrine administered by the endotracheal route, although effective in a normally functioning cardiovascular system, is poorly absorbed and produces minimal physiologic response when administered during cardiac arrest. [3] [4]

In other emergency situations such as air and ground transports of severely compromised patients and mass casualties (situations from accidents, fires, or explosions), it may be difficult or impossible, even for experienced professionals, to gain IV access in children or adults. In these situations where obtaining rapid vascular access is essential, the IO route is indicated. The American Heart Association, the American Academy of Pediatrics, and the American College of Surgeons recommend vascular access via the IO route in emergency situations in children when venous access is not immediately possible. [5] [6] In addition, recent studies suggest this approach may also have a place in the management of premature infants, term neonates, and extremely ill or injured adults. [7] [8] [9] [10] [11] [12] [13] At this juncture there is no universally accepted standard of care promulgated for IO access in the general medical community, but its use is becoming more familiar to many clinicians outside the pediatric critical arena.

IO access is not, however, universally successful. Studies using the IO route in acutely ill children and adults have demonstrated that success rates are highest (85%) in children younger than 3 years old and lowest (50%) in children older than 10 years and in adults. [14] The main causes for failure were errors in landmark identification and bending of the needles. The difficulty with needle penetration has been overcome by the Bone Injection Gun (BIG) (Wais Medical, Tri-anim, Sylmar, CA), a spring-loaded device designed to penetrate adult bone, and First Access for Shock and Trauma ([FAST], Pyng Medical Corporation, Vancouver, BC, Canada), a device designed to penetrate the sternum. [15] This device is not widely used at this time but may hold promise if its benefit can be verified in the routine ED setting.

BACKGROUND

One of the earliest references describing the IO route was by Drinker and colleagues, who in 1922 examined the circulation of the sternum and suggested it as a site for transfusion.[16] The route was not used clinically until 1934 when Josefson, a Swedish clinician, administered liver concentrate into the sternum of 12 adult patients with pernicious anemia and reported that all 12 improved.[17] Subsequently, the technique became widespread in Scandinavian countries.

In 1940 the technique was introduced to American clinicians by Tocantins, who described a series of animal and clinical studies that demonstrated fluid was rapidly transported from the medullary cavity of long bones to the heart. [18] [19] He recommended using the manubrium sternum in older children and adults and the upper tibia or lower femur in children age 3 or younger. [19] [20] Over the next two decades, thousands of cases of IO infusion of blood, crystalloid substances, and drugs were reported.[21] [22] [23] The procedure was more commonly used in children because of difficulty with other forms of IV access. Nevertheless, during the 1940s IO infusion was also used extensively in adults, and a sternal puncture kit for bone marrow infusions was a common component of emergency medical supplies during World War II.[8] [24] During this time relatively few complications were reported, considering the needles were often left in place for 24 to 48 hours. Heinild and coworkers in 1947 reviewed 982 cases of IO infusion and reported only 18 failures and 5 cases of osteomyelitis. None of the cases of osteomyelitis occurred in patients who received isotonic solutions.

With the introduction of plastic catheters and improved cannulation techniques, the need for IO infusion as an alternative route for IV access diminished, and the technique was all but abandoned. It was not until the mid-1980s that the technique was reintroduced in response to the need for immediate vascular access during cardiopulmonary resuscitation (CPR).[2] [25] Since then, the technique has become widespread throughout the United States and is recognized as an accepted alternative to IV access in pediatric emergencies and, increasingly, in neonatal and adult emergencies. In addition, the safety, ease, and effectiveness of the technique have led to its use for prehospital emergency care. [14] [26] [27] [28]

In addition to the FAST and BIG devices, described earlier in this chapter, a much broader selection of needle types and sizes has made IO access easier and more successful in children and adults.[8] Today, IO devices are available in most trauma rooms and prehospital environments, and have recently been reissued to medical elements of the U.S. military.[8]

and rapidly transporting fluids or drugs to the central circulation. The bone, like most organs, is supplied by a major artery (nutrient artery). The artery pierces the cortex and divides into ascending and descending branches, which further subdivide into arterioles that pierce the endosteal surface of the stratum compactum to become capillaries. The capillaries drain into medullary venous sinusoids throughout the medullary space, which in turn drain into a central venous channel (Fig. 26-1). The medullary sinusoids accept fluid and drugs during IO infusion and serve as a route for transport to the central venous channel, which exits the bone as nutrients and emissary veins.[29] The medullary cavity functions as a rigid, non-collapsible vein, even in the presence of profound shock or cardiopulmonary arrest. [30] Radiographic studies have demonstrated that radiopaque dye spreads only a few centimeters in the medullary space before being transported to the venous system.[31] The richly vascular red marrow cavity of the long bones is gradually replaced by less vascular yellow marrow after age 5. [32]

Almost every drug and fluid commonly used in resuscitation has been reported in clinical and preclinical IO studies. Medications and fluids that have been administered through IO infusion are listed in Table 26-1 . Crystalloid infusion studies in animals have demonstrated that infusion rates of 10 to 17 mL/min may be achieved with gravity infusion and rates as high as 42 mL/min with a pressure infusion. [33] [34] [35] IO crystalloid infusion has been shown to produce a significant increase in blood pressure in a hemorrhagic shock model in rabbits. [36] In small animals (7 to 8 kg) the size of the marrow cavity is the rate-limiting factor, whereas in larger animals (12 to 15 kg), the size of the needle determines the flow. [34] Blood under pressure can be infused approximately two thirds as fast as crystalloid fluids. [34]

Comparisons of IO and IV infusion of drugs have demonstrated that the drugs reach the central circulation by both routes in similar concentrations and at the same time (Fig. 26-2). [18] [37] This holds true even during CPR, where sodium bicarbonate has been shown to provide greater buffering capacity when administered by the IO route than by the peripheral IV route. [38]

Data from Getschman SJ, Dietrich AM, Franklin WH, et al: Intraosseous adenosine. As effective as peripheral or central venous administration? Arch Pediatr Adolesc Med 148:616, 1994; Sawyer RW, Bodai BI, Blaisdell FW, et al: The current status of intraosseous infusion. J Am Coll Surg 179:353, 1994.

Voelckel demonstrated that bone marrow blood flow responds to both the physiologic stress of hemorrhagic shock and vasopressors given during resuscitation after hypovolemic cardiac arrest in dogs. After successful resuscitation, bone marrow blood flow decreased following high-dose epinephrine but was maintained after high-dose vasopressin. These findings emphasize the need for pressurized IO infusion techniques during hemorrhagic shock and certain drug therapy in animal models.[39]

INDICATIONS AND CONTRAINDICATIONS

IO infusion is a means of achieving rapid temporary vascular access until a patient can be stabilized and traditional IV access obtained. It is indicated when fluid or drugs must be

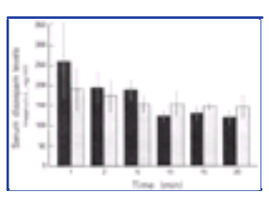

Figure 26-2 Serum diazepam levels (ng/mL, mean ± SE) graphed for the intraosseous (IO) *(shaded area)* and intravenous (IV) *(blackened area)* groups as a function of time when injected during normal perfusion. Initially the IV drug level is slightly higher, but overall the difference between the two routes of administration is not significant.

introduced into the circulation rapidly and venous access is not readily available. The primary indication is cardiac arrest in an infant or child, but there are increasing reports of successful use in preterm and term infants. In one study, 30 IO lines were placed in 20 preterm and 7 full-term neonates with a variety of illnesses (e.g., respiratory distress syndrome, perinatal asphyxia, congenital cardiac anomalies) in whom conventional venous access had failed. All survived the resuscitation with no long-term effects from IO line placement. Gestational age ranged from 32 to 41 weeks and birth weight ranged from 515 to 4050 g. [9] In 1999, Abe et al studied the speed and ease of establishing newborn emergency vascular access using turkey bones and plastic infant legs to simulate IO access. They used fresh umbilical cord to simulate umbilical venous catheterization (UVC). They demonstrated that for individuals who do not frequently perform newborn resuscitation, IO placement was easier and quicker to perform than UVC. The results of this study have yet to be confirmed in a clinical trial with live infants.

IO infusion is also indicated in adult patients in whom peripheral and central venous access has been unsuccessful. In pediatric patients it may be used as a first line of vascular access if peripheral vascular access does not appear to be readily obtainable. Other indications include shock, trauma, extensive burns, severe dehydration, status epilepticus, or any situation in which the emergency administration of fluids or drugs is necessary but not feasible by other routes. [40] IO infusion into the tibia has also been used as a site for lower extremity venography. [41]

There has also been renewed interest in the IO route by the military for use in special operations where adverse environmental conditions make obtaining IV access very difficult. Operations conducted in the dark, during harsh weather conditions, or under other highly stressful situations (e.g., nuclear, biological, or chemical attack) may make IV access impractical or impossible. The Army Institute for Research has compared several IO infusion devices including the FAST, the BIG, the SurFast Hand-Driven Threaded-Needle (Cook Critical Care, Bloomington, IL), and the Jamshidi Straight-Needle (Allegence Health Care, McGaw Park, IL). [15] Success rates for these devices were similar (94% to 97%) and all were inserted in <2 minutes. The participants rated no one device as significantly better than the others. It was concluded that each device was easy to master and could be appropriately used during Special Operations when IV access could not be accomplished. [15]

The revival of IO anesthesia has also significantly improved dental anesthetic techniques. Primary IO anesthesia is useful for short procedures where it is desirable to minimize the feeling of numbness and the ballooning of tissue. [42] IO anesthesia provides profound anesthesia of sufficient duration for most dental procedures and is particularly useful for situations that are refractory to conventional anesthetic techniques [42] [43]

In addition to serving as a route for fluid administration, the IO needle may be used for obtaining blood type, cross-match, and blood chemistry determinations from the marrow cavity. Serum electrolyte, blood urea nitrogen (BUN), creatinine, glucose, and calcium levels are very similar to those in samples obtained from an IO aspirate.[44] [45] Blood gas values obtained from the IO site also are similar to those obtained from central venous sites during steady- and low-flow states in one animal model and may be an acceptable alternative to judging central acid-base status during CPR. [46] A complete blood cell count may not be reliable because it reflects the marrow cell count rather than the cell count in the peripheral circulation. Furthermore, the aspirated blood usually clots within seconds, even if it is placed in a tube that contains heparin. Brickman and colleagues demonstrated that bone marrow aspirates obtained from an IO needle in the iliac crest could be reliably used to type and screen blood for transfusion. [47]

Relatively few contraindications to IO infusion exist. Osteoporosis and osteogenesis imperfecta are associated with a high fracture potential; therefore, the procedure should be avoided when these diagnoses are known unless absolutely necessary. A fractured bone must be avoided because as fluid is infused, it increases the intramedullary pressure and forces fluid to extravasate at the fracture site. This may slow the healing process, cause a nonunion of the bone, or lead to a compartment syndrome. A similar extravasation of fluid can occur through recent IO puncture sites placed in the same bone. Hence, recent prior use of the same bone for IO infusion represents a relative contraindication to IO line placement. Needle insertion through areas of cellulitis, infection, or burns should also be avoided.

EQUIPMENT AND SETUP

The only equipment necessary for establishing IO access is a sturdy needle with a stylet and a syringe for aspiration. Needles range in size from 13 to 20 G and are made by several companies. Standard needles for drawing blood or administering medications are *not adequate* for IO infusions; generally, they are not sturdy enough to penetrate bone. A cadaver study of IO puncture suggests that non-styletted needles (2.5-cm, 18-G phlebotomy needles and 7.6-cm, 14-G IV needles) enter the marrow space successfully only about half the time.[48] In the past, an 18-G spinal needle was commonly used for children younger than 12 to 18 months. This needle, although readily available in most EDs, often bends, is too long for rapid fluid infusion, and has a greater risk of occlusion from clotted blood. [49]

Figure 26-3 Needles used for intraosseous (IO) infusion. *Left to right,* Illinois bone marrow aspiration needle, Illinois sternal/iliac aspiration needle, Jamshidi disposable sternal/iliac aspiration needle, Cook IO needle with 45° trocar, and Sur-Fast IO needle.

Several needles are currently used in EDs for IO infusion (Fig. 26-3). Bone marrow aspiration needles such as the Rosenthal or Osgood can be used if available. They are large enough (16-ga) to be used on older children or adults and are good for fluid administration. The 16-G Illinois sternal/iliac aspiration needle (Monoject, Division of Sherwood Medical, St. Louis, MO) has an adjustable plastic sleeve to prevent the needle from penetrating too deeply or through the opposite cortex. Its disadvantage is that it has a long shaft and cumbersome handle, which make it vulnerable to dislodgment from the bone during transport or other procedures. The Cook IO needle (Cook Critical Care, Bloomington, IN) comes in 18- and 16-ga sizes and has a detachable handle that decreases the likelihood of its being dislodged. A useful feature of this

Figure 26-4 The FAST sternal intraosseous (IO) infusion device. *(Courtesy of Pyng Medical Corporation, Richmond, British Columbia.)*

Figure 26-5 The Bone Injection Gun (BIG).

needle is a line located 1 cm from its tip, which serves as a depth marker. The Sur-Fast needle (Cook Critical Care, Inc, Bloomington, IN) has a threaded shaft to permit a more secure needle placement. The Jamshidi Disposable sternal/iliac aspiration needle (Allegence Health Care, McGaw Park, IL) comes in either 15- or 18-G sizes and, like the larger Illinois sternal/iliac aspiration needle mentioned earlier, features an adjustable plastic sleeve. However, its shorter shaft length and smaller handle make it much easier to use. A 13-G needle manufactured by MedSurg Industries (Rockville, MD) is good for fluid resuscitation. However, like the Illinois sternal/iliac aspiration needle, it has a large handle that makes it cumbersome.

Several other devices approved by the FDA for IO access are gaining popularity with both military and prehospital care providers for use in adults. Although not commonly used in the ED, the FAST needle (Fig. 26-4) is designed only for sternal use. The device includes a hand-held introducer that allows insertion of a stainless steel-tipped flexible infusion tube to a predetermined depth in the sternal manubrium. The FAST needle has a bone probe that detects the anterior surface of the bone and a built-in mechanism that releases the handle from the stylet and infusion tube once the infusion tube has reached the preset depth. These features help prevent overly penetrating the sternum. [50]

The BIG (Fig. 26-5) incorporates a loaded spring to allow easy penetration of the bone. The depth of injection can be adjusted allowing for use in different locations.[15] Hubble compared IO versus saphenous vein cutdown access times and success rates in human adult cadavers using the BIG. He concluded that IV access was achieved more rapidly with a higher success rate and fewer complications using the BIG via the IO route than saphenous vein cutdown in adult cadavers.[51]

TECHNIQUE

Originally the sternum was the primary site for IO infusion. After several cases of osteomyelitis and mediastinitis in

Figure 26-6 Schematic diagram demonstrating intraosseous (IO) insertion sites. *A*, The proximal tibia. The IO needle is inserted 1 to 3 cm distal to the tibial tuberosity and over the medial aspect of the tibia. *The bevel of the needle is directed away from the joint space. B,* The distal tibia. The IO needle is inserted on the medial surface of the distal tibia at the junction of the medial malleolus and the shaft of the tibia, posterior to the greater saphenous vein. The needle is directed cephalad, away from the growth plate. *C,* The distal femur. The IO needle is inserted 2 to 3 cm above the external condyles in the midline and directed cephalad away from the growth plate.

children, the site was abandoned.[52] Other sites, such as the clavicle and humerus, have been used, but neither has gained popularity. Currently the site of choice is the proximal tibia, followed by the distal tibia and distal femur. However, introduction of the FAST needle has resulted in renewed interest in the sternum in adults. [50]

The tibia is popular because it is a large bone with a thin layer of subcutaneous tissue that allows landmarks to be readily palpated. It is the preferred site of IO insertion in infants and children younger than 6 years old, and its insertion does not interfere with airway management and cardiopulmonary resuscitation. On the proximal tibia, the broad, flat, *anteromedial surface* is used, with the tibial tuberosity serving as a landmark. The site of IO cannulation is approximately 1 to 3 cm (2 fingerwidths) below the tuberosity on the medial or flat surface of the tibia (Fig. 26-6*A*). This location is far enough from the growth plate to prevent damage but is in an area in which the bone is still soft enough to allow easy penetration of a needle. This site may be used in adults but is more difficult and requires a 13- to 16-G needle to penetrate. If a smaller-gauge needle is desired, use of the spring-loaded BIG is required.

The patient's leg should be supported by placing a small sandbag or towel roll behind the knee. The site is prepared with a povidone-iodine solution or alcohol. Local anesthesia is usually unnecessary since the majority of patients in whom IO infusion is used have altered mental status from shock or are in cardiopulmonary arrest. However, if the patient is conscious, the skin and periosteum should be anesthetized. The proximal tibia is grasped with the palm of the nondominant hand (Fig. 26-7). The fingers and thumb stabilize the proximal tibia. To avoid self-puncture, care must be taken to ensure that the hand does not extend behind the insertion site.

Figure 26-7 Insertion of an intraosseus (IO) needle. The fingers and thumb are wrapped around the proximal tibia to stabilize it. A towel (not shown) may be placed behind the knee for support. The needle is grasped firmly in the palm, and a rotary motion is applied with moderate pressure. The plastic sleeve can be adjusted to prevent it from being forced too deeply into the bone or through the bone. Note that the needle is directed away from the joint space.

Figure 26-8 Intraosseus (IO) needle in situ. *A*, The needle and tubing are secured with tape and the extremity is immobilized on a leg board. A long leg board may be needed with an active child. *B*, The needle is protected from accidental dislodgement by wrapping a stretch bandage around the extremity and placing a small plastic drinking cup around the needle.

The bony landmarks are palpated and the site is identified. The needle should be grasped firmly in the palm of the hand and directed either perpendicular (90°) to the long axis of the bone or slightly caudad (60°–75°) to avoid penetration or injury to the growth plate. The needle is then advanced with a *twisting or rotary motion* to cut the bone and facilitate puncture of the cortex. Considerable resistance will be encountered, but once the cortex has been penetrated, there is a sudden decrease in resistance and a crunching feeling as the needle moves through the bony trabeculae into the marrow cavity. The distance from the skin through the cortex of the bone is rarely greater than 1 cm in an infant or child, and penetration to this depth is usually adequate. A common mistake is to advance the needle through the opposite side of the bone. This can best be avoided by holding the needle in the palm of the hand with the index finger approximately 1 cm from the bevel of the needle to avoid pushing it past this mark. Another method is to use a needle with a preset plastic depth indicator on the shaft. [53] The stylet is then removed, and a 5- to 10-mL syringe is used to aspirate blood and marrow contents for confirmation of position. Many times, particularly during cardiac arrest, blood aspiration is not possible. Other signs of successful needle insertion include the needle's ability to stand upright without support and infused fluids that flow easily without evidence of swelling or extravasation.

If there is excessive resistance to fluid infusion, the needle may be pulled back a few millimeters and another attempt made to infuse fluids. If continued resistance is met or evidence of extravasation exists, the needle should be removed and an attempt made on the other extremity. If the needle appears to be infusing properly, the test syringe is disconnected, and the needle is then connected to infusion tubing. The needle and tubing should be secured with tape and the extremity immobilized on a leg board (Fig. 26-8*A*). The needle should be protected from accidental dislodgement by wrapping a stretch bandage around the extremity and placing a small plastic drinking cup or commercially available shield around the needle (see Fig. 26-8*B*). The IO needle should be removed as soon as secure IV access has been obtained. A sterile dressing is placed over the puncture site, and pressure should be applied to the dressing for 5 minutes. [54]

The distal tibia, although a preferred site in adults, may be used as well in children. [49] [55] The cortex of the bone and the overlying tissue are both thin. The site of needle insertion is the medial surface at the junction of the medial malleolus and the shaft of the tibia, posterior to the greater saphenous vein (see Fig. 26-6*B*). The needle is inserted perpendicular to the long axis of the bone or 10°–15° cephalad to avoid the growth plate. [53]

The distal portion of the femur is occasionally used as an alternate site, but because of thick overlying muscle and soft tissue, it is more difficult to palpate bony landmarks (see Fig. 26-6*C*). If chosen, the needle should be inserted 2 to 3 cm above the external femoral condyles in the midline and directed cephalad at an angle of 10°–15° from the vertical.[56]

The introduction of the FAST needle, which allows safe and effective penetration of the sternum, has resulted in renewed interest in the sternum as an IO site in adults. Currently this site is rarely used in the ED but it may be attempted in life-threatening situations. The sternum has several advantages over peripheral bones including a large, relatively flat body that can be readily located by unskilled clinicians; retention of a high proportion of red marrow; and thinner, more uniform cortical bone overlying a relatively uniform marrow space. In addition, it is less likely to be fractured in major trauma. [50]

The FAST needle is packaged with alcohol and iodine, a protective dressing that also acts to secure the needle in place, and a threaded tip remover (Fig. 26-9). After prepping the overlying skin with iodine and alcohol, an adhesive target patch is placed over the midline of the manubrium with the target zone hole approximately 1.5 cm below the sternal notch (Fig. 26-10*A*). The introducer is placed in the center of the target zone. The introducer contains a "bone cluster" of needles forming a circle, which sense the cortex of the sternum (see Fig. 26-10*B*). Pressure on the handle also releases an inner needle upon which a plastic

infusion tube with a small metal tip is loaded. The central needle advances exactly 5 mm beyond the circular cluster of needles, stopping at the cortex. The metal tip is then positioned in the cortex-medullary junction. Withdrawal of the handle leaves only the plastic infusion

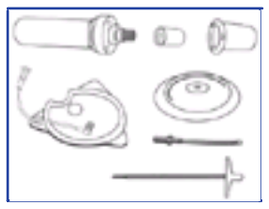

Figure 26-9 The FAST sternal intraosseous (IO) infusion device comes packaged with all necessary equipment.

Figure 26-10 *A*, After prepping the overlying skin with iodine and alcohol, an adhesive target patch is placed over the midline of the manubrium with the target zone hole approximately 1.5 cm below the sternal notch. *B*, The introducer, which contains a "bone cluster" of needles, is placed in the center of the target zone. *C*, Pressure on the handle releases an inner needle upon which a plastic infusion tube with a small metal tip is loaded. The central needle advances exactly 5 mm beyond the circular cluster of needles, stopping at the cortex. The metal tip is now positioned in the cortex-medullary junction. Withdrawal of the handle leaves only the plastic infusion tube protruding from the insertion site. A plastic dome is attached via Velcro fasteners to the target patch, securing the tube in place.

tube protruding from the insertion site. Marrow aspiration and rapid flow of fluid help verify position. A plastic dome is attached via Velcro fasteners to the target patch, securing the tube in place (see Fig. 26-10*C*). Removal of the infusion tube requires the use of an included threaded-tip remover. The tube can also be removed by direct pulling; however, the metal tip is sometimes left behind and must be extracted through a small incision. [15]

The BIG incorporates a loaded spring to facilitate penetration of the bone. Removing the safety pin from one end and screwing or unscrewing the opposite end adjusts the depth of the injection (Fig. 26-11*A* (Figure Not Available)).

Palmar force on the back of the unit, combined with pulling on flanges with the middle and ring fingers, results in firing of the gun (directions on package) (see Fig. 26-11*B* (Figure Not Available)). Aspiration of marrow, followed by flushing with the same syringe, and flow through the IV tubing help confirm placement. The slotted safety pin is slid into the needle to maintain stability and the needle is removed with small clamps that are rotated back and forth (Fig. 26-11 *C* (Figure Not Available)). The site is then dressed in a manner determined by the care provider. [15]

Figure 26-11 (Figure Not Available) The BIG is positioned with one hand to the site while the other hand is used to pull out the safety latch *(A)*. Palmar force on the back of the unit, combined with pulling on the flanges with the middle and ring fingers, results in firing of the gun *(B)*. Before firing, be sure the BIG is 90° to the surface. The BIG is then removed *(C)*, followed by the stylet *(D)*. Aspiration of marrow, followed by flushing with the same syringe, and flow through the IV tubing help confirm placement. The slotted safety pin is slid into the needle to maintain stability and the needle is removed with small clamps that are rotated back and forth *(E)*. *(Courtesy of WaisMed, Caesarea, Israel.)*

COMPLICATIONS

As with any procedure, complications may arise when attempting to use the bone for vascular access. Complications may be divided into two categories: technical difficulties and latent soft tissue or bone problems. Technical difficulties are the most common, but these decrease as familiarity with the technique increases (Fig. 26-12). The most common mistake is to place excessive pressure on the needle during insertion and force it entirely through the bone (Fig. 26-13). This may be avoided by placing the index finger against the skin to prevent the needle from going in too deeply. Also, attention to depth of the needle or use of a sheath on the needle to prevent excess penetration will decrease occurrences of this problem. Incomplete penetration of the bone may also occur, in which case blood will not be aspirated and fluid will extravasate if infused. Serum levels of medication are decreased when IO infusion is performed through bones with multiple cortical defects. [57] If several attempts are made to place a needle in the same bone, fluid may extravasate from previous puncture wounds. If extravasation occurs, the needle should be removed and pressure applied.

The needle may be blocked periodically by clots forming around the bevel or by bony spicules obstructing the flow of fluid. This complication may require that the line be flushed with 3 to 5 mL of sterile saline every 10 to 15 minutes to keep it open.

A major concern for any person receiving IO infusion is infection. This concern often leads clinicians to shy away from using the bone and to continue searching for other methods of vascular access. Although the potential for infection is real, its actual incidence is low. A literature review of more than 4000 cases from 1942 to 1977 found a 0.6% incidence of infection. [2] Although most of the affected access sites were not placed under emergency conditions, the needles were often left in 1 to 2 days, thus increasing the likelihood of infection. A survey of more than 1000 U.S. and foreign medical schools

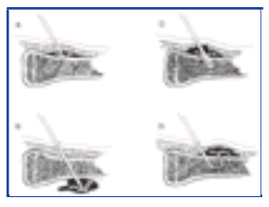

Figure 26-12 Schematic diagram of possible problems encountered with intraosseous (IO) infusion. *A*, Incomplete penetration of the bony cortex. *B*, Penetration of the posterior cortex. *C*, Fluid escaping around the needle through the puncture site. *D*, Fluid leaking through a nearby previous cortical puncture site.

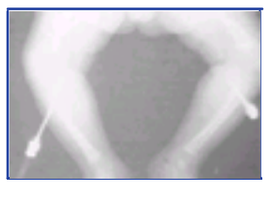

Figure 26-13 Radiograph of bilaterally misplaced IO needles with penetration through the posterior tibial cortices.

found that the incidence of infection for IO needles placed in emergency conditions was less than 3%. [58]

The most common infection is cellulitis at the puncture site, which usually responds well to antibiotics. Osteomyelitis is less common, but it also usually responds to antibiotics. Heinild and colleagues reported three cases of osteomyelitis in 25 patients who received infusions of undiluted 50% dextrose in water ($D_{50}W$). [23] Undiluted $D_{50}W$ injected into rabbit femurs produces edema and pyknotic marrow nuclei that improve within 1 month. [59] In addition to infection, inflammatory reactions of the bone may be seen. These are most common when hypertonic or sclerosing agents are used and may produce an elevation of the periosteum with a positive bone scan (Fig. 26-14). Unlike the clinical appearance of a patient with osteomyelitis due to bacteria, a child with a sterile inflammatory reaction does not look "toxic." One hypertonic sclerosing drug that may be used during cardiac arrest is sodium bicarbonate. Heinild and colleagues [23] reported 78 cases of bicarbonate infusion with no complications. Animal studies have reported a decrease in cellularity with edema and destruction of some cells, but these changes are temporary and completely resolve in a few weeks. [59] [60] [61]

Another complication that has been reported is necrosis and sloughing of the skin at the site of infusion. [62] This occurs if fluid or drugs extravasate from the puncture site into the surrounding tissues. Care should be taken when infusing drugs such as calcium chloride, epinephrine, and sodium bicarbonate to prevent dislodgement of the needle and extravasation into the tissue. It is best to infuse such drugs gently and not under pressure, because pressure frequently causes extravasation.

Injury of the growth plate and developmental abnormalities of the bone are ongoing concerns. These fears have not been supported in the literature, however. There have been no reports of growth plate damage or permanent abnormalities of the bone. One animal study specifically examined damage to the epiphysis; sodium bicarbonate was injected directly into the epiphysis, and no radiologic evidence of epiphyseal injury was found. [63] [64] By pointing the needle away from the joint space and using the previously mentioned landmarks for insertion, the danger of epiphyseal injury is remote.

Fat embolism is frequently mentioned as a potential complication. [2] [49] However, this condition is rare and has been

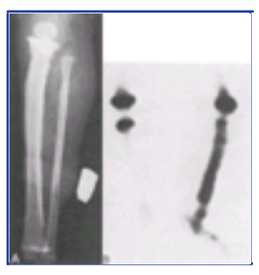

Figure 26-14 Radiograph *(A)* and bone scan *(B)* of the tibia demonstrating an inflammatory reaction 4 days after the patient received intraosseous (IO) phenytoin and phenobarbital. The periosteum is elevated along the length of the bone, mimicking osteomyelitis on the plain films and the bone scan. A diagnosis of osteomyelitis requires either clinical evidence of infectious toxicity or positive cultures (blood or periosteal aspirate).

reported only in adult patients. [65] Animal studies addressing this issue found no changes in blood gases during IO infusion and limited evidence of fat globule collection in the lungs. [66] [67] Because the marrow in infants and children is primarily hematopoietic, this potential complication is unlikely to occur. In one animal study, no significant hemolysis was detected in the setting of pressurized IO blood infusion. [67]

Compartment syndrome following IO line use during cardiac resuscitation has been reported. [68] [69] Tibial fractures have also been reported. [70] [71] Follow-up radiographs of patients who have undergone IO needle placement or attempts at such placement are indicated. Cortical defects may be seen on radiographs for up to 40 days after injection. [72]

One study evaluating the use of the FAST sternal IO device in 50 adults found no serious adverse effects. Minor complications included bruising, swelling, redness, or tenderness at the time of removal. Difficulty with use of the removal tool was reported in 12 cases and 2 devices required removal using a small incision. [50]

INTERPRETATION

The determination of whether an IO infusion is functioning may be made by assessing the ease with which fluid infuses and the clinical response of the patient. If the needle is properly placed, fluid should flow smoothly, with only occasional flushes necessary to keep it open. A clinical response to fluid or medications should be seen at approximately the same time and in the same magnitude as with IV administration.

CONCLUSION

Although not always successful, IO infusion provides a means of rapidly accessing the cardiovascular system in emergencies. The technique is not intended to replace traditional venous access; instead, it should serve as a temporizing measure for resuscitation until venous access can be obtained. It is currently used throughout the United States and Canada and has been reviewed extensively in emergency medicine and pediatric literature. The technique is also used by prehospital emergency care personnel, who have demonstrated a high success rate in the field. [14] [50] [73] The technique renders hope for those who infrequently care for critically ill or injured children, because this skill is easily mastered even if done infrequently. Recent use in adults, dental anesthesia, and in neonatal resuscitation underscore the need for emergency care providers to become familiar with the equipment and techniques.

Complications are most commonly related to technical mistakes. By carefully locating landmarks, staying away from the growth plate, and paying attention to the depth of the needle, complications can be minimized. Finally, as with any technique, practice on cadaver or animal leg bones (e.g., chicken, pig) greatly improves one's skill.

Chapter 27 - Endotracheal Drug Administration

James H. Bryan

Endotracheal (ET) administration of selected medications is a simple, rapid, and effective method of drug delivery to the central circulation. However, this technique of drug administration should be reserved for use in situations in which a patient's condition warrants immediate pharmacologic intervention and when more conventional means of drug delivery, such as by intravenous (IV) or intraosseous (IO) access, are not readily available. Such circumstances occur infrequently, but when they do, knowledge of the appropriate drugs and dosages that can be delivered effectively by this route may prove to be life-saving. It is important, therefore, that clinicians be familiar with the concept and method of ET drug therapy.

ET drug administration dates to 1857, when Bernard demonstrated the ability of the lung to rapidly absorb an instilled solution of curare. [1] In this experiment, curare was instilled into the upper respiratory tract of dogs by way of a tracheostomy. After the dogs were tilted to an upright position, they died within 7 to 8 minutes. Bernard concluded that the alveoli must be permeable to curare. Over the following decades, other investigators expanded this work and demonstrated that solutions containing salicylates, atropine, potassium iodide, strychnine, and chloral hydrate were also absorbed rapidly from the lung and excreted in the urine after injection of their aqueous solutions into the tracheas of experimental animals. [2]

In 1915, Kline and Winternitz provided experimental data suggesting that intratracheal therapy in pulmonary disease might prove to be an effective therapeutic route.[3] Further studies showed that moderate quantities of fluid could be insufflated into the lungs without marked changes in the lung architecture. [4] The use of intrapulmonary medication in the treatment of lung disease gained further acceptance when studies demonstrated that the inhalation of epinephrine mist dramatically relieved the symptoms of asthma.[5]

In the late 1930s and 1940s, when certain chronic suppurative disorders of the lung failed to respond to parenteral antibiotics, drugs were administered by direct instillation into the lungs. During this period, several important observations were made concerning ET drug therapy: (1) penicillin delivered by the ET route demonstrated a depot effect, resulting in therapeutic blood levels that lasted twice as long as those noted with intramuscular injections [6] ; (2) various diluents mixed with penicillin affected both the rate and the degree of absorption from the lungs [7] ; and (3) higher serum drug levels were attained with direct ET drug administration than with aerosolized administration. [7]

In the 1950s investigators attempting to elucidate the mechanism responsible for adverse anesthetic reactions made two important findings. The first was that drugs delivered endotracheally were absorbed much more rapidly than those applied to the posterior pharynx. A second discovery was that the rapid absorption of drugs applied locally to the larynx and trachea resulted in blood levels significant enough to cause adverse anesthetic reactions. [8]

In 1967 Redding and coworkers studied the use of ET administration as a route of drug delivery in a canine model of cardiopulmonary arrest. [9] They administered epinephrine by the IV, intracardiac, and intratracheal routes, and then evaluated its effectiveness in the resuscitation of dogs that had undergone both respiratory and circulatory arrest secondary to hypoxia. Their study revealed that all three routes of drug administration were equally effective in restoring the circulation of dogs in hypoxia-induced cardiac arrest, again demonstrating that the ET route of drug delivery provides an effective window to the systemic circulation. They concluded that whichever of these routes is most immediately available should be used. A decade passed before further research was published concerning the use of ET drug therapy as an alternative means of systemic drug administration.

RECOMMENDATIONS REGARDING ENDOTRACHEAL DRUG DELIVERY

In the late 1970s Roberts and Greenberg and associates revived the study of ET drug delivery with a series of laboratory experiments and clinical uses of ET epinephrine.[10] [11] [12] [13] Since then, a number of important animal and human studies, as well as a number of case reports, have been published dealing with various aspects of ET drug administration. These investigations addressed: (1) appropriate drug dosing; (2) the effect of drug solution volume; (3) the effect of different diluent solutions; (4) the role of different ET drug delivery techniques; and (5) the effects of hypoxia, hypotension, shock, and cardiopulmonary arrest on the absorption, distribution, and efficacy of endotracheally administered drugs.

Although the American Heart Association (AHA) makes specific recommendations regarding the use of ET drug delivery for cardiac resuscitation (Table 27-1),[14] [15] [16] [17] much of the literature remains controversial and is at times contradictory. It is likely, therefore, that many of these issues will continue to be the subject of future investigations. Specific studies related to each of these topics are discussed as follows.

Appropriate Dose

All investigators agree that the ET dose of a medication should be at least equal to the IV dose of the same drug given for the same indication. Most studies on the subject indicate that higher doses are needed endotracheally than intravenously. For Advanced Cardiac Life Support medications in adults, the AHA recommends a dose 2 to 2.5 times the usual IV dose.[14] This recommendation is supported by the results of a study of epinephrine administered immediately following intubation in the prehospital setting,[18] as well as studies of endotracheally administered lidocaine, indicating a 3 mg/kg dose was needed to obtain therapeutic serum levels. [19] [20] Other studies, however, suggest that ET administration requires higher doses.

Studies and case reports of ET epinephrine have produced conflicting results. Some animal studies [21] and case reports [12] have shown positive effects or recovery from cardiovascular collapse, or both, when epinephrine was used in doses equal to recommended IV doses. In other animal [22] and

TABLE 27-1 -- American Heart Association Guidelines for Tracheal Drug Administration

	Adults	Pediatric	Neonatal
Medication dose	2–2.5 times recommended IV dose	Epinephrine 10 times the IV dose (class IIb); it is logical to similarly increase the dose of other resuscitation drugs compared to IV dose	Same as IV dose (specified for epinephrine and naloxone only)
Total volume to instill	10 mL	5 mL	1 mL
Diluent	Normal saline or distilled water	Normal saline	Normal saline

Adult data from American Heart Association.[14]

Pediatric data from American Heart Association.[15]

Neonatal data from American Academy of Pediatrics. [16] [17]

human[23] studies, however, epinephrine in doses of approximately 0.02 mg/kg and 0.01 mg/kg, respectively, were shown to be unreliable in producing a physiologic response. In addition, studies using both normotensive and cardiac arrest canine models have shown that epinephrine doses of 0.01 mg/kg produce serum levels approximately one-tenth that produced when the same dose is given intravenously. [11] [24] [25] These studies recommend increasing the ET epinephrine dose to 0.1 mg/kg and are the basis for the AHA recommendation to use a 10-fold increased dose when administering ET epinephrine to pediatric patients. [15] However, ET drug delivery is associated with a depot effect. That is, when larger doses of drugs are administered via the ET route, the drug is "stored" and released slowly over time, similar to a continuous IV drip. This presumably occurs due to local vasoconstriction or lymphatic storage of the drug, or both, [10] or from pooling in the lung tissue due to poor lung perfusion.[26] With epinephrine use, the depot effect produces a potential for postresuscitative arrhythmias, hypertension, and tachycardia, with resultant increased myocardial oxygen demand.

Given these data, it seems reasonable in adults to start with a dose 2 to 2.5 times the usual IV dose. If this appears ineffective, higher doses may be used on subsequent administration.

Single-Dose Volume

The need to increase the volume of the instilled medication to enhance effectiveness was recognized by Redding and associates during their early studies. [9] The goal is to use a volume that will enhance delivery and absorption of the drug while producing minimal deleterious effects on pulmonary gas exchange. The AHA recommends a total volume of 10 mL in adults, [14] 5 mL in pediatric patients,[15] and 1 mL in neonates.[16] In canine studies, Mace compared undiluted lidocaine to diluted lidocaine (volume, ~6.5 mL) and found significantly higher plasma lidocaine levels in the animals receiving diluted lidocaine. [27] There were no changes in the arterial blood gas values before and after ET drug administration. In another animal study, lidocaine diluted with normal saline to volumes up to 25 mL produced no changes in arterial blood gases or clinical condition, and no change was seen in lung gross anatomy or histology. [28] In contrast, a study comparing normal saline to distilled water revealed a decreased PaO_2 for both solutions (water producing the greatest effect), but this study used large volumes (2 mL/kg) of solution. [29]

Studies of endotracheally administered lidocaine in human subjects revealed that dilution with distilled water to a total volume of 10 mL resulted in higher plasma lidocaine levels, but also produced a decrease in PaO_2 of approximately 40 mm Hg that persisted for more than 1 hour.[30] A total volume of 5 mL yielded lower plasma levels but also produced a shorter period of hypoxemia. The authors concluded that a total volume of 5 to 10 mL (in agreement with the AHA guidelines) would produce optimal results. Volume recommendations in a clinical setting requiring multiple drug doses (e.g., prehospital arrest without peripheral venous access in a patient facing long transport) are lacking. In this setting it may be appropriate to limit the diluent volume for an individual adult administration to 5 mL.

Appropriate Diluent

Due to their availability during emergency situations, both normal saline and distilled water have historically been the diluents of choice for ET drug administration. The AHA Adult Advanced Cardiac Life Support Guidelines recommend either diluent, noting that "tracheal absorption is greater with distilled water as the diluent than with normal saline, but distilled water has a greater adverse effect on PaO_2 ".[14] Naganobu and colleagues studied epinephrine diluted to 2 mL with either normal saline or distilled water and administered through the ET tube into a distal bronchus of dogs. They found that peak serum epinephrine levels were 13 times higher when diluted with distilled water vs normal saline. In addition, the mean arterial pressure increased significantly when diluted with distilled water but it did not change significantly when diluted with normal saline. They found only minimal changes in the PaO_2 with either diluent and concluded that distilled water is a better diluent than normal saline.[31] Finally, a study of ET epinephrine diluted with normal saline vs distilled water found no difference in arterial blood gases following delivery of either diluent solution.[32] In this latter canine cardiac arrest model, survival rates for ET epinephrine in either diluent were equal to the survival rate with IV epinephrine.

The use of saline is supported by the canine study of Greenberg and associates, which reported that administration of normal saline via the ET route produced fewer detrimental effects on arterial blood gases than did distilled water. [29] The safety of endotracheally administered normal saline is further supported by a study in which

no changes in pulmonary

status (arterial blood gas, oxygen saturation, gross anatomy, or histology) were observed in dogs given lidocaine diluted with normal saline to total volumes of between 6 and 25 mL.[28] Hence, while some diluent is helpful and recommended, the optimal diluent is controversial; saline may produce less pulmonary dysfunction, but distilled water appears to deliver a greater amount of drug.

Technique for Endotracheal Drug Delivery

Multiple techniques have been used to deliver medications via the ET tube, including direct instillation into the proximal end of the ET tube, administration via a catheter that extends just beyond the distal tip of the ET tube, deep endobronchial administration using a longer catheter, administration via ET tube monitoring ports, and injection through the side of the ET tube with a needle. The AHA guidelines for adults recommend the use of a catheter that extends beyond the distal tip of the ET tube.[14] However, the pediatric guidelines advise against using a catheter or feeding tube, noting they are often cumbersome and require finding the correct size to place through the ET tube.[15] Neonatal guidelines recommend either direct instillation into the proximal end of the ET tube or use of a 5Fr feeding tube that is inserted down the ET tube.[16] Several studies have, however, indicated that use of a catheter or feeding tube may not be needed to enhance the drug's effectiveness.

Greenberg and Spivey instilled radiopaque contrast material directly into the proximal end of the ET tube and compared its distribution to contrast instilled via a catheter extending out the distal end of the tube.[33] Their study revealed that both techniques were equally effective in distributing the contrast agent to the peripheral lung fields as long as instillation was followed by five rapid manual hyperventilations. Although some studies have suggested that drug absorption with direct instillation into the ET tube is inconsistent during cardiopulmonary arrest,[20] [23] at least one case report has shown successful resuscitation using this method.[12] Using a porcine cardiopulmonary arrest model, Jasani and coworkers showed no difference in resuscitation rates or physiologic responses between epinephrine administered by direct injection into the ET tube, via a catheter extending out the distal end of the ET tube, or via a monitoring lumen built into the sidewall of the ET tube.[34] In a related study, no difference was detected in resuscitation rates or plasma epinephrine levels when epinephrine was instilled during apnea vs instillation during the ventilator inspiratory cycle.[35]

However, in studies in which subjects had normal perfusion, conflicting results have been reported. In a study using female volunteers, no difference was found in plasma lidocaine levels when the drug was administered directly into the proximal end of the ET tube vs deeper administration into the trachea or lungs.[36] However, a later report by the same group demonstrated significantly higher plasma lidocaine concentrations when the drug was administered directly into the proximal end of the ET tube.[37] In direct contrast, when administered to dogs, significantly higher plasma epinephrine levels were obtained via the deep endobronchial route vs direct ET tube instillation.[38]

Given these conflicting studies, use of a catheter to enhance deep pulmonary delivery seems reasonable. However, if a catheter is not readily available, any method of ET drug administration is reasonable.

Effects of Hypoxia, Hypotension, and Cardiopulmonary Arrest

Several authors have examined the effect of cardiopulmonary arrest on the absorption of medications administered via the ET route. Although concern existed that medication absorption might decrease in states of hypoxia or low blood flow, studies reveal the opposite to be true. In a hemorrhagic shock model, Mace demonstrated that higher plasma lidocaine levels were obtained via the ET route during shock than during nonshock states.[39] In a lamb model, when epinephrine was administered endotracheally, higher plasma epinephrine levels were achieved during hypoxia-induced low pulmonary blood flow than during baseline, normal pulmonary blood flow.[40] Finally, higher plasma lidocaine levels were initially observed when lidocaine was administered endotracheally to dogs with hypoxemia than to dogs that were not hypoxemic.[41] However, this study did not find a difference in the pharmacokinetics of lidocaine (i.e., pharmacological effect) in hypoxemic and nonhypoxemic dogs when the drug was administered via the ET route.

Despite evidence indicating that cardiopulmonary arrest does not inhibit absorption of endotracheally administered medications, other studies have indicated that ET drugs are unreliable during cardiopulmonary arrest.[20] [22] [23] [42] [43] In addition, in a neonatal ventricular fibrillation model using newborn piglets, 0.01 mg/kg ET epinephrine did not produce significant increases in serum epinephrine levels or in mean arterial pressures.[44] While high-dose epinephrine has never been recommended for neonates due to a fear of hypertension and intracranial hemorrhage, these data suggest that using the higher dosage of the recommended range (0.01 to 0.03 mg/kg) might be a reasonable alternative. More importantly, these studies serve to emphasize that ET drug administration should not be used in lieu of attempts to obtain definitive access to the systemic circulation. ET drug administration should not be performed when another more direct means of accessing the central circulation is available.

INDICATIONS

ET drug therapy is indicated whenever there is a need for emergent pharmacologic intervention and other access, either IV or IO, is not readily available. This most frequently occurs in patients with poor veins (e.g., chemotherapy or dialysis patients, intravenous drug users, elderly patients), in patients with small or obscured veins (e.g., pediatric patients, burn patients, obese patients), or during prehospital cardiovascular collapse.

Specific indications for the delivery of a drug endotracheally are the same as those for IV and IO administration. However, there are only a limited number of emergency drugs that can be given safely and effectively by the ET route (Table 27-2 and Table 27-3). Medications that have been administered endotracheally and found to be safe and effective in both experimental animal models and human studies or case reports include epinephrine, [10] [12] [45] atropine, [46] [47] [48] lidocaine, [36] [39] [41] [49] and naloxone. [50] [51]

Diazepam has also proven effective. [52] [53] However, in one animal model, it produced pneumonitis when 0.5 mg/kg was administered via the ET route. [54] Because diazepam is sparingly soluble in water, it is available only in a solution of

*See text—effective, but produced pneumonitis in one animal model. Midazolam may be preferred when rapidly active anticonvulsant must be given via the endotracheal route.
†See text—effective in one human study in elective surgery patients. Clinical application in the emergency department remains uncertain.

propylene glycol, ethanol, and benzyl alcohol. It is unknown if the reported pneumonitis was due to the direct effects of the diazepam or to that of the diluent.

In one case report, 5 mg of diazepam (i.e., approximately 0.1 mg/kg) was administered via a tracheostomy to an adult female, resulting in cessation of seizure activity within 2 minutes. [53] In this report, no change in arterial blood gas values or chest x-rays was noted over the ensuing 5 days. Whether the apparent lack of adverse pulmonary effects in this patient implies that diazepam can be safely used via the ET route is still speculative. The lower dose used (0.1 mg/kg) may have been a factor in reducing pulmonary damage. A further issue, given the low solubility of diazepam in water, is the ability to dilute stock diazepam solutions to a total volume of 10 mL (as is recommended for ET drug administration). A volume of 10 mL of propylene glycol or ethanol used as diluent may further compromise pulmonary function. Additional studies are needed to resolve these issues, but some authors and the American Heart Association have removed diazepam from their list of medications that can be given safely via the ET route. [15] [55] [56]

It is of interest to note that in one study of midazolam, no pathologic changes were seen in lung sections after drug administration. [57] In addition, midazolam is available commercially in aqueous solution and could, therefore, be diluted with normal saline or sterile water for ET administration. Given the less irritating solvent solution used for commercial midazolam, this agent seems to be the better choice when a rapidly acting anticonvulsant must be given via the ET route. Fortunately, both diazepam and midazolam are readily administered and effective when given rectally.

Experimental studies of vasopressin, [58] midazolam, [57] propranolol, [47] and metaraminol [59] in animal models suggest that these medications also may be effective when administered endotracheally, but no clinical studies have been conducted to date to verify these findings. In 6 patients undergoing elective surgery, Palmer and colleagues demonstrated that therapeutic blood levels of flumazenil were obtained

Metaraminol
Midazolam
Propranolol
Vasopressin

within a minute after ET delivery of 1 mg of drug diluted in 10 mL of saline. [60] Interestingly, aliquots of 0.1 to 0.2 mg of the drug are currently recommended during IV administration. The role of flumazenil by this route at these doses remains to be determined.

CONTRAINDICATIONS

At present, the only true contraindication to the ET delivery of an appropriate drug is the presence of another form of access to the systemic circulation through which the needed drug can be delivered rapidly and effectively. The pharmacokinetics and pharmacodynamics of ET drugs delivered during various states of cardiovascular or pulmonary compromise are to a large extent unknown, and, for this reason, more conventional routes of rapid and effective drug administration should be used when available.

No drug should be delivered by the ET route without experimental or clinical evidence to support its effectiveness and safety. A complete list of drugs that are contraindicated relative to delivery by the ET method is not available. Specific emergency medications that have been shown to be ineffective or unsafe when given via the ET route include sodium bicarbonate, isoproterenol, and bretylium. In a study using a canine model, sodium bicarbonate was shown to inactivate lung surfactant.[61] Isoproterenol, even when given in doses 10 times the IV dose, failed to produce significant changes in arterial blood pressure or heart rate. [47] Studies of bretylium also indicate low serum levels after ET administration, even when administered at doses of 20 mg/kg. [62]

EQUIPMENT

Patients in need of ET drug therapy first require management of the airway, usually in the form of tracheal intubation. Once this procedure has been performed (see Chapter 4), little other equipment is needed for the ET delivery of a drug. It should be noted that studies of endobronchial administration of medications via a Combitube (Kendall-Sheridan, Argyle, NY) or laryngeal mask airway (LMA) [Intavent International SA, Henley-on-Thames, UK] reveal subtherapeutic absorption of drugs when administered at recommended ET doses.[63] [64] [65] Kofler and colleagues determined that use of epinephrine with a Combitube required 10 times more epinephrine than that used with an ET tube to obtain the same serum concentration and hemodynamic effects. [63] The studies using a Combitube specifically evaluated effectiveness when the tube was placed in the esophagus, requiring medications to travel out the side holes to reach the trachea. Presumably, a Combitube that enters the trachea directly would function equivalently to an ET tube, but no studies have been done to support this assumption.

In the Procedure section that follows, several different techniques for ET drug administration are described. The equipment listed is required to perform any of the four different techniques described. This equipment is suggested for the ideal situation or technique, or both. *At no time should drug delivery be delayed while searching for the "perfect" piece of equipment.*

1. Manual bag-valve ventilation device capable of delivering an FiO_2 of at least 50%. In circumstances in which ET drug delivery is indicated, the patient's condition almost

always warrants supplemental oxygen. Although the technique may not result in any significant deterioration in respiratory function, it is still advisable to administer additional oxygen after drug delivery. The bag-valve ventilation device also is used to deliver several rapid insufflations immediately after drug delivery to assist delivery of the drug distally, where it may be absorbed more rapidly and effectively. [33]
2. A fine-bore catheter or special ET tube to deliver the drug at or beyond the distal end of the ET tube. The ideal catheter is at least 8 Fr in size and at least 35 cm (14 in.) in length. The most effective length or diameter of the catheter is unknown, but it is recommended that the catheter be long enough to protrude past the distal end of the ET tube. The diameter of the catheter should be large enough to allow rapid delivery of a 10-mL volume of solution. Several different types of tubes and catheters commonly available in the emergency department can be used for this purpose:

   A 16-ga central venous pressure or cutdown catheter. Since most of these catheters are only 30 cm long, the proximal end of the ET tube requires shortening if the catheter is to protrude past the distal end of the ET tube.

   An 8 or 10 Fr polyethylene pediatric feeding tube (e.g., Argyle, St. Louis). These tubes are much longer than needed and should be cut to the desired length to reduce dead space. Luer-Lok-type syringes and IV adapter locks both fit nicely onto the proximal end of the tube.

   An 8 Fr (or larger) pediatric pulmonary suction catheter without the control port. Because this catheter is designed to extend past the tip of the ET tube, it is an ideal length. However, with some brands, it is difficult to attach a syringe or IV adapter lock after the suction control port is removed.

   Alternatively, two ET tubes with built-in ports are available. They allow ET instillation of drugs without removing the bag ventilation device. Unless these special tubes are used for all patients requiring intubation, the major drawback is the obvious need to re-intubate or decide before intubation if IV access is expected to be a problem. In these cases, the patient can be intubated using one of these specialty tubes. The available ET tubes include the following:

   ET tubes designed for bronchoscopy (e.g., Hi-Lo Jet Tracheal Tube, Mallinckrodt Medical, St. Louis, MO). These tubes have two additional ports, one used for monitoring or irrigation (opaque lumen) and one used for jet ventilation (transparent lumen). They are available in adult and pediatric sizes (cuffed and uncuffed). In a porcine cardiopulmonary arrest model, successful resuscitation using this tube was comparable to resuscitation using other forms of ET drug administration.[34] The major disadvantage of this ET tube is the need to be familiar with the specific ports before use. Determining which is the irrigation port if one has never seen the tube previously could be time consuming. In addition, the port requires placement of an IV adapter lock to use prefilled syringes (in which most emergency medications are now supplied).

   ET tube with side port (ETSP) [EMT tracheal tube, Mallinckrodt Medical, St. Louis, MO]. This tube is designed specifically for ET drug administration. The instillation lumen opens into the tube at the eye, approximately 1 cm from the end of the tube. The injection port has an IV adapter lock, which makes it amenable to use with prefilled syringes. The ETSP is not available in pediatric sizes. In addition, in one study comparing the administration of lidocaine via the ETSP vs administration to the proximal end of the standard ET tube, serum lidocaine measurements never reached therapeutic levels in the ETSP group [in contrast to the ET group and IV control group]. [66]

3. An IV adapter lock. This can be placed as needed onto the proximal end of the ET tube or catheters described previously to convert them for use with prefilled syringes. This adapter is usually unnecessary if a standard syringe is used.
4. A 10- to 20-mL syringe, preferably a Luer-Lok type, big enough to deliver the desired volume of drug solution plus an additional 5 mL of air. Unfortunately (for ET drug therapy), most of the medications now prescribed for emergency situations come in prefilled syringes with built-in needles (Fig. 27-1). This type of apparatus usually does not allow one to draw up an additional volume of air to empty the catheter of solution. Also, the needle on the prefilled syringe requires an IV adapter lock in order to adapt to most catheters for injection.
5. Desired diluent solution. As previously described, the drug should be delivered in a final volume of 10 mL for adults, 5 mL for children, and 1 mL for neonates. An adequate volume of diluent, usually normal saline, must be available. Distilled water is an acceptable alternative.
6. Desired medication to be instilled (see Table 27-2).
7. An 18- or 19-ga needle for use in drawing up the drug solution or for injecting the solution, or both. Use of an 18-ga, 8.9 cm (3.5 in.) spinal needle is recommended for direct instillation of medications into the proximal end of the ET tube.
8. Alcohol wipes for cleaning vials or injection ports, or both.
9. Gloves, mask, and eye protection. After instillation, the solution often refluxes out of the ET tube, making blood and body fluid precautions of paramount importance.

Figure 27-1 Example of a prefilled syringe, which is frequently used in endotracheal therapy.

PROCEDURE

Four procedures are described in this section, listed in order of generally accepted use, but definitive studies have not

clearly identified the best technique. Most important, the procedure of choice is the method that will deliver the medication to the patient in the timeliest fashion. As stated previously, one should not delay drug administration to find the perfect piece of equipment or diluent (normal saline or distilled water are both acceptable in most cases).

It is assumed for all procedures that vials and IV adapter locks will be cleaned with alcohol wipes before use and that universal precautions will be practiced at all times. In addition, all patients require prior intubation (see Chapter 4), and the ET tube should be secured to prevent the tube from being expelled if the patient coughs. If present, the cuff of the tube should be inflated.

Use of a Catheter

Provide ventilations with the bag-valve ventilation device with supplemental oxygen while the required drug dose is drawn up in either a 10- or a 20-mL syringe. Dilute the drug with normal saline as needed to attain a total volume of 10 mL (for adults), 5 mL (for children), 1 mL (for neonates). Draw back the plunger to add 5 mL of air to the liquid in the syringe. If the drug to be delivered is in a prefilled syringe, place an IV adapter lock on the catheter. The syringe can be attached to the catheter at this time or once the catheter has been placed within the ET tube (Fig. 27-2).

Interrupt the connection between the proximal end of the ET tube and the bag-valve ventilation device. Place the catheter within the lumen of the ET tube, ideally in such a

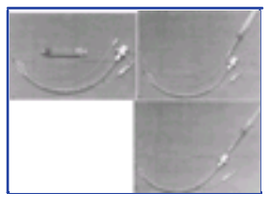

Figure 27-2 Use of a central venous catheter for endotracheal drug delivery.

manner that the distal end of the catheter extends ~1 cm beyond the distal end of the ET tube. For the catheter to reach deep enough, the proximal end of the ET tube may need to be cut to a shorter length. Hold the proximal ends of the catheter and the ET tube at all times during the procedure. If it has not already been done, attach the syringe to the catheter. If external cardiac compressions are being performed, *they should be interrupted during drug delivery*. Inject the drug solution rapidly and forcefully through the catheter into the trachea followed by the 5 mL of air needed to flush the catheter of any remaining drug solution. Promptly remove the syringe and catheter from the ET tube. If the patient makes an effort to cough, place a thumb over the opening of the ET tube to prevent expulsion of the solution. As soon as possible after drug delivery, reconnect the bag-valve ventilation device with supplemental oxygen to the ET tube. Deliver five rapid ventilations to promote distal dispersion of the drug. Resume chest compressions if necessary.

Direct Instillation into the Endotracheal Tube

When special ET tubes or catheters are not available, the drug may be instilled directly into the proximal end of the ET tube. Studies using this technique have diluted the medication with normal saline and also flushed the tube with normal saline after the drug is instilled. [34]

While the patient is being ventilated, draw up the desired drug into a syringe (or use a prefilled syringe). Because no catheter is used, there is no need to draw up an additional

volume of air into the syringe. Dilute the drug to a final volume of 10 mL (adults), 5 mL (children) or 1 mL (neonates) with normal saline or distilled water. Attach an 18- or 19-ga needle (some authors recommend using an 8.9 cm [3.5 in.] spinal needle). If using a prefilled syringe, in a second syringe, draw up an appropriate volume of normal saline such that the total instillation volume (drug plus saline) equals 10 mL (adults), 5 mL (children) or 1 mL (neonates). Attach an 18- or 19-ga needle. This will be used to flush the ET tube after drug instillation.

Interrupt the connection between the proximal end of the ET tube and the bag-valve ventilation device. Insert the needle of the first syringe (drug) into the proximal opening of the ET tube. Hold the proximal end of the needle with one hand to prevent loss of the needle into the tube. Discontinue cardiac compressions, and inject the drug solution rapidly and forcefully. If using a prefilled syringe, flush the tube immediately with the diluent in the second syringe. If the patient makes an effort to cough, place a thumb over the opening of the ET tube to prevent expulsion of the solution. Reattach the bag-valve ventilation device and deliver five rapid insufflations. Resume chest compressions if needed.

Use of Endotracheal Tubes with Irrigation/Drug-Delivery Lumens

Unless these ET tubes are used for every intubation, their usefulness in emergent ET drug delivery is dependent on the provider's recognition before intubation that IV access will be problematic. If this is recognized, intubate the patient using an ET tube with monitoring lumen (e.g., Hi-Lo Jet ET tube) or with an ETSP (e.g., EMT tracheal tube). While ventilating the patient with supplemental oxygen, draw up the required drug dose in either a 10- or 20-mL syringe with an 18- or 19-ga needle attached (or use a prefilled syringe). If necessary, dilute the drug with normal saline or distilled water to attain a total volume of 10 mL (adults), 5 mL (children) or 1 mL (neonates). Draw back the plunger to add 5 mL of air to the liquid in the barrel of the syringe. Attach the syringe or insert the needle into the IV adapter lock on the ET tube monitoring/irrigation lumen (Hi-Lo Jet tube) or on the drug-delivery lumen (EMT tube). Discontinue chest compressions and rapidly and forcefully inject the drug solution during the inspiratory phase of ventilation (i.e., when the bag is squeezed). Deliver five rapid hyperventilations with the bag-valve ventilation device and resume chest compressions if necessary.

The advantage of this method of drug delivery is that it does not require interruption of the connection between the bag-valve ventilation device and the ET tube. In addition, it offers the theoretical advantage of allowing drug delivery during the inspiratory phase of ventilation, although at least one study has shown that this is not an important factor. [35]

Injection Through the Endotracheal Tube Wall

This method of drug delivery has not yet been evaluated scientifically but has been used clinically. [67] [68] While the patient is being ventilated, draw up the desired drug into a syringe with an attached 18- or 19-ga needle (or use a prefilled syringe). Dilute the drug with normal saline or distilled water to attain a total volume of 10 mL (adults), 5 mL (children) or

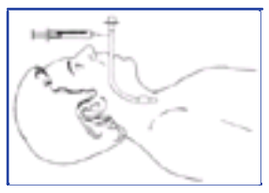

Figure 27-3 Method of drug injection through the endotracheal tube wall.

1 mL (neonates). No additional air needs to be added to the syringe. Insert the needle into the side of the ET tube proximally (Fig. 27-3). Discontinue chest compressions and rapidly and forcefully inject the drug solution into the ET tube during the inspiratory phase of ventilation (i.e., when the bag is squeezed). Deliver five rapid hyperventilations with the bag-valve ventilation device and resume chest compressions, if necessary. As with ET tubes with drug-delivery lumens, this technique requires no interruption of the connection between the bag-valve ventilation device and the ET tube. In addition, placing an IV adapter lock on the needle allows it to be left inserted in the ET tube for use with additional medications. [68]

COMPLICATIONS

Reported complications of ET drug therapy are rare, due in part to the infrequent use of this technique. In addition, because most or all patients who receive ET drug therapy are in cardiopulmonary arrest or are otherwise critically ill, it is difficult to ascertain if an adverse outcome is the result of the therapy or the patient's underlying condition.

With regard to the techniques of ET drug administration, no serious complications have been reported. A theoretical complication is the loss of a needle or catheter down the ET tube, but specifically holding the catheter or needle while instilling the drug can prevent this complication. Thus the techniques of ET drug administration seem to provide a safe method of drug delivery.

Following ET drug administration, the administered emergency drugs may produce adverse effects. Epinephrine administered during CPR has been noted to produce prolonged hypertension, tachycardia, and dysrhythmias after the return of a perfusing rhythm in both animal models [24] and human case reports.[12] It appears that this side effect is related to the depot effect, in which larger doses of drugs administered endotracheally are released slowly over time (similar to an IV drip). In addition to epinephrine, atropine and lidocaine also exhibit a depot effect when administered endotracheally. [61] No serious long-term sequelae have been reported, however, due to this effect.

A second area of potential concern with ET drug therapy is a transient decrease in arterial oxygen content during or after drug delivery. As discussed previously, if total volumes

are maintained between 5 and 10 mL in adults, the effect on pulmonary function appears minimal and likely of no clinical consequence. It should be remembered, however, that any decrease of PaO_2 in a critically ill patient, regardless of how small or how transient, may have deleterious effects. The potential for this adverse effect should always be considered when administering drugs by the ET route, and supplemental oxygen should always be administered in an effort to improve oxygenation and offset any transient drop in arterial oxygen content that might develop.

CONCLUSION

It is important that clinicians be familiar with ET drug therapy as it may be a life-saving procedure in some emergent situations. The great variability in the effectiveness of this procedure, however, mandates that it be used only when IV or IO access is not available. Little information is available on the pharmacokinetics, pharmacodynamics, and effectiveness of medications administered via the ET route during cardiopulmonary arrest. Consequently, the ideal dose, diluent, volume, and technique have yet to be determined and may be drug and situation dependent. Despite these limitations, ET drug therapy has been beneficial for some patients. If other access is not available, appropriate medications should be delivered via the ET route using the procedure that will ensure delivery to the patient in the shortest time period.

Chapter 28 - Autotransfusion (Autologous Blood Transfusion)

Charlene Babcock Irvin

Traumatic injury affects men and women during their most productive years.[1] This fact, coupled with increasingly efficient and rapid emergency transportation systems, has resulted in growing numbers of traumatic injury victims arriving at emergency facilities in potentially salvageable condition. The ensuing urgent demand for blood often exceeds the immediately available supply of homologous banked blood.[2] Successful approaches to this problem have included earlier hemostasis (i.e., definitive surgery), use of volume expanders (crystalloid, colloid), and autotransfusion. Other approaches to treat acute hemorrhagic shock that are currently under investigation include the use of hypertonic saline[3] and manufactured blood substitutes.[4]

Autotransfusion may be defined as "collection and reinfusion of the patient's own blood for volume replacement."[5] Emergency autotransfusion most often involves collection of shed blood from a major body cavity, usually the pleural space (hemothorax) and occasionally the peritoneal space. Autotransfusion in the emergency department (ED) is generally limited to acute hemothorax with clinically significant hypovolemia. The following discussion examines the advantages and potential complications of emergency autotransfusion, patient selection, available equipment, and procedural technique for several widely used devices.

While autotransfusion is a basic technique that is theoretically possible in any ED, it is not a standard of care under all settings. Since the procedure requires familiarity with the equipment and continuing education and quality control, it may be counterproductive to institute it in a hospital that has a low trauma census or in a setting where it will be used infrequently enough that staff education issues are problematic. Autotransfusion will be most useful in trauma centers or high-trauma-volume community hospitals where the technique is used often enough to be considered routine by clinicians and nursing staff.

BACKGROUND

Reports of autotransfusion can be found in the Western medical literature as early as 1818. Blundell, [6] an English practitioner, considered the possibility of reinfusion of shed blood after witnessing a woman exsanguinate from uterine hemorrhage. His subsequent work with autotransfusion of shed blood in dogs suggested that the procedure was clinically feasible. In 1886, Duncan [7] used the technique without noticeable ill effects to reinfuse blood shed during an amputation. In 1914, the use of the technique in ectopic pregnancies was popularized by Thies [8] , and 3 years later Elmendorf[9] published a description of the first case of autotransfusion from traumatic hemothorax. Also in 1917, Lockwood [10] used the procedure for the first time in the United States during a splenectomy. In 1922, Burch [11] reviewed 164 cases of autotransfusion published over the preceding 8 years in the European medical literature, largely originating from Germany.

The discovery of ABO blood typing at the turn of the century and the institution of blood banks in the 1930s led to the almost exclusive use of homologous blood up to and following World War II. Interest in autotransfusion concomitantly declined, and only sporadic reports appeared in the literature during this period. During the 1960s and 1970s, cardiopulmonary bypass surgery generated extensive data regarding intraoperative retrieval of large quantities of blood for reinfusion. Concurrently, the Vietnam War created a new demand for readily available blood in areas remote from conventional reserves of homologous bank blood. Thus, revitalized interest, coupled with growing experience, generated the early publications of such investigators as Dyer and associates, [12] Klebanoff and colleagues[13] [14] , and Symbas and coworkers,[15] thus initiating the "new era" of autotransfusion.

ADVANTAGES

The advantages of autotransfusion over banked blood transfusion in patients who are hypovolemic from traumatic blood loss include the following:

1. Shed blood is immediately available (collection and initiation of reinfusion can be accomplished within minutes).
2. Blood compatibility is not a problem, which avoids both transfusion reactions and delays associated with crossmatching.
3. Shed blood when rapidly reinfused is normothermic, consequently reducing the complications related to the administration of room-temperature fluids. [16]
4. The risk of indirect patient-to-patient transmission of infectious diseases (e.g., hepatitis, malaria, cytomegalovirus, or human immunodeficiency virus) is eliminated. [17]
5. Levels of 2,3-diphosphoglycerate (2,3-DPG) have been found to be significantly higher in autotransfused red blood cells (RBCs) than in stored homologous cells. [18] [19]
6. There are no direct complications due to hypocalcemia or hyperkalemia. [20] [21]
7. There is less risk of inadvertent circulatory overload and adult respiratory distress syndrome (ARDS). [22]
8. Autotransfusion allows preservation of limited stores of banked blood, thereby ensuring its availability for other uses. [17]
9. Autotransfusion lowers the cost of medical care. [17] No blood drawing, typing, or crossmatching is required; thus, time, money, and personnel expenditures may be conserved. Davidson[23] reported the cost of autologous blood to be three- to eightfold cheaper per unit compared with banked blood.
10. Reinfusion of autologous blood may be acceptable to those patients whose religious convictions prohibit transfusions with homologous blood. Techniques for intraoperative or extraoperative collection of autologous blood that involve blood storage or reinfusion of shed blood are objectionable to Jehovah's Witnesses. Nonetheless, salvage when extracorporeal circulation is

uninterrupted may be acceptable to many members of that religion. [24]

PATIENT SELECTION

Indications

In general, all victims of severe trauma, whether blunt or penetrating, should be considered potential candidates for autotransfusion. More specifically, Reul and colleagues[25] have described three categories of patients for whom emergency autotransfusion is suitable. The ideal candidate is a blunt or penetrating trauma victim with a hemothorax containing 1500 mL or more. A second category is the hemorrhaging patient with an immediate need for transfusion, for whom insufficient homologous blood is available because of the urgency of the situation, a blood bank shortage, or a difficult crossmatch. Under these circumstances, Reul and coworkers used autotransfusion regardless of the type of injury or degree of contamination. A third category is the patient with massive blood loss (less than one whole-body blood volume) for whom autotransfusion can serve as a supplement to homologous replacement. O'Riordan [21] added a fourth category, the trauma patient who urgently requires blood transfusion and whose religious convictions prohibit homologous transfusion.

It is reasonable to consider use of autotransfusion in all patients who have a hemothorax and require even minimal blood replacement. When the need for homologous blood transfusion is borderline, autologous blood can be readily reinfused without the risk of complications associated with banked blood. Reasonable indications for initiating blood collection for possible autotransfusion may be summarized by these four situations:

1. Blunt or penetrating chest trauma with significant hemothorax (500 mL or more) suggested on a chest film
2. Multiple trauma with shock of uncertain etiology when emergent tube thoracostomy is performed prior to chest film
3. Emergency thoracotomy
4. Any hemothorax when there is an urgent need for blood and the patient's religious beliefs prohibit homologous transfusions

Because of the equipment required and the need for specialized care, autotransfusion is generally performed in the ED, operating room (OR), or intensive care unit (ICU) settings. Although seldom used in the out-of-hospital setting, it may be useful under certain circumstances. Barriot and colleagues reported on the emergency medical services of the Paris Fire Brigade's experience with autotransfusion from a hemothorax. They concluded that this technique may be effectively used in the out-of-hospital setting.[26] [27]

Contraindications

Reul and coworkers[25] suggested the following general contraindications to the use of emergency autotransfusion:

1. The known presence of malignant lesions in the area of traumatic blood accumulation.
2. Known renal or hepatic insufficiency (relative contraindication based on individual scenario).
3. Wounds older than 4 to 6 hours (because of the theoretical problem of bacterial overgrowth).
4. Gross contamination of pooled blood, usually as a result of injury to the gastrointestinal tract.

Huth and colleagues[28] found that major combined pancreatic-proximal intestinal injury may also constitute a contraindication owing to the potential for systemic reinfusion of large amounts of pancreatic enzymes.

Depending upon the clinical situation, particularly the urgency of the need for blood, some of these contraindications may be overruled by the lack of available (banked) blood. The National Blood Resource Education Program Expert Panel [29] has limited contraindications to active infection or gross contamination and the possibility of malignant cells in the salvaged blood. Investigation has confirmed that even when using systems that separate and wash cells, tumor cells will be resuspended and reinfused to the patient.[30]

Several investigators believe that the reinfusion of limited amounts of contaminated blood from the peritoneal cavity may be accomplished with an acceptable risk, [31] [32] [33] but the current consensus is that exsanguinating hemorrhage is the only acceptable indication for autotransfusion when there is recognized intestinal contamination. Indeed, Klebanoff[34] believes that autotransfusion has "no place" when there is extensive fecal or urinary contamination of the pooled blood. Thus, the advisability of autotransfusing possibly contaminated blood from the peritoneal cavity remains controversial (see Complications later in this chapter).

EQUIPMENT AND MATERIALS

Autotransfusion Units

While there are several commercially available systems that provide easy initiation of autotransfusion in the ED setting, items currently available in most EDs will also allow rapid infusion of autotransfused blood. Symbas [35] described a simplified collection system using standard ED materials (Fig. 28-1). After insertion of a chest tube, drainage is established into a standard chest tube bottle containing 400 mL of normal saline, maintaining a suction of 12 to 16 mm Hg. If autotransfusion is required, the collected blood in the chest bottle is reinfused in one of two ways:

1. The chest bottle may be disconnected from the pleural drainage tube and simply inverted on an intravenous (IV) stand for reinfusion through a filter into the patient. During infusion, a second sterile chest bottle with saline is connected to the chest tube for continuing collection.
2. After disconnection from the pleural drainage tube, the chest bottle may be connected to a standard blood collection bag and the salvaged blood transferred to this bag for subsequent reinfusion through a blood filter in the conventional manner. Symbas [35] reported on more than 400 patients autotransfused by this method since 1966, with no adverse effects attributable to the procedure.

Two other highly simplified techniques have been described that do not involve use of commercial autotransfusion units. Schweitzer and coworkers [36] reported successful autotransfusion in dogs by means of a chest tube connected to a Heimlich flutter valve (Bard-Parker, Rutherford, NJ). The valve is connected in turn to a 1900-mL Abbott Receptal blood collection bag. Drainage is entirely by gravity; no

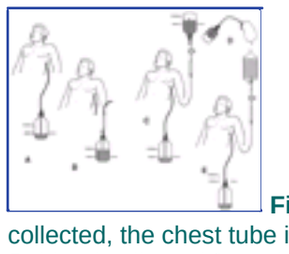

Figure 28-1 Technique of autotransfusion from traumatic hemothorax. *A*, Blood is collected into sterile blood collection bottle with 400 mL normal saline. *B*, After blood is collected, the chest tube is disconnected from the collection bottle. *C*, Blood is infused directly from the blood collection bottle while a new chest tube drainage bottle is connected to the chest tube. Or, *D*, blood collected from the chest tube is transferred into a sterile blood bag. *E*, Blood transferred into blood bag is infused into patient. *(From Symbas PN: Extraoperative autotransfusion from hemothorax. Surgery 84:722, 1978.)*

suction is applied (Fig. 28-2). Similarly, Barriot and colleagues [26] [27] described the European experience with a device called a Hemotraum that is adapted for out-of-hospital autotransfusion. Blood from the chest tube fills a 750-mL sterile bag by gravity via a 120-µm micropore filter. When full, the bag is clamped and disconnected, and the collected blood is reinfused through a 50-µm micropore filter. While this blood is being transfused, a second sterile bag is connected to the chest tube. No anticoagulant is used. Neither

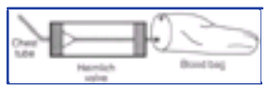

Figure 28-2 Heimlich valve connected directly to Abbott Receptal Bag. *(From Von Koch L, Defore WW, Mattox KL: A practical method of autotransfusion in the emergency center. Am J Surg 133:770, 1977.)*

of these techniques has undergone clinical trials in the United States. They may offer advantages for autotransfusion on the battlefield, in small rural hospitals, or the out-of-hospital care setting.

Although the described method for autotransfusion using these easily assembled items did not include the addition of anticoagulant, it may be appropriate to add an anticoagulant, especially when blood is rapidly accumulating from a great vessel injury (see Anticoagulation later in this chapter).

There are many types of commercially available autotransfusion systems designed for intraoperative use, but only two are practical for use in the ED. One type uses a chest tube to withdraw shed blood into an autotransfusion bag, while the other type uses a suction catheter. Systems using a chest tube differ based on the presence of an in-line thoracostomy unit incorporating a water seal. Several units offer this feature, including the Pleur-Evac, Thora-Klex, and Sahara autotransfusion systems (Genzyme Biosurgery Corporation, Falls River, MA: http://www.genzymebiosurgery.com/1-800-367-7874), the Atrium Ocean and Oasis ATS systems (Atrium Medical Corporation, Hudson NH: http://www.atriummed.com/1-800-528-7486), and the Throa-Seal and Aqua-Seal (Kendall Health Care, Mansfield, MA: www.kendallhq.com/1-800-962-9888).

The Abbott Receptal System, manufactured by Abbott Laboratories (Abbott Park, IL: http://abbott.com/1-847-938-4310), uses a chest tube and blood collection unit, but does not include a standard chest tube drainage system with a water seal. This device uses wall suction to withdraw blood through the chest tube into a blood collection bag for future reinfusion. Because there is no chest tube drainage system in series with this device, it is unable to detect air leaks. It also has no overflow protection. In other autotransfusion units in series with disposable chest tube drainage systems, excess blood spills over to the collection chamber of the chest tube drainage unit.

Von Koch and associates[37] reported their experience with the Sorenson unit (now the Abbott Receptal system) in autotransfusing an average of 1000 mL of salvaged blood in 30 trauma patients. They found that this unit could be assembled quickly and easily operated. Its use resulted in minimal air-blood interfacing (a source of hemolysis). They also described the unit as "efficacious, inexpensive, cost-effective, and safe." Davidson [23] described the step-by-step use of this system in the ED and characterized it as "simple to use, efficacious, cost-effective, and safe" for the emergency setting. Autotransfusion using this device is described in the following section.

ED autotransfusion systems that use a suction catheter instead of a chest tube include the Bloodless Surgery Station (Harvest Blood Conservation Inc., Plymouth, MA: www.harvesttech.com/1-877-842-7837) and the Autovac Intraoperative (IO)(Boehringer Laboratories, Norristown, PA: http://www.boehringerlabs.com/1-800-642-4945). The Harvest unit is freestanding and can be connected to a standard electrical outlet. This system provides its own suction while collecting blood through a special suction catheter. It is capable of suctioning 3.75 liters of blood per minute with less than 100 mm Hg suction pressure. The Autovac unit is designed to suction blood directly to a reservoir that is connected in series to wall suction (similar to the Abbott Receptal but collection of blood occurs from a suction catheter instead of a chest tube).

Blood Filters

In-line filtration is used routinely during reinfusion of blood products to reduce the danger of microembolization and resultant pulmonary insufficiency. [20] [38] [39] The relationship between the presence of microaggregates and the development of acute respiratory distress syndrome (ARDS) [39] is controversial; however, most investigators advise some form of micropore filtration. Pore size seems to be the only issue, and recommendations range from 20 to 170 µm. [40] [41] The majority of

investigators believe that a pore size of 40 µm minimizes the risk of microembolization without undue elevations in filtration pressures. [16] [25] [42]

Vacuum Suction

There is general agreement that the level of vacuum suction should be limited to minimize red cell hemolysis. [43] The exact level at which clinically significant hemolysis occurs is uncertain and there is wide variation (5 to 100 mm Hg) in the levels used by various investigators. [23] [25] [37] [40] [43] Dyer and coworkers[12] reported that levels below 100 mm Hg kept hemolysis to a minimum. Pressure of 60 mm Hg or less has been preferred by several researchers for aspiration of hemothorax or hemoperitoneum,[25] [37] [40] but in the operating room, adequate suction to maintain a bloodless surgical field may require pressure well over 100 mm Hg. [12] [31] [41] With most commercial systems, the manufacturer's recommendations specify a suction limitation of 150 mm Hg.[44] A second vacuum source of 300 mm Hg should be available for occasions when high-flow suction is required. [45]

To minimize hemolysis, reducing the air-blood interface is as important as limiting the vacuum level. Therefore, suctioning should be from pooled blood whenever possible, with the suction tip kept well below the surface of the blood. [46] [47]

Anticoagulation

Anticoagulation of the aspirate during autotransfusion has been accomplished using several methods. These include local and systemic heparin, [13] [48] [49] acid citrate dextrose (ACD),[20] [41] [50] citrate phosphate dextrose (CPD),[25] [37] and normal saline (i.e., no anticoagulant). [15] [27] Local heparinization of the tubing and reservoir may lead to the formation of platelet microaggregates on the filter and in the line [25] [51] and systemic heparinization could lead to further life-threatening hemorrhage in an already bleeding patient.[25] [34] [51] Therefore, the use of heparin as an anticoagulant during emergency autotransfusion of the trauma patient is discouraged by most investigators.[25] [34] [52]

In several early studies, ACD was used as an alternative to heparin. [20] Raines and coworkers[41] found no clinical or laboratory evidence of intravascular coagulopathy after autotransfusion using ACD, even in patients who received more than 8000 mL of autologous blood. More recent studies report the use of CPD for extracorporeal anticoagulation. CPD avoids the complications of heparinization, [25] necessitates less volume as an anticoagulant, and results in less acidosis than does ACD.[25] [46] [53] Reul and colleagues[25] found CPD to be well-tolerated, even in large amounts. CPD undergoes such rapid metabolism that anticoagulation is confined, to a large degree, to blood in the autotransfusion apparatus. Rarely, excessive use of CPD can cause citrate intoxication because of chelation of calcium and subsequent cardiac dysrhythmias. Use of insufficient or outdated CPD may result in clotting of collected blood.

Investigators have recommended a range of 25 to 70 mL of CPD per 500 mL of collected blood.[25] [37] A 1:7 ratio of CPD to blood has also been suggested, [46] [52] which is comparable to the standard 67 mL of CPD per unit of banked donor blood.[25] Klebanoff [34] stated that CPD is the safest method of anticoagulation for autotransfusion and that the use of CPD avoids the problem of clot formation on the blood filter, thus maintaining higher platelet counts in reinfused blood.

Davidson has noted that for the average chest wound, added anticoagulant may not be required. [23] Blood retrieved from pleural and abdominal cavities frequently will not clot because it is devoid of fibrinogen, [54] likely because moderate rates of bleeding allow time for defibrination by contact with serosal (pleural and peritoneal) surfaces and by mechanical agitation from respiratory and cardiac movements. Dog studies have documented pleural deposition of fibrin following experimental hemothorax, further substantiating this mechanism as the cause of hypofibrinogenemia in collected blood. [55] Others[15] [27] [56] report corroborating clinical findings and recommend simple reinfusion through a filter without any anticoagulant. However, wounds of the great vessels may

bleed at a rate that allows coagulable blood to enter the collection reservoir, clotting off the entire system. [23] [37] [52] In such an instance, an anticoagulant, specifically CPD, is appropriate.

PROCEDURE

Mattox[57] described the properties of the ideal autotransfusion device: (1) easy and quick assemblage, (2) cost-effectiveness, (3) easy operation, (4) in-line microfiltration, (5) minimization of air-fluid interfaces, and (6) simple anticoagulation technique. Several devices currently being marketed conform to these specifications, and these are discussed in detail.

Pleur-Evac Autotransfusion System

The Pleur-Evac autotransfusion device is an example of an autotransfusion system that allows for chest tube collection of blood in series with a disposable chest tube drainage system. It consists of a sterile, single-use, disposable, rectangular-shaped, flexible blood collection bag supported by a rigid metal frame. The bag and frame are designed to attach in series directly to a standard Pleur-Evac underwater seal chest tube drainage unit. On another type of Pleur-Evac, the water suction control chamber is replaced by a dry suction control with a dial that may be set to regulate suction between 0 and 40 cm H_2O, regardless of the amount of source suction applied. Inside the collection bag in line with the incoming drainage tube is a 200 µm nylon mesh filter. Attached to the collection bag are two latex tubes, one (red-tipped) for collecting shed blood from the drainage site and one (blue-tipped) for connection to the Pleur-Evac drainage unit. An injection port is provided on top of the autotransfusion system (ATS) bag for the addition of anticoagulant to collected blood.

Collection

1. The Pleur-Evac underwater seal drainage unit (Fig. 28-3 (Figure Not Available)) is first prepared in standard fashion and connected to a source of suction. Slide the metal hanger over the patient drainage tubing port on the right-hand side of the unit (Fig. 28-4), and pull it down flush with the top and side of the drainage unit.
2. Unwrap a replacement ATS bag and fit it into the wire frame provided (Fig. 28-5). Close both white clamps on the bag tubing, and place the frame and bag on the wire hanger.
3. Connect the ATS bag in series to the chest tube drainage system (see Fig. 28-3 (Figure Not Available)):
   a. Clamp the drainage tubing coming from the patient (*A*).
   b. Remove the red protective cap from the collection tubing (*B*) on the ATS replacement bag and connect it to the patient chest drainage tubing (*C*) using the red connector.
   c. Remove the blue protective cap from the suction tubing (*D*) on the ATS replacement bag and connect to the underwater seal drainage unit (*H*) using the blue connector.
4. Using a syringe and an 18-gauge (or smaller) needle, inject anticoagulant through the rubber diaphragm (*E*) on the ATS bag cap. The manufacturer of the Pleur-Evac unit does not offer recommendations regarding specifics of anticoagulation of blood collected in the unit; however, general guidelines are a 1:7 ratio of CPD to blood, or an ACD-to-blood ratio of 1:7 to 1:20.
5. Open all clamps; make sure all connections are airtight. The system is now operational.

Reinfusion

1. Removal of ATS bag from chest drain and patient chest tube:
   a. When the ATS bag is full, use the negative-pressure relief valve (located on top of the drainage unit) (see Fig. 28-3 *F* (Figure Not Available)) to reduce excessive suction in the unit, and close the white clamps on the chest drainage tubing and ATS bag.
   b. Disconnect all connections to the ATS bag.
   c. Attach the male (blue) and female (red) connectors on top of the ATS bag to each other, and remove the bag from the drainage unit by spreading and disconnecting each metal support arm.
2. ATS bag reinfusion setup and priming:
   a. Prepare a standard Y-type blood infusion line with a high-capacity 40-µm in-line micropore filter, prime the line and filter with normal saline, and connect it to a large-bore IV access (14-gauge or larger) (Fig. 28-6).
   b. Invert the bag so that the spike port (see Fig. 28-3 *G* (Figure Not Available)) points upward. Remove the protective cap and insert the free recipient arm of the Y tube infusion line into the spike port using a constant twisting motion.
   c. Return ATS bag to upright position and place on standard-height IV pole (Fig. 28-7).
3. Reinfusion using the Pleur-Evac autotransfusion bag may be assisted using a pneumatic pressure blood pump, not to exceed 150 mm Hg infusion pressure. However, if a pneumatic pump is used, all air in the bag must be removed before infusion to minimize the risk of air embolism. To accomplish this, the red and blue connectors may be disconnected temporarily, one clamp opened, and the bag slowly squeezed until all air is out of the unit. Then the clamp is closed again, and the red-to-blue connection reestablished.
4. During reinfusion, autologous blood collection may be continued with a second ATS bag, repeating steps 2 through 5 under Collection.

Atrium Ocean Series

Atrium Medical Corporation also offers an array of chest tube drainage systems with optional in-series autotransfusion bags. The Atrium 2050 is one example. This system is very similar to the previous chest drainage system with in-series autotransfusion capabilities.

Collection

1. After the Atrium chest tube drainage system has been appropriately set up, attach the blood collection bag hanger on the front face of the chest drain or adjacent bed rail.
2. Insert the Atrium ATS blood collection bag into the hanger (Fig. 28-8). Be sure both ATS clamps are firmly closed prior to connector cap removal.
3. Connect in-line ATS bag in series to chest drain:
   a. Close the patient chest tube slide clamp firmly and separate by depressing connector lock (Fig. 28-9).

   b. Remove cap from female ATS bag (*A*) connector and insert male patient chest tube connector (*B*) (Fig. 28-10).
   c. Remove second male ATS cap (*C*) and insert into female chest drain connector (*D*) (see Fig. 28-10). This will complete the connection of the ATS bag to the patient and the chest drain.
4. Open both in-line ATS bag clamps prior to opening the patient chest tube clamp. The patient tube and ATS bag should be free of dependent loops to ensure maximum drainage efficiency.
5. When required, anticoagulant should be added directly to the ATS bag through the anticoagulation injection site located on the front face of the ATS bag. After appropriate alcohol swabbing of the anticoagulant port, a 20-gauge or smaller needle can be inserted for administering anticoagulant via syringe. When anticoagulation is desired, the manufacturer recommends an ACD-to-blood ratio range of 1:7 to 1:20, or the use of CPD anticoagulation.

Reinfusion

1. To remove the ATS bag from the chest drain and patient chest tube:

a. Securely close the patient chest tube clamp and both ATS bag clamps.
b. Disconnect the chest drain side first (*D*), and then disconnect the patient chest tube connector (*B*) (see Fig. 28-10).
c. Immediately place the male patient chest tube connector (*B*) into the female chest drain connector (*D*) and open the patient chest tube clamp (Fig. 28-11).
d. Reconnect the ATS bag connectors to each other (see Fig. 28-11).

2. To set up and prime the ATS bag reinfusion:
   a. Prepare a standard Y-type blood infusion line with a high-capacity 40-µm in-line filter, prime the line and filter with normal saline, and connect it to a large-bore IV access (14-gauge or larger) (see Fig. 28-6).
   b. Prime the IV blood administration set and microemboli blood filter with sterile saline.
   c. Invert the ATS bag with the spike port pointing upward and remove the tethered cap using a sterile technique.
   d. Insert the saline blood filter spike into the ATS bag using a firm twisting motion.
   e. Return the ATS bag to an upright position and place it on a standard-height IV pole.
   f. Open the filtered air vent located on top of the ATS bag first, followed by the IV clamp to complete priming. All remaining air within the IV circuit must be evacuated prior to patient connection.
3. During reinfusion, autologous blood collection may be continued with a second ATS bag, repeating steps 2 through 5 under Collection.

OTHER THORACOSTOMY SET AUTOTRANSFUSION SYSTEMS

In addition to the units described, the companies Genzyme Biosurgery, Atrium, and Kendall make other chest tube

Figure 28-7 Reinfusion of collected blood with the Pleur-Evac system. A second collection may be obtained while this blood is infusing. *(Courtesy of Deknatel, Inc., Fall River, MA 02720. Reproduced by permission.)*

drainage systems with autotransfusion capabilities. These systems offer numerous features. Genzyme Biosurgery offers several products that are very similar to the Pleur-Evac. The Thora-Klex, for example, uses a patented one-way valve in the chest tube drainage system. This allows it to maintain function even if the unit is tipped over. The Sahara, also available through Genzyme, is 100% latex-free. The procedures

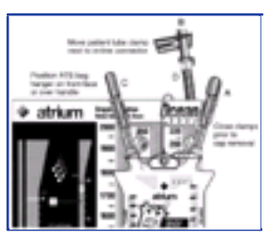

Figure 28-8 Atrium chest tube and autotransfusion system (ATS) prior to connection. *A*, Female ATS connector. *B*, Patient chest tube connector. *C*, Male ATS connector. *D*, Chest tube drain connector. *(Courtesy of Atrium Medical Corporation, Hudson, NH 03051.)*

outlined earlier are very similar for most units with in-line chest tube drainage systems.

Analysis of the minor differences among these systems is beyond the scope of this chapter. Therefore, users should obtain specific information regarding a particular system directly from the manufacturer.

Continuous Reinfusion Systems

An optional feature called *continuous reinfusion* or *autotransfusion* is available from the major manufacturers of chest tube drainage systems (Genzyme, Atrium, and Kendall). In this chest tube drainage system, a catheter on the bottom of the first collection chamber can be hooked to an IV infusion pump, permitting blood to be pumped directly back into the patient (it essentially uses the first blood collection chamber as the autotransfusion bag). This system is somewhat more hazardous as there is greater potential for air embolism and incorrect anticoagulant dosing. The procedure to initiate continuous reinfusion is as follows (Fig. 28-12):

1. Set up the chest tube drainage system and initiate blood collection from the chest tube to chest drain as recommended.
2. Inject appropriate anticoagulant into the front "anticoagulant injection site" after swabbing the area with alcohol. The appropriate dose can be estimated based on the volume of blood in the chamber at the initiation of continuous reinfusion.
3. Drape the end of the ATS access line (*B*) (Fig. 28-13) up over the top of the drain hanger or patient chest tube so that the end of the ATS access line is hanging down (Fig. 28-14).
4. Insert a microemboli blood filter (*C*) into the end of the ATS access line (*B*) (see Fig. 28-13).
5. Attach a non-vented IV set to the filter so that the IV tubing is in a "spike up" position (*D*) (see Fig. 28-13).
6. Insert IV tubing into a "self-priming" IV pump (*E*) and set the infusion pump to priming mode.

7. Open the ATS access line (*A*) by releasing the clamp (*F*) (see Fig. 28-12) and commence priming until ALL air in the ATS access line, filter, and IV tubing is fully purged. (Note, if a non "self-priming" infusion pump is used, the system MUST be manually primed prior to initiation of the infusion to avoid massive air embolism).
8. Attach the primed administration set to the patient's IV line (*G*) (see Fig. 28-14).
9. To prevent air from entering the system, keep at least 75 mL of blood in the blood collection compartment of the chest drain at all times. If this is not done, air embolism is a significant risk (see Nonhematologic Complications later in this chapter). One way to reduce the risk of air embolism is to set the IV pump dose (or volume to be infused) equal to the amount currently in the chest tube drainage compartment minus 75 mL. Using this technique, the IV pump will automatically stop when that volume has been infused and will ensure that, in the event no more blood is collected in the chest tube, the system will remain primed and the risk of air embolism will be reduced.
10. If continuous reinfusion is used, maintenance of proper proportions of anticoagulant to collected blood may become problematic.

Abbott Receptal Disposable Suction Liner System

The Abbott Receptal ATS consists of a closed, rigid, nonsterile plastic canister into which a gas-autoclaved plastic bag is placed for blood collection. The canister can be mounted on an IV pole and connected to a vacuum regulator valve for control of negative suction pressure. The collection bag is placed in line with disposable collection tubing that has a separate inlet valve for admixture of anticoagulant and aspirated blood. This inlet is connected via sterile tubing to a bottle of CPD (Fig. 28-15). Unlike systems described previously, the Abbott unit does not include an in-line thoracostomy drainage device.

Collection

1. To collect autologous blood from a hemothorax, first open the included "Trauma Drainage Tubing Set" containing one 36 Fr chest tube, latex drainage tubing (see Fig. 28-15*B* and *C*), and a male-to-male connector (*D*). While tube thoracostomy is being performed in the usual manner, the burette set (*A*) is connected to the CPD bottle, and the burette is filled with 150 mL of CPD.
2. Connect the yellow-tipped (*E*) end of the latex drainage tubing (the end with the side port) to the inlet port (*F*) of

the red liner cap attached to the collection canister (see Fig. 28-15 and Fig. 28-16). Then remove the protective cap from the side port and connect the anticoagulant (CPD) administration line (Fig. 28-17). Prime the liner with 50 mL of CPD from the burette.
3. Connect the downstream suction hose (see Fig. 28-15*H*) to wall suction and turn wall suction to maximum. Be sure that the regulator on the autotransfusion stand does not exceed the preset 60 mm Hg during collection (100 mm Hg in special situations such as post-thoracotomy); otherwise, excessive hemolysis of RBCs may result.
4. When the chest tube is in place, connect the latex drainage tubing and begin collection. During collection, stay ahead of the accumulating blood volume with the CPD in 50-mL increments. Always keep the ratio no less than 1 part CPD to 10 parts blood (1:7 ratio of CPD to blood is recommended by the manufacturer); otherwise, the collected blood may clot, especially with massive ongoing hemorrhage. Do not overfill the liner bag; it will overflow, spilling blood into the regulator valve.

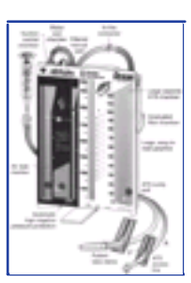

Figure 28-12 Atrium continuous autotransfusion system. *A*, Autotransfusion system (ATS) access line. *F*, ATS access line clamp. *(Courtesy of Atrium Medical Corporation, Hudson, NH 03051.)*

Reinfusion

1. Prepare a standard Y-type blood infusion line with a high-capacity 40-µm in-line filter, prime the line and filter with normal saline, and connect it to a large-bore IV access (14-gauge or larger) (see Fig. 28-6 and Fig. 28-18).
2. When the liner bag is full, temporarily clamp the chest tube, discontinue suction, and remove the yellow end of the latex drainage tubing (*E*) from the red liner lid. The liner lid tubing connector (*J*) is now removed from the canister tee (*K*) (Fig. 28-19) and connected to the inlet port (*F*) of the liner cap, thus sealing the top of the collection lid (Fig. 28-20).
3. Remove the liner assembly from the canister by pushing upward on the thumb tab (see Fig. 28-20). Lift out the

liner bag, invert the bag, and unscrew the protective cap (*N*) over the bottom stem of the liner. Now insert the free recipient arm (see Fig. 28-6*L*) of the Y-tube infusion line into the stem of the collection bag, and hang the liner bag on the IV stand by the attached tab (*M*) (see Fig. 28-18). Before infusion, briefly disconnect the liner lid tubing connector (see Fig. 28-18*J*), vent all air from the bag (to eliminate the possibility of air embolism), and then reconnect it to the inlet port.
4. Gravity flow, manual squeezing of the liner bag, or an in-line roller pump may be used to hasten reinfusion. Although some reports [22] [35] mention the use of encircling pneumatic blood pumps during reinfusion, Abbott cautions that such devices may damage the pump or rupture the liner bag.
5. During reinfusion, autologous blood collection may be continued with a second liner bag. Be sure that the new liner bag is fully extended before placing it into the canister (Fig. 28-21). If the bag is crumpled at the top of the canister, blood may be sucked directly into the regulator valve. Insert the new liner into the canister, and snap the lid in place with the thumb tab directly over the canister tee (Fig. 28-22). The unit is now ready for collection assembly as previously outlined.

Boehringer Autovac Intraoperative System

This system is designed to be used with a suction catheter. A unique advantage of the Boehringer Autovac IO is the optional integral vacuum regulator built into the cap. This feature allows direct attachment to a wall vacuum without an external regulator. It automatically limits applied suction to a maximum of 100 mm Hg, thereby minimizing RBC hemolysis. The number of connections on the collection line has been reduced to one, and the male connector has a skirt shield, reducing the chances of inadvertent contamination through contact with nonsterile surfaces. The collection bag is prepackaged within a disposable rigid plastic canister and will hold up to 1000 mL of blood. Inside the collection chamber is a shutoff system consisting of a hydrophobic filter that, upon contact with blood or any liquid, quickly occludes, preventing overflow into any downstream component (e.g., wall suction regulators).

Collection

1. The vacuum line is attached to the connector on the canister (Fig. 28-23). Models not equipped with the optional integral regulator must be attached to a wall regulator set at no greater than 100 mm Hg vacuum.

2. Anticoagulant is injected through a port on top of the canister. Boehringer Laboratories recommends (and offers for sale) anticoagulant citrate dextrose solution A (ACD-A), which contains 0.73 g of citric acid, 2.2 g of sodium citrate, and 2.45 g of dextrose per 100 mL. Initially 40 mL is injected into the bag, and as collection proceeds, ACD-A is added to maintain a proportion of 1:5 to 1:10 ACD-A to blood.
3. During collection, the canister is periodically agitated to facilitate mixing of blood and anticoagulant.
4. When full, blood will come into contact with the hydrophobic filter at the top of the canister, automatically shutting off the system.

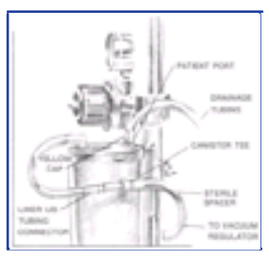

Figure 28-16 Abbott Receptal collection apparatus. Detail of canister connections before attachment of anticoagulant line. *(Courtesy of Abbott Laboratories, Abbott Park, IL 60064. Reproduced by permission.)*

Reinfusion

1. Engage both slide clamps at the top of the canister. Both collection and vacuum lines are now occluded, creating a closed system.
2. Disconnect the canister from suction and collection lines. If further collection is desired, another canister can now be attached to these lines.
3. The flexible blood bag is removed from the rigid canister by first removing the white safety tape and then popping the lid from the lower portion of the canister.
4. Keeping the bag upright, temporarily loosen the slide clamp over the vacuum connector and gently squeeze the bag to expel any residual air through the filter shutoff mechanism. Then re-engage the slide clamp.
5. The bag may now be attached to a blood administration set in the usual fashion (Fig. 28-24). The manufacturer recommends using an in-line microaggregate filter (20 to 40 µm).
6. An external pneumatic cuff around the bag may be used to increase flow rates, but cuff inflation pressures should not exceed 300 mm Hg.

HARVEST BLOODLESS SURGERY STATION

A newer device on the market for direct suctioning of blood (through a suction catheter and not a chest tube) in anticipation of autotransfusion is the Harvest Bloodless Surgery Station. While this unit also provides additional capabilities not generally useful for autotransfusion in the ED setting (like RBC washing), some features do make it potentially attractive for ED use. It requires only an electrical outlet to function as it has a built-in suction system. It is a freestanding unit that comes attached to a specifically designed stand, so it is freely mobile to different locations. It also has a specially designed suction catheter that allows rapid suction of up to 3.75 L per minute (Fig. 28-25).

Additional General Autotransfusion Information

1. Use each liner bag only once.
2. After reinfusing a total of 3500 mL, or 7 units, of autologous blood, it has been suggested that 1 unit of fresh frozen plasma be given for every 2 units (1000 mL) of autotransfused blood.[41]
3. To minimize risk from bacterial overgrowth, collected blood must not be allowed to stand for prolonged periods of time before reinfusion. Some authors [46] [52] [58] advise a limit of no more than 4 hours between collection and reinfusion. The age of collected blood should be calculated from the time of injury, and reinfusion of blood older than 4 to 8 hours should be considered hazardous. Because one is performing the procedure for significant hypovolemia in the ED, the collected blood should generally be transfused as soon as the collection bag is full.
4. If some or all of the collected blood becomes clotted in the liner bag, the blood should be discarded.
5. The blood filter used during reinfusion is changed as needed (usually after each 1000- to 2000-mL transfusion). In practice, the need for a new filter will become apparent as perfusion pressures increase and flow rates visibly slow down.

COMPLICATIONS

Complications from autotransfusion generally are clinically insignificant if the proper technique is followed and if less than 3000 mL of blood is reinfused. They may be categorized as hematologic and nonhematologic (Table 28-1).

Hematologic Complications

The most frequent hematologic consequence of autotransfusion is thrombocytopenia. Samples taken from collected autologous blood generally show very low platelet counts although not as low as found in banked blood. [56] Until patients receive greater than 3500 mL of autologous blood, in vivo platelet counts do not drop below 60 × 10^9 /L.[26] [35] [43] Above this level, trauma surgery can be satisfactorily performed. [58] Platelets collected from autotransfusion reservoirs function abnormally when tested in vitro by aggregation or serotonin uptake and release, but postinfusion samples drawn from

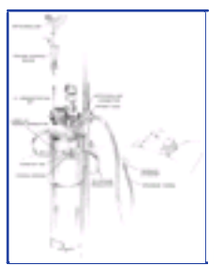

Figure 28-17 Proper attachment of anticoagulant line for Abbott Receptal device. The preferred anticoagulant is citrate phosphate dextrose (CPD) in a 1:7 volume ratio of anticoagulant to blood. *(Courtesy of Abbott Laboratories, Abbott Park, IL 60064. Reproduced by permission.)*

patients aggregate normally.[41] A canine study demonstrated significant in vivo platelet dysfunction when autotransfused volumes exceeded an amount equivalent to 1 total blood volume.[19] Thus, platelet counts should be followed and significant thrombocytopenia treated with platelet infusion.

The most common coagulation factor abnormality after autotransfusion is hypofibrinogenemia, especially when the volume of autologous blood used exceeds 4000 mL.[15] [51] [56] Because of the liver's capacity to replenish fibrinogen rapidly, the low postautotransfusion levels have not proved to be clinically significant. [25] [27] [52] Yet some investigators[25] believe that hepatic insufficiency is a relative contraindication to autotransfusion unless fibrinogen is supplemented.

Symbas and colleagues[15] [35] [59] extended their work with laboratory dogs to the clinical study of victims of traumatic hemothorax. They found no clinical evidence of coagulopathy following autotransfusion as long as the volume collected and reinfused remained equal to or less than one half the patient's

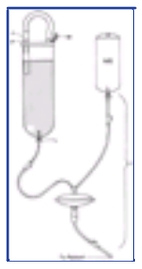

Figure 28-18 Reinfusion apparatus. Inlet port of liner cap (*F*), Y-type blood infusion line with in-line 40-µm filter (*I*), liner lid tubing connector (*J*), liner bag connection with infusion line (*L*), attached hanger tab at top of liner bag (*M*), and normal saline IV fluid for priming and maintaining patency of the system during liner bag changes (*N/S*). *(Modified from Young GP, Purcell TB: Emergency autotransfusion. Ann Emerg Med 12:180, 1983. Reproduced by permission.)*

total blood volume. In those few patients who required a larger autotransfusion volume, a proportional decrease in platelets and fibrinogen occurred, requiring subsequent correction with fresh frozen plasma and platelets. Other investigators [20] [23] have confirmed these findings and have shown that both platelet and fibrinogen levels return to normal by 48 to 72 hours, without replacement therapy. Similarly, elevations in prothrombin and partial thromboplastin times, which were encountered routinely, were not clinically significant. These coagulation abnormalities also self-corrected within 48 to 72 hours. [23] [25] [43] On the other hand, Schonberger and colleagues found that intraoperative autotransfusion of greater than 800 mL shed blood may provoke a significant derangement of hemostasis. [60]

Hemolysis occurs with autotransfusion in part because of prolonged exposure of the cells to serosal linings of the traumatized body cavities. [61] Hemolysis also results from

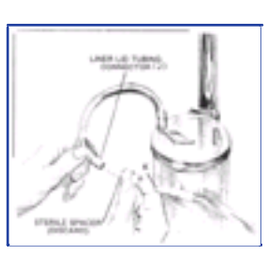

Figure 28-19 Preparation for reinfusion. Removal of liner lid tubing connector (*J*) from canister tee (*K*). Inlet port (*F*) is shown. *(Courtesy of Abbott Laboratories, Abbott Park, IL 60064. Reproduced by permission.)*

mechanical factors during collection and reinfusion, such as high vacuum pressures during aspiration, roller pump trauma, or excessive exposure to air-fluid interfaces. [25] An elevated plasma-free hemoglobin is a consistent finding in patients who have received autotransfusions. [25] [35] [51]

Most samples of blood taken from the autotransfusion reservoir have free hemoglobin levels of less than 1.0 g/L, [25] [35]

Figure 28-20 Preparation for reinfusion. Removal of liner assembly from the canister after connecting the liner lid tubing connector (*J*) to the inlet port of the liner cap. *(Courtesy of Abbott Laboratories, Abbott Park, IL 60064. Reproduced by permission.)*

Figure 28-21 Straightening the liner bag before insertion into the canister. *(Courtesy of Abbott Laboratories, Abbott Park, IL 60064. Reproduced by permission.)*

but some levels have been reported to be as high as 13.9 g/L). [51] Plasma-free hemoglobin values immediately after autotransfusion range from 0.1 to 1.0 g/L. [25] [35] [51] When the binding capacity of haptoglobin is saturated and the threshold of tubular resorption of hemoglobin is exceeded, hemoglobinuria is seen. This threshold corresponds to a plasma-free hemoglobin concentration of 1.0 g/L. [62]

In the past it was believed that elevated levels of free hemoglobin following hemolytic transfusion reactions caused renal failure by precipitation of hemoglobin in and obstruction of renal tubules. However, more recent evidence suggests that the mechanism of renal failure in this setting is independent of free hemoglobin. Rather, it is a result of an antigen-antibody-induced intravascular coagulation that, compounded by vaso-constriction and hypotension, leads to renal ischemia. [63] Indeed, it has been shown that "massive hemoglobinuria may follow the transfusion of immunologically compatible hemolyzed RBCs with minimal symptoms and a benign outcome" and that isolated free hemoglobin levels of up to 130 g/L may be tolerated without renal compromise. [64] Even though renal failure as a direct consequence of autotransfusion has not been reported, [34] transient elevations in serum creatinine do occur, [21] and in the presence of shock and systemic acidosis, acute tubular necrosis remains a potential complication. [62] Some researchers [25] believe that renal insufficiency is only a relative contraindication to autotransfusion. The clinician must judge the urgency of the need for blood and the availability of an alternate source.

Finally, the hematocrit falls in direct proportion to the quantity of blood transfused, averaging a decline of 10% to 20%. [25] [35] [32] However, nontraumatized RBC survival has been reported to be normal in all cases studied. [15] [36] [41]

In general, although coagulation problems should be anticipated, they have not proven to be clinically important when volumes of autotransfused blood remain below 2000 mL in adult patients. [52] When reinfused volumes exceed 3500 mL, [41]

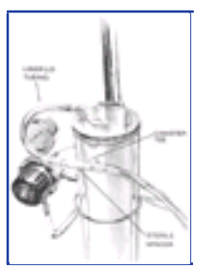

Figure 28-22 Proper placement of the liner bag lid on the canister. *(Courtesy of Abbott Laboratories, Abbott Park, IL 60064. Reproduced by permission.)*

laboratory evidence of a dilutional coagulopathy may become evident. When volumes of autotransfused blood are greater than the patient's total blood volume, animal studies suggest that there is increasing risk of a true consumptive coagulopathy. [19]

Recommendations regarding the volume of autologous blood that should trigger infusion of fresh frozen plasma or platelets range from 25% of total blood volume (about 1250 mL in a 70-kg adult) [55] to 3500 mL. [41] Others advise reliance on laboratory tests and clinical findings rather than a volume-based protocol. [52] Prudent clinical judgment dictates application of the more liberal guidelines for replacement therapy in those patients with extensive hepatic injury, intractable shock, or ongoing losses requiring immediate surgical intervention.

Nonhematologic Complications

The theoretic risk of sepsis after the administration of potentially contaminated blood always exists within the nonsterile surroundings of the typical ED resuscitation area. Experience has shown this risk to be minimal after competent autotransfusion from an isolated hemothorax, [14] [20] [34] and there is no evidence to suggest that routine prophylaxis with systemic antibiotics is beneficial in this situation.

The issue of whether to autotransfuse shed intraperitoneal blood is somewhat more complex. Recovery and reinfusion of hemoperitoneum without evidence of bowel perforation has proved to be relatively safe. Klebanoff and associates have concluded that "for contaminant-free conditions at least, as in ruptured ectopic pregnancies, ruptured

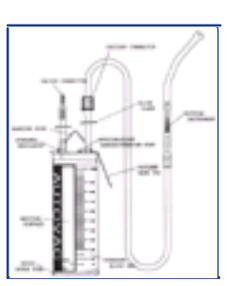

Figure 28-23 Boehringer Autovac System, collection configuration. *(Courtesy of Boehringer Laboratories, Inc., Norristown, PA. Reproduced by permission.)*

spleen and liver, traumatic hemothorax, and vascular surgery, autotransfusion can be performed readily to reduce the need for homologous blood replacement." [14]

Reinfusion of autologous blood with possible enteric contamination is still considered by most investigators to be ill-advised in all but the most desperate of circumstances, such as in the patient who will exsanguinate before homologous blood can be made available. If contaminated blood is infused, systemic antibiotics should be given. [33] [52] [65] Several small series describing collection and reinfusion of intestinally contaminated hemoperitoneum have been reported. [31] [65] [66] [67] [68] The overall mortality rate among this select group approximates 20%, not unexpectedly high considering the severity of associated injuries. Experimental studies with dogs also show that autotransfusion of hemoperitoneum contaminated by intestinal contents, urine, or bile is tolerated. [14] [32]

Another complication, microemboli secondary to platelet microaggregation or fat emboli, has largely been eliminated by the use of micropore filters. [25] [41] [43] In most instances, during reinfusion of collected blood, there is a mild increase in screen filtration pressures, indicating the formation of microemboli trapped by the filter. [43] There has been no clinical evidence of pulmonary insufficiency or unexplained elevation of the alveolar-to-arterial oxygen gradient that might be attributed to the passage of microemboli beyond the micropore filter systems. [25]

Air embolism has been reported sporadically as a complication of autotransfusion. [20] [66] [69] [70] This uncommon but often fatal complication has been associated, in all cases

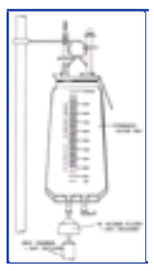

Figure 28-24 Boehringer reinfusion apparatus. *(Courtesy of Boehringer Laboratories, Inc., Norristown, PA. Reproduced by permission.)*

reviewed, with autotransfusion systems using automated roller pump units in which the aspirate reservoir was inadvertently allowed to run dry. Air embolism with gravity or with a manually assisted technique is rare.

Available data indicate that although autotransfusion is not free of complications, the risk-to-benefit ratio weighs heavily in its favor in the resuscitation of select trauma victims. Klebanoff and coworkers reviewed the evidence as of 1970 and determined that "in over 1000 documented cases of autotransfusion in the Western literature, not a single death or major complication was attributed directly to the transfusion." Klebanoff [14] and Symbas[35] reported autotransfusing more than 400 patients with traumatic hemothorax without any significant morbidity related to the procedure. Mattox and associates [20] reported autotransfusing 69 patients an average of 3.9 units, with only 1 death (from air embolism) directly attributable to the procedure.

CONCLUSION

Autotransfusion, a technique almost 200 years old, has become a subject of renewed interest in the emergency setting. The previously feared complications of hematologic or metabolic embarrassment and sepsis have not proved to be of clinical significance when appropriate patient selection and

Figure 28-25 The bloodless surgery station. *(Courtesy of Harvest Blood Conservation, Inc., Plymouth MA 02360.)*

careful technique are followed. In addition, the use of autologous blood has several advantages over the transfusion of stored homologous blood in the emergency patient, including ready availability of compatible blood, homeostasis of core temperature, higher levels of 2,3-DPG in RBCs, and cost-effectiveness. Autotransfusion has been endorsed by the Council on Scientific Affairs of the American Medical

Microembolism
Air embolism

Association as a procedure that has been found to be "effective, safe, and cost-effective for many trauma and surgical patients" when used by experienced health care providers. [17] Although the technique is not totally free of complications, the benefits to be gained from autotransfusing the selected trauma patient outweigh the relatively limited risks.

While no generally accepted standard of care has been promulgated mandating the routine use of autotransfusion in the ED setting, many hospitals, especially trauma centers, have instituted the technique with success. Current equipment allows autotransfusion from the chest cavity to be performed relatively easily, and without highly technical devices. However, low-volume hospitals, or those with a low trauma census may find this technique impractical or cumbersome.

Chapter 29 - Transfusion Therapy: Blood and Blood Products

Diane L. Gorgas

Transfusion of blood components (red cells, white cells, platelets, whole plasma, or plasma fractions) is an everyday occurrence in the practice of emergency medicine. Technical advances have made component therapy directed at specific acute and chronic pathologic conditions practical and affordable. Thus the emergency clinician must possess knowledge of the appropriate indications for transfusion therapy, the associated complications, and the techniques of administration.

BACKGROUND

Red Cell Antigens and Antibodies

In the early 1900s the Austrian Karl Landsteiner found that an individual's serum reacted with the red cells of some but not all other individuals, thereby discovering the red cell antigen-antibody system. Red blood cell (RBC) membranes contain a series of glycoprotein moieties, or antigens, which give the cell an individual identity. Two different genetically determined antigens, type A and type B, occur on the cell surface. Any individual may have one, both, or neither of these antigens. Because the type A and type B antigens on the cell surface make the RBC susceptible to agglutination, these antigens are termed *agglutinogens*. The presence or absence of agglutinogens is the basis for the ABO blood group classification and the blood types are named accordingly as A, B, or AB. Blood type O contains neither the A nor the B agglutinogen. The relative frequencies of the different blood groups are listed in Table 29-1 .

Genes on adjacent chromosomes determine the presence or absence of agglutinogens and hence the individual's specific ABO blood group. These allelomorphic genes can be only one of the three different types—that is, A, B, or O—allowing for six possible combinations of genes (OO, OA, OB, AA, BB, and AB). There is no dominance among the three different allelomorphs; however, type O is basically functionless in that it causes such weak agglutination that it is

TABLE 29-1 -- Frequency of Blood Groups in the General Population

normally insignificant. The different combinations of genes signify the individual's genotype, and each person is one of six different genotypes. The resultant blood groups for the various genotypes are listed in Table 29-2 .

Within the first year of life, antibodies begin to form against the standard red cell agglutinogens not present in the individual patient. These *agglutinins* are ?-globulins of the IgM and IgG types and are probably produced by exposure to agglutinogens in food, bacteria, or exogenous substances other than blood transfusions. Agglutinins reach their peak titer between 8 and 10 years of age and then gradually decline throughout the remaining years of life. In the absence of type A agglutinogens (blood types B and O), anti-A antibodies, or *agglutinins,* spontaneously develop in the plasma. Similarly, in the absence of type B agglutinogens (blood types A and O), anti-B antibodies develop. When both A and B agglutinogens are present (blood type AB), no agglutinins are formed.

The reaction between red cell antigens and the corresponding agglutinins results in red cell destruction when noncompatible blood types are mixed. As many as 300 different red cell antigens have been identified, but clinically the A and B antigens are most important given their potential to cause transfusion reactions. With the first transfusion of ABO-*incompatible* blood, severe, potentially fatal agglutination can occur. The Rh system is likewise very important because there is a high likelihood (30% to 50%) that a transfusion of Rh-positive blood to an Rh-negative patient will result in formation of Rh antibodies. These antibodies are capable of causing severe hemolysis following a second exposure to the Rh antigen. Of the 40 antigens in the Rh system, D is the most antigenic, but others can also stimulate the production of antibodies in recipients lacking the antigen (e.g., E), thus complicating future transfusions. Other antigen systems in which antibodies could potentially cause hemolytic reactions are the Kell (K and k alleles), Duffy (Fy^a and Fy^b), Kidd (Jk^a and Jk^b), and MNS (M and N; closely linked S and s) systems. Other antigen systems are rarely of clinical importance in transfusion therapy.

Crossmatching

Compatibility testing, or *crossmatching*, involves mixing the donor's RBCs and serum with the serum and RBCs of the recipient to identify the potential for a transfusion reaction. "Major" and "minor" crossmatch procedures are outlined in Table 29-3 . The end point of all crossmatches is the presence of RBC agglutination (either gross or microscopic) or hemolysis. Testing is performed immediately after mixing, after incubation at 37°C for varying times, and with and without an antiglobulin reagent to identify surface immunoglobulin or complement. Each unit of blood product, when properly crossmatched, can be administered with the expectation of safety.

TABLE 29-2 -- The Blood Groups with Their Genotypes and Constituent Agglutinogens and Agglutinins

Genotypes	Blood Groups	Agglutinogens	Agglutinins
OO	O	—	Anti-A and anti-B
OA or AA	A	A	Anti-B
OB or BB	B	B	Anti-A
AB	AB	A and B	—

TABLE 29-3 -- Crossmatch Procedures

	Major Crossmatch	Minor Crossmatch
Donor	Red cells	Serum
Recipient	Serum	Red cells
End point	Agglutination or hemolysis at 37°C	

Transfusion Reactions

While the most common complication of transfusion is a minor allergic reaction, the immediate life-threatening complications of transfusion are usually related to transfusion reactions. Based on 1995 data, the risks associated with transfusion are outlined in Table 29-4 . [1]

Most serious transfusion reactions occur because of patient-blood product mis-assignment related to clerical error.

When incompatible blood is given, the result may range widely from no effect to death. If the recipient does *not* have antibodies (naturally occurring or acquired) directed against the foreign RBC antigen received, there will be no immediate reaction, but antibodies to the infused blood may develop within weeks, limiting the safety of subsequent transfusions from the same donor or same antigenic type. If the recipient's serum *has* preformed antibodies directed against the donor RBCs (incompatibility in the *major* crossmatch), the recipient will begin to hemolyze the donor cells within seconds or minutes.

In most cases of major crossmatch reactions, RBCs of the *donor* blood are agglutinated and hemolyzed. It is rare for transfused blood to produce agglutination of the recipient's cells, because the plasma portion of the donor blood becomes diluted by the plasma of the recipient. This reduces the titer of the infused agglutinins to a level too low to cause significant agglutination. Because the recipient's plasma is not diluted to any significant degree, the recipient's agglutinins can react with donor cells.

The end result of antigen-antibody incompatibility is red cell hemolysis. Occasionally, this is immediate, but more often, the cells first agglutinate. They are then trapped in small vessels and become phagocytized over hours to days, releasing hemoglobin into the circulatory system.

Clinical manifestations of acute hemolysis are chills, fever, tachycardia, abdominal pain, back pain, hypotension, fainting, and an anxious "feeling of impending doom." From

TABLE 29-4 -- Estimated Risks of Transfusion per Unit in the United States (1995)

Minor allergic reactions	1:100
Bacterial infection (platelets)	1:2,500
Viral hepatitis	1:5,000
Hemolytic transfusion reaction	1:6,000
HTLV I/II infection	1:200,000
HIV infection	1:420,000
Acute lung injury	1:500,000
Anaphylactic shock	1:500,000
Fatal hemolytic reaction	1:600,000
Graft-vs-host disease	Rare
Immunosuppression	Unknown

From Greenburg AG: Am J Surg 173:49, 1997.

the liberation of intracellular material associated with hemolysis, vasoactive substances may cause hypotension and shock; other substances may precipitate disseminated intravascular coagulation and high-output cardiac failure. Alternatively or additionally, anoxic acute renal failure may result. Hemolytic transfusion reactions are estimated to occur once per every 6000 blood units transfused, with a fatality rate of 1 per every 100,000 units transfused.

An incompatibility in the *minor* crossmatch usually causes no serious reaction, although the recipient's red cells can be hemolyzed if the titer of the antibody is sufficiently large. Even when major and minor crossmatch compatibility indicates the safety of a transfusion, a delayed hemolytic transfusion reaction can occur days to weeks later. Usually seen in multiply transfused patients or in multigravida women, these reactions may be unavoidable without complete RBC antigen typing, a procedure occasionally indicated for recipients of repeated transfusions. Fortunately, 90% of transfusions are now given as packed RBCs that contain a small volume of plasma, minimizing the chance for a transfusion reaction due to donor sensitization.

Additional antibodies *not* caused by sensitization from transfused RBCs include autoantibodies (both cold- and warm-reacting) and various agglutinins. Autoantibodies can be "cold," reacting with red cells *more strongly at 4°C* than at 37°C. These antibodies are common and usually harmless; however, they may be associated with disease states in higher titers (e.g., anti-I in *Mycoplasma* infections). If active at higher temperatures (up to 28 to 32°C), pathologic cold antibodies may cause hemolysis or sufficient RBC agglutination to obstruct blood flow through the small vessels of the hands and feet on exposure to cold. These would also be present and identifiable at 37°C. The primary significance of cold antibodies stems from their ability to complicate crossmatching procedures in the blood bank.

Warm antibodies, reacting *more strongly at 37°C* than at lower temperatures, may be harmless or have the potential to cause hemolytic anemia of variable severity. Characteristics of the IgG antibody itself determine its significance to the patient. Usually harmless warm autoantibodies that can occasionally cause hemolysis are seen in patients taking a-methyldopa. Harmful warm autoantibodies are encountered in approximately 80% of patients with autoimmune hemolytic anemia.

Additional problems in pretransfusion testing may occur with antibodies directed against substances that can attach themselves to the RBC surfaces and cause agglutination of "innocent bystanders." Examples are the fatty acid-dependent agglutinins; penicillin and cephalosporin antibodies; bacterial polysaccharides; and nonspecific agglutination associated with a high erythrocyte sedimentation rate, caused by high levels of the acute-phase reactants fibrinogen, a $_2$ -macroglobulin, and IgM. A delay in pretransfusion testing may occur when the blood bank has to identify various proteins on RBC surfaces to ascertain their clinical significance.

Miscellaneous Transfusion Problems

Pyogenic transfusion reactions, such as fever and chills, are common and result from the presence in the donor plasma of proteins to which the recipient is allergic. Full-blown anaphylactic reactions occasionally result.

Theoretically, citrate salts, which are the usual anticoagulants in donor blood, may combine with ionized calcium in

the plasma, producing hypocalcemia. In clinical practice, the hemodynamic consequences of citrate-induced hypocalcemia are minimal, although the Q-T interval may be prolonged on the electrocardiogram (ECG) with citrate infusion. Supplemental calcium administration is usually not necessary even during massive blood replacement as long as circulating volume is maintained, because the liver is able to remove citrate from the blood within a few minutes. Alterations in this recommendation may be necessary in the presence of severe liver disease.

Concern has been raised regarding an association between transfusions and diminished organ function or death, or both, in critically ill adult patients. [2] In contrast, Wu and colleagues, in a U.S.-based study of Medicare patients with acute myocardial infarction, found RBC transfusions beneficial in elderly patients when hematocrit values were <33%.[3] A prospective randomized trial of trigger-guided transfusion vs more liberal transfusion in adults showed a trend for greater survival when a transfusion trigger was used, especially among those less acutely ill with a transfusion trigger of 7 g/dL hemoglobin. [4] Hence, blood transfusion may have deleterious end-organ effects in certain patient populations. The use of transfusion triggers is recommended. It is believed that leukocyte-depleted packed RBC

transfusions have a better safety profile in these critical patients. For example, Jensen and colleagues found that postoperative infection in transfused patients can be reduced by using leukocyte-depleted packed RBCs.[5] Clinicians can expect transfusion triggers and recommendations regarding the use of leukocyte-depleted RBCs to evolve as additional studies are performed.

Infectious Complications of Transfusions

Although relatively uncommon, transmission of infectious diseases is the transfusion-related complication most feared by the lay public. Transmission of a wide variety of infectious diseases has been reported, but modern screening methods have sharply reduced the frequency of transmission. Viral illnesses remain the most problematic.

It is estimated that 0.1% of all transfusions may transmit virulent bacteria. However, sepsis is an uncommon occurrence because both the citrate preservative and refrigeration kill most bacteria. Concern over sepsis is responsible for the practice of completing transfusions within 4 hours and returning unused blood products to the blood bank refrigerator for future use only if they have been unrefrigerated for <30 minutes. The virulent pathogens most commonly transmitted are the gram-negative organisms.

Syphilis may theoretically be transmitted by transfusion, but both refrigeration and citrate markedly reduce the survival of *Treponema pallidum*. Therefore, only fresh blood or platelet transfusions are of concern for this specific infectious risk. Currently all U.S. blood is screened for syphilis, and to date the largest recall in the United States was prompted by incorrect testing for syphilis in 138,000 units.[6] The incubation period for syphilis transmitted by transfusion is 4 weeks to 4 months, and the initial clinical manifestation is commonly a rash.

The risk of parasitic infection via transfusion is exceedingly low (<1:1,000,000), although prospective blood product donors who have been to an endemic region within 6 months or treated with malarial prophylaxis within 3 years are not allowed to donate blood products.

Viruses are the organisms most likely to be transmitted by transfusion and the agents with the greatest potential to cause serious disease. Important agents include hepatitis virus, cytomegalovirus, Epstein-Barr virus, human immunodeficiency virus, and West Nile virus.

Most blood products have the potential to transmit hepatitis, with type C being the most common (90% of transfusion-related hepatitis). Historically, the likelihood of developing post-transfusion hepatitis ranges from 1 per 1000 to 1 per 30,000 units of blood administered. Routine testing of blood donors for hepatitis C has occurred since 1991, but initial screening tests were relatively inaccurate. Since April 1999 use of the nucleic amplification technique (NAT) to detect hepatitis C virus ribonucleic acid (HCV RNA) has been mandatory. This test has essentially eliminated false positives, and has a sensitivity of >99%.[7] The incubation period for HCV is 2 to 12 weeks following parenteral infusion.

Both cytomegalovirus and Epstein-Barr virus may cause a mononucleosis-like syndrome 2 to 6 weeks after a transfusion. Blood products with negative serologic findings for both agents should be used for seronegative recipients in high-risk groups, such as pregnant females, premature or low-birth-weight newborns, marrow or organ transplant recipients, and immunosuppressed patients.

The acquired immunodeficiency syndrome (AIDS) epidemic has affected transfusion therapy profoundly. In the United States, 3% of AIDS cases have been linked to blood products. The estimated likelihood of transmitting HIV through transfusion is 1 per 493,000 units of blood donated. One inadvertent consequence of transfusion therapy during the AIDS epidemic has been exposure of the virus to approximately 65% of hemophiliacs through their frequent use of pooled blood products. Fortunately the risk has decreased due to improved screening of donated blood. Using the U.S. blood pool as a standard, a hemophiliac patient requiring a monthly infusion of cryoprecipitate over a lifetime of treatment (estimated 60 years) has a 2% risk of developing HIV based on current screening practices and HIV prevalence in the donor pool.[8] [9] The risk of HIV transmission to hemophiliacs has been further decreased by the availability of biosynthetic coagulation factors developed using recombinant deoxyribonucleic acid (DNA) technology.

Efforts to reduce the risk of HIV transmission to the general population receiving blood products began early in the course of the epidemic and have had considerable success. Voluntary deferment of blood donation by high-risk groups was encouraged beginning in 1983, and formal screening of all blood products began in 1985. All units testing positive for the HIV antibody are routinely discarded, but the potential for HIV transmission has existed during the 6- to 8-week "window" before development of detectable antibody. This problem was addressed through improved screening techniques and the prevalence of HIV in the U.S. blood supply declined throughout the 1990s.[10] In addition to improved screening techniques, efforts are now being made to inactivate viruses in blood products before transfusion.

Directed and Autologous Donations

The system of "*directed donations*," by which friends or family members may give blood to a specific individual, has been proposed to answer the concern over HIV transmission. Some believe that the blood products derived from a relative or a friend have a lower likelihood of testing positive for an HIV infection. At this time, directed donation systems are in place

in some institutions, but the practice has not been widely supported. Limited studies have shown an increased association between direct donor units and infectious disease markers, malaria, and high-risk activities.[11] There is concern that direct donor products may be less safe because social pressures may limit self-deferment of high-risk donors and because clerical errors may increase owing to the increased complexity of this system. Finally, there is concern that the directed donation plan will disrupt the normal anonymous blood donor system, leaving fewer units available for other needy patients.

Although of limited clinical applicability in emergencies, autologous donations are commonplace in elective surgery. It has been suggested that up to 10% of the blood supply could be provided through this mechanism. Most appropriate applications at this time include elective cardiac, gynecologic, orthopedic, and vascular surgical cases. Benefits of this system include avoidance of exogenous bloodborne disease and sensitization. The individual can donate 1 unit of blood weekly, until 3 days before surgery. As blood can be stored up to 35 days, the donations usually begin 5 weeks before needed. The blood donor will require iron supplements and must maintain a hemoglobin >11 g/dL.

COLLECTION AND STORAGE OF BLOOD PRODUCTS

Table 29-5 lists some characteristics of blood and its components. Whole blood is collected from donors into 500-mL plastic bags containing 63 mL of citrate-phosphate-dextrose (CPD) with a resultant hematocrit of 35% to 40%. Immediately after collection, sophisticated techniques permit separation of the whole blood into various components and fractions. Blood components such as fresh frozen plasma

TABLE 29-5 -- Characteristics of Blood and Its Components

Component	Volume	Shelf Life	Requirements for Transfusion
Whole blood*	450 mL blood	21 days at 4°C	Crossmatched
ACD	63 mL anticoagulant and preservative 35–40% hematocrit		
CPD			
CPD-A		35 days at 4°C	
	280 mL 70% hematocrit	Same as for whole blood	Crossmatched
Packed red cells concentrate washed	250 mL 70% hematocrit	1 day at 4°C	Crossmatched
Frozen-thawed red cells†	250 mL 70% hematocrit	? years when frozen, 1 day after thawing	Crossmatched
Platelet concentrate	30 mL 10^{10} platelets	5 days at 22°C	Type-specific if possible, but not essential, not crossmatched
Fresh frozen plasma	200–250 mL	1 year at -18°C, 24 hr after thawing‡	ABO-compatible; random donor, not crossmatched
Cryoprecipitate	10–25 mL per bag 60–120 units of factor VIII	1 year at -18°C, 6 hr after thawing	ABO-compatible; random donor, not crossmatched
Factor IX or prothrombin concentrate	25 mL per vial	Check label	None required
Granulocyte† concentrate	400 mL 10^{10} leukocytes	Transfuse within 24 hr at 22°C	Specific donors for each patient, crossmatched

*ACD, acid-citrate-dextrose; CPD, citrate-phosphate-dextrose; CPD-A, citrate-phosphate-dextrose-adenine.
†Special order—few hospitals have facility inhouse.
‡Use immediately to correct deficiency of coagulation factors.

(FFP), packed RBCs, granulocytes, and platelets are prepared from a single donor, separated, and transfused as single units. Minor blood fractions including albumin, ?-globulin cryoprecipitate, and fibrinogen are often pooled from multiple donors. Within 24 hours, blood is essentially devoid of normally functioning platelets and some clotting factors, especially the labile factors V and VIII. Separation into individual components permits specialized storage and transfusion techniques designed to optimize the survival and availability of each component.

As is true of whole blood, packed RBCs can be stored up to 21 days, although newer preservatives such as ADSOL (adenine, dextrose, saline, mannitol, and water) may allow 49-day storage. Red cell viability decreases approximately 1% per day. The storage of blood contributes to a variety of other derangements or "storage lesions." Cell metabolism continues during storage, causing a mild acidosis. This acidosis is buffered effectively by the bicarbonate derived from metabolism of citrate, assuming normal hepatic function. Even in massive transfusions, acidosis is usually more the result of the disruption of normal physiologic function than the storage of blood products themselves. Levels of 2,3-diphosphoglyceric acid (2,3-DPG) decrease during storage, shifting the oxygen-hemoglobin dissociation curve to the left. This shift is of small clinical significance, because 2,3-DPG levels are usually normal in transfusion recipients within 24 hours of infusion. Potassium commonly leaks from red cells during storage because of a less efficient sodium-potassium adenosine triphosphatase (ATPase)-dependent pump. Most of the potassium is either absorbed by the remaining blood cells, excreted by the kidney, or shifted back into the cells owing to the alkalosis produced by metabolism of the citrate in the preservative. Hyperkalemia is clinically relevant only in newborns and patients with renal impairment.

USE OF BLOOD PRODUCTS

Whole Blood

Once commonly used to provide red cells, coagulation factors, and plasma proteins, whole blood transfusion has been replaced to a great extent by component therapy. Although intuitively an ideal transfusion agent, whole blood is seldom used except for autologous transfusions (e.g., autotransfusion) and for exchange transfusions. Whole blood is *not* the indicated treatment for hypovolemic shock that can be treated effectively with crystalloids (e.g., lactated Ringer's solution, 0.9% sodium chloride), colloids (e.g., plasma protein, albumin), or packed red cells; it is *not* indicated for correction of thrombocytopenia, replacement of coagulation factors, or treatment of anemia.[12] The plasma of whole blood is no more effective than 5% albumin as a volume expander. In addition to providing components or fractions that are potentially unnecessary, whole blood transfusion exposes the patient to additional risk. The incidence of transfusion reactions following transfusion with whole blood is approximately 2.5 times greater than the incidence of reactions following transfusion with packed RBCs. [13] In addition, whole blood contains antigenic leukocytes and serum proteins, which may produce allergic reactions (a risk of 1%). Because of the recognized advantages of component therapy, most blood banks currently do *not* stock significant quantities of whole blood.

Packed Red Blood Cells

Packed RBCs are prepared by centrifugation and removal of most of the plasma from citrated whole blood. One unit of packed RBCs contains the same red cell mass as 1 unit of whole blood at approximately half the volume and twice the hematocrit (70% to 80%). One unit of packed RBCs raises the hematocrit approximately 3% in an adult or increases the hemoglobin level of a 70-kg individual by 1 g/dL. In children, there is an approximate rise in hematocrit of 1% for each mL/kg of packed cells. For example, if 5 mL/kg of packed RBCs is transfused, the hematocrit will rise by approximately 5%. Actual changes depend on the state of hydration and the rate of bleeding.

Because most of the plasma has been removed, packed RBCs cause fewer transfusion and allergic reactions than whole blood. After centrifugation, red cells can be washed to further remove leukocytes, platelets, microaggregates, and plasma proteins. Washing reduces the titer of anti-A and anti-B, permitting safer transfusion of type O packed RBCs in non-O recipients. Washing does not totally eliminate the risk of hepatitis. Frozen deglycerolized RBCs are also relatively free of platelets, plasma, and white blood cells, having been washed after an indefinite period of frozen storage in glycerol. Frozen and fresh RBCs function similarly; frozen RBCs provide normal levels of 2,3-DPG. Washed or frozen preparations should be given to patients who have had febrile (nonhemolytic) reactions to previous transfusions as a result of leukocyte antibodies or IgA sensitization. Blood bank procedures require that these be prepared to order, with routine crossmatching. Considerable delay (6 hours) may occur if the transfusion service does not have the capability to wash RBCs.

Packed RBCs contain less sodium, potassium, ammonia, citrate, and antigenic protein and fewer hydrogen ions than whole blood. This may offer an advantage in patients with reduced cardiovascular, renal, or hepatic function. The rate of urticaria is still relatively high at 1% to 3% of transfusions, but the incidence of adverse reactions to packed cells is approximately one third that noted with whole blood. The benefit of increased hemoglobin must be weighed against the potential for electrolyte and acid-base imbalances following packed RBC administration. Especially in cases of massive transfusion (>10 units), there is a significant risk of metabolic and respiratory acidosis, and hypocalcemia, which can reach life-threatening levels. Although underlying illness or injury plays a major role in cause of death, the overall mortality of patients requiring massive packed RBC transfusions is approximately 70%. [14]

Transfusion of packed RBCs is indicated to provide additional oxygen-carrying capacity and expansion of volume. Packed cells are most commonly used to treat acute hemorrhage and anemia not amenable to nutritional correction. When treating acute hemorrhage, packed RBCs are usually given: (1) if the hemoglobin level falls below 10 g/dL, (2) after rapid crystalloid infusion fails to restore normal vital signs, or (3) concurrently with crystalloid infusion in the treatment of obvious life-threatening blood loss.

Criteria for transfusion of packed RBCs to patients with anemia, also known as "transfusion thresholds," vary. [15] A hemoglobin level <10 g/dL is 1 criterion commonly suggested for transfusion before surgery. The National Institutes of Health does not recommend transfusion in asymptomatic nonsurgical patients with a hemoglobin >7 g/dL (hematocrit 21%). Healthy individuals sustaining acute blood loss may have no significant physiologic impairment with hemoglobin levels as low as 6 to 8 g/dL (hematocrit, 18% to 24%). The patient with circulatory shock and a hemoglobin concentration of 8 g/dL or greater may not benefit from a transfusion if volume-resuscitation has already been undertaken. [16] Patients with severe or chronic anemia or heart disease or those who otherwise require fluid restriction can receive packed RBCs more safely than whole blood. Furthermore, to prevent circulatory overload in susceptible patients, a rapid-acting diuretic, such as furosemide, can be administered intravenously at the beginning of the transfusion.

Blood Substitutes

Concerns over infection, the limited blood supply, the availability of blood in isolated locations, storage difficulties, and the risk of transfusion reactions has fueled interest in the development of blood substitutes that are viable in the clinical setting. Blood substitutes can be categorized as synthetic emulsions and modified hemoglobin.

Synthetic emulsions are made from fluorinated hydrocarbons, a perfluorocarbon base with particle size of 0.2 microns, thereby permitting capillary flow. These emulsions can dissolve large quantities of oxygen in a linear relation to the partial pressure of oxygen. At high inspired oxygen levels in the lungs, oxygen goes into solution and the process is reversed at the comparatively low oxygen tensions found in the tissues. The emulsions are subsequently eliminated unchanged by the lungs. Research with perfluorocarbons has been directed at finding a safe short-term vehicle for oxygen delivery in the absence of available blood. It is unlikely that synthetic emulsions will be used in the long-term management of anemia or blood loss. [17]

Modified hemoglobin solutions are biosynthetic products in which the hemoglobin molecule is altered by polymerization or encapsulation, or both. This creates a product that is fully oxygen saturated at ambient FiO_2, and also mimics the sigmoidal oxygen dissociation curve. A significant advantage of modified hemoglobin solutions is the absence of antigenic characteristics of blood groups, obviating the need for compatibility testing. Because hemoglobin solutions are derived from either human or bovine sources, the potential for disease transmission exists. It is possible that recombinant DNA technology will be used in the future, substantially eliminating this risk. Modified hemoglobin has been used successfully in the clinical setting, notably in cardiac and orthopedic surgery, and also in trauma resuscitation.[18]

Fresh Frozen Plasma

FFP is prepared by separating plasma from the cellular components of single-donor whole blood, followed by rapid freezing and storage at =18°C. Freezing preserves soluble coagulation factors of the intrinsic and extrinsic clotting systems, including the labile factors V and VIII. FFP also contains fibrinogen, although not as much as cryoprecipitate. Plasma stored for 3 months retains approximately 60% of the normal factor VIII activity and the product has a shelf life of up to 1 year. Ideally, transfused plasma should be compatible with the recipient's ABO group. Rh compatibility is not considered essential. [19] Each unit of FFP has a volume of approximately 200 to 250 mL.

FFP should be given to patients with a hereditary or acquired deficiency of coagulation factors, provided that a preparation of the specific deficient factor is not available. FFP is indicated for the clotting factor deficiencies resulting from massive blood replacement. However, pathologic hemorrhage following massive

transfusions is often caused by thrombocytopenia rather than by a depletion of clotting factors. One unit of FFP per 5 to 6 units of packed cells or whole blood is a reasonable replacement formula if specific clotting tests are not rapidly available, but plasma replacement is best dictated by evaluation of prothrombin time (PT) and partial thromboplastin time (PTT). FFP is indicated for rapid reversal of serious acute bleeding from warfarin (Coumadin) anticoagulants or for prophylaxis before surgery or an invasive procedure. In an emergency situation, 5 to 10 mL/kg of FFP will effect a rapid reversal of the vitamin K-dependent factors II, VII, IX, and X. As a rough guide, 1 unit of FFP increases all coagulation factor levels by 2% to 3% in the average-sized adult. In *life-threatening* hemorrhage from warfarin excess, factor IX concentrate (Konyne 80, Proplex, Mononine) may be used, but such therapy should not be routine because of the high incidence of hepatitis and the possibility of thrombosis with these products.[20]

FFP may be valuable in patients with other clotting abnormalities, such as a congenital deficiency of factor II, V, VII, X, XI, or XIII; von Willebrand syndrome; hemophilia A (factor VIII deficiency); hemophilia B (factor IX deficiency); or hypofibrinogenemia. However, the effectiveness is limited in severe clotting abnormalities because of the large volume that is generally required. For example, FFP may be successful in the treatment of hemarthrosis or other minor bleeding tendencies in hemophilia, but specific factor replacement is preferred. FFP is also used to treat the acquired deficiency of multiple factors such as those seen in severe liver disease, disseminated intravascular coagulation, or vitamin K depletion, and for plasma exchange in thrombotic thrombocytopenic purpura or hemolytic uremic syndrome. FFP should not be used for volume expansion or to enhance wound healing.

Reactions to FFP include fever, chills, allergic responses, HIV infection, and a risk of hepatitis similar to the risk with whole blood. FFP should be infused rapidly and given immediately after thawing because of the rapid loss of labile clotting factors.

The usual starting dose is 2 bags of FFP if the PT is >1.5 times normal or the activated PTT (aPTT) is >1.5 times the top normal value. If the PT is <22 seconds or the aPTT is in the 55 to 70 second range, 1 bag of FFP may be sufficient to bring the deficit into the hemostasis range (Table 29-6). Each 5 to 6 units of platelets contain the equivalent of 1 unit of FFP, so concomitant platelet infusions may lower FFP requirements.

Cryoprecipitate

Cryoprecipitate is prepared from single-donor plasma by gradual thawing of rapidly frozen plasma. This process causes precipitation of proteins rich in fibrinogen as well as clotting factors VIII and XIII. Each 15- to 25-mL bag of cryoprecipitate contains 60 to 120 units of factor VIII, 125 to 250 mg of fibrinogen, and an unknown amount of von Willebrand factor. Cryoprecipitate is a plasma product and as such requires ABO compatibility.

Cryoprecipitate is used to correct a deficiency of coagulation factor VIII (in hemophilia A and in von Willebrand syndrome), factor XIII, or fibrinogen. It is of no value in the treatment of factor IX deficiency (hemophilia B). One bag of cryoprecipitate per 5 kg of body weight will raise the recipient's factor VIII level to approximately 50% normal. The large number of units that must be given increases the chance of exposure to bloodborne diseases—thus cryoprecipitate is not recommended for the treatment of HIV-negative hemophiliacs. Factor VIII concentrate is a better choice because of improved methods of viral inactivation and the availability of factor VIII prepared using recombinant DNA technology.

Mild deficiencies of factor VIII are considered to exist at 10% to 30% of normal activity. Severe deficiencies exist at <3% of normal activity. The goal when treating bleeding depends on the site and severity of hemorrhage, but in general, one should seek at least 50% of normal factor VIII activity. Life-threatening hemorrhage requires correction to 100% activity. The amount of cryoprecipitate required to correct coagulation defects ranges from 10 to 20 units/kg for minor bleeding, such as hemarthrosis, to 50 units/kg for bleeding control in surgery or trauma. Specific replacement should be guided by laboratory assay of factor VIII activity. The half-life of factor VIII in plasma is 8 to 12 hours.

Rarely, cryoprecipitate may be required to correct significant hypofibrinogenemia (<100 mg/dL). FFP may also be used to treat mild degrees of hypofibrinogenemia.

Factor VIII Concentrate

Human Antihemophilic Factor

Factor VIII extracted from pooled human plasma produces a concentrated stable product with a shelf life of up to 2 years. Significantly more concentrated than cryoprecipitate and

TABLE 29-6 -- Transfusion of Blood Products

Blood Product	Waiting Time to Receive in Emergency Department	Initial Amount to Transfuse	Expected Response in 70-kg Adult
Un-crossmatched Rh^+ or Rh^- RBCs	5 min	2–10 units, 10 to 20 mL/kg per hr or as needed based on clinical condition	Stabilize patient in shock
Un-crossmatched type-specific whole blood	15 min		Change in hemoglobin/hematocrit depends on hydration and rate of bleeding
Typed and screened whole blood	25 min		Approximate rise of 1 g/dL hemoglobin per unit
Crossmatched whole blood	1 ¼ hr		Each unit raises hematocrit 2–3%
Packed RBCs	1 ½ hr		In children, each mL/kg of packed cells raises hematocrit by 1%
Frozen RBCs	4–6 hr (if not prepared inhouse)		
Platelet concentrate†	5 min if available	1 unit per 10 kg, usually 6 to 10 units per transfusion in an adult	Rise of 5000 to 10,000 platelets per mm^3 per unit; 6 units usually sufficient to stop bleeding
Cryoprecipitate	20 min	1–2 bags per 10 kg (7–15 bags) 10-min push, or 20–50 units/kg	Rise of 3% in factor VIII level per bag (40–100% activity desired)
Factor IX or prothrombin concentrate	Immediately available (reconstituted powder)	10–50 units/kg	30–100% rise in factor IX activity
Fresh frozen plasma	40 min	1 bag per 7 kg (4–10 bags for adult) 10-min push,* 3–10 mL/kg, depending on clinical condition	Correction in coagulation status; 1 unit raises all coagulation factors by 2–3% in average-sized adult

†Also consider thrombocytopenia as a cause of bleeding from massive transfusion.
*Administer 1 bag per 4 to 6 units of blood transfused to replace diluted and inactivated coagulation factors.

available for home use, factor VIII concentrate was a major breakthrough in the treatment of hemophilia. Unfortunately the presence of viruses in the donor pool contributed to the high prevalence of hepatitis and HIV in hemophiliacs who used earlier versions of this product. Newer products (Alphanate, Hemofil, Humate-P, Koate-DVI, Monarc-M, Monoclate-P) are produced using one or more methods to reduce viral contamination including heat treatment, pasteurization, organic solvents and detergents, gel filtration, and immunoaffinity chromatography. These methods have markedly reduced the risk of viral transmission, especially lipid encapsulated

viruses (HIV, hepatitis B and C). To date there are no reports of transmission of these viruses with the products listed earlier.

Recombinant Antihemophilic Factor

Since the gene for factor VIII production was discovered in 1984, research into recombinant genetics has aimed to provide a safer product that theoretically will be more readily available and less expensive to produce. Two recombinant-DNA derived factor VIII preparations (Recombinate, Kogenate) were approved by the FDA in 1993. More recent introductions include Bioclate, Helixate, Helixate FS, and Kogenate FS. These genetically engineered products have hemostatic activity equivalent to plasma-derived factor VIII and minimal risk of viral contamination. Because some of these products are prepared using human albumin and other animal proteins, there is potential for viral transmission. Products such as Helixate FS and Kogenate FS are prepared without human albumin, which should eliminate viral contamination. Although costlier, they are a better choice for young and newly diagnosed patients who have not already been exposed to hepatitis or HIV. [21]

Use of Factor VIII Concentrate

Administration of 1 unit of factor VIII concentrate per kg of body weight should increase the factor VIII activity by 2% to 2.5%. Dosage should be individualized based on the severity of bleeding, the known deficiency of factor VIII activity, and the presence of factor VIII antibodies. Factor VIII levels should be increased to 20% to 40% of normal for minor bleeds (small joint), 40% to 60% for moderate bleeds (large joint, neck, oral cavity), and 60% to 100% for life-threatening bleeds (intracranial, intra-abdominal, pharyngeal).

Antibodies develop in up to 15% of factor VIII recipients. Administration of massive doses of factor VIII has proven beneficial in overwhelming the endogenous antibody response. In addition, immunoadsorbent techniques to remove the antibody have met with some success. The general use of immunosuppressives and plasmapheresis has had limited success. Activated prothrombin complex has been effective, but concern over the cost of preparation, the significant hepatitis risk, and the thrombogenicity associated with its use limits its application.

DDAVP

A synthetic analogue of pituitary vasopressin, 1-deamino-(8-D-arginine)-vasopressin (DDAVP), has been found to stimulate the endogenous production of factor VIII in a subset of mild hemophiliacs. The exact mechanism is unknown, but treatment with 0.3 mg/kg intravenously over 15 minutes has been recommended when avoidance of the inherent risks of the factor VIII concentrate is desired.

Factor VIII Inhibitor Bypassing Activity

Factor VIII inhibitor bypassing activity (FEIBA) is a product derived from pooled human plasma containing factors II, VII, IX, and X. It promotes coagulation by bypassing the need for factors VIII and IX. FEIBA is vapor heated to achieve >10 logs of reduction in all target viruses. FEIBA is used to treat bleeding episodes in hemophilic patients with antibodies to factor VIII. Adverse reactions include headache, fever, chills, flushing, nausea, vomiting, and an occasional allergic reaction. The risk of thrombotic complications exists, especially in patients with liver and heart disease, or those who are pregnant or breast-feeding. [22]

Factor IX Concentrate

Factor IX is prepared from pooled human plasma and is available as a lyophilized powder either as an isolated factor concentrate (Alphanine, Mononine) or as prothrombin complex concentrate, which also includes the liver-synthesized, vitamin K-dependent factors II, VII and X (Bebulin, Konyne, Profilnine, or Proplex). Factor IX is also available using recombinant technology.

Historically, the use of factor IX concentrate has carried a very high risk of hepatitis transmission. However improved donor screening and new methods of viral reduction have substantially reduced the risk of viral transmission. As with factor VIII concentrate, the risk of HIV and hepatitis transmission is very low using current human-derived products. Recombinant factor IX is not derived from human products and carries no risk of viral transmission.

Factor IX is indicated for the treatment of bleeding episodes in hemophilia B patients with severe deficiency of factor IX. FFP is the preferred treatment in patients with mild-moderate deficiency. Administration of 1 unit/kg body weight will increase the factor IX concentration approximately 1%. High levels of factor IX are not required to control bleeding. Levels should be increased to 15% to 25% of normal for mild-moderate bleeding, and 25% to 50% of normal for more serious bleeds or before major surgery.

Hypercoagulable states have been reported following factor IX infusions, particularly with use of prothrombin complex concentrate.

Platelet Concentrates

Platelet concentrates are prepared by rapid centrifugation of platelet-rich plasma. Platelets are obtained by single-donor apheresis or from random donor whole blood units. HLA-matched platelets may be used when patients develop HLA antibodies from repeated random donor platelet transfusions. Platelet concentrates contain most of the platelets from 1 unit of blood in 30 to 50 mL of plasma. One unit (pack) of platelets per 7 kg of body weight will raise the platelet count by 50,000/mm^3 in the absence of antibodies; therefore, 1 unit of platelet concentrate raises the platelet count by 5000 to 10,000/mm^3. The usual adult dose is 6 to 10 units of platelet concentrate, depending on the clinical condition. Assuming a zero platelet level, 6 units given to a normal-sized adult should increase the platelet count to >50,000 per mm^3. If there is no evidence of platelet consumption, this transfusion should be adequate for 3 to 5 days. In cases of severe platelet consumption, the transfusion may be required every 6 to 24 hours. Some hospital blood banks prepare platelet concentrates regularly; in some cities a central blood bank service, such as the American Red Cross, prepares platelet concentrates regularly and delivers units on an "as-needed" basis within 1 to 2 hours of the request. Platelet concentrates are viable for 5 days when kept at *room temperature* and gently agitated at intermittent periods or when kept in motion. They should not be refrigerated.

This issue of prophylactic platelet transfusion remains controversial. Spontaneous bleeding rarely occurs if the platelet count is >10,000 to 20,000/mm^3. Even in the event of surgery or trauma, excessive bleeding is uncommon in patients whose platelet count exceeds 50,000/mm^3. It is generally recommended that active hemorrhage be treated with platelet transfusion if the platelet count is <50,000/mm^3, but prophylactic transfusion may be safely withheld until the platelet count is <20,000/mm^3. Patients with idiopathic thrombocytopenic purpura (ITP) should not receive platelets prophylactically, but they may be transfused if life-threatening bleeding occurs.

Crossmatching is unnecessary for platelet transfusion, but the donor and the recipient should be ABO- and Rh-compatible. Note that platelet concentrates contain enough RBCs to sensitize an Rh-negative individual. There may be a diluting effect to the platelet count that results in thrombocytopenia with massive blood transfusions. When more than 8 to 10 units of blood are transfused, the platelet count must be routinely evaluated, and platelets must be replaced accordingly. Clinically significant platelet depletion rarely occurs if <15 units of blood (or 1.5 to 2 times blood volume) have been transfused.

Each 5 to 6 units of platelets contains 250 to 350 mL of plasma (about 1 bag of FFP), which includes coagulation factors that may reduce the requirements of FFP. Platelets may be infused rapidly (1 unit/10 minutes), using specialized platelet filters.

Granulocyte Transfusions

Granulocyte transfusions are indicated in severely neutropenic patients with suspected or proven bacterial infections unresponsive to appropriate treatment. They are rarely given in the emergency setting. White blood cell transfusions require prior arrangements with a large blood bank service that has the capabilities of collecting granulocytes from a suitable donor; the collection procedure takes 4 to 6 hours on a continuous-flow cell separator. Transfusions must be repeated frequently (every 12 hours) to provide a sufficient number of white blood cells to help the patient.

Blood Products for Jehovah's Witnesses

There are more than 1.5 million Jehovah's Witnesses in the United States. Based on the religious belief that the Bible prohibits blood or blood product transfusion (Acts 15:28–29), Jehovah's Witnesses do not accept transfusions of whole blood, packed cells, white blood cells, platelets, plasma, or autologous blood. Some may permit infusion of albumin, clotting factor solutions, or dextran or other plasma expanders and intraoperative autotransfusion. [23] Although no guidelines for administration of blood products to Jehovah's Witnesses are absolute, certain recommendations can be made. Even though a transfusion may be necessary to save a patient's life and would otherwise be considered standard care, the administration of blood or blood products, or both,

---

in the face of refusal after informed consent can be legally considered as battery or a violation of a patient's right to control what is done to his or her body. In the awake and otherwise competent adult, courts have ruled that clinicians cannot be held liable if they comply with a patient's directive and withhold life-saving blood administration following specific and detailed informed consent of the consequences of such an omission of treatment. The issue becomes clouded when patients are incompetent, unconscious (most Jehovah's Witnesses carry cards informing medical personnel of their religious beliefs), or minors.

In the absence of specific directives to the contrary, it is prudent to administer blood products to patients who are unconscious, judged to be incompetent adults, or who are minors. Although case law often upholds the patient's wishes, actual damages against clinicians are difficult to document in the United States. When done under documented life-threatening circumstances, significant clinician liability would be extremely unusual. Pregnant females and significant providers for dependents have been deemed appropriate recipients of blood products against their wishes. Explicit documentation of the intent of the clinician to preserve life coupled with an accurate description of the discussion of the issue with the patient or the family and a clarification of the patient's mental capacity is mandatory. Furthermore, emergency legal assistance (such as court orders, appointment of a temporary guardian) should be sought immediately with rapid judicial resolution. Various clinical techniques to maximize oxygen delivery and minimize oxygen consumption should be used. Examples include limited blood draws, the use of erythropoietin and nutritional support, hypothermia, volume expansion, sedation, and oxygen.

ADMINISTRATION OF BLOOD COMPONENTS

When it has been decided that a patient needs a transfusion and the patient's condition is stable enough, the clinician should question the patient or the patient's relatives concerning any previous transfusion reactions and whether the patient abides by any religious prohibitions to transfusions. A tube of blood (approximately 2 mL for every unit of blood product to be crossmatched) should be drawn from the patient and put into a red-topped, nonanticoagulated tube. The tube must *not* contain a serum separator gel. The label should be signed by the individual drawing the blood sample. This identifying signature will be used in the blood bank's crossmatching procedures.

Emergency Transfusion

In an emergency or life-threatening situation, three alternatives to fully crossmatched blood exist. The preferred substitute is type-specific blood with an abbreviated crossmatch. The abbreviated crossmatch includes ABO and Rh compatibility. In addition, the recipient's serum is screened for unexpected antibodies, and an immediate "spin" crossmatch is performed at room temperature. This abbreviated crossmatch requires approximately 30 minutes. Many institutions are now using this procedure as their standard crossmatch for most patients. The safety and utility of the type-specific abbreviated crossmatch have been demonstrated repeatedly, and transfusion reactions occur only rarely. [24]

The second preference for an alternative to fully crossmatched blood is type-specific blood that is only ABO- and Rh-compatible, without screen or immediate spin crossmatch. The patient's ABO group and Rh factor can be determined within 2 minutes, and, in an emergency, typing of the blood group and the Rh factor is all that is necessary before transfusion. Type-specific blood that is not crossmatched has been given in numerous military and civilian series without serious consequences. While the type-specific blood is being transfused, the antibody screen and the crossmatch are carried out in the laboratory; the transfusion should be stopped if an incompatibility is found.

Ideally, type-specific blood should be compatible for both Rh factor and ABO group; however, Rh-positive blood may be transfused to Rh-negative patients in an extreme emergency or in times of disaster or blood shortage. Sensitization to the Rh factor is most problematic for Rh-negative women of reproductive age. [25] Any sensitized patient may experience a transfusion reaction if exposed again to Rh-incompatible blood. However, significant, subsequent transfusion reactions with Rh-incompatible blood in men sensitized to the Rh factor are very rare.

A third alternative to fully crossmatched blood is group O blood, although type-specific blood is generally preferable. [26] It is rare that a few minutes cannot safely be expended to allow the blood bank to release type-specific blood. This assumes, however, that transport of the blood specimens and other logistic issues can be resolved to make type-specific blood available within minutes. Often this is not the case. In addition, type O blood is often stored outside of the blood bank so as to be readily available for life-threatening emergencies. Thus, despite the theoretical preference for type-specific blood in emergency situations, type O is often a reasonable and practical alternative.

Group O negative *whole* blood was in the past designated the "universal donor" blood, because a recipient's naturally occurring antibodies (anti-A and anti-B) do not react with donor group O RBCs. Nonetheless, some donor serum may have a high titer of naturally occurring anti-A and anti-B antibodies capable of hemolyzing the recipient's (patient's) RBCs if large quantities of blood are transfused. True universal donor blood is low in anti-A and anti-B titer. Because group O donors are not regularly screened for unsafe levels of anti-A and anti-B titers, the use of even small amounts of group O *whole blood* that is not crossmatched is potentially dangerous. The significance of varying titers of anti-A and anti-B antibodies in the donor whole blood may be essentially eliminated if *packed cells* are used instead of whole blood. Other RBC antigens on type O RBCs may sensitize the patient or cause antibody production, complicating future crossmatching or possibly causing future hemolytic transfusion reactions.

Approximately 25% of patients receiving a transfusion of 5 or more units of type O whole blood develop hyperbilirubinemia suggestive of a minor hemolytic reaction. Large amounts of group O whole blood may cause the patient to acquire significant amounts of anti-A and anti-B antibodies that have been passively transfused; hemolysis of RBCs may then occur when the recipient's original blood group is subsequently transfused. In a resuscitation, one should continue to use group O blood if large amounts (i.e., >2 units) of *whole blood* have already been given.

One may transfuse both Rh-positive and Rh-negative group O packed cells in patients who are in critical condition.

It is a common *misconception* that patients who are Rh-negative will have an immediate transfusion reaction if given Rh-positive blood. There is no particular advantage in the Rh factor determination because preformed, naturally occurring anti-Rh antibodies do not exist. Theoretically, individuals who are Rh-negative may become sensitized either through pregnancy or by previous transfusions, resulting in a delayed hemolytic transfusion reaction if Rh-positive blood is transfused. However, this scenario is very rare and is of no great clinical significance when compared with life-threatening blood loss. Many advise the routine use of the more widely available *O Rh-positive* packed cells in all patients for whom the Rh factor has not been determined, except in females of childbearing age, for whom future Rh sensitization may be an important consideration. Once resuscitated with Rh-positive packed cells, patients may receive their own type without a problem. Because individuals with O Rh-negative blood represent only 15% of the population and the blood may be in short supply, it is reasonable to save O Rh-negative blood for Rh-negative females of childbearing potential and to use *group O Rh-positive packed cells routinely as the first choice for emergency transfusions*. In a study of emergency blood needs, Schmidt and colleagues reported 601 units of Rh-positive type O blood transfused to 193 patients, including 8 Rh-negative women, before blood type was determined. No acute hemolytic reaction occurred, and no women were sensitized. *Rh immune globulin prophylaxis is recommended only for Rh-negative women with childbearing potential receiving Rh-positive blood.*

If noncrossmatched blood is transfused, the laboratory should receive a plain (without a serum separator) red-top tube of venous blood as soon as possible to begin a formal crossmatch procedure. Whenever possible, this should be drawn before any blood is transfused. Brickman and coworkers have demonstrated that bone marrow aspirates obtained by an intraosseous needle can be used for crossmatching. [27]

Rh immune prophylaxis with human immune globulins (RhoGAM) is indicated for Rh-negative pregnant women who may be bearing Rh-positive children and may have fetomaternal transplacental hemorrhage. These events include bleeding in early pregnancy, such as spontaneous or elective abortion, ectopic pregnancy, and other potential causes of antepartum hemorrhage such as trauma. Administration of Rh immunoglobulin in *threatened abortions* is advocated by some. The product suppresses the immune response of Rh-negative women to Rh-positive RBCs, and it is effective when given up to 72 hours after exposure to fetal erythrocytes. Dosing of Rh immunoglobulin is 50 µg intramuscularly (IM) for first-trimester bleeding and 300 µg IM for later bleeding. [28] In the setting of *significant fetal-maternal transfusion* (usually only in the third trimester), doses may be increased. In such circumstances, Rh immunoglobulin is prepared in the blood bank and the correct dose is suggested on an individual basis, following confirmation of Rh status, evidence of prior sensitization, and testing for fetal erythrocytes in the mother's blood.

Transfusion Coagulopathy

Within the past 10 years it has been appreciated that pathologic hemostasis occurs following massive blood transfusions. [29] [30] [31] The exact cause of the transfusion coagulopathy is not well understood. Although such abnormalities rarely develop within the time frame of the initial resuscitation in the emergency department (ED), an understanding of the problem leads to a more intelligent approach to transfusion practices and the anticipation of potential problems. The term *massive transfusion* is loosely defined but is usually considered to be the transfusion of >10 units of blood to an adult (equivalent to 1 blood volume) within 24 hours. In patients who are given a transfusion equal to 2 blood volumes, only approximately 10% of the original elements remain. Considering the significant alteration in blood and blood products that occurs during storage, one can readily appreciate the underlying problem associated with such massive transfusions. The development of transfusion coagulopathy is multifactorial and in large part is related to tissue injury and duration of shock. [32] Abnormalities in platelets and plasma clotting factors also play a

role.

Platelets

Transfusion coagulopathy is related in part to dilution of the recipient's platelets by transfused blood, which is devoid of functioning platelets. Dilutional thrombocytopenia is a well-recognized complication of massive transfusion, and a platelet count should be obtained routinely if >5 units of blood are transfused. Generally, platelet therapy should be considered after the first 10 units of blood have been given, although the most useful parameter for estimating the need for platelet transfusions is the platelet count.

Plasma Clotting Factors

Disseminated intravascular coagulopathy plays a secondary role in post-transfusion bleeding. Factors V and VIII are labile in stored blood and absent in packed cells. Fibrinogen is relatively stable in stored blood but is absent in packed cells. A deficiency of most clotting factors, especially factors V and VIII and fibrinogen, occurs with massive transfusions. This deficiency probably occurs on a "washout" (i.e., dilutional) basis, although the dynamics are poorly understood. The replacement of these factors may be required. Specific assays for the individual factors are available, but it is more practical to measure PTT, PT, and fibrinogen levels. FFP has been used to correct clotting factor abnormalities secondary to dilution from massive transfusions, but its effectiveness has not been firmly established. Cryoprecipitate has also been used to replace factor VIII and fibrinogen, but it is rarely required, because FFP contains some fibrinogen. FFP should be infused to correct the coagulopathy as indicated by clotting studies, but as a general guide, 1 to 2 units of FFP may be given empirically for each 5 to 6 units of blood in the massively traumatized or bleeding patient. Cryoprecipitate may be required if fibrinogen levels fall below 100 mg/dL and are not adequately supplemented with FFP.

ORDERING OF BLOOD

Ordering a type and crossmatch procedure on a blood product implies that the decision has already been made to administer a transfusion. A "type and hold" or "type and screen" (no crossmatch) request alerts the blood bank to the *possibility* that a blood product will be required for the patient, so appropriate units can be acquired and kept on hand. A type and crossmatch procedure takes 45 minutes and restricts a unit of blood to a specific patient. This limits a valuable resource and should not be requested lightly. In the ED, a crossmatch procedure should be requested for a blood product only if the adult patient (1) manifests shock, (2) has *symptomatic* anemia

(usually associated with a hemoglobin <10 g/dL) in the ED, (3) has a documented loss of 1000 mL of blood, or (4) requires a blood-losing operation immediately (e.g., thoracotomy).[33] A type and hold can safely be requested for all other situations in which a blood transfusion is considered possible during the patient's care; a desirable ratio of units crossmatched to units transfused can thus be achieved. Hooker and colleagues found that the empiric trigger of pre-hospital hypotension (systolic blood pressure <100 mm Hg) was a useful discriminator for ordering early crossmatched blood. [34]

The number of units requested for a crossmatch procedure is determined by the size of the patient, response of the patient to the injury and subsequent emergency treatment, and presence of ongoing blood losses (e.g., arterial or massive gastrointestinal bleeding). In the majority of fatalities from massive hemorrhage, the patients die from hypovolemia rather than from lack of oxygen-carrying capacity. Table 29-6 provides specific guidelines for administering blood components.

RBC preparations for transfusion are not routinely tested for the presence of sickle hemoglobin. Donors with sickle trait are not excluded, and blood with sickle trait can be safely given to almost every patient, because occlusion of blood flow caused by intravascular sickling would occur only in extreme conditions of acidity, hypoxia, or hypothermia that are unlikely to be compatible with life. Nonetheless, when transfusion is being performed in infants and patients with known sickle cell anemia, the blood bank should be alerted, and a "sickle prep" should be requested for donor blood to avoid the infusion of sickle-trait blood into such patients. In rare instances, blood from a donor with a mild variant, such as hemoglobin SC disease, has caused massive intravascular sickling and death in a sick, hypoxic, acidotic infant.[35]

Blood Request Forms

The most important part of ordering blood components for a patient is proper identification of the patient and the intended unit of blood. Transfusion of an incorrect unit is a potentially fatal error. *Most transfusion mistakes are clerical errors.* Several identification systems have been established to minimize the

Figure 29-1 The Typenex blood recipient identification system. The identity of the patient and the blood sample are ensured by numbered labels on the tube and on the bracelet. *(Courtesy of Fenwal Laboratories, Deerfield, IL.)*

Figure 29-2 In the blood bank, crossmatched units of blood are identified with numbered labels from the patient's blood sample. *(Courtesy of Fenwal Laboratories, Deerfield, IL.)*

risk of improper transfusions (Fig. 29-1). Just before administering the blood, the nurse or clinician must check the identity of the numbered labels. In addition, the blood bank laboratory slip must identify the patient by name and number and contain the identification number of the unit of blood. Because most serious transfusion reactions are due to misidentification issues, one cannot be overcautious in adhering to these identification procedures (Fig. 29-2).

Usual procedures require a separate *blood bank request form* for each unit of RBCs or whole blood ordered. A number of units of FFP, cryoprecipitate, and platelet concentrates may be ordered on one form with proper identification (depending on individual blood bank procedures). When the blood bank indicates that the units ordered are ready, the person picking up the blood, along with the blood bank technician, must check the notation on the *blood release form (transfusion form)* to verify the identity of the patient (name, hospital number) and to ensure that the blood unit has been prepared for that patient (blood group and type, unit number). Immediately before administering the blood to the patient, the nurse or clinician must check the release form, blood unit, and patient tag for identity as well as the expiration date of the unit (Fig. 29-3).

INTRAVENOUS ADMINISTRATION

One should not open the unit of blood until and unless a free-flowing intravenous (IV) access line has been established in a large-bore vein. A 14-ga IV catheter is preferred, both to minimize hemolysis and to ensure rapid infusion of fluid for the treatment of hypovolemia or hypotension. When much blood must be given rapidly, administration by means of a high-flow infusion system is preferred. Standard central venous pressure lines are generally too small for adequate volume resuscitation in patients whose conditions are critical. Likewise, the purpose of a large-bore infusion line is defeated

Figure 29-3 Before administration of the blood unit, the numbered labels on the patient's bracelet and on the unit of blood are checked for identity. *(Courtesy of Fenwal Laboratories, Deerfield, IL.)*

if blood is piggybacked with an 18- to 20-ga needle through a side port in the infusion tubing. For an elective transfusion, however, blood may be given through a smaller lumen. Combining hemodilution (250 mL saline to 1 unit packed RBCs) and pressurization can safely increase the flow rate through 20- and 22-ga catheters several-fold.[36] No significant hemolysis occurs when small-gauge (21-, 23-, 25-, and 27-ga) short needles are used for transfusion of fresh blood or packed cells in infants and children and when the maximum rate

Figure 29-4 An example of a blood administration Y set with two adapters for insertion into a unit of blood or saline; note the in-line filter. *(Courtesy of Fenwal Laboratories, Deerfield, IL.)*

Figure 29-5 One upper adapter has been inserted into a bag containing normal (0.9%) saline. *(Courtesy of Fenwal Laboratories, Deerfield, IL.)*

of infusion is <100 mL/hour.[37] For rapid infusion, however, the blood administration tubing is connected directly to the infusion catheter. The infusion site should be monitored for infiltration, infection, or local reactions. Antiseptic technique is essential (Fig. 29-4 Fig. 29-5 Fig. 29-6 Fig. 29-7 Fig. 29-8).

If the patient already has a suitable IV line in place, a solution of 0.9% normal saline only should be used to flush

Figure 29-6 The entry site of the unit of blood, into which the other upper adapter of the Y set should be inserted. *(Courtesy of Fenwal Laboratories, Deerfield, IL.)*

Figure 29-7 Inserting the hard plastic spike of the upper adapter. *(Courtesy of Fenwal Laboratories, Deerfield, IL.)*

the system before administering the blood. Other IV fluids are *not* to be used because of the risks of hemolysis or aggregation (with 5% dextrose in water) [38] or clotting (with lactated Ringer's solution). [39] No medications should be placed into the unit of blood or added to the infusion line for the same reasons.

Filters

All blood and blood products should be infused only through an appropriate filter, such as those supplied in-line in the

Figure 29-8 After the plastic tubing has been primed with saline, the blood flows through into the patient. *(Courtesy of Fenwal Laboratories, Deerfield, IL.)*

Figure 29-9 Administration of blood through a microaggregate filter attached between the unit of blood and the hard plastic spike of the administration set. *(Courtesy of Fenwal Laboratories, Deerfield, IL.)*

blood administration tubing sets. In the past, filtration was required merely to keep the IV line from becoming blocked by clots. Adverse consequences that result from infusing unfiltered blood products have since been recognized. Debris consisting of clots and aggregates of fibrin, white blood cells, platelets, and intertwined RBCs (ranging in size from 15 to 200 µm) accumulate progressively during storage of blood. The usual filter, made of a single layer of plastic with multiple 170-µm pores, traps larger particles yet allows rapid infusion of 2 to 3 units of blood before flow is obstructed. Purified *components* of blood plasma can be safely administered through a filter with pores as fine as 5 µm.

It has been suggested that microaggregates of debris, which could pass through a 170-µm filter, may in part contribute to the syndrome of "shock lung" seen after transfusions of many blood units in patients suffering from severe trauma and hemorrhage. Some clinicians therefore recommend the use of a microaggregate blood infusion filter with a mesh pore size of 40 µm (Fig. 29-9) when multiple units of blood are administered to a trauma victim, a patient with compromised pulmonary function, or a neonate. Microaggregate filters tend to become blocked, impeding the rate of infusion more quickly, and are not commonly required in the emergency setting. In addition, whether the infusion of microaggregates (between 40 and 170 µm in size) is in fact harmful is still an unsettled issue. [40] Standard filters should be replaced after 2 to 3 units of blood product have been administered; most microaggregate filters should be changed after each unit. It is generally agreed that a significant number of platelets is removed by microaggregate filters, and some advise against

using these filters when platelet packs are infused. Others believe that although platelets are removed with the microaggregate filters, the trapped platelets can be removed with saline flush without any significant loss. [41] Table 29-7 lists some available in-line filters.

Rate of Infusion

One unit of whole blood can be safely administered to a hypotensive patient at a rate of 20 mL/kg per hour. In the setting of hypovolemic shock and continued hemorrhage, there is no limit to the transfusion rate, Multiple units may be transfused simultaneously, even under pressure (see Chapter 24). In the stable patient, 1 unit of *whole blood* (500 mL) should be administered over approximately a 2-hour period (3 to 4 mL/kg per hour). After this time, RBCs begin to lose metabolic activity. In addition, the unit of blood, which is an excellent culture medium, is likely to become contaminated if bacteria and fungi are allowed to grow at room temperature. Packed cells should be given at approximately the same rate; plasma products may be given more rapidly. In a patient with a healthy cardiovascular system, one should administer FFP more rapidly (about 15 to 20 minutes/unit) to correct coagulation deficits, because the coagulant activity begins to deteriorate rapidly after 20 to 30 minutes of thawing. In patients with severe anemia and congestive heart failure, a rapidly acting diuretic, such as furosemide, can be given (0.5 mg/kg IV) at the onset of transfusion to obviate circulatory overload.

If a transfusion of blood must be interrupted or delayed for some reason, the remainder of the blood unit should be returned to the blood bank. More convenient refrigerators in

TABLE 29-7 -- In-Line Filters for Blood Transfusion

Filter	Pore Size	Use and Contraindications
Standard		
Fenwal STD Blood Filter	170 µm	All blood components
McGaw STD Blood Filter	170 µm	All blood components
Special Use		
Fenwal 4C2100	170 µm	Platelets, cryoprecipitate, antihemophilic factor concentrates, fresh whole blood
Microaggregate Filters		

Fenwal Microaggregate Blood Filter 4C2423 or 4C2131	20 µm	Removes most platelets and leukocytes from blood being transfused; do not use with fresh whole blood or concentrates of platelets or WBCs; primarily indicated for use with patients receiving *multiple transfusions* of stored blood, patients with *compromised pulmonary function,* and those undergoing cardiopulmonary bypass; recommended for use in most newborns

the ED or on the hospital unit *should not* be used to store blood products unless they are temperature-controlled or continuously monitored and alarmed.

Patients who are in hemorrhagic shock can receive blood through two large-bore catheters at different sites. Usually gravity provides a sufficient pressure gradient if the unit is raised above the patient to increase the rate of infusion when the clamps are wide open. If a pressure pump is used (Fig. 29-10 and Fig. 29-11), the infusion can be quicker.[42] A standard sphygmomanometer cuff should never be wrapped around a unit of blood to create increased infusion pressure, because the nonuniform application of pressure could burst the plastic bag containing the blood component.

One can dilute packed RBCs with *normal saline* (0.9%, without dextrose) before infusion simply by opening the clamps on the upper tubes of the Y infusion set and leaving the lower (recipient end) clamps closed. Although it is generally agreed (and recommended by the editors) that lactated Ringer's solution should never be mixed with blood because of possible clot formation, two studies have demonstrated that small amounts of lactated Ringer's solution *is* compatible with blood. King and associates found that 100 mL could be added to a unit of packed RBCs without precipitating blood clotting, [43] while Cull and coworkers suggest that up to 150 mL of lactated Ringer's solution may be safely added as a diluent to each unit of packed RBC. [44] Therefore, blood inadvertently mixed with small amounts of lactated Ringer's solution need not be routinely discarded. Dilution will allow for more rapid infusion by decreasing the blood viscosity, which is dependent on hematocrit, at the risk of increasing volume. Alternatively, the direct addition of approximately

Figure 29-10 A controlled-pressure administration device for rapid infusion of blood products. *(Courtesy of Fenwal Laboratories, Deerfield, IL.)*

200 mL of normal saline to the bag of packed RBCs has been recommended to bring the hematocrit in the blood bag to approximately 45%.

Rewarming

Blood is stored at approximately 4°C to maintain cellular integrity and to prevent the overgrowth of microorganisms. Blood products usually passively warm to 10°C by the time they are administered to the recipient, unless administered under pressure. Adverse effects of hypothermia on cardiac conduction and flow rates are evident when rapid administration of a large volume of blood is performed without prewarming.

Various mechanisms have been used to warm blood to 35 to 37°C. An ideal blood warmer should allow liberal flow rates while preventing thermal hemolysis of blood cells. Commonly used devices are bath coils that allow a plastic tube to reside in a closely regulated warm water bath, as well as dry heat devices that allow blood to circulate through flat, thin bags sandwiched between aluminum blocks that contain electric heating elements. Both devices have relatively low flow rates and suboptimal thermal clearance.[45] Blood bag immersion in warm water baths is safe, but it is considered imprecise and slow. Although much interest surrounds the use of microwave heating devices, the technique is not recommended by the Association of Blood Banks because of the risk of hemolysis. Herron and colleagues advocate keeping the packed RBC temperature <50°C as they noted significant hemolysis beginning at 51 to 53°C. [46]

Rapid admixture warming is a promising alternative technique (see Chapter 24).[47] The unit of whole blood is

Figure 29-11 A rubber bladder is pumped up, and the blood unit is squeezed uniformly against a reinforced mesh. *(Courtesy of Fenwal Laboratories, Deerfield, IL.)*

mixed with an equal amount of normal saline, which has been preheated to 60 to 70°C. Once mixed, the product is administered to the patient with a resultant delivery temperature of approximately 35°C. This technique combines dilution of blood product and warming into one step. Regardless of the rewarming technique used, warming refrigerated blood to body temperature decreases its viscosity two-fold to three-fold and avoids venous spasm, thus facilitating transfusion.

Monitoring

During the first 5 to 10 minutes and then every 15 minutes during a transfusion of any blood product, the patient must be carefully monitored for evidence of a transfusion reaction. Signs and symptoms are hives, chills, diarrhea, fever, pruritus, flushing, abdominal or back pain, tightness in the chest or throat, and respiratory distress. A potentially life-threatening acute hemolytic transfusion reaction in a patient who has received prior transfusions may differ clinically from a minor allergic reaction only by its effects on the patient's pulse and blood pressure. One can safely treat an allergic reaction to leukocytes or plasma proteins that cause hives, itching, fever, or chills by administering an antihistamine (but not into the blood infusion line) and stopping the transfusion.

Transfusion should be stopped immediately when the following signs are encountered: an increase in pulse rate, a decrease in blood pressure, respiratory symptoms, chest or abdominal discomfort, or a sensation of "impending doom." Normal saline should be administered to maintain blood pressure and urine output. Samples of urine and blood should be sent to the laboratory to verify the presence of free hemoglobin. The blood bank should also receive a clotted sample of

blood to reassess the presence of any immune reaction. If the blood bank concludes that the reaction is a nonhemolytic allergic response, premedication with antihistamines (diphen-hydramine or hydroxyzine) and antipyretics is indicated before the next transfusion. Alternatively, washed cells could be used.

The patient in whom a hemolytic transfusion reaction is suspected should be treated vigorously and promptly. [48] Most mortality and morbidity is secondary to hypotension and shock leading to cardiovascular instability, renal insufficiency, respiratory manifestations, or hemorrhagic complications of disseminated intravascular coagulation. The initial treatment is directed at treating the hypotension by infusion of 5% dextrose in saline or lactated Ringer's solution or vasopressors, if required. The volume and rate of infusion are determined by blood pressure response. Symptomatic treatment with acetaminophen, a warming blanket, an inhaled or subcutaneous ß-agonist agent for bronchospasm or subglottic edema, or antipruritics or antihistamines is of secondary importance.

If an acute hemolytic transfusion reaction occurs, there may be some benefit from alkalinization of the urine with IV sodium bicarbonate to prevent the precipitation of free hemoglobin. Forced diuresis with mannitol to maintain the urine output at 50 to 100 mL/hour has also been advocated. The benefit from alkalinization and diuresis in the prevention of acute renal shutdown is uncertain, although the use of these techniques is commonly advocated. After shock is controlled, an assessment of hemostasis, respiratory function, renal function, and cardiac function will help direct later therapy of the complications; disseminated intravascular coagulation may require the administration of plasma, platelets, or fibrinogen, and acute tubular necrosis may dictate careful fluid management. Hemolytic transfusion reactions have become unusual. They are rarely fatal and are usually attributable to an error in identification (such as can result from the treatment of two "John Doe" patients simultaneously).

Delayed, or "late," hemolytic transfusion reactions may occur days, or even weeks, after transfusion of RBCs. They are characterized by falling hemoglobin levels, jaundice, hemoglobinemia, and indirect hyperbilirubinemia. [49] This complication is usually self-limited and is not life-threatening. Therapy is symptomatic, but future attempts at crossmatching for transfusions may be difficult because of the presence of RBC antibodies. Individuals so affected should wear identification tags or bracelets to alert medical personnel that prior transfusion reactions have occurred.

On completion of a transfusion, an entry in the patient's record should indicate the type and volume of the transfusion and the presence or absence of any reaction. The progress note, the transfusion record sheet, or the transfusion laboratory slip can be used for this purpose and should be signed and dated by the clinician or nurse, in accordance with hospital policies. The bag in which the blood was stored might be discarded or returned to the blood bank, as individual policies dictate.

The clinician should emphasize to the patient and family how critically important any blood transfusion is to the patient's care. It could then be suggested that the family consider arranging for replacement donations of units of blood to afford future patients the luxury of an ample, available supply of blood products.

CONCLUSION

Transfusion therapy is an essential part of resuscitation from traumatic blood loss, as well as life-saving therapy for familial and acquired coagulopathies or bleeding disorders. Although transfusion of blood products always poses a potential risk to the patient, improvement in transfusion protocols, donor screening, and viral-reduction methods have greatly improved the safety. Nonetheless, recognition of potential risks, proper product selection, careful patient education and rigorous adherence to hospital policies and protocols continue to be essential. Future research will focus on development of blood substitutes and genetically derived blood products.

Section V - Anesthetic and Analgesic Techniques

Chapter 30 - Local and Topical Anesthesia

Douglas McGee

Local anesthetic agents are important tools used in the everyday practice of emergency medicine. This chapter describes the mechanism of action, the nuances of clinical use, and adverse reactions to anesthetics commonly used in the emergency department (ED). Detailed technical guidance for the performance of topical and infiltrative local anesthesia is provided.

BACKGROUND

The first local anesthetic was cocaine, an alkaloid in the leaves of the *Erythroxylon coca* shrub from the Andes Mountains. Early Incan society used cocaine for invasive procedures, including cranial trephination. In 1884, Koller used topical cocaine in the eye and was credited with the introduction of local anesthesia into clinical practice.[1] In the same year, Zenfel used a topical solution of alcohol and cocaine to anesthetize the eardrum, and Hall introduced the drug into dentistry.[2] In 1885, Halsted demonstrated that cocaine blocked nerve transmission, laying the foundation for nerve block anesthesia.[3] The search for alternatives to cocaine led to the synthesis of the benzoic acid ester derivatives and the amide anesthetics used today. It was not until the 1960s that a detailed understanding of the physiochemical properties, mechanism of action, pharmacokinetics, and toxicity of these agents emerged.

PHARMACOLOGY AND PHYSIOLOGY

Chemical Structure and Physiochemical Properties

Most useful local anesthetic agents share a basic chemical structure:
Aromatic segment—Intermediate chain—Hydrophilic segment

Subtle variations of this basic structure determine each agent's main physiochemical properties: the negative log of dissociation constant (p K_a), the partition coefficient (a measurement of lipid solubility), and the degree of protein binding. Each of these properties determines the drug's potency, onset, and duration of action. Physiochemical properties are not the sole determinant of clinical activity; other factors influence the drug's effect.

The intermediate chain between the aromatic and hydrophilic segments is either an amino-ester or an amino-amide; these two chemical structures form the basis for the two main classifications of local anesthetics. *Ester*-type agents include procaine, chloroprocaine, cocaine, and tetracaine. The *amide*-type agents include lidocaine, mepivacaine, prilocaine, bupivacaine (Marcaine), and etidocaine. Different pathways metabolize each class. Esters are hydrolyzed by plasma pseudocholinesterase. Cocaine, an ester, is also partly metabolized via N-demethylation and nonenzymatic hydrolysis. Individuals with pseudocholinesterase deficiencies may have a greater potential for cocaine toxicity if large doses are used. Although this has not been an issue when cocaine is used clinically as an anesthetic. Amides are metabolized in the liver by enzymatic degradation. Local anesthetics are poorly soluble weak bases combined with hydrogen chloride to produce the salt of a weak acid. In solution, the salt exists both as uncharged molecules (nonionized) and as positively charged cations (ionized). The nonionized form is lipid-soluble, enabling it to diffuse through tissues and across nerve membranes. The ratio of nonionized to ionized forms depends on the pH of the medium (vial solution or tissue milieu) and on the p K_a of the specific agent. The pK_a is the pH at which 50% of the solution is in the uncharged form, and 50% is in the charged form. When the pH of the solution or tissue is less than the p K_a , more of the drug is ionized. When the pH increases, more of the drug is in the nonionized form. Because the nonionized form of drug can diffuse through tissues and nerves, manipulating the pH of the solution can alter a drug's diffusion properties.

Local anesthetics are available in single-dose vials or ampules and in multidose vials, with and without epinephrine. Most solutions have a pH greater than 5. Multidose vials contain methylparaben, an antibacterial preservative. Local anesthetics premixed with epinephrine also contain an antioxidant (sodium bisulfite or sodium metabisulfite) to prevent deactivation of the vasoconstrictor. These solutions must be adjusted to a more acidic pH, approximately 3.5 to 4.0, to maintain the stability of epinephrine and its antioxidant. These properties as they relate to the amide group are depicted in Table 30-1 .

Nerve Structure and Impulse Transmission

Functional and Structural Components of a Peripheral Nerve

The functional nerve unit includes the nerve axon and its surrounding Schwann cell sheath. The Schwann cell (Fig. 30-1) may surround several unmyelinated axons, or a single myelinated nerve fiber, forming a myelin sheath. Junctions between sheaths along the axon called *nodes of Ranvier* contain sodium channels necessary for depolarization. As myelin sheath thickness increases from autonomic to sensory to motor fibers, the nodes of Ranvier are spaced farther apart. The most important structure affecting nerve impulse transmission is the axon membrane (Fig. 30-2). The membrane is made of a double layer of phospholipids into which are embedded

TABLE 30-1 -- pH and Additives of Amide Local Anesthetics

Solution Content	pH (Range)	Preservative (Methylparaben)	Antioxidant
Plain, single dose	4.5–6.5	-	-
Plain, multidose	4.5–6.5	+	-
Commercial epinephrine, single dose	3.5–4.0	-	+
Commercial epinephrine, multidose	3.5–4.0	+	+
Prepared epinephrine, single dose	4.5–6.5	-	-

protein molecules that serve as channels containing pores for the movement of ions in and out of the cell. Most pores have a filter, or gate, that controls ion-specific movement, and a sensor mechanism that opens or closes the gate. Bundles of nerve fibers (Fig. 30-3) are embedded in the *endoneurium,* which is made of collagen fibrils, and are surrounded by a cellular layer, the *perineurium*. The perineurium functions as a diffusion barrier and maintains the composition of extracellular fluid around the nerve fibers. Surrounding the entire structure is the outer layer of a peripheral nerve, the *epineurium*, composed of areolar connective tissue.

The Nerve Impulse and Transmission

At rest, the inside of a nerve fiber, or axoplasm, is negative (-70 mV) compared with the outside. This resting potential is the net result of the differences in ionic concentrations on each side of the axonal membrane and the forces that tend to maintain that difference. Specifically, there is a surplus of sodium extracellularly and of potassium intracellularly. The sodium channel is closed, preventing these ions from moving along their concentration gradient (out ? in). Although potassium can leave the cell to follow its concentration gradient (in ? out), the need to maintain electrical neutrality inside the cell prevents it from completely doing so. Potassium is in equilibrium between the concentration gradient and the electrochemical gradient, creating the negative resting potential.

The sodium channel opens when a nerve is stimulated. Sodium ions enter slowly at first until a critical threshold is reached. Sodium ions then enter the cell rapidly, along the electrochemical and concentration gradients, causing depolarization. The influx of sodium is halted when the membrane potential reaches +20 mV but potassium continues to move out of the cell, repolarizing it until the resting potential is reached. When the excitation process has been completed and the nerve cell is electrically quiet, the relative excess of sodium inside the cell and potassium outside the cell is

readjusted by the adenosine triphosphate (ATP)-dependent sodium-potassium pump.

Depolarization of a portion of the nerve causes a current to flow along the adjacent nerve fiber. This current makes the membrane potential less negative and actuates the sensor to open the next sodium channel. The action potential cycle is repeated, propagating the impulse. Nerve conduction is essentially unidirectional because the sodium channel is not only closed but inactivated as well, and delayed closure of specific potassium channels prevents the critical threshold from being reached in the segment just depolarized. An impulse spreads continuously down the axon in unmyelinated nerve fibers. In myelinated fibers, current flows from node to node causing intervening segments to depolarize at once. This saltatory conduction causes a faster rate of impulse transmission in myelinated fibers.

Mechanism of Action

How local anesthetic agents produce nerve conduction blockade depends on the active form of the agent and specific physiologic and cellular activity.

The Active Form

Anesthetic solutions contain uncharged and charged forms. The concentration of the uncharged form increases in more alkaline milieus. Only this uncharged lipid-soluble form can cross tissue and membrane barriers. Once the uncharged drug is through a barrier, the uncharged form re-equilibrates into uncharged and charged forms in a proportion dependent on the prevailing pH. Because local anesthetics are more effective in alkaline solutions, it was originally thought that the uncharged form was responsible for conduction blockade. Alkaline solutions are currently believed to be more effective because of increased penetration through tissue barriers. The cationic charged form is responsible for the actual neuronal blockade.

The Physiologic and Cellular Basis for Neuronal Blockade

The prevention of sodium influx across the nerve membrane forms the physiologic basis for conduction blockade. Local anesthetics slow sodium influx, decreasing the rate of rise and amplitude of depolarization. If sufficient anesthetic is present and the firing threshold is not reached, the action potential is not formed. With no action potential, no impulse is transmitted, and impulse conduction is blocked, resulting in local anesthesia.

The means by which anesthetic agents prevent sodium influx is still not completely understood. It is believed that the cationic charged form blocks the action potential from inside

the membrane; the agent enters the sodium channel from the axoplasmic side and binds to a receptor.[4] [5] This "specific receptor" theory is well accepted and is considered the predominant mechanism in preventing sodium influx. However, this theory cannot account for the action of benzocaine and other neutral compounds or the uncharged base forms of the common local anesthetics.

In summary (Fig. 30-4), when a local anesthetic (other than benzocaine) surrounds the perineurium, it equilibrates into its uncharged and charged forms based on the tissue pH and pK_a . The uncharged lipid-soluble form penetrates tissue, nerve sheath, and nerve membrane to gain access to the axoplasm and re-equilibrates into both forms. The charged form enters the sodium channel and decreases sodium movement into the cell thereby halting nerve transmission. The uncharged base is also involved with sodium channel blockade, but the exact nature of this mechanism is unknown.

Activity Profile during Neuronal Blockade

A local anesthetic's activity profile (onset, potency, and duration) and its ability to produce a differential blockade in mixed nerves are a function of physiochemical properties, the physiologic environment, and, to some extent, manipulation by the clinician.

Onset of Action

The pK_a of an anesthetic is the primary physiochemical factor that determines onset of action. Increased tissue penetration and shortened onset of action is found in drugs with a lower pK_a because more of the lipid-soluble uncharged form is present (Table 30-2 and Table 30-3). Although in isolated nerve fibers onset of action directly parallels p K_a , other physiochemical factors influence drug activity. For example, prilocaine and lidocaine have the same p K_a , but lidocaine's onset is faster because of its enhanced ability to penetrate through non-nervous tissue.

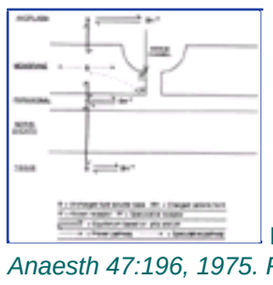

Figure 30-4 Mechanism of action of local anesthetic agents (see text for details). *(Modified from Ritchie JM: Mechanism of action of local anesthetic agents and biotoxins. Br J Anaesth 47:196, 1975. Reproduced by permission.)*

TABLE 30-2 -- Activity Profile with Primary Physiochemical Determinant

Agent	Onset: pK_a	Potency: Lipid Solubility	Duration: Protein Binding
Tetracaine	Slow	8	Long
Procaine	Slow	1	Short
Chloroprocaine	Fast	1	Short
Lidocaine	Fast	2	Moderate
Mepivacaine	Fast	2	Moderate
Prilocaine	Fast	2	Moderate
Bupivacaine	Moderate	8	Long
Etidocaine	Fast	4–6	Long

The site of administration also influences the onset of action. Onset times are prolonged as the amount of interspersed tissue or the size of the nerve sheath increases because of the greater distance that the agent must travel to reach its receptor. The pattern of onset for large nerves is determined by the structural arrangement of fibers. Peripheral (mantle) fibers are blocked before core fibers. Because mantle fibers innervate more proximal regions, nerve blockade proceeds in a

proximal-to-distal progression.

Adding sodium bicarbonate to raise the anesthetic solution's pH yields a higher concentration of the uncharged lipid-soluble form and decreases onset time. Increasing the total dose by using a higher concentration of the same volume or a greater volume of the same concentration also shortens onset time. For most procedures performed in the ED, the onset time of most agents is short enough that manipulation to achieve shorter times is unnecessary.

Potency

The lipid solubility of an anesthetic is a primary physiochemical factor determining potency. The drug's partition coefficient, not the concentration of lipid-soluble form determined by pK_a or pH, confers its lipid solubility. Because the nerve membrane is lipid, lipophilic anesthetics pass more easily into the cell and few molecules are needed for conduction blockade (see Table 30-2 and Table 30-3).

The degree of vasodilation produced by the anesthetic also affects potency since vasodilation promotes vascular absorption, reducing the amount of locally available drug. Lidocaine is more lipid-soluble than prilocaine or mepivacaine, but it produces more vasodilation. Although lidocaine is twice as potent as prilocaine or mepivacaine in vitro, it is equipotent in vivo. Although not a primary reason for its use, epinephrine, by producing vasoconstriction and making more molecules available to the nerve, increases the depth of anesthesia. Drugs more readily absorbed by fat have reduced potency. Increased concentration also increases potency. Choosing an anesthetic for its potency is usually not necessary for any given site, since the concentration of an agent may be manipulated to make most drugs equianesthetic. For example, lidocaine, being one-fourth as potent as bupivacaine, is usually used at 4 times the concentration (1% to 2% vs. 0.25% to 0.5%, respectively). For different sites and techniques, different concentrations and volumes of a given agent are needed to produce adequate blockade.

Duration

The degree of protein binding of an anesthetic primarily determines the duration of action. Agents that bind more

TABLE 30-3 -- Physiochemical Properties of Selected Local Anesthetics

Agent	Type	Site of Metabolism	pK_a	Lipid Solubility (Partition Coefficient)	Protein Binding (%)
Tetracaine	Ester	Plasma	8.5	High (4.1)	76
Procaine	Ester	Plasma	8.9	Low (0.02)	6
Chloroprocaine	Ester	Plasma	8.7	Low (0.14)	—
Lidocaine	Amide	Liver	7.9	Medium (2.9)	64
Mepivacaine	Amide	Liver	7.6	Medium (0.8)	78
Prilocaine	Amide	Liver	7.9	Medium (0.9)	55
Bupivacaine	Amide	Liver	8.1	High (27.5)	95
Etidocaine	Amide	Liver	7.7	High (141.0)	94

tightly to the protein receptor remain in the sodium channel longer (see Table 30-2 and Table 30-3). Like potency, the duration of action is reduced by the vasodilation produced by local anesthetics. Prilocaine, which is less protein-bound than lidocaine, produces a longer duration of action because of its lesser degree of vasodilation. The duration of action also varies with the mode of administration. The duration of action is shorter when agents are applied topically.

The duration of action may be prolonged by several methods. Increasing the dose, usually by increasing the concentration, prolongs duration to limits imposed by toxic effects. Although controversial, raising the pH of the anesthetic solution also has been shown to prolong duration. [6] [7] The most practical way to increase duration is to use solutions that contain epinephrine. [8] Epinephrine causes vasoconstriction, decreases systemic absorption, and allows more drug to reach the nerve. The effect of epinephrine varies according to the agent. Anesthetics that intrinsically produce more vasodilation (e.g., procaine, lidocaine, mepivacaine) benefit more from epinephrine's vasoconstrictive action. The long-acting, highly lipid-soluble agents (e.g., bupivacaine, etidocaine) are less affected because they are substantially taken up by extradural fat and released slowly. In fact, lidocaine with epinephrine may be effective as long as bupivacaine without epinephrine. Generally, most ED procedures can be accomplished quickly before anesthesia wears off regardless of which drug is selected. Choose agents with a long duration of action when the procedure is lengthy or if postoperative analgesia is desired.

TOPICAL ANESTHESIA

Local anesthetic agents may be applied topically to mucous membranes, intact skin, and lacerations. There are sufficient differences among these sites to merit a separate discussion of each one. Topical anesthesia of the eye is discussed in Chapter 64 .

Mucous Membranes

Agents and Properties

Effective anesthesia of the intact mucous membranes of the nose, mouth, throat, tracheobronchial tree, esophagus, and genitourinary tract may be provided by several anesthetics (Table 30-4). Tetracaine, lidocaine, and cocaine are the most effective commonly used agents (Table 30-5). Benzocaine (14% to 20%) is commonly used for intraoral or pharyngeal anesthesia. Prilocaine-phenylephrine (Prilophen) is another topical agent. The anesthesia produced is superficial and does not relieve pain that originates from submucosal structures.

Tetracaine solution is an effective and potent topical agent with a relatively long duration of action. It is used in concentrations from 0.25% to 1% with a recommended maximum adult dose of 50 mg. However, in an overdose, it has the disadvantage of severe cardiovascular toxicity without any preceding central nervous system stimulatory phase.

Lidocaine also is an effective topical agent that is marketed in a variety of forms (solutions, jellies, and ointments) and concentrations (2% to 10%). It is commonly employed as the 2% viscous solution prescribed for inflamed or irritated mucous membranes of the mouth and pharynx. Patient misuse by repeated self-administration can lead to serious toxicity. Topical lidocaine provides an adequate duration for most procedures, with a maximum safe dose of 250 to 300 mg.

Cocaine is an effective, but potentially toxic, topical agent applied to mucous membranes of the upper respiratory tract. Although it is an ester, hepatic metabolism occurs, as does hydrolysis by plasma pseudocholinesterase. Absorption is enhanced in the presence of inflammation. Cocaine is the only anesthetic that produces vasoconstriction at clinically useful concentrations. This major advantage is offset by its susceptibility to abuse and its toxic potential. Stimulating the central nervous system directly and blocking norepinephrine reuptake in the peripheral nervous system causes the toxic

TABLE 30-4 -- Common Local and Topical Anesthetics Used in the Emergency Department

1. Benzocaine spray will produce transient anesthesia of mucus membranes. Rarely, it can precipitate methemoglobinemia in standard doses. Anbesol is a popular over-the-counter benzocaine anesthetic for dental problems, such as teething.
2. EMLA cream (lidocaine and prilocaine) will produce anesthesia of the intact skin but it must be in place for about 60 minutes to provide significant benefit. ELA-Max is another topical lidocaine preparation with a more rapid onset of action.
3. "Magic mouthwash" contains equal parts of diphenhydramine elixir, Maalox, and 2% viscous lidocaine. Each 5 mL teaspoon contains <50 mg lidocaine. It is swished, held in the mouth for 1–2 minutes, and expectorated.
4. Viscous lidocaine (2%) may be used intraorally but repeated use may produce systemic toxicity, especially in children. Each 5 mL teaspoon contains 100 mg lidocaine. It should not be swallowed, but instead expectorated after holding it in the mouth for a few minutes. Viscous lidocaine is not useful for acute pharyngitis. Systemic narcotics are preferred if pain is severe.

TABLE 30-5 -- Practical Agents for Emergency Department Use—Mucosal Application

		Maximum Dosage*			
Agent	***Usual Concentration (%)***	***Adult (mg)***	***Pediatric (mg/kg)***	***Onset (min)***	***Duration (min)***
Tetracaine	0.5	50	0.75	3–8	30–60
Lidocaine	2–10	250–300†	3–4†	2–5	15–45
Cocaine	4	200	2–3†	2–5	30–45

*These are conservative figures; see text for explanations.
†The lower dosage should be used for a maximum safe dose when feasible.

effects. Cocaine should not be administered to patients who are sensitive to exogenous catecholamines or who are taking MAO inhibitor antidepressants. Clinical manifestations of toxicity include central nervous system excitement, seizures, and hyperthermia. Central and peripheral effects of hypertension, tachycardia, and ventricular arrhythmias may be seen. Acute myocardial infarction has been reported after topical application. [9] Cocaine is commonly used as a 4% solution with a maximum safe dose of 200 mg (2 to 3 mg/kg). Coronary vasoconstriction may occur with doses as low as 2 mg/kg applied to the nasal mucosa. Topical cocaine should be used cautiously, if at all, for patients with coronary artery disease.

Dyclonine offers advantages over other topical anesthetic agents. Dyclonine is a ketone derivative without an ester or amide linkage and may be used in patients who are allergic to the common anesthetics. Extensive experience with the topical preparation has shown it to be effective and safe. [10] Dyclonine is marketed in 0.5% and 1% solutions, with a maximum adult recommended dose of 300 mg.

Benzocaine is an ester that is marketed in its neutral form in 14% to 20% preparations (Cetacaine, Americaine, Hurricaine). Its low water solubility prevents significant penetration of the mucous membranes, reducing systemic toxicity if applied to intact mucosa. However, it is not a potent anesthetic and has a brief duration of action. It is more allergenic than other topical agents are. Benzocaine is usually dispensed in an admixture with other therapeutic ingredients and is clinically effective only at relatively high (>14%) concentrations. Benzocaine is available as a nonprescription gel and liquid (Anbesol, 6.3% to 20%). It is commonly used by dentists to produce mucosal anesthesia before intraoral nerve blocks (see Chapter 31). Adriani and Zepernick recommend this agent for lubricating catheters, airways, endotracheal tubes, and laryngoscopes and describe only one adverse reaction (methemoglobinemia) in their experience with approximately 150,000 patients. [10] Methemoglobinemia may rarely occur secondary to mucosal absorption of Anbesol used repeatedly for teething infants and after standard doses of benzocaine sprays used in endoscopic procedures. [11]

Like infiltrated anesthesia, toxic reactions to topically applied anesthetics correlate with peak blood levels achieved and not necessarily the dose administered. Systemic absorption of a topical agent is more rapid, achieving a higher level than the same dose given by infiltration (Fig. 30-5 (Figure Not Available)). *The total dose for a topical anesthetic should be considerably less than that used for infiltration at a given site.* Fractionating the total dose into three portions administered over several minutes effectively reduces peak blood levels. Inadvertent suppression of the gag reflex, combined with difficulty swallowing, may lead to aspiration, an important potential adverse reaction to topical anesthesia of the nose, mouth, and pharynx. Infections from drug solutions in multidose vials for topical anesthesia of the larynx and trachea have not been substantiated.

Technique and Precautions

A commonly used "magic mouthwash" for the topical treatment of painful gingivostomatitis in children is often prescribed by emergency clinicians and pediatricians. There is little scientific study of the preparation, and it is not available commercially, but it has been safely used for decades. It consists of equal parts of viscous lidocaine (2%), Maalox as a binder, and diphenhydramine elixir. The creamy mixture is swished around the mouth and expectorated, or painted on specific lesions with a cotton swab. Packing an area with a cotton ball soaked with this mixture may be an option. Repeated doses or swallowing of the elixir can, of course, produce systemic toxicity, so careful instruction should be given to limit use of the solution to every few hours. This combination would be theoretically less toxic than simply using topical lidocaine.

Emergency physicians often prescribe 2% viscous lidocaine (20 mg/mL) for patients with pharyngitis, stomatitis, dental pain, or other inflammatory or irritative lesions in the oropharynx. Although this is a widely used intervention, and generally safe, the common misconception that topical

Figure 30-5 (Figure Not Available) Comparison of blood levels of tetracaine obtained after rapid intravenous (IV) injection of 30 mg of tetracaine over a 30- to 60-second interval, after topical application to the pharyngeal mucous membranes, after subcutaneous infiltration, and after slow IV infusion. *(From Adriani J, Campbell D: Fatalities following topical application of local anesthetics to mucous membranes. JAMA 162:1528, 1956. Copyright 1956, American Medical Association. Reproduced by permission.)*

anesthesia is totally innocuous may result in poor patient instruction with serious consequences. Topical lidocaine is helpful for painful mouth lesions, but is of little practical value for acute pharyngitis, where systemic analgesics are a better option. Seizures and death from topical lidocaine have been described when excessive repeated doses have been administered.[12] [13] Toxic blood levels may occur because the anesthetic effect of viscous lidocaine lasts only for 30 to 60 minutes, and patients with recurrent pain may either ignore or be ignorant of the safe dosing interval of 3 hours, medicating themselves more frequently. Patients tend to increase each dose to obtain greater relief and inflammation may increase systemic absorption. In addition, painful oral lesions may last for several days.

Children are at higher risk for the rare toxicity of oral lidocaine. Compared to adults, children may exhibit increased lidocaine absorption, decreased clearance, and a longer half-life.[14] Continued medication use allows lidocaine and its major metabolites, monoethylglycinexylidide (MEGX) and glycinexylidide (GX), to accumulate. Both MEGX and GX are produced from the hepatic metabolism of lidocaine and are excreted in the urine. They possess anesthetic and antiarrhythmic activity and have central nervous system toxicity potential. Although these metabolites are less potent than lidocaine, their elimination half-lives are considerably longer. Several investigators regard MEGX and GX to be the causes of central nervous system toxicity with prolonged topical use.[13]

The length of time viscous lidocaine is retained in the mouth and whether the excess is expectorated or swallowed also affect the blood level produced. Expectorating the medication after swishing it in the mouth produces much lower blood levels than when it is swallowed. It seems logical that the most hazardous mode of administration would be to retain the solution in the mouth "until absorbed."

Clearly explain the proper way to use viscous lidocaine and inform patients *not to dose themselves ad libitum*. Note that a 2% solution contains 20 mg/mL, or 100 mg per standard teaspoon (5 mL). The recommended maximum adult dose is 300 mg (15 mL of a 2% solution) no more frequently than every 3 hours. When possible, instruct the patient to decrease the dose by using direct cotton swab applications. When gargled or swished in the mouth, limit application time to 1 to 2 minutes, and instruct the patient to expectorate excess solution. Limit use to 2 or 3 days, especially if swallowing the solution is necessary to obtain relief. Prescribe lower doses for patients at risk for decreased clearance (see Systemic Toxic Reactions later in this chapter). Doses for children are prescribed at 3 mg/kg. Because infants cannot expectorate well, do not use viscous lidocaine for minor oral irritation and teething. Recommend that no food be eaten for one hour after application because anesthesia of the oropharynx can interfere with swallowing and cause aspiration. Special note should be made of the over-the-counter availability of benzocaine, commonly used for toothaches and teething. A gel or liquid (Anbesol) is available in 6.3% to 20% formulations. When used repeatedly in the oral cavity on irritated tissue, systemic toxicity, including methemoglobinemia, may occur.

Lidocaine 4% solution can be atomized using a standard nebulizer device and inhaled by the patient before nasogastric tube insertion. This method effectively anesthetizes the nasopharyngeal and oropharyngeal tissues, easing the pain of tube insertion.[15]

Intact Skin

Agents and Uses

The stratum corneum provides a cutaneous barrier that prevents the commonly marketed aqueous solutions (acid salts) from producing anesthesia but saturated solutions of the bases of local anesthetics are effective on intact skin. When applied topically to *abraded* skin, most anesthesia agents result in peak blood levels similar to those resulting from infiltration in 6 to 10 minutes.

Lidocaine cream.

Lubens and coworkers have used 30% lidocaine cream, saturated on a gauze pad adherent to an elastic patch, for a myriad of procedures. Despite its effectiveness, safety, and painless application, the practicality of its use in an emergency setting is limited. Lubens reports an impressive list of uses, including minor operative procedures (e.g., excision of lesions, incision and drainage of abscesses), lumbar puncture, venipuncture, and allergy testing.[16]

EMLA cream, ELA-Max, and tetracaine base patch.

Various topical anesthetics have been suggested to decrease the pain of venipuncture or injections, and to provide topical anesthesia to painful skin abrasions and lesions. Most have little practical application in the ED, either because of inadequate efficacy or a delayed onset of action. These agents have been extensively studied and are safe, but they are not practical in many ED settings due to the slow onset of action. However, their activity profiles make them more applicable to emergency medicine than 30% lidocaine cream. Tetracaine base is available as a solution, gel, and as a patch preparation. It is effective in crossing the lipid-rich barrier of the stratum corneum because it is highly lipophilic. EMLA, which stands for *eutectic mixture of local anesthetics*, was approved in the United States in 1992. It contains 2.5% lidocaine and 2.5% prilocaine in a unique oil-and-water emulsion yielding 5% EMLA. The mild lipophilic and hydrophilic properties of the component drugs are greatly increased when mixed together, allowing absorption through intact skin. ELA-Max and ELA-Max5 are topical lidocaine anesthetic creams with more rapid onset of action that EMLA cream. ELA-Max is a 4% concentration while the 5% ELA-Max is marketed as an anorectal cream that may benefit painful rectal procedures. Neither product has prilocaine, found in EMLA cream, and neither has FDA approval for pain relief prior to painful injections or IV insertion, but both have such potential.[17]

Tetracaine base seems to offer the advantage of being able to obtain effective anesthesia with a shorter application time and a longer duration.[18] For both preparations, onset, depth of anesthesia, duration, and blood levels vary directly with application time, use on thinner or inflamed skin, or larger dose.[19] Both preparations exhibit a reservoir effect.[20] The drug is deposited in the stratum corneum and continues to diffuse along its concentration gradient, even after it is removed from the skin.

Tetracaine base and EMLA can be useful in the ED for providing anesthesia for many procedures: venous cannulation, venipuncture, or any needle insertion including preinfiltration anesthesia and lumbar puncture; a variety of minor surgical procedures; and anesthetizing the tympanic membrane and external auditory canal. EMLA has been used effectively for ulcer debridement.[21] It requires about 60 minutes post application for EMLA cream to provide optimal topical analgesia to the intact skin for such procedures as venipuncture. Therefore early cutaneous placement of these agents (e.g.,

over common IV sites while the patient is being triaged) is important for practical ED use.

Ethyl chloride and fluori-methane sprays.

These topical agents are often used for limited skin incisions (e.g., small abscess drainage). Many patients ask for these preparations, and there is likely a placebo effect associated with their use. These agents evaporate quickly from the skin, cooling it to the point of freezing. Anesthesia is effective and immediate, but drawbacks include its short duration (only up to 1 minute), potential pain on thawing, and possible lowered resistance to infection and delayed healing. Highly volatile ethyl chloride spray is flammable.

Technique

Lidocaine cream.

This 30% cream is saturated on a gauze pad adherent to an elastic patch and placed over the area to be injected or incised during the procedure. [16] The high concentration of anesthetic and an occlusive patch are needed to achieve effective skin penetration. The duration of action varies with the application time. A 45-minute application time is needed for most procedures. To achieve a topical anesthetic duration of 30 minutes, a 2-hour application is necessary.

Tetracaine base patch and EMLA cream.

Because both agents demonstrate a reservoir effect, the anesthesia may increase, or begin, many minutes after drug removal. A precise description of application times and duration is not possible. Tetracaine base requires a minimum of 20 to 30 minutes of application time to produce several hours of anesthesia. EMLA requires an application time of 1 to 2 hours for a reported duration of 30 minutes to several hours. Occlusive dressings seem to increase EMLA penetration whenever the cream is used. Patches are more convenient and cause no loss of effectiveness.

EMLA dosing is based on the amount of cream applied, not on the amount of anesthetic. Each gram of EMLA cream contains 25 mg of lidocaine and 25 mg of prilocaine. Dosages are given in *grams of cream*, not milligrams of anesthetic. In general, apply EMLA as a thick layer to intact skin under an occlusive dressing for about 1 hour before a procedure. A thick layer approximates 1 to 2 g applied per 10 cm^2. For minor procedures such as needle insertions, apply 2.5 g of EMLA over 20 to 25 cm^2 for at least 1 hour. For more painful procedures, apply about 2 g of cream per 10 cm^2 for at least 2 hours. The maximum application area (MAA) determines the appropriate total dose applied. Base the MAA on the patient's weight as follows: up to 10 kg, MAA = 100 cm^2; 10 to 20 kg, MAA = 600 cm^2; more than 20 kg, MAA = 2000 cm^2.

Ethyl chloride and fluori-methane sprays.

Invert the bottle 25 cm from the skin and spray a stream along the proposed incision until the area turns white and hard. Make the incision or local anesthetic injection immediately, *or during the actual spraying of the agent*, because the effect is fleeting. Some clinicians use these vapocoolant sprays to decrease the pain of an injection of a more traditional local anesthetic such as lidocaine.

Iontophoresis.

Anesthetic agents may be drawn without needles into the skin by electrical current applied through electrodes using a process called iontophoresis. Lidocaine with epinephrine administered with iontophoresis provides adequate anesthesia prior to venipuncture in pediatric patients and is superior than EMLA in providing cutaneous anesthesia. [22] [23] [24] Iontophoresis is not widely used in emergency medicine but may be another alternative to applied anesthetic agents.

Adverse Events

General adverse reactions to anesthetic agents are discussed in the Complications section later in this chapter.

Tetracaine base is quite safe with low blood concentration after proper use. In one study, approximately 25% of the patients developed cutaneous erythema at the site of application. [20] This vasodilatory effect may actually be an advantage when starting IV lines or performing venipuncture. EMLA is also quite safe. Although there is a high rate of local skin reactions, these are mild and transient, disappearing 1 to 2 hours after cream removal. Despite the reported successful use of EMLA cream on skin ulcers, Powell and colleagues described an increase in bacterial growth, infection, and inflammation when used in experimental wounds. [21] [25] Methemoglobinemia resulting from the metabolites of prilocaine may occur with EMLA. [19] The risk of clinically significant methemoglobinemia seems remote when EMLA is used properly. It is contraindicated in any infant younger than 3 months of age and in those infants between 3 and 12 months of age who are currently taking methemoglobinemia-inducing drugs (nitrites, sulfonamides, antimalarials, phenobarbital, and acetaminophen). The risk of adverse effects is increased in patients with anemia, respiratory or cardiovascular disease, and glucose-6-phosphate dehydrogenase (G6PD) or methemoglobin reductase deficiencies. Prolonged inhalation of ethyl chloride spray may produce general anesthesia, coma, or cardiorespiratory arrest. Ethyl chloride is also flammable, precluding its use with electrocautery.

Lacerations

In 1980, Pryor and colleagues reported their experience with a topical anesthetic solution (tetracaine-adrenaline-cocaine [TAC]) for wound repair. [26] The original formula, used in most subsequent studies, consists of a solution of 0.5% tetracaine, 1:2000 epinephrine (adrenaline), and 11.8% cocaine. Traditionally, anesthesia is produced by firmly applying a solution-saturated gauze pad or cotton ball directly to the laceration for 10 minutes. The resulting loss of cutaneous sensation is centered about the area of application. Gel formulations of TAC and alternative mixtures of agents promise to improve the ease and safety of topical anesthetic solutions for wound repair in the ED.

Indications and Contraindications

The use of TAC (and related topical wound anesthetics) is generally restricted to young children with wounds less than 5 cm in length in whom the delay for anesthetic application is acceptable and proper application can be assured. TAC is generally not used in structures without collateral blood supply (e.g., the digits, the tip of the nose, the pinna of the ear, the penis) because of the vasoconstrictor agents (epinephrine and cocaine) in TAC. When some wound preparation is desired before anesthesia, remove large debris and clotted blood to allow for the appropriate application of TAC and then finish wound preparation once the wound is properly anesthetized.

The advantages of TAC include painless application, no distortion of wound margins, good hemostasis, and good patient and parental acceptance in the pediatric age group. TAC appears to be less effective on the trunk and extremities than on the face and scalp and less effective than lidocaine infiltration in these areas. The 10- to 20-minute onset time

may be unacceptable in a busy ED. [27] The cocaine complicates its use because of cost and federal regulations that require storage in a locked cabinet and maintenance of separate written records of its use.

Two other often mentioned drawbacks may be more theoretical than real. Vasoconstrictor-induced higher infection rates (see Complications later in this chapter) have not been clearly demonstrated. The argument that the necessary 10-minute application period is time-consuming and takes valuable nursing time is partially offset by using the child's caretaker or adhesive paper tape alone to hold the solution in place. It is not necessary for anyone to "hold" the medicine in place when gel is used.

Agents and Effectiveness

Three clinical trials directly compared TAC with infiltrated lidocaine. Without specifying wound location, Pryor's group found equal anesthetic effect. [26] Complete

anesthesia produced by TAC ranged from 82% to 86%, compared with 83% to 92% for subcutaneous lidocaine. The remaining patients obtained partial anesthesia. Hegenbarth and Anderson demonstrated results similar to Pryor. [28] Hegenbarth found TAC to be equal to lidocaine only on the face and scalp, and inferior to it at other locations. Other investigators using different study designs found TAC effectiveness to be equal to or slightly less than seen in earlier studies. [29] [30] [31] More recent studies confirm excellent rates of effectiveness, especially on the face and scalp. [32] [33] TAC is more effective than its component drugs alone. On the face and scalp, TAC was found to be superior to tetracaine alone, although on nonfacial areas, both produced equally poor results. [29] TAC was found more effective than cocaine alone and more effective than a tetracaine-epinephrine solution in the same dosage ratio. [31] [34]

In 1990, Bonadio and Wagner showed that an epinephrine-cocaine solution (epinephrine 1:2000, cocaine 11.8%) was equal to TAC in effectiveness. [32] Bonadio and Wagner also found that half-strength TAC (tetracaine 0.25%, epinephrine 1:4000, cocaine 5.9%) achieved excellent results for dermal lacerations of the face, lip, and scalp.[30] Smith and Barry compared three strengths of TAC and found equal effectiveness among them, recommending the lowest strength cocaine formulation (tetracaine 1%, epinephrine 1:4000, cocaine 4%). [35] Ernst and colleagues found similar effectiveness to TAC using a slightly different lidocaine-epinephrine-tetracaine solution (lidocaine 4%, epinephrine 1:2000, tetracaine 1%). [36]

TAC has also been compared with EMLA placed in a wound for 60 minutes prior to wound repair. In a study of 32 wounds, supplemental anesthesia was required less often with EMLA.[37] The non-cocaine-containing formulations are generally considered less toxic and have advantages in terms of reduced cost and avoidance of controlled substance precautions during storage. Schilling found that a lidocaine-epinephrine-tetracaine (LET) solution (lidocaine 4%, epinephrine 1:1000, tetracaine 0.5%) was as effective as TAC.[38] LET gel preparations are at least as effective as LET solutions. [39] Singer and Stark determined that EMLA or LET gel placed in a wound on presentation and prior to infiltration with lidocaine reduced the pain of infiltration, allowing for essentially painless injection of lidocaine. [40]

Application and Dosage

Because the topical mixtures noted earlier (especially TAC) are not innocuous anesthetics, pay close attention to the technique of application and recommended maximum dose. There is no uniformly accepted application technique, component composition, or component concentrations.

Generally, apply topical solutions such as TAC to the wound in a gravity-dependent position, carefully filling the wound cavity. After 3 minutes, place a single 2-cm × 2-cm gauze pad or cotton ball saturated with TAC to the wound. Tape or hold the pad firmly for 15 to 20 minutes. The person holding the gauze should wear latex examination gloves to minimize the risk of cutaneous absorption of the solution. The average dose of TAC solution is 2 mL.

Hegenbarth and colleagues estimated the maximum safe dose of full-strength TAC to be 0.09 mL/kg based on the known maximal safe dose of infiltrative tetracaine and mucosal application of cocaine and an estimate of solution absorption onto the applicator. [28] The key to safety is to avoid TAC on mucosal surfaces or in areas in which sniffing or swallowing may accidentally occur. Prilophen has been compared with infiltrated lidocaine for the repair of intraoral lacerations. Although the lidocaine was slightly better, little difference was demonstrated in clinical anesthesia and pain. [41] Prilophen (prilocaine-phenylephrine) may be an acceptable alternative to TAC when lacerations are repaired in close proximity to mucous membranes. Topical mucosal anesthesia is discussed elsewhere in this chapter.

One can prepare an epinephrine-cocaine gel by adding 0.15 g of methylcellulose to 1.5 mL of epinephrine-cocaine solution. Stir the mixture thoroughly for a minute or two until a gel consistency is obtained. After sterile preparation, place the wound in a gravity-dependent position apply the gel by a cotton-tipped swab to coat the entire wound cavity and margins. Allow the wound to stand for 15 to 20 minutes and thoroughly wash the wound cavity to remove the gel. In Bonadio and Wagner's study, the average dose used was 0.35 mL of gel containing only 40 mg of cocaine. [33]

Adverse Events

Mucosal application may rarely lead to significant systemic toxicity; fatalities have been reported following application. Even after nonmucosal TAC use, cocaine levels appear in the blood (tetracaine does not) and cocaine metabolites appear in the urine in the majority of patients. [42] [43] Gel formulations of TAC tend to stay in the wound and reduce the risk of solution runoff onto mucosal surfaces. There is no need to use a gauze pad to apply the medication in gel formulation or to hold it in place. Since the entire applied dose will stay in the wound, a lower dose can be used. Gel also provides a more uniform application to tissues, improving anesthetic effect. Ischemia caused by vasoconstrictors in tissues containing end arteries may occur. Avoid TAC on the digits, the tip of the nose, the penis, and the pinna. Use TAC with caution on patients with coronary artery disease, uncontrolled hypertension, seizures, and peripheral vascular disease. Patients with decreased plasma cholinesterase levels are at increased theoretical risk for systemic toxic effects, but this potential risk is of little clinical concern.

INFILTRATION ANESTHESIA

The injection of an anesthetic agent directly into tissue prior to surgical manipulation is known as infiltration anesthesia. Field block anesthesia is also considered a form of infiltration

TABLE 30-6 -- Maximum Allowable Volume (Adults)

Agent	Concentration (%)	Maximum* Safe Dose (mg)	Maximum Volume (mL)
Lidocaine	0.5	300	60
	1	300	30
Bupivacaine†	0.25	175	70
Lidocaine-epinephrine	0.5	500	100
	1	500	50
Bupivacaine-epinephrine	0.25	225	90

*These are conservative figures; see text for explanation.
†Some physicians recommend 400 mg as the maximum safe dose for bupivacaine.

anesthesia, particularly because the agents, concentrations, and recommended maximum dosages are the same. A field block is created when a field of anesthesia is injected around the operative site. The injection is made proximal to or surrounding the area to be manipulated.

Indications and Contraindications

Infiltration anesthesia is indicated when good operative conditions can be obtained by using this technique. It may be used for the majority of minor surgical procedures such as excision of skin lesions, incision of abscesses, and suturing of wounds. Infiltration anesthesia is considered quicker and safer than nerve block and general anesthesia. Local infiltration can provide hemostasis, both by direct distention of tissue and by the concurrent use of epinephrine.

The major disadvantage of local infiltration compared with nerve blocks is that a relatively large dose of drug is needed to anesthetize a relatively small area. For extensive wounds, the amount of anesthetic required may risk systemic toxicity. The maximum allowable volume can be increased by adding epinephrine, by using a lower concentration of anesthetic agent, or by doing both (Table 30-6). When large volumes are anticipated and a nerve block is anatomically feasible, the nerve block is preferred. Infiltration is avoided for large procedures in small children and in apprehensive patients, especially those with prior adverse reactions (whether vasovagal or otherwise). Local infiltration distorts the tissues that will be incised or repaired, making it undesirable in areas requiring precise anatomic alignment (e.g., some lip repairs).

TABLE 30-7 -- Practical Agents for Emergency Department Use—Local Infiltration

		Maximum Dose*,†			
Agent	***Concentration (%)***	***Adult (mg)***	***Pediatric (mg/kg)***	***Onset (min)***	***Duration‡***
Procaine	0.5–1.0	500§ (600)	7 (9)	2–5	15–45 min
Lidocaine	0.5–1.0	300 (500)	4.5 (7)?	2–5	1–2 hr
Bupivacaine	0.25	175 (225)	2 (3)¶	2–5	4–8 hr

*These are conservative figures; see text for explanation.
†Higher maximum dose for solutions containing epinephrine is in parentheses.
‡These values are for the agent alone; they can be extended considerably with the addition of epinephrine.
§Some authorities recommend up to 1000 mg or 14 mg/kg for procaine.
?Some authorities recommend up to 7 mg/kg for plain lidocaine in children older than 1 year.
¶Because of lack of clinical trial experience, drug companies do not recommend the use of bupivacaine in children under age 12, but bupivicaine is commonly used in children without problems.

Choice of Agent

Local anesthetic agents most frequently used for infiltration are 0.5% to 1% lidocaine, 0.5 to 1% procaine, and 0.25% bupivacaine (Table 30-7). Higher concentrations are of *no* additional benefit. Lidocaine is most commonly used because of its excellent activity profile, low allergenicity and toxicity, user familiarity, and ready availability. Procaine is useful for patients who are allergic to amide anesthetics. Some clinicians prefer bupivacaine because of its prolonged duration. Bupivacaine may be preferred when postoperative analgesia is desired, for prolonged procedures, or even for short procedures that may be interrupted in a busy ED.

A comparison of equianesthetic doses of lidocaine and bupivacaine for infiltration anesthesia (Table 30-8) reveals the duration of action to be the major difference between the two agents. For the majority of ED procedures, it is not necessary to extend the duration of anesthesia beyond 1 hour. Plain lidocaine would seem to be a logical anesthesia choice. Patients experience a moderate amount of pain after laceration repair when the lidocaine wears off in about 1 hour. [44] Bupivacaine reduces the pain following laceration repair for at least 6 hours. This benefit of a prolonged duration of anesthesia must be weighed against the hazards of injury to an unprotected limb or the annoyance of prolonged numbness to patients who have had simple surgical procedures.

A prolonged duration of anesthesia can be achieved by adding epinephrine, sodium bicarbonate, or both to lidocaine. Epinephrine provides excellent wound hemostasis and slows systemic absorption. This latter property decreases the peak blood level, decreasing the potential for a toxic reaction and allows a greater volume of agent to be used for extensive lacerations. The major disadvantage of epinephrine is the theoretical, but generally clinically inconsequential, damage to host defenses (Table 30-9). Added bicarbonate decreases the pain of administration, but such an addition is usually made at the bedside. Bupivacaine, if used with due caution, is safe and easy to use. The deciding factors are many, but some logical choices are as follows:

- For a wound with excessive bleeding: lidocaine with epinephrine and sodium bicarbonate
- For an apprehensive patient: lidocaine with sodium bicarbonate
- For anticipated prolonged postprocedure pain: bupivacaine

TABLE 30-8 -- Comparison of 1% Lidocaine (L) and 0.25% Bupivacaine (B)—Infiltration Anesthesia

	Lidocaine	Bupivacaine	Advantage
Onset	2–5 min	2–5 min	Equal
Effectiveness (equianesthetic dose)	Excellent	Excellent	Equal
Duration	1–2 hr	4–6 hr	B
Infection potential	No	No	Equal
Administration pain	Less	More	L
Maximum volume* —plain lidocaine	Less	More	B
Maximum volume—epinephrine	Less	More	B
Toxic potential	Less cardiotoxic; equal CNS	More cardiotoxic; equal CNS	L

CNS, central nervous system.

*See Table 30-6 for volume and concentration comparison.

Equipment

The pain of injection is reduced by use of small-gauge needles. Ideally, a 30-gauge needle is used if injection is made through the skin. If the injection is made through the cut edges of the wound, a 25- to 27-gauge needle suffices. A small-gauge needle slows the rate of injection and reduces the rate of tissue distention. A 10-mL syringe is recommended both for its ease of handling and for the relatively slow rate of injection it allows.

Technique

Once an agent has been chosen, proper administration technique minimizes pain, prevents bacterial spread, and avoids intravascular injection. Buffering, warming, and careful infiltration reduce the pain of injection.

Buffering

Lowering the pH of an anesthetic by adding epinephrine increases pain, whereas raising the pH by adding sodium bicarbonate decreases pain dramatically. It is probable that pH is not the sole factor in producing pain, since the pain produced by various agents does not correlate strictly with the pH. Sodium bicarbonate probably works by increasing the ratio of nonionized to ionized molecules, which either renders the pain receptors less sensitive or causes a more rapid diffusion of solution into the nerve and a shorter time to anesthetic onset.

To alkalinize lidocaine, add 1 mL of sodium bicarbonate (8.4%, 1 mmol/mL) to every 10 mL of anesthetic solution. As the pH of the solution is raised, the anesthetic becomes unstable and has a decreased shelf life. It was initially recommended that buffered lidocaine be prepared just prior to use to

TABLE 30-9 -- Epinephrine Use

Advantages	Disadvantages
1. Prolongs duration	1. Impairs host defenses—increases infection*
2. Provides hemostasis	2. Delays wound healing*
3. Slows absorption:	3. Do not use for:
Decreases agent toxic potential	Areas supplied by end arteries
Allows increased dose	Patients "sensitive" to catecholamines
4. Increases level of blockade	4. Toxicity—catecholamine reaction†

*Based on laboratory studies and of unknown clinical importance.
†For example, in patients taking MAO inhibitors.

avoid precipitation and degradation, but buffered lidocaine retains its effectiveness for 1 week and refrigeration may further increase its shelf life. [45] [46] Bicarbonate may be combined with plain lidocaine for both infiltrative anesthesia [47] [48] and digital nerve blocks.[49] In one volunteer study, sodium bicarbonate was effectively combined with lidocaine and epinephrine. [46]

Sodium bicarbonate can be added to bupivacaine, but the solution tends to precipitate as the pH rises. Precipitation varies directly with the concentration of bupivacaine and the time since mixture.[50] Cheney showed that 0.05 mL of 8.4% sodium bicarbonate (measured in a tuberculin syringe) could be mixed with 10 mL of 0.5% bupivacaine without precipitation.[51] Since the goal of using bupivacaine is to prolong the duration of anesthesia, and this effect can also be accomplished somewhat by using buffered lidocaine (plain or with epinephrine), it seems impractical to risk precipitation by "buffering" bupivacaine.

Warming

Warming an anesthetic to body temperature (37°C to 42°C) reduces the pain of infiltration. [52] [53] Bartfield found that lidocaine warmed to 38.9°C was more painful than room temperature buffered lidocaine during intradermal injection.[54] Brogan, using lidocaine warmed to 37°C, found the warmed lidocaine and room temperature buffered lidocaine to be equivalent during wound infiltration. [55] Neither study found a synergistic effect with combined warming and buffering. Martin found warmed (37°C) lidocaine to be no less painful than buffered lidocaine. [56] Anesthetic solutions can be warmed in a baby food warmer with thermostatic temperature control or in an IV solution warmer. Warming is not believed to adversely affect shelf life of the local anesthetic.

Injection

Place the injection in the subdermal tissues to minimize needle puncture pain and the tissue distention that occurs with intradermal placement. Placing the needle "up to the hub" and injecting while withdrawing along the just-created subdermal tunnel also minimizes tissue distention. After an initial injection, instead of totally withdrawing the needle from the tissue, redirect it along another path to lessen the number of punctures. Slowly injecting the smallest volume necessary reduces pain.

Because the patient barely feels a needle placed subcutaneously and skin puncture is often quite painful, *make all wound injections through the wound edge and not through the skin* (Fig. 30-6).[57] Infection spread beyond the wound margin has not been demonstrated clinically with this technique. Some clinicians may choose to

inject the anesthetic through intact skin in a grossly contaminated wound. Bierman described a technique of patient distraction by applying light pressure to alternate sides of the wound with one's fingers and repeated ambiguous questioning about feeling the light pressure rather than the ongoing wound injection. [58] School-age children can be asked to count backward or say the "ABCs" to distract them during injection.

Preventing a systemic toxic reaction is best accomplished by avoiding an intravascular injection. However, for infiltration anesthesia with small-gauge needles, aspiration is usually unnecessary unless the injection is deeper than the subcutaneous (SQ) area or the area to be injected contains many large vessels.

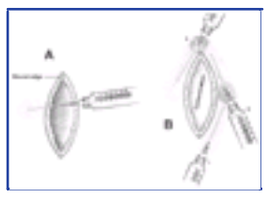

Figure 30-6 *A,* Except in the setting of gross contamination, wounds should be anesthetized by inserting the needle through the cut edges, not through the intact skin. Patients often will not feel a 25-gauge or smaller needle passed into the subcutaneous tissue when it is advanced slowly through the cut edge. However, pain generally occurs with tissue distention by the anesthetic, and hence, injection should be slow and deliberate. *B,* If a wound is grossly contaminated, the anesthetic may be introduced through the intact skin. The operator should limit the number of needle sticks. The needle is first introduced at a point in line with the wound and beyond the wound edge (*1*), and while the anesthetic is slowly injected, the needle is advanced to include 1 entire side of the wound (if possible) to a point well past the opposite end of the wound. The other side may be anesthetized by passing the needle through the area already infiltrated by the first injection (*3*), making the skin puncture painless. A 3.8-cm (1.5-in.) 27-gauge needle is a good choice. If the needle is not long enough to encompass the entire wound, the skin is painlessly punctured at a midway point that has already been anesthetized (*2*).

SPECIAL CONSIDERATIONS

Hematoma Block

Hematoma block has been used for many years to provide anesthesia for reduction of fractures, particularly of the distal forearm and hand. Its popularity has waned somewhat because of the fear of introducing infection at the fracture site and its limited efficacy. Although several studies show the hematoma block to be safe, the anesthesia it provides is not as good as that provided by the Bier block (see Chapter 33). Nevertheless, there are several reasons to consider this technique. [59] [60] The procedure is simple and quick to perform and does not require additional personnel. There is no need to wait for an anesthesiologist or for the patient to digest a meal. A lower dose of anesthetic agent is required compared with that required for the Bier block (see Chapter 33). A hematoma block is useful when the Bier block and general anesthesia are contraindicated.

Prepare the skin over the fracture site with Betadine and insert the needle into the hematoma (confirmed by aspirating blood). Slowly inject from 5 to 15 mL of plain 1% lidocaine or 5 to 10 mL of plain 2% lidocaine (larger fractures require larger volumes of local anesthetic) into the fracture cavity and around the adjacent periosteum. Adequate anesthesia occurs in about 5 minutes and may last for several hours. Do not perform this procedure through dirty skin, in open fractures, or in small children.

Intra-articular Anesthesia

The history and physical examination of an acutely traumatized joint, such as the knee often underestimates the severity of an injury. Instillation of 5 mL of 1% lidocaine after joint aspiration may help relieve pain and facilitate an examination, but its use is not routinely recommended. [61] Spasm and apprehension are often not relieved by local anesthesia, and the information gained usually does not influence the ED treatment plan. Intra-articular anesthesia of the knee has no effect on gait pattern or joint proprioception. [62] Post-procedure weight bearing may be allowed without fear of producing or increasing injury if otherwise indicated. Intra-articular anesthesia may enhance elbow use following aspiration of a hemarthrosis associated with a radial head fracture. [63] The technique of administration is analogous to arthrocentesis (see Chapter 54).

Intrapleural Anesthesia

Indications

Intrapleural anesthesia introduces local anesthetic into the pleural space (i.e., between the parietal and visceral pleura) through an epidural catheter. The anesthetic can be introduced through a previously placed chest tube. The technique can provide relief for several conditions, primarily post-thoracotomy pain; post-cholecystectomy pain; and, most importantly for emergency clinicians, posttraumatic chest pain (i.e., rib fractures, pneumothorax, hemothorax). This procedure is useful not only for pain relief, but also facilitates turning, coughing, and deep breathing. Although not unanimous, most studies show that intrapleural anesthesia is effective in providing analgesia. [64] [65] Concern has been raised that intrapleural anesthesia may create a level of anesthesia below the umbilicus and make posttraumatic abdominal examinations unreliable. Until this issue is clarified, it seems prudent to rule out intra-abdominal injury before intrapleural anesthesia is used. [66]

Technique

If a chest tube is in place, it is preferable to inject anesthesia into the pleural space through the chest tube. Theoretically, the tube should be clamped for 10 to 15 minutes to allow the anesthetic to diffuse. When the tube cannot be taken off suction, or if no tube is present, the local anesthetic is injected percutaneously. [67] With the patient in the lateral position (with the affected side up), place a 16-gauge Tuohy needle 8 to 10 cm from the posterior midline in the 8th intercostal space. The needle is angled at 30° to 40° to the skin, aimed medially, bevel up, and directed just above the rib. After perforating the posterior intercostal membrane (felt as a distinct resistance), remove the stylet and attach a well-wetted, air-filled glass syringe to the Tuohy needle. Advance the needle until it enters the pleural space, denoted by the plunger being drawn down the syringe due to the negative pressure created during inspiration. Remove the syringe and introduce an epidural catheter 5 to 6 cm into the pleural space. Remove the Tuohy needle, obtain a chest radiograph to confirm proper position, and secure the catheter.

The most commonly used anesthetic and dose is 20 mL of 0.5% bupivacaine. A repeat dose every 8 hours has been shown safe. [68] The solution presumably diffuses from the pleural space "back" through the parietal pleura and the intercostal muscle to reach the intercostal spaces, where it blocks the intercostal nerves. The level of anesthesia can extend from T2 to T12 and involve skin, chest, abdominal wall, and potentially the viscera if the visceral afferent fibers are blocked at the sympathetic chain in the paravertebral gutter.

Although not yet a consistently proven or a completely standardized technique, intrapleural anesthesia offers promise for patients and is a potentially valuable procedure for the emergency clinician.

COMPLICATIONS

Local Anesthetic Effect on Wounds

Wound Healing

Local anesthetics produce cytotoxic effects on cell structure and function in a dose- and time-related manner. These effects, at doses well below those used clinically, involve fibroblasts more than nervous tissue. Collagen synthesis is inhibited by lidocaine and bupivacaine. [69] Morris and Tracey found that lidocaine in increasing concentrations progressively reduced the tensile strength of wounds. [70] Epinephrine added to 1% and 2% concentrations of lidocaine further reduced tensile strength, but when epinephrine was added to distilled water or to 0.5% lidocaine, it had little effect. Several conclusions may be clinically relevant. Although it may delay anesthetic onset, lidocaine 0.5% solution, without epinephrine if possible, may be best for wound strength.

Eriksson and colleagues found that lidocaine reduces the inflammatory response in wounds by decreasing the number of white cells and their metabolic activity. [71] While an inflammatory response may be beneficial in a contaminated wound, it can be detrimental in a sterile wound because of the tissue toxicity that is created by the release of superoxide anions, lysosomal enzymes, thromboxanes, leukotrienes, and inter-leukins. The clinical relevance of this is unknown. None of the concerns mentioned earlier should prohibit the use of standard anesthetics or epinephrine when their use is otherwise indicated.

Wound Infection

Although not generally appreciated, it has long been known that local anesthetics possess antimicrobial activity in vitro. Lidocaine and procaine at 2% concentrations inhibit the culture growth of most gram-negative organisms, with only *Pseudomonas aeruginosa* being particularly resistant. [72] [73] Gram-positive isolates are also significantly affected by lidocaine and, to a lesser extent, by procaine. Administering anesthetics before obtaining culture material, including injecting a joint prior to arthrocentesis, may give false-negative culture results and is avoided if possible. This effect may also be significant when anesthetic ointments have been applied prior to culture. Furthermore, it has been shown that adding sodium bicarbonate to lidocaine greatly enhances its inhibitory effect on bacteria. [74] Although local anesthetics can interfere with culture testing, several studies show that, by themselves, local anesthetics do not appear to alter the incidence of wound infection. [75] [76]

Epinephrine appears to exert a deleterious effect on host defenses, at least in animal models. Studies with infiltrated and topically applied epinephrine solutions in contaminated animal wounds show an increased potential for infection. [75] [76]

Epinephrine-induced vasoconstriction may contribute to tissue hypoxia, retarding the killing of *Staphylococcus aureus* by leukocytes, and reducing leukocyte migration into the tissue. [77] Most clinical studies using topical anesthesia with vasoconstrictor properties (e.g., tetracaine, epinephrine, and cocaine mixtures) do not demonstrate significantly increased infection rates. [26] [28] [34] [78] The concerns mentioned earlier should not prohibit the use of epinephrine for wound preparation when its use is otherwise appropriate.

Local Injuries

Injuries may result from direct application of an anesthetic agent to a nerve or from passage of a needle through soft tissue structures. Factors implicated in transient or persistent neuropathy include acidic solutions, additives, the agent itself, needle trauma, compression from hematomas, and inadvertent injection of neurolytic agents. Born described a series of 49 wrist and metacarpal blocks using bupivacaine in which 8 patients developed a significant neuropathy. [79] He postulated that damage occurred from the trapping of the drug in a confined space and recommended that whenever bupivacaine is used in this situation, it be used in low concentration and volume. Infection, hematomas, and broken needles are other local problems that can be averted by using proper technique. Erroneous needle placement also can produce complications such as pneumothorax during brachial plexus or intercostal block.

It is commonly stated that epinephrine-containing solutions injected into tissues containing end arteries can cause profound ischemia and gangrene. Given the short duration of epinephrine combined with the vasodilation that accompanies many local anesthetics (e.g., lidocaine), this cause and effect is difficult to accept and hard to substantiate. Despite admonition in most textbooks, the concept remains largely theoretical. Areas of special concern include the digits, penis, tip of the nose, or earlobe. This concern is promulgated but is certainly overrated when dilute concentrations of epinephrine-containing solutions are used (1:200,000). Some authors state that small quantities of such solutions are usually tolerated on the nose and pinna but advise against their use in the fingertips. [80] Because bupivacaine can be used when prolonged anesthesia is required, and because tourniquets can be used in the digits, there is little need for vasoconstrictors in the digits, although some clinicians use a dilute epinephrine solution there, as well. The dogmatic admonition against the use of epinephrine containing anesthetics in the digits is not supported by scientific data in the context of ED laceration repair. Denkler performed an extensive review of the literature back to 1880 and identified only 48 cases of digital gangrene after digital block. Only 21 cases involved the use of epinephrine, clearly raising the question of causation. Other variables including hot soaks, tourniquets, and infection made it impossible to clearly link gangrene to the epinephrine alone. [81] Other authors have demonstrated the safe use of epinephrine containing anesthetics in digital blocks, suggesting the risk of tourniquets could be minimized if epinephrine was used instead. [82] [83] Despite a lack of evidence against its use, most clinicians tend to avoid the use of epinephrine containing anesthetics when performing digital anesthesia.

The use of phentolamine (Regitine), which produces postsynaptic a-adrenergic blockade, is recommended for vasoconstrictor-induced tissue ischemia. This medication is usually given by local infiltration in a dose of 0.5 to 5.0 mg diluted 1:1 with saline. If local infiltration is ineffective or limited by tension within a tissue compartment, or if the area of vasoconstriction is large, phentolamine may be given by the intra-arterial route. [84]

Systemic Toxic Reactions

Although they occur in only 0.1% to 0.4% of local anesthetic administrations, systemic toxic reactions are the most frequent serious adverse reactions encountered (Table 30-10). [85] After administration of a local anesthetic, some of the drug reaches its intended target, and some is absorbed quickly into the systemic circulation. Peak blood levels are generally produced within 30 minutes. Many vagal reactions, nonspecific anxiety reactions, and sensitivity to preservatives have been attributed to "allergies" or systemic toxicity to local anesthetics. Patients may also demonstrate systemic reactions to hidden allergens that may mimic a systemic reaction, such as anaphylactic reactions to the latex in surgical gloves.

High Blood Levels

Systemic toxic reactions result from high blood levels of local anesthetic. Several factors are important in producing high blood levels, including site and mode of administration, rate, dose and concentration, addition of epinephrine, specific drug, clearance, maximum safe dosage, and inadvertent intravascular injection.

Site and mode of administration.

Comparing the routes of administration for a given dose, the intravascular route produces the highest levels, followed by topical mucosal application, then infiltration (see Fig. 30-5 (Figure Not Available)). The more vascular the site, the more systemic absorption that occurs and the higher the level obtained. The following blocks are arranged in decreasing order of systemic absorption: intercostal, caudal, epidural, brachial plexus, and subcutaneous. It follows that the site of administration is an important variable in determining the safe dose of an anesthetic. For example, lidocaine 400 mg may produce a nontoxic blood level with abdominal wall subcutaneous infiltration, but when used for an intercostal nerve block, a toxic level would likely result from this dose.

Rate.

A more rapid IV injection will produce a higher blood level than a slower injection. A single topical application leads to a higher level than a dose that is fractionated over time.

Dose and concentration.

The larger the total dose, the higher the peak blood level. It is uncertain whether increasing the concentration while maintaining the total dose by decreasing the volume affects the serum level.

Addition of epinephrine.

Epinephrine produces vasoconstriction and reduces systemic absorption, thereby resulting in lower peak blood levels. Occasionally, the apprehension, tachycardia, or palpitations induced by epinephrine can be incorrectly interpreted by both clinician and patient as an "allergic" reaction.

Specific drug.

The more potent agents are more toxic on a milligram-to-milligram basis. Because anesthetics are used in equipotent doses (e.g., 1 mg bupivacaine versus 4 mg lidocaine), they are approximately equitoxic. Blood levels achieved by a particular agent depend on the agent's absorption, distribution, and clearance from the circulation. Agents with high lipid solubility and lower protein binding

TABLE 30-10 -- Differentiating Systemic Adverse Reactions

Findings	Toxic Reactions	Allergy	Vasovagal	Excess Catecholamines, Anxiety[1] (Endogenous), Vasoconstrictor (Exogenous)
Relatively specific signs and symptoms	Metallic taste	Acute rhinitis	Syncope*[2]	Headache
	Tongue numbness	Pruritus*		Hypertension*
	Drowsiness	Dermatitis		Palpitations
	Nystagmus	Urticaria*		Apprehension*[3]
	Slurred speech	Facial swelling		
	Seizures*	Laryngospasm		
	Coma	Bronchospasm*		
	Respiratory arrest*			
Overlapping signs and symptoms	Paresthesia	Lightheadedness	Lightheadedness	Paresthesia*
	Lightheadedness	Tachycardia*	Tinnitus	Lightheadedness*
	Tinnitus	Hypotension*	Tachypnea	Tremor
	Tremor	Cardiac arrest	Tachycardia (early)	Tachypnea*
	Tachypnea	Nausea and vomiting		Tachycardia*
	Tachycardia (early)		Bradycardia*	Nausea and vomiting
	Bradycardia*	Dyspnea	Hypotension*	Dyspnea
	Hypotension*		Diaphoresis	Diaphoresis
	Cardiac arrest			

1. Anxiety reaction, including hyperventilation syndrome.
*Denotes common and significant reactions:
2. Vasovagal syncope occurs with patient upright; any loss of consciousness in the recumbent position implies a severe toxic or anaphylactic reaction.
3. Although apprehension is classically associated with anxiety and vasoconstrictor reactions, milder toxic and allergic reactions may cause patient apprehension.

(etidocaine > bupivacaine > lidocaine > mepivacaine) tend to become sequestered in tissue and have a slower absorption and lower blood levels. Agents with a greater volume of distribution or a faster clearance (etidocaine > lidocaine > mepivacaine > bupivacaine) also produce lower blood levels. Together these effects produce margins of safety for each anesthetic, with etidocaine having the greatest safety margin, followed by bupivacaine, which is equal to or better than lidocaine.

Esters are difficult to measure in the blood because of their rapid hydrolysis by pseudocholinesterase. As a group, toxicity is inversely proportional to the rate of hydrolysis. Tetracaine is slowly hydrolyzed and is most toxic. Chloroprocaine is quickly hydrolyzed and is least toxic. Procaine falls between the two.

Clearance.

The liver metabolizes amides where the clearance rate is a function of hepatic blood flow and extraction capacity of the liver. Decreased hepatic blood flow, produced by norepinephrine, propranolol, or general anesthesia, slows clearance and potentially raises drug blood levels. Decreased drug extraction, associated with congestive heart failure, cirrhosis, or hypothermia, may produce a higher blood level. Hypovolemia, which decreases hepatic flow, does not raise blood levels because it causes an offsetting decrease in absorption.

Decreased clearance of esters and an increased risk for toxicity occurs in patients with either low levels of pseudocholinesterase or an atypical form of pseudocholinesterase. Low levels occur in various disease states, including severe liver disease and renal failure, and in pregnancy. Atypical pseudocholinesterase is an inherited trait, and its presence reduces the hydrolysis rate of procaine to a greater extent than low levels do.

There are significant differences between pediatric and adult drug distribution and metabolism. Neonates exhibit both reduced levels of pseudocholinesterase and reduced hepatic metabolism, increasing the risk of toxicity. In older children, the effects of increased hepatic metabolism and a relatively larger volume of distribution increase their tolerance for higher doses.

Maximum safe dosage.

The *maximum safe dose* for a drug may be defined as the dose that produces a blood level of the drug just below the toxic level (Table 30-11). One maximum dose for an anesthetic agent appropriate for all patients and all conditions cannot be stated. A maximum safe dose cannot be based solely on the weight of a patient. In an adult, peak blood levels do not correlate well with weight, because the volume of the drug distribution is relatively constant. [86] [87] As an approximation, Arthur and McNicol have recommended maximum dosages for children based on weight.[88] Plain lidocaine may be used in doses of up to 4.5 mg/kg and the addition of epinephrine allows for a maximum dose of 7 mg/kg. Bupivacaine is not recommended for children under the age of 12 years; although it is commonly used without adverse consequences. Furthermore, the dose should be modified according to the site and mode of administration.

Maximum safe doses as stated in package inserts should be used only as guidelines because most of them are derived from animal experiments and are based on absorption data only. Levels vary with administration site, use of a vasoconstrictor, and to some extent, the health of the patient. Levels can often be exceeded safely when the drug is accurately administered. Drugs may be toxic even within the "safe range" when inadvertently injected intravenously.

Inadvertent intravascular injection.

Most toxic reactions are caused by inadvertent intravenous (IV) injections of anesthetics whose doses were calculated for their intended extravascular sites. For example, lidocaine 300 mg is a safe infiltrated dose that would likely cause toxicity if directly injected into the bloodstream.

Anesthetics that are injected intravascularly must pass through the lungs before they reach other organs. Lung tissue sequesters a significant amount of drug, lowering the arterial blood concentration. Anesthetics that bypass the lungs, in cases of inadvertent injection into the carotid or vertebral arteries or in patients with intracardiac right-to-left shunts, can produce central nervous system toxicity at low doses.

TABLE 30-11 -- Calculation of Anesthetic Doses

Anesthetic solutions are marketed with drug concentration expressed as percentages (e.g., bupivacaine 0.25%, lidocaine 1%). To ascertain the strength of a solution in milligrams per milliliter, consider the following:	
A 1% solution is prepared by dissolving 1 g of drug in 100 mL of solution.	
Therefore, 1 g/100 mL = 1000 mg/100 mL = 10 mg/mL.	
To calculate the strength from the percentage quickly, simply move the decimal point 1 place to the right. Examples:	
0.25% = 2.5 mg/mL	(e.g., bupivacaine)
0.5% = 5 mg/mL	(e.g., tetracaine)
1% = 10 mg/mL	(e.g., lidocaine)
2% = 20 mg/mL	(e.g., viscous lidocaine)
4% = 40 mg/mL	(e.g., cocaine)
5% = 50 mg/mL	(e.g., lidocaine ointment)
20% = 200 mg/mL	(e.g., benzocaine)
When combined in an anesthetic solution, epinephrine is usually in a 1:100,000 or 1:200,000 dilution.	
1 mL of 1:1000 epinephrine = 1 mg.	
0.1 mL of 1:1000 epinephrine in 10 mL anesthetic solution = 1:100,000 dilution = 0.010 mg/mL.	
0.1 mL of 1:1000 epinephrine in 20 mL anesthetic solution = 1:200,000 dilution = 0.005 mg/mL.	
Some examples detailing *epinephrine* content:	
	1:100,000 / **1:200,000**
5 mL	0.050 mg / 0.025 mg
10 mL	0.100 mg / 0.050 mg
20 mL	0.200 mg / 0.100 mg
Therefore, 50 mL of 1% lidocaine with epinephrine 1:200,000 contains 500 mg lidocaine and 0.25 mg epinephrine.	

Intra-arterial injections in subcutaneous end-arteries about the head or neck are capable of retrograde flow into the cerebral circulation, if the injection pressure exceeds the arterial pressure. Because the blood volume in the brain is only about 30 mL at any given moment, even 1 mg of lidocaine injected into the carotid artery can theoretically produce toxic concentrations. Patients with low cardiac output or hypovolemia and preferential cerebral blood flow may suffer enhanced central nervous system toxicity.

Host Factors

Four factors tend to lower the body's systemic tolerance to local anesthetic agents: hypoxia, acid-base status, protein binding, and concomitant drug use.

Hypoxia.

It was initially thought that local anesthetic overdose produced central nervous system stimulation and subsequent intracellular hypoxia, which then became the key precipitant to all toxic manifestations of the drug. It is now known that hypoxia may enhance anesthetic toxicity, but it is not the primary factor.

Acid-base status.

Although studies of metabolic alkalosis have produced conflicting results, acidosis, particularly respiratory acidosis, can increase toxicity. The elevated CO_2 produced by respiratory acidosis crosses the blood-brain barrier, where it may act directly on the receptor and indirectly by lowering intracellular pH. The lower pH causes more drug to ionize, furthering the block in the sodium channel and increasing the potential for toxicity.

Protein binding.

Unbound drug concentration relates more closely to toxic effects than does total drug concentration (bound plus unbound) as measured in the blood. The amount of a-acid glycoprotein (AAG), the major plasma protein responsible for binding local anesthetics, is considerably decreased in neonates compared with adults. Arthur and McNicol imply that low AAG levels in neonates are responsible for an increased toxic potential. [88] Tucker lists several disease states that alter AAG levels and protein binding but questions whether they lead to changes in free drug concentration in vivo. [89]

Concomitant drugs.

For years, barbiturates were used to prevent and treat local anesthesia-induced seizures. Barbiturates were found to worsen anesthetic-induced apnea and cardiovascular depression. Central nervous system depressants are used with caution when concern exists for local anesthetic toxicity. Central nervous system stimulants have been shown to increase anesthetic-induced excitability and are avoided. Mixtures of local anesthetics have an additive effect on toxicity. If two drugs are used at half strength, they produce the same degree of toxicity as if each were used alone at normal strength.

Recognition of Central Nervous System Toxicity

The earliest manifestation of systemic toxicity is central nervous system stimulation resulting from blockade of inhibitory synapses. Central nervous system depression follows and is produced by direct depression of the medulla, although hypoxia may play a role. Signs and symptoms are dose-related. Potential signs and symptoms of central nervous system toxicity, in progressing order, are numbness of the tongue, light-headedness, tinnitus, visual disturbances, muscle twitching, convulsions, coma, and apnea. Drowsiness, commonly seen at lower doses with lidocaine, is not associated with bupivacaine or etidocaine. Tetracaine may produce apnea or cardiovascular toxicity without central nervous system manifestations.

Recognition of Cardiovascular Toxicity

Moderate blood concentrations of local anesthetics produce slight increases in cardiac output, heart rate, and arterial pressure because of the effects of direct peripheral vasodilation and central nervous system stimulation. At concentrations generally well above central nervous system toxicity levels, local anesthetics cause direct myocardial depression, hypotension, and bradycardia, perhaps leading to cardiovascular collapse. These agents also slow electrical conduction leading to reentry phenomenon and various supraventricular and potentially lethal ventricular dysrhythmias, especially with bupivacaine and etidocaine.

Prevention of Toxicity

Knowledge of factors contributing to toxicity guides preventive measures. Avoid esters in patients with an atypical form or a quantitative deficiency of pseudocholinesterase. Use amides with caution for patients with severe liver disease or congestive heart failure. Pay attention to maximum safe dosages, based on site, technique, epinephrine use, and patient status. Add epinephrine when possible to decrease the drug absorption rate at vascular sites. Reduce drug concentration with saline dilution to increase the volume for administration when a large area must be infiltrated. Frequently aspirate in areas of high vascularity, even though a negative aspiration may not prevent IV administration. [90] Slow infiltration is advised for safety and is also associated with less pain.

Treatment of Systemic Toxicity

No local anesthesia is given without the ability to recognize and treat a toxic reaction, including having all necessary equipment and drugs readily available and being knowledgeable in their use. Despite taking all possible precautions, toxic reactions still occur, and close obseration of the patient allows early detection and treatment.

Providing proper oxygenation and ventilation at the earliest sign of a reaction is the cornerstone of treatment. Encourage patients who are alert to moderately hyperventilate to lower the PCO_2 and raise the seizure threshold. Intubation with high-flow oxygen and hyperventilation is performed for patients who cannot adequately ventilate. Initiate IV access and monitor vital signs and cardiac rhythm closely.

Seizures are generally self-limited but are treated if they persist or prevent adequate ventilation. Because respiratory depression secondary to toxicity may follow, low-dose diazepam, 2 to 5 mg, or an ultrashort-acting barbiturate (thiopental or sodium methohexital) is preferred. Intubate the patient to ensure an effective airway and prevent further lactic acidosis if seizures persist. If toxicity is caused by an ester, especially if there is an associated pseudocholinesterase problem, succinylcholine will compete with the anesthetic for the pseudocholinesterase and may increase the toxicity of both compounds.

Treat hypotension and bradycardia with fluids, leg elevation, a- and ß-agonists (epinephrine, ephedrine, or dopamine), or atropine as the need dictates. Although lidocaine (with diazepam pretreatment) has been shown to be effective for bupivacaine-induced ventricular dysrhythmias, there is strong theoretical and experimental evidence that bretylium is more effective. [91] [92] However, until bretylium becomes available again, amiodarone is a reasonable alternative. High doses of atropine and epinephrine can be successful in correcting pulseless idioventricular rhythm. Cardiopulmonary resuscitation is instituted when necessary.

Allergic Reactions

Allergenic Agents

True allergic reactions are rare, accounting for only 1% to 2% of all adverse reactions, but they are important to recognize because of their serious potential. Ester solutions (procaine, tetracaine), which produce the metabolite para-aminobenzoic acid (PABA), account for the great majority of these reactions. Amide solutions (lidocaine, bupivacaine) are rarely involved and it is usually the preservative methylparaben (MPB), which is structurally similar to PABA, that is responsible. Although pure esters and pure amides do not cross-react, amides may appear to do so if multidose vials containing MPB are used. Patients may manifest an allergic response on first contact to a local anesthetic because of previous sensitization to these agents. MPB is found in creams, ointments, and various cosmetics, and PABA is an ingredient in many sunscreen preparations. Patients who are latex-sensitive may manifest an allergic reaction incorrectly attributed to the local anesthetic.

Although cell-mediated delayed reactions manifesting as dermatitis may occur, it is immediate hypersensitivity that most concerns the emergency clinician. A spectrum of signs and symptoms may occur, from rhinitis and mild urticaria to bronchospasm, upper airway edema, or anaphylactic shock. Onset may be immediate, occurring even during administration of the agent. Treat anaphylaxis in the usual manner.

The more frequent problem facing emergency clinicians is the patient who claims to have a past history of local anesthetic allergy. Most patients assume that any adverse reaction to a local anesthetic procedure is an allergy. Because allergy is rarely the cause, a careful history and a review of prior records, if available, are crucial in evaluating these patients. Uncover the actual cause of the past reaction and the specific agent involved. Ask about the exact signs and symptoms, technique of administration, amount of drug used, and how the patient was treated. If an allergic reaction cannot be ruled out and the drug previously used is known, use an agent from the other class (whether amide or ester). Lidocaine from a dental cartridge does not contain MPB, and if this were the allergenic source, then an ester agent could be used. However, if lidocaine from a multidose vial is implicated, do not use an ester, because MPB may cross-react with PABA. In this case, it may be safer to use an amide without MPB or to choose an alternative (see later). In most cases the allergen is an ester, and the patient can safely be given an amide without MPB. Single-dose ampules of 1% lidocaine without MPB, readily obtainable from a resuscitation cart, can be used for this purpose.

Uncertainty often exists regarding the specific agent involved, and the clinician must choose an alternative approach to local anesthesia. If the wounds are extensive and the risk is acceptable, sedation or general anesthesia may be used. Conversely, if minimal pain is expected and the procedure is short (e.g., one or two sutures or staples in the scalp), no anesthesia may be required. Other alternatives include parenteral narcotics, benzodiazepines, nitrous oxide inhalation, or a combination of these (see Chapter 34). These methods may be useful, but the degree of anesthesia produced is often not sufficient. Antihistamines injected into a wound have been successfully used for many years and represent a good alternative. Local anesthetic efficacy is found in varying degrees in all antihistamines.

Diphenhydramine and Benzyl Alcohol

Several studies demonstrated that 1% diphenhydramine (Benadryl) is as effective as 1% lidocaine for infiltrative anesthesia. [93] [94] [95] As long as diphenhydramine is not used at concentrations greater than 1%, potential problems of skin necrosis or significant sedation are rare. *Dilute the standard 5% parenteral form to 1% concentration for SQ injection* (1 mL drug to 4 mL saline). The duration of action for diphenhydramine is shorter than that for lidocaine but appears to be adequate for most procedures. The injection pain of diphenhydramine exceeds that of lidocaine but can be diminished by reducing the concentration to 0.5%. At this lower concentration, the effectiveness of this agent on facial wounds is lost. [96] The addition of epinephrine to 0.5% diphenhydramine results in a more painful solution with a

shorter duration of action than a standard buffered lidocaine with epinephrine solution. [97] There are scattered reports of benzyl alcohol (0.9%) with epinephrine (1:100,000) being used as an effective local anesthetic. This appears to be useful but is of short duration. [98] [99]

Skin Testing

Skin testing and progressive SQ challenge doses deserve special mention because they appear to be logical and well-studied approaches. However, intradermal skin testing with local anesthetics is controversial. False-positive results are

frequently produced by local histamine release in response to needle trauma, tissue distention, or preservatives in the solution. [100] In addition, a high incidence of false-negative results can occur. It is questionable whether these low-molecular-weight drugs or their allergenic metabolites are ever capable of eliciting positive responses.[101] Other disadvantages of skin testing include its time-consuming nature and its potential hazard when even minute traces of an allergen may precipitate a serious reaction. SQ challenge testing in graduating doses has been advocated and may well eliminate many false responses, but it does not eliminate the problems of time and hazard. Swanson, recognizing that allergy to pure lidocaine is extremely rare, recommends 0.1 mL as a single intradermal skin test. [102] Although his approach eliminates the time disadvantage, the intradermal placement can still produce false responses. It would seem more reasonable to give this test dose subcutaneously while exercising due caution in the unlikely even that a patient exhibits a serious reaction.

Summary of Anesthetic "Allergy" Management

Generally speaking, the optimal approach to the patient with a presumed anesthetic allergy is to determine the specific anesthetic agent associated with a presumed allergic reaction and then use a preservative-free agent from the other class (see earlier discussion). If the agent is unknown, use an antihistamine or give 0.1 mL of preservative-free lidocaine as an SQ test dose, proceeding with the full dose if no reaction occurs within 30 minutes. Given the studies mentioned earlier, the prudent choice would seem to be diphenhydramine (Benadryl).

Catecholamine Reactions

Anxiety and vasoconstrictor (epinephrine) reactions are discussed together because each produces similar manifestations caused by elevated catecholamine levels. These relatively common disorders are difficult to distinguish from each other and are generally not serious.

Excess catecholamine levels produce tachycardia; palpitations; hypertension; apprehension; tremulousness; diaphoresis; tachypnea; pallor; and, on occasion, anginal chest pain. Thus, catecholamine excess may resemble the central nervous system stimulation phase of local anesthetic toxicity.

Catecholamine reactions are usually not caused solely by exogenous epinephrine, because if it is used in its optimal concentration (1:200,000), the maximum safe dose (0.25 mg) is rarely exceeded. However, many patients produce significant endogenous catecholamines due to anxiety about the anesthetic approach or upcoming procedure. In this case, even the addition of small amounts of epinephrine could trigger a catecholamine reaction. Therefore, patient preparation includes proper explanation and reassurance to decrease anxiety. Exercise caution for patients who have hyperthyroidism, hypertension, or atherosclerotic cardiovascular disease, although these conditions do not contraindicate the judicious use of epinephrine-containing anesthetics. Do not give epinephrine-containing anesthetics to patients on monoamine oxidase inhibitors (MAOIs).

Treatment of the catecholamine reaction includes stopping further drug administration; observing the patient closely; and administering a- or ß-antagonists or benzodiazepine agents, if necessary, to combat severe reactions.

Vasovagal Reactions

Vasovagal reactions are common, especially in dental procedures (reported incidence, 2% to 3%), during which the patient is generally in an upright position. The patient initially experiences anxiety when a triggering event, commonly the sight or sensation of needle insertion, causes a loss of sympathetic tone and an increase in vagal tone. The resultant hypotension and bradycardia may lead to syncope. Addressing the patient's anxiety and administering the injections with the patient recumbent are useful preventive measures. Cardiac monitoring may help identify the onset of vagally induced bradycardia when suggested by past history. Lay the patient supine and elevate the legs. Rarely, atropine is required. Should a patient lose consciousness while in a recumbent position, consider diagnoses other than vasovagal syncope, although significant bradycardia, and even complete heart block, may accompany a vagal reaction in the supine patient.

SUMMARY

Emergency medicine cannot be practiced without the use of local anesthetic agents. Their effectiveness when applied topically or by infiltration makes them extremely adaptable to many clinical circumstances. A working knowledge of commonly employed agents is necessary to ensure the safe administration of these medications. Direct specific effort at maximizing the drugs' anesthetic effects while minimizing the pain of administration and risk of toxicity.

Chapter 31 - Regional Anesthesia of the Head and Neck

James T. Amsterdam
Kevin P. Kilgore

The use of intraoral and extraoral regional anesthesia is both simple and convenient. [4] [7] Nerve blocks are used to attain anesthesia in areas of broad distribution in the face with a minimal amount of anesthetic and resultant tissue distortion. Local anesthetic blocks are effective for closing facial lacerations, especially those of the lips, the forehead, and the midface, where the swelling caused by local infiltration is undesirable. Local anesthetic blocks are also effective for the relief of pain, for anesthesia in debridement, and for diagnostic purposes.

Patients with dental pain who do not get relief with a regional dental block most likely do not have pain of dental origin. Regional blocks are also therapeutic for both surgical procedure anesthesia and pain control for dental emergencies such as toothaches and dry sockets (see Chapter 66). In cases in which the patient is thought to be seeking drugs and one wishes to avoid narcotics, a dental anesthetic block is frequently the treatment of choice.

Topical anesthetic solutions such as tetracaine-Adrenalincocaine (TAC) solution are useful in small lacerations of the scalp and face because of the vascularity of these areas. TAC is not to be used on or near mucous membranes or the eye. Detailed information on the use of TAC appears in Chapter 30 . More extensive discussions of the general complications of local anesthetics and of regional anesthesia are provided in Chapter 30 and Chapter 33 , respectively. Ophthalmologic anesthesia is discussed in Chapter 64 . Blocks about the ears and nasal anesthesia are discussed in Chapter 65 .

The procedures and techniques described here generally carry a low morbidity. The supraperiosteal and mental nerve infiltrations can generally be learned through reading and experimentation; more sophisticated blocks (e.g., inferior alveolar block) are best learned under the instruction of an experienced clinician, a dentist, or an oral and maxillofacial surgeon.

ANATOMY OF THE FIFTH CRANIAL (TRIGEMINAL) NERVE

The fifth cranial nerve, the trigeminal nerve, is the sensory nerve to the face (Fig. 31-1 *A* (Figure Not Available)) and is the largest of the cranial nerves. It takes its origin from the midbrain and enlarges into the gasserian, or semilunar, ganglion. One gasserian ganglion supplies each side of the face. The gasserian ganglion is a flat, crescent-shaped structure approximately 10 mm long and 20 mm wide that divides into three branches: the ophthalmic, maxillary, and mandibular nerves (Fig. 31-1*B* (Figure Not Available)).

Ophthalmic Nerve

The first division, the *ophthalmic nerve* (V_1), is the smallest branch in the gasserian ganglion. It leaves the cranium through the superior orbital fissure and has 5 cutaneous branches. These branches are as follows:

1. The medial and lateral branches of the supraorbital nerve, which emerge on the face through the supraorbital notch. These two sensory nerves pierce the frontalis muscle and extend to the lambdoid suture on the back of the skull.
2. The supratrochlear nerve, which is sensory to the medial aspect of the forehead just above the glabella.
3. The infratrochlear nerve.
4. The lacrimal nerve.
5. The external nasal nerve.

In addition to being sensory to the forehead, branches of the ophthalmic nerve are sensory to the cornea, the upper eyelid, structures in the orbit, and the frontal sinuses.

Maxillary Nerve

The second division, the *maxillary nerve* (V_2), is sensory to the maxilla and associated structures, such as the teeth, the periosteum and the mucous membranes of the maxillary sinus and the nasal cavity, the soft and hard palate, the lower eyelids, the upper lip, and the side of the nose. The second division exits the cranium from the foramen rotundum and ultimately enters the face through the infraorbital canal; it terminates as the infraorbital nerve. The infraorbital nerve gives sensory branches to the lower eyelids, the side of the nose, and the upper lip.

The anatomy of the maxillary nerve is rather complicated because of its numerous branches. The first branch comprises two short sphenopalatine nerves to the pterygopalatine ganglion, also called the *Meckel ganglion* or the *sphenopalatine ganglion*. The next two branches of clinical importance are the nasopalatine and the greater (anterior) palatine nerves. The nasopalatine nerve arises from the pterygopalatine ganglion, courses down along the nasal septum, and is transmitted through the anterior portion of the hard palate by way of the anterior palatine canal. This canal is located in the midline approximately 10 mm palatally to the maxillary central teeth and immediately behind the incisors. The nasopalatine nerve is sensory to the most anterior portion of the hard palate and the adjacent gum margins of the upper incisors. This nerve is rarely blocked in clinical practice, except in dental operations (Fig. 31-2 (Figure Not Available)).

The anterior, or great, palatine nerve arises from the pterygopalatine ganglion and passes down through the posterior palatine foramen. The posterior palatine foramen is located 10 mm palatally to the third molar and the bicuspid teeth and intermingles with the nasopalatine nerve opposite the cuspid tooth. The greater palatine nerve is sensory to most of the hard palate, as well as the palatal aspect of the gingiva. It is rarely blocked in the emergency department (ED) (see Fig. 31-2 (Figure Not Available)).

The next branch consists of the posterior superior alveolar (PSA) nerve, which courses down the posterior surface of the maxilla for approximately 20 mm, at which point it enters one or several small posterosuperior dental foramina. This nerve supplies all the roots of the third and second molar teeth and two roots of the first molar tooth. A third branch consists of the middle superior alveolar (MSA) nerve, which branches off about midway within the infraorbital canal and then courses downward in the outer wall of the maxillary sinus. This nerve supplies the maxillary first and second bicuspid teeth and the mesiobuccal root of the first molar. The last branch consists of the anterior superior alveolar (ASA) nerve, which branches off into the infraorbital canal approximately 5 mm behind the infraorbital foramen, just before the terminal

Figure 31-1 (Figure Not Available) *A,* Cutaneous distribution of the fifth cranial nerve (the trigeminal nerve). Note that the supraorbital, infraorbital, and mental foramina are all in line just medial to the pupil when the person looks straight ahead. *B,* Branches of the trigeminal nerve. *(Adapted from Eriksson E: Illustrated Handbook in Local Anesthesia. Philadelphia, WB Saunders, 1980.)*

branches of the infraorbital nerve emerge. This nerve descends in the anterior wall of the maxilla to supply the maxillary central, lateral, and cuspid teeth; the labial mucous membrane; the periosteum; and the alveoli on one side of the median line. There is intercommunication among the ASA, MSA, and PSA nerves.

Mandibular Nerve

The third division, the *mandibular nerve* (V_3), is the largest branch of the trigeminal nerve. It exits from the cranium through the foramen ovale and divides into three principal branches:

1. The long buccal nerve branches off just outside the foramen ovale. It passes between the two heads of the external pterygoid muscle and crosses in front of the ramus to enter the cheek through the buccinator muscle, buccally to the maxillary third molar. The buccal nerve supplies sensory branches to the buccal mucous membrane and the mucoperiosteum over the maxillary and mandibular teeth. The cutaneous branch is the sensory nerve to the cheek.
2. The lingual nerve courses forward toward the midline. It runs downward superficially to the internal pterygoid muscle to pass lingually to the apex of the mandibular third molar. It enters the base of the tongue at this point through the floor of the mouth and supplies the anterior two thirds of the tongue, the lingual mucous membrane, and the mucoperiosteum.
3. The largest of the V_3 branches is the inferior alveolar nerve. It is sensory to all of the lower teeth, although the central and lateral incisors and the buccal aspect of the molar teeth may receive additional sensory innervation. The nerve descends, covered by the external pterygoid muscle, and passes between the ramus of the mandible and the sphenomandibular ligament to enter the mandibular canal. It is accompanied by the inferior alveolar artery and vein and proceeds along the mandibular canal, innervating the teeth. At the mental foramen, the nerve bifurcates into an incisive branch, which continues forward to supply the anterior teeth. It gives off a side branch, the mental nerve, which exits from the mental foramen to supply the skin. The mental foramen is located approximately between the apices of the lower first and second bicuspids, or premolar teeth. This is a useful site at which to perform a nerve block, because the mental nerve is sensory to the integument of the chin and the skin and the mucous membrane of the lower lip.

Figure 31-2 (Figure Not Available) The anterior one third of the palate, from canine to canine, is anesthetized by a local injection near the anterior palatine canal. There may be some overlapping branches of the anterior palatine nerve. Anesthesia of the posterior two thirds of the palate is obtained by a local injection in the area of the posterior palatine foramen. Topical anesthesia should precede local infiltration. *Note:* Do not enter the foramen itself, because the anesthetic may reach the middle palatine nerve and produce anesthesia of the soft palate, resulting in gagging. Foraminal injection may also produce pressure necrosis and permanent anesthesia. *(Adapted from Eriksson E: Illustrated Handbook in Local Anesthesia. Philadelphia, WB Saunders, 1980.)*

EQUIPMENT FOR DENTAL AND CRANIAL NERVE BLOCKS

One may easily give extraoral injections with standard injection equipment. A 3-mL Luer-Lok syringe with a 1 ½ inch 25- to 27-ga needle is readily found in the ED. Intraoral local anesthesia is also conveniently administered with a Monoject aspirating dental syringe, which uses Carpule cartridges of anesthetic and disposable needles (Fig. 31-3*A*). A needle no smaller than 27 G is recommended for deep block techniques owing to the inability to perform aspiration with smaller needles. Generally, a long needle is used for block techniques, and a short needle is used for infiltrations.

The needle is screwed to the hub of the Monoject syringe, which is really an adapter that in turn is screwed into the barrel of the syringe. The adapter may be removed for cleaning. When removing the disposable needle, one must take care not to remove and discard the adapter as well; this would render the syringe functionless (Fig. 31-4*A, B*).

One pulls back the end of the syringe on its spring, allowing room for the Carpule cartridge of anesthetic to be inserted (Fig. 31-5*A*). The metal end of the Carpule cartridge is inserted, which engages the needle. The handle of the syringe is then released and tapped to engage a barb into the rubber stopper of the cartridge (Fig. 31-5*B*). One may then perform simple aspiration by retracting the handle, pulling on the rubber stopper within the Carpule (Fig. 31-5*C*).

To discard a Carpule cartridge, one should leave the needle in place on the syringe. The handle of the syringe is then withdrawn rapidly, disengaging the barb. If the needle has been removed, great care must be taken, because the negative pressure created in the Carpule cartridge upon withdrawal of the barb may cause shattering. Other adjuncts that are helpful in the administration of intraoral anesthesia include topical local anesthetic agents such as gels or sprays. It should be noted that dental syringes are not mandatory for intraoral local anesthesia but do make the procedure simpler, particularly aspiration. Reusable glass and disposable plastic aspirating syringes that do not use Carpule cartridges are also available.

The anesthetic agent most frequently used is 2% lidocaine with a vasoconstrictor, such as 1:100,000 or 1:50,000 epinephrine. Many other anesthetic agents, such as mepivacaine (Carbocaine) and Cetacaine (a combination of benzocaine, tetracaine, butamben, and benzalkonium), with or without vasoconstrictor agents, are also available. Bupivacaine (Marcaine) with or without epinephrine is a longer acting anesthetic that is often ideal for the procedures performed in the ED. Bupivacaine with epinephrine is theoretically the best choice in the ED because of its longer duration of action. When this agent is not available in Carpule cartridge form, a Carpule cartridge containing a different anesthetic may be emptied and bupivacaine drawn up in the evacuated cartridge. Because of the rich vascularity of the oral cavity, vasoconstrictors are important in sustaining the duration of anesthesia and should be used wherever possible in the absence of medical contraindications. Buffering with bicarbonate is not recommended for oral anesthesia.

GENERAL RECOMMENDATIONS

Needles no smaller than 27-ga should be used for block techniques, since a higher gauge makes aspiration difficult, possibly resulting in inadvertent intravascular injection. An intravascular injection is not problematic except that the nerve block will not be effective. Intravascular epinephrine, although used

Figure 31-3 *A,* Local anesthesia—basic setup for intraoral application using an aspirating dental syringe. An alternative for a dental syringe is a 3-mL Luer-Lok syringe with a 1 ½ inch 25- or 27-ga needle. *B* and *C,* Intraoral dental blocks may be minimally painless if a topical anesthetic numbs the mucosa. Topical anesthesia is applied prior to injection, illustrated here for an inferior alveolar nerve block. After drying the mucosa with gauze, the pterygomandibular triangle is painted with topical anesthetic. Benzocaine is liberally sprayed into two cotton swabs and held in place by closing the teeth and lips for a few minutes after painting the area of needle penetration. The mucosa is dried with gauze before applying the topical anesthetic.

in small doses, may produce systemic symptoms (anxiety, tachycardia) but the amount of local anesthetic is inconsequential.

When an intraoral block procedure is performed, the needle should not be inserted to its full length at the hub. Should inadvertent breakage occur in such a situation, needle retrieval may be difficult. Furthermore, the direction of a needle should not be changed while the needle is deep in the tissue. One should always aspirate before injection, and inject slowly to minimize pain. A warmed anesthetic solution is also more comfortable for the patient. In addition, topical anesthetics can be placed on mucous membranes before all dental

Figure 31-4 *A,* Proper technique for removal of the disposable hypodermic needle from the dental aspirating syringe. *B,* Incorrect technique involves removal of the carpule adapter, rendering the syringe unable to accept new Carpules.

blocks to make needle puncture painless. This adjunct is suggested whenever possible (Fig. 31-3*B, C*).

An important caveat for intraoral local anesthesia is that the injection should not be made into or through an infected area. This is especially important in inferior alveolar nerve blocks, in which tracking of an infection can be serious and difficult to treat. Trismus with inadequate oral access or direct extension of infection to parapharyngeal spaces can result. Therefore, local anesthesia should be only superficial before incision and drainage, unless a block can be performed far proximal to the site of infections.

Figure 31-5 Loading the dental aspirating syringe. *A,* The end of the syringe is pulled back. When released, the Carpule cartridge engages the needle. *B,* The barb is snapped into place. *C,* Once engaged, the syringe allows aspiration.

TECHNIQUE

Topical Anesthesia

Most patients fear dental blocks greatly, and the anxiety and pain may be lessened considerably with the use of topical anesthetics that are applied to the mucous membranes before injection (see Fig. 31-3*B, C*). The area to be injected is first thoroughly dried with gauze. Copious saliva will wash away the anesthetic prematurely. A cotton-tipped applicator is generously coated with 20% benzocaine (Hurricaine, Beutlich, Inc, Niles, IL) or 5% to 10% lidocaine, and the area of injection is painted. The patient may hold the cotton swab in place. Anesthesia results in 2 to 3 minutes. Note that rather concentrated topical anesthetics must be used, and poor results are obtained with weaker preparations such as 2% viscous lidocaine. Cocaine (4%) is another acceptable topical anesthetic.

Supraperiosteal Infiltrations

The most common technique for intraoral local anesthesia of individual teeth is the supraperiosteal infiltration injection. This technique may supply complete relief of a toothache and is a useful ED procedure that can provide nonnarcotic analgesia in the middle of the night. The area to be anesthetized is selected and dried with gauze. A topical anesthetic, such as 20% benzocaine or 5% lidocaine ointment, is applied as described. The patient is asked to close the jaw slightly to relax the facial musculature. The mucous membrane of the area is grasped with a piece of gauze; the gauze is pulled out and downward in the maxilla and out and upward in the mandible to extend the mucosa fully and to delineate the mucobuccal fold. The mucobuccal fold is then punctured with the bevel of the needle facing the bone. The area is aspirated, and approximately 1 to 2 mL of local anesthetic are deposited at the apex (area of the root tip) of the involved tooth (Fig. 31-6*A, B*). It is helpful to place a finger against the *outer* aspect of the lip overlying the injection site and apply firm and steady pressure against the lip as the local anesthetic is *slowly* injected into the supraperiosteal site.

The purpose of the injection is to deposit the anesthetic near the bone that supports the tooth. Because the anesthetic must penetrate the cortex of bone to reach the nerve of the individual tooth, the injection may fail if the solution is deposited too far from the periosteum, if the needle is passed too far above the roots of the teeth, or if the bone in the area is unusually thick or dense. If anesthesia is unsuccessful, one may also inject the palatal side. It may take 5 to 10 minutes to achieve full anesthesia with this technique, and the procedure may not be as effective for the posterior molars. Infiltration of the area around the maxillary canine and the first premolars will anesthetize the MSA and ASA nerves; lacerations of the upper lip can be treated by bilateral injection in the canine fossa areas.

Figure 31-6 Topical anesthetic is applied to the dried mucosa before injection. *A,* Supraperiosteal injection technique above the incisors for anesthesia of the upper lip or individual teeth. *B,* Diagrammatic representation of supraperiosteal injection. The aim is to deposit the anesthetic right next to the periosteum at the level of the apex (area of the root tip) of the tooth. The palatal side of the tooth may also be injected.

Posterior Superior Alveolar Nerve Block (PSA)

Anatomy

The PSA block is used to anesthetize the maxillary molar teeth. On occasion the maxillary first molar may not be completely anesthetized by this technique alone, and may require an additional block (discussed subsequently). The landmarks for this technique are the posterior-lateral portion of the maxillary tuberosity and the second molar (see Fig. 31-2 (Figure Not Available)).

Intraoral Approach

A topical anesthetic on a cotton-tipped swab is applied for 60 seconds prior to introducing the needle for the nerve block. [4] [5] With the patient's mouth half-open and the jaw swung toward the operator, the cheek is retracted laterally. The puncture is made in the mucosal reflection just distal to the distal buccal root of the upper second molar (Fig. 31-7*A, B*). The needle is directed toward the maxillary tuberosity

Figure 31-7 Posterior superior alveolar nerve block.

(i.e., upward, backward, and inward) and then along the curvature of the maxillary tuberosity to a depth of approximately 2 to 2.5 cm. On reaching this depth, the needle is aspirated and 2 to 3 mL of anesthetic solution is injected.

Complications

Complications includes puncture of the pterygoid plexus and hematoma formation should the syringe not be aspirated before injection. Also, if the needle were advanced too far posteriorly, a Division II block of cranial nerve V will result.

Middle Superior Alveolar Nerve Block (MSA)

Anatomy

The MSA block is used to anesthetize the mesiobuccal root of the maxillary first molar in order to achieve complete anesthesia of this tooth. The landmark for this procedure is the junction between the second premolar and first molar.

Figure 31-8 Middle superior alveolar nerve block.

Intraoral Approach

A topical anesthetic on a cotton-tipped swab is applied for 60 seconds prior to introducing the needle for the nerve block. [4] [5] The cheek is retracted laterally and the

puncture is made in the mucosal reflection adjacent to the mesiobuccal root area of the first molar (the space between the second premolar and the first molar) directing the needle at a 45-degree angle (Fig. 31-8*A, B*). When the correct location has been determined and aspiration has been performed, 2 to 3 mL of anesthetic solution is injected. Massage of the tissue for 10 to 15 seconds after the injection will hasten the onset of the anesthesia.

Anterior Superior Alveolar Nerve Block (ASA)

Anatomy

The landmark for this technique is the apex of the canine tooth.

Figure 31-9 Anterior superior alveolar nerve block.

Intraoral Approach

A topical anesthetic on a cotton-tipped swab is applied for 60 seconds prior to introducing the needle for the nerve block. [4] [5] The patient is asked to close his jaw slightly to relax the upper lip. The lip is retracted anteriorly and the puncture is made in the mucosal reflection at the apex of the canine tooth directing the needle at a 45-degree angle (Fig. 31-9*A, B*). When the correct location has been determined and aspiration has been performed, 2 mL of anesthetic solution is injected. Massage of the tissue for 10 to 15 seconds after the injection will hasten the onset of the anesthesia.

Infraorbital Nerve Block

Anatomy

The infraorbital nerve block injection can be used to anesthetize the midface (Fig. 31-10). A solution of local anesthetic deposited adjacent to the infraorbital foramen anesthetizes not

Figure 31-10 Area of anesthesia of a unilateral infraorbital nerve block. Anesthesia includes the lower eyelid and the upper lip.

Figure 31-11 *A,* Intraoral approach for infraorbital nerve block. *B,* The position of the infraorbital foramen *(arrow)* on the inferior portion of the infraorbital ridge. During infiltration, the needle should be near but not within the foramen. *C,* Incorrect infraorbital injection technique may result in needle entry into the orbit. *(Adapted from Eriksson E: Illustrated Handbook in Local Anesthesia. Philadelphia, WB Saunders, 1980.)*

only the middle and superior alveolar nerves, but also the main trunk of the infraorbital nerve that innervates the skin of the upper lip, the skin of the nose, and the lower eyelid. The nasal mucosa is not anesthetized by this technique.

The infraorbital foramen is difficult to palpate extraorally and almost impossible to feel in the presence of facial swelling. It is found on the inferior border of the infraorbital ridge on a vertical (sagittal) line with the pupil when the patient stares straight ahead. Although one volunteer study found similar patient pain scale scores and overall preference in subjects receiving both intraoral and extraoral approaches, the intraoral approach seemed to provide nearly twice the duration of anesthesia. [6]

Intraoral Approach

A topical anesthetic on a cotton-tipped swab is applied for 60 seconds prior to introducing the needle for the nerve block [4] [5] . When performing the intraoral approach, one keeps the palpating finger in place over the inferior border on the infraorbital rim. The cheek is retracted, as in the supraperiosteal injection, and puncture is made in the mucosa opposite the upper second bicuspid (premolar tooth) approximately 0.5 cm from the buccal surface (Fig. 31-11*A, B*). The needle

should be directed parallel with the long axis of the second bicuspid until it is palpated near the foramen, a depth of approximately 2.5 cm. If the entry is too acute initially, one will encounter the malar eminence before approaching the infraorbital foramen. In addition, if the needle is extended too far posteriorly and superiorly, the orbit may be entered (Fig. 31-11*C*). Therefore, the procedure should be halted if the clinician is unsure of the location of the needle or if patient cooperation is unsatisfactory.

When proper needle location has been determined and aspiration has been performed, 2 to 3 mL of solution are injected *adjacent to, but not within, the foramen*. A finger should be held firmly on the inferior orbital rim to avoid ballooning of the lower eyelid with anesthetic solution. If one is not certain of the exact location of the infraorbital foramen, one may obtain anesthesia by performing a field block. For the latter technique, 5 mL of the anesthetic solution are infiltrated in a fanlike distribution in the upper buccal fold. This technique is not as precise as a discrete nerve block but usually produces the same effect. Massage of the tissue for 10 to 15 seconds after the injection will hasten the onset of the anesthesia.

Extraoral Approach

The infraorbital foramen may also be approached from an extraoral route (Fig. 31-12). The extraoral approach, of course, requires external preparation of the skin. In the extraoral approach, similar landmarks are used to locate the infraorbital foramen. The needle can be felt to pass through the skin, the subcutaneous (SQ) tissue, and the quadratus labii superioris muscle. After injection, the infiltrated tissue, usually visibly swollen, should be firmly massaged for 10 to 15 seconds.

Care must be taken not to anesthetize the facial artery and vein, because these may lie on either side of the needle. Vasoconstrictors should be avoided with this technique to avoid vasoconstriction of the facial artery. If severe blanching of the face occurs, warm compresses should be applied to the face immediately. Local phentolamine also may be administered (see Chapter 30).

Inferior Alveolar Nerve Block

In the setting of extreme dental pain, the emergency clinician may find the use of the inferior alveolar nerve block and the lingual nerve block useful. This injection is

somewhat more difficult than the other techniques described, and the emergency clinician is advised to view demonstrations of this procedure before attempting it. The inferior alveolar nerve block provides anesthesia to all of the teeth on that side of the mandible and desensitizes the lower lip and the chin via block of the mental nerve. This technique is primarily useful for anesthetizing patients who have sustained severe dentoalveolar trauma; those with complaints of postextraction pain, dry socket, or pulpitis (toothache); or those with periapical abscess.

Anatomy

The anatomy of the region should first be reviewed (Fig. 31-13*A*). The patient can be seated either in a dental chair or upright with the occiput firmly against the back of the stretcher, so that when the mouth is opened, the body of the mandible is parallel to the floor. Despite the use of topical anesthesia, the clinician should be ready for an unexpected quick jerk of the head when the anxious patient first feels the

Figure 31-12 *A,* The extraoral approach to the infraorbital nerve. This procedure is more difficult than the intraoral approach, especially when attempting to obtain anesthesia of the upper lip. *B,* During injection, a finger placed above the needle and below the eyelid will limit swelling of the lower lid. Continual pressure with a finger during injection limits edema of the lower eyelid from the anesthetic solution.

needle. The clinician stands on the side *opposite* the one being injected.

The technique first involves palpation of the retro-molar fossa with the index finger or thumb. With this maneuver, the greatest depth of the anterior border of the ramus of the mandible (the coronoid notch) may be identified (Fig. 31-13*B*). With the thumb in the mouth and the index finger placed externally behind the ramus, the tissues are retracted toward the buccal (cheek) side, and the pterygomandibular triangle is visualized (Fig. 31-13*C*). This technique also moves the operator's finger safely away from the tip of the needle.

Approach

The mucosa over the area to be injected may be coated with a topical anesthetic as described previously. When topical anesthesia has been obtained, the syringe should be held parallel to the occlusal surfaces of the teeth and angled so that the barrel of the syringe lies between the first and second premolars on the opposite side of the mandible (see Fig. 31-13*C*). Failing to appreciate this required angle is the most common reason for failure with this nerve block. If a large-barrel syringe is used, the corner of the mouth may hamper

Figure 31-13 Inferior alveolar nerve block. *A,* Transverse illustration of the anatomy of the pterygomandibular triangle and direction of needle *before injection*. *B,* Anatomy of the inferior alveolar nerve block (intraoral approach) *(Adapted from Eriksson E: Illustrated Handbook in Local Anesthesia. Philadelphia, WB Saunders, 1980. Reproduced with permission)*. The greatest depth of the anterior border of the ramus of the mandible, the coronoid notch, is identified with the left index finger or left thumb. *C,* The ramus is grasped between an intraorally placed thumb (positioned on the coronoid notch) and extraorally positioned index finger. The pterygomandibular triangle may then be well visualized. Note the angle of the syringe during injection, with the syringe overlying the first and second premolars on the opposite side of the mandible. Failing to appreciate this orientation is one common cause of failure. The operator should be able to feel the needle contacting the bony surface of the inner mandible. Also note that the injection is 1 cm *above* the level of the teeth. *D,* Directing the needle too far posteriorly during the inferior alveolar nerve block technique will result in entry into the area of the parotid gland. Anesthesia of the seventh nerve may result. This occurs because from an improper entry orientation and is corrected by noting *C*. *E,* To compensate for difficulty in obtaining the correct approach with a straight needle, a 25-ga 1 ½-inch needle is bent 30° with the needle guard.

efforts to obtain the proper angle. The angle is facilitated by carefully bending the 25-ga needle about 30° (Fig. 31-13*E*). Puncture is made in the triangle, at a point that is *1 cm above the occlusal surface of the molars*. If the needle enters too low (e.g., at the level of the teeth), the anesthetic will be deposited over the bony canal and prominence (lingula) that house the mandibular nerve, and not over the nerve itself.

The needle should be felt to pass through the ligaments and the muscles covering the internal surface of the mandible. One should stop when the needle has reached bone, which signifies contact with the posterior wall of the mandibular sulcus; bone *must* be felt with the needle. Failure to do so generally results from directing the needle toward the parotid gland (too far posteriorly) rather than toward the inner aspect of the mandible. The needle should then be withdrawn slightly and aspirated, and approximately 1 to 2 mL of solution should be deposited. Three to 4 mL may be required if needle positioning is suboptimal.

In children, the angulation is not parallel to the occlusal surfaces of the teeth; instead the barrel of the syringe must be held slightly higher, because the mandibular foramen is lower. One may anesthetize the lingual nerve by placing several drops of anesthetic solution while withdrawing the syringe. The anterior two thirds of the tongue can thus be anesthetized. In actual practice, the lingual nerve is consistently blocked with this procedure owing to the close proximity of both nerves. Shortly following a successful injection, the patient will report tingling in the lower lip, however, it usually requires 3 to 5 minutes to achieve complete anesthesia.

Complications

Complications include inadvertent administration of anesthetic posteriorly in the region of the parotid gland, which will anesthetize the facial nerves (Fig. 31-13*D*). This is an annoying but relatively benign complication that will cause temporary facial paralysis (similar to a Bell's palsy) that affects the orbicularis oculi muscle and results in inability to close the eyelid. Should this occur, the eye must be protected until the local anesthetic has worn off (approximately 2 to 3 hours), and the patient must be reassured. Anesthesia with bupivacaine (Marcaine) presents a more significant problem if this

Figure 31-14 Mental infiltration technique. *A,* The correct supraperiosteal approach is an *infiltration* technique. *B,* Actual introduction of the needle into the mental foramen may produce neurovascular damage, and therefore infiltration only is recommended. *(Adapted from Eriksson E: Illustrated Handbook in Local Anesthesia. Philadelphia, WB Saunders, 1980.)*

complication occurs, because bupivacaine anesthesia lasts from 10 to 18 hours in some patients.

Mental Nerve Block

The mental nerve is blocked by the infiltration of local anesthetic about the nerve as it exits its bony foramen (Fig. 31-14*A, B*). Introduction of the needle in the mental nerve foramen is to be avoided, as the needle or injection of liquid into the foramen can produce neurovascular damage. Infiltration about the foramen will

provide for anesthesia of the lower lip. Lacerations of the midline of the lips require administration of anesthetic about the mental nerve on each side of the face; this practice anesthetizes crossover fibers. Generally a 1.3-cm (½ in), 25- or 27-ga needle on a 3-mL syringe is used.

Anatomy

The mental nerve is a continuation of the inferior alveolar nerve, which innervates the mucosa and the skin of the lower lip of the ipsilateral side of the mandible, with limited crossover of midline fibers. The nerve emerges from the mental foramen below the second premolar.

Approaches

Like the infraorbital nerve, the mental nerve may be blocked using an intraoral or an extraoral approach. Syverud and colleagues found that volunteers who received intraoral topical anesthetic followed by an intraoral injection considered the technique to be less painful than the extraoral approach. [9] Before using either approach, the mental foramen should be identified by palpation about 1 cm inferior and anterior to the second premolar. It is generally best to locate the foramen using a gloved finger placed into the labial area over the mandible. Generally the foramen will be just medial to the pupil (while staring straight ahead) along a sagittal plane.

When using the *extraoral* approach, the overlying skin is prepped and anesthetized with an anesthetic skin wheal. The mental nerve is approached through the overlying skin using a needle trajectory perpendicular or at a 45° angle to the foramen. As noted above, the local anesthetic is infiltrated about the nerve approximately 3 to 5 mm *outside* of the foramen. After

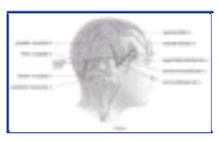

Figure 31-15 The sources of sensory nerve supply to the scalp.

placement of 1 to 2 mL of local anesthetic about the nerve, the needle is withdrawn and the area over the foramen massaged for 10 to 15 seconds to hasten anesthetic onset.

When using the *intraoral* approach, it is best to use topical anesthesia prior to infiltration. The lower labial fold adjacent to the first or second premolar is topically anesthetized. The mental foramen is again approached at about a 45° angle, and the area adjacent to the foramen is infiltrated with 1 to 2 mL of local anesthetic and the area massaged as above.

Scalp Block

Scalp blocks provide surgical anesthesia for the repair of scalp lacerations, drainage of superficial scalp abscesses, and exploration of scalp wounds.

Anatomy

As shown in Figure 31-15 and Figure 31-16 (Figure Not Available) , the scalp receives its nerve supply from branches of the trigeminal nerve (fifth cranial nerve) and the cervical plexus. The forehead is supplied by the supraorbital and supratrochlear nerves. Both nerves are branches of the ophthalmic division of the trigeminal nerve. The

Figure 31-16 (Figure Not Available) Topographic anatomy of the scalp taken above a line drawn from the upper border of the external ear to the occiput and the eyebrows. *(Adapted from Eriksson E: Illustrated Handbook in Local Anesthesia. Philadelphia, WB Saunders, 1980.)*

temporal region receives its nerve supply from the zygomaticotemporal (a V_2 branch nerve), temporomandibular, and auriculotemporal nerves (V_3 branch nerves).

The posterior aspect of the scalp is innervated by the greater auricular and the greater, lesser, and least (third) occipital nerves. The nerves that supply the posterior aspect of the scalp originate from the cervical plexus. All the nerves become superficial above a line drawn from the upper border of the external ear to the occiput and the eyebrows and converge toward the vertex of the scalp (see Fig. 31-15).

Topographically, the nerves and vessels of the scalp are located in the SQ tissue above the epicranial aponeurosis. From this level they divide into small branches that extend to the deeper layers (epicranium and periosteum) (see Fig. 31-16 (Figure Not Available)). [8]

Approaches

A scalp block can be accomplished by individually blocking each nerve that supplies the scalp, but this approach is time consuming, difficult, and cumbersome. Because the nerves on the scalp are superficially located, the scalp block can easily be performed by injecting local anesthetic agents into the SQ tissue circumferentially around the area to be blocked. Injection of local anesthetic to the deeper levels is necessary only if bone is to be removed. Note that injection of local anesthetic agents only in the deeper layers without SQ infiltration results in an unsuccessful block and a greater amount of bleeding during surgical intervention. [2]

In preparation for the block, a band of hair may be clipped (some clinicians prefer to shave the head, but this procedure is of unproven benefit). A band 1 cm wide and 3 cm away from the wound can be circumferentially clipped. Local anesthetics are injected in the clipped area.

The skin is prepared using an antiseptic solution, and a skin wheal is raised at any point along the clipped skin using a 1.3-cm (½ in), 25-ga needle. A 7.6-cm (3 in), 22-ga needle is inserted through the skin wheal into the SQ tissue and advanced along the scalp circumferentially following the previously clipped area. An injection of 0.5% to 1% lidocaine or 0.125% to

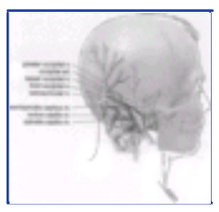

Figure 31-17 Anatomic relationship of the greater and lesser occipital nerves and the adjacent structures at the posterior aspect of the head. Note the proximity of the occipital artery, which is immediately lateral to the greater occipital nerve.

0.25% bupivacaine with epinephrine (1:200,000) is used. Epinephrine should be added to the local anesthetic agent to provide vasoconstriction and to prevent excessive blood loss and local anesthetic absorption. The total dose of the local anesthetic agents should not exceed the recommended dose for the particular agent (see Chapter 30). It may be useful to inject some local anesthetic solution into the temporalis muscle to prevent contraction of the muscle during the primary procedure.

Colley and Heavner demonstrated that when bupivacaine is used, the peak plasma local anesthetic concentrations occur within 10 to 15 minutes after injection. [3]

Thus, the first 10- to 15-minute period after the injection is the most critical period for the occurrence of local anesthetic toxicity. Colley and

Figure 31-18 *A,* The greater occipital nerve is blocked on a line 3 cm lateral to the external occipital protuberance and the base of the occipital bone. *B,* The lesser occipital nerve is blocked by injection of 2 to 3 mL of anesthetic solution along the posterior border of the mastoid process of the temporal bone.

Heavner also found that despite the scalp's high vascularity, the absorption of local anesthetics from the scalp is not excessive. Using the upper limit of the recommended dose of bupivacaine without epinephrine (175 mg), they found that peak plasma bupivacaine concentrations were 0.8 µg/mL with a 0.125% solution and 1.2 µg/mL with a 0.25% solution. Considering that the toxic plasma threshold for bupivacaine is 4 µg/mL, these concentrations suggest that a scalp block using bupivacaine has a wide margin of safety, even without the use of epinephrine. When epinephrine is used with bupivacaine, its effect on absorption becomes more pronounced with concentrations of 0.125% than with those of 0.25%. This is probably because at low concentrations (0.125%), bupivacaine has a vasoconstrictor property.[1]

Greater and Lesser Occipital Nerve Block

This relatively simple block may be useful in the ED for treating occipital neuralgia and tension headaches. For occipital neuritis, a long-acting corticosteroid, such as methylprednisolone (20 to 40 mg) may be combined with the local anesthetic (see Chapter 53).

Anatomy

The posterior aspect of the head is supplied by the posterior rami of the cervical nerves. Two important branches of these nerves are the greater and lesser occipital nerves. The greater occipital nerve becomes superficial on each side at the inferior border of the obliquus capitis inferior muscle and runs superiorly toward the vertex over this muscle. The nerve is located medial to the occipital artery. The lesser occipital nerve is located approximately 2.5 to 3.5 cm lateral and 1 to 2 cm caudal to the greater occipital nerve (Fig. 31-17).[5]

Approach

It is not usually necessary to shave or clip the scalp prior to performing greater and lesser occipital nerve blocks. The greater occipital nerve can best be blocked at the nuchal line, which is in the middle of the external occipital protuberance and the mastoid process. The nuchal line is located between the insertion sites of the trapezius muscle and the semispinalis muscles. At this site, the greater occipital nerve is just medial to the occipital artery.

Figure 31-19 This patient had multiple small pieces of glass embedded in the forehead from a windshield injury. Removal was accomplished painlessly with bilateral supraorbital and supratrochlear nerve blocks.

The occipital artery is first palpated, and a 3.8-cm, 23- to 25-ga needle connected to a syringe that contains 5 mL of local anesthetic is inserted through the skin (Fig. 31-18*A*). After obtaining paresthesia at the vertex, 5 mL of local anesthetic solution is injected. The lesser occipital nerve is blocked by a fanlike injection of a local anesthetic solution 2.5 to 3.5 cm lateral and 1 cm caudal to the point described for the greater occipital nerve (Fig. 31-18*B*).[5]

This procedure is not usually associated with any complications; however, intra-arterial injections should be avoided by careful aspiration.

Ophthalmic (V_1) Nerve Block

The lateral and medial branches of the supraorbital, supratrochlear, and infratrochlear nerves may be blocked by

Figure 31-20 (Figure Not Available) *A,* Site for local injection of the lateral and medial branches of the supraorbital nerve. *B,* It should be noted that a finger may be placed just below the margin of the superior orbital rim to avoid swelling of the eyelid. *(Adapted from Eriksson E: Illustrated Handbook in Local Anesthesia. Philadelphia, WB Saunders, 1980.)*

percutaneous local injection at the point where they emerge from the superior aspect of the orbit. Anesthesia of the forehead and the scalp is achieved as far posteriorly as the lambdoid suture. Although anesthesia is easily obtained for suturing lacerations of the forehead and the scalp, the nerve block may also be used for debridement or topical treatment of burns or abrasions and for delicate lacerations of the upper eyelid. Such anesthesia is ideal for removing small pieces of glass that are embedded in the forehead from a windshield injury (Fig. 31-19).

Anatomy

The subtle supraorbital notch, which is in line with the pupil (when the patient is staring straight ahead), may be palpated along the superior orbital rim. This landmark is the site of injection for blockage of the supraorbital nerves. The supratrochlear nerve is found 0.5 to 1.0 cm medial to the notch. The infratrochlear nerve is not usually blocked but is found in the most medial aspect of the superior orbital rim. If the anesthetic is placed on the forehead proper, this block may not produce complete anesthesia of the skin of the upper eyelid if the sensory branches to the eyelid are given off before the supraorbital nerve transverses the forehead.

Approach

With the patient in the supine position, a skin wheal is raised. Paresthesias in the form of an electric shock sensation over the forehead are sought; these ensure a successful nerve block. One to 3 mL of anesthetic are placed in the area of the supraorbital notch. A finger or a roll of gauze should be held firmly under the orbital rim to avoid ballooning of anesthetic into the upper eyelid (Fig. 31-20 *A, B* (Figure Not Available)).

If paresthesias cannot be elicited or if the nerve block is unsuccessful, a line of anesthetic solution placed along the orbital rim from the lateral to the medial aspect will ensure block of all of the branches of the ophthalmic nerve (Fig. 31-21).

Figure 31-21 A field block of the forehead will anesthetize both the lateral and medial branches of the supraorbital nerve as well as the supratrochlear nerves. The resultant area of anesthesia is represented by the shaded area of the left forehead.

Complications

Hematoma formation or swelling of the eyelid may occur but requires only local pressure. Occasionally, ecchymosis of the periorbital region will appear the next day, and the patient should be warned of this possibility.

Although this block is infrequently used, it is easily performed and is not associated with serious side effects. Its use should be considered when anesthesia of the forehead or the anterior scalp is desired.

CONCLUSION

Nerve blocks about the head and neck are relatively painless when done carefully and slowly following topical mucosal anesthesia (for intraoral approaches) or local skin anesthesia (for extraoral blocks and approaches). Patients who appear anxious may benefit from sedation prior to attempting these blocks (see Chapter 34). These blocks should not be attempted in the uncooperative patient.

Acknowledgments

The material on scalp blocks was originally written by Levon M. Capan, MD, Katie P. Patel, MD, and Herman Turndorf, MD. The authors and the editors appreciate the contribution of the original authors.

Chapter 32 - Nerve Blocks of the Thorax and Extremities

John J. Kelly
Mark Spektor

The use of nerve blocks is an integral part of the practice of emergency medicine. This chapter provides technical guidance for the performance of commonly used nerve blocks.

While virtually every peripheral nerve can be blocked at some point along its course from the spine to the periphery, digital nerve blocks of the fingers and toes are more commonly used than proximal blocks. The reasons for this are unclear but likely include a lack of experience on the part of the clinician, the time required for a block to take effect, and occasional failure to obtain adequate anesthesia. However, with proper training and experience, nerve blocks of the thorax and proximal extremities can be very useful tools for emergency clinicians. Potential applications include femoral blocks for femur fractures, ankle blocks for treatment of foot injuries and infections, intercostal blocks for rib fractures, and wrist blocks for injuries to the palm.

The preparation, technique, choice of anesthetic, precautions, and complications are similar for all nerve blocks and are described in general in the following sections. The clinician is encouraged to use the same basic techniques and precautions for all nerve blocks. Specific precautions unique to a particular nerve block are included with the description of that block; obvious precautions, such as aspiration before injection when the needle is in close proximity to a vascular structure, are not restated to avoid redundancy.

GENERAL CONCEPTS

Indications

For most of the lacerations and injuries seen in the emergency department (ED), local infiltrative anesthesia is adequate and more efficient than using a nerve block (see Chapter 30). Local infiltration is quick, reliable, and effective compared with many of the nerve blocks, which tend to require a more extensive setup and have a less reliable and longer onset. Furthermore, those patients who require extensive repair and anesthesia of the entire extremity are often referred to a specialist, who may prefer to examine an unanesthetized limb.

In general, a nerve block is indicated when it will provide advantages over other techniques. Scenarios in which this requirement is met include the following:

- When distortion from local infiltration hampers closure (e.g., facial wounds) or may compromise blood flow (e.g., fingertip)
- When anesthesia is required over a large area and multiple injections would be painful, or the large amount of anesthetic needed for local infiltration exceeds the recommended dose
- When a nerve block is the most efficacious form of treatment, as in an intercostal block for treating a rib fracture in a patient with chronic obstructive pulmonary disease
- When local infiltration of the wound would be more painful than a regional nerve block, such as in the plantar surface of the foot or the palm of the hand
- When the block is performed in order to decrease pain during finger or toe dislocation reduction
- When extensive limb surgery or manipulation is required (e.g., extensive tendon repair) and other options are not available

Preparation

A brief history, including drug allergies, medications, and systemic illnesses should be taken from the patient. Specific history about allergies to local anesthetics may be prudent to elicit. Peripheral vascular, heart, and liver disease may increase the risk of severe complications; therefore, information about the existence of these diseases should also be sought.

Instructions

The procedure should be explained to the patient, including the pain of the needle insertion, paresthesias that may be felt, and possible complications that may occur. *The possible need for additional anesthetic or alternate procedures if the initial nerve block fails should also be discussed beforehand.* The patient should understand that the additional administration of anesthetic is part of the normal procedure rather than an attempt to correct an incomplete nerve block. It is not standard to obtain written informed consent for the nerve blocks performed in the ED.

Equipment

The degree of equipment preparation depends on the extent of the procedure. For a simple digital block, a 10-mL syringe, an 18-ga needle for drawing the solution from the vial, and a 3.75-cm, 25- or 27-ga needle for the nerve block will suffice. Note that the needle sizes given in the text are general recommendations but for the majority of blocks, a 25-ga needle is ideal. For more elaborate blocks, the necessary equipment is listed in Table 32-1 . Use of an extension tubing set between the needle and a stopcock syringe assembly facilitates independent needle placement and syringe manipulation. In addition, standard resuscitation equipment for advanced cardiac life support should be readily available any time local anesthetic agents are given.

Choice of Anesthetic

The factors influencing the choice of anesthetic agent for nerve block are similar to those for local infiltration (see Chapter 30). In general, most nerve blocks are done for the repair of painful traumatic injuries that are likely to cause pain long after the repair is complete. In such cases, anesthetics with the longest duration of action should be selected to maximize the patient's analgesia. For most of the blocks described in this chapter, 0.25% bupivacaine is suggested as the anesthetic of choice, but equal volumes of 1% lidocaine with epinephrine can be substituted. The use of epinephrine on end-organ areas is generally discouraged (e.g., toes, fingers) although the theoretical risk is largely unsubstantiated in clinical practice (see chapter 30). Higher concentrations of lidocaine (up to 2%) or bupivacaine (0.5%) are commonly used for large nerves. Ropivacaine is a relatively new amide anesthetic with a rapid onset and long duration of action (several hours). It has been reported to have fewer cardiotoxic and central nervous system effects than bupivacaine. [1] [2] Care

TABLE 32-1 -- Equipment Needed for Proximal Nerve Block Trays

6 gauze sponges
4 towels
1 antiseptic-solution receptacle
1 receptacle for saline flush solution
1 anesthetic-solution receptacle (30-mL capacity)
1 10-mL syringe for local anesthetic injection
1 30-mL syringe for nerve block injection
1 three-way stopcock
1 IV extension tubing set
1 18-ga needle for withdrawing anesthetic from the vial
1 each 3.75-cm 23-, 25-, and 27-ga needles for nerve blocks

must always be taken to *avoid exceeding* the recommended dosages of anesthetic.

Buffering the anesthetic will lessen the pain of infiltration. Buffered lidocaine has been shown to be less painful and equally as efficacious as plain lidocaine in digital blocks.[3] One part bicarbonate to 10 parts lidocaine is usually used. Heating the anesthetic from 37°C to 41°C also reduces the pain of digital blocks. [4] Slower rates of injection have also been found to significantly reduce discomfort. [5]

Positioning of the Patient

Ideally, nerve blocks should be performed with the patient in the supine position. This enhances patient comfort and prevents the unexpected vasovagal syncope that may occur when the patient is in an upright position. Vasovagal syncope may be induced from the pain of the injection or "needle phobia." For this reason, the clinician may draw the anesthetic from the vial, taking care that the patient does not see the needle. In addition, common distraction techniques have shown to help in

reducing anxiety and discomfort.[6]

Preparation of the Area to Be Blocked

To limit the incidence of infection, the field should be prepared in an aseptic fashion before needle puncture. This can be accomplished by swabbing the area with a povidone-iodine solution or alcohol and then using a standard aseptic injection technique. The antiseptic solution should be allowed to dry fully to achieve maximal antibacterial effect. Sterile drapes and gloves are not routinely required but may be considered in addition to aseptic skin preparation for the initiation of blocks that (1) are close to large joints, vessels, and nerves; (2) are located in inherently contaminated areas of the body (e.g., groin, perineum); or (3) require simultaneous palpation of the underlying structures while injecting.

Choosing the Nerves to Block

Successful anesthesia requires appropriate knowledge of anatomy. Most areas to be anesthetized have overlapping sensory innervation. Therefore, most cases require two or more nerves to be blocked. In addition, the cutaneous distribution of the various peripheral nerves differs slightly from patient to patient. A liberal margin of error should be used when determining which nerves supply the desired area of anesthesia.

Locating the Nerve

When locating a nerve to be blocked, it is best to approach it from a site with easily identifiable anatomic landmarks. The best sites are those with good structural landmarks (e.g., prominent bones or tendons) immediately next to the nerve. For example, the digital nerves are reliably found at the 2, 4, 8, and 10 o'clock positions around and just superficial to the proximal phalanx, and the median nerve lies between the palpable palmaris longus and flexor carpi radialis tendons at the proximal crease of the wrist. Nerves that course adjacent to easily palpable arteries such as in the axilla and groin are also easy to locate and are good sites for performing nerve blocks. Nerves that do not have adjacent structural or vascular landmarks are much more difficult to block.

Blocking nerves with good structural or vascular landmarks is straightforward: The landmarks are palpated, the course of the nerve in relation to those landmarks is visualized in the mind's eye, and the needle is inserted in close proximity to the nerve.

Blocking those nerves with poor landmarks, such as the radial nerve at the elbow, requires skill through practice, some degree of luck, or a nerve stimulator if such nerves are to be blocked consistently.

Nerve Stimulator

Although not standard or easy to find in any ED, a nerve stimulator is inexpensive and relatively simple to use. With minimal practice, the needle can be placed easily and reliably within a few millimeters of the nerve. The device is simple, consisting of a battery-operated nerve stimulator that delivers current in the range of 0.1 to 0.5 mA, a disposable Teflon-coated needle, and an electrocardiogram pad. One wire electrode from the nerve stimulator is attached to the electrocardiogram pad, which is placed on the limb approximately 10 to 15 cm from the injection site. The other wire electrode is attached to the Teflon-coated needle at its hub. Once inserted into the tissue, the needle tip is electrically active. When in close proximity to the nerve, electric current stimulates the nerve, producing twitching of the muscles supplied by that nerve. For example, when the ulnar nerve is stimulated, the small and ring fingers flex. Radial nerve stimulation would cause extension of the fingers or wrist, depending upon how distal the stimulation takes place. Anesthetic solution can then be injected into the area at the stimulation site.

Paresthesia

When a nerve stimulator is not available, another useful technique to ensure that the needle tip is in close proximity to the nerve is to elicit a paresthesia. By touching and mechanically stimulating the nerve with movement of the needle tip, a tingling sensation or jolt known as a *paresthesia* is felt along the distribution of the nerve. In practice, the jolt of a true paresthesia is often difficult to distinguish from the "ouch" of a pain-sensitive structure. When blocking proximal nerves of the elbow or axilla, the paresthesia travels far enough away from the injection site that it can be distinguished from locally induced pain. Paresthesias at the level of the hand and wrist are much less reliably distinguished from pain. In both cases, the paresthesia is a subjective feeling that requires intelligent and cooperative patients who understand what they are expected to feel and who remain relaxed and attentive so that they are able to distinguish an "ouch" from a jolt. All too often, the patient in pain is willing to tell the clinician what the clinician wants to hear: The sensation that just made the patient jump was a "paresthesia." Before the procedure, a simple

explanation of what the patient should or may feel will facilitate cooperation.

It should also be pointed out that while generally reliable in showing that the needle is close to its target, some authors feel that eliciting paresthesia may theoretically increase the rate of complications due to mechanical trauma or intraneural injection.[7] [8] [9]

Injecting the Anesthetic

One strives to ensure that the anesthetic agent is not inadvertently injected into the vessels or nerve bundle. In practice, such a misplaced intravascular injection is of minimal consequence; however, small amounts of epinephrine may cause systemic symptoms, such as tachycardia or anxiety. Nerve bundle injection has the potential to cause nonspecific nerve injury. Intra-arterial injection, theoretically, is more dangerous than intravenous injection. Before injection, the syringe is aspirated to check for blood. If no blood is aspirated, the anesthetic is injected while the extremity is observed for blanching, which suggests intravascular injection. If blanching occurs, the needle should be repositioned before further injection. The onset and duration of anesthesia are greatly influenced by the proximity of the injected anesthetic to the nerve. Onset is within a few minutes if the anesthetic is in immediate proximity to the nerve. Onset takes longer or may not occur if the anesthetic must diffuse more than 2 to 3 mm, which underscores the importance of locating the nerve before injection.

More anesthetic is required if it must diffuse a large distance to the nerve. A range of suggested volumes of anesthetic is given with each nerve block description. For blocks in which a definite paresthesia is elicited or a nerve stimulator is used, the minimal recommended amount of anesthetic suffices. For many of the blocks of the smaller nerves, paresthesias are not easily elicited, and the anesthetic is placed in the general vicinity of the nerve. For these blocks, or when doubt exists about proximity of the needle to the nerve, larger amounts of anesthetic are recommended. This point cannot be emphasized strongly enough. *The difference between a successful and unsuccessful block may be merely an additional 2 mL of anesthetic.* When in doubt, err on the high side of the recommended dosage. For large nerve blocks, many clinicians opt for 2% lidocaine, rather than the 1% solution that is adequate for most ED nerve blocks.

For most blocks, the onset of anesthesia occurs in 2 to 15 minutes, depending on the distance the anesthetic must diffuse to the nerve, and the type of anesthetic used. One should wait 30 minutes before deciding that the block was unsuccessful.

Complications and Precautions

Complications may result from poor peripheral nerve block technique. General precautions include measures to minimize nerve injury, intravascular injection, and systemic toxicity.

Complications are rare in clinical practice. No actual statistics exist on the complication rate from nerve blocks performed by emergency clinicians. Generally, infrequently performed blocks, blocks that require high doses of anesthetic, and blocks close to major vascular structures are more likely to have complications. The technical ability of the clinician largely determines the outcome.

Nerve Injury

Nerve injury is rare but can occur secondary to (1) chemical irritation from the anesthetic, (2) direct trauma from the needle, or (3) ischemia due to intraneural

injection. Overall, the incidence of serious neuronal injury is rare, occurring in 1.9 per 10,000 blocks. [10] Given that placement of a nerve block is a blind procedure, complications do not necessarily represent an error in technique.

Neuritis, an inflammation of the nerve, is the most common nerve injury.[8] [9] The patient may complain of pain and varying degrees of nerve dysfunction, including paresthesia or motor or sensory deficit. Most cases are transient and resolve completely. Supportive care and close follow-up are the mainstays of treatment. Concentrated anesthetics can produce a chemical irritation of the nerve. Emergency clinicians should not exceed recommended doses and concentrations of anesthetic (Table 32-2). In general, however, lidocaine 1% or 2% or bupivacaine 0.25% or 0.5% are safe for nerve blocks performed by the emergency clinician.

Direct nerve damage can be minimized by proper needle style, positioning, and manipulation. A short beveled needle should be used and maneuvered so that the bevel is parallel to the longitudinal fibers. Sharp pain or paresthesia indicates

TABLE 32-2 -- Recommended Volumes of Anesthetic for Various Nerve Blocks

Nerve	Volume (mL)
Axillary	40–50*
Elbow	
Ulnar	5–10*
Radial	5–15*
Median	5–15*
Wrist	
Ulnar	5–15*
Radial	5–15*
Median	3–5*
Hip	
Femoral	10–30*
3-in-1	30–50*
Knee	
Tibial	5–15*
Peroneal	5–10*
Saphenous	5–10*
Ankle	
Posterior tibial	5–10*
Deep peroneal	3–5*
Saphenous, sural, and superficial peroneal	4–10*
Intercostal	5–15*
Hand	
Metacarpal and web space	2–4†
Finger	1–2†
Foot	
Metatarsal	10–15†
Web space	3–5†
Toe	2–5†

Note: For most nerve blocks performed in the emergency department, 1% lidocaine or 0.25% bupivacaine is adequate. It is also acceptable to use 2% lidocaine or 0.5% bupivacaine for larger nerves (femoral, wrist, and ankle blocks). If the stronger concentrations are used, the volume in the table should be halved.

* Anesthetic: 1% lidocaine or 0.25% bupivacaine (both *with* epinephrine).
† Anesthetic: 1% lidocaine or 0.25% bupivacaine (both *without* epinephrine).

that the needle is close to or in the nerve. Excessive needle movement should be avoided when the needle tip is contacting a nerve. If a 25-ga needle is used, physical damage to a nerve should be minimal, even when directly touched by the needle tip. A 27-ga needle is theoretically attractive but this size limits aspiration testing and may break off in tissue.

Intraneural injection may rarely cause nerve ischemia and injury. Elicitation of a paresthesia or severe pain suggests that the needle has made contact with the nerve. *When a paresthesia is elicited, the needle must be withdrawn 1 to 2 mm before the anesthetic is injected.* If the paresthesia occurs during injection, the needle must be repositioned. Most neurons are surrounded by a strong perineural sheath through which the nutrient arteries run lengthwise. Injection directly into a nerve sheath may increase the pressure within the nerve and compress the nutrient artery. Impaired blood flow results in nerve ischemia and subsequent paralysis. Intraneural injection is often heralded by severe pain, which worsens with further injection and may radiate along the course of innervation. The operator may notice difficulty depressing the syringe plunger. If the needle tip is in proper position, slow injection of the anesthetic should be minimally painful, and the anesthetic should go in without resistance.

Intravascular Injection

Intravascular injection may rarely result in both systemic and limb toxicity. Inadvertent intravascular injection produces high blood levels of the anesthetic, with resultant toxicity, as discussed earlier. Particular care must be taken when administering large amounts of anesthetic in close proximity to large blood vessels.

Intra-arterial injection of anesthetic with epinephrine may cause peripheral vasospasm that further compromises injured tissue. Intravascular anesthetic is not toxic to the limb itself, although it may produce transient blanching of the skin by displacing blood from the vascular tree. Epinephrine, however, can cause a prolonged vasospasm and subsequent ischemia if it is injected into an artery. This is especially worrisome when anesthetizing areas with little collateral circulation, such as toes, fingers, penis, and tip of the nose. Severe epinephrine-induced tissue blanching or vasospasm may be reversed with local or intravascular injection of phentolamine.

Although vasospasm associated with epinephrine in anesthetic solutions used for nerve blocks is rare, experience in related clinical situations can help guide therapy. Roberts and Krisanda used a total of 5 mg of phentolamine infused intra-arterially to reverse arm ischemia following 3 mg of epinephrine inadvertently administered into the brachial artery during cardiac resuscitation. [11] Digital ischemia from inadvertent epinephrine autoinjection has been treated by both proximal "digital block"

with 2 mg of phentolamine[12] and by local infiltration at the ischemic site with 1.5 mg of phentolamine. [13]

The route of phentolamine administration may be guided by the clinical situation. Phentolamine must reach the site of vasospasm. Arterial injection has the advantage of delivering the medication directly to the spasmed arteries. Local infiltration may be effective for ischemia of a single toe or finger. For larger areas of involvement or in instances where local infiltration is ineffective, intra-arterial injection should be used. A dose of 1.5 to 5 mg appears to be effective in most cases, [11] [12] [13] although a total of 10 mg may be used for local infiltration. Phentolamine 5 mg can be mixed with 5 to 10 mL of either normal saline or lidocaine. The small volume of the distal pulp space may limit the infiltration dose volume to 0.5 to 1.5 mL in the fingertip. Larger volumes and dosages can be used in proximal infiltrations. For intra-arterial infusion at the radial artery in the wrist or the dorsalis pedis at the ankle, dosages of 1.5 to 5 mg of phentolamine are suitable. Slow infusion or graded dosages of 1 mg may provide enough phentolamine to reverse ischemia without excessive systemic effects such as hypotension.

Hematoma

Hematoma formation may result from arterial puncture, particularly during blocks where a major blood vessel is being used as a landmark to locate the nerve (e.g., axillary or femoral artery). Direct pressure for 5 to 10 minutes usually controls further bleeding. Use of small-gauge needles (e.g., 25- to 27-ga) minimizes bleeding from the punctured artery.

Infection

Infection is rare and can be minimized by following aseptic technique and using the lowest possible concentration of epinephrine. Injection should be made through non-infected skin that has been antiseptically prepared. Injection through a site of infection may spread the infection to adjacent tissues, fascial planes, and joints. This is particularly a concern in the hand and foot. See Chapter 30 for details.

Systemic Toxicity

The incidence of systemic toxicity to local anesthetics has significantly diminished in the past 30 years. Interestingly, peripheral nerve blocks have been reported to have the highest incidence of systemic toxicity.[10] Allergic reactions account for only 1% of untoward reactions.[14] See Chapter 30 for details.

Limb Injury

Injury to the anesthetized limb can result if the patient is permitted to use the limb or is advised to use heat or cold application or to perform wound care before the anesthesia has worn off. With major nerve blocks, the patient should not be released home until sensation and function have returned. With minor blocks, the patient may be sent home but should be properly cautioned. Care must be taken to avoid ischemia-producing compression dressings (e.g., elastic bandages), because the anesthetized area may not sense impending problems.

SPECIFIC NERVE BLOCKS

Intercostal Nerve Block

Blocking the intercostal nerves produces anesthesia over an area of their cutaneous distribution (Fig. 32-1), providing considerable pain relief for patients with rib contusion or rib fractures. Rib fractures are typically quite painful, causing the patient to splint respirations to avoid excessive movement of the injured site. The resulting hypoventilation, atelectasis, and poor expectoration may cause hypoxia or lead to pneumonia. This is particularly true in patients with preexisting pulmonary disease and minimal respiratory reserve, in whom further impairment of function may cause significant respiratory compromise.

Theoretically, anesthetizing injured ribs eases pain and facilitates deep breathing and coughing. Unfortunately, there are no controlled studies comparing intercostal blocks with oral analgesics in patients with the kinds of rib fractures that are commonly managed on an outpatient basis. However,

Figure 32-1 Area of anesthesia and cutaneous distribution of the intercostal nerve. *(From Moore DC: Regional Block: A Handbook for Use in the Clinical Practice of Medicine and Surgery, 4th ed. Springfield, IL, Charles C Thomas, 1971, p 159. Reproduced with permission.)*

studies do suggest that intercostal blocks may be superior to analgesics in patients who have undergone thoracotomies. [15] [16] [17] In these studies, those receiving intercostal nerve blocks had better results on pulmonary function tests, greater oxygenation, and earlier ambulation and discharge than those receiving opioid analgesics.

There are several arguments against the routine use of intercostal nerve blocks in the ED. First, rib fractures are often tolerated well in young patients, who usually require minimal oral analgesics. Second, these blocks have a relatively short duration of action. The typical duration of action of a long-acting anesthetic with epinephrine is 8 to 12 hours. However, it should be noted that patients often receive partial analgesia for up to 3 days, a period of time that cannot be attributed to the direct action of the anesthetic on the nerve. Perhaps the anesthesia reduces muscle spasm and the associated cycle of pain.

Finally, a perceived high incidence of pneumothorax and unsuccessful blocks deter many clinicians from performing intercostal nerve blocks in the ED. The true incidence of pneumothorax following intercostal nerve blocks is very low and not significant enough to prohibit the procedure. Moore reported that in more than 10,000 individual rib blocks performed, the incidence of pneumothorax was <0.1%. [18] However, Shanti and associates reported that the incidence of pneumothorax was 1.4% for each individual intercostal nerve blocked. [19] If more than one nerve requires blockade, the incidence of pneumothorax may be greater. The suggested approach to discussing intercostal blocks is to give patients the facts with regard to duration of analgesia and possible complications and then allow them to decide on the method for themselves. Often they prefer oral analgesics initially but may return for further relief of pain, at which time they are more amenable to the nerve block.

Anatomy

Each thoracic nerve exits the spine through the intervertebral foramen, which lies midway between adjacent ribs. It immediately gives off the posterior cutaneous branch, which supplies the skin and muscles of the paraspinal area. The intercostal nerve then continues around the chest wall and gives off the lateral cutaneous branches at the midaxillary line. These branches are the sensory supply to the anterior and posterior lateral chest wall.

The intercostal nerve runs with the vein and artery in the subcostal groove (Fig. 32-2). Posteriorly, the nerve is separated from the pleura and the lungs by the thin intercostal fascia. Particular care must be taken to avoid puncture of the thin fascia and underlying lung when blocking the nerve in the posterior aspect of the back. Fortunately, most rib fractures occur in the anterior or lateral portion of the ribs and can be blocked in the posterior axillary line, where the internal intercostal muscle lies between the nerve and the lung's pleura and provides a buffer for minor errors in needle placement.

Technique

For adequate analgesia of most rib fractures, the lateral cutaneous branch needs to be anesthetized. Blocks are usually performed between the posterior axillary and midaxillary line at a point proximal to the origin of this branch. Explanation of the procedure, its benefits, and its risks, including potential pneumothorax, systemic toxicity, and ineffective block, should be done before proceeding.

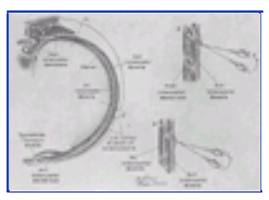

Figure 32-2 Cross section of the chest wall, demonstrating branches of the intercostal nerve, as well as sections of the chest wall at points between which the intercostal block is usually performed: at the posterior angle of the ribs (*A*) and at the midaxillary line (*B*). A block situated at the posterior axillary line is common (see text). *(From Moore DC: Regional Block: A Handbook for Use in the Clinical Practice of Medicine and Surgery, 4th ed. Springfield, IL, Charles C Thomas, 1971, p 146. Reproduced with permission.)*

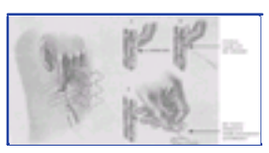

Figure 32-3 Method of retracting skin and the proper needle insertion site for intercostal block. See text for details. *(From Moore DC: Regional Block: A Handbook for Use in the Clinical Practice of Medicine and Surgery, 4th ed. Springfield, IL, Charles C Thomas, 1971, p 153. Reproduced with permission.)*

A 10-mL syringe with a 3.75-cm, 25-ga needle is used. The rib is palpated, and the area is prepared in the usual aseptic manner. The index finger of the non-dominant hand is used to retract the skin at the lower edge of the rib cephalad and up over the rib (Fig. 32-3). With the syringe in the opposite hand, the skin is punctured at the tip of the finger that is retracting the skin. The syringe is held at an 80° angle with the needle pointing cephalad. The hand holding the syringe rests on the chest wall for stability. In this position, the depth of needle penetration is well controlled. The needle is slowly advanced until it comes to rest on the lower

border of the rib.

At this point, the skin retraction is released. The skin returning to its natural position moves the needle shaft perpendicular to the chest wall and the needle tip to the inferior margin of the rib. The syringe is shifted from the dominant hand to the index and thumb of the non-dominant hand. The middle finger of the same hand rests against the shaft of the needle and, by exerting gentle pressure on the shaft, walks the needle off the lower edge of the rib. Again, the palm of the hand is planted firmly on the chest wall to ensure control of the needle. With the help of the dominant hand, the needle is slowly advanced 3 mm. The needle is aspirated, and then 2 to 5 mL of anesthetic are injected while the needle is carefully moved in and out 1 mm, which ensures that the compartment containing the nerve between the internal and external intercostal muscles is penetrated. This may also serve to minimize intravascular injections. The procedure is repeated ideally on the *two ribs above and below* to ensure that the overlapping innervation from adjacent nerves is blocked.

Although the procedure just discussed seems extensive, it takes 1 to 2 minutes to perform once the operator is familiar with the technique, and 3 to 5 intercostals can be blocked in 10 minutes total time.

Precautions

The needle must be initially placed at the lower edge of the rib. If it contacts the rib above this point, it cannot be walked off the lower edge of the rib at the proper angle. If it is inserted too low, over the intercostal space, it may be advanced too deep through the pleura and into the lung before the operator realizes the misplacement. Before inserting the needle, the depth of the bone should be estimated. If the bone is not encountered by this depth, needle position should be reevaluated. Even after the needle has been properly walked off the edge of the rib, care must be taken to avoid puncture of the pleura and lung. The depth of the intercostal groove in which the nerve runs is 0.6 cm posteriorly, diminishing to 0.4 cm anteriorly.

Because the incidence of pneumothorax is low, a chest radiograph is not routinely required after this procedure. The asymptomatic patient is observed for 15 to 30 minutes and instructed to return if problems arise. If the patient has symptoms of pneumothorax (e.g., cough, a change in the nature of the pleuritic pain, or shortness of breath), he or she should have a chest film taken before discharge.

If the clinician inadvertently causes a pneumothorax, treatment depends on the size. Many pneumothoraces are small. Those <20% may be observed for 6 hours. [20] During this time the patient may be administered high concentration oxygen to help decrease the size of the pneumothorax. If the pneumothorax does not grow in size, the patient may be released home with arrangements for follow-up. Needle or catheter aspiration of larger pneumothoraces may be all that is needed. A chest tube is necessary if this method fails.

Nerve Blocks of the Upper Extremity

The upper extremity is supplied by the brachial plexus. Its branches—primarily the median, radial, ulnar, and musculocutaneous nerves—can be blocked at the axilla, elbow, wrist, hand, or fingers. Nerve blocks at the axilla and elbow are seldom used in the ED. Nerve blocks of the wrist are performed occasionally before painful procedures or for repair of injuries to the hand. Metacarpal and digital blocks are used frequently to treat fractures, lacerations, and infections of the fingers.

Nerve Blocks at the Elbow

The median, ulnar, and radial nerves can be blocked at the elbow, providing anesthesia to the distal forearm and hand (Fig. 32-4). For most injuries extensive enough to require nerve block at the elbow, all three nerves must be blocked for successful anesthesia because of the variable and overlapping innervation of the forearm. Furthermore, injuries to the proximal and middle forearm may require additional circumferential subcutaneous (SQ) field blocks of the lateral, medial, and posterior cutaneous nerves.

Ulnar nerve: Anatomy and technique.

The ulnar nerve can be palpated in the ulnar groove on the posteromedial aspect of the elbow between the olecranon and medial condyle of the humerus (Fig. 32-5 and Fig. 32-6). This nerve supplies the innervation to the small finger and ulnar half of the ring finger and the ulnar aspect of the hand (see Fig. 32-4).

With the elbow flexed, the nerve is palpated in the groove. A 3.75-cm, 25-ga needle is inserted 1 to 2 cm *proximal to the groove* and directed toward the groove parallel to the course of the nerve. The needle tip comes to rest close to the proximal end of the groove. Care is taken to avoid blocking the nerve in the groove, where it is prone to damage. For similar reasons, paresthesia may be elicited but is not vigorously sought. Although an elbow ulnar nerve block is common, many physicians prefer to block the ulnar nerve at the wrist to limit the risk of injury. Once the needle tip is properly positioned, 5 to 10 mL of anesthetic are deposited. If a nerve stimulator is used, flexion of the small and ring fingers signals proximity to the nerve.

Radial nerve: Anatomy and technique.

The radial nerve and sensory branch of the musculocutaneous nerve run together in the sulcus between the biceps and the brachioradialis muscles on the anterolateral aspect of the elbow (Fig. 32-7). The block produces anesthesia to the lateral dorsum of the hand and the lateral aspect of the forearm (see Fig. 32-4).

The sulcus in which the nerve runs is palpated between the sharp border of the biceps muscle and the medial border of the brachioradialis muscle in the *antecubital fossa* just proximal to the skin crease of the elbow. Palpation is greatly facilitated by having the patient, with the elbow flexed at 90°, contract and relax these muscles isometrically so that their borders are better defined. The skin is punctured with a 3.75-cm, 25-ga needle halfway between the muscles, or 1 cm lateral to the biceps tendon, at a point 1 cm proximal to the antecubital crease. After proper needle insertion, 5 to 15 mL of anesthetic should be injected at this depth. Because of poor landmarks and the depth of the radial nerve at the elbow, the nerve stimulator greatly facilitates the search for the nerve, which, when stimulated, produces extension of the fingers and wrist.

Median nerve: Anatomy and technique.

The median nerve runs medial to the brachial artery in the anteromedial aspect of the elbow (Fig. 32-8 and Fig. 32-9). The nerve block

Figure 32-4 Cutaneous nerve supply of the right upper limb. *(From Bridenbaugh LD: The upper extremity: Somatic blockade. In Cousins M, Bridenbaugh PO [eds]: Neural Blockade in Clinical Anesthesia and Management of Pain, 2nd ed. Philadelphia, JB Lippincott, 1988, p 412. Reproduced with permission.)*

anesthetizes the index, middle, and radial portion of the ring fingers and the palmar aspect of the thumb and lateral palm (see Fig. 32-4).

The brachial artery is palpated in the flexed arm at the elbow just proximal to the antecubital crease and medial to the prominent biceps tendon. Once the anatomy is defined and marked in the flexed arm, the arm is extended to 30°. A 3.75-cm, 25-ga needle is inserted slightly medial to the artery and perpendicular to the skin to the depth of the artery, about 2 to 3 cm, and 5 to 15 mL of anesthetic are injected. Again, the nerve stimulator facilitates the process and produces flexion of the wrist and

index finger. Most commonly, median nerve blocks occur at the wrist.

Nerve Blocks at the Wrist

The median, ulnar, and radial nerves may be blocked at the wrist, providing anesthesia to the hand. Most extensive injuries and procedures for which a wrist nerve block could be used can also be managed using local infiltration or a digital block. Compared with direct infiltration, wrist block anesthesia can have a slow and unreliable onset and can require more time to take effect if all three nerves are to be blocked. There are several circumstances, however, in which wrist nerve blocks are more advantageous than other types of blocks or anesthesia.

Diffuse lesions that can be difficult to anesthetize with local infiltration can easily be anesthetized with a wrist block. Deep abrasions with embedded debris, commonly the result of "road burn" from bike and motorcycle crashes, can be cleaned and debrided painlessly after a nerve block at the wrist. Hydrofluoric acid burns, which require treatment with numerous SQ injections of calcium gluconate, are better handled after a wrist nerve block. Wrist blocks are also advantageous in the severely swollen and contused hand, where small amounts of anesthetic injected locally may increase the tissue pressure and produce further pain. Deep lacerations of the palm are very painful to anesthetize with local infiltration and will also benefit from a wrist block. Additionally burns of the hand lend themselves to nerve blocks prior to debridement.

Compared with nerves in the axilla and elbow, the nerves in the wrist are more easily located anatomically and can be blocked more reliably. All three nerves lie in the volar aspect of the wrist near easily palpated tendons. A nerve stimulator is not necessary but may be useful in locating the nerves, particularly when one is learning how to perform these blocks.

The anatomy and technique for blocking each nerve follow. Note that the median nerve lies in the midline and deep to the fascia, and the ulnar and radial nerves lie on their respective sides and have branches that wrap around dorsally. Blocking all three nerves at the wrist requires a block that, when viewed end-on, roughly resembles a horseshoe straddling a horseshoe stake (see Fig. 32-5).

Median nerve: Anatomy and technique.

In the wrist, the median nerve lies just below the palmaris longus tendon or slightly radial to it between the palmaris longus and the flexor carpi radialis tendons (see Fig. 32-5 and Fig. 32-6). Both tendons are easily palpated, but the palmaris longus may be absent in up to 20% of patients, in which case the nerve is found about 1 cm in the ulnar direction from the flexor carpi radialis tendon. The nerve lies deep to the fascia of the flexor retinaculum, but at a depth of 1 cm or less from the skin. The superficial position of the median nerve at the wrist is emphasized, since a major cause of failure of this block is too deep instillation of the anesthetic.

The palmaris longus tendon is located by having the patient oppose the thumb and small finger with the wrist flexed against resistance. The site of the nerve block is

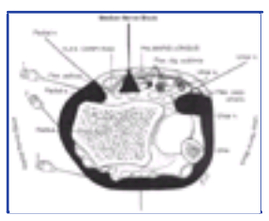

Figure 32-5 Cross section of the wrist looking cephalad. The arrow points to the (covered) median nerve. Shaded triangle depicts the area infiltrated with anesthetic. Note the relatively superficial position of the median nerve, just radial to the palmaris longus. *(Redrawn from Adriani J: Labat's Regional Anesthesia: Techniques and Clinical Applications. 3rd ed. Philadelphia, WB Saunders, 1967, p 234. Reproduced with permission.)*

selected on the radial border of the palmaris longus tendon just proximal to the proximal wrist crease. A 3.75-cm, 25-ga needle is inserted perpendicularly and advanced slowly until a slight "pop" is felt as the needle penetrates the retinaculum and a paresthesia is produced. If no paresthesia ensues, it may be elicited in a more ulnar direction under the *palmaris longus* tendon. If a paresthesia is still not elicited, 3 to 5 mL of anesthetic are deposited in the proximity of the nerve at a depth of 1 cm under the tendon. Although the nerve is surprisingly close to the skin, it is better to err slightly on the deep side of the retinaculum and continue depositing anesthetic

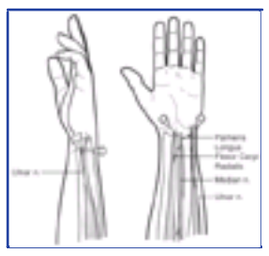

Figure 32-6 Landmarks and anatomy of the median and ulnar nerve block. The median nerve is more superficial than often expected. It lies to the radial side of the palmaris tendon.

as the needle is withdrawn, because the retinaculum is an effective barrier to a successful nerve block from a superficially injected anesthetic.

Radial nerve: Anatomy and technique.

The radial nerve follows the radial artery into the wrist but gives off branches proximal to the wrist. These branches wrap around the wrist and fan out to supply the dorsal radial aspect of the hand (Fig. 32-10).

Nerve block requires an injection in close proximity to the artery and a field block that extends around the dorsal aspect of the wrist. A 3.75-cm, 25-ga needle is inserted immediately lateral to the palpable artery at the level of the proximal palmar crease. At the depth of the artery 2 to 5 mL of anesthetic are injected. Another 5 to 6 mL are distributed in an SQ field block from the initial point of injection to the dorsal midline. The needle must be withdrawn and repositioned to complete the block. The discomfort of numerous needle sticks is decreased if the needle is repositioned to a site that has been anesthetized previously.

Ulnar nerve: Anatomy and technique.

The ulnar nerve follows the ulnar artery into the wrist, where they both lie deep to the *flexor carpi ulnaris* tendon (see Fig. 32-5 and Fig. 32-6). The *flexor carpi ulnaris* tendon is easily palpated just proximal to the prominent pisiform bone by having the patient flex the wrist against resistance. At the level of the proximal palmar crease, the artery and the nerve lie just off the radial border of the *flexor carpi ulnaris* tendon; however, the nerve lies between the tendon and the artery and deep to the artery, making it difficult to approach the nerve from the volar aspect of the wrist without involving the artery.

Nerve block of the ulnar nerve can be carried out by two different approaches: lateral and volar (see Fig. 32-6); the lateral approach may be easier because of the reason stated previously. For the lateral approach, a 3.75-cm, 25-ga needle is inserted on the ulnar aspect of the wrist at the proximal palmar crease and is directed horizontally under the *flexor carpi ulnaris* for a distance of 1.0 to 1.5 cm. At this point 3 to 5 mL

Figure 32-7 Ulnar nerve block at the elbow. *A,* Positioning patient for ulnar nerve block at the elbow. The patient is supine, the elbow flexed, and the medial epicondyle and ulnar groove are exposed. *B,* The ulnar nerve passes between the olecranon (*) and medial epicondyle (•) of the humerus. Avoid injecting large amounts of anesthesia directly into the ulnar groove. Instead, place anesthetic proximal to the groove. Alternatively, the ulnar nerve may be blocked at the wrist.

of anesthetic are deposited. The needle is directed toward the ulnar bone at a point deep to the *flexor carpi ulnaris* tendon, and the anesthetic can be inserted as the needle is withdrawn.

Like the radial nerve, cutaneous nerves branch off the ulnar nerve, wrap around the wrist, and supply the dorsum of the hand. These are blocked with a 5- to 6-mL SQ band of anesthetic from the lateral border of the *flexor carpi ulnaris*

Figure 32-8 Cross section of the elbow, demonstrating (1) the median nerve, (2) the radial nerve, and (3) the ulnar nerve. *(From Adriani J: Labat's Regional Anesthesia: Techniques and Clinical Applications. 3rd ed. Philadelphia, WB Saunders, 1967, p 234. Reproduced with permission.)*

tendon to the dorsal midline (see Fig. 32-6). Another advantage of the lateral approach is that the dorsal branches can be blocked from the same injection site.

Nerve Blocks of the Digits

The digital nerve block is one of the most useful and most used blocks in the ED. Indications for choosing it include repair of finger lacerations and amputations, reduction of fractures and dislocations, drainage of infections, removal of fingernails, and relief of pain (e.g., from a fracture or burn). The digital block is superior to local infiltration in most circumstances. Wound infiltration may be a problem in the finger that has tight skin and can accept only a limited volume of anesthetic. Administration of anesthetic into this restricted space increases the tissue pressure, impairing capillary blood flow and causing pain. *Fibrous septa* in the fingertip also restrict the space available for the injected substance and even limit the spread of small amounts of anesthetic.

Anatomy.

Each finger is supplied by two sets of nerves. These nerves, the dorsal and palmar digital nerves, run alongside the phalanx at the 2 and 10 o'clock positions and the 4 and 8 o'clock positions, respectively (Fig. 32-11*A–D* Fig. 32-11*A–D*).

The principal nerves supplying the finger are the palmar digital nerves, also called the *common digital nerves*. These nerves originate from the deep volar branches of the ulnar and median nerves, where they branch in the wrist. The palmar digital nerves follow the artery along the volar lateral aspects of the bone, one on each side, and supply sensation to the volar skin and interphalangeal joints of all five digits. *In the middle three fingers, these nerves also supply the dorsal distal aspect of the finger, including the fingertip and nailbed.* While many clinicians routinely block both sets of digital nerves, only the volar (palmar) branches must be blocked to obtain adequate anesthesia of the middle three fingers distal to the distal interphalangeal joint.

Figure 32-9 Anatomy for nerve blocks at the elbow and wrist. Black circles on skin indicate site of puncture. *(From Adriani J: Labat's Regional Anesthesia: Techniques and Clinical Applications, 3rd ed. Philadelphia, WB Saunders, 1967, p 226. Reproduced with permission.)*

The dorsal digital nerves originate from the radial and ulnar nerves, which wrap around to the dorsum of the hand. They supply the nailbeds of the thumb and small finger and the dorsal aspect of all five digits up to the distal interphalangeal joints. Unlike the middle three fingers, which require blocking of only the two volar (palmar) digital nerves, all four nerves are usually blocked in the thumb and fifth finger, especially to obtain anesthesia of the fingertip and nailbed (Fig. 32-12*A* and *B*).

Technique.

The digital nerves can be blocked anywhere in their course, including sites in the finger, in the web space between the fingers, and between the metacarpals in the hand. There are a variety of approaches to the nerves, including the dorsal and palmar approaches and the web space approach. Each has its merits. The technique is similar at each level.

The dorsal approach has the advantage of thinner, less pain-sensitive skin compared with volar approaches. The hand can be held firmly and flat on the table, preventing withdrawal. The disadvantage is that two injections are needed from this approach to block both volar digital nerves.

The dorsal approach can be used in the dorsum of the hand at the metacarpals, just proximal to the finger webs at the proximal end of the proximal phalanx, or distal to the web. Clinical situations may dictate which site to use; however,

Figure 32-10 Distribution, anatomy, and blockade of the radial nerve at the wrist.

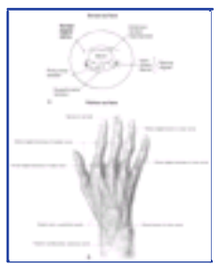

Figure 32-11a *A,* Schematic cross section of the phalanx, demonstrating the relationship of the nerves to the bone. If the anatomy is examined (*B* and *C*), it is obvious that in order to perform a digital block of the thumb and fifth finger, all four digital nerves (two volar, two palmar) must be blocked. Since almost the entire second, third, and fourth fingers are supplied by only the palmar branch (note that each palmar nerve curves around to the dorsum from the palmar surface), only the palmar nerves must be blocked to obtain anesthesia for all but the skin of the proximal dorsal digit. The exception is the ulnar side of the fourth finger, which receives some of its distal dorsal innervation from the dorsal nerve. *D,* On the palmar aspect, the digital nerves are almost adjacent to the flexor tendon, a position that is more palmar than is usually appreciated. *(From Grant's Atlas of Anatomy, 9th ed. Baltimore, Williams & Wilkins, 1978. Reproduced with permission.)*

given equal circumstances, the preferred site is just proximal to the finger web. Here the nerve's location is more consistent than in the hand, and there is more soft tissue space to accommodate the volume of injected substance than there is in the distal finger. Digital block at the web is more efficacious in onset and requires less time to anesthesia than metacarpal block done proximal to the metacarpophalangeal joint. [21]

Digital block requires only aseptic injection technique after the skin is prepared with alcohol or povidone-iodine. Sterile gloves and drapes are not necessary, although examination gloves are recommended.

The clinician must first decide whether two or four digital nerves require blocking (see earlier discussion). Anesthesia is deposited at the positions of the appropriate digital nerves (2, 4, 8, and 10 o'clock in relationship to the bone), using a 3.75-cm, 25- or 27-ga needle (see Fig. 32-11*A*). The block is performed from the dorsal surface, where the skin is thinner, easier to penetrate, and less sensitive than that of the volar surface. The needle insertion site is at the web space, just distal to the knuckle at the lateral edge of the bone (Fig. 32-12*C*). Once the needle tip is subdermal, it usually contacts the bone. A wheal of 0.5 to 1 mL of anesthetic

Figure 32-11b

without epinephrine is injected at this level. This serves to block the dorsal digital nerve and provide anesthesia at the injection site. The needle is then passed lateral to the bone and toward the palmar surface until the palmar skin starts to tent slightly. The needle is withdrawn 1 mm and aspirated to check for an inadvertent IV position, and 0.5 to 1.5 mL of anesthetic are injected. This procedure is repeated on the opposite side of the finger. The result is a circumferential band of anesthesia at the base of the finger. *Firm massage of the injected area* for 15 to 30 seconds enhances diffusion of the anesthetic through the tissue to the nerves.

A variation of the dorsal approach is performed as follows: After injecting one side of the finger, the needle is redirected (without removing it) across the top of the digit to anesthetize the skin on the opposite side (Fig. 32-12*D*). The needle is then withdrawn and inserted at the site that was anesthetized, and the block is continued as described earlier. The presumed advantage of this method is that it minimizes the pain of the second skin puncture. This procedure requires that the needle be placed across the dorsal aspect of the finger, allowing the possible disadvantage of extensor tendon puncture and trauma.

The *palmar* and *web space* approaches can be used most successfully for the middle three fingers where only a single puncture is required to block both volar nerves. This technique takes advantage of the anatomic fact that only the volar digital nerves must be blocked to obtain anesthesia of the total finger (except the proximal dorsal surface). If the thumb or fifth finger must be anesthetized, the dorsal branches must also be blocked to obtain anesthesia of the fingertip and fingernail area.

The palmar approach requires an injection in the palm, which is slightly more painful than an injection in the dorsal skin. The needle is inserted directly over the center of the metacarpal head, and anesthetic is slowly injected while the needle is advanced to the bone. At this point the needle is withdrawn 3 to 4 mm and angled slightly to the left and right of center to block both digital nerves without withdrawing the

Figure 32-12a *A,* Each finger has four digital nerves: two palmar and two dorsal nerves. The palmar nerves travel in a line connecting the top of the skin creases made by flexing the proximal interphalangeal and distal interphalangeal joints *(black line)*. The nerves are more palmar than often appreciated, and are almost adjacent to the flexor tendon, so injecting the true lateral portion of the finger may miss the nerve. If the anesthesia needle is inserted at the tip of the skin creases (see probe) the nerve will be blocked. *B,* When performing a digital nerve block on the thumb, all four digital nerves must be blocked. As in the other fingers, the palmar nerve travels in a line made by connecting the top of the skin creases produced by flexing the digit *(black line)*. The anesthetizing needle (see probe) must be placed almost adjacent to the flexor tendon to block the nerve. *C,* Sites of digital nerve blocks at the base of the finger. *D,* Technique of anesthetizing the second injection site. *(From Adriani J: Labat's Regional Anesthesia: Techniques and Clinical Applications, 3rd ed. Philadelphia, WB Saunders, 1967, p 445. Reproduced with permission.)*

needle (Fig. 32-13 and Fig. 32-14). To be successful, a palpable soft tissue fullness should be appreciated. The technique requires 4 to 5 mL of anesthetic.

A variation of this is particularly useful in fingertip injuries in toddlers. The finger is pinched side-to-side just distal to the proximal finger crease. This tents the skin at the finger crease, which is injected subcutaneously with 0.5 to 1 mL of anesthetic. This single injection diffuses to the volar nerves and provides anesthesia to many fingertip injuries common in toddlers. With the web space approach, the patient's hand is held by the clinician in such a way that the clinician's thumb and index finger are over the dorsal and volar metacarpal head, respectively. The clinician's third finger is used to separate the patient's fingers to expose the web space, while the fourth and fifth fingers support the finger being anesthetized (Fig. 32-15). The needle is inserted into the web space, 1 mL of anesthetic is injected, and the needle is slowly advanced until it is next to the lateral volar surface of the metacarpal head. Anesthetic is injected, and the needle is advanced slowly past the midline of the metacarpal head to the opposite digital nerve (Fig. 32-16). The operator's index finger is used to palpate a fullness as the anesthetic is injected. By redirecting the needle to the adjacent finger without withdrawing it, both fingers may be blocked with a single puncture.

Although epinephrine-containing solutions are used routinely in digital blocks of the toes by podiatrists, without morbidity, when performing a digital block, the authors advise use of anesthetics that do *not contain epinephrine*. The injection should go in smoothly, without resistance of the syringe plunger. Although the finger is forgiving of transient pressure from excessive anesthetic, if the injection site becomes excessively tense digital perfusion may be compromised. This concern is heightened when epinephrine-containing solutions are used. If epinephrine-containing solutions are inadvertently used for a digital block in otherwise healthy individuals without peripheral vascular disease, it is unlikely that serious ischemic injury will occur. Significant vasoconstriction generally lasts less than 60 minutes, within the time interval for which an ischemic tourniquet can safely be used in the same area. [22] However, if the entire digit remains blanched for more than 15 minutes, it is prudent to reverse the a-agonism of epinephrine with phentolamine. Using a pulse oximeter on the affected finger may help quantitate the degree of ischemia.

Figure 32-12b

Figure 32-13 Palmar approach to the metacarpal head. After needle puncture in the midline, the needle is directed slightly to the right and left, and anesthetic is deposited along the course of both volar digital nerves. The needle is not withdrawn until both nerves are blocked. This technique blocks only the palmar nerves.

Onset of anesthesia occurs in 1 to 15 minutes and lasts for 20 minutes to 6 hours, depending on the anesthetic agent used.

Alternative techniques

Jet injection technique.

Jet injection for digital nerve block can be used effectively and is less painful than standard needle techniques. [23] The technique described by Ellis uses 0.15 mL of 1% lidocaine delivered by a jet injector at 2600 psi. Three injections are given to the lateral aspect of the proximal phalanx: the first, midway between the volar and dorsal surfaces; the second, dorsal to this; the third, volar. A combined total of 0.45 mL is administered to each side of the phalanx at the 2, 3, and 4 o'clock positions and the 8, 9, and 10 o'clock positions in relationship to the bone.

The potential disadvantages of jet injection include lacerations that may occur with tangential injection. Holding the injector perpendicular to the skin avoids this problem. Thick skin associated with older age, manual labor, and male gender may require larger volumes of anesthetic.

The advantages of this technique are less pain of injection and avoidance of "needle phobia," particularly in children.

Transthecal digital block technique.

The transthecal block is performed by a single injection into the flexor tendon sheath, which produces rapid and complete finger anesthesia. It was first described by Chiu in 1990 after noting rapid finger anesthesia following injection treatment of a trigger finger. [24]

Figure 32-14 The palmar digital nerves (*N*) are adjacent to the head of the metacarpal (*MC*) in the palm. For a metacarpal head block the anesthetizing needle punctures the palm in the middle of the MC (see probe), and anesthetic is deposited both laterally and medially, blocking both nerves with a single puncture. Injection in this area is usually more painful than injecting in the web space, but it is almost foolproof for obtaining anesthesia.

Cadaver studies suggest that injected fluid diffuses out of the tendon sheath and around the phalanx and all four digital nerves.

The flexor tendon is palpated in the palm proximal to the metacarpal phalangeal joint. A 25-ga needle is attached to a 3-mL syringe and introduced at a 45° angle as it is advanced to the sheath/tendon (Fig. 32-17). Slight pressure is applied to the syringe plunger. If the sheath has been entered, the anesthetic should flow freely. If it does not, it is presumed that the tendon has been entered, and the syringe is withdrawn slowly

Figure 32-15 The palmer web space metacarpal head block allows two of the three inner fingers to be anesthetized with a single needle puncture. The clinician's index finger palpates the patient's metacarpal head on the patient's palm while the injured finger is supported and the web space is exposed. The index finger can feel the tissue distention by the anesthetic, but care must be taken to avoid passing the needle through the skin and puncturing the operator's finger. About 3 to 5 mL of anesthetic is deposited. To anesthetize the adjacent finger the needle is partly withdrawn and redirected to the other metacarpal head. Bending the needle to 30° allows easier access to the proper position without the syringe getting in the way.

Figure 32-16 Nerve block of the third digit. After injection of anesthetic into the web space skin, the needle is advanced to the digital nerve, where it passes just lateral to the volar metacarpal head. Anesthetic is injected, and the needle is advanced to the opposite digital nerve. This procedure requires about 3 to 5 mL of anesthetic. If the index finger also must be blocked, the needle is redirected without withdrawal from the skin. Thus, both fingers are blocked with a single needle puncture.

while constantly applying slight pressure. A total of 2 mL of anesthetic solution is injected. Smaller volumes are used in children. After the needle is removed, pressure is applied over the tendon proximally to facilitate distal spread. Average onset of anesthesia is 3 minutes. [25]

The advantage of this technique is the single injection. However, Hill and colleagues found the technique to be "clinically equal" to traditional digital blocks. [26] Other authors have stated that traditional digital block was easier to administer and produced less pain during and after injection. [27] Theoretically, the technique may increase the risk of injury to the tendon.

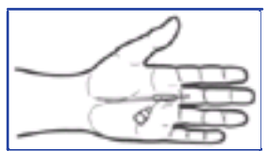

Figure 32-17 Transthecal block. The flexor tendon sheath is entered volarly just proximal to the metacarpophalangeal joint. With the use of a 25-ga needle on a 3-mL syringe the fluid should flow easily. Inject 2 mL of anesthetic and apply proximal tendon sheath pressure.

Complications and precautions.

The small size of the digital arteries and nerves makes intravascular or intraneural injection less likely. Inadvertent intravascular injection may cause digit ischemia from vasospasm or displacement of blood out of the capillary bed by the anesthetic. Blanching of the finger as the anesthetic is injected suggests intravascular injection. If this is observed, the injection should be discontinued. Usually the ischemia is transient and self-resolving, and serious complications are rare. Massage or topical application of nitroglycerin paste may be attempted if ischemia persists. Although the incidence of vasospasm and resultant ischemia is rare and primarily occurs in patients with underlying vascular disease, [28] an anesthetic agent without epinephrine is commonly recommended. As noted earlier, if one mistakenly chooses an epinephrine-containing solution and vasospasm develops, the ischemia should be relieved with local infiltration of phentolamine.

Commonly the digital nerve is lacerated or damaged by the initial injury to the finger. Careful evaluation using 2-point discrimination should be performed to determine the extent of nerve injury before nerve block. Even if nerve injury is questionable, it should be documented in the chart, and the *patient should be advised of the injury before the nerve block*. Careful evaluation and patient education should prevent misconceptions as to the cause of the nerve injury. Although most isolated digital nerve injuries are not debilitating, they heal slowly and can be annoying to the patient. Digital nerve injury proximal to the distal interphalangeal joint may be repaired surgically. Nerve repair may be immediate when specialty consultation is available or delayed following initial simple closure.

Nerve Blocks of the Lower Extremity

Metatarsal and digital blocks in the foot are used frequently to treat ingrown toenails, fractures, and lacerations of the forefoot and toes. However, similar to the upper extremities, *proximal* lower extremity blocks are often overlooked as an anesthetic choice. This is unfortunate, since treatment of many conditions will benefit from these blocks. For example, femoral nerve blocks can provide excellent analgesia for femoral shaft fractures, and nerve blocks at the ankle are an excellent method to obtain anesthesia for the treatment of foot lacerations and to perform otherwise painful procedures on the foot. The lower extremity is supplied by five nerves, the branches of which can be blocked at the hip, knee, ankle, foot, or toes.

Nerve Blocks of the Hip

Nerve blocks of the femoral, obturator, lateral femoral cutaneous, posterior cutaneous, and sciatic nerves at the hip provide anesthesia and paralysis to the skin and muscles of the leg, respectively (Fig. 32-18). These nerves are not contained in a single fascial sheath (as in the upper extremity); therefore local anesthetic injections of both the sciatic and femoral nerves are required for complete proximal lower extremity nerve blocks. Posteriorly, the posterior cutaneous and sciatic nerves can be blocked together with a single injection. Anteriorly, the femoral, obturator, and lateral femoral cutaneous nerves can be blocked by three separate injections or by a single injection using the "3-in-1" technique described by Winnie and colleagues. [29] In this technique a large amount of anesthetic is injected into the femoral nerve sheath and permitted to track into the pelvis to the point at which the anterior nerves run in a common sheath. [29]

Femoral nerve blocks alone may be the analgesia of choice for femoral shaft fractures. Studies supporting the femoral block in the treatment of femoral shaft fractures date back to 1940 and continue to appear. [30] [31] [32] In a study by McGlone and colleagues, patients preferred femoral block to opioid analgesia; however, this means of analgesia has yet to be adopted as routine treatment for femoral shaft fractures. [31] The procedure requires only femoral nerve blockade and does not rely on the performance of a successful 3-in-1 block.

Anatomy.

Anteriorly, the femoral, obturator, and lateral femoral cutaneous nerves arise from the lumbar plexus and travel a short distance in a common nerve sheath (Fig. 32-19). In the pelvis, the lateral femoral cutaneous and obturator nerves exit the sheath. The lateral femoral cutaneous nerve supplies the sensory innervation to the lateral thigh. The obturator nerve supplies the sensory innervation to the anterior medial thigh and the motor supply to the adductor muscles. The femoral nerve continues as the saphenous nerve, which supplies the sensory innervation to the medial calf and ankle.

Posteriorly, the sciatic and posterior cutaneous nerves arise from the lumbar and sacral plexuses and exit the pelvis together in the sciatic notch. The posterior cutaneous nerve supplies sensory innervation to the posterior thigh and buttocks. The sciatic nerve does not supply the thigh but at the knee divides into the tibial and peroneal nerves and supplies much of the calf and foot. The tibial nerve supplies the muscles of the calf and sensation to the plantar surface of the foot. The peroneal nerve supplies sensation to the lateral aspect of the calf and dorsal and plantar aspects of the foot. Both the tibial and peroneal nerves give off branches that form the sural nerve, which supplies sensation to the lateral aspect of the foot (Fig. 32-20*A* and *B*).

Technique for femoral nerve block.

With the patient in the supine position, the skin is prepared in an aseptic fashion. The femoral artery is palpated 1 to 2 cm below the inguinal ligament (see Fig. 32-19), and a wheal of anesthesia is raised immediately lateral to the artery. With the nondominant hand placed firmly on the artery, a 1.25-cm, 22-ga needle, attached to an extension tube setup and a 20-mL syringe, is inserted adjacent to the artery at a 90° angle to the skin and underlying vessels. The needle is advanced until a paresthesia is elicited or the needle pulsates laterally, indicating a position immediately adjacent to the artery. If a paresthesia is felt or the needle is assumed to be in the immediate vicinity of the nerve, 10 to 20 mL of anesthetic are injected. If a paresthesia is not elicited, 10 to 20 mL of anesthetic can be injected in a fan-like pattern lateral to the artery in a blind attempt to anesthetize the femoral nerve. *Given the proximity of this nerve to the femoral artery and vein, aspiration before injection is essential to reduce the risk of intravascular injection.* The onset of anesthesia should occur in 15 to 30 minutes and should last for 3 to 8 hours.

Technique for the 3-in-1 block (also called the inguinal perivascular block).

The 3-in-1 technique differs from the femoral nerve block in that it requires a larger amount of anesthetic solution and compression distal to the injection site. In the thigh, the femoral nerve is sandwiched between the *quadratus lumborum* and *iliopsoas* muscles, whose fasciae are continuous with a nerve sheath that contains all three nerves higher in the pelvis (see Fig. 32-19). A large amount of anesthetic properly placed next to the femoral nerve tracks

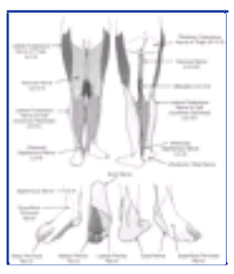

Figure 32-18 Cutaneous distribution of the nerves to the lower extremity. *(From Bridenbaugh PO: The lower extremity: Somatic blockade. In Cousins M, Bridenbaugh PO [eds]: Neural Blockade in Clinical Anesthesia and Management of Pain. 2nd ed. Philadelphia, JB Lippincott, 1988, p 425. Reproduced with permission.)*

back along the sheath and anesthetizes all three nerves (see Fig. 32-20*A*).

The 3-in-1 block requires precise injection of the anesthesia into the nerve sheath. In the 3-in-1 block, once the needle is in the correct position, the fingers palpating the artery are removed and placed gently but firmly distal to the needle while 20 to 30 mL of anesthetic are injected (see Fig. 32-20*B*). Distal pressure should be maintained for 5 minutes while the anesthetic diffuses proximally. It usually takes about 30 minutes to achieve full sensory effect of the 3-in-1 block. [33]

A nerve stimulator facilitates the search for the nerve and placement of the needle tip in the fascial sheath. A thick insulating fascia covers the nerve. When the needle punctures this sheath, the nerve is stimulated at currents of 0.5 mA or less.

Techniques for sciatic nerve block.

Labat's classic technique is performed with the patient in the lateral (Sims) position with the extremity to be blocked up, flexed, and resting on the lower dependent extremity. A line is constructed from the greater trochanter to the posterior superior iliac spine. The line is bisected and a perpendicular line is drawn from the midpoint over the gluteal muscle. A second line is drawn between the greater trochanter and sacral hiatus, and the line intersects the previous line marking the point of needle insertion. Using a 10-cm needle, 30 mL of local anesthetic are injected after the nerve is located. [34] It may take 30 minutes for complete anesthesia (Fig. 32-21).

Precautions.

The femoral nerve block and sciatic nerve block require that large amounts of anesthetic be injected close to large nerves and vessels. Standard precautions should be used to avoid intravascular and intraneural injection, and recommended anesthetic dosages should be observed. Hematoma formation is a potential complication—especially in the gluteal muscle with sciatic block.

Nerve Blocks of the Ankle

Nerve block of the five nerves of the ankle—the deep peroneal (anterior tibial), posterior tibial, saphenous, superficial peroneal (musculocutaneous), and sural nerves—provides anesthesia to the foot. Depending on the desired area of anesthesia, one or more of the five nerves are blocked. These blocks can be used in operative procedures and repair of injuries to the foot. They are particularly useful in providing anesthesia to

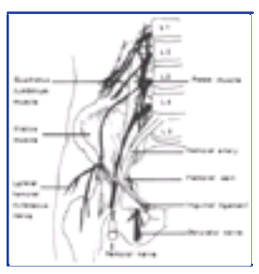

Figure 32-19 Anatomy of the femoral, obturator, and lateral femoral cutaneous nerves and the location of the injection site for the femoral and 3-in-1 nerve blocks. *(Adapted from Winnie AP, Ramamurthy S, Durrani Z: The inguinal paravascular technique of lumbar plexus anesthesia: The "3 in 1 block." Anesth Analg 52:989, 1973. Reproduced with permission.)*

the sole of the foot for laceration repair and foreign body removal.

A nerve block of the foot is better tolerated by the patient than local infiltration in all but the most minor procedures. The skin of the sole is thicker and more tightly bound to the underlying fascia by connective tissue septa than is skin in other parts of the body. Puncturing this skin can be difficult and is always quite painful. The fibrous septa can limit the amount and spread of anesthetic. If large amounts of anesthesia are injected, the volume of injected substance quickly exceeds the space available, possibly leading to painful distention of the tissue and circulatory compromise of the microvasculature. Local infiltrative anesthesia is adequate for treating minor injuries in which only small amounts of anesthetic are needed. For treatment of larger injuries, including incision and drainage, extensive wound care, and foreign body removal, the ankle block is better tolerated.

Anatomy.

The foot is supplied by the five nerve branches of the principal nerve trunks (see Fig. 32-18). Three nerves are located anteriorly and supply the dorsal aspect of the foot. Two nerves are located posteriorly and supply the volar aspect.

The anteriorly located nerves are the superficial peroneal, deep peroneal, and saphenous nerves. The superficial peroneal nerve (also called the *dorsal cutaneous* or *musculocutaneous nerve*) actually consists of multiple branches that supply a large portion of the dorsal aspect of the foot (Fig. 32-22). These are located superficially between the *lateral malleolus* and *extensor hallucis longus* tendon, which is easily palpated by having the patient dorsiflex the big toe. The deep peroneal nerve (also called the *anterior tibial nerve*) supplies the web space between the big and second toes. In the ankle, it lies under the *extensor hallucis longus* tendon. The saphenous nerve runs superficially with the saphenous vein between the *medial malleolus* and *tibialis anterior* tendon, which is

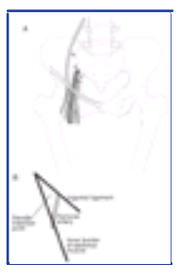

Figure 32-20 *A, B,* 3-in-1 block. See text for details.

prominent when the patient dorsiflexes the foot. The saphenous nerve supplies the medial aspect of the foot near the arch.

The posteriorly located nerves are the posterior tibial and sural nerves. The sural nerve runs subcutaneously between the *lateral malleolus* and the Achilles tendon and supplies the lateral border, both volar and dorsal, of the foot (see Fig. 32-22). The posterior tibial nerve runs with the posterior

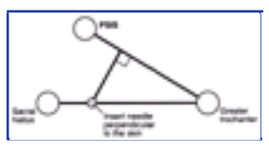

Figure 32-21 Sciatic nerve block (posterior approach). A line is drawn from the greater trochanter to the posterior-superior iliac spine (PSIS). The line is bisected and the needle will be inserted perpendicular to the line at a depth determined by a second line between the greater trochanter and the sacral hiatus.

Figure 32-22 *A* and *B,* Anatomy and innervation of the left calf and foot. See Figure 32-18 for areas for innervation. *(From Shurman DH: Ankle-block anesthesia for foot surgery. Anesthesiology 44:348, 1976. Reproduced with permission.)*

tibial artery, which can be palpated between the *medial malleolus* and the Achilles tendon. It lies slightly deep and posterior to the artery.

The posterior tibial nerve is one of the major nerve branches to the foot. After passing through the ankle, it branches into the medial and lateral plantar nerves, which supply sensation to most of the volar aspects of the foot and toes and supply motor innervation to the intrinsic muscles of the foot.

Technique.

Complete nerve block of the foot requires blocking three SQ nerves and two deeper nerves (Fig. 32-23). Once familiar with the anatomy, the experienced clinician can anesthetize all 5 nerves quickly by placing SQ band blocks around 75% of the ankle circumference and 1 deep injection next to the palpable posterior tibial artery and the other under the extensor tendon of the big toe.

The five nerves of the foot are commonly blocked in combinations of two or more. Small procedures clearly within the distribution of one nerve may require only a single nerve block; however, overlap of the nerve's sensory distribution frequently necessitates blocking a number of nerves for adequate anesthesia. Nerve block of the sural and posterior tibial nerves together anesthetizes the bottom of the foot and is the most useful combination.

Posterior tibial.

The posterior tibial nerve is blocked in the medial aspect of the ankle between the *medial malleolus* and the Achilles tendon. The injection site is determined by palpating the tibial artery just posterior to the *medial malleolus*. A point 0.5 to 1.0 cm superior to this is marked. If the artery is not palpable, a site 1 cm above the *medial malleolus* and just anterior to the Achilles tendon is used (see Fig 32-23 and Fig 32-24).

A 3.75-cm, 25-ga needle is directed at a 45° angle to the mediolateral plane (the needle is almost perpendicular to the skin), just posterior to the artery. At the estimated depth of the artery, approximately 0.5 to 1.0 cm deep, the needle is wiggled slightly in an effort to produce a paresthesia. If the paresthesia is elicited, 3 to 5 mL of anesthetic are injected after careful aspiration to check for inadvertent intravascular placement of the needle tip. If no paresthesia is produced, the needle is advanced inward, again at a 45° angle, until it hits the posterior aspect of the tibia. The needle is then withdrawn slightly, about 1 mm, and 5 to 7 mL of anesthetic are injected while the needle is withdrawn another 1 cm. A rise in the temperature of the foot, due to vasodilation from loss of sympathetic tone, may herald a successful block.

Sural nerve.

The sural nerve is blocked on the lateral aspect of the ankle between the Achilles tendon and the *lateral malleolus* (see Fig. 32-23 and Fig. 32-24). It lies superficially and is blocked at a level about 1 cm above the *lateral malleolus*. A band of anesthesia is injected subcutaneously between the Achilles tendon and the *lateral malleolus* using 3 to 5 mL of anesthetic.

Superficial peroneal nerves.

The superficial peroneal nerves are blocked on the anterior aspect of the ankle between the *extensor hallucis longus* tendon and the *lateral malleolus*. They lie superficially and are blocked using 4 to 10 mL of anesthetic placed subcutaneously in a band between these landmarks (see Fig. 32-23 and Fig. 32-24).

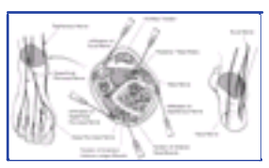

Figure 32-23 Anatomy and injection sites for nerve blocks at the ankle. *(From Bridenbaugh PO: The lower extremity: Somatic blockade. In Cousins M, Bridenbaugh PO [eds]: Neural Blockade in Clinical Anesthesia and Management of Pain, 2nd ed. Philadelphia, JB Lippincott, 1988, p 435. Reproduced with permission.)*

Figure 32-24 Anatomy and injection sites for nerve blocks at the ankle (lateral views). *(Adapted from Locke RK, Locke SE: Nerve blocks of the foot. JACEP 4:698, 1976.)*

Deep peroneal nerve.

The deep peroneal nerve is blocked anteriorly beneath the *extensor hallucis tendon* (see Fig. 32-23 and Fig. 32-24). It is blocked at a level 1 cm above the base of the *medial malleolus* and between the *extensor hallucis longus* and anterior tibial tendons. The tendons are palpated by having the patient dorsiflex the big toe and foot, respectively. After an SQ wheal is placed, the needle is directed about 30° laterally and under the *extensor hallucis* tendon until it strikes the tibia (at a depth of <1 cm). The needle is withdrawn 1 mm, and 1 mL of anesthetic is injected.

Saphenous nerve.

The saphenous nerve is blocked anteriorly between the *medial malleolus* and the anterior tibial tendon. It lies superficially and is blocked with 3 to 5 mL of anesthetic injected subcutaneously between these landmarks.

Nerve Blocks of the Metatarsals and Toes

Like nerve blocks in the hand and fingers, the nerve blocks in the foot and toes are commonly used in the ED. Indications for using these blocks include repair of lacerations, drainage of infections, removal of toenails, manipulation of fractures and dislocations, and otherwise painful procedures requiring anesthesia to the forefoot and toes.

Digital nerve blocks in the foot and toes are superior to local infiltration anesthesia in all but the most minor procedures. In the toes, the limited SQ space does not accommodate enough injected material for adequate infiltrative anesthesia. Furthermore, the fibrous *septa*, which attach the volar skin to the underlying fascia and bone, limit the spread and volume of injected substances. On the plantar surface, even small amounts of local infiltrate can cause painful distention and local ischemia of the tissues.

Anatomy.

Each toe is supplied by two dorsal and two volar nerves. These nerves are branches of the major nerves of

the ankle. The dorsal digital nerves are the terminal branches of the deep and superficial peroneal nerves. The volar nerves are branches of the posterior tibial and sural nerves.

The location of the nerves in relation to the bones varies with the site of the foot. In the toes, the nerves lie at the 2, 4, 8, and 10 o'clock positions in close relationship to the bone. In the proximal foot, the nerves run with the tendons and are not in close relationship to the bones (Fig. 32-25).

Technique.

The digital nerves can be blocked at the metatarsals, interdigital web spaces, or toes. The bones of the foot can be palpated easily from the dorsum and are used as the landmarks for estimating the location of the nerves. Proximally, the nerves' relationship to the bones is less consistent, making definitive needle placement and successful block less reliable. In the toes, the position of the nerves is more consistent; however, there is minimal SQ tissue space available for the injected solution. At the web space, the nerves are located in close relationship to the bone, and there is ample space for injecting the anesthesia; hence, for most procedures, the web space is the preferred site for the digital nerve block.

The technique for toe and metatarsal blocks is similar. All four nerves supplying each toe are usually blocked because of their sensory overlap. The blocks are performed from the dorsal surface, where the skin is thinner and less sensitive than that on the plantar aspect. A total of 5 mL of anesthetic is deposited in a fan-like pattern in the space between the metatarsal bones (see Fig. 32-25). A 1-mL skin wheal is placed dorsally between the metatarsal bones. The needle is then advanced until the volar skin tents slightly, and 2 mL are injected as the needle is withdrawn. Without removing it, the needle is redirected in a different volar direction, and the procedure is repeated. A total of 5 mL is used in each

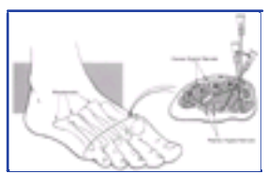

Figure 32-25 Anatomy and technique for digital nerve block at the metatarsals. *(From Bridenbaugh PO: The lower extremity: Somatic blockade. In Cousins M, Bridenbaugh PO [eds]: Neural Blockade in Clinical Anesthesia and Management of Pain, 2nd ed. Philadelphia, JB Lippincott, 1988, p 437. Reproduced with permission.)*

metatarsal space. Again, because of sensory overlap, two or more spaces need to be anesthetized for each toe to be blocked.

For the web space block, a site on the dorsum just proximal to the base of the toe is selected. Using a 10-mL syringe, a 3.75-cm, 27-ga needle is inserted at the lateral edge of the bone (Fig. 32-26). A wheal is placed subcutaneously between the skin and bone, using 0.5 to 1.0 mL of anesthetic. This serves to block the dorsal nerve and minimize pain at the needle insertion site. The needle is then advanced just lateral to the bone and toward the sole until the needle tents the volar skin slightly. The needle is withdrawn 1 mm, and 0.5 to 1.0 mL is injected. As the needle is withdrawn, another 0.5 mL is injected to ensure a successful block. The procedure is repeated on the opposite side of the toe. In this manner, two columns of anesthesia are placed on each side of the toe in the area through which the four digital nerves run. A total of 2 to 4 mL of anesthetic is used. For blocks done in the toe itself, the procedure is the same, but smaller amounts of anesthetic (i.e., <2 mL) are used because of the limited SQ space and fear of vascular compression. Alternative techniques using a single injection site, as described for the finger, can be performed (Fig. 32-27).

Complications and precautions.

The precautions that apply to the hand and fingers apply to the foot and toes. Ischemic complications can be avoided by paying attention to skin changes during the injection. Blanching heralds possible intravascular injection or vascular compression. If the skin blanches, halt the procedure and reevaluate the position of the needle and the amount and content of the injected solution. The total volume of anesthesia should not exceed the recommended amount. Although podiatrists commonly use anesthetics containing small concentrations of epinephrine

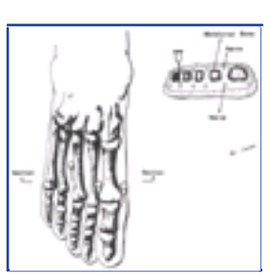

Figure 32-26 Technique of digital nerve blocks in the interdigital web spaces of the foot.

Figure 32-27 Alternative techniques of digital nerve blocks in the toes. *(From Locke RK, Locke SE: Nerve blocks of the foot. JACEP 4:698, 1976. Reproduced with permission.)*

for digital blocks in patients without underlying vascular disease, [16] this practice is generally not recommended because of concern about vasospasm and ischemia (see Complications and Precautions subsection and Chapter 30).

Note any neural or vascular injuries before the injection. The close proximity of these structures to the skin and bones means that they are frequently injured. Deficits, even if questionable, should be documented in the records and brought to the attention of the patient before the nerve block.

CONCLUSION

Regional nerve blocks of the thorax and extremities are valuable adjuncts to the clinician's armamentarium. They may be used for wound anesthesia before exploration, irrigation, debridement, and repair. They may also be used to reduce the pain of certain procedures (e.g., arthrocentesis, fracture reduction, or dislocation manipulation) and may permit better thoracic mechanics (e.g., intercostal nerve block). When these procedures are performed, be mindful of the cautions outlined here and in Chapter 30 .

Chapter 33 - Intravenous Regional Anesthesia*

James R. Roberts

The clinical use of intravenous (IV) regional anesthesia has been well established [1] [2] [3] as a safe, quick, and effective alternative to general anesthesia in selected cases requiring surgical manipulation of the upper and lower extremities. Although often relegated to the operating room, the procedure is readily applicable to outpatient use. In the emergency department (ED) the technique provides quick and complete anesthesia, along with muscle relaxation and a bloodless operating field. The procedure is free from the troublesome side effects associated with other regional blocks, such as the axillary block. The procedure is easily mastered and has a very low failure rate, and consistently good results can be expected.

The first practical use of analgesia associated with IV injection of a local anesthetic agent was described by August Gustav Bier in 1908. [4] Colbern[5] has since proposed the eponym *Bier block*. Although the procedure has been in existence for many years, the need for special equipment and a safe anesthetic agent limited its use. However, the Bier block has now gained wide acceptance as a safe and effective procedure, and several papers extol its virtues. [6] [7] [8] [9] Although complications do exist, no reported fatalities directly attributable to the use of the Bier block have been reported. In this chapter, the techniques and complications are discussed according to their application in the ED.

INDICATIONS AND CONTRAINDICATIONS

Indications for IV regional anesthesia include any procedure of the arm or leg that requires operating anesthesia, muscle relaxation, or a bloodless field. I have used the procedure for the reduction of fractures and dislocations, repair of major lacerations, removal of foreign bodies, debridement of burns, and drainage of infection. The procedure may be carried out on any patient of any age who is able to cooperate with the clinician.

The only absolute contraindications are an allergy to the anesthetic agent and uncontrolled hypertension. Relative contraindications include an uncooperative patient and the recent ingestion of a large meal, both of which may only delay the procedure rather than contraindicate it.

EQUIPMENT

The equipment required for IV regional anesthesia consists of the following:

- 1% lidocaine (Xylocaine), *without epinephrine,* to be diluted to a 0.5% solution (*note:* 1 mL of 1% lidocaine equals 10 mg)
- Sterile saline solution as a diluent
- 50-mL syringe/18-ga needle
- Pneumatic tourniquet (single or double cuff) (*note:* Do *not* use a standard blood pressure cuff)
- IV catheters (18- or 20-ga) or a 21-ga butterfly needle
- Elastic bandage/Webril padding
- 500 mL D_5 W (5% dextrose in water) and IV extension tubing

PROCEDURE

The procedure should be explained in advance to the patient. If the patient is extremely apprehensive, premedication with midazolam (Versed), diazepam (Valium), or an opioid (e.g., morphine, fentanyl) may be helpful but need not be routinely used. The only painful portions of the procedure are the establishment of the infusion catheter and the exsanguination procedure. The procedure should not be done on patients who are intoxicated or obtunded or on those with a previous reaction to a local anesthetic.

The patient need not be free of oral intake for a specific period of time before the procedure, but it is prudent to delay the procedure if the patient has just eaten a large meal. As a precaution, a large-bore catheter and IV line of D_5W are established in the unaffected extremity. Resuscitation equipment, including anticonvulsant drugs and oxygen, should be readily available.

While the patient is being prepared, the lidocaine solution is readied but withheld until the injured extremity is exsanguinated and the cuff is in place and reinflated as discussed below. The standard dose of lidocaine is 3 mg/kg injected as a 0.5% solution (1% lidocaine is mixed with equal parts of sterile saline in a 50-mL syringe). Farrell and associates (1985) have described a procedure termed the *minidose Bier block* using 1.5 mg/kg of lidocaine and reported a 95% success rate. This lower dose may decrease the incidence of central nervous system side effects and is more desirable in the ED setting. (Additional lidocaine may be infused if the initial dose is inadequate.) Lidocaine with epinephrine should *not* be used. Plain lidocaine is also available as a 0.5% solution, and as such, it can be used directly to avoid the necessity of diluting the stronger solution.

A pneumatic tourniquet with cotton padding (to prevent ecchymosis) under the cuff is applied proximal to the pathology (Fig. 33-1). *It is strongly advised that one not use a regular blood pressure cuff*, because these often leak or rupture and are not designed to withstand high pressures for any length of time. A specially designed portable double-cuff pneumatic system, such as that marketed by OEC Zimmer Corporation, is ideal (Fig. 33-2).

The anesthetic is premixed in the syringe. The tourniquet is inflated, and a 20-ga plastic catheter or a metal butterfly needle is placed in the superficial vein, as close to the pathologic site as possible, and is securely taped in place (Fig. 33-3). It is usually desirable to use a vein on the dorsum of the hand, but importantly the injection site should be at least 10 cm distal to the tourniquet to avoid injection of anesthetic proximal to the tourniquet. The hub remains on the catheter to avoid backbleeding or the syringe is attached to the butterfly tubing. This catheter will be the route of injection of the anesthetic agent.

The tourniquet is deflated, and the extremity is exsanguinated so that when the anesthetic agent is injected, it will fill the vascular system. Exsanguination may be accomplished

* This chapter modified with permission from Roberts JR: Intravenous regional anesthesia. JACEP 6:261, 1977.

Figure 33-1 Preparation for induction of anesthesia in a patient with a fracture of the right radius. Note precautionary IV line and deflated tourniquet in place. The procedure has been explained, and preoperative sedation or analgesia has been given if required. *(From Roberts JR: Intravenous regional anesthesia. JACEP 6:263, 1977.)*

by either of two methods. Simple elevation of the extremity for a few minutes may be adequate, but wrapping the extremity in a distal-to-proximal direction with an elastic bandage, being careful not to dislodge the infusion needle, enhances the exsanguination (Fig. 33-4). Wrapping may be painful; this step can be eliminated if it causes too much anxiety to the patient. If the wrapping procedure is not done, the extremity should be elevated for at least 3 minutes. During the wrapping procedure, care must be taken not to dislodge or infiltrate the infusion catheter.

With the extremity still elevated, the tourniquet is inflated to 250 mm Hg, the arm is then placed by the patient's side, and the elastic exsanguination bandage is removed. In a child, the tourniquet is inflated to 50 mm Hg above systolic pressure.

The 0.5% lidocaine solution is then slowly injected into the infusion catheter at the calculated dose. Note that the solution is placed in the arm in which circulation is blocked,

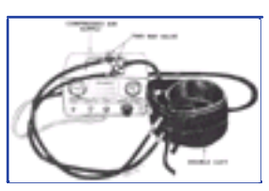

Figure 33-2 Double-cuff apparatus with two-way valves allows longer tourniquet time without pain. A standard blood pressure cuff should never be used. *(From Roberts JR: Intravenous regional anesthesia. JACEP 6:263, 1977.)*

not in the precautionary keep-open IV line on the unaffected side. At this point, blotchy areas of erythema may appear on the skin. This is not an adverse reaction to the anesthetic agent, but merely the result of residual blood being displaced from the vascular compartment, and it heralds success of the procedure.

In 3 to 5 minutes, the patient will experience paresthesia or warmth, beginning in the fingertips and traveling proximally, with final anesthesia occurring at the elbow. Complete anesthesia ensues in 10 to 20 minutes, followed by muscle relaxation. Note that adequate analgesia may exist even though the patient can still sense touch and position and has some motor function. If the "minidose" technique (1.5 mg/kg of lidocaine) does not provide adequate anesthesia, an additional 0.5 to 1 mg/kg may be infused at this time. Additional lidocaine was required in 7% of cases in one series using the minidose regimen. [10] The clinician should be patient, however,

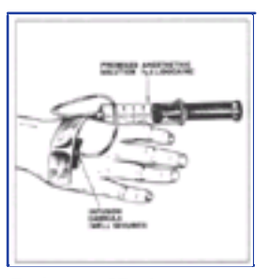

Figure 33-3 Infusion cannula securely taped in the dorsum of hand. A butterfly needle is shown here, but a plastic catheter with the hub attached may also be used. *(From Roberts JR: Intravenous regional anesthesia. JACEP 6:263, 1977.)*

and wait a full 15 minutes before infusing additional lidocaine. Alternatively, if analgesia is slow or inadequate an extra 10 to 20 mL of *saline* solution may be injected

to supplement the total volume of solution to enhance the effect. *Do not exceed a 3 mg/kg total dose of lidocaine.* The infusing needle is then withdrawn, and the puncture site is tightly taped to prevent extravasation of the anesthetic agent. The surgical procedure or manipulation is performed, including postreduction x-ray films and casting or bandaging (Fig. 33-5).

Anesthesia from a fingertip-to-elbow direction seems to occur irrespective of the site of anesthetic infusion, but selecting an injection site near the site of pathology will provide more rapid anesthesia at a lower dosage.

On completion of the procedure, deflation of the tourniquet is *cycled* to prevent a bolus effect of any lidocaine that may remain in the intravascular compartment. The cuff is deflated for 5 seconds and reinflated for 1 to 2 minutes. *This action is repeated three or four times.*

Figure 33-4 Exsanguination by elevation and elastic bandage. The tourniquet has yet to be inflated at this point. Care must be taken not to dislodge the infusion cannula. *(From Roberts JR: Intravenous regional anesthesia. JACEP 6:263, 1977.)*

Figure 33-5 A cast is applied under anesthesia. Because the tourniquet is portable, postreduction radiographs may be obtained without losing anesthesia. *(From Roberts JR: Intravenous regional anesthesia. JACEP 6:263, 1977.)*

If the tourniquet has been in place for less than 30 minutes, it is dangerous to deflate it, because adequate tissue fixation of the lidocaine probably has not occurred. This may result in a higher peak plasma lidocaine level, with increased side effects. If the surgical procedure is completed rapidly and the 3 mg/kg limit of lidocaine has been infused, the tourniquet should remain inflated until a full 30 minutes has elapsed, and only then should it be deflated using the cycling technique. It is reasonable to use a 20-minute cutoff if the minidose technique is used, because this dose is equal to a commonly administered IV bolus.

Sensation returns quickly when the tourniquet is removed, and in 5 to 10 minutes, the extremity returns to its preanesthetic level of sensation and function. After 20 minutes of observation, the patient is released (Table 33-1).

If the procedure takes longer than 20 or 30 minutes, many patients complain of pain from the tourniquet, because the tourniquet is not inflated over an anesthetized area. The use of a double-cuff tourniquet alleviates the problem of pain under the cuff.

In the double-cuff system, there are two separate tourniquets placed side by side on the extremity. One is termed the *proximal cuff*, and the other is called the *distal cuff*. The proximal cuff is inflated at the beginning of the procedure, and anesthesia is obtained under the deflated distal cuff. When the patient begins to feel pain under the proximal cuff, the distal cuff is first inflated over an already anesthetized area, and the pain-producing proximal cuff is then deflated. One must be certain to inflate the distal cuff before the proximal cuff is released; otherwise, the anesthetic will rapidly diffuse into the general circulation.

MECHANISM OF ACTION

Some of the anesthesia is undoubtedly related to the ischemia produced by the tourniquet, but most of the anesthesia is secondary to the anesthetic agent itself. Although the exact mechanism by which anesthesia is produced is unknown, the

TABLE 33-1 -- IV Regional Anesthesia: Step-by-Step Procedure

Begin IV line in uninvolved extremity.
Draw up 0.5% lidocaine (1.5 to 3 mg/kg).
Place padded tourniquet, and inflate upper cuff.
Insert small plastic IV cannula near pathologic lesion and secure.
Deflate tourniquet.
Elevate and exsanguinate extremity.
Inflate tourniquet (250 mm Hg), and remove exsanguination device. Inflate the proximal cuff only, if a double-cuff system is used.
Infuse anesthetic solution.
Remove infusion needle, and tape site.
Perform procedure.
If pain is produced by the application of the tourniquet, first inflate the distal cuff, then deflate the proximal cuff.
After the procedure has been carried out, deflate the cuff for a few seconds, then reinflate it for 1 minute. Repeat 3 times. Do not deflate the cuff if total tourniquet time is less than 30 minutes.
Observe for possible reactions.

From Roberts JR: Intravenous regional anesthesia. JACEP 6:263, 1977. Reproduced with permission.

site of action of the anesthetic may be at sensory nerve endings, neuromuscular junctions, or major nerve trunks. [11] Contrast studies have demonstrated that the anesthetic agent does not diffuse throughout the entire arm, yet anesthesia of the entire limb is obtained. For example, when the anesthetic agent is injected into the elbow and kept in that region with both distal and proximal tourniquets, anesthesia of the entire arm develops. [12] Evidence indicates that the local anesthetic does not simply diffuse from the venous system into the tissue but travels via vascular channels directly inside the nerve. Regardless of where the anesthetic is infused, the fingertips are the first area to experience anesthesia, suggesting that the core of the nerve is in contact with the anesthetic agent initially. Following release of the tourniquet, a considerable amount of the drug still remains in the injected limb for at least 1 hour. [13] This would suggest that at least a portion of the anesthetic leaves the vascular compartment and becomes tissue fixed.

PROCEDURAL POINTS

Anesthetic Agent

Using 0.5% plain lidocaine at a dose of 1.5 to 3 mg/kg is preferred. Other agents have been used without demonstrable advantage and are not recommended. [14] Bupivacaine (Marcaine, Sensorcaine) is *contraindicated* because of the potential for serious cardiovascular and neurologic complications. [15] [16]

Dunbar and Mazze[8] showed that patients with IV regional anesthesia actually had significantly lower plasma lidocaine concentrations than patients with axillary block or lumbar epidural anesthesia for similar procedures. Peak plasma concentrations are reached 2 to 3 minutes after deflation of the tourniquet, and side effects are minimal if the deflation is cycled following the surgical procedure. The plasma half-life of lidocaine is approximately 60 seconds (see the excellent detailed discussion of pharmacokinetics by Covino), [17] but the drug demonstrates a theoretical 3-compartment model similar to a direct IV infusion once the tourniquet is released. [18] Peak blood levels are related to the duration of vascular occlusion and to the concentration of the anesthetic. [17] [18]

Post-release peak plasma lidocaine levels decrease as the time of vascular occlusion (tourniquet time) increases. If the tourniquet is inflated for at least 30 minutes and the deflation-reinflation technique is used when the procedure is finished, plasma concentration of lidocaine should be approximately 2 to 4 µg/mL, below the 5 to 10 µg/mL level at which serious reactions occur. [8] Tucker and Boas[18] demonstrated a peak plasma lidocaine level of 10.3 µg/mL after a 10-minute period of vascular occlusion, compared with 2.3 µg/mL if the tourniquet was inflated for 45 minutes.

More dilute solutions of lidocaine are associated with lower peak lidocaine levels. When equal doses of lidocaine are used, the peak arterial plasma levels are 40% lower when the 0.5% solution is used than when the 1% solution is used. [18] For example, after 10 minutes of vascular occlusion, the peak plasma concentration of lidocaine has been demonstrated to reach 10.3 µg/mL with the 1% solution, compared with only 5.6 µg/mL when the drug was given under similar circumstances as a 0.5% concentration. [18]

Exsanguination

Exsanguination of the extremity before injection of the anesthetic agent is considered essential for success by many clinicians. Others do not believe that it is a critical factor. Exsanguination by simple elevation of the extremity should be done in all cases, but in certain cases one should consider avoiding the painful wrapping of the extremity with an elastic or Esmarch bandage. (Note that applying an Esmarch wrap over a fracture site is usually quite painful.) A pneumatic splint, such as the type used for prehospital immobilization, is also a reasonable alternative to painful wrapping. The process of exsanguination is believed to allow for better vascular diffusion of the anesthetic.

Site of Injection

Anesthesia is usually obtained no matter where the local anesthetic is injected, but some evidence indicates that the procedure is more successful when the anesthetic is injected distally. Sorbie and Chacho [3] note the following failure rates associated with specific sites of anesthetic injection: antecubital fossa, 23%; middle of forearm or leg, 18%; hand, wrist, or foot, 4%. For most cases, a vein in the dorsum of the hand or foot is most often used. If local pathology precludes the use of the hand, the midforearm or antecubital fossa of the elbow are acceptable, albeit less desirable, alternatives as long as the infusion catheter is well below the tourniquet to avoid systemic injection.

Although most of the literature stresses the use of this technique on the upper extremity, it may also be used successfully in the leg. It cannot, however, be used for procedures above the knee. Tourniquet pain appears to be a limiting factor when the procedure is used on the leg. One must be certain to avoid damage to the peroneal nerve by using the tourniquet in the midcalf area only.

COMPLICATIONS

Although IV regional anesthesia is both safe and simple, one should not be lulled into complacency, because complications do occur and are usually related to equipment failure or mistakes in the technique.

Anesthetic Agent

Serious complications seldom occur if proper attention is paid to technique. Reactions to lidocaine are rare and are usually systemic reactions from high blood levels.[8] [16] [19] High levels may result from miscalculation of dosages, from too rapid release of the tourniquet before the anesthetic has become tissue fixed ("bolus effect") or, rarely, from advancement of the infusion catheter proximal to the tourniquet, resulting in direct IV infusion. [20] To emphasize the safety of this procedure it should be noted that the dose of lidocaine used in the "minidose" technique is similar to an IV bolus routinely given to patients with significant cardiovascular disease, in the presence of ventricular dysrhythmias.

Generally, the central nervous system effects of lidocaine are minor, resulting in mild reactions such as dizziness, lethargy, headache, or blurred vision. This should not occur in more than 2% to 3% of patients and requires no treatment. [8] Convulsions may occur but are extremely rare.

The most common complication relating to the anesthetic agent is rapid systemic vascular infusion, which occurs when a blood pressure cuff explodes or slowly leaks, resulting in both loss of anesthesia and high blood levels. [21] Similar complications may occur if the cuff is deflated before 30 minutes after the induction of anesthesia. Both complications are the result of a bolus effect of the anesthetic, resembling an IV injection.

Van Neikerk and Tonkin[19] reported 3 seizures in a series of 1400 patients. Seizures are generally not recurrent and are treated with oxygen and anticonvulsant drugs. Transient cardiovascular reactions, such as bradycardia and hypotension, are possible with large doses of lidocaine. Vasovagal reactions do occur. If resuscitation equipment is available and a precautionary IV line is started in the opposite arm, there should not be any serious sequelae.

One case of cardiac arrest for 15 seconds following the use of 200 mg of lidocaine has been reported, but the actual clinical scenario may have been a vasovagal reaction rather than a true cardiac arrest. [22]

Additional Complications

Thrombophlebitis can occur following IV administration of anesthetics, and the formation of insignificant amounts of methemoglobin with the use of prilocaine hydrochloride (Citanest) has been reported. [23] Methemoglobinemia also can theoretically occur with lidocaine but has not been reported.

A particularly bothersome problem has been the infiltration of the infusion catheter during exsanguination, resulting in tissue extravasation of the anesthetic agent. Also, there has been some leakage of anesthetic after the infusion needle has been removed. Both problems may result in poor anesthesia but may be minimized if a small, well-secured plastic infusion needle is used instead of a metal scalp vein ("butterfly") needle and if the puncture site is tightly taped following with-drawal of the catheter.

This procedure cannot be used in manipulations or operations in which the pulse must be monitored as a guide to reduction (e.g., supracondylar fractures of the humerus), because the tourniquet occludes arterial flow. The use of the Bier block in patients with sickle cell disease is not well documented. It should be used with caution until the ischemic effect of the tourniquet on the red blood cells of such patients has been clarified. In all patients the tourniquet time should not exceed 90 minutes. Ischemia for less than that amount of time is not associated with serious sequelae.

Chapter 34 - Procedural Sedation and Analgesia

Steven M. Green
Baruch Krauss

Procedural sedation and analgesia (PSA) is the use of analgesic, dissociative, and sedative agents to relieve the pain and anxiety associated with diagnostic and therapeutic procedures performed in various settings. PSA is an integral element of emergency medicine residency and pediatric emergency medicine fellowship curricula, and graduates of these programs are skilled in the practice of PSA. Emergency clinicians are skilled in resuscitation, vascular access, and advanced airway management, permitting them to effectively recognize and manage the potential complications associated with PSA.

The most common clinical errors associated with PSA in a recent study of *all practitioners* were delayed recognition of respiratory depression and respiratory arrest, inadequate monitoring, and inadequate resuscitation [1] [2] —mistakes that are unlikely for emergency clinicians. The safety of PSA techniques by emergency clinicians has been well documented in numerous series in both children [3] [4] [5] [6] and adults.[3] [7] Successful and safe application of PSA requires careful patient selection, customization of therapy to the specific needs of the patient, and careful patient monitoring for adverse events. Emergency clinicians must ensure that all patients receive pain relief and sedation commensurate with their individual needs during any procedure.

TERMINOLOGY

The progression from minimal sedation to general anesthesia represents a nonlinear continuum that does not lend itself to division into arbitrary stages. Low doses of opioids or benzodiazepines induce mild analgesia or sedation, respectively, with little danger of adverse events. If, however, clinicians continue administering additional medication beyond this initial level, progressively altered consciousness ensues with a proportionately increased risk of respiratory and airway complications. If further medications are administered, the patient will advance along this continuum until protective airway reflexes are lost and general anesthesia is ultimately reached. This sedation continuum is not drug-specific, in that varying states from mild sedation to general anesthesia can be achieved with virtually all non-dissociative PSA agents (e.g., opioids, benzodiazepines, barbiturates, etomidate, propofol).

In 1985, the American Academy of Pediatrics (AAP) and National Institutes of Health (NIH) issued guidelines for the management and monitoring of children receiving sedation for diagnostic and therapeutic procedures in response to the growing use of opioids and sedative/hypnotic agents in the outpatient setting and a number of sedation-related deaths.[8] [9] In these documents, three levels of sedation were defined (conscious sedation, deep sedation, general anesthesia) to create a common language for describing drug-induced alterations in consciousness (Table 34-1). A key development in

TABLE 34-1 -- Procedural Sedation and Analgesia Terminology and Definitions

GENERAL
• **Analgesia*** **:** Relief of pain without intentional production of an altered mental state such as sedation. An altered mental state may be a secondary effect of medications administered for this purpose.
• **Anxiolysis*** **:** A state of decreased apprehension concerning a particular situation in which there is no change in a patient's level of awareness.
• **Procedural Sedation and Analgesia (PSA)**[3] **:** A technique of administering sedatives, analgesics, and/or dissociative agents to induce a state that allows the patient to tolerate unpleasant procedures while maintaining cardiorespiratory function. PSA is intended to result in a depressed level of consciousness but one that allows the patient to maintain airway control independently and continuously. Specifically, the drugs, doses, and techniques used are not likely to produce a loss of protective airway reflexes.
CURRENT SEDATION STATE TERMINOLOGY
• **Minimal Sedation (Anxiolysis)**[13] **:** A drug-induced state during which patients respond normally to verbal commands. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.
• **Moderate Sedation (Formerly Conscious Sedation)**[13] **:** A drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. Reflex withdrawal from a painful stimulus is not considered a purposeful response. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.
• **Dissociative Sedation**[96] **:** A trance-like cataleptic state induced by the dissociative agent ketamine characterized by profound analgesia and amnesia, with retention of protective airway reflexes, spontaneous respirations, and cardiopulmonary stability.
• **Deep Sedation**[13] **:** A drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully following repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.
• **General Anesthesia**[13] **:** A drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.
ORIGINAL AAP/NIH TERMINOLOGY[8] [9]
• **Conscious Sedation:** A medically controlled state of depressed consciousness that 1) allows protective reflexes to be maintained; 2) retains the patient's ability to maintain a patent airway independently and continuously; and 3) permits appropriate response by the patient to physical stimulation or verbal command (e.g., "open your eyes").
• **Deep Sedation:** A medically controlled state of depressed consciousness or unconsciousness from which the patient is not easily aroused. It may be accompanied by a partial or complete loss of protective reflexes, and includes the inability to maintain a patent airway independently and respond purposefully to physical stimulation or verbal command.
• **General Anesthesia:** A medically controlled state of unconsciousness accompanied by a loss of protective reflexes, including the inability to maintain a patent airway independently and respond purposefully to physical stimulation or verbal command.

*From Sacchetti A, Schafermeyer R, Gerardi M, et al: Pediatric analgesia and sedation. Ann Emerg Med 23:237, 1994.

the field of PSA has been the revision of the original terminology and the adoption of clearer descriptions of varying types and degrees of sedation (see Table 34-1). Although historically popular, the widely misinterpreted and misused term *conscious sedation* has fallen into disfavor, [10] labeled as confusing,[11] "imprecise,"[12] and an "oxymoron"[10] [11] and has been replaced with the term moderate sedation.[13]

Despite improvements in PSA terminology, the system is imperfect and there is still not an objective way to assess sedation depth. Levels of responsiveness remain at best crude surrogate markers of respiratory drive and retention of protective airway reflexes. This is especially true for all levels of sedation in young children (infants and toddlers) who do not understand or are unreliable in following verbal commands. Although respiratory depression and respiratory arrest can be quickly detected using standard interactive and mechanical monitoring, there is no safe and practical way to assess the status of protective airway reflexes. There is currently insufficient data to determine whether deep sedation is associated with impairment of protective reflexes, or whether such danger is only encountered when "pushing" deep sedation to a point at which it approaches or reaches general anesthesia.

PSA GUIDELINES

Prior to the promulgation of PSA guidelines by specialty societies and governmental agencies, clinicians simply administered sedatives in varied clinical settings and applied individual judgment as to the need for specific monitoring devices and supporting personnel. Since 1985, at least 12 sets of PSA guidelines have been published, each crafted for the unique and differing settings in which PSA is practiced. Naturally, not all are in agreement. [5] The intent of each of these guidelines is to better standardize the manner in which PSA is performed in order to enhance patient safety. Those most pertinent to emergency clinicians are from the American College of Emergency Physicians,[3] the American Academy of Pediatrics,[14] and the American Society of Anesthesiologists.[12] [15]

In the early 1990s the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), an independent, not-for-profit organization that evaluates and accredits hospitals in the United States, took a special interest in PSA, with the central theme that the standard of sedation care provided should be comparable throughout a given hospital. Thus, patients sedated in the ED should not receive a significantly different level of attention or monitoring than those sedated for a similar-level procedure in the operating room or in the endoscopy suite. To ensure this, the JCAHO requires specific PSA protocols that apply consistently throughout each institution. These hospital-wide sedation policies will vary from site to site based upon the specific needs and expertise available within each institution. In 2001, JCAHO released new standards for pain management, sedation, and anesthesia care.

At each hospital accreditation survey, the JCAHO will see if practitioners practice PSA consistently with their hospital-wide sedation policy, and whether they provide sufficient documentation of such compliance. Clinicians must be familiar with their hospital's sedation policies, and should work with their medical staff to ensure that such policies are suitably detailed, but yet reasonable and realistic. Unduly restrictive policies do a disservice to patients by discouraging appropriate use of analgesia and anxiolysis. Most hospitals pattern their sedation policies after JCAHO standards and definitions. It is important to note that the unique ketamine dissociative state does not fit into the existing JCAHO definitions of sedation and anesthesia. [16] A ready solution is assigning a distinct definition for "dissociative sedation" (see Table 34-1).

JCAHO[13] requires that PSA practitioners who are permitted to administer deep sedation must be qualified to rescue patients from general anesthesia. Emergency clinicians will typically perform all levels of sedation except general anesthesia. Moderate sedation suffices for the majority of procedures in adults and cooperative children, although it will not be adequate for extremely painful procedures (e.g., hip reduction, cardioversion). Deep sedation can facilitate these, but at greater risk of cardiorespiratory depression than moderate sedation. Moderate sedation is frequently insufficient for effective anxiolysis and immobilization in younger, frightened children, with deep or dissociative sedation typically appropriate alternatives.

EVALUATION PRIOR TO PSA

The practice of PSA has three essential components performed in sequence: the initial pre-sedation evaluation, sedation during the procedure, and post-procedure recovery and patient discharge from the emergency department (ED). In all but the most emergent situations, a directed history and physical examination should precede PSA. If this evaluation suggests additional risk, the advisability of sedation should be reconsidered. High-risk cases may be better managed in the more controlled environment of an operating room.

Presedation assessments are a JCAHO requirement, and most hospitals have developed specific forms to facilitate consistent documentation of the involved items. Except in emergency situations, the risks, benefits, and limitations of any PSA should be discussed with the patient (or their parent or guardian) in advance and verbal agreement obtained. Formal written informed consent is not required as a standard of care (unless a local institutional requirement) though documentation, as discussed earlier, is essential.

General.

Clinicians should assess the type and severity of any underlying medical problems. This is usually best documented by the standard ED medical record, history and physical exam, and nursing notes. Another tool used for this purpose is the American Society of Anesthesiologists' (ASA) physical status classification that is used for pre-operative risk stratification (Table 34-2 (Table Not Available)). Current medications and allergies should be verified. It is advisable to inquire regarding prior adverse experiences with PSA or anesthesia.

Airway.

The airway should be inspected to determine if there are abnormalities that might impair airway management (e.g., severe obesity, short neck, small mandible, large tongue, trismus).

Cardiovascular.

Cardiac auscultation should be performed to assess for rhythm disturbance or other abnormality. In patients with known cardiovascular disease, their degree of reserve should be evaluated, as most PSA agents can cause vasodilatation and hypotension.

Respiratory.

Lung auscultation should be performed to assess for active pulmonary disease, especially obstructive lung disease and active upper respiratory infections that may predispose the patient to airway reactivity.

Gastrointestinal.

As pulmonary aspiration of gastric contents is a dreaded complication of vomiting when protective

TABLE 34-2 -- American Society of Anesthesiologists' (ASA) Physical Status Classification

(Not Available)

From Krauss B, Green SM: Sedation and analgesia for procedures in children. N Engl J Med 342:938, 2000.

airway reflexes are impaired, clinicians should assess the time and nature of last oral intake. For elective procedures, the ASA recommends an age-stratified fasting requirement of 2 to 3 hours for clear liquids and 4 to 8 hours for solids and non-clear liquids. [17] Despite this, they acknowledge that "the literature provides insufficient data to test the hypothesis that preprocedure fasting results in a decreased incidence of adverse outcomes" in PSA. [12] [15] In non-fasting situations for non-elective or emergent procedures, where the ASA guidelines are virtually impossible to achieve, the potential for pulmonary aspiration must be balanced with the timing of the procedure and the required depth of sedation. This is consistent with the ASA guidelines, "in urgent, emergent, or other situations when gastric emptying is impaired, the potential for pulmonary aspiration of gastric contents must be considered in determining the timing of the intervention and the degree of sedation/analgesia" [12] [15] and ACEP PSA guidelines, "recent food intake is not a contraindication for administering PSA, but should be considered in choosing the depth and target level of sedation."[3]

The concept of preprocedure fasting is logistically difficult or impossible for emergency clinicians, who have no control over patients' oral intake prior to ED presentation. In actual practice, emergency clinicians routinely perform safe PSA on patients noncompliant with the ASA elective procedure fasting guidelines. [16] Procedures can sometimes be delayed for a number of hours; however, this must be balanced with prolongation of pain and anxiety for the patient, inconvenience for the patient and family, and expenditure of room space and other finite ED resources. Additionally, many ED procedures require urgent if not immediate attention (e.g., debridement and repair of animal bite wounds, acute burn management, arthrocentesis for suspected septic arthritis, reductions of joint dislocations, lumbar puncture in the uncooperative septic patient, hernia reduction, eye irrigation for ocular trauma or chemical burns, cardioversion in the hemodynamically unstable patient). Although uncommon, there may be occasions where non-fasting patients requiring urgent procedures with a substantial depth of sedation may be more safely managed in the operating room with endotracheal intubation to protect the airway.

Selecting agents less likely to produce vomiting, such as opting for fentanyl over morphine/meperidine, may decrease the aspiration potential. Concomitant antiemetic administration is an unproven adjunct, but a common consideration.

Hepatic/Renal.

The implications of delayed metabolism or excretion of PSA agents in infants less than 6 months of age, in the elderly, and in the presence of hepatic or renal abnormality should be carefully evaluated.

PERSONNEL AND INTERACTIVE MONITORING

The most important element of PSA monitoring is close and continuous patient observation by an individual capable of recognizing sedation complications. This person must be able to continuously observe the patient's face, mouth, and chest wall motion, and equipment or sterile drapes must not interfere with such visualization. This careful observation will allow prompt detection of adverse events such as respiratory depression, apnea, partial airway obstruction, emesis, and hypersalivation.

PSA personnel should understand the pharmacology of analgesic and sedative agents and their respective reversal agents, and be proficient at maintaining airway patency and assisting ventilation if needed. *PSA requires a minimum of two experienced individuals*, most frequently one clinician and one nurse or respiratory therapist. The clinician typically oversees drug administration and performs the procedure, while the nurse or respiratory therapist continuously monitors the patient for potential complications and documents medications administered, response to sedation, and periodic vital signs. The nurse or respiratory therapist may assist with minor, interruptible tasks; however, their ability to remain focused on the patient's cardiopulmonary status must not be impaired. An individual with advanced life-support skills should be immediately available, a requisite easy to fulfill in the ED setting.

During deep sedation, the individual dedicated to patient monitoring should be experienced with this depth of sedation and have no other responsibilities that would interfere with the advanced level of monitoring and documentation appropriate for this sedation level. [14] Individual hospital-wide sedation policies may have additional requirements for how and when deep sedation is administered, based on their specific needs and available expertise.

For situations in which sedation is initiated by the intramuscular, oral, nasal, inhalational, or rectal routes it is not mandatory to have IV access, although this may be preferred based upon anticipated depth of sedation, comorbidity, or for the convenience of additional drug titration. When sedation is performed without IV access, an individual skilled in initiating such access should be immediately available—again a requisite easy to fulfill in the ED setting.

EQUIPMENT AND MECHANICAL MONITORING

The routine use of mechanical monitoring has greatly enhanced the safety of PSA. With current technology, oxygenation (via pulse oximetry), ventilation (via capnography), and hemodynamics (via blood pressure and electrocardiogram [ECG]) can all be monitored non-invasively in spontaneously breathing patients. PSA mechanical monitoring should include continuous pulse oximetry with an audible signal. Pulse oximetry measures the percent of hemoglobin that is bound to oxygen and is not a substitute for monitoring ventilation, as there is a variable lag time between the onset of hypoventilation or apnea and a change in oxygen saturation of hemoglobin molecules.

Capnography provides a continuous, breath-by-breath measure of respiratory rate (RR) and CO_2 exchange and provides the earliest detection of respiratory failure. [18] [19] [20] [21] [22] [23] [24] [25] [26] Hypoventilation and respiratory depression result in a progressive decrease in respiratory rate, increase in the end-tidal CO_2 ($EtCO_2$), and a change in the shape of the CO_2 waveform. Apnea and laryngospasm result in an almost instantaneous loss of the CO_2 waveform. Early detection of respiratory compromise is especially important in infants and toddlers who have smaller functional residual capacity and greater oxygen consumption relative to older children and adults. [27] [28] In the ED setting capnography has been shown to identify respiratory depression undetectable by pulse oximetry. [21] Capnography is currently not considered a standard of care, but this technology should be considered, as it can alert practitioners to respiratory depression and apnea before hypoxemia develops, especially if the patient is on supplemental oxygen.

Although continuous ECG monitoring cannot be considered mandatory nor standard of care in the absence of cardiovascular disease, such monitoring is simple, inexpensive, and readily available.

A monitoring modality that is currently undergoing investigation for use in the ED is the Bispectral Index (BIS), which uses processed electroencephalogram (EEG) signal to measure the effect of sedative/hypnotics on the brain. This technology has been validated as a tool to monitor depth of sedation in the operating room; however, its predictive value for the remainder of the sedation continuum remains unclear. [29] [30] [31] In a 12-patient pilot study of ED BIS, a significant correlation between the BIS and a behavioral assessment of Alertness/Sedation (OAA/S) was found. [32] BIS may prove a valuable PSA monitoring modality if future studies demonstrate a high degree of discriminatory power in predicting sedation depth over the entire sedation continuum (anxiolysis and mild sedation to general anesthesia).

The sedation area should include all necessary age-appropriate equipment for airway management and resuscitation, including oxygen, a bag-valve mask, suction, and drug reversal agents. A defibrillator should be available for subjects with significant cardiovascular disease.

The need for supplemental oxygen during PSA and its benefits have not been studied. Although this intervention will decrease the incidence and severity of hypoxemia due to airway complications, it will also delay the detection of apnea with pulse oximetry. [12] [15] If oxygen is administered and capnography is not available, continual visual inspection of chest-wall motion and air movement is especially important. Supplemental oxygen cannot be considered a standard of care at this time and remains an option best left to the clinician's preference.

Vital signs should be periodically measured at individualized intervals, in most cases including measurements at baseline, after drug administration, on completion of the procedure, during early recovery, and at completion of recovery. During deep sedation it is advisable to assess vital signs every 5 minutes. Patients are at highest risk of complications 5 to 10 minutes following IV medications and during the immediate post-procedure period when external stimuli are discontinued.

DISCHARGE CRITERIA

All patients receiving PSA should be monitored until they are no longer at risk for cardiorespiratory depression (Table 34-3). To be discharged they should be alert and oriented (or returned to age-appropriate baseline), and vital signs should be stable. Many hospitals have chosen to use standardized recovery-scoring systems similar to those used in their surgical post-anesthesia recovery areas (Table 34-4). All patients should leave the hospital with a reliable adult who will observe them after discharge for post-procedural complications. It is desirable to document the name of the individual on the hospital record. Written instructions should be given regarding appropriate diet, medications, and level of activity (Table 34-5 and Table 34-6). Even though patients may appear awake and able to comprehend instructions, they may not remember details once they leave the ED. To be eligible for safe discharge, children are not required to demonstrate that they can tolerate a PO challenge (most PSA agents are emetogenic and forcing fluids post-sedation can lead to emesis before and/or after discharge), nor are they required to walk unaided. The AAP guidelines only require that "the patient can talk (if age-appropriate)" and "the patient can sit up unaided (if age-appropriate)." [14]

GENERAL PRINCIPLES

Therapeutic mistakes resulting in inadequate analgesia and sedation include using the wrong agent, the wrong dose, the wrong route and frequency of administration, and poor use of

TABLE 34-3 -- Post-Sedation Complications

Complication	Etiology
Delayed awakening	Prolonged drug action
	Hypoxemia, hypercarbia, hypovolemia
Agitation	Pain, hypoxemia, hypercarbia, full bladder
	Paradoxical reactions
	Emergence reactions
Nausea and vomiting	Sedative agents
	Premature oral fluids

adjunctive agents. With proper training and technique, adequate PSA can be provided under almost any circumstance. Understanding titration principles is critical to providing safe and effective PSA. Clinicians must have a thorough knowledge of the pharmacokinetics, dosing, administration, and potential complications of the PSA agents that they use. Onset time from injection to initial observed effect must be appreciated, especially when using drugs in combination, to avoid stacking of drug doses resulting in oversedation.

The correct agent (or combination of agents) and the route and timing of administration depend on the following factors: How long will the procedure last? Will it be seconds

TABLE 34-5 -- Sample Adult Disposition Instructions after PSA

1. Do not drive or operate heavy machinery for 12 hours.
2. Eat a light diet for the next 12 hours.
3. Take only your prescribed medications as needed, including any pain medication you were discharged with. Avoid alcohol.
4. Do not make any important decisions or sign important documents for 12 hours. You may be forgetful due to medications that were administered.
5. If you experience any difficulty breathing or persistent nausea and vomiting, return to the emergency department.
6. You should have a responsible person with you for the rest of the day and during the night.

(e.g., simple relocation of a dislocated joint, incision and drainage of a small abscess, cardioversion), minutes (e.g., complex fracture manipulation for reduction, breaking up loculations in a large abscess and then packing it), or prolonged (e.g., complex facial laceration repair)? How likely is it that the procedure will need to be repeated (e.g., fracture reduction)? Can topical, local, or regional anesthesia be used as an adjunct? Does the patient only require sedation for a non-invasive diagnostic imaging study?

Prior to drug administration, every effort should be made to minimize a patient's anxiety and distress, particularly in children. The emotional state of a patient on induction strongly correlates with the degree of distress on emergence and in the immediate days following the procedure. [33] [34] [35] [36] Emergency clinicians must avoid being pressured by consultants to cut corners or rush PSA. Incorporating into the presedation preparation a discussion with the consultant about the sedation plan and the length of time required to safely prepare and sedate the patient can avoid the risks associated with a hurried sedation.

Pediatric emergency clinicians should know the adult doses of the sedation agents they are administering. Understanding that the initial dose of midazolam for PSA in a 100 kg patient on a mg/kg basis is far less than the 0.1 mg/kg used in a child is essential to avoid unexpected mishaps in drug dosing.

TABLE 34-6 -- Sample Pediatric Disposition Instructions after PSA

Your child has been given medicine for sedation and/or pain control. These medicines may cause your child to be sleepy and less aware of his or her surroundings, making it easier for accidents to happen while walking or crawling. Because of these side effects, your child should be watched closely for the next few hours. We suggest the following:
1. No eating or drinking for the next 2 hours. Infants may resume half normal feedings when they are hungry.
2. No playing for 12 hours that requires normal coordination, such as bike riding or jungle gym activities.
3. No playing without an adult to watch and supervise for the next 12 hours.
4. No baths, showers, cooking, or use of potentially dangerous electrical appliances unless supervised by an adult for the next 12 hours.
If you notice anything unusual about your child, call us for advice or return to the emergency department for reevaluation.

ROUTES OF ADMINISTRATION

For non-dissociative agents, IV titration to patient response is the best method of obtaining rapid and safe analgesia and/or sedation. It is important to wait the appropriate time for the medications to produce the intended effect before adding more doses. When using opioids, doses administered in 2 to 3 minute increments, observing for side effects such as miosis, somnolence, decreased responsiveness to verbal stimuli, minimally impaired speech, and diminished pain on questioning, are appropriate initial end points. For sedative/hypnotics similar end points such as ptosis (rather than miosis), somnolence, slurred speech, and gaze alteration should be sought. Repeated doses may be given in a titrated fashion based on the patient's response during the procedure.

Oral, transmucosal (i.e., nasal, rectal), and intramuscular (IM) routes are more convenient means of administration as IV access is not necessary. However, they are much less reliable for timely dose titration to a desired response. The efficacy of intranasal drug administration in particular is operator-dependent (Table 34-7). The main advantage of these other routes is for pediatric patients in whom IV access may be problematic or for procedures that may require only minimal sedation in conjunction with the use of local anesthetics. These routes are also advantageous for simple sedation for diagnostic imaging.

With the exception of ketamine, agents administered IM have erratic absorption and a variable onset of action. As such, prolonged preprocedural and postprocedural observation may be necessary. When required because of limitations in obtaining IV access, the IM route offers little advantage over oral or transmucosal administration.

Another PSA route is via inhalation using nitrous oxide. This gas can either be delivered by a demand flow system using a hand-held mask, or delivered to young children by a continuous flow system under close clinician supervision using a nose mask.

Because individual needs may vary widely, application of arbitrary ceiling doses of analgesic and sedative regimens is unwarranted. The true ceiling dose of an agent is that which provides adequate pain relief or sedation without major cardiopulmonary side effects such as respiratory depression, apnea, bradycardia, hypotension, or allergic reactions.

TABLE 34-7 -- Technique for Intranasal Drug Administration

Proper administration is crucial for maximal nasal mucosal absorption.
The child must be supine with the head held in the neutral position, looking straight up.
The solution is placed in a 1 mL tuberculin syringe and instilled slowly, drop by drop, into the child's nostrils, alternating nostrils as one proceeds.
If the child receives a drop and immediately swallows, the solution bypassed the nasal mucosa and will be absorbed orally.
Likewise, if the child coughs and gags after a drop, the solution has bypassed the nasal mucosa and irritated the glottic area.
Time each instillation with the child's swallowing pattern, ideally instilling the solution immediately after the child swallows.
Crying is helpful in creating back pressure to keep the solution out of the posterior pharynx.
Most, if not all, children will begin to cry after the first instillation.

From Krauss B, Brustowicz R (eds): Pediatric Procedural Sedation and Analgesia. Philadelphia, Lippincott Williams & Wilkins, 1999, p 228.

There are two absolute PSA contraindications: severe clinical instability requiring immediate attention, and refusal by a competent patient. Relative contraindications include hemodynamic or respiratory compromise, altered sensorium, or inability to monitor side effects. However, even in many of these circumstances, appropriate agents can be given to provide analgesia and sedation while minimizing the chances for further deterioration. Although safely sedating patients at the extremes of age is challenging and requires additional care, *age is not a contraindication to PSA*.

DRUG SELECTION STRATEGIES

The majority of ED procedures in older children and adults can be performed without systemic sedation and analgesia. Skilled practitioners can frequently combine a calm, reassuring bedside manner with distraction techniques or careful local or regional anesthesia, or both. [37] [38] Many procedures, however, cannot be technically or humanely performed without PSA. These situations can be divided into three categories.

Insufficient analgesia.

Despite a cooperative patient, for some procedures it is impossible to achieve effective pain control with local or regional anesthesia. Examples of procedures requiring systemic PSA include fracture reductions, dislocation reductions, large loculated abscess incision and drainage, wounds that require scrubbing such as "road rash," cardioversion, bone marrow aspiration/biopsy, and extensive burn debridement.

Insufficient anxiolysis.

Despite effective local or regional anesthesia, some patients will be so frightened that procedures cannot be technically or humanely performed without PSA. Young children requiring laceration repair are frequently terrified, and older children and adults may be highly anxious in anticipation of laceration repairs in sensitive and/or personal regions (e.g., face, genitalia, perineum).

Insufficient immobilization.

Despite effective local or regional anesthesia and anxiolysis, PSA may be indicated to prevent excessive motion during procedures that require substantial immobilization (e.g., repair of complex facial lacerations). Immobilization is most commonly an issue with young children and the mentally challenged.

General considerations.

Clinicians must therefore customize their drug selection (i.e., anxiolysis, analgesia, immobilization) based upon the unique needs of the patient and their individual level of experience with specific agents (Table 34-8 (Table Not Available)). A risk-benefit analysis should be performed before every sedation (Table 34-9). The benefits of reducing anxiety and controlling pain should be carefully weighed against the risks of respiratory depression and airway compromise. Factors influencing the extent of pharmacological management are listed in Table 34-10 . Some general drug selection strategies are discussed below and shown in Table 34-8 (Table Not Available) .

Minor procedures in cooperative adults and older children.

These procedures can usually be managed with topical, local, or regional anesthesia. Systemic PSA is typically unnecessary, although mild anxiolysis (e.g., nitrous oxide, oral midazolam) can make these patients more comfortable.

Larger procedures of longer duration in cooperative adults and older children.

Supplementation of topical, local, or regional anesthesia with either nitrous oxide or IV midazolam and fentanyl permits customization of sedation depth and pain relief to the specific needs of each patient.

TABLE 34-8 -- Procedural Sedation and Analgesia Indications and Sedation Strategies

(Not Available)

From Krauss B, Green SM: Sedation and analgesia for procedures in children. N Engl J Med 342:938, 2000. Adapted with permission.

TABLE 34-9 -- Risk-Benefit Analysis for Procedural Sedation and Analgesia

• Why is PSA needed in the first place? Is the procedure very painful, frightening, or requiring extreme cooperation?
• Are the risks of PSA appropriate for the procedure involved?
• If a child, do the parents or guardian consent to the use of PSA?
• How long will the procedure take? If it is a short procedure, is it worth the added risk and expense to the patient? If it is a longer procedure, is there an appropriate agent that can be titrated to allow adequate PSA throughout the entire length of the procedure?
• Are there significant side effects that limit a particular drug's usefulness?
• Are there enough nurses and support personnel present to safely allow the use of PSA?
• What is the recovery period for a given agent? Are there enough treatment areas and staff in the ED to allow adequate observation during recovery?
• When did the patient last eat? Is a delay in waiting for a sufficient fasting time worth the time lost in performing the procedure?

From Krauss B, Brustowicz R (eds): Pediatric Procedural Sedation and Analgesia. Philadelphia, Lippincott Williams & Wilkins, 1999, p 294.

Procedures in uncooperative adults or the mentally challenged.

Essentially all procedures in uncooperative adult-sized patients are difficult without systemic PSA. Depending upon operator experience, IV midazolam/fentanyl or IM/IV ketamine/midazolam may be used in these situations. Midazolam and fentanyl can be titrated intravenously to a relatively deep level of sedation, although, as discussed previously, the risk of adverse effects increases with sedation depth. Ketamine (typically with co-administered midazolam when used in adults) can also provide the profound analgesia and immobilization necessary to perform painful procedures; however, in adults there is a risk of unpleasant hallucinatory recovery reactions. Ketamine should be used with extreme caution in older adults, as its sympathomimetic properties may aggravate underlying coronary artery disease or hypertension. Occasionally, procedures in extremely uncooperative adults or the mentally challenged are better managed in the operating room with general anesthesia.

Minor procedures in uncooperative older children and in young children.

Minor procedures (e.g., small lacerations, IV cannulation, venipuncture, superficial foreign body removal) in uncooperative children can frequently be managed

TABLE 34-10 -- Factors Influencing the Extent of Pediatric Pharmacological Management

AGE
Selected drugs and routes of administration have age limitations and are not recommended above or below a certain age (e.g., demand flow nitrous oxide in children <5 years old, nasal and rectal routes of administration in children >6 years old).
TIME OF DAY
A toddler presenting at naptime or at 9 p.m. who is tired and sleepy will usually require a smaller dosing and possibly a lower level of procedural sedation and analgesia (PSA) than required at 9 a.m. Young children presenting with facial lacerations at night, after their normal bedtime, may only require topical anesthesia and a quiet room for 20–30 minutes to achieve a painless laceration repair while the child sleeps.
FASTING STATUS
Young children can be extremely difficult and uncooperative when hungry and/or tired. In anticipation of PSA many children are kept NPO from the time they are triaged in the ED. This can further increase hunger and irritability, especially if the child waits 1–2 hours to be seen by a physician.
STAFFING AND EQUIPMENT AVAILABILITY
Staffing availability can affect the use and timing of sedation and is especially important in busy EDs with multiple sedations occurring concurrently and in smaller units that are set up for only one sedation at a time.
LOCATION OF THE INJURY
Injuries located in areas of cosmetic concern (especially on the face) or near sensory organs (e.g., ears, eyes, mouth, nose) will often require a high degree of agitation control and a concomitant level of PSA.
PREVIOUS MEDICATIONS
An accurate history of prior medication administration is important in situations where a child is referred from another facility, as this can affect the type and timing of PSA agents that can be given. In particular, a child may have received opioids or sedative/hypnotics prior to transfer and may still be sedated on arrival, necessitating an adjustment in the PSA regimen.
LEVEL OF ANXIETY
The level of anxiety of both the child and accompanying adult(s) must be accurately assessed. Children manifest anxiety in many different ways, and emergency clinicians must be facile at recognizing the varying expressions of anxiety, especially in young children. A child with a facial laceration quietly sitting on the stretcher during the initial examination will not necessarily be a calm and cooperative patient during laceration repair (infants and toddlers). The nursing assessment at triage of the state of the child and accompanying adult(s) can be very helpful in some cases in determining the need for PSA. The child who was frightened and uncooperative in triage may be calm and compliant during a procedure. Unfortunately, the reverse is also true. When confronted by an extremely anxious child, ED personnel should ascertain what the parents have told the child about the upcoming procedure. Many parents, in the hope of lessening their child's anxiety, will tell the child that he or she will get a "shot" or a "needle" and that the procedure will "only hurt for a minute." This type of parental preparation, especially in young children who do not have the cognitive abilities to mediate their anxiety, often results in a significant increase in the child's anxiety and a decrease in their ability to cooperate, especially if the child has had a previous negative experience with a procedure in the ED. It is also important to assess the parent's level of anxiety, as this will determine the degree to which they can assist during the procedure. An extremely anxious parent or a parent who must take care of other siblings during the procedure will find it difficult to assist in distracting the child or otherwise helping him or her cope with the procedure.
PREVIOUS EXPERIENCE
Childrens' previous experience in hospitals can greatly affect their response to the current situation. Direct experience is not the only way to create anxious, frightened, and uncooperative patients, though. Images from television, stories from peers, or prior witness of a sibling being forcibly restrained for a laceration repair can leave a powerful and lasting impression. This type of influence should be especially suspect in children whose anxiety seems out-of-proportion in the present situation. Eliciting from the parents a history of a previous difficult experience in the ED can be a decisive factor in determining the degree of sedation required. Children who have had a recent unpleasant laceration repair, and who now present with a new laceration, may well require PSA as opposed to simple anxiolysis (either pharmacologic or nonpharmacologic) had there been no previous trauma.
CHILD'S BEHAVIOR AT ROUTINE PRIMARY CARE VISITS
Inquiring into how a child behaves during routine primary care visits can yield important information on how the children reacts to stressful situations, how cooperative he or she will be with the anticipated procedure, and whether pharmacologic management is needed. Children who cry but hold still when vaccinated may be more compliant than children who are described by their parents as being "afraid of doctors" or "wild" during visits to the primary care physician.

by skilled practitioners using a combination of non-pharmacological techniques (e.g., distraction, guided imagery, hypnosis, comforting, breathing techniques) in conjunction with topical anesthesia, careful local anesthesia, and, when necessary, brief forcible immobilization (by personnel or by a restraining device). In other cases, supplementing non-pharmacological techniques with topical or local anesthesia and anxiolysis with oral midazolam may be sufficient to permit successful wound repair. Although oral administration is most popular and least invasive, the nasal or rectal routes can also be used depending upon operator experience and preference.

Major procedures in uncooperative children.

Major painful procedures (e.g., fracture reduction, large loculated abscess incision and drainage, arthrocentesis of a major joint)

require systemic PSA. Options include IV fentanyl/midazolam or IM/IV ketamine. Ketamine may be the best option in such children, as dissociative sedation can consistently provide the immobilization and analgesia while maintaining protective airway reflexes and upper airway muscular tone.

PHARMACOPEIA

There is no universally correct or preferred medication or drug regimen. Many options are acceptable and successful. The best choice is an agent whose pharmacologic properties are familiar to the operator, is used frequently by the operator, is easily titrable, and has a short duration of action or is readily reversible. All drugs should be given in adequate doses, and underdosing narcotics or sedatives provides no useful purpose. Dosing recommendations for PSA drugs are shown in Table 34-11 (Table Not Available) , with specialized protocols for midazolam/fentanyl and ketamine shown in Table 34-12 and Table 34-13 , respectively. Individual agents are discussed in the following section.

Sedative-Hypnotic Agents

Chloral Hydrate

Pharmacology.

Chloral hydrate is a pure sedative hypnotic agent without analgesic properties. When administered orally, the average time to peak sedation is approximately 30 minutes, with a recovery time of an additional 1 to 2 hours. [39] [40] Residual motor imbalance and agitation may persist for several hours beyond this. [41] Rectal administration is erratically absorbed and therefore not recommended.

Adult use.

The use of chloral hydrate is limited to diagnostic imaging studies in children. It has no current uses in adults.

Pediatric use.

Chloral hydrate is widely used as a sedative to facilitate non-painful *outpatient* diagnostic procedures such as EEGs [40] and CT or MRI scanning. [42] [43] [44] [45] [46] Pentobarbital IV appears to be more effective for the latter indication than chloral hydrate, [47] although many centers prefer chloral hydrate in younger children (e.g., younger than 18 months) simply to avoid the need for IV access. [43] [44] [47] This drug does not readily lend itself to frequent use in the ED.

Adverse effects.

Despite a wide margin of safety, chloral hydrate can cause airway obstruction and respiratory depression, especially at higher doses (75–100 mg/kg). [1] [40] [43] [45] [46] The incidence was 0.6% in one large series. [40] There is no known dosage threshold of chloral hydrate below which this potential complication can be consistently avoided, [1] [45] and, accordingly, standard interactive and mechanical monitoring precautions apply to chloral hydrate as they do to other PSA agents.

Because it is a halogenated hydrocarbon, overdoses of chloral hydrate can be arrhythmogenic. Beta blockers may be effective in terminating ventricular arrhythmias. Despite reports of potential carcinogenicity, the AAP has judged that the evidence is currently insufficient to avoid single doses of chloral hydrate for this reason alone. [48]

Midazolam

Pharmacology.

Benzodiazepines are a group of highly lipophilic agents that possess anxiolytic, amnestic, sedative, hypnotic, muscle relaxant, and anticonvulsant properties. They lack direct analgesic properties, and thus are commonly co-administered with opioids. Caution must be exercised when using benzodiazepines and opioids together, since the risks of hypoxia and apnea are significantly greater than when either is used alone. [49]

Midazolam is by far the most common benzodiazepine used for PSA, and is preferred over the longer-acting lorazepam and diazepam. The time to peak effect for midazolam is approximately 2 to 3 minutes when given IV. Unlike diazepam, midazolam and lorazepam are water- soluble, making parenteral administration less painful and mucosal absorption faster. Midazolam is readily reversed with flumazenil.

Adult use.

Midazolam can be effectively used for moderate and deep sedation through careful IV titration to effect, typically together with fentanyl (see Table 34-12).

Pediatric use.

The advantage of midazolam over other benzodiazepines for pediatric PSA is its short duration of action, reversibility, and availability in multiple routes of administration. Midazolam may be used for the same indications and manner as in adults. Some children require larger doses than would be typical for adults on a mg/kg basis, [50] and paradoxical responses (e.g., hyperexcitability) are not uncommon. [41] [51] [52]

To avoid the need for IV access in frightened children, midazolam has been alternatively administered via the IM, [53] oral, [51] [54] [55] [56] [57] [58] intranasal, [54] [59] [60] [61] and rectal [62] [63] routes. However, the inability to effectively titrate using these routes dictates that a reliable depth of sedation cannot be predictably or regularly achieved. Thus, these non-intravenous routes are primarily reserved for pure anxiolysis and/or minimally painful procedures. Respiratory depression can also occur via these routes. [58]

Adverse effects.

When administered by skilled practitioners using standard precautions (see Table 34-12), the safety profile for midazolam is excellent. [5] [6] [64] However, when administering benzodiazepines, one must maintain continuous vigilance for respiratory depression. [1] [41] [49] [64] [65] Such respiratory depression is dose-dependent and greatly enhanced in the presence of ethanol or other depressive drugs, especially opioids. These effects are exaggerated in the elderly. Deaths from undetected apnea have occurred, [49] underscoring the critical role for continuous interactive and mechanical monitoring.

Benzodiazepines induce minimal cardiovascular depression. Although hypotension can occur, it is rare when the agents are carefully titrated. One reason midazolam is ideal for painful procedures is its significant amnesic effect. Even though patients appear to feel pain during the procedure, it is often not remembered.

Pentobarbital

Pharmacology.

Pentobarbital is a barbiturate capable of profound sedation, hypnosis, amnesia, and anticonvulsant activity in a dose-dependent fashion. It has no inherent analgesic properties. When carefully titrated IV, sedation is evident within 5 minutes with a duration of approximately 30 to 40 minutes. [66]

Adult use.

Pentobarbital has no advantage over midazolam for adult PSA and is rarely used for this purpose.

Pediatric use.

Pentobarbital is the IV sedative of choice in many centers for diagnostic imaging in children. [44] [47] [66] [67] [68] [69] It is regarded as superior to midazolam[47] [66] [69] or chloral hydrate[47] for this indication. Pentobarbital, like midazolam, is available in multiple routes of administration.

Adverse effects.

Like other barbiturates, pentobarbital can lead to respiratory depression and hypotension, as it is a negative inotrope. [44] [47] [66] [69]

Ultrashort-Acting Sedatives

The current ultrashort-acting sedatives used or being considered for use in ED PSA are thiopental, methohexital, propofol, and etomidate. Their use is rapidly expanding in the ED setting, but their exact role is still evolving. All can rapidly produce potent sedation, and all exhibit rapid awakening (<5 minutes) following drug discontinuation. As described later, rectal thiopental and methohexital have established safety and efficacy for pediatric neuroimaging.

Some controversy surrounds the IV administration of these agents for ED PSA.[70] Proponents cite their extremely rapid onset and recovery as enormous advantages over other sedatives. Critics cite the level of continuous vigilance required to achieve a desired effect while simultaneously avoiding significant cardiopulmonary depression, as these agents can exhibit rapid swings in levels of consciousness. An additional dedicated clinician (separate from the individual performing the procedure) is required to oversee medication administration; however, critics wonder whether oversedation and impairment of protective airway reflexes can be reliably avoided in spite of this precaution. Currently available series do not sufficiently quantify depth of sedation, and it is unclear whether some subjects experienced periods compatible with general anesthesia. Although such profound obtundation creates superlative procedural conditions, it also raises important issues regarding aspiration risk and compliance with JCAHO and hospital PSA standards. [70]

Thiopental and methohexital.

Because of their lipid solubility, barbiturates are rapidly absorbed rectally. When given by this route in children, thiopental and methohexital can reliably produce anxiolysis and sedation suitable for CT or MRI scanning. [71] [72] [73] [74] [75] [76] Respiratory depression is unusual when using typical doses (see Table 34-11 (Table Not Available)) but can occur. [71] [72] [74] [75] [76] Standard interactive and mechanical monitoring are warranted as with any PSA.

When given IV, both thiopental and methohexital produce sedation within 1 minute. Clinical recovery is rapid (approximately 15 minutes) and reflects the rapid redistribution of these agents from the central nervous system (CNS) to the periphery. These barbiturates have well-established use as sedatives for rapid-sequence intubation. IV methohexital has been administered for brief PSA in both adults [77] and children,[78] [79] a technique labeled "brief unconscious sedation." [78] Procedural conditions were excellent, although in one report apnea occurred in 10% of the patients. [77] The depth of sedation achieved in these small series is not well-described, but appears to be at or past levels consistent with deep sedation. Barbiturates can frequently cause hypotension at typical IV doses, so their use should be avoided whenever possible in patients with volume depletion or cardiovascular compromise.

Propofol.

Propofol has revolutionized the practice of anesthesiology. It is often used in the ICU setting for seizure control and for benzodiazepine-resistant agitation. Carefully titrated by bolus or by using an infusion pump, this drug can induce deep sedation or general anesthesia within 1 minute. Recovery following discontinuation averages 5 to 15 minutes, even after prolonged administration. Propofol exhibits inherent antiemetic and perhaps euphoric properties, and patient satisfaction is typically high. The adverse effects of this drug are potent respiratory and cardiovascular depression. Sudden apnea and hypotension (by direct negative inotropy as well as arterial and venodilatation) are well-known, as are rapid swings in consciousness. [67] [70] [79A] [79B] [79C] [79D] [79E]

Thus far the published experience using propofol for ED PSA is limited. As expected, existing reports cite rapid recoveries and a high level of efficacy. [67] [79A] [79B] [79D] [79E] The depth of sedation achieved in these reports is again not well-described, but appears to be frequently at or past levels consistent with deep sedation.

If it is ultimately shown that emergency clinicians can consistently administer this drug in a manner that avoids oversedation, respiratory depression, and hypotension, propofol could potentially become the IV PSA sedative agent of choice in patients of all ages.

Etomidate.

Etomidate produces sedation, anxiolysis, and amnesia equal to that of barbiturates, but with significantly fewer adverse respiratory or hemodynamic effects. Its onset of action and recovery are similar to those of thiopental and methohexital. In many centers etomidate is the induction agent of choice for rapid-sequence intubation in both adults and children, especially for patients with head trauma or marginal blood pressure. It is now commonly used for PSA. Some clinicians combine etomidate with narcotics, such as fentanyl, but the use of this combination has not been well-studied. If narcotics are used as adjuncts to etomidate, an appropriate reduction in dosing to account for the synergistic effect is required. The primary adverse effects of etomidate are respiratory depression, myoclonus, nausea, and vomiting. [80] [81] [82] Myoclonus is benign but can be disconcerting. It consists of transient jerking or twitching movements that can be mistaken for a seizure. Transient adrenal suppression occurs with etomidate, but appears to lack clinical significance for single doses. [83]

As with the other ultrashort- acting agents, preliminary reports describe rapid recovery and a high level of efficacy using IV etomidate for PSA in both adults and children.[80] [81] [82] Similarly, the depth of sedation achieved in these reports is not well-described, but appears to be frequently at or past levels consistent with deep sedation.

Analgesic Agents

Fentanyl

Fentanyl is the most common opioid used for PSA due to its rapid onset, brief duration of action, rapid reversibility by Narcan, and lack of histamine release. [7] Morphine and meperidine are instead preferred for pure pain control owing to their longer duration of action. ED patients frequently receive morphine or meperidine initially for acute analgesia, and then later are administered shorter-acting agents to facilitate a needed procedure. Although longer-acting opioids can be readily used for analgesia during PSA, they will be associated with longer recovery times and a higher incidence of histamine-related effects (e.g., nausea/vomiting, hypotension, pruritus). Fentanyl lacks these effects and therefore is preferred unless simply unavailable.

Pharmacology.

Fentanyl is 75 to 125 times more potent than morphine and has no intrinsic anxiolytic or amnestic properties. A single dose given IV has rapid onset (<30 seconds), with a peak at 2 to 3 minutes and brief clinical

---

TABLE 34-11 -- PSA Drug Dosing Recommendations

(Not Available)

From Krauss B, Green SM: Sedation and analgesia for procedures in children. N Engl J Med 342:938, 2000. Adapted with permission.

TABLE 34-12 -- Procedure for Moderate to Deep Sedation with Intravenous Midazolam and Fentanyl

Caveats
• Do not consider this procedure if you lack experience with the drugs or do not have the time to perform procedural sedation and analgesia (PSA) properly. Do not attempt this procedure if the pulse oximeter, suction, oxygen, or bag-mask are not working, the IV is not secured, or the room is too small or not set up for PSA.
• This is a two-person procedure, one to monitor the patient and one to perform the procedure.
• Individual response to the drugs is variable and dependent upon the patient's underlying physiologic state and the presence of concomitant drugs/medication.
• Maximum drug effect occurs 2–3 minutes following administration. Proceed slowly and patiently, allowing the medication to take full effect before giving the next dose.
• Have naloxone and flumazenil immediately available for oversedation and/or respiratory depression.
• If the patient seems overly sedated, begin the procedure. The pain of the procedure often stimulates respiration and lessens sedation.
Contraindications—Absolute (Risks Essentially Always Outweigh Benefits)
Active hemodynamic instability
Active respiratory distress or hypoxemia
Contraindications—Relative (Risks May Outweigh Benefits)
Respiratory depression or altered level of consciousness
Anticipated difficulty if ventilatory assistance should become necessary (e.g., facial deformity or trauma, small mandible, large tongue, trismus)
Protocol
• Establish IV access.
• Connect appropriate monitoring equipment to the patient. Routine supplemented oxygen is commonly used but not always mandated.
• Pulse, respiratory rate, blood pressure, and level of consciousness should all be recorded initially, and periodically throughout the procedure depending on the depth of sedation.
• Suction equipment, oxygen, a bag-valve-mask, and reversal agents should be immediately available. An age-appropriate resuscitation cart with oral and nasal airways, endotracheal tubes, and a functioning laryngoscope must be nearby.
• The order of the drugs is one of personal preference. The ratio of analgesia to sedation is determined by the nature of the procedure. Some procedures require primary analgesia and secondary anxiolysis/sedation (e.g., abscess incision and drainage, bone marrow aspiration, arthrocentesis, burn debridement, central catheter placement). In this case, administer fentanyl first. Others require primary anxiolysis/sedation with secondary analgesia (e.g., lumbar puncture, simple foreign body removal); administer midazolam first.
• Administer local anesthesia if indicated after PSA initiated (this often serves to help gauge effectiveness of systemic analgesia).
• Perform the procedure. Additional doses of fentanyl or midazolam may be required if further pain or anxiety are noted based on the response and length of the procedure.
• If hypoxemia, oversedation, or slowed respirations are seen during or after procedure, the patient should be first stimulated while oxygen is applied and the airway repositioned. If the patient's response is insufficient, assist ventilations with a bag-valve-mask. Reversal agents should be considered if there is not a prompt response to assisted ventilation.
• Continue close observation until the patient is awake and alert, and release the patient with a friend, parent, or relative only after a sufficient discharge score has been attained.

duration (20 to 40 minutes). This increase in potency and onset of action is in part related to its greater lipid solubility, which facilitates its passage across the blood-brain barrier. The effects of fentanyl can be rapidly and completely reversed with opioid antagonists (e.g., naloxone, nalmefene). When respiratory depression occurs with fentanyl/midazolam PSA, it is usually due primarily to fentanyl.

Adult use.

Because of its pharmacokinetics, IV fentanyl is an ideal agent when analgesia is required for painful procedures; it can be easily and rapidly titrated. [7] As anxiolysis and sedation do not occur at low doses of fentanyl (1–2 mcg/kg), the concurrent administration of a pure sedative, most commonly midazolam, is advisable, especially in children (see Table 34-12).

Pediatric use.

The combination of fentanyl and midazolam remains one of the most popular PSA sedation regimens in children, with a strong safety and efficacy profile when both drugs are carefully titrated to effect. [6] [64] [84] [85] Any necessary level of mild to deep sedation can be achieved using these agents.

Fentanyl is also available in an oral transmucosal preparation. Although this novel and noninvasive delivery route obviates the need for IV access, titration is difficult and efficacy is variable. [86] Furthermore, the incidence of emesis is high (31% to 45%), [86] [87] and this formulation has never become popular for PSA.

Adverse effects.

Like all opioids, fentanyl can cause respiratory depression. [6] [7] [64] [84] [85] When used for PSA, standard interactive and mechanical monitoring are required. As the opioid effect is most pronounced on the CNS respiratory centers, apnea can precede loss of consciousness. If apnea should occur, verbal or tactile stimulation should be attempted prior to administration of opioid antagonists. As discussed earlier, caution must be exercised when using benzodiazepines and opioids together, since

the risks of hypoxia and apnea are significantly greater than when either is used alone. [5] [49]

In the absence of significant ethanol intoxication, hypovolemia, or concomitant drug ingestion, hypotension is rare, even with very large doses of fentanyl (doses of 50 mcg/kg are common in adult and pediatric cardiac surgery). Because of its safe hemodynamic profile, fentanyl is an ideal analgesic agent for use in critically ill or injured patients. Additionally, nausea and vomiting are rare in distinction to analgesia with morphine or meperidine. A commonly observed reaction to fentanyl is facial pruritis and patients frequently scratch their noses. [7]

A rare side effect of fentanyl with potential for respiratory compromise is chest wall rigidity. This complication is related to higher doses (>5 mcg/kg as a bolus dose) than those used for PSA, and has not been reported in any ED series. [6] [7] [84] [85] If it should occur, chest wall rigidity usually can be reversed with opioid antagonists and/or positive-pressure ventilation. Equipment for urgent pharmacological paralysis should be available if reversal and positive-pressure ventilation are unsuccessful.

Diamorphine

Diamorphine is a promising nasal opioid that is currently available in Great Britain but not the United States. Diamorphine has a similar onset and duration of action to morphine; however, its higher water solubility permits potent doses to be delivered in the small (0.1 mL) volumes necessary

for comfortable intranasal administration. In two studies of children and teenagers with fractures, intranasal diamorphine 0.1 mg/kg provided a similar level of analgesia with faster onset than IM morphine 0.2 mg/kg. Intranasal spray administration was better tolerated than the injection, and there were no adverse events. [88] [89] Diamorphine may prove to be a useful initial analgesic for children and teenagers with acute pain, although, practically, an IV must be established to permit titration to full pain relief and PSA for any needed procedures (e.g., fracture reduction). The role for diamorphine in adults remains to be determined.

Other Short-Acting Opioids

Sufentanil, alfentanil, and remifentanil are other short-acting opioids that have a potential role in PSA. However, currently there is insufficient published experience to warrant their routine use. Although intranasal sufentanil 0.75 mcg/kg appeared promising in one small pediatric trial, [90] in another, doses of 1.5 mcg/kg resulted in oxygen desaturation in 8 of 10 children studied. [59] This low toxic-therapeutic ratio and inability to titrate would appear to limit the utility of intranasal sufentanil. In the one published report of IV remifentanil with midazolam for PSA, there was an unacceptably high incidence of hypoxemia. [91] Currently there does not appear to be a clinically important advantage to these drugs compared to fentanyl.

KETAMINE

Pharmacology.

Ketamine produces a unique state of cortical dissociation that permits painful procedures to be performed more consistently and effectively than with other PSA agents. This state of "dissociative sedation" is characterized by profound analgesia, sedation, amnesia, and immobilization (Fig. 34-1), and can be rapidly and reliably produced with IV or IM administration. Ketamine has been widely used worldwide since its introduction in 1970 and has demonstrated a remarkable safety profile in a variety of settings. [4] [6] [92] [93] [94] In 1999, the JCAHO confirmed that ED ketamine administration is fully compliant with its standards when administered according to protocol. [95] Clinicians administering ketamine must be especially knowledgeable about the unique actions of this drug and the numerous contraindications to its use (see Table 34-11 (Table Not Available)).

Ketamine differs from all other PSA agents in several important ways. First, it uniquely preserves cardiopulmonary stability. Upper-airway muscular tone and protective airway reflexes are maintained. Spontaneous respiration is preserved, although when administered IV, ketamine must be given slowly (over 1 to 2 minutes) to prevent respiratory depression. Second, it differs from other agents in that it lacks the characteristic dose-response continuum to progressive titration. At doses below a certain threshold, ketamine produces analgesia and sedation. However, once a critical dosage threshold (approximately 1 to 1.5 mg/kg IV or 3 to 4 mg/kg IM) is achieved, the characteristic dissociative state abruptly appears. This dissociation has no observable levels of depth, and thus the only value of ketamine "titration" is to maintain the presence of the state over time. Finally, the dissociative state is not consistent with formal definitions of moderate sedation, deep sedation, or general anesthesia (see Table 34-1), and therefore must be considered from a different perspective than agents that exhibit the classical sedation continuum. [13] [96]

Figure 34-1 A child undergoing repair of a laceration while dissociated with ketamine. The blank stare is typical.

Ketamine is most effective and reliable when given IV or IM. Ketamine has a one arm-brain circulation time when given IV with onset of dissociation noted within 1 minute and effective procedural conditions lasting for about 10 to 15 minutes. When given IM, the same effect is achieved within 5 minutes, with effective procedural conditions for about 15 to 30 minutes. The typical duration from dosing until dischargeable recovery is 50 to 110 minutes when given IV, and 60 to 140 minutes when given IM. [92] [97]

Like the benzodiazepines, ketamine undergoes substantial first pass hepatic metabolism. As a result, oral and rectal administration results in less predictable effectiveness and requires substantially higher doses. Clinical onset and recovery are substantially longer than when given parenterally, and thus these routes are rarely used in the ED. [61] [62] [98]

Ketamine can induce salivation, and is routinely coadministered with an anticholinergic. Atropine is most commonly chosen in emergency medicine due to its ready familiarity to clinicians and nurses, although glycopyrrolate is an equally acceptable but not superior alternative (see Table 34-13).

Adult use.

Ketamine is widely and successfully used in adults throughout the developing world for both minor and major surgery, particularly in areas lacking resources for inhalational anesthesia. [92] [93] [99] [100] Hallucinatory so-called "emergence reactions" have been reported in up to 30% of adults receiving ketamine (although rare in children), and can be fascinating and pleasurable, or alternatively unpleasant and nightmarish. [92] Concurrent benzodiazepines are believed to blunt but not entirely eliminate such reactions in adults, [92] [93] [99] [100] and apprehension regarding such unpleasant recoveries has limited the popularity of ketamine administration in the developed world for adults.

One study reported success administering dissociative doses (2 mg/kg IV) of ketamine with concurrent midazolam (0.07 mg/kg IV) to 77 ED adults to facilitate painful procedures (e.g., abscess incision and drainage, fracture reduction). There were no moderate or severe emergence reactions, and only five patients experienced mild reactions. [101] Furthermore,

TABLE 34-13 -- Procedure for Dissociative Sedation with Ketamine

Caveats
Do not consider if you are not experienced with ketamine or if you do not have time to perform such sedation properly. Do not attempt the procedure if the pulse oximeter, suction, oxygen, or bag-mask are not working, or the room is too small or not set up for PSA.
This is a two-person procedure, one to monitor the patient and one to perform the procedure. Both must be knowledgeable regarding the unique characteristics of ketamine.
Ketamine is best suited for (1) short, painful procedures, especially those requiring immobilization (e.g., complex facial laceration, burn debridement, fracture reduction, abscess incision and drainage, central line placement, colonoscopy, tube thoracostomy); or (2) examinations judged likely to produce excessive emotional disturbance (e.g., pediatric sexual assault examination).
Contraindications—Absolute (Risks Essentially Always Outweigh Benefits)
Age <3 months (suggestive evidence of higher risk of airway complications)
History of airway instability, tracheal surgery, or tracheal stenosis (presumed but insufficient evidence of higher risk of airway complications)
Known or suspected psychosis, even if currently stable or controlled with medications (supportive evidence of exacerbatory potential)
Contraindications—Relative (Risks May Outweigh Benefits)
Age 3 to 12 months (higher risk of airway complications)
Procedures involving stimulation of the posterior pharynx (moderately higher risk of laryngospasm)
Active pulmonary infection or disease, including upper respiratory infection or asthma (moderately higher risk of laryngospasm)
Known or suspected cardiovascular disease including angina, heart failure, or hypertension (exacerbation due to sympathomimetic properties of ketamine). Avoid ketamine in patients with ED blood pressures 140/90 or above. Avoid ketamine in older adults with risk factors for coronary artery disease.
Head injury associated with loss of consciousness, altered mental status, or emesis (elevated intracranial pressure with ketamine)
Central nervous system masses, abnormalities, or hydrocephalus (elevated intracranial pressure with ketamine)

Glaucoma or acute globe injury (elevated intraocular pressure with ketamine)
Porphyria, thyroid disorder, or thyroid medication (enhanced sympathomimetic effect)
Protocol
IV access is unnecessary in children receiving IM ketamine. IV access is desirable in adults to permit prompt treatment of unpleasant recovery reactions should they occur.
Connect appropriate monitoring equipment to the patient.
Pulse, respiratory rate, blood pressure, and level of consciousness should all be recorded initially, and periodically throughout the procedure depending on the depth of sedation.
Suction equipment, oxygen, a bag-valve-mask, and reversal agents should be immediately available. An age-appropriate resuscitation cart with oral and nasal airways, endotracheal tubes, and a functioning laryngoscope must be nearby.
Educate accompanying family regarding the unique characteristics of the dissociative state, especially if they will be present during the procedure and/or recovery.
Adults and children of verbal age should be encouraged to "plan" specific, pleasant dream topics in advance of sedation (believed to decrease unpleasant recovery reactions).
Co-administer atropine 0.01 mg/kg (minimum 0.1 mg, maximum 0.5 mg) either IV just prior to ketamine, or draw up and have atropine by the bedside. For IM injection, mix with ketamine in the same syringe (hypersalivation suppression). Glycopyrrolate is an acceptable alternative at equipotent doses.
Benzodiazepine co-administration is unnecessary in children to blunt emergence reactions; however, such drugs should be readily available to treat rare unpleasant recovery reactions should they occur. Midazolam may also be used to attain pre-procedural anxiolysis prior to ketamine administration, especially in frightened toddlers and early school age children. Benzodiazepine prophylaxis should be considered in adults due to their higher baseline risk of unpleasant reactions and to enhance cardiovascular stability. Midazolam 2 to 4 mg slowly IV is an example of such pretreatment.
Ketamine is not administered until the clinician is ready to begin the procedure, as onset of dissociation typically occurs within 5 minutes.
Ketamine is administered as a single IM injection or IV loading dose, and there is no benefit from routine attempts to titrate to effect.
When administered IM, give 4–5 mg/kg with atropine mixed in the same syringe. Repeat ketamine dose (full or half dose IM without additional atropine) if sedation is inadequate after 5–10 minutes (unusual) or if additional doses are later required.
When administered IV, give a loading dose of 1.5 mg/kg IV over 1–2 minutes. 100 mg is a typical adult dose. IV administration more rapidly than over 1–2 minutes produces high CNS levels and has been associated with respiratory depression. Additional incremental doses of ketamine may be given (0.5 mg/kg) if initial sedation is inadequate, or if repeated doses are necessary to accomplish a longer procedure. Repeat doses of atropine are generally unnecessary.
Adjunctive physical immobilization may be occasionally needed to control random motion.
Adjunctive local anesthetic may be needed for incomplete analgesia, although this is unusual.

Route of Administration	**IM**	**IV**
Advantages	No IV access necessary	Ease of repeat dosing
		Slightly faster recovery
Peak concentrations and clinical onset	5 min	1 min
Typical duration of effective dissociation	15–30 min	10–15 min
Typical time from dose to discharge	60–140 min	50–110 min

Whenever possible, minimize lighting, noise, and physical contact during recovery until wakefulness is well-established. Advise family to not stimulate the patient prematurely.

there appears to be no reason to avoid standard dissociative doses when ketamine is administered to adults. In a 1996 study using subdissociative doses (0.2 mg/kg IV) for the goal of bronchodilation in the treatment of acute asthma, three of six adults suffered dysphoric reactions. [102]

Ketamine presents potential risks to patients with coronary artery disease, as it is sympathomimetic and produces mild to moderate increases in blood pressure, heart rate, and myocardial oxygen consumption. The actual risk remains unclear due to limited experience in adults with known coronary artery disease. [99]

Given the available data, it would appear appropriate for emergency clinicians to carefully transpose their experience with ketamine into selected adult situations. Careful patient selection can help minimize potential adverse events (see Table 34-13).[99] [101]

Pediatric use.

Ketamine is an ideal agent to facilitate short, painful procedures in children. The safety and efficacy of ketamine for this indication has been widely documented. [4] [5] [6] [92] [97] The IM route is simple and effective. Venous access is unnecessary, and atropine can be concurrently administered in the same syringe. [4] IV administration is attractive because a lower cumulative dose can be used, and recovery is faster than with the IM route. The primary caution is that with this route, ketamine must be administered slowly (each dose over 1 to 2 minutes) or respiratory depression and transient apnea can occur. [97]

Unpleasant recovery reactions are uncommon in children and teenagers, and are typically mild when they do occur. [103] [104] There is no evidence of any benefit from the prophylactic administration of concurrent benzodiazepines in children, [103] [104] and their role should be confined to treating unpleasant reactions if they should occur.

Adverse effects.

In the largest published ED series (1022 patients) the following adverse airway events were noted: airway malalignment (0.7%), transient laryngospasm (0.4%), and transient apnea or respiratory depression (0.3%). All were quickly identified and treated, and there were no sequelae. [4]

Vomiting was noted in 6.7% from the same series, and in most cases it occurred well into recovery.[4] The incidence was age-related, occurring in 12.1% of children aged 5 years or older, and 3.5% in those younger than 5 years. [94] There was no evidence of aspiration[4] ; indeed, in 30 years of regular use there have been no documented reports of clinically significant ketamine-associated aspiration in patients without established contraindications. Delayed vomiting may occur after discharge, and patients should be advised of this possibility. Because of its unique preservation of protective airway reflexes, ketamine may be preferred over other agents for urgent or emergent procedures when fasting is not assured. [4] [5] [92]

Mild agitation during recovery (whimpering or crying) was noted in 17.6% of children from the same series, with more pronounced agitation in 1.6%. The incidence was age-related, with agitation occurring in 12.1% of children aged 5 or older, and 22.5% in those younger than 5. [94] Only 2 of 1022 children had reactions that treating clinicians judged severe enough to require treatment, and both children responded promptly to small doses of midazolam. [4] Another study quantified the degree of recovery agitation using a 0 to 100 mm visual analog scale; the median rating of recovery agitation was a 5, likely below the threshold of clinical importance.[103]

NITROUS OXIDE

Pharmacology.

Inhaled nitrous oxide provides anxiolysis and mild analgesia. It is commonly dispensed at concentrations between 30 and 50% with oxygen composing the remainder of the mixture. Nitrous oxide quickly diffuses across biologic membranes and accordingly has a rapid onset of action (30 to 60 seconds). Maximum effect occurs after about 5 minutes, and the clinical effect wears off quickly upon discontinuation. At typical PSA concentrations there is preservation of hemodynamic status, spontaneous respirations, and protective airway reflexes. [105] [106] [107] [108] Nitrous oxide is widely used in dentistry at higher concentrations. [105]

Nitrous oxide has an excellent safety profile; however, as a sole agent it cannot reliably produce adequate procedural conditions. [105] [106] [107] [108] Given its relatively weak analgesic properties, in many cases nitrous oxide needs to be supplemented with an IV opioid and/or local anesthesia.

Adult and cooperative child use.

The safest method of nitrous oxide administration is via a self-administered demand-valve mask (Fig. 34-2). [106] [107] [108] Patients must generate a negative pressure of 3 to 5 cm H_2 O within the handheld mask or mouthpiece to activate the flow of gas. They can thus self-titrate themselves by inhaling at will through the mask. Naturally, this will only be effective when the patient is cooperative. This technique provides a built-in fail-safe in that if patients become somnolent, the masks will fall from their faces and gas delivery will cease.

Nitrous oxide can be used as an adjunctive anxiolytic during mildly painful procedures, or during local or regional anesthesia administration for other procedures. It may also be administered during difficult pelvic examinations, during attempts at difficult IV access, etc.

A double-tank system is commonly used to deliver the nitrous oxide and O_2 mixture. The system relies on a mixing valve preset to deliver a fixed ratio and will only deliver gas when O_2 is flowing. The double-tank system contains a fail-safe device that automatically stops the flow of nitrous oxide when the O_2 supply is depleted.

Uncooperative child use.

The primary limitation of self-administration is that it is ineffective in uncooperative patients, including most frightened young children. Continuous-flow nitrous oxide has been used in this population using a mask strapped over the nose, or over the nose and mouth (Fig. 34-3 (Figure Not Available)). [110] [111] [112] Nitrous oxide can effectively produce moderate or deep sedation when administered in this manner; however, this technique necessitates an additional clinician dedicated to continuous gas titration to avoid oversedation. Additionally, for unclear reasons the continuous-flow technique is associated with a higher rate of emesis (10%) [110] [111] [112] than self-administration (0 to 4%), [105] [106] [107] [108] posing a potential hazard when a mask is strapped over the child's mouth. Finally, the requirement of a mask hinders procedures involving the perioral and nasal areas of the face. [111]

Adverse effects and precautions.

A number of generally minor adverse effects may be seen, including nausea, dizziness, voice change, euphoria, and laughter. [105] [106] [107] [108] Nitrous oxide should be avoided in closed-space disease such as bowel obstruction, middle ear disease, pneumothorax, or pneumocephaly. Because of its property of high diffusibility, it has potential to increase the size of the closed space. This should be unlikely for short-term use in typical PSA concentrations.

Figure 34-2 *A*, A demand-flow nitrous oxide/oxygen system. *B*, Example of a face mask for a nitrous oxide system. The mask must be held in contact with the face by the patient.

A scavenging system must be in place to collect exhaled nitrous oxide, and care must be taken to ensure compliance with occupational safety regulations. Care should also be taken to avoid nitrous oxide exposure in pregnant ED staff members as nitrous oxide is a known teratogen and mutagen.

Figure 34-3 (Figure Not Available) Nitrous oxide/oxygen continuous-flow system. *(From Luhmann JD, Kennedy RM, Jaffe DM, McAllister JD: Continuous-flow delivery of nitrous oxide and oxygen: A safe and cost-effective technique for inhalation analgesia and sedation of pediatric patients. Pediatr Emerg Care 15:388, 1999.)*

Although the potential for abuse by ED staff exists, such abuse should be rare if simple steps are taken. As with other agents, a strict protocol of accountability should be in place. A simple locking device can be added to the cylinders of gas. In addition, the delivery valve or mouthpiece may be locked in the same location as controlled substances.

Figure 34-4 The downward spiral of fatal cocaine-induced delirium starts long before the chronic cocaine user is brought to the hospital, but physical restraints applied by police, security guards, and medical personnel only aggravate the situation. When it takes leather restraints and a bevy of personnel to subdue a delirious, violent, and totally out-of-control patient, it's time for aggressive and effective parenteral sedation and evaluation for and rapid correction of hyperthermia and acidosis. In the scenario shown here, it is impossible to even begin to adequately evaluate or treat this patient. The sagacious clinician knows, however, that this individual is an acute medical emergency.

OTHER PSA AGENTS

Historically a popular PSA cocktail was the intramuscular combination meperidine, promethazine, and chlorpromazine ("DPT," "Dem compound"). However, this regimen cannot be titrated, is frequently ineffective, and is associated with prolonged recovery times. [113] [114] Its use can no longer be recommended.

ANTAGONISTS

Reversal agents should not be routinely administered following administration of opioids or benzodiazepines for PSA, but rather should be reserved for rare situations of oversedation or respiratory depression. When administered, caution should be taken to avoid resedation after discharge by continuing to monitor patients until the effects of the PSA agents (which may last longer than the antagonist) wear off.

Naloxone.

Naloxone is an antagonist that competitively displaces opioids from opiate receptors. It rapidly reverses the analgesic and respiratory depressant effects of opioids. It may be administered IV, IM, SC, or even sublingually if needed, [115] and dosing has been standardized for infants and children. [116] Naloxone will not induce systemic opioid withdrawal symptoms in a patient without preexisting physiologic dependence. However, some patients will experience nausea with opioid reversal, and those patients with persistent pain following their procedure will be quite uncomfortable. Rapid reversal also may lead to return of anxiety and sympathetic stimulation. *If the situation permits, careful titration of small amounts of naloxone may permit partial rather than complete reversal.* The only absolute contraindication to the use of naloxone is administration to a neonate born to an opioid-dependent mother due to the risk of precipitating life-threatening opioid withdrawal.

Nalmefene.

Nalmefene is a long-acting opioid antagonist with a duration of action significantly longer than naloxone. [117] Nalmefene may be given IV, IM, or SC, although IV is the preferred route.[117] [118] Intravenously, it can be titrated in incremental doses of 0.25 mcg/kg every 2 to 5 minutes until the desired effect is attained. Although either naloxone or nalmefene will reverse analgesia due to opioids, naloxone is the preferred agent. For ED PSA, short-acting opioids such as fentanyl are commonly used and administration of a reversal agent with as prolonged duration of action as nalmefene does not confer any additional benefit. Furthermore, nalmefene would interfere with post-procedure opioid pain control.

Flumazenil.

Flumazenil is a benzodiazepine antagonist that can promptly reverse benzodiazepine-induced sedation and respiratory depression. [1] [13] [119] [120] In the setting of PSA, flumazenil is a safe and effective method of reversing oversedation caused by benzodiazepines. It is not routinely used to reverse PSA because of the potential for resedation, and many clinicians prefer to allow patients to recover on their own. Flumazenil has not been shown to substantially decrease the time of observation in the ED required of a patient undergoing PSA. Flumazenil lowers the seizure threshold and may rarely lead to life-threatening seizures. It should be avoided in settings of known benzodiazepine dependence, seizure disorder, cyclic antidepressant overdose, and elevated intracranial pressure. [121] It should also be given cautiously to patients who are on medications known to lower the seizure threshold (cyclosporine, tricyclic antidepressants, propoxyphene, theophylline, isoniazid, lithium). [121] These issues, however, are generally not involved in PSA in the ED. It has not been shown that simply taking therapeutic doses of these medications contraindicates flumazenil, and flumazenil-induced seizures are generally only associated with drug overdose. Rapid reversal also may lead to return of anxiety and sympathetic stimulation. If the situation permits, careful titration of small amounts of flumazenil will reduce the risk of adverse effects and may permit partial rather than complete reversal.

CHEMICAL RESTRAINT OF THE PSYCHOTIC OR AGITATED PATIENT

Not infrequently patients present to the ED with combative behavior due to psychosis, dementia, withdrawal syndromes,

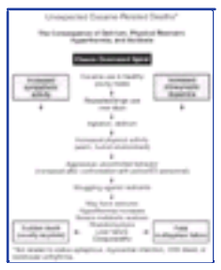

Figure 34-5 The postulated downward spiral of agitated delirium in a cocaine-intoxicated patient. An adverse outcome may theoretically be ameliorated with the aggressive use of chemical restraint.

or alcohol/drug intoxication. The latter occurs commonly in the setting of minor or major trauma and especially with stimulants such as cocaine or phencyclidine. Combative individuals can present a significant threat to themselves and their families, to other ED patients and their families, and to the ED staff.

Figure 34-6 When an indwelling venous catheter cannot be obtained in the violent patient, the clinician may mainline the appropriate medications. By enlisting the help of security personnel, the arm or foot is immobilized by brute force, and medication is given by bolus injection into a large anticubital (*A*) or saphenous vein (*B*). Alternatively, two security guards lie across the upper thighs and lower stomach, and the clinician injects directly into the femoral vein (being careful to avoid an intra-arterial injection).

While a show of force, bargaining, psychological manipulation, enlisting family members, etc., may aid the clinician in controlling disruptive individuals, some patients, particularly those with drug-induced delirium, simply cannot comply with such measures (Fig. 34-4). Security personnel may be reluctant to intervene because of the fear of contracting communicable diseases from biting and bleeding patients. Basic vital signs, tests, or other interventions cannot proceed under such conditions. This scenario taxes the clinician's self-control, patience, negotiating skills, and clinical judgment on a regular basis. *However, it is imperative that wildly agitated, violent, combative, or uncontrollable patients not be physically restrained for prolonged periods without some type of adjunctive pharmacologic intervention.* The restrained yet still struggling patient quickly becomes hyperthermic and acidotic, and may experience rhabdomyolysis or other forms of musculoskeletal trauma from the restraints. In some causes sudden death due to cardiovascular collapse or multisystem failure may ensue, even in young and previously healthy individuals. [122] [123] The prehospital hobble position (hands and feet bound behind the back and placed prone) has been particularly emphasized as an undesirable method of restraint.[124] The classic downward spiral in cocaine-related delirium in the setting of physical restraint without chemical sedation is noted in Figure 34-5 .

Rapid, safe, and effective pharmacological methods (i.e., rapid tranquilization—[RT]) are available for use in these situations to gain control of patients who are agitated, potentially assaultive, destructive, or overtly violent. It is critical to accurately assess the etiology of the combative behavior and not to mistake hypoglycemia, head trauma, pain, or hypoxia for psychosis. However, in many cases, the etiology of the agitation, violence, or uncontrolled behavior simply may not be known prior to intervention being required. Two classes of drugs are currently used for rapid tranquilization: benzodiazepines and neuroleptics.

Under most circumstances, the IV use of such medication is preferred, although venous access may be problematic. When an indwelling intravenous port is not available, direct IV injection (mainlining) may be successful. One method is to restrain the groin, anticubital area, or leg by brute force,

TABLE 34-14 -- Drug Dosing Recommendations for Rapid Tranquilization

Drug	Clinical Effects	Indications	Adult Dose[2]	Pediatric Dose	Onset (Min)	Duration (Min)	Comments
NEUROLEPTICS							
Droperidol (*Inapsine*)	CNS tranquilization, anti-emetic, anti-psychotic	Rapid tranquilization, chemical restraint	2.5–10 mg (start dose at 2.5 mg in elderly patients and patients receiving concomitant CNS depressants)	0.05–0.07 mg/kg IM/IV	IV: 3–10	60–120	May cause EPS. FDA black box warning regarding QT-related dysrhythmias. (see text). Hypotension.
					IM: 3–10		
Haloperidol (*Haldol*)	CNS tranquilization, anti-psychotic	Rapid tranquilization, chemical restraint	5–10 mg IM/IV (start at 2 mg in the elderly and patients receiving concomitant CNS depressants	5–12 years old: 0.1 mg/kg IM/IV >12 years old: Use adult dosing	IV: 5–10	60–120+	May cause EPS.
					IM: 10–20		
SEDATIVE/HYPNOTICS							
Lorazepam* (*Ativan*)	Sedation, motion control, anxiolysis	Anxiolytic and sedative adjunct to neuroleptic	1–4 mg IM/IV	0.05–0.1 mg/kg IM/IV (not to to exceed adult dosing)	IV: 2–3	IV: 45–60	Monitor for respiratory depression
					IM: 10–20	IM: 60–120	
TREATMENT OF EXTRAPYRAMIDAL SYMPTOMS							
Benztropine (*Cogentin*)	Reversal of EPS	EPS (dystonia, akathisia)	2 mg PO/IM	0.5–2 mg PO/IM	PO: 15–60	PO/IM: 24 hours	Anticholinergic effects (e.g., dry mouth, urinary retention, tachycardia).
					IM: 10		

Diphenhydramine (*Benadryl*)	Reversal of EPS	EPS (dystonia, akathisia)	25–50 mg PO/IM/IV	1 mg/kg PO/IM/IV	PO: 30–60	PO/IM/IV: 6–8 hours	Anticholinergic effects (e.g., dry mouth, urinary retention, tachycardia).
					IM: 20–30		
					IV: 5–10		

*There is no maximum dose of benzodiazepines. Massive doses may be required in severely agitated patients. EPS = extrapyramidal symptoms.

with the direct IV injection of the sedating medication (Fig. 34-6). When the patient has been controlled, indwelling venous access can be accomplished. In the less stressful situation, the IM route may be acceptable. The use of IM ketamine to control a dangerous and violent patient without venous access has been described, but the role of ketamine in this situation is presently unclear. [125]

There is no specific maximum dose for drugs used for chemical restraint.

Occasionally massive doses may be required. If benzodiazepine or neuroleptics, or both, are not effective, muscular paralysis and mechanical ventilation may be necessary to gain control of the patient.

Benzodiazepines

Historically, the first drugs used as adjuncts to phenothiazines for RT were barbiturates, allowing decreased dosing of chlorpromazine, thereby minimizing the incidence of hypotension. Benzodiazepines have now replaced barbiturates as adjuncts to neuroleptics in RT. The benzodiazepine of choice for RT in both adults and children is lorazepam (Ativan, adult dosing: 1–4 mg IM/IV; pediatric dosing: 0.05–0.1 mg/kg IM/IV) because of its bioavailability and rapid IM absorption, intermediate duration, and low side-effect profile (Table 34-14). It is commonly given with a neuroleptic (e.g., haloperidol) to achieve rapid anxiolysis and anti-psychosis. [126] This combination has been shown to have a more rapid onset and fewer extrapyramidal symptoms (EPS) than with haloperidol alone, and is well-tolerated with no respiratory depression or hypotension. [127]

Neuroleptics

The first anti-psychotic agents used for rapid tranquilization were the low-potency phenothiazines (e.g., chlorpromazine [Thorazine], thioridazine [Mellaril]). These agents are highly sedating and manifest anticholinergic effects, alpha adrenergic blockade (leading to orthostatic hypotension), a lowered seizure threshold, and cardiac toxicity in overdose. During the 1990s, these agents have been replaced by the butyrophenones haloperidol (Haldol) and droperidol (Inapsine) (see Table 34-14).

Haloperidol (adult dosing: 5–10 mg IM/IV [start at 2 mg in the elderly and patients receiving concomitant CNS depressants]; pediatric dosing—5–12 years old: 0.1 mg/kg IM/IV, >12 years old: use adult dosing) and droperidol (adult dosing: 2.5–10 mg [reduce dose for elderly patients and patients receiving concomitant CNS depressants]; pediatric dosing: 0.05–0.07 mg/kg IM/IV) are high-potency agents that, compared to the phenothiazines, are relatively free of anti-cholinergic effects, alpha-blocking properties, and cardiac toxicity, but cause more EPS. [128] The overall incidence of EPS (e.g., dystonic reactions, akathisia) with butyrophenones is low, occurring in less than 10% of RT patients within the first 24 hours, and such reactions can be effectively treated with IM or IV diphenhydramine (Benadryl, adult dosing: 25–50 mg PO/IM/IV; pediatric dosing: 1 mg/kg PO/IM/IV and/or benztropine; Cogentin, adult dosing: 2 mg PO/IM; pediatric dosing [>3 years old]: 0.5–2 mg PO/IM).[128]

Acute dystonia in particular is a non-dose-dependent, idiosyncratic reaction. Both neuroleptics have minimal effect on respiratory drive and airway reflexes, and their safety and efficacy in the ED have been well-documented.[129] [130] [131] Droperidol has a faster onset time IM, shorter duration, and is more sedating than haloperidol.[129] [132] Neuroleptics will also exacerbate pre-existing Parkinsonism, and should be avoided in these patients. A much-feared idiosyncratic reaction, occurring in 1% of patients on neuroleptics, is neuroleptic malignant syndrome (NMS), characterized by potentially severe autonomic instability (hyperthermia, hypertension, and rigidity). NMS can rarely occur in the setting of RT with patients on chronic antipsychotic medications. Haloperidol has been reported to lower the seizure threshold in animals, but this remains a theoretical concern clinically as there are no reported cases in humans despite its use in post-ictal and alcoholic patients. Although droperidol has been used extensively in the ED over the last 10 years and clinicians experienced in its use consider it safe and effective, its use has decreased since the FDA issued "black box warning" in December 2001 regarding QT-related dysrhythmias. [133] Patients receiving droperidol must be carefully screened for a history of QT-related dysrhythmias and whenever possible receive a baseline ECG or rhythm strip to ensure a normal QT interval. However, there is little rational behind the "black box warning" to justify a change in ED practice with this agent. [134]

Alternative Agents

Ketamine has been effectively used as an alternative tranquilization agent [125] ; however, it may exacerbate intracranial hypertension in patients with head trauma or CNS infections.[92] A reserve option for situations of grave danger is paralysis with succinylcholine IV or IM (1–1.5 mg/kg IV; 4 mg/kg IM), followed by rapid airway control.[135]

Acknowledgment

The editors and author wish to acknowledge the contributions of Kevin R. Ward and Donald M. Yealy to this chapter in previous editions.

Section VI - Soft Tissue Procedures

Chapter 35 - Principles of Wound Management

Richard L. Lammers

Acute traumatic wound management is one of the most common procedures in the practice of emergency medicine. There are many areas of controversy in the medical literature, numerous personal preferences, and a plethora of protocols and individual approaches. Few agreed upon standards of care exist for many aspects of wound care.[1] Also, there are many myths and misconceptions surrounding the vagaries of wound preparation and wound care. The purpose of this chapter is to give the clinician a general approach to wound care and to suggest reasonable techniques; however, lack of data to support or refute many of the described clinical issues that confront clinicians daily renders much of the following discussion intuitively practical but somewhat theoretical.

Wound care involves much more than closure of divided skin. The primary goal of wound care is not the technical repair of the wound; it is providing optimal conditions for the natural reparative processes of the wound to proceed. Primary wound healing is not an inevitable process. For centuries, victims of wounds commonly experienced inflammation, infection, and extreme scarring; in fact, these processes were considered part of normal wound repair. Only in the late 19th century did surgeons first realize that sepsis could be separated from healing. [2]

The cornerstones of wound care are cleaning, debridement, closure, and protection. The primary technical objectives in wound care are as follows:

1. Preserving viable tissue and removing nonviable tissue
2. Restoring tissue continuity and function
3. Optimizing conditions for the development of wound strength
4. Preventing excessive or prolonged inflammation
5. Avoiding infection and other impediments to healing
6. Minimizing scar formation

When presenting to emergency departments (EDs) with acute wounds, patients report that their top priorities in the management of their wounds include prevention of infection, return to normal function, good cosmetic outcome, and minimal pain during repair. [3] [4] This chapter reviews current strategies for achieving all of these goals.

BACKGROUND

Wound Healing

Emergency clinicians should have a basic understanding of the process of wound healing. Highlights of this complex phenomenon as they relate to clinical decision making are presented.

Wounds extending beneath the epithelium heal by forming scar tissue. Inflammation, epithelialization, fibroplasia, contraction, and scar maturation constitute the stages of this nonspecific repair process. [2] [5] [6] Inflammation is a beneficial response that serves to remove bacteria, foreign debris, and devitalized tissue—a biologic debridement. Polymorphonuclear and mononuclear leukocytes concentrate at the site of injury and phagocytose dead and dying tissue, foreign material, and bacteria in the wound. [7]

As white blood cells die, their intracellular contents are released into the wound. In excessive amounts, they form the purulence characteristic of infected wounds. Some exudate is expected even in the absence of bacterial invasion; however, infection with accumulation of pus interferes with epithelialization and fibroplasia and impairs wound healing. Wounds contaminated with significant numbers of bacteria or foreign material may undergo a prolonged or persistent inflammatory response and may not heal. Granuloma formation surrounding retained sutures is an example of chronic inflammation. [8]

As white blood cells remove debris within the wound, epithelial cells at the surface of the wound begin to migrate across the tissue defect. In most sutured wounds, the surface of the wound develops an epithelial covering impermeable to water within 24 to 48 hours. Eschar and surface debris impair this process. The epithelium thickens and grows downward into the wound and along the course of skin sutures. Although there is some "adhesiveness" to the wound edges during the first few days, this is lost because of fibrinolysis.

By the fourth or fifth day, newly transformed fibroblasts in the wound begin synthesizing collagen and protein polysaccharides, initiating the stage of scar formation known as *fibroplasia*. Collagen is the predominant component of scar tissue. Wound strength is a balance between the lysis of old collagen and the synthesis of new collagen "welding" the wound edges together. The amount of scar tissue is influenced by physical forces (e.g., the stresses imposed by movement) acting across the wound. In contrast, a wound that heals by secondary intention closes by contraction. *Contraction* is the movement of skin edges toward the center of the defect, primarily in the direction of underlying muscle.

Significant gains in tensile strength do not begin until approximately the fifth day following the injury. Strength increases rapidly for 6 to 17 days, more slowly for an additional 10 to 14 days, and almost imperceptibly for as long as 2 years (Fig. 35-1). The strength of scar tissue never quite reaches that of unwounded skin. Although the process of collagen formation is essentially completed within 21 to 28 days, the scar widens for another month, and collagen continues to remodel and strengthen the wound for up to 1 year. [2] [8]

Decisions regarding the optimal time for suture removal and the need for continued support of the wound with tape are influenced by (1) wound tensile strength, (2) the period of scar widening, and (3) the cosmetically unacceptable effect of epithelialization along suture tracks. Scars are quite red and noticeable at 3 to 8 weeks following closure. However, the appearance of a scar should not be judged before the scar is well into its remodeling phase. The cosmetic appearance of wounds 6 to 9 months after injury cannot be predicted at the time of suture removal. [9] Therefore, any scar revision should be postponed until 6 to 12 months after injury.

Zitelli states, "The most important factor in predicting the cosmetic result is wound location. In general, wounds on concave surfaces heal with better cosmetic results than wounds on convex surfaces. Besides location, other factors such as *skin color, wound size*, and *wound depth* are helpful in predicting the cosmetic results of wounds healing by secondary intention." [10]

Small, superficial wounds in lax, light-colored skin, especially in areas in which the skin is thin, result in less noticeable scars. Wounds on convex surfaces look better after

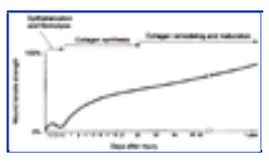

Figure 35-1 Graphic representation of the various phases of wound healing. Note that the tensile strength of scar tissue never reaches that of unwounded skin. Displayed values of tensile strength are approximate and demonstrate the general concept of wound healing.

primary closure than following secondary healing. Static and dynamic forces, and the propensity toward keloid formation, may influence the long-term cosmetic appearance of wounds more than the surgical skills of the clinician who repaired the wound. [9] Repigmentation occurs over 3 to 5 years, even in large wounds that heal by secondary intention. [10]

INITIAL EVALUATION

The approach to the management of a particular wound depends on information gathered during history taking and on the results of physical examination. The decision on whether to close a wound immediately or after a period of observation is based on various factors that affect the risk of infection. Some wounds may appear benign but conceal extensive and devastating underlying tissue damage. The discovery that an extremity wound was produced by a roller or wringer device, a high-pressure injection gun, high-voltage electricity, heavy and prolonged compressive forces, or the bite of a human or a potentially rabid animal radically alters the overall management of the affected patient. The American College of Emergency Physicians' "Clinical Policy for the Initial Approach to Patients Presenting with Penetrating Extremity Trauma" provides a useful approach to the evaluation of all wounds. [11]

History

In the initial evaluation of a wound, the clinician should identify all of the extrinsic and intrinsic factors that jeopardize healing and promote infection. These include the mechanism of injury, the time of injury, the environment in which the wound occurred, and the patient's immune status. Although the clinician would like to believe that all patients are forthright and honest when offering historical data, such is not always the case. A common example of this is the workman who sustains a human bite to the hand during a bar fight on Saturday who steadfastly claims that the injury occurred on the job Monday morning to gain workman's compensation benefits.

Wound Age: The "Golden Period"

In general, the likelihood of wound infection increases with the time that elapses before definitive wound care. [12] [13] [14] A delay in *wound cleaning* is the most important variable, and may allow bacteria contaminating the wound to proliferate. A delay in treatment of a contaminated wound for as little as 3 hours can result in infection. [15] [16] However, there is evidence suggesting that wounds in highly vascular regions such as the face and scalp can be closed without increased risk as long as 24 hours after injury.[17] Some investigators have been unable to establish any significant relationship between time of suturing and subsequent infection rates. [18] Contrary to popular belief, the "golden period"—the maximum time after injury that a wound may be safely closed without significant risk of infection— *is not a fixed number of hours*.[19] Likely this period is longer than commonly believed (Fig. 35-2).

Many factors affect infection risk, and closure decisions should not be based solely on temporal considerations. Peacock points out that "a clean razor slice of highly vascular skin of the face might be closed safely 48 hours after injury, whereas a stable-floor-nail penetration of the foot of an elderly person might not be closed safely 1 minute after injury."[6] Berk and colleagues concluded that there is little change in wound infection rates in most areas of the body for up to 19 hours after various traumatic injuries, and infection rates of simple wounds involving the head are essentially unaffected by the interval between injury and repair. [17] Hence, all data accumulated in the initial evaluation, both historical and physical, must be considered when making the decision to close a wound in a particular patient. In addition, the techniques of wound care in and of themselves may extend the golden period; a skillful clinician can often convert a dangerously contaminated wound into a clean wound that can be safely closed.[6]

Other Historical Factors

Other factors that affect wound healing or the risk of infection include the patient's age and state of health. Patient age appears to be an important factor in host resistance to infection; those individuals at the extremes of age—young children and the elderly—are at greatest risk. [20] [21] Infection rates are reported to be higher in patients with medical illnesses (e.g., diabetes mellitus, immunologic deficiencies, malnutrition, anemia, uremia, congestive heart failure, cirrhosis, malignancy, alcoholism, arteriosclerosis, arteritis, collagen vascular disease, chronic granulomatous disease, smoking or chronic hypoxia, liver failure), in obese patients, and in patients taking steroids or immunosuppressive drugs or those receiving

Figure 35-2 This laceration illustrates that there is no specific time frame (the so-called golden period) during which a laceration must be closed, or else relegated to an unsightly scar or a revision months later. *A*, This woman was punched in the face, suffered a laceration of the cheek, and presented to the ED 36 hours later. The wound was not infected, had contracted, and was beginning to heal by granulation. Under local anesthesia the wound was opened, irrigated, minimally debrided, and the skin edges were trimmed. *B*, Using a No. 15 blade, a 1-mm skin edge was incised. *C*, The trimmed edges were then cut by scissors. *D*, The wound was undermined to relieve tension on the skin. *E*, The wound was closed with 6-0 interrupted sutures that were removed in 5 days. No antibiotics were used and only a small linear scar resulted.

radiation therapy. Shock, remote trauma, distant infection, bacteremia, retained foreign bodies, denervation, and peripheral vascular disease also increase wound infection rates and slow the healing process. [7] [21] [22] [23]

Additional information pertinent to decision making in wound management includes:

Present medications (specifically, anticoagulants and immunosuppressive drugs)

Allergies (especially to local anesthetics, antiseptics, analgesics, antibiotics, and tape)

Tetanus immunization status

Potential exposure to rabies (in bite wounds and mucosal exposures)

Potential for foreign bodies embedded in the wound, especially when the mechanism of injury is unknown or was associated with breaking glass or vegetative matter[24]

Previous injuries and deformities (especially in extremity and facial injuries)

Associated injuries (underlying fracture, joint penetration)

Other factors (availability for follow-up, patient understanding of wound care or compliance)

Physical Examination

All wounds should be examined for amount of tissue destruction, degree of contamination, and damage to underlying structures. A common error in wound management is to assume that a traumatic wound is already contaminated and then, during the examination, to contaminate it further. Despite the fact that all traumatic wounds are contaminated to some degree, these injuries should be examined using aseptic technique. It is prudent for the examiner to wear clean or sterile

gloves and avoid droplet contamination from the mouth by maintaining distance or, preferably, by wearing a mask. [25] It has never been proven, however, that the use of sterile gloves (as opposed to clean ones) has any influence on infection rates for common lacerations, and many clinicians do not routinely

use sterile gloves for all wound care. Wounds should be examined under good lighting and after bleeding is controlled. It is appropriate, and often necessary, to obtain a bloodless field with the use of tourniquets. Distal perfusion and motor/sensory function should be assessed and documented during the evaluation of extremity wounds, and before the use of anesthetics.

Mechanism of Injury and Classification of Wounds

The magnitude and direction of the injuring force and the volume of tissue on which the force is dissipated determine the type of wound sustained. Three types of mechanical forces produce soft tissue injury: shear, tension, and compression forces. The resulting disruption or loss of tissue determines the configuration of the wound. Wounds may be classified into six categories:

1. *Abrasions.* Wounds caused by forces applied in opposite directions, resulting in the loss of epidermis and possibly dermis (e.g., skin grinding against road surface).
2. *Lacerations.* Wounds caused by shear forces that produce a tear in tissues. Tensile and compressive forces also cause separation of tissue. Little energy is required to produce a wound by shear forces (e.g., a knife cut). Consequently, little tissue damage occurs at the wound edge, the margins are sharp, and the wound appears "tidy." The energy required to disrupt tissue by tensile or compressive forces (e.g., forehead hitting a dashboard) is considerably greater than that required for tissue disruption by shear forces, because the energy is distributed over a larger volume. These lacerations have jagged, contused, "untidy" edges; consequently, they have a higher risk of infection. [21]
3. *Crush wounds.* Wounds caused by the impact of an object against tissue, particularly over a bony surface, which compresses the tissue. These wounds may contain contused or partially devitalized tissue.
4. *Puncture wounds.* Wounds with a small opening and whose depth cannot be entirely visualized. Puncture wounds are caused by a combination of forces.
5. *Avulsions.* Wounds in which a portion of tissue is completely separated from its base and is either lost or left with a narrow base of attachment (a flap). [26] Shear and tensile forces cause avulsions.
6. *Combination wounds.* Wounds with a combination of configurations. For example, stellate lacerations caused by compression of soft tissue against underlying bone create wounds with elements of crush and tissue separation; missile wounds involve a combination of shear, tensile, and compressive forces that puncture, crush, and sometimes avulse tissue. [25]

Contaminants (bacteria and foreign material).

Numerous factors affect the risk of wound infection, but the primary determinants of infection are the amount of bacteria and dead tissue remaining in the wound. [27] Also of importance is the ability of the patient's immune system to respond to bacterial invasion and the presence of local tissue ischemia or hypoxia. [28]

Essentially all traumatic wounds are contaminated with bacteria to some extent. The number of bacteria remaining in the wound at the time of closure is directly related to the risk of infection. A critical number of bacteria must be present in a wound before a soft tissue infection develops. In experimental wounds produced by shear forces, an inoculum of $=10^6$ aerobic bacteria per gram of tissue inevitably produces wound infection in time. When the mechanism of injury involves a compressive force, the infective dose of bacteria is $=10^4$ bacteria per gram of tissue. If bacterial counts after injury (or after wound management) are below this level, the wound has a very low probability of becoming infected. [12] [15]

Surgical operations are categorized on the basis of the relative levels of bacterial contamination of the wounds. Most traumatic wounds fall into one of two categories:

1. *Contaminated wounds.* Traumatic wounds <12 hours old (the most common type of wound seen in EDs).
2. *Dirty wounds.* Wounds heavily contaminated with pathogenic organisms, those with significant numbers of bacteria associated with large amounts of devitalized tissue, or traumatic wounds older than 12 hours. [29]

Infection rates in series of contaminated wounds of all types range from 1.1% to 21%; rates in series of dirty wounds range from 7% to 38%. [20] [22] [29] [30] [31] [32] [33] [34] The nature and amount of foreign material contaminating the wound often determine the type and quantity of bacteria implanted. In general, visible contamination of a wound increases infection risk. [21] The presence of undetected reactive foreign bodies in sutured wounds almost guarantees an infection. Although bullet or glass fragments by themselves rarely produce wound infection, these foreign bodies may carry particles of clothing, gun wadding, or soil into the wound. Minute amounts of organic or vegetative matter, feces, or saliva carry highly infective doses of bacteria. The bacterial inoculum from human bites often contains 100 million or more organisms per milliliter of saliva. [35]

Inorganic particulate matter, such as sand or road surface grease, usually introduces few bacteria into a wound and has little chemical reactivity; these contaminants are relatively innocuous. However, soil containing a large proportion of clay particles readily promotes infection. Presumably because of their marked chemical reactivity, clay particles damage local tissue defenses. [36] Soils with a high organic content, such as those in swamps, bogs, and marshes, also have a high infection potential. [37]

Most wounds encountered in the practice of emergency medicine have low initial bacterial counts. If wound cleaning and removal of devitalized tissue are instituted before bacteria within the wound enter their accelerated growth phase (3 to 12 hours following the injury) and if one uses aseptic technique in examining and managing these wounds, bacterial counts will remain below the critical number needed to initiate infection. [12] [15]

Wound Location

The anatomic location of the wound has considerable importance in the risk of infection. Bacterial densities on the skin surface range from a few thousand to millions per square centimeter. [37] Areas with endogenous microflora in numbers sufficient to infect a wound ($>10^5$ bacteria/cm^2) include the hairy scalp, the forehead, the axilla, the perineum, the foreskin of the penis, the vagina, the mouth, intertriginous areas, and the nails. In other regions, skin bacteria are sparse (10^2 to 10^3 bacteria/cm^2) and are not a source of infection. [25] Wounds in regions of high vascularity, such as the scalp and the face, more easily resist bacterial incursions. The high vascularity of the scalp probably accounts for extremely low infection rates with scalp injuries, despite the large numbers of endogenous

microflora. Distal extremity wounds, in contrast, are more at risk for the development of wound infections than are injuries of most other parts of the body. [20] Wounds in ischemic tissue are notoriously susceptible to infection. [38]

Devitalized Tissue

Identifying devitalized tissue is an important part of the examination of a wound. Tissue damage lowers the resistance of the wound to infection. Devitalized or necrotic tissue enhances the possibility of infection in a wound by providing a culture medium in which bacteria proliferate, by inhibiting leukocyte phagocytosis, and by creating an anaerobic environment suitable for certain bacterial species. [25] [27]

Underlying Structures

Identification of injury to underlying structures such as nerves, vessels, tendons, joints, bones, or ducts may lead the emergency clinician to forgo wound closure and consult a surgical specialist. Procedures such as joint space irrigation, reduction and debridement of compound fractures, neurorrhaphy, vascular anastomosis, and

flexor tendon repair are best accomplished in the controlled setting of the operating room, in which optimal lighting, proper instruments, and assistance are available.[25]

CLEANING

The wound should be cleaned as soon as possible after evaluation. Although most wounds are contaminated initially with less than an infective dose of bacteria, given time and the appropriate wound environment, bacterial counts may reach infective levels. The goals of wound cleaning and debridement are the same: (1) to remove bacteria and reduce their numbers below the level associated with infection, and (2) to remove particulate matter and tissue debris that would lengthen the inflammatory stage of healing or allow the growth of bacteria beyond the critical threshold. [23]

Patient Preparation

Before examining, cleaning, exploring, or repairing wounds, medical procedures should be explained to patients to allay fears and encourage patient cooperation. In general, all wound care should be performed *with the patient in a supine position,* since fainting is a common occurrence once wound preparation has commenced (Fig. 35-3). Even the most hardy or brave patient may faint at the sight of a needle, scalpel, or blood. Patient falls are a serious source of comorbidity and litigation. Likewise, relatives and friends should be allowed to stay with the patient only after their propensity for fainting has been assessed and they have been properly cautioned. The wise clinician will insist that any significant others who remain in the room to support the patient sit during the procedure and report any perceived dizziness or nausea. In general it is not suggested that parents or friends actively participate in the wound care procedures.

Wound Handling

Anyone cleaning, irrigating, or suturing wounds should wear protective eyewear and a mask, as virtually any patient may be seropositive for the human immunodeficiency virus (HIV). Although mucosal exposure to blood or tissue products that

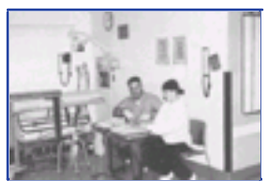

Figure 35-3 What's wrong with this picture? The patient is sitting up during laceration repair. Shortly after this picture was taken the patient fainted and nearly fell off the chair. Even the bravest patients should be *supine* for surgical procedures.

are contaminated by HIV is considered a relatively low risk for subsequent infection, universal precautions are currently recommended.

Thorough cleansing of bacteria, soil, and other contaminants from a wound cannot be accomplished without the patient's cooperation. Scrubbing most open wounds is painful, and the patient's natural response is withdrawal. Therefore, *local or regional anesthesia often must precede the examination and cleaning of a wound*. Approaches to wound anesthesia are discussed in detail in Chapter 30 Chapter 31 Chapter 32 Chapter 33 .

Despite adequate anesthesia, the patient may be unable to cooperate because of apprehension. The clinician should explain the wound cleansing procedure and assure the patient that everything possible will be done to minimize pain. Reassurance may not alleviate the fears of young children, and both sedation and physical restraining devices must be used. Approaches to sedation using parenteral sedative-hypnotics and narcotic agents and the use of inhaled nitrous oxide are discussed in Chapter 34 .

The two primary methods of wound cleaning are mechanical scrubbing and irrigation. Soaking a wound in a saline or antiseptic solution before the clinician arrives is of little value and is not recommended as a routine practice. Indeed, soaking a wound in saline may actually increase bacterial counts. [39] The following section discusses methods of scrubbing and irrigation.

Mechanical Scrubbing

Initially, a wide area of skin surface *surrounding the wound* should be scrubbed with an antiseptic solution to remove contaminants that in the course of wound management might be carried into the wound by instruments, suture material, dressings, or the clinician's gloved hand. Minimal aseptic technique requires the use of gloves during the cleaning procedure. It is important to remove all nonabsorbable particulate matter; any such material left in the dermis may become impregnated in the healed tissue and result in a disfiguring "tattoo" effect. [8] However, scrubbing the internal surface of a wound is controversial. Although scrubbing a wound with an antiseptic-soaked sponge does remove foreign particulates, bacteria, and tissue debris, an abrasive sponge may inflict more damage on tissue and provoke more inflammation.[40] [41]

Some clinicians reserve mechanical scrubbing for "dirty" wounds contaminated with significant amounts of foreign material. If irrigation alone is ineffective in removing contaminants from a wound, the wound should be scrubbed. Because the amount of damage inflicted on tissues by scrubbing correlates to the porosity of the sponge, a fine-pore sponge (e.g., Optipore sponge [90 pores per linear inch]) should be used to minimize tissue abrasion. [40] [42] Detergents have an advantage over saline because they minimize friction between the sponge and tissue, thereby limiting tissue damage during scrubbing. Detergents also dissolve particles, helping to dislodge them from the wound surface. Unfortunately, many of the available detergents are toxic to tissues. [40] [43]

Antiseptics During Cleaning

For many years, antiseptic solutions have been used for their antimicrobial properties in and around wounds (Table 35-1). Studies of antiseptics in wounds demonstrate that there is a delicate balance between killing bacteria and injuring tissue. [44] Intact skin can withstand strong microbicidal agents, whereas leukocytes and the exposed cells of skin and soft tissue can be damaged by these agents. [23]

Many antiseptic solutions have been used for cleaning wounds. Povidone-iodine (Betadine) is widely available as a 10% stock solution. The undiluted solution is best kept out of the wound proper. Although studies on the efficacy and safety of povidone-iodine solution have shown variable results, [29] [39] [45] [46] [47] [48] it appears that *dilute* povidone-iodine solution in concentrations of <1% is both safe and effective for use in contaminated traumatic wounds. The precise concentration that provides the most benefit is unknown. In contrast, povidone-iodine surgical scrub (Betadine scrub) and hexachlorophene (pHisoHex) both contain anionic detergents that are harmful to tissues and increase infection rates when used in wounds. [25] [41] [42] Aqueous iodine is irritating and corrosive to tissue and should not be used in any wound.[45]

In vitro studies have demonstrated the toxicity of chlorhexidine gluconate-alcohol (Hibiclens) to the cellular components of blood. [48] Some clinicians use hydrogen peroxide for its effervescent effect in cleaning wounds. Peroxide has been used for many years without a proven effect on most wounds and its actual role as a detriment to wound healing is probably minimal. However, because peroxide is hemolytic, it is best to use it only to clean surrounding skin encrusted with blood and coagulum or to soak off adherent blood-soaked dressings. Peroxide should not be used on granulation tissue, because oxygen bubbles lift newly formed epithelium off the wound surface.[49] Hexachlorophene was used as an antiseptic for a time but was found to be neurotoxic and teratogenic through skin absorption. Its narrow antimicrobial spectrum makes it no more effective than ordinary soap and water. [50] Quaternary ammonium compounds are less toxic to tissue but have a limited antimicrobial spectrum; gram-positive organisms are more susceptible to these solutions than are gram-negative bacteria. Benzalkonium chloride (Zephiran) is inactivated by soaps, detergents, blood, and other organic matter. Furthermore, *Pseudomonas* can proliferate in stored solutions. Consequently, use of benzalkonium

chloride has fallen into disfavor. [42]

Nonantiseptic nonionic surfactants are attractive alternatives to these toxic cleansing agents. In contrast to antiseptic solutions, these preparations cause no tissue or cellular damage, leukocyte inhibition, or impairment in wound healing. The solutions also cause no corneal injury, conjunctival irritation, or pain on contact with the wound. [48] [51] Poloxamer 188 (Pluronic F-68, Shur-Clens, and Pharma Clens) is nontoxic, even when administered intravenously, and nonallergenic. [43] This pluronic polyol has no antibacterial activity, but scrubbing experimental wounds with poloxamer has reduced infection rates, proving its ability to cleanse a wound effectively and atraumatically. [40]

A survey of wound practice by Howell and Chisholm suggests that a wide range of solutions and techniques are in clinical use in the United States. [1] However, it is important to distinguish between skin antiseptics and irrigating solutions. As a general rule, commercially available antiseptics should be used *only to clean intact skin,* and one should avoid introduction of significant amounts of these products into open wounds. It is recommended that most open wounds be irrigated with copious amounts of saline or a dilute (1%) povidone-iodine solution. Pluronic polyols may be considered when the wound is near mucous membranes and dilute povidone-iodine may be particularly irritating.

Irrigation

Properly performed irrigation is effective in removing particulate matter, bacteria, and devitalized tissue that is loosely adherent to the edges of the wound and trapped within its depths. Rodeheaver and colleagues studied the effect of irrigating experimental wounds contaminated with 20 mg of soil. Irrigating wounds with 400 mL of fluid at 1 psi removed 48.6% of the soil, whereas increasing the pressure to 15 psi removed 84.8%, reducing the infection rate from 100% to 7%. [52] *The effectiveness of irrigation is determined primarily by the hydraulic pressure at which the irrigation fluid is delivered.* [53] [54] There is preliminary evidence suggesting that low-pressure, high volume irrigation of wounds may be as effective in reducing bacterial counts in wounds as syringe irrigation. [55] [56] Port devices spiked into plastic intravenous bags that were squeezed by hand deliver a stream of fluid at 2 psi. The flow rate of irrigation fluid delivered through IV tubing with a blood pressure cuff inflated around a collapsible plastic IV bag provides <10 psi of irrigation pressure. Other studies have shown that bulb syringes or gravity flow irrigation devices deliver fluid at low pressures and are ineffective in ridding wounds of small particulate matter or in lowering wound bacterial counts. [53]

The pressure that can be delivered with a syringe varies with the force exerted on the plunger of the syringe and with the internal diameter of the attached needle. A simple irrigation assembly consisting of a 19-ga plastic catheter or needle attached to a 35-mL syringe produces 25 to 40 psi when the barrel of the syringe is pushed with both hands. [54] This high-pressure irrigation system removes significant numbers of bacteria and a substantial amount of particulate matter from the wound surface (Fig. 35-4). Commercial irrigation systems with a ring-handled syringe and a one-way valve that connects into a standard IV solution are available (Fig. 35-5) (Canyons Wound Irrigation System, Canyons International, Inc., Salt Lake City, UT; Travenol pressure irrigation set, code number 2D2113; Irrijet, Ackrad Laboratories, Garwood, NJ). These devices make irrigation of wounds easier and more efficient.

TABLE 35-1 -- Summary of Agents Used for Wound Care

Agent	Biologic Activity	Tissue Toxicity	Systemic Toxicity*	Potential Uses	Comments
Povidone-iodine surgical scrub (Betadine 7.5%)	Virucidal; strongly bactericidal against gram-positive and gram-negative organisms	Detergent can be toxic to wound tissues	Painful to open wounds; other reactions extremely rare	Hand cleanser	Iodine allergy possible; systemic absorption of iodine from burns, open wounds; not routinely used in open wounds
Povidone-iodine solution (Betadine 10%)	Same as povidone-iodine scrub; virucidal, bactericidal	Minimally toxic to wound tissues at full strength; 1% solution has no significant tissue toxicity	Extremely rare	Wound periphery cleanser; diluted to 1% for wound irrigation	Probably the safest and most effective product currently available; iodine is active agent, povidone is carrier molecule; iodine allergy possible; systemic absorption of iodine from burns, open wounds; dilute 10:1 (saline:Betadine) if used to irrigate wounds
Chlorhexidine gluconate (Hibiclens)	Strongly bactericidal against gram-positive organisms, less strong against gram-negative bacteria	Ionic detergent can be toxic to tissue/cellular components; eye and inner ear toxicity	Extremely rare	Hand cleanser	Generally avoid use in open wounds; not for use in eye/ear
Polaxamer 188 (Shur-Clens; Pluronic F-68)	No antibacterial or antiviral activity	None known; does not inhibit wound healing	None known	Wound cleanser (particularly useful on face)	Nonionic detergent used for cleansing properties; nontoxic even with IV use; will not damage eye/cornea; lack of antibacterial properties limits use
Hexachlorophene (pHisoHex)	Bacteriostatic against gram-positive bacteria, poor activity against gram-negative bacteria	Detergent can be toxic to wound tissues	Possibly teratogenic with repeated use	Alternative hand cleanser; not used on open wounds	Systemic absorption causes neurotoxicity
Hydrogen peroxide	Very weak antibacterial agent	Toxic to tissue/red cells	Extremely rare	Wound cleanser adjunct; very weak antiseptic properties	Breaks down to water and oxygen; foaming activity useful to remove debris/coagulated blood

*Based largely on in vitro studies/animal data.

Figure 35-4 An easy method of high-pressure irrigation. IV tubing with an in-line, one-way valve is attached to a bottle of sterile 0.9% saline solution. The other end is connected to a stopcock. Saline solution is aspirated into the syringe. Maximal force is exerted on the plunger of the syringe, delivering the solution in a fine stream through an attached 19-ga needle held close to the wound. A splash shield may be used instead of a needle (see Fig. 35-6).

Pulsatile jet irrigation of wounds creates pressures of 50 to 70 psi but does not appear to drive significant amounts of bacteria or surface contaminants into the soft tissues of the wound. [57] [58] Although jet irrigation can damage tissue defenses and spread fluid laterally into loose areolar tissue, [59] it is more effective in cleaning wounds, less traumatic to tissues, and less likely to produce edema than conventional scrubbing with a brush. However, this technique should generally be reserved

for use in heavily contaminated wounds in which syringe irrigation proves to be ineffective. The jet irrigation system used by many investigators was a WaterPik unit (Teledyne Aquatic Corp., http://professional.waterpik.com/int.cfm) with a sterile tip nozzle held approximately 4 cm from the wound. [42] [58] [59]

In an uncontrolled study, Hollander et al. found comparable infection rates and cosmetic outcomes in facial and scalp wounds repaired with and without irrigation. [60] Although irrigation may not be required for low risk, uncontaminated facial and scalp wounds, randomized, prospective trials are needed to answer this question.

Minimum recommended volumes of irrigation fluid vary, but for average-sized wounds, 100 to 300 mL should be used. [42] Greater volumes may be required for larger or heavily contaminated wounds. Irrigation should continue until all visible, loose particulate matter has been removed. Approximately 20% of open, undated bottles of "sterile" saline and water are contaminated; only solutions in bottles

Figure 35-5 A spring-loaded irrigation device with ring handles speeds the somewhat tedious process of wound irrigation. *(Courtesy of Canyons International, Inc., Salt Lake City, UT.)*

opened within the past 24 hours should be used to irrigate wounds. [61] [62] A potential complication of wound irrigation is that infectious material can be splashed into the face of the clinician, even when the tip of the irrigation device is held below the wound surface. A plastic cup device that fits on the end of a syringe (ZeroWet Splashield, Zerowet Inc., Palos Verdes Peninsula, CA) can be used to contain the splatter (Fig. 35-6). The wound should be positioned to allow continuous drainage of fluid during irrigation by any method. [63]

Antibiotic Solutions for Irrigation

Antibiotic solutions have been instilled directly into wounds or used as irrigation solutions. Halasz reviewed the studies of several investigators who analyzed the technique of irrigating wounds with antibiotic solutions, including ampicillin, a neomycin-bacitracin-polymyxin combination; tetracycline; penicillin; kanamycin; and cephalothin. He concluded that "organisms in the wound can be exposed to adequate concentrations of antibiotics, and that the concentration of these drugs in the wound remains in the bactericidal range for long periods of time, far exceeding that obtainable by systemic administration." [64] The use of antibiotics in irrigation solutions in lieu of antiseptic solutions avoids the tissue destruction of the antiseptics but theoretically risks topical sensitization of the patient to the antibiotic and the development of toxic tissue levels of the antibiotic. To date, there have been no reports of these complications. Within 3 hours of injury, a proteinaceous coagulum forms within the wound, surrounding the bacteria and probably preventing their contact with topical or systemic antibiotics. Therefore, the wound should be scrubbed before irrigation with an antibiotic solution. Although a decrease in wound infection has been demonstrated in some studies, [64] [66] [67] others have found no substantial benefit to irrigation with antibiotics. [68] The indications for antibiotic solutions in cleaning wounds have not been defined, and this practice is not considered standard.

Recommendations for Cleaning the Wound

The prerequisites of any wound-cleaning technique are a calm or sedated patient, satisfactory anesthesia, and a thorough

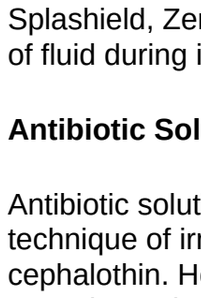

Figure 35-6 *A*, ZeroWet Splashield attached to end of a syringe. This device is used in lieu of a needle. The shield is held near the skin, and the tip of the syringe directs the irrigating solution. *B*, This protective shield allows forceful irrigation without splatter of infectious fluids. *Note that the clinician is holding open the laceration with forceps to allow irrigation of the deep structures. The margins of this small laceration were also extended to allow for better irrigation.*

scrub of the skin surface adjacent to the wound. The importance of ridding the wound of major contaminants and infective doses of bacteria is unquestionable. Two strategies to accomplish the goals of wound cleaning are apparent from this discussion. The contaminated or "dirty" wound can be irrigated or both scrubbed and irrigated with a 1% povidoneiodine solution (Betadine preparation, *not* Betadine scrub). This should be followed by flushing with a 0.9% saline solution. As an alternative, the wound can be scrubbed with pluronic polyols and irrigated with an antibiotic-normal saline solution. *Only pluronic polyols or saline should be used near the eyes.* All scrubbing should be performed with a soft, fine-pore sponge, and high-pressure techniques should be used for all irrigation. The use of hydrogen peroxide on open wounds is discouraged. Gentle scrubbing with poloxamer and normal saline high-pressure irrigation both appear to be satisfactory methods for cleaning minimally contaminated wounds.

Patients frequently irrigate their wounds with tap water before presentation. Some clinicians routinely irrigate wounds, especially extremity wounds, with tap water instead of sterile saline. Some investigators have demonstrated that tap water produced an infection rate comparable to or lower than saline (5.4% vs 10.3%). [69] [70] Even though bacteria were cultured from the faucets in one study, these organisms did not cause any wound infections. The advantage of using tap water is the large volume of irrigant that can be quickly applied to an open wound. Since no studies suggest that tap water is in any way detrimental to wound healing, the editors support the use of tap water for irrigation of wounds in the ED. Interestingly, once irrigating solutions of saline have been opened, bacterial contamination occurs quite rapidly, further supporting the use of tap water. Kaczmarek et al. demonstrated up to a 21% bacterial contamination rate in partially used opened saline bottles collected throughout the hospital. [62]

Preparation for Wound Closure

Before debridement or wound closure, the wound must be prepared and draped. Body hair should generally be left intact, since wounds that are shaved demonstrate higher infection rates. [22] [71] [72] [73] For wounds in hair-bearing areas, hair should be removed by clipping only if the hair interferes with the procedure. [72] However, it is common practice to shave the scalp in preparation for suturing, and this has not been demonstrated to be detrimental to wound healing. Stubborn hairs that repeatedly invade the wound during suturing can be coated with petrolatum jelly or water-soluble ointments to keep them out of the field. Eyebrows should not be shaved, because critical landmarks needed for exact approximation would be lost. Although shaved eyebrows will grow back eventually, shaving produces an undesirable cosmetic effect.

The *skin surface adjacent to the wound* (not the wound itself) can be disinfected with a standard 10% povidoneiodine or chlorhexidine gluconate (Hibiclens) solution. The solution is painted widely on the skin surrounding the wound but should not cover the interior of the wound itself. After hand washing, the clinician and any assistants involved in the procedure must wear gloves. Visible talc or other powders on the gloves should be rinsed before touching the patient's wound. [37] As stated earlier, the use of nonsterile gloves has not been demonstrated to increase infection rates.

Face masks are recommended and are mandatory for any clinician with a bacterial upper respiratory infection. Because droplets of saliva may leak even from around the edges of a face mask, talking in proximity to the wound must be avoided. [74]

A single fenestrated drape or multiple folded drapes are placed over the wound site. For hand wounds, a sterile glove may be applied to the patient to provide a sterile field in lieu of a fenestrated drape (Fig. 35-7). The area to be sutured can be exposed by cutting the glove, and the extremity can be placed on a sterile towel. This technique provides a clean field without the need to continually adjust the drape or to operate through a small opening. If the wound has not yet been anesthetized, anesthesia can be provided at this time (see Chapter 30 Chapter 31 Chapter 32 Chapter 33 for details).

The entire depth and the full extent of every wound should be explored in an attempt to locate hidden foreign bodies, particulate matter, bone fragments, and any injuries to underlying structures that may require repair. *The clinician should avoid the temptation to initially explore wounds with a finger in search of a foreign body or to assess wound characteristics.* Embedded glass, metal fragments, or sharp pieces of bone may cut the clinician, exposing him or her to

Figure 35-7 A sterile glove on the hand with the finger cut out, instead of an annoying drape, and a finger tourniquet to provide a bloodless field make examination and suturing of a wound easier.

contamination with the patient's blood (Fig. 35-8). Exploration with a metal probe and the liberal use of radiographs, combined with direct vision and good lighting, is a much safer approach. Lacerations through thick subcutaneous (SQ) adipose tissue are treacherous, because large amounts of particulate matter can be totally obscured in deeper folds of tissue. Unless a careful search is undertaken, these contaminants may be left in the depths of a sutured wound, and infection usually follows. Some clinicians are reluctant to extend lacerations to properly clean or explore them; however, opening the wound to permit adequate visualization may be needed for successful wound preparation.

Debridement

Debridement of foreign material and devitalized tissue is of undisputed importance in the management of the contaminated wound. With this technique, the clinician can remove

Figure 35-8 *Do not* probe a wound with a finger looking for foreign bodies! If the clinician's skin is broken, the patient's blood may introduce HIV, hepatitis, viruses, and other infectious agents. Betters ways to find a foreign body are obtaining radiographs and exploring wounds with metal probes. Extending the wound edges and performing the examination under a bloodless field and with good lighting will find most foreign bodies.

tissue impregnated with foreign matter, bacteria, and devitalized tissue that otherwise impairs the ability of the wound to resist infection and prolongs the period of inflammation. Debridement also creates a tidy, sharp wound edge that is easier to repair and results in a more cosmetically acceptable scar.

If the wound already is clean and the edges are viable, sharp debridement may not improve the outcome. Irregular wounds have greater surface areas than do linear lacerations. Because skin tension is distributed over a greater length, the scar width is usually less in jagged wounds than if the wound is converted to an elliptical defect with tidy edges. If the edges are devitalized or contaminated, the wound edges must be debrided. To avoid a wide scar in this situation, the wound can be undermined.

Excision

If significant contamination occurs in areas in which there is a laxity of tissues and if no important structures, such as tendons or nerves, lie within the wound, the entire wound may be excised.[6] This technique is the most effective type of debridement, because it converts the contaminated traumatic wound into a clean surgical wound (Fig. 35-9). Complete excision of grossly contaminated wounds such as animal bites allows primary closure of such wounds with no greater risk of infection than in relatively uncontaminated lacerations. [42] Wounds of the trunk, the gluteal region, or the thigh are amenable to this

Figure 35-9 *A–C,* Complete excision of a wound. Grossly contaminated wounds may be excised and sutured primarily.

technique. If necessary, the clinician can judge the adequacy of the excision by coloring the wound surface with a vital dye. The clinician then creates a new wound by excising all dyed tissue.[27] Most traumatic wounds can be excised with an elliptical excision. A lenticular configuration should be marked superficially around the wound with the blade of a No. 15 scalpel by cutting only the epidermis.

If a puncture wound is being excised, the axis of the excision should parallel a wrinkle, a skin line, or a line of dependency or facial expression, and the long axis should be three to four times as great as the short axis. The clinician may plan this type of excision by premarking the skin with a surgical marking pen. Tension should be placed on the surrounding skin with a finger or a skin hook. With the clinician's hand steadied on the table or on the patient, the No. 15 blade is used to cut through the skin at right angles or at slightly oblique angles to the skin surface. If complete excision of the entire depth of the wound is not necessary, the tissue scissors may be used to cut the edge of the wound, following the path premarked in the epidermis by the scalpel blade. If a complete excision is desired, the incision on each wound edge should be carried past the deepest part of the wound (see Fig. 35-9).

Excision should be planned carefully; excessive removal of tissue can create a defect that is too large to close. In hair-bearing areas of the face, particularly through the eyebrows, the incision should be angled parallel to the angle of hair follicles to avoid linear alopecia (Fig. 35-10). The wedge of excised tissue should be removed carefully, without contaminating the fresh wound surface.

Puncture wounds of the feet may contain foreign bodies that are difficult to remove. Contaminated punctures or those likely to contain foreign bodies (e.g., nail punctures through shoes) can be excised by removing a small cone of surrounding tissue with a scalpel or with a 4-mm disposable punch biopsy and the wound irrigated a second time. [77] [78]

Selective Debridement

Complete excision is impossible for most wounds because of insufficient skin elasticity, and selective debridement must be

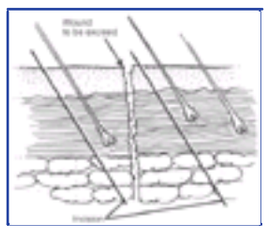

Figure 35-10 Excision through an eyebrow. Use an angled incision to remove tissue in the eyebrow, thus avoiding further injury of hair follicles. *(From Dushoff IM: A stitch in time. Emerg Med 5:2, 1973. Reproduced by permission.)*

used.[6] [27] Simple excision of a wound of the palm or the dorsum of the nose will make approximation of the resulting surgical wound edges difficult. Stellate wounds and wounds with an irregular, meandering course have greater surface areas and less skin tension per unit length than do linear lacerations. In some cases excision of an entire wound would result in the loss of too much tissue (i.e., produce a gaping defect and excessive tension on the wound edges when closed). This problem can be avoided with selective debridement and approximation of the irregular wound edges. This technique involves sharp debridement of devitalized or heavily contaminated tissue in the wound piece by piece and eventual matching of one edge of the wound with the other. Selective debridement is time consuming but preserves more surrounding tissue.

Identifying devitalized tissue in a wound remains a challenging problem. Tissue with a narrow pedicle or base, especially distally based, narrow flaps on extremities, is unlikely to survive and should be excised. Sometimes a sharp line of demarcation distinguishes devitalized skin and viable skin, but in most wounds there is usually only a subtle bluish discoloration. The comparison of capillary refill in wounded tissue with that in adjacent skin is probably the most practical test for tissue viability available to the emergency clinician. [79] If circulation is adequate, viable tissue becomes hyperemic following the release of a proximal tourniquet.

In heavily contaminated wounds, especially those with abundant adipose tissue, all exposed fat and all fat impregnated with particulate matter should be removed. The SQ adipose tissue attached to large flaps or to avulsed viable skin should be debrided before reapproximation of the wound; removal of this fatty layer allows better perfusion of the flap or the graft.

Contaminated bone fragments, nerves, and tendons are almost never removed. Every effort should be made to clean these structures and return them to their place of origin, because they may be functional later. [80]

Instruments usually required for debridement include two fine single- or double-pronged skin hooks, a scalpel with a No. 15 blade, tissue scissors, hemostats, and a small tissue forceps. The jagged wound edges are stabilized with skin hooks or forceps, and the scalpel or scissors are used to cut away devitalized tissue from one end of the wound to the other. Fascia and tendons perform important functions despite potential loss of viability. If they can be cleaned adequately, these tissues should not be debrided. They may be left in wounds as free grafts and covered by viable flaps of tissue. [81]

Following debridement or excision, the wound should be irrigated again to remove any remaining tissue debris.

Control of Hemorrhage

Wound exploration or cleaning sometimes induces bleeding. Hemostasis is essential at any stage of wound care. Not only does persistent bleeding obscure the wound and hamper wound exploration and closure, but also hematoma formation in a sutured wound separates wound edges, impairs healing, and risks dehiscence or infection. If bleeding is not a problem before wound debridement, it frequently becomes a complication once the wound edges are excised.

Several practical methods of achieving hemostasis are available to the emergency clinician. Sustained direct pressure with gloved fingers, gauze sponges, or packing material, combined with elevation, is usually effective in immediately

controlling a single bleeding site or a small number of sites until cut ends of vessels constrict and coagulation occurs. In a patient with multiple injuries and several urgent problems, hemorrhage can be controlled temporarily with a compression dressing. Several absorptive sponges are applied directly over the bleeding site, and these are secured in place with an elastic bandage (e.g., Ace wrap) or elastic adhesive tape (Elastoplast). Pressure is provided by the elasticity of the bandage. The bleeding part should be elevated. Wound care can then be deferred while the clinician attends to more pressing matters.

Although simply crushing and twisting the end of a small vessel with a hemostat avoids the introduction of suture material into the wound, this method provides unreliable hemostasis. Ligation of the vessel with fine absorbable suture material is preferred. Bleeding ends of vessels are clamped with fine-point hemostats, providing immediate hemostasis. Because nerves often course with these vessels, all clamping should be done under direct visualization. The tip of the hemostat should project beyond the vessel to hold a loop of a ligature in place (Fig. 35-11). While an assistant lifts the handle of the hemostat, a synthetic absorbable 5-0 or 6-0 suture is passed around the hemostat from one hand to the other (Fig. 35-12). The first knot is tied beyond the tip of the hemostat. Once the suture is securely anchored on the vessel, the hemostat is released. [76] [82]

In practice, the emergency clinician seldom has an assistant available to ligate vessels by this method. MacDonald describes a technique that enables a single operator to maintain tension on the ligature while removing the hemostatic clamp. [83] A needle holder is used to grasp one tail of the ligature; the other end is held by the third, fourth, and fifth fingers of the left hand. As the clamp held in the right hand is removed from the vessel, the needle holder is moved away from the left hand by extending the thumb and the index finger, maintaining tension on the ligature. The right hand can discard the clamp, grasp the needle holder, and complete the tie (Fig. 35-13).[83] Three knots are sufficient to hold the ligature in place. The ends of the suture should be cut close to the knot to minimize the amount of suture material that is left in the wound.

Clinicians can make the mistake of spending excessive time attempting to tie off small bleeding vessels while the

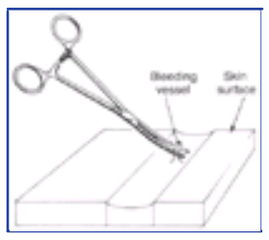

Figure 35-11 When one attempts to tie off a bleeding vessel, the tip of the hemostat should project beyond the clamped vessel.

Figure 35-12 *A,* The handles of the hemostat are raised by an assistant as a ligature is passed under them. *B,* The ligature thread stretched between the index fingertips is carried under the projecting tips of the hemostat. *(Modified from Kirk RM: Basic Surgical Techniques. Edinburgh, Churchill Livingstone, 1978, p 50. Reproduced by permission.)*

patient slowly exsanguinates. In highly vascular areas, such as the scalp, it is sometimes best to suture the laceration following wound exploration and irrigation, despite active bleeding; the pressure exerted by the closure will usually stop the bleeding. If bleeding is too brisk to permit adequate wound evaluation and irrigation, hemorrhage can often be controlled by clamping and everting the galea or dermis of each wound edge using hemostats. Lemos and Clark propose the use of scalp clips as an alternative. [82]

Cut vessels that retract into the wall of the wound may frustrate attempts at clamping and ligation. Bleeding should be controlled first by downward compression on the tissue. A suture is passed through the tissue twice, using a figure-of-eight or horizontal mattress stitch, and then tied. The double thread will constrict the tissue containing the cut vessel (Fig. 35-14). The disadvantage of this method is that the tissue constricted by the ligature may necrose and leave devitalized tissue in the wound.

Vessels with diameters greater than 2 mm should be ligated. Those smaller than 2 mm that bleed despite direct

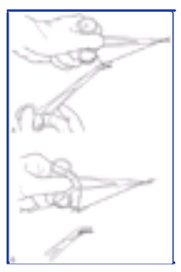

Figure 35-13 *A,* Ligature tension is maintained with one hand by grasping one tail of the suture with a clamp and keeping its base between the thumb and the forefinger. *B,* As the pedicle clamp is removed with the other hand, the ligature is tightened by extending the flexed thumb and index finger to the desired tension. Then the pedicle clamp is discarded from the right hand, and further knots are applied in the usual fashion. *(Modified from MacDonald RT: Maintenance of ligature tension by a single operator with simultaneous removal of a hemostatic clamp. Am J Surg 143:770, 1982. Reproduced by permission.)*

pressure can be controlled by pinpoint electrocautery. A dry field is required for an effective electrical current to pass through the tissues; if sponging does not dry the field, a suction-tipped catheter should be used. Trauma is minimized by using fine-tipped electrodes to touch the vessel or by touching the active electrode of the electrocautery unit to a small hemostat or fine-tipped forceps gripping the vessel. [2] The power of the unit should be kept to the minimum level required for vessel thrombosis. Bipolar coagulation (such as that provided by the Bovie unit) is preferred over monopolar coagulation because it produces approximately one third less necrosis of surrounding tissue. [42] If the amount of tissue cauterized is kept to a minimum, wound healing is no more compromised by this technique than by ligation. Cauterization of medium- and small-sized vessels can quickly provide hemostasis. Self-contained, sterilizable, battery-powered coagulation units also are available. Vessels are cauterized by

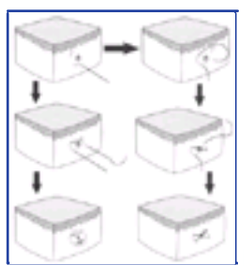

Figure 35-14 Ligation of a retracted, bleeding vessel. *A,* Horizontal mattress technique. *B,* Figure-of-eight technique.

the direct application of a heated wired filament. Although these units may damage more surrounding tissue than electrocautery units, they are compact and simple and thus well suited for use in the emergency center (Fig. 35-15).

Epinephrine is an excellent vasoconstrictor. Topical epinephrine (1:100,000) on a moistened sponge can be applied to a wound to reduce the bleeding from small vessels. Combined with local anesthetics, concentrations of 1:100,000 and 1:200,000 prolong the effect of the anesthetic and provide some hemostasis in highly vascular areas. Because vasoconstrictors theoretically may increase the risk of wound infection, they should be restricted to situations in which widespread small vessel and capillary hemorrhage in a wound is not controlled by direct pressure or cauterization. Hemostasis of a

Figure 35-15 Battery-powered cautery.

specific vessel may be obtained by directly injecting the soft tissues around the base of the bleeder with a small amount of lidocaine/epinephrine solution, even though the wound has been previously anesthetized. The combination of pressure and vasoconstriction may halt bleeding long enough for the vessel to be ligated or cauterized, or allow the wound to be closed and a compression dressing applied.

Fibrin foam, gelatin foam, and microcrystalline collagen may be used as hemostatic agents. Their utility is limited in that vigorous bleeding will wash the agent away from the bleeding site. Their greatest value may be in packing small cavities from which there is a constant oozing of blood. [76] In the vast majority of simple wounds with persistent but minor capillary bleeding, apposition of the wound edges with sutures, followed by a compression dressing, provides adequate hemostasis.

Tourniquets

If bleeding from an extremity wound is refractory to direct pressure, electrocauterization, or ligation, or if the patient presents with exsanguinating hemorrhage from the wound, a tourniquet can be used to control the bleeding temporarily. Tourniquets also are helpful in examining extremity lacerations by providing a bloodless field. However, they can cause injury in three ways:

1. They can produce ischemia in an extremity.
2. They can compress and damage underlying blood vessels and nerves.
3. They can jeopardize the survival of marginally viable tissue.

Although problems rarely develop from tourniquets used in routine wound care, potential problems can be minimized if (1) there is a limit placed on the total amount of time that an extremity is confined by a tourniquet, and (2) excessive tourniquet pressures are avoided. It is also imperative that all tourniquets be removed before releasing the patient. A tourniquet may be overlooked if it is covered by a bulky dressing.

A single-cuff tourniquet (sphygmomanometer cuff) placed around an arm or a leg effectively stops distal venous or arterial bleeding without crushing underlying structures. The length of time that a tourniquet may remain in place is limited by the development of pain underneath and distal to the tourniquet. This occurs within 30 to 45 minutes in a conscious patient, well within the limits of safety. [18]

Before application of the tourniquet, the injured extremity should be elevated and then manually exsanguinated to prevent bothersome venous bleeding. An elastic bandage (e.g., Ace wrap or Esmarch) may be wrapped circumferentially around the extremity, starting distally and moving in a proximal direction. A cuff that is 20% wider than the diameter of the limb is placed around the arm proximal to the wound and inflated to 250 to 300 mm Hg, and the tubing is clamped; the bandage is then removed and the extremity lowered. [84] Some experts recommend a cuff pressure 70 mm Hg higher than the patient's systolic blood pressure. [85] Because tourniquets

impair circulation and may produce neurapraxia, their use in the ED should be limited to a maximum of 1 hour.

Tourniquets on digits have a greater potential for complications. The maximum tourniquet time that is safe for a finger may easily be exceeded inadvertently. Also, finger tourniquets can exert excessive pressures over a small surface area at the base of the finger and injure digital nerves or cause pressure necrosis of digital vessels. For this reason, simple rubber bands should *not* be used as tourniquets. Tourniquet pressures up to 250 to 300 mm Hg are safe in digits, but pressures of only 150 mm Hg are needed for hemostasis.

A 0.5-inch Penrose drain placed around the base of a finger and stretched to no more than two thirds of its circumference provides safe and effective hemostasis. Some clinicians wrap the entire finger with a Penrose drain in the fashion of a miniature Esmarch bandage to exsanguinate the digit. The wrap is unraveled from distal to proximal, leaving two or more turns around the proximal part of the finger to serve as a tourniquet. This technique generates excessive pressures, ranging from a minimum of 300 mm Hg to >800 mm Hg.[86] A finger can be exsanguinated with a Penrose drain, but a separate drain should be used as a tourniquet (Fig. 35-16). A few millimeters of difference in total stretch makes a large difference in the pressure applied by this type of tourniquet. [86] Alternatively, a finger can be exsanguinated with a moistened piece of gauze opened to its fullest length, folded in half, and rolled tightly around the elevated finger from tip to base. A Penrose drain is stretched around the base of the finger and secured with a hemostat, and the gauze is removed.

A latex rubber surgical glove placed over a patient's hand also can serve as a finger tourniquet. The tip of the glove covering the injured digit is removed, and the latex rubber is then rolled proximally along the patient's finger to form a constricting band at the base (Fig. 35-17). Another advantage of this technique is that contamination of the wound during closure is less likely. Rolled surgical gloves produce pressures ranging from 113 to 363 mm Hg, depending on the thickness, the amount of glove finger removed, the number of rolls, and the size of the glove in relation to the size of the patient's hand. [86] Pressure under a Penrose drain ranges between 100 and 650 mm Hg, but it can be more easily controlled.[87] Commercial ring-shaped exsanguinating digit tourniquets are available (Tourni-cot [Mar-Med Company]) (Fig. 35-18). There is a danger of forgetting to remove such a small tourniquet and of accidentally incorporating it in the dressing.

These techniques provide bloodless fields in which to examine, clean, and close extremity wounds. The maximum tourniquet time on a finger should not exceed 20 to 30 minutes.[86] [87] Debridement of questionably devitalized tissue in a wound is best accomplished *without* a tourniquet or pharmacologic vasoconstriction, because bleeding from tissues is often an indication of their viability. [80]

CLOSURE

The various techniques of wound closure are presented in Chapter 36 . The remainder of this chapter addresses issues related to wound management (e.g., secondary closure, wound dressings, antibiotic use, aftercare instructions, and suture removal).

Open vs Closed Wound Management

Wounds that heal spontaneously (i.e., by secondary intention) undergo much more inflammation, fibroplasia, and contraction than those whose edges are reapproximated by wound closure techniques.[8] [87A] During wound healing, contraction covers the defect, yet it may have undesirable consequences—notably, deformity (contracture) or loss of function. Left to itself, the healing process may be unable to close a

Figure 35-16 Use of Penrose drain for exsanguination *(A)* of a wounded digit. A second Penrose drain is applied *(B)* as a finger tourniquet, and the first drain is removed *(C)*. During actual patient care, the clinician would use sterile technique including gloves.

defect completely in areas in which surrounding skin is immobile, such as on the scalp or in the pretibial area. [8] Exposed tendons, bone, nerves, or vessels may desiccate in an open wound. If the patient is careless with an otherwise adequate dressing that covers an open wound, the wound may be further contaminated. [88] The advantages of surgical closure of wounds are apparent: This procedure minimizes inflammation, fibroplasia, contracture, scar width, and contamination.

On the other hand, risks are incurred when wounds are closed. Closure of contaminated wounds increases the

Figure 35-17 Use of a sterile glove to provide a clean field and serve as a finger tourniquet. The distal end of the glove is clipped *(A),* and the glove finger is rolled proximally over the digit *(B, C)*. During actual patient care, the clinician would use sterile technique including gloves.

probability of wound infection, with impaired healing, dehiscence, and sepsis as possible complications. After cleaning and debridement, wounds left unsutured appear to have a higher resistance to infection than do closed wounds.

Sutures in themselves are detrimental to healing and increase the risk of infection. [12] [88] [89] Each suture inflicts an intradermal incision, damaging surface epithelium, dermis, SQ fat, blood vessels, small nerves, lymphatics, and epithelial appendages such as hair follicles, sweat glands, and ducts. These appendages, once divided and separated by a stitch,

Figure 35-18 As in Figure 35-7 , a sterile glove has been used to provide a sterile field for the thumb. In addition, a commercial rubber ring tourniquet device has been applied to enhance hemostasis. The accompanying tag has been left exposed to remind the operator of the tourniquet device.

usually undergo inflammation and resorption. [90] [91] Each suture is another piece of foreign material that provokes inflammation. [8] When a suture is removed, bacteria that have settled on the exposed portion of the suture are pulled into the suture track and deposited there. [90] Raised pretibial flap lacerations in elderly patients often necrose when sutured but survive and heal well by secondary intention if taped back into position. [92]

If the wound is judged to be clean or is rendered clean by scrubbing, irrigation, and debridement, it may be closed. If the wound remains contaminated despite the best of efforts, it must be left open to heal by secondary intention. If the status of the wound is uncertain, the clinician must estimate the risk of infection. Another option available is delayed primary closure.

Delayed Primary or Secondary Closure

There is a common misconception that all wounds must either be sutured within a few hours or left open and relegated to slow healing and an unsightly scar. If there is a substantial risk that closure of a particular wound might result in infection, the decision to close or to leave the wound open can be postponed (Fig. 35-19). The condition of the wound after 3 to 5 days will then determine the best strategy (Fig. 35-20). Although cleaning and debridement should be accomplished as rapidly as possible, there is no urgency in closing a wound. Edlich and coworkers point out that "the fundamental basis for delayed primary closure is that the healing open wound gradually gains sufficient resistance to infection to permit an uncomplicated closure." [25] Despite its effectiveness, delayed primary closure is a technique that is unappreciated and likely underused by most clinicians.

Open wound management is usually an outpatient procedure. The technique consists of the usual careful cleaning and meticulous debridement, followed by packing of the wound with sterile, saline-moistened, fine-mesh gauze. The packed wound is covered by a thick, absorbent, sterile dressing. Depending on the specifics of the wound and the ability of the patient to perform his or her own wound care, the packing may be changed daily at home or in the ED, or the wound

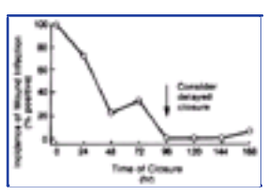

Figure 35-19 Incidence of wound infection over time when delayed closure is performed. Delayed closure is best accomplished on the fourth or fifth day to minimize the risk of infection. *(From Edlich RF, Thacker JG, Rodeheaver GT, et al: A Manual for Wound Closure. St. Paul, MN, 3M Medical Surgical Products, 1979. Reproduced by permission. © 1979 by Minnesota Mining and Manufacturing Company.)*

may be left undisturbed for several days. Sterile saline-soaked packing is standard, and there is no need to impregnate wounds with antiseptics. Prophylactic antibiotics are occasionally prescribed, but their use is neither mandatory nor of proven benefit. On the fourth postoperative day, the wound is reevaluated for closure. If no evidence of infection is present, the wound margins can be approximated (delayed primary closure), or the wound can be excised and then sutured (secondary

closure) with minimal risk of infection. Because the wound is closed before the proliferative phase of healing, there is no delay in final healing, and the results are indistinguishable from those of primary healing.

Certain wounds should almost always be managed open or by delayed closure. These include wounds that are already infected and those heavily contaminated by soil, organic matter, or feces. Also included in this category are wounds associated with extensive tissue damage (e.g., high-velocity missile injuries, explosion injuries of the hand, or complex crush injuries) and most bite wounds. Lacerations to the bottom of the feet, such as those occurring when the patient steps on an unknown object while wading in a stream or running through a field, are ideal candidates for delayed closure. Human bite wounds should probably never be sutured. Clinicians disagree as to which animal bite wounds may be closed initially. Most would suture cosmetically deforming injuries, including facial bites, and bite wounds that can be completely excised.[42] [93] Others would suture nonextremity dog bites.[94] In severe soft tissue injuries, delayed closure allows time for nonviable tissue to demarcate from uninjured tissue. Debridement can then be accomplished with maximal preservation of tissue. [88]

PROTECTION

Dressings

At the conclusion of wound repair, dried blood on the skin surface should be wiped away gently with moistened gauze, and the wound should be covered with a non-adherent dressing.

Figure 35-20 *A*, This dirty contused wound, now 18 hours old, is an ideal candidate for a delayed primary closure. *B*, At presentation the wound is anesthetized, scrubbed, irrigated, and debrided. *C*, The wound is packed with sterile gauze and covered by a dry dressing. No antibiotics were prescribed. *D*, Four days later the packing is removed, and the wound is minimally debrided. *E*, Interrupted sutures are placed as though this is a fresh, clean wound. At suture removal 10 days later, only a linear scar was evident.

Depending on the specifics of the wound and the type of repair, a dressing can consist of a simple dry gauze pad or a complex multilayer dressing. Some wounds, such as sutured scalp lacerations, do not routinely require any dressing. Although various specialized (and expensive) dressings are available, there are little data to support their use over readily available, properly applied gauze dressings.

Function of Dressings

Dressings serve various functions. They protect the wound from contamination and trauma, absorb secretions from the wound, immobilize the wound and the surrounding area, exert downward pressure on the wound, and improve the patient's comfort.[19] [95] [96] Occlusive dressings on burns or abrasions prevent painful exposure of the wound to the air and dehydration of the wound surface.[97] Sutured wounds are susceptible to infection from surface contamination during the first 2 days after wound repair. Dressings effectively protect the wound from contamination during this vulnerable period.

One of the primary functions of a gauze dressing is to absorb the serosanguineous drainage that exudes from all wounds. Absorbent dressings also reduce the development of stitch abscesses to some extent. Surface sutures produce small indentations at their points of entrance; tiny blood clots and debris overlie these indentations, allowing bacterial growth at the site. Small "stitch abscesses" can develop; these are initially undetectable but are nevertheless destructive to epithelium. Stitch abscesses rarely infect the entire wound but can slightly increase the width of the scar and produce noticeable, punctate suture marks.[19]

The most common type of dressing is constructed in three layers: a nonadherent contact layer, an absorbent layer, and an outer wrap (Fig. 35-21).[96] Ideally, this dressing provides nonadherence without maceration.

Contact Layer: Dry, Semiocclusive, and Occlusive Dressings

Petrolatum gauze (e.g., Adaptic, Xeroform, Betadine, Aquaflo) can be applied next to the wound surface to prevent the wound

Figure 35-21 A common three-layer dressing, consisting of antibiotic ointment, Adaptic, and gauze.

from sticking to the dry gauze in the absorbent layer and to protect the regenerating epithelium (Table 35-2). (Nonadherent material should always be used to cover skin grafts.)

Coarse weaves of gauze, usually available in the form of multilayered pads, absorb blood and exudate, but the dressing will adhere if the interstices of the fabric are relatively large. Capillaries, fibrin, and granulation tissue will penetrate and become enmeshed in the material. If the proteinaceous exudate from the wound dries by evaporation, the scab usually clings to the dressing.[98] [99] Some clinicians use this effect to "debride" the wound when the gauze is removed. However, it also destroys healing tissue, particularly the new epithelium. Debridement of the wound with wet-to-dry dressings is quick, but debridement with surgical instruments is more controlled and less traumatic.

Adherence to the wound can be avoided if the dressing is nonabsorbent, occlusive, or finely woven. Some clinicians use fine mesh gauze (41 to 47 warp threads per square inch) rather than petrolatum gauze on abrasions, especially on those wounds that are heavily contaminated, because removal of this type of dressing debrides only the small tufts of granulation tissue that become fixed in the mesh pores, leaving a clean, even surface. Once a healthy, granulating surface is present and re-epithelialization is proceeding, nonporous dressings can be used.[99] Fine mesh gauze also is used next to exposed tissue in wounds being considered for delayed primary closure; a protective and absorptive bulky dressing is placed on top of the wound.

Wounds covered with permeable dressings such as plain gauze tend to dry out. Drying of the wound surface damages a shallow layer of exposed dermis, which impedes epidermal resurfacing of abrasions, burns, and incisions.[96] Wound desiccation results in further epidermal necrosis, crust formation, and increased inflammation.[99] [100] If the wound is kept moist by covering it with an occlusive film soon after wound management and if the film is left in place for at least 48 hours, the epidermis will migrate over the surface of the dermis up to 100% faster than when a dry scab is allowed to form.[101] [102] [103] In one study, the occluded half of a surgical incision produced

TABLE 35-2 -- Advantages of Occlusive Dressings

1. More rapid healing
2. Less pain from air exposure
3. Better cosmetic results
4. Fewer dressing changes

5. Better protection from bacteria

Data from Eaglstein WH: Effect of occlusive dressings on wound healing. Clin Dermatol 2:107, 1984.

a more linear, less pigmented scar.[104] Protection of wounds that are healing by secondary intention with occlusive or semiocclusive dressings has several advantages,[10] including more rapid healing, less pain from air exposure, better cosmetic result, few dressing changes, and protection from bacteria.

This occlusive effect is achieved with various polyurethane-derived membranes, such as Epilock (Derma-Lock Medical Corporation), Op-Site (Smith and Nephew, Ltd.), Tegaderm (3M), Bioclusive (Johnson & Johnson), and Primaderm (ACCO, Inc.); those with soluble collagen or gelatin backing, such as DuoDerm (Convatec) and Biobrane (Woodroof Laboratories); and products with hydrogels, such as Vigilon. [99]

One fear of using occlusive dressings is that microorganisms will proliferate in the moist environment beneath the occlusive film and increase wound infection rates. [96] [105] Occlusive dressings such as DuoDerm actually serve more as a barrier to external pathogenic bacteria [106] ; although *surface* bacteria under occlusive dressings can multiply,[107] chronic wounds, usually contaminated with large numbers of bacteria, are routinely treated with occlusive dressings successfully. [108]

A paint-on collodion dressing over a wound closed with a buried subcuticular stitch provides considerably greater resistance to infection than wounds closed by the same technique but with no dressing. The use of collodion obviates the need for a gauze dressing, frequent dressing changes, and uncomfortable dressings in areas such as the groin, the axilla, and the neck.[109] However, the collodion does not allow drainage of the wound and so is rarely used.

Another concern is that occlusive dressings will macerate underlying skin. Optimal wound appearance under a dressing is a moist red surface with capillary and epithelial growth. Collagen sponge dressings provide this appearance (if they are not accidentally dislodged), whereas both DuoDerm and Op-Site adhere to the wound site, macerate it, and produce a thick eschar that may be difficult to remove. However, underneath the eschar the surface is epithelialized. [110] Wounds covered with certain occlusive dressings or with silver sulfadiazine (Silvadene [Marion Laboratories]) applications appear to be blanketed with pus; this exudate actually represents the beneficial proliferation of macrophages and polymorphonuclear leukocytes. [103] [111]

Adhesive-backed dressings (e.g., DuoDerm and Op-Site) have a tendency to adhere to and remove new epidermis, and they do not allow exudate to drain out the edges of the dressing. Between dressing changes, the wound should be coated with petrolatum or an antibiotic ointment before these products are applied. [10] Epilock has the advantage of thermally insulating the wound by virtue of its thickness, but unlike Tegaderm and Op-Site, it is opaque and does not allow inspection of the underlying wound surface.[111] Because Epilock allows drainage of exudate, it is better tolerated by patients if the overlying gauze bandage is changed daily.

Other nonadherent-type dressings include Adaptic, Xeroform, Betadine, Dermicel, and the nonabsorbent Telfa. Petrolatum gauze does not appear to enhance epidermal healing.[112]

Absorbent Layer

In dressing wounds with considerable drainage, sufficient gauze should be used to cover the wound and to absorb all of the drainage. Dressings on such wounds can be changed daily, which is frequent enough to avoid bacterial overgrowth beneath the dressing. [8] [99] Once a dressing becomes moist, pathogens can pass through it to the underlying wound. [96] Any dressing should be changed whenever it becomes soiled, wet, or saturated with drainage. Fluid accumulating under an occlusive dressing should be aspirated or the dressing changed every 1 to 2 days during the first week or until the exudate no longer accumulates. [113] A dressing that is used to absorb exudate or debride the wound must be changed more frequently than one designed solely to occlude.

Outer Layer

Dressings and bandages can serve as surface splints (as can surgical tape) by reducing mechanical stresses on the wound during the early phases of healing. Even when subcuticular stitches have been placed, these "external splints" are useful in relieving tension across the wound. They are most needed between the 7th and 42nd days, the time of collagen synthesis and remodeling. [19]

Compressive dressings may be helpful in preventing hematoma formation and eliminating dead space within a wound. They are particularly useful in wounds that have been undermined extensively and in facial wounds, in which SQ capillary bleeding and swelling can exert tension on fine skin sutures and jeopardize skin closure. Pressure dressings should be used to immobilize skin grafts. Surgical tape can serve as a pressure dressing in areas such as fingertips on which bandages cannot be easily applied. However, a pressure dressing should not be used as a substitute for good hemostasis. [8]

Pressure dressings should be applied to all ear lacerations to prevent hematoma formation and subsequent deformation and destruction of cartilage. The ear should be enveloped in the dressing so that pressure from the outer bandage is distributed evenly across the irregular surface of the pinna. Moistened cotton is packed into the concavities of the pinna until the cotton is level with the most lateral aspect of the helical rim. Square pieces of gauze cut to fit the curvature of the ear are placed *behind* (medial to) the pinna. Several more gauze squares are placed on the lateral surface of the ear; the packing is then secured in place with a circumferential head bandage. The bandage must not encompass the opposite ear because it would just as easily cause pressure necrosis of that ear if left unprotected. Application of a pressure dressing for the ear is discussed further in Chapter 65 .

Traumatic wounds are bandaged to compress or immobilize the wound or to secure and protect the underlying dressing. Most bandaging is performed on extremities, on which dressings are difficult to secure with tape alone. Rolls of cotton (Kerlix; Kling stretch gauze) are well suited for this purpose. The bandage is wound around the extremity, advancing proximally with circular, overlapping turns. Care should be taken to avoid allowing wrinkles in the bandage, which will later create pressure points, or making loose turns that shorten the effective life of the dressing. When joint surfaces are crossed, the cotton is anchored distally with several turns, unrolled obliquely across the joint several times in a figure-of-eight pattern, and anchored proximally by two complete turns. This process is repeated until the bandage is securely in place. The ends of the bandage are fastened to the skin by strips of adhesive tape.

Bandages over the forearm and the lower extremities are particularly prone to slippage because of the constant motion of these parts and because of the marked changes in extremity diameter over a short distance. The roll of bandage can be rotated 180° after each circular turn, producing a reverse spiral and reducing the bandage's mobility (Fig. 35-22). A "tube" of elastic cotton netting (e.g., Surgifix, Tubex, Surgitube, HygiNet) pulled over the bandage or unrolled from a metal applicator frame effectively stabilizes the entire dressing in these areas (Fig. 35-23). Another useful technique consists of placing strips of tape on opposite sides of the extremity, leaving the ends free. The bandage is wrapped around the dressing, covering the portions of the tape that are attached to the skin. The free ends of tape are then incorporated in the bandage (Fig. 35-24).[114]

Certain chemically treated wide-mesh weaves have the properties of cling and stretch, holding snugly in place but expanding if edema develops. [98] An elastic cotton roll (Kerlix) allows the bandage to conform to body contours, provides some mobility to bandaged joints, and permits the wound to swell without the circumferential bandage constricting the extremity. The inelastic Kling bandage better immobilizes the part. Rigid immobilization with plaster splints or braces is needed to protect wounds in mobile areas, such as around large joints.

Most scalp wounds do well when left uncovered. If a dressing is necessary, it must be held in place by a bandage. There are many techniques for bandaging heads. One method[115] is shown in Figure 35-25 . Methods of bandaging wounds in other locations of the body are described in detail in other texts. [79] [95] Dressings should be changed when they become externally contaminated, saturated with exudate, or when inspection and wound cleaning is required.

Figure 35-22 Snugness of the bandage is increased by 180° rotation of the bandage roll after each circular turn to create a reverse spiral. *(From Norton LW: Trauma. In Hill GJ II: Outpatient Surgery. Philadelphia, WB Saunders, 1980. Reproduced by permission.)*

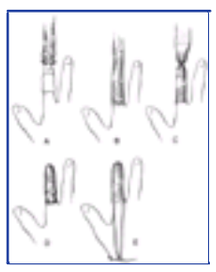

Figure 35-23 Finger dressing. *A,* The inner layer is nonadherent gauze or whatever is required for soft tissue care. The middle layer is 2 × 2 in. gauze sponges wrapped circumferentially and held in place with a small strip of tape. *B,* Begin No. 2 tube gauze at the base of the finger. It is useful to hold this end with one finger while the tube gauze applicator is pulled toward the fingertip. A twisting motion firms the wrap about the digit; generally about 90° is necessary. Excessive stretch or twisting can compromise circulation. *C,* When the fingertip is reached, make a 360° twist. *D,* Pass the applicator toward the finger base with an additional 90° twist. Repeat once more; thus, three layers are in place. *E,* Cut enough gauze to reach the base of the finger, and tape it there. As an alternative, pull the final layer beyond the tip, leaving it long enough to reach to and around the wrist (about three times the finger length). Split this gauze into two strands; bring them dorsally to the wrist, knot, and loosely wrap around the wrist. *(Redrawn from Kaplan EN, Hentz VR: Emergency Management of Skin and Soft Tissue Wounds: An Illustrated Guide. Boston, Little, Brown, 1984, p 86. Reproduced by permission.)*

Dressings vary in their absorbency, adhesiveness, occlusiveness, opacity, and insulating properties. Further research may identify types of dressings best suited for different phases of the healing wound. Currently, a two- or three-layer dressing is used for most traumatic wounds; the choice of material for the contact layer is determined by the characteristics of the individual wound. [116]

Splinting and Elevation

Although splints are readily applied to orthopedic or soft tissue injuries, immobilization of wounds and sutured lacerations is often neglected, despite the fact that these techniques

Figure 35-24 *A,* When a Kling or Kerlix wrap must be applied to an area such as the forearm, start by putting a strip of tape on opposite sides of the arm, leaving the ends free. *B,* Wrap the bandage around the arm, covering the portions of the tape that are attached to the skin. *C,* After completing one layer of wrapping, tuck the free ends of the tape down so that the nonadhesive side faces the first layer of wrapping and the sticky side faces out. Place another layer of wrapping around the arm. *D,* After completing a second layer of wrapping, the dressing will not slip because it is adhered to itself as well as to the skin. *(From Lazo J: Non-slip dressing technique. Res Staff Physician 22:103, 1976. Reproduced by permission.)*

may enhance healing and provide patient comfort. Immobilization of an injured extremity promotes healing by protecting the closure and by limiting the spread of contamination and infection along lymphatic channels. Wounds overlying joints are subjected to repeated stretching and movement, which delays healing, widens the scar, and could

Figure 35-25 *A–E,* Technique for bandaging the head. A strip of bandage (the "tie strip") 3 inches wide and 3 feet long is placed over the head in the frontal plane (*A)*. While the patient maintains downward tension on the first strip of bandage, the clinician places a full-length gauze bandage at the forehead level in a horizontal plane, winding the bandage around the head (*B)*. (The "Kling"-type bandage is preferred.) The main bandage is stabilized with several turns, passing near the patient's ear, then wrapped around one side of the tie in a full turn (*C)*. The main bandage is then taken across the front of the head, wrapped full-turn around the other side of the tie bandage (*D)*. The main bandage is wrapped around the head, from front to back, overlapping with each pass. The dressing is secured in place by tying the ends of the tie strip under the chin (*E)*. This dressing can be removed easily by untying the chin straps and gently pulling both ends of the tie strip upward (*F)*.

possibly disrupt the sutures. [25] Splints are almost always required for lacerations that overlie joints and are frequently necessary for protection of wounds involving fingers, hands, wrists, the volar aspects of forearms, the extensor surfaces of elbows, the posterior aspects of legs, the plantar surfaces of feet, and the extremities when skin grafts have been applied. Splinting is often underused by the emergency clinician in the treatment of lacerations.

A plaster or aluminum splint may be incorporated into a bandage to reduce the mobility of the part. Splinting techniques for extremities are explained more fully in Chapter 51 and Chapter 52 .

Elevation of injured extremities is important in all but trivial injuries. Elevation limits edema formation, an expected sequela of trauma and inflammation, and allows more rapid healing. [25] Elevation also reduces throbbing pain. Patients given this information are often more motivated to elevate the extremity as instructed. Slings can be used to elevate wounds involving the forearm or the hand.

Ointments

The safety and efficacy of topical antibiotic preparations used on wound surfaces are unproven and still debated. Many clinicians routinely suggest the use of antibiotic ointments over sutured wounds, while others opt for a simple dry dressing. No universal standard exists. Since a major benefit from the routine use of topicals has never been substantiated, one would intuit that there is no compelling reason to use them. However, *the application of a topical preparation involves that patient in the ongoing care of the wound, and forces the patient to evaluate the healing process on a regular basis*. These reasons alone make the use of topicals reasonable interventions.

Some investigators warn of skin sensitization by preparations containing neomycin [91] and others, of the emergence of resistant strains of bacteria with any topical antibiotic. [117] Other studies have shown that use of a triple-antibiotic preparation containing neomycin, bacitracin, and polymyxin provides a broad spectrum of

protection against infection in *abrasions* without systemic absorption and toxicity or the emergence of resistant strains of bacteria. Unless this topical antibiotic ointment is used repeatedly or on inflamed skin, there is a relatively low risk of allergic sensitization (Fig. 35-26).[118] There is evidence that the active agents in Neosporin ointment and Silvadene cream, as well as their inert bases and vehicles, improve wound healing. [97] [119] [120] In a prospective, randomized, double-blind study, Dire and colleagues found that bacitracin and Neosporin ointments reduced the infection rate over that seen with plain petrolatum ointment. [121] Mupirocin (Bactroban, GlaxoSmithKline, London), which is a topical antibiotic in a water-soluble base, is an alternative.

Ointments can be used to reduce the formation of a crust that covers and separates the edges of the wound. Lacerations surrounded by abraded skin are especially predisposed to coagulum formation. In such cases the patient can be instructed to cleanse the wound frequently and to follow the cleansing with an application of ointment during the first few days.[25] Ointments also prevent the dressing from adhering to the wound.[6] Some researchers recommend using bacitracin applied in a thin coating, not for protection against infection, but for prevention of these mechanical problems.

Note that the stronger topical corticosteroids have detrimental effects on healing. Application of 0.1% triamcinolone acetonide in an ointment retards healing in wounds by as much as 60%, whereas hydrocortisone probably does not interfere with epithelialization. [102] [112] Some clinicians believe that single and low doses of oral corticosteroids probably have no effect on wound healing but that repeated, large doses of steroids (=40 mg of prednisone per day) inhibit healing, particularly if used before the injury or during the first 3 days of the healing phase. [122] [123] There is some evidence that topical vitamin A may reverse some of the anti-inflammatory and immunosuppressive effects of corticosteroids. [124] The exact value of ointments in the treatment of lacerations has yet to be determined. However, their routine use after wound cleaning does encourage patient inspection of the wound.

Ointments should not be used on wounds closed with tissue adhesive because the ointment will dissolve the adhesive.

Wound Cultures

Cultures taken at the time of wound preparation and closure in the ED serve no useful purpose and are not recommended. Results of such cultures cannot logically guide future antibiotic selection and often only confuse the picture. It is not standard to routinely culture all infected wounds presenting after closure, unless extenuating circumstances exist. Often such cultures reveal multiple organisms, and do not reflect either the principal infecting organism or the antimicrobials that are required to cure a wound infection.

Systemic Antibiotics

Most traumatic soft tissue injuries sustain a low level of bacterial contamination. [88] The standard wound infection rate in unselected ED wounds is 2% to 5%. In a number of clinical studies of traumatic wounds, prophylactic antibiotics administered orally [20] [125] [126] and intramuscularly [13] [126A] [30] [127] in various regimens did not reduce the incidence of infection.

In experimental models of contaminated incisions, antibiotics have no therapeutic value >3 hours after the injury. [128] [129] When the wound is contaminated with >10 [9] bacteria per

Figure 35-26 This patient used a neomycin-containing ointment on a minor wound, and developed redness, swelling, pruritis, and skin changes. The patient thought it was an infection but it was a contact dermatitis from the neomycin. Plain bacitracin ointment will not do this.

gram of tissue (such as wounds in contact with pus or feces), infection will develop despite antibiotic treatment. [42] Most clinical investigations of antibiotic use in emergency patients have omitted heavily contaminated wounds in their series. Studies of antibiotic prophylaxis for animal bite wounds have produced variable results, and no large study providing stratification of the many prognostic factors has been done. [130]

The use of antibiotics varies widely among clinicians, and because of limited scientific data, there is no clear practice standard. [131] In most soft tissue wounds where the level of bacterial contamination after cleaning and debridement is low, antibiotics have not been proven beneficial. Antibiotics may have marginal benefit when the level of contamination is overwhelming or if the amount of questionably viable tissue left in the wound is considerable (e.g., with crush wounds). Antibiotics should be considered for extremity bite wounds, puncture-type bite wounds in any location, intraoral lacerations that are sutured, orocutaneous lip wounds, wounds that cannot be cleaned or debrided satisfactorily, and highly contaminated wounds (e.g., those contaminated with soil, organic matter, purulence, feces, saliva, or vaginal secretions). They also should be considered for wounds involving tendons, bones, or joints; for wounds requiring extensive debridement in the operating room; for wounds in lymphedematous tissue; for distal extremity wounds when treatment is delayed for 12 to 24 hours; for patients with orthopedic prostheses; and for patients at risk of developing infective endocarditis. [25] If systemic antibiotics are considered necessary, they should be given intravenously or intramuscularly in the earliest stages of wound management.

The choice of antibiotic, particularly for bite wound prophylaxis, is as controversial as the indications for usage. Many species of bacteria cause bite wound infections, making complete coverage impossible.[31] [132] [133] Some antibiotic regimens recommended for bite wounds include dicloxacillin or cephalexin for high-risk dog bite wounds, dicloxacillin or cephalexin plus penicillin for human or cat bite wounds, and amoxicillin-clavulanic acid or cefuroxime for any domestic animal bite. The duration of antibiotic prophylaxis also is in question. It is common practice to provide antibiotics for 72 hours, although data from surgical studies indicate that antibiotics administered beyond the first postoperative day provide no additional protection. [134] Short courses of antibiotics do not seem to increase the incidence of resistant strains of organisms. [135] In all cases, the use of antibiotics should remain subordinate to careful cleaning and debridement. If the infection risk is high enough to warrant antibiotics, secondary closure should be considered. See additional comments on animal bites at the end of this chapter.

There are *no data to support the routine use of prophylactic antibiotics for the majority of wounds encountered in the ED*. [136] Antibiotics should not be used as a substitute for proper wound preparation or a measure to overcome factors suggesting delayed wound closure. The downsides of antibiotic use include needless expense; potential side effects (e.g., rash, anaphylaxis, diarrhea, vomiting); and the development of resistant bacteria, both in the wound and in general. If antibiotics are used, they should be given as soon as possible after wounding and continued for only 2 to 3 days in the absence of a developing infection.

Immunoprophylaxis

Although tetanus is rare, it still occurs in the United States (about 50 cases per year) and is a preventable disease. Therefore, any wound should be assessed for its potential to cause tetanus, and prophylaxis should be considered in the ED. Gergen and colleagues demonstrated that about 70% of Americans older than 6 years of age had protective levels of tetanus antibodies. [137] Levels declined as age increased, and elderly women had the lowest levels of protection. Hispanics (and likely other immigrants) were most likely to have inadequate immunity. Hence, efforts at preventing tetanus should be especially addressed in immigrants and the elderly.

Recommendations for tetanus prophylaxis have evolved since the 1980s. The guidelines published by the Public Health Services Advisory Committee on Immunization Practices, Centers for Disease Control and Prevention, differ slightly from those of the American College of Surgeons in the use of tetanus immune globulin. [138] [139]

Many cases of tetanus develop despite prior immunization; tetanus can result from chronic skin lesions and apparently minor or clean wounds. [140] In 10% to 20% of cases, no precedent wound can be identified. Patients' recall of past immunizations is imperfect, and immunity may rarely be inadequate after a complete series of tetanus toxoid.[141] Furthermore, there is no precise consensus on the definition of a "tetanus-prone wound," yet treatment decisions are based on the differentiation between clean and contaminated wounds. Some investigators warn of overtreatment [142] [143] and others maintain that the risk of therapy is minimal compared with the danger of tetanus.[144] [145] After comparing those risks and benefits, most clinicians would agree that a certain amount of overtreatment is acceptable. However, tetanus

boosters given more frequently than advised increase the incidence of adverse reactions to subsequent injections.

While any break in the skin can be classified as "tetanus prone" traditional definitions of tetanus-prone wounds include injuries >6 hours old; wounds contaminated by feces, saliva, purulent exudate, or soil; wounds with retained foreign bodies or containing devitalized or avascular tissue; established wound infections; penetrating abdominal wounds involving bowel; deep puncture wounds; and wounds caused by crush, burns, or frostbite (Fig. 35-27). When patients are questioned about their tetanus immunization status, they should be asked if they completed the primary immunization series, and if not, how many doses have been given.

Patients who have not completed a full primary series of injections may require both tetanus toxoid and passive immunization with tetanus immune globulin. Tetanus immune globulin will decrease, but will not totally eliminate, the subsequent development of clinical tetanus. The preferred preparation for active tetanus immunization in patients 7 years of age and older is 0.5 mL of tetanus toxoid (plus the lower, adult dose of diphtheria toxoid); the dose of tetanus immune globulin is 250 to 500 units given intramuscularly.[137] Mild local reactions consisting of erythema and induration are common after tetanus toxoid injections. Compared to the rate of reactions to tetanus toxoid (about 20%), reactions are about twice as common if diphtheria immunization is coupled with tetanus immunization. Some patients with high antibody levels develop a hypersensitivity reaction of tenderness, erythema, and swelling, or serum sickness. Generalized urticarial reactions and peripheral neuropathy have also been reported.

Figure 35-27 Tetanus immunization guidelines.

A significant percentage of elderly patients fail to develop protective antitoxin antibody titers after 14 days when given tetanus toxoid boosters.

Because protective levels of tetanus antibodies tend to parallel levels of antibodies to diphtheria, it has been recommended that both immunizations be given simultaneously. Both tetanus and diphtheria immunization have been implicated as a cause of adverse reactions. Tetanus and diphtheria toxoid are products of human antisera, and serious reactions are rare.[146] The most common reaction is a painful, indurated, tender eruption at the injection site, occasionally accompanied by a fever and mild systemic symptoms. This is a hypersensitivity reaction (Arthus-type reaction), not an infection or immunoglobulin E (IgE)-mediated allergy. As such, this reaction does not require drainage or antibiotics, nor does it represent an absolute contraindication to further immunizations. Local reactions are more common in patients who have been given multiple immunizations, so it is unwise to give excessive immunizations "just to be safe." In tetanus-prone injuries, "hyperreactors" can be given tetanus immune globulin. A minor febrile illness, such as an upper respiratory infection, is not a reason to delay immunization. The only absolute contraindication to tetanus toxoid is a history of anaphylaxis or a neurologic event. In such cases, tetanus immune globulin can be given safely. Pregnancy is not a contraindication to either toxoid or immune globulin, although some suggest that the toxoid be used with caution during the first trimester. Given the excellent amnestic response to the toxoid, it is likely that the primary immunization series, coupled with intermittent boosters, conveys immunity for most of one's life.

When a wound results from the bite or scratch of a wild or domestic animal, prophylaxis against rabies also must be considered (Table 35-3 and Table 35-4). Further discussion of the prevention of rabies is provided elsewhere.[147] [148]

PATIENT INSTRUCTIONS

Successful wound healing is partly dependent on the care given to the wound once the patient leaves the emergency center. Patient satisfaction depends not only on the cosmetic result, but also on the expectation of that result. [10] Therefore, the patient should receive thorough and clear instructions.

The patient should be informed that no matter how skillful the repair, any wound of significance produces a scar. Most scars deepen in color and become more prominent before they mature and fade. The final appearance of the scar cannot be judged before 6 to 12 months after the repair. [9] [91]

Patients may experience dysesthesias in or around a scar, particularly about the midface. Gentle rubbing or pressing on the skin may relieve the symptoms. If wounds extending to SQ levels lacerate cutaneous nerves, patients may be bothered by hypoesthesia distal to the wound. Dysesthesia and anesthesia usually resolve in 6 months to 1 year.[10]

Because the wound edges are rapidly sealed by coagulum and bridged by epithelial cells within 48 hours, the wound is essentially impermeable to bacteria after 2 days.[19] [149] The patient should be instructed to protect the wound by keeping the dressing clean and dry for 24 to 48 hours. In this initial period the dressing should be changed only if it becomes externally soiled or soaked by exudate from the wound. If possible, the injured part should be kept elevated.

After 48 hours, the patient may remove the dressing in uncomplicated wounds and check for evidence of infection: redness, warmth, increasing pain, swelling, purulent drainage, or the "red streaks" of lymphangitis. Not all patients are able to identify these signs of infection; it is prudent to have patients with complicated or infection-prone wounds examined in 2 days by a clinician or nurse. [150] Interestingly, patients may be more likely to fail to recognize a bona fide infection than to overdiagnose an infection when it is absent. [149] [150]

TABLE 35-3 -- Rabies Postexposure Prophylaxis Guide—July 1984 [147]

The following recommendations are only a guide. In applying them, take into account the animal species involved, the circumstances of the bite or other exposure, the vaccination status of the animal, and presence of rabies in the region. Local or state public health officials should be consulted if questions arise about the need for rabies prophylaxis.

Animal Species	Condition of Animal at Time of Attack	Treatment of Exposed Person*
Domestic		
Dog and cat	Healthy and available for 10 days of observation	None, unless animal develops rabies†
	Rabid or suspected rabid	HRIG‡ and HDCV
	Unknown (escaped)	Consult public health officials. If treatment is indicated, give HRIG‡ and HDCV
Wild		
Skunk, bat, fox, coyote, raccoon, bobcat, and other carnivores	Regard as rabid unless proven negative by laboratory tests§	HRIG‡ and HDCV
Other		
Livestock, rodents, and lagomorphs (rabbits and hares)	Consider individually. Local and state public health officials should be consulted on questions about the need for rabies prophylaxis. Bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, other rodents, rabbits, and hares almost never call for antirabies prophylaxis.	

From Leads from the Mortality and Morbidity Weekly Report. JAMA 252:883, 1984.

**All bites and wounds should immediately be thoroughly cleansed with soap and water.* If antirabies treatment is indicated, both human rabies immune globulin (HRIG) and human diploid cell rabies vaccine (HDCV) should be given as soon as possible, *regardless* of the interval from exposure. Local reactions to vaccines are common and do not contraindicate continuing treatment. Discontinue vaccine if fluorescent antibody tests of the animal are negative.
†During the usual holding period of 10 days, begin treatment with HRIG and HDCV at first sign of rabies in a dog or cat that has bitten someone. The symptomatic animal should be killed immediately and tested.
‡If HRIG is not available, use antirabies serum, equine (ARS). Do not use more than the recommended dosage.
§The animal should be killed and tested as soon as possible. Holding for observation is not recommended.

Patients may fail to appreciate the presence of an infection in >? of cases. Therefore, in high-risk circumstances, a scheduled, rather than an as-needed, wound check should be advised. Patients should be informed that sutures themselves do not cause pain. A painful wound is often a sign of infection or suture reaction, and pain should prompt a wound check. If there is no sign of infection after 48 hours, the patient can care for the wound until it is time for removal of the sutures.

A daily gentle washing with mild soap and water to remove dried blood and exudate is probably beneficial, especially on areas such as the face or the scalp. [147] [150] Although

TABLE 35-4 -- Rabies Postexposure Prophylaxis Schedule, United States

Vaccination Status	Treatment	Regimen*
Not previously vaccinated	Local wound cleansing	All postexposure treatment should begin with immediate thorough cleansing of all wounds with soap and water
	HRIG	20 IU/kg of body weight; if anatomically feasible, up to half the dose should be infiltrated around wounds and rest administered IM in gluteal area; HRIG should not be administered in same syringe or into same anatomic site as vaccine; because HRIG may partially suppress active production of antibody, no more than recommended dose should be given
	Vaccine	HDCV or RVA, 1 mL, IM (**deltoid area**), one each on days 0, 3, 7, 14, and 28
Previously vaccinated‡	Local wound cleansing	All postexposure treatment should begin with immediate thorough cleansing of all wounds with soap and water
	HRIG	HRIG should not be administered
	Vaccine	HDCV or RVA, 1 mL, IM (deltoid area†), one each on days 0 and 3

HDCV, human diploid cell rabies vaccine; HRIG, human rabies immune globulin; RVA, rabies vaccine, adsorbed.

From the Recommendations of the Immunization Practices Advisory Committee, MMWR 40(RR-3):1, 1991.

*These regimens are applicable for all age groups, including children.
‡Any person with a history of preexposure vaccination with HDCV or RVA, prior postexposure prophylaxis with HDCV or RVA, or previous vaccination with any other type of rabies vaccine and a

documented history of antibody response to the prior vaccination.
†The deltoid area is the only acceptable site of vaccination for adults and older children. For younger children, the outer aspect of the thigh may be used. Vaccine should never be administered in the gluteal area.

patients may bathe with sutures in place, prolonged immersion in water should be avoided. Undiluted hydrogen peroxide may theoretically destroy granulation tissue and newly formed epithelium, and it should not be repeatedly used as a cleaning agent on the healing wound itself. [49] Generally, a wound should be protected with a dressing during the first week, and the dressing should be changed daily. If the wound is unlikely to be contaminated or traumatized, it may be left uncovered.

Many clinicians wrongly admonish patients against getting sutured wounds wet, and prohibit bathing, prompting some patients to keep the original dressing in place for inordinate

amounts of time. Although widely prohibited, there is no evidence that swimming in uncontaminated water with sutures in place delays healing or promotes infection. There is no evidence that gently cleaning a sutured wound even within a few hours of closure adversely impacts infection or healing rates. [149] It is generally recommended that uncovered scalp wounds can be washed after 1 to 2 days, but many clinicians advise showering the same day. Vigorous scrubbing of wounds should be discouraged. The skin surrounding a wound should be gently cleaned in the ED after wound closure to minimize subsequent itching caused by dried blood.

Some wounds heal with wide, unattractive scars despite ideal management and closure. Wounds more likely to have significant scars are those that cross perpendicular to joints, wrinkle lines, or lines of minimum tension (Kraissel lines); that retract >5 mm; and that are over convexities or in certain anatomic locations (e.g., anterior upper chest, back, shoulders) where hypertrophic scars are common. A wound crossing a concave surface may result in a bowstring deformity; one crossing a convexity may leave a scar depression. To avoid these complications, a Z-plasty procedure can be done at the time of initial wound management, or the scar can be revised later. The patient should be told to expect suboptimal outcomes in these situations. [37]

If an injured extremity or finger is protected by a splint, it should be left undisturbed until the sutures are removed. Patients with intraoral lacerations should be instructed to use warm salt water mouth rinses at least three times a day.

Patients may ask about the efficacy of various creams and lotions (e.g., vitamin E, aloe vera, cocoa butter) in limiting scar formation. At this time there are no data to evaluate the use of these substances. Patients should be told to avoid aspirin, as it has been shown to decrease the development of tensile strength and increase the likelihood of hematoma formation. [151]

SECONDARY WOUND CARE

Reexamination

Patients with simple sutured wounds may be released with appropriate instructions for home care and told to return for suture removal at an appropriate time. High-risk wounds should be examined in 2 to 3 days for signs of infection. All wounds should be inspected if the patient experiences increasing discomfort or develops a fever, or believes that the wound is infected. [95] Bite wounds and other infection-prone wounds should be inspected in 2 days. Wounds being considered for delayed primary closure are evaluated in 4 to 5 days. [87A]

Wounds in which extensive dissection of SQ tissue has been performed may develop an intense inflammation similar in appearance to a low-grade, localized cellulitis. It is rarely necessary to open these wounds. The removal of one or two stitches may relieve some of the tension caused by mild swelling. With daily cleansing using water and a mild soap and with application of warm compresses, this type of wound reaction should subside within 24 to 48 hours. [95]

A wound that has become infected should be evaluated for the presence of a retained foreign body.

Also, in most sutured wounds that become infected, the sutures must be removed to allow drainage. If a wound exhibits a minor infection, a few sutures, or all of them, may be removed, but grossly infected wounds should be packed open to allow for further drainage. The presence of sutures in a contaminated wound considerably limits the activity of various antibiotics. [152] Infection around a suture can lead to the formation of a stitch mark. [75] Infected wounds should be treated with daily cleansing, warm compresses, and antibiotics. Wounds that have been opened should be left to heal by secondary intention, which involves wound contraction, granulation tissue formation, and epithelialization.

Suture Removal

Sutures are usually removed by medical personnel, but reliable patients can be given the appropriate materials and instructions to remove simple interrupted sutures themselves. Because wounds do not heal at a standard rate, no strict guidelines can be set for time of suture removal. The optimal time for suture removal varies with the location of the wound, rate of wound healing, and amount of tension on the wound. Certain areas of the body such as the back of the hand heal slowly, whereas facial or scalp wounds heal rapidly. Speed of wound healing is affected by systemic factors such as malnutrition, neoplasia, or immunosuppression. At the time that suture removal is being considered, one or two sutures may be cut to determine whether the skin edges are sufficiently adherent to allow removal of all the sutures. [6] Removing sutures too early invites wound dehiscence and widening of the scar, whereas leaving sutures in longer than necessary may result in epithelial tracts, infection, and unsightly scarring. [153]

Small stitch abscesses are common in wounds in which sutures remain more than 7 to 10 days. Localized stitch abscesses generally resolve following removal of the sutures and application of warm compresses. There is usually no need for antibiotic therapy with localized stitch abscesses.

Percutaneous sutures stimulate an inflammatory reaction along the suture track. Factors that determine the severity of stitch marks include the length of time skin stitches are left in place, skin tension, the relationship of the suture to the wound edge, the region of the body, infection, and tendency for keloid formation. [75] [154] The skin of the eyelids, palms, and soles and the mucous membranes seldom show stitch marks. In contrast, oily skin and the skin of the back, the sternal area, the upper arms, the lower extremities, the dorsum of the nose, and the forehead are likely to develop the permanent imprints of suture material on the skin surface. [75]

If sutures are removed within 7 days, generally no discernible needle puncture or stitch mark will persist. [154] However, at 6 days, the wound is held together by a small amount of fibrin and cells and has minimal strength (see Fig. 35-1).[90] The tensile strength of most wounds at this time is adequate to hold the wound edges together, but only if there are no appreciable dynamic or static skin forces pulling the wound apart. [6] Minimal trauma to an unsupported wound at this point could cause dehiscence. The clinician should decide on the proper time of suture removal after weighing these various factors. If early suture removal is necessary, wound repair can be maintained with strips of surgical skin tape. The key to wound tensile strength after suture removal is an adequate deep tissue layer closure.

There are some general guidelines for suture removal. Sutures on the face should be removed on the fifth day following the injury, or alternate sutures should be removed

on the third day and the remainder on the fifth day. On the extremities and the anterior aspect of the trunk, sutures should be left in place for approximately 7 days to prevent wound disruption. Sutures on the scalp, back, feet, and hands and over the joints must remain in place for 10 to 14 days, even though permanent stitch marks may result.[75] Some clinicians recommend the removal of sutures in eyelid lacerations in 48 to 72 hours to avoid epithelialization along the suture tract, with subsequent cyst formation.[155]

Removing sutures is relatively simple and the removal technique is not known to affect infection rates or scarring. The wound should be cleansed, and any remaining crust overlying the wound surface or surrounding the sutures should be removed. The skin is wiped with an alcohol swab. Each stitch is cut with a scissors or the tip of a No. 11 scalpel blade at a point close to the skin surface on one side. The suture is grasped on the opposite side with forceps and is pulled across the wound (Fig. 35-28). The amount of exposed suture dragged through the suture tract is thereby minimized. It is difficult to remove sutures with very short ends. At the time of suture placement, the length of the suture ends should generally equal the distance between sutures to permit easy grasping of the suture during subsequent removal yet avoiding entanglement during the knotting of adjacent sutures.

Once the skin sutures are removed, the width of the scar increases gradually over the next 3 to 5 weeks unless it is supported. Support is provided by previously placed SQ stitches that brought the skin edges into apposition, by a previously placed subcuticular stitch, or by the application of skin tape (Fig. 35-29). A nonabsorbable subcuticular suture can be left in place for 2 to 3 weeks to provide continued support for the wound. Although complications such as closed epithelial sinuses, cysts, or internal tracts can occur from prolonged use of this stitch, they are unusual and can be avoided by the placement of a buried subcuticular stitch using an absorbable suture.[19]

If a subcuticular stitch with reliefs has been used, the suture is cut at the midpoint of the relief. Half of the suture is removed at the original point of entry into the skin and the other half through the original exit point (Fig. 35-30).[156] If a nonabsorbable subcuticular suture cannot be removed or a portion of it ruptures during removal, the protruding end should be grasped with a hemostat, pulled taut, and cut with scissors as close to the skin as possible so that the end of the suture retracts under the skin.

If time and effort have been invested in a cosmetic closure of the face, the repair should be protected with skin tape after the skin sutures have been removed. Wound contraction and scar widening continue for 42 days after the injury. [90] Because the desired result is a scar of minimal width, the tape

Figure 35-28 Technique for suture removal. Pull should be toward the wound line *(A)* rather than away from it *(B),* which causes the wound to tear apart. *(Modified from Stuzin J, Engrav LH, Buehler PK: Emergency treatment of facial lacerations. Postgrad Med 71:81, 1982.)*

should be used for 5 weeks following suture removal. With exposure to sunlight, scars in their first 4 months redden to a greater extent than surrounding skin. In

exposed cosmetic areas and when prolonged exposure to the sun is anticipated, this should be prevented with the use of a sunscreen containing para-amino benzoic acid (PABA).

COMPLICATIONS

Infection is probably the most common cause of dehiscence. If the patient is careless or unlucky, reinjury can reopen a wound despite the protection of a thick dressing. If the suture size is too small, the stitch may break. A stitch that is too fine or tied too tightly may cut through friable tissue and pull out. Knots that have not been tied carefully may unravel. The suture material may be extruded or absorbed too rapidly. Finally, if a stitch is removed too early (i.e., before tissues regain adequate tensile strength), the wound loses needed support and falls open. If the wound edges show signs of separating at the time of suture removal, alternate stitches can be left in place and the entire length of the wound supported by strips of adhesive tape.

There are several reasons why wounds fail to heal; some are related to decisions made at the time of wound closure, and others are consequences of later events. Some of the impediments to healing include ischemia or necrosis of tissue, hematoma formation, prolonged inflammation caused by foreign material, excessive tension on skin edges, and immunocompromising systemic factors. In attempting to repair wounds, clinicians sometimes inadvertently retard the healing process (e.g., with premature closure of contaminated wounds). With the development of new methods and solutions for cleansing wounds and the discovery of the optimal concentrations of solutions currently in use, tissue-toxic antiseptic solutions can be abandoned. Better suture materials are replacing the reactive sutures that often served as foreign bodies rather than tissue supports. Improved materials used for dressing wounds enhance wound healing.

A primary cause of delayed healing is wound infection. Wound cleaning and debridement, atraumatic and aseptic handling of tissues, and the use of protective dressings minimize this complication. Inversion of the edges of a wound during closure produces a more noticeable scar, whereas skillful technique can convert a jagged, contaminated wound into a fine, inapparent scar. However, the patient's actions also affect wound healing. Delay in seeking treatment for an injury may significantly affect the ultimate outcome of the wound. Furthermore, in the first few days following an injury, the

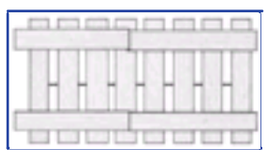

Figure 35-29 Support of the wound with surgical tape.

patient must take responsibility for protecting the wound from contamination, further trauma, and swelling.

The final appearance of a scar is determined by several factors. Infection, tissue necrosis, and keloid formation widen a scar. Wounds located in sebaceous skin or oriented 90° to dynamic or static skin tension lines result in wide scars.

Miscellaneous Aspects of Wound Care

Many parameters and scenarios are involved in the preparation for repair and definitive treatment of wounds. Many specific questions are discussed in other sections of this text but a few specific caveats are included below for completeness.

Figure 35-30 At the time of suture removal, the suture is cut at the midpoint of the relief *(A)*. The proximal portion is removed at the point of original entry into the skin *(B)*, and the distal portion is removed through the original exit point *(C)*. *(From Grimes DW, Garner RW: "Reliefs" in intracuticular sutures. Surg Rounds 1:48, 1978. Reproduced by permission.)*

Digital nerves.

The key to the best possible outcome of a digital nerve injury is making, or suspecting, the diagnosis at the time of initial presentation. Usually injury to a digital nerve is obvious, but numerous factors will hinder the timely diagnosis, and the presence or extent of nerve injury may not be immediately discernible in the ED. Numbness in the area of digital innervation, concomitant injury to a digital artery (flash/pulsating bleeding), or an electric shock sensation when exploring a laceration should alert the clinician to a possible digital nerve injury. When the presence of a digital nerve injury is in question, a follow-up visit usually confirms or eliminates this injury, so it is not critical that all decisions be made at the first visit. With regard to wound preparation issues, lacerations to the hand and fingers should be approached with caution. Debridement should be minimal, and wound preparation should be gentle yet meticulous. Digital nerves that are transected distal to the metacarpophalangeal joint may be candidates for surgical repair. It is not known exactly how far distal in the finger can the nerve be lacerated for a repair to be successful, and proper referral is therefore essential. Often injuries proximal to the distal inter-phalangeal joint are not repaired, but many other factors will influence operative decisions. Repair of a digital nerve will frequently result in return of good sensory function (but it takes months) and repair can prevent painful neuromas from developing. Most hand surgeons will not repair digital nerves at the time of initial presentation. Instead, they advise wound cleaning, skin closure, splinting, and outpatient follow-up in 24 to 36 hours, followed by delayed nerve repair.

Animal bites.

The use of prophylactic antibiotics is discussed in a previous section of this chapter. However, many aspects of the treatment of animal bites are controversial and no universal standards exist. Most bites are caused by dogs or cats, with most being sustained from family pets. Numerous organisms will accompany a bite from a dog or cat. If a bite appears clinically grossly infected within the first 24 hours, the offending organism is usually the gram-negative rod *Pasteurella multocida*. If the infection appears later than 24 hours, a host of bacteria, but predominantly *Staphylococcus aureus* and *Streptococcus viridans*, are the culprits. *Pasteurella* infections are common in cat bites. Cat bites, probably because they are puncture wounds that can not be completely cleaned, frequently become infected. The incidence of infection following dog bite lacerations is not significantly greater than lacerations in general. Many clinicians have advocated the primary closure of large dog bite lacerations. Markedly contused lacerations are good candidates for delayed primary closure. Wound cultures taken at the time of an animal bite are worthless. The use of prophylactic antibiotics for animal bites is controversial and various approaches are advocated (see earlier discussion). The best way to approach bite wounds is to adhere to the general principles and details of wound care as outlined in earlier discussions. No specific intervention has been demonstrated to be superior for the preparation of bite wounds. Care should be taken to search for underlying fractures or tooth fragments in deep animal bites.

Gunshot wounds.

A certain subset of gunshot wounds may be definitively handled in the ED, with outpatient follow-up. The landmark studies by Ordog et al. [157] [158] document a very low infection rate in gunshot wounds treated on an outpatient basis. In a retrospective study of nearly 17,000 subjects, the vast majority of patients did well, with only a 1.8% infection rate. Standard wound care was given and

prophylactic antibiotics were withheld, and satisfactory results were obtained even when the missile was left in place, and minor fractures were present (Fig. 35-31). Since most gunshot wounds are puncture wounds, minimal deep wound cleaning is possible.

Puncture wounds.

The approach to specific puncture wounds is discussed in other sections, but a few caveats are repeated here. As a general rule, it is impossible to completely clean a puncture wound. In fact, it may be counterproductive to attempt to do so in some areas of the body. Superficial soft tissue wounds having entrance and exit wounds in proximity may be debrided by passage of a sterile gauze back and forth through the wound tract. Coring out a puncture wound is usually overly aggressive initial treatment, but it may be an option if gross contamination or infection is present. In selected punctures, it may be possible to incise the skin and cutaneous tissue over the tract, converting a puncture into a linear laceration. If a through-and-through stream cannot be established, attempting to irrigate the tract of a puncture

Figure 35-31 Minor gunshot wounds may be treated as outpatients, even when bullet fragments remain and there are *minor* fractures. *A* and *B*, This through-and-through injury transversed the hypothenar eminence. No bullet remained and no bones were involved. *C*, Usually it is impossible to irrigate a puncture wound, but in this case note the saline at the exit site. *D*, After the entrance wound is debrided of the powder burn, a hemostat is passed through the wound. *E*, The instrument grasps gauze packing and pulls it into the wound. The gauze was pulled back and forth to debride the wound tract, and then a clean gauze was left in place. No antibiotics were given, the pack was removed at wound check in 24 hours, and the patient did well. Many gunshot wounds cannot be irrigated to this extent but the treatment principles are similar.

wound by inserting a needle into the depths of the wound and forcibly injecting irrigating solution has the potential to disseminate contamination and increase soft tissue swelling, and is discouraged. If gross contamination remains in a puncture wound, it is unlikely that antibiotics will prevent or totally treat an infection. This leaves the clinician with the reality that many puncture wounds usually do quite well with minimal intervention, while others do quite poorly because of their inaccessibility to wound cleaning techniques. Simply stated, it may be impossible to predict the outcome of most puncture wounds on the first encounter. The key to success with any puncture wound is to acknowledge the issues discussed earlier, relay them to the patient, and provide the necessary follow-up.

CONCLUSION

The objective of traumatic wound management is the restoration of tissue continuity and strength in the least possible

time, with maximal preservation of tissues and minimal scar formation, deformity, or loss of function.

It is important that clinicians follow the basic principles of wound care when cleaning, debriding, closing, and protecting wounds and continue to refine their management of wounds as further improvements in techniques and materials become available.

Chapter 36 - Methods of Wound Closure

Richard L. Lammers
Alexander T. Trott

Once the decision to close a wound has been made, the clinician must select the closure technique best suited for the location and configuration of the wound. Available techniques include hair typing (in the scalp) and use of tape, tissue adhesive, metal staples, and sutures. All traumatic wounds should be cleaned, and wounds containing devitalized tissue should be debrided before closure (see Chapter 35).

HAIR TYING OF SCALP WOUNDS

Scalp wounds that gape have traditionally been closed with suture material or skin staples. One "folk method" of scalp wound closure that has received limited discussion and study is the technique of tying together "roped" strands of hair from opposite sides of the wound. [1] [2]

The advantages of this technique are that no surgical instruments are required; no foreign material is placed in the wound; and it is relatively painless, because a local anesthetic injection is not needed. This technique may be of particular value in wilderness settings when wound repair equipment is unavailable and the wound is relatively clean. In certain superficial scalp wounds in children, this technique offers a particularly humane method of wound closure.

Indications and Contraindications

Closure by hair tying can be performed on small scalp wounds (i.e., 1 to 2 cm in length). Davies suggests the following six criteria for consideration of this technique [2] :

1. The patient's hair must be of adequate length to form "roped" strands that can be tied across the wound.
2. The wound edges should not be contused.
3. There should be no gross wound contamination.
4. There must be good wound hemostasis.
5. The galea (occipitofrontalis aponeurosis) must not be divided.
6. There must be no underlying skull fracture.

When these conditions cannot be met, the technique should not be undertaken. If local anesthesia must be used to permit evaluation of the deep structures of the wound, it may be best to simply repair the wound with sutures or staples.

Procedure

When possible, the area surrounding the wound should be cleansed with mild disinfectant, avoiding contact with the unanesthetized wound. The wound should be irrigated with normal saline. The wound should be gently explored using a gloved hand or cotton-tipped applicator to verify that the galea is not compromised and that no foreign material remains in the wound.

Hair on each side of the laceration is then twisted to form "ropes" of hair (Fig. 36-1*A*). These "roped" strands are tied across the wound in a surgical knot, with several additional throws (Fig. 36-1*B*) to tightly appose the skin edges. Davies recommends spraying a plastic sealant on the knot to avoid loosening it. [2]

Postclosure wound care is similar to that for routine scalp closure. The patient may gently shampoo the hair, but *vigorous* hair massage or combing in the area should be avoided. The knot is allowed to grow away from the wound edge and can be cut free in 2 to 4 weeks.

Complications

In 1 series of 25 children under 8 years of age whose scalp wounds were closed by hair tying, 48-hour follow-up showed no evidence of wound infection and 2 cases of mild (2 to 4 mm) wound separation.[2] The investigators noted that some children complained of the sensation that their hair was "being pulled" during wound closure, but all cooperated without restraints or anesthesia. The most common complaint noted at follow-up was that the hair-tie knot was untidy. There is little control over apposition of wound edges with this technique.

Conclusion

Closure of scalp wounds by hair tying offers an alternative for closure of small, superficial scalp wounds in children and for clean scalp wound repair in wilderness settings.

WOUND TAPE

The use of surgical tape strips to close simple wounds has become routine in recent years. Tape strips can be applied by health care personnel in many settings, including emergency departments (EDs), operating rooms, clinics, and first-aid stations. Advantages include ease of application, reduced need for local anesthesia, more evenly distributed wound tension, no residual suture marks, minimal skin reaction, no need for suture removal, superiority for some grafts and flaps, and suitability for use under plaster casts. One main advantage of wound tapes is their greater resistance to wound infection compared with standard sutures and wound staples.[3] [4] [5] [6]

Background and Tape Comparisons

Tape closure of wounds has been reported since 1600 BC.[7] It was not until the late 1950s, however, with the introduction of woven tapes and nonsensitizing adhesive, that tapes gained widespread acceptance in the United States.[8] Since then, there have been rapid advances in the manufacture of tapes with increased strength, improved adhesiveness, and presterilized packaging.

Currently there are several brands of tapes with differing porosity, flexibility, strength, and configuration. Steri-Strips (3M Corporation, St. Paul, MN) are microporous tapes with ribbed backing. They are porous to air and water, and the ribbed backing provides extra strength. Cover-Strips (Beiersdorf, South Norwalk, CT) are woven in texture and have a high degree of porosity. They allow not only air and water, but also wound exudates to pass through the tape. Shur-Strip (Deknatel, Inc., Floral Park, NY) is a nonwoven microporous tape. Clearon (Ethicon, Inc., Somerville, NJ) is a synthetic plastic tape whose backing contains longitudinal parallel serrations to

Figure 36-1 *A,* Hair on each side of a laceration is twisted to form "ropes" of hair. *B,* The "roped" strands are tied across the wound in a surgical knot along with additional throws to oppose the skin edges.

permit gas and fluid permeability. An iodoform-impregnated Steri-Strip (3M Corporation) is intended to further retard infection without sensitization to iodine.[3] Other tape products include Curi-Strip (Kendall, Boston), Nichi-Strip (Nichiban Co., Ltd, Tokyo), Cicagraf (Smith & Nephew, London), and Suture Strip (Genetic Laboratories, St. Paul, MN).

Scientific studies of wound closure tapes have been limited, and because of different investigators' choices of products and methods, it is not always easy to compare results. Koehn showed that the Steri-Strip tapes maintained adhesiveness about 50% longer than Clearon tape.[9] Rodeheaver and coworkers compared Shur-Strip, Steri-Strip, and Clearon tape in terms of breaking strength, elongation, shear adhesion, and air porosity.[10] The tapes were tested in both dry and wet conditions. The Steri-Strip tape was found to have about twice the breaking strength of the other two tapes in both dry and wet conditions; there was minimal loss of strength in all tapes when wetted. The Shur-Strip tapes showed approximately two to three times the elongation of the other tapes at the breaking point, whether dry or wet. Shear adhesion (amount of force required to dislodge the tape when a load is applied in the place of contact (angle = 0°) was slightly better for the Shur-Strip tape than for the Steri-Strip tape and approximately 50% better than for the Clearon tape. Of these three wound tapes, the investigators considered Shur-Strips to be superior for wound closure.

One comprehensive study of wound tapes compared Curi-Strip, Steri-Strip, Nichi-Strip, Cicagraf, Suture Strip, and Suture Strip Plus.[11] All tapes were 12 mm wide except for Nichi-Strip, which was 15 mm. Each tape was compared for breaking strength, elongation under stress, air porosity, and adhesiveness. Curi-Strip, Cicagraf, and Steri-Strip exhibited equivalent dry breaking strengths. However, when wet (a condition that can occur in the clinical setting), Cicagraf outperformed all tapes. All of the tested tapes had similar elongation-under-stress profiles with the exception of Suture Strip Plus. This tape did not resist elongation under low or high forces. Excessive elongation may allow wound dehiscence. Nichi-Strip was the most porous to air, and Cicagraf was almost vapor impermeable. Nichi-Strip and Curi-Strip had the best adherence to untreated skin. When the skin was treated with tincture of benzoin, however, Steri-Strip dramatically outperformed all other products. When all of the study parameters were considered, Nichi-Strip, Curi-Strip, and Steri-Strip achieved the highest overall performance rankings.

Indications

The primary indication for tape closure is a superficial straight laceration under little tension. If necessary, tension can be reduced by undermining or placing deep closures. Areas particularly suited for tape closure are the forehead, chin, malar eminence, thorax, and nonjoint areas of the extremities. Tape also may be preferred for wounds in anxious children when suture placement is not essential. In young children who are likely to remove tapes, tape closures must be protected with an overlying bandage. However, adhesive bandages (e.g., Band-Aids) should be avoided (see later).

In experimental wounds inoculated with *Staphylococcus aureus*, tape-closed wounds resisted infection better than wounds closed with nylon sutures.[6] Therefore, tape closures may be considered on wounds with potential for infection, although infection rates are generally comparable to those of sutured wounds. Tape closures work well under plaster casts when superficial suture removal would be delayed. Tape closures effectively hold flaps and grafts in place, particularly over fingers, the flat areas of the extremities, and the trunk (Fig. 36-2).[3] [4] Wounds on the pretibial area are difficult to close. This area is particularly problematic in the elderly because of tissue atrophy. One report found that wound tapes outperformed suture closure of the pretibial area with regard to time to healing and complications.[12] Tape closures can be applied to wounds following early suture removal to maintain wound edge approximation while reducing the chance of permanent suture mark scarring. Finally, because of the minimal skin tension created by tapes, they can be used on skin that has been compromised by vascular insufficiency or altered by prolonged use of steroids.

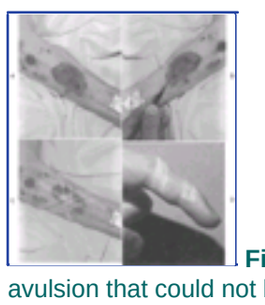

Figure 36-2 *A,* A skin avulsion is an ideal wound to close with closure tapes. An elderly woman who was on steroids had extremely thin skin and suffered an anterior tibial skin avulsion that could not be replaced with sutures. *B,* The skin edges are uncurled, stretched, and anatomically replaced. *C,* The wound should heal when closure tapes keep the skin in place. A compression dressing, such as an elastic bandage or a Dome paste (Unna) boot dressing, can be applied to minimize flap movement and decrease fluid buildup under the flap. *D,* Tape should be placed in a semicircular or spiral pattern on digits to avoid constriction.

Contraindications

There are disadvantages to tape closures. Tape does not work well on wounds under significant tension or on wounds that are irregular, on concave surfaces, or in

areas of marked tissue laxity. In many cases tape does not provide satisfactory wound edge apposition without concurrent underlying deep closures. Tape does not stick well to naturally moist areas, such as in the axilla, the palms of the hands, the soles of the feet, and the perineum. Tape also has difficulty adhering to wounds that will have copious exudates. Tape strips are also at risk for premature removal by young children.

Tape closures are contraindicated in wounds that are irregular or under tension and in those that cannot be appropriately dried of blood or secretions. They are of little value on lax and intertriginous skin and in the scalp and other areas with high concentration of hair follicles.

Tapes should never be placed circumferentially around digits because they have insufficient ability to stretch or lengthen. If placed circumferentially, the natural wound edema of an injured digit can make the tape act like a constricting band, which can lead to ischemia and possible necrosis of the digit. Semicircular or spiral placement techniques should be used if digits are to be taped (Fig. 36-2*C*).

Equipment

For a simple tape closure, the required equipment includes forceps and tape of the proper size. Most taping can be done in the ED with ¼-inch × 3-inch strips. In wounds larger than 4 cm, however, ½-inch-wide strips might be desirable. Most companies manufacture strips up to 1 inch wide and up to 4 inches long.

Procedure

Application of the tape must be preceded by proper wound preparation, irrigation, debridement, and hemostasis. Fine hair may be cut short or shaved, and the area of the tape application *is thoroughly dried to ensure proper adhesion*. Attempting to apply tapes to a wet area or over a wound that is slowly oozing blood will usually result in failure of the tapes to stick to the skin. On fingers, tapes can be applied to a wound that is kept dry by a tourniquet temporarily placed at the base of the finger.

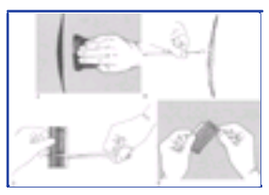

Figure 36-3a Proper technique for application of tapes for skin closure. *A,* After wound preparation (and placement of deep closures, if needed), dry the skin thoroughly at least 2 inches around the wound. Failure to dry the skin and failure to obtain perfect hemostasis are common causes of failure of tapes to stick to the skin. *B,* If desired, apply a thin coating of tincture of benzoin around the wound to enhance tape adhesiveness. Benzoin should not enter the eye, and it causes pain if it seeps into an open wound. *C,* Cut the tapes to the desired length before removing the backing. *D,* The tapes are attached to a card with perforated tabs on both ends. Gently peel the end tab from the tapes.

Tincture of benzoin and Mastisol are liquid adhesives that can be applied initially to increase tape adhesion. [6] The clinician should use sterile technique at all times. Wound tapes do not adhere unduly to surgical gloves. All tapes come in presterilized packages and can be opened directly onto the operating field.

The technique of applying tapes is shown in Figure 36-3*A–J* Figure 36-3*A–J* . After the wound has been dried and a liquid adhesive has been applied and has dried, the tapes, with backing attached, are cut to the desired length. Tapes should be long enough to allow for approximately 2 to 3 cm of overlap on each side of the wound. After the tape is cut to length, the end tab is removed. The tape is gently removed from the backing with forceps by pulling straight back. Do not pull to the side because the tape will curl and be difficult to apply to the wound. One half of the tape is securely placed at the midportion of the wound. The opposite wound edge is gently but firmly apposed to its counterpart. The second half of the tape is then applied. The wound edges should be as close together as possible and at equal height to prevent the development of a linear, pitted scar. Additional tapes are applied by bisecting the remainder of the wound. A sufficient number of tape strips should be placed so that the wound is completely apposed without totally occluding the wound edges. Finally, additional cross tapes are placed to add support and prevent blistering caused by unsupported tape ends. [5]

Taped wounds are left open, without occlusive dressings. Adhesive bandages (e.g., Band-Aids) and other dressings promote excessive moisture, which can lead to premature tape separation from the wound. The bandage also may adhere to the closure tapes, causing separation of the closure tape from the skin at the time of the removal. Tapes may remain in place for approximately 2 weeks, longer in some cases. The duration of application is a decision that varies with the requirements of each wound. The patient can be allowed to clean the taped laceration gently with a moist, soft cloth after 24 to 48 hours. However, if excessive wetting or mechanical force is used, premature separation may result. Patients may be instructed to gently trim curled edges of the closure tape with fine scissors to avoid premature removal of the tape.

Complications

Complications are uncommon with tape closure. The infection rate is approximately 5% in clean wounds closed with tape. [5] This compares favorably with rates for other standard

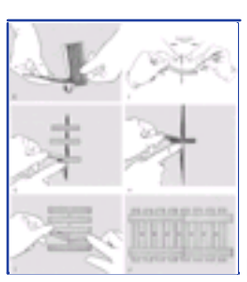

Figure 36-3b *E,* Use forceps to peel the tape off the card backing. Pull directly backward, not to the side. *F,* Place one half of the first tape at the midportion of the wound; secure firmly in place. *G,* Gently but firmly oppose the opposite side of the wound, using the free hand or forceps. If an assistant is not available, the operator can approximate the wound edges. *H,* The tape should be applied by bisecting the wound until the wound is closed satisfactorily. *I,* Wound margins are completely opposed without totally occluding the wound. *J,* Additional supporting tapes are placed approximately 2.5 cm from the wound and parallel to the wound direction. Taping in this manner prevents the skin blistering that may occur at tape ends.

closures. Premature tape separation occurs in approximately 3% of cases. [10] Other complications include (1) skin blistering, which occurs if the tape is not properly anchored with the cross-stay strip or the tape is stretched excessively across the wound; and (2) wound hematoma, which results if hemostasis is inadequate.

When tincture of benzoin is used, it should be applied carefully to the surrounding uninjured skin. If spillage occurs into the wound, the wound is at higher risk for infection.[13] Benzoin vapors cause pain when applied near an open wound that has not been anesthetized. Benzoin can also injure the mucous membranes of the eye.

Summary

Most investigators believe that the results of proper tape closure are as successful as those of suture closure. [5] [7] However, some investigators believe that tape closure leads to inferior cosmetic results. [14] In the aggregate, modern tape products and techniques serve a valuable role in minor wound

management of selected patients in the ED. Generally, closure tapes are underused, and many wounds that are currently sutured in cosmetically unimportant areas could be adequately closed with tapes. As a general guide, tapes should be considered in those cases where sutures are not clearly required, but the wound is too wide for a simple dressing.

TISSUE ADHESIVE

Adhesive tape can only be used on superficial wounds on relatively flat, hairless body surfaces. The tissue adhesive *N*-2-octylcyanoacrylate (Dermabond, Ethicon Inc.) is a bonding agent that can be used on superficial wounds, even in hair-bearing areas. Tissue adhesive (also called *tissue glue*) polymerizes when it comes in contact with water. This substance is biodegradable but remains in the wound until well after healing. [15]

Procedure

Tissue adhesive can be used to approximate wounds not requiring deep-layer closure. In preparation for closure, the wound should be anesthetized and cleaned, and when necessary, debrided. Bleeding must be controlled.

As the wound edges are held together with forceps or fingers, a small, cylindrical plastic container is squeezed to expel droplets of tissue glue through a cotton applicator tip at the end of the container. The glue is applied in at least 3 to 4 thin layers along the length of the wound's surface (Fig. 36-4). Alternatively, one can place the glue in strips perpendicular to the laceration (analogous to placement of closure tapes). The purple color of the solution facilitates placement of the droplets. The wound edges should be supported with edges approximated for at least 1 minute while the glue dries. The closure can be reinforced and protected with a bandage such as Elastoplast.

The primary advantage of tissue glue is the speed of closure. Wounds can be closed in as little as one sixth of the time required for repair with sutures. Application is rapid and painless. Wounds closed with tissue glue have less tensile strength than sutured wounds in the first 4 days [16] [17] but 1 week after closure the tensile strength and overall degree of inflammation in wounds closed with tissue glue were equivalent to those closed with sutures. [15] [18] Cosmetic results are similar to those obtained with suture repair. [17] [19] [20] [21] [22] [23] [24] [25]

Tissue glue serves as its own wound dressing and has an antimicrobial effect against gram-positive organisms. [26] [27] The material sloughs off in 7 to 10 days, thereby saving the patient from a clinician visit. Ointments or occlusive bandages should not be placed on wounds closed with tissue glue.

Complications

Percutaneous sutures provide a more secure immediate closure than tissue glue. [15] Although tissue glue is classified as nontoxic and does not cause a significant foreign body reaction, it should not be placed within the wound cavity. [17] [18] If the wound edges cannot be held together without considerable tension, tissue glue should not be used.[25] Tissue glue should not be used near the eyes, over or near joints, on moist or mucosal surfaces, or on wounds under significant static or dynamic skin tension. After polymerizing, tissue glue can

Figure 36-4 Tissue adhesive, 2-octyl cyanoacrylate in a commercially available application dispenser.

fracture with excessive or repetitive movement. Although gentle rinsing is permitted, if the adhesive is washed or soaked, it will peel off in a few days, before the wound is healed.[17] If hemostasis is inadequate or an excessive amount of glue is applied too quickly, the patient can experience a burning sensation from the heat of polymerization.

One risk involving the use of tissue glue is its ease of use. Clinicians may fail to adequately clean wounds before closure with tissue glue. [27A] Tissue glue should not be used to close infected wounds. If the clinician's gloved fingers contact the tissue glue during application, the glove may adhere to the patient's skin. Tissue glue can be removed with antibiotic ointment, petrolatum jelly, or more rapidly with acetone. [25]

Summary

Tissue glue has been approved for use in the United States since 1998. Dermabond is packaged in sterile, single-use ampules. It is best suited for superficial wounds that are under little tension and that do not require prolonged support. Cosmetic results are generally equivalent to sutured wounds when used properly. 276

WOUND STAPLES

Background

Wound stapling devices date back to the early part of this century. Several Russian, Hungarian, and Japanese investigators pioneered various instruments, but it was not until the early 1960s that significant interest in the use of these devices developed in the United States. [28] [29] Since then there has been a steady improvement in technology, including the introduction of automatic and disposable devices, precocking mechanisms, and optimal staple configurations.

Automatic stapling devices have become commonplace for closure of surgical incisions and are finding acceptance among clinicians for closure of traumatic wounds. Clinical studies of patients with stapled surgical incisions have consistently revealed that there is no significant difference between stapling and suturing when infection rates, healing outcome,

and patient acceptance are compared.[30] [31] [32] [33] [34] Four important studies have demonstrated that selected traumatic wounds in both adult and pediatric patients can be closed successfully with staples in the ED setting. [35] [36] [37] Wound stapling and nylon suture closure of skin compared favorably in wound tensile strength, complication rates, patient tolerance, efficiency of closure, scar width, color, general appearance, suture or staple marks, infection rates, and cost. However, in one study more patients in the staple group reported discomfort with removal. [37] In animal models, staples cause less wound inflammation, preserve wound defense mechanisms, and offer more resistance to infection in contaminated wounds.[38] [39] [40] [41]

The most significant advantage of wound stapling over suturing is speed of closure. On average, stapling is three to four times faster than suturing traumatic wounds.[35] [37] [42] The time for actual staple application is =30 seconds for a laceration 3 to 5 cm in length. [43] [44] [45] Cost has been cited as a disadvantage of staple closure, particularly when large, multistaple (25 to 35) surgical units are the only product available. [43] However, with the introduction of smaller devices more appropriate for the average laceration, the cost of stapling devices has been reduced significantly. [43] When clinician time and cost of instruments are considered, the cost difference is minimal[35] or favors stapling.[46]

Indications and Contraindications

Currently the indications for stapling are limited to relatively linear lacerations with straight, sharp edges located on an extremity, the trunk, or the scalp. Staples may be especially useful for superficial scalp lacerations in the agitated or intoxicated patient. Because of their superficial placement in the adult scalp (usually above the galea), staples are *not* ideal for *deep* scalp lacerations. Staples may not provide the same hemostasis that is possible with deep sutures. Also, they should not be placed in scalp wounds if computed tomography head scans are to be performed because staples produce scan artifacts. Similarly, staples should not be used if the patient is expected to undergo magnetic resonance imaging, because the powerful magnetic fields may avulse the staples from the skin surface. As they are currently configured and manufactured, staples *should not be used on the face, neck, hands, or feet*.

Equipment

Standard wound care should precede wound closure (see Chapter 35). In many cases, when debridement and dermal (deep) closures are unnecessary, only tissue forceps are needed to assist in everting wounds.

Many stapling devices are commercially available. The most versatile and least expensive stapler is the Precise (3M Corporation). Different units that hold between 5 and 25 staples can be purchased. The 10-staple unit will suffice for most lacerations. Other devices include the Proximate 11 (Ethicon, Inc.), Cricket (US Surgical, Irvine, CA), and Appose (Davis & Geck, Columbus, OH). These staplers have a minimum of 15 staples and are 3 to 5 times more expensive than the Precise stapler.

Procedure

The wound is prepared in the manner described in Chapter 35 . Whenever necessary, deep, absorbable sutures are used to close deep fascia and to reduce tension in the superficial fascia and dermal layers. Before stapling, the wound edges should be everted, preferably by a second operator. The assistant precedes the operator along the wound and everts the wound edges with forceps or pinches the skin with the thumb and forefinger. This technique allows the staple to be precisely placed. Once the edges are held in eversion, the staple points are gently placed across the wound (Fig. 36-5). By squeezing the stapler handle or trigger, the staple is advanced automatically into the wound and bent to the proper configuration (Fig. 36-6 and Fig. 36-7). One must take care not to press too hard on the skin surface in order to prevent placing the staple too deeply and causing ischemia within the staple loop. When properly placed, the *crossbar of the staple is elevated a few millimeters above the skin surface* (Fig. 36-8). Enough staples should be placed to provide proper apposition of the edges of the wound along its entire length.

After the wound is stapled, an antibiotic ointment may be applied to minimize dressing adherence, and a sterile dressing is applied. If necessary, the patient can remove the dressing and gently clean the wound in 24 to 48 hours.

Removal of staples requires a special instrument that is made available by each manufacturer of stapling devices. The lower jaw of the staple remover is placed under the crossbar (Fig. 36-9). One brings down the upper jaw by squeezing the handle (Fig. 36-10). This action compresses the crossbar, thereby releasing the staple points for easy removal. If the patient is referred for office removal of staples, it may be advisable to provide the patient with the staple removal device on ED release because many clinicians do not routinely stock the instrument. The interval between staple application and removal is the same as that for standard suture placement and removal.

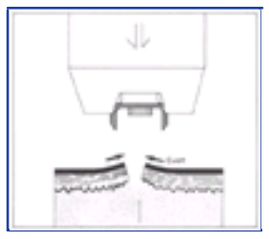

Figure 36-5 The skin edges must be approximated and everted by hand or with forceps before they are secured with staples. Failure to evert the wound edges is a common error that may cause an unacceptable result. *(Adapted with permission from Edlich RF: A Manual for Wound Closure. St. Paul, MN, 3M Medical-Surgical Products, 1979. Reproduced by permission.)*

Figure 36-6 By squeezing the stapler handle, a plunger advances one staple into the wound margins. *(From Edlich RF: A Manual for Wound Closure. St. Paul, MN, 3M*

Medical-Surgical Products, 1979. Reproduced by permission.)

Complications

Complications can occur with staple-closed wounds, although the incidence is low and equivalent to that for sutured wounds. In 2 studies of traumatic wounds closed with staples, the infection rates were reported to be 0% and 5%.[37] [43] Staple acceptance and comfort have been reported to be equal to those of sutures, but in one study, removal of staples was somewhat more uncomfortable than removal of sutures.[37] Wound dehiscence has been reported, but the incidence is not considered significant. [37] A common error is failure to *evert* the skin edges before stapling (Fig. 36-11*A* and *B*). Eversion avoids the natural tendency of the device to invert the closure. Eversion may be accomplished with forceps or by pinching the skin with the thumb and index finger, a procedure that requires some practice. Staples do cause marks in the skin similar to sutures. In patients who tend to scar more easily, the resulting scar from the staples may be more pronounced than that produced by sutures, especially if the staples are left in place for prolonged periods.

Figure 36-7 An anvil automatically bends the staple to the proper configuration. *(From Edlich RF: A Manual for Wound Closure. St. Paul, MN, 3M Medical-Surgical Products, 1979. Reproduced by permission.)*

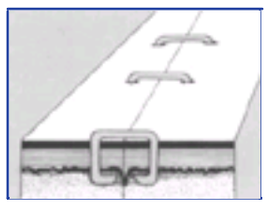

Figure 36-8 Care should be taken to ensure that a space remains between the skin and the crossbar of the staple. Excessive pressure created by placing the staple too deep causes wound edge ischemia, as well as pain on removal. Note that the staple bar is 2 to 3 mm above the skin line. *(From Edlich RF: A Manual for Wound Closure. St. Paul, MN, 3M Medical-Surgical Products, 1979. Reproduced by permission.)*

Conclusion

Overall results are favorable when staples are used for surgical incisions and traumatic lacerations of the scalp, trunk, and extremities. Wound stapling does not differ significantly from suturing in infection rates, wound healing, and patient acceptance. Stapling is clearly superior in reducing time to closure. With the introduction of new devices, the cost of wound stapling is comparable to that of suturing. Because of the increased availability and versatility of stapling instruments, they are being used more frequently in ED wound management.

SUTURES

In most situations, suturing is the closure method of choice. Currently in the United States, most traumatic wounds are closed with sutures.

Equipment

Instruments

In addition to the instruments used for debridement, a needle holder and suture scissors are required for suturing. The size of the needle holder should match the size of the needle selected for suturing—that is, the needle holder should be large enough to hold the needle securely as it is passed through tissue, yet not so large that the needle is crushed or bent by the instrument. The mechanical performance of disposable needle holders distributed by different surgical instrument companies varies considerably.[47] Instruments used to debride a grossly contaminated wound should be discarded

Figure 36-11 A very poor result occurred when staples (*some marked with arrows*) were used to close this deep scalp laceration (*A*). The wound edges were not everted (in fact, the skin overlapped significantly), and poor hemostasis was obtained because the galea was not closed by the superficial staples. Three days later during a wound check, the staples were removed, and the laceration was closed with 3-0 interrupted nylon sutures (*B*). The clinician should attempt to obtain a cosmetic closure on all scalp lacerations, because as patients lose their hair, a previously hidden, unsightly scar emerges. In general, staples should not be used to close full-thickness scalp lacerations, especially wounds that are actively bleeding.

and fresh instruments obtained for the closure of the wound. Instruments covered with coagulated blood can be cleansed with hydrogen peroxide, rinsed with sterile saline or water, and then used for suturing.

Suture Materials

A wide variety of suture materials are available. For most wounds that require closure of more than one layer of tissue, the clinician must choose sutures from two general categories: an absorbable suture for the subcutaneous (SQ) layer and a nonabsorbable suture for skin closure.

Sutures can be described in terms of four characteristics:

1. Composition (i.e., chemical and physical properties)
2. Handling characteristics and mechanical performance
3. Absorption and reactivity
4. Size and retention of tensile strength

Composition.

Sutures are made from natural fibers (cotton, silk), from sheep submucosa or beef serosa (plain gut, chromic gut), or from synthetic materials such as nylon (Dermalon, Ethilon, Nurulon, Surgilon), Dacron (Ethiflex, Mersilene), polyester (Ti-Cron), polyethylene (Ethibond), polypropylene (Prolene, Surgilene), polyglycolic acid (Dexon), and polyglactin (Vicryl, coated Vicryl). Stainless steel sutures are rarely, if ever, useful in wound closure in the ED setting because of handling difficulty and fragmentation. Some sutures are made of a single filament (monofilament); others consist of multiple fibers braided together (Table 36-1).[48]

Handling and performance.

Desirable handling characteristics in a suture include smooth passage through tissues, ease in knot tying, and stability of the knot once tied (Table 36-2). Smooth sutures pull through tissues easily, but knots slip more readily. Conversely, sutures with a high coefficient of friction have better knot-holding capacity but are difficult to slide through tissues. Smooth sutures will loosen after the first throw of a knot is made, and a second throw is needed to secure the first in place. However, the clinician may

TABLE 36-1 -- Examples of Suture Materials

Absorbable Sutures	Nonabsorbable Sutures
Monofilament	
Plain gut	Dermalon (nylon)
Chromic gut	Ethilon (nylon)

PDS (polydioxanone)	Prolene (polypropylene)
Maxon (polyglyconate)	Silk
	Steel
	Surgilene (polypropylene)
	Tevdek (Teflon coated)
Multifilament	
Dexon (polyglycolic acid)	Ethibond (polyethylene)
Coated Vicryl (polyglactin)	Mersilene (braided polyester)
	Nurulon (nylon)
	Surgilon (nylon)
	TiCron (polyester)

want to tighten a knot further after the first throw is made. This is difficult with rougher types of sutures.

Multifilament sutures have the best handling characteristics of all sutures, whereas steel sutures have the worst. In terms of performance and handling, significant improvements have been made in the newer absorbable sutures. Gut sutures have many shortcomings, including relatively low and variable strength, a tendency to fray when handled, and stiffness despite being packaged in a softening fluid. [49] [50] Multifilament synthetic absorbable sutures are soft and easy to tie and have few problems with knot slippage. Polyglactin 910 (coated Vicryl) sutures have an absorbable lubricant coating. The "frictional drag" of these coated sutures as they are pulled through tissues is less than that of uncoated multifilament materials, and the resetting of knots following the initial throw is much easier. This characteristic allows retightening of a ligature without knotting or breakage and with smooth, even adjustment of suture line tension in running subcuticular stitches. [51] Synthetic monofilament sutures have the trouble-some property of "memory"—a tendency of the filament to spring back to its original shape, which causes the knot to slip and unravel. Some nonabsorbable monofilament sutures are coated with polytetrafluorethylene (Teflon) or silicone to reduce their friction. This coating improves the handling characteristics of these monofilaments but results in poorer knot security. [50]

TABLE 36-2 -- Characteristics of Suture Materials

Suture Material Handling	Knot Security	Tensile Strength	Tissue Reactivity	Duration of Suture Integrity (days)	Tie Ability
Absorbable					
Surgical gut	poor	fair	greatest	5–7	poor
Chromic gut	fair	fair	greatest	10–14	poor
Coated Vicryl	good	good	minimal	30	best
Dexon	best	good	minimal	30	best
PDS	fair	best	least	45–60	good
Maxon	fair	best	least	45–60	good
Nonabsorbable					
Ethilon	good	good	minimal		good
Prolene	least	best	least		fair
Silk	best	least	greatest		best

Modified with permission from Hollander J, Singer A: Laceration management. Ann Emerg Med 34:361, 1999.

Three square knots will secure a stitch made with silk or other braided, nonabsorbable materials, and four knots are sufficient for synthetic, absorbable and nonabsorbable monofilament sutures. [52] Five knots are needed for the Teflon-coated synthetic Tevdek. [53] With the use of coated synthetic suture materials, attention to basic principles of knot tying is even more important. An excessive number of throws in a knot weakens the suture at the knot. If the clinician uses square knots (or a surgeon's knot on the initial throw, followed by square knots) that lie down flat and are tied securely, knots will rarely unravel. [54]

Absorption and reactivity.

Sutures that are rapidly degraded in tissues are termed *absorbable*; those that maintain their tensile strength for >60 days are considered *nonabsorbable* (see Table 36-1). Plain gut may be digested by white blood cell lysozymes in 10 to 40 days; chromic gut will last 15 to 60 days. Remnants of both types of sutures, however, have been seen in wounds more than 2 years after their placement. [49] [52] [55] The Ethicon catgut is rapidly absorbed within 10 to 14 days but with less inflammation than that caused by chromic catgut. [56] Vicryl is absorbed from the wound site within 60 to 90 days [49] [52] and Dexon, within 120 to 210 days. [57] [58] When placed in the oral cavity, plain gut disappears after 3 to 5 days, chromic gut after 7 to 10 days, and polyglycolic acid after 16 to 20 days. [59] In contrast, SQ silk may not be completely absorbed for as long as 2 years. [52] The rate of absorption of synthetic absorbable sutures is independent of suture size. [57]

Sutures may lose strength and function before they are completely absorbed in tissues. Braided synthetic absorbable sutures lose nearly all of their strength after about 21 days. In contrast, monofilament absorbable sutures (modified polyglycolic acid [Maxon, Davis & Geck] and polydioxanone [PDS, Ethicon]) retain 60% of their strength after 28 days. [60] [61] Gut sutures treated with chromium salts (chromic gut) have a prolonged tensile strength; however, all gut sutures retain tensile strength erratically. [49] [52] Of the absorbable types of sutures, a wet and knotted polyglycolic acid suture is stronger than a plain or chromic gut suture subjected to the same conditions. [50] [62]

Polypropylene remains unchanged in tissue for longer than 2 years after implantation. [63] In comparison testing, Hermann found that sutures made of natural fibers such as silk, cotton, and gut were the weakest; sutures made of Dacron, nylon, polyethylene, and polypropylene were intermediate in tensile strength; and metallic sutures were the

strongest. [50] Kaplan and Hentz used the comparison of suture strength vs wound strength as a measure of the usefulness of a suture. They stated that catgut is stronger than the soft tissue of a wound for no more than 7 days; chromic catgut, Dexon, and Vicryl are stronger for 10 to 21 days; and nylon, wire, and silk are stronger for 20 to 30 days. [64]

All sutures placed within tissue will damage host defenses and provoke inflammation. Even the least reactive suture impairs the ability of the wound to resist infection. [63] The magnitude of the reaction provoked by a suture is related to the quantity of suture material (diameter × total length) placed in the tissue and to the chemical composition of the suture. Among absorbable sutures, polyglycolic acid and polyglactin sutures are least reactive, followed by chromic gut. Nonabsorbable polypropylene is less reactive than nylon or Dacron. [50] [65] [66] Significant tissue reaction is associated with catgut, silk, and cotton sutures; highly reactive materials should be avoided in contaminated wounds. Adams found absorbable polyglycolic acid sutures to be less reactive than those of nonabsorbable silk. [67]

The chemical composition of sutures is an important determinant of early infection. The infection rate in experimental wounds when polyglycolic acid sutures are used

is less than the rate when gut sutures are used. It is surprising that plain gut sutures elicit infection less often in contaminated wounds than chromic gut sutures. [63] Lubricant coatings on sutures do not alter suture reactivity, absorption characteristics, breaking strength, or the risk of infection. [51] [63] Multifilament sutures provoke more inflammation and are more likely to produce infection than monofilament sutures if left in place for prolonged periods. [68] [69] Monofilament sutures elicit less tissue reaction than do multifilament sutures, and multifilament materials tend to wick up fluid by capillary action. Bacteria that adhere to and colonize sutures can envelop themselves in a glycocalix that protects them from host defenses,[70] or they can "hide" in the interstices of a multifilament suture and, as a result, be inaccessible to leukocytes.[68] Polydioxanone (PDS) provides the advantages of a monofilament suture in an absorbable form, making it a good choice as a subcuticular stitch. Polypropylene sutures have a low coefficient of friction, and subcuticular stitches with this material are easy to pull out. [71]

Size and strength.

Size of suture material (thread diameter) is a measure of the tensile strength of the suture; threads of greater diameter are stronger. The strength of the suture is proportional to the square of the diameter of the thread. Therefore, a 4-0 size suture of any type is larger and stronger than a 6-0 suture. The correct suture size for approximation of a layer of tissue depends on the tensile strength of that tissue. The tensile strength of the suture material should be only slightly greater than that of the tissue, because the magnitude of damage to local tissue defenses is proportional to the amount of suture material placed in the wound. [52] [72]

Synthetic absorbable sutures have made the older, natural suture materials obsolete. Polyglycolic acid (Dexon) and polyglactin 910 (coated Vicryl) have improved handling characteristics, knot security, and tensile strength. Their absorption rates are predictable, and tissue reactivity is minimal. [73] [74] The distinct advantages of synthetic nonabsorbable sutures over silk sutures are their greater tensile strength, low coefficient of friction, and minimal tissue reactivity. [63] [73] They are extensible, elongating without breaking as the edges of the wound swell in the early postoperative period. [72] [73] In contrast with silk sutures, synthetics can be easily and painlessly removed once the wound has healed. The monofilament synthetic suture Novofil has elasticity that allows a stitch to enlarge with wound edema and to return to its original length once the edema subsides. Stiffer materials lacerate the encircled tissue as the wound swells. [75]

The suture materials most useful to emergency clinicians for wound closure are Dexon or coated Vicryl for SQ layers and synthetic nonabsorbable sutures (e.g., nylon or polypropylene) for skin closure. Fascia can be sutured with either absorbable or nonabsorbable materials. In most situations, 3-0 or 4-0 sutures are used in the repair of fascia, 4-0 or 5-0 absorbable sutures in SQ closure, and 4-0 or 5-0 nonabsorbable sutures in skin closure. Lips, eyelids, and the skin layer of facial wounds are repaired with 6-0 sutures, whereas 3-0 or 4-0 sutures are used when the skin edges are subjected to considerable dynamic stresses (e.g., wounds overlying joint surfaces) or static stresses (e.g., scalp).

Needles

The eyeless, or "swaged," needle is used for wound closure in most emergency centers (Fig. 36-12). The traditional closed-eye needle requires additional handling to enable one to thread the needle with the suture, and its increased width causes more damage when passing through tissue than does a swaged needle.

Selection of the appropriate needle size and curvature are based on the dimensions of the wound and the characteristics of the tissues to be sutured. The needle should be large enough to pass through tissue to the desired depth and then to exit the tissue or the skin surface far enough that the needle holder can be repositioned on the distal end of the needle at a safe distance from the needle point (Fig. 36-13). While it is inviting to use the fingers to grasp the needle tip to pull the needle through the skin, this practice is an invitation for a needle stick. The clinician should either reposition the needle holder or use forceps to disengage the needle from the laceration.

In wound repair, needles must penetrate tough, fibrous tissues—skin, SQ tissue, and fascia—yet should slice through these tissues with minimal resistance or trauma and without bending. The type of needle best suited for closure of SQ tissue is a *conventional cutting needle* in a three-eighths or one-half circle (Fig. 36-14). The use of double curvature needles (coated Vicryl with PS-4-C cutting needles, Ethicon) may enhance the clinician's ability to maneuver the needle in narrow, deep wounds. For percutaneous closure, a conventional cutting-edge needle may

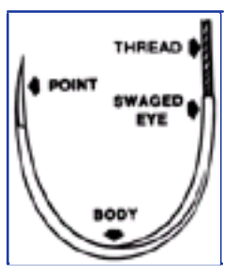

Figure 36-12 The eyeless, or "swaged," needle. *(From Suture Use Manual: Use and Handling of Sutures and Needles. Somerville, NJ, Ethicon, Inc., 1977, p 29. Reproduced by permission.)*

Figure 36-13 The needle should be large enough to pass through tissue and should exit far enough to enable the needle holder to be repositioned on the end of the needle at a safe distance from the point.

permit more precise needle placement and require less penetration force (Fig. 36-15).[76] [77]

Suturing Techniques

Skin Preparation

Before closing the wound, the skin surrounding it is prepared with a povidone-iodine solution and covered with sterile drapes. Some surgeons do not drape the face but prefer to leave facial structures and landmarks adjacent to the wound uncovered and within view. A clear plastic drape (Steri-Drape, 3M Corporation) can be used to provide a sterile field and a limited view of the area surrounding the wound. If no drapes are used on the face, the skin surrounding the wound should be widely cleansed and prepared. Wrapping the hair in a sheet prevents stray hair from falling into the operating field (Fig. 36-16). Some EDs keep a supply of oversized scrub hats to use as an alternative to wrapping.

Closure Principles

Three principles apply to the suturing of lacerations in any location: (1) minimize trauma to tissues, (2) relieve tension exerted on the wound edges by undermining and layered wound closure, and (3) accurately realign landmarks and skin edges by layered closure and precise suture placement.

Minimizing tissue trauma.

The importance of careful handling of tissue has been emphasized since the early days of surgery. Skin and SQ tissue that has been stretched, twisted, or crushed by an instrument or strangled by a suture that is tied too tightly may undergo necrosis, and increased scarring and infection may result. When the edges of a wound must be manipulated, the SQ tissues should be lifted gently with a toothed forceps or skin hook, avoiding the skin surface.

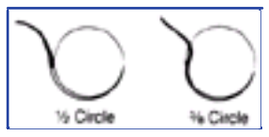

Figure 36-14 One-half and three-eighths circle needles, used for most traumatic wound closures.

When choosing suture sizes, the clinician should select the smallest size that will hold the tissues in place. Skin stitches should incorporate no more tissue than is needed to coapt the wound edges with little or no tension. Knots should be tied securely enough to approximate the wound edges but without blanching or indenting the skin surface.[78]

Relieving tension.

Many forces can produce tension on the suture line of a reapproximated wound. Static skin forces that stretch the skin over bones cause the edges of a fresh wound to gape and also continuously pull on the edges of the wound once it has been closed. Traumatic loss of tissue or wide excision of a wound may have the same effect. The best cosmetic result occurs when the long axis of a wound happens to be parallel to the direction of maximal skin tension; this alignment brings the edges of the wound together.[75]

Muscles pulling at right angles to the axis of the wound impose dynamic stresses. Swelling following an injury creates additional tension within the circle of each suture.[78] Skin suture marks result not only from tying sutures too tightly, but also from failing to eliminate underlying forces distorting the wound. Tension can be reduced during wound closure in two ways: undermining of the wound edges and layered closure.

Figure 36-15 Types of needles. *A,* The conventional cutting needle has two opposing cutting edges, with a third edge on the inside curvature of the needle. The conventional cutting needle changes in cross section from a triangular cutting tip to a flattened body. *B,* The reverse cutting needle is used to cut through tough, difficult-to-penetrate tissues, such as fascia and skin. It has two opposing cutting edges, with the third cutting edge on the outer curvature of the needle. The reverse cutting needle is made with the triangular shape extending from the point to the swage area, with only the edges near the tip being sharpened. *(From Suture Use Manual: Use and Handling of Sutures and Needles. Somerville, NJ, Ethicon, Inc., 1977, p 31. Reproduced by permission.)*

Figure 36-16 *A–D,* Technique for wrapping the scalp to keep stray hair from falling into the operating field. A scrub hat is an acceptable alternative.

Undermining.

The force required to reapproximate the wound edges correlates with the subsequent width of the scar.[79] Wounds subject to significant static tension require the undermining of at least one tissue plane on both sides of the wound to achieve a tension-free closure. Undermining involves the creation of a flap of tissue freed from its base at a distance from the wound edge approximately equal to the width of the gap that the laceration presents at its widest point (Fig. 36-17). The depth of the incision can be modified, depending on the orientation of the laceration to skin tension lines and the laxity of skin in the area. A No. 15 scalpel blade held parallel to the skin surface is used to incise the adipose layer or the dermal layer of the wound. The clinician also can accomplish this technique by spreading scissors in the appropriate tissue plane. Undermining allows the skin edges to be lifted and brought together with gentle traction.[80] Because undermining may harm the underlying blood supply, this technique should be reserved for relatively uncontaminated wounds.[76] Other potential complications of this procedure include injury to cutaneous nerves and creation of a hematoma under the flap.[64]

Layered closure.

The structure of skin and soft tissue varies with the location on the body (Fig. 36-18*A–D* Fig. 36-18*A–D*). Most wounds handled in an ED require approximation of no more than three layers: fascia (and associated muscle), SQ tissue, and skin surface (papillary layer of dermis and epidermis).[81]

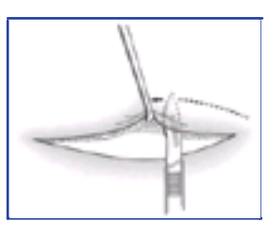

Figure 36-17 The technique of undermining. The scalpel is used to find an appropriate site; a natural plane often exists at the epidermis-dermis junction. Undermining relieves tension on the wound and renders a better cosmetic result. This technique is simple to master, but sometimes overlooked.

Closure of individual layers obliterates "dead space" within the wound that would otherwise fill with blood or exudate. The presence of dead space enhances the development of infection; however, it is not necessary to close the adipose layer of soft tissue with a separate stitch. A "fat stitch" is not necessary, because little support is provided by closure of the adipose layer, and the additional suture material that is required may enhance the possibility of infection.[6] [82]

Separate approximation of muscle and SQ layers hastens the healing and return of function to the muscle. However, *one should suture fascia, not muscle*. Muscle tissue itself is too friable to hold a suture. Layered closure is particularly important in the management of facial wounds; this technique prevents scarring of muscle to the SQ tissue and consequent deformation of the surface of the wound with contraction of the muscle. If a deep, gaping wound is closed without approximation of underlying SQ tissue, a disfiguring depression may develop at the site of the wound. Finally, layered closure provides support to the wound and considerably reduces tension at the skin surface.

There are exceptions to the general rule of multilayered closure. Scalp wounds are generally closed in a single layer. For lacerations penetrating the dermis in fingers, hands, toes, and feet, the amount of SQ tissue is too small to warrant layered closure; in fact, SQ stitches may leave tender nodules in these sensitive locations. In the sebaceous skin of the nasal tip, SQ sutures should be avoided, because they provoke inflammation and increase the risk of infection. However, deep sutures do not increase the risk of infection in minimally contaminated wounds.[83] Layered closure is not recommended in wounds without tension, those with poor vascularity, and those with moderate infection potential. With single-layer closure, the surface stitch should be placed more deeply.[64]

Suture Placement

Before suturing, the clinician should ensure adequate exposure and illumination of the wound. The clinician should assume a comfortable standing or sitting position, with the patient placed at an appropriate height. The best position for

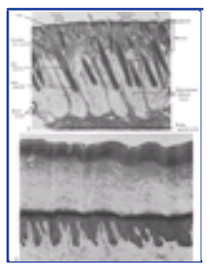

Figure 36-18a Variation in the structure of skin. *A,* Section of the skin of the scalp, ×15. *B,* Skin of the human fingertip, illustrating a very thick stratum corneum. Hematoxylin and eosin, ×65.

the clinician is at one end of the long axis of the wound. Knot construction using the instrument tie technique is described in other references. [84]

SQ layer closure.

Once fascial structures have been reapproximated, the SQ layer is sutured. Although histologically the fatty and fibrous SQ tissue (hypodermis) is an extension of (and is continuous with) the reticular layer of the dermis, [85] suturing of these layers is traditionally referred to as an "SQ closure." One approach is to close this layer in segments, placing the first stitch in the middle of the wound and bisecting each subsequent segment until the closure of the layer has been completed. [48] This technique is useful in the closure of wounds that are long or sinuous and is particularly effective in wounds with one elliptic and one linear side. The needle is grasped by the needle holder close to the suture end. Greater speed in suturing is possible if the fingers are placed

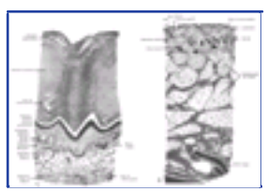

Figure 36-18b *C,* Section of human sole perpendicular to the free surface, ×100. *D,* Section through human thigh perpendicular to the surface of the skin. on the midshaft of the needle holder rather than in the rings of the instrument (Fig. 36-19).

The suture enters the SQ layer at the bottom of the wound (Fig. 36-20*A*) or, if the wound has been undermined, at the base of the flap (Fig. 36-20*B*), and exits in the dermis. Once the suture has been placed on one side of the wound, it can be pulled across the wound to the opposite side (or the wound edges pushed together) to determine the matching point on the opposite side. It is at this matching point along the opposite side of the wound that the needle is inserted. The needle should enter the dermis at the same depth as it exited from the opposite side, pass through the tissue, and exit at the bottom of the wound (or the base of the flap). The edges of the wound can be closely apposed by pulling the two tails of the suture in the same direction along the axis of the wound (Fig. 36-21). Some clinicians place their SQ suture obliquely rather than vertically to facilitate knot tying. When the knot in this SQ stitch is tied, it will remain inverted, or "buried," at the bottom of the wound. Burying the knot of the SQ stitch avoids a painful, palpable nodule beneath the epidermis and keeps the bulk of this foreign material away from the skin surface. The techniques of tying knots by hand and by instrument are well described and illustrated in wound care texts. [86] [87] Once the knot has been secured, the tails of the suture should be pulled taut for cutting. The scissors are held with the index finger on the junction of the two blades. The blade of the scissors is slid down the tail of the suture until the knot is reached. With the cutting edge of the blade tilted away from the knot, the tails are cut. This technique prevents the scissors from cutting the knot itself and leaves a tail of 3 mm, which protects the knot from unraveling (Fig. 36-22). [88] The entire SQ layer is sutured in this manner.

Figure 36-19 The thenar grip technique of handling the needle holder. The index finger is placed on the side of the needle holder, where it guides the placement of the needle. Neither the index nor the middle finger is placed in the ringlet hole. An alternate method (the thumb-ring finger grip) is shown in Figure 36-27 .

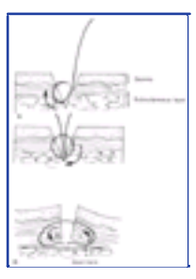

Figure 36-20 *A* and *B,* Inverted subcutaneous stitches.

After the SQ layer has been closed, the distance between the skin edges indicates the approximate width of the scar in its final form. If this width is acceptable, percutaneous sutures can be inserted. [89] Despite undermining and placement of a sufficient number of SQ sutures, on rare occasions a large gap between the wound edges may persist. In such cases a horizontal dermal stitch may be used to bridge this gap (Fig. 36-23).

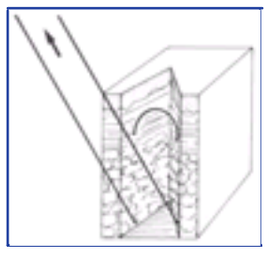

Figure 36-21 The two tails of the subcutaneous suture are pulled in the same direction, tightly opposing the edges of the wound.

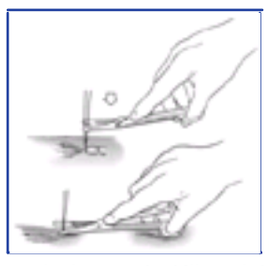

Figure 36-22 Cutting the tails of the subcutaneous suture. Note that the cutting blade is tilted away from the knot to avoid cutting it. *(Modified from Anderson CB: Basic surgical techniques. In Klippel AP, Anderson CB (eds): Manual of Outpatient and Emergency Surgical Techniques. Boston, Little, Brown, 1979. Reproduced by permission.)*

Skin closure.

The epidermis and the superficial layer of dermis are sutured with nonabsorbable synthetic sutures. The choice of suture size, the number of sutures used, and the depth of suture placement depend on the amount of skin tension remaining after SQ closure. If the edges of the wound are apposed following closure of deeper layers, small 5-0 or 6-0 sutures can be used simply to match the epithelium of each side. If the wound edges remain retracted or if SQ stitches were not used, a larger size suture may be required. Skin closure may be accomplished with sutures placed in segments (Fig. 36-24) or from end to end. Either technique is acceptable.

Unless the wound edges are uneven, sutures should be placed in a mirror-image fashion such that *the depth and width are the same on both sides of the wound*.[52] In general, the distance between each suture should be approximately equal to the distance from the exit of the stitch to the wound edge. [48] [86] Grabb suggests that "the number of sutures used in closing any wound will vary with the case, location of the repair, and degree of accuracy required by the clinician and patient. In an area such as the face, sutures would probably be placed between 1 and 3 mm apart and 1 to 2 mm from the wound edge."[65]

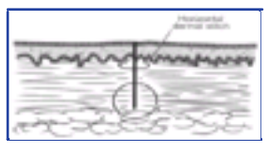

Figure 36-23 Horizontal dermal stitch. (A vertical suture also closes the deep tissue.)

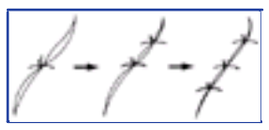

Figure 36-24 Closure of the surface of the wound in segments.

Sutures act as foreign bodies in a wound, and any stitch may damage a blood vessel or strangulate tissue. Therefore, the clinician should strive to use the smallest size and the least number of sutures that will adequately close the wound (Fig. 36-25). [63] Wounds with greater tension should have skin stitches placed closer to each other and closer to the wound edge; layered closure is important in such wounds. If sutures are tied too tightly around wound edges or if individual stitches are under excessive tension, blood supply to the wound may be impeded, increasing the chance of infection, and suture marks may form even after 24 hours. [52] [86A]

When suturing the skin, right-handed operators should pass the needle from the right side of the wound to the left. The needle should enter the skin at an oblique angle to produce an everting, bottle-shaped stitch that is *deeper than it is wide* (Fig. 36-26). If the skin stitch is intended to produce some eversion of the wound edges, the stitch must include a sufficient amount of SQ tissue. However, encompassing too much tissue with a small needle is a common error. Forcefully pushing or twisting the needle in an effort to bring the point out of the tissue may bend or break the body of the needle. Using a needle of improper size will defeat the best suturing technique. The needle should be driven through tissue by flexing the wrist and supinating the forearm; the course taken by the needle should result in a curve identical to the curvature of the needle itself (Fig. 36-27). The angle of exit for the needle should be the same as its angle of entrance so that an identical volume of tissue is contained within the stitch on each side of the wound.

Once the needle exits the skin on the opposite side of the wound, it is regrasped by the needle holder and is advanced through the tissue; care should be taken to avoid crushing the

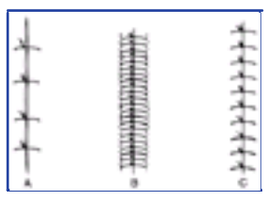

Figure 36-25 *A,* Too few stitches used. Note gaping between sutures. *B,* Too many stitches used. *C,* Correct number of stitches used for a wound under an average amount of tension.

point of the needle with the instrument. Forceps are designed for handling tissue and thus should not be used to grasp the needle. The forceps can stabilize the needle by holding the needle within the tissue through which the needle has just passed. An assistant can keep excess thread clear of the area being sutured, or the excess can be looped around the clinician's fingers. If the point of the needle becomes dulled before all of the attached thread has been used, the suture should be discarded.

If these techniques are applied to most wounds, the edges of the wound will be matched precisely in all three dimensions.

Eversion techniques.

If the edges of a wound invert or if one edge rolls under the opposite side, a poorly formed, deep, noticeable scar will result. Excessive eversion that exposes the dermis of both sides also will result in a larger scar than if the skin edges are perfectly apposed, but inversion produces a more visible scar than does eversion. Because most scars undergo some flattening with contraction, optimal results are achieved when the epidermis is slightly everted without excessive suture tension (Fig. 36-28). Wounds over mobile surfaces, such as the extensor surfaces of joints, should be everted; in time, the scar will be flattened by the dynamic forces acting in the area.

Numerous techniques can be used to avoid inversion of the edges of the wound. If the clinician angles the needle away from the laceration, percutaneous stitches can be placed so that their depth is greater than their width. [80] Converse described this method as follows: "The needle penetrates the skin close to the incision line, diverging from the edge of the wound in order to encircle a larger amount of tissue in the lower depths of the skin than at the periphery." [90] The edge of the wound can be lifted and everted with a skin hook or fine-tooth forceps before insertion of the needle on each side (Fig. 36-29). Eversion can also be obtained simply by slight retraction of the wound with the thumb (Fig. 36-30). This technique puts the operator at risk for a needle stick; eversion may be done more safely by applying slight pressure on the wound edge with a closed forceps. Each of these methods also serves to steady the skin against the force of the needle. [86] [90] Vertical mattress sutures are particularly effective in everting the wound edges and can be used exclusively or alternated with simple interrupted sutures (Fig. 36-31).[90] In wounds that have been undermined, an SQ stitch placed at the base of the flap on each side can in itself evert the wound (Fig. 36-32 (Figure Not Available)).

Interrupted stitch.

The simple interrupted stitch is the most frequently used technique in the closure of skin. It consists of separate loops of suture individually tied. Although the tying and cutting of each stitch are time consuming, the advantage of this method is that if one stitch in the closure fails, the remaining stitches continue to hold the wound together (Fig. 36-33).

Continuous stitch.

In a continuous, or "running," stitch, the loops are the exposed portions of a helical coil tied at each end of the wound. A continuous suture line can be placed more rapidly than a series of interrupted stitches. The continuous stitch has the additional advantages of strength (with tension being evenly distributed along its entire length), fewer knots (which are the weak points of stitches), and more effective hemostasis. This stitch will accommodate mild wound swelling. The continuous technique is useful as an epithelial or "surface" stitch in cosmetic closures; however, if the underlying SQ layer is not stabilized in a separate closure, the continuous surface stitch tends to invert the wound edges.

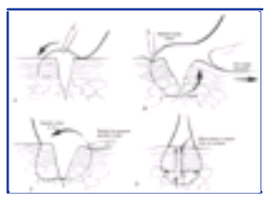

Figure 36-26 The simple suture. *A,* Hold the needle pointing down by excessively pronating the wrist so that the needle tip initially moves farther from the laceration as the needle penetrates deeper into the skin. Thus, there is more dermis in the depth of the wound than at the surface. Drive the needle tip downward and away from the cut edge, into the fat. *B,* Advance the needle into the laceration. The needle tip can be advanced directly into the opposite side. This can be achieved by rolling the needle holder as the needle enters the opposite side at the same level, and the arc pathway of the needle is controlled by retracting the skin edge. This causes more dermis to be incorporated into the depths than at the surface. As an alternative, if a small needle is used in thick skin or the distance across the wound is great, the needle can be removed from the first side, remounted on the needle holder, and advanced to the opposite side. *C,* Advance the needle upward toward the surface so that it exits at the same distance from the wound edge as on the contralateral side of the wound. Grasp the needle behind the tip and roll it out in the arc of the needle. *D,* The final position, with more tissue in the depth than the surface. The distance from each suture exit to the laceration is one half the depth of the dermis. *(Redrawn from Kaplan EN, Hentz VR: Emergency Management of Skin and Soft Tissue Wounds: An Illustrated Guide. Boston, Little, Brown, 1984, p 86. Reproduced by permission.)*

The continuous suture technique has other disadvantages. This technique cannot be used to close wounds overlying joints. If a loop breaks at one point, the entire stitch may unravel. Likewise, if infection develops and the incision must be opened at one point, cutting a single loop may allow the entire wound to fall open. There is also the theoretical problem of impeded blood supply to the wound edges, particularly if the suture is interlocked. [52] Speer found that wounds closed with an interrupted stitch had 30% to 50% greater tensile strength, less edema and induration, and less impairment in the microcirculation at the wound margin than did wounds closed with a continuous stitch.[91] The simple continuous stitch has a tendency to produce suture marks if used in large wound closures and if left in place for more than 5 days.[78] However, if all tension on the wound can be removed by SQ sutures, stitch marks are seldom a problem.

Among the variations of the continuous technique, the simple continuous stitch is the most useful to emergency clinicians (Fig. 36-34). An interrupted stitch is placed at one end of the wound, and only the free tail of the suture is cut. As suturing proceeds, the stitch encircles tissue in a spiral pattern. After each passage of the needle, the loop is tightened slightly, and the thread is held taut in the clinician's nondominant hand. The needle should travel perpendicularly across the wound on each pass. The last loop is placed just beyond the end of the wound, and the suture is tied, with the last loop used as a "tail" in the process of tying the knot (Fig. 36-35). A locking loop may be used in continuous suturing to prevent slippage of loops as the suturing proceeds (Fig. 36-36). The interlocking technique allows the use of the continuous stitch along an irregular laceration. [80]

A continuous stitch is an effective method for closing relatively clean wounds that are under little or no tension and are on flat, immobile skin surfaces in patients who have no medical conditions that would impair healing.

Figure 36-27 Motion of the needle holder. *(From Anderson CB: Basic surgical techniques. In Klippel AP, Anderson CB (eds): Manual of Outpatient and Emergency Surgical Techniques. Boston, Little, Brown, 1979. Reproduced by permission.)*

Continuous subcuticular stitch.

Nonabsorbable sutures used in percutaneous skin closure outlast their usefulness and must be removed. On occasion, wounds require an extended period of support, longer than that provided by surface stitches. Some patients with wounds that require skin closure are unlikely or unwilling to return for suture removal. Some sutured wounds are covered by plaster casts. On occasion, the patient (child or adult) is likely to be as frightened and uncooperative for suture removal as for suture placement. The continuous subcuticular (or "dermal") suture technique is ideal for these situations; the wound can be closed with an absorbable subcuticular stitch, obviating the need for later suture removal. In patients prone to keloid formation, the subcuticular technique can be used in lieu of percutaneous stitches, and disfiguring stitch marks can thereby be avoided. (Because children's skin is under greater tension than that of adults, percutaneous sutures are more likely to produce stitch marks in children.) Because stitch marks are avoided, a nonabsorbable subcuticular suture can be left in place for a longer period than a percutaneous suture.[90]

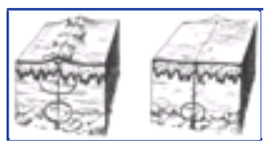

Figure 36-28 Skin edges that are everted will gradually flatten to produce a level wound surface. *(From Grabb WC: Basic technique of plastic surgery. In Grabb WC, Smith JW: Plastic Surgery: A Concise Guide to Clinical Practice. Boston, Little, Brown, 1979. Reproduced by permission.)*

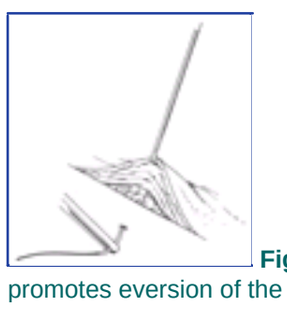

Figure 36-29 The use of a skin hook to evert the wound edge. This technique allows the operator to see the needle path, ensuring that the proper depth has been reached, and promotes eversion of the skin edges.

Although this technique is commonly used in cosmetic closures, some researchers believe that closure of the subcuticular layer alone does not alter the scar width. [92] This technique does not allow for perfect approximation of the vertical heights of the two edges of a wound [93] and in cosmetic closures it is often followed by a percutaneous stitch. Although theoretically the large amount of suture material left in the wound might increase the risk of infection, some investigators report a lower infection rate with the subcuticular technique. [92] [94] Buried, absorbable subcuticular stitches do not appear to provoke more inflammation than percutaneous running stitches with monofilament nylon.[83]

The subcuticular stitch requires a 4-0 or 5-0 suture made of either absorbable material or nonabsorbable synthetic monofilament. An absorbable suture can be "buried" within

Figure 36-30 Eversion can often be obtained by slight thumb pressure. Care should be taken to avoid a needle stick, a common complication of this technique. *(From Converse JM: Introduction to plastic surgery. the wound, whereas a nonabsorbable suture is used for a "pullout" stitch. The absorbable synthetic monofilament suture polydioxanone (PDS, Ethicon) is designed for subcuticular closure. It passes through tissues as easily as nonabsorbable monofilament sutures and is absorbed if left in the wound.

Before the subcuticular stitch is placed, the SQ layer should be approximated with interrupted sutures to minimize tension on the wound. The pullout subcuticular stitch is started at the skin surface approximately 1 to 2 cm away from 1 end of the wound. The needle enters and exits the dermis at the apices of the wound (Fig. 36-37). Bites through tissue are taken in a horizontal direction, with the needle penetrating the dermis 1 to 2 mm from the skin surface. These intradermal bites should be small, of equal proportion, and at the same level on each side of the wound. [74] [90] Accidental interlocking of the stitch should be avoided. Each successive bite should be placed 1 to 2 mm *behind* the exit point on the opposite side of the wound so that when the wound is closed, the entrance and exit points on either side are not directly apposed (see

Figure 36-34 Simple continuous stitch. *(From Grabb WC: Basic techniques of plastic surgery. In Grabb WC, Smith JW (eds): Plastic Surgery: A Concise Guide to Clinical Practice. Boston, Little, Brown, 1979. Reproduced by permission.)*

Figure 36-35 Completing the simple continuous stitch. A series of square knots is tied, with the loop as one of the ties.

Fig. 36-37). Small bites should be taken to avoid puckering of the skin surface. Some clinicians prefer to place a fine (6-0) running skin suture in addition to the subcuticular suture for meticulous skin approximation. The skin suture is removed in 3 to 4 days to avoid suture marks.

of plastic surgery. In Grabb WC, Smith JW (eds): Plastic Surgery: A Concise Guide to Clinical Practice. Boston, Little, Brown, 1979. Reproduced by permission.)

If the subcuticular stitch is used on lengthy lacerations, it is difficult to remove the suture. The placement of "reliefs" consisting of periodic loops through the skin during the length of the stitch facilitates later removal (Fig. 36-38). Reliefs should be placed every 4 to 5 cm. The suture is crossed to the opposite side, and the needle is passed from SQ tissue to the skin surface. The suture is carried over the surface for approximately 2 cm before reentering the skin and SQ tissue. The subcuticular stitch is then continued at approximately the point at which the next bite would have been placed had the relief not been used.

At the completion of the stitch, the needle is placed through the apex to exit the skin 1 to 2 cm away from the end of the wound. One should tighten the stitch by pulling each end taut. If reliefs have been used, one can take up any slack in the stitch by pulling on the reliefs. The clinician can secure the two ends of the stitch by taping them to the skin surface with wound closure tape, by placing a cluster of knots on each tail close to the skin surface, or by tying the two ends of the suture to each other over a dressing. Laxity of the subcuticular stitch is often noted with a decrease in tissue swelling 48 hours after wound closure. Some clinicians tighten the stitch when they reexamine the wound after 48 hours.

Subcuticular closure using absorbable sutures that do not penetrate the skin is possible. The closure is begun with a dermal or SQ suture placed at one end of the wound and secured with a knot. After placement of the continuous subcuticular stitch from apex to apex, the suture is pulled taut, and a knot is tied using a tail and a loop of suture (Fig. 36-39). The final knot can be buried by inserting the needle into deeper tissue; the needle exits several millimeters from the wound edge. If one pulls on the needle end, the knot disappears into the wound. [73] The obvious advantage of this technique is that there are no suture marks in the skin. Another method that avoids penetrating the skin is the interrupted subcuticular

Figure 36-38 In constructing the relief to facilitate suture removal, the suture is crossed to the opposite side, going into the subcuticular area beneath the skin for approximately 2 cm before exiting *(A)*. The suture is then carried over the epidermis for approximately 2 cm *(B)* and then back under the dermis again *(C)*. Reentry is made into the wound area *(D)* at approximately the same location where the next "bite" would have been placed had the relief not been used. *(From Grimes DW, Garner RW: "Reliefs" in intracuticular sutures. Surgical Rounds 1:47, 1978. Reproduced by permission.)*

stitch (Fig. 36-40).[90] Wounds with strong static skin tension may benefit from a few interrupted dermal stitches placed horizontal to the skin surface instead of a continuous subcuticular stitch.

Nonabsorbable sutures can be left in place for 2 to 3 weeks, thus providing a longer period of support than percutaneous sutures, without the problem of stitch marks.[78] If skin sutures are used in conjunction with the subcuticular stitch, they are removed in 3 to 4 days. A subcuticular closure in itself is stronger than a tape closure. If the subcuticular technique is used exclusively to approximate the skin surface, it is advisable to apply skin tape to correct surface unevenness and to provide a more accurate apposition of the epidermis.

Mattress stitch.

The various types of mattress stitches are all interrupted stitches. The *vertical mattress stitch* is an effective method of everting skin edges (Fig. 36-41 and see Fig. 36-31). The vertical mattress stitch may be used to take a deep bite of skin in lieu of a layered closure in areas where excessive tension does not result. If the superficial loop is placed first, the tails can be pulled upward while the deep loop is placed, ensuring wound eversion in less time than with the traditional technique. [95] Unfortunately, this stitch causes more ischemia and necrosis inside its loop than either simple or continuous stitches. [96] The *horizontal mattress stitch* approximates skin edges closely while providing some degree of eversion (Fig. 36-42). [78] The horizontal mattress suture may be ideal for areas where eversion is desirable but there is little SQ tissue. The *half-buried horizontal mattress stitch,* also called a *mattress stitch with a dermal component*, combines an interrupted skin stitch with a buried intradermal stitch (Fig. 36-43). It is effective in joining the edges of a skin flap to the edges of the "recipient site"; the dermal component is placed through the dermis of the flap.[90] The half-buried horizontal mattress stitch is also useful at the scalp-forehead junction when there is tension on the wound edges. This technique halves the number of suture marks in the skin and avoids necrosis of the edge of a skin flap.

The half-buried horizontal mattress stitch is particularly useful in suturing the easily damaged apex of a V-shaped flap (Fig. 36-44). In the execution of the "corner stitch," the suture needle penetrates the skin at a point beyond the apex of the wound and exits through the dermis. The corner of the flap is elevated, and the suture is passed through the dermis of the flap. The needle is then placed in the dermis of the base of the wound and returned to the surface of the skin. All dermal bites should be placed at the same level. The suture is tied with sufficient tension to pull the flap snugly into the corner without blanching the flap. [78] [97] If the tip of a large flap with questionable viability may be further jeopardized by postoperative swelling, a cotton stent can be placed underneath the knot of the corner stitch. The cotton absorbs the tension produced by swelling.

Figure-of-eight stitch.

The figure-of-eight stitch is useful in wounds with friable tissue, on the eyelids where the skin is too thin for buried sutures, or in areas in which buried sutures are undesirable (Fig. 36-45).[98] This stitch reduces the amount of tension placed on the tissue by the suture, allowing the stitch to hold in place when a simple stitch would tear through the tissue. One disadvantage of this technique is that more suture material is left in the wound. A vertical variation of the figure-of-eight stitch is sometimes used to approximate close, parallel lacerations (Fig. 36-46).[99] Another technique involves a vertical mattress stitch. The central "island" of tissue is secured by passing the superficial portion of the stitch through the island at the subcuticular level (Fig. 36-47).[100] If the viability of the central island is questionable and the surrounding tissue is loose, it can be excised.

Correction of dog-ears.

When wound edges are not precisely aligned horizontally, there will be excess tissue on one or both ends. This small flap of excess skin that bunches up at the end of a sutured wound is commonly called a *dog-ear*. This effect also occurs when one side of the wound is more elliptical than the opposite side or when an excision of a wound is not sufficiently elliptical—that is, when it is either too straight or too nearly circular. [48] [90]

If a dog-ear is present, it can be eliminated on one side of the wound in the following manner: The flap of excess skin is elevated with a skin hook, and an incision is carried at an oblique angle from the apex of the wound toward the side with the excess skin. The flap is then undermined and laid flat. The resulting triangle of skin is trimmed, and the closure is completed (Fig. 36-48*A*).[89] [97] An alternative method consists of carrying the incision directly from the apex, in line with the wound. The flap of excess tissue is pulled over the incision while skin hooks are used to retract the extended apex of the wound. Excess tissue is excised, and the remainder of the wound is sutured. [90] If dog-ears are present on *both* sides of one end of the wound, the bulge of excess tissue can be excised in an elliptical fashion, and the wound can be closed (Fig. 36-48*B*).[97]

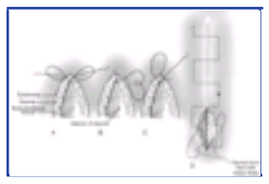

Figure 36-39 Subcuticular closure without epidermal penetration. *A,* The initial knot is secured in the dermal or subcutaneous tissue. *B,* The short strand is cut, and the needle is inserted into the dermis at the apex of the wound. *C,* The needle in the dermis, close to the corner of the wound and exiting the wound at the same horizontal level. *D,* After the subcuticular stitch has been completed, a knot is tied with the tail and the loop of the suture. *(Modified from Stillman RM: Wound closure: Choosing optimal materials and methods. ER Reports 2:43, 1981.)*

V-Y advancement flap.

If a corner stitch produces excessive tension on the tip of the flap, a V-Y closure can be used to approximate the edges without undue tension. An incision carried away from the apex of the wound converts it from a V to a Y configuration (Fig. 36-49). The newly formed wound edges are undermined, and the repair is completed. A half-buried mattress stitch is placed at the fork of the Y. [97]

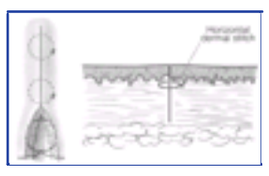

Figure 36-40 Interrupted subcuticular stitch (also called a *horizontal dermal stitch*). Absorbable sutures are used. A deep vertical suture is also shown.

Stellate lacerations.

The repair of a stellate laceration is a challenging problem. Usually a result of compression and shear forces, these injuries contain large amounts of partially devitalized tissue. The surrounding soft tissue is often swollen and contused. Much of this contused tissue cannot be

Figure 36-41 Vertical mattress stitch. The key to a tight closure is to place the inner sutures very close to the suture line (wound edge). *(From Grabb WC: Basic techniques of plastic surgery. debrided without creating a large tissue defect. Sometimes tissue is lost, yet the amount is not apparent until key sutures are placed. In repairing what often resembles a jigsaw puzzle, the clinician can remove small flaps of necrotic tissue with an iris scissors; large, viable flaps can be repositioned in their beds and carefully secured with half-buried mattress stitches. If interrupted stitches are used to approximate a thin flap, small bites should be taken in the flap and larger, deeper bites in the base of the wound. A modification of the corner stitch can be used to approximate multiple flaps to a base (Fig. 36-50). The V-Y advancement flap technique is also useful. Thin flaps of tissue in a stellate laceration with beveled

Figure 36-50 View from *above* stellate laceration, showing closure with half-buried mattress stitches.

edges are often most easily repositioned and stabilized with a firm dressing. [78]

Closure of stellate lacerations cannot always be accomplished immediately, especially if there is considerable soft tissue swelling. It may be best in some instances to consider delayed closure or revision of the scar at a later date. In complicated lacerations, inexact tissue approximation may be all that is possible initially.

Repair of Special Structures

Facial Wounds (General Features)

The ideal result in the repair of a facial laceration is an extremely narrow, flat, and unapparent scar. In addition to basic wound management, a few additional techniques can be used to achieve this result. One factor that contributes to wide scars is necrosis of partially devitalized wound edges. However, skin with apparently marginal circulation may survive because of the excellent vascularity of the face. SQ fat, which in other locations may be debrided thoroughly, should be preserved if possible in facial wounds to prevent eventual sinking of the scar and to preserve normal facial contours. Therefore, debridement of most facial wounds should be conservative.[81] Facial and forehead lacerations that follow natural skin creases or lines will heal with a less noticeable scar than those that are oblique or perpendicular to the natural wrinkles of the skin (Fig. 36-51).

Converse pointed out that "precise approximation of skin edges without undue tension ensures primary healing with minimal scarring." [90] A layered closure is essential in the cosmetic repair of many facial wounds. Approximation of the dermis with an SQ stitch or a combination of SQ and subcuticular stitches should bring the epithelial edges together or within 1 to 2 mm of apposition—close enough that the use of additional sutures seems almost unnecessary. [89] If an SQ stitch is the only stitch used to close the deeper layers, it should pass

Figure 36-51 Lacerations following natural skin lines (shown here) heal with a less noticeable scar than those that are oblique or perpendicular to natural lines (or wrinkles).

through the dermal-epidermal junction or within 1 to 2 mm of the skin surface without causing a dimpling effect. The clinician must tie this stitch snugly, pulling the two ends of the suture in the same direction (see Fig. 36-21). Should the first SQ stitch placed at the midpoint of a wound perfectly appose the skin edges, one can "protect" that stitch from disruption during further suturing by immediately placing a percutaneous stitch in the same location. If there is a slight gap in the wound edges after SQ closure, the skin can be partially approximated with a few guide stitches. The first is placed at the midpoint of the wound, and subsequent stitches bisect the intervening spaces. Guide stitches allow the definitive epithelial sutures to be placed with little tension on each individual stitch, and they protect the SQ stitches from disruption. Once the definitive stitches have been placed, the guide stitches, if slack, can be removed. Because a needle damages tissue with each passage through the skin, guide stitches should be used only when necessary.

The epithelial stitch should never be used to relieve the wound of tension; it serves only to match the epidermal surfaces precisely along the length of the wound. If there is significant separation of the wound edges after closure of the SQ layer, a 5-0 or 6-0 subcuticular suture can be used to eliminate the tension produced by this separation and to provide prolonged stability. Once the skin edges are apposed, the epithelial stitch can be used to correct discrepancies in vertical alignment. A 6-0 synthetic nonabsorbable suture is an excellent material for this stitch. A continuous stitch is preferable because it can be placed quickly, but interrupted stitches are acceptable. In a straight laceration, better apposition is achieved if the wound is stretched lengthwise by finger traction or by the use of skin hooks. When the needle is placed on one side of the wound, if that side is higher than the opposite side, a shallow bite is taken. The needle is used to depress the wound edge to the proper height, after which the needle "follows through" to the other side, pinning the two sides together. If the first side entered is lower, the needle is elevated when entering the second side to match the epithelial edges.

Grabb pointed out that "the closer the needle lies to the skin edge, the greater will be its effect in controlling the ultimate position of that edge." [68] Epithelial stitches should be spaced no more than 2 to 3 mm apart and should encompass no more than 2 to 4 mm of tissue. [80] If widely spaced, the sutures will leave marks. [89] Once skin closure is complete, final adjustments in the tension on any continuous suture line are made before the end of the stitch is tied. If any level discrepancies persist, interrupted sutures or tape can be used to flatten these few irregularities.

Surgical tape is useful as a secondary support, protecting the epithelial stitch from stresses produced by normal skin movements (Fig. 36-52). Facial wounds have a tendency to swell and place excessive stretch on an epithelial stitch. This can be minimized by applying a pressure dressing and cold compresses to the wound following closure. Surgical tape can serve to a limited extent as a pressure dressing.

Forehead

Although the forehead is actually a part of the scalp, lacerations in this region are treated as facial wounds. Vertical lacerations across the forehead are oriented 90° to skin tension lines, and the resulting scars are more noticeable than those

Figure 36-52 Wound closure tape can be used to provide additional support while sutures are in place and after they are removed. This may be especially useful in cosmetic areas, such as the face.

from horizontal lacerations. Midline vertical forehead lacerations may result in cosmetically acceptable scars with standard closure techniques; uncentered lacerations may benefit from S-plasty or Z-plasty techniques during the initial repair or during later revision of the scar.

Superficial lacerations may be closed with skin stitches alone, but deep forehead lacerations must be closed in layers. The periosteum should be approximated before the closure of more superficial layers. If skin is directly exposed to bone,

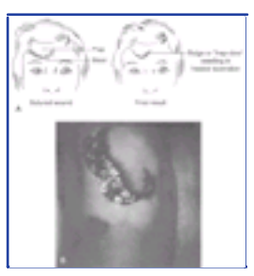

Figure 36-53 *A*, Elevation of a forehead flap. The "trap-door effect" is a natural healing process of elliptical or round lacerations. Patients should be advised of this phenomenon. *B,* This flap-type laceration of the knee will heal with a puffed-up center (trap door), even under the best of circumstances. *(A from Grabb WC, Kleinert HE: Technics in Surgery: Facial and Hand Injuries. Somerville, NJ, Ethicon, Inc., 1980. Reproduced by permission.)*

adhesions may develop that in time may limit the movement of skin during facial expressions. The frontalis muscle fascia and adjacent fibrous tissue should be approximated as a distinct layer; if left unsutured, the retracted ends of this muscle will bulge beneath the skin. If the gap in a muscle belly is later filled with scar tissue, movement of the muscle pulls on the entire scar and makes it more apparent. [81]

A U-shaped flap laceration with a superiorly oriented base poses a difficult problem. Immediate vascular congestion and later scar contraction within the flap produce the "trap-door effect," with the flap becoming prominently elevated (Fig. 36-53). This effect can be minimized by approximation of the bulk of SQ tissue of the flap to a deeper level on the base side of the wound; the skin surfaces of the two sides are apposed at the same level (Fig. 36-54*A*). A firm compression dressing helps eliminate "dead space" and hematoma formation within the wound. Despite these efforts, secondary revision is sometimes necessary. [78] Often, swelling of the flap resolves over a 6- to 12-month period. Because flap elevation can be quite disconcerting, the clinician should forewarn the patient and family about a possible trap-door effect.

When a forehead laceration borders the scalp and the thick scalp tissue must be sutured to thinner forehead skin, a horizontal or vertical mattress stitch with an intradermal component can be used (Fig. 36-54*B*).[90]

Eyebrow and Eyelid Lacerations

Jagged lacerations through eyebrows should be managed with little, if any, debridement of untidy but viable edges. The hair shafts of the eyebrow grow at an oblique angle, and vertical excision may produce a linear alopecia in the eyebrow,

Figure 36-54 *A,* Repair of a U-shaped flap laceration with a superiorly oriented base to minimize the trap door effect. *A,* Excision of edges. *B,* undermining. *C,* Approximation of SQ tissue on the flap to SQ tissue at a deeper level on the base; *D,* skin closure. *B* and *C,* When a laceration in the thin skin of the forehead borders the thicker skin of the scalp, a horizontal mattress suture with an intradermal component can enhance healing by bringing tissues to the same plane. These figures show eversion of thinner skin to obtain adequate approximation with thicker scalp tissue. *(B from Converse JM: Introduction to plastic surgery. In Converse JM (ed): Reconstructive Plastic Surgery: Principles and Procedures in Correction, Reconstruction, and Transplantation, vol 1, 2nd ed. Philadelphia, WB Saunders, 1977. Reproduced by permission.)*

whereas with simple closure, the scar remains hidden within the hair. If partial excision is unavoidable, the scalpel blade should be angled in a direction parallel to the axis of the hair shaft to minimize damage to hair follicles.

Points on each side of the lacerated eyebrow should be aligned precisely; a single percutaneous stitch on each margin of the eyebrow should precede SQ closure. The edges of the eyebrow serve as landmarks for reapproximation; therefore, the eyebrow must not be shaved, as these landmarks will be lost. Shaved eyebrows grow back slowly and sometimes incompletely, and shaving them often results in more deformity than the injury itself. Care must be taken not to invert hair-bearing skin into the wound. [93]

The thin, flexible skin of the upper eyelid is relatively easy to suture. A soft 6-0 suture (or smaller) is recommended for closure of simple lacerations. Traumatized eyelids are susceptible to massive swelling; compression dressings and cool compresses can be used to minimize this problem.

It is essential that the emergency clinician recognize complicated eyelid lacerations that require the expertise of an ophthalmologist. Lacerations that traverse the lid margin require exact realignment to avoid entropion or ectropion (Fig. 36-55*A*). Injuries penetrating the tarsal plate frequently cause damage to the globe. A deep horizontal laceration through the upper lid that divides the thin levator palpebrae muscle or its tendinous attachment to the tarsal plate produces ptosis. If this muscle

cannot be identified and repaired by the emergency clinician, a consultant should repair the injury primarily. A laceration through the portion of the upper or lower lid *medial* to the punctum frequently damages the lacrimal duct or the medial canthal ligament and requires specialized techniques for repair (Fig. 36-55*B*). If adipose tissue is seen within any periorbital laceration, one must assume that the orbital septum has been penetrated and that retrobulbar fat is herniating through the wound (Fig. 36-55*C*). The repair of lid avulsions, extensive lid lacerations with loss of tissue, and any of the other complex types of lid lacerations mentioned earlier should be left to ophthalmologists.

Ear Lacerations

The primary goals in the management of lacerations of the pinna are expedient coverage of exposed cartilage and minimization of wound hematoma (Fig. 36-55*D*). Cartilage is an avascular tissue, and when ear cartilage is denuded of its protective, nutrient-providing skin, progressive erosive chondritis ensues. The initial step in the repair of an ear injury involves trimming away jagged or devitalized cartilage and skin. If the skin cannot be stretched to cover the defect, additional cartilage along the wound margin can be removed. Depending on the location, as much as 5 mm of cartilage can be removed without significant deformity. Cartilage should be approximated with 4-0 or 5-0 absorbable sutures initially placed at folds or ridges in the pinna representing major landmarks. Sutures tear through cartilage; therefore, the anterior and posterior perichondrium should be included in the stitch. No more tension should be applied than is needed to touch the edges together.

In through-and-through ear lacerations, the posterior skin surface should be approximated next, using 5-0 nonabsorbable synthetic sutures. Once closure of the posterior surface is completed, the convoluted anterior surface of the ear can be approximated with 5-0 or 6-0 nonabsorbable synthetic sutures, with landmarks joined point by point. On the free rim, the skin should be everted if later notching is to be avoided. Care should be taken to cover all exposed cartilage. In heavily contaminated wounds of the ear (e.g., bite wounds) that already show evidence of inflammation, the necrotic tissue should be debrided, the cartilage covered by a loose approximation of skin, and the patient placed on antibiotics. [78] [101] After a lacerated ear has been sutured, it should be enclosed in a compression dressing (see Fig. 65-29).

Lacerations of the Nose

In the repair of lacerations of the nose, reapproximation of the wound edges is difficult because the skin is inflexible, and even deeply placed stitches will slice through the epidermis and pull out. When the wound edges cannot be coapted easily,

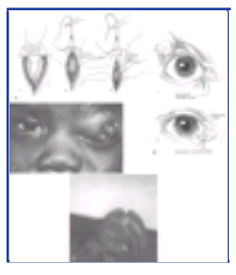

Figure 36-55 *A,* Repair of a simple lid laceration. The first sutures are placed at the lid margin so that the lid can be extended by traction with a hemostat. Interrupted absorbable sutures are used to close the tarsus (1), followed by separate closure of the muscle layer with absorbable sutures (2), and finally by closure of the skin with interrupted 8-0 black silk or synthetic sutures (3). Such a repair should not be performed by the novice. *B*, A method of identifying and repairing the canaliculus. This repair is best left to the ophthalmologist, but recognizing the potential for a canaliculus injury is the task at hand in the emergency department. *C,* Deep laceration of the left upper lid with herniation of orbital fat. For fat to prolapse, the orbital septum (and potentially the globe itself) must have been perforated. This is a wound requiring operating room exploration and repair. *D*, Lacerations of the ear require a special repair aimed at covering cartilage and preventing hematoma formation. With this through-and-through laceration of the margin of the pinna, the cartilage is trimmed just enough to allow the skin to be approximated to cover all exposed cartilage. The repair is easiest if the posterior pinna is sutured first.

6-0 absorbable sutures can be placed in the fibrofatty junction in an SQ stitch before skin closure. Because it is difficult to approximate gaping wounds in this location, debridement must be kept to a minimum. Nasal cartilage is frequently involved in wounds of the nose, but it is seldom necessary to suture the cartilage itself.

The free rim of the nostril must be aligned precisely to avoid unsightly notching. Many clinicians recommend early removal of stitches to avoid stitch marks, yet the oily nature of skin in this area makes it difficult to keep the wound closed with tape. A subcuticular stitch is recommended if the wound is gaping before closure, as this will provide support for a prolonged period. [102]

Lip and Intraoral Lacerations

Lip lacerations are cosmetically deforming injuries, but if the clinician follows a few guidelines, these lacerations usually heal satisfactorily.

The contamination of all intraoral and lip wounds is considerable; they must be thoroughly irrigated. Regional nerve blocks are preferred to local injection, because the latter method distends tissue, distorts the anatomy of the lip, and obscures the vermilion border. Losses of <25% of the lip permit primary closure with little deformity; losses of >25% require a reconstructive procedure. Extensive lacerations directly through the commissure of the mouth also require surgical consultation in most cases.[101] Deep scars in the vermilion of the upper lip may produce a redundancy of tissue that requires later revision. [101]

Large through-and-through lacerations of the lip should be closed in three layers. With a multilayer closure, the muscle layer is approximated with a 4-0 or 5-0 absorbable suture securely anchored in the fibrous tissue located anterior and posterior to the muscle. The vermilion-cutaneous junction of the lip is a critical landmark that, if divided, must be repositioned with precision; a 1-mm "step-off" is apparent and cosmetically unacceptable. The vermilion border should be approximated with a 5-0 or 6-0 nonabsorbable stay suture before any further closure to ensure proper alignment throughout the remainder of the repair (Fig. 36-56). The

Figure 36-56 *A,* In the repair of lip lacerations, the first stitch should be placed at the vermilion-cutaneous border to obtain proper alignment. *(A from Grabb WC, Kleinert HE: Technics in Surgery: Facial and Hand Injuries. Somerville, NJ, Ethicon, Inc., 1980. Reproduced by permission.)*

vermilion surface of the lip and the buccal mucosa are then closed with interrupted stitches using an absorbable 4-0 or 5-0 suture. Finally, the skin is closed with 6-0 nonabsorbable sutures.[103]

Small puncture-type lacerations heal well only if the skin is closed and the small intraoral laceration is left open. Such injuries are common from a punch in the face when the victim's tooth lacerates the lip. In general, small lacerations of the oral mucosa heal well without sutures. If a mucosal laceration creates a flap of tissue that falls between the occlusal surfaces of the teeth or if a laceration is extensive enough to trap food particles (e.g., 2 to 3 cm or greater in length), it should be closed. Small flaps may be excised. Closure is easily accomplished with 4-0 Dexon or Vicryl using a simple interrupted suturing technique. These materials are soft and less abrasive than gut sutures, which become hard and traumatize adjacent mucosa. Similarly, nylon sutures whose sharp ends are annoying and painful should be avoided inside the mouth. Muscle and mucosal layers should be closed separately. Sutures in the oral cavity easily become untied by the constant motion of the tongue. Each suture should be tied with at least four square knots. These sutures need not be removed; they either loosen and fall out within 1 week or are rapidly

absorbed.[81] [103] [104]

All lacerations that penetrate the oral mucosa should be evaluated for the presence of a tooth fragment. A retained tooth fragment should be searched for in the depths of the wound if a tooth is missing or chipped. The search should be intensified if the patient returns with an infection of a sutured wound. Probing the wound with forceps may identify fragments not seen directly in the wound. In the setting of marked facial swelling, a radiograph of the soft tissue may help identify an embedded tooth fragment.

Tongue Lacerations

There is some controversy regarding when to suture tongue lacerations. Simple, linear lacerations, especially those in the central portion of the tongue, heal quickly with minimal risk of infection. Most tongue lacerations that occur from falls or seizures do not require sutures. Most tongue lacerations in children heal well without sutures. Snyder suggests that only those lacerations that involve the edge or pass completely through the tongue, flap lacerations, and lacerations that continue to bleed excessively need to be sutured (Fig. 36-57). All lacerations bisecting the tongue require repair. [102] Small flaps on the edge of the tongue may be excised, but large flaps should be sutured. When dilute peroxide mouth rinses and a soft diet are used for a few days, healing is rapid. Persistent bleeding from minor lacerations brings most patients to the hospital, and closure may be necessary to prevent further bleeding.

The repair of a tongue laceration in any patient is somewhat difficult, but in an uncooperative child, the procedure may prove impossible under anything other than general anesthesia. A Denhardt-Dingman side mouth gag aids in keeping the patient's mouth open. A localized area of the tongue may be anesthetized topically by covering the area with 4% lidocaine-soaked gauze for 5 minutes; the maximum safe dose of local anesthesia should be determined and exposure to greater doses avoided. Large lacerations require infiltration anesthesia (1% lidocaine with buffered epinephrine) or a lingual nerve block. If the tip of the tongue has been anesthetized, a towel clip or suture can be used to

Figure 36-57 Through-and-through injuries and lacerations of the tongue margins require sutures to achieve anatomic healing. Dexon, Vicryl, or silk sutures are ideal for suturing the tongue surface. Bleeding is usually controlled with direct pressure and local infiltration of lidocaine with epinephrine. For through-and-through lacerations, the muscle layer should be closed separately (with absorbable sutures) to prevent hematoma formation. In general, buried sutures are better tolerated by the patient.

maintain protrusion of the tongue. Further anesthesia and subsequent wound cleansing and closure are possible while an assistant applies gentle traction to the tongue.

Size 4-0 absorbable sutures should be used to close all 3 layers—inferior mucosa, muscle, and superior mucosa—in a single stitch, or the stitch should include one half of the thickness of the tongue, with sutures placed on the superior and inferior surfaces as well as on the edge of the tongue. [102] Sutures on the tongue frequently become untied. This problem can be avoided if the stitches are buried. Do not use nylon sutures in the tongue, because the sharp edges are quite uncomfortable. [81] Closure of the lingual muscle layer is usually sufficient to control bleeding and return motor function to the lacerated tongue. Mucosal healing is rapid, and closure of the muscle layer with only a deep absorbable suture may be sufficient.

Scalp

The scalp extends from the supraorbital ridges anteriorly to the external occipital protuberances posteriorly and blends with temporalis fascia laterally. There are five anatomic layers of the scalp: skin, superficial fascia, galea aponeurotica, subaponeurotic areolar connective tissue, and periosteum (see Fig. 36-18*A*). Surgically, the scalp may be divided into three distinct layers. The outer layer consists of the skin, superficial fascia, and galea (the aponeurosis of the frontalis and occipitalis muscles), which are firmly adherent and surgically are considered as one layer. The integrity of the outer layer is maintained by inelastic, tough, fibrous septa, which keep wounds from gaping open unless all three portions have been traversed. Wounds that gape open signify a laceration extending beneath the galea layer. The galea itself is loosely adherent to the periosteum by means of the slack areolar tissue of the subaponeurotic layer. The periosteum covers the skull. The periosteum is often mistakenly identified as the galea, and vain attempts are made to suture the flimsy periosteum in the hope of "closing the galea" (Fig. 36-58). [105]

Several unique problems are associated with wounds of the scalp. The presence of a rich vascular network in the superficial fascia results in profuse bleeding from scalp wounds. Severed scalp vessels tend to remain patent, because the fibrous SQ fascia hinders the normal retraction of blood vessels that have been cut, allowing persistent or massive hemorrhage in simple lacerations. The subgaleal layer of loose connective tissue contains "emissary veins" that drain through diploic vessels of the skull into the venous sinuses of the cranial hemispheres. In scalp wounds that penetrate this layer, bacteria may be carried by these vessels to the meninges and the intracranial sinuses. Thus, a scalp wound infection can result in osteomyelitis, meningitis, or brain abscess. [102] Careful approximation of galeal lacerations not only ensures control of bleeding, but also protects against the spread of infection.

Shear-type injuries can cause extensive separation of the superficial layers from the galeal layer (Fig. 36-59). Debris and other contaminants can be deposited several centimeters from the visible laceration. Careful exploration and cleaning of scalp wounds are important.

Because the scalp is vulnerable to blunt trauma and because its superficial fascial layer is inelastic and firmly adherent to the skin, stellate lacerations are common in this region. Stellate lacerations not only pose additional technical problems in closure, but also have a greater propensity for infection. Multiple scalp wounds that are hidden by a mat of hair are easily overlooked.

When scalp wounds are debrided, obviously devitalized tissue should be removed, but debridement should be conservative, because closure of large defects is difficult on the scalp. When facing profuse bleeding, especially from extensive lacerations, the clinician should instruct an assistant to maintain compression around the wound during the closure rather than try to tie off bleeding vessels. Unless the vessels are large or few, ligation of individual scalp vessels seldom provides effective hemostasis, and considerable blood loss can occur during the attempt. Bleeding from scalp lacerations is best controlled by expeditious suturing. [97] A simple procedure that often provides hemostasis of scalp wounds is placing a *wide*, tight rubber band or Penrose drain around the scalp, from forehead to occiput (Fig. 36-60*A*). Sterile rubber bands may be kept on the suture cart for this purpose. The clinician also may control bleeding temporarily in some cases by grasping the galea and the dermis with a hemostat and everting the instrument over the skin edge. The disadvantage of this technique is that tissue grasped by the hemostat may be crushed and devitalized[97] and if the SQ tissue also is everted for a prolonged period, necrosis can occur.

If an assistant is not available to apply direct pressure, local anesthetics containing epinephrine are sometimes effective in controlling the persistent bleeding from small vessels in scalp wounds. If bleeding from the edge of the scalp wound is vigorous, and definitive repair must be postponed while the patient is resuscitated, Raney scalp clips can be applied quickly to the edge of the scalp wound to control the hemorrhage. The applicator is loaded by inserting the tip of the instrument into the back of the clip and then locking the handles. The clip is slid onto the bleeding wound edge and released from the applicator. When the wound is repaired at a later time, the clip is removed by reversing the procedure. The plastic clips are radiolucent and do not interfere with plain radiography or computed tomography scanning (Fig. 36-60*B*). [106] [107]

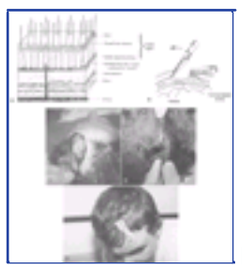

Figure 36-58 *A*, Anatomy of the scalp. Note that the skin, superficial fascia, and galea are adherent and constitute the outer layer. Blood vessels in the fascia are the major source of the blood loss noted in scalp lacerations. *B,* To temporarily control bleeding from vessels in the fascia, the galea can be everted to compress the fascia. *C,* The galea has been transected in wounds that gape open like this one, and to achieve hemostasis and obtain the best closure, the galea should be sutured. This is most easily accomplished with the use of a long needle, forceps, and 3-0 sutures that incorporate the skin, SQ tissue, and galea in a single bite *(D)*. In this figure, the needle is passing through the galea from the underside, having traversed all three layers on the other side of the laceration. If this technique is used, individual buried sutures in the galea are not required, and hemostasis is ensured. At the base of this wound is the periosteum, a tissue-like covering of the skull. In *C*, the galea is actually adherent to the avulsed flap; the anesthetic needle is touching the underside of the galea. A simple laceration that does not gape open *(E)* means the galea is intact. It can be easily closed with superficial sutures or staples.

Figure 36-59 Large partial scalp avulsion.

Before wound closure, the underlying skull should be visually examined and palpated in an attempt to detect fractures. More small skull fractures are detected with the clinician's eyes and gloved finger than with radiographs. A common error is to mistake a rent in the galea or the periosteum for a fracture during palpation inside the wound. Direct visualization of the area should resolve the issue. In wounds that expose bone but do not penetrate the skull, prolonged exposure may leave a nidus of dead bone that may develop osteomyelitis. Exposed bone that is visibly necrosed should be removed with rongeurs until active bleeding appears. [97] Hair surrounding the scalp wound usually must be clipped far enough from the wound edge so that suturing can proceed without entangling the hair in knots or embedding hair within the wound. If hairs along the wound

Figure 36-60 *A,* To achieve hemostasis of a scalp laceration, a wide, tight, sterilized rubber band or Penrose drain may be placed around the forehead and occiput. This compresses the arterial supply to the scalp. *B,* Alternatively the wound margins can be temporarily clamped to control hemorrhage. Raney scalp clips and accompanying instrument for application to scalp wound edges are shown.

edges become embedded in the wound, they will stimulate excessive granulation tissue and delay healing. [108] Vaseline or tape may be placed on stubborn hairs that persistently fall into the wound. Although clipping scalp hair is not popular with some patients, failure to expose an area adequately is a common cause of improper cleaning and closure of scalp wounds.

Unlike most wounds involving multiple layers of tissue, scalp wounds can be closed with a single layer of sutures that *incorporate skin, SQ fascia, and the galea* (Fig. 36-58*D*). The periosteum need not be sutured. To minimize the chance of infection, SQ deep sutures generally are avoided. The galea is firmly attached to the underside of the SQ fascia and is rarely identified as a distinct layer in the depths of a wound. In superficial wounds, skin and SQ tissue should be approximated with simple interrupted or vertical mattress stitches using a nonabsorbable 3-0 nylon or polypropylene suture on a large needle. Smaller suture material tends to break while firm knots are being tied and should not be used. The ends of the tied scalp sutures should be left at least 2 cm long to facilitate subsequent suture removal. The use of blue nylon, as opposed to black, may make suture removal easier. If the galea is also torn, it should be included in the skin stitch. [109] Some investigators recommend a separate closure of the galea with an absorbable 3-0 or 4-0 suture, using an inverted stitch that "buries" the knot beneath the galea. [97] Separate closure of the galea introduces additional suture material into the wound, but in extremely large wounds provides a more secure approximation of the galea than obtained with large needle single layer closure.

With microvascular techniques, large sections of skin avulsed from the scalp can be reimplanted. The emergency clinician should use the same techniques in salvaging avulsed scalp as are used for amputated extremities [109] (see Chapter 48 for further discussion).

Figure 36-61 Anatomy of the fingernail. The fingernail rests on the nailbed, also termed the *matrix*. The distal nail covers the sterile matrix; the proximal nail arises from and covers the germinal matrix. The tissue adherent to the proximal dorsal nail is the eponychium (also termed the *cuticle*), and the potential space between the nail and the eponychium is the nail fold.

There may be no absolute time interval between injury and closure that automatically precludes primary suturing of scalp lacerations. Because of the extensive collateral blood supply of the scalp, most lacerations in this area heal without problems. Nonetheless, wound care must be thorough to avoid the devastating complication of scalp infection.

Sutured scalp lacerations need not be bandaged, and patients can rinse their hair in 24 hours. If bleeding is persistent, an elastic bandage can be used as a compression dressing. Gauze sponges are placed over the laceration to provide direct local pressure beneath the elastic bandage.

Figure 36-62 This subungual hematoma occupies about two thirds of the nail and should be drained by simple nail trephination. The injury does not require nailbed repair, because the nail is still firmly attached to the matrix. Even though there must be a nail matrix laceration (the source of the bleeding), the cosmetic result will be excellent. The presence of an underlying digital tuft fracture does not change management (see also description of nail trephination in Chapter 38).

Nail Lacerations

Injuries to the nail and nailbed (also called the *nail matrix*) are common problems in emergency medicine, yet controversy exists over proper management (Fig. 36-61). Sixty percent of patients with subungual hematomas that are greater than one half the size of the nailbed and with associated fractures of the distal phalanx have a nailbed laceration. [110] [111]

In the case of a simple subungual hematoma (even in the presence of a tuft fracture) in which the nail is firmly adherent and the disruption of the surrounding tissue is minimal, the nail *need not be routinely removed to search for nailbed lacerations* (Fig. 36-62).[112] Despite the presence of a nailbed laceration, a good result can be

expected as long as the tissue is held in anatomic approximation by the intact fingernail. Nail trephination is discussed in Chapter 38 . If the nail is partly avulsed (especially at the base) or loose, or if there are deep lacerations that involve the nailbed, the nail should be lifted to assess and potentially repair the nailbed (Fig. 36-63). When the integrity of the fingernail is disrupted a rippled nail may develop (Fig. 36-34). Anatomic repair of the nailbed theoretically should minimize subsequent nail deformity.

If the nailbed is exposed and has been extensively lacerated or partially avulsed, it may be necessary to refer the patient to a hand surgeon who can raise a flap of tissue extending from the proximal nail fold, explore the wound for foreign bodies, and clean under the nailbed. A simple nailbed laceration should be approximated with 6-0 or 7-0 absorbable sutures (to obviate the need for suture removal), generally using loupe magnification and a finger tourniquet to maintain a bloodless field (Fig. 36-65). The exposed nailbed should be protected by reapplying the avulsed nail (best choice) or by applying a nonadherent dressing or Silastic sheet for approximately 3 weeks. Reinsertion of the nail may occasionally result in infection, so cleaning the nail is recommended. After cleaning, the avulsed nail may be sutured in place or secured with wound closure tape.

The replaced nail serves three purposes: (1) it acts as a splint or mold to maintain the normal anatomy of the nailbed, (2) it covers a sensitive area and facilitates dressing changes,

Figure 36-63 This fingernail was avulsed at the base *(A)*, a common result of having a door slam on the digit. Since the nail is mobile *(B)* and there is subungual bleeding, the nail can be removed and the nailbed inspected. Any large laceration should be meticulously repaired. Absorbable sutures size 6-0 or smaller should be used. After repair, the nail is replaced under the eponychium (cuticle). See Figure 36-68 for a simple technique for removal of the fingernail.

and (3) it maintains the fold for new nail growth. Splinting should be maintained for 2 to 3 weeks. If longitudinal scar bands are formed between the proximal nail fold and the matrix, a permanently split or deformed nail may result.

A nail that is partially avulsed distally can be used as a temporary splint or "dressing" that protects and maintains the integrity of the underlying nailbed. When the base of the nail is avulsed from the germinal matrix, some authors advocate trimming the proximal portion of the traumatized nail so that it can be placed more easily in the nail fold.[113] If the *germinal matrix* of the nail is avulsed intact, the nail should be reimplanted using a 5-0 or 6-0 absorbable suture in a mattress stitch (Fig. 36-66).[81] [114] If the root is not replaced, the space between the proximal nail fold and the nailbed is obliterated within a few days. [115] [116] If an open fracture exists, the matrix must not be allowed to remain trapped in the fracture line.[117] A replaced nail may grow normally, acting as a free graft,

Figure 36-64 This nail is permanently deformed with ridges. Although crush injury to the nailbed is likely responsible for this deformity, nailbed repair is believed to minimize the resultant deformity.

but often it is dislodged by a new nail. Nails grow at a rate of 0.1 mm/day, and it requires approximately 6 months for a new nail to reach to the fingertip.

If part of the nailbed has been lost, the patient should be referred to a surgical consultant for a matrix graft. [81] [113] [118] Conservative therapy that allows large portions of an avulsed nailbed to granulate is inadvisable, although this is quite acceptable therapy for a fingertip avulsion that does not involve the nailbed. If the exposed nailbed is left open to granulate, it will heal with scar tissue and could produce a distorted and sensitive digit.

Wounds should be rechecked in 3 to 5 days following repair. At that time the nail fold may be repacked if nonadherent material was used, and the wound is assessed for infection. The use of absorbable suture for nailbed repair makes suture removal unnecessary. Tape or sutures are removed from any replaced nail in 2 weeks, and the old nail is allowed to fall off as the new nail grows. The value of antibiotics is unproven. All patients with nail injuries should be advised of a possible cosmetic defect in the new nail.

When repairing distal digit lacerations involving a nail, the clinician should first approximate the onychial fold (Fig. 36-67). A sturdy needle attached to a 4-0 thread is recommended for suturing lacerated nails. Needles seem to penetrate nails with the least difficulty when they enter at 90°. The point of the needle carves a rigid path through the nail. Unless the entire length of the needle is allowed to follow this path as it passes through the nail, the needle is likely to bend or break. Alternatively, an electrical cautery instrument or a heated paper clip can be used to perforate the nail, thus permitting easy passage of the needle. The method for atraumatically removing a nail is demonstrated in Fig. 36-68 .

Drains in Sutured Wounds

Drains do not prevent infection; they primarily keep wounds open to encourage drainage of purulence or blood that may

Figure 36-65 A laceration involving the nailbed, germinal matrix, and skinfold must be carefully approximated. First the nail is completely removed. (see Fig. 36-68). Fine, absorbable sutures are used to repair the nailbed under a bloodless field provided by a finger tourniquet. The avulsed nail (trimmed at the base) or a gauze pack is gently placed between the matrix and eponychium for 2 to 3 weeks to prevent scar formation *(A)*. If the original nail is replaced (the best option), it may be sutured or taped in place *(B)*. A large hole in the nail will allow drainage. The old nail is gradually pushed out by a new one. If the nail matrix is replaced quickly and atraumatically, the nail may act as a free graft and grow normally. Note: Only absorbable sutures are used to repair the nailbed.

otherwise collect in the wound. When no infection exists and drains are used in soft tissue wounds "prophylactically," they are more harmful than beneficial. Edlich and coworkers state that "drains act as retrograde conduits through which skin contaminants gain entrance into the wound. Furthermore, the presence of a drain impairs the resistance of the tissue to infection."[72] Magee and colleagues found that drains placed in experimental wounds contaminated with subinfective doses of bacteria greatly enhanced the rate of infection, whether the drain was placed entirely within the wound or was brought out through the wound. [119] Drains behave as foreign bodies, provoking rather than preventing infection. If the wound is considered at high risk for infection, instead of suturing the

Figure 36-66 Avulsion of the nail, leaving the matrix intact, requires only a nonadherent dressing to separate the skinfold from the nailbed. If the germinal matrix is avulsed, as shown in this figure, it should be replaced to its original position under the eponychium with 6-0 plain absorbable sutures. *(From Grabb WC, Kleinert HE: Technics in Surgery: Facial and Hand Injuries. Somerville, NJ, Ethicon, Inc., 1980. Reproduced by permission.)*

Figure 36-67 Repair of a distal finger laceration involving the nail and the onychial fold. In this case the nail is still adherent to the nail matrix and acts as a natural splint. If the nail is loose or completely transected, it is prudent to remove the entire nail and then carefully suture the nailbed under direct vision. *(From Dushoff IM: Handling the hand. Emerg Med 1976, p 111. Reproduced by permission.)*

Figure 36-68 To remove a fingernail or toenail atraumatically, the blades of iris scissors are held parallel to the nailbed to avoid lacerating the matrix. A digital block is usually performed to make the procedure painless. The closed blades are slowly advanced in the plane between the nail and the nailbed *(A)* and then gently spread *(B)* to loosen the nail. The scissors are advanced and spread in stages until the base of the nail is reached and the entire nail is loose. The nail is grasped with a hemostat and pulled from the base *(C)*, exposing the nail matrix *(D)*. The nail can be replaced, if desired, once the nailbed laceration has been repaired.

wound with a drain in place (in anticipation of disaster), the clinician should leave the wound open and consider delayed primary closure later when the risk of infection is minimal. Furthermore, drains should not serve as substitutes for other methods of achieving hemostasis in traumatic wounds.

SUMMARY

Various techniques are available for reapproximating wound edges. Stapling is fast, but this technique does not allow meticulous control of wound edges, as may be necessary for a cosmetically appealing repair. Tape and tissue adhesive are the quickest and least painful methods of wound closure. Both eliminate the risk of self-injury with suture needles. These techniques can be used only on small superficial wounds or after approximation of the SQ layer.

The traditional and most commonly used method of closure is suturing. Stitches provide the most secure closure initially, but placement of sutures is time consuming and technically more difficult than other methods. All suture materials provoke inflammation and increase the risk of infection. Suture repair is the most appropriate method for wounds with complex configurations, those that extend into SQ tissue, and those in mobile areas.

At the conclusion of any wound repair, dried blood on the skin surface should be wiped away gently with moistened gauze, and the wound should be covered with a dressing. Dressing techniques, wound care instructions, and suture removal skills are discussed in Chapter 35 .

Chapter 37 - Foreign Body Removal

Daniel B. Stone
Theodore K. Koutouzis

Soft tissue foreign bodies (FBs) are a common occurrence in emergency departments (EDs). FB identification and removal is rewarding to both the patient and clinician. *However, it is not possible, or considered standard of care, that all soft tissues or wound FBs be identified or removed on the initial encounter.* Although the history or physical examination may suggest the presence of an FB, and a reasonable attempt should be made to find or remove it, some foreign material simply defies suspicion, identification, or removal on the first clinician examination. Missed FBs are, however, among the leading causes of malpractice claims made against emergency clinicians, usually because of simple errors in documentation or communication. Often litigation arises merely because the clinician does not pay attention to details of the mechanism of injury or nuances of the examination, or fails to inform the patient that not all foreign material is immediately accessible to diagnosis or removal. Many times known, suspected, or identified FBs can be removed at a later date without a significant increase in morbidity if the patient is properly informed and prepared. This chapter will provide guidelines for the identification, evaluation, and removal of a variety of FBs.

GUIDELINES FOR APPROACHING FOREIGN BODIES

A thorough history and physical examination must initially be performed. It is important to determine the exact mechanism of injury and to determine if the specific characteristics of the foreign material are known. For instance, did the patient step on a rusty nail or piece of broken glass? Was an FB initially present but removed before arrival by the patient? Under many circumstances, a simple direct question to the patient, asking if he or she suspects the presence of a retained FB, will initiate the proper clinical scenario.

The history, physical examination, and localization techniques available will determine the best time and place for FB removal. Some material, such as wood, should be removed immediately when accessible. Retained wood will invariably lead to inflammation and infection. Other material, such as glass or plastic, may be removed on an elective basis, whereas innocuous metallic FBs may often be permanently left embedded in soft tissue. If localization is certain and if removal can be produced under local anesthesia within a manageable period of time (1 hour is usually the upper limit of operative time using local anesthesia), and without unacceptable worsening of the injury, an attempt at removal is generally indicated on the initial visit (given clinician and support staff availability). *Before the procedure, it is prudent to inform the patient that the FB may not be located in the time allotted and that subsequent referral or additional procedures may be necessary.*

With deeply embedded, small, and inert materials (such as a BB) that are not located near any vital structures, the time, effort, and trauma involved with removal may be excessive compared with the possible adverse effects of the foreign material remaining in place. An ill-conceived extended search for an elusive but otherwise harmless FB often results in frustration for the clinician and discomfort and dissatisfaction for the patient.

When reviewing the decision of when and how to remove the FB, the possibility of the FB migrating to involve vital structures, while quite remote, should be discussed with the patient. Cases of reported missile embolization in the vascular system are influenced by missile caliber, impact velocity, physical wound characteristics, point of vessel entrance, body position and movement, and velocity of blood flow. [1] Retained bullets usually remain in soft tissues, but rarely make their way into the vascular system. This usually occurs at the time of injury. Schurr and colleagues [2] reported a paradoxical bullet embolization from the left external iliac vein to the left iliac artery via a patent *foramen ovale*. When clinicians first examined the patient, a bullet was noted on the chest radiograph, and an isolated chest wound was suspected. However, the bullet had apparently entered the chest, traversed the abdomen to the iliac vein, and then embolized back to the chest and arterial system.

All clinical decisions require an evaluation for the possibility of infection. Some FBs may produce an inflammatory reaction or infection in a few days and other objects may not cause such problems for weeks or months, often flaring up for no apparent reason. FBs such as wood will always produce inflammation eventually, while others, such as bullets, rarely do. Some inert FBs may carry dirt particles, pieces of clothing, or other sources of bacterial contamination. Expeditious removal may be necessary, even though the FB itself is relatively small and unlikely to cause a reaction. In old injuries, a thorough history of the type of foreign material and method of introduction is warranted. However, a hasty or extensive exploration for the foreign material that may or may not still exist is not recommended. The initial history should also include any unusual medical problems that would preclude use of adequate local anesthesia, such as allergy to local anesthetics, bleeding diathesis, and medical problems (including diabetes mellitus, vascular disease, uremia, or a compromised immune status) that might lead to unusual or more difficult wound management. Finally, a cooperative and willing patient is essential. *Attempting to remove an FB in an intoxicated, drugged, mentally retarded, or overtly uncooperative patient is obviously self-defeating.*

It is not uncommon to serendipitously encounter soft tissue FBs, even though their presence was not suggested by history. Anderson and associates reported that clinicians who initially treated a series of hand injuries did not suspect FBs in 75 of 200 consecutive cases. [3] A patient who experiences a sharp, sudden pain in the foot while walking barefoot across a carpet may have a sewing needle or toothpick embedded, rather than a "sprained foot" (Fig. 37-1). *An abscess or cellulitis that recurs or wounds that do not heal as expected should always be investigated for retained FBs.* [4] [5] Finally, it should be determined if metallic or other FBs that are captured on radiograph are extrinsic to the patient (located in clothes or on the table) or actually embedded within soft tissue (Fig. 37-2).

If a FB is left in place, remember to inform the patient as to why it was not removed. If the patient is referred for delayed removal, this should also be carefully explained and documented. Regardless of whether the FB is removed, all wounds should be cleaned appropriately and tetanus prophylaxis updated if indicated (see Chapter 36).

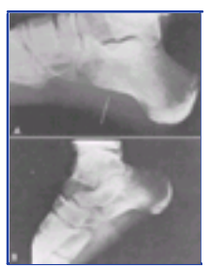

Figure 37-1 A common foreign body (FB) of the foot is a splinter, toothpick, pin, or needle that is impaled while walking barefoot on a carpet. This sewing needle was obvious, but some FBs may be mistaken for a heel spur, contusion, or tendinitis. Preoperative *(A)* and postoperative *(B)* radiographs demonstrate complete removal.

Rarely do retained lead FBs, such as bullets or shotgun pellets, leach out lead into the general circulation and produce systemic lead poisoning (Fig. 37-3). If this process occurs, it may take years to develop and can cause vague or nondescript symptoms (e.g., fatigue, arthralgia, headache, or abdominal pain) many years after the initial injury. Elevated blood lead levels are more likely to occur if bodily fluids such as joint, pleural, peritoneal, or cerebrospinal fluids bathe the lead. Bullets retained in muscle or other soft tissues are not likely to produce any sequelae related to their lead content. However, Farrell and coworkers reported unsuspected elevated lead levels in patients with retained lead fragments who presented to the ED with a variety of complaints. [6] Lead levels of up to 50 µg/dL were reported. Levels >45 µg/dL are generally considered an indication for chelation therapy. The relation between the retained lead and presenting symptoms was unclear, but this report verifies the observations of others that retained lead FBs in selected areas can significantly elevate blood lead levels and may produce symptomatic plumbism.

Finally, the patient should be clearly informed that there is no absolute guarantee that *all* foreign material has been identified or extracted, regardless if some or any FB was removed during initial exploration. The prudent clinician always leaves open the option that an occult FB may still remain in any wound and informs the patient of signs and symptoms of problems related to any retained material. Some centers routinely add this caveat on all discharge instructions for patients treated

Figure 37-2 This patient fell, landed on a metal pipe, and suffered a laceration to the thigh. A radiograph was taken to rule out a fracture, and the key was seen but thought to be an artifact (i.e., an item left on the backboard). During the examination the key was found embedded in the wound. It had been in the patient's pants pocket and was forced into the wound by the pipe during the injury.

for lacerations or soft tissue defects. Patients should be assured that additional steps may be undertaken should the presence of foreign material be subsequently suspected.

IMAGING TECHNIQUES

A variety of imaging techniques are available to emergency clinicians to help detect and localize FBs. Many emergency clinicians mistakenly believe that, in the absence of adipose tissue, if the base of the wound can be clearly visualized and explored, an FB can always be ruled out. While this is commonly true, Avner and Baker detected glass by routine radiographs in 11 of 160 wounds (6.9%) that were inspected and believed by the clinician to be free of glass. [7] Whenever there is an index of suspicion for a retained FB as a result of the history, mechanism of injury, patient complaint, or examination, attempts should be made to visualize it. Modalities available include plain radiographs, fluoroscopy, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound (US) (Fig. 37-4). Fluoroscopy is not a standard technique in the ED but is helpful for localizing FBs that are

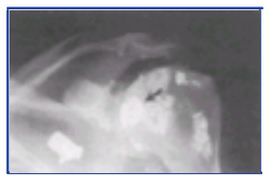

Figure 37-3 Most lead foreign bodies are well tolerated, but if a bullet is bathed in synovial, pleural, peritoneal, or cerebrospinal fluid, the lead may leach out over time and produce a significant elevation in blood lead levels. Symptoms are often vague, and the relation between the retained lead and the patient's clinical scenario may be difficult to sort out. *(From Schwartz DT, Goldfrank LR: Toxicologic imaging. In Goldfrank LR, Flomenbaum NE, Lewin NA, et al [eds]: Goldfrank's Toxicologic Emergencies. 5th ed. Norwalk, CT, Appleton & Lange, 1994, p 116. Reproduced with permission.)*

visualized on routine plain films. Yet even fluoroscopy under magnification may not identify plastic or wooden FBs. [8]

Plain Radiography

Plain radiographs are readily available, easily interpreted, and cost significantly less than CT, US, or MRI. [9] The ability

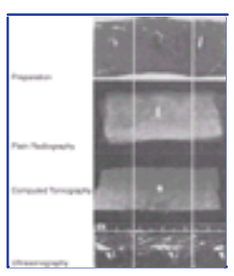

Figure 37-4 Comparison of plain radiography, computed tomography, and ultrasonography in imaging wooden, glass, and plastic foreign bodies (FBs) in an in vitro preparation. Computer manipulation of a digitized radiograph may aid in FB assessment. *(From Ginsburg MJ, Ellis GL, Flom LL: Detection of soft-tissue FBs by plain radiography, xerography, computed tomography, and ultrasonography. Ann Emerg Med 19:701, 1990. Reproduced with permission.).*

of plain films to detect FBs in soft tissues depends on the object's composition (relative density), configuration, size, and orientation. Multiple views should always be obtained when attempting to visualize an FB since many clearly radiopaque objects are obscured by superimposed bone on one view, but are quite obvious when viewed from another angle. However, certain FBs that are radiolucent may still not be visualized with this approach. Metallic objects, such as pins, bullets, and BBs, are readily visualized. Aluminum, which has traditionally been deemed radiolucent, can occasionally be visualized on plain films if the object is projected away from underlying bone. Ellis demonstrated that pure aluminum fragments as small as 0.5 mm × 0.5 mm × 1 mm could be identified in a chicken wing model simulating a human hand or foot. Ellis cautioned that other aluminum FBs, such as pull tabs from cans, may not be visualized in other parts of the body such as the esophagus or stomach.[10]

It is a common misconception that glass must contain lead to be visualized on a plain radiograph. Almost all types of glass objects in soft tissue (bottles, windshield glass, light bulbs, microscope cover slips, laboratory capillary tubes) can be detected by plain radiographs, unless they are obscured by bone (Fig. 37-5).[9] [11] Very small glass fragments (<1 mm) may be more difficult to detect by this technique, but the absence of an FB on multiple projections is strong, although not absolute, evidence that glass is not contained in a wound. [12] Other nonmetallic objects readily visualized include teeth, bone, pencil graphite, asphalt, and gravel. [9] [13]

Detection of FBs on plain films can be enhanced by requesting that the technician use an underpenetrated soft tissue technique. [14] Digitized radiographs may be manipulated to enhance identification of a suspected FB. Plain films may provide indirect evidence of the presence of an FB if one sees trapped or surrounding air, a radiolucent filling defect, or secondary bony changes such as periosteal elevation, osteolytic or osteoblastic changes, or pseudotumors of bone. [14] Vegetative material, such as thorns, wood, splinters, and cactus spines, are not readily visualized by plain radiographs.

Figure 37-5 Almost all glass is visible on a plain radiograph. Small size is the major limiting factor, not the lead content. If glass is superimposed over bone, it may be obscured, so multiple projections are required. Samples of glass are superimposed on the abdomen and exposed to x-rays. *(Reproduced with permission from Zatzkin HR: The Roentgen Diagnosis of Trauma. Copyright © 1965 by Year Book Medical Publishers, Chicago. Reproduced with permission.)*

These materials absorb body fluids as they sit in situ and become isodense with the surrounding tissues. Because of their varying chemical composition and density, plastics may or may not be visible on plain films. [15]

Computed Tomography

CT is readily available to most emergency clinicians. Since CT depends on x-ray absorption, it generally visualizes the same materials that are detected on plain films.[13] CT, however, can detect subtle differences in soft tissue densities, and may detect FBs not readily visible on plain films. [9] Depending on the degree of hydration, wood FBs may be detected using CT. Because it produces a better three-dimensional image of tissue than plain films, CT can visualize objects embedded in or behind bone.

Magnetic Resonance Imaging

Although MRI is expensive and not readily available to emergency clinicians, it may be superior to CT in detecting small, *nonmetallic*, radiolucent FBs, such as wood,

particularly in the orbit.[16] FBs, which have little or no free water, appear as a signal void on MRI.[9] Plastic is more easily visualized with MRI than with CT. MRI cannot be used for metallic objects and gravel, which contain various ferrometallic particles that produce signal artifacts on MRI.[9] Metallic objects, in addition to producing a high degree of artifact on MRI, have a theoretical risk of shifting within the magnetic field and causing structural damage to adjacent structures. This is of little importance in superficial extremity wounds, but it is particularly important when evaluating FBs in the eye, brain, or deep structures of the neck, face, or extremities.

Ultrasound

US offers an alternative way to localize radiolucent FBs. In fact, US has become the modality of choice for difficult-to-find FBs. Like fluoroscopy, it can be used to guide the tip of a hemostat to a nonvisualized object while not exposing the operator or patient to ionizing radiation.[14] US is both highly sensitive and highly specific in localizing FBs of all types.[17] US is especially useful in detecting nonradiopaque FBs such as wood or thorns. A wooden object is usually seen as a bright hyperechoic focus when the scan plane parallels the long axis of the FB or is at right angles to its long axis.[17] US may have more difficulty in visualizing small FBs in the hand or foot, where there are many echogenic structures.[18] While extremely useful for larger FBs in extremities, US may be difficult to use in some sites such as the web space of the hand. A high-resolution, high-frequency transducer provides the greatest anatomic detail. Advantages include low cost, real-time examination, and the ability to define the object in three dimensions. As with all US studies, accuracy is operator dependent. Also, the presence of air in surrounding tissue may result in false-positive results.[18] In addition, US may give a false-positive reading due to calcific tissue or small sesamoid bones. Overall, the sensitivity and specificity of high-resolution US in detecting radiolucent FBs are about 90%.

General Imaging Approach

A reasonable initial approach for localizing nonvisualized FBs in the ED is to obtain multiple-projection plain radiographs with a soft tissue technique. This technique will visualize the majority of FBs, especially metal and glass. US may be considered for objects known to be radiolucent, such as wood or thorns. Both US and fluoroscopy may be used to guide FB extraction. CT or MRI probably should not be routinely ordered from the ED during initial wound evaluation unless one suspects a particularly dangerous FB. *For suspected intraorbital or intracranial FB, CT is recommended.* CT or MRI is also warranted when a previously negatively explored wound exhibits recurrent infection, poor healing, or persistent pain.

FOREIGN BODY REACTION

Many soft tissue FBs must be removed because of either infection or FB reaction. A purulent bacterial infection *may* develop in the presence of any FB, but not in all cases. Karpman and coworkers found a 15% infection rate (*Staphylococcus aureus* and Enterobacteriaceae) in a series of 25 patients treated for cactus thorn injuries of the extremities. [19] Certain thorns (black thorns, rose thorns), redwood and Northwest cedar splinters, toothpicks, hair, and stingray or sea urchin spines are noted for their ability to initiate chronic FB reactions. Sea urchin spines and other marine FBs are covered with slime, calcareous material, and other debris that

commonly initiate an FB granuloma. The inflammatory reaction seen with cactus thorns may be an allergic reaction to fungus found on the cactus plant. Many FB reactions are thought to be due to the inflammatory response to organic material or they may represent infection from bacteria introduced at wounding. Clinically evident reactions may be delayed for weeks or even years following injury (Fig. 37-6). The chronic infection or inflammatory reaction may not be accompanied by the production of pus, but it may be quite painful or result in loss of function. FBs may also be associated with the formation of a chronic pseudotumor, development of a sinus tract, or evidence of osteomyelitis-like lesions of bone and soft tissue. [4] Organic material has also been noted to induce chronic tenosynovitis, chronic monarticular synovitis, and chronic bursitis.

Rapidly traveling projectiles with considerable inherent heat (e.g., bullets) are less likely to cause infection but are more apt to cause damage during passage through tissue. As noted earlier, the composition and location of an FB, as well as patient medical status and vocational/avocational activities, greatly affect decision making related to FB removal. One must judiciously evaluate and manage each FB injury individually.

FOREIGN BODY SCENARIOS

Certain mechanisms of injury, such as punching or kicking out a window or stepping on an unknown object while walking in a field or stream, are highly suggestive of a retained FB (Fig. 37-7). Although not all lacerations caused by glass require a radiograph, imaging should be used generously under such circumstances.

Most lacerations from metal objects do not contain foreign material, but if the patient states that considerable force was applied during injury and the instrument is not available for inspection, radiographic imaging may be warranted. Occasionally, as a knife encounters the bone, the tip of the

Figure 37-6 This foreign body (FB) granuloma developed after the FB was stable for 6 months in this laborer's hand. There was no gross infection, but the pain was quite bothersome. The FB and reactive tissue were excised under local anesthesia.

knife's blade may break off. Radiographs of animal or human bites should be used to assess for associated fractures. These films should be observed carefully for embedded teeth. Since the patient's perception of an FB correlates with the presence of an FB, *it is suggested that the clinician ask the patient if he or she thinks a wound may harbor foreign material*. In fact, Steele and coworkers found the positive predictive value of patient perception was 31% and negative predictive value was 89%.[20]

Many, but not all, retained FBs will produce pain when the patient moves the injured area or when the wound edges are palpated or depressed. It is prudent to carefully palpate the periphery of all wounds to elicit such tenderness. Superficial FBs may be palpated through the skin, but surprisingly large FBs may be found in seemingly minor wounds, without much external evidence. While puncture wounds are more likely to contain an FB than wide, gaping lacerations, the external characteristics of the wound do not yield firm evidence as to the presence or absence of an FB.

GUIDELINES FOR FOREIGN BODY REMOVAL

Following the initial history, examination, and *preoperative and preanesthetic documentation of the neurovascular status of the patient*, a decision must be made as to the time and place of removal. If the decision is made to have the FB removed in the ED, a 30-minute time limit is a reasonable self-imposed limit for the provider when attempting the removal of an FB. More difficult procedures should be referred. Many FBs appear superficial on radiographs, suggesting that removal will be quite easy. However, surprisingly large or presumed superficial FBs often prove quite elusive.

Localization

Superficial FBs, such as splinters, bullets, or embedded glass, may be palpated if they are near the skin surface. Deeper FBs must be localized by other techniques. A metal probe may identify the FB by feel or sound. Since glass is difficult to identify by sight in soft tissue, touching it with metal causes a characteristic grating sound. Because of the increasing incidence of human immunodeficiency virus (HIV), *probing a wound with a gloved finger to locate or identify an FB is strongly discouraged* (Fig. 37-8), since sharp objects can easily penetrate a gloved finger, exposing the clinician to bloodborne diseases such as HIV and hepatitis.

Radiographs are the best method for estimating the general location, depth, and structure of radiopaque FBs. If one strategically attaches a marker (needle or paper clip) to the skin surface at the wound entrance before taking a radiograph, the FB will be seen in relation to the entrance wound. This also helps to identify the path that leads to the FB and the relative distance from the surface to the FB. [21] Needles at two angles may also be used to aid localization (Fig. 37-9). A special technique using measurements on anteroposterior and lateral radiographs and a blind dissection method have been advocated to remove needles from the foot. [22] High-resolution US, CT, or MRI should be considered when the FB is suspected of being difficult to visualize on a conventional radiograph.

While rarely available, fluoroscopic image-intensifying equipment may be used to follow a wound's entrance, localize

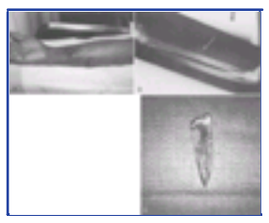

Figure 37-7 This intoxicated patient punched out a window and sustained seemingly minor puncture wounds *(A)*. He did not believe that glass was in the wound, there was little pain, and no FB could be palpated externally. A radiograph *(B)* revealed a large shard of glass deeply embedded in the wound *(C)*.

Figure 37-8 What's wrong with this picture? Although historically suggested as a useful technique to find FBs, probing the depths of a wound with a gloved finger may result in a puncture wound in the operator. The practice is strongly discouraged because of the prevalence of hepatitis and human immunodeficiency virus infections.

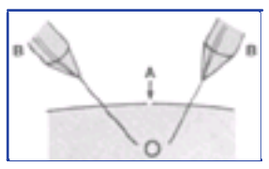

Figure 37-9 When a small entrance wound *(A)* is noted but the foreign body (FB) is not seen, noninvasive localization is preferable to blind probing. Metal markers taped to the skin or needles inserted close to the FB under local anesthesia *(B)* and radiographed at different angles provide a guide to FB localization and extraction. *(Reproduced from Hospital Medicine, © January 1981, with permission of Cahner's Publishing Co.)*

the material, grasp the FB, and remove it without making a larger incision. A potential disadvantage of this procedure is the increased amount of radiation that may be required. Ariyan has described a technique in which two needles are placed in the soft tissue from opposite directions, pointing toward the FB. [23] The extremity is rotated while the clinician watches the image under the image intensifier to obtain a three-dimensional effect. An incision is placed perpendicular to the plane of the needles, and the object is removed. US can also be used to remove an FB under direct visualization, and is particularly useful for radiolucent FBs.

Some authors have suggested injecting the entrance wound with methylene blue to outline the tract of the FB. [24] The blue line of injected dye is followed into the deeper tissues. This technique is of limited value, because the tract of the FB often closes tightly and does not allow passage of the methylene blue.

Equipment

A standard suture tray with a scalpel is usually adequate equipment for removal of most simple FBs. Tissue retractors, special pickups, and loupes may be added if needed. Since good light is essential, many clinicians use a headlamp. And, sitting on a stool makes the procedure easier on the clinician's legs and back.

Local soft tissue injection with buffered bupivacaine or lidocaine (with epinephrine for other than digital blocks) is the recommended anesthesia for removal of most soft tissue FBs. Regional intravenous anesthesia or selected nerve blocks may also be useful. *The judicious use of sedation (parenteral, rectal, or oral) is strongly advised if the clinician senses undue apprehension or anxiety in the patient.* This may be especially helpful in children. If the patient is totally uncooperative, exploration should be postponed for a more appropriate time (e.g., under regional or general anesthesia in the operating room).

To successfully remove an FB in the soft tissue of an extremity, an arterial tourniquet will provide a bloodless field. A blood pressure cuff or portable self-contained pneumatic cuff inflated above arterial pressure may be used on the upper arm, forearm, leg, or thigh. To limit bothersome backbleeding, the extremity needs to be elevated and wrapped with an elastic bandage to exsanguinate the extremity before inflating the tourniquet. In the digits, a Penrose drain or specialized tourniquet may be used as a tourniquet at the base of the finger or toes. A sterile glove may also be used as a finger tourniquet. The fingertip of the glove on the involved finger is cut, and the glove is rolled down to the base of the finger. Most patients can tolerate an ischemic tourniquet for 15 to 30 minutes, and it is safe to stop circulation to an extremity for this time period.

Operative Technique

The specific technique for removal of an FB is tailored to each clinical situation. In general, FBs should be removed only under direct vision. *Blind grasping into a wound with a hemostat in an effort to remove an FB should be avoided.* This technique is especially dangerous in the hand, foot, neck, or face, where vital structures

may be easily damaged.

In most cases one should *enlarge the entrance wound with an adequate skin incision*. Attempting to remove an FB through a puncture wound or an inadequate skin incision is a common

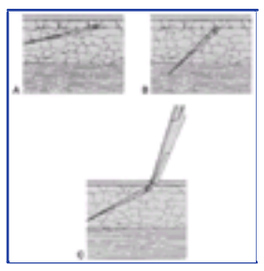

Figure 37-10 A sewing needle completely embedded below the surface *(A* and *B)* is easily located by a radiograph. Following local anesthesia, a small incision over the superficial end permits removal with a hemostatic forceps *(C)*. The hemostat is introduced through an adequate incision, spread to open the tissue, and used to "feel" the foreign body as the hemostat is advanced. *(Reproduced from Hospital Medicine, © January 1981, with permission of Cahner's Publishing Co.)*

error that is both frustrating and self-defeating. Following a proper skin incision, the wound is explored by carefully spreading the soft tissue with a hemostat (Fig. 37-10). Occasionally, the FB can often be felt with an instrument before it can be seen. In an extremity that has been made ischemic by a tourniquet, the tract of the FB may be followed, although the tract frequently cannot be identified in muscle or fat.

If the FB is difficult to visualize (such as with fiberglass or plastic FBs) or if it is located in the superficial soft tissue, excision of a small block of tissue, rather than removal of the FB alone, may be necessary. If the FB has contaminated the surrounding soft tissue, a block excision may also be required. It must be noted that excision of a block of tissue is done only under direct vision and after nerves, tendons, and vessels have been identified and excluded from the excision.

If an FB such as a thorn or needle enters the skin perpendicularly, a linear incision may pass to one side of the FB, and it will be difficult to determine where the FB lies in relation to the incision (Fig. 37-11*A* and *B*). The search must then be extended into the walls of the incision rather than through the skin. [25] In such cases it is advisable to excise a small ellipse of skin and undermine the skin for 0.5 to 1.0 cm in all directions (Fig. 37-11*C*). The tissue is then compressed from the sides in hopes that the FB will extrude and can be grasped with a hemostat.

Following FB removal, the wound is irrigated under pressure with saline. If a small incision has been made in a noncosmetic area (such as the bottom of the foot), the incision is left open and bandaged. The area may be soaked in hot water for a few days, and a return visit is necessary only if signs of infection develop. If a large incision has been created, the skin may be primarily sutured. In cases in which gross contamination has occurred, the wound should not be closed on the initial visit. The wound may be packed open and the

Figure 37-11 If a linear skin incision is used to locate a mobile foreign body (FB) that is perpendicular to the skin in the subcutaneous fat *(A),* the FB may be displaced *(B).* A modified elliptical incision is made *(C),* and the skin edges are undermined, displacing the FB into the middle of the wound. Pressure with the thumbs may be applied to the skin to force the FB into view. *(From Rees CE: The removal of FBs: A modified incision. JAMA 113:35, 1939. Copyright 1939, American Medical Association. Reproduced with permission.)*

skin may be subsequently sutured in 3 to 5 days, if free of signs of inflammation (delayed primary closure). Although the use of postoperative antibiotics is not standard, tetanus prophylaxis should be given. Antibiotics may be indicated for immunocompromised patients, but there are no data to support the routine use of antibiotics for wounds that have been thoroughly cleaned and in which all foreign material has been removed. Prophylaxis may be considered if there was excessive time between injury and removal, obvious contamination, or when the ability to adequately clean a wound is suspect. However, under these circumstances it is more prudent to opt for an open wound and a delayed closure. If prophylactic antibiotics are prescribed, 5 days of a penicillinase- resistant penicillin or first-generation cephalosporin should suffice. Under certain circumstances (e.g., stepping on a nail or a marine FB), alternative antibiotics may be indicated.

Puncture wounds to the bottom of the feet, especially through rubber-soled shoes, have been associated with *Pseudomonas* infections. Saltwater marine FBs may be contaminated with *Vibrios* species, usually sensitive to tetracyclines, aminoglycosides, or third-generation cephalosporins. Even if all foreign material has been removed, stings from marine animals may initiate a prolonged local irritation that simulates cellulitis. *However, the presence of a wound infection on a subsequent visit strongly raises concern for an occult retained FB rather than the simple conclusion that the wound is merely infected by bacteria introduced during the initial insult.*

Traumatic Tattooing

Ground-in foreign material or tattooing of the skin is a difficult problem because permanent disfigurement may occur. These injuries occur most often from falls on blacktop surfaces or asphalt, or falls from bicycles or motorcycles on a variety of surfaces. Many cases may be managed with adequate local anesthesia and meticulous debridement with a sponge, scrub brush, or toothbrush. If all foreign material cannot be removed with these methods, careful consideration should be given to a secondary excision of the tattooed area and primary closure with subsequent plastic surgery to repair the defect. However, it is usually impossible to completely remove traumatic tattooing in the ED. Referral for more extensive surgical treatment following local wound care is quite acceptable. Dermabrasion may be an acceptable delayed treatment when tattooing is superficial. [26] An alternative, although not currently available in EDs, is to refer patients to a dermatologist for laser removal of traumatic tattoos. Certain lasers have proved to be an excellent alternative. [27] The process is more specific in removing embedded material without harming surrounding tissue. The type of material will determine the number of treatments that are required. Not all tattoos can be completely removed. [28]

Foreign Bodies in Fatty Tissue

FBs located in fatty tissues may be removed by making an elliptical incision surrounding the entrance wound; grasping the incised skin loosely with an Allis forceps; undercutting the incision until the FB is contacted; and removing the FB, skin, and entrance tract in one block (Fig. 37-12). In most instances, a small portion of subcutaneous (SQ) fat should be removed along with the FB to minimize infection. FBs in fat are very mobile, and probing may displace them even further. FBs that are embedded in fat and are perpendicular to the skin may also be removed, as shown in Figure 37-11 .

Puncture Wounds to the Sole of the Foot

FBs may be introduced with puncture wounds to the sole of the foot (Fig. 37-13). A common scenario is stepping on a nail while wearing tennis shoes and socks. If the patient reports that the nail was removed intact, the possibility still remains that small fragments or fibers from the shoe or sock were introduced into the wound. When present in the wound, this material will invariably serve as a nucleus for infection. Therefore, these wounds should always be evaluated for the presence of foreign material, and some may require exploration. Proper evaluation requires adequate lighting, with the patient placed prone on a stretcher. A magnifying device may be helpful. Most retained material is usually radiolucent and routine radiographs are only required if bony injury is suspected. If a deep FB is suspected, CT, MRI, or US may be indicated.

Figure 37-12 Foreign bodies (FBs) in deep fat *(A)* may be approached by a small elliptical incision around the entry point *(B)*. The incision is then laterally undercut and grasped (without pulling) with an Allis clamp *(C)*. The ellipse is then further undercut until contact with the FB is made *(D)*. The FB may be grasped and removed along with the entry tract and the soiled local fat *(E)*. *(Reproduced from Hospital Medicine, © January 1981, with permission of Cahner's Publishing Co.)*

Initially, one visualizes the punctured area searching for obvious threads or pieces of rubber by merely elevating the small flap of calloused epidermis that commonly covers the entrance wound. Superficial and readily seen FBs, including small pieces of rust or debris, are often present. When foreign material is found, it should be removed by excising a small piece of tissue. A large laceration under the skin flap also necessitates local wound exploration. Although local anesthesia is often sufficient, regional nerve blocks for the sole should be considered if extensive exploration or debridement is anticipated (see Chapter 32). The surface of the site is irrigated, left open, and appropriately bandaged. Generally this is all that is required under these circumstances, but patients should be instructed to elevate the extremity for 24 to 48 hours so as to reduce swelling and help prevent hematoma formation.

If an infection is already present, the incidence of a retained FB is high. The puncture site may be cored out with a 2- to 4-mm-diameter incision carried up to 2 cm deep, superficially irrigated, and left open. It is best to avoid advancing an irrigating catheter into the deep recesses of the tract, as this serves no useful purpose and may disseminate infection.

Routinely removing a plug of tissue or coring a noninfected wound with no visible foreign material is quite controversial. [29] [30] This empiric procedure has been advocated by some, but it increases patient discomfort and disability, and has never been shown to reduce the incidence of serious sequelae. It is best reserved for patients with early inflammation or other findings on wound inspection that suggest a contaminated wound or a retained FB. It is likely over-treatment in the majority of cases.

A first-generation cephalosporin or a penicillinase-resistant penicillin is a reasonable antibiotic choice for obviously infected puncture wounds. These infections will be evident within a few days following the puncture. Noninfected puncture wounds have not been shown to benefit from antibiotics and their use is discouraged, except in high-risk patients. The vast majority of patients who step on a nail will have transient discomfort and will not develop complications. Although rare, the most dreaded complication of a deep puncture wound of the foot is *Pseudomonas* osteomyelitis (an organism that may live in the rubber soles of tennis shoes), but there is no evidence that routine use of prophylactic antibiotics will prevent this complication. In fact, routine antibiotics can theoretically select out resistant organisms. Lavery and coworkers demonstrated that *Pseudomonas* was the most common cause of osteomyelitis among nondiabetic patients, while polymicrobial infections and *Staphyloccoccus aureus* were more common in diabetic bone and soft tissue infections.[31] Diabetic patients are also three times more likely to develop osteomyelitis after a puncture wound compared to non-diabetics. Therefore, diabetic patients should be considered differently with respect to puncture wounds of the foot. *The key to a successful outcome of any puncture of the foot is to realize that pain, drainage, or swelling that persist for more than a few days after stepping on a nail, or that develop after a period of clinical quiescence, may represent the beginning of a serious but indolent infection or signal a retained FB.* Early in the course of a deep *Pseudomonas* infection, or osteomyelitis, the physical examination may be quite normal except for persistent aching or pain when walking. Fever is typically absent. A complete blood cell (CBC) count and sedimentation rate are usually normal. Plain films will be of no value. In this case, a bone scan or MRI may be used to evaluate for a deep FB or osteomyelitis.

Subungual Foreign Bodies

Special attention is required for deeply embedded subungual FBs. [32] Some cases may require removing a small portion of the nail with double-pointed heavy scissors and grasping the foreign material with splinter forceps (Fig. 37-14). Occasionally, complete removal of the nail may be required. A digital block should be used for any manipulation of the nail or nailbed.

An interesting technique has been suggested in which a sterile hypodermic needle, bent at its tip, is slid under the nail, hooking the FB, thereby allowing its withdrawal. Alternatively, a 19-ga hypodermic needle can be slid under

Figure 37-13 The vast majority of patients who step on a nail have no long-term consequences, but a few experience soft tissue infections or serious and debilitating osteomyelitis. The depths of a fresh puncture wound are not routinely explored, but key to avoid missing a superficial foreign body (FB) is to examine the patient under good lighting, supine, and with an arterial tourniquet if necessary (*A*). If the patient was wearing socks or tennis shoes, a small FB, like this piece of rubber, may be introduced into the wound. It may only be evident when the edges of the skin are trimmed and the wound is explored (*B*). Coring out the puncture wound tract is controversial and unproven, but it is one way to remove foreign material. In this case a No. 11 blade is inserted to the hilt and a 2 to 3 mm core of tissue is removed with the FB (*C*). This tract may be left open or a small packing applied. If a patient returns with an infection within a few days after a seemingly simple puncture wound (*D*), it is most likely a soft tissue infection, but persistent pain demands a search for osteomyelitis or a deep FB.

the nail to surround a small splinter. The needle tip is then brought against the underside of the nail to secure the splinter. The needle and splinter are then removed as a unit.[33]

A technique that can be performed by dermatologists and plastic surgeons is CO_2 laser vaporization. Starting a few millimeters from the nail edge, the nail is vaporized above the FB, allowing exposure. The FB can then be grabbed with forceps and removed. The advantages include decreased nail bed injury, less nail removal, faster recovery, and no bleeding. [34] Wooden splinters are commonly embedded under the fingernail. *Such FBs must be completely removed, because subsequent infection is certain.* If complete removal cannot be achieved with the techniques described earlier, the entire nail must be removed. This will allow all fragments to be visualized and removed. The proximity of the distal phalanx to the subungual area is a constant concern for the development of osteomyelitis.

Fishhooks

There are several methods of removing a fishhook. The preferred method depends on the location, depth of penetration, and conditions under which removal is to take place.[35] [36] [37] Initially, it should be noted whether the fishhook is single, multiple, or trebled. In addition, note the number and location of barbs. Any remaining exposed hooks should be removed or covered before removal in order to prevent subsequent injury. As with most injuries, vascular and neurologic status should be documented before and after removal.

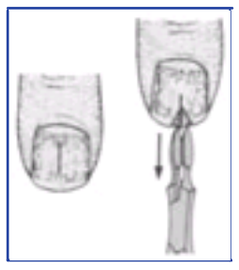

Figure 37-14 For an FB deep in the nailbed, take as small a wedge of nail as will allow access to the proximal end of the splinter, then extract the FB with splinter forceps. All wood particles should be removed. A digital nerve block is usually necessary. *(Reproduced from Hospital Medicine, © January 1981, with permission of Cahner's Publishing Co.)*

Traditionally, four removal techniques have been described: advance and cut technique, string-yank technique, needle cover technique, and retrograde technique. [38]

Advance and cut technique.

The advance and cut technique for removal requires advancement of the fishhook and cutting proximal to the barb. This method is particularly well suited for superficially embedded fishhooks. Generally, local anesthesia (1% lidocaine) is infiltrated into the tissue overlying the barb; the barb is forced through the anesthetized skin and clipped off, while the rest of the hook is removed retrograde, along the direction of entry (Fig. 37-15). The advantage to this technique is an almost always successful outcome.

String-Yank technique.

In the field or stream, removal of a fishhook may be accomplished without local anesthetic using a string-yank technique. This technique may be used in the ED, as well. Some clinicians prefer to use local 1% lidocaine to facilitate removal. This "stream" technique (Fig. 37-16) uses a looped string or fishing line passed around the belly of the hook at the point at which it enters the skin. Approximately 1 foot of string should be wrapped around the dominant hand to give strong traction, the shank of the hook should be held parallel to and in approximation with the skin by the index finger of the opposite hand, and the thumb and middle finger of the opposite hand should stabilize and depress the barb, which helps the index finger to disengage the barb from the SQ tissue. When the barb has been disengaged, a *sharp* pull (i.e., a quick tug with a snapping motion) with the dominant hand removes the hook. Care should be taken to keep bystanders out of the expected path of the hook

Figure 37-15 Method of removing an embedded fishhook when anesthesia is available and when the point of the fishhook is close to the skin. *A,* Obtain local anesthesia overlying the point of the hook. *B,* Force the point through the anesthetized skin. *C,* Clip off the barb. *D,* Remove the rest of the hook by reversing the direction of entry. *(Reproduced from Hospital Medicine, © July 1980, with permission of Cahner's Publishing Co.)*

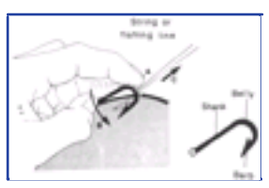

Figure 37-16 Method of removing an embedded fishhook when anesthesia is unavailable or when the barb of the fishhook lies too deep to force it out through a second wound without causing significant additional damage. Loop a piece of string (or thick suture material) around the belly of the hook and hold it down against the skin with the index finger of the left hand *(A).* Depress the shaft of the hook against the skin with the middle finger and thumb while applying light downward pressure with the index finger of the left hand to disengage the barb from the subcutaneous tissue *(B),* and pull *sharply* on the ends of the string with the right hand *(C)* to remove the hook through its entry wound. Bystanders should be out of the expected path of the hook. *(Reproduced from Hospital Medicine, © July 1980, with permission of Cahner's Publishing Co.)*

as the hook often flies out of the patient. A commercial fishhook extractor device that is based on this method but grasps the hook during removal is available (Minto Research and Development Inc., Redding, CA).

Needle cover technique.

Alternatively, an 18-ga needle may be used to cover the barb (Fig. 37-17). After adequate local anesthetic has been administered, the needle should be passed through the entrance wound of the hook parallel to the shank of the hook to sheath the barb and allow the hook to be backed out while the barb is covered. An alternative to this procedure is to insert a No. 11 blade parallel to the shank of the hook down to the barb, and using the point of the blade, free the SQ tissue that is engaged on the barb, cover the barb with the point of the No. 11 blade, and back the hook out, with the blade protecting the barb.

Retrograde technique.

This is the simplest but least successful method. By applying downward pressure to the shank of the hook, one may disengage the barb, allowing for successful removal. If resistance is observed, the procedure should be abandoned and another technique attempted. If the

Figure 37-17 Method of removing an embedded fishhook using anesthesia when the hook is large and not too deep in the skin. After anesthetizing the area with 1% lidocaine *(A),* insert a short-bevel 18-ga needle through the entry wound of the hook and attempt to sheathe the barb of the hook within the needle *(B).* If this is done correctly, the hook and needle may then be backed out together *(C). (Reproduced from Hospital Medicine, © July 1980, with permission of Cahner's Publishing Co.)*

barb does not already protrude from the skin, the retrograde technique may cause less tissue trauma. As with all wounds, tetanus prophylaxis should be administered if indicated; however, prophylactic antibiotics are not necessary.

Wooden Splinters

Because of the potential for inflammation, *pieces of wood must be completely removed from soft tissue*. By simply grasping the end of a superficial, protruding splinter, it may be adequately removed, but care should be taken not to leave small pieces of material in the wound. Some splinters cannot be visualized at the point of entry but can be easily and readily palpated beneath the skin. When a wood FB is SQ, it is advisable to cut down on the long axis of the FB to remove it via a skin incision, rather than pulling it out through the entrance wound (Fig. 37-18 Fig. 37-18). Although an incision may seem extensive and creates a laceration where only a puncture wound existed, opening the tract allows for thorough cleaning and mandatory removal of small pieces of the splinter that may otherwise remain. If the incision is linear, it may be sutured.

Particular mention should be made of certain wood splinters that are pliable and reactive, such as California redwood and northwest cedar. Any wood that is easily fragmented requires meticulous care to ensure removal of all material. Wood is generally not visible on a standard radiograph unless it is covered with lead paint. US is the technique of choice to evaluate for a wood FB, but CT or MRI may also be helpful. [39] Occasionally, the fastest method of removing small wooden splinters is complete excision of the entrance tract and the FB en bloc, followed by a linear closure.

Pencil Lead

Good judgment must be used in removing graphite from pencils when lodged in the skin. Embedded graphite is radiopaque. Because graphite invariably leaves a pigmented tattooing in the soft tissue, it is preferable to excise the material en bloc when pencil lead is found in a cosmetic area. The graphite specks cannot be irrigated or scrubbed off, and tattooing results if they are not removed. Furthermore, pencil-lead FB may resemble malignant melanoma over time and US has been

shown to be useful in differentiating between pencil-lead FB and melanoma. [40]

Metallic Fragments

High-velocity fragments (e.g., bullets, BBs, or other metallic particles caused by metal striking metal) are easy to visualize radiographically and relatively simple to remove if embedded in areas that are anatomically accessible. Before removal, the area in which the fragments are embedded should be assessed to determine which structures are involved and which structures might be encountered during removal. It is preferable to defer the removal of deeply embedded metallic FBs unless symptoms of infection develop.

The treatment of high-velocity FBs and their associated wounds (as seen with modern military or sporting ammunition) is beyond the capacity of this discussion. Retained nonexplosive metallic fragments are inert and rarely cause infection. They usually become encysted after a period of time. Lead toxicity from bullet fragments is rare, but lead fragments that are in contact with synovium are reason for concern and immediate removal (see previous discussion). In one study, Farrell and colleagues found that patients with retained lead FBs had statistically significant elevated blood lead levels. [41] The study did not differentiate the location of the FB and whether patients were, in fact, symptomatic from plumbism. Nevertheless, it may be prudent for the patient's primary care provider to monitor blood lead levels in patients with known lead FBs to prevent the development of future lead toxicity. The value of routine prophylactic antibiotics for metallic FBs left in the soft tissue has not been proven.

A sterile magnet may be used to facilitate removal of small metallic fragments. [42] The magnet is introduced into the entry site using a small scalpel and hemostat to extend and open the wound as needed. When the magnet comes in contact with the metal, a click is heard and the FB is removed while attached to the magnet. If resistance to extraction occurs, exploration can be done with the FB attached to the magnet.

Taser darts used for immobilization of violent individuals are like fishhooks and must be removed under local anesthesia after the attached wires have been cut. Backing the dart out, as with a fishhook, is not possible due to the dart's unique construction. Cutting down on the dart under local anesthesia is the preferred method of removal. [43] [44]

Marine Foreign Bodies

While most marine FBs, such as shell fragments, may be treated like other FBs, a number of marine animals carry toxins and may leave FBs that require special consideration.

Catfish.

Several species of catfish in North America contain toxic venom, and their sting can embed a FB. Envenomation occurs when the fish becomes agitated. Its dorsal and pectoral spines become locked in the extended position and penetrate the hand or foot. The venom is then

Figure 37-18a The course and depth of penetration of this large wood splinter of the leg *(A)* is uncertain, but it is axiomatic that all pieces of wood must be removed to prevent infection. To ensure complete FB removal, an incision is made over the entire course of the splinter *(B)* (*see inset*). All pieces of wood are carefully removed under direct vision *(C),* and the laceration is sutured primarily *(D)*. While it may be tempting to simply pull out the splinter and irrigate the puncture tract, such actions often lead to retained particles and complications.

secreted from an epidermal gland at the base of the spine. [45] The pain is usually ephemeral and since no specific antitoxin exists, treatment consists of local care and analgesics. The affected part should be immersed in hot water (approximately 43.3°C [110°F]) for at least 30 minutes if pain is severe. This is believed to provide symptomatic relief by decreasing vascular and muscle spasm. [46] Local injection of the wound with alkalized bupivacaine provides local analgesic and may also neutralize the toxin. [45] The wound should be inspected and any remaining spine removed. A radiograph may be taken to confirm the absence of FBs, but catfish spines and cartilage may be radiolucent. The wound should be thoroughly cleaned and irrigated. Tetanus prophylaxis should be updated. Some authors recommend empirical antibiotic therapy to cover gram-negative bacilli (e.g., *Aeromonas hydrophila*), but infection is quite rare, and routine antibiotic prophylaxis is not standard. [45]

Coelenterates.

Coelenterates including the Portuguese man-of-war, true jellyfish, fire coralbox jellyfish, and sea anemones inject several different toxins that are responsible for many marine envenomations. Reactions may be local or systemic, and pain may be severe, often described as shock-like, itching, burning, or throbbing. Substances such as tetramine, histamine, and 5-hydroxytryptamine are thought to be responsible for the localized reaction. Proteinaceous substances are implicated in the systemic response. Systemic reactions usually consist of fever, chills, and muscle spasm, but severe reactions may result in neurologic sequelae ranging from malaise and headache to paralysis and coma. Cardiopulmonary manifestations including dysrhythmias, hypotension, syncope,

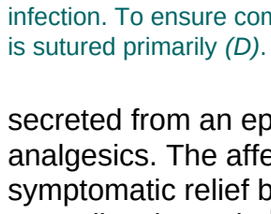

Figure 37-18b Here is another example of longitudinal incision of the overlying skin followed by withdrawal of a wood foreign body en mass to avoid retained fragments (*E*, *F*, *G*, and *H*.)

bronchospasm, laryngeal edema, and cardiorespiratory failure have been reported. [47] [48] Coelenterates deposit their venom-containing organelles, called nematocysts, onto the victim's skin (Fig. 37-19). The tentacles of coelenterates contain thousands of nematocysts and even minimal contact causes tentacles to adhere to skin. Nematocysts are then released from the tentacles onto the skin and discharge venom. Decontamination and removal of unfired nematocysts will decrease pain and systemic reactions.

Vinegar (5% acetic acid) is the initial decontaminating agent of choice and will inactivate unfired nematocysts of most species of jellyfish, Portuguese man-of-war, and sea anemones. [47] [49] This should be applied continuously for 30 minutes, or until the pain is gone. [48] Fresh water should not be applied to the area, for the osmotic shock will activate any unfired remaining nematocysts, thus discharging toxin into the dermis and increasing pain and toxicity. Other suggested, but unproven remedies, include meat tenderizer, ammonia, baking soda, urine, olive oil, sugar, and papaya latex.

After the wound has been decontaminated, any remaining tentacle fragments should be removed. Large fragments may be removed with forceps. Individual nematocysts are very small (<1 mm in length) and are not easily visible. If pain persists, it should be assumed that organelles still remain and further cleansing is required. To remove remaining nematocysts, the skin should be scraped with a hard edge, such as a credit card held perpendicular to the skin. Applying shaving cream and shaving the area gently may also remove the remaining fragments. [48] Note: Nematocysts should not be removed by rubbing the skin with sand, as this

increases venom discharge. In addition, the application of warm or cold packs to the area has not been shown to reduce pain. [49]

After decontamination, topical anesthetics or steroids may be used but prophylactic antibiotics are not necessary. Routine wound care should be followed. Allergic and systemic reactions should be treated appropriately. Antivenin is available only for box jellyfish envenomation, but its use remains incompletely understood and controversial.

Coral.

Fire corals are another type of coelenterate that produce toxicity by the presence of stinging nematocysts. After contact, a burning and intense pruritis may occur along with a series of skin eruptions. Within minutes of contact, urticaria-like lesions may appear and blister formation may result within hours. Eventually, the lesions will become lichenoid and complete resolution may not occur for 15 weeks following contact. Ultimately, hyper-pigmented areas where initial contact occurred will result. Immediate care with oral antihistamines and topical steroids tends to reduce,

Figure 37-19 Magnified view of venom-containing nematocyst in its resting or "cocked" state *(A)*. After contact with the skin, a dart-like tail is extended and penetrates the dermis *(B),* and venom is injected *(C)*. Further stimulation of the attached nematocyst can expel more venom (see decontamination/removal technique in text).

but not prevent, symptoms. Other corals are sharp and irritating if touched. Coral is comprised of a calcium carbonate core and thousands of small marine animals. "Coral cuts" occur in divers and snorkelers exploring coral reefs. These organisms can produce deep lacerations, with local reactions such as pruritus, erythema, and urticaria occurring at the site of injury. Delayed healing may occur with secondary development of cellulitis or ulceration, perhaps as a result of contamination of the wound with bacteria or microparticles of coral. [47] Treatment consists of saline irrigation. Hydrogen peroxide may be used to remove small coral particles from the wound. [47] The wound should not be closed; wet-to-dry dressings may be used.

Sponges.

Sponges produce both an irritant and a contact dermatitis. The irritant dermatitis occurs as a result of sponge spicules embedded in the victim's skin. These spicules may be removed with adhesive tape (applied to the skin and then peeled back) and the area should then be bathed with vinegar. [47] The contact dermatitis, which is believed to be caused by a toxin, produces erythema, pruritus, and vesicles similar to poison oak. [47] Treatment is initial immersion in vinegar followed by local steroid creams.

Sea urchins and starfish.

Sea urchins and starfish are free-living echinoderms covered with venomous spines, sharp and brittle, and venom-secreting pincers located near the mouth. If sea urchins or starfish are handled or inadvertently stepped on, these spines may become embedded in the patient and a severe local reaction may result from venom contained in the spines. Systemic symptoms including muscle weakness, paralysis of lips, tongue, face, hypotension, abdominal pain, and respiratory distress may occur. Local pain usually responds quite well to immersion in hot water (43.3°C to 46.1°C [110°F to 115°F]) for 30 to 90 minutes. Retained spines may become infected or cause delayed (up to 1 to 2 months) FB granulomas. This reaction is not adequately understood but may produce an intense and persistent inflammatory reaction. Spines that penetrate joints may induce a synovitis. Echinoderm spines may discharge a purple dye that may be mistaken for a retained spine. [48] Spines are usually visible on radiographs and should be removed if possible, although they are brittle and can break off in the skin. If located in a joint or near a nerve, surgical extraction may be necessary using an operative microscope. [47] Otherwise, if removal is difficult, the spine may be left in place until it resorbs or a local reaction takes place. The wound may then be opened and drained and allowed to close by secondary intention.

Stingrays.

Stingray envenomation usually occurs by accidentally stepping on the creature that is resting on the bottom in shallow water, covered by sand (Fig. 37-20). This causes the stingray to lash out its whip-like caudal appendage, or tail, which contains 1 to 4 venom-containing serrated spines. Portions of the spine may become buried in the victim's skin. Each spine is covered with a sheath containing venom glands, and in addition to immediate toxin-induced pain, pieces of the spine or sheath may remain embedded in the wound. These fragments, while often difficult to locate, do not dissolve and must be removed. Persistent pain and inflammation, even weeks to months after the attack, mandate consideration of a retained FB, but a persistent and difficult-to-treat irritative process can occur in the absence of a retained spine or sheath. Immediate local and systemic reactions occur as a result of injection of a complex toxin. Systemic reactions may be severe and can include muscle cramps, vomiting, seizures, hypotension, arrhythmias, and (rarely) death.

Treatment consists of irrigation with saline followed by hot water immersion at 43.3°C to 46.1°C (110°F to 115°F) for 30 minutes to 1 hour in order to inactivate the heat-labile toxin. Local digital blocks without vasoconstrictors provide effective analgesia for hand wounds. All wounds should be explored and debrided, all remnants of the spine and integumentary sheath removed. [47] Wounds should heal by secondary intention. The venom can cause significant local tissue necrosis, and surgical debridement may be required.

Antibiotic therapy.

Prophylactic antibiotic therapy for marine injuries is common, although there are no convincing data to support or refute the practice. Unlike other soft tissue infections, marine injuries become infected with unusual gram-negative organisms, particularly *Vibrio* species. Although there are few studies evaluating the effects of specific antibiotics, it is recommended that quinolones, trimethoprim-sulfamethoxazole, tetracyclines, third-generation cephalosporins, or aminoglycosides be used in lieu of penicillin, ampicillin, erythromycin, or first-generation cephalosporins. [48] It is always difficult to differentiate chronic inflammation caused by toxins and foreign material from true infection, and often surgical exploration is required in persistent cases. Tetanus prophylaxis should be routine.

Figure 37-20 *A,* Stingray resting on the bottom of the ocean, usually covered by a layer of sand. An unsuspecting victim steps on the stingray, and the whiplike tail impales the foot (even through a heavy boot) with one or more spines *(B).* The spine has backward-facing barbs covered by a sheath with venom-containing cells (*C*), causing a toxic envenomation and the potential for multiple FBs.

Cactus Spines

The sizes of cactus spines fluctuate considerably. The difficulty of removal is generally inversely proportional to the FB size. [50] Larger embedded cactus spines are managed like wood splinter and sea urchin spine FBs. More advanced imaging techniques (US, CT, or MRI) may be required for localization of deeply embedded spines.

Deeply embedded cactus spines generally produce granulomatous reactions, and infections are rare. [19] Hence, efforts to remove deeply embedded spines should be made after carefully weighing the benefit and potential harm related to a deep exploration, especially in a sensitive location. [50] Using forceps, superficially embedded, medium- to large-sized cactus spines are best removed by direct axial traction of each spine. Smaller spines (glochids) may be difficult and tedious to remove individually. Adherent facial mask gel application and removal of spines en masse with the mask are recommended (Fig. 37-21). Depilatory wax melted in a microwave oven and applied warm, commercial facial gels, and household glue (Elmer's Glue-All [Borden Inc., Columbus, OH])

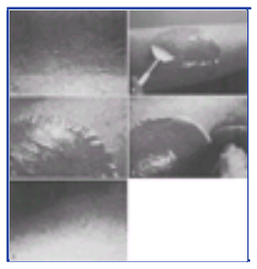

Figure 37-21 *A,* A thousand or more glochids affixed to the skin by contact with a single pad of polka dot cactus. *B,* The *professional* facial gel is spread with a fan brush. *C,* The gel is spread thin at the edges. *D,* The gel rollup is started by picking at the edge with the fingernails. *E,* When the *professional* gel is peeled off, all of the very small spines come with it. *(From Lindsey D, Lindsey WE: Cactus spine injuries. Am J Emerg Med 6:362, 1988. Reproduced by permission.)*

have all been recommended for this purpose. [50] [51] [52] [53] Over-the-counter "home use" facial mask gels are not adherent enough to be effective without multiple applications (up to eight or more).

Body Piercing and Removal

The art of body piercing predates most history books. Over the last decade, an enormous increase in the practice of body piercing has occurred. With these piercings have also come the complications associated with the practice. For centuries, the most common place was the ears. Today, the lips, tongue, eyebrow, nose, navel, nipples, and genital areas have become sites of body piercing. To date, there are a limited number of studies on post-piercing infections in areas other than the ears. Three major types of jewelry are used: (1) barbell studs, which are straight bars with a ball threaded onto both ends; (2) labret studs, which are straight bars with a ball threaded on one end and a disc permanently fixed on the other end (more commonly used on the lips); and (3) a captive bead ring, which consists of a bead with small dimples on opposite sides, held "captive" by tension from both sides of an incompetent ring. The "bead ring" is a variation of this: One bead is permanently fixed to one end, and an opening is made by removing the free end of the ring. [54]

The most common reason for removal is infection. Other symptoms such as bleeding, edema, allergic reaction, and keloid formation may prompt removal. Occasionally, tongue piercings must be removed to permit intubation. In order to remove the barbell and labret type studs, one may hold the bar with forceps and unscrew the bead on the other end. To remove the captive bead ring, hold the ring on both sides of the captive bead to release the tension on the bead. This will dislodge the bead from the ring, which is holding it in place. If the jewelry is near the mouth or nose, care must be taken to prevent aspiration of the bead. The microbiology of infections related to body piercing has not yet been determined. However, organisms such as *Staphylococcus epidermidis* and *S. aureus*, along with *Pseudomonas aeruginosa*, have been commonly implicated pathogens. Other infectious complications from body piercing such as septic arthritis, endocarditis, hepatitis B and C, and HIV have been reported. [55] [56]

Most commonly, however, local wound infections predominate and can be managed with warm compresses, antibacterial soap, and topical antibacterial ointment once the FB is removed.

Postoperative Foreign Bodies

FBs in the form of non-absorbed suture material are frequently encountered in the postoperative period. Drainage, localized pain, tenderness, and inflammatory reaction along the suture line are characteristic of a retained FB (suture abscess). In this instance, probing the wound with a sterilized needle bent in the shape of a crochet hook is frequently successful. Hooking the suture material through the sinus tract and removing it allows the wound to heal over the tract.

Ring Removal

Frequently, a ring must be removed to prevent laceration of tissue or vascular compromise. The use of thorough lubrication (a water-soluble lubricant [e.g., K-Y jelly]) and a circular motion with traction on the ring are usually sufficient. However, the string-wrap method or physically cutting off the ring may be necessary. Preferably, all rings should be removed before edema is extensive enough to cause pain or vascular compromise.

String-wrap method.

An occasional patient can remain calm during this procedure, but if swelling is significant or the digit has been traumatized, anesthesia is necessary (Fig. 37-22 Fig. 37-22). A proximal digital or metacarpal block provides sufficient anesthesia and helps to minimize tissue distention at the ring site. Before ring removal, a wide Penrose drain is wrapped circumferentially in a distal-to-proximal direction to reduce soft tissue swelling, and the wrap should remain in place for a few minutes to reach the maximum effect. Some non-anesthetized patients panic during the procedure because of increasing pain due to compression and unwinding. [57]

A 20- to 25-inch piece of string, umbilical tape, or thick silk suture is first passed between the ring and finger. Shorter lengths are discouraged, as one may need to repeat the wrapping procedure midway. If there is marked soft tissue swelling, the tip of a hemostat may be passed under the ring to grasp the string and pull it through. The distal string is wrapped clockwise around the swollen finger (proximal to distal) to include the proximal interphalangeal (PIP) joint and the entire swollen finger. The wrapping starts next to the ring. The wrap should be snug enough to compress the swollen tissue. Successive loops of wrap are placed next to each other to keep any swollen tissue from bulging between the strands. When the wrapping is complete, the proximal end of the string is carefully unwound in the same clockwise direction, forcing the ring over that portion of the finger that has been compressed by the wrap. The PIP joint is the area that is most difficult to maneuver and causes the most pain to the patient.

Occasionally, the finger must be rewrapped if it was not carefully done initially. It is not uncommon to produce abrasions or other trauma to the skin during this procedure. If the finger with the ring is lacerated or there are underlying fractures, it is prudent to cut off the ring instead of attempting this technique.

Another alternative uses an entire skein of 2-0 surgical silk ties instead of a single piece of string. The procedure is the same. The ties are passed underneath the ring with a hemostat. The short ends of the ties are clamped with a hemostat on the hand side of the ring. The long end of the skein is wrapped around the finger and then unwound from the short end, as described earlier. This method may be less traumatic to the finger than a single piece of string. [58]

Certain rings are made of extremely hard materials such as tungsten carbide or ceramic. In these cases, cracking the material with standard vice grip pliers can break

the ring. Place the pliers on the ring and adjust the jaws to fit tightly, then remove and readjust, increasing the tension with each subsequent adjustment. Continue until the material cracks and falls apart. Some rings may be lined with a metal band. A standard ring cutter can then be used to remove the band.

Ring cutter.

A ring cutter should be used when there is excessive swelling or other methods fail. Manual and power devices are available. The ring cutter has a small hook that fits under the ring and serves as a guide for a saw-toothed wheel that cuts the metal. The cut ends of the ring are spread using large hemostats (e.g., Kelly clamps), and the ring is removed. If the tension is too great to spread the ring, another cut 180° apart from the original ring cut can be performed. This will allow the ring to fall off in two pieces. A jeweler can subsequently repair cut rings.

Tick Removal

The early removal of ticks is recommended, since the hard tick of the ixodid family is likely to transmit disease. Rocky Mountain spotted fever, Lyme disease, tularemia, and ascending paralysis have been identified as tick-borne diseases. It is important to note that the rate of disease transmission before 48 hours of attachment is exceedingly small.[59] Tick removal of Ixodid ticks is difficult, because the mouthparts become cemented within 5 to 30 minutes of contact with the host's skin (Fig. 37-23*A*). Removal will become more difficult the longer the tick is attached. Inadequate or partial removal of the entire tick may cause infection or chronic granuloma infection. Traditional and folk methods of forcing the tick to disengage (e.g., the use of petroleum jelly, fingernail polish, a hot match, or alcohol) are not advised. Removal

Figure 37-22a String removal technique for a tight ring. Note the absence of a laceration or underlying fracture *(A)*. A digital or metacarpal block is suggested. Edema is lessened by compression of the finger with a Penrose drain *(B)*. A long piece of umbilical tape is placed under the ring with the winding portion left long *(C)*.

by mechanical means is recommended.[60] Nonmechanical means of tick removal can cause the tick to regurgitate, increasing the possibility of infectious transmission.

Straight or curved forceps or tweezers is the recommended method of removal. If these instruments are not available, a gloved hand will suffice. Grasp the tick as close to the patient's skin surface as possible and gently apply steady axial traction (Fig. 37-23*B*). Take care not to squeeze or crush the tick body as this may expel infective agents. Do not twist or jerk the tick in order to prevent the mouthparts from breaking off during extraction. If mouthparts are left behind after removal of the body, they may be removed with tweezers. If one is still unable to remove the mouthparts, excision under local anesthesia will be needed to prevent local infection.

Many patients have great anxiety over subsequent tick-borne diseases following tick removal. Recent work has demonstrated that single-dose doxycycline (200 mg) may prevent the development of Lyme disease.[59] However, it is still not reasonable to treat all patients. When patients are in areas where the incidence of Lyme disease is high, or when a partially engorged deer tick in the nymphal stage is discovered on them, they are more likely to benefit from prophylaxis. Regardless of whether prophylaxis is given, patients should be instructed on the symptoms and signs of Lyme disease and encouraged to return or seek medical evaluation.

Zipper Injuries

The skin of the penis may become painfully entangled in a zipper mechanism. Unzipping the zipper frequently lacerates the skin and increases the amount of tissue caught in the mechanism. Although the clinician may anesthetize the skin and excise the entrapped tissue, a less invasive method may be useful.

Cutting the median bar between the faceplates of the zipper mechanism remains the most common method. The interlocking teeth of the zipper then fall apart when the median bar (diamond or bridge) of the zipper is cut in half (Fig. 37-24 (Figure Not Available)) and the skin is subsequently freed. A bone cutter or wire clippers and a moderate amount of force may be required to break the bar. The addition of mineral oil followed by traction has been demonstrated with some success. Patients with penile lacerations warrant urologic follow-up to assess for urethral injury.

Hair-Thread Tourniquet

Hair or thread fibers adherent to infant clothing occasionally become tightly wrapped around a child's digits or genitals (Fig. 37-25).[61] If these are left in place, amputation may eventually occur. The offending fibers may be difficult to visualize, and the child is often brought for evaluation only after signs of distal ischemia appear. Occasionally, the fiber can be grasped with toothless forceps or a small hemostat and unwrapped. More commonly, fibers cannot be identified because they are deeply embedded in swollen tissue.

Figure 37-22b Begin winding either clockwise (*inset*) or counterclockwise (*photograph*) to compress the skin *(D) (see details in inset)*. The ring is removed by unwrapping the tape proximally and in the same direction it was wrapped *(E* and *F)*. The most difficult area to negotiate is the proximal interphalangeal joint. Note abrasion of skin after removal.

A No. 11 blade can be used to cut the constricting bands under a regional nerve block. [62] It may be difficult to identify individual hairs that are deeply embedded in a swollen digit and even more difficult to assess the success of the intervention. Often, multiple hairs are involved. Because the bands may be quite deep, the incision should avoid known neurovascular tracts. Barton and colleagues recommend a dorsal, rather than lateral, incision on the digits. [62] If the soft tissue of the distal digit has been rotated following a circumferential dermal laceration from the tourniquet, the distal tissue can be realigned with the proximal tissue and two dorsolateral sutures placed or tissue adhesive glue applied to maintain the digit in alignment.

Generally, conservative wound care is sufficient once the band has been removed. Application of an antibiotic ointment may enhance healing and allow easier removal of serous drainage from the circumferential laceration. Clinical reassessment in 24 hours will indicate whether any constricting bands remain.

Acknowledgment

The authors wish to acknowledge Gail S. Rudnitsky and Richard C. Barnett who authored this chapter in the previous editions.

Figure 37-23 Ticks should be removed as soon as possible to minimize the transmission of tick-borne pathogens and to limit their fixation to the skin by a secreted cement compound. This engorged tick has been attached for about a day *(A)* and has burrowed under the skin. Most home remedies are worthless. A recommended approach is to grasp the tick with forceps near its head *(B)* where it enters the skin (avoid the soft body) and gently pull it out. Some advise twisting the head counterclockwise, but this has not objectively been found to be more effective. If pieces of the tick remain, they should be dug out.

Figure 37-24 (Figure Not Available) When loose skin is caught in the teeth of a zipper (*A*) one can release it quickly and without risk to the patient by cutting the diamond that holds the slider together with a bone cutter or a pair of wire clippers. *B, C,* Alternatively, the zipper teeth can be separated by cutting the cloth between the teeth, either above or below the zipper head. The head is then moved forward or backward. Local anesthesia may be injected in to the incarcerated skin if this procedure is painful. *(From Emergency Medicine, October 15, 1982, p. 215. Used by permission.)*

Figure 37-25 This child has multiple hairs compromising the circulation to two toes. The hairs are deeply embedded in the skin creases and cannot be visualized. The only way to ensure removal of the constriction is to cut the depth of the folds with a scalpel blade (using a dorsal incision to avoid the neurovascular bundle) and attempt to extricate individual fibers. Return of circulation should be obvious by temperature and color change in the affected digit(s), before it is assumed that all of the fibers have been cut.

Chapter 38 - Incision and Drainage

Kenneth H. Butler

Incision and drainage in the emergency department (ED) is most commonly done for soft tissue abscesses. Similar techniques are used for foreign body excision (see Chapter 37) or drainage of hematomas or seromas. The latter topic is discussed at the end of this chapter.

Much of this chapter deals with cutaneous abscesses, which account for 1% to 2% of ED visits. In contrast to most bacterial diseases, which are usually described in terms of their etiologic agent, cutaneous abscesses are best described in terms of their location. There has been little systematic investigation into the bacteriology of simple cutaneous abscesses, and there have been few new recommendations for improved management over the years. The probable reason for this lack of scientific rigor is the predictable and striking clinical recovery once a mature abscess is incised and drained. The exact reasons for this amelioration of local and constitutional symptoms are unknown; however, it is clear that the exact bacteriology of cutaneous abscesses, while academically interesting, is essentially inconsequential to the final outcome in most cases.[3]

ABSCESS ETIOLOGY AND PATHOGENESIS

Localized pyogenic infections may develop in any region of the body and usually are initiated by a breakdown in the normal epidermal defense mechanisms, with subsequent tissue invasion by normal resident flora. Thus, an abscess is likely to be caused by the flora that are indigenous to that area. An exception is direct inoculation of extraneous organisms, such as infections that follow mammalian bites.

Staphylococcal strains, which are normally found on the skin, produce rapid necrosis, early suppuration, and localized infections with large amounts of creamy yellow pus. This is the presentation of a typical abscess. Group A ß-hemolytic streptococcal infections, on the other hand, tend to spread through tissues, causing a more generalized infection characterized by erythema and edema, a serous exudate, and little or no necrosis. This is the presentation of a typical cellulitis. Anaerobic bacteria proliferate in the oral and perineal regions, produce necrosis with profuse brownish, foul-smelling pus [3] , and may cause both abscess and cellulitis.

Normal skin is extremely resistant to bacterial invasion, and few organisms are capable of penetrating the intact epidermis. In the normal host with intact skin, the topical application of even very high concentrations of pathogenic bacteria does not result in infection. The requirements for infection include a high concentration of pathogenic organisms, such as occurs in the hair follicles and their adnexa; occlusion, which prevents desquamation and normal drainage, thus creating a moist environment; adequate nutrients; and trauma to the corneal layer, which allows organisms to penetrate. [4] Trauma may be the result of abrasions, hematoma, injection of chemical irritants, incision, or occlusive dressings that cause maceration of the skin. Foreign bodies can also potentiate these infections and decrease the number of bacteria necessary for infection. An example of this is the ubiquitous suture abscess, which frequently develops in otherwise clean wounds closed with suture material. In recent years, body piercing has become a widespread fashion trend in western industrialized countries. Unfortunately, this body art is not without complication. The invasive application of ornaments through cutaneous and mucosal surfaces allows the penetration of various pathogens into subcutaneous (SQ) tissue.[5]

When favorable factors are present, normal flora of cutaneous areas can then colonize and infect the skin. The body area involved depends primarily on host factors. In persons performing manual labor, the arms and the hands are infected most frequently. In women, the axilla and submammary regions are frequently infected because of minor trauma from shaving and garments and because of the abundance of bacteria in these areas. IV drug users may develop infections anywhere on the body, although the upper extremities are most commonly affected.[6] [7] Deep soft tissue abscesses have also been described following attempts at access to the deep venous structures in addicts who have exhausted all peripheral venous access sites. [8] In addition, areas with compromised blood supply will be more prone to infection, because normal host cell-mediated immunity is not as available. [4] Septic emboli from endocarditis may cause abscess formation by bacteremic migration of infected material into SQ tissue.

Infections in the soft tissue often begin as a cellulitis. Some organisms cause necrosis, liquefaction, and accumulation of leukocytes and debris, followed by loculation and walling off of pus, all of which result in the formation of one or more abscesses. There may be involvement of the lymph tissues, producing lymphangitis and subsequent bacteremia. As the process progresses, the area of liquefaction increases until it "points" and eventually ruptures into the area of least resistance. This may be toward the skin or the mucous membrane, into surrounding tissue, or into a body cavity. If the abscess is particularly deep-seated, spontaneous drainage may occur, with persistence of a fistulous tract and the formation of a chronic draining sinus. This development, or the recurrence of an abscess that has been previously drained, should always suggest the possibility of osteomyelitis, a retained foreign body (FB), or the presence of unusual organisms such as *Mycobacterium* or *Actinomyces*.[3]

Bacteriology of Cutaneous Abscesses

Meislin and coworkers[1] cultured abscesses in 135 patients, and their report typifies the bacteriology and natural history of cutaneous abscesses. Their patients received simple incision and drainage, and all subjects were followed as outpatients. Both aerobic and anaerobic cultures were taken. Most (96%) cultures were positive for bacteria (Table 38-1).

In this series predominantly mixed aerobic bacteria were isolated in abscesses of the trunk, axilla, extremities, and the hand. In pure cultures, *Staphylococcus aureus* was found in 72% of cases. One third of the cultures from the perianal region contained only anaerobes. Mixed cultures of both aerobic and anaerobic bacteria were obtained from all sites of the body, but there was a 67% incidence of such mixed cultures from the perirectal area. Commonly isolated anaerobes included various *Bacteroides* spp, peptococci, peptostreptococci, *Clostridium* spp, *Lactobacillus* spp, and *Fusobacterium* spp.

TABLE 38-1 -- Characterization of 135 Outpatient Abscesses*

			Type of Bacterial Growth (Percent from Each Area)				Bacterial Species per Abscess*	
Anatomic areas	***Abscesses***	***Percent of total cultures***	***No growth***	***Aerobes only***	***Anaerobes only***	***Aerobes and anaerobes***	***Aerobes***	***Anaerobes***

From Meislin HW, Lerner SA, Graves MH, et al: Cutaneous abscesses: Anaerobic and aerobic bacteriology and outpatient management. Ann Intern Med 87:146, 1977. Reproduced with permission.

*Cultures with no growth were excluded.

Bacteria from abscesses in areas remote from the rectum were generally aerobic strains and were primarily indigenous microflora of the skin. *S. aureus* was the most prevalent aerobic organism; it was isolated in 24% of all abscesses.

Gram-negative aerobes were isolated infrequently from cutaneous abscesses. *Escherichia coli, Neisseria gonorrhoeae,* and *Pseudomonas* spp were rarely found. The most commonly isolated gram-negative organism was *Proteus mirabilis*. This organism was found almost exclusively in the axilla, and its presence may be related to

the use of underarm deodorants.[9]

Brook and Finegold[10] studied the bacteriology of cutaneous abscesses in children. Their results closely correlate with those of Meislin and associates.[1] Brook and Finegold found aerobes (staphylococci and group A ß-hemolytic streptococci) to be the most common isolates from abscesses of the head, neck, extremities, and trunk, with anaerobes predominating in abscesses of the buttocks and perirectal sites. Mixed aerobic and anaerobic flora were found in the perirectal area, head, fingers, and nailbed area. This study found an unexpectedly high incidence of anaerobes in nonperineal abscesses. Anaerobes were found primarily either in areas adjacent to mucosal membranes, where these organisms tend to thrive (e.g., the mouth), or in areas that are easily contaminated (e.g., by sucking fingers, which causes nailbed and finger infections or bite injuries).

Parenteral drug users develop somewhat atypical abscesses. The injection of a cocaine/heroin mixture ("speedball") may predispose users to abscesses by inducing soft-tissue ischemia.[11] Webb and Thadepalli[12] found anaerobes to be a major pathogen, regardless of anatomic location. After comparing the bacteriology of abscesses in intravenous (IV) drug abuser and non-drug-users, Summanen and colleagues[13] reported isolates of oral origin in 67% and 25%, respectively. Some injection drug users lick their needles prior to injection for "lubrication", perhaps accounting for the presence of unusual oral pathogens as *Eikenella corrodens*. Schnall and associates[14] found that skin abscesses at the site of injection contain predominantly staphylococcal and streptococcal species. Four of the 20 staphylococcal isolates were oxacillin-resistant. Anaerobes and gramnegative bacilli accounted for 24% of the isolates. Because IV drug use is associated with immunodeficiency syndromes, unusual isolates such as *Candida albicans*[15] and acid-fast bacilli[16] [17] have been obtained.

The polymicrobial nature of abscesses does not lend itself to a strict scientific interpretation of culture results, but if an unexpected or atypical organism is found in an abscess culture, the clinician should consider an underlying process not readily apparent from the history or physical examination. Most typical is finding tuberculosis or fungal isolates in immunocompromised patients (e.g., those with diabetes or acquired immunodeficiency syndrome [AIDS]). Finding *E. coli* suggests an enteric fistula or even self-inoculation of feces in some patients with a psychiatric illness such as Munchausen syndrome. Recurrent abscesses without an obvious underlying cause could indicate clandestine drug use ("skin popping"). What appears to be a typical recurrent abscess may be a manifestation of an underlying septic joint or, rarely, metastatic or primary cancer (Fig. 38-1).

Special Considerations

Parenteral drug users, insulin-dependent diabetics, hemodialysis patients, cancer patients, transplant recipients, and individuals with acute leukemias have an increased frequency of abscess formation compared with the general population. Local symptoms may not be the primary complaint, and the patient may present only with an exacerbation of the underlying disease process or an unexplained fever. These abscesses tend to have exotic or uncommon bacteriologic or fungal causes and typically respond poorly to therapy.[12] [14] [15] [16] The diabetic patient with diabetes-induced ketoacidosis should be evaluated extensively for an infectious process; a rectal examination should be included with the physical examination to rule out a perirectal abscess. This also holds true for other patients with abnormal cell-mediated immunity. The increased frequency of abscess formation in these patients and in the parenteral drug user is multifactorial. There may be intrinsic immune deficiencies in all these patients; they have an increased incidence of *Staphylococcus* carriage, and they have frequent needle punctures, which allow access by pathogenic bacteria.[18]

It is important to note that a substantial percentage of abscesses in parenteral drug users are sterile and are the result of the injection of necrotizing chemical irritants. Drug users frequently use veins of the neck and the femoral areas, producing abscesses and other infectious complications at these sites.[19] Any abscess near a vein of the antecubital fossa or dorsum of the hand should alert the clinician to possible IV drug use; however, substance users may also inject directly

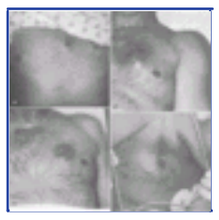

Figure 38-1 An abscess that appears in an atypical place or recurs after initial treatment is successful should raise the possibility of rare or underlying conditions. *A*, This IV drug user had an "abscess" of the chest wall drained in various EDs several times over a 2-month period, and it seemed to initially respond to drainage and antibiotics. He still manifested an area of cellulitis, minor fluctuance, and continued drainage near the center of the chest. This is an atypical place for a simple cutaneous abscess. Magnetic resonance imaging demonstrated an abscess of the sternolclavicular joint that was draining to the skin, simulating a recurrent cutaneous abscess. He required extensive surgical debridement and prolonged antibiotics. The etiologic organism was never ascertained, but pseudomonas is often present. *B*, This patient has a large "abscess" of the lateral chest wall that initially drained unusual gelatinous material, not frank pus. *C*, At follow-up 3 days later the abscess was much improved. The contents of the abscess had been sent for pathologic analysis since it had an unusual consistency, and it demonstrated a highly undifferentiated malignancy. The fluid was sterile. Normally, analyzing or culturing the contents of an abscess will not yield helpful information, but in this case the unusual consistency of the collection prompted further analysis. *D*, This patient had a sternotomy for bypass surgery a few months ago. She had been sporadically treated for a minor wound infection but then presented with a draining fluctuant mass at the inferior border of the sternum. This is the external manifestation of an extensive sternal osteomyelitis.

into the skin ("skin popping"), causing cutaneous abscesses away from veins (Fig. 38-2).

The presence of a FB may serve as a nidus for abscess formation. A history of a possible FB at the site of an abscess should be sought. Because IV drug users frequently break needles off in skin toughened by multiple injections, the clinician should maintain a high index of suspicion for retained needle fragments. If an abscess is recurrent or if the patient is a known or suspected IV drug user, radiographs or other techniques should be considered to search for foreign bodies, an underlying septic joint, or osteomyelitis.[20]

MANIFESTATIONS OF ABSCESS FORMATION

The diagnosis of cutaneous abscess formation is usually straightforward. The presence of a fluctuant mass in an area of induration, erythema, and tenderness is clinical evidence that an abscess exists. An abscess may appear initially as a definite tender soft tissue mass, but in some cases the presence of a distinct abscess may not be readily evident. If the abscess is quite deep, as is true of many perirectal, pilonidal, or breast abscesses, the clinician may be misled by the presence of only

Figure 38-2 This patient presented with a large abscess of the deltoid area (arrow) and could offer no explanation for it *(A)*. This is a typical scenario for a drug user who injects directly into the skin, and the characteristic circular skin lesion from "skin popping" found on the legs *(B)* confirmed the clinical suspicion. Even though a drug screen was positive for opioids, the patient still denied drug use and attributed the leg lesions to frequent trauma on the job.

a firm, tender, indurated area without a definite mass. To avoid misdiagnosis of an early abscess, one may aspirate the suspicious infected area with a needle and syringe to confirm the presence of pus.[21] This approach also may help identify a mycotic aneurysm or an inflamed lymph node simulating an abscess. A specific entity that is commonly mistaken for a discrete abscess is the sublingual cellulitis of Ludwig angina (see Chapter 66). Parenteral injection of illicit drugs can produce signs of simple cutaneous abscesses that unpredictably advance to extensive necrotizing soft-tissue infections. The emergency clinician must maintain a high index of suspicion to avoid missing this potentially serious condition.[22] Cellulitis and abscess formation may lead to bacteremia and sepsis, especially in the immunocompromised patient, and the presenting complaints may draw attention away from the primary focus of infection.[12]

The pain of an abscess often brings the patient to the hospital prior to spontaneous rupture. Often, however, the patient will present with a draining abscess that appears to have undergone spontaneous rupture and is manifesting a self cure. Also, the patient may have punctured the abscess in an attempt to drain it. In most cases a formal incision, drainage, and packing procedure will be helpful in eliminating the process, even though copious drainage will not be encountered. While no formal drainage may be required following the spontaneous rupture of simple cutaneous abscess, such conditions as a perirectal abscess, Bartholin gland abscess, or breast abscess often will be best served by further drainage and packing.

LABORATORY FINDINGS

Laboratory tests offer no specific guidelines for therapy of a cutaneous abscess and are not generally indicated.

An exception would be a blood or urine glucose determination to assess diabetes in patients with appropriate clinical scenarios. An abscess may produce leukocytosis, depending on the severity and duration of the abscess process; however, the majority of patients with an uncomplicated cutaneous abscess will have a normal complete blood cell (CBC) count and will not experience fever, chills, or malaise. *The presence or absence of leukocytosis has virtually no diagnostic or therapeutic implications.* In the absence of extenuating circumstances, it is not standard to send blood cultures on patients with typical cutaneous abscesses. Bacteremia may occasionally manifest a peripheral abscess from septic emboli, but this usually produces clinical characteristics that are dissimilar to cutaneous abscesses. The cutaneous abscess itself rarely produces the bacteremia.

Gram stain is not indicated in the care of uncomplicated simple abscesses.

Patients who appear "toxic" or immunocompromised and those patients who require prophylactic antibiotics (see Prophylactic Antibiotics later in this chapter) may rarely benefit from Gram stain and cultures. Gram stain results have been shown to correlate well with subsequent culture results, and in compromised hosts the test can be used to direct antibiotic choice. [21] [23] Anaerobic infections should be suspected when multiple organisms are noted on Gram

stain, when a foul odor is associated with the pus, when free air is noted on radiographs of the soft tissue, or when no growth is reported on cultures. [12]

In uncomplicated abscesses, *routine culture of pus is unnecessary* because of the expected prompt response to surgical therapy and the polymicrobial nature of abscess formation. However, in complicated cases; recurrent, unusual, or atypical abscesses; or in immunosuppressed patients, additional information may be gleaned if the abscess contents are sent for culture. The information obtained may later be useful if there is poor response to the initial surgical drainage, secondary spread of the infection, or the occurrence of bacteremia. [3] If one takes a culture, it is best to aspirate the pus with a needle and syringe *before* incision and drainage. Material should be cultured for aerobic and anaerobic bacteria. The finding of a "sterile" culture in an abscess that has been cultured with a standard cotton swab *after* incision is frequently the result of improper anaerobic culture techniques. As a side note, there is a general misconception that foul-smelling pus is a result of *E. coli*. This foul odor is actually caused by the presence of anaerobes; the pus of *E. coli* is odorless.

Unusual material from an abscess may prompt additional laboratory investigation. Occasionally a malignancy may mimic a cutaneous abscess (see Fig. 38-1*B, C*).

INDICATIONS AND CONTRAINDICATIONS

Surgical incision and drainage is the *definitive treatment* of a soft tissue abscess.[21] Antibiotics alone are *ineffective* in the setting of a localized cutaneous collection of pus. The drainage of a suppurative focus results in a marked improvement in symptoms and rapid resolution of the infection in uncomplicated cases. In the initial stages, only induration and inflammation of an area later destined to produce an abscess may be found. Premature incision before localization of pus will not be curative and theoretically may be deleterious, because extension of the infectious process and, rarely, bacteremia from manipulation can result. In some cases the application of heat to an area of inflammation may ease pain, speed resolution of the cellulitis, and facilitate the localization and accumulation of pus. It must be stressed that nonsurgical methods are not a substitute for surgical drainage and should not be continued for more than 24 to 36 hours before the patient is reevaluated. Diagnostic needle aspiration is recommended if one is unsure of pus localization.

ED bedside ultrasound can play a key role in the management of soft-tissue infections. It is an easily accessible image modality that can be used after plain radiographs have been obtained. Ultrasound offers a safe, real-time, convenient technique guiding needle aspiration of any suspicious fluid collection. [24] [25] ED ultrasound similarly can guide incisions in the setting of deep soft tissue infections (see Chapter 69).

ANCILLARY ANTIBIOTIC THERAPY

The use of antibiotics remains unproven for both prophylaxis and treatment of cutaneous abscesses. As an overview, there are no data that definitively demonstrate the need for antibiotic therapy in conjunction with incision and drainage of uncomplicated cutaneous abscesses in healthy, immunocompetent patients without valvular heart disease. The common practice of prescribing antibiotics if there is "significant surrounding cellulitis" is a vague concept that is not easily quantified, and is not supported by prospective data. The specific value of concomitant antibiotics in the immunocompromised patient, while intuitively attractive and commonly practiced, is also unproven. If antibiotics are prescribed, they should likely be given for 2 to 3 days only, and their continuation reassessed at the first follow-up visit. Since the bacteriology of abscess is complicated and multifactorial, no single specific antibiotic can be prospectively supported. Most clinicians use antibiotics that are generally effective for "soft tissue infections," but this concept is vague and frustrating to the clinician. While antibiotics are usually not harmful, the editors do not recommend the routine use of antibiotics for simple cutaneous abscesses unless there are extenuating circumstances. Unfortunately those circumstances are not clearly defined by scientific literature and remain in the realm of clinical judgment.

Patients with risk factors for endocarditis comprise a third group of patients. Because of the concern of inducing a bacteremia by manipulation of infected tissue, parenteral antibiotics are commonly given *prior to the incision-and-drainage procedure* in patients at risk from such bacteremia. Transient bacteremia has been documented (incidence range, 7% to 50%) following manipulation of noninfected tissue (brushing teeth, sigmoidoscopy, Foley catheter, rectal examination) and following simple incision and drainage of abscesses. While common, the clinical importance of transient bacteremia is uncertain. In a report by Fine and colleagues, 6 of 10 patients with cutaneous abscesses were noted to have positive blood cultures immediately following incision and drainage, whereas all cultures were negative before the procedure. [26] Blick and associates[27] evaluated the use of prophylactic antibiotics in abscesses managed in the operating room under general anesthesia. Three of 19 patients developed bacteremia after the procedure. A similar group treated with parenteral antibiotics before the procedure had only one patient with a positive blood culture. That culture yielded an organism resistant to the prophylactic antibiotic used.

Prophylactic Antibiotics

Prophylaxis for Endocarditis

The precise risk for endocarditis following incision and drainage of cutaneous abscess is unknown, and it is impossible to predict which patients will develop this infection or which particular procedure will be responsible. However, since bacteremia clearly occurs with manipulation of infected tissue, it is generally agreed that those patients at risk for cardiac complications related to transient bacteremia should be treated with appropriate antibiotics within the hour preceding the procedure. The transient bacteremia secondary to abscess drainage is of no proven concern in otherwise healthy, immunocompetent individuals without valvular heart disease. Bobrow and associates[28] demonstrated that incision and drainage of cutaneous abscesses in afebrile patients is unlikely to result in transient bacteremia.

No adequate controlled trials of antibiotic regimens appear in the literature, and data predicting the incidence of endocarditis in patients with preexisting cardiac disorders are lacking, thereby making the decision regarding antibiotic prophylaxis quite arbitrary. Although no definitive standards exist, the Committee on Rheumatic Fever and

Infective Endocarditis of the American Heart Association (AHA) has recommended that prophylactic antibiotics be given prior to incision and drainage of infected tissue in patients who have *cardiac lesions that place them at high risk for developing endocarditis*.[29] Table 38-2 (Table Not Available) lists conditions that may warrant antibiotic coverage. Durack also recommends prophylactic antibiotics for a variety of procedures known to have a significant incidence of bacteremia, including incision and drainage of cutaneous abscesses. [30] Interestingly, the antibiotic regimen suggested by the AHA (Table 38-3) does not include antibiotics effective against many organisms commonly found in some cutaneous abscesses, specifically *S. aureus*, but is mainly directed against *Streptococcus viridans* and enterococcus. These latter organisms have a predilection for valvular infection. The AHA recommends the same prophylaxis for incision of soft tissue infection that is recommended for genitourinary procedures, but with additional consideration of therapy "directed against the most likely pathogen." [31]

Two clinical situations deserve special note. Because of the frequent incidence of pre-existing valvular damage in the patient who uses IV drugs, prophylactic antibiotics may be indicated prior to the incision and drainage of abscesses in these patients. Clearly, any patient with a documented history of endocarditis must receive prophylactic antibiotics prior to the incision-and-drainage procedure. Because cutaneous abscesses may result from active endocarditis and prophylactic antibiotics may obscure subsequent attempts at identifying an etiologic organism, two or three blood cultures (aerobic and anaerobic) should be obtained from those at risk for endocarditis prior to antibiotic therapy. Patients with the diagnosis of mitral valve prolapse have traditionally been included for treatment with prophylactic antibiotics. The indication for this is unclear. The risk of an allergic reaction may outweigh the benefits of treatment in this group, [32] and clinical judgment is required. Kaye[33] suggests prophylaxis only for patients who have a holosystolic murmur secondary to mitral valve prolapse.

TABLE 38-2 -- Estimated Risk of Infective Endocarditis Associated with Bacteremia in the Presence of Preexisting Cardiac Disorders

(Not Available)

Prophylaxis for Bacteremia in Other Conditions

Immunocompromised patients have not been adequately studied, but this is a subgroup that intuitively may benefit from prophylactic antibiotics. In contrast to patients with endocarditis risks, immunocompromised patients are at risk for developing septicemia secondary to a brief bacteremia. Since IV drug users have a high incidence of human immunodeficiency virus (HIV)-related disease,[34] [35] [36] the treating clinician must anticipate various degrees of immunodeficiency in these patients. Clinical judgment must determine the use of antibiotics in these situations.

No specific guidelines have been offered for the antibiotic regimen used prior to incision and drainage of infected cutaneous tissue in patients at risk for conditions *other than endocarditis*. Choice of antibiotics is guided by the organism anticipated to cause the bacteremia. Although the location of the abscess will give some clue to the organism involved, most abscesses contain multiple strains of bacteria. Not all bacteria are potent pathogens, so their mere presence does not predict their role in subsequent morbidity. Because *Staphylococcus* continues to be a significant organism in this setting, a broad-spectrum anti-staphylococcal drug is indicated. [6] Prophylaxis should consist of a single IV dose given a half-hour prior to incision and drainage. A first-generation cephalosporin or penicillinase-resistant penicillin is a good initial choice. Vancomycin may also be considered. Others may prefer cefazolin (Ancef, Kefzol), 1 g, IV, given a half-hour before surgery. This regimen covers staphylococcal and streptococcal species, many gram-negative organisms, and many anaerobes.

Although not widely used in the United States, parenteral antibiotics have been used to "sterilize" the abscess cavity following curettage in Great Britain. The concentration of clindamycin in the abscess cavity has been shown to be equivalent to the concentration of antibiotics found in the blood. [27] Some British articles reported success with "primary closure under antibiotic coverage," [37] [38] [39] although other British reports

TABLE 38-3 -- Prevention of Bacterial Endocarditis: Regimens for Genitourinary/Gastrointestinal Procedures [*]

Drug	Dosing Regimen[†]
Standard Regimen	
Ampicillin, gentamicin, and amoxicillin	IV or IM administration of ampicillin, 2 g, plus gentamicin, 1.5 mg/kg (not to exceed 80 mg), 30 min before procedure; followed by amoxicillin, 1.5 g orally 6 hr after initial dose; alternatively, the parenteral regimen may be repeated once 8 hr after initial dose
Ampicillin/Amoxicillin/Penicillin—Allergic Patient Regimen	
Vancomycin and gentamicin	IV administration of vancomycin, 1 g, over 1 hr plus IV or IM administration of gentamicin, 1.5 mg/kg (not to exceed 80 mg), 1 hr before procedure; may be repeated once 8 hr after initial dose
Alternative Low-Risk Patient Regimen	
Amoxicillin	3 g orally 1 hr before procedure; then 1.5 g 6 hr after initial dose

From Dajani AS, et al: Prevention of bacterial endocarditis. Circulation 83:1174, 1991.

*In the case of abscess drainage, include antibiotics directed against most likely pathogen if not included in this regimen.
†Initial pediatric doses are as follows: ampicillin, 50 mg/kg; amoxicillin, 50 mg/kg; gentamicin, 2 mg/kg; and vancomycin, 20 mg/kg. Follow-up dose should be one half the initial dose. Total pediatric dose should not exceed total adult dose.

continue to recommend the traditional procedure.[40] [41] One limitation to the abscess curettage technique is the need for general anesthesia, because the performance of curettage is extremely painful.

Therapeutic Antibiotics

In contrast to prophylaxis prior to surgery, the routine use of oral antibiotics following incision and drainage of simple cutaneous abscesses in otherwise healthy patients with no immunocompromise appears to have no value, and their empiric use cannot be scientifically supported. Llera and Levy [2] performed a randomized double-blind study to compare outcomes of patients treated with a first-generation cephalosporin following drainage of cutaneous abscesses in the ED. They found no significant difference in clinical outcome between the two groups and concluded that antibiotics are unnecessary in individuals with normal host defenses. This confirmed previous less well controlled studies.[27] [39] [40] It should be noted that high-risk patients were often excluded from these studies. The immunocompromised patient has not been adequately studied in this situation and is therefore often given antibiotics empirically, but this practice, while common, has not been supported by rigorous prospective studies.

Patients with cutaneous abscesses often have concomitant disease processes that may warrant the consideration of parenteral or oral antibiotics. Most abscesses have a defined surrounding area of induration, but this may not necessarily qualify as "significant surrounding cellulitis." While cellulitis or lymphangitis often accompany abscesses, and therapeutic antibiotics may have value under these circumstances, this concept is difficult to quantify and not well addressed nor supported in the literature. Cellulitis and lymphangitis usually subside following the draining of the abscess itself. Meislin [42] noted that pathogen identification in cases of cellulitis without abscess can be difficult, and empiric antibiotics may be helpful. IV drug users who present with an abscess and fever require parenteral antibiotic therapy after blood cultures have been drawn until bacterial endocarditis can be ruled out.[43] Obviously, patients who are clinically septic require immediate IV antibiotics as well as aggressive surgical drainage of pus. By administering IV ampicillin/sulbactam (2 g/1 g) every 6 hours, Talan and colleagues [44] achieved 100% eradication of pathogens from major abscesses in hospitalized IV drug users and non-drug users.

As a general guideline, therapeutic antibiotics should be considered for immunocompromised patients (e.g., patients with AIDS or diabetes, patients receiving chemotherapy or steroids, transplant recipients, and alcoholic patients) and to the immunocompetent patient with "significant" cellulitis, lymphangitis, or systemic symptoms, such as chills or fever. Although it has not been studied, it makes sense to also give *antibiotics prophylactically, before surgery, to all patients who will obviously be given therapeutic antibiotics*. As with prophylactic antibiotics, a first-generation cephalosporin or semisynthetic penicillin is a reasonable therapeutic choice unless the specific abscess site dictates alternative therapy. The ideal duration of therapeutic antibiotics is unknown. As a general guideline, immunocompromised patients should receive antibiotics for 5 to 7 days and immunocompetent patients, for 3 to 5 days after the procedure, depending on the severity of the condition and clinical response at follow-up.

Facial abscesses should be handled carefully and checked frequently. Any abscess above the upper lip and below the brow may drain into the cavernous sinus, and thus manipulation may predispose to septic thrombophlebitis of this system. Treatment with antistaphylococcal antibiotics and warm soaks following incision and drainage has been recommended pending resolution of the process. Areas *not* in this zone of the face can be treated in a manner similar to that used for other cutaneous abscesses.

INCISION-AND-DRAINAGE PROCEDURE

Procedure Setting

Definitive incision and drainage of soft tissue abscesses are performed in either the ED or the operating room (OR). When abscesses are drained in the ED, some centers prefer to use a special area to avoid contamination of general treatment rooms.

The choice of the locale for the procedure depends on a number of important factors. The location of the abscess may dictate management in the OR. Large abscesses or abscesses located deep in the soft tissues require a procedure involving a great degree of patient cooperation, which may only be possible under general or regional anesthesia. Proximity to major neurovascular structures, such as in the axillae or antecubital fossa, may necessitate specific management. Infections of the hand (with the exception of distal finger infections) have traditionally been managed in the OR because of the many important structures involved and the propensity for limb-threatening complications.

Lack of adequate anesthesia is the most common limiting factor in ED incision and drainage. If the clinician believes the abscess cannot be fully incised and drained because of inadequate anesthesia, the patient should be taken to the OR for management under general anesthesia. In addition to limiting proper drainage, it is inhumane and unethical to subject a patient to extreme pain when alternatives are available.

Equipment and Anesthesia

A standard suture tray provides adequate instruments if a scalpel and packing material are added. Although sterility is impossible during the procedure, one should avoid contamination of surrounding tissue. Some clinicians prefer to use an obligatory skin scrub with an antiseptic solution, but the value of this step is dubious.

It is often quite difficult to obtain local anesthesia by direct infiltration because of the poor function of local anesthetic agents in the low pH of infected tissue. Furthermore, the distention of sensitive structures by a local injection is quite painful and hence poorly tolerated by most patients. Skin anesthesia is usually possible, but total anesthesia of the abscess cavity itself generally cannot be achieved. If a regional block can be performed (see Chapter 31 Chapter 32 Chapter 33), this type of anesthesia is preferred. Alternatively, a field block may be used. It should be noted that infected tissue is very vascular, and local anesthetics are quickly absorbed. Strict adherence to maximum safe doses of the local anesthetic is required.

The skin over the dome of an abscess is often quite thin, making skin anesthesia difficult. If a 25-ga needle is carefully used, one can often inject the dome of the abscess subcutaneously. The anesthetic solution spreads over the dome through the SQ layers into the surrounding skin and provides excellent skin anesthesia. If the needle is in the proper plane (best accomplished by holding the syringe parallel, rather than perpendicular, to the skin), the surrounding skin blanches symmetrically during infiltration without having to reposition the needle (Fig. 38-3*A*). In the extremely anxious or uncomfortable patient, the judicious use of preoperative sedation (see Chapter 34) with IV opioids and sedatives or nitrous oxide makes the procedure easier for both patient and clinician. If adequate anesthesia cannot be obtained and pain limits the procedure, the patient should be treated under general anesthesia.

Some clinicians recommend the use of topical ethyl chloride or Fluori-Methane spray for the initial skin incision, but while this is an attractive concept to patients, the pain relief offered by these agents is variable and fleeting. Ethyl chloride is also highly flammable. These vapocoolant sprays may be useful to provide momentary anesthesia for local anesthetic injection or for the initial skin incision if the injection or incision is made immediately after blanching of the skin. In general, however, these agents are a poor choice for a stand-alone anesthetic agent for all but the smallest of superficial abscesses (e.g., purulent folliculitis).

Incision

One should make all incisions conform with skin creases or natural folds to minimize visible scar formation (Fig. 38-4). Extreme care should be taken in such areas as the groin, the posterior knee, the antecubital fossa, and the neck, so that vascular and neural structures are not damaged.

A No. 11 or 15 scalpel blade is used to nick the skin over the fluctuant area, and then a simple linear incision is carried the *total length of the abscess cavity* (see Fig. 38-3*B*). This will afford more complete drainage and will facilitate subsequent breakup of loculations. Attempting to drain an abscess with an inadequate incision is counterproductive and makes packing changes more difficult. A cruciate or "X" incision, or an elliptical skin *excision* is to be avoided in the routine treatment of cutaneous abscess. The tips of the flaps of a cruciate incision may necrose, resulting in an unsightly scar (Fig. 38-5). A timid "stab" incision may produce pus but is generally not adequate for proper drainage. *The scalpel is used only to make the skin incision and is not used deep in the abscess cavity*.

Exceptions to this rule regarding aggressive incision are abscesses in cosmetic areas, in areas under significant skin tension (e.g., extensor surfaces), or in areas with extensive scar tissue (e.g., sites of multiple prior drainage procedures). In these special circumstances, a stab incision or simple aspiration alone may be initially attempted, with the goal of limiting tissue injury and resultant scar formation. Use of this less aggressive approach requires that the patient be counseled that multiple decompressions (e.g., via needle aspiration) or delayed aggressive incision and drainage may be required. The abscess will need reassessment in 24 to 48 hours to determine the need for additional intervention.

Wound Dissection

Following a standard incision, the operator should probe the depth of an abscess to assess the extent of the abscess and ensure proper drainage by breaking open loculations (see Fig. 38-3*D*). An ideal instrument for this procedure is a hemostat wrapped in gauze (or a cotton swab for small abscesses) that is placed into the abscess and swirled around to all sides of the cavity (see Fig. 38-3*E*). Traditionally the operator's gloved finger has been suggested as an ideal way to assess the depth of the abscess cavity and to break up loculations, but *this is a potentially dangerous practice that should be avoided* unless it is certain that the abscess contains no sharp foreign body. Of particular concern is the abscess caused by skin popping or IV drug use. Such patients have a high incidence of hepatitis and HIV infection, and occasionally these abscesses harbor broken-off needle fragments (Fig. 38-6). One is often surprised at the depth or extent of an abscess during probing. Sharp curettage of the abscess cavity is usually not required and may produce bacteremia. [27] Although tissue probing is usually the most painful aspect of the technique and total local anesthesia is difficult to obtain, this portion of the procedure should not be abbreviated. If the procedure is limited because

Figure 38-3 *A,* To anesthetize an abscess, hold the syringe parallel to the skin and insert a 25-ga needle into the middle of the dome of the abscess, so the needle is just slightly under the skin. The anesthetic will spread over the entire abscess without moving the needle position. *B*, Note the blanching of the skin that spreads to cover the entire abscess without repositioning the needle. *C,* The skin over the abscess is incised the full length of the abscess. A small stab incision does not allow for proper drainage. *D,* An instrument is inserted into the abscess cavity to spread the skin, drain the pus, and break up loculations. *E*, One way to break up loculations is to wrap a hemostat with gauze and, *F*, swirl it around the margins of the wound. *Do not use a gloved finger to*

break up loculations in an abscess that may contain a sharp or jagged foreign body.

of pain, the use of appropriate analgesia/anesthesia is mandated. Failing to adequately pack the abscess on the first visit makes follow-up packing changes more problematic.

Wound Irrigation

Following the breaking up of loculations, some clinicians advocate copious irrigation of the abscess cavity with normal saline to ensure adequate removal of debris from the wound cavity. Although it may seem intuitively to be a helpful step, irrigation of the abscess cavity has not been experimentally demonstrated to significantly augment healing or affect outcome. Hyperemic tissue may bleed profusely, but bleeding usually stops in a few minutes if packing is used. Abscesses of the extremities can be drained during the use of a tourniquet to provide a bloodless field.

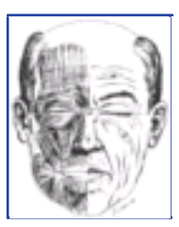

Figure 38-4 The relation of the elective lines of tension in the face to the underlying mimetic musculature. Only in the lower eyelid are these lines not perpendicular to the muscles. The left side of the drawing shows the use of this principle when common facial lesions are excised or a facial abscess is drained. *(From Schwartz SI, Lillehei RC: Principles of Surgery, 2nd ed. New York, McGraw-Hill, 1974. Reproduced with permission.)*

Packing and Dressing

After irrigation, a loose packing of gauze or other material is placed gently into the abscess cavity to prevent the wound margins from closing and to afford continued drainage of any exudative material that may otherwise be trapped. The packing material should make contact with the cavity wall so that upon removal, gentle debridement of necrotic tissue will spontaneously occur. A common error is to attempt to pack an abscess too tightly with excessive packing material. In essence, the pack merely keeps the incision open, and its main purpose is not to absorb all drainage—a dressing accomplishes this goal. Care must be exercised to ensure that the packing does not exert significant pressure against the exposed tissue and lead to further tissue necrosis. Some prefer to use plain gauze, some use gauze soaked in povidone-iodine, and some use gauze impregnated with iodine (iodoform). For large abscess cavities, gauze pads (without cotton backing) are ideal packing. *If gauze pads are used, the number of pads placed in the wound should be counted and charted—ideally, the corner of each pad should exit from the wound.* The clinician must ensure that all gauze pads will be removed when the packing is changed or discontinued. More commonly, thin (0.6 to 1.2 cm) packing strip gauze, either plain or iodoform, is used. The iodoform gauze may sting the patient for a few minutes after it is inserted. Packing, especially iodine-containing packing, will be radiopaque on a plain radiograph. If a FB is considered, the x-ray should be

Figure 38-5 A simple linear incision is preferred over an "X" or crosshatched incision. In this case, a cutaneous post-surgical scalp abscess was drained by an "X" incision and the tips of the flap necrosed, leaving a slowly healing full thickness wound.

obtained prior to packing. The value of antibiotic-impregnated gauze is uncertain.

An absorbent gauze dressing should be placed over the packed abscess, or, if an extremity is involved, a lightly wrapped circumferential dressing should be used. Generous amounts of dry gauze are used over the packing to soak up any drainage or blood. The affected part should be splinted if possible, and elevation should be routine. The dressing/splint should not be disturbed until the first follow-up visit. Drainage relieves most of the pain of an abscess, but postoperative analgesics may be required.

Following treatment, packing is often changed periodically. Most patients require a repeat visit to the clinician for packing change, but if the original packing is to be removed and not replaced (e.g., as with paronychia, hair follicle abscess), select patients may remove the packing and perform their own wound care totally at home.

FOLLOW-UP CARE

Reevaluation of a drained abscess should occur in 1 to 3 days, depending on a number of parameters. [21] [27] [40] Most lesions are reevaluated 48 hours following the procedure, with the first packing change occurring at this time. Some wounds warrant closer monitoring. Diabetic patients or other patients with impaired healing capacity, mental impairment, or physical disabilities may require a home care nurse or admission for more frequent wound care/packing changes. Wounds that are at high risk for complications, such as those about the face or hands or those with significant cellulitis, require close follow-up, ideally by the same examiner. The patient should be encouraged to play an active role in wound care. During the first follow-up visit, the compliant and able patient should be taught to perform packing or dressing changes, or both. If this is anatomically impossible, a friend or family member can be instructed in the technique.

Figure 38-6 *A,* This intravenous drug user presented with an abscess *(arrow)* of the antecubital fossa. Following incision, the clinician attempted to break up the loculations with his finger. When a radiograph was obtained, three needle fragments (arrows) were found embedded in the wound *(B).* The patient was HIV-positive and claimed no knowledge of the presence of the needles. Instead of using a finger, loculations should be broken up with an instrument.

The technique of packing change is usually one of personal preference. It should be emphasized that patients often fear a repeat visit and expect significant pain with subsequent wound care, especially if the initial incision drainage was difficult. Therefore, the specifics of packing change should be addressed prior to release home after the initial drainage procedure. Some clinicians suggest an oral opioid be taken 30 to 40 minutes before the next visit or use local anesthesia or parenteral analgesia if significant pain is anticipated. Removal of packing material is often painful, but if the packing is moistened with saline prior to removal, it may be less traumatic. If the original incision was of the proper length, loculations were adequately removed, and packing was adequate, the subsequent packing changing will be considerably easier. Once the packing is removed, the wound is inspected for residual necrotic tissue. The cavity may be irrigated with saline prior to replacing the pack if there is significant exudate, but this is often not required because the packing absorbs most debris.

The frequency of packing or dressing changes is also clinically guided. Some wounds require multiple packing changes, while other wounds require only the initial packing. In all facial abscesses, the packing should be removed after only 24 hours, at which time warm soaks should be started. Wounds large enough to require packing should be repacked at least every 48 hours (occasionally daily for the first few visits) until healing continues in a deep to superficial direction. Large wounds that are allowed to close superficially will create an unsterile dead space that will potentiate the formation of recurrent abscesses. After the first few days (and in the motivated and compliant individual), an alternative to packing is to have the patient clean the base of the abscess three times a day with cotton swabs soaked in peroxide (Fig. 38-7). This promotes drainage, produces gentle debridement, and keeps the incision open. Following cleaning, the abscess can be irrigated with tap water and a dry dressing applied.

In general, once healthy granulation tissue has developed throughout the wound and a well-established drainage tract is present, the packing may be discontinued. The patient should then be instructed to begin warm soaks of the wound. [21] Gentle hydrostatic debridement may be performed by the patient in the shower at home. With this procedure the patient holds the skin incision open and directs the shower or faucet spray into the abscess cavity. Wet-to-dry normal saline dressing changes should then follow until healing is completed. When all signs of infection (e.g., erythema, drainage, pain, and induration) have resolved and healthy granulation tissue is present, the patient may be discharged from medical care.

Complicated wounds that require prolonged care are best followed by a single clinician and should not be routinely referred back to the ED for prolonged wound care. Large perirectal or pilonidal abscesses are some conditions meeting that definition. These patients should receive early referral to their primary care clinician or specialist. Wound care centers or physical therapy departments are ideal outpatient follow-up mechanisms. Wounds in cosmetically important areas may require revision once healing is complete. Patients should be informed of this possibility early on in their care.

In select cases in which extensive or prolonged drainage occurs or in patients who are unable to return for proper follow-up care, a catheter system of drainage may be preferred. [45] [46] Following incision, a balloon-tipped or flared-tip catheter is placed into the abscess cavity, and pus is allowed to drain continuously through the catheter lumen. This technique has been most successful in pilonidal and Bartholin gland abscesses, but the technique is applicable to any abscess *not* on the face.

Figure 38-7 Packing change is usually performed by a health care professional. In the compliant and motivated patient, home care may replace frequent visits. Cotton-tipped applicators dipped in peroxide are used to swirl around the cavity to remove debris and the cavity is held open for tap water irrigation.

SPECIFIC ABSCESS THERAPY

Staphylococcal Diseases

The *Staphylococcus* bacterium is a ubiquitous pathogen that frequently colonizes the nose, skin, perineum, and gut. The umbilicus of neonates is also commonly colonized. It grows on the skin and thrives particularly well in hair follicles, causing boils (furuncles), wound infections, and occasionally carbuncles. The pathogenesis of staphylococcal disease is a complex host-bacteria interaction. *S. aureus* invades the skin by way of the hair follicles or an open wound and produces local tissue destruction followed by hyperemia of vessels. Subsequently,

Figure 38-8 A carbuncle is a complicated abscess on the nape of the neck. It is very common in diabetics *(A)*. Because of many crypts and loculations, simple incision and drainage are often not readily curative. This patient had multiple incisions yet was not cured *(B)*. Antibiotics may augment healing of this abscess, but wide surgical excision may be required.

an exudative reaction occurs, during which polymorphonuclear cells invade. The process then extends along the path of least resistance. The abscess may "point" or form sinus tracts. The process can disseminate by invasion of vessels and thus can infect other organs. Most cases of staphylococcal osteomyelitis, meningitis, and endocarditis occur by this mechanism.[47] [48]

Folliculitis represents a small abscess occurring at the root of a hair. Local measures, including warm compresses and antibacterial soaps and ointments, are the usual treatment, but systemic antibiotics may be required if multiple sites are involved or the patient is a chronic staphylococcal carrier. *Furuncles*, or boils, are acute circumscribed abscesses of the skin and SQ tissue that most commonly occur on the face, the neck, the buttocks, the thigh, the perineum, the breast, or the axilla. *Carbuncles* are aggregates of interconnected furuncles that frequently occur on the back of the neck (Fig. 38-8). In this area the skin is thick, and extension therefore occurs laterally rather than toward the skin surface. Carbuncles may attain large size and can cause systemic symptoms and complications. They are found in increased frequency in diabetics, and all patients with a carbuncle should be evaluated for this underlying disease. Treatment should consist of surgical drainage and administration of systemic antibiotics. Large carbuncles may be impossible to drain adequately in the ED. Carbuncles usually consist of many loculated pockets of pus, and simple incision and drainage are often not curative. Occasionally, wide excision and skin grafting are required.

Most cases of recurrent staphylococcal skin infections are caused by autoinfection from existing skin lesions or nasal reservoirs. Prevention is directed at eliminating the organism. This is accomplished by application of bacitracin to the nares and by good hygiene, including frequent cleansing with antibacterial soap. If these measures are unsuccessful, then systemic oral antistaphylococcal treatment is instituted for 2 to 3 weeks. Detection and treatment of infection in family members may be necessary.[47] [48]

S. aureus produces the ubiquitous suture abscess. A *suture abscess* is often misdiagnosed as a wound infection,

but in fact, it is a local nidus of inflammation or infection, or both, caused and potentiated by suture material. Such an abscess usually appears after sutures have been present for at least 3 to 5 days, with single or multiple discrete areas of redness and tenderness noted at the site of suture penetration of the skin. Simply removing the suture (a drop of pus may be expressed) and providing warm compresses and topical antibiotic ointment is usually all that is required. Wide opening of the wound and systemic antibiotics are seldom required. When the suture is buried, a small incision should be followed by probing of the wound with a small hook or bent needle (see Chapter 36) to snare the suture for its removal.

Hidradenitis Suppurativa

Hidradenitis suppurativa (Greek *hidros* = sweat, *aden* = gland) is a chronic, relapsing, inflammatory disease process affecting the apocrine gland that primarily involves the axilla, the inguinal region, or both. [49] Its prevalence is 0.3% to 4% in industrialized countries; most affected individuals are young women. [50] The condition results from occlusion of the apocrine ducts by keratinous debris, which leads to ductal dilation, inflammation, and rupture into the SQ area. Secondary bacterial infection ensues, leading to abscess formation and scarring. This chronic recurring process leads to draining fistulous tracts, which involve large areas and are not amenable to simple incision-and-drainage procedures (Fig. 38-9). [51]

Genetic factors may play some role in hidradenitis suppurativa. Family history is often significant in these patients. Fitzsimmons has proposed a single dominant gene transmission.[52] Individuals of African descent appear to have an increased incidence compared with Caucasians. Although certain groups appear to be predisposed to this condition, the precipitating factor for this process is unclear. Because apocrine glands become active during puberty, it is rare to find hidradenitis suppurativa in the pediatric population. [49] B-mode ultrasound images reveal larger hair follicles in affected individuals than in controls. [53]

Women are affected more frequently than men, for uncertain reasons. Shaving and depilation have frequently been

Figure 38-9 Hidradenitis suppurativa of the groin or axilla is a complicated series of abscesses that may not be amenable to simple incision and drainage. In the case of involvement with the groin, extensive surgery was required to excise recurrent infection.

suggested as causes of this discrepancy; however, this theory was not supported in a study that compared the frequency of these behaviors in patients with hidradenitis suppurativa and a group of controls. [54] Obesity is associated with an increased incidence of the disease. [55] Excessive dermal folds provide dark, wet, and warm areas, which are ideal for the proliferation of the bacteria that are needed for this infectious process. Antiperspirants and deodorants may decrease wetness and bacterial overgrowth, but they have been known to produce inflammatory responses, which could exacerbate the disease process.

The bacteriology of acute abscess formation in hidradenitis suppurativa reflects organisms seen in other soft tissue abscesses. *Staphylococcus* is the most commonly isolated organism,[56] with *E. coli* and ß-hemolytic *Streptococcus* being other important pathogens. In the perineal region, enteric flora are often found. Many of these abscesses have multiple isolates, and anaerobic bacteria are frequently found.

Hidradenitis suppurativa begins as a single inflammatory event involving an apocrine gland, which progresses to frank suppuration and at this stage is no different from a simple furuncle. The clinical entity is distinguishable only in its chronic scarring phase. By then the lesion exhibits multiple foci coupled with areas of induration and inflammation that are in various stages of healing. Progression of the process reveals coalesced areas of firm, raised violaceous dermis. The lesion is usually markedly tender. This disease classically involves the axilla and perineal or inguinal region, although multiple sites are often involved.

Initial outpatient management usually involves intervention in an acute suppurative lesion. Any fluctuant area requires drainage as described in the section on general abscess management. In cases of extensive cellulitis, a broad-spectrum, antistaphylococcal antibiotic should be used. Unfortunately, hidradenitis suppurativa is often not readily cured with localized incision and drainage. The chronic nature of the disease produces multiple areas of inflammation and SQ fistulous tracts that induce routine recurrences. The patient must be informed of this rather unfavorable prognosis and should be referred to a dermatologist or surgeon for long-term care.

Milder forms of the disease are initially treated with conservative measures. Many different approaches have been tried, with numerous case reports and case series noted in the literature. Unfortunately, few controlled studies have been performed. Patients are often counseled to lose weight, refrain from shaving, stop using deodorants, and improve personal hygiene. The benefits of these efforts are unknown. Oral antistaphylococcal antibiotics are most commonly used, with varying results.[57] There have been reports of success with topical clindamycin, [58] [59] isotretinoin,[60] [61] and laser therapy,[62] but these treatments have not been studied in a controlled setting and require further investigation. Dermal infection results from breakdown of the normal host defense mechanism, which occurs with irritation, traumatic injury, or inflammation, coupled with the availability of concentrated opportunistic bacteria. Therefore, the clinician must institute therapies that will decrease bacterial availability without causing further injury to the affected dermis.

Advanced stages of the disease are routinely managed with wide or local excision and primary or delayed closure (Fig. 38-9).[63] [64] [65] Skin grafting may be warranted.[66] Despite such radical approaches, recurrences do occur. [67] Patients must be counseled about the likelihood of recurrence before the procedure.

Breast Abscess

Postpartum mastitis occurs in 1% to 3% of nursing mothers within the first 2 to 6 weeks after delivery. The infection is usually precipitated by milk stasis following weaning or missed feedings. The cause is usually bacterial invasion through a cracked or abraded nipple by *S. aureus* or streptococci originating from the nursing child. Manifestations are redness, heat, pain, fever, and chills. Treatment consists of antistaphylococcal antibiotics, continued breast emptying with a breast pump, and application of heat. It is important to encourage continued breast emptying to promote drainage. Nursing can be continued with the noninfected breast, although passage of the antibiotics through the breast milk may result in some infant diarrhea. Cellulitis may progress to frank abscess formation. These patients may be quite ill and may appear toxic. Abscess formation complicating postpartum mastitis usually necessitates OR management, because the area is extremely tender, and adequate local anesthesia is difficult to obtain. Strict adherence to nipple hygiene to avoid cracks or inflammation is helpful in prophylaxis.

Surprisingly, most breast abscesses occur in women who are not in the puerperium, and have been termed *nonpuerperal breast abscesses*.[68] Scholefield and coworkers [69] reviewed 72 breast abscesses over a 10-year period and noted that only 8.5% of the patients were in the puerperium. These lesions have been classified anatomically.

Peripherally located abscesses are most commonly caused by *Staphylococcus* and respond well to traditional conservative incision and drainage. [69] Superficial abscesses in the SQ tissue may be drained under local anesthesia by means of an incision that radiates from the nipple (Fig. 38-10*A*).

Periareolar abscesses exhibit a more troublesome profile. The microflora often include multiple organisms, and anaerobic bacteria are important isolated pathogens.[68] [69] [70] [71] These infections may be the result of occluded and inflamed mammary ducts. Chronic disease may lead to ductal ectasia that provides a nidus for infection. The deeper and more extensive intramammary abscess appears as a generally swollen, tender breast (Fig. 38-10*B*). Fluctuance is not always obvious, since the abscess is located in the mammary tissue itself. Maier and colleagues reported that more than half of their series of 96 patients had nipple inversion due to chronic scarring.[72] These intramammary infections are complex and require incision and drainage under general anesthesia. Dixon has reported successful treatment with repeated aspiration in both lactating [73] and nonlactating patients. [74] This approach is probably best left to surgeons able to see such patients on a regular scheduled basis to track the progress of abscess resolution.

A *retromammary abscess* lies in the undersurface of the breast between the breast and the chest wall (Fig. 38-10*C*). Fluctuance may be difficult to appreciate because of the depth of the infection. Drainage under general anesthesia is required.

Recurrent abscesses are a common, troublesome complication, occurring in up to 38% of primary periareolar abscesses treated with standard incision, drainage, and antibiotics.[75] These cases require total excision of the involved area and necessitate the care of a general surgeon and further intraoperative management. It may be difficult to diagnose a breast abscess in the early stages, when cellulitis predominates. In equivocal cases antibiotics may be curative, but when pus is

Figure 38-10 *A,* A superficial breast abscess may be drained with a linear incision that radiates from the nipple. *B* and *C,* Diagrams of intramammary abscess *(B)* and retromammary abscess *(C)*. Both require drainage under general anesthesia. The abscess itself may not be fully appreciated if it is deep-seated, and the mistaken diagnosis of cellulitis may be made. *(Redrawn from Wolcott MW: Ferguson's Surgery of the Ambulatory Patient, 5th ed. Philadelphia, JB Lippincott, 1974. Reprinted with permission.)*

present, incision and drainage must be performed. Bedside ultrasound can be helpful for real-time visualization and guidance during aspiration. [76]

An active breast abscess may be the initial presentation of squamous cell carcinoma. In these cases, aspirate from the abscess should be sent for both culture and cytology. If drainage is performed, a biopsy of the abscess cavity is imperative. [77] [78] Breast abscesses may also be a complication of breast implants.[79] In general, most breast abscesses require early consultation with a surgeon.

A breast abscess in a man is an unusual occurrence. Malignancy or underlying bone or joint infection are considerations (see Fig. 38-1).

Bartholin Gland Abscess

The Bartholin glands (vestibular glands) are secretory organs located at the 5 and 7 o'clock positions on each side of the vestibule of the vagina. Asymptomatic cysts frequently occur from duct blockage and retention of secretions. Chronic low-grade inflammation from gonococcal infections has been implicated as an etiologic factor in cyst formation, but occasionally frank abscess formation results. Such patients present with swollen and tender labia and a fluctuant, grape-sized mass that may be palpated between the thumb and the index finger. *Neisseria gonorrhoeae* organisms are infrequently cultured from the abscess cavity, and various anaerobes, especially *Bacteroides* species and other colonic bacteria, are usually found. It is reasonable to take cervical and anal cultures for gonorrhea from women with Bartholin gland abscesses because of the association of these infections with venereal disease, [80] but one need not routinely treat patients for gonorrhea.

Word[81] described an effective treatment of Bartholin gland abscess with a single-barreled, sealed-stopper, balloon-tipped catheter that serves as initial and long-term therapy and may obviate the need for marsupialization (Fig. 38-11*A* and *B*). The editors recommend this technique as the standard therapy of a Bartholin gland abscess. In his original description, Word reported only 2 recurrences in 72 lesions, both of which were successfully treated with a second catheter; no patient required marsupialization. The procedure involves fistulization of the duct cavity by a catheter, which acts as a FB. While not a traditional incision-and-drainage procedure, the technique permits continued drainage of the Bartholin gland. Theoretically this catheter may be used for most abscess drainage procedures, but its use for other conditions is not widespread.

Following a small incision into the mucosa, the scalpel or a hemostat is used to puncture the abscess cavity proper (Fig. 38-12 Fig. 38-12). This may be the most difficult portion of the procedure and it can be difficult to enter this rather deep abscess cavity. Failure to obtain frank pus, or appreciate the "pop" of entering the abscess, often prognosticates failure of the procedure. It is helpful to stabilize the abscess with the thumb and forefinger, hold the hemostat in place, and *skewer the abscess onto the hemostat* to ensure entrance into the abscess. Trying to push the hemostat into the immobilized abscess is technically more difficult (see Fig. 38-12*E*). Care is required to make a stab incision only large enough to accommodate the catheter and small enough to prohibit the inflated balloon from being extruded. Once the abscess has been entered (signaled by a palpable pop or the free flow of pus), the deflated balloon is placed in the abscess cavity. Using a 25-ga

needle to minimize the hole in the stopper, the balloon is then filled with 2 to 4 mL of water (not air). Persistent pain indicates that too much fluid has been used. Most cases are cured with drainage for a few days, and the Word catheter often falls out in within a week. However, the device is ideally left in place for 2 to 4 weeks to allow for fistula formation, so follow-up is required. If the catheter falls out prematurely, it should be quickly replaced to fulfill the times needed for fistulization. This is an interesting technique that even allows for sexual intercourse with the catheter in place. Some clinicians will not reinsert the catheter if healing has progressed significantly, and it is the first drainage procedure.

Although the Word catheter is likely the best initial treatment of a Bartholin gland abscess, even if the catheter falls

Figure 38-11 Use of the Word catheter for outpatient drainage of a Bartholin gland abscess. This is a fistulization procedure rather than a standard incision and drainage. A stab incision is made on the mucosal surface *(A)*. A catheter is inserted into the cyst cavity *(B)* and filled with 3 to 4 mL of water *(C)*. *D,* Inflatable bulb-tipped catheter. *Left,* Uninflated. *Right,* Inflated with 4 mL water. *(A through C from Word B: Office treatment of cyst and abscess of Bartholin gland. JAMA 190:777, 1964. D from Word B: Office treatment of cyst and abscess of Bartholin gland duct. South Med J 61:514, 1968. Reproduced with permission.)*

out in a few days, another acceptable therapy is standard incision and drainage. The abscess is packed for 24 to 48 hours, and sitz baths are started after the first revisit. Broad-spectrum antibiotics are helpful if there is significant cellulitis or actual abscess formation has not yet occurred, but these agents are not required following routine incision and drainage.

It is preferable to make the drainage incision on the mucosal surface rather than on the skin surface. The incision is made over the medial surface of the introitus on a line parallel to the posterior margin of the hymenal ring. The abscess

Figure 38-12a *A,* An alternative to formal incision, drainage, and packing for the treatment of this Bartholin abscess is to place a Word catheter. *B*, The abscess is stabilized with the thumb and index finger, and a local anesthetic is injected into the mucosal (not skin) surface. *C*, A stab incision is made with a scalpel. *D*, The abscess is punctured with a hemostat. Deep abscesses may be difficult to puncture.

cavity is slightly deeper than most cutaneous abscesses, and one must be certain to enter the actual abscess cavity to achieve complete drainage. This is most easily accomplished if one inserts a hemostat through the mucosal incision and spreads the tips of the instrument in the deeper soft tissue. If the abscess recurs, more definitive therapy in the form of marsupialization or complete excision of the gland may be required, but these procedures are not performed initially. Because recurrence is common with simple incision and drainage, some authorities suggest definitive surgery routinely following the first infection, whereas others prefer to wait until a recurrence, or multiple recurrences, are documented.

Particular care must be taken when treating pregnant women with Bartholin gland abscess. The development of sepsis in a pregnant woman after marsupialization of an abscess has been reported,[82] so this subset of patients should be considered at high risk for complications and managed accordingly.

Pilonidal Abscess

Pilonidal sinuses are common malformations that occur in the sacrococcygeal area. The etiology of the sinus formation is unclear, but the malformation may occur during embryogenesis. Pilonidal cyst formation is thought to be secondary to blockage of a pilonidal sinus. The result of pilonidal sinus obstruction is repeated soft tissue infection, followed by drainage and partial resolution with eventual reaccumulation. The blockage is most commonly the result of hairs in the region, and the lesion may in part be a FB (hair) granuloma. Although pilonidal sinuses are present from birth, they usually are not manifested clinically until adolescence or the early adult years, and pilonidal abscess formation most commonly affects young (often white) adults. The sinuses and cysts are lined with stratified squamous epithelium and may contain wads of hair and debris when excised. When cultured, pilonidal abscesses generally yield mixed fecal flora with a preponderance of anaerobes. [83] Poor hygiene and repeated

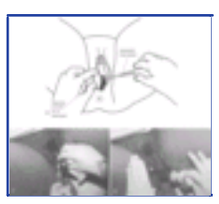

Figure 38-12b *E*, It is technically easier to enter the Bartholin gland abscess cavity if the hemostat is held steady and the abscess, held with the thumb and index finger, is skewered onto the hemostat. Attempting to puncture the deep immobilized abscess by stabbing with the hemostat may be more difficult. A palpable pop when entering the abscess or drainage of frank pus is expected. *F*, The catheter is placed to its hilt into the abscess cavity, and the balloon is filled with saline. Use a 25-ga needle to fill balloon. *G*, The catheter is left in place for 2 to 4 weeks to form a fistula.

trauma (so-called Jeep bottom in World War II) may precipitate acute infection.

The patient with a pilonidal abscess will seek care for back pain and local tenderness. On physical examination the area is indurated, but frank abscess formation may not be appreciated in this deep abscess. One will usually see barely perceptible dimples or tiny openings at the rostral end of the gluteal crease (Fig. 38-13). A hair or a slight discharge may be noticed at the opening. One may find a more caudal cyst or abscess, possibly with a palpable sinus tract connecting the two. The sinus and cyst may be chronically draining, or they may become infected as the size increases and blockage occurs. [84]

Treatment of the acutely infected cyst is the same as previously discussed for any fluctuant abscess; all hair and pus should be removed, and the lesion should be packed (Fig. 38-14). Antibiotic therapy is not usually required. The abscess cavity may become quite large, necessitating a rather lengthy incision to ensure complete drainage. It may take many weeks for the initial incision to heal. The area may be repacked at 2- to 4-day intervals as an outpatient procedure, although some prefer to discontinue packing after the first week. Because simple incision and drainage are often not curative, secondary removal of both the cyst and the sinus should be planned after the inflammatory process has resolved. The elective surgical procedure should be complete and should involve all of the possible arborizations of the sinus.

Recurrence is occasionally prevented by simple incision and drainage, especially if the incision is wide, and adequate drainage is obtained. More commonly, recurrence can be expected unless excision of the sinus tract is performed. Small abscesses may be incised and drained as an outpatient procedure performed under local anesthesia, but the disease process is often extensive, and general anesthesia may be required to complete drainage. One is often surprised by the extent of the

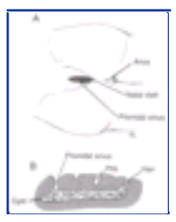

Figure 38-13 Pilonidal sinus. *A*, Sinuses occur in the midline some 5 cm above the anus in the natal cleft. *B*, Longitudinal section showing sinuses and pits. *(From Hill GJ II: Outpatient Surgery, 3rd ed. Philadelphia, WB Saunders, 1988. Reproduced with permission.)*

cyst cavity and the volume of pus that is encountered when the area is probed during initial incision; because of the degree of these abscesses, only localized infection lends itself to outpatient therapy. A method of catheter drainage for pilonidal abscesses has been described [45] [46] in which a flared-end de Pezzer catheter is used for extended periods in the abscess cavity. The catheter allows the patient more freedom from local care and provides continual drainage (Fig. 38-15).

Perirectal Abscesses

Perirectal infections can range from minor irritations to fatal illnesses. Successful management depends on early recognition of the disease process and adequate surgical therapy. Because of the morbidity and mortality associated with inadequate treatment of these conditions, patients with all but the most localized abscesses should be promptly admitted to the hospital for evaluation and treatment under general or spinal anesthesia (Fig. 38-16).

It is important to understand the anatomy of the anal canal and the rectum in order to appreciate the pathophysiology of these abscesses and their treatment (Fig. 38-17). The mucosa of the anal canal is loosely attached to the muscle wall. At the dentate line, where columnar epithelium gives way to squamous epithelium, there are vertical folds of tissue, called the rectal *columns of Morgagni*, which are connected at their lower ends by small semilunar folds called *anal valves*. Under these valves are invaginations termed *anal crypts*. Within these crypts are collections of ducts from anal glands. These glands are believed to be responsible for the genesis of most, if not all, perirectal abscesses. These glands often pass through the internal sphincter but do not penetrate the external sphincter.

The muscular anatomy divides the perirectal area into compartments that may house an abscess, depending on the direction of spread of the foci of the infection (Fig. 38-18). [84] [85] The circular fibers of the intestinal coat thicken at the rectum-anus junction to become the internal anal sphincter. The muscle fibers of the levator ani fuse with those of the outer longitudinal fibers of the intestinal coat as it passes through the pelvic floor. These conjoined fibers are connected by fibrous tissue to the external sphincter system, which consists of three circular muscle groups.

Pathophysiology

As described previously, the anal glands are mucus-secreting structures that terminate in the area between the internal and external sphincters. It is believed that most perirectal infections begin in the *intersphincteric* space secondary to blockage and subsequent infection of the anal glands. Normal host defense mechanisms then break down, followed by invasion and overgrowth by bowel flora. [86]

If the infection spreads across the external sphincter laterally, an *ischiorectal abscess* is formed. If the infection dissects rostrally, it may continue between the internal and external sphincters, causing a *high intramuscular abscess*. The infection may also dissect through the external sphincter over the levator ani to form a *pelvirectal abscess*.[85]

When infection of an anal crypt extends by way of the perianal lymphatics and continues between the mucous membrane and the anal muscles, a *perianal abscess* forms at the anal orifice. The perianal abscess is the most common variety of perirectal infection. The abscess lies immediately beneath the skin in the perianal region at the lowermost part of the anal canal. It is separated from the ischiorectal space by a fascial septum that extends from the external sphincter and is continuous with the SQ tissue of the buttocks. The infection may be small and localized or very large, with a wall of necrotic tissue and a surrounding zone of cellulites. [47] Perianal abscesses may be associated with a fistula in ano. The fistula in ano is an inflammatory tract with an external opening in the skin of the perianal area and an internal opening in the mucosa of the anal canal. The *fistula in ano* is usually formed after partial resolution of a perianal abscess, and its presence is suggested by recurrence of these abscesses with intermittent drainage. The external opening of the fissure is usually a red elevated piece of granulation tissue that may have purulent or serosanguineous drainage on compression. Many times the tract may be palpated as a cord. Patients with anal fistulas should be referred for definitive surgical excision.[85]

Ischiorectal abscesses are fairly common. They are bounded superiorly by the levator ani, inferiorly by the fascia over the perianal space, medially by the anal sphincter muscles, and laterally by the obturator internus muscle. These abscesses may commonly be bilateral, and if so, the two cavities communicate by way of a deep postanal space to form a "horseshoe" abscess.[47]

Intersphincteric abscesses are less common. They are bounded by the internal and external sphincters and may extend rostrally into the rectum, thereby separating the circular and longitudinal muscle layers.

The *pelvirectal*, or *supralevator, abscess* lies above the levator ani muscle in proximity to the rectal wall and remains extraperitoneal. The etiology of this abscess is controversial. Kovalcik and colleagues[86] suggest that supralevator abscesses

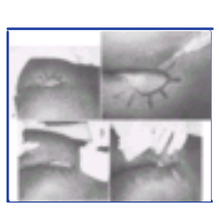

Figure 38-14 *A*, A pilonidal abscess can be quite extensive (*induration outlined by marker*) but it may be difficult to feel fluctuance because of the depth of the infection. *B*, Local anesthesia and conscious sedation make the initial ED incision and drainage successful. *C*, A deep incision yields copious pus, and occasionally other debris, such as hair. *D*, The abscess cavity is packed open. *Not shown*: When infection and inflammation have subsided, definitive treatment may include wide excision of the sinus and its lateral tracks.

are primarily an extension of an intra-abdominal process, such as diverticulitis or pelvic inflammatory disease. Read and Abcarian [87] evaluated 404 patients with perirectal abscesses in a prospective study and found that of the 36 supralevator abscesses, none was caused by an intra-abdominal or pelvic pathologic condition. They determined that supralevator abscesses were most commonly associated with ischiorectal abscesses and suggested that these conditions may be an extension of ischiorectal abscesses through the floor of the levator ani. Nonetheless, they found rare isolated pelvirectal abscesses without intra-abdominal, pelvic, ischiorectal, or perianal infection.

Causes of perirectal abscesses other than the so-called cryptoglandular process have been documented but are fairly rare. It is believed that hemorrhoids, anorectal surgery, episiotomies, or local trauma may cause abscess formation by altering local anatomy and thus destroying natural tissue barriers to infections. [86] [87] [88] Perirectal abscesses may serve as a portal of entry for organisms responsible for necrotic soft-tissue infections such as Fournier's gangrene. [89]

Epidemiology

Anorectal abscesses occur most commonly in healthy adults and are more frequent in males (a greater than 2:1 ratio). [86] [87] These abscesses commonly appear during the fourth decade of life. Possible predisposing medical conditions are diabetes mellitus, inflammatory bowel disease, and other immunocompromised states. Many patients (30%) have a history of previous perirectal abscess, and 75% of anorectal abscesses occur in the same location as the prior abscesses. [86] Of perirectal

abscesses, usually more than 45% are perianal, 20% are ischiorectal, 12% are intersphincteric, and 7% are pelvirectal. [87]

Physical and Laboratory Findings

The diagnosis of a perianal abscess is generally not difficult. The throbbing pain in the perianal region is acute and is aggravated by sitting, coughing, sneezing, and straining. There is swelling, induration, and tenderness, and a small area of cellulitis is present in proximity to the anus. Rectal examination of the patient with a perianal abscess reveals that most

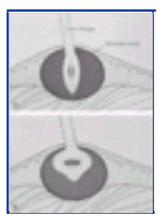

Figure 38-15 A method of prolonged drainage of a pilonidal abscess with a flared-end de Pezzer catheter. Following a stab incision, a stretched catheter (probe inside lumen) is inserted into the abscess cavity *(A).* When the probe is removed, the head of the catheter expands and remains in the abscess cavity *(B).* Drainage is continuous through the lumen of the catheter. *(From Phillip RS: A simplified method for the incision and drainage of abscesses. Am J Surg 135:721, 1978. Reproduced with permission.)*

of the tenderness and induration is below the level of the anal ring. Deeper abscesses may be difficult to localize. A CT scan is may be required to provide definitive diagnosis.

Patients with *ischiorectal abscesses* present with fever, chills, and malaise, but at first there is less pain than with the perianal abscess. Initially on physical examination, one will see an asymmetry of the perianal tissue, and later erythema and induration become apparent. Digital examination reveals a large, tense, tender swelling along the anal canal that extends above the anorectal ring. If both ischiorectal spaces are involved, the findings are bilateral.

Patients with *intersphincteric abscesses* usually present with dull, aching pain in the rectum rather than in the perianal region. No external aberrations of the perianal tissues are noted, but tenderness may be present. On digital examination one frequently palpates a soft, tender, sausage-shaped mass above the anorectal ring; if the mass has already ruptured, the patient may give a history of passage of purulent material during defecation. [85] [86] [87]

Diagnosis of *pelvirectal abscesses* may be very difficult. Usually fever, chills, and malaise are present, but because the abscess is so deep-seated, few or no signs or symptoms are present in the perianal region. Rectal or vaginal examination may reveal a tender swelling that is adherent to the rectal mucosa above the anorectal ring.

Laboratory findings usually do not aid in the diagnosis. Kovalcik and coworkers [86] found that less than 50% of their patients had a white blood cell count greater than 10.0×10^9 /L. Cultures of perirectal abscesses usually show mixed infections involving anaerobic bacteria, most commonly *Bacteroides fragilis* and gram-negative enteric bacilli.

Treatment

Successful management of perirectal abscesses depends on adequate surgical drainage. Complications from these infections may necessitate multiple surgical procedures, prolong hospital stay, and result in sepsis and death. Bevans and associates [88] retrospectively studied the charts of 184 patients who were surgically treated over a 10-year period. These patients were evaluated primarily to identify the factors that contributed to morbidity and mortality. Initial drainage was performed under local anesthesia in 38% of the patients and under spinal or general anesthesia in 62%. The authors identified three key factors in excessive morbidity and mortality: (1) a delay in diagnosis and treatment, (2) inadequate initial examination or treatment, and (3) associated systemic disease. It was their belief that the only way to examine effectively and drain adequately all but superficial well localized perirectal abscesses was under spinal or general anesthesia. This assessment was supported by evidence of an increased incidence of recurrence and of sepsis and death in patients treated with local anesthesia. Drainage of deep abscesses under local anesthesia generally does not allow drainage of all hidden loculations. In addition, local anesthesia is not adequate for treatment of associated pathologic conditions.

Small, well-defined perianal abscesses are the only perirectal infections that lend themselves to outpatient therapy. The result of incision and drainage is almost immediate relief of pain and rapid resolution of infection. Indications for inpatient drainage are failure to obtain adequate anesthesia, systemic toxicity, extension of the abscess beyond a localized area, or recurrence of a perianal abscess. Recurrence may be caused by the presence of a fistula in ano.

A perianal abscess is drained through a single linear incision over the most fluctuant portion of the abscess in a manner previously described for other cutaneous abscesses. It is extremely painful to probe a perianal abscess and to break up loculations, and liberal analgesia is advised. The patient may begin sitz baths at home 24 hours following surgery. Packing is replaced at 48-hour intervals until the infection has cleared and granulation tissue has appeared. This usually occurs within 4 to 6 days. Antibiotics are generally not required. All other perirectal abscesses require hospitalization for definitive therapy.

Use of de Pezzer catheters in anorectal abscesses has been described as an alternative to traditional incision and packing. Kyle and Isbister reported a series of 91 patients treated in this manner. They found equivalent rates of subsequent fistula surgery, less need for general anesthesia, and a shorter postoperative hospital stay when compared with patients treated with traditional incision and packing. [90] Beck and colleagues reported successful use of catheter drainage in 55 patients with ischiorectal abscess. [91] Due to the complexity of ischiorectal abscesses, this technique is probably best left to the surgeon providing ongoing care.

Figure 38-16 *A*, If a perirectal abscess spontaneously ruptures and drains, a formal incision, drainage, and packing should still be performed. *B*, A deep, poorly localized perirectal abscess of this size simply cannot be adequately drained in the ED. Arrows outline the area of induration. This patient requires extensive drainage under general anesthesia. A computed tomography scan may further evaluate the location of this abscess.

Perirectal abscesses are currently recognized as a fairly common cause of fever in the granulocytopenic patient. These abscesses have a different bacteriologic profile: *Pseudomonas aeruginosa* organisms are isolated most frequently. These patients present later because pain develops later in the course, and fever may be the first manifestation. Therefore, any patients who are granulocytopenic with vague anorectal complaints, especially those with fever, should be examined carefully for perirectal abscesses. Any abscess that is found should be drained immediately under appropriate anesthesia, and extensive IV antibiotic coverage should be initiated.

Patients who present with a spontaneously ruptured perirectal abscess may appear to have experienced a self cure, but under most circumstances they should undergo formal incision, drainage, and packing. Cases should be individualized.

Infected Sebaceous Cyst

A common entity that appears as a cutaneous abscess is the infected sebaceous cyst. Sebaceous cysts may occur throughout the body and result from obstruction of sebaceous gland ducts. The cyst becomes filled with a thick, cheesy, sebaceous material, and the contents frequently become infected. Sebaceous cysts may be quite large and may persist for many years before they become infected. When infected, they clinically appear as tender, fluctuant SQ masses, often with overlying erythema.

The initial treatment of an infected sebaceous cyst is simple incision and drainage. The thick sebaceous material must be expressed, since it is too thick to drain spontaneously (Fig. 38-19*A*). An important difference exists between infected sebaceous cysts and other abscesses. *A sebaceous cyst has a definite pearly white capsule that must be excised to prevent recurrence* (Fig. 38-19*B* and *C*). Traditionally, in the presence of significant inflammation, it is preferable to drain the infection initially and remove the shiny capsule on the first follow-up visit or a later visit, when

Figure 38-18 Classification of perirectal abscesses: 1, Perianal. 2, Ischiorectal. 3, Intersphincteric. 4, High intramuscular. 5, Pelvirectal. *(From Hill GJ II: Outpatient Surgery, 3rd ed. Philadelphia, WB Saunders, 1988. Reproduced by permission.)*

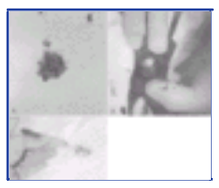

Figure 38-19 The thick, cheesy sebaceous material of a sebaceous cyst must be expressed after incision *(A)*. The shiny capsule of this infected sebaceous cyst is easily visible *(B)* and was removed in its entirety on the initial visit *(C)*.

it may be more easily identified. Alternatively, the entire cyst can be removed at the time of initial incision. At the time of capsule removal, the edges are grasped with clamps or hemostats, and the entire capsule is removed by sharp dissection with a scalpel or scissors. Following excision of the capsule, the area is treated in the same manner as a healing abscess cavity. Simple drainage without excision of the capsule often leads to recurrence.

Kitamura and associates reported a randomized study of 71 patients treated with either traditional incision and drainage or primary resection of the cyst, followed by irrigation and wound closure. In this study, the patients treated with primary resection had faster healing, fewer days of pain, and less scarring. [92]

Paronychia

A paronychia is an infection localized to the area around the nail root (Fig. 38-20). Paronychias are common infections probably caused by frequent trauma to the delicate skin around the fingernail and the cuticle. When a minor infection begins, the nail itself may act like a FB. Usually the infectious process is limited to the area above the nail base and underneath the eponychium (cuticle), but occasionally it may spread to include tissue under the nail as well, forming a subungual abscess. Lymphadenitis and lymphadenopathy are usually not seen. Generally, a paronychia is a mixed bacterial infection. *Staphylococcus* is commonly cultured from these lesions; however, anaerobes and numerous gram-negative organisms may be isolated. [93] Paronychias in children are often caused by anaerobes, and it is believed that this is the result of finger sucking and nail biting. Occasionally, a group A ß-hemolytic infection will develop in a paronychia if a child with a streptococcal pharyngitis puts his or her fingers in the mouth. [94]

A paronychia appears as a swelling and tenderness of the soft tissue along the base or the side of a fingernail (Fig. 38-21). Pain, often around a hangnail, usually prompts a visit to the ED. The infection begins as a cellulitis and may form a frank abscess. If the nailbed is mobile, the infectious process has extended under the nail, and a more extensive drainage procedure should be performed. If soft tissue swelling is present without fluctuance, remission may be obtained from frequent hot soaks (6 to 8 times a day) and a short course of oral antibiotics (3 to 4 days). [93] Incision will be of no value at this early cellulitic phase. If a significant cellulitis is present, a broad-spectrum antistaphylococcal antibiotic (cephalosporin or semisynthetic penicillin) may be tried. However, plain penicillin or erythromycin is often sufficient for limited inflammation. The digit should be splinted and elevated. [95] [96] One should never rely solely on antibiotic therapy once frank pus has formed.

Technique

When a definite abscess has formed, drainage is usually quickly curative. A number of invasive operative approaches

Figure 38-20 Paronychia. *1*, The site of the abscess at the side of the nail. *2*, The infection has extended around the base of the nail. It has raised the eponychium but has not penetrated under the nail. *3*, End stage of paronychia with a subeponychial and subungual abscess. *(From Wolcott MW: Ferguson's Surgery of the Ambulatory Patient, 5th ed. Philadelphia, JB Lippincott, 1974. Reproduced with permission.)*

have been suggested, but actual skin incision or removal of the nail is rarely required, and *neither procedure should be the initial form of treatment*. One can invariably obtain adequate drainage by simply lifting the skin edge off the nail to allow the pus to drain. This is usually curative, because a paronychia is not a cutaneous abscess per se, but rather a collection of pus

Figure 38-21 A paronychia may occur with obvious pus localization between the eponychium (cuticle) and the nail. *A*, Actual pus may be seen or, *B*, the area is swollen and tender. *C*, A paronychia can also occur in the toe. This is not a true cutaneous abscess but rather a collection of pus in a potential space. Actual skin incision is not required if eponychial elevation results in adequate drainage.

in the potential space between the cuticle and proximal fingernail. Drainage may be accomplished without anesthesia in select patients but frequently requires a digital nerve block. After softening the eponychium by soaking, a No. 11 blade, scissors, or an 18-ga needle is advanced *parallel to the nail* and under the eponychium at the site of maximal swelling (Fig. 38-22).[96] [97] Pus rapidly escapes, with immediate relief of pain. A tourniquet placed at the base of the finger may limit bleeding and aid the clinician in determining the exact extent of the infection during the drainage procedure.

If more than a tiny pocket of pus is present, one should fan the knife tip or needle or spread the scissors under the eponychium, keeping the instrument parallel to the

plane of the fingernail. When a large amount of pus is drained, a small piece of packing gauze is slipped under the eponychium for 24 hours to provide continual drainage. Cultures are generally not indicated. Antibiotics are frequently prescribed, although they are not essential if drainage is complete or if the surrounding area of cellulitis is minimal. An alternative to systemic antibiotics is to keep the operative site bathed in antibiotic ointment. After anesthesia has worn off, the patient may be started on frequent soaks in warm tap water at home. In most cases the patient may easily remove the packing. At 24 to 36 hours, the finger is soaked in hot water and the gauze pulled out; a repeat visit to a clinician is not required if healing is progressing. Once the packing is removed, the area is covered with a dry, absorbent dressing. An antibiotic ointment may be applied to the site for a few days. The benefit of antibiotic ointments in reducing infection is unproved, but instructing the patient concerning the detailed use of the ointment may prompt soaking. In addition, the ointment helps to keep the bandage from sticking.

If the infection has produced purulence beneath the nail (subungual abscess), a portion of the nail must be removed or the nail trephined to ensure complete drainage. As an alternative to nail removal, a hole may be placed in the proximal nail with a hot paper clip. A large opening or multiple holes are required to ensure continued drainage. Most commonly the proximal portion of the nail is involved. This may be treated by

Figure 38-22 An initial treatment method for a well-localized paronychia. Following a digital nerve block, the eponychium (cuticle) is elevated at the area of greatest fluctuance, and no actual skin incision is made. A tourniquet can be used to limit bleeding and facilitate drainage. *A* and *B*, A sharp instrument (scissors or a No. 11 blade) is held parallel to the nail and advanced until pus is drained. *C* and *D*, A hemostat or scissors is placed into the base and all margins of the pus collection and spread in a fan-like fashion to open up the abscess. The entire pocket is opened to break up loculations and create a cavity. *E*, A small packing is placed for 2 days. At recheck a new pack may be placed or the cavity left open to heal. *Actual incision of tissue or removal of the nail is reserved for complicated or resistant infections and is not first-line therapy.*

bluntly elevating the eponychium to expose the proximal edge of the nail. The proximal one third of the nail is then elevated from the nailbed and resected with a scissors. The distal two thirds of the nail is left in place to act as a physiologic dressing and to decrease postoperative pain (Fig. 38-23). If purulence is found below the lateral edge of the nail, the affected part may be gently elevated and excised longitudinally. [98] Care must be exercised during this procedure to avoid damage to the nail matrix. A wick of gauze should be placed beneath the eponychium for 48 hours to ensure continued drainage.

Most paronychia resolve in a few days, and one to two postoperative visits should be scheduled to evaluate healing and reinforce home care. For compliant patients with a small paronychia, home care alone may suffice after the initial drainage. A well-known but very rare complication of even a properly drained paronychia is osteomyelitis of the distal phalanx. Clinical infection lasting longer than a few weeks should prompt evaluation for this complication.

Patients occasionally present to the ED complaining of a chronic, indolent infection of the paronychia. These seldom

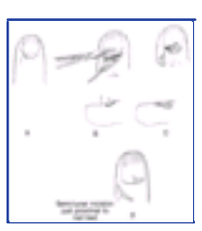

Figure 38-23 *A–C*, Aggressive treatment of recurrent paronychia or subungual abscess includes removal of a portion of the proximal nail and incision of the eponychium. *D,* Some physicians prefer to use a semilunar incision proximal to the eponychium rather than directly incising and potentially injuring the cuticle permanently. *These aggressive therapies are seldom required.*

respond to ED intervention. Frank purulence is seldom present, and conservative treatments are often unsatisfactory. Many etiologies have been described for this frustrating condition, including fungal, bacterial, viral, and psoriatic conditions. Patients with chronic paronychia unresponsive to therapy should be screened for malignancy.[99] Treatment

Figure 38-24 A well-developed felon. In this advanced case, the patient had little pain at the time of presentation, and the distal phalanx was almost completely resorbed owing to the extensive pressure and inflammation. This infection is extensive and warrants consultation with a hand specialist.

modalities are varied, and controlled studies evaluating the various techniques are lacking. Meticulous hand care, oral and topical antimicrobial medications, and occasionally aggressive surgical intervention have been suggested. [96] [100] These patients should be referred to a dermatologist or hand surgeon because of the prolonged treatment required.

Herpetic Whitlow

Herpetic whitlow is an infection of the distal phalanx caused by the herpes simplex virus. Digital inoculation occurs through a discontinuity of the skin. [98] Health care providers and patients with other herpes infections are most commonly infected. [100] [101] [102] [103] [104] The entity is recognized by the presence of herpetic vesicles, a burning or pruritic sensation, absence of frank pus, slow response to treatment, and a tendency to recur. In questionable cases, viral cultures can be obtained. Herpetic lesions are generally quite painful but are self-limited and resolve in 2 to 3 weeks. Surgical intervention is contraindicated, as this may potentiate a secondary bacterial infection and delay healing. [105] [106] [107] [108] Treatment is symptomatic, consisting of splinting, elevation, and analgesia as needed. Antibiotics effective against herpes infections (acyclovir, famciclovir, and others) probably shorten the course of the disease if given early. After accidental needlestick in health care workers, oral famciclovir may help prevent herpetic whitlow. [109] Consideration must be given to preventing spread of the infection to other individuals. Although an occlusive dressing may lessen the chance for viral transmission, any health care provider with this entity should refrain from patient contact until all lesions have crusted over and viral shedding has stopped. [101] [102] [103]

Felon

A felon is an infection of the pulp of the distal finger (Fig. 38-24). The usual cause is trauma with secondary invasion by bacteria. A felon may develop in the presence of an FB, such

as a thorn or a splinter, but often a precipitating trauma cannot be identified. An important anatomic characteristic of this area is that there are many fibrous septa extending from the volar skin of the fat pad to the periosteum of the phalanx; these subdivide and compartmentalize the pulp area. When an infection occurs in the pulp, these same structures make it a closed space infection. The septa limit swelling, delay pointing of the abscess, and inhibit drainage after incomplete surgical decompression. Pressure may increase in the closed space, initiating an ischemic process that compounds the infection. The infection can progress readily to osteomyelitis of the distal phalanx. Although the septa may facilitate an infection in the pulp, they provide a barrier that protects the joint space and the tendon sheath by limiting the proximal spread of infection.

The offending organisms are usually *Staphylococcus* or *Streptococcus,* although mixed infections and gram-negative infection may occur. A felon is one of the few soft tissue infections in which a culture may be helpful, since osteomyelitis and prolonged infection may occur. An initial culture may aid in the subsequent choice of antibiotics for complicated infections.

The patient developing a felon will describe gradual onset of pain and tenderness of the fingertip. In a few days the pain may be constant and throbbing and gradually becomes severe. In the initial stages, physical examination may be quite unimpressive, because the fibrous septa limit swelling in the closed pulp space. As the infection progresses, swelling and redness may become obvious. Occasionally one may elicit point tenderness, but frequently the entire pulp space is extremely tender. The patient characteristically arrives with the hand elevated over the head because pain is so intense in the dependent position. Cessation of pain indicates extensive necrosis and nerve degeneration.

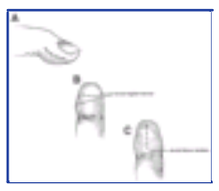

Figure 38-25 The preferred initial incision for draining a felon is one made directly into the area of most fluctuance. More aggressive incisions should be reserved for complicated cases, since they have a greater morbidity and require more complicated wound care. The unilateral longitudinal approach is a good first choice *(A)*. Fat pad incisions are acceptable but may be associated with a painful scar in an area that is often traumatized. The transverse fat pad incision should not injure digital nerves *(B),* and the longitudinal fat pad incision should avoid the flexor tendon *(C)*.

Proper treatment of a well-developed felon consists of early and complete incision and drainage. [98] Antibiotics alone are not curative once suppuration has occurred. Delaying surgery may result in permanent disability and deformity. Most surgeons routinely administer broad-spectrum antibiotics to patients for 5 to 7 days following surgical incision.

Technique

Complicated or advanced felons are best handled in the OR by a hand specialist. Minor felons lend themselves to ED management but followup is required and these infections heal slowly. The surgery of a minor felon can usually be performed as an outpatient procedure using a digital nerve block. A long-acting solution (bupivacaine) will prolong anesthesia. A tourniquet (1.25 cm Penrose drain) should be used to allow digital incision in a bloodless field.

Surgical drainage must be carefully performed to avoid injury to digital nerves, vessels, and flexor tendon mechanisms. Most commonly, a felon can be successfully managed with a limited procedure, but many surgical options have been advocated, none of which has been proven superior for all circumstances. [98] The preferred initial treatment is a simple longitudinal incision made over the area of greatest fluctuance, [110] which may occur laterally or along the volar surface (Fig. 38-25). A potential drawback to an incision in the middle of the fat pad is the production of a scar in a very sensitive and commonly traumatized area. The incision must not extend to the distal interphalangeal crease because of the danger of injuring the flexor tendon mechanism. The SQ tissue is bluntly dissected using a hemostat to provide adequate drainage. A gauze pack may be placed in the wound for 24 to 48 hours to ensure continued drainage.

Figure 38-26 Hockey-stick incision for the drainage of a felon. *Note:* An incision on the ulnar side of the index, middle, and ring fingers is appropriate. The little finger is best incised on the radial side. The site of the incision on the thumb is also preferably on the radial side, but this may depend on the occupation of the patient. *(From Chase RA: Atlas of Hand Surgery. Philadelphia, WB Saunders, 1973. Reproduced with permission.)*

Recurrent or more severe infections may require a more aggressive approach by a hand specialist. The following traditional incisions have a greater propensity for complications such as sloughing of tissue and postoperative fat pad anesthesia or instability, [110] although they may provide for more complete drainage.

The hockey-stick incision is a well-accepted drainage procedure (Fig. 38-26). This incision is advantageous if the infection points to one side of the finger. The incision begins in the midline of the tip of the fat pad, just under the distal edge of the fingernail. It is extended to the lateral tip of the finger and proximally along the side of the distal phalanx (at the junction of the volar and dorsal skin markings) to 3 to 5 mm distal to the distal interphalangeal joint. The tip of the knife blade is inserted just under the bone to a depth corresponding to the opposite edge of the distal phalanx—slightly more than halfway across the volar surface of the finger. A hemostat is inserted into the incision and is spread in the plane of the fingernail (perpendicular to the septa) to break open remaining septa and loculations. Necrotic tissue or any foreign matter is excised under direct vision, and the wound is irrigated. A small gauze pack is placed in the incision. Because the incision may produce partial numbness of the fingertip by associated digital nerve injury, the incision should *not* be made on the radial aspect of the index finger or the ulnar aspect of the thumb or little finger.

An acceptable alternative to the hockey-stick, or median, incision is the through-and-through incision (Fig. 38-27). This is basically a hockey-stick-type incision (without the curved distal portion of the "hockey stick") that is carried through to the opposite side of the finger. A hemostat is used to break up loculations, and a rubber drain (Penrose) is placed through the incision for continual drainage. The through-and-through incision is probably the easiest procedure for most felons.

The fishmouth, or horseshoe, incision is basically two hockey-stick incisions that meet at the tip of the finger. A gauze pack is placed between the flaps and should be removed in a few days. This is a rather radical procedure but allows complete visualization and debridement of necrotic tissue (Fig. 38-28). Some clinicians advise against this incision, because it is extensive and may take a long time to heal. In addition, it produces a sizable scar and an unstable finger pulp. The fishmouth incision may be used if more conservative incisions are not successful, but it is not recommended for use initially.

No matter which incision is made, it must not be carried proximal to the closed pulp space because of the danger of entrance into the tendon sheath or the joint capsule. The patient should be rechecked in 2 to 3 days. A snug dressing, splinting and elevation, and adequate opioid analgesics are prerequisites for a successful outcome and a happy patient.

On the first postoperative visit, a digital block may again be performed and any packing removed. The incision is irrigated copiously with saline, and any additional necrotic tissue is removed. At this time, the drain may be replaced for 24 to 48 hours if there is continued drainage, but usually it can be removed and a dressing reapplied. Soaking may be advised. At the first revisit, the sensitivities of the bacterial cultures are checked, and a decision to continue or change antibiotics is

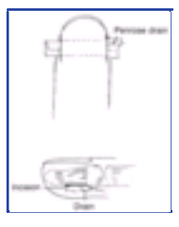

Figure 38-27 Through-and-through incision for a felon. A Penrose drain is placed for a few days to promote the withdrawal of fluid. This is an alternative to the hockey-stick incision.

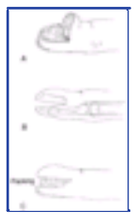

Figure 38-28 *A–C,* Fishmouth incision. This is a rather radical incision that is best reserved for resistant cases. Its advantage is that it allows for complete drainage and visualization of the infection in complicated cases. This incision takes longer to heal than others and may leave a large and sensitive scar. The fingertip may also be left unstable as a result of the lysis of all septa. The incision is seldom used on an outpatient basis for these reasons.

made. Most felons are empirically treated with antibiotics for at least 5 days. A broad-spectrum cephalosporin is a reasonable choice, pending cultures (if done).

A few additional points should be emphasized at this time. Frank pus may be encountered during incision, but usually only a few drops are expressed. One more often drains a combination of necrotic tissue and interstitial fluid. A careful search for a FB should be made even if the history is not known. Some clinicians advocate radiographic evaluation for retained FBs and a baseline evaluation of the bone for subsequent evaluation of osteomyelitis at the initial visit. Other clinicians will reserve radiographs for wounds not showing significant improvement in 5 to 7 days. Evidence of osteomyelitis, however, may not be found radiographically for several weeks after the appearance of the lesion. More radical incision and drainage may be required in persistent infections. Following adequate drainage, osteomyelitis may respond surprisingly well to outpatient antibiotic therapy with almost complete regeneration of bone if incision and drainage have been adequate. Persistent cases may require IV antibiotics.

Resistant fingertip infections are not uncommon.

Difficult or persistent cases require evaluation and care by a hand surgeon. In these cases, early consultation is advisable to avert catastrophic complications such as loss of function or amputation.

SEROMA AND HEMATOMA DRAINAGE

Although most incision-and-drainage procedures are performed for decompression of purulent collections, drainage of sterile hematomas or seromas may be required in the ED. In general, the same principles used for formal drainage of pus in the soft tissues apply to drainage of a sterile fluid collection, and hence one can directly apply the principles of this chapter to the drainage of sterile fluids. In addition, when a sterile fluid collection is drained, the operator has the option of primarily closing the incision site following wound irrigation (see Chapter 35 and Chapter 36 for wound management techniques). Drainage of a soft tissue hematoma is generally best postponed several days following an initial injury to permit hemostasis and to minimize the risk of hematoma reaccumulation following drainage. The procedure is generally reserved for those soft tissue hematomas that are large and painful (secondary to tissue distention) and are expected to either resolve slowly or result in soft tissue deformity if not drained. Seromas and hematomas rarely become infected if the overlying skin remains intact. It is best to avoid needle aspiration since this procedure rarely drains the collection completely, and it has the potential to introduce infection into a good culture medium in a closed space. If a hematoma becomes infected, it should be treated as a cutaneous abscess.

Although tempting to drain a small seemingly fluctuant noninfected hematoma that has persisted for many days, *a conservative nonoperative approach is usually best*. A persistent mass after trauma is usually concerning to patients, so a thorough explanation should be forthcoming. Most hematomas will resolve, albeit slowly (weeks), and incision often is disappointing in its yield (unless the hematoma is large and superficial) and leaves a scar. Drainage of a subungual hematoma represents a special case of hematoma drainage.

Subungual Hematoma

Subungual hematoma is an injury that is frequently seen in the ED. Any digit may be affected. The hematoma often results from hitting the fingertip with a hammer or slamming it in a door. The main concern of the patient is relief of the terrible throbbing pain that accompanies the condition as the pressure of the hematoma increases. Pain relief can be accomplished quickly with nail trephination. Trephination may be performed with a large paper clip that has been heated until it is red hot. The instrument is applied to burn a hole at the base of the nail (Fig. 38-29). Blood rapidly exits, and the blackened nail regains its normal color (Fig. 38-30). The blood usually remains fluid for 24 to 36 hours and is easily expressed with slight pressure. Care should be taken to make multiple holes or a single hole that is large enough to allow continued drainage. An oversized paper clip is the simplest apparatus. Although a portable hot-wire electrocautery unit is available and is frequently recommended, it is difficult to obtain an adequate drainage hole without adapting the instrument and its use. One can modify the electrocautery device to burn a larger hole by "fattening" the end of the wire loop and rotating the device slowly as the nail is penetrated or by removing a small rectangle of nail with the cautery device. In addition to being convenient, the cautery device is desirable because the wire stays hotter longer, thus enhancing nail penetration. In the stoic patient, no anesthesia may be necessary, but a digital block affords painless trephination, and its routine use is suggested with the anxious patient.

The majority of subungual hematomas are painful but minor injuries. Complicated cases involve fractures of the distal phalanx. When the fingertip is unstable or the mechanism

Figure 38-29 *A*, This patient slammed his finger in a car door, sustaining an acute flexion of the distal phalynx and a crush injury. It appears to be a simple subungual hematoma, but note the blood in the paronychial space. There is a communication between the nail bed laceration and the eponychium. *B*, All of the blood did not drain when the nail was trephinated. *C*, Blood accumulated in this area because the base of the fingernail has been avulsed, and lies between the eponychial fold and the skin of the cuticle. This is appreciated when the skin is debrided. The closed nature of the injury causes the confusion. With the nail removed, the nail bed laceration can be appreciated and repaired. *D*, The old trephined nail can now be replaced to its original position to keep open the eponychial space, or that space is packed with gauze for a few weeks to discourage scar formation and a subsequent nail deformity.

of injury suggests a significant distal phalanx fracture, a radiograph should be obtained. Radiographs help differentiate tendinous and bony mallet-type injuries. [111] If a significant fracture is present, the digit should be splinted. A distal phalangeal fracture with a subungual hematoma is technically an open (compound) fracture. Such injuries usually heal without problems, although osteomyelitis of the tuft is a theoretical complication. The value of routine antibiotic prophylaxis in such cases is unproved, and their use is not standard in minor cases but may be of value in significant crush injuries. The presence of an underlying fracture does not contraindicate nail trephination for fear of changing closed fracture into an open one.

It is difficult to predict the fate of the fingernail following drainage of a subungual hematoma. Some patients with subungual hematomas will lose the nail, but if the nail root or nailbed is not significantly disrupted and the nail remains implanted, a normal-appearing nail is the usual final result. Treatment of subungual hematomas by simple trephining gives an acceptable result in most patients; poor outcome cannot be predicted at presentation. [112] If the nailbed is significantly lacerated or the edges of the nail are unstable, the nail may be removed and the nailbed repaired (see further discussion in Chapter 36). Patients should be informed of possible future cosmetic problems.

One condition that may be mistaken for a simple subungual hematoma is the closed avulsion of the base of the fingernail that occurs in conjunction with a subungual hematoma from a nailbed laceration. A common mechanism is slamming a finger in a car door, with sudden flexion of the distal phalynx in conjunction with a crush injury of the nail bed. The nail itself is usually stable, so generally no repair of the nailbed appears required. However, if the subungual hematoma extends past the confines of the nail bed, such as in the paronychial space (under the skin of the cuticle), there must be a communication between the nailbed and this space. This essentially produces a paronychial hematoma, where blood occupies the space that pus occupies in an infectious paronychia (see Fig. 38-29). When this condition is present, the avulsed proximal portion of the fingernail overlies the nail fold of the cuticle, but this is only evident once the overlying skin is opened. An open reduction (replacement) of the nail must be performed. The replaced nail often grows normally but the final result may be a lost or deformed nail. Repair of the nailbed laceration is optional at this juncture, but may not be required if the nail is stable. Once the injury is anatomically

Figure 38-30 *A,* Subungual hematoma with a blackened nailbed. *B,* Following trephination, blood flows freely from the puncture site. An adequately sized drainage hole may be placed in the nail with a heated paper clip. Small holes, which tend to clog and inhibit drainage, should not be made. The hole should be large enough to allow continued drainage of blood. Note that in this example, the blood only accumulates under the nail, not in any paronychial areas.

correct, splinting and soaking follows that of a simple subungual hematoma. These injuries rarely become infected and there are no firm indications for antibiotics. Clinical judgment is suggested on individual cases.

Acknowledgment

The editors and author wish to acknowledge the significant contributions of Todd M. Warden, Mark W. Fourre, and Howard Blumstein to this chapter in previous editions.

Chapter 39 - Burn Care Procedures

Courtney A. Bethel
Thomas J. Krisanda

Each year in the United States some 2 million people suffer a burn-related injury. Typical victims are children younger than 5 years of age or young adults who are exposed to fire or hot or corrosive substances. [1] Fortunately, 95% of these burns are classified as minor and are amenable to outpatient management, with most patients completing their treatment course within 2 weeks.

The classification of burns is based on three criteria [2] : depth of skin injury, percentage of body surface area involved, and source of injury (thermal, chemical, electrical, or radiation). The *seriousness* of a burn injury is determined by the characteristics and temperature of the burning agent, the duration of exposure, the location of injury, the presence of associated injuries, and the age and general health of the victim (Table 39-1).

The American Burn Association defines *minor* burns as uncomplicated partial-thickness burns of <5% of the total body surface area (TBSA) in children (<10 years old) or the elderly (>50 years old) or <10% TBSA in adults, or full-thickness burns <2% TBSA. [3] *Moderate or major* burns include injuries that involve a greater TBSA, as well as burns to areas of specialized function, such as the face, hands, feet, or perineum. More serious burns also include those due to a high-voltage electrical injury or those with associated inhalation injuries or other major trauma.

The TBSA burned may be estimated in a number of ways. It is more common to overestimate the size of a burn than to underestimate it. In adults, the "rule of nines" is a useful rule of thumb, but the formula is only a guide and *must be modified for children* who have proportionately larger heads and smaller legs (Fig. 39-1). The Lund and Browder charts are another (more precise) guide to estimating the percentage of TBSA burned (Fig. 39-2). For smaller or multiple burns, one can rapidly estimate the TBSA burned by using the area of the patient's palm as approximately 1.25% TBSA.

Throughout the course of history, clinicians have experimented with burn therapies to relieve pain and promote healing. Many treatment regimens and useless home remedies have been successful, largely due to the fact that minor burns generally do well with a modicum of intervention, and common sense wound care. While little has changed in the care of minor ambulatory burns over the past 20 years, the treatment of major burns, the development of sophisticated burn centers, increased knowledge of burn wound physiology, and the prevention of infection have significantly altered the care of seriously burned patients.

WOUND EVALUATION

Emergency clinicians should be aware that the depth of a burn wound cannot always be determined accurately on clinical grounds alone at the time of presentation and that burn injury is a dynamic process that may change over time, particularly during the 24 to 48 hours after the burning process has been arrested. It is common, for example, for a seemingly minor or superficial burn to appear deeper on the second or third return visit (Fig. 39-3). This phenomenon is not a continuation of the burning process but is considered to be a pathophysiologic event related to tissue edema, dermal ischemia, or desiccation. [4]

First-degree burns involve the epidermis only. The skin is reddened but is intact and not blistered. This injury ranges from mildly irritating or even pruritic to exquisitely painful. Minor edema may be noted. Causes include ultraviolet light (as in sunburn) and brief thermal "flash" burns. First-degree burns frequently blister within 24 to 36 hours, so the patient should be instructed appropriately. Often the skin begins to flake or peel within 5 to 10 days, but healing eventually occurs with no scarring.

Second-degree burns involve the entire epidermis and extend into the dermis to include sweat glands and hair follicles. *Superficial partial-thickness burns* involve only the papillary dermis. These burns are pink, moist, and extremely painful. Blisters may be present or the skin may slough. The burn blanches with pressure, and mild to moderate edema is common. Hair follicles are often noted to be intact. This is the most common depth of minor burn seen in the emergency department (ED). The usual causes are scalds, contact with hot objects, or exposure to chemicals. Barring infection or repeated trauma, these burns heal completely without scarring in about 2 weeks. Areas of first- and second-degree burns may be sensitive to subsequent sunburn, windburn, and skin irritation for months after the original injury appears healed.

Deep partial-thickness burns extend into the reticular dermis and appear as mottled white or pink. There is obvious edema and sloughing of the skin, and any blisters are usually ruptured. Blanching is absent. These burns are generally not painful initially, but pressure can be perceived. Within a few days, however, these burns can become exquisitely painful. This type of burn can easily be converted to a full-thickness injury by further trauma or infection. Partial-thickness burns heal by re-epithelialization from dermal appendages, including hair follicles, sebaceous glands, and sweat glands.

In *full-thickness burns,* coagulation necrosis extends into the subcutaneous (SQ) tissues. These burns may appear in a variety of colors but are usually dry, pearly white, or charred. They are initially painless, with a leathery texture. Marked edema and decreased elasticity may necessitate escharotomy when circulation is compromised. Exposure of the skin to - temperatures in excess of 77°C for more than 3 to 4 seconds generally causes a full-thickness injury. Although initially painless, in a few days these deep burns can become painful. Chemical burns often produce full-thickness injuries affecting a small or scattered surface area. Flame burns produce full-thickness injuries in less than 2 seconds if the temperature of the flame exceeds 500°C. Generally, any burn wound that is not re-epithelialized or does not possess dense epidermal budding by 14 days post-burn should be considered a full-thickness injury. [4]

Fourth-degree burns extend deeply into SQ tissue, muscle, fascia, or bone. These burns are characteristically caused by contact with molten metal, flame, or high-voltage electricity.

HISTOPATHOLOGY OF BURNS

One thermal wound theory describes 3 zones of injury in burns [5] :

1. *Zone of coagulation:* dead, avascular tissue that must be debrided.

2. *Zone of stasis:* injured tissue in which blood flow is impaired. Desiccation, infection, or mechanical trauma may lead to cell death.
3. *Zone of hyperemia:* minimally injured, inflamed tissue that forms the border of the wound. The hyperemia usually resolves within 7 to 10 days but may be mistaken for cellulitis.

TABLE 39-1 -- Characteristics of Burns, by Depth*

Classification of Burn	Etiology	Appearance	Sensation	Time to Complete Healing	Scarring
FIRST DEGREE					
• Superficial epidermal layers	• Sunburn, other UV exposure	• Dry, red	• Present	• 3–7 days	• No
	• Short flash flame burns	• Blanches with pressure	• May be quite painful		
SECOND DEGREE					
• Varying depth, blisters, or bullae formation					
• Dermal appendages spared (i.e., sweat glands, hair follicles)					
• Includes entire epidermis and some portion of the dermis					
Superficial partial thickness	• Water scald	• Blisters, peeling skin	• Painful	• 7–21 days	• Unusual if no infection and proper follow-up
	• Longer flash burn	• Blanches with pressure Skin red/moist under blisters	• Exposure to air and temperature is painful		• Pigment change may be seen
					• Burned area may be sensitive to frostbite, windburn, sunburn for many months
					• Itching may be problematic for weeks after healing
Deep partial thickness	• Flame	• Variable color	• Pressure only	• >21 days	• Severe; risk of contracture
	• Water immersion	• Wet or waxy dry, does not blanch			
	• Oil, grease, hot foods (e.g., soup)	• Blisters easily removed, skin peeling off			
THIRD DEGREE					
• Loss of all skin elements; thrombosis and coagulation of vessels	• Flame, steam, oil grease	• Leathery appearance, white or charred dry, inelastic; blanching with pressure	• Deep pressure only	• Never heals	• Very severe, high risk of contracture
	• Immersion, scald			• Requires grafting	
	• Caustic chemical, high voltage				
		• May be present under blisters			

**Modified after: Clayton and Solem, Post Grad Med 97:151, 1995 and Morgan, Bledsoe and Barker, Am Fam Phys 62:2015, 2000.*

Histologically, full-thickness burns are characterized by confluent vascular thrombosis involving arterioles, venules, and capillaries. Edema due to loss of microvascular integrity results not only from the effects of direct thermal injury, but also from the release of vasoactive mediators. The increase in vascular permeability is linked to complement activation and histamine release. Histamine increases the catalytic activity of the enzyme xanthine oxidase, with resultant production of hydrogen peroxide and hydroxyl radicals. These by-products increase the damage to dermal vascular endothelial cells and result in progressive vascular permeability. [6]

The cellular debris and denatured proteins of the eschar provide a substrate for the proliferation of microorganisms. The devitalized tissue (eschar) sloughs spontaneously, usually as a result of the proteolytic effect of bacterial enzymes. The greater the degree of wound bacteriostasis, the greater the delay in sloughing.

Partial-thickness burns result in incomplete vascular thrombosis, usually limited to the upper dermis. The dermal circulation is gradually restored, usually over several days, resulting in a significant interval of relative ischemia. The eschar in deep partial-thickness burns is thinner than in a full-thickness burn and sloughs as a result of re-epithelialization rather than bacterial proteolysis.

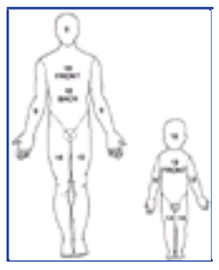

Figure 39-1 The "rule of nines" for estimating percentage of area burned. (As a rough guide, the area covered by the individual's palm is approximately 1.25% the total body surface area [TBSA].) The rule of nines is a rough estimate of the TBSA burned. Note that adults and children are different. This formula frequently *overestimates* the extent of a burn in clinical practice. See Figure 39-2 for a more accurate method of determining the TBSA burned for children.

OUTPATIENT VS INPATIENT CARE

One of the first steps in minor burn care is to select patients for whom outpatient care is appropriate (Table 39-2). *Generally there are no "unnecessary" initial admissions for patients with burn injuries.* Candidates for outpatient treatment are generally adults and children who meet the minor burn criteria detailed earlier. Clinical judgment is always the most reasonable way to decide on where the burn patient would be best cared for, and there is considerable latitude in this decision. Persons who have deep burns of the hands, face, feet, neck, or perineum; burns resulting from abuse or attempted suicide; burns involving other significant trauma or inhalation injuries; or electrical burns should generally be managed as *inpatients*.

Poor candidates for outpatient care of even minor burns include those who have concomitant medical problems such as diabetes mellitus, peripheral vascular disease, congestive heart failure, and end-stage renal disease; patients who are using steroids or other immunosuppressive agents; patients who are very young or very old; those who are mentally retarded; alcoholics; the homeless; those who are malnourished; and any individual with a suspect or unacceptable home support system. Inpatient treatment should be considered under these circumstances even though the burn might be considered "minor" by TBSA formulas. Pain control, the ability to obtain follow-up, the capacity to understand home care, and the overall social situation must influence the final decision. [7]

PROCEDURE

Initial Care of the Minor Burn Victim

Prompt cooling of the burned part is an almost instinctive response and is one of the oldest recorded burn treatments, having been recommended by Galen (129 to 199 A.D.) and Rhazes (852 to 923 A.D.).[4] Room-temperature tap water irrigation, immersion, or compresses (20 to 25°C) are optimal in obtaining pain relief and providing some measure of protection for burned tissues without the problems of hypothermia that iced solutions can cause. [8] [9] First-aid telephone advice from the emergency clinician includes immediately immersing the wound in room-temperature tap water. While immediate cold water immersion may limit the extent of a burn, and provide significant pain relief, *packing the wound in ice must be avoided*.

Emergency Medical Service (EMS) personnel should have a clear understanding of proper management of the minor burn victim. The benefits and details of early cooling should be understood and implemented. The victim should first be removed from danger. All involved clothing and jewelry, along with any gross debris, should be removed from the burned area. Chemical burns to the skin or eyes require prolonged tap water irrigation. The burn should be otherwise covered with a moist, sterile dressing—nonmentholated shaving cream makes an excellent temporary covering for out-of-hospital use if a dressing is not available. [10] Common home remedies such as butter, grease, or petrolatum usually do not adversely influence subsequent care, but they are best avoided. [11]

In the ED, the burned area should be immediately immersed in room-temperature water or covered with gauze pads soaked in room-temperature water or saline (Fig. 39-4). The gauze must be kept cool and moist to provide continued pain relief; the patient will quickly let the clinician know when additional cooling is required. Burns should be cooled or immersed until supplemental analgesia is effective and dressings are ready to be applied. Many clinicians use sterile saline for cooling, but it has no proven benefit over tap water, even when the skin is broken. It is acceptable to add ice chips to water or saline to lower the temperature. However, immersion of burned tissue in ice or ice water should be avoided, because ice immersion increases pain and risks frostbite injury or systemic hypothermia.

The potential benefits of burn cooling are listed in Table 39-3 . With the exception of pain relief and removal of debris, the benefits of burn cooling are experienced only if the burn is cooled promptly, within the first 3 minutes after injury. [12]

Prompt burn cooling arrests cell death processes by inhibiting the release of toxic substances by the dying cells. If cooling is not performed, continued cell death results as oxygen free radicals are released, which can cause a "chain reaction" of cell membrane injury, arachidonic acid release, and increased local ischemia. [13]

The threshold temperature for cutaneous pain sensation is approximately 43°C. The prompt alteration in capillary permeability and resultant edema induced by heat have been attributed to histamine release from stimulated or damaged mast cells. The tissue threshold for this phenomenon has been estimated at 52°C. Cooling produces prompt and complete, but reversible, inhibition of histamine release. Tissue edema also results from damage to the membrane sodium pump,

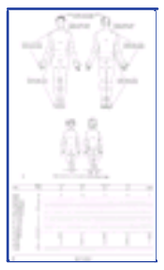

Figure 39-2 *A,* The Lund and Browder charts are somewhat more accurate than the rule of nines in estimating the TBSA burned. *B,* The proportion of TBSA of individual areas, according to age. Compared with adults, children have larger heads and smaller legs. Other areas are relatively equivalent throughout life. The rule of nines is not accurate in determining the percentage of TBSA burned in children.

Figure 39-3 It may be difficult to accurately assess the depth or severity of a burn on the first visit. *A*, This is a full-thickness burn that will not heal without a skin graft. *B*, This blistered hot water burn is likely second degree, but full-thickness burns can develop under blisters.

with resultant influx of sodium into tissue and loss of protein into the interstitial spaces. Unfortunately, this contribution to tissue edema is less responsive to local cooling.[1]

Minor burns are considered tetanus-prone, and tetanus toxoid should be administered if the patient is unsure of his or her tetanus immunization status or when it has been more than 10 years since the last immunization. Nonimmunized patients should receive human tetanus immune globulin, 250 units intramuscularly, along with tetanus toxoid, and a booster injection of toxoid in about 3 weeks.

Definitive Care of the Minor Burn

Few areas in medicine are fraught with as much mysticism, personal bias, and unscientific dogma as the care of the minor burn wound. Many clinicians are rigidly committed to a specific ritual or approach merely because "it is the way it's done" in a specific institution or because the practitioner has had success with a particular therapy in the past. In reality, the plethora of successful regimens attests to the fact that almost any noninjurious approach results in a favorable outcome. Many misconceptions probably arise because the issues associated with major thermal injury are often erroneously extrapolated to the minor burn wound. Most minor outpatient burns do very well, regardless of therapy, and it is difficult to do anything wrong if common sense is evoked.

Minor burns are *not* associated with immunosuppression, hypermetabolism, or increased susceptibility to infection. [14] Many complications seen in minor burn care result from

TABLE 39-2 -- American Burn Association's Grading System for Burn Severity and Disposition of Patients

	Type of Burn		
	Minor	***Moderate***	***Major***
Criteria	<10% TBSA burn in adult	10%–20% TBSA burn in adult	>20% TBSA burn in adult
	<5% TBSA burn in young or old	5%–10% TBSA burn in young or old	>10% TBSA burn in young or old
	<2% full-thickness burn	2%–5% full-thickness burn	>5% full-thickness burn
		High-voltage injury	High-voltage burn

		Suspected inhalation injury	
		Circumferential burn	Known inhalation injury
		Concomitant medical problem predisposing the patient to infection (e.g., diabetes, sickle cell disease)	Any significant burn to face, eyes, ears, hands, feet, genitalia, or joints
			Significant associated injuries (e.g., fracture, other major trauma)
Disposition	Outpatient management	Hospital admission	Referral to burn center

Burn = partial-thickness or full-thickness burn, unless specified; TBSA = total percentage of body surface area affected by the injury; young = patient younger than 10 years of age; adult = patient 10 to 50 years of age; old = patient older than 50 years of age.

Adapted with permission from: Hospital and prehospital resources for optimal care of patients with burn injury: Guidelines for development and operation of burn centers. American Burn Association. J Burn Care Rehabil 11:98, 1990, with additional information from Hartford CE: Care of outpatient burns. In Herndon DN (ed): Total Burn Care. Philadelphia, Saunders, 1996, p 71.

overtreatment of the injury rather than undertreatment. Examples include too-vigorous dressing changes that may peel off newly formed skin and secondary infections or pseudomembrane formation that results from topical or systemic antibiotic use.

Burn Dressings

Open burn care.

Burns are cared for using two general methods: open or closed. In the *open* method, a burn wound dressing is not used. The area is left open to the air and is washed two to three times per day, followed by application of a topical agent. This is the preferred method for managing burns of the face and neck and is an excellent way to manage minor hand burns, because it allows continuous inspection and range-of-motion exercises. The open method is impractical in young active persons, in children, or in other individuals in whom wound contamination is likely. Although many burns may be treated with this method, many patients prefer a dressing over a wound for cosmetic reasons.

Simple closed dressing.

The *closed* burn treatment method involves a dressing, of which there are various types. This is the method of choice for managing most minor burns treated in the ED. Wound preparation and basic bandaging should include the following steps (Fig. 39-5):

1. The hair in the burn itself or around the wound should *not* be shaved. The burn may be washed gently with a clean cloth or gauze pads and a mild nonalcohol-based soap or detergent (e.g., Ivory, Dove, Hibiclens) and then flushed with normal saline. However, the benefit of this

seemingly rational intervention has never been proven, and this step should be minimal. There is no need to vigorously wash a minor wound with strong antiseptic preparations (such as Betadine and others). [15]
2. Obviously sloughed skin should be debrided. This may be accomplished with scissors and forceps, but an expeditious and effective (and often painless) method is to use a dry 10-cm × 10-cm gauze pad (Fig. 39-6) to quickly debride loose skin. Meticulous and time-consuming instrument debridement is often quite stressful to the patient. Analgesia should be provided for any painful debridement. Some clinicians prefer to debride a wound on a subsequent follow-up visit when the wound has matured and reached its full extent, thereby hoping to subject the patient to this procedure only once.
3. In the absence of infection, intact blisters are often left alone at the first visit (see subsequent discussion on blisters). Ruptured blisters are usually debrided as soon as they are recognized (Table 39-4). All sloughed skin and blisters are debrided if infection is present.
4. A fine mesh gauze or a commercial nonadherent gauze such as Adaptic or Aquaphor is applied to the dry burn wound.
5. The burn is covered with loose gauze fluffs. If fingers and toes are included in the dressing, *the web spaces are padded and the digits are individually wrapped and separated with strips of gauze*. Failure to individually wrap fingers and toes may result in further injury (see Figure 39-5*D*).
6. The entire dressing is wrapped snugly (but not tightly) with an absorbent, slightly elastic material such as Kerlix.
7. Antibiotic creams or ointments may be used as an option with this dressing. The topical antibiotic may be applied to the burned skin directly or impregnated into the gauze after step 3.

Figure 39-4 To cool a burn that cannot be easily immersed in water, cover the area with unfolded gauze pads that have been soaked in room-temperature saline. Continue to frequently soak the gauze with cool saline or tap water drawn up in a syringe. Adding a few ice chips to the liquid is helpful, but do not cover the burn with ice. Towels are generally too bulky for this procedure.

TABLE 39-3 -- Advantage of Prompt Burn Cooling

Reduction or cessation of pain
Elimination of local hyperthermia
Inhibition of postburn tissue destruction
Decreased edema
Reduced metabolism and toxin production

Burn dressings should enhance healing. Much is made of specific dressings and dressing materials, but no single approach has proven superior efficacy. *The most important characteristic of a dressing is that it is capable of controlling fluid balance.* To accelerate healing, a burn dressing should be designed to keep the wound surface moist but avoid pooling of fluids. [16] The best material for this purpose is a generous amount of *simple dry gauze* applied over a nonadherent dressing or topical preparation. The outer dressing layer should be porous to permit the evaporation of water from the absorbent dressing material. Some clinicians prefer to eschew a nonadherent portion of the dressing so that subsequent dressing removal aids in minor debridement.

Biologic dressings.

Biologic dressings are natural tissues, including skin, that consist of collagen sheets containing elastin and lipid. They are not routinely used in emergency care of minor wounds. Benefits of biologic dressings include a reduction in surface bacterial colonization, diminished fluid and heat loss, prevention of further wound contamination, and prevention of damage to newly developed granulation tissue. Examples of biologic dressings include cadaveric human skin and commercially available porcine xenograft or collagen sheets.

Synthetic dressings.

Synthetic dressings are manufactured in various forms. Film-type dressings have a homogeneous structure and are usually polymers. Because these dressings are

nonpermeable, there have been problems with retention of wound exudate. Some second-generation dressings have been developed to address these problems. These products include *Tegaderm*, *Vigilon*, *DuoDerm*, *Biobrane*, *Op-Site Omniderm*, *Sildimac, and others*.[17] These preparations have theoretical benefits under certain circumstances, but none has proven superior performance over simple gauze dressings for minor outpatient burns. These products are most often used by burn centers and have little applicability for minor burns discharged from the ED.

Application of biologic and synthetic dressings.

All of these dressings are best used on fresh *partial-thickness burns*; placement over a contaminated wound often results in nonadherence and infection. Biologic and synthetic dressings are readily available. These dressings provide immediate relief of pain and are the only dressings that may actually promote faster wound healing.[2] In addition, these dressings have the potential for a reduced number of dressing changes.

Biologic dressings, such as porcine xenograft, are applied as follows: The dressing is reconstituted as instructed by the manufacturer and is carefully "fit" to the wound. All fluid and air under the graft are pressed out. The dressing is secured with edge tapes and covered with coarse mesh gauze, and then the dressing is wrapped with absorbent gauze and a semi-elastic wrap. With healing, the biologic dressing dries, curls, and separates from the healed edge underneath. The loose edges should be trimmed frequently, any blisters debrided, and fluid accumulations drained.

Synthetic dressings are applied after standard wound cleansing. Blisters must be debrided before application of the

Figure 39-5 Outpatient burn dressing of the hand. Persons with serious hand burns should be admitted to the hospital, but persons with minor burns can be treated in the outpatient setting. Following application of an antibiotic ointment or a dry, nonadherent dressing, the fingers are separated with fluffs in the web spaces *(A),* and the entire hand is enclosed in a position of function *(B)* (here with the help of a roll of Kerlix). If the wrist is involved, a removable plaster splint may be applied over the dressing *(C)*. *D,* The result of a minor burn to the hand when the fingers were not wrapped individually. Initially there were only a few blisters, but this patient now has second-degree skin loss due to an improper burn dressing that caused maceration of normal skin. Not only were the fingers *incorrectly* wrapped together in one gauze wrap, but the first wound check was *incorrectly* scheduled in 6 days, too long for the first wound check in a hand burn.

synthetic dressings. The thicker membranes are cut to size and applied to the burn surface. The edge of the membrane should extend 2 to 3 cm beyond the burn onto the surrounding unburned tissue. Membranes such as DuoDerm can be wrapped about burned digits to permit continued function with limited motion during healing. [18]

Should fluid collect between the debrided burn and the dressing, one attempt at aspiration should be performed. If the fluid reaccumulates beneath the DuoDerm or Biobrane membranes after aspiration, the nonadherent portion of the fabric should be removed. For the first 5 to 8 days, the dressing should be checked at least every other day for adherence. After epithelialization is complete, the dressing begins to separate spontaneously and may be peeled away. [13]

If infection develops under a synthetic or biologic dressing, the dressing should be removed, the wound cultured, and treatment with topical (and possibly oral) antimicrobials instituted. Xenografts should not be used on superficial partial-thickness injuries, because the xenograft tissue may become incorporated into the healing wound in as many as 35% of patients so treated.[19]

Occasionally, application of a permanent dressing—or skin autograft—is appropriately performed in the outpatient setting. Appropriate patient selection is crucial; patients should be healthy and well motivated, with small (<2% TBSA), noncosmetic deep partial-thickness or full-thickness burns. These burns may initially be treated as outlined previously, with the use of a topical antimicrobial agent recommended. The wound should be reevaluated for excision and grafting within 4 days.

Specific Clinical Issues in Minor Burn Care

Analgesia

Pain is a much-feared feature of any burn injury. Pain relief by the appropriate and judicious use of narcotic analgesics is of paramount importance in the initial care of all burn patients. Analgesia should be provided *before* extensive examination or debridement is performed. Inadequate analgesia is probably the most common ED error in the treatment of burn injuries. This error is most common in children. Parenteral narcotic analgesics have been erroneously relegated to pain control in only major burns, but it is suggested that intramuscular (IM) or intravenous (IV) narcotics be generously administered in the initial treatment of even minor painful burns.

Even with minor burns, patients often present with significant pain. Reassurance is important, but adequate analgesia is critical for gaining the patient's cooperation and ensuring comfort. Cooling may dramatically relieve pain temporarily, but parenteral opioids (meperidine, 1 to 2 mg/kg, or morphine, 0.1 to 0.2 mg/kg) are usually required, especially if painful procedures such as debridement and dressing changes are planned. We prefer to use IV opioids (occasionally supplemented with a short-acting benzodiazepine such as midazolam) for all painful procedures. For complicated debridement or dressing changes, adequate analgesia and sedation (see Chapter 34) is strongly advocated.

IM medications following the procedure are helpful for prolonged analgesia. Regional or nerve block anesthesia is an excellent alternative when practical, and when feasible, nitrous

Figure 39-6 It is difficult to do anything wrong with minor burn blisters, and many regimens are acceptable. Eventually, however, blisters will have to be debrided. An expeditious and relatively painless way to debride a burn is to use a dry gauze pad to grasp the dead skin *(A)* and peel it off *(B)*. Meticulous instrument debridement is often time consuming and stressful to the patient. Be aware that pain occurs when air comes in contact with the debrided skin and prophylactic analgesia should be provided.

oxide analgesia may be used. Oral opioids are inappropriate for initial treatment of significant pain but can be used for continued outpatient analgesia. Local anesthetics may be injected in small quantities when appropriate, such as for the debridement of a deep ulcer or other small burn. Topical analgesics have no role in burn care. A properly designed dressing will do much toward preventing further discomfort after release home; however, home burn care and dressing changes may be quite painful. For this reason an adequate supply of an oral opioid analgesic should be provided, and responsibility should be encouraged in analgesic use.

Edema

Minor burns lead to immediate inflammation mediated by the release of histamine and bradykinins, causing localized derangements in vascular permeability, with resultant burn wound edema. This edema is harmful in several ways. First, the increase in interstitial fluid increases the diffusion distance of oxygen from the capillaries to the cells, increasing hypoxia in an already ischemic wound. Second, the edema may produce untoward hemodynamic effects by a purely mechanical

mechanism: compression of vessels in muscular

TABLE 39-4 -- General Approach to Blisters in Minor Burns*

If treated <48 hours after the burn:
1. Leave all intact blisters alone.
2. If blisters have ruptured, treat them as dead skin and debride them completely.
3. Needle aspiration is generally not advised but may be used to decompress large burn blisters that appear ready to burst.
On follow-up, or >48 to 72 hours after the burn:
1. Debride large (>5 cm in diameter) intact blisters and all blisters that have ruptured. Large, firm blisters of the palms and soles may be left intact longer. Do not aspirate blisters.
2. Do not debride small or spotty blisters until they break, or until 5 to 7 days after the burn.
Five to 7 days after the burn:
1. Debride all blisters completely
Note: Intact blisters provide significant pain relief. Be prepared for an exacerbation of pain immediately after debridement.
Prophylactic analgesia is recommended.

*All blisters and burned skin are debrided in the presence of infection.

compartments. Third, edema has been associated with the inactivation of streptococcicidal skin fatty acids, thus predisposing the patient to burn cellulites. [20]

The successful management of burn edema hinges on *immobilization* and *elevation*. Most patients are unfamiliar with the medical definition of elevation and are not aware of or convinced of its value. Patient education in this regard is critical; however, certain burns (e.g., burns in dependent body areas) are prone to edema, despite everyone's best intentions. It is for this reason that lower extremity burns in general, and foot burns in particular, are prone to problems. Major burns of the hand should be elevated while the patient is still in the ED. This is most readily accomplished by hanging the injured hand from an IV pole, with stockinette used to support the bandaged hand (Fig. 39-7).

Use of Topical Preparations/Antimicrobials

Minor burns result in insignificant impairment of normal host immunologic defenses, and burn wound infection is usually not a significant problem. Topical antimicrobials are often used; however, some believe these agents may actually impair wound healing. [21] Although the procedure is of unproven value, many clinicians routinely use antibiotic creams or ointments on even the most minor of burns. Most patients expect some type of topical concoction, so a discussion of their use, or nonuse, is prudent.

Topical antimicrobials were designed for the prevention and care of burn wound sepsis or wound infection, primarily in hospitalized patients with major burns, and there is no convincing evidence that their use alters the course of first-degree burns and superficial partial-thickness injuries. As noted, the burn dressing is the key factor in minimizing complications in all burns. Nonetheless, topical antimicrobials are often soothing to minor burns, and their daily use prompts the patient to look at the wound, assess healing, perform prescribed dressing changes, or otherwise become personally involved in his or her care. Keep in mind that if a topical antimicrobial is used, its effectiveness is decreased in the presence of proteinaceous exudate, necessitating regular dressing changes if the antimicrobial benefit of topical therapy is to be realized. In reality, once-daily dressing changes are most practical and are commonly prescribed, and there are no data to indicate that this regimen is inferior to more frequent dressing changes.

Figure 39-7 Elevation of a burned hand should begin in the ED. After a properly applied hand dressing is applied, the arm is suspended from an IV pole with stockinette.

All full-thickness burns should receive topical antimicrobial therapy, because the eschar and burn exudate are potentially good bacterial culture media, and deep escharotic or subescharotic infections may not be easily detected until further damage is done. All deep partial-thickness injuries likewise benefit from the application of a topical antimicrobial. In deep partial-thickness injuries, re-epithelialization occurs from a few remaining deep epidermal appendages whose protection is important. Clinical studies and culture results support the hypothesis that surface destruction of dermal islands by bacterial enzymes and catabolic processes has the potential to convert a deep partial-thickness injury to a full-thickness injury. [22]

Initial topical therapy is prophylactic. [23] A burn wound infection that develops despite this therapy mandates a change to a different agent. Topical therapy, if chosen, should cover the usual bacteria responsible for burn wound infections (see later discussion of minor burn infections). Although topical agents are an important part of a burn treatment program, they are not substitutes for good local wound care or a careful program of management. Their successful use may prevent the conversion of deep thermal burns to deeper injury and allow better wound healing for earlier (and more successful) skin grafting.

Criteria for choosing a specific topical agent include in vitro and clinical efficacy, toxicity (absorption), superinfection rate, ease and flexibility of use, cost, patient acceptance, and side effects. Note that there are no firm scientific data that convincingly support the use of any specific topical antimicrobial in minor outpatient burns.

Specific Topical Agents

Silver sulfadiazine (Silvadene).

This poorly soluble compound is synthesized by reacting silver nitrate with sodium sulfadiazine. It is the most commonly used topical agent for outpatients, and it is well tolerated by most patients. It has virtually no systemic effects and moderate eschar penetration, and it is painless on application. Although Silvadene is commonly used, many burn specialists prefer plain bacitracin ointment as the topical of choice because of its cost, equal efficacy, and good patient acceptance.

Silver sulfadiazine is available as a "micronized" mixture with a water-soluble white cream base in a 1% concentration that provides 30 milliequivalent (mEq)/L of elemental silver. It does not stain clothes, is nonirritating to mucous membranes, and washes off easily with water. It may be used on the face, but such use may be cosmetically undesirable for open treatment. Its broad gram-positive and gram-negative antimicrobial spectrum includes ß-hemolytic streptococci, *Staphylococcus aureus* and *Staphylococcus epidermidis*, *Pseudomonas* spp., *Proteus* spp., *Klebsiella* spp., Enterobacteriaceae spp., *Escherichia coli*, *Candida albicans*, and possibly *Herpesvirus hominis*.

Silver sulfadiazine often interacts with wound exudate to form a pseudomembrane over partial-thickness injuries. The pseudomembrane is often difficult and painful to remove. Except for term pregnancy and in newborns (i.e., due to possible induction of kernicterus), there are no absolute contraindications to the use of silver

sulfadiazine. Allergy and irritation are unusual, although there is a potential cross-sensitivity between silver sulfadiazine and other sulfonamides.

Other topical preparations.

Mafenide acetate (Sulfamylon), gentamicin, chlorhexidine, povidone-iodine, and silver nitrate are products that have been replaced with newer topicals, but they are mentioned for historical interest. These products are not used in modern burn therapy, although they are generally acceptable alternatives.

Broad-spectrum antibiotic ointments.

Many nonprescription topical antimicrobials are used for minor burn therapy. Included are bacitracin zinc ointment, polymyxin B-bacitracin (Polysporin), triple-antibiotic ointments such as polymyxin B-neomycin-bacitracin (Neosporin), and nitrofurazone (Furacin). These are all soothing, cosmetically acceptable for open treatment (such as on the face), and are effective antiseptics under burn dressings. Some researchers caution against agents containing neomycin because of a potential for sensitization (Fig. 39-8). The editors suggest plain bacitracin ointment as the routine topical agent, although Silvadene is a very acceptable alternative.

Aloe vera cream.

Aloe vera cream is commercially available in a greater than or equal to 50% concentration with a preservative. It exhibits antibacterial activity against at least four common burn wound pathogens: *Pseudomonas aeruginosa*, *Enterobacter aerogenes*, *S. aureus*, and *Klebsiella pneumoniae*. Heck and colleagues compared a commercial aloe vera cream with silver sulfadiazine in 18 patients with minor burns. [24] Healing times were found to be similar, and there was no increase in wound colonization in the aloe vera group as compared with the patients treated with silver sulfadiazine. Other authors have promulgated the use of aloe gel preparations for minor burns. [25] Aloe vera cream is an acceptable inexpensive option for open or dressed outpatient care of minor burns.

Honey.

Honey has long been advocated as an inexpensive and effective topical for minor outpatient burns. The

Figure 39-8 *A*, The most popular topical burn preparation is Silvadene cream. While commonly used on minor burns, it likely has little beneficial effect on healing, and minor burns rarely become infected. Nonetheless, Silvadene is a standard intervention that at least causes the patient to look at the burn and become involved in dressing changes. *B*, Many burn specialists suggest inexpensive topical antibiotic ointments (such as bacitracin and neosporin) for all outpatient burns. They are commonly used on face and neck burns. Bacitracin is preferred since a contact dermatitis, such as noted in this abrasion, can occur from the neomycin portion of some topicals.

physicochemical properties of honey (osmotic effect, pH) give this product antibacterial and anti-inflammatory properties that support its use. It may be superior to Silvadene with regard to minor burn wound healing. Honey is not widely used, but it has been promulgated as a safe, effective, and inexpensive dressing for the management of outpatient burn wounds. [26] [27] [28]

Corticosteroids.

High-potency topical steroid preparations have no beneficial effects on the rate of healing, or limitation of scarring, of thermal burns. Although likely not harmful, their use is not supported. [29]

FOLLOW-UP CARE OF MINOR BURNS

The specifics of outpatient follow-up of minor burns are controversial and often based on clinician preference and personal bias rather than on firm scientific data. Follow-up should be individualized for each patient and should be based on the reliability of the patient, the extent of the injury, the frequency and complexity of the dressing changes, and the amount of discomfort anticipated during a dressing change. Often fast-track sections of the ED are used for burn checks. The physical therapy departments of most hospitals have excellent facilities to follow outpatient burns with periodic clinician oversight.

If a topical antibiotic agent is used, the dressing should be changed daily with removal and reapplication of the topical preparation. The wound should be rechecked by a clinician after 2 to 3 days and periodically thereafter, depending on compliance, healing, and other social issues. If a dry dressing is opted for, follow-up every 3 to 5 days is usually adequate. The purpose of any burn dressing changes or home care regimen is defeated if the patient cannot afford the material or is not instructed in the specifics of burn care. Many EDs supply burn dressing material on patient release. (A complete pack includes antibiotic ointment/cream, gauze pads [fluffs], an absorbent gauze roll, a sterile tongue blade to apply cream, and tape.) Providing limited supplies of the items necessary for dressing changes may enhance compliance to follow-up if the patient has to return for additional supplies. Writing a prescription and merely stating that the dressing should be changed daily is often futile.

Daily home care can be performed by the patient with help from a family member or visiting nurse (Table 39-5). The dressing may be removed each day and gently washed with a clean cloth or a gauze pad, tap water, and a bland soap. Sterile saline and expensive prescription soaps are not required. A tub or shower is an ideal place to gently wash off burn cream. The affected area may be put through a gentle range of motion during dressing changes. After the burn is cleaned, it is inspected by the patient. The patient is instructed to return if signs or symptoms of infection, significant blistering, or skin slough develop. Following complete removal of the old cream, a new layer is applied with a sterile tongue blade and covered with absorbent gauze.

If the undermost fine mesh gauze of a dry dressing is dry and the coagulum is sealed to the gauze, the patient should simply reapply the overlying gauze dressing. If the wound is macerated, the fine mesh gauze should be removed and the wound cleaned and redressed. The patient is instructed *not to remove a dry adherent fine mesh gauze from the underlying crust*. When epithelialization is complete, the crust will separate, and the gauze can be removed at that time. Dryness in healing skin may be treated with mild emollients such as Nivea (Beiersdorf, Inc., Norwalk, CT) or Vaseline Intensive Care lotion (Chesebrough Ponds, Inc., Greenwich, CT). Natural skin lubrication mechanisms usually return by 6 to 8 weeks. [14] Excessive sun exposure should be avoided during wound maturation, as this may lead to hyperpigmentation. When the patient is outdoors, a commercially available sun block should be used. Exposure of the recently healed burned area to an otherwise minor trauma (chemicals, heat, sun) may result in an exaggerated skin response. Pruritus is common, and may be treated with oral antihistamines or a topical moisturizing cream.

Deep partial-thickness burns, along with small third-degree burns, may be initially managed in the outpatient setting with proper follow-up. Topical antimicrobials are recommended.

TABLE 39-5 -- How to Change a Burn Dressing at Home: Patient Instructions

1. Take pain medicine ½ hour before dressing change if you find dressing changes to be painful.
2. If the burn is on the hand, foot, or other area that is difficult to reach, have someone help you.
3. Have all material available. Gloves may be worn.
4. Remove the dressing and rinse off all burn cream or ointment with tap water, under a shower, or in the bathtub. The area can be gently washed with mild soap and a clean cloth or gauze pads.
5. Look at the burn and assess the healing, blistering, and amount of swelling. Note any signs of infection.
6. Gently exercise the area through range of motion.
7. Apply the burn ointment with a sterile tongue blade.
8. Cover the cream with fluffed-up gauze.
9. Wrap the area in bulky gauze.
10. Repeat this dressing change daily.

Outpatient Physical Therapy for Burn Care

When the hospital's outpatient physical therapy department is equipped to treat minor burns, it is prudent to consider this option. Many centers make available daily or periodic burn treatment, consisting of dressing changes, whirlpool debridement, and range-of-motion exercises. When patients are unable to handle their own burns at home, this can be an invaluable adjunct. An additional advantage is that medically trained personnel evaluate the burn daily, thereby decreasing clinician visits and enabling identification of problems prior to the development of serious complications. Generally all that is required from the clinician is to write a prescription for "burn care and dressing changes" and set up the appointment. The physical therapy department, or wound care center, can receive clinician input as needed during subsequent visits.

Burn Healing

Follow-up care will in part be guided by expectations of burn healing and observed healing. The following discussion is intended to serve as a general guide. However, burn healing is different from that of other wounds. [2] The timing is often variable, but it is proportional to burn depth. The inflammatory phase lasts 3 to 7 days (at times longer) and, if the burn is severe enough, is accompanied by the release of histamine and bradykinins, along with complement degradation. This degradation of complement may lead to immunologic, coagulation, and metabolic aberrations.

Within 1 to 3 weeks, neovascularization of the burn occurs, accompanied by fibroblast migration. Macrophages begin to replace the tissue neutrophils. Collagen production begins, but the molecules are often laid down in random fashion, leading to a scar. Re-epithelialization follows, but the presence of necrotic tissue and eschar impedes all aspects of wound healing. The amount of scar tissue produced is directly related to healing time. Burns requiring fewer than 16 days to heal generally do not scar excessively. [2]

Healing in superficial partial-thickness burns occurs within 10 to 14 days. After healing, the new epithelial layer tends to dry easily and crack. Using bland, lanolin-containing creams for 4 to 8 weeks following healing alleviates this problem. Deep partial-thickness burns heal by re-epithelialization from the wound edge and from residual dermal elements. Healing is slow and often unsatisfactory, frequently taking longer than 3 weeks, producing an unstable epithelium that is prone to hypertrophic scarring and contractures. This is a particular problem in burns that extend across joints. Burns that take longer than 2 to 3 weeks to heal are prone to infection; hence, topical antimicrobials should be used. Because these burns often heal in complicated fashion, they should be considered for referral to expedite early excision, grafting, and physical therapy.

Full-thickness burns can heal only by contraction and epithelialization at the wound edge. Burns larger than 2 to 3 cm must be excised and grafted.

Cosmetic and functional recovery follows complete epithelialization of a partial-thickness injury or successful skin grafting of a full-thickness burn. The ultimate goal is to prevent scar thickening; achieve and maintain optimal range of motion; and prevent secondary environmental damage to the skin, particularly from sun exposure. [15] Nonscented skin lotions may be used after epithelialization to keep the burn scar soft. Compression dressings are especially helpful in preventing scar thickening. Repeated evaluations are important, because burn contractures can occur up to 12 months after the injury. Nighttime splinting is useful in maintaining full extension of joints.

SPECIAL MINOR BURN CARE CIRCUMSTANCES

Blisters

The management of blisters in minor burns is controversial. *In reality, there is little one can do wrong when it comes to a clinical approach to blisters in minor burns.* Management arguments are generally theoretic or emotional; the ultimate outcome of a minor burn is rarely determined by how one deals with blisters. Intact blisters do offer a physiologic dressing that rarely becomes infected; however, most large blisters spontaneously rupture after 3 to 5 days and eventually require debridement. When the integrity of the blister is breached, the fluid becomes a potential culture medium. Clinical choices include debridement, aspiration, or simply leaving the blister intact.

Some studies suggest that intact burn blisters may allow for reversal of capillary stasis and less tissue necrosis. [2] Madden and colleagues have shown that burn exudate (as contained within intact blisters) is beneficial for the stimulation of epidermal cell proliferation. [30]

Swain and colleagues demonstrated that the density of wound colonization with microorganisms was much lower in minor burns with blisters left intact. [31] They also found that 37% of patients with aspirated blisters experienced a reduction in pain versus none of those whose blisters were unroofed. Other investigators believe that undressed wounds with debrided blisters have additional necrosis secondary to desiccation, which can convert a partial-thickness burn to a full-thickness injury. [3] Finally, intact blisters clearly provide some pain relief, as evidenced by a sudden increase in pain immediately following debridement. Increased pain should be anticipated and analgesia offered as appropriate when debridement is necessary. We suggest the guidelines in Table 39-4 as a general approach to burn blisters.

Minor Burn Infections

Prophylactic systemic antibiotics are not warranted in the routine treatment of outpatient burns.

It may be difficult to separate the erythema of the injury or healing process from cellulitis, but minor burns rarely become infected, with infection rates well under 5%. [32] There are bacteria on the skin at all times—normal skin usually harbors nonvirulent pathogens such as *S. epidermidis* and diphtheroids. Therefore, all burns are *contaminated* but not necessarily *infected*. Thermal trauma results in a coagulative necrosis. Burn wounds therefore contain a variable amount of necrotic tissue, which, if infected, acts much as an undrained abscess, preventing access of antibiotics and host defensive factors.

The microbial flora of outpatient burns varies with time after the burn. Shortly after injury, the burn becomes colonized with gram-positive bacteria such as *S. aureus* and *S. epidermidis*. After this period of time there is a gradual shift toward inclusion of gram-negative organisms, 80% of which originate from the patient's own gastrointestinal tract. [4] Common organisms seen on days 1 to 3 include *S. epidermidis*, ß-hemolytic streptococci, *Bacillus subtilis*, *S. aureus*, enterococci, *Mima polymorpha*, *Enterobacter* spp., *Acinetobacter* spp., and *C. albicans*. One week after the burn, these organisms may be seen along with *E. coli*, *P. aeruginosa*, *Serratia marcescens*, *K. pneumoniae,* and *Proteus vulgaris*.

Anaerobic colonization of burn wounds is rare unless there is excessive devitalized tissue, as occurs in a high-voltage electrical injury. [33] For this reason, routine anaerobic cultures are generally unnecessary in an assessment of infective organisms that produce minor infections.

The vast majority of superficial burns that have been treated properly do not get infected. Infection rates are well below 5%. [32] However, it is sometimes difficult to differentiate wound infection from the normal healing process, as both involve pain, edema, and erythema. A healing burn may produce a leukocytosis and a mild fever in the absence of infection, especially in children. Early (days 1 to 5) burn infections are generally caused by gram-positive cocci, especially ß-hemolytic streptococci. Streptococcal cellulitis is characterized by marked, spreading erythema extending outward from the wound margins. Despite the plethora of organisms and the presence of some gram-negative pathogens noted in superficial burn cultures, first-line treatment in the normal host is oral penicillin, 1 to 2 g/day. Alternatives include erythromycin, cephalosporins, and dicloxacillin.

Effective topical treatment at the time of initial burn care and subsequent dressing changes is meant to delay bacterial colonization, maintain the wound bacterial density at low levels, and produce a less diverse wound flora. Because outpatient management of burns should be attempted only when the risk of infection is minimal, the use of systemic antibiotics is unnecessary for minor burns, even in the setting of delayed treatment, diabetes, and steroid use. [34] Unnecessary antibiotic use may select out resistant organisms. Antibiotics in the management of minor burns have been recommended for patients undergoing an autograft procedure. [35] There are no data on the use of antibiotics as prophylaxis for patients with burns in the setting of valvular heart disease, although their use seems logical.

In minor burn care, wound cultures are not required or recommended. It is useless, for example, to culture blister fluid in the patient who presents for emergency care immediately after a thermal injury. Cultures are necessary only when overt infection develops, especially when this occurs while a topical or systemic antibiotic is being used. Cultures may also be of benefit when the infected wound is old, when hygiene is poor, or when there are old abrasions nearby. [36] Swab surface cultures are generally eschewed. Although they may adequately reflect wound flora, falsely sterile cultures are relatively frequent. These cultures do not reflect deep burn flora and give no quantitative information.

Sterile wound biopsy for culture is most satisfactory for the assessment of intraescharotic, subescharotic, or invasive infections and allows for quantification of bacterial flora. If a wound culture is taken, it should be obtained from the deepest or worst-appearing area of the burn.

Surface bacterial densities greater than 10^5 /cm^2 or tissue bacterial densities greater than 10^5 /g correlate with invasive infection. Surface colonization may be treated with an alternative topical agent, but truly invasive infection warrants the administration of systemic antibiotics. Generally, the infectious process resolves in 24 to 48 hours.

Foot Burns

Despite their relatively small surface area, foot burns tend to heal poorly, usually due to excessive edema; therefore, they are formally categorized as major burns. Foot burns are the most common burn category to fail outpatient therapy and subsequently require admission and inpatient care (Fig. 39-9). Zachary and coworkers reported on a series of 104 patients with foot burns. [37] No patient admitted on the day of injury developed burn cellulitis; in contrast, 27% of delayed admission patients had cellulitis. Their study also noted a higher incidence of hypertrophic scarring and need for skin grafting in the delayed admission group. Overall, fewer days of hospitalization were required for the initially admitted group.

Specific problems in the care of foot burns include pain, wound drainage, difficulty in changing dressings without help, inability of even motivated patients to comply with requirements for elevation, and prolonged convalescence. Hospital admission allows for splinting, intensive local burn care, physical therapy, and bed rest with elevation, which minimizes edema. For these reasons, initial admission for all but the most minor of foot burns is advised.

Hand Burns

Because of their functional importance, hand burns can be a devastating injury, despite involvement of a relatively small TBSA. Hand function is critical, regardless of whether the patient is dealing with loss of use during healing, later limitation by scar contractures, a long-term appearance change, or loss due to amputation. [38]

As with other burns, the depth and extent of the burn determine the severity of the injury. The entire surface of one hand represents only 2.5% TBSA, yet even small

burns can cause a disproportionate functional loss. Deep partial- or full-thickness hand burns, even if quite small, often warrant referral for early excision and grafting in order to limit scarring and maintain function. The skin on the dorsum of the hand is thinner than that on the palm and is more susceptible to burn injury, but must remain flexible to allow for finger motion. Any exposed tendon or bone, such as may be seen with an electrical burn, constitutes a true fourth-degree injury, which

Figure 39-9 Burns of the feet are specialized burns that require a careful evaluation and an individualized treatment plan, even if the burn surface area is relatively small. It is difficult for most patients to provide ideal burn care at home when the feet are involved. *A*, It is tempting to initially treat this seemingly minor superficial second-degree foot burn in an outpatient setting, but the patient's compliance and social situation must be ideal for a successful outcome. Hospitalization until home health care can be established is prudent. *B*, An example of a foot burn that is a potential disaster, in this case due to a late presentation in a diabetic.

requires either flap closure or amputation in order to heal the wound.

Many of the issues complicating outpatient management of foot burns are relevant to the care of hand burns. After initial burn cooling, the wound should be gently cleansed with mild soap. Any loose skin or ruptured blisters should be gently debrided, rinsed, patted dry, and covered with a topical antimicrobial agent and a nonadherent, bulky gauze dressing. *The fingers should be carefully separated and bandaged individually.* Small, intact blisters that do not interfere with hand function should be left intact to serve as a biologic dressing. Elevation of the hand is very important in the first few days after a burn injury in order to minimize edema. Deep partial-or full-thickness burns to the dorsum of the hand should be splinted after bandaging to avoid the development of contractures or a boutonniere deformity.

Hospital admission should be considered for all hand burns, particularly full-thickness injuries and circumferential burns involving the digits (Fig. 39-10). If outpatient treatment is attempted, the patient must be given comprehensive instructions and should have the resources available to perform daily dressing changes and range-of-motion exercises of the fingers and wrist during these dressing changes. An initial follow-up visit should be arranged in 48 to 72 hours, but the patient should be encouraged to return if there is development of a burn cellulitis, worsening pain, fever, or lymphangitis. Ideally, the patient should be seen twice in the first week after injury and once a week after that until the burn is healed.

Facial Burns

Facial burns commonly result from unexpected ignition flash burns (e.g., from a stove, oven, or charcoal grill) or from car radiator accidents (Fig. 39-11).[39] [40] Facial burns from these sources usually do well, but often result in singeing of facial hair, significant edema, and pain. However, facial burns from these etiologies may rarely produce airway problems and require skin grafting. Concurrent globe or corneal injury is quite rare due to protective blinking reflexes. If the eye is burned, it is usually in the setting of a life-threatening concomitant burn injury. [41] Burns to the eyelids can cause significant scarring. Fluorescein staining and slit-lamp examination should be used to confirm the diagnosis of suspected corneal injury. The treatment of a corneal injury involves irrigation, topical ophthalmic antibiotic ointment, and consideration of eye patching versus protective soft contact lens (see Chapter 64). Referral to an ophthalmologist is usually prudent. Facial burns are otherwise treated in the usual fashion, and with an open (no dressing) technique. Patients are instructed to wash the face two to three times a day with a mild soap and then apply a thin layer of antibiotic ointment,

Figure 39-10 This badly burned hand requires referral to a burn center and should not be handled as an outpatient.

Figure 39-11 *A*, Flash burns to the face from lighting a gas stove. These burns are painful and may cause edema, but usually they do well. Note the singed facial hair. The eyes are usually protected by rapid reflex blinking and carbon monoxide poisoning and pulmonary burns are not an issue. Most can be handled in the outpatient setting with bacitracin ointment and no dressing. Pain control may be problematic unless opioids are prescribed. *B*, Facial and neck burns when a radiator cap was removed and the victim was sprayed with steam and hot antifreeze.

such as bacitracin zinc. There are no compelling reasons to avoid Silvadene on the face, but by tradition bacitracin ointment has become the preferred topical. Car radiator burns result from the combination of a hot liquid and steam burn. Antifreeze does not produce a caustic injury, nor is it systemically absorbed. Neck burns are treated similarly.

All patients presenting with head or neck burns should be carefully evaluated for a concomitant inhalation injury. Such patients may present with direct evidence of injury, such as oral burns, blisters, soot, or hyperemia, a history of being in an enclosed space, or with indirect evidence, such as dyspnea, wheezing, arterial hypoxemia, or an elevated carboxyhemoglobin level. The definitive diagnostic test for inhalation injury is fiberoptic bronchoscopy. [42] Flash ignition burns to the face do not pose a problem with carbon monoxide poisoning and inhalation injuries are generally not a consideration Inpatient care should be considered for all patients with significant facial burns. Outpatient pain control may be difficult in facial burns, the degree of edema may be difficult to predict, and home care can be problematic. There are no universally agreed-upon standards for admission versus outpatient treatment of facial burns, but a liberal admission policy is suggested.

Corneal contact burns, as from accidental contact with a curling iron, often present rather dramatically, with opacified, "heaped-up" corneal epithelium. Despite their appearance, the end result is usually excellent. Treatment is the same as for a corneal abrasion. [43]

Abuse of Children and Elderly Individuals

Recognition of the possibility of deliberate abuse by burning in the pediatric and geriatric populations is essential. In addition, children younger than 2 years old have a thinner dermis and a less well-developed immune system than do adults. Elderly patients (older than 65 years) likewise tolerate burns poorly. These two populations are the most prone to abuse, often by family members (Fig. 39-12). For these reasons, both groups of patients often require inpatient care. [9]

The majority of abused children are 18 to 36 months old, and for unknown reasons the majority are male. [21] Immersion burns are a common type of abuse. These are characterized by circumferential, sharply demarcated burns of the hands, feet, buttocks, and perineum. Cigarette burns and burns from hot objects such as irons should be obvious. Contact burns on "nonexploring" parts of the child also warrant suspicion. A delay in seeking treatment may be a tip-off that a burn results from abuse.

Burns in Pregnancy

There is little information in the literature concerning the special problems of the pregnant burn victim. Ying-bei and Ying-jie reported on 24 pregnant burn patients representing a wide range of burn severity. [44] Complications of the burn injuries included abortion and premature labor, although all patients in this series with burns covering less than 20% TBSA did well and delivered living full-term babies.

As the resistance of pregnant women to infection is lower than that of nonpregnant women, control of burn wound infection is paramount. Gestational age appears to have no direct bearing on prognosis. Silver sulfadiazine cream should be avoided near term because of the potential for kernicterus.

SPECIFIC BURNING AGENTS

Hot Tar Burns

Asphalts are products of the residues of coal tar commonly used in roofing and road repair. These products are kept heated to approximately 450°F. When spilled onto the skin, the tar cools rapidly, but the retained heat is sufficient to produce a partial-thickness burn. Fortunately, full-thickness burns are unusual. Cooled tar is nonirritating and does not promote infection. When cooled tar is physically removed, the adherent skin is usually avulsed (Fig. 39-13). Careless removal of the tar may inflict further damage on burned tissues. Agents such as alcohol, acetone, kerosene, or gasoline have been used to remove the tar, but these are flammable and may cause additional skin damage or toxic response secondary to absorption.

There is no great need to meticulously remove all tar at the first visit.

Obviously devitalized skin can be debrided, but adherent tar should be emulsified or dissolved rather than

Figure 39-12 Burns can be a manifestation of child abuse, spouse abuse, or abuse of the elderly. *A*, Abuse burns from contact with a hot metal grate, from a child allegedly falling. *B*, This burn was the result of spouse abuse, caused by throwing hot soup during an argument. The delayed presentation to the hospital was a clue. *C*, Burns of the face and neck are common when a toddler pulls hot liquid from a stove. This case was never proven to be child abuse, but burns in young children often are due to abuse, especially if they are in atypical places. Although the body surface area of this burn is relatively small, the patient's age and the burn's location, coupled with the possibility of child abuse, require that this child be hospitalized.

manually removed (Fig. 39-14). Polyoxyethylene sorbitan (Tween 80 or polysorbate 80) is the water-soluble, nontoxic emulsifying agent found in neosporin and several other topical antibiotic creams. Note that the cream formulations, not the ointments, contain the most useful tar dissolvers. The creams contain a complex mixture of ethers, esters, and sorbitol anhydrides that possess excellent hydrophilic and lyophilic characteristics when used as nonionic, surface-active emulsifying agents. With persistence, most tar may be removed (emulsified) on the initial visit.

Another household product (De-Solv-It multi-use solvent) also appears logical for topical ED use. [45] The De-Solv-It product has a surface-active moiety that wets the chemical's surface and emulsifies tar and asphalt. Since the latter product is itself a petroleum-based solvent, it should be applied only briefly, and the operator should wear gloves and protective eyewear during application. It should be used only for external exposure to tar or asphalt.

Many clinicians prefer instead to emulsify the majority of tar on an outpatient basis. A generous layer of polysorbate-based ointment can be applied under a bulky absorbent gauze dressing. The patient is then released home, and the residual is easily washed off after 24 to 36 hours (Fig. 39-15). A number of dressing changes may be required. Once the residual tar is removed, the wound is treated like any other burn.

Shur-Clens, a nontoxic, nonionic detergent, also works well for tar burn wound cleansing, as do mineral oil; petrolatum; and Medisol (Orange-Sol, Inc, Chandler, AZ), a petroleum-citrus product. Butter-soaked gauze has been suggested as an emulsifier of tar.

Chemical Burns

Chemical burns usually occur in the workplace, and the offending substance is usually well-known. More than 25,000 chemicals currently in use are capable of burning the skin or mucous membranes. Commonly used chemical agents capable of producing skin burns are shown in Table 39-6 .

Injury is caused by a chemical reaction, rather than a thermal burn. [46] Reactions are classified as oxidizing, reducing, corrosive, desiccant, or vesicant or as protoplasmic poisoning. The injury to skin continues until the chemical agent is physically removed or exhausts its inherent destructive capacity. The degree of injury is based on chemical strength, concentration, and quantity; duration of contact; location of contact; extent of tissue penetration; and mechanism of action.

Immediate flushing with water is recommended for all chemical burns, with the exception of those caused by alkali metals. Flushing serves to cleanse the wound of unreacted surface chemical, dilute the chemical already in contact with tissue, and restore lost tissue water. Leonard and colleagues clearly demonstrated that patients receiving immediate copious water irrigation for chemical burns showed less

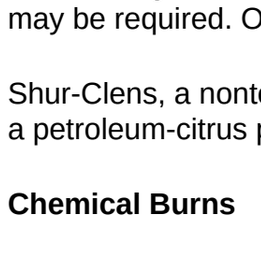

Figure 39-13 There is no compelling reason to remove all tar on the first visit. Physical removal of cooled tar usually results in avulsion of the underlying skin. Skin that is obviously loose should be debrided, but adherent tar is best liquefied with an emulsifying agent. Neomycin cream, not ointment, is a suggested emulsifier, but others are acceptable (see text). Final removal may be delayed for several days to permit loosening of the tar. Frequent dressing changes using an emulsifying agent can be performed by the patient, removing the tar over a few days.

full-thickness burn injury and a greater than or equal to 50% reduction in time of hospital stay. [47]

Acid and Alkali Burns

Alkalis cause saponification and liquefactive necrosis of body fats. Alkaline burns are *penetrating* and cause much tissue destruction. With acid burns, tissue coagulation produces a thick eschar that limits the penetration of the agent. Desiccant acids, such as sulfuric acid, create an exothermic reaction with tissue water and can cause both chemical and thermal injury. With extensive immersion injuries, acids may be systemically absorbed, leading to systemic acidosis and coagulation abnormalities.

Chemical burns may be excruciatingly painful for long periods of time. Discomfort can be out of proportion to what one might expect from the depth or extent of the burn.

The emergency care team should remove all potentially contaminated clothing. Any dry (anhydrous) chemical should be brushed off the patient's skin. The involved skin should be irrigated with large amounts of water under low pressure. Any remaining particulate matter should be carefully debrided during irrigation.

Strong alkali burns may require irrigation for 1 to 2 hours before the tissue pH returns to normal. Some recommend that *after extensive irrigation*, if the burn continues to feel "slippery" or tissue pH has not returned to normal, chemical neutralization may be helpful. [48] [49] Given that any heat of neutralization will be carried away with the irrigation solution, [50] prompt irrigation with a dilute acid (e.g., vinegar; 2% acetic acid) may hasten neutralization and patient comfort.

Wet Cement Burns

The major constituent of Portland cement, an alkaline substance, is calcium oxide (64%), combined with oxides of

Figure 39-14 Tar stuck to the face *(A)* can be emulsified with various agents and a lot of patience and persistence *(B)*. Fortunately, tar burns are usually not full-thickness burns.

silicon, aluminum, magnesium, sulfur, iron, and potassium. There is considerable variability in the calcium oxide content of different grades of cement, with concrete having less and fine-textured masonry cement having more. [47] The addition of water exothermically converts the calcium oxide to calcium hydroxide, a strongly corrosive alkali with a pH of 11 to 13. As the cement hardens, the calcium hydroxide reacts with ambient carbon dioxide and becomes inactive.

Both the heat and the $Ca(OH)_2$ produced in this exothermic reaction can result in significant burns. Because of its low solubility and consequent low ionic strength, a long exposure to calcium hydroxide is required to produce injury. This usually occurs when a worker spills concrete into his or her boots or kneels in it for a prolonged period. The burn wound and the resultant protein denaturation of tissues produce a thick, tenacious, ulcerated eschar. Concrete burns are insidious and progressive. What may appear initially as a patchy, superficial burn may in several days become a full-thickness injury requiring excision and skin grafting. [51] The pain of these burns is often severe and more intense than the appearance of the wound might suggest (Fig. 39-16). Interestingly, many workers are not warned of the dangers of prolonged contact with cement, and because initial contact with cement is

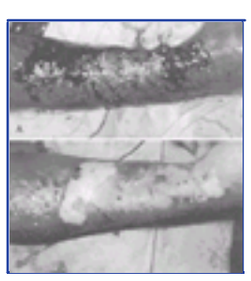

Figure 39-15 There is no need to remove all the tar on the first visit *(A)*. This extremity was covered with an emulsifying agent and with gauze, and the residual tar was washed off easily 36 hours later *(B)*.

usually painless, exposure may not be realized until the damage is done.

Treatment is as follows: Any loose particulate cement or lime is brushed off, contaminated clothing is removed, the wound is copiously irrigated with tap water (the pH of the effluent is tested and irrigation continued if the effluent is still alkaline). Compresses of dilute acetic acid (vinegar) may be applied to neutralize the remaining alkali and provide pain relief after irrigation, and antibiotic ointment is applied to the eschar during the early postburn period.

Sutilains ointment (Travase, Flint Pharmaceuticals, Deerfield, IL) is often recommended because it contains proteolytic enzymes and helps speed eschar separation, but any common topical burn preparation is acceptable. The depth of burns from wet cement can be difficult to assess in

TABLE 39-6 -- Commonly Used Acids and Alkalis

the first several days. If it becomes apparent that the burns are full-thickness burns, early excision and skin grafting are recommended.

Cement burns should be differentiated from cement dermatitis, which is far more common. The latter is a contact sensitivity reaction, probably due to the chromates present in cement. The contact dermatitis can initially be treated as a superficial partial-thickness burn.

Air Bag Keratitis/Thermal Burns

Safety legislation has mandated increased use of air bags to protect automobile occupants in the event of collision. Burns from air bags can be thermal, friction, or chemical. The automobile air bag is a rubberized nylon bag that inflates on spark ignition of sodium azide, yielding nitrogen gas, ash, and a small amount of sodium hydroxide. Within seconds the superheated air is vented, and this can produce a thermal burn if it contacts an extremity, face, or upper torso. [52] [53] If the air bag ruptures, the alkaline contents of the bag are dispersed as a fine, black powder that usually causes no problems unless the eyes are exposed. Patients present with clinical evidence of a chemical keratoconjunctivitis, including photophobia, tearing, redness, and decreased visual acuity. The tear pH is usually elevated, and there may be a small amount of particulate material in the fornices. [54]

The severity of an ocular alkaline burn is related to the duration of exposure and the concentration and pH of the chemical. For this reason, prompt, copious irrigation of the eyes with frequent assessment of tear pH is essential to prevent or minimize the injury (see Chapter 64). A rising pH suggests that trapped particulate matter is releasing additional chemical. Corneal edema and conjunctival blanching are signs of serious injury and necessitate immediate ophthalmologic consultation.

Hydrocarbon Burns

Hydrocarbons are capable of causing severe contact injuries by virtue of their irritant, fat-dissolving, and dehydrating properties. Cutaneous absorption may cause even more dangerous systemic effects. Gasoline, the usual agent involved, is a complex mixture of C_4 to C_{11} alkane hydrocarbons and benzene; the hydrocarbons appear to be the major toxic agent. Lead poisoning caused either by absorption through intact skin or burns from "leaded" gasoline exposure have been previously reported but are currently quite rare, as unleaded gasoline has virtually replaced the leaded version for most purposes. [55]

Depth of injury is related to the duration of exposure and concentration of the chemical agent. Gasoline immersion injuries resemble scald burns and are usually partial thickness.[56] Occasionally, gasoline-injured skin exhibits a pinkish brown discoloration, possibly related to dye additives. A common source of exposure is a comatose patient from a motor vehicle crash who had been lying in a pool of gasoline.

The lungs are the usual site of systemic absorption and are often the only major route of excretion. The resultant high pulmonary concentrations may lead to pulmonary hemorrhages, atelectasis, and adult respiratory distress syndrome (ARDS). Treatment of hydrocarbon burns includes the following: removal of contaminated clothing, prolonged irrigation or soaking of the contaminated skin, early debridement in significant burns caused by lead-containing gasolines (to reduce systemic lead absorption), and use of topical antibiotic ointments.

Figure 39-16 Alkali burns from wet cement develop insidiously, are extremely painful, and are frequently full-thickness injuries. They are most common on the feet when cement leaks over the top of the boots *(A)* or from kneeling in wet cement while working *(B)*. The alkali can penetrate clothing.

Phenol Injury

Phenol is a highly reactive aromatic acid alcohol that acts as a corrosive. Carbolic acid, an earlier term for phenol, was noted to have antiseptic properties and was used as such by Joseph Lister in performing the first antiseptic surgery. Hexylresorcinol, a phenol derivative, is in current use as a bactericidal agent. Phenols, in strong concentrations, cause considerable eschar formation, but skin absorption also occurs and can cause systemic effects such as central nervous system depression, hypotension, hemolysis, pulmonary edema, and death. Interestingly, phenol acts differently from other acids in that it penetrates deeper when in a dilute solution than when in a more concentrated form.[46] Therefore, irrigation with water is suboptimal for phenol burns, but because water commonly is readily available, it is frequently used for irrigation.

Full-strength polyethylene glycol (PG 300 or 400) is more effective than water alone in removing phenolic compounds and should be obtained and used after water irrigation has begun. Polyethylene glycol is nontoxic and nonirritating and may be used anywhere on the body. When immediately available, polyethylene glycol can be used to remove the surface chemical before water irrigation (and chemical dilution) is begun.

Hydrofluoric Acid Injury

Hydrofluoric acid (HFA) is one of the strongest inorganic acids known; it has been widely used since its ability to dissolve silica was discovered in the late 17th century.[57] Currently, HFA is used in masonry restoration, glass etching, and semiconductor manufacturing; for control of fermentation in breweries; and in the production of plastics and fluorocarbons. It is also used as a catalyst in petroleum alkylating units. It is available in industry as a liquid in varying concentrations up to 70%. It is also readily sold in home improvement and hardware stores. Significant concentrations of HFA are present in many home rust-removal products, and in aluminum brighteners, automobile wheel cleaners, and heavy-duty cleaners in concentrations of less than 10%. Despite its ability to cause serious burns, unregulated and poorly labeled HFA products are recklessly used on a regular basis in the home and in small businesses. The public and many clinicians are generally unaware of the potential problems with this acid (Fig. 39-17).

Although HFA is quite corrosive, the hydrogen ion plays a relatively insignificant role in the pathophysiology of the burn injury. The accompanying fluoride ion is a protoplasmic poison that causes *liquefaction necrosis and is notorious for its ability to penetrate tissues and cause delayed pain and deep tissue injury*. This acid can penetrate through fingernails and cause nailbed injury. With home products, the unwary user does not realize that the substance is caustic until the skin (usually the hands and fingers) is exposed for a few minutes to hours, at which time the burning begins and becomes progressively worse. At this point the damage is done, and the absorbed HFA cannot be washed off. With higher-strength industrial products, symptoms are almost immediate.

The initial corrosive burn is due to free hydrogen ions; secondary chemical burning is due to the tissue penetration of fluoride ions. Fluoride is capable of binding cellular calcium, resulting in cell death and liquefaction necrosis. The ionic shifts that result, particularly shifts of potassium, are believed to be responsible for the severe pain associated with HFA burns.

In high concentrations, the fluoride ions may penetrate to the bone and produce demineralization. Skin exposure to concentrated HFA involving as little as 2.5% TBSA can lead to systemic hypocalcemia and death from intractable cardiac arrhythmias; it has been calculated that exposure to 7 mL of anhydrous HFA (HFA gas) is capable of binding *all* of the free calcium in a 70-kg adult.[58] [59] If the hands are exposed, the acid characteristically penetrates the fingernails and injures the nailbed and cuticle area. As with most caustics, *the pain is generally out of proportion to the evident external physical injury*. HFA burns produce variable areas of blanching and erythema, but rarely are blisters or skin sloughing seen initially. Skin necrosis and cutaneous hemorrhage may be noted in a few days.

Figure 39-17 *A*, Initially this very painful hydrofluoric acid burn of the thenar and hypothenar emminence appeared minimal. *B*, Despite infiltration with calcium gluconate, a deep burn developed 3 days later.

Immediate treatment should begin with copious irrigation with water. Another approach is to wash the area with a solution of iced magnesium sulfate (Epsom salts) or a 1:500 solution of a quaternary ammonium compound such as benzalkonium chloride (Zephiran) or benzethonium chloride (Hyamine 1622). Magnesium and calcium salts form an insoluble complex with fluoride ions, preventing further tissue diffusion. While frequently recommended, topical preparations are often ineffective in limiting injury or controlling pain.

If there is no or only minimal visible evidence of skin injury and minimal pain, the burn may be dressed with topical calcium gluconate paste. This is not commercially available in the United States but is easily compounded in the pharmacy by mixing 3.5 to 7 g of pulverized calcium gluconate with 5 oz of a water-soluble lubricant such as K–Y Jelly. This will form a thick paste with a calcium gluconate concentration of 2.5% to 5.0%. Some have suggested dimethyl sulfoxide (DMSO) as a vehicle to aid in skin penetration of the calcium. Plastic wrap (e.g., Saran wrap) is used over a standard dry burn dressing to cover the calcium paste on the limbs; a vinyl or rubber glove is used over the paste when used on the hands. The wound should be completely redressed and the paste reapplied every 6 hours for the first 24 hours.

As with most topical treatments of HFA burns, calcium gluconate is only minimally effective in relieving pain, and its value is likely overestimated in the literature.

A digital or regional nerve block with long-acting bupivacaine is an excellent way to provide prolonged pain relief if the hands are involved, but this does nothing to ameliorate the injury. In most cases oral opioids are required. If bullae or vesicles have formed, these should be debrided to decrease the amount of fluoride present, and the wound should then be treated as any partial-thickness burn. Burns with HFA of less than 10% strength will heal spontaneously, usually without significant tissue loss, but pain and sensitivity of the fingertips may persist for 7 to 10 days. In addition, the fingernails may become loose.

The presence of significant skin injury or intense pain implies penetration of the skin by fluoride ions. This scenario is particularly common with exposure to HFA solutions in concentrations of greater than or equal to 20%, but tissue injury can occur with prolonged exposure to less concentrated products.

Initial treatment of a more concentrated exposure begins as described earlier and includes immediate debridement of necrotic tissue to remove as much fluoride ion as possible. Following this, a 10% solution of calcium gluconate *(note: avoid calcium chloride for tissue injections)* is injected intradermally and subcuticularly with a 30-ga needle about the exposed area, using about 0.5 mL/cm^2 of burn. Pain relief should be almost immediate if this therapy is adequate. Since the degree of pain is a measure of the effectiveness of treatment, the use of anesthetics, especially by local infiltration, may be deleted if the burn is on the arm or leg. HFA can penetrate fingernails without damaging them. Soft tissue can be injected without prior anesthesia, but if the fingertips or nailbeds are involved, they may be injected after a digital nerve block has been performed (Fig. 39-18). Before anesthesia and prior to injecting calcium, the patient can outline the affected areas with a pen to ensure accurate injection of the antidote (see Fig. 39-18*B*). Although some investigators recommend that the fingernails be removed routinely, we strongly advise *against* this unless the nails are very loose or there is obvious necrosis of the nailbed. Fingers are best injected with a 25- or 27-ga needle (a tuberculin syringe works well). [60] Nails frequently become loose in a few days, but often they return to normal and do not require removal, particularly when lower concentration nonindustrial products are involved.

Although calcium gluconate infiltration is somewhat effective, the technique has certain limitations. Injections are painful, and the calcium gluconate solution itself causes a burning sensation. Because of the volume restrictions, not enough calcium may be delivered to bind all the free fluoride ions present. For example, 0.5 mL of 10% calcium gluconate contains 4.2 mg (0.235 mEq) of elemental calcium, which will neutralize only 0.025 mL of 20% HFA.

Several authorities have advocated intra-arterial calcium infusions in the treatment of serious HFA burns of the extremities. [58] [61] Although very effective, this technique is not recommended for burns secondary to dilute HFA (i.e., concentrations <10%), because morbidity is usually quite mild. When using this technique, 10 mL of 10% calcium gluconate are diluted in 50 mL of a 5% dextrose-and-water solution. The dilute solution is given by a slow infusion into an arterial catheter. It is unclear which artery best delivers the calcium to injured tissues. If only the radial three digits are

Figure 39-18 Hydrofluoric acid burns to the fingertips are extremely painful, despite minimal clinical findings. In this case the pain was excruciating, but the patient manifested only hyperemia and minor ecchymosis. *A,* Note that the acid has penetrated the intact fingernail, producing a significant injury to the nailbed. *B,* Prior to performing digital block anesthesia in order to painlessly infiltrate the fingertips with calcium gluconate, the patient outlines the painful areas with a felt-tip marker to ensure accurate placement of the antidote. *C,* In the treatment of hydrofluoric acid burns, topical therapy is often ineffective. Calcium gluconate may be injected subcutaneously with a 25- to 27-ga needle into the nailbed via the fat pad under a digital nerve block. *Fingernails should not be removed routinely* if burns are mild, such as those seen with household products containing <10% concentration of the acid. Intra-arterial calcium infusions are often quite successful in relieving pain and limiting necrosis.

involved, probably only the radial artery need be cannulated. Otherwise, a percutaneous catheter is inserted into the brachial artery. However, some investigators have advocated the use of the radial artery in all cases, and since the arterial supply of the hand is interconnected, this may be a reasonable recommendation. [62] The radial artery is usually more easily cannulated than is the brachial artery. When the arterial access has been accomplished, *the solution is slowly infused over 4 hours*. At this point, the catheter is left in place, and the patient is observed. If pain returns at any time over the next 4 hours, the infusion is repeated. If the patient is pain free over the 4-hour observation period, the burn is dressed, and the patient is released home. This technique may be initiated in the ED but many clinicians are reluctant to cannulate an artery and infuse calcium in the ED. Such patients require hospitalization, or burn center referral, for further evaluation and observation.

Advantages of the intra-arterial method are elimination of the need for painful SQ injections and avoidance of the volume limitations of the SQ route while providing substantially more calcium to neutralize the fluoride. Both the chloride and gluconate salts of calcium have been used intra-arterially. A volume of 10 mL of 10% calcium gluconate contains 4.7 mEq of calcium, whereas the same volume of 10% calcium chloride contains 14 mEq of calcium. Thus, intra-arterial calcium chloride may provide nearly three times as much neutralizing calcium equivalent as the gluconate salt; however, because calcium chloride can irritate tissues, it is not recommended for SQ use. Disadvantages of intra-arterial calcium therapy include the possibility of local arterial spasm (which can be treated with vasodilators such as phentolamine or removal of the catheter), local arterial injury or thrombus, and the long duration of treatment required.

Infusing calcium into the general venous circulation is of no benefit for HFA burns. Some authors have advocated the use of regional intravenous calcium gluconate, similar to the method used with the Bier block for regional anesthesia. [63] Case reports have noted variable success, but this technique has neither been well studied nor rigorously compared to other options. This method would only be useful for upper extremity burns. To perform regional calcium therapy, an IV catheter is placed in the dorsum of the hand on the involved extremity. The arm is partially exsanguinated by elevation or wrapping with an elastic bandage, or both. A Bier block tourniquet, or a heavy duty blood pressure cuff, is applied proximal to the burn and inflated to 20 to 30 mm Hg above systolic pressure to stop blood flow to and from the arm. Slow deflation of a regular blood pressure cuff may thwart success of the procedure, and the use of a specialized tourniquet is recommended. Then 10 mL of 10% calcium gluconate, diluted with 30 to 40 mL of saline, is infused into the venous catheter, and the solution is kept in the arm by the tourniquet for 20 to 30 minutes. Some patients cannot tolerate arm ischemia for this period, limiting the effectiveness of this procedure. Theoretically the calcium diffuses out of the venous system and into the injured tissues. After 20 to 30 minutes, the cuff is deflated and normal circulation to the extremity is achieved. It may require 10 to 20 minutes post tourniquet deflation before the patient experiences pain relief. This procedure is safe but its efficacy is variable.

HFA burns to the eye are potentially devastating injuries that deserve special mention. Ophthalmologist referral is mandatory. Ocular exposure to liquid or gaseous HFA will result in severe pain, tearing, conjunctival inflammation, and corneal opacification or erosion. Complications include decreased visual acuity, globe perforation, uveitis, glaucoma, conjunctival scarring, lid deformities, and keratitis sicca. Optimal therapy for ocular HFA burns, other than initial irrigation, is unknown. Irrigation may be performed with water, isotonic saline, or magnesium chloride. [64] We advise copious saline irrigation. Topical antibiotics and cycloplegics, along with light pressure patching, are also recommended. The use of topical steroids has been advocated by some in order to lessen corneal fibroblast formation, but other attempted therapies such as subconjunctival injections of calcium gluconate and ocular irrigation with quaternary ammonium compounds have been associated with additional injury. [65]

Chromic Acid Injury

Chromium compounds are used extensively in industry, mainly in metallic electroplating. Chromic acid is commonly used in concentrated solutions containing up to 25% sulfuric acid. It causes sufficient skin damage to allow absorption of the toxic chromium ion if intensive irrigation is not undertaken immediately. Heated (60 to 80°C) chromic acid makes the problem of chromium absorption much worse.

Dichromate salts containing hexavalent chromium are the most readily absorbed and the most toxic because they can cross cell membranes. The mortality rate from these burns is very high if the burn exceeds 10% TBSA. Chromium absorption leads to diarrhea, gastrointestinal bleeding, hemolysis, hepatic and renal damage, coma, encephalopathy, seizures, and disseminated intravascular coagulation.

Treatment includes immediate excision of the burned tissues to lessen the total body dichromate burden. Wounds should be washed with a 1% sodium phosphate or sulfate solution and dressed with bandages soaked in 5% sodium thiosulfate solution. These actions reduce the hexavalent chromium ion to the less well absorbed trivalent form.[66]

Chelation therapy with ethylenediaminetetraacetic acid (EDTA) should be instituted, and IV sodium thiosulfate and ascorbic acid given. Hemodialysis, peritoneal dialysis, or exchange transfusion may be indicated.

Phosphorus Burns

White phosphorus is a translucent, waxy substance that ignites spontaneously on contact with air. For this reason, it is usually stored under water. It is used primarily in fireworks, insecticides and rodenticides, and military weapons.

Phosphorus causes both thermal burns from the flaming pieces and acid burns, which result from the oxidation of phosphorus to phosphoric acid. The burns classically emit a white vapor with a characteristic garlic odor. [67]

These burns are treated first with immersion in water, followed by debridement of any gross debris. The wound is then washed with a 1% copper sulfate solution, which reacts with the residual phosphorus to form copper phosphate; the latter appears as black granules and allows for easy debridement. Following debridement, the residual copper is removed by a thorough water rinse, and the wound is dressed and treated as any other burn.

Elemental Alkali Metal Burns

The commonly encountered alkali metals (sodium, lithium, and potassium) are highly reactive with water and with water vapor in air, producing their respective hydroxide with liberation of hydrogen gas. Therefore, water should never be used for extinguishing or debridement of the metal. A class D fire extinguisher or plain sand may be used for smothering the fire, followed by application of mineral oil or cooking oil to isolate the metal from water and allow safe debridement. The burn is then treated as an alkali burn.

Magnesium burns in a less intense fashion but otherwise acts as do other alkali metals. These burns may be particularly injurious, however, because if all of the metallic debris is not removed, the small ulcers that form will slowly enlarge until they become quite extensive.

EMERGENCY ESCHAROTOMY

Full-thickness burns result in an eschar that is inelastic and may become restrictive. During fluid resuscitation and as a direct result of transcapillary extravasation of fluid from thermal injury, intracellular and interstitial edema progresses. As the soft tissues become edematous and pressure rises under the unyielding eschar, first venous and then lymphatic, capillary, and ultimately arterial flow to the underlying and distal unburned tissue may be compromised. Full-thickness and extensive partial-thickness circumferential extremity burns are most likely to impede peripheral blood flow. Circumferential chest burns may restrict chest wall movement, impairing ventilation, and circumferential neck burns may result in tracheal obstruction. In such cases immediate escharotomy may be indicated.

On occasion, because of high-volume fluid resuscitation, noncircumferential and even unburned limbs may develop progressive tissue edema and ischemia requiring surgical decompression to prevent complications of nerve or muscle damage. Early elevation of the limb and active range-of-motion exercises every 15 minutes may minimize tissue edema, but once signs and symptoms of vascular impairment are present, the clinician must act quickly to prevent tissue hypoxia and cellular death. This pathophysiology may manifest itself within a time frame that mandates that the emergency clinician must intervene. Frequent reassessment of capillary refill, Doppler signals, pulsoximetry, and sensation to light touch are important to detect developing ischemia. The reluctance of non-burn specialists to perform an adequate escharotomy is illustrated by the report of Brown and colleagues, [68] who found that 44% of pediatric burn cases were inadequately decompressed prior to arrival at a referral burn unit.

Indications

The indications for escharotomy are based on clinical examination, compartment pressure, or both. A high index of suspicion and a low threshold for intervention are essential for a successful outcome. Skin temperature and palpation of pulses are unreliable and imprecise indicators of adequacy of circulation because of peripheral vasoconstriction and local edema. The patient with circulatory embarrassment significant enough to warrant escharotomy may complain of deep aching pain, progressive loss of sensation, or paresthesias, but these

parameters are difficult to quantitate in the severely burned, sedated, or mechanically ventilated patient. In the awake and cooperative patient, alteration in vibratory sensory testing with a 256-cps tuning fork may be a reliable indicator of increased compartment pressure. [69] However, gross motor activity and peripheral pulses may remain intact despite severe underlying muscle ischemia. In the series by Brown and colleagues, [68] peripheral pulses were present in 74% of the limbs that required decompression. Serial assessment of capillary refill, arterial flow (with the use of Doppler technique), arterial oxygen (with peripheral oximetry), [70] [71] and compartmental pressures (using the technique described in Chapter 55) are sensitive indicators to monitor. Muscle compartments with pressures in excess of 30 mm Hg should be decompressed. Measurements should be taken before and after escharotomy to ensure adequate decompression.

In the patient with absent distal arterial flow (as determined by Doppler ultrasonic flowmeter) but an otherwise adequate blood pressure, immediate escharotomy is indicated. Bardakjian and colleagues suggest that an oxygen saturation below 95% in the distal extremity as demonstrated by pulse oximetry (in the absence of systemic hypoxia) also is a reliable indicator of the need for emergency escharotomy. [71]

Technique of Escharotomy

Because full-thickness burns are insensible to pain and involve coagulation of superficial vessels, some SQ nerve function may exist and local anesthesia with 1% lidocaine with epinephrine may be necessary. Sedation of the awake patient is highly recommended. A properly executed escharotomy releases the eschar to the depth of the SQ fat only. This results in minimal bleeding, which can be controlled by local pressure or electrocautery. These incisions, although limb- or life-saving, are potential sources of infection for the burn patient and should be treated as part of the burn wound. The wounds should be loosely packed with sterile gauze impregnated with an appropriate topical antimicrobial such as silver sulfadiazene cream. Fasciotomy, which involves a deeper incision, may be needed for thermal or electrical burns.

Limbs

Under sterile conditions the lateral and medial aspects of the involved extremity are incised with a scalpel or electrocautery 1 cm proximal to the burned area, extending to 1 cm distal to the involved area of constricting burn (Fig. 39-19). The incision is carried through the full thickness of skin only and results in immediate separation of the constricting eschar to expose SQ fat. Because joints are areas of tight skin adherence and potential vascular impingement, incisions should cross these structures (Fig. 39-20). Care must be taken to avoid vital structures, such as the ulnar nerve at the elbow, the radial nerve at the wrist, the superficial peroneal nerve near the fibular head, and the posterior tibial artery at the ankle. The incision should extend to the great toe medially and the little toe laterally in circumferential burns of the feet, and to the thenar and hypothenar aspects of the hands (see Fig. 39-19 and Fig. 39-20). Improvement in color, sensation, Doppler flow signal strength, and oximetry values indicate adequate release.

Chest

Full-thickness circumferential chest or upper abdominal burns may impair respiration. For release of this eschar, the incision should extend from the clavicle to the costal margin

Figure 39-19 The circulatory embarrassment caused by edema beneath the encircling full-thickness burns of the legs of this patient was relieved by escharotomy incisions placed in the midmedial line of each limb. The restriction of the ventilatory excursion of the chest wall caused by the encircling full-thickness truncal burns was relieved by escharotomies placed in both anterior axillary lines and by a costal margin escharotomy. Compression of the abdominal contents and restriction of diaphragmatic excursion by the constricting deep abdominal wall burns were relieved by placement of escharotomy incisions in the lateral abdominal wall bilaterally. *(From Davis JH, Drucker WR, Foster RS, et al: Clinical Surgery. St. Louis, CV Mosby, 1987.)*

in the anterior axillary line bilaterally, avoiding breast tissue in females, and may be joined by transverse incisions, resulting in a chevron-shaped escharotomy.

Neck

Neck escharotomy should be performed laterally and posteriorly to avoid the carotid and jugular vessels.

Penis

Penile escharotomy is performed midlaterally to avoid the dorsal vein.

Complications

Complications of escharotomy include bleeding, infection, and damage to underlying structures. Complications of inadequate decompression include muscle necrosis, nerve injury (such as

Figure 39-20 Diagram showing preferred sites for escharotomy incisions. *Dotted lines* indicate the escharotomy sites. *Bold lines* indicate areas where caution is required since vascular structures and nerves may be damaged by escharotomy incisions. *(From Davis JH, Drucker WR, Foster RS, et al: Clinical Surgery. St. Louis, CV Mosby, 1987.)*

foot drop), and even amputation of the limb. Systemic complications of inadequate decompression include myoglobinuria and renal failure, hyperkalemia, and metabolic acidosis.

CONCLUSION

Patients with circumferential or nearly circumferential burns should be evaluated for deep tissue ischemia. Emergency clinicians should not hesitate to perform an escharotomy prior to transfer of the patient to the burn center if there is evidence of reduced perfusion.

Section VII - Gastrointestinal Procedures

Chapter 40 - Esophageal Foreign Bodies

David W. Munter
Alan C. Heffner

Patients with foreign bodies (FBs) lodged in the esophagus commonly present to the emergency department (ED) for evaluation and treatment. Objects may be accidentally or purposefully swallowed. Patients may present with minor annoying irritation, life-threatening airway obstruction, or other significant complications. The emergency clinician faced with such situations needs a clear understanding of the presentation, evaluation, and treatment of these patients.

GENERAL FEATURES

Anatomy

The esophagus is a muscular tube, from 20 to 25 cm in length. There are three anatomic areas of narrowing in which FBs are most commonly entrapped (Fig. 40-1): the upper esophageal sphincter, which consists of the cricopharyngeus muscle; the crossover of the aortic arch in the mid-esophagus; and the lower esophageal sphincter (LES). The LES is the narrowest point of the esophagus and of the entire gastrointestinal tract.

Epidemiology

Patients with retained esophageal FBs generally fall into one of the following categories: pediatric patients, psychiatric patients, prisoners, and adults who are either edentulous or have underlying esophageal pathology.

Children account for 75 to 85% of esophageal FBs seen in the ED, with the peak incidence at ages 18 to 48 months. [1] [2] [3] [4] [5] [6] [7] [8] [9] The

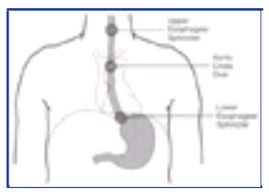

Figure 40-1 Blunt esophageal foreign bodies are most commonly lodged at one of three anatomical areas of narrowing: the cricopharyngeus muscle; the level of the aortic crossover; and the lower esophageal sphincter.

incidence is equal in boys and girls. Children frequently place objects in their mouths, and unintentional swallowing is common. As a result, children most commonly ingest coins, buttons, marbles, beads, screws, or pins. [1] [2] [4] [9] [10] [11]

Prisoners and psychiatric patients ingest a wide variety of objects, some of which may be quite unusual: spoons, razor blades, pins, nails, or practically any other object.[10] [12]

Adults who have dentures or underlying esophageal anatomic or motor abnormalities may accidentally ingest food boluses, chicken or fish bones, glass, toothpicks, fruit pits, or pills while in the act of eating. [11] Patients with an anatomic abnormality of the esophagus or a motor disturbance are more prone to entrapment of foreign objects.[10] [12] Anatomic abnormalities include strictures, webs, rings, diverticuli, and malignancies. Motor disturbances include achalasia, scleroderma, and esophageal spasm.

Complications

Impacted FBs of the esophagus must be removed or dislodged.

The time frame under which this mandate must be carried out varies widely, and depends on many circumstances. In general, however, the esophagus does not tolerate FBs well, or for prolonged periods of time, being sensitive to pressure, edema, necrosis, infection, and eventually perforation. FBs can transit the esophagus in a matter of seconds or minutes, but retained objects may become less symptomatic after time. However, the clinician must resist the urge to allow foreign objects to "pass by themselves" or "dissolve"—once they become stuck in the mucosa, they rarely do.

A wide array of complications can arise from retained esophageal FBs (Table 40-1). These include benign mucosal abrasions, lacerations, vocal cord paralysis, [13] esophageal stricture,[14] and necrosis from corrosive agents such as button batteries. Esophageal perforation [15] [16] [17] [18] [19] [20] can lead to life-threatening conditions such as retropharyngeal abscess,[21] mediastinitis, pericarditis, pericardial tamponade,[22] pneumothorax, pneumomediastinum, tracheoesophageal fistula, and vascular injuries including the subclavian vein and the aorta. [10] [23] [24] Complications are more common when FBs are entrapped for >24 hours[2] [25] and when they are sharp.[26] An estimated 1500 deaths occur annually from esophageal FBs, primarily from complications of esophageal perforation. [9]

Presentation

An esophageal foreign body impaction usually presents acutely, particularly in adults who will have a clear history of ingestion. Children commonly remember an ingestion also, but some will have a vague presentation or history. As many as one-third of children with proven esophageal FBs are asymptomatic on presentation [24] [27] [28] [29] ; therefore, a high index of suspicion is indicated, especially in a child who was seen with an object in his or her mouth that disappeared. This is especially true if there was transient coughing or gagging, even though actual ingestion was not witnessed. Poor feeding, irritability, fever, stridor, cough, and aspiration can all be caused by an underlying esophageal foreign body in a child, usually young infants. [12] [30] [31]

Dysphagia is a common presenting complaint in esophageal FBs. Drooling is suggestive of a high-grade obstruction, and the complete inability to handle oral secretions is a sign of complete obstruction.

The esophagus is well-innervated proximally, and patients typically can accurately localize foreign objects in

the oropharynx or upper one-third of the esophagus. However, scratches or abrasions of the esophagus can create a foreign body sensation. Upper esophageal foreign objects often cause gagging or vomiting. In rare cases, an upper esophageal foreign body can impinge upon the trachea, especially in children, creating stridor or frank respiratory distress. The lower two-thirds of the esophagus is not as well-innervated, and FBs in this location typically cause vague symptoms of discomfort, fullness, or non-localizing pain.

The location of retained esophageal FBs is age-related (Table 40-2). Children more typically have entrapped objects in the upper esophagus at the level of the cricopharyngeus muscle, while adults more commonly have entrapments at the lower esophageal sphincter. [31] [32] [33] [34] [35] With regard to esophageal coins in children, one report noted the frequency of impacted coins at various levels of the esophagus as: proximal esophagus 64%, middle third 8%, and distal third 26%. [35]

Evaluation

The most useful aspect of the evaluation is the history. The time of the ingestion, size and shape of the ingested object, and any current symptoms should be ascertained. The physical examination is frequently normal in patients with esophageal FBs, unless they present with a complete obstruction. In this case they will be drooling and unable to handle oral secretions. Even though asymptomatic on presentation, transient coughing or gagging should raise the index of suspicion for an esophageal FB. An examination of the oropharynx, neck, respiratory system, cardiac system, and abdomen are essential in the evaluation of possible complications.

After attending to life-threatening conditions such as airway compromise, the goal of the ED evaluation is to localize the foreign body to determine what, if any, interventions need to be undertaken to remove it or assist its transit into the stomach. Once a foreign body passes into the stomach, it

TABLE 40-2 -- Level of Entrapment of Esophageal Foreign Bodies

Level	Pediatric	Adult
Cricopharyngeus muscle	74%	24%
Aortic crossover	14%	8%
Lower esophageal sphincter	12%	68%

has a greater than 90% likelihood of passing through the entire gastrointestinal tract without any further problems. [26] Even large, irregular, and seemingly dangerous FBs will often target the entire gastrointestinal tract with relative ease.

RADIOLOGY OF ESOPHAGEAL FOREIGN BODIES

Background

Radiographic imaging of a patient with a suspected esophageal foreign body is common, and is particularly useful for the detection of radiopaque foreign objects. Traditionally, the inability to quickly identify the object by physical examination encouraged the use of plain radiography in attempts to verify and localize the retained foreign body. Plain radiography limitations require that other diagnostic approaches be considered as well.

Indications

Interactive, verbal patients can provide valuable information about the ingested culprit and can typically localize the retained body with reliable accuracy. [36] In these cases, the diagnostic workup should be tailored to the localization of symptoms and the ingested material. However, non-verbal patients including preschool children and those who are senile or debilitated warrant a low-threshold for screening radiography in cases with a suspicious history. Examples include a child seen with an object in the mouth that "disappeared" or a patient with symptomatology suggestive of an esophageal foreign body such as drooling, gagging, or unexplained respiratory symptoms.

Plain Radiographs

Plain radiographs reliably verify and localize radiopaque FBs such as glass and metal and are indicated as the main method of radiologic evaluation for these objects. As previously mentioned, FBs are most frequently entrapped at one of three locations in the esophagus: the cricopharyngeus muscle (Fig. 40-2), the aortic cross-over (Fig. 40-3), and the lower esophageal sphincter (Fig. 40-4).

Unfortunately, many ingested FBs are non-opaque including non-bony foods, plastic, wood, and aluminum such as the pull-tab from beverage cans. A magnetic metal detector has been reported to help localize radiolucent aluminum pull-tabs. [37] [38] Calcification of fish and chicken bones is often incomplete, making them radiolucent on plain films. The degree of bony calcification varies with fish species and varies between different samples of the same species, thus preventing useful guidelines.[39] [40] [41] [42] For these reasons, plain films provide little substantive evidence in the majority of cases of fish or chicken bone dysphagia. They detect only 25 to 55% of endoscopically proven bones and carry a high rate of false-negative and false-positive interpretations. [36] [42] [43] [44] [45] [46] Because of the lack of diagnostic value for detecting bones, many clinicians do not routinely order plain radiographs, opting for a computed tomography (CT) scan if radiographic evaluation is required.

When considered, a complete oropharyngeal radiograph series includes the nasopharynx to the lower cervical vertebra in both lateral and anteroposterior views. Optimum quality radiographs are mandatory. Patients should be positioned

Figure 40-2 PA radiograph of an esophageal foreign body (coin) lodged at the level of the cricopharyngeus muscle. This is the most common area of the esophagus to harbor a coin in children.

upright with the neck extended and the shoulders held low. Soft tissue technique enhances the discrimination of weak radiopaque FBs. Phonation of "eeeee" during radiography prevents motion artifact from swallowing, distends the hypopharynx, and enhances soft tissue landmarks.

Figure 40-3 Posteroanterior radiograph of an esophageal foreign body (coin) lodged at the level of the aortic cross-over.

Figure 40-4 A posteroanterior radiograph of an esophageal foreign body (coin) lodged at the level of the lower esophageal sphincter (LES).

Plain radiography of the neck is limited by the radiographic properties of ingested materials and the complicated anatomy of the upper aerodigestive tract. The tongue base, palatine and lingual tonsils, vallecula, and pyriform recesses are common regions of entrapment for small, sharp objects and deserve careful interpretive attention (Fig. 40-5). Superimposition of the mandible contributes to suboptimal resolution of this region on lateral neck films. [47] Calcified

Figure 40-5 A lateral neck radiograph showing a chicken bone lodged in the pharynx with associated soft tissue swelling. The arrow points to the bone. Plain radiographs have poor diagnostic accuracy for detecting bones in the esophagus and they are often eschewed in favor of a CT scan if radiographic evaluation is deemed necessary.

airway cartilages often masquerade as FBs and contribute to false-positive rates as high as 25%. [36] [41] [43] [45] [48] [49] [50] Normal ossification of airway cartilages begins in

the third decade and progresses with age.[51] The typical curvilinear contour and well-defined margins of bony FB fragments may help distinguish them from normal laryngeal calcifications. Orientation of bony FBs is variable. The C6 vertebra approximates the level of the cricopharyngeus, a common site of FB impaction. Increased prevertebral soft tissue width, air within the cervical esophagus, and soft tissue emphysema are rare indirect findings that may help identify radiolucent objects.[42] [52]

Posteroanterior and lateral views of the chest evaluate the remainder of the esophagus. Both projections are indicated to identify multiple objects and those FBs visible in only one plane. Esophageal FBs typically lie in the vertical plane and are differentiated from airway bodies or calcifications by their location posterior to the tracheal air column on lateral radiographs. As a rule, flat objects such as coins perch in the coronal plane in the esophagus and in the sagittal orientation in the trachea. Intra-esophageal air and air-fluid levels represent indirect evidence of esophageal obstruction and may aid in verification of radiopaque FBs. Soft tissue swelling, extraluminal air, and aspiration pnuemonitis can occasionally help identify complicated impactions radiographically. Xeroradiography provides no additive benefit over plain films.[53]

In children, a "mouth-to-anus" film is frequently obtained, allowing visualization of the entire esophagus as well as the abdomen in case the foreign body has passed into the stomach or beyond. Swallowed coins or other FBs have become lodged in the nasopharynx, usually after gagging or vomiting, and could be missed if this area is not included on the radiograph. In adults, if neck or chest films are negative, abdominal films are sometimes obtained for reassurance of the presence of the foreign body in the stomach.

Contrast Esophagrams

Background

The contrast esophagram is another somewhat controversial method to evaluate for esophageal foreign body but may be considered when plain radiographs are negative. In clinical practice, however, they are seldom used since CT scanning has become widely available. This technique uses swallowed contrast to help identify the presence and location of an impacted radiolucent foreign body, the degree of obstruction, underlying anatomical abnormalities, and the presence of perforation. A variation of this technique is to have the patient swallow contrast-soaked cotton pledgets. This technique uses smaller contrast loads and may identify impacted FBs by impeding progression of the cotton or by tagging sharp irregular objects with radiopaque cotton as the bolus passes. Theoretically this variation might interfere less with follow-up endoscopy due to attenuated contrast loads. Unfortunately, liquid contrast ingestion yields overall results no better than plain film radiography. Two series document 19% to 26% false-positive and 40% to 55% false-negative interpretations using this technique, and the authors legitimately question the utility of this test. [43] [54] More importantly, contrast may interfere with the detection and extraction of FBs at endoscopy and may increase the risk of aspiration. [42] [55] [56] Routine, serial contrast esophagrams following negative plain radiography for patients with known or suspected FBs are unnecessary for diagnostic purposes in most cases. Selective use in complicated cases is reasonable but may be substituted by CT or endoscopy in many institutions.

Procedure

Esophagrams couple voluntary ingestion of enteric contrast and plain radiography. Immediately after ingestion, erect and horizontal radiographs are performed at right-angle projections (posteroanterior [PA] and lateral or right and left anterior oblique). In addition to anatomic abnormalities, radiolucent FBs may be identified by contrast delineation or filling defects within the contrast column (Fig. 40-6).

The initial choice of contrast agent is debated and should be individualized depending on the threat of aspiration and perforation. Water-soluble Gastrografin is indicated first in most cases of suspected perforation as it causes less mediastinal inflammation when extravasated; however, it can cause a severe chemical pneumonitis if aspirated and is relatively contraindicated in patients with a complete esophageal obstruction. [10] Patients without evidence of complete esophageal obstruction are instructed to swallow progressively larger aliquots of contrast agent up to approximately 50 mL. If these films are normal, the procedure is repeated with half-strength and then full-strength barium to delineate small esophageal injuries. Note that water-soluble contrast causes more pulmonary reaction than barium when inadvertently aspirated and should be used in small aliquots if aspiration or complete esophageal obstruction is a concern. Contrast esophagrams coupled with fluoroscopy are seldom used in acute esophageal FB impactions, although slowed progression or abnormal peristalsis may suggest a retained FB or anatomic abnormality. Barium interferes with endoscopy and should not be used when endoscopy is anticipated.

Figure 40-6 A barium swallow demonstrating a complete esophageal obstruction in the proximal to mid-esophagus.

Computed Tomography

Non-contrast CT of the neck and mediastinum is an easy, rapid, and non-invasive means of detecting (and ruling out) upper gastrointestinal FBs (Fig. 40-7).[41] [42] [44] First reported in 1983, CT has garnered increasing support in the clinical setting of suspected FB entrapment. [57] [58] [59] One series of 45 patients revealed 100% sensitivity with one false-positive CT interpretation yielding 93% specificity and 96% positive predictive value, [44] while another yielded equally impressive results in patient and cadaver models, respectively. [41] [42] CT further excels at localization and characterization of the impacted FB and identification of associated complications such as perforation.[42] [57] [60] [61] [62]

The exact role of CT for symptomatic stable patients with cervical aero-digestive FB sensation remains to be delineated. It clearly provides improved diagnostic utility for fish bone FB compared to plain radiography with and without barium. [41] [42] [44] Application to every patient with acute bone dysphagia is probably unwarranted. Use in cases with high clinical suspicion of a retained FB has the potential to reduce the number of unnecessary endoscopies. [44] Cost analysis data for this practice have not yet been published. Optimum non-contrast CT scans of the neck and mediastinum use axial 2- to 2.5-mm cuts with bone and soft-tissue windows.

Conclusions

Diagnostic radiography for esophageal FB requires case individualization. Plain radiographs clearly assist the clinician in two situations: (1) screening of children, senile adults, and nonverbal patients with a history or symptoms suspicious for purposeful or inadvertent FB ingestion, and (2) localization of known radiopaque ingestants to clarify the necessity and means of FB extraction. Conversely, attempts to verify radiolucent bodies, including bones, are often misleading. Contrast esophagrams may be used in special situations but

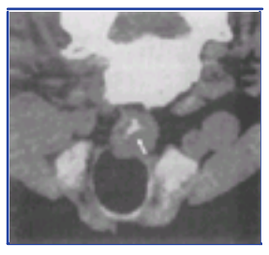

Figure 40-7 Computed tomography demonstrating an esophageal foreign body.

have largely been replaced by CT and direct endoscopy. The utility of CT to exclude fish bone FB is promising but requires discriminatory application to achieve cost efficiency.

VISUALIZATION OF ESOPHAGEAL/PHARYNGEAL FOREIGN BODIES

Direct Pharyngoscopy

Background

Direct visualization of the oropharynx is simply a physical examination using a light source and aided by a tongue blade. This examination is limited to visualizing only the upper oropharynx, tonsils, tonsillar pillars, and in some cases, the tip of the epiglottis. In many cases, a foreign body such as a fish bone can be visualized and then removed with forceps.

Indications

Direct visualization is indicated in most patients who have a foreign body sensation in the oropharynx or upper neck. The only contraindication is a patient with potential airway obstruction.

Procedure

The supplies needed for a direct visualization are a light source and a tongue depressor. Although penlights are traditionally used for this purpose, a fiberoptic headlight or a head mirror reflecting a bright light source are superior for a thorough examination. When using a headlamp, the lamp should be positioned on the forehead between the eyes, with the beam focused at a distance of approximately 2 feet. This can be tested by focusing the beam on the examiner's thumbs held together at a comfortable working distance. A head mirror is positioned with the central hole over the examiner's dominant eye. Normally the light source is positioned behind one shoulder of the patient and reflected by the head mirror into the oropharynx.

For the best direct visualization, the patient is placed in a sitting position, with the examiner standing. The entire visible oropharynx is examined using a tongue depressor to carefully depress the base of the tongue for better visualization of the pharyngeal wall, tonsils, and tonsillar pillars. Having the patient apply gentle but firm traction to their own tongue can aid exposure. The patient should generally assume a "sniffing" position with the neck slightly flexed and the head extended. Using a preprocedural topical anesthetic on the pharyngeal mucosa will minimize discomfort and gagging when using the tongue blade. In some patients, especially children, the tip of the epiglottis can be seen. If a foreign body is visible, forceps can be used to grasp and remove the object.

Indirect Laryngoscopy

Background

Indirect laryngoscopy is an examination of the middle and lower oropharynx using a mirror. This technique allows evaluation of the epiglottis, vallecula, arytenoids, arytenoid folds, and the vocal cords. Indirect visualization requires experience with the procedure and a cooperative patient.

Indications

Indirect visualization is indicated in patients who have a FB sensation in the oropharynx or upper neck, with the exception of those with airway compromise.

Procedure

Indirect visualization requires a light source (head lamp or head mirror), a gauze pad to hold the patient's tongue, a laryngeal mirror, and frequently, a topical anesthetic agent. Place the patient in a sitting position leaning slightly forward as discussed for direct pharyngoscopy. Standing in front of the patient, grasp the tongue with the gauze pad and pull lightly while having the patient open his or her mouth widely. Warm the laryngeal mirror either in warm water or a mirror warmer, check the temperature of the mirror with the back of the hand, and insert the mirror without touching the tongue (see Chapter 65 , Fig. 65-2). The mirror can elevate the uvula and soft palate slightly, but should avoid the pharyngeal wall. If the patient cannot tolerate this maneuver without gagging, instill some topical anesthetic and reattempt. Evaluate the base of the tongue, the epiglottis, vallecula, arytenoids, arytenoid folds, and the vocal cords. Use forceps to attempt to remove a visible FB. Failure to extract a visible FB with forceps is an indication for otorhinolaryngology referral for removal.

Nasopharyngoscopy

Background

Careful visualization of the oropharynx and hypopharynx is vital in the evaluation of patients presenting with complaints of FB sensation of the neck. Although a significant proportion of complete evaluations will not discover any abnormalities, the combination of direct, indirect, and flexible endoscopic nasopharyngoscopy is simple, fast, and curative in those with an identifiable FB. [36] [47] [63] One series of 168 oral, pharyngeal, and esophageal retained fish bones demonstrated the efficacy of thorough examination. Clinicians removed 73% of the bones via direct or indirect laryngoscopy. [47] Flexible nasopharyngoscopy with topical analgesia was successful in an additional 15% of cases, thereby reducing by half the need for rigid esophagoscopy and general anesthesia in this series of patients.

Indications and Contraindications

Indications for this procedure span the scope of clinical situations necessitating thorough visual examination of the pharynx and proximal esophagus, including patients with foreign body sensation and acute pill and postprandial food dysphagia.

Croup is quoted as the sole absolute contraindication to flexible nasopharyngoscopy. [64] The risk-to-benefit ratio of endoscopy should be considered in patients with coagulopathy or severe bleeding diathesis, although the risk of initiating significant hemorrhage is low. Medication allergy precludes the use of some topical agents.

Equipment

All equipment should be assembled and checked before initiation of endoscopy (Table 40-3). Nasopharyngoscopy is best accomplished via a 3- to 6-mm external diameter flexible fiberoptic nasopharyngoscope (see Chapter 65 , Fig. 65-4). Scope side ports enable suction, anesthetic injection, and FB extraction via forceps, but are not mandatory. Traditional scopes require an external light source while some newer generation fiberoptic scopes include battery-powered, self-contained light sources. Inexpensive adapters enable a laryngoscope handle to double as an endoscopy light source. The endoscope eyepiece should be adjusted to accommodate the operator's visual acuity. Yankauer suction and angled McGill forceps or a Kelly clamp should be available to retrieve

TABLE 40-3 -- Equipment for Nasopharyngoscopy

identified FBs orally. Topical cocaine, phenylephrine (Neo-synephrine), oxymetazoline (Afrin) and liquid or viscous lidocaine may be used for anesthesia and vasoconstriction, but are not a necessity.

Procedure

Nasopharyngoscopy is generally well-tolerated, but patients should have a clear understanding of the examination procedure prior to initiation. Discussion of the procedure with the patient should include potential complications and alternatives.

Topical anesthesia is recommended for patient comfort but is not mandatory. [36] [47] Examine the nares and choose the one with the least anatomical resistance for endoscopy. Cotton balls or pledgets soaked with 10% cocaine or a combination of 0.05% oxymetazoline (Afrin) and 2% lidocaine (Xylocaine) provide nasal mucosal anesthesia and vasoconstriction within minutes. Viscous 2% to 4% lidocaine applied by a cotton-tipped applicator is an alternative anesthetic. Atomized 2% lidocaine (Xylocaine) or topical benzocaine spray (20% Hurricane spray, Cetacaine) can be used to further anesthetize the hypopharynx. Patients may complain of discomfort or globus sensation following anesthesia and may require explanation and reassurance. Patients only rarely need an anti-sialogogue, such as glycopyrrolate. Others may need mild sedation with a short-acting benzodiazepine.

The patient is seated erect in a chair with posterior headrest support to prevent movement during examination. The examiner stands upright in front of the patient, holding the body of the scope in the non-dominant hand (see Chapter 65 , Fig. 65-5). Scope maneuvers are controlled solely with the hands. The dominant hand controls the depth of scope insertion at the naris and directs the scope along the horizontal plane at the floor of the nose. This hand should rest lightly on the patient's face for comfort and to prevent abrupt changes in scope position in case of movement during examination. Flexion in the sagittal plane is achieved with the thumb lever on the scope handle. Rotation clockwise and counterclockwise is performed via simple rotation of the wrist, not the entire upper body. It is important to maintain mild tension on the two ends of the scope for wrist action to be translated to motion at the tip of the scope. Warming the tip of the scope in water and applying silicone drops helps prevent scope fogging. Manipulation against the patient's mucosa will clear the scope during endoscopy. Water-soluble lubricant aids in passing the scope but should not be applied to the distal 2 cm of the scope.

Effective examination of the oropharynx requires some practice and reference to normal anatomy. Although many patients can localize the FB, systematic examination in a caudal direction is vital. [36] Direct the patient to focus on slow, steady mouth breathing to attenuate discomfort and gagging during the procedure. Insert the scope horizontally along

the floor of the nose and pass it below the inferior turbinate. Upon reaching the soft palate, deflect the scope tip inferiorly (via directing the thumb lever toward the eyepiece) and advance it into the oropharynx. Examine the laterally located palatine tonsils and palatopharyngeal arches, along with the proximal tongue and lingual tonsil. Advance the scope caudally to allow further visualization of the tongue base, epiglottis, and the interposed spaces, known as the epiglottic vallecula. Voluntary or manual protrusion of the tongue helps reveal this anatomy. Scan posteriorly to reveal the vocal cords, aryepiglottic folds, and pyriform recesses. Patients can gently exhale against a closed mouth and nose to distend the lower pharyngeal structures and improve visualization of these areas. Avoid contact with the epiglottis and vocal cords. Explore all pharyngeal walls fully and compare the structures bilaterally, even when patients localize symptoms to one side. Signs of trauma, including bleeding, mucosal hyperemia, and edema require close investigation to differentiate retained FBs from mucosal irritation.

If a FB is visualized (Fig. 40-8), the method of extraction depends on the location and size of the retained object. Small FBs may be extracted transnasally via forceps passed through the scope side port. Large or irregular bodies may be withdrawn orally with angled forceps. [47] Alternatively, endoscopy may be used primarily for FB confirmation. Extraction can then be performed via handheld forceps under endoscopy guidance, subsequent direct laryngoscopy, or under general anesthesia. Careful attention to prevent FB dislodgment into the airway is critical with any extraction attempt.

Complications

Complications of nasopharyngoscopy are rare and typically mild. Reflex tearing, sneezing, and coughing are the most common and are self-limited. Some patients experience a residual FB sensation for several hours after manipulation. Mild bleeding, including epistaxis, is common secondary to mucosal abrasion. Extraction of an embedded FB may result in bleeding but is also generally self-limited. Vasovagal syncope has been reported in up to 3% of patients undergoing this procedure. [64] Inadvertent dislodgement of the FB farther into the esophagus or into the airway may occur with manipulation or attempted extraction.

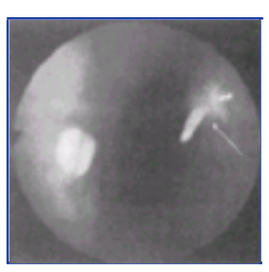

Figure 40-8 Esophageal foreign body seen on nasopharyngoscopy.

Esophagoscopy

Esophagoscopy is the definitive diagnostic and therapeutic procedure for impacted esophageal FBs. [9] [33] Although esophagoscopy is not a procedure performed by the emergency clinician, its proper role in the ED evaluation of FBs must be understood. With esophagoscopy the clinician can document the presence and location of the FB along with any underlying lesion. The clinician can then remove the object and reevaluate the esophagus after FB removal to rule out perforation or underlying pathology. Esophagoscopy may be necessary even if a radiologic contrast study does not reveal complete obstruction, because x-ray studies are not always conclusive. [8] [65] Esophagoscopy may be necessary to rule out predisposing pathology or resultant perforation, even when symptoms presumed to be due to an esophageal FB have resolved.

Esophagoscopy is the preferred method for removal of sharp or pointed objects such as bones, open safety pins, and razors. In the case of sharp objects prone to causing esophageal perforation, IV antibiotics should be administered before the procedure. Esophagoscopy is also indicated for a FB retained for more than 24 to 48 hours both to remove it and to examine for esophageal wall erosion or perforation. Esophagoscopy is the only appropriate removal technique for multiple or large esophageal FBs. This technique is also indicated in the patient with a FB proven to have passed into the stomach and who has persistent symptoms possibly caused by esophageal wall injury.

The flexible endoscope is more commonly used than the rigid esophagoscope. Flexible endoscopic procedures can usually be performed without general anesthesia, even in most children. [66] The success rate of flexible endoscopy in patients with retained esophageal FBs exceeds 96%. [33] [67]

Traditionally, esophagoscopy is more expensive than other maneuvers such as Foley catheter removal or esophageal bougienage (described later), [3] [7] [68] largely due to charges for the surgical suite, but it has a higher success rate than the other two techniques. Recently, the ED removal of esophageal FBs in children by experienced **endoscopists, while the child is under** ketamine sedation administered by the emergency clinician, has been reviewed. [69] In select cases, this approach can shorten the interval to procedural completion and expense.

ESOPHAGEAL PHARMACOLOGIC MANEUVERS

Background

Because the lower esophageal sphincter (LES) is the narrowest portion of the entire gastrointestinal tract, most FBs that reach the stomach eventually move through the gastrointestinal tract without further problems. As a large number of entrapped esophageal FBs are lodged at the LES, especially in adults, several therapeutic maneuvers have been developed to assist transit into the stomach including pharmacologic relaxation of the LES. In theory, agents that promote smooth muscle relaxation should improve mobility through the LES. Although many clinicians use pharmacologic adjuncts for all esophageal FBs, objects lodged at the LES will probably benefit most from such interventions. Nonspecific pain relief, anxiolysis, and spontaneous passage may account for the success of many pharmacologic manipulations of esophageal FBs.

Several pharmacologic agents have been shown to be unsuccessful for removing or resolving esophageal FB impactions, including diazepam, meperidine, and atropine.[11] These agents, alone or in combination, have success rates below 10%, which is no better than observation alone. [2] Glucagon, nitroglycerin, nifedipine, and gas-forming agents (Table 40-4) are described later and are the most effective pharmacologic agents for treatment of distal esophageal food impactions.

Indications and Contraindications

The indication for pharmacologic relaxation of the LES is the presence of a smooth or blunt FB such as a coin or food bolus. Angulated, abrasive, or sharp FBs should not be treated with pharmacologic modalities but instead should be removed by esophagoscopy. *Analgesics and sedatives are routinely indicated if pain is present or if the patient is excessively anxious.*

Glucagon

Pharmacology

Glucagon has been a prototype for the spasmolytic agents. [70] [71] [72] Its use has been advocated for enhancing the passage of esophageal FBs since 1977, and there have been several isolated reports of dramatic relief. [70] [73] [74] [75] Glucagon theoretically relaxes esophageal smooth muscle and decreases the LES resting pressure. One study of normal subjects found that glucagon significantly lowers the mean LES resting pressure, but causes no significant difference in the mean amplitude of contraction in the distal esophagus. [76] Glucagon has no effect on the upper third of the esophagus, a common site of coin impaction in children, where striated muscle is present and some voluntary control is operative. It only minimally affects the middle third of the esophagus, although the successful use of glucagon to dislodge food in the middle third of the esophagus has been reported. [70] [73] Peristalsis is not affected by glucagon. Glucagon was successful in approximately 30 to 69% of lower esophageal obstructions in several studies [70] [72] [73] [74] [75] ; however, in two studies glucagon was not significantly different from treatment with a placebo. [76A] [77] Its use, however, is still advocated by some authorities and has little downside. Glucagon may cause vomiting, and this action may be responsible for some of the drug's success. [78]

TABLE 40-4 -- Recommended Pharmacologic Therapies for Esophageal Foreign Bodies

Class and Agents	Site of Action	Dose and Route	Adverse Effects
Spasmolytics			
Glucagon	LES	1–2 mg IV*	Nausea, vomiting, hyperglycemia, hypersensitivity
Nitroglycerin	Body and LES	0.4–0.8 mg SL†	Hypotension, tachycardia, or bradycardia
Nifedipine	LES	10 mg SL‡	Hypotension, tachycardia (*use with caution*)
Gass-forming agents			
Tartaric acid	Distal and proximal	15 mL tartaric acid	Vomiting, increased intraesophageal pressure
		(18–20 g/100 mL)§	
		15 mL sodium bicarbonate	
Sodium bicarbonate		(10 g/100 mL)§	
Carbonated beverage	Distal and proximal	100 mL PO	Vomiting, increased intraesophageal pressure

IV, intravenously; LES, lower esophageal sphincter; PO, per os; SL, sublingually.

* May be repeated once or used in conjunction with nitroglycerin.
† 1–2 inches of nitroglycerin paste applied under an occlusive dressing may be an alternative.
‡ A capsule is punctured, chewed, held in the mouth for 3 minutes, and then swallowed. *Do not use if the patient has cardiovascular disease, is hypotensive, or has also been recently given nitroglycerin.*
§ Alternatively, dissolve 2–3 g tartaric acid and 2–3 g sodium bicarbonate in 30 mL water.

Indications and Contraindications

Glucagon is most useful for smooth FBs or food impactions at the LES that are suspected because of the patient's complaint of pain or "something stuck" in the lower chest or epigastrium. The clinical diagnosis is usually straightforward, especially if there is a complete esophageal obstruction and the patient is unable to tolerate oral secretions. Nevertheless, some clinicians recommend that the FB be localized first with radiographs (with or without contrast) to establish that the impaction is indeed there. The radiographs can then serve as the baseline study for comparison following glucagon administration. However, with a classic history and physical examination, most investigators agree that an initial contrast study can be omitted. Glucagon is not effective in upper and middle esophageal obstructions, and it is not widely recommended for use in children. Also, glucagon is usually not effective in patients with fixed fibrotic strictures or rings at the gastroesophageal (GE) junction.[71] Glucagon is contraindicated if the patient has an insulinoma, a pheochromocytoma, Zollinger-Ellison syndrome, a hypersensitivity to glucagon, or a sharp esophageal FB.

Administration of Glucagon

Some reports recommend a small test dose to check for hypersensitivity to glucagon. In practice, this is rarely done. The therapeutic dose is 0.25 to 2 mg administered intravenously over 1 to 2 minutes in the sitting patient, although one study found that in normal subjects, 1 mg provides no significant additive benefit over 0.5 mg glucagon.[76] The patient is given water orally within 1 minute after the injection of glucagon to stimulate normal esophageal peristalsis; this helps push the food through the relaxed LES into the stomach. Glucagon has a rapid onset and short duration of action. The gastrointestinal smooth muscle relaxes within 45 seconds, and the duration of action is about 25 minutes. If there are no results within 10 to 20 minutes, a second administration of 0.25 to 2 mg may be tried. Success

rates are higher when combining glucagon with gas-forming agents or even carbonated beverages. [79] [80] It is recommended that a small volume of

some oral fluid be routinely given to enhance the activity of glucagon.

Complications

Glucagon is associated with a few minor side effects. If administered too rapidly, it causes nausea and vomiting. Therefore, the adult patient must be alert and mobile enough to avoid aspiration. Occasionally vomiting dislodges the impacted food bolus. Theoretically, there is a risk of rupture of the obstructed esophagus during induced emesis, so slow injection is preferred to minimize this side effect.

The administration of glucagon is also associated with dizziness. Mild elevation of blood glucose levels is also common but is not of clinical concern and blood glucose levels do not need to be monitored. No fatalities have been reported. Although theoretically glucagon can stimulate catecholamine release with a pheochromocytoma and induce hypoglycemia from reflex insulin release with insulinoma, these endocrine tumors are rare. Nonetheless, precipitation of either profound catecholamine or insulin reactions with glucagon use should direct a workup for these underlying tumors.

Further Evaluation and Therapy

If the patient experiences symptomatic relief following glucagon administration, a post-procedure radiograph or contrast study may be obtained to confirm passage of a radiopaque object, but this is not mandatory. Adult patients with successful passage into the stomach may also be discharged home, but careful follow-up should be obtained to rule out coexistent esophageal pathology. This is because a significant number of patients (65% to 80%) will have underlying esophageal disorders. [9] If glucagon fails to produce symptomatic relief or resolve radiograph findings, its use does not preclude other methods from being used.

Nitroglycerin and Nifedipine

Pharmacology

Both sublingual nitroglycerin and nifedipine have been used in a manner similar to that of glucagon to relieve LES tone and allow the passage of a distal esophageal FB.[81] [82] [83] Although these two agents have been used less than glucagon for the treatment of esophageal FBs, both agents are useful for the relief of chest pain associated with esophageal smooth muscle spasm[57] and may be administered concurrently with glucagon. Manometric and radiographic studies after the administration of nitroglycerin reveal abolition of repetitive high-pressure wave contractions characteristic of esophageal spasm. Nifedipine, on the other hand, significantly reduces LES pressure without changing contraction amplitudes in the body of the esophagus. Thus, nitroglycerin may relieve partial or complete obstruction of the middle or lower esophagus secondary either to intrinsic esophageal disease or to simple FB impaction, and nifedipine, like glucagon, is most likely to succeed when the bolus is lodged at the GE junction.

Indications and Contraindications

Similar to the clinical indications for the use of glucagon, any patient presenting with an impacted smooth esophageal FB, especially a food bolus, may be a candidate for nitroglycerin and/or nifedipine. Also, similar to the mode of action of glucagon, neither of these agents is expected to relax a fixed fibrotic stricture or ring at the GE junction.[71] Nevertheless, because both agents have a relatively benign side effect profile, if the patient has no contraindication to their use, they may be tried with or without previous documentation of the distal esophageal obstruction by contrast study. Contraindications to their use include a history of allergic reactions, a sharp esophageal FB, hypovolemia, and hypotension.

Use and Complications

Doses of 1 to 2 (0.4 mg) sublingual nitroglycerin tablets, 1 to 2 inches of nitroglycerin paste, or 10 mg of nifedipine have been reported. [81] [82] [83] Remember that some patients with esophageal FBs may present with some degree of dehydration due to the inability to swallow liquids or their own saliva. These patients may be prone to hypotension from the vasodilation associated with the use of either agent. Ideally, rehydration should precede therapy with these agents. Sublingual niphedipine has been rarely implicated in cerebral or coronary insufficiency in patients with cardiovascular disease, so caution is warranted.

Further Evaluation and Therapy

As with the use of glucagon, if nitrate therapy fails to produce symptomatic relief or resolve radiographic findings, its use does not preclude trying another method. If a patient experiences symptomatic relief, a post-procedure radiograph may be obtained to confirm passage of a radiopaque object, but this is not mandatory. The adult patient may be discharged home, but careful follow-up should be obtained to rule out coexistent esophageal pathology, as a significant number of patients will have underlying esophageal disorders.

Gas-Forming Agents

Pharmacology

The use of gas-forming agents for the treatment of distal esophageal food impactions, especially meat boluses, was first described in 1983. [84] The combination of tartaric acid solution followed immediately by a solution of sodium bicarbonate or even carbonated beverages was reported. In theory, the use of this acid-base mixture or of a carbonated beverage (e.g., Coca-Cola) may produce sufficient carbon dioxide to distend the esophagus, relax the LES, and push impacted food through the GE junction into the stomach. [85] [86]

Indications and Contraindications

Gas-forming agents are indicated for the relief of smooth distal esophageal FB impactions, with or without prior FB confirmation by a radiographic study. They are often given to patients with food impaction or retained coins. Although gas-forming agents are more likely to succeed with distal esophageal impactions, they have also been successful in relieving obstructions in the proximal esophagus. Concurrent administration of spasmolytic agents may improve the effectiveness of gas-forming agents.[80]

Use and Complications

A solution of 15 mL of tartaric acid (18.7 g/100 mL), followed by 15 mL of a sodium bicarbonate solution (10 g/100 mL), or 1.5 to 3 g of tartaric acid and 2 to 3 g of sodium bicarbonate dissolved in 15 mL of water can be used. [84] [85] Carbonated beverages (100 mL) have also been successful in the transit of FBs into the stomach. [84] [86] Many patients with esophageal FB impactions have been noted to retch after receiving gas-forming agents, which theoretically puts

patients at risk for esophageal trauma. The only reported complication with the use of gas-forming agents for this indication was a mucosal tear of the esophagus (requiring surgical exploration to rule out mediastinitis) in a 66-year-old patient with an 18-hour-old esophageal impaction. [85] For this reason, gas-forming agents should not be given to patients with impactions of more than 6 hours duration or to patients with chest pain that might be indicative of an esophageal injury.

Further Evaluation and Therapy

As with the use of glucagon, nitroglycerin, or nifedipine, even if administration of the gas-forming agent is successful, as judged by relief of symptoms, follow-up evaluation is necessary to determine the underlying esophageal abnormality that potentially led to the FB impaction.

Papain

Papain is not recommended for treatment of an esophageal FB. It is a proteolytic enzyme that has been touted for dissolving meat impactions. [87] Papain is available commercially in a variety of meat tenderizers. This therapy has never been tested in a clinical trial. In vitro studies suggest that the commercial preparation may have no intrinsic proteolytic activity. [88] Although it is harmless when in brief contact with the normal esophagus, if it is left too long in the obstructed esophagus, papain may begin to dissolve the esophageal mucosa underlying a foreign body. [88] [89] This is likely to occur when the esophageal wall is ischemic owing to FB impaction and resultant wall pressure, when esophageal injury results from small bony spicules in the FB, or when an underlying lesion is responsible for the obstruction. The subsequent rupture and leakage of the proteolytic enzymes result in a self-perpetuating mediastinitis. Patients with esophageal FBs are at increased risk for aspiration, and pulmonary aspiration of papain results in acute hemorrhagic pulmonary edema. In general, papain is not currently recommended because of the unacceptable complication risk and the availability of safer, more effective interventions.

FOLEY CATHETER REMOVAL OF ESOPHAGEAL FOREIGN BODIES

Introduction

Foley catheter removal of esophageal FBs was first described in 1966 [90] and in the emergency medicine literature in 1981. [91] The technique is essentially unchanged since the first reports, and is now used by emergency clinicians, radiologists, otolaryngologists, and general surgeons. [92] [93] [94] [95] [96] The classic patient for this technique is a small child who is brought to the hospital shortly after swallowing a coin that is documented by radiograph, but the procedure may be used for a wide variety of smooth FBs in all ages of patients. Success rates for Foley catheter removal of FBs have been cited from 85% to 100%, with complication rates of 0 to 2%. [7] [67] [97] [98] [99] [100] Many of the reported complications were due to the nasal insertion of the catheter, and complication rates are lower when the catheter is inserted orally and at centers that perform the procedure frequently. Foley catheter extraction costs significantly less than endoscopy. [7] [101] Fluoroscopic assistance may be preferable, but it is not essential. Whether the procedure is performed in the ED or the radiology department, equipment and personnel capable of emergency pediatric airway management must be present.

Indications and Contraindications

Recently ingested smooth, blunt objects that are radiographically opaque are most suitable for balloon catheter extraction. Recently ingested FBs carry little likelihood of causing pressure necrosis, perforation, or other significant injury; however, 24 to 48 hours duration of impaction should be the upper limit for consideration of this technique. [7] [26] [102]

Coins are particularily amenable to Foley manipulation, but food boluses and button batteries have also been extracted successfully. [93] Radiographically opaque objects are most easily located by plain radiographs. Radiolucent objects can be manipulated, but uncertainties about location mandate contrast esophagrams.

Contraindications to catheter removal of esophageal FBs include total esophageal obstruction, as manifested by an air-fluid level on plain radiograph or contrast esophagram, or when patients are unable to handle oral secretions. The presence of a total obstruction prevents passage of the catheter tip distal to the FB. Esophageal perforation, as recognized by the typical symptoms and signs, requires immediate surgical consultation and precludes blind esophageal manipulation, as does airway distress. The presence of multiple esophageal FBs also precludes Foley catheter use. Sharp, irregularly shaped FBs should not be removed with this technique because esophageal perforation or laceration can result, and the balloon may burst during the procedure. Finally, lack of expertise or equipment to handle an airway problem arising during the procedure is a contraindication.

Equipment

The necessary equipment is basic and present in most EDs (Table 40-5). Although never reported, airway obstruction during the procedure is the most feared potential complication. Thus, the proper equipment and personnel capable of managing airway obstruction must also be present, including suction devices. Forceps (bayonet and Magill) of various sizes should be available to extract the FB from the pharynx. Foley catheters ranging in size from No. 8 Fr with 3-mL balloons to No. 26 Fr with 30-mL balloons have been used. In settings in which both children and adults are treated, sizes ranging from 10 Fr to 16 Fr with 5- to 10-mL balloons should suffice. Child restraint devices (e.g., papoose board), topical anesthetics, or moderate sedation may be used.

TABLE 40-5 -- Equipment for Foley Catheter Extraction of Esophageal Foreign Bodies

Child restraint device*
Fluoroscope*

*Optional equipment.

Procedure

Every patient should be appropriately coached concerning the procedure. Young children should be restrained. Moderate sedation and nasopharyngeal topical anesthesia may be used; however, this may increase the risk of aspiration due to decreased airway protective reflexes. The patient is then placed in a head-down Trendelenburg, lateral decubitus, supine, or prone position. The procedure is often done under fluoroscopic guidance, although this is not mandatory if the FB has been localized on plain radiographs.

Assuming the procedure is being performed on a young child, a 12 Fr to 16 Fr Foley catheter is used. After checking for symmetric balloon inflation, the balloon is inflated and the catheter is inserted orally (Fig. 40-9). When using fluoroscopy, the catheter is visually passed distal to the FB. Intermittent inflation with 1 to 2 mL of contrast may be needed to verify the catheter tip location. If performed without fluoroscopy, the distance from nose or mouth to FB is estimated, and the catheter is inserted accordingly. On occasion, the operator feels the catheter tip passing the object. The balloon is slowly filled with 3 to 5 mL of saline or contrast agent (if fluoroscopy is used). Balloon inflation should be stopped if the patient complains of increased pain and the catheter should be repositioned before an attempt at reinflation. Fluid is preferable to air, as it is less compressible. Overdistention of the balloon is undesirable, and in children no more than 5 mL of fluid should be used.

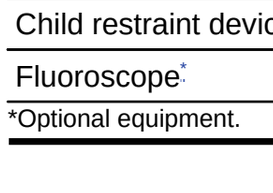

Figure 40-9 Technique of Foley catheter extraction. In children, this procedure is best done with the patient restrained on a papoose board, or consciously sedated, with the head lowered. Some operators place the patient in a prone position or roll the patient to the prone position after catheter insertion to enhance oral expulsion of the foreign body. *A,* A catheter is inserted orally into the esophagus distal to the coin. A bite block may be used to assist oral passage. *B,* The balloon is inflated. Gentle traction moves the coin proximally through the esophagus. *C,* The coin is moved steadily past the glottis. *D,* The coin is present in the mouth to be expectorated or grasped. *(Adapted from McSwain N: Esophageal foreign body. Emerg Med 21:85, 1989.)*

The catheter with its balloon inflated beyond the FB is then withdrawn with steady, gentle traction. Contact with the object can be sensed as the friction of withdrawal increases. Significant impedance to traction requires termination of the attempt. If the catheter slides past the object without dislodging it, the balloon can be deflated and repositioned. An additional 2 to 3 mL can be used to enlarge the balloon and another attempt made. Often when the object reaches the hypopharynx, the balloon and gravity act in concert to fully externalize the FB. The patient can be instructed to spit it out or the operator can grasp the object with the fingers, forceps, or a

clamp.

A follow-up radiograph may be necessary to exclude the possibility of multiple objects. If fluoroscopy is not used and no FB is retrieved, another radiograph should be obtained, because 10% to 20% of the time, the FB will pass distally into the stomach. [103]

Multiple attempts should not be required if catheter size, placement, and balloon inflation are correct. Failed attempts are best followed by a change in one of the aforementioned parameters or repeat x-ray studies to confirm the continued presence of the esophageal FB before esophagoscopy.

Complications

Complication rates of 0% to 2% have been reported. [7] [67] [97] [98] [99] [100] Many complications (nosebleeds or displacement of the foreign object into the nose) have been related to the nasal

insertion of the catheter. Complication rates are lower when the catheter is inserted orally and generally lower at centers that perform the procedure frequently. No deaths have been reported. One esophageal rupture has occurred. [100] Laryngospasm and aspiration are rare complications. Failure to either remove the object or displace it into the stomach occurs in approximately 2 to 10% of carefully selected patients, [98] [99] [100] but success rates are lower in adults or patients with underlying esophageal disorders. [100]

Disposition

Children who have a FB successfully removed by the Foley catheter need no further follow-up if they remain asymptomatic. If the FB was moved into the stomach, clinical follow-up should be adequate to verify movement of gastric FBs through the alimentary tract. Discharge instructions should include warnings about potential symptoms of gastrointestinal obstruction, perforation, and hemorrhage. Parents of children who swallow coins can be instructed to watch for coins in the stool. Adults with esophageal FBs that have been removed successfully must be referred for evaluation of possible esophageal pathology. Should a FB remain lodged in the esophagus, immediate referral for endoscopy is necessary.

ESOPHAGEAL BOUGIENAGE

Background

Displacement of esophageal FBs into the stomach can be done using naso- or orogastric tubes or esophageal bougienage. Esophageal bougienage is a technique for dislodging impacted esophageal coins by blind mechanical advancement of the coin into the stomach, a procedure first described in 1965. [104] The technique has a greater than 95% success rate with essentially no reported complications. [7] [68] [105] [106] Rates as successful as endoscopy have been reported. [102] Furthermore, bougienage is unrivaled in overall cost-effectiveness, approximating 10% of the cost of endoscopic removal. [7] [68] [102] [107]

There have traditionally been warnings against forceful advancement of esophageal FBs, but growing evidence verifies the efficacy and safety of blind esophageal bougienage as first line therapy for coin ingestions in properly selected patients. Although early articles suggested that esophageal bougienage should be performed exclusively by pediatric surgeons, the technique is easily mastered and used by emergency clinicians and junior surgical residents. [68] [106]

Indications and Contraindications

Strict patient selection is paramount for successful and uncomplicated bougienage. The criteria have changed little since initially proposed and define a group in whom a round, smooth object can be forcibly passed into the stomach with little risk. [105] [108] While many swallowed objects meet this description, only coins hold clear supportive evidence in the literature. Selection criteria are the following: a single, smooth FB, lodged <24 hours, in a patient with no respiratory distress or history of esophageal disease including prior FB or surgery. The procedure is contraindicated in patients who do not satisfy all criteria. It is important to ascertain time period of esophageal impaction to avoid the procedure when there may be underlying esophageal injury. For this reason, some advocate requirements for clearly witnessed ingestions <24 hours before presentation. [106] Plain radiographs are indicated to verify coin location and the absence of multiple esophageal bodies. Pre-procedure esophagrams are not required.

Equipment

The necessary equipment should be assembled prior to initiation of the procedure (Table 40-6). Airway equipment and drugs, topical anesthetic, suction, tongue depressor blades, bougie dilator set, water-soluble lubricant, an emesis basin, and an assistant are needed. Hurst-type esophageal dilators refer to weighted, flexible rubber bougies with a blunt, rounded tip. Nasogastric tubes and taper-tipped dilators should not be substituted. Bougie dilator size is selected based on age: 1 to 2 years, size 28 Fr; 2 to 3 years, 32 Fr; 3 to 4 years, 36 Fr; 4 to 5 years, 38 Fr; older than 5 years, 40 Fr. [106]

Procedure and Technique

Although not painful, bougienage may be frightening for patients and their parents. Both should have a clear understanding of the procedure, including the possible complications, prior to initiation. Small children may require physical restraint with bed sheets or papoose. All patients require guidance and reassurance throughout the procedure.

Topical anesthesia may be achieved with gargled 2% to 4% viscous lidocaine (Xylocaine), atomized 2% lidocaine, or topical benzocaine (20% Hurricane spray, Cetacaine). Sedation is generally not needed. Anxiolysis may be of use in some cases but must be weighed against the potential for aspiration from uncontrolled secretions or induced vomiting.

Blind esophageal bougienage is relatively straightforward and resembles placement of an orogastric tube. Patients may be positioned prone or seated upright for the procedure. The distance from nose to midepigastrium approximates the length to reach the stomach and should be noted prior to passage. The patient is asked to flex the head slightly forward and protrude the tongue. A tongue blade may be used to displace the tongue in uncooperative children. The well-lubricated, appropriately sized bougie is passed posteriorly along the roof of the mouth following the natural curve of the soft palate caudally to the hypopharynx. The patient will momentarily gag as the bougie meets resistance at the level

of the cricopharyngeus muscle. Encourage the patient to swallow and gently pass the dilator through the cricopharyngeus muscle. Asking the patient to phonate helps exclude accidental laryngeal intubation; marked hoarseness or inability to phonate indicates airway obstruction and incorrect placement.

Once past the cricopharyngeus muscle, head extension enables the bougie to pass distally to the stomach with little resistance. The bougie is withdrawn after a single pass. The procedure should be terminated immediately for pain or resistance to advancement. A post-procedure radiograph of the chest and upper abdomen documents coin location and should be scrutinized for evidence of complications. Routine post-procedure esophagrams are not indicated unless a complication is clinically suspected. Barring a suspicion of complications, asymptomatic patients are released to home with appropriate precautions including the need to return for signs of respiratory compromise, chest or abdominal pain, dysphagia, hematemesis, persistent vomiting, or other concerns. Follow-up abdominal radiographs may be performed to document passage of the coin if it is not identified in the feces within one week. For adult patients, follow-up is mandated due to the 65% to 80% chance of underlying esophageal disorders. [9]

Complications

Gagging and self-limited non-bloody vomiting are not uncommon after the procedure and may reveal the dislodged coin. Patients may experience a residual FB

sensation for several hours. Pulmonary aspiration and inadvertent passage into the airway are potential complications. Likewise, traumatic pharyngeal and esophageal injury, ranging from mild self-limited bleeding to frank esophageal perforation with concomitant infection, are possible but rare.

SPECIAL SITUATIONS

Childhood Coin Ingestions

Coins are among the most commonly ingested objects in preschool-aged children. In most cases the ingestion is quickly realized by a caretaker, and in the majority of cases, the coins pass uneventfully.[109] Rarely, an esophageal coin can be clandestine for many weeks or months, producing a variety of vague respiratory or gastrointestinal symptoms. Most coins pass from the esophagus to the stomach with only transient symptoms. The child may be in pain for a few minutes as the coin migrates, but on arrival in the ED, the child is often asymptomatic. Coins that remain in the esophagus are likely to, but do not always, produce continued symptoms (e.g., drooling, pain, dysphagia, refusal to eat or drink). Rarely, esophageal coins can produce airway distress by external compression of the trachea, simulating an asthmatic attack. Coins below the diaphragm are asymptomatic and the presence of pain or symptoms requires further evaluation. Coins in the trachea produce immediate and obvious respiratory distress.

The evaluation and management of children with ingested coins is evolving.[110] The first clinical decision is whether or not to obtain a radiograph. Although some authors recommend that asymptomatic children not be radiographed,[27] it is important to remember that up to 44% of children with esophageal coins may be asymptomatic. Therefore, it is prudent to perform a film on all children with a suggestive history.[29] In most cases a single film that includes the pharynx, esophagus, and stomach will suffice to prove or exclude an ingested coin. Another advantage of obtaining radiographs is to rule out multiple FB ingestions (Fig. 40-10), which are not uncommon in children.[111] Only a single PA chest film is needed to prove the presence of a coin. If the flat surface of the coin is seen (see Fig. 40-2 , Fig. 40-3 , Fig. 40-4), this orientation assures an esophageal position. If the edge of the coin is seen, this orientation suggests that it transversed the vocal cords, but a coin in the airway is not subtle. It is advisable to routinely obtain a lateral radiograph to determine if multiple coins are stacked on top of each other (Fig. 40-10A).

Another technique to localize swallowed coins in children is to use a metal detector.[37] [112] [113] Although reported sensitivity and specificity are good for determining esophageal versus non-esophageal location, the device cannot rule out multiple ingestions, which are a contraindication to Foley catheter or bougienage removal.

Once a coin's presence has been documented, a decision concerning removal must be made. Coins in the upper and middle third of the esophagus are unlikely to pass spontaneously.[35] Coins in the distal esophagus are more likely to pass spontaneously within a few hours.[28] [35]

The decision on managing these patients depends on various factors: clinician comfort and experience with removal techniques, local protocols and procedures developed by the medical staff of each institution, and comfort level of the caretakers with various therapeutic options.

One suggested protocol (Fig. 40-11) involves radiologically localizing the coin, and if the child is *symptomatic*, immediately removing the coin. If the patient is *asymptomatic*, the coin may be removed immediately or the patient may be observed either as an inpatient or at home. If the child is asymptomatic, one common practice is to allow the child to drink a carbonated beverage and eat a small amount of soft food in the ED, wait about 1 hour, and perform another radiograph. If sent home, with an asymptomatic retained FB, the patient is allowed to eat or drink but should be rechecked in 12 to 24 hours, with the knowledge that up to 60% of asymptomatic coin FBs will pass into the stomach spontaneously.[28] [35]

The techniques of esophageal bougienage and Foley catheter removal have been described earlier. Both are options for single coins in the esophagus present for <24 to 48 hours. Another option for coins at the LES is pharmacologic relaxation of the sphincter to aid passage into the stomach. The most common method to remove esophageal coins in use today is esophagoscopy.

About half of ingested coins are in the stomach at the time of first investigation, and such patients can be safely released home to allow for almost certain spontaneous passage with a normal diet. Spontaneous passage of a coin from the stomach to the anus usually requires 5 to 7 days. There is no need for routine cathartic. Parents should be advised to check the stool for the coin and return for repeat radiographs if the coin is not found in 1 to 2 weeks. Most coins are passed unknowingly by the patient. Any abdominal discomfort or distention warrants reevaluation in the ED. If a follow-up radiograph demonstrates a persistent coin in the intestines for more than 3 to 4 weeks, an obstructive lesion may be present, and surgical referral is warranted.

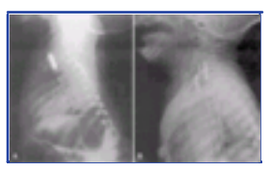

Figure 40-10 *A*, Lateral radiograph of the child shown in Figure 40-2 . This lateral view shows four coins at the same location. Multiple swallowed coins are common in children. It is important to obtain both posteroanterior and lateral films to ascertain the exact number and location of swallowed coins. *B*, A single coin was seen on the PA chest film, but this lateral film suggests three coins. However, they do not seem to be stacked directly on top of each other. This digital radiograph was accidentally exposed three times, and actually only one coin was swallowed.

Figure 40-11 Flow diagram outlining an approach to the management of swallowed coins.

Fish or Chicken Bones in the Throat

Patients who complain of a "bone" in their throat usually present to the ED within several hours of the onset of symptoms and usually have tried a home remedy, such as swallowing a piece of bread. These patients are typically able to pinpoint the location of their discomfort and present with an FB sensation. Patients who are markedly symptomatic, vomiting, or unable to swallow require definitive therapy. Those with minor complaints may be safely evaluated over a few days, often as outpatients.

In cooperative patients, a careful examination of the oropharynx, with either direct or indirect laryngoscopy or both, should be made. If the bone is seen, removal with forceps should be performed (Fig. 40-12).

If the patient feels pain in the upper throat, special attention is directed to the tonsils, since bones often lodge in this area. Strands of saliva may mimic a bone, and small bones may be difficult to see. More commonly, the area of complaint is below the oropharynx. In these patients, indirect laryngoscopy or nasopharyngoscopy should be the first step, once again removing the bone if one is seen.

Most patients presenting with an oropharyngeal FB will not have an easily identified or visualized object on examination. These patients present a diagnostic dilemma

for several reasons. Only 17% to 25% of patients complaining of a FB sensation after eating chicken or fish have an endoscopically proven bone present, and only 29% to 50% of endoscopically proved bones are seen on plain films. [57] [114] [115] The symptoms in those patients with an FB sensation but no FB on endoscopy are believed to be due to esophageal abrasions.

For these reasons, a two-tiered approach to managing these patients is proposed. [6] [9] [26] [63] The patient receives a physical examination and appropriate bone removal if one is seen. Be certain to carefully examine the tonsils, posterior pharynx, and base of the tongue, common places for bones to lodge. If no bone is seen on physical examination, plain films of the neck are obtained. Positive films are an indication for endoscopic removal of the bone. If these films reveal no FB, and the patient is stable, he or she is discharged home with follow-up within 24 hours. Patients with oropharyngeal abrasions will usually be asymptomatic at that time. If still symptomatic on follow-up, endoscopy is advocated.

This approach may well be modified at individual institutions due to increasing evidence of CT's ability to identify bones

Figure 40-12 Many fish bones become impaled in the soft tissues of the upper digestive tract. This woman felt a bone catch in her throat while eating fish. As is often the case, she was able to consistently localize the FB to the submandibular area (*A*). With only a tongue blade, local anesthetic spray, and good lighting, a fish bone was found embedded in the tonsil and was easily removed with forceps (*B*). Strands of saliva can mimic a fish bone, so be careful when probing and grasping.

in the throat, an accuracy rate exceeding 90%. [41] [44] [57] [114] A thorough physical examination including direct and indirect laryngoscopy is still indicated in these patients, as is nasopharyngoscopy in appropriately equipped facilities. These examinations may obviate the need for CT. If the initial examination is negative, reasonable alternatives include following the management approach outlined earlier or obtaining CT of the neck with appropriate referral for removal if a bone is identified.

A small bone lodged in the esophagus for a few days is annoying and painful, but it is generally not an emergency. However, impacted bones can cause serious sequelae, often weeks later, and continued complaints cannot be ignored. Importantly, *a lodged bone will not dissolve and rarely passes spontaneously once lodged in the mucosa*. Referral, and possible endoscopy, are necessary if complaints persist for more than 2 to 3 days, even if the examination and CT scan are negative.

Sharp Objects in the Esophagus

Sharp objects cause the majority of complications seen in patients with esophageal FBs. These objects include tacks, pins (Fig. 40-13), open paperclips, bobby pins, toothpicks, and razor blades. They will usually not pass spontaneously and should be removed. The only appropriate removal technique is under direct visualization with endoscopy.

Attempts at radiographic localization are appropriate for metallic or radiopaque FBs. If the object is in the stomach, most will transit the remainder of the gastrointestinal tract if less than 6 cm in length or 2 cm in diameter. If larger than this, consultation with a gastroenterologist is appropriate. If radiographs show the FB in the esophagus, endoscopic removal is indicated and attempts to remove such objects in the ED are not indicated. Complication rates for endoscopic removal of sharp FBs ranges from 0% to 3%.[8] [10] [32]

Non Radiopaque Objects in the Esophagus

Objects such as toothpicks, aluminum tabs from beverage cans, and food boluses cannot be visualized on plain radiographs, and will not normally pass spontaneously. Toothpicks cause a higher percentage of complications than any other type of esophageal FB. Localization of the FB may be accomplished by esophagram with contrast material, although the

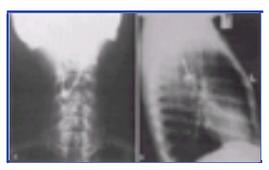

Figure 40-13 *A*, Posteroanterior radiograph of an open safety pin lodged in the upper esophagus. Sharp foreign bodies in the esophagus are best removed with endoscopic visualization. *B*, This 10-year-old child came to the ED with severe chest pain. No history of a foreign body was given. Even when the radiograph demonstrated this metallic object in the esophagus, it remained a mystery how it got there. Objects such as this are removed under anesthesia with an endoscope, and no ED intervention, except for pain relief, is indicated.

yield is low with toothpicks. As with fishbones, toothpicks often lodge in the tonsils or posterior pharynx and can be seen on direct vision.

Food boluses may be amenable to pharmacologic relaxation of the LES. The mainstay of therapy for other non radiopaque FBs in the esophagus is consultation for endoscopic evaluation and removal.

Button Battery Ingestion

Button batteries lodged in the esophagus should be considered an emergency because of the potential for serious morbidity and mortality. [15] [17] [116] These batteries range in size from 7 to 25 mm and are radiopaque (Fig. 40-14). Batteries appear as round densities, similar to an impacted coin, but some demonstrate a "double contour" configuration (Fig. 40-15). It is important to distinguish between a coin and a button battery,

Figure 40-14 Button batteries. These batteries have a wide range of sizes and can mimic coins on radiographs.

because button batteries require immediate removal. Batteries consist of two metal plates joined by a plastic seal. Internally they contain an electrolyte solution (usually concentrated sodium or potassium hydroxide) and a heavy metal, such as mercuric oxide, silver oxide, zinc, or lithium.

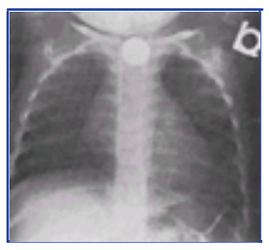

Figure 40-15 Posteroanterior radiograph of a button battery lodged in the esophagus, which can easily be confused with a coin. Button batteries can cause esophageal wall necrosis within 2 hours and must be removed expeditiously. *(From Kost KM, Shapior RS: Button battery ingestion: A case report and review of the literature. J Otolaryngol 16:4, 1987.)*

If ingested, these batteries often lodge in the esophagus. The mechanisms of injury include electrolyte leakage, injury from electrical current, heavy metal toxicity, and

pressure necrosis. Of particular concern is the development of a corrosive esophagitis or perforation as a result of caustic injury and prolonged mucosal pressure. Although essentially harmless in the stomach and intestines, batteries lodged in the esophagus should be considered an emergency situation, because even new batteries demonstrate corrosion, leakage, and mucosal necrosis within a few hours of contact with the esophagus. [16] [17]

Esophageal impaction mandates immediate removal. Options include Foley catheter removal, esophageal bougienage, or esophagoscopy. Esophagoscopy allows for direct esophageal evaluation and a more controlled extraction. In addition, the "invasive" nature of batteries may lead to rapid edema, making the catheter technique more difficult.

Once in the stomach, button batteries do not require removal. They may be followed radiographically to demonstrate passage, with little risk of gastrointestinal injury or heavy metal poisoning, even if the battery opens. [117] [118]

CONCLUSION

Patients with esophageal FBs are frequently seen in the ED. There are several important considerations in evaluating these patients (Table 40-7).

Sharp FBs in the esophagus must be removed by endoscopy. Button batteries in the esophagus must be removed expeditiously. Fish and chicken bones are problematic for a variety of reasons, and an individualized approach is appropriate. Coins are the most common ingested FB in children, and can also be managed on an individual basis.

Appropriate esophageal FBs may be removed by the Foley catheter technique, or passage into the stomach aided by esophageal bougienage or pharmacologic agents. All esophageal FBs may be removed by esophagoscopy.

TABLE 40-7 -- Important Considerations in Management of Esophageal Foreign Bodies

The esophagus does not tolerate foreign bodies (FBs) for prolonged periods of time. Do not expect impacted FBs to eventually pass by themselves. Fishbones will not dissolve over time.
1. As many as one third of pediatric patients with esophageal FBs are asymptomatic.
2. Consider esophageal FBs in the differential of the infant who is irritable, has recurrent pulmonary infections, or failure to thrive.
3. Multiple esophageal FBs are common in children and psychiatric patients.
4. Button batteries in the esophagus can cause necrosis within 2 hours and should be expeditiously removed.
5. A high percentage of adults with food boluses lodging in the esophagus have underlying esophageal disorders and require follow-up for evaluation.
6. Sharp FBs in the esophagus account for the preponderance of complications. These objects, including toothpicks, are best evaluated and treated with endoscopy.
7. Plain radiographs have little diagnostic value except for detecting metallic objects. A computed tomography scan is the best way to evaluate for bones and radiolucent objects.

Chapter 41 - Nasogastric and Feeding Tube Placement

Leonard E. Samuels

A wide variety of patients require nasogastric (NG) intubation, including those with obstructed, preoperative, or potentially hemorrhaging upper gastrointestinal systems. Although the initial placement of feeding tubes is rarely the province of emergency clinicians, patients with feeding tube complications, and those requiring replacement of tubes, frequently present to the emergency department (ED). Therefore, the emergency clinician must be familiar with the different types of enteral tubes, as well as with their care, cleansing, and means of replacement.

PROPERTIES OF NASOGASTRIC AND FEEDING TUBES

Enteral tubes are made of various materials. Polypropylene is the most common material used for Levin and Salem sump NG tubes (Fig. 41-1), but it is too rigid for long-term use for a feeding tube. Although they are less likely to kink than others, polypropylene tubes are more capable of creating a false passage during placement. Latex (rubber) tubes are moderately firm, require greater lubrication for passage, are relatively thick-walled, and induce a greater foreign body reaction than tubes of other commonly used materials. Latex, especially in latex balloons, deteriorates more rapidly than other materials. [1] Foley catheters are primarily latex, although totally silicone Foley catheters are available for those with latex allergies. Silicone tubes are thin-walled, quite pliable, and nonreactive. However, the walls of silicone tubes are less strong and may rupture if fluid is introduced into a kinked tube. [2] Polyurethane tubes are quite nonreactive and relatively durable. Rigidity varies from manufacturer to manufacturer, depending on tube thickness. A stylet may aid in the passage of polyurethane and silicone tubes, but its use increases their rigidity and capability of tissue dissection, especially in tubes that have a small distal end bulb. [3] Some feeding tubes have weights, usually made of tungsten, which are nontoxic if released into the gastrointestinal tract.

NASOGASTRIC TUBE PLACEMENT

Indications and Contraindications

The simplest NG tube is the Levin tube, which has a single lumen and multiple distal "eyes." The advantage of the Levin tube is its relatively large internal diameter in proportion to its external diameter. The theoretical disadvantage is that a Levin tube should not be left hooked up to suction after the initial contents of the stomach have been drained, because the suction will cause the stomach to invaginate into the eyes of the tube, blocking future tube function and potentially causing injury to the stomach lining. Levin tubes are useful for diagnostic aspiration of stomach contents or for simple instillation of therapeutic agents. Tubes with lumens larger than 16 Fr are preferred for lavage procedures if large particulates are anticipated.

In practice, the Levin tube is no more prone to bleeding complications than the Salem sump tube, provided that the *intermittent* suction setting for the Levin tube is =40 mm Hg.[4] The Salem sump tube is preferred to the Levin tube for more chronic use as a drainage device because of the presence of a separate (blue-colored) channel that vents the distal main lumen to the atmosphere (Fig. 41-2). When extended gastric drainage is desired, Salem sump tubes should be placed on intermittent suction, even though the vent generally will prevent excessive vacuum at the tube tip. Note that potentially both intermittent suction and wall unit vacuum can exceed the venting capacity of the second lumen; for intermittent suction, the vacuum setting should be =120 mm Hg. [4]

The major indication for NG intubation is to aspirate the stomach contents. Aspiration may be useful in the management of upper gastrointestinal bleeding, particularly to differentiate upper from lower gastrointestinal bleeding.

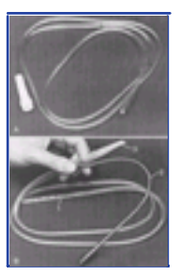

Figure 41-1 Standard nasogastric tubes. *A,* Standard Levin tube. This tube has a single lumen. It is sufficient for instilling material into the stomach or for diagnostic stomach aspiration. *B,* Salem sump tube. This tube contains a second lumen that allows venting during continuous suction. *1,* Gastric end with suction eyes. *2,* Pigtail extension (blue) of the air vent lumen. *3,* Connector for attachment of suction lumen to vacuum line.

Except when frankly bloody fluid is obtained, the sensitivity and specificity of aspiration to detect upper intestinal bleeding are not good. [5] [6] [7] Use of Hemoccult or guaiac cards to detect bleeding in gastric aspirates is unreliable, because false-positive tests are obtained frequently. [5] Although variceal rupture has occurred during insertion of instruments into the esophagus, several studies suggest that NG tube passage is generally safe, even in the presence of esophageal varices. [8] [9] NG suction is indicated in cases where vomiting is likely to be recurrent or dangerous, such as with a paralytic ileus or intestinal obstruction, or to relieve acute gastric dilation. The trauma patient may need an NG tube as part of the evaluation for gastrointestinal injury or to decompress the stomach before surgery or peritoneal lavage. A radiopaque NG tube may help delineate transdiaphragmatic hernia of the stomach after trauma.

NG tubes are contraindicated in a few groups of patients with special predispositions to injury from tube placement. Patients with facial fractures who have a cribriform plate injury may suffer intracranial penetration with a blindly placed nasal tube. [10] A severe coagulopathy may be a relative contraindication for nasal passage of an NG tube. For patients with a coagulopathy or significant facial or head trauma, an NG tube passed through the mouth may be a better alternative (Fig. 41-3). Patients who have esophageal strictures or a history of alkali ingestion, especially recent alkali ingestion, may suffer esophageal perforation. Comatose patients may vomit during or after NG tube placement; their airways should be protected before placing the NG tube. Gagging will decrease venous return and increase cervical and intracranial venous pressure, which may be clinically significant in selected trauma patients with cervical or intracranial bleeding and in the presence of significantly elevated intracranial pressure. Indwelling NG tubes predispose patients to pulmonary aspiration because of tube-induced hypersalivation, depressed cough reflex, or mechanical or physiological impairment of the glottis. [11] Aspiration is also quite common with nasoenteral feedings in debilitated patients.

Despite their traditional use, *NG tubes are not routinely required in patients with mild to moderate pancreatitis*, [12] [13] and NG tubes may actually prolong hyperamylasemia and pain. Extended irrigation of the stomach with water in a patient with upper gastrointestinal hemorrhage can lower serum potassium levels, [14] and animal studies suggest that cold water lavage can cause rather than control bleeding. [15] [16] No study has shown irrigation to be effective in the control of bleeding,[6] [17] and vigorous lavage with cold water may lower the body temperature. However, a NG tube may be used to

Figure 41-3 An NG tube may enter the cranium or facial soft tissues in patients with severe head or facial trauma. Those with a coagulopathy may experience significant bleeding from nasal or pharyngeal trauma during passage of an NG tube. In such cases, a standard NG tube inserted through the mouth may be a better alternative.

instill air into the stomach for documentation of a suspected gastric perforation by enhancing visualization of free air under the diaphragm on an upright chest film.

Equipment

Passage of standard NG tubes or feeding tubes can be messy and may be accompanied by coughing, retching, sneezing, bleeding, and spilled water or stomach fluid. Both patient and clinician should be gowned; cleanup may be reduced if the bib area is covered with a towel and a supply of tissue or washcloths is available. The clinician requires gloves; the appropriate NG or feeding tube; a penlight or other light source; a tongue blade; an emesis basin; a glass of water with drinking straw (or an extra syringe if the patient is uncooperative); water-soluble lubricant; a stethoscope; a safety pin; a rubber band; topical anesthetic jelly, spray, or ointment; and vasoconstrictor nasal spray or liquid. For standard NG tube placement, a piston or bulb syringe (with a catheter slip-tip) should be available. NG feeding

tubes should have a compatible 50- or 60-mL syringe (some are Luer compatible and others are slip-tip compatible).

Tape torn in 4-in strips or a commercial NG tube holder (e.g., Suction Tube Attachment Device, Hollister, Libertyville, IL) should be handy for securing the tube after placement. Cotton-tipped applicators and tincture of benzoin may be helpful if the skin is greasy. Depending on the indication, other equipment may be needed (e.g., saline for irrigation, Magill forceps in an uncooperative or anesthetized patient). Make sure

Figure 41-4 Estimation of tube insertion depth. Before inserting the nasogastric tube, the clinician should estimate the length of tubing that will be required to ensure intragastric positioning without excess coiling. Holding the tube against the patient's body, measure the distance from the tip of the xiphoid to the earlobe *(A)*. Add the distance from the earlobe to the tip of the nose *(B)*. Then add another 15 cm *(C)*. Note the total distance using markers on the tube, or attach a piece of tape to the tube.

the feeding tube is designed for duodenal passage if that is desired—such tubes are usually longer than regular feeding tubes.

An antireflux valve (Keith Antireflux Valve, Sherwood Medical Industries, St. Louis) is a one-way valve used on the vent port of the Salem sump tubes. One study found the device to be cost-effective by reducing the need for gown and linen changes during inpatient NG tube use. [18] Placement of this device in the ED should be considered if extended use is anticipated. A topical anesthetic and a vasoconstrictor are also common adjuncts to tube passage.

Procedure

Explain the procedure to the patient. If the patient is alert, the head of the bed should be raised so that the patient is in the high Fowler position or upright. A towel is placed over the patient's chest to protect the gown, and an emesis basin should be available on the patient's lap. [19] The tube (typically a 16 or 18 Fr sump) should be positioned so that insertion distance can be estimated, and this distance should be marked with tape or noted using the markers printed on the proximal tube. A simple method is to extend the tube from the xiphoid to the earlobe and then from there to the tip of the nose and *then add 15 cm* (6 in) (Fig. 41-4).[20] Although other techniques of estimating appropriate NG tube insertion distance using formulas may be more accurate than the nose-ear-xiphoid method, the formulas are difficult to memorize and calculate. [21] [22] It is a common error to fail to estimate the

proper length of the tube before passage. The nares should be checked for obstruction and the tube passed down the more patent naris. Patency can be assessed by direct visualization or by having the patient sniff while first one and then the other nostril is occluded.

The pain and gagging associated with tube placement can be ameliorated significantly with the use of vasoconstrictors and topical anesthetics. The editors advocate the use of such adjuncts whenever the time and clinical situation permit. When logistically possible, topical vasoconstrictors, such as phenylephrine (Neo-Synephrine 0.5%), or oxymetazoline (Afrin 0.05%) should be sprayed into the nasal passages, usually both sides initially since one side may prove to be problematic, at least 3 to 5 minutes before the procedure. The nares, nasopharynx and oropharynx, should all be anesthetized at least 5 minutes before the procedure. Many clinicians neglect to anesthetize the pharynx and target only the nose, but gagging is reduced if the pharynx is included. Numerous topical anesthetics are available. Combinations of tetracaine, butyl aminobenzoate, and benzocaine (Cetacaine); nebulized or atomized (spray cans/bottles) lidocaine (4%); and lidocaine gels (2%) are most commonly used. Lidocaine preparations of 4% are most useful. Nebulized 4% lidocaine (2.5 mL containing 100 mg), delivered by face mask with the equipment used to administer bronchodilators to asthmatics, has been found to be superior to lidocaine spray as an anesthetic to reduce gagging and vomiting and to increase the chance of successful passage (Fig. 41-5).[23] [23A] After topical vasoconstrictor and anesthetic are administered, the tube is lubricated with viscous lidocaine or lidocaine jelly.[24] Lubrication of the nares can be facilitated using a syringe (without needle) filled with 5 mL of lubricant (Fig. 41-6). Simply putting anesthetic jelly on the tube before insertion, without prior nebulized/atomized anesthetic, will not provide satisfactory anesthesia. The mucosa should be anesthetized *at least 5 minutes before tube passage* if possible.

Topical anesthetics are generally quite safe, but attention must be paid to the total dose of administered anesthetic to

Figure 41-5 If time and situation permit, administration of nebulized lidocaine (2.5 mL of 4% solution) via a face mask and standard nebulizer used to deliver asthma medications, can decrease pain and gagging without increasing aberrant placement. The patient is instructed to breathe through the mouth and nose to anesthetize the nose and pharynx.

Figure 41-6 Whenever possible, some form of topical anesthesia should be used before passing a nasogastric tube. The method pictured can be used in addition to atomized anesthetic, and will be more effective than treating only the nasal opening. Fill a syringe barrel with 5 mL of 2% viscous lidocaine. Without using a needle, squirt the solution along the floor of the nose and allow it to drip into the nasopharynx and be swallowed. This method works best with the patient supine. Wait 5 minutes for the anesthetic to take effect.

avoid toxicity.[25] Note that each milliliter of a 4% lidocaine solution contains 40 mg of lidocaine that is absorbed systemically. Topical benzocaine used in endoscopy procedures may rarely cause methemoglobinemia. [26]

The tube is inserted into the naris along the floor of the nose and not toward the nasal bridge (Fig. 41-7) (i.e., directed posteriorly and not cephalad). Mild resistance may occur in the posterior nasopharynx, but only gentle pressure should be required to overcome this resistance. Bleeding or dissection into retropharyngeal tissue may occur if force is used, and it is better to try the other nostril or an oral tube if significant resistance is encountered. Once the tube passes into the oropharynx, *a pause will help the patient regain composure and enhance the chances for cooperation with the rest of the procedure* .

Have the patient, if he or she is alert and cooperative, sip water from a straw and swallow while the tube is advanced into and down the esophagus. This often helps ease passage of the tube. Once the tube is in the nasopharynx, flexing the neck also tends to direct the tube into the esophagus rather than the trachea. Excessive choking or gagging or any coughing, change in voice, or the appearance of condensation on the inner aspect of the tube should alert the clinician to the possibility of tracheal tube position, prompting withdrawal of the tube into the oropharynx. The tube may be inspected through the mouth to detect coiling or respiratory passage. A tube position lateral to the midline suggests correct position in the esophagus. [27] Once the tube is in the esophagus, *it should be advanced rapidly* to the previously determined depth. Slow passage of the tube prolongs discomfort and may precipitate more gagging. [19]

Confirmation of Tube Placement

Before the NG tube is secured, nonradiographic confirmation of its successful placement should be obtained. All confirmation methods have some possibility of error, so it is wise, when in doubt, to use more than one method. Radiographic evaluation is the most definitive way to confirm the position of an NG tube, but it is not standard to routinely obtain x-ray confirmation.

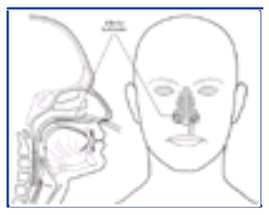

Figure 41-7 Tube location in the nostril. The nasogastric tube is directed along the *floor* of the nose, not toward the nasal bridge. The tube often slides through the tunnel beneath the inferior turbinate.

Insufflation of air into the NG tube is simple and quick. The requirement of increased pressure to instill air or the absence of borborygmi with instillation should raise concern about tube malposition or kinking. If the patient immediately burps on air instillation, an esophageal tube position should be suspected. A tube in the lungs or trachea is immediately discernible in an awake patient. Unfortunately, unrecognized passage of nasal tubes into the lungs occurs, but only in comatose, struggling, or demented patients, and insufflation is often insufficient to detect this type of malpositioning. [3] [29] [30] [31] [32] [33] [34] [35] The insufflation test also is unreliable in detecting whether the tube has advanced past the stomach into the small bowel.[32] In such patients, radiographic verification may be prudent.

Aspiration of stomach contents, especially if pH tested, is more reliable, and can be performed if positioning is in question. If the pH is less than 4, the nasoenteral tube has an approximately 95% chance of having its tip in the stomach. Furthermore, nonrespiratory placement is almost guaranteed. [28]

Aspirated fluid can occasionally be obtained from the lung or pleural space, but the pH should be 6.0 or higher. [28] [36] Approximately 2% of patients have an alkaline stomach pH.[37] Causes include duodenal reflux, antacids, H_2 blockers, or recent instillation of formula or medications. [37] [38]

Ask the patient, if he or she is awake and cooperative, to talk. If the patient cannot speak, respiratory placement is likely. Note that with small-bore tubes, patients may still be able to speak despite tracheal placement. [38]

Once correct tube position is tentatively confirmed, the tube should be secured. If the patient requires abdominal or chest radiographs for other diagnostic purposes, it is best to place the NG tube *before* obtaining the films. An NG tube deviated to the right may occasionally be seen in patients with traumatic rupture of the aorta, but this is not a reliable indicator.

Securing the Tube

The NG tube is generally secured to the patient with tape attached to both tube and nose. A butterfly bandage (or tape on each side of the nose) that then coils around the NG tube is a typical approach. The tube should be clean and possibly prepped with tincture of benzoin, as should the nose. If a tape should let go or require repositioning, both the tape and the tincture of benzoin must be replaced. It is wise to also secure the tube to the patient's gown, so that a tug on the tube will encounter this resistance before pulling on the material securing the tube to the patient's nose. A rubber band tied around the tube with a slip knot (Fig. 41-8*A, B*) and pinned to the gown near the patient's shoulder is effective. It is critical to ensure that the tube is not secured in such a way that it presses on the medial or lateral nostril. Necrosis or bleeding can result if a tube is not secured correctly.

When a Salem sump is used, the blue pigtail must be kept *above* the level of the fluid in the patient's stomach, or stomach contents may leak back through the vent lumen. If a patient needs to ambulate with a sump tube in place, the blue pigtail can be fitted into the plastic connector at the end of the suction lumen, creating a closed loop that should not leak. For a Levin tube, a syringe can be attached to the lumen and taped to the patient's gown. Alternatively, a commercial antireflux valve may be attached.

Placement Issues

NG tube placement in the unconscious patient can be attempted using the same technique as in the conscious patient, omitting those steps requiring patient cooperation. If the patient is intubated, the balloon of the endotracheal tube should be deflated briefly to allow passage of the NG tube. The NG tube is easily misplaced into the pulmonary tree in the unconscious patient, but quite unlikely if the patient is intubated. This complication may be missed during the procedure, because gag and cough reflexes may be suppressed and the patient cannot talk. In addition, the absence of swallowing may prevent successful passage of the tube. Several techniques may be used to successfully pass a NG tube in a difficult unconscious patient.

If initial standard attempts fail, the NG tube may be placed initially through a naris into the oropharynx. The tip of the tube is then visualized with a laryngoscope, grasped with Magill forceps, and pulled out of the mouth. An endotracheal

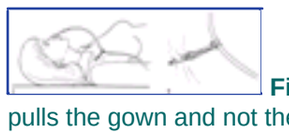

Figure 41-8 Attachment of tube to gown. *A,* Attach the nasogastric tube to the patient's gown using a rubber band and a safety pin as shown, so that the first tug on the tube pulls the gown and not the tape holding the tube in the patient's nose. *B,* Close-up view of attachment site.

tube with an internal diameter that is slightly larger than the external diameter of the NG tube is selected and is slit along its lesser curvature from its proximal end to a point 3 cm from its distal end. The slit endotracheal tube (generally 8 mm internal diameter [ID]) is then passed through the mouth into the esophagus. [39] Alternatively, a 7-mm ID slit endotracheal tube may be passed directly through the nose into the esophagus. [40] Passage into the esophagus is facilitated by the stiffness of the larger endotracheal tube and does not require active swallowing. The tip of the NG tube is then threaded into the endotracheal tube and advanced into the stomach (Fig. 41-9). The slit endotracheal tube is then removed from

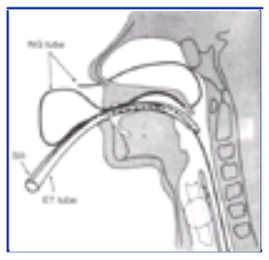

Figure 41-9 Diagrammatic representation of the separation of the nasogastric tube from the guiding endotracheal (ET) tube through the slit in the guiding ET tube. The nasogastric tube has first been passed through the nose and is pulled out through the mouth. The tip of the tube is then threaded into the guiding ET tube to ensure passage down the esophagus. The guiding ET tube is removed from the esophagus before separation from the nasogastric tube. Note the prior placement of another endotracheal tube in the trachea (partially shown) to avert passage of the guiding ET tube into the trachea. *(From Sprague DH, Carter SR: An alternate method for nasogastric tube insertion. Anesthesiology 53:436, 1980.)*

the esophagus. When the distal part of the endotracheal tube is visible, the unslit 3-cm distal part is slit with scissors. The endotracheal tube is removed, and the NG tube remains in place.[41] Any slack tubing is then advanced with the forceps or pulled back nasally, depending on the final depth required for the NG tube. The technique can also be performed by passing the slit endotracheal tube nasally, which also saves the trouble of orally advancing or nasally retracting any slack tubing.[40] [41]

In particularly passive, sedated, unconscious or toothless patients, guiding the NG tube with the fingers in the pharynx is occasionally successful (Fig. 41-10).[42] Displacing the larynx forward by manually gripping and lifting the thyroid cartilage has aided tube insertion, [43] as has simple jaw elevation. A soft nasopharyngeal airway, well lubricated, is at times easier to pass nasally than the NG tube, and then the lubricated NG tube can be passed through it. In addition, it affords some

protection to the nasal mucosa if multiple attempts to pass the NG tube are necessary, or if it is particularly important to minimize bleeding or trauma.

Cooling a NG tube increases its rigidity, and coiling it can increase the tube curvature, both of which may help pass the tube. Note that a cooled tube is more likely to dissect into tissue.

Ultimately, if all other methods fail, a flexible fiberoptic bronchoscope or esophagoscope can be placed under direct vision into and through the esophagus. [44] A guidewire is threaded into the stomach. The NG tube can be placed over the guidewire into the stomach; the guidewire is then removed. [45]

Complications

Complications of standard NG tube placement are similar to problems noted with NG feeding tube placement. The complications related to tube misplacement are discussed in that section. In addition, the clinician placing the NG tube in the patient with neck injuries should be cautious of potentiating cervical spine injuries with excessive motion during passage (especially in association with coughing and gagging in the awake patient). Furthermore, passage of a NG tube in the awake patient with a penetrating neck wound may exacerbate hemorrhage, should coughing or gagging result. Particularly serious forms of tube misplacement are

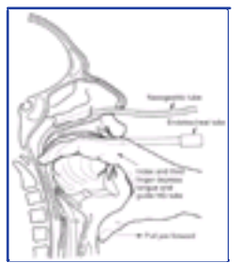

Figure 41-10 The passage of an nasogastric tube through the nose of an intubated patient. An endotracheal tube is in the tracheal via the mouth. The second and third fingers are placed into the posterior pharynx. Fingers depress the tongue. The nasogastric tube is guided down the esophagus by passing it through the second and third fingers that are in the posterior pharynx. The thumb is under the jaw and pulls the jaw forward.

pulmonary placement (Fig. 41-11) and intracranial placement (Fig. 41-12).

A tension gastrothorax can develop in patients with intrathoraracic stomach. The tension gastrothorax can occupy much of the left hemithorax, displacing the heart and lungs and causing a clinical syndrome identical to tension pneumothorax. While successful passage of a NG tube will relieve a tension gastrothorax, the high pressures of a tension gastrothorax often develop because torsion of the stomach in the chest prevents egress of air; that torsion may prevent ingress of the therapeutic NG tube. The condition is rare enough that further emergent therapy is based on case reports rather than substantial series. Relief of the tension gastrothorax has been accomplished with transthoracic puncture of the stomach with a 16-G catheter over needle. The catheter over needle was inserted in the second intercostal space in the mid-clavicular line, and then the needle was removed. The catheter was left in place attached to IV tubing with the distal end under a water seal.[46] A single 16-G puncture of the stomach is unlikely to leak and cause pleuritis; such punctures have long been used in percutaneous endoscopic gastrostomy tube placement. Inserting a chest tube into the stomach is not advisable because gastric fluid may leak into the pleural space. Once the tension on the stomach is relieved, it may be possible to pass the NG tube to prevent reoccurrence of the problem. The stomach, no longer tense and wedged in the chest, can twist to allow the tube to pass. Surgical correction of the condition permitting intrathoracic herniation of the stomach is the definitive treatment to prevent reoccurrence of tension gastrothorax.

Figure 41-11 Levin tube inadvertently placed in the right main stem bronchus; an alveolar infiltrate consistent with early pneumonia is also shown. *(From Johnson JC: Letter to the editor: Back to basics for morbidity-free nasogastric intubation. JACEP 8:289, 1979.)*

NG tubes, when in place for prolonged periods, are a common cause of innocuous gastric bleeding and gastric erosions.

NASOENTERIC FEEDING TUBES

Indications and Contraindications

The most common indication for feeding tube replacement in the ED is unintentional removal of a pre-existing feeding tube. In one prospective study, 38% of tubes were removed unintentionally. Although some of these tubes had fallen out or been coughed out, more than half had been pulled out by the patient. [47] Tube rupture, deterioration, or clogging may also necessitate replacement. Management of the clogged or nonirrigating feeding tube is discussed in the section on clogged feeding tubes.

Enteric feeding tube replacement is contraindicated in the presence of vomiting, intestinal obstruction, severe ileus, upper gastrointestinal bleeding, distal enteric anastomoses, and conditions in which bowel rest is desired. [48] Occasionally, the patient whose feeding tube is displaced does not require nasoenteric feeding tube replacement because oral intake is adequate for nutritional needs. Patients suffering erosions or discomfort may be candidates for percutaneous endoscopic gastrostomy (PEG) placement.

Choice of Feeding Tube Site

Three major classes of enteral feeding tubes are in common use; classification is according to site of insertion. Tubes can enter through the nares, a cervical ostomy, or an abdominal ostomy. The mode of nutritional support is determined by the

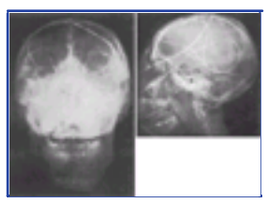

Figure 41-12 Anteroposterior and lateral skull radiographs demonstrating intracranial insertion of a nasogastric tube in a patient with multiple skull fractures. *(From Johnson JC: Letter to the editor: Back to basics for morbidity-free nasogastric intubation. JACEP 8:289, 1979.)*

patient's physiologic requirements and degree of debilitation, the disease process, the anticipated duration of inadequate oral intake, and the facilities and equipment available to initiate and maintain delivery of nutritional support. [49]

Tube feeding may be either a temporary or a permanent means of nutritional support and may have supplemental or complete responsibility for meeting the patient's nutritional needs. Enteral nutrition is less expensive and easier to use than total parenteral nutrition [50] and probably safer.[46] [51] Enteral nutrition is indicated when oral intake is less than two thirds of the patient's requirement, despite a functioning gastrointestinal system. Nasoenteric feedings are appropriate when fewer than 4 weeks of feeding are required,[48] although in some cases a pharyngostomy may be preferred because it is less irritating and cosmetically easier to conceal. Cervical or abdominal ostomies are recommended when more than 4 weeks of feeding are necessary.[48] Oral ingestion may continue with gastrostomy tubes and may be possible with NG and cervical ostomy tubes with a gauge of 12 or lower.

Enteral tubes are often categorized by the position of the tip of the tube. Tubes may terminate in the stomach (gastric tube, PEG tube) or the small intestine (jejunostomy tube, J tube). To confuse the issue, some tubes enter the stomach and terminate in the stomach (G tube) or in the proximal small bowel (J tube), whereas some tubes enter the GI tract directly through the small bowel wall (J tube). Gastric tubes are almost entirely PEG tubes. They are placed endoscopically with local anesthesia and without a surgical incision. Jejunostomy tubes are surgically placed under general anesthesia, require a surgical incision, and result in a surgical scar at the insertion site. Gastric feeding results in better digestion than intestinal feeding. J tubes are less likely to result in reflux and aspiration. Normally about 20% of gastric antral contents pass into the duodenum, with 80% refluxing back into the body of the stomach for further mixing. [22] If the feeding tube is placed in the antrum of the stomach or in the small bowel, enteral feeding solution passing into the small bowel may not be tolerated, resulting in diarrhea and paradoxical decreased nutrition.[21] [22]

The most common rationale for small intestinal feeding is to reduce regurgitation and aspiration. Disagreement exists concerning the clinical significance and frequency of regurgitation-induced aspiration. [47] [50] [51] [52] [53] [54]

Procedure

Nasoenteric feeding tube replacement requires greater time and effort if the patient is uncooperative or has a physically obstructing lesion. Nasoenteric feeding tube migration into the duodenal bulb generally requires patient positioning in the right decubitus position for about an hour after successful intragastric passage. [55]

The clinician should explain the procedure to the patient before tube passage. The patient's assistance with esophageal passage can be enlisted in two ways. First, the patient can assist with swallowing the tube. Second, the patient can vocalize when requested to confirm that the tube is not passing down the trachea. Many patients find it helpful to develop a signal to indicate to the clinician when they need a temporary reprieve and rest. It is generally advisable to restrain the hands of demented, impaired, or otherwise uncooperative patients.

The nares should be prepared before passage with generous application of a lubricant and local anesthetic. A local vasoconstrictor will dilate the nasal passages slightly and help prevent bleeding. Viscous lidocaine or water-soluble jellies (e.g., Surgilube) are excellent lubricants. A small amount of lidocaine with epinephrine can be squirted from a syringe into the nares a few minutes before lubrication. Application of lidocaine with epinephrine, application of the lubricant, or both, can also be accomplished with soaked cotton-tipped applicators. Alternatively, viscous lidocaine can be introduced into the nose with a gloved finger. The clinician should be prepared and garbed for the inevitable sneeze that this will provoke. Patients with a hyperactive gag reflex should gargle with viscous lidocaine or with benzocaine (Cetacaine) or lidocaine (Xylocaine) spray before the placement attempt.

The feeding tube stylet should be lubricated and inserted into the feeding tube before the insertion of the feeding tube into the nares. Tube stylets can be lubricated with water-soluble jelly. Dobbhoff, EntriFlex (Biosearch), and several other tubes have a preapplied lubricant that must be activated with a 5-mL flush of water. Frying pan lubricant sprays (e.g., Pam) also may work well on the stylet. Other types of lubricants may have greater potential for pulmonary complications or may damage the substance of the tubes. *The stylet should never protrude beyond the end of the feeding tube* , because these stiff, small-diameter wires have the capacity to scratch the esophagus and can encourage the creation of a false passage. The stylet may lock into position on the tube at the proximal end and should be properly secured.

An upright patient position is more comfortable for the clinician during NG passage. The distal end of the feeding tube should be moistened or lubricated and then passed down the more patent of the two nasal passages. Most persons' nostrils are fairly symmetric, but, in some cases, growths or old trauma may narrow the passage. The tube should be inserted into the nostril and then directed toward the ear. A common mistake of the inexperienced practitioner is to continue directing the feeding tube in a cranial direction. If the first nostril is impassable, the opposite side may permit tube passage. In particularly difficult cases, it may be desirable to first

pass a lubricated nasal airway (trumpet) and then pass the feeding tube through it, reducing nasal and nasopharynx stimulation.

The tube's passage into the nasopharynx can usually be detected by a lessening of resistance. One can then proceed with esophageal passage. Topical anesthesia of the pharynx may be required to ameliorate any excessive gagging that may occur at this point. Cough should warn of incipient respiratory placement of the tube. If the patient can vocalize, the tube has not yet passed through the vocal cords. The patient should bend the head forward if possible. This encourages the tube to pass into the esophagus and aids airway closure. If the patient is gagging or choking, it may be because the tube is beginning to coil in the oropharynx. Look in the mouth with a penlight to see if this is occurring. If the tube is coiled on entering the airway, temporarily pulling the tube back should relieve the problem. When pulling back, some resistance is again felt as the thicker end bulb of the tube begins to enter the posterior nasal passages; at that point, the tube has been pulled back far enough for a fresh try at esophageal intubation. The cooperative patient should swallow ice chips or take small sips of water with a straw to facilitate tube passage down the esophagus. In some cases it may be impossible to avoid coiling when the tube is advanced, unless the patient is swallowing. When the patient is uncooperative, the introduction of 5 to 15 mL of water into the mouth or into the proximal end of the feeding tube with a syringe may induce swallowing, facilitating tube passage. Although the patient may not swallow for several minutes, waiting for the swallow may mean the difference between a coiled or pulmonary tube placement and successful passage.

Another technique for passing soft feeding tubes involves attaching the distal end to a Salem sump tube by means of a gelatin cap (one half of a size-0 gelatin capsule, as used for a large medication capsule). Lubricate the joined tubes, avoiding lubrication of the soluble capsule. The Salem sump-soft tube complex is passed nasogastrically. Once the tubes are positioned in the stomach, both tubes are irrigated several times with 10 to 20 mL of water. After about 5 minutes the gelatin capsule should have dissolved, allowing independent removal of the Salem sump tube (Fig. 41-13). [2]

Placement Confirmation

Auscultatory confirmation of tube placement can be misleading. [3] [34] [35] The proper technique for auscultation is to inject 20 mL of air into the tube rapidly while listening with a stethoscope in the left upper abdomen. Air insufflation should occur without resistance and without delay in borborygmi. If the sound is muffled, faint, or delayed, the clinician may reinject another 20 mL of air and listen over the lower lung. If the sound is clearer, the tube may be in the lung. The injected air should be aspirated from the stomach after placement is confirmed so that the patient is less likely to burp or regurgitate.

Proper placement of NG feeding tubes should be confirmed with a radiograph. Tubes should be secured with tape before taking the radiograph. Tincture of benzoin applied to the tube and the patient makes the tape stick better. Commercial tube fixation devices may also be used. The position before and after the radiograph is taken is more likely to be the same if the tube is secured before filming.

Gordon suggests that radiographs are not necessary to check NG feeding tube placement if the following criteria are met in order. [2] The tube must be passed beyond the 50-cm mark in a normal-sized adult; palpation and visual inspection

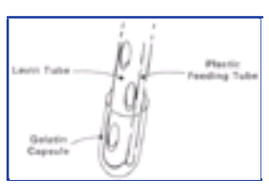

Figure 41-13 To facilitate the passage of a soft or very pliable plastic feeding tube, the tip of the feeding tube is joined to the tip of a stiffer nasogastric tube (such as a Salem sump) with the aid of a gelatin capsule. The capsule dissolves in the stomach in a few minutes, and the companion nasogastric tube separates and is withdrawn, leaving the feeding tube in place.

confirm that the tube is not coiled in the mouth or oropharynx; air insufflation occurs without resistance and without delay in epigastric borborygmi; 10 mL of water advances through the tube without difficulty; and some water can be retrieved with aspiration. Do *not* inject water into the tube if any of the preceding criteria suggest that placement may be in the lung or upper esophagus. A risk of delivering water into the airway exists. [48]

Aspirated pleural or pulmonary fluid contents can be mistaken for return of intragastric fluids. [3] In addition, radiographic confirmation of tube placement may be misleading. In viewing the radiograph, it is particularly important to study the area around the carina. An esophageal tube shows at most a mild change in course, whereas a tracheally placed tube usually deviates significantly as it travels into the right or left main stem bronchus. The end of an NG tube may appear to be in the stomach yet be in the left lung behind and below the top of the diaphragm. [56] When a stylet has been used for passage, the stylet should be left in the feeding tube for the radiograph, because the tube's course is not always visible without it. The stylets of most tubes are designed to allow insufflation and aspiration while in place. Even when stomach entry is certain, the intestinal location may be misleading on radiograph: A nasoenteric tube may lie completely to the left of midline and yet have its tip in the duodenum, or it may have a position overlying the right abdomen yet not have entered the duodenum. A contrast study is necessary to ascertain duodenal position when pulmonary placement has been ruled out. [55] [57]

The radiograph should also be examined for the presence of mediastinal air and a pneumothorax, which may suggest pulmonary or esophageal puncture. An esophageal puncture should be evaluated with endoscopy and may require surgery, depending on the size of the rent.

The end bulb of most nasoduodenal tubes will pass into the duodenum after patient positioning in the right decubitus position for an hour. Some researchers recommend pretreatment with metoclopramide to enhance gastric emptying. [50] [58] [59] One investigator found that metoclopramide enhances duodenal passage of nasogastrically placed feeding tubes in diabetic, but not in nondiabetic, patients. [55] Gastric antral motility in diabetics is often impaired; metoclopramide helps restore normal synchronized activity in these patients but has little effect on emptying in subjects who have normal antral function. The usual dose of metoclopramide is 10 mg administered IV. Also, 3 mg/kg of erythromycin lactobionate given IV over 1 hour works similarly and may be effective even if metoclopramide fails. [60] Endoscopy or fluoroscopy may be necessary if positioning and metoclopramide are not successful. [61]

Complications

Pulmonary intubation is an uncommon but well-known and potentially fatal complication of nasal feeding tube insertion (see Fig. 41-11). Coughing and respiratory distress are the most common symptoms of respiratory passage of an NG tube, but there may be relatively few symptoms in a demented or comatose patient. [62] Decreased mentation and an absent cough reflex are predisposing factors for unrecognized nasopulmonary intubation with NG tubes. [3] A small end bulb (e.g., 2.7 mm diameter) can slip past a tracheal high-volume, low-pressure cuff and pass easily to the lung periphery. [3] [62] [63]

To prevent nasopulmonary feeding tube intubation, one may choose to use the wire stylet only for initial tube passage. This will prevent pulmonary parenchymal penetration but not tracheobronchial intubation. It also will make passage of tubes positioned in the esophagus more difficult. [3] Esophageal entry of the feeding tube can be checked with the use of a laryngoscope. The metal stylet can be left in the tube during esophageal tube passage when an esophageal position has been confirmed by laryngoscopy. [64] A stylet should never be reinserted into a tube already in the patient. The stylet may puncture the tube at a kink or exit the side holes and puncture the esophagus. [65]

A pneumothorax may result when an NG tube dissects into or is withdrawn from the pulmonary parenchyma. [33] Bloody aspirate from a tube should heighten awareness of tissue damage.

A clogged or nonfunctional NG tube may prove difficult to remove. Fluoroscopy may allow careful insertion of a guidewire or stylet into an in situ tube to facilitate removal. Fluoroscopy also may identify the mechanical problem interfering with the removal. Bent-double segments are probably the most common; knots are uncommon but do occur. Excessive force should not be used in the removal of a NG tube, because serious injury to the patient may result.

Premature removal of the NG tube is the most frequent complication of feeding tube use. To help prevent removal by the uncooperative patient, the NG tube may be secured to a loop anchor passed in the same naris. The anchor works by aversive stimulation of the soft palate and nose with distraction of the NG tube, rather than by mechanical stabilization of the tube.

Sax and Bower recommend a technique for creating a separate NG tube anchor.[66] A soft weighted nasoenteric tube is cut approximately 12 in from the top. A heavy (2–0) silk suture is passed through the tube to exit the side hole. The guidewire is inserted with care, as it must not protrude from the cut end. The patient should be sedated if uncooperative. The tube is inserted through the anesthetized naris into the nasopharynx, grasped with Magill forceps, and pulled to exit from the mouth (Fig. 41-14*A*). The excess tube is trimmed without cutting the silk suture. A closed loop is made by tying the silk suture in front of the nose. The loop must be slack enough that it does not apply continuous pressure to the nose or palate at rest. The nasal feeding tube is passed through the same nostril and secured to the loop (Fig. 41-14*B*). This anchor is simpler to construct and more comfortable than anchors passed through the opposite nostril. [66]

Complications of properly placed nasoenteric tubes include nasopharyngeal erosions, esophageal reflux, tracheoesophageal fistulas, gagging, rupture of esophageal varices, and otitis media.[48] One survey of nasogastrically fed patients found that the most distressing features of NG feeding tube use were deprivation of tasting, drinking, and chewing of food; soreness of the nose; rhinitis; esophagitis; mouth breathing; and the sight of other patients who were eating. [67]

Checking feeding tolerance is difficult with small-gauge feeding tubes. Aspiration of tubes to check for residual is not recommended with tubes of 9 Fr or smaller. Aspiration is likely to clog the tubes, because they collapse under pressure and because relatively small particles can occlude the tube. For the same reasons the residual is likely to be inaccurate.[51]

Figure 41-14 Placement of a nasogastric tube anchor to secure a companion nasogastric or feeding tube in an uncooperative patient who repeatedly pulls out the feeding tube. *A*, Forceps grasp the tube in the pharynx and pull it out through the mouth. This will serve as an anchor tube. *B*, The ends of the short anchor tube are tied together to form a loop, and the companion nasogastric or feeding tube is tied to the anchor loop.

Patient Instructions

Patient instructions should include a proscription against aspiration in small tubes. To maintain catheter patency, small tubes should be flushed with 20 to 30 mL of tap water at least two to three times daily and after administration of medication. [51] [57] Water is a more effective irrigant than cranberry juice. [68] Medications should be in liquid form or be completely dissolved, or they may clog the tube. Methods of dealing with a clogged tube are discussed subsequently.

The tube should be anchored to the nose and face in such a way that it is not in contact with the skin at the nasal opening. This reduces tube discomfort and prevents necrosis of the alae, nares, and distal septum. Patients who exhibit a tendency to pull on their tubes need adequate restraints. Patients receiving tube feedings should have their heads elevated to at least 30° above the horizontal. [51] [69]

PHARYNGOSTOMY AND ESOPHAGOSTOMY FEEDING TUBES

Indications

Cervical pharyngostomy and cervical esophagostomy both have been developed relatively recently. Cervical esophagostomy was first described by Klopp in 1951, [70] and cervical pharyngostomy was described in 1967 by Shumrick.[71] Cervical esophagostomies are generally performed at the time of cervical or maxillofacial operations. Malignant growths of the proximal esophagus, head, or neck are the primary indications for esophagostomy. Cervical esophagostomies may eventually evolve a permanent sinus, allowing the feeding tube to be removed between meals.

As with an esophagostomy, a pharyngostomy may be either a simple ostomy or a permanent tract formed by suturing pharyngeal mucosa to the skin.[71] [72] [73] The more common version is a simple opening that closes very rapidly (within a few hours) if it is not stented with a tube (Fig. 41-15). Pharyngostomy is a simple procedure and does not require general anesthesia. It is useful when NG feeding tubes are contraindicated or when prolonged tube feeding is anticipated. [49] Patients with traumatic or congenital anomalies of the maxillofacial region who are undergoing an operation and patients with impaired swallowing from neuromuscular disorders are potential candidates for cervical pharyngostomy. [73] A pharyngostomy is also indicated to bypass obstructing lesions for feeding, to assist healing after head or neck surgery for malignancy, and to feed the unconscious patient. A pharyngostomy can also be used for gastric decompression if it is required for more than 3 days.[72] Cervical pharyngostomy tubes produce only mild discomfort. Patients do not usually complain about pharyngostomy tubes, as they do about a

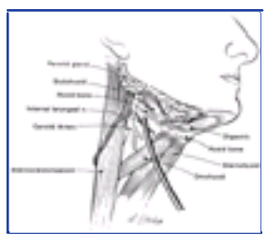

Figure 41-15 Pharyngostomy feeding tube.

NG tube. The additional comfort and ease of productive coughing are especially important in critically ill and elderly patients.

Technique of Tube Passage

The feeding tubes commonly used for esophagostomy and pharyngostomy feeding are the same as those used for NG feeding. Polyurethane feeding tubes are the most frequently used. The large (>3 g) bolus weights on some feeding tubes may be inconvenient to pass through the ostomy. Tubes that are approximately 90 cm (3 feet) long are appropriate for gastric feeding; tubes that are longer—108 to 112 cm (43 or 45 in)—are used for duodenal feeding.

The feeding tube replacement technique is the same for pharyngostomy and esophagostomy. The outside of the tube tip can be lubricated with a small amount of water-soluble lubricant jelly. Mineral oil, which irritates the airways if aspirated, should never be used. The tip of the tube is inserted into the ostomy and directed caudally to ensure that it enters the esophagus and does not pass upward into the nasopharynx or mouth (Fig. 41-16). The patient may be able to assist by attempting to swallow. The length of feeding tube required varies depending on the position of the ostomy and is several centimeters longer than the distance from ostomy to xiphoid. For duodenal feeding, the tube should be advanced about 20 cm beyond the distance from ostomy to xyphoid.

If the feeding tube persistently exits the mouth during attempts at passage instead of passing down the esophagus, the following two techniques may prove useful. After insertion of the feeding tube a short distance into the ostomy, a flashlight is used to visualize the tube in the pharynx. The feeding tube is grasped slightly proximal to the end bulb using Magill forceps, and the end bulb is directed toward the esophagus in the posterior inferior pharynx. Once the tube is properly directed, it may be possible to advance the

Figure 41-16 Proper path for an esophagostomy or a pharyngostomy tube.

remainder of the tube through the external ostomy. Sometimes it is necessary to use the forceps to advance the entire length of the feeding tube. An alternative method is to allow the feeding tube placed through the ostomy to exit the mouth for the entire distance that must be passed down the esophagus. The end bulb of the tube is then directed into the posterior pharynx, and the patient is directed to swallow as for an orogastric tube. Toward the end of tube passage, it may be necessary to use a Magill forceps or to pull back the tube slightly at the ostomy to eliminate a short loop of extra tubing in the oropharynx.

Tube replacement is more difficult in the first week after the creation of a pharyngostomy or an esophagostomy. A tract forms after the first week and helps prevent tissue dissection by the tube. The angle of a well-formed tract also encourages appropriate esophageal passage. A well-formed tract closes more slowly than a new ostomy, although in some people even a long-term ostomy may begin sealing within a few hours. If an ostomy is too narrow for the replacement tube, the ostomy should be stented with a narrower tube and the patient's surgeon contacted.

Complications

Complications of pharyngostomy and esophagostomy include local soft tissue irritation, accidental extubation because of excess length of the external tube, pulmonary aspiration from vomiting, arterial erosion with exsanguination, and esophagitis or stricture of the esophagus from reflux. Accidental pulmonary intubation is less common with cervical ostomy tubes than with NG tubes, at least partially because patients with cervical ostomies are more likely to be alert and have functioning cough reflexes. Auscultation and aspiration are still advisable techniques to check tube placement. Radiographic evaluation may also be necessary and is essential to confirm duodenal feeding.

GASTROSTOMY, GASTROENTEROSTOMY, DUODENOSTOMY, AND JEJUNOSTOMY TUBES

The mid-19th century clinician Sedillot described the first functioning gastrostomy, which formed as a complication of a war wound. The gastrostomies performed by Sedillot on two patients resulted in peritonitis and death. [73] [74] The jejunostomy procedure was first performed by Surmay in 1879. It was not until the 1890s that further innovations in surgical technique allowed the gastrostomy to be popularized. The Witzel serosal-lined gastric tunnel technique (Fig. 41-17) and the Stamm procedure of concentric pursestring sutures placed around the gastrostomy tube were developed in the 1890s. These two techniques prevent significant intraperitoneal gastric fluid leakage, a complication that had frequently resulted in the deaths of gastrostomy patients. Both Witzel and Stamm gastrostomies tend to close rapidly without a stenting gastrostomy tube. In the early 1900s, the tubular (Depage-Janeway) gastrostomy was developed. The Depage-Janeway gastrostomy results in the creation of a permanent mucocutaneous ostomy. Since the turn of the century, more than 30 different operative techniques have been described for tube gastrostomy.[49]

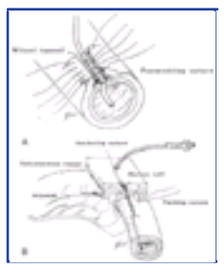

Figure 41-17 *A,* Formation of the Witzel tunnel. *B,* Final catheter placement. *(From Wiedeman JE, Smith VC: Use of the Hickman catheter for jejunal feedings in children. Surg Gynecol Obstet 162:69, 1986.)*

Operative Indications and Contraindications

Neurologic diseases constitute the most frequent indication for a gastrostomy tube. [52] Facial fractures, oropharyngeal trauma, and tracheal and laryngeal injuries may be indications for placement of a temporary feeding gastrostomy. Rare indications for gastrostomy include enhancement of nutrition by continuous feeding in severely debilitated patients who still are capable of oral intake, provision of a route for bile replacement in patients with an external biliary fistula, and the need for long-term gastric decompression. Indications for gastrostomy tube placement in children include neurologic diseases, facial reconstructive surgery for congenital deformities, and maxillofacial trauma. Young children who require long-term administration of unpalatable medications or dietary components may also require a gastrostomy. Tube duodenostomies are created almost exclusively for duodenal decompression after partial gastrectomy with Billroth II anastomoses. [73] Permanent jejunostomies are rarely used. Tube jejunostomy is indicated when the proximal bowel has a fistula or is obstructed, when recovery of small bowel motility is anticipated long before recovery of gastric motility, and after a gastrectomy.[49] [73]

Contraindications for gastrostomy feeding include severe gastroesophageal reflux, upper gastrointestinal fistulas, repeated aspiration of gastric contents, and intestinal or gastric outlet obstruction.[49] Jejunal feeding is contraindicated if the highly osmolar feeding solutions required for jejunal feeding are poorly tolerated and cause copious diarrhea.

Indications and Contraindications for Tube Replacement

The nursing home patient with a nonfunctioning or dis-placed feeding tube represents a common ED presentation. The clinician cannot always determine the location of the original feeding tube by simply looking at the patient who arrives in the ED for tube replacement. Nevertheless, the emergency clinician should attempt to ensure that the terminal end of a replaced tube is in the same viscus as the original. External inspection may or may not reveal where a feeding tube should terminate. A de Pezzer (mushroom) or Foley gastrostomy tube is designed only for intragastric termination. Some tubes have two lumina, one terminating in the stomach for decompression and the other in the small bowel for feeding. These can be confused with tubes that have two entrances to one lumen (one for continuous feeding and the other for medications) and tubes that have a second lumen leading to an inflatable balloon.

The clinician has a few options when faced with the task of replacing a feeding tube. Unfortunately, old records or nursing home personnel rarely give specific information that is helpful to the emergency clinician. If the tube is blocked, yet still present, a contrast study may demonstrate the final position of the tube. If only a stoma exists, one may request that the nursing home describe or send the prior tube to the ED. If a blocked tube is removed, it can be replaced with a similar device. If no surgical scar is seen at the stoma site, the tube is almost certainly a G tube, or a G tube that terminated in the jejunum. Placing a new tube followed by a contrast study usually settles the issue and allows the clinician to make decisions on balloon inflation, or possibly substitute a new device. When in doubt there is no downside of passing a Foley catheter without balloon inflation, taping it to the skin, and referring the patient to a consultant or the original referring clinician. It is unwise to avoid placement of some type of tube since the stoma will quickly close and may necessitate a more complicated procedure later. The only real concern of placing a gastric tube into the jejunum is that the balloon will produce intestinal obstruction if it is fully inflated.

If the tube is nonfunctioning yet still in place, the clinician must make a judgment as to the risk versus benefit of removal and replacement versus an attempt at unclogging the tube (see subsequent section on unclogging). *The major concern is that a new tube may be misplaced (i.e., into the peritoneal cavity)*. If it appears that a skin incision was used to place the tube, it is unlikely that the patient has an easily removable tube. If the patient has signs of a complication (e.g., infection, ileus, intestinal obstruction), surgical consultation is warranted.

Ease and safety of transabdominal feeding tube replacement depend on the surgical procedure performed and the length of time since placement of the feeding tube. For a simple gastrostomy, the insertion site of the tube through the gastrointestinal wall is sealed by either annular or plication sutures. The gastrointestinal wall is approximated to the peritoneum around the site of penetration to provide a further leakage barrier. The tube is then secured outside the abdominal wall. A Witzel tunnel is a serosal tunnel created when the feeding tube is placed alongside the viscus for a distance after exiting the viscus, and the bowel is pulled up over it along this distance and secured with sutures (see Fig. 41-17).[75] [76] In one type of Hickman catheter jejunostomy, the tube passes

through a Dacron cuff and a Witzel tunnel. [76] Reinsertion of a Hickman catheter through a tortuous, rough Witzel tunnel is unlikely to be simple. [77] A percutaneous gastrostomy may have been placed without any attempt to affix the stomach to the abdominal wall.

Nonoperative tube replacement techniques are safe only through an established tract between the skin and the bowel. Catheter replacement should not be attempted in the immediate postoperative period. A simple gastrostomy takes about a week to form a tract.[72] A Witzel tunnel may take up to 3 weeks after the operation to mature sufficiently for safe nonoperative tube replacement. A nonfunctional tube can still serve as the stent for the gastrostomy tract and should not be removed if it cannot be promptly and safely replaced.

Equipment

Gastrostomy tubes come in an unusually varied selection of styles and materials. Rubber, silicone, and polyurethane tubes are all in common use. Many gastrostomy tubes are designed with a flange or a crossbar (bumper) to anchor them in the stomach and prevent migration into the small bowel. A Foley catheter may be used as a replacement tube but it is more temporary, difficult to secure to the skin, and the latex balloon may be weakened by stomach acid. When possible, a dedicated feeding

tube should be used instead of a Foley catheter (Fig. 41-18).

Equipment for feeding tube insertion includes gloves, stethoscope, feeding tube, external bolster, lubricant, basin, and a syringe that fits the tube. Tincture of benzoin, tape, and absorbent dressing material may be used to dress the wound, although many are better left undressed. [78] Some feeding tubes require special plugs or connectors. Others need to be pinched with a clamp when not in use to prevent leakage. Some tubes are placed with the aid of accompanying guidewires or stents. For still others, it is necessary to use a clamp or hemostat, endotracheal tube stylet, urinary or uterine sound, laryngeal dilator (no. 14), guidewire, or other appropriate rod or support as an aid to tube passage (Fig. 41-19*A, B*).

A stylet to assist introduction of de Pezzer catheters can be fashioned by cutting half the stylet from a 9 Fr pediatric chest tube inserter. The tip can be filed smooth. The device will be 10 to 12 cm long and can be inserted alongside the de Pezzer catheter and into its tip to distend and flatten the mushroom (Fig. 41-20).

Transabdominal Feeding Tube Removal

A feeding tube may have to be removed because it is irreversibly clogged, leaking, or broken; persistently developing kinks; too large or too small; causing a hypersensitivity reaction; associated with an abscess; or not the appropriate length for feeding into the desired viscus. Before a new transabdominal feeding tube is inserted, the old tube must be removed. Most, but not all, tubes can be removed without endoscopy. It is imperative to know whether the tube in place is safe to remove before attempting to remove it. Standard de Pezzer or mushroom catheters *that have been modified with bolsters or rings at the time of endoscopic or surgical insertion* may no longer be safe to remove with traction. Tubes are occasionally secured with sutures or rigid internal bumpers or stays. It is rare, however, to encounter a tube that cannot be removed with traction. Recently placed feeding tubes may need to be left in until a tract has formed (1 to 2 weeks depending on the procedure) even if the tube is nonfunctional. *The externally visible tube does not always reveal the internal stabilization* (see Fig. 41-18).

A simple Foley catheter gastrostomy is easiest to remove. Once the Foley balloon is deflated, the tube should slide right out. If the Foley balloon cannot be deflated, cutting the tube may allow the balloon to deflate. The catheter must not be cut so close to the abdomen that it will be impossible to maintain a grip on it for a traction removal if the balloon still does not deflate. The balloon also may be punctured to cause it to deflate. To puncture a Foley balloon, traction is applied to the catheter to draw the balloon up against the ostomy. Using the taut feeding tube as a guide, a 20- or 21-ga needle is passed along the tube to puncture the balloon. It may be necessary to try again on the other side of the catheter, because the balloon may be asymmetrically inflated, and contact with the needle may be established on one side and not the other. The clinician should be careful not to track away from the ostomy into the patient's abdominal wall or to cause separate punctures of the stomach. The balloon is allowed a minute to deflate before another attempt is made at traction removal. Large nondeflating balloons should probably be punctured, whereas small balloons may be removed with traction.

Traction is an acceptable removal technique for feeding tubes that are secured by a small mushroom. A towel is placed over the orifice, and the clinician applies counterpressure with the flat part of the hand against the abdominal wall as the tube is placed under tension (Fig. 41-21). This causes the tube and end mushroom to narrow, and the tube should come out easily. The inner crossbar, if present, may remain in the stomach when the rest of the feeding tube complex is removed by traction. Obstruction from the crossbar, which will pass in the stool, has yet to be reported for adults. In small children, obstruction is a possibility, and the crossbar should be removed by endoscopy. [77] [79]

A local anesthetic may be useful in selected cases of feeding tube removal, especially when the tube is in some way secured subcutaneously—for example, by a Dacron cuff. [76] It may be difficult to remove a catheter accidentally caught by a fascial suture during operative closure. [80]

Removal of gastrostomy tubes with moderate to large mushrooms may be easier if the mushroom is distended with a sound or stylet. The length of the gastrostomy tube should be known so that the sound may be inserted to the correct depth. Firm resistance should be noted at that point. Firm resistance at deeper depths represents pressure on the viscus wall and can result in viscus puncture. [59] The premeasured stylets that come with feeding devices are useful instruments for assisting in removal. This is particularly true of gastrostomy "buttons," whose ends resemble de Pezzer catheters. Because buttons come in a variety of lengths, it is important to have the proper stylet. Following elective permanent removal of a gastrostomy tube, a pressure dressing should aid in closure of the fistula. [59]

If it is not possible to pull the inner bolster or mushroom out through the ostomy, it may be acceptable to cut the tube at the skin, push the remaining short stump into the stomach, and rely on later rectal passage. Although obstruction or impaction is infrequent, it can occur, and this alternative has the potential to be problematic with children or patients who have had previous impaction, potential for bowel obstruction,

Figure 41-18 *A,* Various types of gastrostomy tubes. *1,* Polyurethane catheter with collapsible foam flange (CORPAK MedSystems of Kentec Medical Inc, Irvine, CA). *2,* Silicone catheter (American Endoscopy [Bard Interventional Products, Billerica, MA]). *3,* Latex catheter with a movable external bolster and an internal mushroom or de Pezzer-type flange on the end (American Endoscopy [Bard Interventional Products, Billerica, MA]). *4,* Balloon (Foley) catheter (Wilson-Cook Co., Winston-Salem, NC). *B,* A user-friendly gastrostomy tube is supplied by CORPAK MedSystems (Wheeling, IL). The tube is packaged with lubricant, a prefilled syringe for inflating the balloon, and an extension set. The color-coded inflation valve indicates tube size (12–24 Fr). The silicone tube uses a retention balloon and a movable bolster, similar in design to a Foley catheter. Note that the retention bolster is designed to prevent inward migration of the tube and is not to be an anchoring device sutured to the skin. *C,* Placement of the CORPACK feeding tube and inflation of the balloon. Note that the bolster on the external tube is advanced to the skin to secure the tube. *D,* A standard Foley catheter may serve as a more specialized feeding tube replacement. The latex balloon may deflate or be weakened by gastric acid; so, this catheter is not ideal for long-term use. In addition, unless the Foley catheter is secured to the skin, it may migrate and the balloon may cause a pseudo obstruction.

or stool-passing problems. Rigid or large internal mushrooms and bolsters, the very kind that cause the most difficulty with percutaneous removal, also are more likely to cause difficulty with rectal passage. In no case should a device be released into the gut with a long length of tubing attached. Remember that double-part tubes may have an additional length of tubing for duodenal or jejunal feeding that extends far past the inner bolster. Korula and Harma [81] reported the successful intestinal elimination of 63 of 64 gastrostomy tubes that were cut at the skin entrance and advanced into the stomach through the stoma. These cases included tubes with internal bumpers, and success occurred regardless of the nature of the patient's underlying medical disorder, age, or method of original tube placement. However, no patient had suspected obstruction or potential for obstruction (e.g., no prior radiotherapy, inflammatory bowel disease). The one lodged tube required endoscopic removal from the pylorus. In most cases, tube passage was documented by sequential radiographs, with a mean interval to passage of 24 days (range, 4 to 181 days).

Some clinicians and surgeons may strongly condemn cutting off the tube at the skin, even when the risks posed by the procedure are very low. It is always advisable to contact

Figure 41-19 *A,* An endotracheal tube stylet used to distend the flange of the de Pezzer catheter. *B,* A lubricated wooden cotton-tipped swab can also be used as a makeshift stylet.

the patient's private clinician before cutting the tube. In some cases endoscopic retrieval of the tube remnant will be preferred to allowing rectal passage, and the tube should not be cut until just before or during endoscopy to ensure that migration does not occur before endoscopy.

Transabdominal Feeding Tube Replacement

Dislodged tubes should be replaced as soon as possible. If a similar sized tube will not easily pass, it is preferable to replace

Figure 41-20 A modified pediatric chest tube inserter used to distend the flange of the de Pezzer catheter. The sharpened end of the inserter (trocar) has been rounded.

a dislodged tube with a smaller or temporary tube to maintain the patency of the tract, rather than wait for an ideal situation. The tract may close or narrow in a matter of hours, and it is very difficult to easily replace tubes that have been out for more than a day. Some clinicians will first gently explore the tract with a blunt probe, such as a cotton swab, to ascertain the patency and course of the tract (Fig. 41-22*A*). Gently dilating the ostium and carefully probing and dilating the tract with a hemostat may facilitate passage (Fig. 41-22*B*). It is emphasized that a false tract may be created with vigorous exploration or manipulation. Ideally the new tube slips into position with minimal force, but a number of attempts may be required to negotiate tissue planes and manipulate the tube into the proper position. A relaxed patient aids in placement. Injecting a local anesthetic into the opening of the tract may ameliorate pain. Systemic sedation/analgesia is seldom required but should be considered in the combative or extremely uncooperative patient. *The clinician should not use excessive force to pass a tube since misplacement may result.* It is not uncommon to precipitate some bleeding, and although this may be distressing to the patient or family, it is not a significant clinical issue.

A Foley catheter is a simple gastrostomy tube to replace. After the tract opening and distal Foley catheter are lubricated, the Foley balloon's integrity is checked by inflation. The catheter is then inserted into the tract. Good placement can be recognized by easy passage, prompt borborygmi with 20 mL of air insufflation, and rapid return of stomach juices with aspiration. The balloon is then inflated with saline (30-mL balloons are best), and gentle traction is applied to draw the balloon against the stomach wall. *Always inflate the Foley balloon with saline*, because balloons inflated with air deflate more easily. Tube replacement is usually successful if the tube has not been dislodged for more than 4 to 6 hours. If passage is impossible, a radiologist may be consulted to advance the tube over a guidewire that has been passed through the tract using fluoroscopy.

Figure 41-21 Gentle, firm traction *(A),* using the flat part of the opposite hand for countertraction, may remove most percutaneous endoscopic gastrostomy tubes, even those with internal mushroom bumpers *(B).*

An external bolster may be threaded onto the catheter. The external bolster is a ring or bar of material threaded onto a tube that creates a large bulge on the tube and prevents inappropriate ingress of the tube into the ostomy. The anchor must adhere strongly to the tube so that mild stress on the tube does not cause the bolster to migrate up the tube. The bolster can be salvaged from the old tube or constructed in a number of ways. An anchor may be made from the end nipple of a de Pezzer catheter. The ring from a 24 Fr catheter, taken off at its junction with the end nipple, fits snugly over a 22 Fr Foley catheter when the balloon is distended slightly. The nipple can be pushed forward to an anchoring position near the stoma. The nipple can be fixed in this position by fully distending the Foley balloon and applying a circle of adhesive tape just adjacent to the nipple on the stem on the

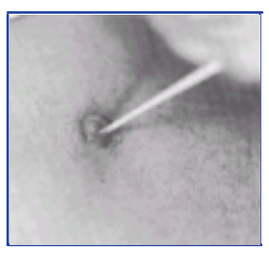

Figure 41-22 The tract of a feeding tube may close or become narrowed within a few hours after removal. When replacing a tube that has been removed, gentle probing of the tract of the previously placed feeding tube gives the clinician an idea of the patency and direction of the tract. In this case, a sterile cotton swab is gently advanced, being careful not to produce a false tract.

side away from the body.[82] Adhesive tape sticks better if the lubricant is removed and the stem is prepared with tincture of benzoin.

An external anchor may be made from a segment of tube from a large rubber catheter (Fig. 41-23). A segment approximately 3 cm in length is cut to form the bolster. Two diamond-shaped openings can be formed on both sides of the segment by bending the segment and clipping it with scissors on either side of the bend. The diameter of the holes should be slightly smaller than the catheter. A hemostat or a Kelly clamp can be inserted through both holes to grasp the external end of the gastrostomy tube, which can be bent in half—with some difficulty—to narrow its diameter (Fig. 41-24). The hemostat can then pull the tube through the bolster, which can be threaded down the tube and anchored with tape as described previously (Fig. 41-25). The outer crossbar should be located 1 cm away from the skin. [83] Contact between the crossbar and the skin promotes moisture entrapment and maceration. Too much tension on the gastrostomy tube can result in necrosis of the gastric wall where it abuts the inner mushroom or balloon. Proper placement of the external bolster helps avoid this complication (Fig. 41-26).

Many clinicians prefer mushroom or de Pezzer gastrostomy tubes, which are more difficult to replace than Foley catheters. The advantage of these catheters over Foley catheters is that the mushroom nipple keeps its shape more reliably than the Foley balloon, which tends to deflate. [67] Foley catheters also have a greater tendency to migrate internally and block the pylorus. [49] A Kelly clamp or other stylet can be placed through a side hole into the tip of a gastrostomy mushroom and used to elongate the end for easy passage through the gastrostomy (see Fig. 41-19 and Fig. 41-20). Lubrication of the mushroom may make it more difficult to maintain the stylet's position in the mushroom. Some stylets are suitable for passage down the catheter lumen to elongate the end. Tubes should never be forced through a stoma for replacement, because this can cause separation of the viscus from the external stoma and lead to viscus leak or tube misplacement. [59]

The replacement tube provided in the ED does not have to be—and in a few cases should not be—the same type placed at surgery. The tube must be compatible with the feeding system, terminate in the same viscus, and fit through the ostomy. When a Witzel tunnel jejunostomy is created, the catheter most frequently used is a Broviac catheter.

Figure 41-23 *A,* A 3-cm segment of thick latex tubing is cut from the proximal segment of a catheter. This segment is used to make an external bolster for a feeding tube and anchors the feeding tube, preventing unwanted ingress of the tube into the patient. *B,* A 3-cm segment of latex tubing is bent in half and cut to create a hole on each side of the segment.

An appropriate replacement is a lubricated polyurethane tube shortened to a total tube length of 30 to 40 cm. Although the polyurethane tube is strong enough to be used for tube replacement through the Witzel tunnel without a guidewire, Broviac (silicone) catheters are too pliant to be coaxed

Figure 41-24 A hemostat is inserted through the holes in the completed bolster and grasps the feeding tube. The end of the feeding tube has been folded to reduce its external diameter.

through the resistive tunnel.[76] Jejunal feeding tubes are generally advanced 20 to 30 cm into the jejunum.

Jejunal feeding tubes may be placed through or alongside a decompressing gastrostomy. Original placement of the jejunal feeding tube is endoscopic. Replacement of these tubes also

Figure 41-25 The feeding tube is pulled through the bolster. The bolster is advanced to 1 cm above the skin of the external abdomen.

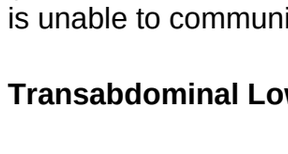

Figure 41-26 A Foley catheter can always be used as a temporary feeding tube replacement *(A)*. The thin-walled Foley balloon usually only remains inflated for a month or so, and a specialized feeding tube, such as the CORPAK (see Fig. 41-18) is preferred for long-term use. A bolster can be made to prevent inward migration of the tube. In this case the previously removed Foley catheter was used to make the bolster for the new one *(B)*.

generally requires endoscopic assistance.[84] [85] [86] Fluoroscopic techniques can be used to help guide these tubes; however, these techniques are out of the realm of emergency practice.[48] Occasionally, feeding tubes are placed in the jejunum because of gastric ileus.[49] [87] If gastric ileus is no longer present, a gastrostomy tube may suffice. The rationale for jejunal feeding, risk of aspiration, and acceptability of gastric feeding to the primary clinician should be established before changing from a jejunal feeding tube to a feeding gastrostomy tube. Techniques discussed in the nasoenteric feeding section of this chapter (metoclopramide and right decubitus position) may in selected cases coax gastrostomy-placed feeding tubes into the small bowel. Gastric decompression tubes are either clamped or put at continuous drainage.[85]

Verification of tube placement can be made radiographically using a fluoroscope or with a small amount of contrast material passed into the tube (Fig. 41-27 and Fig. 41-28). In the latter scenario, a catheter-tip syringe is used to introduce water-soluble contrast solution (e.g., diatrizoate meglumine-diatrizoate sodium [Gastrografin]) into the tube. *Barium is contraindicated.* Generally 20 to 30 mL of water-soluble solution is adequate for documenting the intraluminal tube position. A supine abdominal film should be taken within 1 to 2 minutes of dye instillation to optimize gut visualization. Since the film must be quickly obtained, it is easiest to perform the injection in the radiology suite, followed by an x-ray. *If the contrast material does not flow freely into the tube, the procedure should be terminated immediately and the position of the tube questioned.* With proper positioning, contrast will outline the gut containing the tube (e.g., stomach with gastrostomy tube). An irregular or rounded blotch with wispy edges or streamers suggests peritoneal leakage. In questionable cases, dye injection can be performed under fluoroscopy.

It should be noted that there is no universally agreed upon standard of care with regard to performing a confirmatory contrast study for all easily replaced feeding tubes. Some clinicians verify position routinely with a contrast radiograph while others use the clinical criteria outlined earlier. The editors advocate a cautious and conservative approach. The routine use of post placement contrast radiography to confirm proper placement should be considered when the tube tract is immature (i.e., <3 months duration). Passage of the replacement catheter has been difficult, aspiration of intestinal contents is not possible post tube placement, or the patient is unable to communicate symptoms that might occur with tube misplacement.

Transabdominal Low-Profile Feeding Tube Replacement

Low-profile feeding tubes are almost flush with the skin, held in place with a preformed plastic external bolster. Especially popular in children and active adults who require intermittent feedings, they are only slightly more difficult to remove and replace than Foley catheters. The tubes come in two main types, those with an internal balloon and those with an internal flange.

Tubes with a balloon can be deflated with a syringe for removal. Seat the syringe well and do not let fluid flow back into

Figure 41-27 Contrast study demonstrating correct placement of a feeding tube. Note the outline of the gastric rugae and the characteristic mucosal folds of the small intestine.

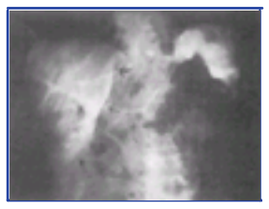

Figure 41-28 Although this feeding tube seemed to be easily replaced in an uncommunicative nursing home patient, gastric contents could not be aspirated; therefore, a contrast study was performed. Note the free flow of contrast material throughout the abdomen, especially outlining the liver *(arrows)*. This film indicates placement of the feeding tube into the peritoneum. Placing food through this tube could be disastrous.

the balloon once it is withdrawn into the syringe, or the diameter of the balloon will not be at a minimum as it is withdrawn through the stoma. If no fluid is obtained at all, the balloon may already be deflated, and a trial of gentle removal may be warranted before attempting balloon puncture techniques. If the stem appears to get stuck as you are withdrawing it through the stoma, a second attempt to withdraw fluid may obtain a few more drops and free it up. In children especially, make sure the head is resting and not flexed. A flexed neck encourages tight abdominal muscles which can squeeze the stoma around the stem. If the balloon will not deflate at all, see the instructions above for balloon puncturing techniques.

Tubes with a flange should be removed, ideally, with the obturator that comes with the tube. While this obturator is usually unavailable, many patients with this kind of tube will have a replacement of the same size and type and the obturator from the new tube can be used to remove the old one. The obturator should be well seated to distend the flange and minimize its diameter during removal. An obturator from another type or length tube may also work, but the length must be as long as or longer than the original and the seating becomes a matter of continuous pressure. A blunted pediatric chest tube inserter, a sound, or an endotracheal tube stylet may also work. Many low-profile feeding tubes are made of silicone, which is softer and more fragile than the polyurethane of the de Pezzar catheters, and a lesser degree of pressure may be appropriate.

A bolster regulates the depth of Foley catheters and most other gastrostomy tubes, but the depth of each low-profile tube is fixed. A tube of appropriate depth and diameter needs to be selected for the ostomy. All low-profile gastrostomy tube companies make a stoma measuring device, some packaged with every tube and some as a separate item. The stoma measuring device is inserted through the stoma and has a retaining hook or balloon on the end and markers on the portion protruding from the abdomen. By counting the numbers of markers, the clinician determines whether a long, medium, or short tube is appropriate. When a tube of a certain type and depth had been functioning well until it cracked, clogged, or was lost, it may be reasonable to replace it with another tube of the same type and depth without any measurements.

Once the appropriate tube is selected, the stoma should be lubricated and the tube can be passed through it. Tubes with a flange must first be distended with the accompanying obturator. Fill the balloon of balloon-stabilized tubes with saline (not air) at the end of the procedure.

Complications

If the ostomy is not a mucocutaneous type, it will close rapidly without a stenting tube. Often the stoma begins to contract within hours of feeding tube removal. The clinician may be presented with a very narrow ostomy and a tract that is difficult to identify or thread. A sound or blunt stylet can be passed down the tract more easily than a tube. This procedure can identify the opening and direction of the tract for easier tube passage. When a guidewire passes easily down a narrow tract but the needed feeding tube does not, it may be possible to dilate the tract with dilators or a dilation catheter. [88] Viscus puncture, viscus abdominal wall separation, and false tract creation with subsequent tube misplacement are risks of dilation procedures. Such procedures should generally be left to the surgeon. If tube replacement will be delayed, maintain the narrow tract with the largest available easily placed stent, usually a Foley catheter. Always secure the stent against internal migration.

The position of the gastrostomy tube should be checked by air insufflation and aspiration of gastric fluid, as is done with nasoenteric tubes. It is wise to document the results of this testing in the medical record. Air should enter the stomach without resistance and should produce immediate borborygmi. Gastric fluid should return with aspiration. It may be necessary to insert a small volume of water to get good return. Water pooling in the soft tissue may be aspirated back through a misplaced catheter. Good tube placement is indicated when more fluid returns with aspiration than was originally placed into the catheter. If replacement of the gastrostomy or jejunal tube required the overcoming of any resistive force or if either the air or the aspiration test yields uncertain results, a radiographic study with contrast should be performed. Peritoneal infusion of feeding solution can be fatal.

Complications of gastrostomy include wound infections around the catheter, performance of an unnecessary laparotomy for suspected leakage, gastrocolic fistula, pneumatosis cystoides intestinalis, bowel obstruction, peritonitis, and hemorrhage. [79] Jejunostomies can cause most of these complications, as well as other types of fistulas and small bowel obstruction from adhesions or volvulus around the jejunostomy site. [59] [73] The most common complications of gastrostomy and gastroenterostomy are local skin erosions from leakage, wound infections, hemorrhage, and tube dislodgment. [51] Peritonitis and aspiration are the most critical complications of gastrostomy feedings. [51] [73] Jejunostomies are less prone to stomal leakage and cause less nausea, vomiting, bloating, and aspiration than do gastrostomies. [49] [53]

Dislodgment of gastrostomy and jejunostomy tubes is most common in the 2 weeks after ostomy creation. [89] Extrusion of the gastrostomy tube is usually caused by excessive tension applied to the tube. Only gentle contact of the

gastric and abdominal walls is desirable. Uncooperative patients should be restrained, and mittens are often particularly helpful. Sutures and large mushrooms or balloons do not prevent purposeful removal of the gastrostomy tube by the uncooperative patient.

A small amount of drainage is to be expected at the tube entry site. Local leaks of gastric juices may macerate and irritate the skin, predispose to local infections and abscesses, and encourage the development of small granulomas. [49] [75] Granulomas are particularly common in children. They can be treated with silver nitrate at the time of dressing changes. Any dressing used around the entry site of an enteral nutrition tube should absorb fluid and not encourage persistent moisture. [78] An unusually large stoma may promote a leak. Although insertion of a larger tube or firmer traction on the tube may be transiently effective, these measures often result in further stomal enlargement. Rigid gastrostomies promote leakage by widening the stoma as they pivot. Insertion of a soft, pliant feeding tube through the widened stoma is often easy and allows later contraction of the stoma. [1] If these techniques are ineffective, temporary removal of the feeding tube may allow the stoma to shrink. Large amounts of drainage around the stoma site may occur with high residual volumes. [84] The residual should be checked and feedings withheld until residuals are less than 100 mL. Feeding residual should be checked every 4 hours when a patient is on continuous drip feeding. [87]

Pneumoperitoneum after percutaneous gastrostomy is neither unusual nor dangerous. Benign pneumoperitoneum may be present as long as 5 weeks after percutaneous endoscopic gastrostomy. [79] [84] Pneumatosis cystoides intestinalis can occur through the defect in the bowel wall created for the enterostomy tube. Although often clinically insignificant, its occurrence suggests air under pressure in the small bowel. NG suction and diet change generally permit resolution of the problem. Catheter or feeding tube removal is usually not required. [80]

Clinically significant pulmonary aspiration can occur with gastrostomy feeding. Methods of checking for silent pulmonary aspiration include checking tracheal aspirates with a glucose oxidant reagent strip or placing methylene blue in the formula and monitoring tracheal aspirate for pigmentation. [48] [54] [90]

A Foley balloon accidentally inflated in the small bowel or esophagus can lead to perforation or obstruction. [91] Careful inflation of the balloon soon after it has entered the stomach prevents viscus perforation. A gastrostomy tube may migrate in the stomach and obstruct the gastric outlet. This complication manifests itself clinically with vomiting and high residuals of feeding solution. Volvulus and jaundice may also occur as a result of balloon migration. This problem can be alleviated by gently pulling back the tube. If the balloon of a Foley catheter has migrated into the small bowel, deflation of the balloon before pulling it back further reduces the risk of intussusception. An outer crossbar will prevent distal migration. [77] [84]

Gastrocolic fistula usually manifests itself as copious diarrhea. Once it is confirmed, treatment consists of removal of the gastrostomy tube. Later creation of a gastrostomy in a different location may be possible. The patient may require hospital admission for nutritional support and monitoring of fluid and electrolyte status.

An external bolster that is snugged down too tightly may result in a short stoma and embedding of the internal bolster into the abdominal wall. An abscess may result.

Overly tight external bolsters should be loosened. The correct position is 1 cm from the external abdomen.

Dacron cuffs can serve as the nidus for an abdominal wall abscess. Generally the cuff cannot be removed independently of the tube. A replacement tube without the cuff can be inserted, if one is careful not to dissect the tube into the wall of the abscess. Extensive abscesses may require incision and drainage.

CLOGGED FEEDING TUBES

Clogging is a problem common to all feeding tubes. Although it may only be a temporary solution, it is prudent to attempt to unclog a tube before it is replaced, especially if the tube has a complex placement or the clinician is unsure of how the tube is secured internally. However, whenever feasible, clogged tubes should be replaced with a new tube. Large gastrostomy tubes are the least likely to clog. Gastrostomy tubes at least 28 Fr in size can tolerate home-blenderized foods and viscous feeding solutions. Isosmotic feeding solutions are tolerated by fairly narrow tubes and cost one sixth of what elemental feedings cost. Isosmotic feedings will clog needle catheters.[50] When tube lumina are 14 Fr or smaller, all pills and the contents of all capsules should be dissolved in water to prevent tube obstruction. [78]

Acid precipitation of feeding formulas is an important factor in the occlusion of gastrostomy and NG feeding tubes. Sodium and calcium caseinate and soy protein molecules are most soluble at a pH of 6.3 to 6.6 and least soluble at a pH of approximately 4.7. [92] They are insoluble in nonpolar organic solvents. A study of 14 feeding solutions showed Pulmocare, Ensure Plus, and Osmolite to be the most clog-prone on exposure to acidic solutions; Citrotein had the least tendency to clog. [93]

Kinking is a frequent cause of tube blockage during the immediate post-reinsertion period. Withdrawing the tube a few centimeters usually relieves the kink and obstruction. A persistently recurring kink requires tube removal and insertion of a fresh tube.

Accumulated feeding solution or medication precipitates are very difficult to clean or remove. Milking a pliant tube backward may remove some of the cheesy precipitates. Guidewires or stylets may clear the proximal portion of a clogged tube lumen but are unsafe to use in subcutaneous (SQ) areas of the lumen because they can puncture the tube and injure the patient or create a tube leak.

Fogarty arterial embolectomy catheters can be used to unclog jejunostomy [94] and gastrostomy tubes. The soft tip of the Fogarty catheter is inserted into the feeding tube and advanced while the insertion distance is monitored to avoid penetrating farther than the length of the feeding tube. The allowable length of insertion should be premeasured. A No. 4 embolectomy catheter is suitable for a 10 or 12 Fr tube, whereas a No. 5 catheter should be used in 14 Fr feeding tubes. When the catheter meets an obstruction, the balloon can be inflated, which usually opens the obstruction sufficiently that catheter passage can continue. Once the Fogarty has been manipulated to just proximal to the internal feeding opening, it is withdrawn while the balloon is intermittently inflated and deflated gently. The catheter should not be withdrawn while inflated, because it and the feeding tube tend to move as a unit.

The procedure may need to be repeated several times. Contrast injection to confirm tube position and integrity should be performed after declogging is completed. [94]

Irrigation with carbonated beverages and high-pressure irrigation with small-volume syringes have also been recommended as techniques for unclogging feeding tubes. Although irrigation seems like a straightforward and simple solution, these techniques are generally ineffective; furthermore, the possibility exists for dangerous tube ruptures with internal leakage. Broviac catheters are especially prone to tube aneurysms that can rupture under pressure. [75] Tubes unclogged by forceful irrigation or by deep luminal probing should be radiographed after injection of contrast to check tube integrity.

Enzymatic declogging of feeding tubes may sometimes be effective. Most enzymatic preparations are insoluble in an acidic environment and require mild alkalinity for effective action. Such precipitates can add to the obstructing material. One study suggested that two enzyme preparations can soften clog consistency sufficiently to enhance tube clearing with insufflation. [92] A crushed chymotrypsin tablet or two papain tablets (effervescent Allergan) can be dissolved in 2 mL of distilled water and irrigated into the drained feeding tube. A 12.5-cm catheter may make such irrigation more effective. The feeding tubes should be closed or clamped and left for 1 to 4 hours. One study attempted tube insufflation only at 4 hours, but clog changes were noted after one-half hour. [92] Insufflation of air with a 50-mL syringe also may clear the tube.

Most clogged tubes should be replaced. Tubes that have been unclogged by using force should be radiographed after water-soluble contrast injection (see section on transabdominal feeding tube replacement) to check for internal leaks. Regular tap water irrigations and selection of a feeding solution appropriate for the diameter of the feeding tube are vital to prevent tube clogging.

CONCLUSION

Emergency clinicians must commonly manage the patient who requires NG tube placement or management of a dislodged or malfunctioning feeding tube. Although placement of these tubes is generally straightforward in the cooperative patient, many patients requiring such tubes will be uncooperative or have an altered sensorium. Therefore, careful attention to the details recommended for these procedures is encouraged, as the complications associated with a misplaced tube can be disastrous.

Chapter 42 - Balloon Tamponade of Gastroesophageal Varices

Edward A. Panacek

More than 2% of all hospital admissions in the United States and more than 5% of admissions from emergency departments (EDs) are related to acute gastrointestinal (GI) bleeding. In the vast majority of these patients, the bleeding source is in the upper GI tract. Bleeding from varices, both esophageal and gastric, is the third most common cause of upper GI bleeding, accounting for about 20% of cases.[14] Variceal hemorrhage is the most dramatic and life-threatening complication of portal hypertension. After one bleeding episode, the risk of a second is 70%, accounting for up to 50% of all deaths in patients with cirrhosis. [29] The risk of mortality from each bleeding episode ranges from 20% to 84% and depends on the etiology of the portal hypertension, the hepatic functional reserve of the patient, and the duration of hemorrhage prior to presentation.[25] Individuals with noncirrhotic portal hypertension and intact hepatic function generally tolerate the hemorrhage better than those patients with cirrhosis and advanced hepatic dysfunction. The greatest risk of death is in the first few days after the onset of variceal hemorrhage. [25] Therefore, prompt and effective therapy during this initial period is essential to maximize the patient's chance of survival.

BACKGROUND

The use of balloons to control variceal hemorrhage dates back to the 1930s, although the balloons were initially filled with water rather than air. [30] In 1950, Sengstaken and Blakemore first described the technique of a double-balloon tamponade system similar to what is currently used. During the subsequent 30 years, the Sengstaken-Blakemore tube underwent a number of modifications or refinements by Linton, Nachlas, Boyce, and Edlich. [3] [4] [11] These modifications generally carried the name of their originator and altered the size or shape of the respective balloons or added aspiration ports in the stomach or the esophagus to allow monitoring of ongoing bleeding.

Currently there are two types of gastroesophageal balloon tamponade (GEBT) tubes available: the three-lumen Sengstaken-Blakemore tube (gastric balloon, esophageal balloon, and gastric aspiration) and the four-lumen Minnesota tube (which adds an esophageal aspiration port). [2] [11] Figure 42-1 and Figure 42-2 show these two types of tubes. Institutions generally stock a single type of tube. Most hospitals also generally only stock adult sizes, although pediatric tamponade tubes do exist.[18] However, since the advent of endoscopy, such devices are rarely used. It would not be considered standard care that all emergency clinicians have experience, or expertise with there tubes. Although GEBT tubes are used less frequently today than previously, their use can still be temporizing or life-saving. Although these tubes are not usually placed in the ED, some emergency clinicians will encounter a GEBT tube during their professional career. This chapter attempts to make emergency clinicians familiar with their structure, placement, function, and management. This may be especially helpful in more remote settings, where an invasive gastroenterologist is not readily available.

INDICATIONS AND CONTRAINDICATIONS

A nasogastric (NG) tube should be placed in all patients in whom GI bleeding is suspected or known, regardless of the presumed source or degree of the bleeding. There is no evidence that passage of an NG tube in a patient with esophageal varices results in variceal trauma or increases bleeding. [21] Lavage should be carried out, ideally with the patient in the left lateral decubitus position, to determine if the upper intestinal bleeding is limited in extent (i.e., gastric aspiration becomes clear with about 1 to 2 L of fluid). Lavage is generally performed to decompress the stomach and minimize the risk for further emesis. Removal of large clots also allows gastric wall contraction in those cases where the upper GI bleed has a gastric origin (see Chapter 41). Ongoing lavage has little effect on gastric hemorrhage, and extended lavage with cold solutions does little for hemostasis and may induce hypothermia.

When the gastric aspirate does not clear with lavage, more aggressive therapeutic approaches must be considered. The approach to patients with acute hemorrhage from esophageal varices is substantially different from that used with other causes of upper GI bleeding. [21] The presence of advanced hepatic disease, evidence of portal hypertension, or prior known variceal hemorrhage greatly increases the likelihood of a variceal source for the bleeding. [14] However, in 25% to 50% of such cases, upper GI bleeding can still be due to nonvariceal sources. [10] For this reason, emergent endoscopy is indicated in such patients whenever available. [21] Endoscopic sclerotherapy and other techniques are the most effective therapy to stop active bleeding from varices and to stabilize varices that have recently bled. [27] [28]

The other early therapeutic option for variceal hemorrhage is IV octreotide, or somatostatin, potent nonselective vasoconstrictors. They can be used in conjunction with sclerotherapy or as the sole therapy when sclerotherapy is unsuccessful or unavailable. These drugs must be used with caution in patients with coronary artery or other vascular disease because of the risk of adverse ischemic effects. [26]

When sclerotherapy is unavailable or unsuccessful and vasoconstrictor therapy is not adequate, balloon tamponade is the next therapeutic option. Balloon therapy is less successful than sclerotherapy but can control bleeding acutely in up to 80% of cases. [6] [12] [20] The role of balloon tamponade in these other therapies is depicted in Figure 42-3 .

Some authors have advocated the use of esophageal balloon tamponade based upon transfusion requirements or ongoing hemorrhage exceeding a certain amount (usually 2000 mL of blood within a 24-hour period). [14] Other recommendations have focused on endoscopic findings, including active variceal bleeding that cannot be controlled with sclerotherapy or traumatic longitudinal tears of the esophagogastric junction (Mallory-Weiss tear), with active persistent bleeding. [20] However, these indications are generally more relevant for the inpatient setting. In the absence of endoscopy, the indication in the ED would be a patient with known portal

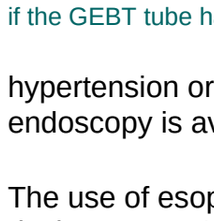

Figure 42-1 *A,* Photograph of the three-lumen Sengstaken-Blakemore tube with the balloons deflated. *B,* Diagram of GEBT tube with nasogastric tube attached. This is not required if the GEBT tube has esophageal aspiration ports.

hypertension or prior variceal hemorrhage who has substantial ongoing upper GI bleeding that does not clear with gastric lavage and vasoconstrictor therapy. When endoscopy is available, the indication for a GEBT tube is substantial ongoing variceal hemorrhage that cannot be controlled with endoscopic interventions. [20]

The use of esophageal balloon tamponade tubes is associated with a number of serious and potentially lethal complications. Although potentially lifesaving, these devices are not always easy or safe to use; but, their use is supported in critical situations. The overall complication rate is much higher than for most other procedures that emergency clinicians perform. [22] Therefore, clear indications for GEBT tube use and a complete understanding of the instructions for their placement are required. GEBT tubes are best placed by the individual most knowledgeable about their use.

GEBT tubes are meant only for temporary bleeding control. [20] Although most studies have shown that they provide initial hemostasis in up to 80% of patients with bleeding from esophageal varices, they have not measurably affected the long-term mortality of these patients. [6] Their success rate improves when used in conjunction with vasoconstrictor therapy. [23] However, these therapies often do not control hemorrhage definitively, and arrangements for more definitive endoscopic procedures should be initiated. [12] [20]

EQUIPMENT

Most hospitals stock only one type of GEBT tube. Ideally, the tubes are stocked in the ED itself or are readily available when needed. Multiple companies make these tubes, and each

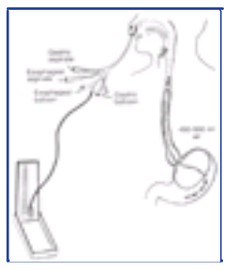

Figure 42-2 Diagrammatic representation of the four-lumen Minnesota tube with the balloons properly positioned and inflated. Note manometer attached to esophageal balloon port to measure pressures foam rubber cuff at nose as a fixation device, and the esophageal aspiration lumen.

company may include some of the items listed below. The equipment required for this procedure is as follows:

1. GEBT tube
2. Traction device or setup, including weights (discussed later)
3. Manual manometer or sphygmomanometer
4. Y tube connector, if not already part of the tamponade balloon ports
5. Vacuum suction device
6. Connectors for the suction tubing
7. Plastic tubing to connect to suction
8. Soft restraints
9. Topical anesthetic (spray and jelly)
10. Water-soluble lubricating jelly
11. 4 tube clamps (see text)
12. Large (e.g., 50 mL) catheter tip irrigating syringe
13. Surgical scissors for emergency balloon decompression

Figure 42-3 Algorithm for management of acute variceal hemorrhage, showing the role for balloon tamponade. After endoscopy banding and/or lauage have been used. Note that balloon tamponade can also be used after failed sclerotherapy as a temporizing measure pending emergency surgery, or between repeat attempts at sclerotherapy.

Optional: Standard NG Tube

There are multiple ways of providing a traction setup for the tube, and individual hospitals may have specific policies. [2] Tubes can be taped to the mouth guard of a football helmet, although currently it is extremely unusual to see that technique used. Even in those institutions that try to keep a helmet available, it can rarely be located when needed. More often traction is maintained with a cube of foam rubber that is generally included in the package with the tube itself, as shown in Figure 42-2 . The tube is inserted between the two halves of the foam, and the foam "cuff" is placed against the nose and taped.

The more common way of providing traction, and generally the way considered most effective, is through a pulley apparatus similar to the system used for orthopedic traction on lower extremity fractures.[15] It is a bit more cumbersome, and there are concerns regarding its use in disoriented or agitated patients, but it can effectively and consistently maintain the desired 0.45 to 0.91 kg (1 to 2 lb) of traction. The usual trapeze bar apparatus is used, but this requires two pulleys: one over the patient and one at the end of the bed. It also requires a longer rope (about 3 m [10 feet]), as well as the suspension hook and 0.23- to 0.45-kg (0.5- to 1.0-lb) weights.

Clamps are needed for the process of inflating the balloons, checking pressures, and maintaining balloon inflation. Never use bare standard hemostats for this purpose, as the serrations on the clamp jaws can puncture the rubber tubing. Specific tube clamps are best, if available (e.g., hosecock clamps). Alternatively, large surgical clamps or large hemostats can be modified by covering the clamping surfaces with sections of plastic or rubber tubing or multiple layers of tape.

If the GEBT tube does not have an esophageal aspiration lumen, secretion can be removed by attaching a standard NG tube along side the GEBT tube (Fig. 42-1B). This will decrease the risk of aspiration. This is not required if the GEBT has esophaged suction parts.

PROCEDURE AND TECHNIQUE

Patients requiring GEBT tubes are critically ill and must be closely monitored within the ED or in an intensive care unit. In the best of circumstances, these tubes can be difficult to place. However, these patients are often uncooperative and sometimes even combative due to encephalopathy. Control of the patient is imperative. Soft restraints should be used routinely, and sedating medications considered in most patients. If the patient is not awake, alert, and fully able to protect the airway, endotracheal intubation should precede placement of the GEBT tube (see Chapter 4). These patients are at extremely high risk for regurgitation and aspiration, and the threshold for endotracheal intubation should be lower than usual. [19]

The procedure itself is unfamiliar to most emergency clinicians and requires a number of items of equipment. Each of these should be checked prior to beginning the procedure. In particular, the balloons on the tamponade tube must be checked for patency and lack of leaks. If there is any question, the balloons should be submerged beneath water for checking. During testing, inflation of the gastric balloon is done in progressive steps (generally in 100-mL increments), up to the maximum recommended volume (generally 500 mL), while the pressure is monitored with the manometer. The pressure within the gastric balloon should not increase by more than 15 mm Hg with each progressive administration of 100 mL of air. The operator should note the pressure at full inflation of the gastric balloon. If the optimal NG tube is to be used, it is now tied along the course of the GEBT tube with sulk sutures. The tip of the NG tube should be 3–4 cm proximal to the esophageal balloon (Fig. 42-1B). The esophageal balloon is simply checked for patency. The balloons are then deflated and coated with water-soluble lubricating jelly, preferably with a topical anesthetic.

The patient is positioned for the procedure by having the head of the bed elevated to about 45 degrees, if possible. If the patient is unable to tolerate that position, the left lateral decubitus position is also acceptable. The posterior pharynx and nostrils are anesthetized with a topical anesthetic. The patient should already have undergone gastric lavage with a standard NG tube. At this point the stomach is maximally evacuated (to decrease regurgitation), and the NG tube is removed.

After suctioning all air from the gastric and esophageal balloons and ensuring that they are maximally collapsed, each of the balloon ports is clamped, or the plastic plugs (if provided with the tube) are inserted into the lumens. This maneuver maintains deflation of the balloons during placement. In awake and alert patients, passage through the nostril is an option, but passage through the mouth is preferred, especially in tracheally intubated patients. The alert patient can assist the process by taking sips of water through a straw. The tube is then passed to at least the 50-cm mark, or the maximum depth allowed by the length of the tube, in the same manner as a standard NG tube. Suction is then applied to the gastric and esophageal aspiration lumens to minimize chances of further regurgitation or aspiration. Aspiration of gastric juice or fresh blood from the gastric lumen provides further evidence for proper location of the tube. However, its position must be confirmed radiographically.

Some authors recommend initial inflation of the gastric balloon with 50 mL of air to assist with radiographic visualization to ensure that the gastric balloon is below the diaphragm.[20] However, this is not routinely necessary, and the position of the distal end of the tube is usually obvious on radiograph. Absolute confidence regarding tube location is extremely important to reduce the risk of esophageal perforation caused by inflation of a misplaced balloon. Once gastric positioning of the distal balloon is ensured, the tube clamps (and plastic plugs if used) are removed from the gastric balloon inflation ports.

The pressure monitoring outlet for the gastric balloon lumen is connected to a manometer, similar to Figure 42-2 and Figure 42-4 . Increments (generally 100 mL) of air are then introduced through the gastric balloon inflation lumen until the recommended total volume (generally 450 to 500 mL) fills the gastric balloon. Only air, never water or any liquid, is used to inflate the balloons. As the air is introduced into the gastric balloon, the intragastric balloon pressure is monitored. If the gastric balloon pressure at any step is 15 mm Hg greater than the intragastric balloon pressure at an identical volume noted before intubation (i.e., during testing), the gastric balloon may be located within the esophagus, and further inflation of the balloon could result in overdistention and rupture of the esophagus. If an elevated intragastric balloon pressure is recognized, the balloon should be deflated, advanced, and reintroduced into the stomach. A repeat radiograph is then
