Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

PREFACE

When our chief resident was asked what he thought of *Reese and Betts' A Practical Approach to Infectious Diseases*, he responded, "It is logically organized and thoroughly referenced. It provides a comprehensive, up-to-date guide for diagnosing and managing common and obscure infectious diseases. It is an invaluable resource for any resident or practicing physician."

This book was written to provide helpful information on infectious disease problems for medical students, house officers, community practicing physicians, and other health care practitioners such as hospitalists, nurses, and infection control officers.

Reese and Betts' A Practical Approach to Infectious Diseases uses an outline format to make the information readily available and succinct. This approach provides the reader with rapid access to the information that they need to find, while at the same time it leads their thinking in a logical fashion step-by-step through the management of the problem at hand. Up-to-date references are provided for readers to expand their understanding of the specific problem with which they are confronted.

The original intent of this text, when it was conceived by Dr. Richard Reese during his fellowship in infectious diseases in the late 1970's, was to answer the questions most often asked of the infectious disease consultant by the practicing physician. That philosophy is maintained in this edition. The difference between this edition and the earlier ones is that some of the questions have changed, and some quite dramatically.

This new edition provides the reader with up-to-date information in several areas: In-depth discussions of the rapidly emerging resistant gram positive, gram-negative, and mycobacterial infections, and the newest antimicrobial approach to combat these problems of resistance is discussed in detail in the respective chapters; analysis of evolving fungal infections and the new antifungal agents, some of which are not yet fully approved; an in-depth analysis of antivirals available to combat HIV infection is provided, as well as thoughtful analysis of their use in adults, in children, and in pregnant women, and will bring the generalist and the infectious diseases expert up-to-date in this field; investigational new antiretroviral agents are presented; emerging problems in bioterrorism can be found in the pneumonia and skin and soft tissue chapters; and each of the organ system chapters provides new information that has emerged since the last edition.

Whether in the intensive care unit, in the emergency department, or in the office, the practitioner can turn to this compact, yet complete, text to find the answers that he or she needs. The problem may be as complicated as a bone marrow transplant patient with fever and a new pulmonary infiltrate; or an HIV-infected patient who has failed previous regimens; or it may be as straightforward as the office patient with an upper respiratory infection or with cellulitis. The information to help the practitioner think through a logical approach to these and many other problems is provided.

An additional, and unusual, feature of this text is the inclusion of hard-to-find information on the approach to infection in the neonate, infections of the eye, use of vaccines to prevent infectious diseases problems, in-depth information on international travel, infections in transplantation patients, and management of employee health problems.

What prompted us to bring this new edition forward is the excellent response we have had from the house staff and students who have used our book previously. They have urged us to update the information and we have responded with this new edition.

We thank all of our contributors for their outstanding effort to update their contributions and Dr. Geneen Gibson, who provided the important cost information concerning antibiotics. Dr. Richard Reese was most helpful with suggestions along the way. We acknowledge Margaret Aldrich, who helped prepare portions of the text. We extend our sincere appreciation to Hal Pollard and Denise Martin of Lippincott Williams & Wilkins for helping us keep up the momentum that led to the completion of the task. Most of all, we thank our wives Sherrill, Rachel, and Stephanie, without whose patient understanding and support we could not have completed this work.

Robert F. Betts, M.D.
Stanley W. Chapman, M.D.
Robert L. Penn, M.D.

REESE AND BETTS'
A PRACTICAL APPROACH TO
INFECTIOUS DISEASES
FIFTH EDITION

1. FEVER AND FEVER OF UNKNOWN ETIOLOGY

Rayhan H. Hashmey and Norbert J. Roberts, Jr.

Fever has been recognized for centuries as a characteristic sign of infection. However, fever also may be due to such noninfectious causes as tumors, collagen vascular diseases, and drugs. Close to a third of patients admitted to the hospital have an episode of fever, particularly on medical and surgical services [1]. The clinician must remain aware, however, that very young and very old individuals may present with serious infections without a febrile response, as can individuals with significant malnutrition [2,3] or with preceding stress to their thermoregulatory systems. An example of the latter circumstance would be an individual admitted with hypothermia due to exposure [4]. As many as 41% of such patients had serious infections in one study, and more than a third of the infections were not diagnosed at the time of admission.

The **pathophysiology** of fever has been elucidated relatively recently, and the thermometer remains an essential diagnostic tool even in this era of sophisticated technology. Fever had been viewed as a beneficial response to disease until the last century, when the concept that fever itself required treatment gained acceptance [5–7]. This transition may have occurred because the antipyretic agents that came into widespread use had additional antiinflammatory and analgesic activities, and the treated patients improved with regard to several parameters of illness [6].

Fever phobia (undue parental fear of fever in their children) was clearly documented in 1980 [8] and, despite recent efforts to inform medical practitioners and the public, persists even today, at least in part because of mixed messages to the public [9]. The role and impact of fever in host responses to challenge continue to be reassessed [5–7]. **The data and the analyses suggest that routine suppression of a febrile response is not warranted.** Judgment should be applied regarding therapeutic intervention (antipyresis) in any individual case, with consideration of both the potential benefits of fever suppression and the deleterious effects of temperature elevation for the individual. See the text by Mackowiak [10] for in-depth discussions of thermoregulation, fever, fever of unknown etiology, and other relevant aspects of this host response.

FEVER

I. Definitions

- A. Normal basal body temperature** often is thought to be 37°C (98.6°F), determined orally, but should more accurately be considered as a temperature that falls within specified ranges for different times of the day, with variation among individuals. The normal oral temperature range ($\geq 99\%$ of healthy young adults) over an entire day is 36° to 37.7°C (96.8°–99.9°F). Diurnal variation is discussed in section C [11]. **Rectal temperatures are higher by approximately 0.6°C (1°F).** The usual temperature range of an individual can rarely be determined beforehand in clinical practice. Therefore, an oral temperature exceeding 37.2°C (98.9°F) in the early morning and 37.7°C (99.9°F) in the late afternoon or evening may ordinarily be considered higher than the normal range for healthy adults 40 years of age or younger [11].
- B. The method used to determine the body temperature** is important with regard to both the expected range and the accuracy of the reading (related to confounding factors). Traditionally, clinicians have relied on oral and rectal sites for temperature measurement using **mercury thermometers**, now more often measured using digital electronic devices that are widely available. **Infrared tympanic thermometry (ITT)**, which measures the flow of heat from the surfaces of the tympanic membrane and ear canal, is increasingly used in clinical settings. Although generally reliable, accuracy of measurements using ITT are more dependent on user technique [12], and correlation with rectal temperature may be poor in intensive care unit patients, in very young children, and in the presence of ear pathology [13–17].
- C. Diurnal variation.** Diurnal variation may be 1°C (1.8°F) or more in any given individual, but the mean diurnal temperature oscillation is approximately 0.5°C (0.9°F) [18], with women generally having slightly higher normal temperatures than men. **Temperature is lowest in the early morning and highest in the late afternoon or early evening** (4–8 P.M.).

2 1. Fever and Fever of Unknown Etiology

The diurnal rhythm is consistent in each person and usually is preserved with a fever [19], with the absolute temperature range elevated for that individual. Its absence may suggest the possibility of factitious fever if other causes for the fever cannot be identified (assuming no hypothalamic disorder exists).

D. **Fever and hyperthermia** are two distinct processes physiologically.

1. **Fever** is said to exist whenever the body temperature rises above the maximum of the normal range, in a physiologically regulated manner, in response to a new temperature set point that has been established (see section II).

2. **Hyperthermia** does not involve the resetting of the normal temperature set point. Hyperthermia most commonly results from thermoregulatory responses that are inadequate for the body's needs or from adverse reactions to anesthetics or other pharmacologic agents. Hyperthermia is more likely to develop in those individuals with less effective thermoregulation (the very young and the very old) but may occur even in healthy young adults (e.g., as a result of prolonged intense exercise in warm, humid weather, such as with participation in a marathon). Heat production exceeds heat loss, and the temperature exceeds the individual's set point. Heat stroke and malignant hyperthermia are extreme and highly dangerous examples of hyperthermia [20,21].

3. A **practical clinical concept** that results from this distinction is that antipyretics (drugs that lower the set point) are effective in treating fever but are unlikely to affect hyperthermia. Therefore, physical measures to lower the body temperature usually must be applied in hyperthermia cases.

E. **Lethal temperature ranges.** Body temperature is actively and effectively controlled, both in the basal state and in response to the higher set point that is induced by an exogenous pyrogenic challenge. In the latter case, temperatures exceeding 41°C are uncommon, even with infections that are characteristically associated with high fevers [22].

1. **The lower lethal temperature** is approximately 26°C (78.8°F) (excluding therapeutic hypothermia).

2. **The average upper lethal limit** is approximately 43°C (109.4°F), although morbidity and mortality of such suprathysiologic temperatures are related to both the degree and the duration of the temperature elevation. Thus, temperatures in excess of 42.5°C commonly are required and used to produce hyperthermic treatment of tumors. Such temperatures do affect the immune system [23] but, with appropriate control of the intensity and duration of the hyperthermia (especially if applied locally to tumor), are well tolerated by patients.

II. **Physiology of fever and associated responses**

A. **Proinflammatory cytokines, fever, and associated responses.** Fever results when exogenous pyrogens (bacteria, viruses, fungi, other microorganisms, allergens, etc.) or endogenous pyrogenic factors (immune complexes, complement, lymphokines from sensitized lymphocytes, etc.) encounter circulating monocytes or monocyte-derived tissue macrophages, the major sources of biologically defined endogenous pyrogen (EP), which was molecularly defined and termed Interleukin-1 (IL-1) [24]. Extensive studies have determined that IL-1 is only one of several cytokines that produce fever by acting directly on the hypothalamus. This list currently includes IL-1 α , IL-1 β , tumor necrosis factor (TNF)- α , TNF- β , interferon (INF)- α , IL-6, and RANTES [6,24–26]. Other cytokines, acting within a complex regulatory network, also likely contribute to fever production, especially those using gp130 as a signaling receptor (IL-11, oncostatin M, ciliary neurotrophic factor, cardiotropin-1, and leukemic inhibitory factor).

The precise roles of these cytokines in the induction of fever are still under investigation. Animal models of experimental bacteremia have suggested that TNF is induced first after endotoxin challenge, followed rapidly by IL-1, and then (to a lesser extent) by IL-6 induction. However, the levels of IL-6 correlate best with the severity of the infectious disease [24,27]. Since IL-1 and TNF can induce the production of IL-6 and not vice versa—and IL-6-deficient mice do not produce fever when injected with lipopolysaccharide (LPS), IL-1, or TNF—it has been postulated that IL-6 provides an eventual quantitative “readout” for the proinflammatory cytokine response [24]. Cytokines do not diffuse across the **blood-brain barrier** (BBB);

thus, active transport systems have been postulated as a potential entry mechanism [28,29]. It also has been proposed that the cytokines may circumvent the BBB by acting on the **organum vasculosum laminae terminalis** (OVLT), an organ that lacks the BBB. More recently, chemosensitive abdominal vagal afferents have been shown to participate in neural pyrogen signaling to the brain [30–33].

A relatively recent field of investigation has arisen from the recognition that **several endogenous antipyretic systems exist that can modulate the fever response**. Exogenous pyrogens such as viruses induce the concomitant production of both IL-1 and inhibitors of IL-1, or IL-1 receptor antagonists (IL-1ra), by monocytes-macrophages [34,35]. Treatment of rats with anti-IL-1ra at the time of LPS injection significantly prolonged the duration of fever [36]. IL-10 and TNF- α (in subpyrogenic doses) inhibit LPS-induced fever in mice [37,38]. In addition, IL-1 induces the release of stress hormones—including adrenocorticotrophic hormone (ACTH), melanocortin, and vasopressin—which possess a broad range of anti-inflammatory and cytokine-inhibitory properties [6,22,37–40]. The full breadth of biologic activity of these endogenous cryogens are currently being determined, and it is likely that the febrile and other acute responses to infection or similar pyrogenic challenges are regulated in an integrated fashion by the several mediators that are produced [40,41]. Such observations extend our knowledge well beyond the long-recognized activation of the pituitary–adrenal axis during an infection, and the cortisol-mediated or other glucocorticoid-mediated suppression of the immune response, including production of the proinflammatory cytokines IL-1, TNF, and IL-6.

B. The sepsis syndrome and septic shock. (Sepsis is discussed in detail in Chapter 2.) It is important to note here that many of the features of the sepsis syndrome and septic shock have been related to production of the proinflammatory cytokines associated with fever, particularly TNF [24]. Interference with the inflammatory cascade, it was thought, would provide non-etiology-specific intervention that would likely affect the outcome by providing support until specific medical intervention (administration of antimicrobial or other appropriate agents) or specific immune responses become effective. However, blockade of cytokine mediators and their receptors has not proved therapeutically successful, because blockade of mediators alone does not block the direct activation of processes such as coagulation and complement in efforts to reduce the morbidity and mortality of sepsis and septic shock [42–44].

C. Central nervous system events in the production of fever. The **preoptic area (POA)** of the anterior hypothalamus appears to be the major thermoregulatory center. Although the POA reacts rapidly to locally injected IL-1, it is unclear whether pyrogenic cytokines cross the BBB in sufficient amounts to induce fever directly, or act by release of secondary mediators, especially prostaglandin-E from the OVLT [30,45–48]. The POA contains temperature-sensitive neurons that respond not only to changes in core temperature by altering firing rates, but also react to afferent sensory input from thermoreceptors throughout the body. Because of the rapidity of onset of fever after injection of LPS and the delay in appearance of cytokines in the blood, neural pathways of pyrogen signaling to the brain have been proposed with evidence emerging especially for the vagus nerve [30–33].

III. Metabolic and physiologic responses, and the acute-phase reaction. A variety of physiologic and metabolic alterations begin at the onset of an infection or shortly thereafter [3,24,49–53]. Many of these changes were considered to be the results of the accompanying fever, but they also might ensue from the direct action of the proinflammatory cytokine mediators induced by the invading microorganisms or their products (see section **II.A**). The extent to which physiologic responses are due to, or aggravated by, temperature elevation of a fever as opposed to resulting from direct coordinated effects of proinflammatory cytokines is still being delineated.

A. Prominent metabolic changes associated with pyrogenic infections and other etiologies of fever include:

1. Metabolic rate increases of approximately 10% to 12% with each 1°C elevation in body temperature. If the need for calories and amino acids is not met, body wasting can eventually ensue.

4 1. Fever and Fever of Unknown Etiology

2. **Increased insensible water loss**, which is influenced by the degree of fever, hyperpnea, humidity, and ambient temperature. Generally, there will be an increased loss of 300 to 500 mL/m²/°C/day.
 3. **Heart rate increases** of up to 15 beats/min per °C increase in temperature, which could induce heart failure or angina in individuals with significant cardiovascular disease.
 4. **Electrolyte depletion** through loss via sweating and, if associated with the infection, via diarrhea or vomiting.
- B. Secondary nutritional consequences** (the “costs”) of an acute infection or recurrent mild infections are unlikely to be significant for the well-nourished child or adult but may be substantial for those who are marginally nourished and are severely or frequently challenged by infection [3]. The latter individuals are susceptible to a vicious cycle: malnutrition leading to increased susceptibility to infection leading to increasing malnutrition [3].
- C. Altered hepatocyte functions** in acute generalized infection include the following [24,53,54]: increased uptake of free amino acids from plasma, increased gluconeogenesis with glycogenolysis, increased ureagenesis, increased liponeogenesis, impaired ketogenesis, increased uptake and sequestration of iron (in transferrin and hemosiderin) and zinc (with metallothionein), and synthesis of acute-phase proteins (see section **D**).

Some metabolic changes vary during the course of an infection. For example, hyperglycemia may be a prominent feature early in the infection, whereas hypoglycemia secondary to depletion of carbohydrate stores may be troublesome later in the course of an uncontrolled infection.

- D. In the acute-phase response**, certain proteins, referred to collectively as **acute-phase reactants**, are synthesized by the liver in response to the proinflammatory cytokines IL-1, TNF, and IL-6 [53,55,56]. Changes in these proteins (C-reactive protein, α_1 -antitrypsin, haptoglobin, serum amyloid P component, serum amyloid A protein, and others) commonly are associated with the temperature elevation of a fever, but their precise roles in host defense are not entirely clear [56]. Despite production of acute-phase proteins, there is an overall negative nitrogen balance. Furthermore, additional changes in other body constituents such as circulating iron or zinc, which decrease in this setting [51,54,57], are commonly associated with infection and the febrile response and may play integrated roles in host defense (see section **V**).

IV. Fever patterns

- A. Background.** Before the advent of modern diagnostic techniques, the pattern of the febrile response was stressed as an important diagnostic clue. **Generally, a fever pattern (temperature course) cannot be considered pathognomonic for a particular infectious agent in a given patient** [19]. (See section **B.7** and the next major section of this chapter regarding drug fever, which illustrate this important point.) Despite this general concept, in certain circumstances (and especially when combined with other information) the fever curve may provide a clue to the etiology of the fever.
- B. Types of fever** (temperature over time). Because fever patterns often are discussed in the literature and at times provide some clinical clues, they are summarized briefly here. As noted earlier, diurnal variation often is preserved during a febrile episode, with more than 90% of patients with remittent or intermittent fever due to infection showing diurnal variation in one study [19].
1. **Intermittent fevers** are characterized by wide swings in temperature ($>0.3^\circ\text{C}$ [0.5°F] and $<1.4^\circ\text{C}$ [2.5°F]), with the temperature returning to normal at least once during any 24-hour period. This is the second most common type of fever encountered by an infectious diseases consulting service [19].
 - a. **Pyogenic abscesses and irregular use of antipyretics are the most common causes** of the intermittent pattern. This pattern also can be seen in disseminated tuberculosis, acute pyelonephritis with bacteremia, and malaria.
 - b. **A double fever spike** occurring daily is said to be suggestive of gonococcal endocarditis and has been noted with miliary tuberculosis. It is also

much more commonly associated with sporadic use of antipyretics in a febrile patient.

c. Variants of intermittent fevers

- (1) Alternate-day fever may be seen in *Plasmodium vivax* infections and steroid withdrawal fevers (patients on alternate-day dosage schedules).
 - (2) Fever spikes every third day occur in *Plasmodium malariae* infections.
 - (3) Any form of malaria in the early stages of infection may present with intermittent or remittent fevers without periodicity.
2. **Remittent fever** is similar to intermittent fever except the fluctuations in temperature are less dramatic and the temperature does not return to normal. This is the most common type of fever encountered by an infectious diseases consulting service [19]. Examples include acute respiratory viral infections, mycoplasmal pneumonia, and *Plasmodium falciparum* malaria.
 3. **Hectic ("septic") fever** can be either an intermittent or a remittent fever with a difference of 1.4°C (2.5°F) or more between peak and trough temperatures.
 4. **Sustained (continuous) fever** is a moderately persistent elevation in temperature with only minimal fluctuations. Examples include gram-negative bacterial pneumonia, brucellosis, typhoid fever, tularemia, psittacosis, pneumococcal pneumonia, rickettsial infections, and fever in a comatose patient with central nervous system (CNS) damage.
 5. **Relapsing (recurrent) fever** is characterized by periods of fever and periods of normal temperature alternating cyclically. During the febrile episodes, the fever may follow any of the previously listed patterns. Examples include lymphomas, rat-bite fever, borreliosis, and dengue.
 6. **Temperature-pulse disparity** (i.e., high temperature with a relatively slow pulse) may be seen in factitious fever, brucellosis, typhoid fever, psittacosis and Legionnaires disease. A clue to factitious fever may be the absence of diurnal variation when there is no hypothalamic disease.
 7. **Drug fever** may present with any of the patterns described in sections 1 through 6 [18,19]. Hectic fever spikes may simulate sepsis at times. Drug fever is discussed in more detail later in this chapter.

C. Hyperpyrexia, heatstroke (hyperthermia), and malignant hyperthermia.

Extreme temperature elevation often generates concern in both parents and physicians. However, as noted earlier, temperatures exceeding 41°C (105.8°F) are rare even with infections commonly associated with high fevers [22]. Thermoregulatory failure resulting in hyperpyrexia is more likely to occur at extremes of age and in patients with debilitating illness. Infection appears to be an important trigger. During the 1995 heat wave in Chicago, 57% of heatstroke victims had evidence of infection on admission to the hospital [58]. Patients present with signs of fluctuating consciousness and autonomic nervous system lability. Tachycardia and blood pressure instability are common. Hyperpyrexia also can be triggered in susceptible individuals after severe exercise in hot conditions or exposure to suxamethonium or halogenated anesthetic agents [20]. When precipitated by the effects of neuroleptic drugs (e.g., butyrophenones, loxapine, phenothiazines, thioxanthenes, antidepressants, and antiemetics), it is called **neuroleptic malignant syndrome**. A dangerous hypermetabolic state results, often accompanied by increased muscle tone and rhabdomyolysis. A specific inherited muscle membrane defect related to mutation in the ryanosine receptor (RYR) gene has been detected in 20% of cases [20,59,60]. There is increasing evidence that tissue injury, especially endothelial damage, results from extreme elevations in temperature [21,61]. Immediate action to decrease the core body temperature using external cooling methods is imperative (see section VII). **Dantrolene sodium is considered the drug of choice to treat malignant hyperthermia** (2.5 mg/kg intravenously (i.v.) initially, with total doses up to 10.0 mg/kg i.v. to control the event) [20].

D. Attenuated fever responses. Although significant infection may exist, fever sometimes may be absent.

1. **Seriously ill newborns** with infection may lack a fever or may even have sub-normal temperatures. (In contrast, young children may have exaggerated febrile responses to relatively insignificant infections.)

6 1. Fever and Fever of Unknown Etiology

2. **Elderly patients** occasionally do not exhibit a febrile response [62] or, when febrile, have a limited response compared with a younger patient.
 3. Patients with **uremia** may not have a fever or may have a fever with temperatures normally not considered febrile. (Such patients may have a basal temperature somewhat lower than normal, and a temperature in the usual high-normal range might therefore represent a fever for them.)
 4. **Significantly malnourished individuals** may show reduced production of the proinflammatory cytokines and a diminished febrile response [3].
 5. Patients receiving **corticosteroids** or **continuous treatment with antiinflammatory or antipyretic agents** may not have a febrile response.
- V. Potential reasons for not treating fever.** There seems to be a tendency—almost a reflex—among physicians as well as parents to attempt to lower body temperature in a patient with fever, an attitude that likely stems from a general belief that fever is noxious to the body [63,64]. Although associated with seizures in young children, fever per se has not been shown to be harmful in humans and there is no evidence to suggest that its suppression, at least in the short term, is beneficial. In fact, conservation of the febrile response across the animal kingdom argues strongly that fever is a protective and adaptive response, and the decision to use antipyretic therapy should be weighed carefully.

Experiments using animal models have demonstrated the beneficial effect of fever in enhancing resistance to infection. Elegant experiments using the poikilothermic lizard *Dipsosaurus dorsalis* showed a direct correlation between temperature and survival from infection with *Aeromonas hydrophilia* [65]. Increased resistance to a variety of viruses also has been demonstrated using mice, dogs, and ferrets [64,66]. Immunologic pathogen-specific responses are generally enhanced in the setting of temperature elevation within the physiologic range [41]. Temperature elevation appears to affect primarily the phase of recognition and sensitization or activation of mononuclear leukocytes. Evans et al. showed that fever-range temperatures caused a three- to fourfold increase in L-selectin and $\alpha_4\beta_7$ integrin-dependent trafficking of lymphocytes to secondary lymphoid tissues [67,68].

Good clinical data regarding the role of fever in recovery from infection are lacking. Studies based on retrospective analysis and chart reviews support the relationship between a febrile response and favorable outcome [6,64]. Antipyretic therapy has not been shown to protect against recurrence of febrile seizures in children [69]. In addition to the inherent toxicities of antipyretic compounds [70], studies have shown adverse effects of aspirin or acetaminophen therapy on parameters associated with recovery from infection (e.g., prolonged shedding of rhinovirus or varicella virus [during chickenpox] [71]).

Fever remains one of the sentinel indicators of disease and is one of the most frequent causes prompting patients to seek medical attention. Its persistence may aid in the evaluation of a chosen therapeutic regimen, as well as redirect investigation to rule out noninfectious etiologies. **The decision regarding whether to treat a fever per se (and if so, how) should be a considered decision every time**, not merely a routine, predetermined response to detection of a fever.

- VI. Potential reasons to treat fever.** The preceding section discusses reasons why most individuals and the human species overall may benefit from the existence of the febrile response. Nonetheless, individual subjects may be anticipated to have morbidity—derived from the fever—that is unacceptable in the context of current therapeutic capabilities and sound medical judgment regarding relative risks. Specific situations exist where use of antipyresis may be justified. It has been argued that elderly individuals with pulmonary and cardiovascular disease are particularly vulnerable to the additional metabolic and cardiovascular effects of a fever-related temperature elevation, which could lead to greater morbidity or even increased risk of mortality. Additionally, persistence of fever could have detrimental metabolic consequences, exacerbating poor nutrition or dehydration, particularly if the fever is prolonged. Risks considered in the analysis should also include nonmedical factors such as interference with required daily activities due to illness (which might be alleviated by analgesia or antipyresis). It is thus reemphasized that **the decision regarding whether to suppress a fever should be specific for the individual patient.**

VII. Methods of lowering temperature. Antipyretic orders commonly are written imprecisely and as a routine for hospitalized patients; acknowledgment of the intervention appears in the progress notes for only a small percentage of patients, with a rationale appearing even less frequently [72].

The most common antipyretic order may be for as-needed administration, often not even prompted by detection of a fever. If aspirin or another antipyretic agent is given intermittently in response to fever spikes, its use may cause precipitous decreases in temperature and produce a hectic fever that is more stressful for the host than maintenance of a continued febrile temperature.

If the decision is made to suppress a patient's fever, it is usually more appropriate to do so by continuous administration of the antipyretic for a period of time (24–48 hours) after the fever's characteristics have been noted, followed by withholding of the antipyretic agent to determine whether the fever persists. The withholding of antipyretic therapy allows one to observe the temperature curve for evidence of therapeutic efficacy if antimicrobial or other agents have been administered (i.e., absence of fever with appropriate specific therapy for the infection or illness responsible for inducing the fever) and, in the absence of such evidence, indicates the potential need for further evaluation.

A. Antipyretics

1. Nonsteroidal antiinflammatory drugs (NSAIDs). Aspirin is the prototypic drug of this class and has been in clinical use for more than 100 years. Examples of other drugs in this class include indomethacin, ibuprofen, naproxen, and diclofenac. NSAIDs act by inhibiting cyclooxygenase (COX), the rate-limiting enzyme in prostaglandin synthesis, thereby producing potent antipyretic, analgesic, and antiinflammatory effects [73]. Inhibition of COX is also responsible for the serious toxicities associated with NSAIDs, which include renal insufficiency, gastrointestinal (GI) tract ulcers, and coagulation abnormalities [70]. More recently, the discovery of two distinct isozymes of COX (COX-1, present constitutively in cells and involved in tissue homeostasis; and COX-2, the inducible, “inflammatory” form) has led to the development of isozyme-specific drugs (COX-2 selective), with safer toxicity profiles [74–76]. Two drugs, celecoxib and rofecoxib, are currently available. However, it appears that these drugs are not completely devoid of GI side effects, with cost-effective benefit demonstrable only in patients at high risk for GI bleeding [77].

2. Alternatives to NSAIDs are necessary in allergic or anticoagulated patients, or in patients who have hemostatic or platelet abnormalities or GI tract ulcers, or who are otherwise intolerant of these agents. Additionally, it is **advisable to avoid salicylates to treat fever in children with viral illnesses, particularly chickenpox and influenza-like illnesses, because salicylate use has been associated with Reye syndrome** (see Chapter 10). **Acetaminophen** is often used as an aspirin substitute and is approximately as effective as aspirin in reducing fever in either adults or children [78]; however, it possesses weak antiinflammatory properties. It has been postulated that acetaminophen acts on a yet unidentified isoform of COX (?COX-3), mainly in the central nervous system [73].

3. Duration. In patients with infectious causes of fever, specific antibiotic therapy alone usually controls infection and fever within 24 to 72 hours (or, in a viral syndrome, the acute febrile phase may be over in 1–3 days). At this point if not before, it is advantageous to withhold antipyretic therapy as noted previously and to monitor the temperature to determine whether it would be appropriate to discontinue the aspirin (or alternate antipyretic agent).

B. Sponging the body with isopropyl alcohol or water may be done. Because water has the highest heat of vaporization, it is the preferred liquid. Tepid (rather than cold) water may decrease the tendency toward peripheral vasoconstriction, a counterproductive reflex.

C. The Turkish massage of Weinstein [79] is a method of reducing fever by rubbing the patient's skin with a Turkish towel and tepid water. This method takes advantage of the heat of vaporization while encouraging cutaneous vasodilatation. The increased cutaneous blood flow functions as a heat exchanger, and core temperature is lowered.

- D. Cooling blankets** also are popular and may have an appropriate role in temperature reduction. These blankets enhance conductive heat loss and are effective. However, the clinician should not attempt to reduce the temperature to normal, which may result in hypothermia by “overshooting.” The body responds with peripheral vasoconstriction and shivering, making the patient feel miserable. **The cooling blanket should be turned off when body temperature reaches approximately 37.7° to 38.3° C (100°–101° F), to minimize overshooting.** When possible, an antipyretic drug should be used in association with the cooling blanket in an attempt to blunt wide swings in temperature.
- E. Combined evaporation and convection.** Sprays of tepid water at an ambient temperature of 20° C have been used effectively to treat heatstroke victims during the annual pilgrimage at Mecca [80]. Water can be atomized under pressure and combined with air blown by a fan.
- F. Ice water immersion.** Although there is no agreement on the most effective way of quickly reducing the core body temperature, one commonly used method is to immerse the patient in an ice-water bath until the temperature is reduced to 39.5° C (103° F) [81]. At this point more moderate measures (see sections A, B, and D) should be continued to control the fever.

DRUG FEVER

Drugs are a fairly common cause of fever [18,82,83]. **Drug fever should be suspected** whenever a fever occurs (with or without associated findings) in a patient who is taking a drug known to produce fever (Table 1.1). The diagnosis should always be considered, but **especially when the patient either looks or feels well** on current therapy and has no obvious uncontrolled or superimposed infections or is at least hemodynamically stable with no localized infection. Antimicrobial agents, as a group, have been linked to the greatest number of cases [84]. Rigors (43% [corrected calculation]), myalgias (25%), rashes (18%, less than half pruritic), headache (18%), relative bradycardia, leukocytosis (22%), eosinophilia (22%), serum sickness, abnormal liver function tests, and proteinuria may occur [18].

Onset occurs typically within 10 days after a patient begins taking a drug [85]. **Discontinuation of the suspect drug** with a decrease in the temperature within 1 or 2 days lends support to the diagnosis. **Rechallenge with the offending agent is not generally recommended** unless done carefully in a controlled setting (i.e., in a hospital). However, one study suggested that rechallenge with agents responsible for drug fever (>45% of cases reported) was associated with a low risk of serious sequelae, although it was not altogether free from risk [18].

Table 1.1. Agents Responsible for Episodes of Drug Fever

Common	Less Common	Rare
Atropine	Allopurinol	Salicylates
Amphotericin B	Azathioprine	Corticosteroids
Asparaginase	Cimetidine	Aminoglycosides
Barbiturates	Hydralazine	Macrolides
Bleomycin	Iodides	Tetracyclines
Methyldopa	Isoniazid	Clindamycin
Diuretics	Rifampin	Chloramphenicol
Penicillins	Streptokinase	Quinolones
Cephalosporins	Imipenem	Linezolid
Phenytoin	Vancomycin	
Procainamide	Calcium channel blockers	
Interferon	Beta blockers	
	Nonsteroidal antiinflammatory drugs

FEVER OF UNKNOWN ETIOLOGY

I. Definitions. Fever of unknown origin (FUO) was defined by Petersdorf and Beeson [86] in 1961 as a febrile illness of more than 3 weeks' duration. To qualify as FUO, temperatures must exceed 38.3°C (101°F) on several determinations with no diagnosis reached after 1 week of study in the hospital. These criteria are chosen because they tend to eliminate acute, self-limited infectious illnesses such as common viral diseases, postoperative fevers, and febrile illnesses of obvious cause; the criteria exclude patients who defervesce spontaneously, and they also allow time for the completion of the usual initial laboratory studies. Because of the expense of hospitalization and the frequent ability to investigate an FUO as an outpatient, **Petersdorf [87] modified this definition** by proposing that, in lieu of 1 week in hospital, 1 week of intelligent and intensive investigation be undertaken, which in most patients is possible on an outpatient basis.

Durack and Street [88] have recommended further modifications. They have proposed subdividing FUO into four groups:

A. Classic FUO

1. Fever of 38.3°C (101°F) or higher on several occasions.
2. Fever of more than 3 weeks' duration.
3. Diagnosis uncertain, despite appropriate investigations, after at least three outpatient visits or at least 3 days in hospital.

B. Nosocomial FUO

1. Fever of 38.3°C (101°F) or higher on several occasions in a hospitalized patient receiving acute care.
2. Infection not present or incubating on admission.
3. Diagnosis uncertain after 3 days despite appropriate investigation, including at least 2 days' incubation of microbiologic cultures.

C. Neutropenic FUO

1. Fever of 38.3°C (101°F) or higher on several occasions.
2. Fewer than 500 neutrophils/mm³ within 1 to 2 days.
3. Diagnosis uncertain after 3 days despite appropriate investigation, including at least 2 days' incubation of microbiologic cultures.

D. Human immunodeficiency virus (HIV)-associated FUO [89–93] (see Chapter 18)

1. Fever of 38.3°C (101°F) or higher on several occasions.
2. Confirmed positive serology for HIV infection.
3. Fever of more than 4 weeks' duration for outpatients or more than 3 days' duration in hospital.
4. Diagnosis uncertain after 3 days despite appropriate investigation, including at least 2 days' incubation of microbiologic cultures.

II. Causes of FUO [87,94,95]

A. Although infections are still the most common cause of FUOs, the incidence of multisystem or collagen vascular diseases remains significant and there is a decrease in the number of tumors presenting as FUOs. However, Barbado et al. [96] found that collagen vascular diseases, especially vasculitides, are more frequent (29%) than infections (11%). Endocarditis, abdominal abscesses, and hepatobiliary diseases have become less important causes of FUOs. Tuberculosis remains an important cause of FUO.

1. **Infections (23%–36%).** Tuberculosis, bacterial endocarditis due to slow-growing organisms, culture-negative endocarditis, localized suppurative process (within the biliary tract, liver, or kidney), intraabdominal abscesses, septic pelvic vein thrombophlebitis, and certain viral infections such as cytomegalovirus (CMV) and Epstein-Barr virus (EBV) should be considered. **In HIV-positive patients, however, opportunistic infections (OIs) account for most FUOs** and fever should not be attributed to HIV-infection itself without extensive investigation to rule out other infections [89–93]. Common OIs in the United States include tuberculosis, atypical mycobacterial infections, *Pneumocystis carinii* infection, disseminated fungal infections (e.g., histoplasmosis), and CMV infection. Infection due to *Coccidioides immitis* (Southwest United States), *Trypanosoma cruzii* (Latin America), and *Penicillium marneffeii* (Southeast Asia) are endemic in those regions [91,97,98].

10 1. Fever and Fever of Unknown Etiology

- 2. Neoplasms (7%–31%).** Lymphoma, leukemia, renal cell carcinoma, GI tumor, and metastatic ovarian carcinoma are the most common neoplasms associated with FUOs. In more recent studies of FUOs [95], there was a marked decrease in the incidence of neoplasms. This is believed to be due to the widespread use of ultrasonography and computed tomography (CT) scanning. In HIV-positive patients, tumors account for only 10% of FUOs, 90% of which are lymphomas [90–92]. Observational and time-trend data indicate that the incidence of Kaposi sarcoma (KS) and primary brain lymphoma have decreased, but suggest that current therapies have not had a proportionate effect on systemic non-Hodgkin lymphomas [99–101]. It is likely that lymphoma will become proportionately more important as an FUO in these patients.
- 3. Collagen vascular diseases (9%–20%).** Systemic lupus erythematosus, rheumatoid arthritis, mixed connective tissue diseases, temporal arteritis, juvenile rheumatoid arthritis of the adult (adult Still disease), and vasculitis can present as an FUO.
- 4. Miscellaneous causes (17%–24%)** include drug fever, recurrent pulmonary emboli, inflammatory bowel disease (especially regional enteritis), sarcoidosis, and factitious or fraudulent fever. However, there are numerous unusual causes of FUOs [102,103].
- 5. In adults, 10% of FUOs remain undiagnosed.** In Knockaert's study [95], there was a noticeably higher incidence of undiagnosed cases (26%). This is because, in contrast to other reports, Knockaert and co-workers [95] categorized as FUOs fever in patients with diseases of unknown origin, such as granulomatous hepatitis or pericarditis; these were labeled *nondiagnosis* rather than being relegated to the miscellaneous category [87]. It is reassuring, though, that the vast majority of patients that remain undiagnosed do well in follow-up [104–106].
- 6. The spectrum of causes of FUOs among community hospital patients and the elderly (≥ 65 years old) is similar to the general population, with a few noticeable differences [107–109].** In the community hospital group, infections (abscesses, tuberculosis, endocarditis, acute HIV infection, and CMV) represented approximately 33% of the FUO population; neoplasms, primarily lymphomas, were present in 24% of the population; and 16% had collagen vascular diseases. Alcoholic hepatitis and recurrent pulmonary emboli are relatively common in this group. The most common causes of FUOs in the elderly are leukemias, lymphomas, abscesses, tuberculosis, and temporal arteritis.

B. Factitious fever refers to fever produced artificially by the patient.

- 1. A diagnosis of factitious fever [110]** should be considered in any FUO, especially in young women or persons with medical training, or if the patient looks clinically well and there is a disparity between temperature and pulse. The advent of digital thermometers has reduced the frequency of this diagnosis.
- 2. Absence of the normal diurnal pattern** should alert the physician to this diagnostic possibility.
- 3. Some practitioners recommend several temperature determinations in the presence of a nurse or physician.** Others have suggested the use of a thermocoupling device (electric thermometer) to allow immediate recording of results. Urine temperatures also have been suggested as a means to uncover factitious fever due to manipulation of the glass thermometer.
- 4. The diagnosis should be considered especially in paramedical personnel.**

C. Fraudulent fever is akin to factitious fever. In this case, the fever is authentic but is induced by the patient's self-inoculation or ingestion of foreign material.

III. Approach to the FUO.

Although the clinical investigation of a patient with FUO should be individualized, Knockaert [111] has developed a detailed diagnostic strategy for the patient with an FUO. This report also presents an algorithmic approach to the diagnosis of FUOs.

- A. Rule out common infections or other causes of fever.** Although it may seem obvious, initial assessment of the nonseptic febrile patient must rule out the common infections causing fever, including respiratory and urinary tract infections, wound and pelvic infections, GI infections, and superficial and deep phlebitis, including intravenous-related phlebitis in hospitalized patients.

B. Determine whether the patient has a true FUO. Before launching what may be an intensive workup for FUO, the fever should be present, at least by history, for a prolonged period as noted above, and the routine evaluation should be unremarkable. Only then may a case be defined as an FUO.

C. Workup of the patient with a true FUO.

1. A careful history is essential to discover clues from the patient's travel background, exposure to tuberculosis, animal exposure, drug use, work environment, hobbies, geographic origins, HIV risk factors, and other habits. With the differential diagnosis of FUO in mind, the physician explores each of the diagnostic categories. If the workup is unrewarding initially, **serial follow-up histories** may provide additional clues to a specific diagnosis. Interviews with the immediate family or close relatives may be helpful.

2. A complete and careful physical examination should be repeated if the patient is believed to have a true FUO. Again, the differential diagnosis is kept in mind and particular attention is directed to the skin, lymph nodes, hepatosplenomegaly, rectal and pelvic examination, and cardiac examination. **Serial physical examinations are crucial!** While the patient is hospitalized, his or her clinical status might change, and a new lymph node, murmur, or rash could appear and provide an important clue to the diagnosis.

3. Laboratory examinations and biopsies. By definition, the routine complete blood count, urine and sputum cultures, chest radiograph, and other determinations have already been unrewarding in the early evaluation of the FUO. Studies of antibodies to EBV and CMV, especially IgM antibodies, may be helpful (see Chapter 9). **Further testing must be individualized**, and a variety of tests are available.

IV. Laboratory and diagnostic aids in the FUO evaluation

A. Blood cultures. Advances in blood culture methodology have resulted in earlier detection of pathogens causing bloodstream infections [112]. **In continuous bacteremia** (such as endocarditis), three sets of blood cultures will be adequate to recover the organism in more than 95% of cases [113]. However, any oral or parenteral antibiotic therapy given before the initial blood cultures are drawn may inhibit the growth of the organisms (e.g., in partially treated BE). In addition, some fastidious organisms may take several days or weeks (e.g., *Brucella*) to grow or may have special growth requirements [112]. Fungal and mycobacterial blood cultures are of particular importance in HIV-positive patients [89–93]. **Culture-negative endocarditis** is a recognized entity that accounts for 5% to 15% of cases of endocarditis (see Chapter 12) [114]. It can occur even in patients who have had no prior exposure to antibiotics and is well described in the literature of the preantibiotic era. **This diagnosis should be considered in the patient with FUO, negative initial blood cultures, and underlying cardiac disease** (such as rheumatic or congenital heart disease). When possible, infectious disease consultation should be sought for such patients before one commits a patient to a prolonged course of antibiotics.

B. Sedimentation rate. The erythrocyte sedimentation rate (ESR) is a nonspecific marker of inflammation and can be elevated in noninfectious conditions, for example, in uremia. In the older patient (≥ 55 years) with FUO and an ESR in excess of 100 mm/h, the diagnosis of **temporal arteritis** should be considered. The patient's history should be reviewed carefully with respect to headaches, visual problems, and myalgias. **When temporal arteritis is suspected, the patient should undergo bilateral temporal artery biopsies** for definitive diagnosis. Initiation of high-dose steroid therapy (e.g., oral prednisone 60–80 mg/day) may help to prevent blindness, a major complication of temporal arteritis.

C. Collagen vascular disease screening. Because up to 15% of adult patients with FUO have a collagen vascular disease, histories must be elicited carefully.

1. ESR and antinuclear antibody studies generally are used for screening.

2. Muscle or skin biopsies (or both) of suspicious rashes may uncover a vasculitis.

D. Serology. As a general rule, serologic tests assume importance when a fourfold or greater increase in titer can be demonstrated (see Chapter 25). Serologic studies should only be ordered if potential diagnostic clues to a particular infection exist. In

a recent prospective study of 167 patients, serologic tests were never helpful in the absence of diagnostic clues [115].

1. **An acute-phase blood sample** should be drawn; serum should then be frozen and set aside in an FUO evaluation. This will assure an early specimen if careful serologic studies are indicated as the workup proceeds.
2. **Blood for convalescent titer** usually is drawn 2 to 4 weeks after the acute titer.
3. Occasionally only a single serum specimen is available for study. Characteristic titer elevations may be very suggestive, or even diagnostic, in certain clinical settings. For example, an indirect fluorescent antibody titer of 1:1,024 or greater to *Toxoplasma gondii* is suggestive of toxoplasmosis. A specific IgM antibody response is highly suggestive of a recent primary infection, more so than is the presence of IgG antibody.

E. Skin tests

1. **The intermediate purified protein derivative (PPD) test** should be performed routinely unless the patient is known to be a reactor. A negative test should be repeated in approximately 1 week to test for a “booster effect” (see Chapter 11) [116]. Anergy testing is not routinely recommended [117].
2. **Fungal skin tests** generally are not helpful (see Chapter 17). For example, skin tests with histoplasmin and blastomycin are not useful diagnostically, especially in an endemic area. In addition, these tests may induce an antibody response that would either lead to a false diagnosis or preclude future serologic studies.

F. Imaging

1. **CT and magnetic resonance imaging (MRI).** The advent of modern imaging modalities such as CT and MRI has almost completely supplanted older radiographic techniques such as intravenous pyelograms, nephrotomograms, and barium imaging of the GI tract. Due to their greater resolution, they provide a sensitive tool for identifying and localizing intracranial, intraabdominal, and intrathoracic abscesses. MRI with gadolinium contrast is the study of choice for diagnosing intracranial lesions in patients with HIV infection. Due to their wide availability, CT scan and ultrasonography are often used in a blind fashion for detection of intraabdominal abscesses and lesions; thus, their overall diagnostic yield per test performed has been quite low [118]. CT imaging is also used in the guidance of percutaneous procedures in order to enhance the diagnostic yield.
2. **Ultrasonography. Abdominal or pelvic studies** may help localize an abscess or differentiate a solid from a cystic mass. Ultrasonography is useful in visualizing hepatobiliary and renal abnormalities. **Transesophageal echocardiography** has added a new dimension to the sensitivity of detecting valvular vegetations, especially those on prosthetic valves [119]. **Venous duplex imaging** may be useful in identifying cases of deep venous thrombosis as a cause of FUO [120].
3. **Radionuclide scans.** Of the various radiopharmaceutical-based tests available, gallium-67 and indium 111–labeled leukocyte scanning have the highest yield [121]. Indium 111–labeled polyclonal human immunoglobulin (HIG) has not proved to be superior to ¹¹¹In leukocyte scanning [121]. Total-body gallium scanning has occasionally been useful in detecting occult abscesses and lymphoma as well as thyroiditis and unusual tumors, such as leiomyosarcoma and pheochromocytoma. Indium 111 is less likely to accumulate in noninfected foci. Bone scans and ¹¹¹In scans appear to be useful in distinguishing osteomyelitis from a cellulitis that is in close proximity to the bone. Three-phase bone scanning frequently is not specific enough to delineate cellulitis clearly from osteomyelitis (see Chapter 5). More recently, [(18)F]fluoro-deoxyglucose positron emission tomography scan was used in 58 consecutive cases of FUO and was helpful in reaching a diagnosis in 35% of abnormal scans as compared with 25% with gallium scintigraphy [122].

G. Tissue biopsies

1. **Lymph nodes** that are pathologically enlarged should be examined via biopsy early in the workup, because underlying malignancy or granulomatous disease might be uncovered.
2. **Liver.** In patients with hepatomegaly, abnormal liver function test results, or possible miliary tuberculosis or disseminated fungal disease, a liver biopsy may

provide the diagnosis either by histologic examination or by culturing. **The biopsy should be cultured aerobically and anaerobically and for acid-fast organisms and fungi.** The yield in HIV-related FUO appears to be much higher [123]. Rarely, the organism involved in infective endocarditis may be cultured from the liver biopsy.

3. **Bone marrow biopsy.** The overall yield for bone marrow biopsy in FUO is less than 15% [87,94,95], but, as for liver biopsy, it is useful in diagnosing disseminated mycobacterial and fungal infection in the setting of HIV infection, where its diagnostic yield has been as high as 40% [124].
4. **Skin nodules and rashes** may provide a clue to metastatic disease or an underlying vasculitis.
5. **Temporal artery biopsy** (bilateral) may be diagnostic in the elderly patient with an unexplained elevated ESR.

H. Indications for exploratory laparotomies in patients with FUO. Exploratory laparotomy seldom is indicated if scanning procedures, ultrasonographic studies, and percutaneous biopsies are used appropriately. Laparotomy is not considered a routine procedure but is reserved as a concluding step in the workup of selected patients [125–127] and for use when abnormalities apparent on scanning need clarification, biopsy, or possible drainage. However, laparoscopy should be considered first if it is technically feasible [128].

1. **Therapeutic drug trials in patients with FUO.** In general, the use of medication in the absence of a definitive diagnosis is discouraged. However, a therapeutic trial may be justified if, after one has done careful investigation and culturing, the clinical and laboratory data support certain etiologies, but a definitive diagnosis cannot be reached. **Infectious disease consultation should be sought in such situations.** A trial of antibiotics in culture-negative endocarditis, and of antituberculous agents in granulomatous hepatitis and cases suspicious for tuberculosis can be life saving.

V. Miscellaneous diseases that cause FUOs

- A. **Granulomatous hepatitis** may be documented by a liver biopsy performed as part of the FUO evaluation. This represents a histologic reaction pattern with many etiologies, among which are tuberculosis, histoplasmosis, brucellosis, Q fever, syphilis, sarcoidosis, Hodgkin disease, berylliosis, Wegener granulomatosis, and drug reactions.
- B. **Juvenile rheumatoid arthritis** is characterized in children by fever, polyarticular or monoarticular arthritis, salmon-colored maculopapular rash, generalized lymphadenopathy, hepatosplenomegaly, and, occasionally, pericarditis (rarely, myocarditis). Iridocyclitis occurs frequently and should be sought by an ophthalmologist, even if ocular symptoms are minimal. Rheumatoid factor is absent. A similar clinical picture may be seen in young adults.
- C. **Familial Mediterranean fever (periodic disease)** is an autosomal-recessive disease characterized by periodic fevers contracted predominantly by men, particularly those of Italian, Sephardic Jewish, or Irish descent. Peritonitis, pleuritis, arthritis, and skin lesions may accompany the fever.
- D. **Whipple disease** is seen in middle-aged to older men and is characterized by low-grade fever, progressive weight loss, diarrhea, malabsorption, arthralgias, abdominal pain, increased skin pigmentation, and lymphadenopathy. Jejunal biopsy can establish the diagnosis.
- E. **Bacterial hepatitis** is comprised of chronic nonsuppurative bacterial infections of the liver (e.g., *Staphylococcus aureus*) other than those causing a granulomatous reaction. Fever and minimally elevated alkaline phosphatase may be the only evidence of liver involvement. A liver biopsy will be helpful and, as usual, the biopsy specimen should be cultured aerobically and anaerobically.
- F. **Hyperimmunoglobulinemia D and periodic fever** is a rare syndrome of fever in children of Dutch ancestry that has been linked to a deficiency of mevalonate kinase [129]. The clinical picture is similar to that of familial Mediterranean fever.
- G. **Ehrlichiosis.** The majority of symptomatic patients with ehrlichiosis present with an abrupt onset of fever, chills, and headache, often accompanied by nausea, myalgias, arthralgias, and malaise. Roland et al. [130] reported six patients in whom the principal finding was protracted fever ranging from 17 to 51 days' duration. The

14 1. Fever and Fever of Unknown Etiology

diagnosis was delayed due to lack of consideration of the diagnosis, patient's delay in seeking medical care, or both [130]. See Chapter 21.

H. Other unusual causes of FUO have been described [102,103].

- VI. Recurrent or episodic FUO.** In some patients with a classic FUO, the fever spontaneously resolves for at least 2 weeks and then recurs. On further workup, approximately 20% of these patients will have demonstrable underlying infection, tumor, or connective tissue diseases [106]. Miscellaneous causes (e.g., Crohn disease, factitious fever) are common. Overall, these patients generally do well [106] and often can simply be followed carefully and assessed serially as outpatients.

2. SEPSIS

Nancy J. Dorman

The development of penicillin during World War II transformed the practice of medicine dramatically. The advent of antimicrobial therapy in the latter half of the 20th century was associated with a precipitous decline in mortality and morbidity from infections. Since that time, however, the incidence of severe sepsis is rising, and associated mortality rates remain high despite an ever-increasing armamentarium of antibiotics and continued advances in critical care medicine.

The leading cause of death in intensive care units, sepsis is one of the most important modifiable causes of death overall in the United States. Lacking uniformly accepted definitions and specific International Classification of Diseases codes for septic shock and other life-threatening complications of infection, typical morbidity and mortality reports probably do not reflect the true magnitude of sepsis-associated disease. Nevertheless, based on discharge codes for bacteremia and septicemia, the Centers for Disease Control and Prevention reported a distressing 139% rise in the incidence of sepsis from 1979 to 1987 [1]. Figures reporting 500,000 septic episodes per annum in the United States underestimate the incidence of sepsis. More recent estimates conclude there are 751,000 new cases of sepsis annually in the United States, leading to nearly a quarter of a million fatalities [2], rivaling myocardial infarction as one of the most important causes of death in the developed world. Furthermore, because most studies focus on short-term outcome (<30 days), reported 30% to 50% mortality rates underestimate the overall impact of sepsis on survival. Independent of underlying disease, sepsis is associated with increased mortality risks for at least 1 year and probably as long as 5 years beyond the acute septic episode [3].

Reporting problems aside, the incidence of sepsis and associated mortality rates are rising despite better understanding of underlying pathophysiology, technologic improvements in critical care, and advances in antimicrobial therapy. In addition to improved reporting, factors that probably contribute to the increasing incidence of sepsis include the expanding use of invasive procedures, emergence of increasingly resistant pathogens, increasing number of patients with compromised immune status, and aging populations. Medical progress, undoubtedly, drives the rising incidence of sepsis. Comorbid illnesses are major outcome determinants, and patients presenting with sepsis today typically have severe underlying conditions not seen a few decades ago. Despite aggressive antimicrobial therapy and intensive medical care, mortality rates for sepsis remain high because we lack specific treatment for the systemic inflammatory response triggered by infection and reliable diagnostic assays to identify those patients at risk for developing severe sepsis.

A practical approach to sepsis requires working knowledge of current terminology, fundamental understanding of etiology or pathophysiology, appropriate utilization of innovative diagnostic technology, clinical application of new therapeutic interventions as these become available, and implementation of advancing strategies for prevention.

I. Definitions

Sepsis is a syndrome, not a specific clinical entity. Over the past two decades, clinical trials examining new treatment strategies for septic shock generated disappointing failures and occasional surprising toxicities (see section IV). Similar to the difficulties determining accurate incidence and prevalence statistics for sepsis, a lack of uniformly accepted definitions hinders clinical research. Without consistent clinically applicable definitions for sepsis and its major sequelae, appropriate patient enrollment in multicenter clinical trials is unfeasible. Until rapid, sensitive, and specific diagnostic laboratory tests become available, sepsis remains a bedside diagnosis defined in clinical terminology.

In 1992, the Society of Critical Care Medicine (SCCM) and the American College of Chest Physicians (ACCP) published consensus definitions for sepsis and organ failure along with guidelines for the use of innovative therapies in sepsis [4]. These definitions serve as a framework for consistent clinical descriptions of sepsis and its sequelae, providing a common language among clinicians and investigators from center to center. Acknowledging the complexity of the systemic inflammatory response to infection and the importance of timely diagnosis, the definitions are intentionally rather simple in

context and broad in scope. Some experts assert that broad nonspecific ACCP/SCCM consensus definitions lack practical applicability, especially in clinical research protocols. ACCP/SCCM Consensus Conference participants recognized these problems with their current definitions, anticipating modifications as our understanding of sepsis evolves [4]. Until future refinements improve the discriminatory value of sepsis terminology, these definitions provide clinicians and researchers with a consistent vocabulary that is currently accepted widely in clinical practice and in research.

A. Infection describes a microbial phenomenon characterized by an inflammatory response to the presence of microorganisms or the invasion of otherwise sterile host tissues by those organisms.

B. Bacteremia describes the presence of viable bacteria in the blood. Similarly, the presence of other pathogens in the blood would be described appropriately as viremia, fungemia, or parasitemia. Used previously to describe the presence of microorganisms or their toxins in the blood, the term septicemia was eliminated from the Consensus Conference definitions for sepsis because of ambiguities that cause confusion and difficulties in data interpretation.

C. Systemic inflammatory response syndrome (SIRS) denotes a generalized inflammatory response to a medley of severe clinical insults. Perhaps the most controversial definition from the Consensus Conference [5,6,22,23], the term SIRS was not developed as a stand-alone entity and should be viewed in combination with other clinical information [7]. As developed, SIRS deliberately presents low threshold clinical evidence for defining systemic inflammatory response regardless of cause. The definition of SIRS may be refined as prospective studies using the consensus definitions identify new variables that will improve prognostic accuracy and clinical applicability [8]. As it stands currently, the new term highlights the systemic inflammatory response as a syndrome, or constellation of signs and symptoms, that warrants early recognition and aggressive search for the underlying cause. SIRS is triggered by a number of noninfectious pathologic processes including, but not limited to, pancreatitis, burns, severe trauma, major tissue injury, ischemia, hemorrhagic shock, immune-mediated organ injury, and exogenous administration of putative mediators (e.g., **certain cytokines such as tumor necrosis factor [TNF]**) (Fig. 2.1). During diagnostic evaluation, only physiologic alterations representing an **acute change from baseline without other known causes (e.g., chemotherapy-induced neutropenia, drug-induced tachycardia, etc.)** should be used as clinical criteria to define SIRS. The term SIRS describes the presence of two or more of the following clinical manifestations, including but not limited to

1. Temperature higher than 38°C or lower than 36°C;
2. Heart rate higher than 90 beats/min;
3. Tachypnea (**respiratory rate >20 per minute**) or hyperventilation (**PCO₂ <32 Torr**);
4. White blood cell count alterations more than 12,000/ μ L or less than 4,000/ μ L or the presence of more than 10% immature neutrophils.

D. Sepsis is defined as the systemic inflammatory response to infection. In association with infection, the manifestations of sepsis are the same as described above for SIRS. The term sepsis should be reserved for those instances when the clinical manifestations of systemic inflammation are related directly to an infectious process. Recognizing that sepsis and its sequelae represent a continuum of clinical and pathophysiologic severity, the degrees of which may independently affect prognosis, additional definitions are used to describe clinically recognizable stages of sepsis.

E. Severe sepsis describes sepsis associated with organ dysfunction, hypoperfusion, or sepsis-induced hypotension. Clinically recognizable hypoperfusion and perfusion abnormalities include but are not limited to

1. Lactic acidosis;
2. Oliguria;
3. Acute mental status changes.

F. Sepsis-induced hypotension is defined by a systolic blood pressure less than 90 mm Hg or a decrease of at least 40 mm Hg from baseline in the absence of other causes (e.g., **cardiogenic shock**).

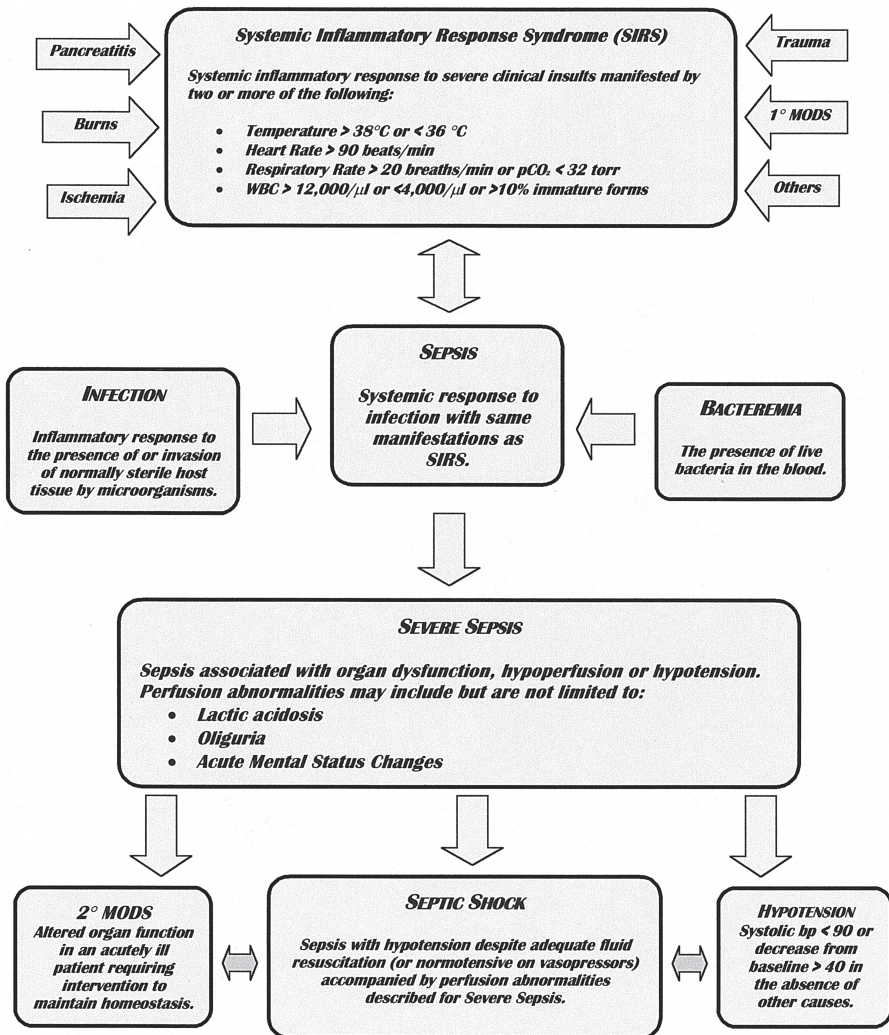

FIG. 2.1 Sepsis-related definitions and interrelationships. (Based on Bone RC, Balk RA, Cerra FB, et al. American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference. Definitions for sepsis and organ failure and guidelines for the use of innovative therapies in sepsis. *Crit Care Med* 1992;20:864–874).

G. Septic shock describes a subset of severe sepsis characterized by sepsis-induced hypotension unresponsive to adequate volume resuscitation, in addition to hypoperfusion abnormalities or organ dysfunction. The term **septic shock** still applies to patients with **severe sepsis** whose systolic blood pressure normalizes on vasopressor or inotropic support before developing hypoperfusion abnormalities or organ dysfunction.

H. Multiple organ dysfunction syndrome (MODS) describes a syndrome characterized by a continuum of physiologic derangements in organ function such that

homeostasis cannot be maintained. Older terminology referring to organ failure implies that organ function is present or absent, thus excluding the dynamic physiologic process more characteristic of the syndrome encountered clinically. As defined during the Consensus Conference, multiple organ dysfunction may be absolute or relative but is more readily viewed as a continuum of change over time. Currently, there are no universally accepted criteria for quantifying organ dysfunction in MODS, but consensus criteria may evolve from outcomes data in the near future. MODS is classified as **primary** or **secondary** based on two pathogenetic pathways that are not mutually exclusive.

1. **Primary MODS** occurs early and is directly attributable to a clearly defined insult. One example would be chest trauma leading to lung dysfunction. The initiation and progression of primary MODS stem from direct response to a specific insult rather than host systemic inflammatory responses. Primary MODS can trigger SIRS, subsequently instigating other organ system dysfunction (secondary MODS).
2. **Secondary MODS** occurs as a consequence of host responses identified within the context of SIRS rather than as a direct response to a specific insult. Secondary MODS characteristically develops after a latent period separating it from the primary insult and is most commonly a complication of severe sepsis. Secondary MODS is viewed as a consequence rather than a cause of SIRS.

II. Etiology

Invading pathogens do not cause septic shock directly. Infection triggers physiologic changes evolving from sophisticated and exquisitely complex interplay among multiple mediators. Over the past decade, important scientific advances identifying cytokine cascades provided a solid foundation for understanding the pathophysiology of sepsis. Despite these major advances, medical science has only begun to scratch the surface of comprehension prerequisite to developing reliable therapeutic interventions for treating severe sepsis and septic shock. Early excitement surrounding the discovery of new inflammatory mediators engendered enthusiastic search for therapeutic agents that attenuate adverse physiologic responses to infection. Unfortunately, therapeutic agents used successfully to treat sepsis in animal models typically lack efficacy in clinical trials [14], as seen with multiple earlier studies evaluating cyclooxygenase (COX) inhibitors, antiendotoxin antibodies, anti-TNF antibodies, and interleukin (IL)-1 receptor antagonists. Clearly, there will be no single “magic bullet” for treating sepsis. As medical science has unraveled the complexities of host–pathogen interaction, interest has shifted from intervening at the level of single mediators toward modifying the **interplay** among important pathways.

The view that severe sepsis stems from a predominance of proinflammatory mediators is now challenged as an over-simplification of the complex interplay among intracellular, intercellular, local, and systemic responses to infection. Indeed, recent arguments question the concept that overwhelming systemic inflammation causes severe sepsis, focusing on the notion that although local response to infection is proinflammatory, the clinically manifest systemic response overall is predominantly antiinflammatory [10]. Most likely, the **balance** between **proinflammatory** and **antiinflammatory** processes determines the final outcome during infection, with deleterious sequelae resulting when the scales tip too far in either direction (Fig. 2.2).

Whereas medical science once focused on pathogen virulence factors, current sepsis research has shifted toward exploring genetic variations in host response as outcome determinants [11–13]. Clearly, as biomedical research strives to define better ways to treat severe sepsis, clinicians must come to grips with a growing array of immunologic mediators and, eventually, genetic variations therein if they hope to apply new therapeutic options. Although detailed discussion of all potential pathogen- and host-derived inflammatory mediators is beyond the scope of this text, certain key areas of current interest warrant consideration, recognizing there are still major gaps in our knowledge base and that new horizons in sepsis research are expanding rapidly.

A. Cytokines are small pleiotropic proteins that signal cells and orchestrate the immune response by binding to appropriate receptors on multiple tissues [16,19]. The birth of “cytokine biology” dates back to the isolation of “endogenous pyrogen” and

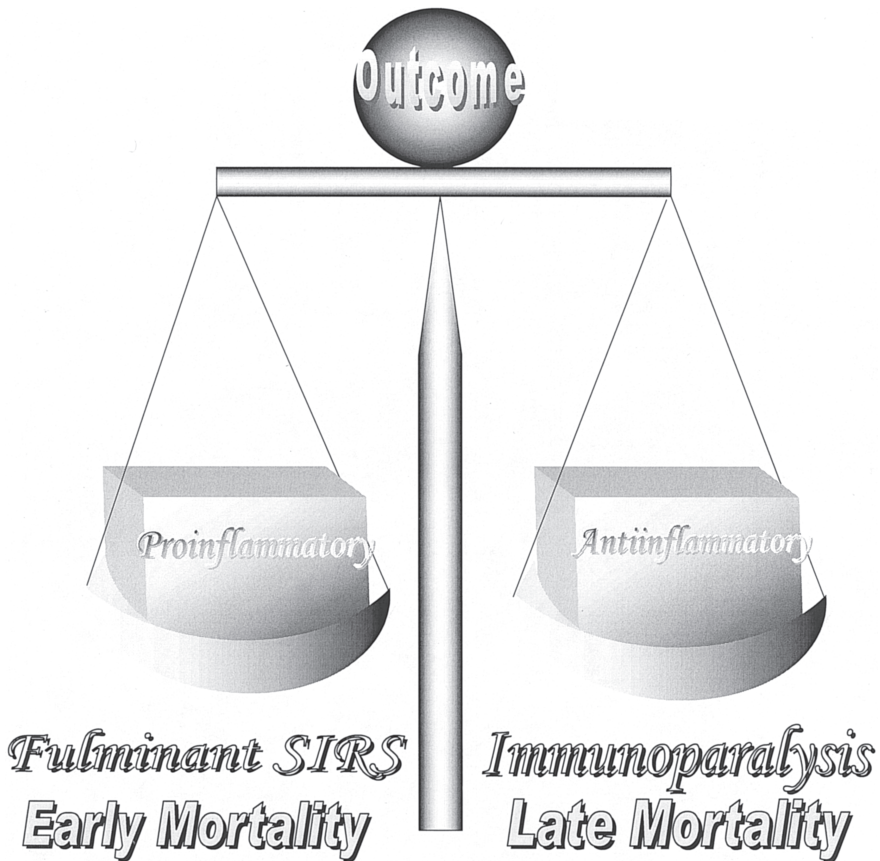

FIG. 2.2 Balance between proinflammatory and counter-regulatory antiinflammatory events in response to infection determines clinical outcome. Infection triggers several inflammatory cascades, including proinflammatory cytokine, complement, coagulation system, and neutrophil activation. Compensatory antiinflammatory mechanisms, including antiinflammatory cytokine production, natural inhibitor release, stress hormone response, and immune cell inactivation, regulate the inflammatory response to prevent systemic toxicity. Localized proinflammatory response is essential for host defense against microbial invasion. Excessive proinflammatory response causes systemic toxicity clinically manifested as sepsis. Excessive antiinflammatory response causes immunoparalysis associated with increased propensity for overwhelming infection and late mortality.

the subsequent recognition that IL-1 is a potent pyrogen. Since that time, a number of cytokines have demonstrated pyrogenicity, linking the ancient concept of fever to a present-day understanding of inflammation-induced perturbations in cell biochemistry [15]. Historically, different research groups discovered certain cytokines simultaneously, each applying various descriptive names to a single mediator. For example, IL-6 has also been called B-cell stimulating factor and hybridoma growth factor. Cytokine nomenclature remains rather confusing. The term interleukin improved nomenclature somewhat but is still misleading because cells other than leukocytes may produce these factors. Currently, when a cytokine is

characterized sufficiently, it is assigned an IL designation (e.g., **IL-1**, **IL-2**, **IL-6**, etc.). To date, there are 18 cytokines with the name IL. Despite these more recent designations, certain cytokines still bear descriptive names such as TNF, colony-stimulating factor (CSF), and interferon, even though these names tend to represent only one of many biologic activities. In addition to confusing nomenclature, clinical application of the cytokine network is complicated further by the fact that any given cytokine may have divergent biologic effects in different body compartments; this is highlighted in Munford and Pugin's discussion of context-dependent mediator activity regulating the inflammatory response [10]. Most cytokines are produced by more than one cell type, and many cytokine-producing cells generate more than one cytokine. Any given cytokine may regulate its own production in addition to modifying the release of other cytokines or similar components of the regulatory network. Host defense mediators and cytokine networks are examined in a number of texts and recent publications [15–19]. Although a detailed review of cytokine network intricacies is beyond the scope of this text, fundamental understanding of currently recognized key mediators is essential for a practical approach to applying innovative diagnostic tests and implementing new treatment options in sepsis management plans.

1. **IL-1** is actually a designation for two separately encoded polypeptides, IL-1 α and IL-1 β . Both recognize the same cellular receptors, but IL-1 α appears to regulate intracellular events and local effects, whereas IL-1 β is more involved in systemic effects. Their naturally occurring antagonist, IL-1 receptor antagonist, binds to the same receptors. IL-1 is a proinflammatory cytokine produced by many cell types during acute and chronic inflammation, but mononuclear cells, particularly macrophages, are a major source. IL-1 has highly diverse biologic activities, reproducing many physiologic changes observed in septic patients. Fever, acute phase response, and corticotrophin release are major biologic effects of IL-1. Therapies directed against IL-1 for treating severe sepsis are discussed in section IV.
 2. **TNF- α** is a proinflammatory cytokine and a major mediator of septic shock. Generated predominantly by T cells and macrophages, TNF functions primarily in regulating cell proliferation and apoptosis. This proinflammatory cytokine recruits and activates neutrophils, lymphocytes, and macrophages, in addition to stimulating cytokine, eicosanoid, and acute phase protein (APP) production. TNF administration reproduces many of the physiologic and laboratory changes associated with severe sepsis. Therapies developed to counteract the effects of TNF in sepsis are discussed in section IV.
 3. **IL-6** has both proinflammatory and antiinflammatory properties by virtue of diverse biologic activities. IL-1 and TNF stimulate the release of IL-6, which subsequently influences a number of inflammatory responses. IL-6 plays a major role in the APP response, stimulating hepatocytes to produce noncytokine proteins such as C-reactive protein (CRP), fibrinogen, α_1 -antitrypsin, serum amyloid A, and α_1 acid glycoprotein. In contrast to the more toxic effects of TNF and IL-1, exogenous IL-6 administration induces only mild symptoms such as fever and chills. Generally regarded as a proinflammatory cytokine, IL-6 also has antiinflammatory influences by decreasing TNF and IL-1 production and increasing circulating levels of the natural inhibitors, soluble TNF receptors and IL-1 receptor antagonist. IL-6 is present in the serum during sepsis, and levels correlate with the disease severity and outcome in patients with severe sepsis. Serum IL-6 measurement may provide useful diagnostic and prognostic data in patients with sepsis, as discussed in section III.
- B. CSFs** are growth factors produced by a number of cell lines such as monocytes, macrophages, endothelial cells, and fibroblasts. Four CSFs isolated and characterized to date are granulocyte CSF (G-CSF), granulocyte-macrophage CSF (GM-CSF), macrophage CSF (m-CSF), and IL-3 (multi-CSF). G-CSF and GM-CSF are available commercially, and growing clinical experience has prompted studies exploring their potential as adjunct therapy for infections (see section IV). Produced by a number of cell lines, G-CSF specifically targets neutrophil proliferation and activity, whereas GM-CSF has broader hematopoietic effects on multiple cell lines, particularly monocytes, macrophages, and eosinophils. G-CSF stimulates committed stem

cell proliferation and differentiation into mature neutrophils, mobilizes mature granulocytes from the marrow, and enhances neutrophil functions such as phagocytosis, oxidative burst, microbicidal activity, and chemotaxis. Unlike the proinflammatory effects on neutrophil function, G-CSF appears to have antiinflammatory effects on mononuclear cells. When exposed to endotoxin or other bacterial stimuli *in vitro*, whole blood from human volunteers treated with G-CSF generated less TNF than pretreatment samples [24]. Furthermore, antiinflammatory mediators IL-1 receptor antagonist and soluble TNF receptors increase after G-CSF treatment. Added to its previously known stimulatory effect on neutrophil antimicrobial function, the discovery that G-CSF attenuates TNF production and enhances antiinflammatory mechanisms fosters continued interest in clinical trials using G-CSF as adjunct therapy for treating infection. In contrast, animal studies suggest that GM-CSF increases circulating TNF levels and is actually associated with increased mortality in some infections. GM-CSF also increases leukotriene (LT) biosynthesis in mature human leukocytes [39]. Currently, recombinant human G-CSF (filgrastim) and GM-CSF (sargramostim) are available commercially for clinical use in the United States. Potential clinical applications for CSF in the management of sepsis are discussed in section IV (Table 2.1).

- C. **Chemokines** are small chemotactic cytokines that play a central role in trafficking inflammatory cell migration and extravasation. Chemokines also influence the inflammatory response by altering cytokine profiles and mediating leukocyte migration and degranulation. Chemokine receptors are an attractive target for therapeutic interventions to limit deleterious inflammatory responses [37].
- D. **Other mediators** implicated in sepsis include a vast array of substances ranging from acute phase proteins to phospholipase A₂ (PLA) with its resultant arachidonic acid (AA) metabolites and associated highly reactive oxygen species.

1. **PLA** plays a pivotal role in cellular metabolism by hydrolyzing the *sn*-2 acyl bond of phospholipids releasing free fatty acid (**commonly AA**) and 2-lysophospholipid. Decades ago, PLA was recognized as one of several enzymes comprising pancreatic secretions and snake venoms. More recently discovered diverse intracellular PLAs are now known to generate inflammatory mediator precursors. This association with inflammation prompts further research to characterize these enzymes with an eye toward developing new antiinflammatory agents [25].

Mechanical trauma, specific cytokines, growth factors, and other stimuli (e.g., **collagen and adenosine diphosphate in platelets, thrombin and bradykinin in endothelial cells**) initiate cell signals that activate PLAs with subsequent AA release. The resultant secondary mediators act in an autocrine fashion, orchestrating PLA activity via exquisitely intricate interplay that is currently only partially understood [26].

PLA appears to play a vital role in the pathogenesis of acute lung injury associated with infection (**acute respiratory distress syndrome [ARDS]**) [28], a common and potentially lethal consequence of sepsis for which there is no specific treatment beyond supportive measures [31,32]. Increased PLA activity associated with multiple organ failure in severely injured patients has spurred interest in investigating these enzymes as both prognostic markers and clinical targets for inflammatory processes [33]. PLA also appears to play an important role during pathogen invasion in infectious diseases such as bacterial meningitis [29]. Forthcoming advances in phospholipid and eicosanoid biology will likely engender novel therapeutics for treating harmful systemic inflammatory responses associated with sepsis [31].

2. **AA metabolites** are a class of lipid mediators also called **eicosanoids** based on their derivation from the parent 20-carbon polyunsaturated essential fatty acid. In addition to the somewhat better understood role of eicosanoids in inflammation [26], medical science is beginning to define lysophospholipid functions in cell signaling and immunity [27]. Nonsteroidal antiinflammatory drugs (NSAIDs) used commonly as antipyretics to reduce core temperature during infection impact eicosanoid production at many levels. Reducing infection-associated febrile response does not clearly improve outcome [50], and some would argue

that fever is potentially beneficial as a natural physiologic response to pathogen invasion [51,52]. Recently reviewing the clinical use of antipyretics in fever suppression, Aronoff and Neilson [53] cautioned against using antipyretics indiscriminately and, like others, advocated reserving NSAID use for clinical situations where infection-associated fever risks may outweigh benefits. Over the last few decades, it has become clear that most antipyretics work by inhibiting COX. Medical science, however, has yet to resolve how inhibiting this pivotal enzyme impacts host defense overall and whether shifting eicosanoid production can affect outcome by altering the balance between proinflammatory and antiinflammatory mediators.

a. Prostaglandins (PGs) are synthesized *de novo* by most cells in response to PLA-mediated AA release from membrane phospholipids. Prostaglandin G

(PGG) synthase, known more commonly as COX, converts AA into the initial eicosanoid intermediate endoperoxide PGG₂, which is rapidly hydrolyzed into PGH₂. COX currently has two recognized isoforms, known as COX-1 and COX-2. COX-1 is constitutively expressed in most tissues, minimally affected by proinflammatory stimuli, and considered responsible for homeostatic PG formation. In contrast, COX-2 activity is absent in most tissues until inflammatory or mechanical stress induces enzyme expression with resultant proinflammatory PG synthesis. Although oversimplified, this classification has found application as selective COX-2 inhibitors are now used clinically as analgesics and NSAIDs. Although PGH₂ formation is common to most cell types, its fate is more cell specific. For example, platelets convert PGH₂ predominantly to thromboxane, endothelial cells to prostacyclin, uterine cells to PGF_{α2}, and brain and mast cells to PGD₂. Extremely potent biologic mediators with very short half-lives, PGs typically exert direct biologic activity at or near their sites of synthesis. However, PGs interplay with other mediator cascades should be viewed within the context of a complex milieu, culminating either in systemic inflammation or its control. For example, PGE₂ induces biochemical changes that mediate features of inflammation such as edema [46] but can also downregulate host inflammatory responses [47], perhaps by enhancing lipoxin synthesis [45] in addition to feedback on COX-2. The biosynthesis and actions of PGs were reviewed recently [26]. Inhibiting COX-2 (**selectively or nonselectively**) impacts all “downstream” eicosanoid production.

- b. **Prostacyclin (PGI₂)**, synthesized by endothelial cells from COX-derived precursor PGH₂, is an extremely potent antiplatelet mediator and vasodilator with a short (**5-minute**) half-life. PGI₂ inhibits platelet aggregation, neutrophil attachment to endothelium, and endothelial cytokine production (IL-6, IL-8, TNF). High circulating prostacyclin levels are associated with increased mortality in patients with sepsis [34]. Although not required for the development of systemic hypotension, prostacyclin may mediate sepsis-induced increases in oxygen consumption, arterial hypoxemia, and lactic acidosis [35,36].
- c. **Thromboxane A₂**, the predominant AA metabolite synthesized by platelets, is an extremely potent vasoconstrictor with a fleeting (**30-second**) half-life. COX inhibitors such as NSAIDs block thromboxane A₂ production by decreasing PGH₂, the substrate for platelet thromboxane synthetase. Opposed by vascular endothelial cell derived prostacyclin, thromboxane A₂ is a powerful platelet aggregation inducer. High circulating thromboxane levels are associated with increased mortality in patients with sepsis [34] and apparently contribute to increased oxygen consumption, arterial hypoxemia, and lactic acidosis [36] exhibited during severe sepsis. Thromboxane production is essential for normal hemostasis and an important outcome determinant during vascular endothelium–platelet interplay.
- d. **LTs** are biologically active AA metabolites with potent proinflammatory characteristics. So named because they were discovered in leukocytes and share a characteristic conjugated triene feature, LTs are formed from AA by leukocyte 5-lipoxygenase via pathways unrelated to COX. LT synthesis is diminished by PLA inhibitors such as steroids but unaffected by COX inhibitors such as NSAIDs. Indeed, Samuelsson [38] discovered LTs two decades ago while searching for novel AA metabolites that might account for differences noted between the antiinflammatory effects of NSAIDs and steroids. It took an additional 15 years to develop anti-LT agents for treating human disease (see section IV). Collectively, LTs recruit and activate leukocytes, enhance vascular permeability, and induce vascular and nonvascular smooth muscle contraction. The slow-reacting substance of anaphylaxis, first described in 1938, is now recognized as a mixture of interrelated LTs. Interest in blocking LT synthesis to prevent allergic bronchoconstriction led to developing anti-LT drugs for treating asthma [40]. The cysteinyl-LTs (LTC₄, LTD₄, and LTE₄) cause

bronchoconstriction, vasoconstriction, endothelial contraction, and plasma extravasation (**1,000 times more potent than histamine**). The dihydroxy acid LTB₄, on the other hand, recruits leukocytes and induces neutrophil degranulation in addition to causing plasma extravasation [41]. Still in its infancy, LT research is evolving beyond asthma therapy and exploring potential intervention in other inflammatory diseases, including sepsis [42,43].

- e. **Lipoxins** are AA derivatives that antagonize LT actions such as LTB₄-induced chemotaxis, leukocyte-endothelial adhesion, and plasma extravasation. Formed via 15-lipoxygenase pathways, lipoxins constitute a distinct eicosanoid class characterized as antiinflammatory mediators and modulators [44]. Lipoxins are generated at sites of injury or inflammation during cell-cell interactions, limiting the inflammatory response through a complex mediator-modulator network [45]. Although detailed discussion of these complex biochemical pathways is beyond the scope of this text, clinicians should recognize that drugs targeting one pathway (e.g., **COX-2 inhibitors, aspirin**) might impact other pathways with consequences yet unrecognized. For example, low dose aspirin-acetylated COX-2 no longer produces PG but remains catalytically active to generate biologically active endogenous lipoxin mimics, 15-epi-lipoxins, which likely contribute to aspirin's beneficial effects [44,45]. Other NSAIDs can negate this desirable aspirin effect. Medical science has not yet established clearly the temporal relationships among eicosanoid classes. Defining these complex temporal relationships is essential for understanding lipid mediator roles in inflammation and timing therapeutic interventions to control dangerous sequelae without paralyzing appropriate immune function. NSAIDs feasibly have unrecognized effects on sepsis-induced inflammation and its resolution. Presently it is uncertain what impact the pervasive use of NSAIDs as antipyretics might have on clinical outcome in patients with severe sepsis.
3. **Platelet-activating factor (PAF)** is a proinflammatory cell membrane phospholipid metabolite implicated in the sepsis cascade [48,49]. PAF amplifies inflammatory mediator release and produces many physiologic changes associated with septic shock. Many cell types, including neutrophils, monocytes, basophils, eosinophils, lymphocytes, endothelial cells, and platelets, produce PAF from phospholipase-generated lysophospholipids. Proinflammatory cytokines and other factors that activate PLA, *de facto*, also trigger PAF production. Conversely, drugs that inhibit PLA, such as glucocorticoids, decrease PAF production. PAF binds to specific receptors present on numerous inflammatory cells, activates neutrophils, aggregates platelets, and facilitates nitric oxide (NO) production. PAF is implicated in sepsis-associated coagulation abnormalities, pulmonary hypertension, myocardial depression, and gut ischemia. Like other proinflammatory mediators, PAF increases during sepsis. Furthermore, the enzyme responsible for degrading PAF to an inactive metabolite is decreased in patients who die from sepsis [54]. The important role PAF plays in the sepsis cascade prompted research into developing antagonists that prevent associated adverse physiologic events. Encouraging results from experimental studies culminated in clinical trials investigating PAF receptor antagonist use for treating patients with severe sepsis (see section IV).
 4. **NO** plays a central role in regulating vascular tone and determining responsiveness to endogenous and exogenous vasopressors [55]. NO is formed from the amino acid L-arginine by the enzyme nitric oxide synthase (NOS). NOS exists in both constitutive (calcium/calmodulin-dependent) and inducible (calcium/calmodulin-independent) isoforms. The constitutive enzymes are found in endothelial (NOS III) and neuronal cells (NOS I), the former responsible for generating NO in response to shear stresses and vasorelaxing substances such as histamine, bradykinin, or acetylcholine. Normal function of this constitutive enzyme is essential for maintaining normal vasomotor tone. In contrast, inducible NOS (NOS II) is formed by endothelial cells, smooth muscle cells, macrophages, and cardiac myocytes in response to inflammatory mediators such as endotoxin, peptidoglycan, lipoteichoic acid, IL-1, TNF, and PAF. The inducible NOS generates

considerably more NO than its constitutive counterpart (**nanomolar vs. picomolar quantities**), accounting for the high levels of circulating NO noted in patients with septic shock [56]. NO activates guanylate cyclase, increasing cGMP levels with subsequent smooth muscle relaxation. As reviewed recently [57], NO is thought to mediate the hypotension and low systemic vascular resistance (SVR) observed in sepsis. NO is also implicated in sepsis-associated myocardial depression. If NO attains cytotoxic concentrations, it might participate in tissue and, ultimately, organ damage during sepsis. On the other hand, NO also has beneficial potential. For example, NO-induced vasodilation promotes microvascular and visceral blood flow, serving as a counter-regulatory mechanism for thromboxane-initiated vasoconstriction. By decreasing platelet aggregation and leukocyte adhesion, NO may help counterbalance mediators that promote microvascular stasis and thrombosis [57]. Given the high circulating levels observed in septic shock, however, NO (**along with its biologically active metabolites**) is considered the penultimate mediator of sepsis-associated cardiovascular dysfunction. As such, controlling NO production to reverse sepsis-induced cardiovascular dysfunction and hypotension is an attractive interventional target. Accordingly, after promising results in animal models of sepsis, NOS inhibitors have entered clinical trials for treating patients with sepsis (see section IV).

5. **APPs** reflect systemic changes, or acute phase response, accompanying inflammation. Defined as a serum proteins whose concentrations increase (**positive APPs**) or decrease (**negative APPs**) by 25% during inflammatory disorders [58], the term APP is somewhat misleading in that altered levels occur in chronic and in acute inflammatory processes. Interest in APPs dates back to 1930 when CRP was identified in patient serum during the acute phase of pneumococcal pneumonia [59]. Numerous APPs are recognized currently. Medical science continues to identify new acute phase response markers and their significance in the sepsis cascade. Conditions that cause sizable changes in APP concentrations include infection, immune-mediated inflammatory conditions, tissue infarction, surgery, burns, trauma, and advanced cancer. Smaller changes can occur with strenuous exercise, childbirth, heatstroke, and even psychological stress. Induced by cytokines, particularly IL-6, individual APP level changes vary both in timing and degree during the acute phase response. More than just reflecting inflammatory syndrome presence and intensity, APPs influence the process [60]. Despite lacking specificity as diagnostic markers in sepsis, APP (**e.g., CRP**) measurements can provide useful prognostic and treatment response information. In contrast to APPs, increased procalcitonin levels observed in sepsis appear more specific for infection-induced inflammation. Pending further study, procalcitonin holds promise as a possible diagnostic marker for sepsis (see section III).
6. **Pathogen factors** responsible for triggering the cytokine cascade are numerous and diverse. In addition to immune cell interaction with intact invading pathogens, microbial components can also induce host inflammatory responses culminating in shock and multiple organ failure [68–70,76].
 - a. **Endotoxin**, a glycopeptide comprising a major portion of the outermost membrane in gram-negative bacteria, can induce pathophysiologic changes associated with severe infection. The discovery that endotoxin can cause septic shock generated prolific research investigating antiendotoxin strategies for treating sepsis. Notwithstanding promising data from animal studies, clinical trials using antiendotoxin therapies in patients with sepsis yielded disappointing results (see section IV).
 - b. **Other toxins**. Lacking endotoxin, gram-positive pathogens can cause septic shock clinically indistinguishable from gram-negative counterparts. Gram-positive bacterial cell wall components currently known to have proinflammatory activity include **teichoic acid**, **lipoteichoic acid**, and **peptidoglycan** [67,69,70]. **Exotoxins**, such as toxic shock syndrome toxin from *Staphylococcus aureus* or pyrogenic exotoxins from *Streptococcus pyogenes* (group A streptococci), and **enterotoxins**, such as staphylococcal enterotoxins A–H,

act as **superantigens** [69]. Superantigens induce excessive proinflammatory cytokine production and are associated with septic shock in humans.

- c. **Bacterial DNA** itself is proinflammatory, although approximately 10-fold less potent on a per weight basis than endotoxin [71].
- d. **Other bacterial components** also participate in host inflammatory response during infection [67,69]. A century ago, Jarisch [72] and Herxheimer and Krause [73] described a complex clinical reaction that occurred in patients within hours of initiating treatment for secondary syphilis. Now well known as the Jarisch-Herxheimer reaction, the complex systemic reaction to initial treponemal killing is manifested by fever, chills, headache, myalgias, hyperventilation, tachycardia, vasodilation, and hypotension. Although the responsible treponemal components are currently unidentified, recent data demonstrating that anti-TNF antibodies block the Jarisch-Herxheimer reaction suggest bacterial lysis induces cytokine production [74]. In gram-negative bacteria, a Jarisch-Herxheimer-like reaction was first described in patients treated for typhoid fever. Increasing understanding of what bacterial components induce host inflammatory responses and how these substances participate in sepsis-induced injury has renewed interest in studying antimicrobial-induced bacterial lysis. Certain cell-wall active antibiotics (e.g., **β -lactams**) cause a rapid cell lysis and release of proinflammatory or toxic bacterial components. The resulting sudden increase in proinflammatory bacterial components may sway clinical outcome. Studies to date suggest that bacterial component release varies across and within antibiotic classes. Antibiotic concentration also influences bacterial component release. High antibiotic concentrations are associated with less bacterial component release compared with drug levels closer to the minimum inhibitory concentration. Antibiotics that interfere with bacterial protein synthesis (e.g., **clindamycin, rifampin, macrolides, tetracyclines, quinolones, streptogramins**) inhibit bacterial component release. Combining protein synthesis inhibitor antibiotics with β -lactams attenuates the release of proinflammatory compounds from bacteria. In a recent review, Nau and Helmut [67] summarized current information from studies investigating antibacterials as inflammatory response modulators and how antibiotic choices may influence outcome in sepsis and meningitis. Although intriguing, pending confirmatory clinical trials, the therapeutic relevance of antibacterial immune modulating effects is currently unclear. However, these concepts are applicable in certain circumstances where antibiotics that inhibit protein synthesis are used for more than their bactericidal activity. For example, in addition to its bactericidal activity, clindamycin also inhibits toxin production providing added therapeutic advantage when included in antimicrobial regimens for treating patients with necrotizing fasciitis caused by group A streptococci (*S. pyogenes*). Despite current limited therapeutic application, choosing antimicrobial therapy based on potential immunomodulatory actions is not currently recommended for clinical routine.

E. Microbiology. Sepsis has an extensive microbiologic differential diagnosis. Although, in theory, virtually any microorganism can trigger systemic inflammatory responses, bacteria and fungi are the most common pathogens identified in practice. Unfortunately, cultures are often negative, leaving the microbiologic diagnosis uncertain in approximately 50% of patients with clinically suspected sepsis [61]. Nevertheless, data from documented bloodstream infections provide useful information, because bacteremias reflect the microbiology of sepsis.

1. **Among nosocomial bloodstream pathogens**, gram-positive organisms currently predominate [62]. However, gram-negative bacteremias are more common in patients with septic shock [63]. *Candida* and *Enterococcus* species currently comprise the third and fourth most common bloodstream isolates in hospitalized patients (63–65).
2. **Variou factors influence recovery of causal pathogens** from cultures such as prior antimicrobial therapy, source accessibility, specimen collection or handling, and microorganism growth characteristics.

3. **The microbiology of any given infection reflects its clinical source.** Likewise, the clinical source of infection determines its microbiology. For example, bacteremias from urinary tract sources most often involve gram-negative pathogens, whereas intravenous (i.v.) line sources more frequently involve gram-positive pathogens. Intra-abdominal and pelvic infections typically involve polymicrobial mixtures of gram-negative enteric flora, anaerobes, and enterococci.
4. **Identifying the infection source is crucial** for choosing appropriate antimicrobial therapy pending culture results or for treating clinically suspected sepsis in the absence of positive cultures. Sepsis-associated mortality risks increase when diagnostic evaluation fails to identify the causal pathogen(s) and clinical source of infection. Further details regarding the microbiologic etiology of specific infections are detailed in subsequent chapters spotlighting noteworthy infections.

III. Diagnosis

Timely diagnosis and early intervention are key factors in preventing morbidity and mortality from sepsis. Sepsis is most amenable to treatment when identified early during incipient phases, before irreversible damage occurs. Infection is often accompanied by suggestive clinical and laboratory findings such as fever, tachycardia, and leukocytosis. These signs and symptoms are not present in all patients with impending sepsis, however, and may be manifestations of inflammatory diseases with noninfectious etiologies. The clinical challenge lies in not only recognizing early signs of systemic infection, but also distinguishing between patients with infection and those with noninfectious causes of SIRS. In this era of increasing antimicrobial resistance, clinicians must balance the indiscriminate or unnecessary use of antibiotics against treatment delays that increase risk for infection-associated morbidity and mortality. Definitive microbiologic diagnoses eliminate the need for empiricism. Unfortunately, clinicians must deal frequently with clinical signs of sepsis in patients without evident sources of infection. **Common diagnostic dilemmas** stem from wide variation in clinical signs and symptoms; classic signs of sepsis without clinically apparent source; false-positive cultures due to contamination or colonization; false-negative cultures due to fastidious pathogens, prior antimicrobial therapy, or improper collection techniques; and lack of specific and sensitive clinical or laboratory parameters that distinguish between infection and other causes of systemic inflammatory responses.

In the search for sensitive and specific markers for sepsis, some laboratory parameters have merit in certain clinical circumstances. Because no parameter is 100% sensitive and specific for diagnosing sepsis and its cause, appropriate management remains embedded in clinical judgment based on careful consideration of data from multiple sources.

A. History and physical examination are the foundation for all diagnoses. In most cases, a sagacious clinician leaves the bedside with an accurate diagnosis, using diagnostic tests to confirm clinical impressions, obtain baselines for following treatment efficacy, and establish a definitive microbiologic etiology. Once the infection source is established and appropriate cultures obtained, antimicrobial therapy should commence without delay. Pending culture results, the suspected infection source guides antibiotic choice, focusing on the most likely pathogens. However, if an infection source is not readily apparent from routine assessment, a more detailed approach is crucial, including painstaking attention to **clinical history**.

1. **Underlying diseases.** Underlying diseases predispose patients to certain types of infections or particular pathogens. Certain medical conditions also alter the clinical presentation of common infections or predispose to infection with uncommon pathogens.
 - a. **Immunosuppression**, whether due to underlying disease or induced by treatment, increases mortality risks from common infections and predisposes to infections uncommon in immunocompetent individuals. Determining whether the immunodeficiency primarily affects cell-mediated versus humoral immunity alerts clinicians to consider particular pathogens in the microbiologic differential diagnosis.
 - b. **Diabetes mellitus** predisposes to pulmonary, urinary tract, and soft tissue infections. Concurrent neuropathy and vascular disease attenuate symptoms and physical signs of infection, increasing tissue damage. Patients with diabetes are prone to malignant otitis externa (*Pseudomonas aeruginosa*)

and its complications. Diabetes-associated infections are discussed further in Chapter 5.

- c. **Hormonal abnormalities** or shifts can alter immune function and increase risk for certain infections. For example, hormonal changes in late pregnancy and excessive adrenocorticotrophic hormone production in Cushing disease cause cellular immune dysfunction, increasing risk for serious infections associated with decreased cell-mediated immunity.
 - d. **Chronic obstructive pulmonary disease** increases risk for bronchitis and pneumonia. Underlying lung disease increases mortality risk from other serious infections as well as pneumonia. Infections due to *Haemophilus*, *Moraxella*, *Legionella*, and other gram-negative pathogens are more common in persons with chronic obstructive pulmonary disease [21]. Gram-negative pathogens are more difficult to treat, require broader spectrum antimicrobial therapy, and increase mortality risk.
 - e. **Valvular and congenital heart diseases** predispose to infective endocarditis [20]. Endocarditis prevention, microbiology, and treatment are discussed in Chapter 12. Preexisting cardiovascular disease increases mortality risk in patients with sepsis.
 - f. **Hyposplenism or asplenia (functional or surgical)** predisposes to infection with certain pathogens such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*, *Capnocytophaga canimorsus*, *Salmonella* species, and *Babesia* species. Infections in asplenic patients are frequently fulminant, rapidly progressing to septic shock barring early intervention.
 - g. **Cirrhosis** increases infection risk at a number of levels. Cirrhosis is associated with neutrophil chemotactic defects, predisposing to infection with *S. pneumoniae* and *H. influenzae*. Concurrent ascites, edema, hypoglobulinemia, hypoalbuminemia, portal hypertension with varices, and other associated abnormalities increase risk for developing infection (e.g., **spontaneous bacterial peritonitis, cellulitis**) and decrease appropriate immune response. Cirrhosis and its associated complications increase mortality risk for infections in other organ systems (e.g., **pneumonia**).
 - h. **Malignancies** increase risk for infection in a number of ways. Organ dysfunction from primary or metastatic disease can predispose to sepsis by (a) disrupting natural barriers (e.g., **skin, mucous membranes**), (b) obstructing passages (e.g., **ureters, bronchi, bowel**), (c) creating fistulas between sterile sites and contaminated tissues (e.g., **bronchopleural fistulas, esophageal perforation by mediastinal tumors**), (d) causing metabolic derangements that alter host defense and acute phase responses (e.g., **hypoalbuminemia, hypogammaglobulinemia cachexia**), and (e) infiltrating tissues essential to immune function (e.g., **bone marrow, liver, spleen**). Treatment inevitably impairs normal host defenses and often damages healthy tissue, increasing risk for invasive infection. Frequently colonized with multiply resistant pathogens resulting from prior antimicrobial therapy, infections in this patient population require rapid aggressive treatment to prevent sepsis and its high mortality risk.
 - i. **Malnutrition** compromises host defenses by causing metabolic derangements that decrease, in particular, cellular immune function. Iron deficiency, for example, decreases neutrophil killing capacity and T-lymphocyte function *in vitro*. Certain nutritional abnormalities predispose to infection with particular pathogens, as exemplified in the association between iron overload and increased risk for listeriosis and mucormycosis. Furthermore, malnutrition-associated abnormalities impact clinical outcome as epitomized in the association between hypoalbuminemia and increased mortality in patients with community-acquired pneumonia.
2. **Medication history.** Knowledge regarding a patient's past and present medications provides vital clues to infection type and severity. By modifying host flora, **prior antimicrobial therapy** alters disease epidemiology and warrants broadening microbiologic differential diagnoses to include resistant or unusual pathogens. Resistant or unusual pathogens, in turn, can increase mortality risks

and influence empiric antibiotic choices. Antimicrobial therapy influences diagnostic culture results and affects microbiologic data interpretation. **NSAIDs** and **corticosteroid therapy** attenuate fever and other signs or symptoms of infection, delaying diagnosis. **Corticosteroids** or other **immunosuppressive drugs** increase risk for unusual infections or opportunistic pathogens. **Beta-blockers** may prevent infection-induced tachycardia, mimicking the pulse-temperature disassociation classically linked with certain intracellular pathogens such as *Brucella*. **Drug-related adrenal insufficiency**, as seen with sudden cessation of chronic corticosteroid therapy, mimics septic shock clinically. **Allergic reactions** to medications can also cause distributive shock mimicking sepsis.

3. **Invasive procedures or surgery.** Invasive and surgical procedures increase risk for sepsis from particular pathogens. Although antimicrobial therapy for surgical prophylaxis covers typical flora for the system involved, clinicians should include iatrogenic infections in the differential diagnosis when evaluating septic patients. Even seemingly minor wound infections involving toxin-producing staphylococci or streptococci may cause toxic shock or toxic strep syndromes. Prior antimicrobial therapy alters colonizing flora, resulting in procedure-related infections with unusual or resistant pathogens. Central lines, antibiotics, and hyperalimentation predispose to sepsis from *Candida* species. Procedure-related infections due to difficult pathogens such as vancomycin-resistant enterococci, methicillin-resistant *Staphylococcus aureus*, *Stenotrophomonas*, *Pseudomonas*, *Enterobacter*, *Acinetobacter*, and *Burkholderia* show considerable geographic and demographic variation. It is important for clinicians to check local microbiologic trends and report unusual causes of postprocedure infections.
4. **Obstetric and gynecologic history.** Obstetric and gynecologic histories are important for assessing sepsis in women. Tampon use is associated with toxic shock syndrome caused by exotoxin TSST-1 producing *S. aureus*. Not typically isolated from blood cultures, the causal *S. aureus* is at times recovered from other sites such as vagina, cervix, or nares. Obstetric and gynecologic history is also important to assess risk for infection from a pelvic source. Characteristically polymicrobial, pelvic infections typically involve enteric gram-negative bacteria, anaerobes, and enterococci.
5. **Social history.** A patient's social history often provides vital clues to sepsis etiology. Social history and exposure history are often synonymous. Exposure history identifies infection risks, directs preventive therapy (**postexposure prophylaxis, immunization**), and guides empiric antimicrobial therapy pending culture results.
 - a. **Travel** is commonplace. **Foreign travel** raises concern for otherwise uncommon causes of sepsis, such as malaria, plague, and hemorrhagic fevers. **Domestic travel** is associated with exposure to indigenous pathogens such as Rocky Mountain spotted fever, brucellosis, babesiosis, leptospirosis, and endemic mycoses. Even **intrastate travel** is associated with exposure to prevailing local pathogens, influencing the microbiologic differential diagnosis (e.g., **influenza, Legionnaires**).
 - b. **Residence** locale may increase exposure to certain pathogens such as tick-borne rickettsia in wooded areas. Local disease outbreaks, such as methicillin-resistant *S. aureus* and Legionnaires, factor into the microbiologic differential diagnosis of sepsis. Infections in the homeless, including the high risk for blood-borne diseases, have been reviewed recently [75].
 - c. **Occupation** at times poses certain exposure risks, such as *Salmonella* species, *Vibrio* species, and *Escherichia coli* in poultry, seafood, and beef processing industries, respectively. Veterinarians and others working with animals are at increased risk for various zoonoses. Some occupations involve extensive travel with attendant exposure to endemic infections. Other occupations, such as teaching or health care professions, involve close association with particular populations at risk for certain communicable diseases (e.g., **tuberculosis**).
 - d. **Recreational activities** can expose individuals to otherwise unexpected pathogens as seen in leptospirosis, brucellosis, and tularemia. Recreational activities often also involve travel with attendant exposure risks.

- e. **Alcoholism**, with or without cirrhosis, increases risk for serious infections with *S. pneumoniae* and *H. influenzae*. Alcohol intoxication can increase risk for aspiration pneumonia involving anaerobes and other oral flora not routinely involved in community-acquired pneumonia. Gastrointestinal disease associated with alcoholism can predispose to infections involving gut flora. Severe pancreatitis at times mimics sepsis and causes distributive shock indistinguishable from septic shock. Alcohol withdrawal, particularly delirium tremens, can obscure symptoms associated with serious infections such as bacterial meningitis or brain abscess.
 - f. **Smoking** inhibits mucociliary function and diminishes local immune defense, predisposing to respiratory tract infections (e.g., **pneumonia, sinusitis**).
 - g. **Recreational drug use history** can provide important clues when assessing patients with sepsis. Intravenous drug use increases risk for serious staphylococcal infections, including bacteremia. Marijuana is often contaminated with molds, particularly *Aspergillus*, that may cause serious infection in immunocompromised hosts. Cocaine and other illicit drugs are at times obtained in exchange for sexual favors, increasing risk for sexually transmitted diseases such as gonorrhea and human immunodeficiency virus (HIV).
 - h. **Sexual history** provides important information regarding potential pathogens that cause sepsis (e.g., **gonococcemia**) or predispose to infections that can alter host response to infection (e.g., **HIV**).
6. **Epidemiology.** Although many characteristics of sepsis are documented, the epidemiologic picture remains incomplete. Hampered by lack of reliable case definitions and the remarkable complexity of the condition, epidemiologic studies continue seeking to clarify risk factors, course, treatment, and outcomes.
- a. **Currently identified mortality risk factors** include antibiotic inadequacy, underlying disease, shock, need for vasopressors, multiple organ failure, neutropenia, infection source, and cause [8,76].
 - b. **Gender and genetic predisposition factors** are gaining recognition as important epidemiologic issues in sepsis [77].
 - c. **Infection site** can influence outcome, with higher mortality rates reported for intraabdominal or lower respiratory tract infections or when source is unidentified [8,78].
 - d. **Microbiology** also influences sepsis outcome as suggested by high attributable mortality rates associated with bloodstream infections caused by *Candida* species and *Enterococcus* species [79]. In addition to affecting antimicrobial therapy, the type of invading pathogen also influences treatment response to sepsis interventions. In a recent review, Opal and Cohen [80] discussed clinical trials with antiinflammatory agents (e.g., **corticosteroids, IL-1 receptor antagonists, PAF antagonists**), noting poorer outcomes in patients with gram-positive versus gram-negative sepsis.
 - e. **Changing epidemiology.** In a recent retrospective review spanning 40 years, Friedman et al. [81] noted several important factors in the changing epidemiology of septic shock, most notably the infection site and pathogen type. Infection site shifted from the abdomen before 1990 to chest in subsequent years. Causal pathogen type also shifted over the same time course with gram-positive pathogens becoming proportionately much more important.
 - f. **Hospital-acquired infections** require special consideration compared with community-acquired counterparts. Nosocomial infections often involve multiply resistant pathogens, affecting both antimicrobial therapy choice and efficacy. Most hospital microbiology laboratories track antimicrobial susceptibility data to document resistance trends and facilitate appropriate antibiotic prescribing practices. Knowledge regarding these resistance patterns is especially relevant when selecting empiric antimicrobial therapy for treating sepsis. Awareness regarding community outbreaks and resistance patterns is also useful, alerting clinicians to increased risk for less common or resistant pathogens in otherwise common infectious diseases (e.g., **postinfluenzal staphylococcal pneumonia, Legionnaires disease, penicillin (PCN)-resistant pneumococcal disease, vancomycin-resistant enterococci**).

B. Physical examination. Meticulous physical examination is central to diagnosing sepsis, its cause, and appropriate treatment. The initial exam must rapidly ascertain overall clinical stability and guide prompt resuscitation to correct physiologic abnormalities such as hypotension, hypoxia, and impaired tissue oxygenation. The presence of shock constitutes a medical emergency. Because early recognition and prompt treatment of sepsis chiefly determine outcome, confirming infection and identifying its source are supremely important. Failure to initiate prompt appropriate empiric antimicrobial therapy increases sepsis mortality rates by 10% to 15% [82]. Because blood cultures are negative in approximately 70% of patients with sepsis, identifying the infection source is essential for guiding empiric antimicrobial therapy and recovering the causal pathogen(s) from infected sites. Typically, the most common infection sites are lung, abdomen/pelvis, and urinary tract [83]. Routine physical examination often identifies the site of infection. However, a definite infection site is not identified in 20% to 30% of patients with sepsis [82,83]. The fact that empiric antimicrobial choices cannot possibly cover every pathogen contingency for all cases underscores the merit in meticulous search for frequently overlooked subtle clinical clues to the site and cause of sepsis. A practical approach to diagnosing and treating sepsis begins at the bedside with heightened perspicacity for subtle findings.

1. Vital signs. Routine vital signs often provide the first clues to impending or evolving sepsis. Although “normal” ranges are common knowledge, sagacious clinicians recognize that baselines vary among individuals and interpret vital signs accordingly. **Vital sign trends** are often more informative than actual numbers.

a. Temperature. Fever, often accompanied by **chills** or **rigors**, is a common early sign of infection and should prompt evaluation for impending sepsis. Temperature data should be interpreted along a continuum from the patient’s personal baseline. As discussed in Chapter 1, fever pattern occasionally suggests underlying cause. **Fever does not always accompany serious infection**, most notably in neonatal or geriatric age groups and in debilitated patients, age notwithstanding. Steroidal and nonsteroidal **antiinflammatory drugs can attenuate or delay fever**. In some patients, temperature abnormalities are inexplicably delayed or absent. **Hypothermia**, although less common than fever, is also seen in septic patients and portends poor prognosis.

b. Pulse. Tachycardia is common and frequently due to fever or compensatory changes associated with sepsis-induced hypotension. However, tachycardia without fever or hypotension is not rare and can be an early sign of impending sepsis. In febrile patients, a normal or low pulse, commonly termed “temperature-pulse disparity or disassociation,” can indicate infection with certain intracellular pathogens (e.g., *Legionella*, *Brucella*, *Chlamydia*). Other common conditions that cause temperature-pulse disparity include beta-blockade, intrinsic conduction abnormalities, and diabetes mellitus.

c. Blood pressure. Hypotension, defined as systolic blood pressure less than 90 mm Hg and mean arterial pressure (MAP) less than 70 mm Hg, or more than a 40 mm Hg decrease from baseline, should prompt immediate volume resuscitation. **Volume depletion** is commonplace in patients with sepsis due to reduced intake and increased losses (**fever, tachypnea, etc.**). In eu-volemic febrile patients without underlying cardiac disease, hypotension implies maldistribution of blood flow, heralding severe sepsis. High cardiac output with bounding pulses and wide pulse pressure characterize early sepsis. Low cardiac output with rapid weak pulses typifies late sepsis. **Hypotension unresponsive to adequate volume resuscitation** connotes **shock** and must be regarded as a **medical emergency**.

d. Respiratory rate. Hyperventilation, often overlooked because it precedes the onset of fever and chills, is the **earliest clinical manifestation of bacteremia**. In critical care settings, otherwise unexplained hyperventilation foreshadows bacteremia and warrants blood cultures along with clinical evaluation for signs of impending sepsis.

2. **General findings.** In **early sepsis**, patients frequently appear apprehensive, tachypneic, and toxic or ill. Malaise occurs often but irritability is not uncommon. Typically, extremities are warm and dry. Rigors suggest bacteremia but also are associated with fungemia, viremia, and parasitemia. At times, mental confusion is evident, especially in the elderly. Sepsis-associated capillary leak causes peripheral edema that evolves rapidly with fluid resuscitation, mimicking intravascular volume overload. Peripheral edema alone does not justify fluid restriction. In **late sepsis**, clinical findings reflect progressive organ dysfunction. Depressed respiration, decreased pulses, cyanosis, cold extremities, lethargy, and coma characterize terminal phases.
3. **Skin.** At times subtle and easily overlooked, cutaneous manifestations of infectious diseases are valuable diagnostic opportunities as well as clues to cause (Table 2.2). When evaluating patients with sepsis, otherwise elusive microbiologic diagnoses are at times established simply from Gram stain and culture of material from cutaneous lesions. Direct fluorescent antibody stains performed on specimens collected from suspicious skin or mucosal lesions provide rapid diagnostic data for certain viral infections (e.g., **varicella zoster**, **herpes simplex**). In addition to intimating primary infection focus and microbiologic etiology, skin findings provide useful staging and prognostic information. In septic patients, certain important skin findings are at times subtle, evanescent, or temporally variant, underscoring the need for meticulous serial inspections. Antimicrobial therapy may alter, trigger (e.g., **ampicillin-induced rash in Epstein-Barr virus infections**), or cause rashes outright. Nevertheless, when analyzed in conjunction with historical, clinical, and epidemiologic clues, it is possible to construct a reasonable differential diagnosis when evaluating the acutely ill patient with fever and cutaneous lesions or rash.
 - a. **Petechiae**, although less specific than other cutaneous manifestations of infectious diseases, are associated with several rapidly fatal diseases. These small red or brown spots do not blanch with pressure and may coalesce into larger areas of discoloration or ecchymosis. Formed by bleeding into the skin, petechial rashes comprise purpuric eruptions, including purpuric vesicles. Any bacteremia can cause petechial rash, with or without disseminated intravascular coagulation (DIC). Acutely ill patients with fever and petechial rash typically have bacteremia or rickettsial disease. Petechial rashes are commonly associated with meningococemia, gonococemia, and staphylococemia. Petechiae are the most common skin finding in patients with endocarditis, although Osler nodes, Janeway lesions, splinter hemorrhages, and conjunctival hemorrhages are more readily associated with the disease. Microbiologic etiology notwithstanding, petechial lesions in septic patients connote striking underlying pathology warranting further evaluation, including platelet count, coagulation studies, and DIC panel. Other infectious diseases associated with petechial rashes are listed in Table 2.2. Noninfectious mimics of sepsis, particularly certain rheumatologic diseases, can also present with petechiae or other vasculitic skin lesions associated with SIRS.
 - b. **Ecthyma gangrenosum**, characteristically oval or round lesions with erythematous indurated borders and necrotic ulcerated centers, implies gram-negative bacteremia, most notably *Pseudomonas aeruginosa*. Gram stain and culture may recover the causal pathogen.
 - c. **Purpuric macules, papules, or vesicles**, signaling poor prognosis in patients with meningococemia, at times accompany bacteremias involving *S. aureus*, *Neisseria gonorrhoeae*, and *P. aeruginosa*. These lesions can also reflect bacterial endocarditis, drug hypersensitivity, allergic vasculitis, enteroviral illness, rickettsial disease, acquired immunodeficiency syndrome (AIDS), systemic lupus erythematosus, and other processes that trigger systemic inflammation. Biopsy with appropriate stains and cultures can often distinguish between infectious and noninfectious causes.
 - d. **Diffuse erythroderma** is associated with toxin-producing gram-positive infections such as toxic shock or toxic streptococcal syndromes, with or without

Table 2.2. Rash Etiologies in the Evaluation of Patients with Sepsis

Rash Type	Bacterial	Other Infectious	Noninfectious
Petechial	<ul style="list-style-type: none"> • Endocarditis • Staphylococemia • Pseudomonas bacteremia • Meningococemia • Gonococemia • Rocky Mountain spotted fever • Endemic typhus • Rat-bite fever 	<ul style="list-style-type: none"> • Dengue fever • Enterovirus • Hepatitis B • Epstein-Barr virus • Rubella 	<ul style="list-style-type: none"> • Drug allergy • Hypersensitivity vasculitis • Acute rheumatic fever • Henoch-Schönlein purpura • SLE • HIV • Thrombocytopenia • Hyperglobulinemia • Amyloidosis • Scurvy

SLE, systemic lupus erythematosus; HIV, human immunodeficiency virus; HHV-6, human herpes virus.

bacteremia. In lieu of positive blood cultures, uncovering the occult site is vital to management as in cases involving drainable abscess or other removable source.

- e. **Cellulitis** often suggests both microbiology and source. In addition to primary soft tissue infections (see Chapter 4), occult infections such as infected i.v. lines, drug injection sites, sinusitis, septic arthritis, or osteomyelitis can

manifest as focal cellulitis, the source governing empiric antimicrobial therapy pending definitive microbiologic diagnosis.

- f. **Furuncles, pustules, or vesicles** offer readily accessible diagnostic opportunity. Properly collected specimens submitted for appropriate stains and cultures can recover otherwise elusive pathogens.
 - g. **Nodules**, at times more subtle than other cutaneous manifestations of infectious diseases, are often overlooked. Discrete, raised, mildly erythematous skin nodules suggest **candidemia**. In neutropenic patients with candidemia, the erythema associated with these nodules is often subtle or absent. Biopsy specimens readily obtained at bedside yield rapid diagnosis, because Gram stain results showing the budding yeast are available immediately, days earlier than blood culture results.
4. **Head and neck.** Head or neck infection is the primary focus for sepsis in some patients. Sinus or ear infections can lead to meningitis or central nervous system (CNS) abscesses. Rheumatic fever associated with group A streptococcal pharyngitis is associated with clinical manifestations consistent with systemic inflammatory responses. At times, peritonsillar and retropharyngeal abscesses are foci for life-threatening infectious sequelae, including septic shock. Sinusitis involving toxin-producing staphylococci or streptococci can cause toxic shock syndrome without bacteremia or other invasive infection. Sinusitis occasionally leads to septic cavernous sinus thrombosis with attendant morbidity or mortality if not treated appropriately. Odontogenic infections can cause endocarditis and other life-threatening diseases, such as Ludwig angina and Vincent angina/Lemierre disease. Funduscopic examination, often difficult and deferred in the acutely ill patient, provides rapid diagnostic clues in sepsis, such as Roth spots associated with infectious endocarditis or retinal findings connoting disseminated candidiasis. When the differential diagnosis of sepsis includes infectious diseases with characteristic funduscopic findings, timely diagnosis justifies ophthalmology consultation for thorough retinal examination.
 5. **Heart murmurs** characterizing valvular abnormalities or septal defects raise suspicion for infective endocarditis. Scrupulous baseline and serial cardiac examinations are important for detecting new or changing murmurs that connote endocarditis. Clinical findings suggesting pericarditis or myocarditis are also helpful diagnostic clues to underlying etiology (see Chapter 12).
 6. **Lungs.** Community-acquired and nosocomial pneumonias are common causes of sepsis. Subtle clinical findings such as egophony or whispered pectoriloquy may precede radiographic signs of consolidation. Both clinical and radiographic findings suggesting pneumonia are often minimal during early disease, particularly in dehydrated, elderly, or immunocompromised patients. Chest radiographs are warranted in all patients with sepsis, because roentgenographic studies may reveal infiltrates or other pulmonary pathology imperceptible on clinical exam. Serial clinical examination and chest radiographs often detect abnormal findings because pulmonary disease manifestations evolve with hydration and time. In septic patients, pulmonary infiltrates may represent infectious or non-infectious processes such as noncardiogenic (ARDS) or cardiogenic pulmonary edema. In critically ill patients, pulmonary infiltrates are often multifactorial. Microbiologic studies typically distinguish between infectious and noninfectious causes.
 7. **Abdominal, rectal, and pelvic examinations** provide important clinical data for determining septic foci and choosing appropriate empiric antimicrobial therapy. If a detailed history is unreliable or unavailable, telltale scars from prior abdominal (e.g., **splenectomy, cholecystectomy, appendectomy**) or pelvic (e.g., **hysterectomy, laparoscopy, prostatectomy**) surgery provide important clues to underlying pathology and risk for certain infections. Localized or early manifestations of intraabdominal or pelvic infections are often subtle in elderly, neurologically compromised, or immunosuppressed patients, especially those taking steroids. Often deferred in acutely ill patients, rectal and pelvic examinations are crucial for identifying rectal abscess (**especially in patients with neutropenia or inflammatory bowel disease**), prostatitic abscess,

attempted abortion, or pelvic inflammatory disease. Splenomegaly is occasionally the only clinical finding in febrile patients with subacute bacterial endocarditis. Duodenal ulcers occasionally perforate into the pancreas, presenting with signs of fulminant pancreatitis, peritonitis, and septic shock.

8. **Extremities.** In septic patients, inflammatory arthritis is both a diagnostic sign and opportunity. In the absence of penetrating joint trauma, septic arthritis points toward systemic infection, most notably staphylococemia, streptococemia, meningococemia, and gonococemia. Acute joint pain as a presenting complaint warrants assessment for systemic infection, especially if the patient has fever or complete blood count shows neutrophilia and/or increased immature forms. Early diagnosis and timely antimicrobial therapy can prevent sepsis and its sequelae. Arthrocentesis for synovial fluid analysis and culture provides rapid diagnostic data. Synovial fluid Gram stain often discloses the invading pathogen long before blood or joint aspirate cultures yield a microbiologic diagnosis. Septic arthritis and its causes are detailed in Chapter 5. Osteomyelitis also implicates systemic infection, therefore warranting full skeletal evaluation in septic patients, including examination for vertebral point tenderness. When examining extremities, signs of phlebitis implicate pulmonary emboli as cause for fever, tachypnea, and/or hypotension in acutely ill patients, stipulating further diagnostic studies.
9. **Central nervous system.** Fever associated with focal neurologic deficits demands timely evaluation for CNS infection, particularly brain or spinal cord abscess. Meningitis at times causes focal neurologic findings, particularly when the basilar meninges are involved extensively (**notably tuberculosis or fungal meningitis, although bacterial infections may also do so**). (CNS infections are detailed in Chapter 6.) Unless otherwise contraindicated, lumbar puncture for appropriate cerebrospinal fluid analysis is imperative for diagnosing CNS infections. Stroke in the febrile septic-appearing patient warrants evaluation for infectious endocarditis (see Chapter 12). Evaluation for endocarditis (especially subacute bacterial endocarditis [SBE]) is justified in all patients with embolic stroke, even if lacking overt signs of infection.
10. **Wounds and soft tissues.** Skin and soft tissues are important infection foci in sepsis. Although most suppurative wounds are apparent on routine physical examination, certain noteworthy soft tissue infections present with minimal clinical findings and progress so rapidly that septic shock develops before the underlying infection is apparent. Group A streptococcal necrotizing fasciitis often presents with severe localized pain without objective clinical findings to implicate infection, commonly eluding timely diagnosis unless clinical vigilance motivates further evaluation and appropriate laboratory tests. Immature granulocytes, lymphopenia, hypoalbuminemia, and hypocalcemia are diagnostic clues warranting further evaluation with an eye toward rapid surgical intervention and timely antimicrobial therapy. Seemingly minor wound and soft tissue infections, when caused by certain toxin-producing staphylococci or streptococci, can present as a toxic shock syndrome. Soft tissue crepitance identified during physical examination or air visualized in radiographic studies (e.g., **computed tomography (CT)**) suggests infection with gas-producing pathogens such as *Clostridium* or mixed enteric gram-negative bacteria.

C. Diagnostic microbiology

1. **Blood cultures** are essential tools for diagnosing sepsis. True positive blood cultures constitute the best criteria for defining sepsis and its cause. Unfortunately, blood cultures are negative in a substantial number of patients with sepsis. Multiple factors obscure blood culture yield. **Transient bacteremias** accompany most serious infections [84] but pass before fever or other clinical manifestations motivate orders for blood cultures. **Intermittent bacteremias**, recognized as recurrent transient bacteremias, are associated with sporadic obstruction or manipulation of infected sites. **Continuous or sustained bacteremias**, defined by multiple positive blood cultures obtained at intervals from several hours to days, typify intravascular infections such as endocarditis, suppurative thrombophlebitis, and intravascular catheter or graft infections. Occasionally,

continuous bacteremia accompanies extravascular infections (e.g., **intraabdominal abscess**) in immunosuppressed hosts. **Persistent bacteremia** despite appropriate antimicrobial therapy portends endovascular infection and warrants rigorous search for an intravascular source. Prior antimicrobial therapy decreases blood culture yield. Using resin-containing media to lower antibiotic concentrations in blood cultures, although attractive theoretically, does not improve sensitivity and may decrease specificity by facilitating recovery of contaminants, most notably coagulase-negative staphylococci [85]. Fastidious or slow-growing blood-borne pathogens, often overlooked by standard blood culture protocols, are recoverable if clinicians inform the microbiology lab that the differential diagnosis includes such pathogens. The single most important factor governing blood culture sensitivity is the volume of blood cultured [86]. False-negative blood cultures are less common than false-positive ones. Blood culture specificity is not absolute, requiring appropriate interpretation to distinguish true pathogens from possible contaminants. False-positive cultures due to contamination or colonization pose diagnostic problems, especially in patients with increased risk for infection caused by otherwise typical skin contaminants (e.g., **coagulase-negative staphylococci or diphtheroids cultured from patients with indwelling i.v. catheters, prosthetic heart valves, or joint prostheses**). Several factors influence the predictive value of positive blood cultures, including pattern (number of positive culture sets), pathogen identity, and clinical context.

- a. **Blood volume.** Blood volume is the single most important variable governing blood culture yield or sensitivity [86]. Pathogen concentration is no more than 1 colony-forming unit (CFU) per mL of blood in 50% of bacteremic adults and less than 0.1 CFU/mL in 20% of bacteremic adults [87]. Pediatric bacteremias are often higher grade, with blood pathogen concentrations reaching more than 100 CFU/mL [88], although low-level bacteremias (**1–10 CFU/mL blood**) are also documented [89]. In adults, blood culture yield increases 3% per mL of blood cultured [86]. In adults, culturing at least 10 mL and preferably 20 mL of blood maximizes bloodstream pathogen recovery. Culturing more than 20 mL of blood does not increase yield substantially and is not recommended except, possibly, in cases of suspected viridans streptococcal subacute bacterial endocarditis. In pediatric patients, recommended blood volumes per culture are as follows: 1 to 2 mL for neonates, 2 to 3 mL for infants aged 1 month to 2 years, 3 to 5 mL for older children, and 10 to 20 mL for adolescents [88]. Because low-level bacteremia can occur in pediatric populations, some experts recommend using weight-based determinations, culturing up to 4.5% of a child's estimated total blood volume [89].
- b. **Blood culture set number.** Although a single blood culture is inadequate for documenting bacteremia or fungemia, two to three properly collected blood cultures will detect 99% of clinically important bloodstream infections caused by common bacterial and fungal pathogens [90,91]. It is rarely necessary to collect more than two blood culture sets in a 24-hour period, although many clinical microbiology laboratories will process more if notified that the clinician suspects subacute bacterial endocarditis. When treating patients with intravascular infections, daily blood cultures (**until negative**) are warranted to assess antimicrobial efficacy, establish adjunct interventional requirements (e.g., **heart valve replacement**), and determine treatment duration.
- c. **Site selection.** Venipuncture site selection is a controllable variable that has significant impact on blood culture results. Blood obtained from femoral vessels is associated with higher contamination rates than specimens collected from antecubital veins or other upper extremity vessels [90]. Blood obtained from sites with overlying cellulitis or dermatologic disease is also associated with higher contamination rates. Culturing arterial blood offers no higher yield than venous blood [92]. The American College of Physicians guidelines [93] and expert opinion [94] discourage culturing blood from intravascular catheters. A recent retrospective analysis comparing 551 paired venipuncture and i.v. catheter specimens from hospitalized cancer patients demonstrated a high negative but low positive predictive value in blood cultures obtained

through indwelling central i.v. catheters [95]. Although negative blood cultures obtained from central i.v. lines may rule out bacteremia, positive cultures require careful clinical interpretation and likely require confirmation to distinguish true bacteremia from line colonization. When clinical circumstance necessitates culturing blood from central i.v. lines, these specimens should be paired with blood cultures obtained by peripheral venipuncture [88,94].

- d. **Timing.** The optimal time for obtaining blood culture specimens is immediately before onset of rigors. Because predicting such clinical events is impossible, a practical approach calls for blood cultures as soon as fever or rigors are detected. In acutely ill patients likely requiring immediate antimicrobial therapy, it is reasonable to obtain two sets of blood cultures simultaneously from different sites. In less urgent situations, blood cultures may be spaced at intervals. Spacing blood collection over a 24-hour period does not improve yield [96] but may provide useful clinical information by distinguishing between transient and continuous bacteremia or fungemia.
- e. **Incubation duration.** Five-day incubation periods are adequate for detecting most pathogens via the continuous-monitoring blood culture systems used in contemporary U.S. clinical microbiology laboratories. By protocol, blood culture specimens are discarded if negative after 5 to 7 days of incubation. Some fastidious pathogens such as *Legionella*, *Bartonella*, *Brucella*, and certain fungi require longer incubation periods. Alerting the clinical microbiology laboratory when fastidious pathogens are suspected averts untimely discard of blood culture specimens. Fungal and mycobacterial blood cultures are incubated for 4 to 6 weeks.
- f. **Positive blood culture interpretation.** Blood culture interpretation is straightforward in many cases such as when multiple blood cultures grow *S. aureus* in the clinical context of infective endocarditis. In contrast, recovery of less credible microorganisms such as coagulase-negative staphylococci and diphtheroids is commonplace and complicates blood culture interpretation. Because any microorganism can, given the right circumstance, become a blood-borne pathogen, clinicians must interpret accurately the clinical relevance of positive blood cultures. Several factors improve blood culture predictive values.
 - (1) **Pattern.** When all or most blood cultures obtained from a series of separate venipunctures yield the same isolate, bloodstream infection is highly probable regardless of microorganism identity.
 - (2) **Microorganism identity.** Certain blood isolates virtually always (>90%) represent true infection such as *Streptococcus pneumoniae*, *S. aureus*, *N. meningitidis* and *gonorrhoeae*, *E. coli* and other *Enterobacteriaceae*, *Pseudomonas aeruginosa*, *Candida albicans*, *Histoplasma capsulatum*, and *Cryptococcus neoformans*. In contrast, *Corynebacterium* species, *Propionibacterium acnes*, and *Bacillus* species rarely (<5%) cause true bloodstream infections and, with rare exception (e.g., ***Corynebacterium jeikeium* in neutropenic patients with permanent i.v. catheters**), likely represent contaminants when recovered sporadically in blood cultures. Coagulase-negative staphylococci, viridans streptococci, and enterococci are particularly problematic blood culture isolates, representing true bacteremia in 15%, 38%, and 78% of cases, respectively [97]. Because there are no laboratory gold standards for distinguishing between true bloodstream pathogens and contaminants, judging positive blood culture relevance remains embedded in clinical context.
- g. **Clinical context.** Blood culture isolates are virtually always relevant when the microorganism identity parallels clinical context. Credible pathogens as related to specific infections are discussed in their respective chapters. Less plausible blood culture isolates gain relevance in certain clinical situations and deserve further consideration.
 - (1) **Endocarditis or endovascular infections.** *S. aureus* bacteremias are common in patients with high carriage or colonization rates such as individuals with (a) atopic dermatosis, (b) diabetes, (c) chronic renal failure

requiring hemodialysis, (d) chronic indwelling catheters, (e) i.v. drug use, (f) recent or chronic corticosteroid therapy, (g) recent hospitalization, and (h) institutional living requirements, such as nursing homes or prisons. ***S. aureus* bacteremia** without an identifiable source or as a community-acquired infection often signifies endocarditis. Coupled with clinical evidence suggesting subacute bacterial endocarditis, especially when temporally related to dental procedures, blood cultures growing **viridans streptococci** signify true bacteremia. **Coagulase-negative staphylococci** occasionally cause native valve endocarditis but assume greater importance as a bloodstream isolate in patients with indwelling central i.v. catheters, prosthetic heart valves or other artificial endovascular devices, joint prostheses, and ventriculoperitoneal (VP) shunts. Community-acquired **enterococcal bacteremia** without an identifiable source in patients with valvular heart disease warrants further evaluation for endocarditis. **Candidemia** may represent serious endovascular infection in certain patients, most notably those with neutropenia or prolonged hospitalization involving central i.v. catheters, broad-spectrum antimicrobial therapy, and total parenteral nutrition. Persistent bacteremia or fungemia, especially in patients receiving appropriate antimicrobial therapy, suggests intravascular infection such as endocarditis, suppurative thrombophlebitis, or infected i.v. catheters or grafts. Endocarditis and its causes are discussed further in Chapter 12.

- (2) **Pneumonia and respiratory tract infections.** Common pulmonary pathogens such as *S. pneumoniae* or *H. influenza* isolated from blood cultures in patients with pneumonia inarguably represent true bacteremias. Less virulent organisms such as *Stenotrophomonas maltophilia*, *Burkholderia cepacia*, and *Acinetobacter baumannii* gain relevance as blood culture isolates in patients at increased risk for pneumonia caused by these bacteria (e.g., **ventilator-associated pneumonia, nosocomial pneumonia in patients receiving broad-spectrum antibiotics, patients with cystic fibrosis**). In patients with pneumonia, recovering even unusual organisms from multiple blood cultures and purulent sputum helps distinguish true bacteremia from contaminants. Occasionally, lung abscess is associated with polymicrobial bacteremia.
- (3) **Abdominal and pelvic infections.** Positive blood cultures yielding multiple organisms may reflect inappropriate collection technique or central i.v. line contamination, particularly when drawn from femoral sites. However, true **polymicrobial bacteremias (accounting for 6%–18% of all bacteremias)** commonly stem from intraabdominal or pelvic infections. In patients with documented or suspected intraabdominal or pelvic infections, appropriately collected polymicrobial positive blood cultures likely represent true bacteremia, particularly if the isolates include *Enterobacteriaceae*, anaerobes, enterococci, *S. aureus*, *Pseudomonas*, and *Candida*. True polymicrobial bacteremia in the absence of intraabdominal or pelvic sources often represents line-related nosocomial infection. *Streptococcus bovis* identified in blood cultures from patients with colon cancer signifies bacteremia. Conversely, identifying *S. bovis* bacteremia in patients with no known malignancy calls for painstaking evaluation for colon cancer or other occult gastrointestinal pathology.
- (4) **Urinary tract.** In patients with clinical findings consistent with urinary tract infection, blood cultures growing typical pathogens (e.g., *E. coli*, *Klebsiella pneumoniae*) undoubtedly represent true bacteremia. Disparate results from urine and blood cultures raise doubt and justify repeat studies. Indwelling urinary catheter use is a common hospital practice, especially in critical care settings, increasing risk for urinary tract infections caused by atypical pathogens. Polymicrobial urinary tract colonization is common in patients with urinary catheters. If clinical and laboratory data suggest a urinary tract source in patients with sepsis, positive blood cultures yielding isolates matching those from urine likely represent true bacteremia.

S. aureus recovered from both blood and urine cultures suggests hematogenous seeding of the urinary tract rather than a primary urinary source and warrants careful evaluation for intravascular infection. A similar approach applies when both urine and serial blood cultures grow *Candida*, *Enterococcus*, or coagulase-negative staphylococci in patients with indwelling central i.v. lines.

- (5) **Soft tissue infections.** Positive blood cultures with what might otherwise represent skin contaminants may represent true bacteremia in patients with serious skin or soft tissue infections. Appropriately collected serial blood cultures usually distinguish between potential contaminants and true bloodstream infection, especially when coagulase-negative staphylococci are isolated. At times, decubitus ulcer sepsis is associated with polymicrobial bacteremia, in which case blood isolates should match those obtained from wound cultures. For obvious reasons, blood cultures must not be collected from venipunctures through infected appearing skin or soft tissues. *N. meningitidis* or *P. aeruginosa* recovered from vasculitic appearing or ecthyma-like skin lesions and blood cultures reflects systemic infection rather than a primary soft tissue source and warrants careful evaluation for other cause.
 - (6) **Central nervous system.** Positive blood cultures in patients with meningitis usually yield obvious pathogens such as pneumococcus and reflect true bacteremias. Positive blood cultures with what might otherwise represent contaminants may represent true bacteremia in patients with meningeal signs when associated with extenuating clinical history such as neurosurgical procedures, ventriculostomy or epidural catheter placement, VP shunts, or spina bifida. In these patients, coagulase-negative staphylococci, enterococci, or unusual gram-negative bacteria isolated from blood cultures and cerebrospinal fluid signifies true bloodstream infection.
2. **Gram stain and other stains.** The three main methods for rapid detection of infection in critically ill patients are detecting pus in a normally sterile site, demonstrating microorganisms (**bacteria, fungi, viruses, or parasites**) in a normally sterile site by stains or culture, and detecting pathogen genome in a normally sterile site using molecular biology techniques. For most bacterial pathogens, Gram stain remains the fastest, simplest, and most universally available diagnostic tool for identifying infection. In settings where antimicrobial therapy is initiated before obtaining specimens for microbiologic studies, the Gram stain may be the only way to diagnose infection if cultures prove negative. A positive Gram stain facilitates rapid distinction between infectious and noninfectious causes of inflammatory exudates obtained from normally sterile sites such as the peritoneal cavity and pleural, pericardial, epidural, or articular spaces. Interpreting Gram-stained specimens obtained from normally nonsterile sites (e.g., **lung, sinuses, wounds**) is less straightforward but often valuable nonetheless, especially when visualized organisms corroborate clinical impression. Acid-fast stains (e.g., **Kinyoun**) are rapid diagnostic tools for identifying mycobacteria when differential diagnoses include tuberculosis or nontuberculous mycobacterial disease. In some clinical laboratories, gene probe technology permits rapid identification of *Mycobacterium tuberculosis* and other clinically important mycobacterial species. Modified acid-fast stains are used to detect *Nocardia* in clinical specimens. Direct fluorescent antibody stains permit rapid detection of certain pathogens where cultures are unreliable or require prolonged incubation (e.g., **Legionella, Varicella zoster virus**). Fungal stains often provide rapid diagnostic data where culture results are not available for several weeks.
 3. **Cultures.** Although microbiologic stains often provide valuable diagnostic data, definitive microbiologic diagnoses are established by isolating the causative pathogens from appropriate cultures. Cultures also permit *in vitro* susceptibility testing, an important clinical tool for guiding antimicrobial therapy and epidemiologic tool for monitoring resistance trends. Certain clinical situations call for special culture media or techniques. Good communication between the

clinician and microbiology laboratory is imperative when microbiologic differential diagnoses include unusual or fastidious pathogens that may require special handling or unconventional selective media. **Quantitative cultures** defining precise bacterial numbers in clinical specimens are useful for diagnosing infection in certain sites. It is now standard clinical laboratory practice to perform quantitative cultures on urine specimens based on the widely accepted premise that more than 10^5 CFU/mL correlates with urinary tract infection. For other sites, bacterial colony counts are only semiquantitative (e.g., **colony counts from bronchoalveolar lavage specimens for diagnosing ventilator-associated pneumonia or i.v. catheter tips for diagnosing catheter-associated bloodstream infections**). No unequivocal clinical data show presently that quantitative blood culture results improve diagnostic accuracy or medical management of sepsis [98].

4. **Molecular diagnostics.** Recent advances in automated molecular testing methods are changing clinical microbiology laboratory diagnostic practice for infectious diseases. Previously relegated to detecting slow-growing or uncultivable pathogens, technological advances now make molecular diagnostic testing adaptable for use in clinical microbiology laboratories and applicable for detecting common pathogens [99]. Molecular (**genotypic**) susceptibility testing is gaining similar practical application in infectious disease treatment and epidemiology [100]. Molecular testing is available presently for diagnosing group A streptococcal pharyngitis, pulmonary tuberculosis, HIV, hepatitis C virus infection, Herpes simplex virus encephalitis, CNS toxoplasmosis, progressive multifocal leukoencephalopathy, and *Chlamydia trachomatis* and *N. gonorrhoeae* urogenital infections. Molecular biology testing methods hold promise for clinical application in the rapid diagnosis of life-threatening infections, especially in situations where prior antimicrobial therapy or pathogen characteristics render standard microbiologic methodology inadequate [101]. Clinicians should check with their clinical microbiology laboratory regarding the applicability and availability of specific molecular diagnostic tests.

D. Hematology. Complete blood count with differential is a simple, rapid, readily available test that provides valuable clinical and diagnostic information.

1. **Granulocytosis with increased immature forms** ("left shift") suggests infection. Granulocyte counts can be normal or reduced in severe sepsis, but the differential will still reveal the telltale left shift. Granulocyte count and differential consistent with infection is one of several recommended drug utilization criteria for using human recombinant activated protein C (hrAPC; drotrecogin alpha [activated]) in the treatment of patients with severe sepsis (see section IV.D). Neutropenia (**absolute granulocyte counts <1,000**) increases risk for severe infection with both common and opportunistic pathogens, disseminated fungal infections, nosocomial infections, poor response to antimicrobial therapy, and increased mortality.
2. **Thrombocytopenia** portends DIC and justifies further tests to assess for this common complication of sepsis (**fibrinogen, D-dimers, prothrombin time/partial thromboplastin time**). Platelet count is both an inclusion and exclusion criterion for using rhAPC in the treatment of severe sepsis (see section IV.D). Sepsis-associated thrombocytopenia can be severe, requiring platelet transfusions to prevent life-threatening hemorrhage.
3. **Anemia** diminishes oxygen-carrying capacity of the blood and potentially worsens tissue hypoxia in septic patients, especially when hemoglobin concentration drops below 8 g/dL.
4. **Peripheral blood smears** occasionally detect bloodstream pathogens such as *Histoplasma capsulatum*, *Plasmodium* species, *Babesia* species, certain spirochetes, and even bacteria in cases of overwhelming sepsis (**most notably S. pneumoniae**). Both **thick and thin blood smears** should be ordered and scrutinized for *Plasmodium* parasites when **malaria** is suspected.

E. Coagulation studies. Prothrombin time and partial thromboplastin time provide useful information when evaluating septic patients. Prothrombin time/partial thromboplastin time are prolonged in sepsis-associated DIC. Prothrombin

time/partial thromboplastin time are also excellent markers for liver function and, when prolonged in the absence of DIC or anticoagulation therapy, herald hepatic dysfunction and secondary MODS in patients with sepsis.

F. Chemistry. Routine chemistries are readily available and provide rapid prognostic and diagnostic data when assessing patients with sepsis.

1. **Serum electrolytes** provide important information regarding metabolic status. In septic patients, an elevated anion gap metabolic acidosis implies lactic acidemia from tissue hypoxia and warrants checking serum lactate levels. Serum electrolytes should be monitored closely during volume resuscitation to assess efficacy and detect potentially life-threatening electrolyte abnormalities (**notably hypokalemia and hypophosphatemia**) that can develop rapidly as renal function improves and acidosis resolves.
2. **Baseline and serial renal panels** provide information for guiding and assessing resuscitative measures. Elevated serum creatinine and blood urea nitrogen at presentation may simply reflect volume contraction that should respond rapidly to volume repletion or, more ominously, connote renal failure due to sepsis-induced acute tubular necrosis. Severe pyelonephritis occasionally causes acute renal failure directly, in which case urinalysis will detect white blood cell casts.
3. **Liver panel** abnormalities are common in patients with severe sepsis and can reflect underlying cause or imply end-organ dysfunction.
 - a. **Isolated baseline alkaline phosphatase elevation** in the absence of severe sepsis may connote liver abscess.
 - b. **Elevated direct bilirubin** levels can signify underlying gallbladder disease as a source of sepsis. Elevated direct bilirubin levels in the absence of gallbladder disease likely reflects sepsis-associated intrahepatic cholestasis and accompanies other liver panel abnormalities due to liver dysfunction in the continuum of secondary MODS.
4. **Amylase and lipase** elevation in the absence of shock suggests pancreatitis as an underlying cause for systemic inflammatory responses mimicking sepsis. Elevated amylase and lipase levels associated with refractory hypotension in patients with septic shock signifies end-organ damage and is a part of the organ dysfunction constellation comprising secondary MODS. Procalcitonin levels offer promise for distinguishing between SIRS caused by pancreatitis versus sepsis (see following).
5. **Procalcitonin**, a calcitonin propeptide normally produced in the C cells of the thyroid gland, has recently drawn attention as a specific marker of systemic inflammatory response to infection. During systemic infection, extrathyroid tissues produce procalcitonin; the exact site of production during sepsis is uncertain. Procalcitonin levels increase dramatically in patients with sepsis, are detectable within 3 hours of induction onset (**at least 20 hours earlier than CRP**), have a much longer half-life than cytokines, and are stable in serum or plasma at room temperature (**>90% in 12 hours**). Various stimuli, other than bacterial infection, may increase procalcitonin levels in certain clinical conditions (e.g., **severe trauma, major surgical procedures, prolonged circulatory failure**). As a rule, however, procalcitonin levels detected under these conditions are substantially lower than those seen in patients with sepsis. Procalcitonin levels, presently, can be measured with a commercially available immunoluminometric assay. Procalcitonin assays, although not widely available in clinical laboratories presently, hold promise for clinical application by rapidly detecting invasive bacterial infection, discriminating between infectious and noninfectious causes of SIRS, and following response to therapy in patients with sepsis. Establishing optimal procalcitonin thresholds for appropriate application in clinical settings is the subject of ongoing investigations. Procalcitonin measurements, in the near future, probably will become a part of routine diagnostic testing for rapid identification of infection in several clinical settings.
 - a. **Elevated procalcitonin levels (>0.5 ng/mL)** in emergency department patients with suspected infectious or inflammatory disease **indicate ongoing and potentially severe systemic infection with an increased risk of**

- fatal outcome** [102]. The specificity of procalcitonin threshold more than 0.5 ng/mL approaches 100%, but levels below this threshold do not rule out infection.
- b. Procalcitonin levels correlate strongly with infection severity** and therefore may provide useful objective data for stratifying patients into various sepsis stages [103,104]. There are those, however, who question the value of procalcitonin as a marker for infection [105]. Optimal procalcitonin thresholds for discriminating among the various stages of the sepsis continuum are not defined clearly at present but remain the subject of ongoing clinical investigations.
 - c. In critically ill pediatric patients**, procalcitonin concentration appears to be a better diagnostic marker for sepsis than CRP in children but no better than CRP in neonates [106].
 - d. Procalcitonin helps discriminate between infectious and noninfectious causes of early ARDS.** Limited clinical data suggest that procalcitonin is a useful diagnostic tool for differentiating between infectious and noninfectious underlying disease in patients with early ARDS [107].
 - e. Procalcitonin discriminates between infection and acute graft rejection** in organ transplant patients [108,109].
 - f. Procalcitonin discriminates between bacterial and viral infections.** Bacterial meningitis, in neonates and children, is associated with substantially higher procalcitonin levels than viral meningitis.
 - g. Procalcitonin predicts infectious complications in patients with necrotizing pancreatitis and abdominal sepsis.** Procalcitonin in patients with necrotizing pancreatitis appears to be a good predictor of infection versus noninfectious pancreatic necrosis [110]. Procalcitonin, similarly, appears to have clinical applicability for identifying septic complications after abdominal surgery [111].
- 6. CRP** is used widely to determine inflammatory status but is not specific for infection and does not correlate with severity. In patients with documented sepsis, however, CRP provides useful prognostic information for after treatment efficacy as levels normalize with successful therapy and is readily available presently in most clinical laboratories.
- 7. Cytokine levels** rise rapidly during sepsis and are detectable earlier than procalcitonin. The short half-life of cytokines, however, causes rapid fluctuations in plasma levels, making serial assessments difficult and reducing clinical applicability.
- a. IL-6 and IL-8**, among all cytokines studied to date, show most consistent correlation with outcome in critically ill patients but do not discriminate between infectious and noninfectious causes of systemic inflammation [101].
 - b. IL-6 levels** appear to provide useful prognostic information and may be useful for following therapeutic response in patients with sepsis [101]. Whether IL-6 levels offer an advantage over procalcitonin levels presently is uncertain.
- G. Arterial blood gases.** Arterial blood gases should be checked in all patients with impending or established sepsis.
- 1. Respiratory alkalosis**, reflecting hyperventilation, is an early sign of impending sepsis.
 - 2. Respiratory acidosis** signifies ventilatory failure and calls for careful evaluation of lungs and CNS to identify cause. Arterial blood gases facilitate decisions regarding the need for ventilatory support and timing of intubation.
 - 3. Metabolic acidosis** cannot be assessed on the basis of serum chemistries alone. Arterial blood gases in patients with sepsis-associated metabolic acidosis provide accurate blood pH measurements useful in formulating management plans (e.g., **dialysis needs**) and following treatment efficacy (e.g., **resolution of lactic acidosis with resuscitative measures**).
 - 4. Elevated AaO₂ gradient**, calculated from arterial blood gas results, often precedes the appearance of infiltrates on chest roentgenogram in patients with ARDS and certain forms of pneumonia (e.g., *Pneumocystis carinii* pneumonia [PCP]).

- H. Urinalysis.** Urinalysis provides useful data relevant to both cause and effect in patients with sepsis. Urinary tract infections are a leading cause of sepsis, and urinalysis provides rapid diagnostic information in acutely ill patients, especially when white blood cell or fungal casts are detected. Urinalysis results consistent with urinary tract infection justify urine cultures to corroborate infection and identify its cause. In the absence of primary urinary tract infection, abnormal sediment may reflect end organ damage associated with secondary MODS (e.g., **acute tubular necrosis [ATN]**).
- I. Serology.** Serologic tests for detecting microbial antigens and host antibodies can, in limited clinical circumstances, provide diagnostic information in the workup of sepsis.
- 1. Legionellosis** presents a diagnostic challenge. Sputum cultures often fail to grow the pathogen, and sputum direct fluorescent antibody stains, in most clinical laboratories, lack adequate specificity and sensitivity. An enzyme immunoassay currently is available for detecting *L. pneumophila* serogroup 1 antigen in urine and may be useful in areas with high prevalence of this serovariant but does not detect the 62 other Legionella serovariants. A test kit for detecting a broad group of Legionella serovariants has recently become available, but performance characteristics must be established to determine widespread clinical applicability [112].
 - 2. Cryptococcal antigen testing** is available in most clinical laboratories and is useful for rapidly detecting *C. neoformans* in serum and CSF of immunosuppressed patients (e.g., **AIDS, organ transplant recipients**) with cryptococemia and meningitis.
 - 3. Acute and convalescent antibody titers**, although useful for confirming diseases such as rickettsiosis, ehrlichiosis, viral encephalitis, and hemorrhagic fevers, do not provide immediate diagnostic data in the acute setting. Treatment, in these settings, must be based on clinical assessment with serologic data providing confirmatory and epidemiologic diagnoses.
- J. Radiology.** A wide variety of imaging techniques is available to facilitate evaluation and intervention in the management of sepsis. Appropriate diagnostic imaging presupposes thorough clinical evaluation and close consultation with the imaging specialist. Diagnostic imaging in sepsis has been reviewed, including the advantages and limitations of imaging studies for specific conditions, and in specific anatomic areas [113].
- 1. Plain radiographs** are rapid, inexpensive, and portable; require no special preparation; and carry low risks limited to minimal radiation exposure. Plain radiographs are relatively nonspecific and insensitive in many situations but, in some cases, provide rapid diagnostic data (e.g., **some pneumonias, visceral perforation**).
 - a. Lung.** Chest radiographs are helpful for diagnosing community-acquired pneumonia, and lung abscess but are less reliable for ventilator-associated pneumonia [114] and PCP. Pulmonary effusions, adenopathy, and masses detected on plain radiographs can be detailed further by chest CT, which also provides direct visualization for guiding invasive diagnostic and interventional measures.
 - b. Abdomen and pelvis.** Plain radiographs, at times, provide diagnostic data when images detect free air or demonstrate classic signs of bowel obstruction. Contrast studies are useful for evaluating hollow viscera; soluble contrast should be used when clinical findings suggest perforation. Masses and organomegaly, at times, are discernible with plain radiographs, but ultrasound, CT, and magnetic resonance imaging (MRI) are more reliable and provide better detail.
 - 2. CT and MRI** offer diagnostic information as well as diagnostic and interventional opportunity.
 - a. Chest CT or MRI** provides detailed images for detecting subtle abnormalities in lung, mediastinum, and bony thorax. Contrast studies help distinguish between inflammatory and noninflammatory processes. CT or MRI allows image-guided fine-needle aspiration and biopsy that often establish microbiologic and histopathologic diagnoses in lieu of higher risk open

surgical procedures. CT or MRI of chest, abdomen, and pelvis is recommended for disclosing infection foci in septic patients when the source is uncertain despite detailed clinical evaluation.

- b. Abdomen and pelvis CT or MRI** are preferred when clinical circumstance calls for a global view of intraabdominal and pelvic structures [113]. MRI or CT using i.v. and oral contrast can detect (a) abscesses (**including hepatosplenic microabscesses commonly associated with disseminated staphylococcal and fungal infections**); (b) cholecystitis and cholangitis; (c) pancreatitis (**with or without phlegmon**); (d) renal and perinephric abscesses; (e) enteric and peritoneal conditions associated with sepsis (e.g., **bowel wall inflammation, including extension into mesenteric or peritoneal regions, localized phlegmon, pneumatosis intestinalis, obstruction, fistulas, etc.**); (f) neutropenic typhlitis; (g) perirectal abscess (**particularly in septic neutropenic patients**); (h) prostatic, tuboovarian, and other pelvic abscesses; (i) endometritis; and (j) arterial or venous thrombosis. CT or MR image-guided percutaneous fine-needle aspiration and drain placement, in many cases, provide both diagnosis and intervention in patients with focal sources of infection.
- c. Head and neck CT or MRI** is recommended when clinical evaluation suggests meningitis, encephalitis, intracranial abscess, or serious infections of soft tissues not detected by physical examination (e.g., **retropharyngeal abscess**). **Sinus CT or MRI is justified in patients with sepsis of uncertain origin**, particularly in critically ill patients with *in situ* endotracheal or nasogastric tubes. Sinus-associated toxic shock syndrome has been described [115]. MRI with i.v. gadolinium is superior to CT for detecting basilar meningitis and other CNS-related inflammatory processes, including intraspinal, epidural, and paraspinous abscesses.
- d. Extremity and spine CT or MRI** is a valuable diagnostic tool for assessing patients with suspected myositis, necrotizing fasciitis, or osteomyelitis. Vertebral osteomyelitis and discitis, extremely difficult diagnoses to establish clinically, are characterized well using MRI technology. Spinal MRI provides accurate anatomic information and allows diagnostic fine-needle aspiration and biopsy.
- 3. Ultrasonography** is a simple and inexpensive means of detecting abnormal fluid collections in the soft tissues and joints. Ultrasound offers advantages over CT and MRI in certain clinical situations by virtue of portability (**particularly in critically ill patients unable to tolerate transport**), safety (**scans do not involve contrast or radiation exposure**), and low cost. Ultrasound is useful for detecting visceral and soft tissue abscesses, cholelithiasis and nephrolithiasis, and obstruction (e.g., **hydronephrosis, biliary ductal dilation**).
- 4. Nuclear medicine imaging** provides information on pathophysiologic and pathobiochemical processes not visualized using other imaging procedures. In patients with fever of unknown origin, nuclear medicine techniques provide whole body imaging and can localize inflammatory foci, permitting subsequent CT- or MRI-guided biopsy for definitive diagnosis. Conversely, nuclear medicine imaging can be used after CT or MRI localization to ascertain whether an identified focus represents an inflammatory or noninflammatory process. Decisions to perform specific infection or inflammation nuclear medicine scans must be based on applicability and clinical circumstance. There is no general consensus regarding the appropriate sequencing of imaging technology in septic patients [113]. In critically ill patients, it is reasonable and expedient to begin with cross-sectional scans and, if negative, follow with nuclear medicine imaging when clinical circumstances permit. In patients who are not critically ill, nuclear medicine scanning can be used as the initial diagnostic imaging modality. A detailed review has been published recently discussing the current and future role of nuclear medicine imaging in infection and inflammation [116].

IV. Treatment

Ideally, prevention is the best “treatment” for sepsis. In reality, there are no absolute methods for anticipating or preventing sepsis. Effective treatment of sepsis requires (a) timely institution of appropriate antimicrobial therapy; (b) aggressive supportive

measures, including immediate resuscitative measures in patients with impending or established septic shock; and (c) appropriate adjunct interventions such as surgical drainage of abscesses and debridement of necrotizing soft tissue infections.

A. Antimicrobial therapy. Selecting appropriate initial antimicrobial therapy is a high priority for treating sepsis. The life-threatening nature of sepsis justifies empiric broad-spectrum antibiotic coverage administered by parenteral route. **Specific antibiotic choices and dosing regimens are governed** by the presumed **source** of infection, suspected or known **organism(s)**, **Gram stain** results, and **resistance patterns** of common pathogens prevalent within the acquisition setting (**community-acquired vs. hospital-acquired**). **Antimicrobial selection** must also account for **host factors** such as **immune status (especially patients with neutropenia or receiving immunosuppressive drugs)**, **allergies, hepatic dysfunction**, and **renal failure**. Most hospitals limit the number of antibiotics on formulary based on availability, recognized hospital resistance patterns, and patient demographics and associated clinical variables. Hospital formulary listings and regional patient demographics aside, general guidelines apply for choosing antimicrobial therapy based on the documented or suspected source of sepsis [117,118]. Efficacy and safety are prime directives when selecting empiric antimicrobial therapy to treat life-threatening infections. Antibiotic selection is governed by target site and tailored to individual patient variables (e.g., **drug allergy or interactions, renal function, hepatic dysfunction**). Detailed discussions of individual antibiotics are included in Chapter 27.

1. Severe sepsis or septic shock without identifiable source. Broad-spectrum antimicrobial therapy for treating patients with severe sepsis or septic shock without identifiable source requires combination regimens.

a. Antipseudomonal cephalosporin (e.g., **cefepime, ceftazidime**) or **antipseudomonal penicillin** (e.g., **piperacillin, mezlocillin**) + **aminoglycoside** (e.g., **gentamicin, tobramycin, amikacin**) or **quinolone** (e.g., **ciprofloxacin, levofloxacin**). The β -lactam/aminoglycoside combination is a synergistic alliance, but in patients at increased risk for nephrotoxicity a quinolone may be preferred. With rare exception, aminoglycoside therapy may be discontinued and another suitable agent substituted in its place when clinical recovery is certain and signs of sepsis have resolved.

(1) **Clindamycin** or **metronidazole** should be added to these regimens if **anaerobes** are suspected.

b. Imipenem, meropenem, and piperacillin-tazobactam, as single agents offer broad coverage (**including anaerobes, methicillin-susceptible staphylococci, and gram-negative aerobes including *Pseudomonas* species**).

(1) **Aminoglycoside** or an **antipseudomonal quinolone** should be added if *P. aeruginosa* is suspected. None of these regimens covers methicillin-resistant staphylococci, common causes of hospital-acquired wound, or vascular catheter infections (see sections IV.5.b and IV.6).

c. Vancomycin should be added to the antimicrobial regimen if methicillin-resistant staphylococci are suspected. A **streptogramin** (e.g., **dalfopristin/quinupristin**) or an **oxazolidinone** (e.g., **linezolid**) is an acceptable alternative in patients with vancomycin allergy.

d. Linezolid or **dalfopristin-quinupristin** should be added to the antimicrobial regimen in place of vancomycin when vancomycin-resistant *Enterococcus faecium* (VRE) or vancomycin intermediate susceptible *Staphylococcus aureus* (VISA) are highly suspected. Linezolid has a better safety profile, is active against both *E. faecalis* and *E. faecium*, and offers an oral formulation for step-down therapy. Specific details regarding indications, contraindications, and warnings are included in Chapter 27.

2. Pneumonia. Sepsis related to community-acquired pneumonia in the immunocompetent host may be treated with antimicrobial regimens appropriate for community-acquired pneumonia as detailed in recent guidelines published by the Infectious Diseases Society of America [119] or the American Thoracic Society [120]. **Pneumonia in immunosuppressed patients,**

patients with structural lung disease, hospital-acquired pneumonia, and ventilator-associated pneumonia are at risk for multidrug-resistant or unusual pathogens. Appropriate antimicrobial regimens for specific clinical circumstances can be summarized as follows.

a. Immunocompetent patients with severe sepsis and community-acquired pneumonia. Suitable antimicrobial regimens include

- (1) **Third-generation cephalosporin** (e.g., ceftriaxone, cefotaxime, cefepime) + **macrolide** (e.g., erythromycin, azithromycin), or **quinolone** (gatifloxacin, levofloxacin, moxifloxacin). Ceftazidime and older fluoroquinolones (**ciprofloxacin, ofloxacin, lomefloxacin**) lack adequate activity against *S. pneumoniae*. When treating community-acquired pneumonia in elderly or critically ill patients, a quinolone may be preferable in place of a macrolide in combination with an appropriate β -lactam agent.
- (2) **β -Lactam/ β -lactamase inhibitor** (e.g., ampicillin-sulbactam, piperacillin-tazobactam, ticarcillin-clavulanate) + **macrolide** or **quinolone** as described above in section IV.1.a.(1).
- (3) **Clindamycin + quinolone** is an alternative regimen in patients with β -lactam allergy **unless meningitis accompanies pneumococcal disease**, in which case **vancomycin plus rifampin** should be added to the antimicrobial regimen.
- (4) **Vancomycin** or a **quinolone** must be included in the antimicrobial regimen when **penicillin-resistant *S. pneumoniae* is suspected** and adding **rifampin** should be considered. **Linezolid** or **dalfopristin/quinupristin** are appropriate alternatives to vancomycin **unless meningitis is present**.

b. Immunosuppressed patients with severe sepsis and community-acquired pneumonia. When community-acquired pneumonia is the source of sepsis in immunocompromised hosts, invasive diagnostic testing (**bronchoscopy or open lung biopsy**) should be considered to detect opportunistic pathogens such as mycobacteria, fungi, parasites, and *Nocardia*. When medical circumstances prevent invasive diagnostic testing, expanded empiric antimicrobial therapy to cover for opportunistic pathogens must be based on clinical judgment.

- (1) **Trimethoprim-sulfamethoxazole** should be added to regimens described section IV.2.a for **patients with HIV**.
- (2) **Trimethoprim-sulfamethoxazole (unless PCP or *Nocardia* are unlikely) + a regimen described in section IV.2.a that includes, specifically, those agents with antipseudomonal activity (e.g., cefepime, piperacillin/tazobactam) for organ transplant recipients and patients receiving chronic or high dose corticosteroid therapy.**
- (3) **Neutropenic patients** should receive antimicrobial therapy as described for sepsis of unknown source (see section IV.1) **provided the regimen selected includes adequate coverage for *S. pneumoniae* (e.g., antipseudomonal β -lactams, imipenem, or meropenem for PCN-susceptible isolates; levofloxacin, vancomycin, dalfopristin/quinupristin, or linezolid \pm rifampin for PCN-resistant isolates) and *Legionella pneumophila* (a quinolone or a macrolide).** A common contaminant in respiratory secretions, *Aspergillus* detected in sputum from neutropenic hosts justifies including **amphotericin B** empirically in the antimicrobial regimen based on the premise that this patient population is at extremely high risk for invasive aspergillosis.

c. Patients with severe sepsis, structural lung disease, and community-acquired pneumonia. Patients with structural lung disease such as cystic fibrosis are at increased risk for infection involving multidrug-resistant pathogens. Suitable regimens include the following.

- (1) **Antimicrobial regimens as detailed in section IV.2.b.(2) for immunosuppressed patients.**

- (2) **Vancomycin** or **linezolid** or **dalfopristin-quinupristin** should be included for patients with cystic fibrosis to cover *S. aureus* pending susceptibility testing results or unless staphylococci are unlikely.
- d. **Patients with severe sepsis and lung abscess and postobstructive or aspiration pneumonia.** Lung abscesses, postobstructive pneumonia, and aspiration pneumonia typically involve polymicrobial flora, including oral anaerobes. Recommended antimicrobial therapy includes the following.
- (1) **Regimens described in section IV.2.a or IV.2.b**, based on the patient's immune status, **provided the selected regimen includes adequate coverage for anaerobes.**
 - (2) Regimens containing β -lactam/ β -lactamase inhibitor combinations, **imipenem**, or **meropenem** provide sufficient anaerobic coverage. **Ertapenem** provides anaerobic coverage similar to the other carbapenems but, unlike imipenem and meropenem, lacks adequate activity against certain multidrug-resistant gram-negative aerobes, including *P. aeruginosa*.
 - (3) **Clindamycin** or **metronidazole** should be added to those regimens lacking sufficient anaerobic coverage.
- e. **Patients with severe sepsis and ventilator-associated or nosocomial pneumonia.** Nosocomial pneumonia is the most common infection among patients in intensive care units. Traditional diagnostic methods, including chest radiographs and respiratory secretion cultures, are suboptimal. Up to 50% of cases are polymicrobial; *Enterobacter* species, *Klebsiella* species, *P. aeruginosa*, and *S. aureus* are the major pathogens [121]. Appropriate antimicrobial therapy includes the following.
- (1) **Antibiotic regimens described in section IV.1 for sepsis of unknown source.**
- f. **Nursing home patients with severe sepsis and pneumonia.** *S. pneumoniae* is the most common bacterial cause of pneumonia in nursing home patients, but aerobic gram-negative pathogens, including *P. aeruginosa*, are commonly encountered. Empiric treatment in these cases includes the following.
- (1) **Extended-spectrum cephalosporin (e.g., cefepime) + clindamycin.**
 - (2) **Piperacillin-tazobactam or carbapenem (e.g., imipenem or meropenem).**
3. **Abdominal and pelvic infections.** Serious abdominal and pelvic infections associated with severe sepsis typically involve polymicrobial flora, most notably enteric gram-negative aerobes, enterococci, and anaerobes. Arguably, in a limited number of clinical situations, when *P. aeruginosa* and enterococci are unlikely, monotherapy using imipenem, meropenem, ampicillin/sulbactam, or piperacillin/tazobactam might be considered adequate; combination therapy, however, is recommended in most cases. Recommended combination therapy includes the following.
- a. **Ampicillin + gentamicin** or **tobramycin + metronidazole** or **clindamycin** if multidrug-resistant pathogens are unlikely.
 - b. **Ampicillin/sulbactam + gentamicin** if multidrug-resistant pathogens are unlikely.
 - c. **Piperacillin/tazobactam** or **imipenem + gentamicin** or **tobramycin** if multidrug-resistant pathogens are suspected. **Neutropenic patients** should receive combination regimens that provide double coverage for *P. aeruginosa*. For patients with serious β -lactam allergy, treatment options are less clearly defined but might reasonably include the following.
 - d. **Ciprofloxacin** (or other quinolone if *P. aeruginosa* is unlikely) + **aminoglycoside** or **aztreonam** (if *P. aeruginosa* is likely) + **metronidazole + enterococcal coverage.**

Note: Enterococci, intrinsically resistant to cephalosporins, are particularly relevant in sepsis associated with intraabdominal or pelvic infections. Cell-wall active agents (**penicillins**, **imipenem**, **vancomycin**) are only bactericidal in synergistic combination with aminoglycosides. For life-threatening enterococcal infections, bactericidal combinations including an aminoglycoside

are recommended despite potential for nephrotoxicity or ototoxicity. Streptomycin may be an alternative for synergy against enterococci that are highly resistant to gentamicin. Serious infections involving enterococci resistant to both gentamicin and streptomycin should be treated aggressively with alternative antibiotics in lieu of aminoglycoside synergy. Ampicillin is the drug of choice for treating penicillin-susceptible strains, but piperacillin or imipenem provide adequate coverage in regimens recommended above. Enterococci are resistant to ticarcillin (**with or without clavulanate**), nafcillin, and oxacillin. Imipenem is the only carbapenem reliably active against ampicillin-susceptible enterococci. Meropenem and ertapenem are not reliably active against enterococci. Vancomycin and linezolid are alternatives for treating ampicillin-resistant enterococci or as alternative agents in patients with β -lactam allergy. Linezolid and dalfopristin/quinupristin are options for treating vancomycin-resistant *Enterococcus faecium*. Linezolid is active against *E. faecalis* and *E. faecium*; dalfopristin/quinupristin is active against *E. faecium* but not *E. faecalis*.

4. **Urinary tract infection.** Urinary tract obstruction (e.g., **calculi, prostatism, congenital abnormalities; functional obstruction associated with neurogenic bladder**) is the major intrinsic risk factor for developing overwhelming sepsis associated with urinary tract infections. Major extrinsic risk factors include urinary tract instrumentation and indwelling Foley catheters. In addition to appropriate antimicrobial therapy, adjunct treatment includes removal of catheter or obstruction and surgical drainage of abscesses (e.g., **prostate**). Urosepsis is usually caused by gram-negative aerobes. Therapeutic options for treating septic patients due to urinary tract infections include the following.
 - a. **Third-generation cephalosporin + aminoglycoside.**
 - b. **Aztreonam or quinolones** are suitable alternatives for patients with β -lactam allergies.
 - c. **Antipseudomonal β -lactam, aztreonam, imipenem or meropenem + aminoglycoside or quinolone** are recommended when *P. aeruginosa* or other multidrug-resistant gram-negative aerobes are suspected (e.g., **nosocomial or catheter-associated urinary tract infection**).
 - d. **Enterococcal coverage** should be included when urine Gram stain shows streptococci. Suitable regimens when enterococci are suspected include the following.
 - (1) **Regimens, preferably synergistic combinations, as described in section IV.3.**
 - e. **Antifungal coverage** should be added if *Candida* species are likely. *Candida* species are being identified with increased frequency in severe hospital-acquired urinary tract infections. Clinical suspicions of systemic candidiasis can be corroborated expediently with urinalysis or urine Gram stain and antifungal treatment implemented pending urine and blood culture results.
 - (1) **Amphotericin B** should be used in life-threatening fungal infections pending culture results.
 - (2) **Fluconazole** may be appropriate if candidiasis is caused by *Candida albicans* or related species with known susceptibility to azoles.
5. **Skin and soft tissue infections.** Staphylococcal and streptococcal toxic shock syndrome associated with cellulitis, wound, and necrotizing soft tissue infections are well described. Necrotizing soft tissue infections (e.g., **cellulitis, fasciitis, myositis**) caused by *Clostridium perfringens* or *Clostridium septicum* are characterized by rapid development of pain, erythema, swelling, foul-smelling drainage, gas formation, and marked systemic toxicity. Clostridial infections may be difficult to distinguish from mixed synergistic necrotizing infections involving other anaerobes (e.g., **Bacteroides species** and **Peptostreptococcus species**) in combination with nongroup A streptococci and aerobic gram-negative bacteria (see Chapter 4). Treatment includes emergent surgical debridement and broad-spectrum antibiotics. Antimicrobial therapy may be modified based on intraoperative Gram stain and culture results.

- a. Toxic shock syndrome associated with soft tissue infections** typically involves *S. aureus* or *S. pyogenes*. Appropriate antibiotic regimens include the following.
- (1) **Nafcillin** or **oxacillin**, appropriate for treating infections caused by methicillin-susceptible *S. aureus*, also covers most nonenterococcal streptococci.
 - (2) **Vancomycin** should be used in place of antistaphylococcal penicillins if methicillin-resistant *S. aureus* or coagulase-negative staphylococci are suspected.
 - (3) **Clindamycin** should be added, particularly if *Streptococcus* is suspected, based on the premise that, in addition to inhibiting bacterial growth, it suppresses bacterial exotoxin production. Neutralization of toxins using intravenous immunoglobulin (IVIG) appears to provide additional clinical benefit in patients with streptococcal toxic shock syndrome.
- b. Other necrotizing soft tissue infections** typically involve polymicrobial flora as described above. Suitable antibiotic regimens include the following.
- (1) **Ampicillin-sulbactam + aminoglycoside** if multidrug-resistant pathogens are unlikely.
 - (2) **Piperacillin-tazobactam** or **imipenem** or **meropenem + aminoglycoside** if multidrug-resistant pathogens are likely.
 - (3) **Vancomycin** or **linezolid** or **quinupristin-dalfopristin** should be added if methicillin-resistant *S. aureus* or coagulase-negative staphylococci are suspected.
- c. Unique causes of severe sepsis associated with soft tissue infections** warrant consideration in special circumstances.
- (1) ***Vibrio vulnificus*** and ***Aeromonas hydrophila***, particularly in patients with underlying liver disease, cause fulminant infections associated with bacteremia, cutaneous lesions, and septic shock. Bacterial invasion occurs via wounds or penetrating injury during salt-water exposure. *Vibrio* sepsis associated with raw shellfish consumption has been reported in patients with underlying liver disease. Appropriate antimicrobial regimens in these settings include the following.
 - (a) **Quinolone** or **third-generation cephalosporin**.
 - (b) **Doxycycline** if *V. vulnificus* is documented.
 - (2) ***Capnocytophaga canimorsus*** can cause fulminant sepsis after dog bite injuries, most notably in asplenic individuals or those with underlying chronic liver disease. Peripheral blood Gram stain, in such cases, may reveal gram-negative bacilli within neutrophils and is considered diagnostic in the appropriate clinical setting. This gram-negative anaerobe, part of the normal oral flora in canines, is resistant to aminoglycosides and trimethoprim-sulfamethoxazole. **Quinolones** or **β -lactams** provide suitable antimicrobial therapy for infections caused by this pathogen.
- 6. Intravascular catheter infections.** Infected intravascular catheters cause as many as 150,000 bloodstream infections annually with associated mortality rates of 10% to 20%. Risk factors for intravascular catheter-related bloodstream infections include longer duration of line placement, underlying acute leukemia, AIDS, and IL-2 therapy. Staphylococci cause most line-related infections. On the other hand, line-related infections are the most common cause of *S. aureus* bacteremia in hospitalized patients. Gram-negative bacteria (e.g., *Enterobacter*, *Pseudomonas*, *Acinetobacter*) and *Candida* species also commonly cause intravascular catheter-associated infections, especially after prior broad-spectrum antimicrobial therapy. Central venous catheters should be removed from patients with severe sepsis who have no obvious source of infection. Persistent fever and bacteremia after intravascular catheter removal warrant evaluation for endocarditis, septic thrombophlebitis, or metastatic foci of infection. Pending blood and catheter-tip cultures, appropriate antibiotic regimens include the following.
- a. Vancomycin + aminoglycoside** or **extended-spectrum cephalosporin** (e.g., cefepime, ceftazidime) or **aztreonam** (if β -lactam allergy documented).

- b. **Rifampin** should be considered for patients with intravascular or life-threatening staphylococcal infections, especially when accompanied by persistent bacteremia.
 - c. **Persistent bacteremia justifies multidrug combinations** for prolonged periods, as described for endocarditis in Chapter 12.
- B. Supportive care.** Effective treatment for patients with sepsis requires resuscitation, supportive care, and monitoring. The first priority in the management of septic patients is to assess airway, respiration, and perfusion, implementing appropriate supportive measures as needed. Unstable acutely ill patients should be monitored closely in an intensive care setting.
 1. **Airway.** Intubation, for airway protection, may be required when sepsis is complicated by encephalopathy and depressed level of consciousness.
 2. **Oxygenation.** All patients with sepsis should receive supplemental oxygen. Baseline arterial blood gases should be obtained and oxygenation monitored using continuous pulse oximetry.
 3. **Perfusion.** Sepsis-associated hypotension results from plasma volume loss into interstitial spaces, decreased vascular tone causing maldistribution of blood flow, and myocardial depression limiting compensatory increases in cardiac output. Intravenous fluids, packed red blood cells, and vasopressors are administered based on intravascular volume, cardiac status, and severity of shock. A detailed discussion of hemodynamic support measures is beyond the scope of this text. The SCCM recently published practice guidelines for hemodynamic support of adult patients with sepsis [122] that can be summarized briefly as follows.
 - a. **Fluid resuscitation.** Fluid resuscitation represents the best initial therapy for treatment of hypotension in sepsis. Isotonic crystalloid solutions (e.g., **0.9% sodium chloride [normal saline], lactated Ringer solution**) or iso-oncotic colloid solutions (e.g., **albumin, dextrans, hydroxy ethyl starch, plasma protein fraction, gelatins**) and packed red blood cells can be used for intravascular volume repletion. Crystalloid and colloid solutions are equally effective when titrated to the same hemodynamic end points [122].
 - b. **Vasopressor therapy.** Vasopressor therapy should be implemented in patients with clinical signs of septic shock unresponsive to aggressive empiric fluid challenge. Dopamine is considered the first-line agent for increasing blood pressure. Pulmonary artery catheterization is useful to guide therapy. Details regarding specific vasopressor selection, indications, contraindications, monitoring, dosage, and administration are included in the practice guidelines published by the SCCM [122].
 - c. **Inotropic therapy.** Patients with sepsis-associated myocardial dysfunction may benefit from inotropic therapy as detailed in guidelines published by the SCCM [122].
 - d. **Transfusion therapy.** Hemoglobin concentrations should be maintained above 8 to 10 g/dL. Higher hemoglobin concentrations may be desirable in patients with low cardiac output, mixed venous oxygenation desaturation, lactic acidosis, widened gastric-arterial PCO₂ gradients, or coronary artery disease [122].
 4. **Nutritional support.** Optimal nutritional support is vital for maintaining immune function and appears beneficial for both preventing and deterring sepsis. Early enteral nutrition appears to enhance gut function and deter bacterial translocation. Immunonutritional therapy is discussed in section V.
 5. **Control of infection source.** Antimicrobial therapy, at times, may not eradicate infection unless the source is removed. Physical measures to eradicate ongoing infectious sources may include (a) changing or removing intravascular or urinary tract catheters; (b) changing or removing VP shunts or other implanted CNS devices; (c) removing or replacing intravascular grafts; (d) removing prosthetic heart valves, pacemakers, or defibrillator implants; (e) removing prosthetic joints or internal fixation devices; (f) draining abscesses or other infected fluid collections (**percutaneously or surgically**); (g) debriding infected tissues; and (h) removing obstructions that prevent normal drainage or emptying function.

V. Immunomodulatory Interventions

Immunomodulatory interventions are attractive potential strategies for the treatment of life-threatening inflammatory responses associated with infection. Recent clinical research, focused on reducing sepsis-associated mortality by way of modulating immune response during sepsis, has identified several promising agents or interventions that warrant consideration presently or if clinical trials corroborate efficacy. Immunomodulatory therapies, for convenience, can be roughly grouped into categories [123], recognizing there is overlap that reflects the complex nature of the SIRS called sepsis.

A. Nonspecific interventions. A number of potential nonspecific immunomodulatory therapies involve innovative application of conventional treatments used for diseases other than sepsis.

1. Steroids. Corticosteroid therapy, proposed as early as 1940 for treating patients with severe sepsis or septic shock [124], has been debated for decades. Despite initial enthusiasm engendered by anecdotal reports and early clinical trials, data from well-designed prospective studies published in 1987 showed no overall outcome benefit from empiric high-dose steroid therapy implemented early in septic shock [125,126]. Subsequent meta-analyses confirmed that brief high-dose corticosteroid treatment were ineffective [127] or possibly harmful [128]. A recent retrospective report examining prognostic factors in 80 critically ill adults with pneumococcal meningitis suggested that corticosteroids, as adjunct to appropriate antimicrobial therapy, might improve clinical outcome in patients with life-threatening meningitis [129]. Current evidence suggests that septic shock causes relative adrenal insufficiency [130]. Recent clinical trials, based on this premise, suggest that lower doses of glucocorticoids administered over longer periods (5–14 days) have beneficial hemodynamic effects and improve survival in patients with septic shock [131–133]. Presently, there are neither speculative nor corroborating guidelines for using corticosteroid therapy in the treatment of septic shock.

2. Pentoxifylline. Pentoxifylline, a phosphodiesterase inhibitor, licensed by the U.S. Food and Drug Administration (FDA) for the treatment of intermittent claudication in patients with atherosclerotic peripheral vascular disease, has multiple effects on the inflammatory cascade, including TNF and NO production. There is an increasing number of reports in the medical literature describing beneficial effects from pentoxifylline in a number of clinical syndromes such as cerebral malaria [134], acute alcoholic hepatitis [135], and postoperative organ dysfunction [136]. Small clinical trials investigating pentoxifylline effects in sepsis and ARDS, however, have not produced reliable evidence that its use improves outcome [137,138].

3. Hemofiltration. Hemofiltration, the principal underlying continuous renal replacement therapy, is effective at removing molecular weight compounds in ranges that include putative mediators of sepsis. Favorable outcome trends have been reported in limited clinical trials using hemofiltration as adjunct treatment in patients with septic shock [139], but as yet there have been no controlled clinical trials to corroborate efficacy in general. Barring more convincing evidence, it is doubtful that hemofiltration for the nonspecific removal of inflammatory mediators will prove widely applicable for treating septic shock [140]. Polymyxin B effectively binds to lipopolysaccharide and, when bound to polystyrene fibers in dialysis filters, creates a system that removes endotoxin during hemofiltration. Limited clinical reports using such a system in the treatment of patients with septic shock are encouraging [123].

B. Antimodulator interventions. Treatment interventions aimed at influencing specific mediators of the systemic inflammatory response include those that effect coagulation, cytokine, and eicosanoid cascades or modulate the production of oxygen free radicals and nitrous oxide. Although a complete review of all antimodulator therapies is beyond the scope of this text, FDA-approved drugs and a select number of other agents merit discussion.

1. APC, a natural endogenous anticoagulant, interrupts several pathways in sepsis and decreases morbidity and mortality in some patients with severe sepsis. [141]. APC inhibits thrombin generation by proteolytic inactivation of clotting factors

Va and VIIIa. Although generally not viewed as antiinflammatory agents, recent scrutiny suggests that some anticoagulant strategies affect inflammatory pathways distinct from the coagulation system. Three anticoagulant strategies tested in patients with sepsis that have drawn attention include antithrombin [142], tissue-factor-pathway inhibitor [143], and APC. Presently APC is the only agent in this class licensed by the FDA for use in patients with severe sepsis. A recent large, randomized, placebo-controlled, double-blind, international, multicenter study reported on the safety and efficacy of rhAPC (drotrecogin alpha [activated]) in 1,690 patients with severe sepsis and organ failure [144]. In two decades of failed sepsis treatment trials, this is the first investigation to demonstrate a positive effect on 28-day all-cause mortality. The only safety concern identified in the trial involved an increased incidence of serious bleeding in the rhAPC-treated group, including fatal intracranial hemorrhage in two patients. Differences in the incidence of serious bleeding were limited to the infusion period only, after which the incidence was similar in the rhAPC and placebo groups. In the study by Bernard et al. [144], rhAPC (drotrecogin alpha [activated]) administration was associated with reduced plasma D-dimer and serum IL-6 levels, evidence that the treatment diminishes the procoagulant effects of sepsis and attenuates the inflammatory cascade. In late November 2001, the FDA approved drotrecogin alpha for use in patients with severe sepsis and organ failure. However, physicians should recognize that currently the reported drotrecogin alpha success story is limited to patients meeting very specific inclusion criteria for severe sepsis, including evidence of end-organ dysfunction with shock, acidosis, oliguria, or hypoxemia (see Table 2.3). Furthermore, physicians should note the very important exclusion criteria used in this landmark clinical trial. Most notably, the study excluded patients at increased bleeding risk, including those with chronic renal failure requiring dialysis, chronic liver disease, recent surgery, organ-transplant recipients, thrombocytopenia ($<30,000$), and aspirin therapy. The study also excluded patients under 18 years of age. Unless further trials show benefit in these other groups, rhAPC (drotrecogin alpha) should not be given to patients with clinical signs of mild to moderate sepsis without evidence of end-organ damage, in those with increased bleeding risk, or individuals younger than 18 years old (Table 2.3) [145,146]. Guidelines for utilization of drotrecogin alpha are summarized in Table 2.4. Currently, there are no published clinical studies evaluating rhAPC efficacy beyond the 28-day mortality figures reported by Bernard et al. The predicted cost for drotrecogin alpha therapy at current recommended doses is \$8,000 to \$10,000.

2. **Anti-TNF therapy.** Therapies directed aimed at modulating TNF proinflammatory effects offered promise in early studies [147,148]. Subsequent large clinical trials found no beneficial effects on outcome in patients treated with anti-TNF monoclonal antibody or soluble TNF receptor preparations [123]. Infliximab, a humanized monoclonal against TNF- α , is licensed for use in the United States and elsewhere for the treatment of rheumatoid arthritis and Crohn disease. Recent reports identifying increased rates of tuberculosis in patients treated with infliximab suggests that TNF may play an important role in protecting against certain infections [149].
3. **PAF antagonist therapy.** Clinical trials involving PAF antagonists have not demonstrated reduced mortality rates in patients with sepsis [123]. Preliminary studies using recombinant PAF acetylhydrolase report promising results; confirmatory clinical data from a large multicenter clinical trial are, presently, not available.
4. **Antioxidant therapy.** Antioxidant therapy using *N*-acetyl cysteine, an agent that restores cellular antioxidant capacity, showed some promise in early studies. However, subsequent clinical trials have yielded conflicting results [123]. Selenium supplementation may be beneficial effects on renal function and outcome in patients with SIRS, but currently data are from pilot studies and require corroboration in larger clinical trials [150].
5. **NO inhibition therapy.** NOS blockade has mixed hemodynamic effects, increasing blood pressure and systemic and pulmonary vascular resistance while lowering the cardiac output. **Methylene blue**, more selective in its modulatory

Table 2.3. Recommended Indications and Contraindications for Treating Severe Sepsis with Recombinant Human-Activated Protein C (Drotrecogin Alpha [Activated])

Infection criteria	<ul style="list-style-type: none"> • Known infection or • Suspected infection (one or more of the following): <ul style="list-style-type: none"> WBC in normally sterile body fluid Perforated viscus CXR evidence of pneumonia + purulent sputum Syndromes with high risk for infection
SIRS criteria (modified)	<p>At least 3/4 of the following:</p> <ul style="list-style-type: none"> • Core temperature $\geq 38^{\circ}\text{C}$ or $\leq 36^{\circ}\text{C}$ • Heart rate ≥ 90 • Respiratory rate ≥ 20 or $\text{PaCO}_2 \leq 32$ • Mechanical ventilation for acute respiratory process • WBC $\geq 12,000$ or $\leq 4,000$ or $>10\%$ immature neutrophils
Organ dysfunction criteria	<p>One or more of the following:</p> <ul style="list-style-type: none"> • SBP ≤ 90 or MAP ≤ 70 (for ≥ 1 hr despite adequate volume resuscitation or vasopressor support) • Urine output ≤ 0.5 mL/kg/hr (for ≥ 1 hr despite adequate volume resuscitation) • $\text{PaO}_2/\text{FiO}_2 \leq 250$ + other organ dysfunction or <200 alone • Platelets $<80,000$ or 50% decrease over 3 days • Metabolic acidosis: pH ≤ 7.30 or base deficit ≥ 5 mmol/L + plasma lactate $>1.5 \times$ normal
Contraindications	<p>Clinical situations with increased bleeding risk:</p> <ul style="list-style-type: none"> • Active internal bleeding • Hemorrhagic stroke within 3 mo • Intracranial-intraspinal surgery within 2 mo • Severe head trauma within 2 mo • Trauma with increased risk of life-threatening bleeding • Epidural catheter • Intracranial neoplasm • Intracranial mass lesion • Evidence of cerebral herniation • Known hypersensitivity to drotrecogin or components

WBC, white blood cell count; CXR, chest x-ray; SBP, systolic blood pressure; MAP, mean arterial pressure.

effects on NO activity, has been used in small uncontrolled studies and appears to have beneficial hemodynamic effects. These effects were transient in earlier studies using short-term infusions of methylene blue. A more recent pilot study found that continuously infused methylene blue, in a small number of patients with septic shock, counteracted myocardial depression, maintained oxygen transport, and reduced adrenergic support requirements when compared with conventional treatment alone [151]. Larger trials are needed to delineate efficacy and safety of this antioxidant therapy.

C. Immunostimulation therapies. Immunostimulation therapies include treatment regimens directed toward enhancing immune function and recovery during sepsis.

1. Immunonutrition involving specific nutrients such as arginine, glutamine, and omega-3 fatty acids influences nutritional, immunologic, and inflammatory parameters in critically ill patients. It is unclear whether these observed nutritional effects translate into improved clinical outcomes. Treatment effects may vary with patient populations, specific nutritional formulations, and study methodology. In trials to date, immunonutrition has not clearly reduced mortality, and in one published study a certain enteral formulation was associated with increased mortality [152]. However, overall, arginine-enriched formulas may decrease

Table 2.4. Recombinant Human-Activated Protein C (Drotrecogin Alpha [Activated]) Guidelines

Administration	<ul style="list-style-type: none"> • Initiate within 24 h onset of severe sepsis • 24 $\mu\text{g}/\text{kg}/\text{h} \times 96$ h • No known antidote for overdose • Stop immediately if clinically significant bleeding develops
Surgery and invasive procedures	<ul style="list-style-type: none"> • Stop infusion 2 h before surgery or invasive procedure • Restart 12 h after achieving adequate hemostasis • Restart immediately after uncomplicated less invasive procedures
Pregnancy and lactation	<ul style="list-style-type: none"> • Pregnancy category C—effects on fetus unknown • Effects on reproductive capacity unknown • Concentration in breast milk unknown
Pediatric use	<ul style="list-style-type: none"> • Safety and efficacy in children not established
Geriatric use	<ul style="list-style-type: none"> • Safety and efficacy same as for younger adults
Hepatic dysfunction	<ul style="list-style-type: none"> • No dosage adjustment based on liver dysfunction alone
Renal dysfunction	<ul style="list-style-type: none"> • No dosage adjustment based on renal dysfunction alone • Use in end-stage disease not established
Drug interactions	<ul style="list-style-type: none"> • Formal studies not conducted • Caution advised when combined with drugs affecting hemostasis
Warnings	<ul style="list-style-type: none"> • Ischemic stroke within 3 mo • Intracranial AV malformation or aneurysm • GI bleeding within 6 weeks • Chronic severe liver disease • Known bleeding diathesis • Concurrent therapeutic heparin (≥ 15 units/kg/h) • Platelet count $< 30,000$ (even if increased posttransfusion) • Antiplatelet drugs within 7 days (e.g., ASA > 650 mg q.d.) • Thrombolytic therapy within 3 days • Oral anticoagulants or glycoprotein IIb/IIIa inhibitors • PT INR > 3.0 • Any condition with significant bleeding hazard • Bleeding hazard in location difficult to manage

Guidelines based on information current at the time of writing. Check for postmarketing updates regarding safety, indications, contraindications, and dosing recommendations. AV, arteriovenous; GI, gastrointestinal; ASA, aspirin; PT, prothrombin time; INR, international normalized ratio.

infectious complication rates and length of intensive care unit stay in critically ill patients [153]. Hopefully, further research will identify immunonutrition formulations that are safe and efficacious and define patient subsets that clearly benefit from such intervention.

2. **CSFs**, in addition to stimulating proliferation, enhance neutrophil antimicrobial function. Currently, recombinant human G-CSF (filgrastim) and GM-CSF (sargramostim) are available commercially for clinical use in the United States. The availability of these two CSFs and the finding that they enhance neutrophil antimicrobial function kindled interest in exploring their efficacy as adjunct therapy for treating bacterial and fungal infections in nonneutropenic hosts (Table 2.1) [154]. Clinical trials of G-CSF for treating nonneutropenic patients with sepsis have yielded conflicting results [123]. As with many other potential therapeutic modalities, the heterogeneous nature of sepsis as a syndrome and nonspecific nature of terminology contribute to inconsistent data regarding the use of G-CSF for improving outcomes in patients with sepsis.

D. IVIG should be administered routinely when treating septic patients with underlying immunoglobulin deficiencies. IVIG has been used as in patients without documented immunoglobulin deficiency, based on the premise that this immunomodulatory therapy improves host defense. In certain countries, despite a lack of clinical efficacy data, IVIG is used regularly for treating patients with severe sepsis. To date, well-designed, large, randomized clinical trials have not been undertaken to support the use of IVIG as routine adjunct therapy in the treatment of severe sepsis. Results from a recent small nonblinded study showed that IVIG reduced mortality (**67% untreated vs. 34% treated, $p = 0.02$**) in patients with streptococcal toxic shock syndrome [155]. A recent meta-analysis involving a limited number of patients suggested that IVIG may be beneficial for treating sepsis and septic shock [156]. Pending further data to support its routine use for treating patients with severe sepsis or septic shock, IVIG is currently recommended for treating sepsis in patients with underlying immunoglobulin deficiency syndromes and streptococcal toxic shock syndrome.

E. Antitoxin interventions. Many components of invading microorganisms are capable of triggering the systemic inflammatory response. Antitoxin interventions include therapeutic agents or modalities directed at blocking or neutralizing or removing pathogen factors that trigger or sustain ongoing SIRS.

1. Antiendotoxin therapy. Antiendotoxin strategies have been studied extensively over the past two decades [157]. Several antiendotoxin monoclonal antibody preparations have been used in large clinical trials with disappointing results. Attributing earlier clinical trial “failures” to inconsistent terminology and related sepsis trial designs, the most recent large clinical trial using E5 murine monoclonal antiendotoxin was tailored to eliminate trial design problems identified in earlier studies. The study involved more than 1,000 patients with gram-negative sepsis and concluded the antiendotoxin therapy tested had no effect or an effect too small to be detected using standard approaches to sepsis trial design and sample size [158]. Lacking definitive proof of efficacy, the future for antiendotoxin therapy is questionable, despite a frustrating tendency to show beneficial effect in post-hoc analyses from large clinical trials.

2. Bactericidal/permeability-increasing protein (BPI) is a 55-kDa protein constituent of human neutrophil azurophilic granules with selective activity against gram-negative bacteria. BPI belongs to a family of proteins of lipid and endotoxin binding proteins. Although BPI has a high affinity for the highly conserved lipid A portion of the lipopolysaccharide shared by all gram-negative bacteria, antibacterial activity depends on the envelope structure of a particular pathogen, which determines accessibility. BPI antibacterial action mechanisms are unclear but appear related to outer membrane perturbation followed by inner membrane disruption through a number of sequential interactions [159]. Cathelicidin and defensin proteins appear to enhance the early effects of BPI on bacteria, including growth inhibition and phospholipid hydrolysis activation. Later bactericidal effects, accelerated by complement membrane attack complex and phospholipid hydrolysis, require BPI penetration to the bacterial inner membrane. Although predominantly an intracellular antibacterial agent, during inflammation neutrophils also release BPI into the extracellular environment. In the search for novel anti-infectives, a recombinant amino-terminal BPI fragment (rBPI₂₁) was developed as potential treatment for gram-negative sepsis. In phase II and a limited number of phase III clinical trials, rBPI₂₁ appears to be nontoxic and nonimmunogenic and has shown some therapeutic benefit in humans [160].

VI. Prevention

Despite an increasing armamentarium of antimicrobial agents and remarkable technologic advances in critical care medicine, mortality rates for sepsis remain disturbingly high, de facto, due to lack of specific interventions and reliable diagnostic assays. Although molecular research is discovering intriguing details regarding cytokine gene polymorphisms associated with severe sepsis, clinical applicability for disease prevention is presently uncertain [161]. Sepsis prevention should be a major priority for all health care providers and institutions. Handwashing, barrier precautions, use of antibiotic-impregnated catheters, and other infection control measures reduce

risk for nosocomial infections. Rotating empiric antibiotic therapy is associated with declines in antimicrobial resistance and holds promise for reducing infectious mortality, particularly in intensive care unit settings [162].

3. NEONATAL SEPSIS AND INFECTIONS

George K. Siberry and Mark C. Steinhoff

The frequency and severity of bacterial infections are greater in the newborn period than at any time thereafter. The newborn often does not manifest the classic clinical signs of infection usually observed in children and adults. Moreover, the maturing physiology of the newborn requires that drug therapy be carefully individualized. This chapter is designed to help practitioners manage infectious diseases in these especially vulnerable patients.

I. Background. Infection and disease caused by bacteria and viruses are not uncommon in newborn infants (Table 3.1). Systemic bacterial infection occurs in fewer than 1% of newborns, and viral disease may occur in 6% to 8% of all neonates [1]. The rate of septicemia is 3.5 per 1,000 full-term infants [2]. Among full-term infants evaluated for suspected bacterial infection, only 2.2% have culture or clinical evidence of bacterial infection [3]. Nosocomial bacterial infection has been reported in 2% to 25% of newborns in intensive care nurseries [4]. **The mortality rate of neonates from infections varies among nurseries but has been reported as 15% to 50% for early-onset sepsis and 10% to 20% for late-onset sepsis. The mortality rate is higher still among premature infants.** Thus, even in this antibiotic era, the rates of morbidity and mortality from neonatal infections are extraordinarily high. Some of the reasons for the higher incidence and increased severity of neonatal infections are examined in the following sections.

A. Definitions

1. **Fetus:** from eighth week of gestation to birth.
2. **Neonate:** birth to 28 days of age.
3. **Infant:** 1 month to 1 year.
4. **Early-onset neonatal infection:** occurs within the first 7 days of life and usually is caused by organisms acquired during the intrauterine or intrapartum stages.
5. **Late-onset neonatal infection:** occurs after 7 days and frequently results from postpartum (often nosocomial) colonization.

B. Perinatal environments. Infections may be caused by pathogenic organisms acquired before, during, or after birth. In passing from intrauterine to independent existence, the newborn is exposed to and becomes colonized with many microorganisms.

1. **Intrauterine.** The fetus develops in a sterile ecosphere, protected from maternal microorganisms by the placenta and the amniotic membranes. Intrauterine infection can result from:
 - a. **Transplacental passage of pathogens** with placentitis, as seen in **viral infection** (e.g., rubella, cytomegalovirus [CMV], herpes simplex virus [HSV], hepatitis, human immunodeficiency virus [HIV], mumps), **bacterial infections** (e.g., syphilis, tuberculosis, *Listeria*, and *Salmonella* infections), and **protozoal infections** (e.g., toxoplasmosis and malaria).
 - b. **Infection that ascends** through the cervix, causing amnionitis.
2. **Intrapartum.** During normal delivery, the sterility of the amniotic space is lost when the membranes rupture. As the neonate passes through the birth canal, he or she is newly colonized with the wide variety of organisms resident in the maternal cervicovaginal canal. Common organisms include streptococci, *Escherichia coli*, and other aerobic and anaerobic enteric bacteria. The neonate also may be exposed to *Chlamydia*, *Neisseria gonorrhoeae*, HSV, HIV, and CMV if the mother is infected.
3. **Postpartum.** In the postpartum period, the neonate is in contact first with the hospital nursery and then with the household. If ill, the newborn will be exposed to a large number of staff as well as devices used for respiratory and metabolic support, all of which increase the likelihood of infection. Organisms that may spread in the nursery include enteroviruses, HSV, respiratory syncytial virus (RSV), and parainfluenza viruses.

II. Ontogeny of the immune system. In addition to movement from one environment to another, the newborn also progresses from one level of immune function to another. The

Table 3.1. Frequency of Perinatal Infections Due to Selected Microorganisms

Microorganism	Mother (per 1,000 Pregnancies)	Fetus (Intrauterine per 1,000 Live Births)	Neonate (Intrapartum per 1,000 Live Births)
Cytomegalovirus			
During pregnancy	16–130	5–15	—
At delivery	110–280	—	50–100
Hepatitis B ^a	1–2 acute 5–15 chronic	Rare	0.1–0.3
<i>Chlamydia</i>	40–50	—	10–60 (conjunctivitis) 3–10 (pneumonia)
Rubella			
Epidemic	20–40	4–30	0
Interepidemic	0.1–1.0	—	0.2
<i>Toxoplasma gondii</i>	1.5–6.4	1.3–7.0	0
Herpes simplex	1–10	Rare	0.1–0.5
Hepatitis C ^b (incomplete data)	0–43	Unknown	Unknown
Human immuno- deficiency virus	1.6 ^c		
<i>Treponema pallidum</i>	0.2	0.13 ^d	0
Group B streptococcus	50–250	—	0.6 ^e –1.4 ^f
<i>Escherichia coli</i>	Common	—	0.6 ^f

fetus may be viewed as a compromised host in a protected, sterile environment. Similarly, the newborn is a less compromised host whose immune function matures rapidly while in contact with the normal environment [5]. Because of the unique environment and the maturing immunocompetence of the neonate, the microorganisms that cause disease are different from those seen later in childhood or in adults.

A. B-lymphocytes are present by the 10th week of gestation. **Antibody production** is noted by the 20th week. Virtually all the immunoglobulin G (IgG) present at birth has been passively transferred from the maternal circulation. This transfer occurs predominantly between 32 weeks' gestation and birth; consequently, premature newborns have lower levels of IgG than do full-term infants. The half-life of this maternally derived IgG is approximately 25 days; the nadir is reached at 2 to 4 months, before the child's own production increases. Infants have a diminished antibody response to the polysaccharide antigens of the encapsulated bacteria (*Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*). These are not common causes of neonatal disease, probably because of specific antibody acquired from the mother.

B. T-lymphocytes. There is little information about the early development of T-lymphocytes. Homograft rejection is present by the fifth month of gestation. T-cell function probably is intact at birth but may not be fully effective because the non-specific inflammatory response is deficient in newborns.

- C. **Leukocytes** are present early in gestation: granulocytes at 2 months, lymphocytes at 3 months, and monocytes at 4 to 5 months. Leukocyte bactericidal function probably is normal at birth, but there is abnormal chemotaxis and probably deficient phagocytosis.
- D. **Humoral factors. Complement** is synthesized and present early in gestation but, at birth, serum **C1q, C2, C3, C4, C5, factor B**, and total hemolytic levels are **low**. The **opsonic and chemotactic activities** of the sera of premature and term neonates are decreased when compared with adult sera.
- E. **Passive immunity**
 - 1. **Transplacental transport of maternal IgG** provides some protection against the following microorganisms (if the mother has antibodies): *Streptococcus pneumoniae*, other *Streptococcus* species, *Staphylococcus* species, *Haemophilus influenzae*, and common (by natural infection or immunization) viral agents (enteroviruses, measles, rubella, chickenpox). Usually, little protection is transferred against enteric gram-negative organisms.
 - 2. **Breast milk** is rich in **secretory IgA** directed against respiratory and enteric microorganisms. It also contains active T- and B-lymphocytes, leukocytes, macrophages, and nonspecific inhibitors of bacterial and viral replication.

PHARMACOLOGY AND USE OF ANTIBIOTICS IN NEONATES

In addition to changes in immune function, the newborn also experiences rapid physiologic changes that are important in terms of drug dosage. **In the practice of pediatrics, all drugs are administered on the basis of surface area or weight until the child reaches adult size.**

I. Pharmacology

- A. **Route of administration.** Absorption of an oral drug may be affected by the initial decreased gastric acidity of newborns and by the decreased intestinal motility of premature infants. The vasomotor instability of neonates makes the subcutaneous and intramuscular routes unreliable. For these and other reasons, **antibiotics for severe neonatal infections should be administered intravenously.**
- B. **Antibiotic distribution** in infants is unique because of the rapid changes in body composition and compartments that occur after birth.
 - 1. **The extracellular fluid (ECF)** compartment comprises up to 50% of total body weight in neonates and decreases to 25% by 1 year and to 20% in adulthood. **Because the ECF compartment comprises such a high percentage of the neonate's total body weight, the volume of distribution of some drugs, such as the aminoglycosides, is increased, requiring larger doses relative to weight.**
 - 2. **Serum albumin** is quantitatively and qualitatively different in neonates relative to adults, being lower in concentration and showing less affinity for the penicillins. In neonates, albumin is important as a binder of bilirubin. Drugs that displace bilirubin from albumin (sulfonamides and selected cephalosporins) must be used with care to avoid kernicterus [6,7].
- C. **Antibiotic metabolism in the newborn** is different from that in adults and children and changes rapidly in the first week of life.
 - 1. **Hepatic.** Some hepatic enzyme systems are not fully developed at birth, and drugs rendered inactive by those systems must be administered in lower doses. Because of the decreased glucuronidation of chloramphenicol, newborns require less frequent and lower doses to avoid the gray baby syndrome.
 - 2. **Renal.** Renal blood flow, glomerular filtration, and tubular function are diminished.
 - a. **The glomerular filtration rate** is only 30% of adult levels, and this increases the half-life of the aminoglycosides and chloramphenicol.
 - b. **Tubular secretion** is decreased to 20% of adult levels. Thus, the half-life of the penicillin family is lengthened.

II. Some principles of antibiotic use

A. Dosages. Table 3.2 gives recommended dosages for selected antibiotics after consideration of body mass and physiologic maturity. **Note that drug amounts are listed per dose, not per day.**

- 1. Aminoglycosides.** Because of wide individual variation in the excretion of the aminoglycosides, their prolonged use (>5 days) should be guided by serum levels to prevent development of toxic or ineffectual levels (see Chapter 27). Some experts recommend higher doses with longer intervals to attain high-normal peaks and normal troughs.
- 2. Chloramphenicol** doses should be guided by **serum levels** (see section B.3).

B. Adverse reactions

- 1. Penicillins.** The penicillin group of drugs is safe in neonates and infants. IgE-mediated immediate reactions are rare, even in children born to allergic mothers. Methicillin-induced renal toxicity has been reported but is rare in neonates.
- 2. Aminoglycosides.** The older agents (kanamycin and gentamicin) are safe when used as recommended. Experience with amikacin and tobramycin reveals no acute toxicity in newborns when used in recommended doses and when serum levels are monitored.
- 3. Chloramphenicol** is well documented as the cause of the **gray baby syndrome** in neonates. It should be used only when less toxic drugs will not suffice, and serum levels should be monitored. Careful observation for early signs of gray baby syndrome (vomiting, abdominal distention, diarrhea, poor sucking, and respiratory distress) should be undertaken with complete blood counts (CBCs) and platelet counts at least twice weekly to detect hematologic abnormalities. (See Chapter 27.)

C. Special limitations of use of antibiotics in neonates

- 1. Sulfonamides** have only bacteriostatic effects on bacteria. They can cause kernicterus by their competition with unconjugated bilirubin for albumin binding sites. Because of this and the availability of other drugs, there is **no current indication for sulfonamides in neonates** except for treatment of toxoplasmosis and *Pneumocystis carinii* pneumonia (PCP).
- 2. Tetracyclines** are bacteriostatic and have considerable toxicity. They bind to bone and teeth by chelation with calcium, causing decreased bone growth and permanent discoloration of teeth. **The use of this group of drugs should be avoided from the second trimester of gestation to the eighth year of life.**
- 3. Cephalosporins.** The first-generation (e.g., cephalothin and cefazolin) and most second-generation agents (e.g., cefuroxime and cefoxitin) do not adequately penetrate the cerebrospinal fluid (CSF). The third-generation cephalosporins (cefotaxime and ceftriaxone) penetrate the CSF well and are active against many gram-negative bacilli. These agents are discussed in detail in Chapter 27. **Ceftriaxone should be avoided in the first 4 weeks of life because it affects bilirubin-albumin binding and may increase the risk of bilirubin encephalopathy in jaundiced neonates [6,8]; therefore, cefotaxime is preferred in the neonate [9,10].**
- 4. Nafcillin should not be used in premature or very young infants** because its excretion is predominantly by hepatic mechanisms, which may be deficient.

III. Antibiotic use in the pregnant or lactating woman (see Chapter 27)

A. Placental transfer of antibiotics. As a general rule, pregnant women should avoid **all unnecessary drugs** because of the risk of fetal toxicity. **Sulfonamides** given to mothers late in pregnancy have caused kernicterus or hemolytic anemia in infants deficient in glucose-6-phosphate dehydrogenase (G6PD). Similarly, **tetracycline** has caused dental deformities and discoloration. Of the aminoglycosides, **streptomycin** used during pregnancy has been associated with eighth nerve dysfunction in neonates. The documented fetal toxicity of these antibiotics warrants careful evaluation of their use in pregnancy [11].

B. Antibiotics in breast milk. There are limited data on nursing neonates regarding adverse effects associated with antibiotics administered to their mothers [11,12]. Nevertheless, nursing mothers should avoid all unnecessary drugs. In order to minimize infant exposure to necessary drugs, mothers should generally take their drugs

Table 3.2. Recommended Dosages of Selected Antibiotics for Neonates by Age and Birth Weight

Antibiotic	Route of Administration	Dose (mg/kg ^d) at 0–7 Days of Age		Dose (mg/kg ^d) at 8–30 Days of Age	
		Wt <2,000 g	Wt >2,000 g	Wt <2,000 g	Wt >2,000 g

^bPenicillin doses are expressed in units per kilogram.

^cSerum antibiotic levels must be monitored. Listed doses are for initiation of therapy. Target amikacin peak drawn 30–60 minutes after dose is 20–30 mg/L, and trough drawn within 30 minutes before dose is 5–10 mg/L.

^dMeningitis requires 300–400 mg/kg/day of ampicillin.

^eCefotaxime and other third-generation cephalosporins are described in detail in Chapter 27.

^fLoading dose of 20 mg/kg i.v. or orally. Target chloramphenicol peak drawn 30 minutes after IV dose or 2 hours after PO dose is 15–25 mg/L for meningitis and 10–20 mg/L for other infections. Trough drawn within 30 minutes of i.v. or oral dose should be 5–15 mg/L for meningitis and 5–10 mg/L for other infections.

^gSerum antibiotic levels must be monitored. Listed doses are for initiation of therapy. Target gentamicin peak drawn 30–60 minutes after dose is 6–10 mg/L and trough drawn within 30 minutes before dose is <2 mg/L. Some experts recommend higher doses with longer intervals to attain high-normal peaks and normal troughs.

^hExcretion predominantly hepatic; use with caution in young and premature infants.

ⁱGroup B streptococcal sepsis requires 200,000 units/kg/day of penicillin G. Group B streptococcal meningitis requires 450,000 units/kg/day of penicillin G.

^jSerum antibiotic levels must be monitored. Listed doses are for initiation of therapy. Target tobramycin peak drawn 30–60 minutes after dose is 6–10 mg/L and trough drawn within 30 minutes before dose is <2 mg/L.

^kSerum antibiotic levels usually monitored. Listed doses are for initiation of therapy. Target vancomycin peak drawn 60 minutes after dose is 25–40 mg/L and trough drawn within 30 minutes before dose is <10 mg/L.

immediately after breast-feeding. Short-acting instead of long-acting drug preparations are preferred for lactating women. An important consideration is the total daily “dose” a nursing baby would receive; in many cases, this dose is not toxicologically significant.

Few drugs are absolutely contraindicated in breast-feeding (bromocriptine, cyclophosphamide, cyclosporine, doxorubicin, dextroamphetamine, ergotamine, lithium, methotrexate, phenindione, all drugs of abuse). For many drugs, however, there are case reports of adverse effects or theoretical adverse effects on the infant that warrant caution and consideration of temporary suspension of breast-feeding. Examples of such antibacterial drugs include chloramphenicol, ciprofloxacin and other quinolones, doxycycline and other tetracyclines, metronidazole, and sulfonamides (although trimethoprim-sulfamethoxazole is categorized as compatible with breast-feeding by the American Academy of Pediatrics [AAP]). The reader is referred to references 11 and 12 for a complete review of available data and concerns of drugs with breast-feeding.

NEONATAL SEPSIS (SEPSIS NEONATORUM)

I. Bacteriology. The most common organisms causing neonatal sepsis and meningitis in the United States have changed over the decades. In the 1940's, the group A streptococci and, in the 1950's, the staphylococci (especially phage group I) were prominent. Since the early 1960's, *Escherichia coli* and, currently, the group B streptococci have been the major causative bacteria [1,2]. The prevalent pathogenic organisms in a single nursery change with time and may not be similar to organisms found on other wards. It is valuable to be aware of the most common pathogens in one's own nursery as well as of their antibiotic susceptibilities.

A. *E. coli* is one of the maternal enteric organisms that colonize the gastrointestinal (GI) tract of the newborn, and can invade the blood and meninges (see section on Neonatal Meningitis).

B. Group B streptococci have become the most common cause of bacteremia and sepsis in many nurseries [13].

1. Acquisition of group B streptococci. The organisms can be acquired **intrapartum** from the maternal cervix or vagina and colonize the skin and upper respiratory and GI tracts of the neonate. Colonization rates among pregnant women range from 5% to 40% depending on the population and culture technique. **Of infants born to colonized mothers, 40% to 75% are themselves colonized, but only 1% to 2% will develop early-onset disease.** The infants are colonized with the strains borne by their mothers. The presence of specific maternal antibody appears to protect the infant from early-onset sepsis. Determining the most efficacious and cost-effective time to screen for group B streptococcal colonization has been hampered by lack of sensitive and specific rapid diagnostic techniques, poor adherence to prenatal care, and the intermittent nature of maternal group B streptococcal colonization. **Prevention guidelines** [14] from the Centers for Disease Control, American Academy of Pediatrics, and American College of Obstetrics and Gynecology **recommend** either screening by rectovaginal culture for group B streptococci carriage at 35 to 37 weeks' gestation followed by intrapartum prophylaxis with intravenous penicillin for all carriers, or no screening but prophylaxis based on defined risk factors (Figs. 3.1 through 3.3). No economic analysis of this strategy is available, but analyses of similar prevention strategies have demonstrated cost savings [15].

2. Syndromes caused by group B streptococci

a. Early-onset disease occurs in the first 5 to 7 days of life, often as overwhelming sepsis with apnea and shock [16,17]. This devastating presentation frequently is associated with obstetric complications and prematurity. The pulmonary manifestations may be difficult to differentiate clinically or radiologically from the respiratory distress syndrome. Meningitis occurs in 15% to 30% of cases. Mortality rates of 50% in the 1960's and 1970's have declined to 10% to 20% with early aggressive management. Recurrences occur in approximately 3% of cases.

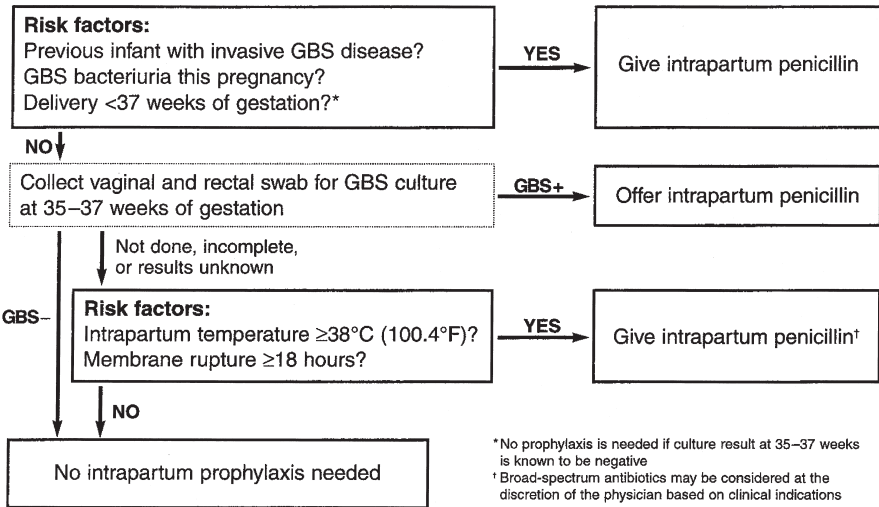

FIG. 3.1 Prevention strategy for early-onset group B streptococcus disease using prenatal culture screening at 35 to 37 weeks of gestation.

b. Late-onset disease occurs after 7 days of age (to 4 months of age) and usually presents as sepsis, meningitis, or another localized infection.

C. *Listeria monocytogenes* is a gram-positive rod that may cause congenital disease resulting in abortion or stillbirth. It is likely that peripartum colonization leads, in some neonates, to early- or late-onset disease [18].

1. Early-onset disease appears in the first week of life, often in premature infants, with pneumonia, shock, and salmon-colored dermal papules. Assisted ventilation often is required, and the mortality rate may reach 50%.

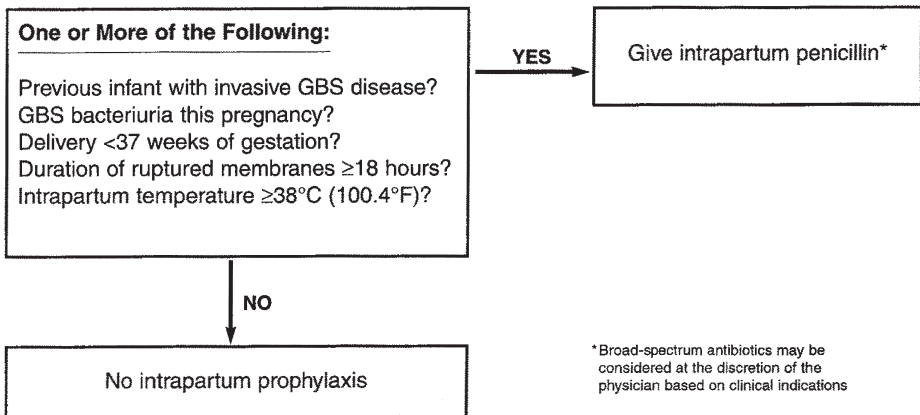

FIG. 3.2 Prevention strategy for early-onset group B streptococcus disease using risk factors without prenatal culture screening.

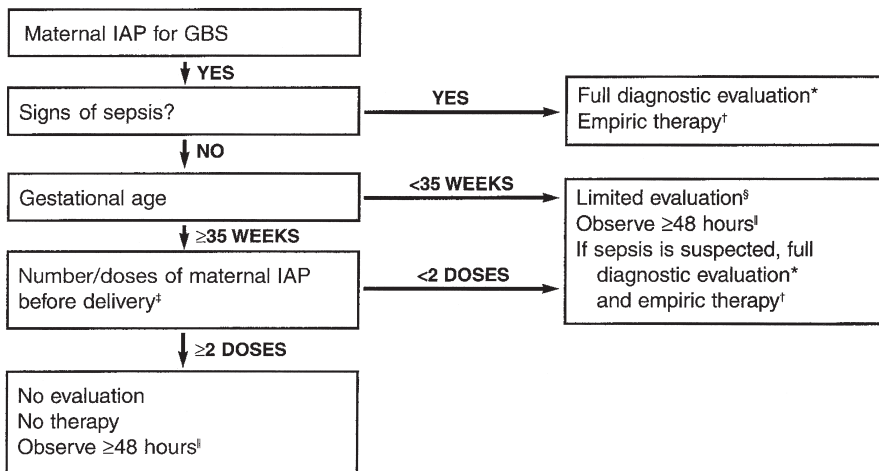

FIG. 3.3 Empiric management of neonate born to a mother who received intrapartum antimicrobial prophylaxis (IAP) for prevention of early-onset group B streptococcus disease. This algorithm is suggested but is not an exclusive approach of management. *Includes CBC and differential, blood culture, and chest radiograph if respiratory symptoms. A lumbar puncture is performed at the discretion of the physician. †Duration of therapy will vary depending on results of blood culture and CSF findings (if obtained), as well as on the clinical course of the infant. If laboratory results and clinical course are unremarkable, duration may be as short as 48 to 72 hours. ‡, applies to penicillin or ampicillin chemoprophylaxis; §, CBC and differential, blood culture. ¶Does not allow early discharge.

2. Late-onset disease often presents as meningitis in full-term infants. In some cases, the CSF is characterized by a lymphocytosis rather than polymorphonuclear leukocytes; however, this is unusual [19]. Therapy with ampicillin, alone or with gentamicin, results in a lower mortality rate than that associated with early-onset disease.

D. Anaerobes cause approximately 10% to 25% of all neonatal bacteremias [20], although only a portion of affected neonates will be septic. However, the clinical manifestations of neonatal anaerobic bacteremia are indistinguishable from other causes of neonatal sepsis. Therefore, **anaerobic cultures** using special media **should be performed routinely in neonates with suspected sepsis**, especially when aerobic cultures have been negative.

E. Miscellaneous. Many other bacteria rarely cause neonatal sepsis and meningitis. Most frequent among these are group D streptococci, *Haemophilus influenzae* (commonly nontypeable), and enteric gram-negative organisms. In high-risk newborns, *Staphylococcus epidermidis* is a common cause of vascular catheter-associated bacteremia.

F. Nonbacterial causes of sepsis syndrome. HSV and enteroviruses can present with a clinical picture similar to bacterial sepsis in the newborn (see section IV under Selected Specific Infections in the Newborn, and Disseminated Intrauterine Infections). Noninfectious diseases such as inborn errors of metabolism and congenital heart disease must also be included in the differential diagnosis of these infants.

II. Clinical features. The signs and symptoms of neonatal sepsis are **often subtle** and may be noted only by close observers such as the mother or nurse. **A high level of suspicion must be maintained** for the possibility of neonatal sepsis. Meningitis is a common complication.

A. Factors associated with neonatal sepsis are listed in Table 3.3. When any of these factors is present, at least a CBC and blood culture should be performed.

Table 3.3. Factors Associated with Neonatal Sepsis

Source or Cause	Remarks
Early-onset sepsis	
Maternal perinatal infection	Fever, pyuria, and foul amniotic fluid are signs of maternal infection.
Prolonged rupture of the membranes	Variably defined as >12, 18, or 24 h.
Prolonged labor, difficult delivery	Meconium staining may reflect stress and hypoxia of infant.
Prematurity and low birth weight	Rate of septicemia is inversely correlated with birth weight and gestational age. ^a
Low Apgar score, resuscitation	Hypoxia, hypoperfusion, aspiration, and intubation are all associated with septicemia.
Late-onset sepsis	
Congenital anomalies	Meningomyelocele, sinus tracts, and the like provide routes for infection.
Prolonged intensive care nursery admission	Increased risk of nosocomial infection.
Procedures or manipulations	Fetal monitoring electrodes, umbilical vein or artery catheters, chest tubes, arterial cannulas, and such provide routes and sites for infection.
Gender	Male infants are more likely to become septic than are female infants.

^aData from Buetow KC, Klein SW, Lane RB. Septicemia in premature infants. *Am J Dis Child* 1965; 110:20.

Most neonates with suspected sepsis are started empirically on antibiotics after appropriate laboratory studies have been performed. In some cases, the infant may simply be observed for further signs of illness before antibiotics are started.

B. Symptoms and signs in neonatal sepsis are shown in Table 3.4.

III. Diagnosis. The clinician must suspect sepsis with the report of any of the signs listed in Table 3.4. A history and physical examination will provide further information [21,22].

A. Samples of blood, urine, and CSF [23] must be obtained, examined, and cultured. Body surface cultures (ear canal, nasopharynx, axilla, umbilicus, groin, and gastric aspirate) are of limited value [24], except with HSV disease.

B. Laboratory tests may be useful in making the diagnosis.

1. Peripheral white blood cell (WBC) count (Table 3.5). Many infected infants, particularly premature infants, exhibit leukopenia rather than leukocytosis. Leukopenia should heighten concern about possible infection, although it is nonspecific. Birth asphyxia, pregnancy-induced hypertension, prematurity, low birth weight, and other conditions also may cause a low WBC count [25]. Various hematologic scoring systems have been studied, including the ratio of immature to total neutrophils, but these scoring systems are imperfect predictors of sepsis [26].

2. Latex agglutination (LA) is not routinely recommended in the diagnosis of group B streptococcal sepsis.

3. Other tests, when used individually, are unreliable indicators of neonatal sepsis. These include the erythrocyte sedimentation rate, nitroblue tetrazolium test, and levels of C-reactive protein, haptoglobin, interleukin-6, and procalcitonin. A combination of a complete leukocyte count, microerythrocyte sedimentation rate, and C-reactive protein level may be more accurate than any single test. Serial normal C-reactive protein levels over the first 1 to 3 days may be the best marker of absence of sepsis [4].

C. Presumptive therapy. Ultimately, the clinical condition of the baby should determine whether presumptive therapy is begun. **Because neonatal sepsis often**

progresses rapidly and is associated with a high mortality rate, early presumptive therapy must be instituted when this diagnosis is suspected, as soon as cultures are obtained. Many infants are treated for minimal indications, and only a few will prove to have sepsis. In one report [27], 6.5% of 1,551 infants in two nurseries were treated with antibiotics for presumed sepsis, but only 6% of those treated had positive blood cultures. Rapid early treatment is essential, even though it is recognized that many patients may be treated unnecessarily.

Table 3.6. Suggested Initial Empiric Antibiotic Therapy of Neonatal Infections

Clinical Syndrome	Suggested Therapy
Early-onset sepsis, meningitis	Ampicillin and either gentamicin or cefotaxime
Late-onset sepsis, meningitis	Ampicillin (or vancomycin) and cefotaxime
Early-onset pneumonia	Ampicillin and either gentamicin or cefotaxime
Catheter sepsis	Vancomycin and cefotaxime
Necrotizing enterocolitis	Ampicillin (or vancomycin), gentamicin, and clindamycin

IV. Therapy (Table 3.6)

A. Antibiotics

- 1. Early-onset disease.** Therapy must be directed against group B streptococci, other gram-positive cocci including enterococci, gram-negative enteric organisms, and *Listeria*. **Intravenous ampicillin and either an aminoglycoside** (the choice based on local susceptibility patterns) **or cefotaxime** intramuscularly or intravenously should be used initially. Culture results will guide more specific therapy [10,28,29].
- 2. Late-onset disease** is caused by the same organisms listed for early-onset disease, plus hospital-acquired staphylococci and gram-negative organisms. **Ampicillin and either an aminoglycoside or cefotaxime** are most often used parenterally for initial therapy. If methicillin-resistant staphylococci are epidemiologically important in the neonatal intensive care population, **vancomycin and a third-generation cephalosporin should be used** until culture and sensitivity results are available.
- 3. Duration of therapy.** Specific management must be individualized, taking into consideration maternal antibiotic therapy prepartum and intrapartum, quality of culture specimens, culture results, and the overall clinical course. In some instances, infants are treated empirically in the face of negative cultures.
 - a. If initial cultures are negative** and the infant is asymptomatic, most clinicians would stop antibiotic therapy after 3 days and observe closely.
 - b. If initial blood cultures are positive** and meningitis is not present, most authorities recommend a 10-day course of treatment, based on susceptibility data.
- Anaerobic infection, resistant bacterial infection, viral infection (especially HSV), fungal infection and noninfectious disorders should be suspected in any infant not doing well on the recommended initial therapy.

B. Ancillary care is of equal importance and usually requires an intensive care nursery.

- 1. Vital signs**, including blood pressure and blood gases, should be monitored.
- 2. Ventilatory support** often is required because of hypoxia and hypercapnia.
- 3. Fluid and electrolytes** must be monitored closely, because acidosis, hypoglycemia, and electrolyte imbalances are common in the ill neonate.
- 4. Red blood cell transfusions** may be necessary to improve intravascular volume and oxygen-carrying capacity.
- 5. Other blood products** such as white cells, intravenous immunoglobulin (IVIG), and fresh frozen plasma have all been used as adjuncts to antibiotic therapy [30]. IVIG has not been consistently effective or beneficial as prophylaxis in premature neonates or as adjunctive therapy for septic neonates, and is not routinely recommended [31–33]. Fresh frozen plasma should be used for infants with disseminated intravascular coagulation (DIC) and has been advocated to improve the diminished serum complement and opsonic activity of neonates. The data on the efficacy of granulocyte transfusions in neonates is mixed and incomplete, and their use varies by center.

NEONATAL MENINGITIS

- I. Clinical features.** The presenting features of meningitis in the neonate may not be different from those listed for sepsis (see Table 3.4). In some series, convulsions,

Table 3.7. Composition of Normal Cerebrospinal Fluid in Newborns

Age	Total WBC/mm ³		ANC		Glucose (mg/dL)		Protein (mg/dL)	
	Mean	Range	Mean	Range	Mean	Range	Mean	Range
Premature newborn	9.0	0–29	NR	NR	50	24–63	115	65–150
Full-term newborn	8.2	0–22	NR	NR	52	34–119	90	20–170
0–4 wk	11.0	0–50	0.40	0–7.5	46	36–61	84	35–189
4–8 wk	7.1	0–50	0.18	0–2.1	46	29–62	59	19–121

WBC, white blood cell; ANC, absolute neutrophil count; NR, not reported.

Adapted from Bonadio WA. The cerebrospinal fluid: physiologic aspects and alterations associated with bacterial meningitis. *Pediatr Infect Dis J* 1992;11:423, with permission.

irritability, or lethargy were more prominent. Only rarely will an infant with meningitis exhibit a bulging fontanelle or nuchal rigidity.

II. Diagnosis. Samples of blood, CSF, and urine should be obtained, examined, and cultured. The tests listed in section III under Neonatal Sepsis may be useful, especially detection of antigen by counter immunoelectrophoresis (CIE) or the latex agglutination (LA) test. Table 3.7 lists normal values for CSF analysis in newborns.

III. Bacteriology. *E. coli* and group B streptococci cause up to 70% of neonatal meningitis, with *Listeria monocytogenes* accounting for another 5%. Eighty percent of all *E. coli* meningitides are due to organisms carrying the K1 polysaccharide capsular antigen. Approximately 30% of all newborn babies are colonized with K1 strains, and the rate of meningitis is estimated to be 1 of every 100 colonized infants. Carriage of K1 strains has been demonstrated in a high percentage of nursery personnel, so infants may be colonized postnatally as well. The severity of disease and the presence of sequelae have a positive correlation with the presence and concentration of the K1 antigen in the CSF. Other pathogens known to cause meningitis include other “typical” bacteria (*Staphylococcus aureus*, *S. epidermidis*, *Citrobacter diversus* [34]), mycobacteria (tuberculosis), syphilis, viral infections (HSV, CMV, enteroviruses), toxoplasmosis, *Candida* species, and noninfectious causes (hemorrhage, malignancy).

IV. Therapy

A. Antibiotics

- 1. Initial therapy. Parenteral ampicillin and either an aminoglycoside or cefotaxime should be used. The highest doses indicated in Table 3.2 should be administered** because of the limited penetration of some of these antibiotics into the CSF. If gram-negative bacilli are seen on CSF Gram stain, some experts would use ampicillin with both an aminoglycoside and cefotaxime pending culture results [35–37].
- 2. Group B streptococci (suspected or proved). Usual regimens include cefotaxime alone or a combination of penicillin or ampicillin with gentamicin for a total of 14 to 21 days.** Because of the relative resistance of group B streptococci to penicillin and reports of relapse after therapy, the recommended doses of penicillin have been raised. Aqueous penicillin should be given at 450,000 units/kg/day (see Table 3.2). If combination therapy is initiated and CSF sterilization is documented at 24 to 48 hours, gentamicin can be discontinued and therapy completed with penicillin or ampicillin alone. Some experts recommend repeat CSF examinations at 24 to 48 hours into therapy to document sterilization and again at the completion of therapy to document decrease in CSF protein (<200 mg/dL) and neutrophils (<20%–30%) [4].
- 3. *Listeria monocytogenes* should be treated with parenteral ampicillin or penicillin.** The duration of therapy is as recommended for group B streptococci (see section 2). Some experts add a parenteral aminoglycoside (e.g., gentamicin) for synergy.

4. **Enteric gram-negative bacteria** are more difficult to eradicate from the CSF than gram-positive bacteria, in part because of the low levels of aminoglycosides achieved therein. Several routes of antibiotic administration have been studied, including the intralumbar and intraventricular routes. Controlled trials have shown either no additional benefit over the intravenous route or detrimental effects [38], and appropriate parenteral antibiotics remain the standard of care.
- a. **Third-generation cephalosporins.** Cefotaxime appears useful and safe in infants [9,10,29]. It achieves good CSF levels and has broad activity against gram-negative enteric bacteria. However, this third-generation agent is not active against *Pseudomonas* species, enterococci, or *L. monocytogenes* and does not have optimum activity against most staphylococci. Ceftriaxone, although similar to cefotaxime in its spectrum of activity, affects bilirubin-albumin binding and may increase the risk of bilirubin encephalopathy in jaundiced neonates; therefore, it should be avoided if possible [6,8]. Ceftazidime has a spectrum of activity similar to that of cefotaxime, with the added benefit of antipseudomonal activity. It may be used in the setting where *Pseudomonas* is a suspected pathogen.
 - b. **Aminoglycosides** remain important in the management of meningitis, particularly with penicillin-tolerant strains of group B streptococci and enteric gram-negative organisms. They are used together with another antibiotic, usually a β -lactam.
 - c. **Chloramphenicol** has been used in patients with susceptible bacteria, but this is not an ideal agent. Serum levels must be carefully monitored in neonates to avoid toxicity. Furthermore, chloramphenicol is usually bacteriostatic rather than bactericidal against gram-negative bacilli.
 - d. **Recommendation.** Because of the difficulties and controversies involved in treating enteric gram-negative bacilli meningitis, we **suggest an infectious disease consultation. Combination therapy with cefotaxime or ceftazidime plus gentamicin is recommended once a gram-negative organism is diagnosed by CSF gram stain or culture, pending final identification and susceptibilities.** A third-generation cephalosporin alone can be used for susceptible *E. coli* or *Klebsiella* species. For *Pseudomonas* species and most other gram-negative bacteria, combination therapy with a β -lactam and an aminoglycoside is used for the entire course; choice of specific agents is guided by isolate susceptibilities and adequacy of CSF penetration (see Chapter 27).

In general, repeat lumbar punctures are performed at 48 to 72 hours to document sterilization of the CSF, and therapy is continued for 14 days after sterilization or for a total of 21 days. Many experts recommend neuroimaging for cases of meningitis caused by gram-negative bacilli.

- B. Ancillary care** (see section IV.B under Neonatal Sepsis). It is particularly important to monitor free water intake to avoid the hyponatremia due to inappropriate secretion of antidiuretic hormone associated with meningitis. Above all, support of blood pressure and perfusion must be optimized. Corticosteroids have not been studied in the neonate and are not recommended (see Chapter 6). Other important evaluations after recovery from acute meningitis include hearing screens and careful neurodevelopmental follow-up.

SELECTED SPECIFIC INFECTIONS IN THE NEWBORN

- I. **Ophthalmia neonatorum, or conjunctivitis** in an infant under 4 weeks of age usually is caused by organisms acquired in the birth canal [39]. *Chlamydia trachomatis*, staphylococci, gonococci, streptococci, and viruses including HSV are all documented as etiologic agents of this disease. Prophylaxis is mandated in most of the United States. Silver nitrate drops 1% (Crede solution), tetracycline, or erythromycin ointment have efficacy against gonococcal conjunctivitis. One of these three products should be applied to the neonate's eyes within an hour of birth. The silver nitrate solution may cause an early, nonpurulent discharge that should resolve within 24 to 48 hours. Conjunctivitis due to *Neisseria gonorrhoeae* and other gram-negative organisms requires appropriate parenteral antibiotics. Ophthalmia caused by staphylococci

and gonococci often is of earlier onset than conjunctivitis caused by *C. trachomatis* or adenovirus. The approach to and therapy for this problem are discussed further in Chapter 7 (section IV under Conjunctivitis). **The conjunctival discharge is infectious, so handwashing control measures are important to prevent spread to attendants and other patients in the nursery.**

II. Upper respiratory tract infections. Otitis media is common in infants with cleft palate and not uncommon in normal infants in the first month of life. This infection may present in isolated fashion or as part of a generalized septicemia. A full review of this topic is available [40]. (See also Chapter 8.)

A. Bacteriology. Published reports implicate gram-negative organisms such as *E. coli* and *Klebsiella* species, as well as *S. aureus*, *Haemophilus* species, and streptococci.

B. Diagnosis is based on the finding of a gray or red tympanic membrane with decreased mobility. Tympanocentesis should be attempted to confirm the diagnosis and to direct therapy, because sepsis or meningitis may be a consequence of inappropriate therapy. A full sepsis workup should be performed for all ill-appearing infants. If a tympanocentesis is not performed, close follow-up must be assured to evaluate for possible treatment failures.

C. Therapy. Initial therapy is controversial. We advocate tympanocentesis followed by parenteral ampicillin and either an aminoglycoside or a third-generation cephalosporin for all neonates with otitis media, until culture results are available. Others suggest that outpatient amoxicillin therapy in a well-appearing older neonate is safe and sufficient initial therapy. Treatment should continue for 7 to 10 days or longer if purulent tympanic abnormalities persist (see Table 3.2 for doses).

III. Lower respiratory tract infections in neonates can be classified as congenital, intrapartum, or postnatal, depending on when the pathogen was acquired. Rales, decreased breath sounds, and percussion dullness may be difficult to detect in the neonate. **The finding of respiratory distress should lead to chest radiography, which is the most useful tool in confirming or ruling out pneumonia.** A CBC and blood culture also should be performed.

A. Congenital pneumonia usually is part of a transplacental infection. Rubella, CMV, HSV, congenital syphilis, and *Toxoplasma gondii* can all cause this type of pneumonia.

1. Clinical features. Infants with transplacental congenital pneumonia are often small for gestational age and bear the other stigmata of their infection. (See the discussion under Disseminated Intrauterine Infections.)

2. Therapy. There is no therapy for rubella infection. Clinical trials are underway to assess the possible role of ganciclovir in congenital CMV infections. The pneumonias associated with toxoplasmosis, congenital syphilis, and herpes virus should be treated as discussed under Disseminated Intrauterine Infections.

B. Intrapartum pneumonia is due to the aspiration of maternal cervicovaginal organisms or of infected amniotic fluid and is manifested at birth or shortly thereafter.

1. Clinical presentation. Babies with bacterial pneumonia may present as asphyxiated newborns with fulminant disease. Group B streptococci may cause devastating early-onset sepsis with pneumonia and respiratory distress.

2. Cultures. Cultures of blood and culture and Gram stain of respiratory secretions should be obtained. The latter is best obtained by tracheal aspiration under direct vision with a laryngoscope. If a pleural effusion is present, needle aspiration should be performed for diagnostic studies.

3. Therapy. Intrapartum pneumonia should be treated with parenteral ampicillin and either an aminoglycoside or cefotaxime for 10 days. If group B streptococci are suspected, the higher dose of ampicillin in Table 3.2 should be doubled.

C. Postpartum pneumonia often is nosocomial in origin, the infant acquiring an organism from the nursery attendants or equipment.

1. Etiology. Of particular concern are hospital-acquired staphylococcal and gram-negative bacterial pneumonias. RSV, parainfluenza viruses, and influenza

viruses are all common causes of postnatally acquired pneumonia. Because these agents often cause respiratory tract disease that cannot, with certainty, be clinically distinguished from bacterial disease, antibiotic therapy is usually initiated in lower respiratory tract disease of acute onset in the first month of life.

2. **Clinical features.** These neonates present with the development of respiratory distress: cyanosis, tachypnea, cough, apnea, expiratory grunting, nasal flaring, and subcostal and sternal retractions.
3. **Cultures** should be performed as discussed under section **B.2**. Viral cultures also should be obtained from the skin, rectum, conjunctiva, throat, and nasopharynx. Viral antigen detection tests are available for many respiratory viruses.
4. **Therapy.** Postpartum pneumonia should be treated initially with broad-spectrum parenteral antibiotics (e.g., cefotaxime and an aminoglycoside) (Table 3.6). If the organism is either staphylococcus or a gram-negative organism, therapy with the appropriate antibiotic should continue for 3 weeks. Ribavirin is not routinely recommended for the treatment of RSV infection; monthly palivizumab or RSV-IVIG can prevent severe disease and is indicated for selected infants during respiratory season. Amantadine, rimantidine, and the neuraminidase inhibitors have not been approved for treatment of influenza in newborns.

D. Chlamydial pneumonitis is a clinically distinct syndrome in infants infected intrapartum. Of those neonates who are exposed, 10% to 20% develop pneumonitis (Table 3.1).

1. **Clinical features.** Symptoms usually become apparent at 4 to 12 weeks of age. Half of the infants have a history of conjunctivitis. There is a gradual worsening of cough, which may occur in staccato paroxysms that result in cyanosis. There is no whoop, and fever is rare. Inspiratory crepitations and abnormal tympanic membranes are common features found on physical examination. Radiographs show patchy alveolar infiltrates and hyperinflation. Many affected infants have eosinophilia of more than 400/mm³ [41,42]. Infants may excrete *C. trachomatis* for up to 2 years [43].
2. **Diagnosis** is suggested by the history and clinical features. Swabs of conjunctivae and nasopharynx can be submitted for chlamydia culture and antigen detection tests for diagnostic confirmation.
3. **Therapy of conjunctivitis or pneumonia is with systemic antibiotics.** Regimens include 2 weeks of erythromycin 40 to 50 mg/kg/day, or sulfisoxazole 150 mg/kg/day [44]. Erythromycin therapy has been associated with pyloric stenosis; azithromycin at 20 mg/kg daily for 3 days may be an effective alternative [45].

E. *Ureaplasma urealyticum* and *Mycoplasma hominis* have been associated with pneumonia in the newborn. Colonization rates of up to 80% have been estimated among pregnant women; 15% to 30% of their newborns are surface-colonized at birth. The presence of these organisms in the placenta has been associated with chorioamnionitis, spontaneous abortion, prematurity, and congenital pneumonia. High antibody levels to *U. urealyticum* have been found in infants with respiratory disease and chronic lung disease [46,47].

1. **Clinical features** are not unique in pneumonia caused by these organisms.
2. **Diagnosis.** Because of high colonization rates, these pathogens should be considered when pneumonia is diagnosed. Isolation of these organisms requires special media.
3. **Therapy.** Erythromycin has been recommended for treatment of *U. urealyticum* cases [48], but no efficacy data for this agent are available.

IV. GI infections

A. Diarrheal disease is more prevalent in infancy and childhood than at any later period; this may be due to the diminished immunocompetence previously mentioned. Local antimicrobial factors such as gastric pH, peristalsis, and secretory IgA are also altered and may contribute to increased susceptibility. Breast milk probably compensates for some of the deficiencies of local immunity, but only a

fraction of neonates receive it. Enteric pathogens may be acquired orally, either intrapartum or postpartum.

1. Etiology. It is possible that a proportion of neonatal diarrheal disease is not infectious in origin, being due instead to changes in the composition and volume of the diet or to changes in bowel function. Of the infectious diarrheas, rotavirus is the most frequent; *Salmonella* and *Shigella* species and *E. coli* account for some of the remainder [49]. *Campylobacter* enteritis has occurred in neonates (see Chapter 13). *Clostridium difficile* rarely causes disease in neonates, because *C. difficile* is part of the normal neonatal flora, recovery of this organism or detection of its toxin in neonates does not indicate *C. difficile* disease. It is likely that other agents exist that are not yet identified.

2. Evaluation. A fresh stool smear should be examined for leukocytes by methylene blue staining to determine whether an invasive organism is responsible. Fecal leukocytes are often present in diarrhea caused by *Salmonella* and *Shigella* species or invasive *E. coli*, whereas they are usually absent in toxicogenic bacterial or viral disease. (For further discussion, see Chapter 13.) **Fresh stools should be cultured** for enteric pathogens, and blood cultures should be obtained.

3. Therapy

a. Replacement of fluid losses is the most important aspect of treatment. Monitoring of the infant's output, weight, and vital signs must be meticulous.

b. Antibiotic therapy for bacterial diarrhea is somewhat controversial. The following are suggested guidelines.

(1) *Salmonella* and *Shigella* species. A neonate ill with the invasive organisms *Salmonella* and *Shigella* should be treated initially with parenteral cefotaxime (pending susceptibility data) because of the risk for systemic involvement and metastatic infection. Blood cultures and CSF cultures are recommended for infants under 3 months of age with *Salmonella* infection even in the absence of fever or toxic appearance. Antibiotic sensitivities should be determined on all bacterial isolates to guide further therapy. *Shigella* should be treated for at least 5 to 7 days. Treatment of *Salmonella* gastroenteritis may prolong the carrier state, but initially ill-appearing or febrile young infants and those infants with proven invasive *Salmonella* infection require antibiotics. Ten to fourteen days of therapy are recommended for *Salmonella* bacteremia and 4 weeks for *Salmonella* meningitis [50].

(2) *E. coli*. Diarrhea in neonates and infants has been associated with certain enteropathogenic serotypes of *E. coli* (mechanism unknown), invasive *E. coli*, or strains of *E. coli* that produce an enterotoxin. Unfortunately, the tests for identification of the latter two groups of *E. coli* are not widely available. An infant with prolonged diarrhea who has an enteropathogenic serotype of *E. coli* in the stools might benefit from a course of oral neomycin (100 mg/kg/day) or colistin (15 mg/kg/day).

(3) *Campylobacter*. Erythromycin therapy has been suggested (see Chapter 13).

c. Isolation. The affected infant should be isolated immediately to prevent nosocomial spread. Infection control methods such as isolation, the placing of infants in cohorts, and enforced gowning and handwashing for all caregivers are paramount in the management of enteric infections in the nursery.

B. Necrotizing enterocolitis (NEC) [51–54] is an often severe GI disturbance of unknown primary etiology accompanied by systemic illness, and often associated with sepsis and peritonitis. Most cases (62%–94%) occur in premature infants, though it can occur in full-term infants. Age at onset is inversely proportional to gestational age. NEC occurs both sporadically and as a nursery epidemic. It has an incidence of about 10% (range 3%–22%) of all premature infants, and the mortality rate may reach 20% to 40%. Mortality is highest among infants with lower birth weights and lower gestational age, and in earlier case series. Blood cultures are positive in up to 50% of cases. The organisms found in the blood are similar to

the enteric flora seen in peritoneal fluid, with *E. coli*, *Klebsiella*, and *Enterobacter* species predominating.

1. Diagnosis

- a. **Presenting systemic signs** include temperature instability, apnea, lethargy, glucose instability, DIC, and acidosis. Common GI signs include abdominal distention, feeding intolerance, increased gastric residuals, vomiting, diarrhea, and blood (occult or gross) in the stools. Physical signs in advanced disease include peritonitis and crepitation or cellulitis of the abdominal wall. Onset is generally sudden in full-term infants but can be sudden or insidious (over 1–2 days) in preterm infants.
- b. **Roentgenographic evaluation** may show ileus, bowel distention, pneumatosis intestinalis, portal vein gas, or free peritoneal gas.
- c. **Laboratory tests** are nonspecific. Thrombocytopenia and neutropenia often occur, and frank DIC may develop. The stool may exhibit reducing substances, occult blood, or gross blood. Acidosis is usually metabolic or mixed. Blood cultures may be positive up to 50% of the time.

2. Medical therapy should be instituted as soon as this diagnosis is suspected.

- a. **Fluids and nutrition.** Enteral feedings are immediately stopped and nasogastric suction begun. Because oral feedings must be discontinued for at least 2 weeks, intravenous alimentation by the central or peripheral route should be started as soon as the baby is stable. Infants with NEC generally require increased fluids and sodium, and a urine output of ≥ 1 to 2 mL/kg/h should be maintained.
- b. **Antibiotics.** Parenteral ampicillin (or vancomycin) and an aminoglycoside (or broad-spectrum cephalosporin) should be started. Some neonatologists advocate the addition of parenteral clindamycin or metronidazole, particularly if perforation is suspected, but there is no evidence that these antibiotics improve outcome [54,55] and there is some concern that routine use of clindamycin may increase the risk of strictures. Antibiotics should generally continue for *at least* 10 to 14 days, longer if surgery is required or clinical response is slow.
- c. **Transfusion** may be necessary for volume repletion, and some clinicians advocate the use of fresh frozen plasma.
- d. **Serial radiographs.** Repeat lateral and supine radiographic views of the abdomen should be obtained every 8 hours to detect advancement or perforation.
- e. **Surgical intervention** is indicated for clinical or radiographic evidence of perforation, cellulitis of the anterior abdominal wall, or clinical deterioration despite optimal medical management.

V. Genitourinary (GU) infections. Urinary tract infections are not uncommon in the newborn; in this period, they are more common in boys than in girls. Rates for bacteriuria range from 1% in full-term infants to 3% in premature infants. The most common causative organisms are *E. coli*, *Klebsiella* species, and, less commonly, enterococci [55,56].

- A. **Clinical presentation.** Failure to gain weight, vomiting, fever, and jaundice are the most common symptoms. Local symptoms are rare; occasionally, a poor urinary stream in boys may draw attention to the GU tract. Bacteriuria may be the first sign of sepsis.
- B. **Diagnosis.** Examination of clean-catch urines can be confused by the presence of WBCs from circumcision or vaginal discharge. Most clinicians accept that clean catch urine with 20 to 25 WBCs/mm³ or more in the first week and 10 to 25 WBCs/mm³ or more in the second week is abnormal. A suprapubic bladder tap or bladder catheterization provides uncontaminated urine for urinalysis, Gram staining, and culture. The presence of any bacterial growth in a bladder tap or at least 1,000 colonies/mL in a catheterized specimen may be significant and is an indication for blood cultures and the initiation of therapy.
- C. **Initial treatment** should be guided by findings on Gram stain and usually consists of ampicillin and an aminoglycoside. Urine should be sterile 48 hours after initiation of therapy, and specific treatment should be continued for 10 to 14 days.

D. Further investigation. After control of the infection, **renal ultrasonography** and **voiding cystourethrography** are mandatory, because GU malformations are found in 5% to 10% of these patients. **Follow-up urine cultures** after completion of therapy are important because reinfection is frequent. Daily antibiotic prophylaxis (usually with amoxicillin for the first 6 to 8 weeks of life and either cotrimoxazole or nitrofurantoin thereafter) is indicated for vesicoureteral reflux and many genitourinary anomalies (see Chapter 15).

VI. Musculoskeletal infections

A. Neonatal osteomyelitis is rare but important because of its morbidity [57]. See also Chapter 5.

1. Pathogenesis. Pathogens gain access to the bone through bacteremia, direct inoculation (e.g., monitoring electrodes or venipuncture), or spread from adjacent infection. Because the fetal vascular connections extend from the metaphysis through the epiphyseal plate into the epiphysis and persist until 18 months of age, epiphysitis (with permanent damage of the growth plate) and secondary arthritis can result. The femur, humerus, tibia, and radius are the most commonly affected bones. Ninety percent of neonatal osteomyelitis is due to *S. aureus*, streptococci, *H. influenzae*, and pneumococci. Coliforms are rare causative agents.

2. Clinical presentation. Affected infants often appear well, are afebrile, and may manifest only guarding of the affected area with decreased spontaneous movement, local swelling, and tenderness. Other babies may exhibit septicemic symptoms that overshadow the local findings.

3. Diagnosis

a. X-ray findings are very useful. Because of the rapid remodeling of bone in infants, changes may be evident within 7 days. **Bone scans** may be positive within days of onset of symptoms.

b. Needle aspiration of the involved bone and secondarily infected joint space will provide material for Gram staining and culture.

4. Therapy. If gram-positive organisms are seen, a parenteral penicillinase-resistant penicillin should be given. If gram-negative organisms are seen, ampicillin and an aminoglycoside should be adequate. If no organisms are seen, a penicillinase-resistant penicillin and an aminoglycoside should be used. Drainage may be required if there is localization of pus. Specific parenteral therapy should continue for at least 3 weeks. If available, infectious disease and orthopedic consultations should be obtained.

B. Septic arthritis. A primary infectious arthritis without involvement of nearby bone may be secondary to a bacteremia or to direct inoculation (as by femoral venipuncture). *S. aureus*, gram-negative organisms (*E. coli*, *Pseudomonas* species, *Haemophilus* species, gonococci), and *Streptococcus* species account for most cases [58]. This presents in a manner identical to osteomyelitis in the newborn. The affected joint should be aspirated. The initial therapy and duration of therapy are similar to those suggested for osteomyelitis. Drainage and immobilization of the joint are important elements of treatment.

VII. Skin infections. The neonate is particularly susceptible to local skin infections because of the presence of one or two wounds (umbilical cord and circumcision), the immaturity of the stratum corneum, and the initial absence of the normal dermal bacterial flora. Only some local infections will be discussed here.

A. Superficial pustular rashes are usually due to streptococci or staphylococci and can be treated topically with hexachlorophene or an antibiotic ointment. Widespread or invasive lesions should be Gram-stained and cultured and treatment started with parenteral antibiotics to prevent septicemia. Cellulitis, erysipelas, folliculitis, and impetigo should all be treated with a parenteral penicillinase-resistant penicillin while awaiting cultures.

B. Staphylococcal scalded skin syndrome may appear in any one of its manifestations, either sporadically or as a nursery outbreak [59]. Staphylococci in phage group II that produce an exotoxin (exfoliatin) may cause (a) bullous impetigo, (b) Ritter disease in infants, (c) Lyell disease or toxic epidermal

necrolysis in older children, or (d) a scarlatiniform rash (staphylococcal scarlet fever).

1. **Clinical presentation.** Initially, the rash is erythematous, and at times tender, and it often has a sandpaper texture. Skin creases may have increased erythema (Pastia lines). Within 2 days, the epidermis peels off at sites of minor trauma (Nikolsky sign), and large, flaccid bullae appear, which also may exfoliate. The areas of exfoliation dry out, and seborrhea-like flakes appear. These flakes often are found around the mouth and desquamate over 3 to 5 days, leaving normal skin underneath. During the exfoliative stage of the disease, infants are febrile, irritable, and uncomfortable, but usually not severely ill. Children with the scarlatiniform rash syndrome do not develop a strawberry tongue and do not exfoliate.
 2. **Diagnosis** is made based on the clinical findings, because the toxicogenic staphylococci may not be recovered from the local lesion.
 3. **Therapy.** All forms of this disease should be treated with a parenteral penicillinase-resistant penicillin. Fluid therapy may be necessary because of the increased insensible fluid loss through the damaged skin.
- C. **Omphalitis** occurs when pathogenic bacteria predominate in the normally necrotic umbilical stump. It is manifested by oozing and purulent discharge from the stump and by local periumbilical inflammation and erythema. The most common causative organisms are staphylococci, *Streptococcus* species, and coliforms. Gram staining and culture should be performed. Because omphalitis can serve as the source of an ascending phlebitis (funisitis) leading to peritonitis or septicemia, it should be vigorously treated with local care and parenteral antibiotics, initially a penicillinase-resistant penicillin and either an aminoglycoside or cefotaxime.
- D. **Circumcision wound infections** are caused by the same organisms that cause omphalitis and are treated similarly.
- E. **Neonatal breast abscess** occurs in full-term infants. It is usually unilateral and occurs more often in girls. *S. aureus* is the most common pathogen, although streptococci and coliforms also have been described. Early in the course of infection, fluid should be expressed from the iodine-cleansed nipple for Gram staining and culture. In early infection, parenteral antibiotics probably will suffice for cure. Incision and drainage may be required in advanced cases. In either situation, treatment should begin with penicillinase-resistant penicillin and an aminoglycoside and should continue for 10 days with the appropriate drug (Table 3.2).
- VIII. **Hepatitis B virus (HBV)** has a unique natural history in newborns, who have difficulty clearing the infection; infants have a high probability of becoming chronic carriers of the virus. Chronic carriers of HBV have an estimated 25% risk of developing cirrhosis or hepatocellular carcinoma. (See Chapter 14.) **Since 1991, universal immunization of infants with HBV vaccine has been recommended as the best approach to eliminating transmission of HBV** [60]. We will discuss the specific recommendations for prevention of perinatal transmission. (See further discussion of HBV vaccine in Chapter 23.)
- A. **Infants acquire HBV from their mothers.** The probability of infection of the infant is increased if the maternal HBV infection is symptomatic or occurs late in pregnancy. Mothers who are positive for hepatitis surface or e antigen (HBsAg or HBeAg) transmit the virus to 80% of their infants. Most of these infants do not have symptomatic disease, but **90% become chronic HBV carriers, and up to 25% die of chronic liver disease in adulthood** [60].
- B. **Passive protection with either HBV immunoglobulin (HBIG) or immunization with HBV vaccine** is approximately 70% effective in preventing chronic infection in the newborn. Passive and active immunization used together is 90% effective. **Current recommendations** [61] are that all infants born to HBsAg-positive mothers, regardless of the mother's HBeAg or anti-HBe status, should receive both **HBIG** (0.5 mL intramuscularly [i.m.]) and **HBV vaccine** (0.5 mL i.m. at a separate site) within 12 hours of birth, and additional vaccine doses at 1 month and 6 months of age (see Chapter 23). Immunized infants should be tested for HBsAg and anti-HBs 1 to 3 months after the final (third) vaccine dose.

C. All pregnant women, particularly those at increased risk, **should be routinely tested for HBsAg during an early prenatal visit in each pregnancy.** If screening has not been done during pregnancy or the results are not available, an HBsAg test should be administered at the time of admission or soon afterward. **Infants of mothers with pending tests or of mothers who did not receive prenatal care should receive HBIG and HBV vaccine** within 12 hours of birth in the dosage appropriate for infants born to HBsAg-positive mothers (5 μ g Recombivax HB or 10 μ g Engerix-B). In full-term infants, HBIG (but not HBV vaccine) can be safely postponed up to 7 days if maternal HBsAg results are expected by that time. The HBV vaccine dose given immediately after birth to preterm infants weighing less than 2 kg (because of positive or unknown maternal HBsAg status) should not be counted in the required three-dose schedule; three subsequent doses are still required.

D. Infants should be managed with hepatitis precautions in the nursery. There is no contraindication to breast-feeding.

IX. Hepatitis C virus (HCV) is the major cause of non-A non-B hepatitis. Mothers infected with HCV transmit the virus to their infants at an average rate of 5% to 6% (range 0%–25%). Higher maternal titers of HCV RNA have been associated with increased risk of transmission, but no threshold titer has been clearly established. Maternal infection with HCV and HIV increases the risk of transmission to 14% (5%–36%) and 17%, respectively. Although transmission is thought to occur intrapartum, vaginal and cesarean deliveries have similar transmission rates. Breast-feeding is not contraindicated because it does not appear to increase the risk of transmission [62,63]. Diagnosis of HCV infection of the infant rests on persistence of anti-HCV antibody beyond 12 months of age; however, if earlier diagnosis is needed (e.g., symptomatic infant), HCV-RNA detection in blood can be performed after 1 to 2 months of age. The natural history of perinatal HCV infection is unknown. Treatment with recombinant α -interferon or ribavirin has not been evaluated in infancy [64]. (See Chapter 14.)

X. Enteroviruses, specifically **coxsackievirus**, have been implicated in neonatal disease [65]. They probably infect the neonate in the peripartum or postpartum period. Echoviruses and coxsackie B serotypes have caused nursery outbreaks during community epidemics. Most enteroviruses are capable of causing meningoencephalitis or GI disease. They can cause an undifferentiated febrile illness that leads to the consideration of sepsis in neonates. Coxsackie B serotypes have caused a serious disease consisting of encephalitis, myocarditis, and hepatitis, whereas echoviruses are associated with a hepatitis-sepsis syndrome.

Diagnosis is by culture or polymerase chain reaction (PCR) (of stool, urine, nasopharyngeal aspirate, CSF) or serologic evaluation, and treatment is supportive. Pleconaril is a promising orally active agent with limited safety and efficacy data for treatment of severe enteroviral illness in neonates and other age groups [66]. At this writing, the drug has not been licensed but may be obtained on a compassionate care basis from the manufacturer Viropharma (Exton, PA, 610-217-7541, *questions@viropharma.com*). A placebo-controlled trial of neonatal enterovirus sepsis is underway by the Collaborative Antiviral Study Group of the NIH. **Infants in the nursery with suspected coxsackievirus disease should be isolated** to prevent spread of this devastating infection.

XI. Varicella is a rare infection in the neonate but is discussed here because of the availability of therapy [67]. Infection of the fetus early in pregnancy is associated with a congenital syndrome in 2.3% of neonates, consisting of cutaneous scars, limb hypoplasia and paralysis, encephalitis, and chorioretinitis [68]. **The outcome of perinatal varicella depends on the time of exposure of the infant.** If maternal disease occurs more than 5 days before delivery, there is little or no risk of dissemination or sequelae. If maternal disease occurs within 5 days before or 2 days after delivery, approximately half the newborns will develop varicella with a risk of severe disseminated varicella and a 30% mortality rate.

Infants in the high-risk group should receive zoster immune globulin (125 units, 1.25 mL i.m.) as soon as possible after delivery [61]. If clinical varicella develops, **acyclovir** should be used. An infectious disease consultation is advised.

Infants born to mothers with varicella should be isolated in the nursery. Infants cannot receive the varicella vaccine.

XII. *Candida* species are the most common cause of fungal infection seen in newborns. True congenital candidiasis may be either local cutaneous or systemic disease, and differs from neonatal systemic candidiasis by age at onset and organ involvement. Neonatal systemic candidiasis usually involves multiple organs (rarely is skin involved) and can be divided into two forms: catheter-associated sepsis and disseminated candidiasis. Premature infants and infants with hyperalimentation catheters or with prolonged exposure to broad-spectrum antibiotics are at highest risk of disease [69,70].

A. Diagnosis is made by recovery of *Candida* from blood, CSF, or joint, pleural, or other normally sterile fluid. Antigen and antibody detection techniques have not been useful.

B. Therapy. Most authorities recommend removal of vascular catheters and administration of amphotericin B in doses of 0.5 to 1.0 mg/kg intravenously once daily over a period of 4 to 6 hours. Flucytosine (5-FC) may provide additional therapeutic benefit in selected fungal infections (100–150 mg/kg/day in three to five divided doses orally). Conclusive clinical data are available only for the use of 5-FC in *Cryptococcus neoformans* meningitis. The duration of antifungal therapy remains controversial. In disseminated infection, a total dose of 25 to 30 mg/kg of amphotericin B has been recommended. Some authorities suggest limiting the maximum maintenance dose of amphotericin B to 0.5 mg/kg/day in very-low-birth-weight (<1,500 g) infants [70,71]. Both drugs are nephrotoxic and hepatotoxic; appropriate monitoring of organ function and antifungal blood levels are recommended, as is an infectious disease consultation. (See Chapters 2 and 17.) For a review of antifungal agents in neonatal systemic candidiasis, see van den Anker et al. [72]. There is increasing experience with fluconazole in neonates, particularly for treatment of urinary candidiasis without evidence of disseminated disease.

DISSEMINATED INTRAUTERINE INFECTIONS

The syndrome of disseminated intrauterine infection is caused by diverse organisms that generally result in distinguishable clinical conditions with overlapping features. These infections have been given the acronym TORCH (toxoplasmosis, other, rubella, cytomegalovirus, herpes), which has led to the false perception that they are clinically identical and uniformly diagnosed by serology, commonly referred to as TORCH titers. These titers usually refer to measurement of organism-specific IgG; however, an infant's IgG is maternal in origin. IgM assays for these congenital infections do not have a high enough sensitivity or specificity to make them useful single diagnostic tests. Therefore, **a single TORCH titer is not a complete laboratory evaluation.** A comprehensive evaluation for suspected perinatal infection includes consideration of epidemiologic factors, maternal history, physical examination, and laboratory and radiographic findings [73]. The laboratory investigation must be undertaken in a logical, reasoned, and timely manner. Every attempt should be made to establish a definitive diagnosis because prognosis and treatment vary by disease; however, a firm diagnosis cannot always be made immediately. Careful clinical and serologic follow-up for 6 to 15 months may be necessary before an infection can be excluded or implicated.

Intrauterine infections may present with a variety of manifestations or no clinical findings at all. **Some signs that should lead to consideration of an intrauterine infection are listed in Table 3.8.** These signs are not unique to congenital infections; therefore, other diagnostic possibilities also must be explored (e.g., cardiac disease, inherited metabolic defects, immunologic disease). **In many situations, infants with congenital infections share the following characteristics:** (a) inapparent or mild disease in the mother, (b) a wide range of severity of infection in the fetus, (c) overlapping clinical features, and (d) variability of long-term sequelae. When a congenital infection is suspected, evaluations usually include (but are not limited to) placental pathology, plotting growth parameters, cranial imaging, ophthalmologic examination, liver function tests, and CBC.

Infectious agents that may cause congenital infections (disseminated or localized, intrauterine or peripartum) **include but are not limited to** toxoplasmosis, syphilis, rubella, CMV, enterovirus, parvovirus B19, HIV, herpes simplex virus, varicella-zoster

Table 3.8. Common Clinical Features Associated with Intrauterine Infection in Neonates

Growth retardation	Myocarditis
Hepatosplenomegaly	Cardiac abnormalities
Jaundice	Chorioretinitis
Hemolytic anemia	Keratoconjunctivitis
Petechiae, ecchymoses	Cataracts
Microcephaly, hydrocephalus	Glaucoma
Intracranial calcification	Nonimmune hydrops
Pneumonitis	Bone abnormalities

virus, HBV, and HCV. A brief summary of the common causes of disseminated intrauterine infections follows. For an in-depth discussion, refer to the textbook of Remington and Klein [4].

- I. *Toxoplasma gondii*** is a protozoan that may infect the fetus by transplacental passage during maternal parasitemia. Approximately 50% of infants whose mothers seroconvert during pregnancy are infected, although only 10% of these infants have clinical manifestations. Acute maternal infection early in pregnancy is less likely to cause fetal infection but more likely to cause symptomatic disease in infected fetuses; maternal infections late in pregnancy result in infection in most fetuses, but the vast majority of cases are subclinical. The estimated frequency of clinically evident infection in the United States is 1 to 4 per 1,000 live births [4].
- A. Clinical presentation.** The affected newborn exhibits chorioretinitis, CSF pleocytosis and elevated protein, microcephaly, and cerebral calcifications. Petechiae, hepatosplenomegaly, jaundice, a maculopapular rash, and interstitial pneumonitis have been described in these infants.
- B. Diagnosis is made** using the following methods:
1. Rising toxoplasma-specific IgG titers over the first 4 to 6 months of life
 2. IgM assays (double-sandwich technique, state or reference laboratory)
 3. Direct demonstration of tachyzoites in placenta or infant tissue
 4. Culture of toxoplasma from infant blood, cord blood, placenta, CSF, amniotic fluid
 5. PCR of fetal blood, amniotic fluid, neonatal blood, and CSF under study
- C. Therapy for 1 year** should include a combination of pyrimethamine (2 mg/kg/day for 2 days with maximum of 25 mg/day, then 1 mg/kg/day for 2 to 6 months, then 1 mg/kg/day Monday, Wednesday, and Friday to finish the year of total therapy) and sulfadiazine (50 mg/kg/dose twice daily), with folinic acid (10 mg three times weekly) to prevent bone marrow toxicity. Enrollment in the National Collaborative Treatment Trial is encouraged (phone 773-834-4152). CBC and platelet counts should be monitored twice weekly. Corticosteroids (prednisone 1–2 mg/kg/day) may be added for patients with active macular chorioretinitis or a CSF protein level of greater than 1 g/dL. Infectious disease consultation is recommended.
- II. Rubella.** Congenital rubella is still a problem [74]. Fetal rubella infection may result in teratogenesis or abortion if it occurs in the first 2 months of gestation. Infection after the first trimester is associated with disseminated disease.
- A. Clinical presentation.** The majority (up to 68%) of neonatal infections are subclinical. The classic presentation is of a small, full-term, “blueberry muffin” baby with thrombocytopenic purpura, cataracts, cardiac lesions, and hepatosplenomegaly. Pneumonitis, metaphyseal radiolucencies, and CNS involvement, with bulging fontanelles, are also seen. Hearing defects and mental retardation may become apparent only later in childhood.
- B. Diagnosis** is made by any one of these tests:
1. High or rising complement fixation or hemagglutination inhibition titers (IgG)
 2. Elevated specific IgM
 3. Viral culture from respiratory secretions or urine (notify laboratory that rubella is suspected)

C. Therapy is symptomatic. Infected neonates may excrete the virus for months, and they should be placed in strict isolation.

III. Cytomegalovirus is the most common virus of neonates [75], and may be acquired transplacentally, peripartum, or postnatally. Of pregnant women, 4% have cytomegaloviruria, and 10% to 15% have positive cervical cultures. It is likely that infants infected early *in utero* are affected more than those who acquire the agent later. Cytomegaloviruria has been demonstrated in 1% of neonates (range 0.2%–2.0%); most of these acquired the organism transplacentally. Maternal antibody does not prevent infection of the fetus, but it does ameliorate severity. Infants of mothers with primary CMV infection who presumably did not have passive antibody were more likely to have symptomatic infection and sequelae [76].

A. Clinical presentation. It is estimated that 95% of all babies with intrauterine CMV infection are asymptomatic. Symptomatic disseminated intrauterine disease is characterized by: (a) intrauterine growth retardation, (b) hepatosplenomegaly, (c) jaundice, (d) petechiae, and (e) pulmonary involvement. Of 106 symptomatic cases, 70% had hepatosplenomegaly, petechiae, and jaundice, and 53% had microcephaly at birth [77].

B. Diagnosis of CMV intrauterine disease is made using any of these tests:

1. Viral culture from urine or throat in the first 2 weeks of life
2. Persistently high complement fixation titers (IgG)
3. Persistently high IgM fluorescent antibody assay

C. Therapy is largely symptomatic. A trial of ganciclovir for symptomatic and asymptomatic neonatal disease is underway by the Collaborative Antiviral Study Group of the NIH. Careful hand-washing and secretion precautions are advised.

D. Prognosis. Mortality is 12% in those with disseminated disease [77]. Survivors may develop chorioretinitis, periventricular cerebral calcifications, and deafness.

The cytomegaloviruria may continue intermittently for years.

IV. Herpes simplex virus (HSV) usually is acquired peripartum but may be transmitted transplacentally as well. Both HSV types 1 and 2 cause disease in neonates.

A. Clinical manifestations. One should suspect this diagnosis when caring for a septic neonate [78]. Three syndromes are recognized: skin, eyes, and mouth (SEM), CNS, and disseminated disease. However, not all exposed infants are infected. Rates of infection in newborns are 30% to 50% following exposure to primary maternal disease and 3% to 5% following recurrent maternal disease. Although there are many more women with recurrent disease than primary disease, the higher attack rate for the latter results in 50% of the neonatal cases. **Neonatal HSV disease cannot be ruled out on the basis of maternal history** [79,80].

1. Disseminated infections. These infants may have jaundice, hepatomegaly, pneumonitis, bleeding diathesis, and CNS manifestations. Only half develop the typical vesicular rash. Mortality is 80%, and most survivors have sequelae.

2. Local disease implies involvement of only one organ system: CNS, or skin, eyes, or mouth.

B. Diagnosis may be made by using one of the following tests:

1. Viral culture of skin, rectum, throat, nasopharynx, conjunctiva, urine, stool, and CSF (CSF PCR also available)
2. Cytologic evaluation of skin lesion (multinucleate giant cells on Tzanck smear)
3. Rising complement fixation titers
4. Elevated specific IgM titers

C. Treatment of all forms of HSV infection or suspected HSV infection with **acyclovir** (20 mg/kg/dose i.v. every 8 hours for 10–21 days) should be started as soon as viral cultures have been obtained [81,82]. The use of suppressive oral acyclovir therapy following intravenous therapy for disease in a neonate is controversial. Advice should be sought from a Pediatric Infectious Disease consultant. The evaluation and management of a well infant born to a mother with active herpetic lesions is also controversial (see section D).

D. Prevention. When the mother has documented active genital HSV infection, cesarean section has reduced neonatal acquisition rates from 50% to 6% in some studies. Evaluation and management of an exposed infant is controversial. Some

experts recommend the use of routine surface (conjunctiva, nasopharynx, umbilicus, rectum) cultures obtained after 48 hours of life, and if positive, should lead to a full workup and consideration of therapy. Close follow-up by a physician and immediate evaluation of the infant for any signs of illness are the cornerstones of management. (See Chapter 16.)

V. Syphilis. The number of cases of congenital syphilis has increased steadily since the 1980's, in parallel with adult primary cases, so clinicians must again be alert for this important intrauterine infection, which has devastating sequelae if untreated. The treponema usually is acquired transplacentally, although intrapartum acquisition is possible. A mother with untreated primary or secondary syphilis is unlikely to have any normal children; half will be premature or suffer perinatal death, and the remainder will have congenital syphilis [83]. The rates of these outcomes decrease with maternal infection in late gestation to 10% perinatal death and 10% congenital syphilis.

A. Clinical presentation. Approximately 50% of infected newborns are initially asymptomatic. Infants with congenital infection may demonstrate a vesicular or bullous rash that includes the palms and soles; they may have chronic rhinitis (snuffles), maculopapular rash, abnormal CSF, pneumonitis, myocarditis, nephrosis, pseudoparalysis, nonimmune hydrops, condylomata lata, hepatosplenomegaly, and generalized lymphadenopathy. These manifestations may not be apparent at birth but may develop during the first few weeks of life [84,85].

Bony lesions appear roentgenographically at 1 to 3 months and are characteristic: symmetric metaphyseal involvement with elevation of the periosteum, and osteomyelitic lesions, most often involving the humerus and tibia. These bone changes are said to occur in 90% of infants who manifest congenital syphilis [86]. Osteochondritis and periostitis may be painful and manifested by the pseudoparalysis of a limb due to pain (pseudoparalysis of Parrot).

B. Diagnosis may be problematic. Therefore, appropriate treatment often is administered without a definitive diagnosis. **Because the risks of therapy with penicillin are minimal and the sequelae of untreated syphilis can be permanent, treatment is advised in doubtful cases.** Infants born to mothers with no prenatal care should be tested by VDRL or a similar serologic screening test for syphilis.

1. Diagnosis depends on the following:

- a. Identification of the spirochete in any of the skin lesions or in the nasal discharge by **dark-field examination**, or
- b. **Serologic evaluation** (see Chapter 16). Serum from the mother or infant is preferred over cord blood specimens for serology, because of false-positive and false-negative rates in the latter [87]. Infected infants are often asymptomatic at birth and, if maternal or infant infection occurred late in pregnancy, infected infants also may be seronegative. The RPR or VDRL test usually is used for screening, and the fluorescent treponemal antibody absorption (FTA-ABS) test is used for confirmation. Maternal antibody is transmitted to the infant, and these tests measure both IgG and IgM.

2. All newborns suspected of having congenital syphilis on the basis of maternal history, maternal serology, or physical findings should be fully evaluated by (a) careful examination for clinical signs of syphilis; (b) serology, including IgM if available; (c) radiologic survey of long bones; and (d) a lumbar puncture to collect CSF for cell count, protein, a dark-field examination, and a Venereal Disease Research Laboratory (VDRL) test (not a rapid plasma reagin [RPR] test). If available, the placenta should be examined for focal villitis and spirochetes.

C. Therapy. Recommendations account for reports of **failure of benzathine penicillin**. Initiation of therapy is based on maternal and infant serology, clinical findings, and history of maternal treatment. The mother's data are assessed first. If a serologically positive mother did not receive adequate therapy or received nonpenicillin therapy, or if adequate follow-up is not assured, her infant should be treated with penicillin at birth [85].

Infants with proven or probable disease should receive 10 to 14 days of aqueous crystalline penicillin G. Current Centers for Disease Control and American Academy of Pediatrics recommendations are for 10 to 14 days of intravenous therapy with crystalline penicillin G 50,000 units/kg/dose every 12 hours for the first week and every 8 hours after the seventh day [61,85]. Some authorities suggest procaine penicillin (50,000 units/kg/day i.m. in one dose) for 10 to 14 days. A few infants will manifest a Herxheimer reaction, with a fever spike 6 to 8 hours after the first penicillin dose. (See Chapter 16.)

Management of **asymptomatic infants** with normal CSF and normal long-bone radiographs is also determined by the adequacy of maternal therapy. Only if the mother received documented adequate penicillin therapy more than 1 month before delivery, and follow-up of the infant is ensured, can observation without therapy be contemplated. For all other situations (likely the majority), **10 to 14 days of intravenous aqueous crystalline penicillin is recommended.**

- D. Follow-up.** Treated infants should be seen at 3 months, and then at 6-month intervals for repeat serologic evaluation, CSF examinations (if initial CSF results are abnormal), and clinical reevaluation, until it is clear that RPR or VDRL titers are falling. Untreated or benzathine-treated infants should be seen at 1, 2, 4, 6, and 12 months. The RPR or VDRL titers should decrease by 3 months of age, and FTA-ABS titers should decrease by 6 months. If antibody titers remain stable or increase, reevaluation and therapy are mandatory.

VI. Human parvovirus B19, the etiologic agent of erythema infectiosum, has been associated with adverse fetal outcome following maternal infection. Case reports include spontaneous abortions, hydrops fetalis, and stillbirths, as well as normal infants. Data are not yet adequate to determine fully the risk for fetal morbidity and death following acute maternal infection with parvovirus B19. Available studies suggest that the risk of fetal death following acute maternal infection in the first 20 weeks of gestation is 3% to 9%, whereas the risk following household exposure of a woman with unknown serologic status is approximately 1% to 2% [87].

A. Clinical presentation. The principal adverse fetal outcome has been nonimmune hydrops with severe ascites and pericardial and pleural effusions, which result from severe anemia caused by direct infection and destruction of reticulocytes by parvovirus B19 (aplastic crisis) [73,88–90].

B. Diagnosis may be made by using any of the following tests:

1. Specific IgM determination in cord or neonatal blood
2. PCR for viral DNA
3. Persistent infant B19 IgG at 12 months of age and IgM; although these are not readily available

Until such tests and further data are available, the findings of elevated maternal α -fetoprotein levels, hydrops fetalis, and fetal aplastic crisis may be the best indicators of B19 infection.

C. Therapy. No specific therapy is available.

VII. HIV can be transmitted from mothers to infants *in utero*, intrapartum, or postpartum through breast milk. The reader is referred to the website www.hivatis.org [91] for continually updated guidelines for prevention of perinatal transmission and management of exposed and infected infants. The risk for **perinatal transmission** varies according to patient population and geographic location; in North America this is in the range of 20% to 25% for untreated patients, but only 1% to 2% when infected women receive prophylaxis. Issues of concern in the neonatal period center around early diagnosis of HIV infection, evaluation for *Pneumocystis carinii* prophylaxis, and management of associated conditions such as low birth weight, drug withdrawal, congenital syphilis, or hepatitis.

A. Prevention [91]. All pregnant women should be offered HIV testing regardless of identifiable risk factors; HIV testing should be sought for newborns whose mothers were not tested during the pregnancy. A placebo-controlled trial of zidovudine (ZDV; formerly azidothymidine [AZT]), in pregnant women and their newborn infants demonstrated a significantly reduced transmission rate compared with placebo (8% vs. 25%). In an African study, combined ZDV and 3TC given intrapartum and to the newborn for 1 week resulted in 10% transmission compared

with 17% with placebo. A single maternal dose of nevirapine (NVP) during labor combined with a single postnatal dose reduced transmission from 21% to 12% compared with ZDV (abbreviated course) in an African study. In a developed countries study, addition of NVP to ZDV did not reduce the transmission rate below the already low rate of 2% with ZDV alone. Thus, it is recommended that the ZDV regimen (antepartum from second trimester, intrapartum, and 6 weeks in newborn) be offered to all mother-infant pairs; addition of 3TC or NVP should be considered for women presenting in labor without prior HIV treatment/diagnosis. ZDV combined with other antiretrovirals should be offered to pregnant women with high viral loads or an immunologic, virologic, or clinical indication for antiretroviral treatment. The use of resistance testing should follow standard practice, and may help guide the choice of antiretroviral drugs in these scenarios.

Higher viral loads are associated with increased risk of transmission, although transmission has been documented despite low viral loads (<1,000 HIV copies/mL). Elective cesarean section (prior to onset of labor or membrane rupture) has been shown to decrease transmission for women not receiving antiretroviral therapy or with a viral load of greater than 1,000 copies/mL. (See related discussion in Chapter 19.)

- B. Clinical presentation.** No recognizable dysmorphic syndrome has been associated with HIV infection. **Most perinatally infected infants are asymptomatic at birth.** A small number of infants may develop symptoms within the first few days or weeks of life, including PCP, active CMV disease, or acute bacterial infections. There appear to be two distinct patterns of natural history among perinatally infected children. One group develops symptoms within the first year of life, whereas the other group remains asymptomatic for 3 to 5 years or more. Ongoing studies are attempting to delineate the factors responsible for this variation in disease progression. Symptoms most commonly include oral candidiasis, failure to thrive, developmental delay, loss of developmental milestones, lymphadenopathy, recurrent or severe bacterial infections, pneumonia (PCP), lymphocytic interstitial pneumonitis, chronic or recurrent diarrhea, and hepatosplenomegaly [92].
- C. Diagnosis. The reader is referred to *hivatis.org* [90].** Because infants acquire maternal IgG transplacentally, routine HIV testing with IgG antibody-based assays (enzyme-linked immunosorbent assay, Western blot) are not diagnostically useful. It is, however, **important to establish the diagnosis by other means as early as possible for preventive, therapeutic, and prognostic reasons.** Evaluation should include HIV DNA PCR (or HIV culture) and T-cell subsets prior to discharge (<48 hours of age), at 1 to 2 months of age, and 3 to 6 months of age. A positive PCR result or abnormal T-cell subsets or clinical concern for HIV infection require prompt and thorough reevaluation for HIV infection and of immunologic status in consultation with an HIV specialist. It is currently recommended that all infected infants be offered combination antiretroviral treatment. **A referral to a local or regional pediatric HIV specialist is advised.**
- D. Therapy.** Infants should generally receive ZDV 2 mg/kg/dose orally every 6 hours (every 12 hours if preterm with change to every 8 hours at 2 to 4 weeks depending on degree of prematurity) for the first 6 weeks. At 6 weeks, all exposed infants should receive PCP prophylaxis with cotrimoxazole until HIV infection is absolutely excluded. It is currently recommended that all infected infants be offered combination antiretroviral treatment in consultation with a pediatric HIV specialist.
- E. Routine care.** Careful attention to growth and development is essential. HIV-exposed infants should not receive oral polio vaccine (not in routine use for normal infants in the United States). CBC with T-cell subsets should be followed. Any suspicious clinical or laboratory findings merit careful and close follow-up.
- VIII. Other infectious agents** should be considered when evaluating an infant with a suspected intrauterine infection. These include tuberculosis [93], *L. monocytogenes*, *Leptospiriosis*, hepatitis B, enteroviruses, adenoviruses, varicella-zoster virus and Epstein-Barr virus. Infants with these infections have demonstrated findings included in Table 3.8. As more is learned about the pathogenesis of old and new microbial

agents, identification of other agents active in intrauterine infection will undoubtedly continue.

Although much is known about neonatal infections, controlled trials of therapy are limited in number [94]. As a consequence, many recommendations are expert opinions based on limited data. Therefore, close individualized care should be afforded all ill neonates.

- IX. Infections contraindicating breast-feeding.** Breast-feeding should be discontinued for active maternal tuberculosis, maternal herpetic breast lesions, and maternal HIV infection (in the United States).

4. SKIN AND SOFT TISSUE INFECTIONS

Fred A. Lopez and Charles V. Sanders

In organizing this chapter on skin and soft tissue infections, the syndrome of fever and rash will be addressed briefly. Afterward, more limited, superficial skin problems will be addressed (e.g., impetigo, folliculitis, cutaneous abscesses), followed by more involved infections (e.g., pedal puncture wounds, bite wounds, cellulitis, necrotizing soft tissue infections). The chapter will conclude with the basic principles of surgical site infections, tetanus prophylaxis, and infectious agents of bioterrorism (i.e., anthrax, smallpox, tularemia, and plague) that can present with cutaneous manifestations.

FEVER AND RASH

Skin and soft tissue infections are common problems confronting the physician in the office, emergency department, and inpatient hospital settings. Often, patients present with the syndrome of fever and rash. **An organized approach to this syndrome should include a meticulous history** that addresses the following points:

- I. Age of the patient.** Historically, virus-associated exanthems (i.e., measles; rubella; varicella; rubeola; roseola; hand, foot, and mouth disease; erythema infectiosum; Kawasaki syndrome) have been seen in the pediatric population. Enhanced and expanded immunization attempts have impacted significantly the epidemiology of many of these infections [1]. The most recent recommended childhood immunization schedules (www.cdc.gov/nip/) for the United States target hepatitis B, diphtheria, tetanus, pertussis, *Haemophilus influenzae* type b, polio, *Streptococcus pneumoniae*, measles, mumps, rubella, varicella, and hepatitis A. **Immunization histories** are important because many of these agents can cause fever and rash syndromes.
- II. Time of the year.** The season of the year may be helpful in prioritizing a differential diagnosis. Traditionally, rubella infections have been observed in the winter and spring; varicella (Color Plate 4.1) in the winter and early spring; rubeola in the winter and spring; *Coxsackievirus*-associated herpangina or hand, foot, and mouth disease (Color Plate 4.2 and 4.3) in the summer and fall; and erythema infectiosum in the winter and spring. The presence of infections can reflect when vectors for transmission are most widespread. Examples of vector-dependent diseases that are seen in the summer and fall include tick-borne diseases such as Lyme disease (Color Plate 4.4) and Rocky Mountain spotted fever. Mosquitoes are vectors for the West Nile virus infections recently seen in the northeastern United States during the summer and fall of 1999 [2]. Higher ambient temperatures seen in the summer months are responsible for sustaining growth of organisms such as *Vibrio vulnificus*, which can cause necrotizing skin infections in swimmers in Gulf Coast waters (Color Plate 4.5).
- III. Geography and travel.** An appreciation of the epidemiology of infectious diseases in different parts of the world is essential when assessing fever in the returned traveler [3]. For example, certain fungi are endemic in selected regions of the United States. *Histoplasma capsulatum* and *Blastomyces dermatitidis* (Color Plate 4.6) are found in the Mississippi and Ohio River valleys, whereas *Coccidioides immitis* is found in the southwestern United States. In contrast, a traveler to southeastern Asia would be exposed to the fungus *Penicillium marneffeii*. In the United States, typhoid fever due to *Salmonella typhi* is often a consequence of travel to developing countries in Latin America, Africa, and Asia where there is decreased access to safe food and drinking water. Travelers from tropical areas of South America and Africa who present with petechiae or ecchymoses may have acquired a mosquito-borne disease such as yellow fever or dengue fever. The Centers for Disease Control and Prevention (CDC) provides a webpage that highlights infectious disease concerns for travelers (www.cdc.gov/travel/).
- IV. Medication history.** Drug-induced cutaneous reactions occur in approximately 2% to 3% of patients in the hospital [4,5]. Severe adverse cutaneous reactions to drugs occur less frequently and have been estimated to occur in approximately 1 of every 1,000 inpatients [6]. These cutaneous reactions include the Stevens-Johnson syndrome (SJS)

and toxic epidermal necrolysis (TEN), disorders that are associated with more than one mucosal erosion, fever, and possible respiratory and gastrointestinal (GI) tract involvement. At least 50% of these reactions are medication related, usually developing 7 to 21 days after initiation of the offending drug. Sulfonamides, anticonvulsants, aminopenicillins, certain nonsteroidal antiinflammatory drugs, and allopurinol are more frequently reported causes of drug-induced SJS and TEN.

- V. Host immune status** [7]. Individuals with humoral- and complement-associated immunodeficiencies (e.g., splenectomy) are at increased risk for infections with encapsulated organisms such as *S. pneumoniae* (Color Plate 4.7), *Neisseria meningitidis* (Color Plate 4.8), and *Haemophilus influenzae*. Patients with cell-mediated immunodeficiency are susceptible to infections with organisms such as *Salmonella* species, *Mycobacteria* species, herpes viruses, *C. immitis*, *H. capsulatum*, *P. marneffe*, *Cryptococcus neoformans*, and *Strongyloides* species, to name a few. Neutropenia or neutrophil dysfunction is associated with infections due to staphylococci, enterococci, anaerobic bacteria, the Enterobacteriaceae, *Pseudomonas aeruginosa*, *Candida* species, and *Aspergillus* species.
- VI. Predisposition to infective endocarditis.** Risk factors for endocarditis should be sought, such as predisposing cardiac conditions [8] (see Chapter 12). Intravenous drug use is also considered a predisposition for development of infective endocarditis [9]. Skin lesions associated with endocarditis include Osler nodes (Color Plate 4.9), Janeway lesions, splinter hemorrhages, and cutaneous and subconjunctival petechiae.
- VII. Exposure history.** An exposure history is important to obtain in patients who present with fever and rash. Specific etiologies may be dictated by occupation. Healthcare workers are exposed to blood-borne diseases such as human immunodeficiency virus (HIV), hepatitis B, and hepatitis C, as well as aerosolized agents such as *N. meningitidis* and *Mycobacterium tuberculosis*. Fishermen and butchers may be exposed to *Erysipelothrix rhusiopathiae*; wilderness workers to ticks infected with rickettsial organisms; animal handlers to a broad range of microbes including *C. neoformans*, *Chlamydia psittaci*, *Bacillus anthracis*, *Francisella tularensis* (Color Plate 4.10), *Streptobacillus moniliformis*, *Yersinia pestis*, *Brucella* species, *Pasteurella multocida* (Color Plate 4.11), *Bartonella henselae*, and the rabies virus, to name a few.
- A thorough **sexual history** is a priority. Although many of the sexually transmitted diseases manifest as localized genital diseases, some such as syphilis and gonorrhea may produce systemic symptoms and a more generalized rash. Infection-associated genital ulcer diseases include syphilis, herpes simplex, chancroid, donovanosis, and lymphogranuloma venereum. *Neisseria gonorrhoeae* and *Chlamydia trachomatis* primarily affect the urogenital tract. Reiter syndrome, manifesting as a triad of conjunctivitis, arthritis, and urethritis, can be seen after chlamydial urethritis. An underdiagnosed condition is the acute seroconversion syndrome associated with primary HIV infection. Signs or symptoms seen in more than 50% of patients presenting with acute HIV infection include fever, myalgia, rash, pharyngitis, malaise, and lymphadenopathy [10,11] (see Chapter 19).
- VIII. Specific characteristics of the rash** that should be addressed when evaluating the patient with fever and skin lesions include the following [12–15]:
- A.** History of similar rash
 - B.** Description of lesions
 - C.** Time of onset of the rash
 - D.** Initial location of rash
 - E.** Change or progression of rash
 - F.** Duration of rash
 - G.** Exacerbating or ameliorating interventions
 - H.** Associated signs and symptoms
 - 1.** Abnormal chest findings
 - 2.** Headache and stiff neck
 - 3.** Lymphadenopathy
 - 4.** Joint pains
 - 5.** Desquamation
 - 6.** Mucous membrane lesions

IMPETIGO

Impetigo is a primary pyoderma classically seen in children who are 2 to 5 years of age. Two forms of impetigo exist: nonbullous (i.e., simple superficial impetigo) and bullous.

I. Clinical characteristics

- A. Nonbullous impetigo** is more common. Typically, multiple lesions initially present as a vesicle before progressing to a pustule and finally a plaque with a dried, thick, honey-colored crust (Color Plate 4.12). Traumatized and exposed areas of the face, scalp, or extremities are most frequently involved. Predisposing factors of impetigo include varicella infection, ulcers associated with trauma, reactions to insect bites or stings, burns, diabetes mellitus, hypogammaglobulinemia, HIV infection, scabies, and atopic dermatitis [16]. Patients are relatively asymptomatic, and rarely complaining of fever, pain, or itching. Local lymphadenopathy is often present. Impetigo usually resolves without any therapy.
- B. Bullous impetigo** presents as clear to yellow-colored flaccid bullous lesions that become pustular with surrounding erythema (Color Plate 4.13). After rupturing, these lesions develop crusted centers that resemble nonbullous impetigo. Coalescence of these lesions may create lesions that are several centimeters in diameter. These lesions are typically nonpruritic and occur on the trunk, face, neck, perineum, or periumbilical areas. Local lymphadenopathy is more common in nonbullous disease. Systemic symptoms are usually absent.

II. Epidemiology

- A. Nonbullous impetigo** is more common in humid, warm climates. The agents responsible for infection include *Streptococcus pyogenes* (group A streptococcus) and *Staphylococcus aureus*, often in combination [17]. Highly contagious, impetigo can spread among individuals in close living situations, for example, among infants in nursery and day-care settings or family members at home. Spread may be from infected individuals or carriers of *S. pyogenes* and *S. aureus*; carriage of these organisms also predisposes to infection.

Bullous impetigo is usually caused by group II phage type 71, exfoliative toxin A-producing strains of *S. aureus*.

III. Diagnosis and therapy

A. Nonbullous impetigo

- 1. Diagnosis** is usually based on the clinical presentation, and microbiologic workup is not recommended unless there is uncertainty about the diagnosis or failure of the infection to resolve with appropriate antibiotics. Identification in gram-stained specimens or isolation of the etiologic agent from culture of skin lesions can be used for definitive diagnosis. Histopathologic examination reveals neutrophils and lymphocytes in intracorneal and subcorneal epidermal and dermal pustules. Titers of anti-DNAse B can help document recent skin infection with group A streptococci.
- 2. Based on the microbiology of impetigo, therapy should target both streptococci and staphylococci.**
 - a.** Lesion-associated crusts should be debrided and cleansed with agents such as povidone-iodine or chlorhexidine.
 - b. Oral antibiotic therapy** consisting of approximately 10 days of dicloxacillin, erythromycin (equivalent dosing of clarithromycin or azithromycin), cephalexin, or clindamycin is effective and preferred for widespread disease. Some clinicians favor its use in close living situations where several members are already infected because topical agents do not eliminate streptococci from the respiratory tract [18].
 - c. Mupirocin** therapy, applied **topically** three times daily for 10 days, can be used for limited disease that does not involve the mouth or scalp and is as effective as oral regimens [19–21].

B. Bullous impetigo

- 1. A clinically based diagnosis** can be made in obvious cases. Definitive diagnosis requires microbiologic studies (i.e., Gram stain and culture of bullae fluid).
- 2. Therapy. Topical mupirocin is not as effective as in nonbullous impetigo.** Oral agents directed against staphylococci are recommended. Dicloxacillin,

a first-generation cephalosporin, amoxicillin/clavulanic acid, erythromycin, clarithromycin, or clindamycin for 7 to 10 days can be used. Disseminated disease may dictate the use of an intravenous antistaphylococcal agent.

IV. Complications. Cellulitis, osteomyelitis, septic arthritis, lymphangitis, lymphadenitis, and glomerulonephritis are potential complications of impetigo [16]. Nephritogenic strains of group A streptococcus include M serotypes 2, 49, 55, 57, 59, 60, and 61. The latency period between the pyoderma and renal disease is approximately 3 weeks. Treatment of streptococcus-associated impetigo does not appear to change the risk for development of glomerulonephritis.

V. Prophylaxis and control measures

- A. Strict attention to personal hygiene** including regular bathing and clothing that protects infected areas of the body that are usually exposed can be helpful.
- B. Some experts have recommended that skin lesions such as those associated with insect bites or minor trauma with abrasions should be treated with topical antibiotic agents such as neomycin-bacitracin to prevent development of impetigo** [22].
- C. Antibiotic prophylaxis with penicillin** has been used in the management of patients with acute poststreptococcal glomerulonephritis and their family members with streptococcal colonization as well as in the control of some epidemics in other high-risk settings. However, no standard recommendations exist for prophylaxis.
- D. Hospitalized patients with extensive group A streptococcal skin infections that cannot be adequately covered should be in contact isolation** for at least 24 hours after antibiotic therapy has been initiated. Children with impetigo should refrain from close contact with others (including school) for at least 24 hours after initiation of antibiotic therapy [18].

FOLLICULITIS

I. Clinical characteristics

A. Superficial folliculitis is best defined as a pyoderma confined to the hair follicle. Usually manifested as erythematous, pruritic papules (≤ 5 mm in diameter) with a central pustular component, these lesions are often found on the face, scalp, back, buttocks, arms, and legs (Color Plate 4.14). Rupture of the pustule results in a crusted lesion. Predisposing factors for this superficial follicular infection include poor hygiene, warmer weather associated with high humidity, and occlusive ointments and dressings. The causative organism is usually *S. aureus*. **Hot tub folliculitis** refers to a folliculitis that develops after exposure to a high density of *P. aeruginosa* in a contaminated whirlpool, hot tub, or swimming pool. Multiple erythematous pruritic papulopustular lesions typically appear in the axillae, buttocks, legs, trunk, and waist within a couple of days of the exposure (Color Plate 4.15).

II. Diagnosis can often be made on clinical grounds, although organisms may be cultured from pustular lesions.

III. Treatment

- A. Folliculitis typically resolves without therapy.** Warm saline compresses may provide symptomatic relief, and topical agents such as erythromycin, clindamycin, or gentamicin are usually adequate for treatment.
- B. Preventative measures are most important** and include optimizing good hygiene and skin cleansing, avoiding sources of infection and in the case of "hot tub folliculitis," improved pool maintenance. Patients with recurrent staphylococcal folliculitis may benefit from monthly application of nasal mupirocin ointment (see nasal carriage of *S. aureus* below) [23].

CUTANEOUS ABSCESSSES

I. Types

A. Furuncles. Usually a result of a preceding infection of a hair follicle, a furuncle (or boil) is a tender, fluctuant, subcutaneous inflammatory nodule that extends to the dermis. Risk factors for development include defects in neutrophil function, obesity, corticosteroid use, occlusive dressings, hemodialysis-dependent renal failure, atopic dermatitis, parenteral drug use, diabetes, malnutrition, contact sports and exposure to individuals with follicular infections [16,24,25]. These lesions tend to form

in areas of friction and sweating, including the back of the neck, axillae, face, groin, thighs, and buttocks. Often solitary, a furuncle can enlarge and become painful before spontaneously draining purulent material. A surrounding cellulitis may be present. Associated constitutional symptoms are not frequently observed. The causative organism is most commonly *S. aureus*, although the microbiology is dictated by the organisms that colonize involved areas. Healthy individuals with recurrent furunculosis are often nasal carriers of *S. aureus*. Abscesses consisting of aerobic and anaerobic bacteria are more prevalent in the perirectal area [26].

- B. **Carbuncles.** A carbuncle refers to a series of coalescent furuncles that express pus from multiple tracts. These collections of multiple abscesses can be quite painful and are more likely to be accompanied by fever. In patients with cellulitis and fever, incision and drainage are usually required in addition to oral antibiotics.
- C. **Skin abscesses other than furuncles/carbuncles** are common and typically reflect extension of superficial skin infections to the deeper dermis and subcutaneous fat. On occasion, bacteremic seeding of skin and soft tissue can result in a localized abscess. Although many patients will develop spontaneous cutaneous abscesses, predisposing risk factors include trauma, intravenous drug use, diabetes mellitus, and chronic carriage of *S. aureus*. These lesions are usually solitary, erythematous nodules associated with localized pain, swelling, and lymphadenopathy. Although bacteremia and adjacent septic arthritis and osteomyelitis can occur, these lesions often drain spontaneously and are not associated with systemic toxicity. The microbiology of these abscesses results from organisms that colonize the local mucocutaneous structures. As a result, *S. aureus* is the most common organism isolated from cutaneous abscesses, but mixed flora can be appreciated in abscesses found in perirectal, oral, and genitourinary (GU) areas [27].

II. Evaluation of cutaneous abscesses

- A. **Clinical evaluation should include assessment for fever and other signs of systemic infection.** A complete blood count and blood cultures should be obtained if systemic signs of infection are present. Gram stains and cultures of drainage or aspirated material are also recommended.
- B. **Incision and drainage**
 - 1. **Abscesses on the lips and nose should not be drained** due to emissary venous drainage resulting in possible extension to the cavernous sinus.
 - 2. Because incision and drainage of lesions may result in transient bacteremia with organisms associated with infective endocarditis, **prophylaxis with antibiotics should be administered to individuals with cardiac conditions that are associated with increased risk for cardiac valvular infection** [8].

III. **Treatment.** For smaller furuncles, the application of moist heat can be helpful in promoting drainage. Incision and drainage is often needed for larger cutaneous abscesses, particularly in patients with cellulitis and fever. Antibiotics are used in selected clinical circumstances.

- A. **Incision and drainage** should be performed except for abscesses on the lips and nose. These lesions can be managed with warm compresses and, if indicated, antibiotics.
- B. **Antibiotics** should be reserved for the following situations:
 - 1. **Immunocompromised patients (including those with diabetes mellitus)**
 - 2. **Fever and systemic symptoms**
 - 3. **Surrounding cellulitis, lymphangitis, osteomyelitis, or invasion of blood stream**
 - 4. **Infective endocarditis prophylaxis in patients with at-risk cardiac conditions**
 - 5. **Chronic nasal carriage in patients who have recurrent furunculosis**
- C. **Antibiotic regimens should be pathogen directed** based on the results of Gram stain and culture of purulent material. Recommended regimens for adults include:
 - 1. **Gram-positive cocci**
 - a. **Oral therapy.** Dicloxacillin, 250 to 500 mg every 6 hours, or cephalexin, 500 mg every 6 hours, for approximately 10 days can be used. In the penicillin- or cephalosporin-allergic patient, oral clindamycin, 300 mg every 6 hours can be used.

- b. Parenteral therapy.** Nafcillin or oxacillin, 1 to 2 g intravenously (i.v.) every 4 to 6 hours, is recommended. In the patient with a delayed penicillin allergy, cefazolin, 1 g i.v. every 8 hours, can be used. If penicillin allergy is immunoglobulin E (IgE) mediated, clindamycin, 600 to 900 mg i.v. every 8 hours, or vancomycin, 15 mg/kg i.v. every 12 hours, is recommended.
- 2. Mixed cutaneous abscess (i.e., perirectal, oral, and GU areas) treatment should include coverage for *S. aureus*, streptococci, gram-negative bacilli, and anaerobic bacteria, including *Bacteroides* species.**
 - a. Oral therapy.** Amoxicillin (500 mg) and clavulanate (125 mg) orally every 8 hours can be used empirically.
 - b. Parenteral therapy.** Ampicillin-sulbactam 3 g i.v. every 8 hours, piperacillin-tazobactam 3.375 i.v. every 6 hours or 4.5 g i.v. every 8 hours, and ticarcillin-clavulanate 3.1 g i.v. every 4 to 6 hours can be administered.
- 3. Nasal carriage of *S. aureus*.** Eradication of *S. aureus* from the nares should be pursued in individuals with recurrent furuncles. Twice daily application of 2% mupirocin for 5 days every month is often effective [23,28]. Ten days of oral rifampin 600 mg daily combined with dicloxacillin 500 mg every 6 hours also may be effective. For methicillin-resistant *S. aureus* colonization, 7 to 14 days of mupirocin is recommended. Oral clindamycin 150 mg daily for 3 months has been used successfully for prevention [29]. Patients with recurrent furuncles and impaired neutrophil function may benefit from vitamin C 1 g daily for approximately 6 weeks [30].

IV. Prevention measures against deep follicular infections include eradication of nasal carriage of *S. aureus*, avoidance of risk factors associated with development of furuncles/carbuncles (e.g., intravenous drug use), improved hygiene including the use of antiseptic soaps (e.g., chlorhexidine), and the use of nonirritating clothing that fits loosely.

PUNCTURE WOUNDS OF THE FEET

- I. Clinical characteristics.** Plantar surface puncture wounds have been reported to constitute approximately 7% of lower extremity trauma cases evaluated in the emergency department [31]. Most of these injuries are due to nails and typically occur during the warmer summer months [32]. Three percent to 15% of nail puncture wounds become infected, and complications include cellulitis, localized deep soft tissue abscess, osteomyelitis, or pyoarthrosis [33]. The factors contributing to the development of infection include the presence of a foreign body, depth and location of the wound, host immune status, presence of a sneaker, type of penetrating object, and time elapsed from injury to presentation [34]. Most bone infections are due to *P. aeruginosa*, particularly when the puncture wound occurs through the inner sole of the sneaker, a site of pseudomonad colonization. Other organisms reported to cause infection include *S. aureus*, *S. pyogenes*, Enterobacteriaceae, and anaerobes. Polymicrobial osteomyelitis is more common in diabetic adults [35].
- II. Treatment. Initial management** of the puncture wound should include the following:
 - A.** Use detergent or iodophor to clean the wound.
 - B.** Trim the epidermal flap of the wound.
 - C.** Consider probing the wound for depth and the presence of a foreign body.
 - D.** Consider plain films of the foot when uncertain whether a foreign body remains in wound.
 - E.** Tetanus assessment and administration as recommended (see section on Tetanus below).
 - F. The decision to administer prophylactic antibiotics is controversial and left to the treating physician** particularly in wounded patients who are immunocompromised. Antibiotics should be administered when soft tissue infection is present.
 - G. Remove foreign bodies, debride necrotic infected tissue and drain abscesses when present.** Raz and colleagues [33] have reported on the successful management of nail puncture wound infections (primarily caused by *Pseudomonas aeruginosa*) by using routine surgical incision, debridement, and drainage of abscess material. Following surgery, oral ciprofloxacin (750 mg orally twice daily) is administered for 7 days to patients with deep tissue abscess and cellulitis;

duration is 14 days for patients with early bone involvement [33]. If the microbiologic etiology is uncertain, then empiric therapy for skin and soft tissue infections is directed primarily against *S. aureus* (penicillinase-resistant semisynthetic penicillins or first-generation cephalosporins) and for bone and joint infections, *S. aureus* and *P. aeruginosa* (i.e., nafcillin and ceftazidime or levofloxacin) [36].

ANIMAL BITES AND RABIES PREVENTION

Approximately 0.5% to 1% of all emergency room visits in the United States are due to bite wounds, an impressive statistic when one recognizes that more than 75% of individuals who receive a bite wound will not present for medical evaluation [37]. Hospitalization is required in about 1% to 5% of these visits [38].

I. Types of bite wounds

A. Dog bites. Dogs account for more than 75% of all animal bites. Children are most commonly involved, and the location of injury typically includes an extremity or the head and neck. **Almost 20% of these wounds become infected.**

1. Bacteriology. The microbiology of dog bite-associated infections is complex and includes streptococci, *S. aureus*, *Pasteurella canis* (most common isolate) and *P. multocida*, *Eikenella corrodens*, *Capnocytophaga canimorsus*, and anaerobes such as *Fusobacterium*, *Bacteroides*, *Porphyromonas*, and *Prevotella* species [39].

C. canimorsus, a gram-negative facultative anaerobic bacillus that normally colonizes the dog's oral cavity, can cause fulminant sepsis and disseminated intravascular coagulopathy in immunocompromised patients, particularly those without splenic function.

2. Evaluation and management [37]

a. In all types of bites, a thorough history should be obtained including the type of animal, the circumstances surrounding the bite (i.e., provoked or unprovoked), and the immune status of the individual bitten. A physical examination should include investigation for signs of infection and joint, nerve, bone, or vascular penetration. **Risk for infection is increased in puncture- or crush-associated injuries.**

b. Normal saline **irrigation of all wounds is recommended**, with the need for surgical debridement dictated by the degree of injury.

c. **Wound cultures** are not helpful when there are no signs of infection except in the setting of puncture wounds or tears. Cultures are recommended from all infected wounds, and radiographs can be helpful in assessing for bone involvement.

d. **Hand wound infections, necrotic wounds, and possible walled-off infections should precipitate a surgical consultation.** Wounds should be examined more than 1 day after a bite. Infected wounds, deep puncture wounds, and bites to the hand should not be closed primarily. With the exception of facial wounds, which may be closed primarily, no clear recommendations exist for **primary closure** of fresh wounds seen less than 6 to 8 hours after a bite. Delayed primary closure is often allowed in uninfected higher risk wounds.

e. The best use of **prophylactic antibiotics** in patients who present within 8 hours of a dog bite is unclear. Some experts recommend **prophylactic antimicrobial treatment for 3 to 5 days** after most dog bites, particularly high-risk wounds associated with deep punctures; crush injuries; hand, foot, or facial wounds; immunocompromised patients; wounds near joints or bones (particularly if prosthesis in place); and moderate and severe wounds, especially those requiring surgical debridement [37,40]. Minor wounds may not require treatment. **The duration of treatment for infected wounds is at least 10 days.** Bone or joint involvement dictates an extended course.

f. **The suggested empiric choice for hospitalized patients requiring parenteral therapy** is a penicillin and β -lactamase inhibitor combination such as ampicillin-sulbactam, 3 g i.v. every 6 hours. **The choice for oral outpatient therapy** is amoxicillin-clavulanate, 500 mg orally every 8 hours or 875 mg orally every 12 hours.

- g. **In the penicillin-allergic patient**, options include a fluoroquinolone (such as levofloxacin or ciprofloxacin) plus clindamycin or clindamycin plus trimethoprim-sulfamethoxazole (for children).
3. **Elevation of the affected area is recommended.**
 4. Tetanus prophylaxis and rabies assessment needs to be addressed.
 5. **Close follow-up** of patients who are not hospitalized.
- B. Cat bites.** The incidence of infection after a cat bite is reported at 28% to 80%, considerably higher than after dog bites [39]. The increased rate of infection is due to the deep puncture wounds (potentially involving joint or bone) created by the sharp and thin teeth of cats (see also Chapter 21).
1. **Microbiology.** *P. multocida* is the most common pathogen isolated from cat bites (>50% of cases) (Color Plate 4.11); otherwise, the polymicrobial spectrum is similar to that for dog bites. However, the number of organisms isolated is usually less.
 2. **Antibiotic therapy. Because of the increased incidence of infection after cat bites, prophylactic antibiotics are commonly used for 3 to 5 days.** Empiric therapy should be active against *P. multocida*, and typically includes agents used for dog bites. *Pasteurella* infections usually develop within 24 to 48 hours and are susceptible to penicillin, aminopenicillins, cefuroxime, doxycycline, and trimethoprim-sulfamethoxazole.
 3. **Assessment and treatment** of infected wounds should follow the same recommendations as for dog bites.
- C. Human bite injuries** occur after a bite from another human (i.e., occlusional bites) or after a closed fist injury that usually involves the metacarpophalangeal joints. **Closed-fist injuries can be devastating** when they involve deeper soft tissues, bones, or joints, and are more susceptible to infection than animal bites. As a result, initial inpatient management is often required, and usually with the assistance of a hand surgeon.
1. **Bacteriology.** *S. aureus*, *E. corrodens*, *H. influenzae*, streptococci, and β -lactamase-producing oral anaerobes are most commonly associated with infection. Potential pathogens can include blood-borne microbes such as hepatitis B or C, herpes simplex virus, HIV and *Treponema pallidum*.
 2. **Antibiotics**
 - a. When patients are seen soon after their injury, **3 to 5 days of prophylactic antibiotics are often recommended. The choice for oral outpatient therapy is amoxicillin-clavulanate.**
 - b. **Obvious wound infections require a more prolonged course that is dictated by the extent of injury. These patients are usually hospitalized and are administered parenteral therapy, usually a penicillin and β -lactamase inhibitor combination such as ampicillin-sulbactam, ticarcillin-clavulanic acid, or piperacillin-tazobactam.** Cefoxitin also may be used. **In the penicillin-allergic patient**, options include a fluoroquinolone (such as levofloxacin or ciprofloxacin) plus clindamycin or clindamycin plus trimethoprim-sulfamethoxazole (for children).
 3. Normal saline irrigation, radiographs to assess for bone involvement, debridement when indicated, and tetanus assessment are essential.
- D. Other animal bites.** Bites from a variety of animals, including primates, pigs, horses, fish, alligators, sheep, rats, and ferrets, have been reported. Infectious disease consultation is recommended for assistance when evaluating and managing these zoonotic infections [37].
- II. Rabies prophylaxis.** In the United States, human-associated rabies infections have decreased to approximately zero to five cases per year [41]. When one examines the 36 cases of rabies in humans in the United States since 1980, more than 50% derive from bats [41]. In contrast, dogs appear to be the most common source of human-associated rabies outside the United States. This infection is incurable, mandating the need for avoidance of high-risk circumstances and rapid institution of prophylaxis when indicated. An understanding of the epidemiology of rabies and circumstances surrounding postexposure treatment is useful (Tables 4.1 and 4.2) [42].

Table 4.1. Rabies Postexposure Prophylaxis Guide: United States, 1999

Animal Type	Evaluation and Disposition of Animal	Postexposure Prophylaxis Recommendations
Dogs, cats, and ferrets	Healthy and available for 10 days observation	Persons should not begin prophylaxis unless animal develops clinical signs of rabies. ^a
	Rabid or suspected to be rabid	Immediately vaccinate.
	Unknown (e.g., escaped)	Consult public health officials.
Skunks, raccoons, foxes, and most other carnivores; bats	Regarded as rabid unless animal proven negative by laboratory tests ^b	Consider immediate vaccination.
Livestock, small rodents, lagomorphs (rabbits and hares), large rodents (woodchucks and beavers), and other mammals	Consider individually	Consult public health officials. Bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, other small rodents, rabbits, and hares almost never require antirabies postexposure prophylaxis.

^a During the 10-day observation period, begin postexposure prophylaxis at the first sign of rabies in a dog, cat, or ferret that has bitten someone. If the animal exhibits clinical signs of rabies, it should be killed and immediately tested.

^b The animal should be killed and tested as soon as possible. Holding for observation is not recommended. Discontinue vaccine if immunofluorescence test results of the animal are negative.

Reprinted from Centers for Disease Control and Prevention. Human rabies prevention—United States, 1999: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR* 1999;48:1–21; with permission.

A. Considerations prior to antirabies therapy are outlined in Table 4.1. The cost associated with rabies prophylaxis is considerable, and prophylaxis cannot be instituted liberally after every animal bite [42].

1. Type of animal. Bats and wild terrestrial carnivorous animals (particularly skunks, raccoons, foxes, and coyotes) are more likely than domestic animals (i.e., dogs, cats, and ferrets), livestock, and rodents to be infected with rabies. Because the probability of rabies infections in particular animals varies geographically, consideration should be given for contacting local or state public health authorities regarding the need for postexposure prophylaxis.

2. Characteristics of attack and animal's vaccination status. An attack by an animal that is unprovoked and not associated with feeding or handling reflects a higher likelihood that the animal is infected with rabies. Dogs, cats, or ferrets that have been appropriately vaccinated are unlikely to be rabid.

3. Characteristics of exposure. Rabies virus transmission requires a rabid animal and introduction of its potentially infectious tissue material onto mucous membranes or into open wounds. Transmission of infectious material such as saliva or neural tissue is most commonly accomplished by animal bites, but contamination of nonintact skin (open wounds, scratches, abrasions) or mucous membranes represent potential nonbite exposures. Exposure to aerosols containing a high density of rabies virus in the laboratory or in caves and transplantation of rabies-infected human corneas should also be considered potentially infectious.

B. Recommendations for wound treatment and vaccination are listed in Tables 4.1 and 4.2. Urgent evaluation and management are needed in potential rabies exposures. Recommendations include the following [42]:

Table 4.2. Rabies Postexposure Prophylaxis Schedule: United States, 1999

Vaccination Status	Treatment	Regimen ^a
Not previously vaccinated	Wound cleansing	All postexposure treatment should begin with immediate thorough cleansing of all wounds with soap and water. If available, a virucidal agent such as a povidone-iodine solution should be used to irrigate the wounds.
	RIG	Administer 20 IU/kg body weight. If anatomically feasible, the full dose should be infiltrated around the wound(s) and any remaining volume should be administered i.m. at an anatomic site distant from vaccine administration. Also, RIG should not be administered in the same syringe as the vaccine. Because RIG might partially suppress active production of antibody, no more than the recommended dose should be given.
	Vaccine	HDCV, RVA, or PCEC 1.0 mL i.m. (deltoid area), ^b one each on days 0, ^c 3, 7, 14, and 28.
Previously vaccinated ^d	Wound cleansing	All postexposure treatment should begin with immediate thorough cleansing of all wounds with soap and water. If available, a virucidal agent such as a povidone-iodine solution should be used to irrigate the wounds.
	RIG	RIG should not be administered.
	Vaccine	HDCV, RVA, or PCEC 1.0 mL i.m. (deltoid area), ^b one each on days 0 ^c and 3.

HDCV, human diploid cell vaccine; PCEC, purified chick embryo cell vaccine; RIG, rabies immune globulin; RVA, rabies vaccine adsorbed; i.m., intramuscularly.

^a These regimens are applicable for all age groups, including children.

^b The deltoid area is the only acceptable site of vaccination for adults and older children. For younger children, the outer aspect of the thigh may be used. Vaccine should never be administered in the gluteal area.

^c Day 0 is the day the first dose of vaccine is administered.

^d Any person with a history of preexposure vaccination with HDCV, RVA, or PCEC; prior postexposure prophylaxis with HDCV, RVA, or PCEC; or previous vaccination with any other type of rabies vaccine and a documented history of antibody response to the prior vaccination.

Reprinted from Centers for Disease Control and Prevention. Human rabies prevention—United States, 1999: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR* 1999; 48:1–21; with permission.

- 1. Management of the wound.** Prompt and complete cleansing of the wound with water and soap and a cidal agent for viruses (e.g., povidone-iodine) is recommended. Tetanus prophylaxis and management of secondary bacterial infections should be instituted as indicated.
- 2. Approach to the potentially infected animal.** A pet that is not suspected to be rabid can be isolated and observed for 10 days. If a veterinarian observes any signs of rabies during the confinement period then the pet should be killed. The intact head should be sent under refrigerated conditions to a qualified laboratory for diagnostic immunofluorescence testing. Animals that are regarded as rabid should be killed and evaluated immediately in the laboratory for the presence of the rabies virus.
- 3. Postexposure prophylaxis should be initiated as soon as possible.** In the previously unvaccinated individual, vaccination includes **passive prophylaxis with rabies immunoglobulin (RIG) and active prophylaxis with rabies vaccine** (Table 4.2).

- a. At the beginning of antirabies prophylaxis, **human RIG** is administered once at a dose of 20 IU/kg body weight. As much of this dose as is anatomically possible should be infiltrated around the wound and the remaining amount should be administered intramuscularly in an area remote from administration of vaccine. A different syringe for administration of RIG and vaccine is also recommended.
 - b. **Active immunization** should begin as soon as possible after the exposure and in conjunction with RIG. Three types of inactivated human rabies vaccine are available in the United States for postexposure prophylaxis: (a) human diploid cell rabies vaccine (HDCV); (b) rabies vaccine adsorbed (RVA); and (c) purified chick embryo cell vaccine (PCEC). These vaccines are alike in efficacy and safety, and 1-mL doses should be administered in the deltoid muscle on days 0, 3, 7, 14, and 28 in the previously unvaccinated individual. If the individual has previously received the rabies vaccine, then 1 mL of the human rabies vaccine is administered in the deltoid muscle on day 0 and day 3.
 - c. **Complete recommendations can be obtained from the CDC** [42]. Table 4.2 can be used as a postexposure antirabies treatment guide.
4. **Preexposure vaccination** is indicated for individuals who are frequently exposed to animals who are at risk for being infected with the rabies virus. These individuals include veterinarians, animal control handlers, investigators in rabies laboratories, spelunkers, wildlife officers, and foreign travelers to countries where contact is expected with animals in regions where dogs infected with rabies is endemic and medical care is inaccessible. Recommendations for preexposure prophylaxis include [42]:
- a. HDCV, PCEC, or RVA, 1.0 mL intramuscularly (i.m.; deltoid area), administered in three separate doses on days 0, 7, and 21 or 28. Three separate doses of HDCV, 0.1 mL intradermally, can be administered over the deltoid area on days 0, 7, and 21 or 28 as an alternative to the intramuscular HDCV regimen.
 - b. A postvaccination rabies antibody titer should be checked every 6 months to 2 years in certain high-risk groups, in order to assess the need for preexposure booster doses of vaccine.
 - c. Preexposure prophylaxis eliminates the need for RIG after a rabies exposure, but 1 mL of human rabies vaccine (HDCV, RVA, or PCEC) still needs to be administered in the deltoid muscle on days 0 and 3.

CELLULITIS AND RELATED SKIN INFECTIONS

Cellulitis is an infectious inflammatory process involving the deepest portion of the dermis of the skin and subcutaneous fat. This infection typically develops in the extremities and presents as a warm, erythematous, tender, swollen, and poorly demarcated skin process (Color Plate 4.16). Systemic symptoms may include fever, chills, and muscle pain. **Predisposing factors** include tinea pedis, substance abuse, diabetes mellitus, burns, trauma from puncture wound or surgery, venous insufficiency, and lymphatic interruption [43]. **Many organisms can cause cellulitis in selected circumstances.**

I. Etiology of cellulitis

- A. ***S. pyogenes* and *S. aureus* are the most common causes of simple uncomplicated cellulitis.** Initial treatment should be directed against both of these bacteria and typically includes parenteral nafcillin or cefazolin when treating patients with systemic signs and symptoms or those who are immunocompromised. If the infection is mild, oral antibiotics can be used.
- B. **Group B streptococci (*S. agalactiae*) can cause skin and soft tissue infections in nonpregnant adults, especially in the elderly and in those with diabetes, a pressure ulcer, underlying malignancy, cirrhosis, or neurologic impairment, as well as in those infected with HIV [44–46].** In fact, skin and soft tissue infections are the most common manifestation of invasive disease with group B streptococci, presenting as cellulitis, ulcerations, and even necrotizing fasciitis (NF). Infections are often nosocomial, associated with the placement of an intravenous catheter, and primarily due to capsular serotypes Ia, III, and V. This organism remains sensitive to penicillin, but increasing resistance to erythromycin and clindamycin is being reported.

For uncomplicated skin infections requiring hospitalization, penicillin G, 2 million units i.v. every 4 to 6 hours is recommended. Vancomycin, 15 mg/kg i.v. every 12 hours can be administered to the penicillin-allergic patient. First- and third-generation cephalosporins also may be used as alternative therapy. Surgical debridement may be essential to remove devitalized skin and soft tissue.

- C. Erysipeloid** refers to a skin infection caused by a gram-positive bacillus, *Erysipelothrix rhusiopathiae*, which is found in many fish, mammals, and birds. The handling of infected material allows the organism to enter through breaks in the skin. Butchers, fisherman, and veterinarians are at increased risk for infection. The site of entry, usually the dorsum of the hand, becomes violaceous, warm, and swollen (Color Plate 4.17). Well-defined maculopapular lesions, bullous lesions, and plaques can be seen. Rarely, bacteremia and endocarditis develop in immunocompromised hosts. Skin infections are usually self-limited after 2 to 3 weeks, but the use of **penicillin G or an aminopenicillin, the drugs of choice**, can hasten recovery. A total daily dose of 12 to 20 million units of i.v. penicillin G administered every 4 to 6 hours for 4 to 6 weeks is recommended for endocarditis. Imipenem, fluoroquinolones, and third-generation cephalosporins are also active against this organism.
- D. *H. influenzae* cellulitis, primarily a bacteremic complication of children,** classically presents as a **violaceous facial cellulitis (often involving the periorbital or cheek areas)**. Although much less commonly observed in adults, ***H. influenzae* cellulitis** is usually associated with respiratory tract infections and typically involves the upper thorax and neck [47]. The treatment of choice is a third-generation cephalosporin or ampicillin (if susceptible).
- E. Skin and soft tissue lesions are observed in up to 30% of patients with pseudomonas sepsis. Usually observed in immunocompromised hosts,** cutaneous manifestations include cellulitis, folliculitis, bullae, nodules, abscesses, and vesicles and plaques [48,49]. **Ecthyma gangrenosum** is the characteristic necrotic skin lesion reported in a significant number of patients with malignancy, neutropenia, and pseudomonas bacteremia. These lesions are usually located in the axilla or perineum. Burn wounds complicated by *Pseudomonas* infection and bacteremia often form eschars and are associated with mortality rates of greater than 75% [50]. Treatment usually includes surgical removal of necrotic tissue and combination therapy consisting of an antipseudomonas β -lactam or quinolone and an aminoglycoside (cefepime, ceftazidime, piperacillin, mezlocillin, imipenem, or ciprofloxacin plus gentamicin, tobramycin, or amikacin).
- F. Wound infections due to water exposure** can develop in patients with lacerations, puncture wounds, or marine-animal bites.
- 1. *Vibrio vulnificus*.** Immunocompromised individuals, particularly those with cirrhosis, are at increased risk for infection with *V. vulnificus*, a gram-negative curved bacillus that is found in warm seawaters. Infections may occur at traumatized sites after exposure to contaminated seawater or seafood, or after ingestion of contaminated seafood. A cellulitis that progresses to an invasive NF with associated hemorrhagic bullae is characteristic (Color Plate 4.5). Optimal therapy includes aggressive surgical debridement, supportive care, and antibiotics. The choice of antibiotics includes a third-generation cephalosporin like ceftazidime (2 g i.v. every 8 hours), plus doxycycline, 100 mg orally or i.v. every 12 hours; cefotaxime, 2 g i.v. every 8 hours, also can be used. Some investigators recommend an aminoglycoside in lieu of doxycycline [51]. The organism is also susceptible to quinolones such as ciprofloxacin (400 mg i.v. every 12 h or 750 mg orally every 12 hours).
 - 2. *Aeromonas* skin infections** can develop in cancer patients receiving chemotherapy or in cirrhotic patients after exposure to contaminated fresh water (Color Plate 4.18). Cutaneous manifestations may be similar to *V. vulnificus*-associated infections. Surgical debridement is indicated, and antibiotic recommendations include ciprofloxacin 400 mg i.v. every 12 hours or 750 mg orally every 12 hours. Trimethoprim-sulfamethoxazole and non-first-generation cephalosporins also may be useful.
 - 3. *Edwardsiella tarda*,** a gram-negative bacillus in the Enterobacteriaceae family, can cause wound infections after exposure to contaminated fresh water [52].

Abscesses, hemorrhagic bullae, cellulitis, and myonecrosis have been described. Antibiotic therapy should be guided by susceptibility testing. This organism is generally susceptible to antimicrobial agents used for treatment of gram-negative bacillary infections, including ampicillin, cephalosporins, aminoglycosides, fluoroquinolones, and trimethoprim-sulfamethoxazole.

4. ***Mycobacterium marinum***, a nontuberculous mycobacteria, is the most common cause of mycobacterial skin disease. Lesions usually develop 2 to 6 weeks after trauma-associated contact with water, including saltwater, lake water, swimming pool water, or aquarium water. Violaceous papules that develop into ulcerative plaques are frequently described, often in a sporotrichoid pattern (Color Plate 4.19). Four antimicrobial regimens are recommended by the American Thoracic Society: doxycycline, 100 mg orally twice daily; clarithromycin, 500 mg orally twice daily; trimethoprim-sulfamethoxazole (160/800 mg) orally twice daily; or ethambutol, 15 mg/kg/day orally, plus rifampin, 600 mg/day orally [53]. Treatment should continue for at least 3 months. Surgical debridement also may be necessary when the infection proves refractory to antimicrobial agents.

II. Erysipelas. This infection involves the upper dermis and superficial lymphatics, and is characterized by skin lesions that are well demarcated, painful, erythematous, and elevated. The lower extremities or face are most often involved, and the diagnosis is usually made on clinical grounds. **The microbiologic cause is almost always *S. pyogenes***, although less commonly other β -hemolytic streptococci, *S. aureus*, and gram-negative bacilli may be involved. If systemic signs of infection are present or if the patient is immunocompromised, parenteral agents such as nafcillin or oxacillin, penicillin G, or cefazolin are indicated. Oral agents such as dicloxacillin, penicillin, or cephalexin can be given in milder cases or those in which improvement is noted. Vancomycin, clindamycin, or erythromycin can be used in the penicillin-allergic patient.

III. Diagnosis. The diagnosis of cellulitis and erysipelas is often made on clinical grounds based on the presence of erythema, swelling, warmth, tenderness and pain, regional lymphadenopathy, and associated tinea pedis. Systemic signs and symptoms such as fever and malaise may not always be present. Other diagnostic studies include the following:

- A. Gram staining of aspirate or biopsy** may be helpful in directing initial therapy.
- B. Results of needle aspiration or punch biopsy to obtain tissue for aerobic and anaerobic cultures** are usually negative but may be pursued. Needle aspiration cultures of the leading edge are reported to yield positive results in less than 20% of cases, but may be indicated and helpful in immunocompromised patients or when isolating the etiologic agent is necessary, antibiotic therapy is failing, or atypical etiologic agents are suspected [54]. Direct aspiration of tissue without injection of saline may increase the yield of aspirate cultures [55]. Punch biopsy cultures have been reported to have a higher yield of microbial isolation than blood cultures or needle aspirates, but add no additional microbiologic information to direct cultures from swabs of primary lesions [56].
- C. Blood cultures** are often obtained. In one recent study of more than 500 adult patients admitted to a hospital with community-acquired cellulitis, cultures were definitively positive in approximately 2% of cases and had minimal impact on the treatment prescribed [57]. The investigators concluded that blood cultures should be obtained in "unusually severe cases, such as possibly elderly patients with acute onset of illness, high grade fever and significant leukocytosis and immunocompromised patients" [57]. Similar results have been reported in the pediatric population [58].
- D. Serologic studies for the presence of group A streptococcus** may help support the diagnosis of streptococcal disease when isolation of the organism has not been achieved.
- E. Radiographic studies are usually unnecessary.** Plain films may be helpful in identifying gas, bony involvement, or the presence of foreign bodies. Computed tomography (CT) or magnetic resonance imaging (MRI) can assist in determining whether the infection is confined to skin and soft tissue or whether fascia, muscle, or bone is involved [59].

IV. Treatment

A. General principles. Clinical and initial microbiologic clues can be helpful in directing therapy while awaiting culture results.

B. Antibiotic treatment suggestions for adults with cellulitis.

1. The most common bacterial causes of cellulitis are group A streptococcus and *S. aureus*. Therapy is typically directed against both of these pathogens.

a. Recommended treatment regimens for hospitalized adult patients include nafcillin or oxacillin, 2 g i.v. every 4 to 6 hours, or cefazolin, 1 to 2 g i.v. every 8 hours. Alternative parenteral agents, particularly for patients with IgE-mediated penicillin allergy, include vancomycin, 15 mg/kg i.v. every 12 hours, or clindamycin, 450 to 900 mg i.v. every 8 hours.

b. Mild infection in adults can be treated orally with dicloxacillin, 500 mg every 6 hours, or cephalexin, 250 to 500 mg every 6 hours. Clindamycin, 300 to 450 mg every 6 hours, can be used in penicillin-allergic patients; oral macrolides such as erythromycin (500 mg every 6 hours) are sometimes used in this setting.

c. The hospitalized adult patient with uncomplicated culture-proven group A streptococcal cellulitis can be treated with penicillin G, 1 to 2 million units i.v. every 4 to 6 hours.

d. Vancomycin treatment of possible methicillin-resistant *Staphylococcus aureus* infection should be considered for **patients who reside in nursing homes or have recently been hospitalized.**

2. Diabetes-associated, perineal, or other suspected mixed aerobic-anaerobic cellulitis dictates the use of broad-spectrum antibiotics. In the hospitalized patient, penicillin and β -lactamase inhibitor combinations such as piperacillin-tazobactam (3.375 g i.v. every 6 hours), ampicillin-sulbactam (3 g i.v. every 6 hours), or ticarcillin-clavulanate (3.1 g i.v. every 4–6 hours) are often recommended. Imipenem (500 mg i.v. every 6 hours) or a third-generation cephalosporin such as ceftriaxone (2 g i.v. every 24 hours) in combination with metronidazole (500 mg i.v. every 6 hours) or clindamycin (600–900 mg i.v. every 8 hours) also can be considered.

3. Antibiotic regimens for culture-proven pathogens are reviewed above in section I.

C. Additional issues. Surgical evaluation is necessary when invasive skin and soft tissue infection is suspected and when cellulitis progresses despite appropriate antibiotic therapy. **Approximately 10 days of antibiotic therapy is adequate** for uncomplicated infections. **Adjunctive measures** may include immobilization of involved areas and local application of moist heat.

PYOMYOSITIS

Pyomyositis, a disease increasingly observed in North America, is a term used to describe a purulent infection of muscle [60,61]. Localized trauma to muscle is often observed in patients prior to the development of muscle infection.

I. Risk factors include HIV infection, diabetes mellitus, thiamine deficiency, scurvy, parasitic myositis, infection with leptospirosis, certain viral myositis infections, and IgM deficiency [60,61].

II. The predominant etiologic agent is *S. aureus*, although streptococci, *Neisseria gonorrhoeae*, *Yersinia enterocolitica*, *H. influenzae*, Enterobacteriaceae, *Clostridium septicum*, and *Candida albicans* also may cause pyomyositis.

III. Clinical characteristics. Patients typically develop muscle pain, local edema, and fever. Examination of the muscle is described as “woody” or indurated. The “purulent” stage develops later. Muscle tenderness is usually present, but fluctuance and inflammation may not be appreciated due to the depth of the infection. Leukocytosis and an elevated erythrocyte sedimentation rate are common, but the muscle enzyme levels are normal. Gram stain and culture of pus is helpful in identifying the etiologic agent. Approximately 5% to 31% of patients will have positive blood cultures [60,61].

IV. Treatment consists of drainage of purulent material and pathogen-directed intravenous therapy, usually targeting staphylococci.

NECROTIZING SOFT TISSUE INFECTIONS

I. Types. Necrotizing infections of the soft tissues are described by a variety of terms, including Meleney synergistic gangrene, clostridial cellulitis, nonclostridial anaerobic cellulitis, gas gangrene, and NF [62]. These infections are usually characterized by rapidly spreading destruction of skin, subcutaneous fat, fascia, and muscle with associated systemic toxicity. **Most of these infections are polymicrobial and include mixed aerobic and anaerobic bacteria.**

A. Meleney synergistic gangrene describes a progressive and indolent necrotizing infection of the skin and epifascial soft tissues (Color Plate 4.20). This infection is typically seen in postsurgical patients, frequently in association with small bowel or large bowel ostomies. Slowly expanding ulcerations that are painful and surrounded circumferentially by necrotic skin are described. Microaerophilic streptococci, *S. aureus*, anaerobes including *Peptostreptococcus* and *Bacteroides*, and occasionally gram-negative bacilli may be isolated from this mixed infection. Surgical drainage and debridement are necessary. Antibiotics are directed against mixed aerobic and anaerobic flora. Options in adults include penicillin and β -lactamase inhibitor combinations used alone, such as piperacillin-tazobactam, 3.375 g i.v. every 6 hours; and clindamycin, 600 to 900 mg i.v. every 8 hours, or vancomycin, 15 mg/kg i.v. every 12 hours, plus ciprofloxacin, 400 mg i.v. every 12 hours.

B. Clostridial anaerobic cellulitis, another necrotizing infection of the epifascial soft tissue, is usually seen after trauma or surgery. The incubation period is often several days, but the infection, once established, extends quickly. Gas formation is often appreciated, although patients do not appear systemically unstable. Surgical removal of necrotic tissue is mandatory. Penicillin G, 24 million units divided doses i.v. every 24 hours, is recommended for adults. Clindamycin, 900 mg i.v. every 8 hours, or metronidazole, 500 mg i.v. every 6 hours, may be used for penicillin-allergic patients. **Nonclostridial nonaerobic cellulitis** is due to anaerobic bacteria other than clostridia, often in association with other bacteria, including staphylococci, streptococci, and aerobic gram-negative bacilli. Predisposing conditions include diabetes mellitus, and the clinical presentation is similar to clostridial cellulitis. Surgical debridement and broad-spectrum antibiotic coverage is indicated. Recommended antibiotic therapy (adult doses listed) includes imipenem, 500 mg i.v. every 6 hours; a penicillin and β -lactamase inhibitor combination such as piperacillin-tazobactam, 3.375 g i.v. every 6 hours; or ceftriaxone, 2 g i.v. every 24 hours, plus metronidazole, 500 mg i.v. every 6 hours.

C. Clostridial gas gangrene (i.e., clostridial myonecrosis) is caused by the inoculation of clostridial species (e.g., *Clostridium perfringens*, *C. histolyticum*, *C. novyi*, *C. septicum*, *C. fallax*, and *C. bifermentans*) into necrotic tissue. These infections are often associated with trauma or bowel-associated surgeries (Color Plate 4.21 and 4.22). A spontaneous and nontraumatic form of clostridial myonecrosis is caused by *C. septicum*; predisposing factors for bacteremia with this organism include GI abnormalities (including colon cancer, GI surgery, and diverticulitis), leukemia, lymphoma, neutropenia, and HIV infection. Clostridial myonecrosis has a sudden onset with associated systemic toxicity, hemodynamic instability, and exquisite pain. The wound is often swollen with surrounding pale-colored skin that may later change to a bronzish-discoloration. A malodorous serosanguinous discharge is often appreciated. Vesicles and bullae may develop, and gas may be detected in the affected tissue. The diagnosis should be suspected in the appropriate clinical situations. A Gram stain of tissue or associated exudate may reveal gram-positive bacilli ("box-cars") with a paucity of polymorphonuclear leukocytes. When bacteremia is present, significant hemolysis may be appreciated. Surgical removal of devitalized infected tissue is the cornerstone of therapy. Antibiotic regimens in adults include clindamycin, 900 mg i.v. every 8 hours, plus penicillin, 24 million units i.v. over 24 hours or in divided doses administered every 4 hours; or metronidazole, 500 mg i.v. every 6 hours; or chloramphenicol, 1 g i.v. every 6 hours. **The exact role of hyperbaric oxygen therapy in this setting is unclear, but its use should not preclude or delay necessary surgical debridement** [63,64].

D. Necrotizing fasciitis is an infectious disease emergency that refers to widespread destruction of deep subcutaneous tissue and fascia with relative sparing of

muscle and skin. Patients with fulminant NF are toxic appearing and often develop multiorgan failure. Other clinical features associated with this infection include severe local pain, lack of skin findings, fever, and evidence of soft tissue gas such as crepitation [65]. Skin manifestations initially include a local cellulitis with progression to diffuse erythema and edema, dusky blue discoloration indicative of necrosis, and often associated bullae formation. By the time cutaneous, fascial, and associated nerve necrosis occurs, localized pain has been replaced by anesthesia. Two types of NF exist: type 1 and type 2 [66].

1. **Type 1 NF** is a polymicrobial infection caused by synergistic anaerobes (especially *Bacteroides* and/or *Peptostreptococcus*), gram-negative aerobic bacilli, and gram-positive aerobes such as group A streptococci and enterococci (Color Plate 4.23). Predisposing factors include surgery, diabetes mellitus, and peripheral vascular disease.
2. **Type 2 NF** is caused by streptococci, usually group A streptococcus (*S. pyogenes*) and, rarely, group B, C, and G streptococci. Predisposing factors for necrotizing infection due to these “flesh-eating bacteria” (group A streptococcus) include blunt trauma, penetrating injuries and minor cuts, varicella infection, intravenous drug use, surgical procedures, burns, exposure to an index case, trauma, and possibly nonsteroidal antiinflammatory drugs [67,68]. The incidence of group A streptococcus-associated NF is increasing significantly and is often associated with a toxic shock–like syndrome.
3. **Management.** Prompt and definitive **surgical incision and debridement is essential** to optimizing the outcome. Intraoperative specimens can be used to tailor pathogen-specific therapy. In addition to supportive care, **antibiotic therapy for type 1 NF** in adults can include cefotaxime, 2 g i.v. every 8 hours or ceftriaxone, 2 g i.v. every 24 hours, plus metronidazole, 500 mg i.v. every 6 hours or clindamycin, 900 mg i.v. every 8 hours; or piperacillin-tazobactam, 3.375 g i.v. every 6 hours; or ampicillin-sulbactam, 3 g i.v. every 6 hours; or ticarcillin-clavulanate, 3.1 g i.v. every 4 to 6 hours; or imipenem, 500 mg i.v. every 6 hours. **Recommendations for treatment of type 2 NF** in adults include penicillin G, 4 million units i.v. every 6 hours or 24 million units i.v. over 24 hours plus clindamycin, 900 mg i.v. every 8 hours. Clindamycin is added because its efficacy is not affected by the inoculum or growth phase of group A streptococci, and because of its inhibition of toxin production. Some anecdotal reports also suggest that adjunctive i.v. immunoglobulin may be beneficial [69]. Hyperbaric oxygen therapy also can be considered as adjunctive therapy for NF but is not considered the standard of care [70].

E. Fournier gangrene is a form of type 1 NF that classically affects the male genital organs and perineum. Combinations of Enterobacteriaceae, anaerobic streptococci, *S. aureus*, enterococci, β -hemolytic streptococci, and various anaerobes can be isolated. Although this infection can occur spontaneously, predisposing factors include GU trauma, GU surgery, GU instrumentation, or extension from intraabdominal, perianal, perirectal, or urinary tract infections. Other risk factors may include diabetes, liver disease, and alcohol abuse. Characterized by severe pain and systemic toxicity, an initially localized cellulitis can spread rapidly and invasively to involve the scrotum, penis, perineum, or anterior abdominal wall. Aggressive surgical evaluation with wide debridement and drainage is essential. The testes' separate blood supply prevents necrosis of the testicles and results in a rare need for orchiectomy. Broad-spectrum antimicrobial regimens used for type 1 NF are required to address the polymicrobial nature of this mixed aerobic and anaerobic infection.

II. Diagnosis. Studies that may be helpful in the assessment and diagnosis of necrotizing infections of the soft tissues include the following:

- A. Vigilant and serial clinical examinations** are paramount for detecting the progression of disease, development of crepitation, and evolution of necrotic skin lesions.
- B. Soft tissue radiographs and CT scans** can reveal the presence of gas in soft tissues that is not palpable on physical examination. Enterobacteriaceae, anaerobic streptococci, *Bacteroides* species, and clostridia can generate gas within tissues. **MRI** appears to be most sensitive in distinguishing necrotizing from non-necrotizing skin and soft tissue infections [71].

- C. A high index of clinical suspicion of necrotizing skin and soft tissue infections is often needed to precipitate surgical exploration and debridement.** Needle aspiration of suspect lesions may assist with determining the etiology of infection [72]. Early performance and examination of **frozen-section full-thickness soft tissue biopsies** can expedite surgical evaluation and therapy [73]. In NF, a blunt probe typically passes without resistance along the deep fascial planes. Direct visualization of necrotic fascia during surgery is diagnostic.
 - D. Gram staining and anaerobic and aerobic culturing of infected tissue or lesion-associated exudate should be performed.** In addition to microbiologic analysis, histopathologic evaluation also should be performed to assist in determining the extent of tissue destruction.
 - E. Standard blood cultures also should be obtained.**
 - F. Nonspecific laboratory abnormalities can include a leukocytosis with a predominance of neutrophils and its early precursor forms as well as increasing creatine phosphokinase levels.**
- III. Approach to therapy is multidimensional and includes the following:**
- A. Supportive care and hemodynamic stabilization, including adequate nutrition, electrolyte supplementation, fluid resuscitation, and maintenance of adequate organ perfusion pressures and oxygenation are required.**
 - B. Early aggressive surgical debridement with possible repeat interventions is a priority [63].**
 - C. Antibiotic therapy is essential.** Empiric broad-spectrum antimicrobial therapy to cover mixed aerobic and anaerobic pathogens is recommended. The regimen can be modified when further clinical and microbiologic data become available. Regimens for specific necrotizing infections are detailed earlier in this section.

GENERAL PRINCIPLES OF WOUND INFECTION MANAGEMENT

Postsurgical and trauma-associated wound infections are well described. Approximately 2% of surgical procedures are complicated by surgical site infections (SSIs). Surgical site infections may be superficial incisional SSIs of the skin and subcutaneous tissue, deep incisional SSIs of the deep soft tissue, fascia, and muscle, or organ space SSIs. They are responsible for approximately 15% of nosocomial infections [74].

- I. Overview of surgical site/wound infections.** A detailed overview and recommendations for prevention of surgical site infections has recently been published by the Centers for Disease Control and Prevention [75]:
 - A. Microbiology.** Data from the National Nosocomial Infections Surveillance System reveals that the most common organisms responsible for SSIs are (in descending order): *S. aureus*, coagulase-negative staphylococci, enterococci, *E. coli*, *P. aeruginosa*, *Enterobacter* species, *Proteus mirabilis*, *Klebsiella pneumoniae*, other streptococci, *Candida albicans*, nonenterococcal group D streptococci, other gram-positive aerobes, and *Bacteroides fragilis* [76]. The endogenous bacterial flora of the patient are common pathogens in surgical wound infections. The pathogens isolated are a reflection of the type of operation [75]. Gram-negative bacilli, enterococci, and anaerobes are likely pathogens after entering a GI organ. *S. aureus* and coagulase-negative staphylococci are likely pathogens after cardiac procedures, neurosurgical procedures, and procedures involving placement of grafts, prostheses, or implants. Gram-negative bacilli are likely pathogens after urologic procedures, and gram-negative bacilli, enterococci, group B streptococci, and anaerobes are likely pathogens after obstetric and gynecologic procedures. Surgical team members and instruments also may serve as exogenous sources of SSI-associated pathogens.
 - B. Pathogenesis.** The risk for SSIs is directly proportional to the inoculum size and virulence of organisms contaminating the surgical site and inversely proportional to the resistance of the host patient; that is, the presence of foreign material and necrotic tissue or the use of immunosuppressive therapy increase the risk for SSIs.
 - C. Patient characteristics** that may increase the risk for SSIs include smoking cigarettes, diabetes mellitus or other immunodeficient states, steroid use, malnutrition, coexistent infections at another body site, microbial colonization, more than 120% of ideal body weight, prolonged preoperative stays, preoperative nasal

colonization with *S. aureus*, perioperative transfusion, and very young or very old age [75].

D. Operation characteristics that may dictate the risk for development of SSIs include duration of surgical scrub, antisepsis of skin, preoperative shaving and skin preparation, length of operation, perioperative antimicrobial prophylaxis, ventilation of the operating room, sterilization of surgical instruments, surgical technique, and the presence of foreign bodies including drains in the surgical site [75].

II. Epidemiology. Three variables are used to reliably predict the risk for development of SSIs. These risk factors include the likelihood that microbes have contaminated the wound site, the length of the surgical procedure, and the general physical status of the patient [77].

A. Surgical wounds can be divided into the following categories to assess the risk for microbial contamination [78]:

1. Clean wounds (class I) involve noncontaminated skin in which sterile technique is maintained and there is no entry into GI, respiratory or GU tracts. In general, the risk of infection is below 2%. Examples of these procedures include breast tumor excision, thyroidectomy, and herniorrhaphy. Antibiotic prophylaxis is not routinely recommended.

2. Clean-contaminated wounds (class II) are created under controlled circumstances when there is entry into body areas that are considered contaminated, i.e., GI, respiratory, or GU tracts. In general, the risk for infection is greater than or equal to 10% in the absence of antibiotic prophylaxis. Examples of these procedures include appendectomy and hysterectomy.

3. Contaminated wounds (class III) result from trauma, procedures associated with major breaks in aseptic technique, or spillage from the GI tract and entry into an area of acute inflammation that is not purulent. The risk of infection in this setting approaches 30%, and antibiotic treatment is recommended. Examples include removal of malignancies with inflammation and repair of perforated diverticulum.

4. Dirty infected wounds (class IV) include older trauma-associated open wounds, those with gross contamination with devitalized tissue or foreign bodies, and those associated with drainage of frankly purulent material. The risk for infection approaches 40%, and treatment with antibiotics is recommended. Examples include repair of open compound fractures and drainage of intraabdominal abscesses.

B. The length of operation is another important independent factor for wound infection assessment. Operations that last longer than the 75th percentile for duration of each specific surgical procedure are associated with increased risk for infection [79]. Abdominal operations also increase the risk for infection [80].

C. The physical status of the patient is also important in risk assessment. Patients with severe systemic disease or multiple comorbidities are at increased risk for development of infection [75].

III. Clinical presentation and evaluation. The diagnosis of a wound infection can be difficult. Criteria for defining superficial incisional surgical site infections have been proposed by the Centers for Disease Control and Prevention and include purulent drainage from the surgical site, isolation of organisms from aseptically obtained tissue or fluid, and the presence of wound-associated tenderness, swelling, erythema, or warmth [81]. In deep incisional SSIs, purulent drainage, dehiscence of the deep incision, fever, pain, and fluctuance indicative of an abscess are helpful criteria. Malodorous wound discharges or crepitation on physical exam also may be helpful in predicting wound infection. In patients who have systemic signs and symptoms, blood cultures should be obtained.

IV. Treatment

A. Surgical drainage with debridement to remove all foreign material and necrotic, infected tissue are often required.

B. Initial antibiotic choices should be guided by the likely pathogens associated with specific operations or exposures and by initial results of Gram staining from wound-associated exudate or tissue. Pathogen-directed therapy can be instituted once culture results become available. Listed below are choices and doses appropriate for adults with normal renal function.

1. **Traumatic wound infection, culture pending.** These infections can be due to numerous combinations of microbes, including staphylococci, streptococci, gram-negative bacilli, and anaerobes including clostridial species. Beta-lactam and β -lactamase inhibitor combinations such as piperacillin-tazobactam (3.375 g i.v. every 6 hours), ampicillin-sulbactam (3 g i.v. every 6 hours), or ticarcillin-clavulanate (3.1 g i.v. every 4 to 6 hours) are often recommended. Imipenem (500 mg i.v. every 6 hours) also can be considered. A quinolone such as ciprofloxacin (400 mg i.v. every 12 hours) also should be considered if trauma was incurred in water.
2. **Surgical site infection, culture pending**
 - a. If surgery involves the GU tract, GI tract, oropharynx, or esophagus, potential microbes include staphylococci, streptococci, enterococci, gram-negative bacilli, and anaerobes. In the hospitalized patient, β -lactam and β -lactamase inhibitor combinations such as piperacillin-tazobactam (3.375 g i.v. every 6 hours), ampicillin-sulbactam (3 g i.v. every 6 hours), or ticarcillin-clavulanate (3.1 g i.v. every 4 to 6 hours) are often recommended. Imipenem (500 mg i.v. every 6 hours) or a third-generation cephalosporin such as ceftriaxone (2 g i.v. every 24 hours) in combination with metronidazole (500 mg i.v. every 6 hours) also can be considered.
 - b. If surgery does not involve the GU tract, GI tract, oropharynx, or esophagus, potential microbes include staphylococci, streptococci, and gram-negative bacilli. In these patients, β -lactam and β -lactamase inhibitor combinations such as piperacillin-tazobactam (3.375 g i.v. every 6 hours), ampicillin-sulbactam (3 g i.v. every 6 hours), or ticarcillin-clavulanate (3.1 g i.v. every 6 hours) are often recommended. Vancomycin (15 mg/kg i.v. every 12 hours) should be considered if methicillin-resistant *Staphylococcus aureus* (MRSA) is suspected or hospital epidemiology documents its increased prevalence.

V. Prophylaxis

- A. **Antibiotic prophylaxis to prevent SSIs** has proven effective when antibiotics are administered preoperatively. Surgical antibiotic prophylaxis is covered in Chapter 27. The use of antibiotics for management of trauma-associated wounds is less well defined and should be dictated by the clinical signs and symptoms if bacterial contamination has already occurred by the time the wound is evaluated.
- B. **Tetanus prophylaxis** is discussed below.

TETANUS

Clostridium tetani is a gram-positive anaerobic spore-forming bacillus that is found in the soil and intestinal contents of many farm animals and even humans. Inoculation of this organism typically occurs in wounds associated with acute injury. These injuries include puncture wounds due to nails, tattooing, body piercing, animal bites, splinters, lacerations, and abrasions. Non-acute injury conditions associated with the development of tetanus include intravenous drug use, diabetes mellitus, otitis media, and tooth infections [82]. Approximately 5% of cases are observed in chronic skin wounds or ulcers [83]. The average incubation period is usually 6 to 12 days and is inversely proportional to the distance between the inoculation site and the central nervous system. After sporulating under anaerobic conditions, this bacteria produces an exotoxin that acts at spinal synapses to interfere with neurotransmission. The resultant effect is uncontrolled muscle contractions and exaggerated reflexes. The clinical case definition for tetanus is the "acute onset of hypertonia and/or painful muscular contractions (usually of the muscles of the jaw and neck) and generalized muscle spasms without other apparent medical cause" [84]. In the United States, a total of 124 cases of tetanus were reported from 1995 through 1997, primarily affecting unvaccinated or insufficiently vaccinated individuals [82]. Individuals over 60 years of age are at increased risk for tetanus, a reflection of decreased prevalence of immunity to tetanus in this age group. Tetanus is completely preventable by effective vaccination.

I. Prevention

- A. **Primary vaccination series and routine tetanus prophylaxis [85].** Routine recommendations for tetanus prevention include a complete primary vaccination

Table 4.3. Summary Guide to Tetanus Prophylaxis in Routine Wound Management

History of Adsorbed Tetanus Toxoid (doses)	Clean Minor Wounds		All Other Wounds ^b	
	Td ^a	TIG ^a	Td ^c	TIG
Unknown or <3	Yes	No	Yes	Yes
>3 ^d	No ^e	No	No ^f	No

^aTd, tetanus and diphtheria (adult type) adsorbed toxoids; TIG, human tetanus immunoglobulin (250 units i.m.). (TIG is preferred over equine antitoxin.) When tetanus toxoid and TIG are given concurrently, the adsorbed toxoid is recommended. (Separate syringes and separate sites should be used.)

^bSuch as, but not limited to, wounds contaminated with dirt, feces, soil, saliva, and so on; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

^cFor children under 7 years of age; DT_aP (DT, if pertussis vaccine is contraindicated) is preferred to tetanus toxoid alone. For persons 7 years and older, Td is preferred to tetanus toxoid alone.

^dIf only three doses of fluid toxoid have been received, a fourth dose of toxoid, preferably an adsorbed toxoid, should be given.

^eYes, if more than 10 years since last dose.

^fYes, if more than 5 years since last dose. (More frequent boosters are not needed and can accentuate side effects.)

Reprinted from Centers for Disease Control. Diphtheria, tetanus, and pertussis. Recommendations for vaccine use and other preventive measures. *MMWR* 1991;40:21–22, with permission.

DTaP (diphtheria and tetanus toxoids and acellular pertussis vaccine) series administered at 2 months, 4 months, 6 months, 15 to 18 months, and 4 to 6 years of age. Subsequent routine tetanus toxoid boosters given as Td (tetanus and diphtheria toxoids) should be administered every 10 years. A complete primary vaccination series for persons greater than or equal to 7 years of age consists of three doses of Td with 4 weeks separating the first and second doses and 6 to 12 months separating the second and third doses; routine toxoid booster should then be administered every 10 years. **Protective antibodies decline over time.** Serologic surveys have shown that in the United States from 1988 to 1991, 72% of adults over 70 years of age did not have immunity to tetanus [86]. **Physicians should not administer toxoid booster to patients with a history of neurologic reaction, urticaria, or anaphylaxis with previous vaccination. Patients with Arthus-like reactions should not be given booster doses at more frequent intervals than every 10 years [85].**

B. Tetanus prophylaxis in wound management. Passive immunization with tetanus immunoglobulin (TIG) or active immunization with tetanus toxoid is an important consideration in wound management. U.S. Public Health Service recommendations (Table 4.3) are dictated by the patient's tetanus immunization history and the type of wound [87–90]. Wounds that are nonpenetrating, superficial, less than 6 hours old, linear in configuration, and manifest no associated tissue necrosis or contamination are classified as clean and minor.

II. Clinical characteristics of tetanus [88,89]. Several clinical types of tetanus have been described. **Most patients who develop tetanus are diagnosed with generalized tetanus.** Trismus (i.e., lockjaw), a reflection of rigidity of the masseters, is the most common presenting sign. Orbicularis oris rigidity produces the characteristic sardonic smile (*risus sardonicus*). Persistent contractions of the chest and back muscles with flexion of the arms and extension of the lower extremities (i.e., opisthotonos) may develop. Painful generalized muscle contractions can be precipitated by minor sensory stimuli, including noise and touch. Spasm of the larynx or glottis can impair gas exchange and swallowing; difficulty with urination and defecation is another potential complication. The overall mortality rate is approximately 30% and residual neurologic complications are not common in survivors.

Neonatal tetanus, a form of generalized tetanus, is seen primarily in undeveloped conditions where tetanus immunization rates for mothers are low and occurs as a result of contamination of the umbilical cord and stump. Infants develop generalized muscle spasms and irritability. **Cephalic tetanus** manifests as cranial nerve

dysfunction, usually in the setting of otitis media or other head-associated injuries and infections. Although not common, **local tetanus** is characterized by muscle contractions in the area where the injury occurs.

- III. Diagnosis.** The diagnosis of tetanus is usually made on clinical grounds in patients with a recent history of injury and the new onset of characteristic neurologic findings. Common laboratory studies such as complete blood counts and chemistries are usually normal. With the exception of an elevated opening pressure, lumbar puncture and the cerebrospinal fluid profiles are normal. The microbiologic identification of *C. tetani* from wound specimens is not very sensitive or specific. Radiographic imaging of the central nervous system is unremarkable. The differential diagnosis includes dystonic reactions to neuroleptic drugs, local infection or trauma to the teeth or masseters, hysteria, hypocalcemia, and strychnine poisoning.
- IV. Treatment.** All the following treatment modalities should be instituted [88,90].
- A. Human tetanus immunoglobulin** administered i.m. is recommended as soon as possible. In general, a single dose of 3,000 to 6,000 units is recommended for children and adults, although a dose of 500 units may be as effective as larger doses [90]. Despite the recommendations of some experts, no increased efficacy has been proven with infiltration of TIG around the area of the wound. In the event that TIG is not available, i.v. immune globulin may be used [90].
 - B.** Because natural infection does not result in immunity, a complete course of active tetanus toxoid immunization is recommended once the patient has recovered.
 - C. If possible, debridement of foreign and necrotic tissue** should be pursued.
 - D. Supportive medical care** should be provided in a quiet environment so that stimuli resulting in spasms or seizures can be minimized. Benzodiazepines and curare-like agents (vecuronium, pancuronium) are indicated for management of spasms or seizures. Mechanical ventilatory support may be required.
 - E. Antibiotic therapy. When compared with penicillin G, metronidazole appears to be more clinically effective for the treatment of tetanus** [91]. Metronidazole, 500 mg i.v. every 6 hours, for 10 to 14 days is recommended for adults. Parenteral penicillin G, 2 million units every 6 hours, is recommended as an alternative choice.
- V. Prognosis.** The overall case fatality incidence for known outcomes among 122 patients in the United States from 1995 through 1997 was 11% [82]. The case fatality incidence in patients 20 to 39 years of age was 2.3%. Patients with tetanus who were 40 to 59 years of age had a case fatality incidence of 16%, increasing to 18% in those greater than 59 years of age.

POTENTIAL BIOLOGIC WARFARE AGENTS

Events of the new millennium have provided an impetus for physicians to be cognizant of biologic warfare agents. Several of these potential agents produce cutaneous manifestations, including *Bacillus anthracis*, variola major, *Francisella tularensis*, and *Yersinia pestis*. This list is not exhaustive, and the reader is referred to the CDC website (www.bt.cdc.gov) for updated details regarding potential biologic warfare agents.

I. Anthrax

- A. Clinical characteristics [92–97].** Anthrax, a gram-positive sporulating rod, can cause inhalational, GI, and cutaneous infections.
- 1. Inhalational disease** occurs after spores of *Bacillus anthracis* are inhaled. Macrophages in the lung ingest these spores and carry them to mediastinal lymph nodes where they proliferate and produce toxins that result in edema and hemorrhage. After an incubation period of 1 to 7 days, infection classically manifests as a biphasic illness with a prodrome of dry cough, muscle pains, headache, fever, and abdominal pain (i.e., flulike symptoms) followed by a short interval of improvement. Afterward, the fulminant development of severe pulmonary failure, hemodynamic instability, and, in 50% of patients, meningeal inflammation is noted.
 - 2. GI disease** develops approximately 2 to 5 days after ingestion of meat that is contaminated with spores. Spores presumably enter through defects in the

mucosal lining of the gut, with ulcerations usually noted in the caecum and ileum and associated mesenteric lymph node inflammation. Patients typically present with nausea, vomiting, abdominal pain, fever, and bloody diarrhea. Ascites also has been reported.

3. **Cutaneous disease** represents the greatest proportion of anthrax infections (>95%). One to 14 days after inoculation, a pruritic, **painless** papule develops that enlarges and then vesiculates. Lesion-associated fluid discharge is often clear to serosanguinous. A brawny, nonpitting, almost gelatinous edema surrounds the vesicle. This lesion then ruptures and develops a necrotic eschar, which can be surrounded by increased edema and numerous vesicles (Color Plate 4.24). The patient presents with fever, particularly if bacteremia is present. Numerous lesions may be observed, typically occurring on the face and extremities.

B. Epidemiology. Endemic areas of infection include western Asia and Africa. Anyone exposed to spores can develop disease, and those at greatest risk include individuals who work in industries where there is exposure to goat hair, wool, cashmere, dying cattle, or infected meat. The spectre of bioterrorism has now placed other individuals at risk, including postal/mailroom workers, laboratorians, media personalities, and governmental figures.

C. Diagnosis of cutaneous anthrax

1. A complete blood count may reveal a leukocytosis with increased band forms.
2. If inhalational anthrax is suspected, a chest radiograph should be obtained (see Chapter 11).
3. Early identification can be made with Gram staining of blood, cerebrospinal fluid, or cutaneous lesion aspirates or biopsies. These organisms are large, gram positive, encapsulated, and rodlike in appearance.
4. *B. anthracis* can be isolated from routine cultures. Culture of skin lesion aspirates, blood, cerebrospinal fluid, and pleural fluid with routine media can be useful for isolation. Speciation should be pursued to differentiate from other potential pathogens associated with the *Bacillus* species (e.g., *B. cereus*).
5. Serologic antibody testing of acute and convalescent serum is helpful for epidemiologic purposes.
6. Enzyme-linked immunoassays for antigen detection and nucleic acid–based testing such as polymerase chain reaction (PCR) are rapid diagnostic tests available primarily at reference laboratories.

D. Treatment [94,95,97]

1. **Recommended initial treatment for inhalational anthrax in adults (including pregnant and immunocompromised patients)** includes ciprofloxacin, 400 mg i.v. every 12 hours or doxycycline, 100 mg i.v. every 12 hours plus 1 or 2 other antibiotics that are active *in vitro* against the implicated strain (i.e., ampicillin, penicillin, clindamycin, clarithromycin, imipenem, vancomycin, rifampin, chloramphenicol). Once the patient is stable, oral monotherapy with ciprofloxacin 500 mg orally twice daily or doxycycline, 100 mg orally twice daily can be used in lieu of intravenous therapy to complete a 60-day course. Steroids can be considered when meningitis or serious edema develops.
2. **Recommended treatment for cutaneous anthrax in adults (including pregnant and immunocompromised patients)** includes ciprofloxacin, 500 mg orally twice daily, or doxycycline, 100 mg orally twice daily for 60 days. If systemic symptoms, extreme edema, or facial/neck edema are present, treat as inhalational anthrax (see above).

E. Prophylaxis [94,95,97]

1. **Postexposure prophylaxis recommendations for adults (including pregnant and immunocompromised patients)** include ciprofloxacin, 500 mg orally every 12 hours, or doxycycline, 100 mg orally twice daily. If the isolate is susceptible, amoxicillin, 500 mg orally every 8 hours, or doxycycline, 100 mg orally twice daily, is optimal. The total duration of antibiotics should be 60 days.
2. **Vaccination.** A six-dose anthrax inactivated cell-free vaccine series is used for U.S. military personnel [98,99]. Availability is limited, and its routine use is currently not recommended. If available, vaccine can be offered to persons exposed from a bioterrorist attack along with prolonged antibiotics [95].

II. Smallpox. Vaccination against variola major (smallpox) was universally discontinued in 1980. Large-scale use of this organism as a biologic warfare agent would likely be devastating in the United States because no American has been vaccinated in over 27 years. Unlike anthrax, person-to-person transmission occurs by droplet nuclei. The case fatality rate is greater than 30% among previously unvaccinated individuals [100,101].

A. Clinical characteristics [100,101]. The virus is transmitted primarily via droplet nuclei that embed in the oropharynx or respiratory tract. After an incubation phase of 7 to 17 days, infected individuals develop flulike symptoms, including fever, back pain, and headache. **A rash described initially as maculopapular then develops over 1 to 2 days on the oropharyngeal mucosa, face, and upper extremities (including palms and soles) before centrifugally involving the thorax and lower extremities. The lesions are typically most dense on the face and extremities, and all lesions appear to be at the same stage of evolution.** The rash then develops a vesiculopustular appearance that eventually crusts over after 8 to 14 days, leaving scars that are described as “pitted.” Encephalitis and keratitis are possible complications.

In contrast, chickenpox has an incubation period of 2 to 3 weeks with a short prodromal period before a more superficial vesicular rash evolves in a centripetal distribution (albeit rarely involving the palms and soles). The lesions appear every few days and are classically found in different stages of evolution. Crusting of the lesions occurs within 1 week.

B. Epidemiology. When smallpox infections existed, occurrences were most common in winter and spring and among younger populations. With no vaccination in the United States for greater than a quarter century, even **vaccinated individuals may be susceptible to smallpox infection due to waning immunity.**

C. Diagnosis [100]. Fluid from vesiculopustular lesions is evaluated with electron microscopy. The clinical presentation and epidemiologic background combined with the visualization of virions consistent with orthopoxvirus are useful in making a presumptive diagnosis. The diagnosis is confirmed by growth of the virus under specialized conditions and strain characterization by nucleic acid–based techniques such as PCR and restriction fragment length polymorphisms. **Laboratory investigations should be pursued in experienced laboratories with high containment capabilities.**

D. Preexposure vaccination. Limited supplies of smallpox vaccine and vaccinia immune globulin exist, but efforts to increase supplies of both will result in a need for reassessment of policy for use in prevention of primary infection. Currently, the CDC controls access to both of these agents. Renewed vaccine production is currently being commissioned by the CDC [100].

E. Postexposure treatment [100]. No antiviral therapy has proven reliably effective against smallpox infection. When infection develops, care is primarily supportive. In a smallpox outbreak, **all infected individuals should be isolated to prevent human-to-human transmission.** Close contacts of these individuals should be vaccinated and observed, preferably in a domestic setting. Vaccination within 96 hours of exposure appears to prevent infection and improve outcome [102]. Because contaminated laundry from these patients can spread the smallpox virus, autoclaving of sheets and clothes is essential. Disinfection of contaminated inanimate objects with hypochlorite and ammonia is also recommended.

III. Tularemia. Quite virulent, only a few organisms of *Francisella tularensis* (tularemia) are required to cause infection. The etiologic agent of “rabbit fever,” this small gram-negative coccobacillary organism primarily causes infections in animals. The usual mode of transmission to humans is by contact with contaminated tissues and body fluids or from the bite of an infected tick, mosquito, or deerfly. Much less commonly, the organism is transmitted from animal bites, ingestion, or inhalation.

A. Clinical characteristics [103–105]. Contingent on numerous factors, including the route of inoculation and the inoculum size, the clinical presentations associated with tularemia are diverse. **The most common type of infection is ulceroglandular disease,** accounting for more than 75% of all tularemia infections. After an incubation period of approximately 3 to 5 days, **a painful pruritic erythematous papule or nodule** develops at the site of inoculation, which typically involves the

distal upper extremities. **Localized tender lymphadenopathy** is also appreciated. **The skin lesion ulcerates with a necrotic center** (Color Plate 4.25). Disease onset is sudden, and the patient may appear toxic, with fatigue, fever, and chills. The organisms can disseminate hematogenously from lymph nodes and reside in organs of the reticuloendothelial system.

Release of this organism in an aerosolized form would be the likely transmission route in biologic warfare, and the pleuropulmonary or inhalational form of tularemia would predominate (see Chapter 11).

B. Epidemiology [103–105]. In nonoutbreak situations, natural infection with tularemia is reported with increased frequency in summer months when ticks are most prevalent. Most cases in the United States are reported from Arkansas, Missouri, Oklahoma, Texas, Utah, and Tennessee. These infections are usually seen in men, perhaps due to increased recreational activities that include hunting or exposure to wild mammals. If used as a biologic weapon, all individuals would be susceptible to *F. tularensis* and health-care providers would need to have heightened clinical suspicion.

C. Diagnosis [103–105].

1. Skin and respiratory abnormalities are not specific. Clinical suspicion is important in directing further workup.
2. Gram staining of infected skin or sputum rarely reveals the organism. Direct fluorescent antibody stains are useful in rapid identification of the organism in body fluids or tissue.
3. Special media are needed for cultivation of this organism from pharyngeal, gastric, sputum, and blood specimens, and include cysteine-enriched broth and blood agar, and thioglycollate broth. Buffered charcoal-yeast and chocolate agar also can be used. Laboratorians need to be informed when the diagnosis of tularemia is suspected. Any activity resulting in aerosolization or droplet formation of culture materials mandates biosafety level 3 conditions [103].
4. Serologic tests using microagglutination, tube agglutination, or enzyme immunoassay technology can be used for diagnostic confirmation and epidemiologic studies.
5. Rapid diagnostic tests, including PCR, enzyme-linked immunosorbent assay, and antigen detection assays, exist but are usually available only in specialized reference or research laboratories [106].

D. Treatment [103].

1. If an individualized approach can be taken toward the infected adult with tularemia, the preferred choice for treatment is streptomycin, 1 gm i.m. twice daily; gentamicin, 5 mg/kg/day i.m. or i.v. is an acceptable alternative. Treatment length is 10 days. Alternative choices include doxycycline, 100 mg i.v. twice daily for 14 to 21 days; ciprofloxacin, 400 mg i.v. twice daily for 10 days; or chloramphenicol, 15 mg/kg i.v. four times daily for 14 to 21 days.
2. In a mass casualty situation, treatment recommendations for adults include a 14-day course of doxycycline, 100 mg orally twice daily, or ciprofloxacin, 500 mg orally twice daily. Antibiotic susceptibility testing should be pursued in order to direct further therapy. In the setting of inhalational exposure, prophylactic therapy with 14 days of oral doxycycline or ciprofloxacin is recommended.
3. Person-to-person transmission does not occur and isolation of infected individuals is not necessary.

E. Vaccination. A live attenuated vaccine for *F. tularensis* exists that has been used for protecting individuals who are at increased risk for infection (e.g., laboratory workers who work with the organism). It is not recommended for postexposure prophylaxis by the Working Group on Civilian Defense [103].

IV. Plague. *Yersinia pestis* is the etiologic agent of plague. It has been identified by the Working Group on Civilian Biodefense as a potentially serious biologic warfare agent because of its high case fatality rate, its human-to-human transmissibility, and its ability to be administered as an aerosol [107]. The reservoir is typically a rodent, and the usual mode of transmission to humans is by a flea bite.

A. Clinical characteristics [107–109]. Approximately 2 to 7 days after the bite of a plague-infected flea, approximately 90% of patients develop high fever, malaise,

nausea and vomiting, chills, headache, and **tender localized matted lymphadenopathy** (usually axillary, cervical, or inguinal) with overlying erythema known as **buboes**, hence the name **bubonic plague**. Other skin lesions described in bubonic plague include a vesiculopustular lesion at the site of inoculation; petechiae, ecchymoses, and gangrene can develop as complications of bacteremia, sepsis, and disseminated intravascular coagulation.

Approximately 5% of individuals develop a **septicemia** with no development of buboes. The case fatality rate approaches 25% to 50%, and these patients also may present with ecthyma-gangrenosum-like lesions, gangrenous lesions, and petechial-purpuric lesions.

Pneumonic plague develops in approximately 5% of patients as a result of the hematogenous spread of bacilli in patients with bubonic or septicemic plague (secondary pneumonic plague) or as a primary process. Primary pneumonic plague occurs in patients who inhale *Y. pestis* when exposed to humans or nonhuman animals with pneumonic plague. These patients present with hemoptysis, cough, shortness of breath, chest pain, fever, malaise, and, occasionally GI disturbances. Complications in patients with a fulminant course include purpura, necrotic skin lesions, and bleeding. Case fatality rates are reported to exceed 50% [109] (see Chapter 11).

B. Epidemiology [107,108]. Most cases of natural plague are reported from Africa, Asia, Central America, and South America. In the United States, most cases are reported in the summer and early fall from the southwestern states of New Mexico, Colorado, California, or Utah. If used as a biologic agent of terrorism, aerosolized transmission would likely be preferred, resulting in primary pneumonic plague (see Chapter 11).

C. Diagnosis [107–109]

1. Clinical suspicion is needed when patients present with suggestive clinical findings.
2. Chest radiography should be performed.
3. Gram staining of aspirates from buboes, sputum, or blood can be helpful in identifying bipolar safety pin–like gram-negative bacilli.
4. The organism can be isolated from standard cultures of blood, sputum, or bubo-associated aspirates. Optimal growth occurs on McConkey or blood agar at 28°C [107]. Laboratorians need to be informed when the diagnosis of plague is suspected. Any activity resulting in aerosolization or droplet formation of culture materials mandates biosafety level 3 conditions [107].
5. Rapid diagnostic confirmatory tests such as PCR, antigen detection, IgM enzyme immunoassay, and immunofluorescence staining are available at reference laboratories, including the CDC.
6. Serologic testing for antibodies is primarily useful for epidemiologic purposes.

D. Treatment [107]

1. If an individualized approach can be taken toward the infected adult with plague, the preferred choice for treatment is streptomycin, 15 mg/kg i.m. twice daily, or gentamicin, 5 mg/kg i.m. or i.v. once daily. Alternative choices include doxycycline, 100 mg i.v. twice daily or 200 mg/day i.v.; ciprofloxacin, 400 mg i.v. twice daily; or chloramphenicol 25 mg/kg i.v. as a loading dose followed by 15 mg/kg i.v. four times daily. Treatment length is 10 days and oral therapy can be used once the patient is stable. Gentamicin is preferred for pregnant patients.
 2. In a mass casualty setting and for postexposure prophylaxis, preferred recommendations for adults include doxycycline, 100 mg orally twice daily, or ciprofloxacin, 500 mg orally twice daily. The alternative choice is chloramphenicol, 25 mg/kg orally four times daily. Treatment length for a mass casualty setting is 10 days and for postexposure prophylaxis 7 days.
 3. Respiratory droplet precautions should be taken in the treatment of all patients with plague until pulmonary involvement is ruled out, or until at least 48 hours of antimicrobial therapy and clinical improvement is observed.
- E. Vaccination.** A formalin-killed vaccine existed (but is no longer available) that was not helpful in preventing primary pneumonic plague [107]. Effective immunizations against pneumonic plague are being pursued.

ACKNOWLEDGMENT

We thank Tami Hotard, MA, Department of Medicine at Louisiana State University School of Medicine in New Orleans, for her expert editorial contributions.

5. BONE AND JOINT INFECTIONS

Rathel L. Nolan and Stanley W. Chapman

OSTEOMYELITIS

Osteomyelitis is an inflammatory process in bone and bone marrow. Most often caused by pyogenic bacteria, it may also be caused by mycobacteria and fungi. Multiple classification schemes have been devised.

- I. Acute versus chronic osteomyelitis.** This clinical distinction is sometimes difficult to make. The following definitions provide a useful separation with implications in therapy and prognosis [1].
 - A. Acute** cases are those in their **first presentation**. The history may be short (days for hematogenous osteomyelitis) or long (weeks to months for contiguous osteomyelitis).
 - B. Chronic** osteomyelitis cases are those that have relapsed in a site of previously identified disease. Chronic osteomyelitis is more difficult to treat successfully and carries a poorer prognosis. Surgical intervention is usually required.
- II. Pathogenic classification.** The most useful clinical classification is based on pathogenesis, as outlined by Waldvogel et al. [1].
 - A. Hematogenous osteomyelitis** results from bacteremic seeding of bone.
 - B. Contiguous-focus osteomyelitis** is caused by spread from an adjacent area of infection, as in postoperative infections, direct inoculation from trauma, or extension from an area of soft tissue infection.
 - C. Peripheral vascular disease-associated osteomyelitis** usually occurs in patients with diabetes with or without large vessel insufficiency.
- III. Other classifications.** Other classification systems are based on special circumstances such as (a) a unique age group (neonatal osteomyelitis), (b) a unique clinical setting (e.g., intravenous drug use or sickle cell disease), (c) a microbiologic cause (gram-negative, anaerobic, etc.), or (d) an unusual anatomic location (e.g., vertebral osteomyelitis). A clinicopathologic classification proposed by Cierny et al. [2] facilitates comparison of therapeutic outcomes.
- IV. The changing spectrum of osteomyelitis.** Previously, osteomyelitis was predominantly hematogenous and caused by *Staphylococcus aureus*. **Presently, osteomyelitis occurs most frequently from contiguous-focus spread after an open fracture or reconstructive surgery or as a result of vascular insufficiency.** There has been an increase in nosocomial cases, as well as an increase in unusual bacterial causes, including gram-negative bacilli, anaerobes, and mixed infections. Increasing prevalence of antimicrobial-resistant bacteria markedly complicates therapy [3,4].

HEMATOGENOUS OSTEOLOGY

Hematogenous osteomyelitis occurs most often in rapidly growing bone, which explains the increased frequency among children. Recent series note an increasing frequency in older patients, so that the age distribution is bimodal [5–7]. Hematogenous osteomyelitis may occur in any bone, but the long bones (i.e., femur, tibia, and humerus) are most frequently involved in children. Older patients tend to have more vertebral involvement.

- I. Pathophysiology and patient age.** The pathophysiology and clinical presentation are age related [8].
 - A. Children.** In children aged 1 to 16 years, disease is most frequent in the metaphysis of long bones (Fig. 5.1). This is believed to result from sluggish blood flow through a sinusoidal venous system, a deficiency of phagocytic cells in this region, and poor collateral circulation. The susceptibility of this region to trauma may also play a role. A history of antecedent trauma may be obtained in 30% of patients with hematogenous osteomyelitis.
 - 1. Anatomic considerations.** In childhood, there are no anastomotic vascular channels between the metaphyseal and epiphyseal circulations (Fig. 5.1). The epiphyseal growth plate acts as a barrier, resulting in the spread of infection laterally and rupture of the cortex into the subperiosteal space, with subsequent subperiosteal abscess formation.

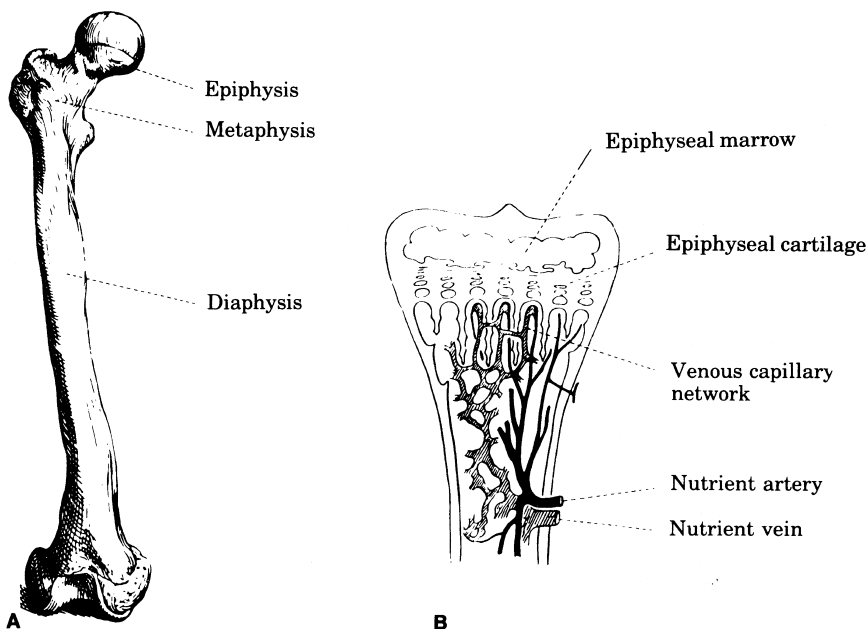

FIG. 5.1 A: Femur, showing diaphysis, metaphysis, and epiphysis. **B:** Vascular supply of a long bone in the area of the metaphysis and epiphysis. (From Waldvogel FA, Medoff G, Swartz MN. Osteomyelitis: a review of clinical features, therapeutic considerations, and unusual aspects. *N Engl J Med* 1970;282:198–206, with permission.)

When infection has reached the subperiosteal space, it may spread longitudinally along the shaft of the bone or rupture through the periosteum. Separation of the bone from the periosteum is accompanied by exuberant periosteal growth and new bone formation. This circumferential new bone covering is referred to as an **involucrum**.

2. **Sequestrum.** In the course of the infection, segments of bone may lose vascular supply due to such factors as increased pressure, acidic pH, and effects of leukocytic enzymes. Such an area of **devitalized bone** is referred to as a **sequestrum**. These areas must be surgically removed because they **act as foreign bodies** and will prevent effective antibiotic therapy.
3. **Associated septic arthritis.** As previously noted, the epiphyseal growth plate serves as a barrier to the spread of infection. In children, osteomyelitis complicated by septic arthritis occurs only in joints in which the metaphysis is intracapsular, such as the proximal femur and proximal humerus.

B. Neonates and infants younger than 1 year

1. **Septic arthritis is common.** In contrast to older children, at this age anastomotic channels exist between the metaphyseal and epiphyseal circulations. **Infection may spread rapidly to the epiphysis and joint space, resulting in septic arthritis** (Fig. 5.1).
2. Involvement of the epiphyseal growth plate may result in growth deformities.
3. The metaphyseal cortex is immature. Spreading exudate rapidly reaches the periosteum and ruptures it, infecting the surrounding periosteal tissues. This accounts for the frequent soft tissue abscesses found in this age group.

- C. Adults.** Hematogenous osteomyelitis is less common in adults. Initial localization is to the subchondral region of bone or the vertebrae.

1. **Anatomic considerations.** In adults, vascular connections between metaphyseal and epiphyseal vessels result after resorption of the growth cartilage. Spread of infection to the joint space by this route can occur. The periosteum is bound tightly to bone and has less osteoblastic activity so that subperiosteal abscess and involucrum formation are unusual.
2. **Vertebral osteomyelitis.** This is most common in adults 50 years of age and older and accounts for the bimodal age distribution of hematogenous osteomyelitis.

D. Special considerations

1. **Sickle cell disease.** The bone infarcts and marrow thrombosis that complicate this hemoglobinopathy predispose to bacterial localization in bone. Osteomyelitis at multiple sites is common. *Salmonella* species and *Staphylococcus aureus* are the most common pathogens [9,10].
2. **Intravenous drug users and hemodialysis patients.** Repeated intravascular injections in intravenous drug users and vascular access infections in hemodialysis patients result in an increased frequency of hematogenous osteomyelitis [11,12].

II. Microbiologic features

A. Staphylococci

1. *S. aureus* remains the most common pathogen, but the percentage of hematogenous osteomyelitis due to *S. aureus* has declined from 80% to 90% of cases in the past to 40% to 60% in recent years [5–7].
2. *Staphylococcus epidermidis* causes approximately 5% or fewer cases of disease. Because inadvertent contamination of cultures by this organism is frequent, its real role as a pathogen is unknown.

B. Streptococci

1. **Group A** streptococcal isolates cause disease in children and occasionally in adults.
2. **Group B** streptococci are common in neonates and may be a more common pathogen in this age group than are staphylococci [13]. Group B streptococci also occur in diabetic patients.

C. *Haemophilus influenzae* is now an infrequent cause of osteomyelitis in the United States due to widespread usage of conjugated polysaccharide vaccine [14].

D. **Gram-negative enteric bacilli** (e.g., *Escherichia coli*, *Salmonella*, and *Klebsiella* species) most often occur in adults and account for 10% to 15% of cases of hematogenous osteomyelitis. **Certain patient groups are predisposed** to hematogenous osteomyelitis caused by gram-negative organisms: neonates (Enterobacteriaceae), patients with sickle cell disease (*Salmonella*), and intravenous drug users (*Pseudomonas*). Patients with underlying chronic illness, including chronic renal disease, alcoholism, diabetes, and malignancy, also have an increased risk of gram-negative infections [15].

E. **Anaerobes** are uncommon causes of hematogenous osteomyelitis [16].

F. **Polymicrobial infections** can occur [17].

G. **Mycobacteria**, particularly tuberculosis, can cause vertebral osteomyelitis. This entity is discussed in section IV under Special Forms of Osteomyelitis, below.

H. **Fungi** can cause an indolent form of osteomyelitis and may have a propensity to involve bones of the feet or hands and the vertebrae. For further discussion, see section V under Special Forms of Osteomyelitis, below. Individual fungal infections are also discussed in Chapter 17.

III. Clinical manifestations

A. **Acute symptoms.** The classic presentation of hematogenous osteomyelitis is sudden onset of bone pain and toxicity with high fevers, rigors, and diaphoresis. Most patients present with symptoms of less than 3 weeks' duration. Children and infants may be symptomatic for less than 1 week. Extensive use of antibiotics for conditions other than osteomyelitis may modify the clinical presentation. Atypical presentations are more common and uncommon sites more frequent [5,7,18].

1. **Localized signs** include limitation of motion of the involved extremity, soft tissue swelling, erythema, warmth, and point tenderness over the involved area.

2. **Systemic manifestations** are seen in 50% or fewer patients. They may include fever, chills, night sweats, malaise, anorexia, and weight loss.
 3. **Minimal vague symptoms** may be reported by as many as 40% of patients for 1 to 2 months. This indolent course is likely in the following situations:
 - a. **Primary subacute pyogenic osteomyelitis (Brodie abscess).** This is characterized by the indolent formation of abscess, most frequently occurring at the metaphysis of long bones. Local pain is the most common presenting symptom [19].
 - b. **Vertebral osteomyelitis** in the adult. See section II under Special Forms of Osteomyelitis, below.
 - c. **Pelvic osteomyelitis.** The presenting symptoms for this condition may be unusual, including abdominal pain, gait disturbance, and sciatica [20].
 - B. **Neonatal osteomyelitis** is often a difficult diagnostic problem. Soft tissue swelling, localized tenderness, and decreased motion of an extremity (pseudoparalysis) are the most common findings. See Chapter 3, section VI.A under Selected Specific Infections in the Newborn, for further discussion.
 - C. **Sickle cell disease.** The **diagnosis** of osteomyelitis in these patients is **challenging**, because the clinical signs and symptoms mimic those associated with an acute pain crisis. For this reason, **blood cultures should always be obtained in patients presenting with an apparent acute sickle pain crisis.**
- IV. **Diagnosis.** Various cultural, hematologic, serologic, and radiographic procedures are helpful in making a clinical diagnosis and substantiating the etiology of disease. In an era of increasing prevalence of unusual and antimicrobial-resistant pathogens, vigorous attempts should be made to establish the specific etiology of disease. Availability of the pathogen for susceptibility testing is essential to guide antimicrobial therapy. The diagnostic modalities described below are applicable to all forms of osteomyelitis.
- A. **Blood cultures** should be drawn in all patients with suspected osteomyelitis. Approximately 50% of patients with acute hematogenous osteomyelitis have positive blood cultures. Neonatal osteomyelitis is often associated with bacteremia. Blood cultures are less likely to be positive in other forms of osteomyelitis, such as contiguous focus disease, chronic osteomyelitis, and osteomyelitis associated with peripheral vascular disease. Two to four separate sets of blood cultures should be drawn.
 - B. **Leukocytosis** can occur, but normal or minimally elevated leukocyte counts are common and cannot be used to exclude the diagnosis of osteomyelitis.
 - C. **The erythrocyte sedimentation rate (ESR)** may be normal early in the disease but will usually rise as the disease progresses. A normal ESR does not exclude the diagnosis. An elevated ESR provides an excellent parameter by which to monitor therapeutic response, because the ESR progressively declines with successful therapy.
 - D. **C-reactive protein** level is usually elevated at the time of presentation and falls with successful therapy. It is used with ESR to monitor therapeutic response [21].
 - E. **Radiographic evaluation** is very helpful and should be done routinely in all patients. The radiologic changes may lag days to weeks behind the clinical presentation. The usual sequence of radiologic changes is as follows:
 1. **Roentgenograms are normal** early in the disease course. Bone scans may detect abnormalities at this stage. However, if bone destruction is present, no further imaging may be necessary [22].
 2. **Soft tissue swelling and subperiosteal elevation** are the earliest abnormalities. These findings may be subtle and may not appear until 10 to 14 days after onset of symptoms. Serial radiographic examinations may be required.
 3. **Lytic changes** on roentgenography do not appear until 30% to 50% of bone is removed and usually are not detectable until 2 to 6 weeks after the onset of disease.
 4. **Sclerotic changes** appear weeks after onset of illness due to delay in mineralization after new matrix formation. Sclerotic changes associated with periosteal new bone formation (involucrum) denote a more chronic process.
 5. **Other diseases** may cause osteomyelitis-like changes on radiographs: chronic venous stasis of the lower extremities with periosteal reaction involving the tibia; osteoid osteoma; and neoplasms involving bone.

- F. Radionuclide scanning** is most helpful early in the course of acute disease, before the development of roentgenographic changes. Positive scans may be seen as early as 24 hours after the onset of symptoms.
1. Scanning with **technetium** radiophosphates is most commonly used, especially the **three-phase scans**. Radiation exposure approximates that of a standard roentgenogram and is not contraindicated in pediatric patients. Because of the possibility of referred pain or multicentric disease, whole body images should be obtained in patients with suspected osteomyelitis. More detailed radiographic examination of suspicious areas may then be obtained. Other processes, such as primary and metastatic tumor, osteonecrosis, arthritis, cellulitis, and abscess, may cause false-positive examinations.
 2. Indium-labeled leukocyte scans have excellent sensitivity and specificity for diagnosis of early osteomyelitis. They are more technically challenging and result in a substantially higher radiation dose than do technetium bone scans [23].
- G. Magnetic resonance imaging (MRI)** is sensitive for the early detection of osteomyelitis. It is used to identify soft tissue infection, distinguish soft tissue from bone marrow involvement, and distinguish between abscess and cellulitis. It is the preferred modality for diagnosis of vertebral osteomyelitis. MRI is also useful in evaluation of treatment failures and in planning surgical intervention. Computed tomography (CT) provides excellent images of bone cortex and is used for biopsy localization [24].
- H. Needle aspirations** from soft tissue collections, subperiosteal abscesses, and intraosseous lesions to obtain culture material should be performed in all patients in whom an unequivocal etiologic diagnosis is not obtained by blood cultures. Needle aspiration is preferably performed before administration of antibiotics.
- I. Joint fluid analysis** should be undertaken if there is an associated joint effusion. The aspirated effusion should be analyzed for cellular content, chemistries, Gram stain, and culture.
- J. Open biopsy** should be entertained in patients in whom a specific etiology is not obtained by blood cultures or needle aspiration, especially when tuberculosis, fungi, or malignancy is suspected. Biopsy material should be submitted for histopathologic examination and appropriate cultures.
- V. Initial therapy.** Initial therapy should be aggressive. Inadequate therapy of acute osteomyelitis may result in relapse and development of chronic disease.
- A. Principles of antibiotic use.** Antibiotics are the mainstay of therapy, although few prospective comparative trials exist on which to base selection of antibiotics and determine duration of therapy. Special aspects of their use are as follows.
1. **Parenteral agents** are generally recommended as the initial treatment to ensure compliance and also to achieve optimal bone levels. Because antibiotic penetration into bone is low, these agents are usually given in high doses. Antibiotic penetration is related to bone vascularity (i.e., cancellous bone levels are higher than cortical bone). Antibiotic levels are also higher in diseased bone. The penicillins, cephalosporins, gentamicin, vancomycin, clindamycin, and ciprofloxacin achieve concentrations in bone that exceed the minimal inhibitory concentration (MIC) of most susceptible organisms causing osteomyelitis [25–27]. In relationship to serum levels achieved, clindamycin and ciprofloxacin penetrate bone especially well. As such, these latter two agents have proven useful in the treatment of all forms of osteomyelitis, whether administered intravenously or as oral therapy.
 2. **Oral antibiotic therapy**
 - a. **Children.** It is common practice to treat acute hematogenous osteomyelitis in children with oral antibiotics after an initial course of parenteral therapy. Patients are treated with intravenous antibiotics for 5 to 10 days. After a favorable clinical response is noted, the patient is switched to high dose oral therapy, which is continued for at least 3 more weeks. **Several aspects of oral therapy deserve special emphasis.**
 - (1) The **causative organism** must be available for study and proven susceptible to the oral agents chosen.
 - (2) Appropriate surgical debridement or drainage must be performed.
 - (3) **Compliance must be ensured.** If there is any doubt as to the patient's

strict compliance with therapy, outpatient treatment must be abandoned [28].

(4) **Monitoring of serum bactericidal levels** is advocated by some experts to ensure adequate gastrointestinal absorption and adequate serum concentrations [29].

(5) **Patients should be without significant underlying diseases.**

(6) Prolonged follow-up is needed, because disease may recur years after an apparent cure.

b. Adults. It is our practice to complete a full course (i.e., 4–6 weeks) of intravenous antibiotics for the initial therapy of most adults with acute hematogenous osteomyelitis. We try to avoid oral therapy in adult patients because of the lower antibiotic concentrations that are achieved in bone. An exception to this exists, however, for the usage of oral quinolones for osteomyelitis, especially that due to gram-negative pathogens. The clinical outcomes of patients with osteomyelitis treated with ciprofloxacin and ofloxacin were reported as similar to those of patients treated with intravenous antibiotics alone [30,31]. It should be noted, however, that the patient cohorts treated were relatively small. As a result of these and other studies, oral ciprofloxacin has been recommended for “step-down” therapy for adults with osteomyelitis after 10 to 14 days of intravenous antibiotics. Before changing to oral therapy, the necessary surgical management should be performed and clinical improvement should be evident. As for osteomyelitis in children, susceptibility of the pathogen to the quinolones must be demonstrated and compliance with therapy must be assured. We usually continue oral treatment for another 4 to 6 weeks after completion of intravenous antibiotics. No *in vitro* or clinical efficacy data exist for the use of the newer quinolones (i.e., levofloxacin, gatifloxacin, and moxifloxacin) in the treatment of osteomyelitis. Some recommend the addition of rifampin to a quinolone regimen to enhance the efficacy of both agents (synergy) and to reduce the development of drug-resistant bacteria. The combination of a quinolone and rifampin has proven useful in the treatment of prosthetic joint infections as outlined later in this chapter. Other antibiotics, such as clindamycin and trimethoprim-sulfamethoxazole, have been used successfully for the oral treatment of osteomyelitis. We recommend infectious disease consultation for osteomyelitis patients being considered for oral therapy.

3. Bactericidal agents are preferred.

4. *In vitro* susceptibility studies performed against the causative organism aid in the selection of appropriate therapy. **Careful susceptibility studies are essential in this disease because of the prolonged therapy required.** Antibiotic combinations, which may have additive toxicities, are best avoided unless clearly indicated based on susceptibility data. This again emphasizes the need to obtain the etiologic pathogen for susceptibility studies.

5. Use of serum bactericidal levels to monitor therapeutic efficacy is advocated by some experts. In this technique the patient’s serum is obtained immediately before and after antibiotic administration. Serial dilutions of the serum are then tested for bactericidal activity against the offending pathogen. It was initially anticipated that this test might predict therapeutic success or failure early in the course of treatment. The real value of the test is unknown, however, due to lack of a standardized protocol and absence of large clinical studies to support its use [29].

6. Prolonged therapy for acute hematogenous osteomyelitis is important. Antibiotics must be administered for a minimum of 4 to 6 weeks. Cure rates of greater than 90% are expected. Administration of oral antibiotics as follow-up therapy in patients receiving adequate courses of parenteral therapy does not improve outcome when given for acute osteomyelitis [1].

7. Evaluation of initial therapeutic response. Failure of the patient to show clinical improvement within 48 to 72 hours should prompt reevaluation. Diagnostic and therapeutic surgery may be necessary.

B. Initial therapy while awaiting cultures (Table 5.1)

1. Adults

Table 5.1. Empiric Initial Therapy of the Seriously Ill Patient with Acute Osteomyelitis

Patient Age	Likely Pathogens	Therapy ^a
Neonates and infants <2 mo old	<i>Staphylococcus aureus</i> , enteric gram- negative bacilli, group B streptococci	Penicillinase-resistant semisynthetic penicillin (PRSP) (e.g., oxacillin), ^{b,c} plus cefotaxime
Children		
Without hemoglobinopathy	<i>S. aureus</i>	PRSP or first-generation cephalosporin or clindamycin or vancomycin ^c
With hemoglobinopathy	<i>S. aureus</i> , <i>Salmonella</i> species	PRSP plus cefotaxime ^c
Adults	<i>S. aureus</i> and enteric gram-negative bacilli in high-risk patients ^d	PRSP. In high-risk patients, add third- generation cephalosporin or aminoglycoside ^{c,e}

^aDosages are discussed in Table 16.2 and in Chapters 3 and 28.

^bNafcillin should be avoided in the premature and in the very young infant, because the child's hepatic excretion may be deficient. If on Gram staining of a needle aspiration of the involved bone gram-negative organisms are seen, cefotaxime is initially suggested. See Chapter 3.

^cIn the patient with a history of delayed penicillin allergy, a first-generation cephalosporin is substituted for a PRSP. In a patient with immediate allergy to penicillin, vancomycin or clindamycin may be substituted. If MRSA is suspected, vancomycin is used.

^dHigh-risk patients include intravenous drug users, hemodialysis patients, diabetics, and patients with underlying debilitating diseases.

^eA third-generation cephalosporin (e.g., ceftriaxone) with PRSP (to ensure optimal *S. aureus* therapy) may be used in patients in whom an aminoglycoside is contraindicated or undesirable and in whom *Pseudomonas* species are not suspected. If MRSA is a concern, intravenous vancomycin can be used while awaiting susceptibility data.

- a. After cultures are obtained, antistaphylococcal therapy, usually with a penicillinase-resistant semisynthetic penicillin, is recommended for cases of uncomplicated hematogenous osteomyelitis. In patients with histories of delayed penicillin reactions, a first-generation cephalosporin may be used. In patients with histories of immediate penicillin reactions, clindamycin is recommended. If methicillin-resistant *S. aureus* (MRSA) is suspected, administration of vancomycin is appropriate while awaiting susceptibility data.
- b. **When gram-negative organisms are suspected** (see section II.D, above), an antistaphylococcal agent plus a third-generation cephalosporin or ciprofloxacin or an aminoglycoside may be used.
2. **Children.** In children less than 2 months of age a penicillinase-resistant penicillin plus cefotaxime is recommended for coverage of *S. aureus*, enteric gram-negative bacilli, and group B streptococci. An identical regimen is recommended in children with sickle cell disease to provide coverage for both *S. aureus* and *Salmonella* species. In children older than 2 months of age without associated hemoglobinopathy, empiric therapy is directed toward *S. aureus* with a penicillinase-resistant penicillin or first-generation cephalosporin or clindamycin or vancomycin as described in section 1.a. above.
- C. **Specific antibiotics and alternatives for commonly used agents are shown in Table 5.2.**
- D. **Surgery**
 1. **When treated with appropriate doses of antibiotics, most cases of hematogenous osteomyelitis are cured without surgery.** Outcomes are better if therapy is begun within 3 to 5 days after the onset of symptoms. It is nonetheless important for an orthopedic surgeon to follow these patients to help assess the future need for surgery.

Table 5.2. Therapy of Osteomyelitis Directed at Specific Pathogens

Pathogen	Antibiotic of Choice ^{a, b}	Alternative Antibiotics ^c
<i>Staphylococcus aureus</i> Methicillin-susceptible	Penicillinase-resistant semisynthetic penicillin (e.g., nafcillin or oxacillin) (adults: 9–12 g/d; children: 200 mg/kg/d)	First-generation cephalosporin (e.g., cefazolin) (adults: 4 g/d; children: 100 mg/kg/d) ^c or clindamycin (adults: 1.8–2.4 g/d; children: 20–40 mg/kg/d)
Methicillin-resistant	Vancomycin (adults: 2 g/d; children 40 mg/kg/d) ^d	
<i>Streptococcus pyogenes</i> (group A streptococci)	Aqueous penicillin G (adults: 12–18 million units/d; children: 200,000–3000,000 units/kg/d)	First-generation cephalosporin or clindamycin ^e
<i>S. agalactiae</i> (group B streptococci)	Aqueous penicillin G (as for group A streptococci)	First-generation cephalosporin ^e or vancomycin ^f
<i>Salmonella</i> species	Ceftriaxone or cefotaxime ^g	Ciprofloxacin ^h
<i>Pseudomonas aeruginosa</i>	Piperacillin or similar agent plus aminoglycoside ⁱ	Ciprofloxacin ^h
<i>Escherichia coli</i>	Ceftriaxone or cefotaxime	Ciprofloxacin ^h
<i>Klebsiella pneumoniae</i>	Ceftriaxone or cefotaxime	Ciprofloxacin ^h
<i>Bacteroides fragilis</i>	Metronidazole or clindamycin	Ampicillin-sulbactam, imipenem
Anaerobic and microaerophilic streptococci	Aqueous penicillin G (as for Streptococci)	First-generation cephalosporin

^aThe daily intravenous dosage recommendations listed are for adults and children older than 4 weeks with normal renal function. See Chapter 3 for dosage recommendations in neonates and infants younger than 4 weeks. See Chapter 27 for a further discussion of antibiotics.

^bHigh-dose intravenous therapy is recommended for acute osteomyelitis.

^cThe first-generation cephalosporins are more active against *S. aureus* than are the second- and third-generation cephalosporins.

^dDue to poor penetration of vancomycin into bone, some experts add oral rifampin in therapy of susceptible strains. (Adults, 600 mg/d; children, 20 mg/kg/d).

^eIn dosages shown for methicillin-susceptible *S. aureus*.

^fIn dosages shown for methicillin-resistant *S. aureus*.

^gFor dosages, infectious diseases consultation is suggested. See Chapter 27.

^hUse of ciprofloxacin may prevent extended hospitalization in puncture wound osteomyelitis in adults. Flouroquinolones should not be used in children, teenagers, or pregnant females. Infectious diseases consultation is advised. See Chapter 27.

ⁱAn aminoglycoside and a penicillin derivative active against *P. aeruginosa* are used together for synergy.

2. Indications for surgery include the following:

- a. **Diagnosis.** Diagnostic aspiration should be routinely performed in osteomyelitis unless blood cultures unequivocally provide the pathogen.
- b. **Hip joint involvement** (osteomyelitis of the femoral metaphysis). Drainage must be done early in these cases because of the likelihood of rupture of the cortex and spread of infection into the hip joint.
- c. **Neurologic complications** of vertebral or cranial osteomyelitis. See section II.D.3 under Special Forms of Osteomyelitis, below.
- d. **Poor or no response to therapy.** When patients fail to respond clinically after 48 to 72 hours of therapy, a drainage procedure may be necessary. Surgical drainage most often is needed in patients with disease caused by gram-negative enteric bacilli. A subperiosteal collection of pus that does not respond to therapy also requires drainage. Cultures should be obtained on all surgical specimens.
- e. **Sequestra.** These should be removed surgically.

E. Monitoring therapeutic response

1. **Signs and symptoms.** Successful therapy is indicated by resolution of fever, local tenderness, and erythema.
2. **ESR.** If the ESR was elevated initially, it should decline with appropriate therapy; however, it may not return to normal on completion of successful therapy.
3. **Elevated C-reactive protein.** Elevated levels of C-reactive protein should also fall toward the normal range with successful therapy.
4. **Radiography.** Radiographic improvement may lag behind clinical improvement. Serial roentgenograms must be interpreted cautiously. We usually repeat a roentgenogram 2 to 3 weeks into the course of therapy and at the end of therapy in uncomplicated cases. A radiograph obtained 2 to 3 months after completion of antibiotic therapy provides a useful baseline if disease recurs.
5. **Serial bone scans.** These should not be used to monitor response to therapy. Bone scans may remain positive months after clinical cure because healing bones absorb radiotracers.

VI. Prognosis. The prognosis for cure in patients with uncomplicated acute hematogenous osteomyelitis is good. Prognosis is, however, related to a variety of factors, including the causative organism, the duration of symptoms before therapy, patient age, and the duration of antibiotic treatment.

- A. **Adequate antibiotic therapy** is essential. There is a 10% to 20% recurrence rate in patients treated for acute hematogenous osteomyelitis [28]. Recurrences are more common in adult patients and also patients who have received less than optimal therapy.
- B. Patients with hematogenous osteomyelitis due to gram-negative organisms appear to have a higher rate of recurrence [32].
- C. **The best opportunity for cure is with initial therapy.** Of patients with recurrent disease, only 50% were cured after complete surgical debridement and 4 to 6 weeks of intravenous antibiotics [1]. **Acute osteomyelitis must be vigorously and adequately treated to prevent the development of chronic infection.**

CONTIGUOUS-FOCUS OSTEOMYELITIS

Contiguous-focus osteomyelitis due to spread from an adjacent focus of infection has some special characteristics that require emphasis.

I. Clinical setting

- A. **Postoperative infections** constitute many cases of contiguous-focus osteomyelitis.
 1. **Open reduction of closed fractures** is the most common predisposing surgical procedure.
 2. **Less common predisposing surgeries** include craniotomies, prosthetic hip and other reconstructive joint surgery, disk surgery, tumor resections, and sternotomy for open heart surgery. These infections can be complicated by the use of foreign materials, including metal, plastic, and bone cement, which serve as a nidus of infection that is resistant to antibiotic therapy.
- B. **Contamination of bone** occurring at the time of an open fracture is also common [4].
- C. **Contiguous soft tissue infections**, with spread to the bone, can involve any site.
 1. Osteomyelitis also may occur by spread from an infected tooth socket or sinuses, skin ulcerations, wounds, or decubitus ulcers and from infections introduced by foreign bodies (e.g., puncture wounds).
 2. Osteomyelitis frequently occurs in bone underlying pressure ulcers and is particularly difficult to diagnose. Bone biopsy may be useful [33].
- D. **Puncture wounds** uncommonly cause osteomyelitis, particularly of the small bones of the feet.

II. Microbiologic features. These infections **often are mixed**, because the adjacent wound infections are commonly due to mixed pathogens.

A. Staphylococci

1. ***S. aureus*** is the most common isolate. Approximately 50% to 60% of cases involve *S. aureus*, especially when disease involves the long bones, hip, and vertebrae. However, *S. aureus* may not be the only pathogen present.
 2. ***S. epidermidis*** must also be considered a pathogen, especially when associated with prosthetic joints. These infections frequently have an indolent course, manifested primarily as constant pain after implantation [34].
- B. Gram-negative bacteria** often are involved in mixed infections. *Pseudomonas* and other gram-negative bacteria are associated with the osteomyelitis secondary to puncture wounds [35]. *Pasteurella multocida* infection may occur after cat or dog bites [36].
- C. Anaerobic infections** have been underestimated because of poor culture techniques. Anaerobes may be involved in osteomyelitis of the long bones subsequent to trauma and fracture, osteomyelitis related to peripheral vascular disease, pelvic osteomyelitis due to spread from decubitus ulcers, or osteomyelitis of cranial and facial bones due to spread from a contiguous soft tissue source.
- D. Osteomyelitis after open fractures** may be due to unusual organisms. Contamination caused by soil may cause infection with *Nocardia*, *Clostridia*, or *Bacillus* species, whereas fresh water contamination predisposes to *Aeromonas* or *Plesiomonas* disease [4].
- III. Clinical manifestations.** Most patients follow an **indolent course** and are diagnosed within 1 to 2 months of the onset of disease. Delay in diagnosis often occurs in postoperative infections. This is related in part to the use of prophylactic or postoperative antibiotics, disease due to atypical organisms of low pathogenicity, and the presence of foreign material.
- A. Presenting symptoms** include fever, regional soft tissue swelling, erythema, and warmth. Purulent drainage from wounds and sinus tracts is common in both the acute and chronic forms.
- B. Site of involvement** may affect the presentation. Osteomyelitis of cranial bones often lacks signs or symptoms of disease, whereas infection of the long bones and pelvis often presents with fever and pain.
- IV. Diagnosis**
- A. Blood cultures** are infrequently positive. Nevertheless, two or three blood cultures should be obtained.
- B. Leukocyte counts** are commonly normal or minimally elevated.
- C. The ESR and C-reactive protein** levels may be elevated, but normal levels do not exclude the diagnosis.
- D. Radiographic evaluation.** In patients with osteomyelitis secondary to a contiguous focus of infection the diagnosis often is delayed, and roentgenographic changes are likely to be detectable at the time of presentation. Such findings may be difficult to interpret due to radiographic changes associated with the precipitating event (e.g., fracture, prosthetic devices, pressure-related change in bone in decubitus ulcers). Serial examinations by a radiologist usually are most helpful in these cases.
- E. Technetium radiophosphate bone scans** may be difficult or impossible to interpret in this setting because of adjacent inflammation and infection or postoperative changes [37]. Other techniques, such as MRI (if a metal prosthesis is not present), may be helpful [24].
- F. Cultures of wounds and draining sinuses are not as helpful as bone cultures.** In patients with draining sinuses or wounds, the interpretation of cultures is complicated because there may be multiple isolates or isolates of low pathogenicity or cultures may be sterile. Cultures of wounds and sinus tracts do not correlate well with those performed on underlying infected bone. A definitive bacteriologic diagnosis requires careful cultures of bone either by needle aspiration or by open biopsy. Needle biopsy for histopathologic and culture confirmation of osteomyelitis under pressure sores is preferred before instituting antibiotic therapy [33,38].
- G. Open biopsy** may be necessary in those patients who have had an unacceptable response to therapy or in whom needle aspiration is indicated but cannot be performed.
- V. Therapy.** Treatment of contiguous osteomyelitis is **less successful** than treatment of the acute hematogenous forms. Relapse may occur in 40% to 50% of cases [1,5–7,39]. **Surgery is an essential aspect of therapy in this disease.**

- A. Poor therapeutic response.** This is a result of a number of factors, including (a) the longer duration of infection before treatment; (b) the presence of foreign bodies after reconstructive orthopedic procedures; (c) the presence of devitalized bone in postfracture cases; (d) the increased frequency of mixed infections, which may not be adequately diagnosed or treated; and (e) malnutrition and chronic illness in patients with pressure ulcers.
- B. Antibiotic therapy**
1. **The basic principles** of antibiotic use (discussed under Hematogenous Osteomyelitis, above) are true also for contiguous-focus osteomyelitis. Because of the high frequency of mixed infections, **it is critical to obtain good specimens for culture** so that antibiotics can be directed against true pathogens rather than wound colonizers.
 2. Selection of **specific antibiotics** depends on the results of susceptibility studies. Common dosage schedules are shown in Table 5.2.
 3. The ideal **duration of therapy** for this form of osteomyelitis is unknown. Each case is affected by many variables, such as the site of involvement, the adequacy of surgical debridement, underlying chronic illness of the patient, and the presence of a foreign body and whether it can reasonably be removed.
 - a. **Prosthetic device-related infections are discussed later in this chapter.**
 - b. **Wound-associated infection (without prosthetic devices).** In general, we usually treat these patients with 4 to 6 weeks of parenteral antibiotics based on susceptibility studies of the causative organism. Because of the poor prognosis of this form of osteomyelitis, we frequently extend our therapy by changing to an oral agent. There is no proof, however, that longer courses of therapy improve outcome.

As discussed in the treatment of hematogenous osteomyelitis, “step-down” to an oral antibiotic (i.e., clindamycin or ciprofloxacin, with or without rifampin) is an option in selected patients. Infectious disease consultation is recommended in these difficult cases.
- C. Surgery.** Wounds or abscesses must be adequately debrided or drained. Sequestra must be removed, because they act as foreign bodies and decrease the likelihood of cure. Surgery usually is necessary early in these cases to obtain diagnostic material. Further debridement may be necessary if clinical response is slow. Whether prosthetic devices should be surgically removed is discussed later in this chapter.
- D. Monitoring response.** See section V.D. under Hematogenous Osteomyelitis, above.

OSTEOMYELITIS ASSOCIATED WITH PERIPHERAL VASCULAR DISEASE

Most patients with osteomyelitis associated with peripheral vascular disease are diabetic. Osteomyelitis does occur, however, in patients with severe atherosclerosis or vasculitis in the absence of diabetes. Most patients are older than 50 years, and the bones of the toes and feet are most often involved. **For a separate discussion of soft tissue infections without obvious osteomyelitis in the diabetic foot, see later in this chapter.**

- I. **Pathophysiology.** Neuropathy is present in most diabetic patients with foot disease predisposing to mechanical or thermal injuries. There is **tissue ischemia** such that ulcers occurring as a result of trauma heal poorly, become chronic, and frequently extend into bone. **Antibiotics penetrate poorly into these ischemic areas, frequently necessitating surgical debridement** [40].
- II. **Microbiologic features.** Most wound or sinus drainage cultures and most surgical bone specimens reveal a mixed flora of gram-positive organisms, gram-negative organisms, and anaerobes [41,42].
 - A. **Common mixed infections.** Staphylococci are most frequently isolated followed in frequency by streptococci and aerobic gram-negative bacilli. Polymicrobial disease is frequent.
 - B. **Anaerobes.** The role of anaerobes is debated. Presence of long-standing disease and tissue necrosis increases the likelihood of anaerobic disease [41,42].

III. Clinical manifestations.

Few patients have systemic symptoms, and sepsis is rare.

A. Local signs and symptoms predominate, including swelling and erythema. Pain may be absent in patients with advanced neuropathy. Osteomyelitis occurs from extension from cutaneous ulcers occurring over bony prominences. Osteomyelitis is more likely the more chronic, deeper, and wider the ulcer. Crepitus of the soft tissues may be present due to either aerobic or anaerobic infection. Foul odor may be due to the presence of anaerobes or necrotic tissue [40,42].

B. Long-standing diabetic complications are often the predominant findings. These include neuropathy, diminished or absent arterial pulses, skin and nail changes, retinopathy, and nephropathy. The presence of such complications may adversely affect disease outcome [40,42].

IV. Diagnosis

A. Blood cultures are seldom positive. Fever occurs most often in bacteremic patients.

B. Leukocyte counts are usually normal.

C. ESRs are usually markedly elevated. A normal ESR in a diabetic patient with a toe or foot ulcer does not, however, rule out osteomyelitis.

D. On radiographic evaluation, diagnosis of osteomyelitis is **often difficult**. Diabetics may have bony changes on routine roentgenography as a result of peripheral vascular disease and neuropathic osteoarthropathy [40]. These changes may be difficult to differentiate from true osteomyelitis. Consultation with an experienced radiologist is indicated.

E. Other imaging modalities

1. Technetium-99m bone scans have low specificity in the presence of underlying neuropathic osteoarthropathy.

2. Indium-111-labeled leukocyte scanning is more specific for infection but may be difficult to interpret if there is overlying soft tissue infection.

3. MRI is superior to CT and probably has superior specificity and sensitivity to the above [23,24].

F. Ulcers with bone exposed, detected either by visualization or by use of blunt probing, should be treated as if there were underlying osteomyelitis. The ability to see bone or reach it by probing has a high specificity and positive predictive value in diagnosing osteomyelitis, but the sensitivity and negative predictive value are low. If bone cannot be detected by probing and plain radiographs do not suggest osteomyelitis, treatment can be aimed at a soft tissue infection [43].

G. Bone biopsy remains the definitive modality for diagnosis of osteomyelitis. Percutaneous biopsy is performed using an approach avoiding infected tissue to prevent contamination of cultures or introduction of bacteria into uninfected bone. Specimens should be submitted for histopathology and aerobic and anaerobic cultures. Cultures of the overlying wound are less satisfactory in that results frequently differ from those taken from bone [33].

H. Doppler or angiographic studies are necessary to detect focal vascular lesions that, if corrected, could improve macrocirculation to the involved extremity. Improvement in blood supply to the lesion promotes healing and enhances delivery of antibiotics to the diseased tissue.

V. Therapy. Response to antibiotics alone often is unsatisfactory. Many patients are hospitalized on multiple occasions for treatment of recurrent disease. Initial therapy is usually conservative, with prevention of major amputations the primary goal. Prolonged courses of antibiotics may improve outcomes [42], but surgical debridement is usually necessary [44].

A. Conservative approach. To avoid more radical surgery, the following conservative measures are undertaken, although they are time-consuming and may be unsuccessful.

1. Limited local incision and drainage is done to remove necrotic debris.

2. The principles of antibiotic therapy are as outlined in section V.A. In one report high dose parenteral antibiotics for at least 4 weeks or a combined intravenous and oral regimen for at least 10 weeks was associated with a good outcome (defined as no ablative surgical procedure) in 29 of 51 patients. A poor outcome after limited surgical drainage and antibiotics was noted in patients with abscess, necrosis, or gangrene. Others advocate more aggressive surgery [42,44].

3. **Vascular surgery** may improve the macrocirculation to the involved extremity in patients with correctable focal arterial lesions.
 4. **Limited amputations** of digits or parts of digits may prevent more radical future amputations. Adjacent areas of cellulitis should be treated with antibiotics preoperatively [45].
- B. Ablative surgery.** Patients who have done poorly with the conservative approach or who have evidence of abscess or gangrene may need ablative surgical therapy. Before amputation, it is important to perform arteriography or Doppler studies to rule out a surgically correctable arterial lesion and to assess the probability of healing of the surgical wound.

SPECIAL FORMS OF OSTEOMYELITIS

- I. Chronic osteomyelitis** is defined as a **recurrent** problem: The patient has been previously treated for osteomyelitis at the same site [1]. Chronic osteomyelitis occurs most often after contiguous-focus osteomyelitis and peripheral vascular disease-associated osteomyelitis [46].
- A. Special considerations.** Chronic osteomyelitis carries a worse prognosis than acute osteomyelitis. Treatment failure rates in chronic osteomyelitis are higher than in the acute form, and the therapy is different.
- B. Clinical manifestations.** Patients only occasionally have acute symptoms. Systemic manifestations such as fever are uncommon. Localized signs and symptoms are also less common, with the exception of sinus tract or wound drainage, which is very common.
- C. Microbiologic features. *S. aureus* is a common pathogen.** Staphylococcal infections may recur years after the initial episode. Gram-negative bacteria may also be involved. Specific therapy should be guided by cultures obtained from biopsy.
- D. Diagnosis.** Determining the extent of disease activity and identifying a causative pathogen may be difficult.
1. **Blood cultures** are not often helpful, because bacteremia is rare.
 2. **White blood cell (WBC) counts** are normal in most patients.
 3. The **ESR** may be elevated, but this is a nonspecific finding.
 4. Radiographic evaluation is complicated by the presence of prior bony abnormalities. It may not be possible to detect new or progressive abnormalities unless older radiographs are available for comparison.
 5. **Technetium radiophosphate scans** are less helpful than in cases of acute osteomyelitis. Because scans may remain positive for years in the absence of active infection, a negative scan usually excludes active disease. **Indium-labeled leukocyte scans** have shown varying sensitivity in detecting active infection [37].
 6. **CT and MRI** are useful in defining sequestra, directing needle aspiration, and planning the operative approach in chronic osteomyelitis [24].
 7. When deciding whether to perform **wound or sinus cultures**, it is important to remember that organisms cultured from draining sinus tracts may not represent the true bacteriology of the underlying bone infection when compared with bone biopsy cultures [46]. **Definitive bacteriologic diagnosis requires culture of bone biopsy specimens.**
 8. **Needle aspiration and surgical biopsy** should be performed before any antibiotic is administered [46]. Aerobic, anaerobic, mycobacterial, and fungal cultures should be performed. Many chronic cases eventually require surgery. A diagnostic and therapeutic procedure is preferred before initiation of antibiotic therapy. Preoperative antibiotics may decrease the yield of cultures obtained at the time of surgery. Gram stains of the surgical specimens may help in the initial empiric choice of antibiotics.
- E. Therapy** is neither well established nor particularly effective. Evidence from controlled trials to guide therapeutic decisions is lacking. Goals of therapy should be thoughtfully considered and individualized. Cure of chronic osteomyelitis is hard to define because relapses are frequent and may occur months to years after the most aggressive therapy [4]. Attempts at “cure” may require extensive, sometimes

limb-threatening, surgery followed by prolonged courses of sometimes toxic and expensive antibiotics. Such treatment courses are unsuitable for some patients in whom chronic symptoms are tolerable. "Suppression" of symptoms with chronic, perhaps lifelong, antibiotic therapy or treatment of exacerbations of symptoms with antibiotics may be more reasonable courses of action. Infectious disease and orthopedic consultation is recommended.

1. Surgical intervention may be required to remove sequestra, to debride necrotic and devitalized material, and to obtain culture material. At times, extensive debridement is done with attempts at autogenous grafting with pulverized bone to fill in all defects [47]. Protocols using combined extensive debridement, antibiotic therapy, and vascularized muscle flaps to cover the wound have shown promising results [48].

2. Antibiotics are used, but the best regimen is debatable. In contrast to the basic principles that guide therapy in acute osteomyelitis (see section V.A under Hematogenous Osteomyelitis, above), the **optimal approach** to antibiotic therapy in chronic cases is **unknown**.

a. Parenteral agents are often used initially, but the duration of therapy is poorly defined.

b. Combination therapy with an antistaphylococcal penicillin and rifampin has been successful in some patients with chronic staphylococcal osteomyelitis [4].

c. The long-term (3–6 months) use of oral agents has reported to be successful in treating chronic osteomyelitis [49]. Although many patients had disease attributable to gram-positive cocci, the quinolone antibiotics may prove especially useful in treating chronic osteomyelitis caused by aerobic gram-negative bacilli, especially *P. aeruginosa*, which previously required parenteral antibiotics [50]. See Chapter 27 for a detailed discussion of these agents.

3. Hyperbaric oxygen is advocated by some clinicians in the treatment of chronic osteomyelitis. Large-scale clinical trials proving efficacy are lacking.

4. Consultation is advised in these difficult cases. Adequate surgical debridement is essential. A regimen of 3 to 6 weeks of parenteral antibiotics is often used initially, followed by prolonged oral or parenteral therapy.

F. Complications of long-standing chronic osteomyelitis

1. Secondary amyloidosis, although reported in some reviews, is very rare.

2. Carcinoma, primarily epidermoid carcinoma, occurs in the sinus tract of fewer than 1% of cases of chronic osteomyelitis. It is usually heralded by increased pain and drainage from the sinus tract. If cancer is suspected, the entire sinus tract is resected because the carcinoma may lie deep within the tract.

II. Vertebral osteomyelitis occurs more frequently in older patients and may result from either hematogenous seeding of the bone or as the result of a postoperative wound infection and contiguous spread. Risk factors include diabetes, immunodeficiency, and intravenous drug abuse. Although uncommon, the incidence of this disease is increasing; it accounts for about 2% to 4% of all cases of pyogenic osteomyelitis [51–53].

A. Special considerations. Intravertebral disk space infections (discitis) refers to an inflammatory and/or infectious process of the vertebral disk. Discitis may result from hematogenous seeding of the disk [54]. Discitis in adults has also been reported postoperatively after spine surgery [55], after discography [56], and in intravenous drug users [57]. In adults pyogenic bacteria are cultured in most cases, and early involvement of contiguous vertebral bodies is documented radiographically. As such, it is our opinion that discitis in adults clinically behaves like pyogenic vertebral osteomyelitis and should be approached as such. In contrast, discitis in children represents a unique clinical syndrome and is discussed later in this chapter [58] (see section III).

B. Pathogenesis and clinical setting

1. Spontaneous cases of vertebral osteomyelitis occur most often from hematogenous seeding. In addition to arterial spread of infection, retrograde spread of infection is purported to occur from a urinary tract or pelvic source via Batson plexus, a venous plexus that forms a direct connection between the vasculature of the pelvis and the spinal column. The extensive anastomoses and lack of valves in the veins of Batson plexus are believed to facilitate spread of infection to adjacent vertebrae,

particularly after urinary tract infection or genitourinary manipulation in the elderly.

2. Other cases occur by spread from the contiguous focus of infection, especially after disk surgery. Contiguous focus vertebral osteomyelitis is being increasingly reported.
 3. **The incidence of vertebral osteomyelitis is highest in adults 50 years of age and older.** This increased incidence is considered to be a result of subchondral vascular changes in vertebrae from the axial stress and osteoarthritis that accompany aging.
 4. When associated with intravenous drug use, vertebral osteomyelitis occurs in younger adults, with peak incidence between 20 and 50 years of age. The duration of symptoms is shorter, usually less than 3 months [57]. Pyogenic **vertebral osteomyelitis in children is uncommon** and has been reviewed elsewhere [58].
 5. The lumbar vertebrae are most commonly involved, followed by thoracic and then cervical vertebrae. In drug addicts, there is a high incidence of cervical spinal involvement [51–53].
 6. Nosocomial infection, usually due to intravenous cannula-related sepsis with staphylococci, has become an increasingly important problem [51].
- C. Microbiologic features.** *S. aureus* is the most common pathogen. *Salmonella* and gram-negative organisms associated with prior urinary tract infection or genitourinary manipulations also are common. *Pseudomonas* species are common in drug addicts. Tuberculosis can mimic bacterial infections (this is discussed further in section IV). MRSA has been reported, usually with nosocomial infections associated with catheter- or wound-related sepsis [59].
- D. Clinical manifestations.** There is commonly an inordinate delay between symptom onset and diagnosis.
1. **Back pain**, described as dull and continuous, is the most common symptom. In a recent series, 85% of patients presented with back pain [59]. It is present at rest and exacerbated by movement or straining but only slightly relieved by analgesics. Regional paraspinal muscle spasm, percussion tenderness of the spinal column, and point tenderness of the involved spinous processes frequently are present.
 2. **Referred pain** due to nerve root irritation may mislead the examiner and direct attention from vertebral involvement. Lumbar disease, for example, can present as pain in the hip or leg.
 3. **Neurologic complications** can occur. Because of the indolent nature of the illness, patients may present with late neurologic sequelae such as paraplegia and meningitis [51–53]. Limb weakness was noted in about one-half of patients in one series [59].
 4. **Fever** is often absent and was reported in only 30% of patients in a recent series and has overall been noted in 20% to 50% of patients [59].
- E. Diagnosis**
1. **Blood cultures** should be obtained but often are negative. Blood cultures have been reported positive in 24% to 50% of patients and when positive for a pathogen are assumed to be the etiologic agent [59].
 2. The **WBC** count is elevated in most patients [59].
 3. The **ESR** is usually elevated (80–90 mm/h) and is considered a useful test supporting the diagnosis of vertebral osteomyelitis. A normal ESR makes the diagnosis of vertebral osteomyelitis open to question. C-reactive protein levels are also usually elevated [52].
 4. **Radiographic evaluation** (i.e., spinal films) is essential. Intervertebral disk involvement favors the diagnosis of pyogenic infection or tuberculosis. Findings are often nonspecific [59].
 5. **Bone scans** are helpful but have the limitations previously discussed.
 6. **MRIs** are highly sensitive and specific in the diagnosis of spinal infection and **provide more accurate anatomic information than bone scans. They have largely supplanted CTs** in the evaluation of vertebral osteomyelitis [52].
 7. **Needle biopsy or open biopsy** is essential to substantiate the diagnosis and provide culture material [52,59] if blood cultures are negative. Unfortunately,

bone biopsy cultures may be negative in up to 25% of cases. When this occurs, histologic examination of the biopsy may confirm inflammatory changes compatible with osteomyelitis. A second needle biopsy is suggested if the first sample is culture negative. If the second needle biopsy is culture negative, an open surgical biopsy should be considered [52].

F. Therapy

1. Antibiotics

- a. The principles of **antibiotic therapy** are as outlined in section V under Hematogenous Osteomyelitis, above.
- b. When infection is due to MRSA, combination therapy with rifampin and intravenous vancomycin is indicated. This recommendation is based on studies of animal models that have shown the combination of vancomycin plus rifampin is superior to vancomycin alone for bone sterilization [59].
- c. **Duration.** Antibiotics usually are given for at least 4 weeks and often for 6 weeks [52]. Often, prolonged intravenous antibiotics are given at home (see Chapter 27). If the patient is very compliant and reliable and susceptibility data allow for an oral agent (e.g., oral quinolones for susceptible gram-negative bacteria), a combination of initial intravenous antibiotics followed by oral antibiotics is used.

The contribution of oral antibiotics after the initial 4 to 6 weeks of therapy is controversial. Some reviewers recommend them for 3 months after 1 month of intravenous therapy; other investigators believe that if parenteral therapy is given for 6 weeks, subsequent oral therapy is not required [59].

- d. Because of the importance of eradicating this infection with the initial regimen and lack of clear-cut guidelines, infectious disease consultation is advised to help select intravenous and oral antibiotic regimens for these difficult problems.
 - e. The ESR and C-reactive protein are good tools to monitor the success of therapy; with proper antibiotic therapy, they should be expected to fall toward the normal range [52].
2. The role of **surgery** is debated. Definite indications include (a) neurologic complications such as cord compression, (b) drainage of paravertebral abscess, (c) failure to make a bacteriologic diagnosis after repeated needle biopsies, (d) poor clinical response, and (e) the presence of gross bone destruction, leading to significant deformity or instability [52].
 3. **Adjunctive therapy** includes bed rest and a half-shell cast or body brace if the spine is unstable.

G. Prognosis. When early diagnosis is combined with adequate antibiotic therapy, prognosis is generally good. Reviews cite a mortality of less than 5% to 7%, with residual neurologic deficits occurring in 7% to 12%. Between 80% and 90% of patients recovered uneventfully with appropriate antibiotic therapy alone or with antibiotics combined with surgery [52,53]. If, while on antibiotic therapy for vertebral osteomyelitis, the patient develops symptoms of a compressive neuropathy, MRI can be performed to determine whether there is a collection of pus that may require neurosurgical drainage.

Relapses can occur. In one series, 15% of patients (three patients) had relapses, and in two of the three patients the infecting organism was MRSA [59].

III. Intervertebral disk space infection (discitis) is most frequently reported in children less than 5 years of age. It occurs almost exclusively in the lumbar region and presents with a painful gait and refusal to walk. The pathophysiology and pathogenesis of discitis in children remains poorly understood and is controversial [58].

A. Pathogenesis. Substantial controversy exists in the pediatric literature concerning the role of inflammation versus infection in the pathogenesis of discitis [59–61]. Some studies report positive blood or disk biopsy cultures (usually *S. aureus*) in more than half of the patients sampled. Other studies, however, have found few positive cultures and have reported resolution of illness without antimicrobial therapy. A number of cases have been reported temporally associated with a viral illness in which no bacterial etiology can be documented. Finally, antecedent trauma has been described in up to one-third of cases, but its role in causation of discitis is uncertain. Discitis in

children is probably due to a variety of causes, including trauma, viral disease, and bacteria. **However, we believe that the prevailing clinical evidence supports a low grade bacterial infection** as the cause of most cases of discitis and that the failure to obtain positive cultures may be due to sterilization of the area by host defenses between the onset of symptoms and biopsy.

- B. Presentation.** Fever and other systemic signs of infection are absent in more than 50% of the patients. When present fever can vary from low grade to high spiking temperatures. In most children the **onset** of discitis is **gradual and subtle**. The presenting symptom is most commonly **back pain**, occasionally with associated difficulties in ambulation. In the very young irritability or refusal to ambulate may be as specific a presentation as can be expected. Children may complain of pain referred to the hip or leg or may show signs suggesting meningeal irritation or an abdominal pathology severe enough to prompt laparotomy.
- C. Diagnosis.** There are two useful investigations in suggesting the likelihood of intervertebral disk space infection: the ESR and roentgenographic examination. Needle aspiration can establish the diagnosis.
- 1. ESR and complete blood count**
 - a. Elevation of the ESR occurs in 90% to 100% of cases** in both children and adults and is commonly the earliest, and sometimes the only, laboratory abnormality seen. **Any postdiscectomy patient with increasing back pain and an ESR greater than 50 at 2 or more weeks after surgery should be considered to have discitis until proven otherwise.** The ESR may be used as an indicator of therapeutic response but occasionally remains elevated for months.
 - b.** The total leukocyte and differential blood cell counts are normal in 50% or more of patients. Marked elevations suggest extension of infection to structures contiguous to the disk space.
 - 2. Roentgenography.** The **hallmark** of intervertebral disk space infection is the roentgenographic finding of **disk space narrowing**. This change may not be present until 2 to 3 weeks after onset of infection [60]. If roentgenograms are negative, either the examination should be repeated after an additional 2 to 3 weeks or a radionuclide scan should be performed. Displacement of vertebrae may occur, and oblique views as well as routine views of the spine should be obtained. Erosion of the vertebral endplates usually follows the narrowing, occurring by 3 to 5 weeks after onset.
 - 3. Scans**
 - a.** ^{99m}Tc bone scans are useful in establishing an early and accurate diagnosis; such scans are positive in many cases within 7 days of onset and in nearly all cases after 2 weeks of back pain. But **^{67}Ga bone scanning has also proven beneficial** [62].
 - b.** There are conflicting reports as to the usefulness of **CT** in making an early diagnosis of discitis [63,64]. Disk space narrowing and adjacent bone involvement may be detected before changes on plain roentgenograms. CT offers greater accuracy than radionuclide scanning in depicting adjacent soft-tissue pathologic processes.
 - c.** Discitis also gives rise to characteristic changes on **MRI**, with an accuracy of diagnosis similar to radionuclide scans. MRI also provides anatomic information about the adjacent thecal sac and spinal cord not shown by radionuclide scans. A recent prospective blinded study using gadolinium-enhanced MRI found that changes in signal intensity in the intervertebral disk space and adjacent marrow are uncommon after routine discectomy. In seven biopsy and culture-proven discitis patients, gadolinium enhancement of the adjacent vertebral bone marrow, disk space, and posterior annulus fibrosus was identified. None of 15 asymptomatic postdiscectomy patients exhibited these changes [64]. **MRI may also be superior to CT** in providing finer resolution of the interface between the disk and adjacent bone.
 - 4. Blood cultures** should be routinely obtained. They are more likely to be positive if the patient is seen early in the course. If they are positive, especially in a child with *S. aureus* infection, a diagnostic needle aspiration may be avoided.

5. **Needle aspiration** of the disk space is the preferred way to obtain material for culture (aerobic, anaerobic, and mycobacterial), **particularly in postoperative discitis**. In some studies, this procedure has provided an etiologic agent for as many as 85% of cases in which it was performed. Aspirations should be performed before antibiotic therapy is started. However, it has now become common practice to treat children with uncomplicated discitis without first performing a culture [61]. A skin test for tuberculosis is recommended.

D. Microbiologic features. In those cases in which a bacterial etiology is established, more than 90% are due to *S. aureus*. Streptococci are implicated occasionally.

E. Differential diagnosis includes acute pyogenic osteomyelitis, trauma, tuberculous vertebral osteomyelitis, paraspinal abscess, and spinal cord tumor.

F. Therapy

1. Although discitis in children is presumed to be of bacterial etiology in most cases, outcome has generally been reported to be the same whether or not the patient receives antibiotics [58,60,65]. **Because no controlled prospective studies have been done, recommendations for treatment remain controversial.**

a. Many authorities now recommend **a trial of immobilization of the spine**, generally with a body cast, as the key to providing relief of pain [58,61]. The duration of immobilization is guided primarily by improvement of the pain and secondarily, by favorable changes in the ESR and roentgenograms, but is generally in the range of 4 weeks.

b. A reasonable recommendation is that **a child who fails to respond to immobilization should receive intravenous antibiotic therapy**, usually with a first-generation cephalosporin or semisynthetic penicillinase-resistant penicillin for 5 to 7 days, followed by 7 to 14 days of a similar oral antistaphylococcal antibiotic [61]. Generally, 3 to 4 weeks of antibiotic therapy have been successful.

G. Prognosis. The clinical data indicate that discitis in children is generally short-lived and carries a good prognosis [65].

IV. Infection associated with prosthetic devices occurs in 1% to 5% of cases [66]. These infections are particularly difficult to manage, but prosthesis removal is not necessary in all cases. Some infections respond to antibiotic management alone.

A. Special considerations. Prosthetic devices act as foreign bodies. The question routinely arises as to whether the prosthesis must be removed or whether prolonged antibiotic therapy alone will be adequate.

B. The approach to these infections is discussed later in this chapter under Prosthetic Joint Infections.

C. Intramedullary fixation nails. These nails represent a unique situation, because their premature removal, even when they are infected, will often result in an unstable fracture, nonunion, and persistent infection. The device must usually be left in place and the infection treated with parenteral antibiotics and careful local surgery for debridement and drainage. The nail is removed when union is achieved [67].

V. Tuberculous osteomyelitis should be suspected in any case of vertebral osteomyelitis or osteomyelitis at any site that has not responded to antibiotic therapy. In the United States one-fifth of tuberculosis cases occur at extrapulmonary sites. One-third of human immunodeficiency virus (HIV)-infected individuals with tuberculosis have extrapulmonary disease with or without pulmonary involvement [68].

A. Pathogenesis. Bone involvement results primarily from hematogenous spread, most commonly from the lung. Extension from a caseating lymph node or lymphatic drainage also may occur. There is a predilection for the coexistence of renal and skeletal tuberculosis. In almost all cases, the organism is *Mycobacterium tuberculosis*, although rare cases of atypical mycobacteria have been reported [69].

B. Clinical manifestations. Tuberculous osteomyelitis is seen primarily in adults. Skeletal tuberculosis, like pulmonary tuberculosis, is less common in children.

1. **Signs and symptoms.** These cases usually have a long indolent course.

a. **Asymptomatic** bone lesions may be discovered on roentgenograms taken for other reasons. As with pyogenic organisms, patients with tuberculosis of the

spine may have a paucity of symptoms and may not present until development of paravertebral abscess or neurologic complications including paraplegia and meningitis (see section II).

- b. **Fever** may or may not be present. Tuberculous osteomyelitis should always be considered, however, in the patient with fever of unknown origin and an asymptomatic bone lesion.
 - c. **Pain** is the most common complaint and may be accompanied by local swelling and tenderness.
 - d. **Chronic draining sinuses** may be present.
2. **Bones involved.** Although any bone may be involved, 50% of cases involve the spine (50% thoracic, 25% cervical, 25% lumbar); 12% pelvis; 10% hip and femur; 10% knee and tibia; 7% ribs; 2% ankle, shoulder, elbow, or wrist; and 3% at multiple sites [68].
- C. **Diagnosis.** In addition to the usual methods of diagnosing bacterial osteomyelitis, the following diagnostic tests are important in patients with suspected tuberculous bone disease.
1. **Chest roentgenography** is necessary to look for evidence of pulmonary tuberculosis. Because only approximately 50% of patients with skeletal tuberculosis have roentgenographic evidence of pulmonary tuberculosis, a negative chest radiograph cannot disprove the diagnosis [70]. Sputum cultures (or gastric cultures if sputum is not available) are necessary if active pulmonary infection is suspected.
 2. A **tuberculin skin test** is part of the workup of any destructive bone or joint lesion, especially when it is monoarthritic or involves the spine. A negative skin test must never be used to rule out disease (see Chapter 11).
 3. **Needle or open biopsy** is important. In chronic infections in which tuberculosis is suspected and in all cases of vertebral osteomyelitis of unknown etiology, **tissue for histopathologic analysis and culture is crucial.** Special stains and cultures for bacteria, mycobacteria, and fungi should be performed.
- D. **Treatment**
1. See Chapter 11. Therapy is similar to that given for pulmonary disease, that is, a four-drug regimen of isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months followed by two drugs, rifampin and isoniazid, for an additional 4 months. Infectious diseases consultation is advised [71].
 2. **Surgery**
 - a. **Nonvertebral disease.** Except in far advanced disease, surgery is seldom necessary. Surgery is indicated to prevent deformity, to improve joint function, and to control disease that has not responded to chemotherapy. Surgery usually is delayed until after 2 to 3 months of chemotherapy [68].
 - b. **Vertebral disease.** In the past, spinal tuberculosis (Pott disease) commonly required surgical fusion. More recent studies show successful treatment in uncomplicated cases by chemotherapy alone. Spinal fusion usually occurs spontaneously with the healing process. Indications for surgery include marked neurologic deficit, drainage of large abscesses, worsening neurologic deficit despite adequate chemotherapy, and progression of kyphosis or instability despite adequate chemotherapy [71,72].
- E. **Prognosis.** With appropriate chemotherapy, the prognosis with skeletal tuberculosis is good.
1. **Nonvertebral disease.** Coexistent joint involvement is frequent. Residual sequelae are often the result of deformity and functional impairment of the involved joint. Most patients, however, do recover normal function after chemotherapy alone [68].
 2. **Vertebral disease.** Central nervous system involvement, including meningitis or paraplegia, is the most serious complication of tuberculous infection of the spine. Spinal deformities, kyphosis, and scoliosis also occur as a result of destruction of vertebrae. In children, these deformities may be progressive [71,72].
- VI. **Fungal osteomyelitis.** Osteomyelitis can result from invasive infections due to a number of fungal pathogens, including *Candida* species, *Aspergillus* species, *Sporothrix schenckii*, *Coccidioides immitis*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*,

Cryptococcus neoformans, and a variety of less commonly encountered pathogens. Fungal osteomyelitis should be considered in any indolent osteomyelitis that has not responded to routine measures or in any patient with evidence of disseminated fungal disease. Therapy is generally complex and prolonged. Adequate discussion of the subject is beyond the scope of this chapter. We refer the reader to a recent review of the subject [73] (see also Chapter 17).

DIABETIC FOOT INFECTIONS

Foot infections are a common cause of morbidity and mortality in patients with diabetes. Twenty-five percent of all diabetics develop severe foot or leg problems. Foot infections account for fully 20% of diabetic hospitalizations. At least 50% of all nontraumatic lower extremity amputations occurring in the United States are performed on diabetics [74].

I. Pathophysiology

A. Peripheral neuropathy. Peripheral neuropathy is likely the most important risk factor for development of foot lesions in diabetic patients. Neuropathy is present in over 80% of diabetics with foot lesions [75].

1. Loss of protective pain sensation due to peripheral neuropathy leads to loss of awareness of traumatic injury and subsequent breaks in the skin and skin ulceration [74]. The initial lesion occurs at weight-bearing points, frequently under the first or fifth metatarsal heads or on the heel. These painless ulcers may go unnoticed and unattended for days to weeks. Bacteria may then invade the base of these neglected ulcers and either spread along fascial planes or penetrate fascia and soft tissue to reach the periosteum.
2. Motor nerve involvement leads to weakness in muscles of the foot, causing a cavus deformity and clawing of the toes. This leads to maldistribution of weight while walking, predisposing to traumatic injury, skin ulceration, and infection.
3. Autonomic neuropathy causes interference with sweating, resulting in dry cracked skin that may allow invasion of microorganisms [75].

B. Ischemia. Arteriosclerosis occurs at a rate 20 times higher in type 2 diabetics than in nondiabetic control subjects matched for sex and age. Peripheral vascular disease is common in patients with diabetes, producing ischemia that contributes to the development of as many as one-third of foot ulcers [75]. Lack of adequate blood supply impedes delivery of antibiotics to infected tissue and impairs tissue healing.

C. Other factors. Other factors leading to ulceration and infection include pressure due to faulty fitting shoes [76], superficial fungal infections, improper trimming of toenails, overgrown nails, or thermal injury due to lack of awareness of heat [75].

II. Microbiologic features. The organisms isolated are related in part to the severity of underlying disease, which has been divided into mild non-limb-threatening infections and more severe limb-threatening infections [44,77] (see discussion in section III). Patients in both groups frequently receive multiple courses of different antibiotics. Recent receipt of antibiotics increases the likelihood of recovery of atypical or drug-resistant organisms, particularly MRSA [78] but also enterococcus and *Pseudomonas aeruginosa* [79]. Recent hospitalization also predisposes to presence of these pathogens [80]. Severity and chronicity of disease, culture technique, and laboratory capabilities also affect culture results.

A. Mild non-limb-threatening infections are caused primarily by *S. aureus* (more than 50% of patients) and aerobic streptococci. Facultative gram-negative bacilli and anaerobic organisms are less frequent. **In half** of these patients, the infections are **monomicrobial** [44].

B. Severe limb-threatening infections usually are polymicrobial. Deep tissue cultures that avoid surface contamination usually yield a mixed culture of aerobes and anaerobes.

1. Aerobes

- a. ***S. aureus* and coagulase-negative staphylococci** are the most common aerobic isolates [80,81]. Staphylococci are found in approximately two-thirds of patients in whom only a single organism is isolated [41].
- b. Approximately 20% of isolates are **streptococci** (including group B) and **enterococci** [41,81]. The pathogenic role of coagulase-negative staphylococci,

enterococci, and corynebacteria often is difficult to discern, particularly when these organisms are cultured along with more typical pathogens. These organisms can be viewed as skin contaminants and not pathogens (unless they are isolated in pure culture or the patient is not responding to therapy that is not aimed at these organisms) [44]. Prior administration of antibiotics or prior hospitalization complicates interpretation of cultures yielding these organisms, as noted above.

- c. **Enterobacteriaceae** account for 24% to 27% of organisms isolated. Common isolates include *Proteus*, *Klebsiella*, and *Enterobacter* species *Morganella morganii*, and *E. coli* [41,81]. *Pseudomonas* and *Acinetobacter* species are common contaminants in specimens from ulcers or open draining lesions but are infrequently isolated from deep tissue cultures [41].
2. **Anaerobes** are isolated from 40% to 80% of patients with severe or advanced disease. They usually are present in cultures yielding multiple organisms [41,81,82].
 - a. The presence of anaerobes is associated with a higher frequency of fever and foul-smelling lesions [81].
 - b. Common anaerobic isolates include anaerobic streptococci (14% to 17%), *Bacteroides* species (9%–14%), and *Clostridium* species (2%–7%). *Bacteroides* species are more frequently found in necrotizing infections and osteomyelitis than in abscesses [41]. Although rare, infection due to *Clostridium* species may be rapidly progressive. Lack of an inflammatory response on Gram stain in the presence of gram-positive organisms should raise suspicion that *Clostridium* is present.

III. Clinical manifestations. Meaningful comparison of the many different studies on diabetic foot infections is hindered by the lack of a uniform grading system accounting for neuropathy, ischemia, and wound depth, all thought to be major predictors of poor outcome. Both the Wagner and the University of Texas wound classification systems hold promise in this regard [83].

A. Non-limb-threatening versus limb-threatening infections. Reviewers have suggested a practical clinical classification of infections [44] that appears to be a useful approach.

1. **Non-limb-threatening infections.** Patients have superficial infection and minimal cellulitis (<2 cm of extension from portal of entry) and lack systemic toxicity. If an ulcer is present, it does not penetrate fully through the skin. These patients do not have bone or joint involvement or significant underlying ischemia.
2. **Limb-threatening infections.** Patients have more extensive cellulitis (>2 cm of extension from the portal of entry) and lymphangitis. Full-thickness ulcers often are present. Infection of contiguous bones or joints occurs frequently.

Significant ischemia with or without gangrene may be present. Fever is seen in only some patients and is more common in those with extensive soft tissue involvement, deep plantar abscesses, bacteremia, or hematogenously seeded remote sites of infection.

B. Local signs and symptoms predominate and include those related to infection, vasculopathy, and neuropathy.

1. **Infection.** The anatomic location of the infection affects prognosis. Proximal infections (along metatarsals, at the heel, or above the ankle) are associated with lower limb salvage and higher mortality [84].
 - a. Most cases of lower extremity infection in diabetics begin as chronic perforating ulcers.
 - b. Infection is heralded by warmth, redness, swelling, and purulent exudate. **Tenderness is often minimal or absent due to neuropathy** [42,85].
 - c. Gas in the soft tissues may be visualized by roentgenography or detected as crepitus on physical examination. Gas usually is from mixed infection with gram-negative bacilli and anaerobes rather than *Clostridium* species infection. A foul odor may be present due to necrosis or anaerobic infection [81]. Gangrene due to infection or ischemia may be seen.
 - d. It is important to determine the extent of deep tissue destruction and possible bone and joint involvement by unroofing all encrusted areas and inspecting

the wound carefully [86]. **Surgical consultation should be obtained routinely. Osteomyelitis underlying diabetic ulcers is common.** Incidence of clinically silent osteomyelitis is as high as 68% when sought with bone biopsy and cultures [87].

2. **Vascular disease.** Patients may complain of intermittent claudication or resting pain relieved by dependency. Pulses may be decreased or absent. Bruits, shiny cold skin, decreased hair and nail growth, atrophy of subcutaneous fat, and a rapid decrease of Doppler pressures may also be present. Other findings include delayed capillary filling time, ischemic rubor, and collapsed veins [75].
3. **Neuropathy.** This is most prominent in the lower extremities. Commonly, the forefoot may have significant neuropathy, whereas the hindfoot and lower leg have relatively normal sensation. A simple method of identifying patients who have lost protective sensation is to press a nylon monofilament against the skin of the foot; the inability of the patient to feel the force of the monofilament correlates with an increased risk of neuropathic foot injury [88].

C. Systemic signs and symptoms often occur late and indicate severe infection.

1. Uncontrolled hyperglycemia may indicate uncontrolled infection [86].
2. Fever occurs with undrained pus, when a virulent organism is involved, or when bacteremia is present. Otherwise, fever is relatively uncommon. Even in patients with limb-threatening sepsis, only 36% had fever exceeding 100°F (37.8°C) during the first day of admission [82], except in bacteremia and in cases in which anaerobes were recovered from deep cultures [44,81] (see section A.2).

IV. Diagnosis

- A. **Leukocytosis** may be minimal or absent even with severe infection. Even with limb-threatening sepsis, leukocytosis (WBC count > 10,000/mm³) was noted in only 53% of patients at admission [82].
- B. The **ESR** is usually elevated.
- C. **Blood cultures** are positive in approximately 10% to 15% of patients but should be obtained in all patients. The highest rates of positive cultures are seen in febrile patients [39].
- D. The **best method for obtaining wound or tissue cultures** from diabetic foot infections **is still debated** [89]. These wounds are chronic and are often colonized superficially with organisms that are not causative (e.g., staphylococci or enterococci).

Several methods are used. Aerobic and anaerobic cultures should be performed before antibiotics are started.

1. **With debridement.** When debridement is performed, cultures of deep tissue or necrotic tissue, including bone, can be obtained. Routine aspirate or biopsy of unexposed bone is not advised.
2. **Direct ulcer culture.** The open ulcer can be cleaned carefully (usually with Betadine, which is allowed to dry and then removed with alcohol sponges) and any overlying eschar debrided; a swab can then be inserted through the opening of the ulcer deeply into the wound to obtain a deep culture. The swab can then be plunged into anaerobic transport media and brought quickly to the laboratory for processing.
3. Bullae or fluctuant collections should be aspirated and cultured [44].
- E. **Gram stains** usually reveal mixed flora and may not be especially helpful; however, the lack of an inflammatory response and the presence of gram-positive rods may indicate a clostridial infection, which may be rapidly progressive [84].
- F. **Radiographs**
 1. Radiolucent areas within the soft tissues may occur due to dissection of air into open ulcers or as a result of debridement. **Presence of air** in the soft tissue also occurs as a result of gas-forming bacterial infection [90]. Gas formation is usually due to other anaerobes, coliforms, streptococci, and, rarely, *Clostridia* species. Because air in the soft tissues can occur secondary to a number of benign causes, its presence alone should not be used as justification for amputation. The differentiation of osteomyelitis from diabetic osteopathy may be difficult [90]. Sequential radiographs may help. Radiographs may be normal in early osteomyelitis [40,42].

(See section IV.D under Osteomyelitis Associated with Peripheral Vascular Disease, above.)

- G. Indium-labeled leukocyte scans are the most sensitive method to detect occult osteomyelitis.** In one study, these scans proved more sensitive than either roentgenograms or bone scans [87] (see Section IV.E under Osteomyelitis Associated with Peripheral Vascular Disease, above).
 - H. MRI** is also highly accurate in the diagnosis of occult osteomyelitis and is used to detect soft tissue abscess [24].
 - I. Probing the base of the ulcer** to detect bone is a useful technique to identify osteomyelitis, as discussed in section IV.G under Osteomyelitis Associated with Peripheral Vascular Disease, above. Because necrotic debris frequently masks the ulcer floor, this technique may be the only way to accurately assess ulcer depth and to identify involvement with contiguous bone [43].
- V. Therapy.** Early surgical and infectious disease consultation is recommended.

A. Medical therapy

- 1. Antibiotics** are the mainstay of treatment and are recommended in the presence of an ulcer with surrounding cellulitis, a foul-smelling lesion, fever, or deep tissue infection.

- a. Empiric antibiotic therapy is necessary until culture results are available.** Few well-controlled comparative trials exist on which to base recommendations for therapy [91]. Recommendations for empiric therapy are increasingly problematic in an era of increasing incidence of antimicrobial resistance. Risk of infection with drug-resistant pathogens is increased with recent prior use of antibiotics and recent hospitalization, as previously noted. Antibiotics are given in full dose due to the potential for poor penetration into diseased tissue. Nephrotoxic antibiotics should be avoided. Possible antibiotic options are summarized in Table 5.3.

- (1) For non-limb-threatening infection,** therapy is directed at staphylococci and streptococci. Outpatient regimens using 2 weeks of oral cephalixin or clindamycin are generally effective. In some patients who have cellulitis surrounding the superficial ulcer, hospitalization for a short course of intravenous antibiotics is warranted. Although the optimal therapy is unknown, empiric monotherapy with ceftazidime, cefoxitin, cefotetan, ceftizoxime, clindamycin, ticarcillin-clavulanic acid, ampicillin-sulbactam, or piperacillin-tazobactam are appropriate [41,42,74,81]. Therapy is modified based on results of deep tissue cultures. Patients may be stepped down to oral therapy when clinical improvement is evident.
- (2) For more severe limb-threatening infections,** broad-spectrum antibiotics are used to treat anticipated polymicrobial infection. Options include piperacillin-tazobactam, combination of ceftriaxone and clindamycin (or metronidazole), combination of ciprofloxacin and clindamycin (or metronidazole), imipenem-cilastatin, or ampicillin-sulbactam [80]. Therapy, again, must be modified based on results of deep tissue culture.
- (3) For life-threatening infections,** imipenem-cilastatin or combination regimens are recommended. Some experts include coverage against enterococci in this setting. Short courses of aminoglycosides in combination with other broad-spectrum agents may be used in the setting of gram-negative sepsis. Short-term use minimizes risk of aminoglycoside nephrotoxicity [82]. Vancomycin is included if MRSA is a concern because of recent hospitalization or recent antibiotic exposure. Less toxic agents are substituted once culture results become available.

- b. The results of deep tissue cultures are used to direct continued antibiotic choices.**

- (1)** If the patient is doing well clinically and is improving on an empiric antibiotic regimen not active against a particular isolate from a deep ulcer culture, the clinical response suggests the organism may be just a colonizer and therefore needs no directed antibiotic therapy.
- (2)** By contrast, if bacteria are isolated that are resistant to the current antibiotic regimen but the patient is not doing well clinically, it is reasonable

Table 5.3. Selected Empiric Antimicrobial Regimens for Foot Infections in Patients with Diabetes Mellitus

Non-limb-threatening infection

Oral regimen

Cephalexin^a
 Clindamycin
 Dicloxacillin
 Amoxicillin-clavulanate

Parenteral regimen

Cefazolin
 Oxacillin or nafcillin
 Clindamycin
 Cefoxitin
 Cefotetan
 Ceftizoxime
 Ticarcillin-clavulanic acid
 Ampicillin-sulbactam
 Piperacillin-tazobactam

Limb-threatening infection

Oral regimen

Fluoroquinolone and clindamycin (or metronidazole)

Parenteral regimen

Ampicillin-sulbactam
 Ticarcillin-clavulanate
 Piperacillin-tazobactam
 Cefoxitin or cefotetan
 Fluoroquinolone and clindamycin (or metronidazole)
 Imipenem-cilastatin
 Ceftriaxone and clindamycin (or metronidazole)

Life-threatening infection

Parenteral regimen

Imipenem-cilastatin
 Vancomycin, metronidazole, and aztreonam
 Ampicillin-sulbactam and an aminoglycoside
 Piperacillin-tazobactam and an aminoglycoside

Note: Regimens require adjustment if the patient has a history of allergies. Consider use of aminoglycosides in the setting of gram-negative sepsis. Consider addition of vancomycin if MRSA suspected due to recent hospitalization or prior recent treatment with antibiotics. Doses are commensurate with the severity of infection, with appropriate modification for impaired renal function.

^aAuthors' note: We favor full doses of cephalexin, i.e., 750–1,000 mg qid, in the adult. In severe renal failure, doses must be adjusted as described in Chapter 27.

Modified from Caputo GM, et al. Assessment and management of foot disease in patients with diabetes. *N Engl J Med* 1994;331:854, with permission.

to expand antibiotic coverage to include these pathogens. At times, unnecessarily broad antibiotic coverage is unavoidable [41].

c. The optimal duration of antibiotic therapy for soft tissue diabetic infections is unknown [44].

- (1) For osteomyelitis, prolonged courses are needed as discussed earlier in this chapter. In patients with pedal osteomyelitis, if all infected bone has not been removed, prolonged antibiotics (e.g., 6–12 weeks) may be reasonable.
- (2) For infections limited to soft tissue, intravenous therapy has often been given for 10 to 14 days. In patients who do well, oral therapy can be used to complete a 2-week course.
- (3) Courses longer than 2 weeks are usually not required in non-limb-threatening infections. After resolution of cellulitis, ulcer care depends primarily on local care.

- (4) Foot infections with a secondary bacteremia, commonly *S. aureus* or *Bacteroides* species, require protracted therapy (see Chapter 2).
 - (5) Decisions regarding amputation versus continued medical management remain controversial. Conservative management with culture-directed antibiotics and local care is successful in most patients without gangrenous tissue [92].
2. **Glycemic control** should be strict. Insulin is used for immediate glycemic control even in non-insulin-dependent patients [86]. An excellent monitor of the adequacy of debridement is blood sugar control, which improves as the infection is controlled [93].
 3. **Weight-bearing of neuropathic ulcers** must be eliminated to allow healing. Various strategies exist from crutches, bed rest, and wheel chairs to casts, braces, and shoe cutouts [94].
 4. **After adequate debridement and antibiotic management**, use of topical recombinant human platelet-derived growth factor (becaplermin) may speed time to complete healing of foot ulcers [95].
- B. In severe infection, early surgical consultation should be obtained.** Simple debridement of soft tissues, wide incision and drainage of pedal compartments, or open amputations may be appropriate. Removal of necrotic tissue and drainage of pus should not be delayed while awaiting medical stabilization [94].
1. **Nonablative procedures. Surgical considerations include the following:**
 - a. Deep infections do not respond to small stab wounds and drains.
 - b. The procedure should ensure later reconstruction, conserving as much healthy tissue as possible.
 - c. The initial procedure is rarely definitive. Follow-up procedures are usually required.
 2. **Amputations.** If the infection is acutely life-threatening or if the architecture of the foot has been destroyed, amputation may be necessary [42]. Amputation may be preferable in patients who have undergone long courses of unsuccessful treatment. Amputation and rehabilitation may improve quality of life in this situation [96].
 3. **Revascularization.** Adequacy of arterial circulation should be assessed in all patients with foot infection [44]. Arterial insufficiency is a factor in 60% of nonhealing ulcers and 46% of major amputations [97]. Appropriate noninvasive studies include Doppler segmental arterial pressures, wave form analysis, ankle-brachial indices, toe pressures, and transcutaneous oxygen tension [94]. Evidence of vascular insufficiency should prompt vascular surgery consultation. Aggressive surgical correction of arterial insufficiency may speed healing and allow management of infection without amputation [44].
- VI. Prevention.** Diabetic foot infections are best prevented by preventing ulcers. Comprehensive diabetic foot care programs reduce the incidence of ulcers and subsequent infections [98]. Effective programs involve multiple disciplines and should include the following.
- A. Tight glycemic control is necessary to slow onset of neuropathy.
 - B. Examination of the foot is performed during any patient contact. At a minimum the examiner should look for skin breaks, increased temperature, and callus formation.
 - C. Calluses should be promptly removed and bony deformities corrected.
 - D. Patients should be taught to avoid extreme bath water temperature, avoid foot soaks, and dry the foot thoroughly after bathing. Nails should be trimmed correctly. Tinea pedis should be treated promptly. Formal educational programs are desirable, with frequent reinforcement during clinic follow-up.
 - E. Patients should be instructed in selection of appropriate footwear that reduces abnormal pressures on the foot. New shoes should be broken in slowly and ill-fitting shoes avoided. Athletic running shoes are beneficial. Custom-made footwear or sole inserts are preferable.

SEPTIC (INFECTIOUS) ARTHRITIS

Septic (infectious) arthritis usually begins acutely in a single joint. Symptoms of inflammation may include pain, erythema, tenderness, swelling, and limitation of motion of the joint.

Occasionally, multiple joints are involved. **A noninfectious inflammatory joint process such as crystal-induced arthritis (gout or pseudogout) may mimic a septic joint.** Early diagnosis with rapid institution of therapy is necessary to minimize joint damage [99–104].

Most cases occur due to hematogenous seeding of bacteria from a distant site. Synovial tissue is susceptible to seeding by bacteria due to lack of a basement membrane and vascularity. After infection, the body's inflammatory response damages the ground substance of the articular surface. Lack of appropriate therapy causes erosion of cartilage and joint space narrowing. Patients with chronic arthritis, particularly those receiving intraarticular injections, are predisposed to joint infections. In patients without chronic arthritis there is frequently a history of antecedent trauma to the joint [101].

I. Clinical presentation. Risk factors for joint infection include rheumatoid arthritis, sickle cell disease, immunosuppression, prior sexually transmitted disease, narcotic use, or presence of a prosthetic joint. Prior or current remote site of infection should be sought during a careful history and physical.

A. History

1. **Multiple joint involvement** occurs in around 10% of patients [101].
2. **Prior joint damage** predisposes to infection. In a patient with rheumatoid arthritis, an inflamed joint that is out of phase with other joints (i.e., especially tender or warm) may be infected.
3. The usual **signs of inflammation** (tenderness, erythema, and swelling) are minimal in some patients.
4. **Systemic symptoms.** Fever occurs in 90% to 95% of patients but may be low grade, especially in immunosuppressed or rheumatoid arthritis patients. Chills are infrequent.
5. **Duration of symptoms** varies. In bacterial infections, symptoms occur usually over a few days unless patients have preexisting joint disease. Mycobacterial or fungal infections may be insidious, with symptoms present for months [103].
6. Most **commonly involved joints** are the knee, elbow, wrist, shoulder, hip, or ankle. In children, 79% occur in the hip, knee, or ankle [105]. Presenting complaint with hip infection may be only pain on motion.
7. **Prosthetic joint infections** are discussed in detail in a separate section in this chapter.
8. **Gonococcal disease is the most common cause of septic arthritis in the 15- to 40-year-old group.** The disseminated gonococcal syndrome occurs predominantly during the second or third trimester of pregnancy or during menstruation.
9. **Viral syndromes**, including rubella, rubella vaccination, hepatitis B, hepatitis C, varicella-zoster, and human parvovirus, can be associated with arthritis [104,106,107].
10. **Joint tuberculosis** classically presents as a subacute monoarthritis of a weight-bearing joint. Fungal infections have a variable presentation but are frequently of gradual onset [103,108,109].
11. **Postinfectious, or reactive, arthritis** is associated with gastrointestinal tract infection with *Shigella*, *Salmonella*, *Campylobacter*, and *Yersinia* species in patients with the HLA-B27 histocompatibility antigen [110].
12. **Lyme disease** (see Chapter 21).

B. Physical examination

1. **Joint inflammation** should be carefully sought.
2. **Range of motion** is markedly decreased due to pain.
3. **Tenosynovitis** (inflammation of the tendon sheath) occurs in rheumatoid arthritis, gout, and trauma but is also a common manifestation of gonococcal disease. Pain due to tenosynovitis occurs with active motion or when the involved joint is flexed to stretch the tendon.
4. **Concurrent infections** at other sites occur in 50% to 75% of cases.
5. **Skin rashes** commonly occur in disseminated gonococcal infections. Lesions may be macular, vesicular, or pustular, often with a necrotic center and are seen most frequently on the distal extremities. Rash occurs during the early bacteremic

Table 5.4. Examination of Joint Fluid

Measure	Normal	Group 1 (Noninflammatory)	Group 2 (Inflammatory)	Group 3 (Septic)
Volume (mL) (knee)	>3.5	Often >3.5	Often >3.5	Often >3.5
Clarity	Transparent	Transparent	Translucent- opaque	Opaque
Color	Clear	Yellow	Yellow- opalescent	Yellow-green
Viscosity	High	High	Low	Variable
WBC/mm ³	>200	200–2,000	2,000–100,000	>100,000 ^a
Polymorphonuclear leukocytes	>25%	>25%	≥50%	≥75% ^a
Culture	Negative	Negative	Negative	Often positive
Mucin clot	Firm	Firm	Firm	Friable
Glucose (mg/dL)	Nearly equal to blood	Nearly equal to blood	>25, lower than blood	>25, much lower than blood

^aLower with infections caused by partially treated or low-virulence organisms.

From Rodnan GP, McEwen C, Wallace SL, eds. Primer on the rheumatic diseases. *JAMA* 1973;224 [Suppl.]:661, with permission.

phase with migratory arthralgias and variable degrees of joint inflammation. Cultures of blood are frequently positive with negative cultures of joints. Within 1 or 2 days, classic joint inflammation is present, but cultures and Gram stains are positive in only some cases. Similar skin lesions are infrequently seen in streptococcal and meningococcal arthritis [104].

6. Prosthetic joints may not appear inflamed. Passive range of motion may be preserved, whereas active range of motion is limited by pain.

7. Joint tuberculosis is associated with swelling, limitation of movement, muscle spasm, and regional lymphadenopathy. Erythema is often absent [104,108,109].

II. Laboratory aids. Examination of the joint fluid is the most important test.

A. Direct joint aspiration should be performed in every case of suspected infection. As a therapeutic maneuver, as much fluid should be removed as possible without risking damage to the synovial lining. Orthopedic or rheumatologic consultation is recommended in difficult cases or in suspected prosthetic joint infection. The characteristics of synovial fluid in pyogenic and other forms of arthritis are shown in Table 5.4. **Joint fluid analysis should include the following:**

1. The total differential cell count and the leukocyte count are the most sensitive and specific synovial fluid tests for pyarthrosis. Total WBC count generally exceeds 40,000/mm³ with polymorphonuclear neutrophils in excess of 75% [110]. Rarely, crystal-induced and rheumatoid flares can cause a similar picture.

2. Synovial fluid glucose and protein levels are neither sensitive nor specific indicators of bacterial arthritis. Glucose levels may be 50% of blood glucose levels but may be normal, particularly in gonococcal arthritis [102,110].

3. Gram stains are positive in 35% to 65% of bacterially infected joints [99–102]. Gram stains are of particular importance in patients who have received antibiotic therapy before evaluation because cultures may have been rendered negative.

4. Cultures and stains should be performed on all inflammatory joints. Aerobic and anaerobic culture should be done on all fluid specimens. In suspected gonococcal disease, **fluid should be plated directly on to chocolate agar media.** Mycobacterial and fungal cultures and smears should be obtained in chronic or ill-defined inflammatory joint problems. In tuberculous arthritis, smears are positive in 20% to 25% of cases and cultures in 80%.

5. Crystal examination under polarized light is important to detect gout or pseudogout. Acute crystal-induced arthritis may mimic bacterial processes, or both processes can occur simultaneously.

- 6. Detection of a pathogen by polymerase chain reaction** is helpful in Lyme arthritis due to *Borrelia burgdorferi* [111].
- B. Blood cultures** may be positive in 10% of cases. A minimum of two sets drawn 20 minutes apart should be obtained in all patients.
- C. Cultures of other sites** may reveal an associated infection. If gonococcal disease is suspected, cultures of cervix, urethra, pharynx, and rectum should be obtained.
- D. Radiography**
- 1. Early** in the course of disease, radiographs show only soft tissue changes (e.g., swelling, fascial plane obliteration, or increased volume of the joint) that suggest an effusion [112].
 - 2. Late** changes in contiguous bony structures occur no sooner than 10 to 14 days after infection. Follow-up radiographs are helpful in detection of intercurrent osteomyelitis [112].
 - 3. Ultrasound** may be useful to demonstrate a joint effusion and guide needle aspiration of the joint.
 - 4. Radioisotope scans** usually three or four phase ^{99m}Tc bone scans are the most rapid method of determination of site and distribution of joint infections.
 - 5. CT** is used mainly to guide needle aspiration. MRI is highly sensitive for detection of early septic arthritis and is much more specific than conventional radiographs or CT [113].
- E. Miscellaneous. Peripheral blood leukocytosis** occurs in 60% to 70% of cases but may be absent in immunosuppressed patient or prosthetic joint infections. ESRs are usually elevated [102]. **Tuberculin skin testing** should be performed in all cases of chronic monoarticular arthritis.
- F. Synovial tissue biopsy** for culture and histologic examination should be considered in chronic arthritis in which routine joint fluid examination has not yielded a diagnosis [114].

III. Microbiologic features of septic joints

- A. Bacterial infection.** Almost any organism can cause septic arthritis; however, certain bacteria are implicated in most cases. Age and predisposing factors predict likely pathogens [99,103]. In the 15- to 40-year-old group, gonococcus remains the most common etiology, although its incidence may be declining. Gonococcal arthritis occurs primarily in women (>75% of cases) and in homosexual men, both of whom are more likely to have asymptomatic or unrecognized infection at other sites [115]. Arthritis due to other agents is seen primarily in men.
- 1. Neonates.** In infants younger than 3 months, adjacent bone is involved in as many as two-thirds of cases [116].
 - 2. Children** [117–121]. In pediatric patients, *S. aureus*, *H. influenzae*, and streptococci are the most important pathogens. However, *H. influenzae* is uncommon after 5 years of age. **Since the introduction and use of the *H. influenzae* b conjugate vaccine, there has been a continuous and marked decline in the percent of cases due to this pathogen in young children** [123]. Before the introduction of this vaccine, staphylococci caused as many as 40% of the cases of these infections [117–121], but in a recent series, in part due to the decline of *H. influenzae* b disease, staphylococci and streptococci accounted for 70% of culture-confirmed cases [122]. Development of sequelae is significantly associated with (a) infection in infants younger than 6 months, (b) delay of 4 or more days in instituting medical or surgical treatment, (c) infection due to *S. aureus*, and (d), most strikingly, involvement of the hip or shoulder with concomitant presence of osteomyelitis [117–121].
 - 3. Adults with nongonococcal arthritis**
 - a. *S. aureus* is implicated in most cases.** In some reported series more than 90% of patients with underlying rheumatoid arthritis and septic arthritis had *S. aureus* infection [100]. **Local prevalence rates of MRSA should be considered in choosing therapy** [123].
 - b. *Streptococcus* species** are important etiologies in all age groups. Reports emphasize the importance of routine serologic typing of streptococcal isolates from joint fluid. The incidence of infections with groups G and B streptococci appears to be increased in patients with several chronic underlying conditions,

such as cirrhosis and diabetes [101,124]. Arthritis caused by these streptococci may be marked by a slow response to therapy, with persistent synovitis and joint destruction [125,126]. Enterococcal infections are unusual but have recently been reviewed [127].

- c. **Gram-negative bacilli** are uncommon but warrant **special consideration in certain patients**, such as those with malignancies; medical immunosuppression; narcotic use; underlying chronic debilitating diseases, especially in the elderly; or prior noninfectious joint disease [99,100,101,103]. Gram-negative bacillary septic arthritis is occasionally seen in young and generally healthy hosts [128]. In heroin addicts with septic arthritis, *Serratia* and *Pseudomonas* species are relatively common. Brucella arthritis may be seen in immigrants to the United States who usually present with involvement of the sacroiliac, knee, or hip joint. The diagnosis is made either by blood cultures or serology [101].
 - d. **Anaerobic bacteria** are uncommon but have received increasing recognition as etiologic agents in septic arthritis. The predominant species are *Propionibacterium acnes*, anaerobic gram-positive cocci, and *Bacteroides* species [129]. Coinfection with facultative or aerobic organisms occurred in only 11% of cases. **Predisposing factors** include trauma, contiguous infection, prosthetic joint, prior surgical or needle entry into the joint, and diabetes. Such factors were present in 75% of cases.
 - e. **Prosthetic joint infections** are associated with a wide spectrum of implicated bacteria. Although staphylococci (both *S. aureus* and *S. epidermidis*) may be involved in more than half the cases, streptococci, gram-negative enteric bacilli, and anaerobic bacteria often are isolated in this setting (see also Prosthetic Joint Infections, below).
 - f. **Polyarticular septic arthritis** occurs in approximately 10% of adult patients with nongonococcal septic arthritis. **Many of these patients do poorly.** In a recent review [130] of 25 patients with nongonococcal polyarticular septic arthritis, all patients were older than 50 years, 52% had concurrent rheumatic diseases (generally rheumatoid arthritis), blood cultures were positive in 86%, and the mortality was 32%. **At presentation, many patients were mistakenly believed to be manifesting flares in their underlying rheumatoid arthritis or systemic lupus erythematosus and 20% were afebrile.** *S. aureus* accounted for 80% of cases, and streptococci, including *S. pneumoniae*, and gram-negative organisms accounted for approximately 20%.
 - g. **Bite wounds** with contiguous joint involvement may be associated with mixed flora (see detailed discussion in Chapter 4).
- B. Reactive arthritis** is a term used to describe a sterile but inflammatory process of the synovium preceded or triggered by an infection occurring anywhere outside the joint. Infectious agents that have been implicated include *Salmonella*, *Shigella*, *Yersinia*, *Campylobacter*, group A β -hemolytic streptococci, *Staphylococcus*, and, most especially, *Chlamydia* [131–133]. The latter has been strongly associated with the subsequent development of Reiter syndrome. Some reports suggest that long-term antimicrobial therapy of chlamydia may favorably impact the course of the associated Reiter syndrome [134].
- C. Nonbacterial disease**
1. **Viral infections generally are distinguished by the sudden onset of severe joint pain with or without effusion. Various types of exanthems occur in almost all.** The most common viral causes of arthritis are **human parvovirus B19 (fifth disease)**, natural **rubella** infection, rubella vaccination, **hepatitis B** virus, and HIV [103,106,107,135]. In outbreaks of **fifth disease**, women present with symmetric arthritis in late winter and in the spring. The onset of joint symptoms in adults occurs with the rash or shortly after the eruption; small joints of the hands are most frequently involved with a self-limited course [136]. **With hepatitis B**, patients may have a history of urticaria for 1 to 6 weeks along with the onset of joint symptoms, resolving commonly with the onset of jaundice. The arthritis is symmetric. Hands are affected most often, followed by knees and ankles. Joint effusions are scanty [101].

HIV has been associated with a variety of arthritis syndromes, including an acute symmetric polyarthritis affecting the small joints of the hands and wrists, a disabling subacute oligoarticular arthritis affecting mainly knees and ankles, and a "painful articular syndrome," lasting fewer than 24 to 48 hours, involving the knees, elbows, or shoulders characterized by severe intermittent arthralgia without synovitis, often requiring narcotic analgesics. Psoriatic arthritis, Reiter syndrome, and a variety of other syndromes are also associated with HIV. Arthritis can be a manifestation of infection with mumps (especially in men), influenza, arboviruses, Epstein-Barr virus (infectious mononucleosis), and varicella. Reviews of viral arthritis have been published [106,135,137].

2. **Mycobacterial and fungal arthritis is characterized by slow evolution** of physical and radiographic findings [101]. Fungal arthritis is seen mainly in immunocompromised patients. Evidence of disseminated disease is common [109]. Among the fungi, sporotrichotic, candidal, and coccidioidal arthritis are the most common, but arthritis can also occur with blastomycosis, cryptococcosis, and histoplasmosis. Bayer and Guze [138] reviewed fungal arthritis in detail. See further discussion in Chapter 17. *Coccidioides immitis* monoarticular infection typically occurs in non-white immunosuppressed men from endemic areas. Joint infections in patients with blastomycosis primarily spread from a contiguous focus of osteomyelitis. Candidal infections of peripheral joints generally are of acute onset due to hematogenous spread [101].

M. tuberculosis and atypical mycobacteria are uncommon but important causes of chronic indolent infectious arthritis [108,109]. These have been reviewed by Meier and Hoffman [139].

Cultures of synovial tissue produce a higher yield than cultures of joint fluid in cases of mycobacterial and fungal infection [101].

3. **Lyme disease** [140–143], caused by the tickborne spirochete *B. burgdorferi*, characteristically occurs in summer. It frequently is characterized by a unique skin lesion, erythema chronicum migrans, and often is accompanied by systemic flu-like symptoms. From several days to as long as 2 years later, approximately 60% of untreated patients develop brief recurring episodes of either an asymmetric oligoarthritis affecting primarily large joints or a migratory polyarthritis [140,142]. Diagnostic issues, problems with serologic testing [140,143], and therapy [140,144] are discussed in detail in Chapter 21.

IV. Differential diagnosis

- A. Conditions that may be associated with joint effusion are listed in Table 5.5. Infectious arthritis (group 3) would more commonly have to be distinguished from the inflammatory joint diseases listed in group 2 than from diseases in the other categories. It must be remembered that **bacterial arthritis may complicate, and in part be obscured by, the inflammatory conditions listed in group 2. The laboratory approach outlined in section II should help sort out such possibilities, including crystal-induced synovitis.**
- B. Arthritis in the presence of bacterial endocarditis is due to bacterial seeding of one or more joints or to immune complex disease. The development of arthritis in an unusual site suggests the possibility of endocarditis.
- C. **Acute transient synovitis of the hip**, sometimes called "toxic synovitis of the hip" or "acute transient epiphysitis," is the most common cause of a painful hip in children under 10 years of age [145]. Boys are most frequently affected, especially between 3 and 6 years, but the disorder can occur in infancy and early adolescence. The etiology is unknown. The onset of hip pain with motion and weight-bearing may be acute or gradual. There may be a slight fever, usually not higher than 100°F to 101°F [145]. There are no changes of the bone on conventional radiographs; scintigraphy with ^{99m}Tc studies are normal or show slight diffuse increase in uptake. The peripheral WBC count and ESR are normal. **Aspiration of the hip joint will yield clear fluid that is sterile on culture.** Antibiotics are not indicated if synovial fluid cultures are negative. Corticosteroids are not effective, but antiinflammatory drugs may be useful. This entity is reviewed in more detail elsewhere [145].
- D. **Postinfectious (reactive) arthritis**, usually with multiple joints involved, can be seen as an immunologic response during infection with certain agents (e.g.,

Table 5.5. Differential Diagnosis by Joint Fluid Groups

Group 1 (Noninflammatory)	Group 2 (Inflammatory)	Group 3 (Septic)	Hemorrhagic
Degenerative joint disease	Rheumatoid arthritis	Bacterial infections	Hemophilia or other hemorrhagic diathesis
Trauma ^a	Acute crystal-induced synovitis (gout and pseudogout)		Trauma with or without fracture
Osteochondritis dissecans	Reiter syndrome		Neuropathic arthropathy
Osteochondromatosis	Ankylosing spondylitis		Pigmented villonodular synovitis
Neuropathic arthropathy ^a	Psoriatic arthritis		Synovioma
Subsiding or early inflammation	Arthritis accompanying ulcerative colitis and regional enteritis		Hemangioma and other benign neoplasm
Hypertrophic osteoarthropathy ^b	Rheumatic fever ^b		
Pigmented villonodular synovitis ^a	Systemic lupus erythematosus		
	Progressive systemic sclerosis (scleroderma) ^b		

^aMay be hemorrhagic.

hepatitis B); see section III.C.1. Postinfectious arthritis also can develop after meningococcal infections, sexually transmitted diseases, or enteric infections due to *Shigella*, *Salmonella*, *Campylobacter*, and *Yersinia* species. The presence of the specific histocompatibility antigen HLA-B27 increases the likelihood of postinfectious arthritis and appears to predispose to more severe disease [101] (see related discussion in section III.B). Joint fluid cultures are sterile.

V. Therapy for bacterial joint infections requires both removal of purulent material (i.e., **adequate drainage**) from the joint and administration of appropriate **antibiotics**. Weight-bearing should be avoided, but immobilization of the joint is unnecessary [103]. In most cases, medical management will be successful if symptomatic improvement occurs within 48 hours.

A. Drainage of purulent material. By needle aspiration, as much purulent material as possible should be removed without damage to the synovial membrane. Frequent aspiration (daily or more often), as fluid reaccumulates, is an essential adjunct to antibiotic therapy.

1. Purposes of joint aspiration

- a. To provide drainage of the enclosed space, which functionally is acting like an abscess.
- b. To provide symptomatic relief.
- c. To relieve joint pressure and remove inflammatory debris including enzymes that cause destruction of articular cartilage.
- d. To ensure that therapy is effective by doing follow-up smears, cultures, and leukocyte counts.

2. Frequency and duration. The infected joint fluid must be removed by needle aspiration or open drainage whenever fluid reaccumulates or in certain special

settings noted later. Repeated aspirations within the first 48 hours of antibiotic therapy usually provides adequate drainage.

B. Repeated aspirations versus open drainage. This remains a controversial subject, with little experimental evidence to support either viewpoint. Several studies [117,118,121,146] support the concept that early drainage is more important than the method of drainage for all joints except the hip, where an initial surgical approach is required (i.e., open drainage). As such, there is no clear-cut benefit to open surgical drainage versus drainage by repeated aspirations [121,146,147]. Whereas repeated needle aspirations (i.e., daily, or more often if fluid accumulates rapidly) of the infected joint are appropriate for most cases of septic arthritis, surgical drainage is to be considered early in the course in certain situations, as follows:

1. **Lack of response to appropriate antibiotic therapy and repeat needle aspirations.** The precise time one should wait is controversial. Some authorities favor open drainage if adequate response has not occurred within 48 to 72 hours of antibiotic therapy and serial aspirations [101]; others allow up to 1 week.
2. **Inability to drain the joint adequately by needle aspiration** due to large amounts of debris, fibrin, or loculations [146].
3. **Infection of a prosthetic joint** (see under Prosthetic Joint Infections, below).
4. **Relative inaccessibility of the joint** or advanced disease and necrosis, as might be the case in an infected hip [103]. The need for surgical (open) drainage of an infected hip often is stated but not established by controlled studies. In the absence of such a study, **most clinicians believe that hip joint infections**, except perhaps gonococcal infections, **require surgical drainage**. Suppurative arthritis of the shoulder also requires either radiographically guided aspiration or surgical drainage [101].
5. **Gram-negative bacillary arthritis.** These patients have a poorer prognosis. Most patients with gram-positive joint infections attain complete recovery of the joint. However, only some patients with gram-negative arthritis achieve such a result. Some authors advocate early explorative arthrotomy in these patients to ensure adequate drainage, to assess and drain perisynovial abscesses, and to debride any contiguous osteomyelitis [128].

C. Antibiotic therapy

1. **Instillation of antibiotics directly into the joint is unnecessary and unwise.** Most antibiotics diffuse readily into the synovial fluid [148,149], and intraarticular injections of antibiotics may induce a chemical synovitis.
2. **Parenterally administered antibiotics** usually are indicated in the treatment of septic arthritis.
 - a. **Penetration of antibiotics into synovial fluid.** According to studies, the following antibiotics are reported to reach levels in synovial fluid that would be adequate in therapy: penicillin G, ampicillin, nafcillin, carbenicillin, cephalothin, cefazolin, cefuroxime, clindamycin, chloramphenicol, tetracycline, sulfonamides, vancomycin, gentamicin, amikacin, ceftriaxone, ceftazidime, aztreonam, imipenem, and probably cefotaxime. It is likely that penetration into synovial fluid is greater earlier in the course of septic arthritis, when the degree of inflammation is greater. This suggests caution regarding too rapid a change in antibiotic therapy to lower doses of parenteral therapy or to oral therapy in nongonococcal infections. Oral ciprofloxacin is a potential agent for susceptible pathogens.
 - b. **Specific recommendations for treatment of nongonococcal arthritis.** Initial antibiotic therapy is based on results of the synovial fluid Gram stain, as **shown in Table 5.6**. When the culture and sensitivity results are available, the initial regimens are modified to include the least toxic effective antibiotic.
 - c. **Gonococcal arthritis.** Treatment of gonococcal infections in the United States is complicated by the spread of infections due to antibiotic-resistant *N. gonorrhoeae* and the high frequency of intercurrent chlamydial infections in persons with gonorrhea; guidelines for therapy have recently been revised [150]. If an organism is isolated from joint fluid cultures, antimicrobial

Table 5.6. Antibiotic Therapy of Bacterial Arthritis Based on Initial Gram Stain

Gram Stain	Drug of Choice	Dosage	Alternatives ^a
Gram-positive cocci	Nafcillin (or oxacillin) or vancomycin (if oxacillin-resistant <i>S. aureus</i> is deemed a significant risk)	9 g/d i.v. in divided doses q4h in adults; 100–200 mg/kg/d i.v. in divided doses q4h in children (for vancomycin, 1 g q12h in adults, with modifications based on creatinine clearance; see Chapter 28)	First-generation cephalosporin (e.g., cefazolin or cephalothin), clindamycin
Gram-negative cocci Adult	Ceftriaxone ^{b,c}	1 g i.v. once daily in adults	Cefotaxime ^{b,c} , ceftiofur ^{b,c} or spectinomycin ^b
Young child (>6 yr)	Ceftriaxone ^{b,c,d}	50 mg/kg/d (max. 2 g) i.v. once daily	Cefotaxime 50 mg/kg/d i.v. in individual doses q8h
Gram-negative bacilli	Gentamicin ^e plus ticarcillin ^f	4.5–5.0 mg/kg/d i.m. or i.v. in divided doses 8qh if renal function is normal 15–18 g/d i.v. in divided doses q4h in adults; 200–300 mg/kg/d i.v. in divided doses q4h in children	Gentamicin and third-generation cephalosporin
No organisms seen	Ceftriaxone	As above	Cefixitin
Young adult, healthy	Nafcillin and gentamicin	As above	Third-generation cephalosporin ^g
Patient with risk factors (see text)	Ceftriaxone ^g	As above	Cefuroxime or ampicillin ^h and nafcillin
Young child (>6 yr)	Cefotaxime ^{g,i} or cefotaxime and gentamicin ^k	See Chapters 3 and 28.	Oxacillin, cefotaxime, ^g and an aminoglycoside ^k
Neonate, infant (>3 mo)			

^aSpecific doses of alternative agents are discussed in Chapter 27. In the penicillin-allergic patient with a delayed reaction, cephalosporins often are used as alternative agents. In patients with an immediate, severe reaction to a penicillin cephalosporin should not be used without skin testing (see Chapter 24).

^bSee discussion in text (section V.C.2.c) under Infectious Arthritis.

^cWhen susceptibility data are not available for gonococcal infections, a third-generation cephalosporin now is preferred [51].

^dMay be coccobacillary forms of *Haemophilus influenzae*, which are susceptible to third-generation cephalosporins (e.g., ceftriaxone, cefotaxime), as are gonococci.

^eLocal aminoglycoside susceptibility patterns must be considered. If gentamicin resistance is common, tobramycin or amikacin is preferred.

^fOr mezlocillin or piperacillin (see Chapter 27).

^gIn the past, the third-generation cephalosporins were believed to have significantly less antistaphylococcal activity than the semisynthetic penicillase-resistant penicillins and first-generation cephalosporins, so some clinicians added an antibiotic (e.g., oxacillin) to ensure **optimal** antistaphylococcal activity while awaiting culture data. However, more recent data suggest that some third-generation cephalosporins (e.g., ceftriaxone and cefotaxime) may have adequate antistaphylococcal activity. See Chapter 27 discussion of cephalosporins. Some experts still favor an antistaphylococcal agent (e.g., oxacillin) added to a third-generation cephalosporin for enhanced *S. aureus* activity.

^hIf ampicillin-resistant *H. influenzae* is common, a third-generation cephalosporin (e.g., ceftriaxone) or cefuroxime is preferred while awaiting culture and susceptibility data (see footnote d).

ⁱSee Chapter 3 for dosages and other options.

susceptibility testing should be performed. Patients should be initially hospitalized for therapy and examined for evidence of endocarditis or meningitis, both of which are rare. The treatment of gonococcal arthritis is similar to that for disseminated gonococcal infection [150].

3. Duration of parenteral therapy

a. Gonococcal arthritis (see Chapter 16).

b. Nongonococcal arthritis

(1) Adults. Therapy is continued until the arthritis appears to be resolved.

The usual duration of therapy is 2 weeks for infections due to *H. influenzae*, streptococci, or gram-negative cocci [101], if there is no underlying joint disease and if the patient does well with initial therapy. Longer courses of therapy (e.g., 3 weeks) are indicated in patients with gram-negative infections, slowly responding infections (despite adequate drainage), or infections with virulent organisms such as *S. aureus* [101]. Whether additional oral therapy is indicated after full courses of parenteral therapy is controversial, although patients with prosthetic joint infections often receive prolonged courses, as noted under Prosthetic Joint Infections (see below).

When an effective oral regimen is available (e.g., trimethoprim-sulfamethoxazole or oral quinolone very active against the pathogen), oral therapy often is used to complete a full course of therapy (see section (3)).

(2) Initial parenteral therapy followed by oral treatment of children.

Short courses of parenteral therapy (i.e., 5–7 days) followed by 10 to 21 days of oral antibiotics in children appears generally successful if the initial clinical response is favorable and adequate serum bactericidal activity is demonstrated (i.e., >1:8) [151]. However, some guidelines and precautions should be heeded.

(a) The serum bactericidal titer (peak) on the day after the initiation of oral therapy should be at least 1:8 when the pathogen is a gram-negative bacillus, *S. aureus*, or *H. influenzae*, and at least 1:32 when the organism is a streptococcus. Therefore, the pathogen causing the septic arthritis must be isolated so the laboratory can provide information on bactericidal levels necessary to eliminate it.

(b) If the bactericidal level is suboptimal, the dosage of antibiotic must be increased. Usually, the oral dose is two to three times that used for minor infections. These higher doses were well tolerated in children [151].

(c) Ideally, the entire course of oral agents should be given in the hospital, especially if there is any doubt about patient compliance. If the therapy is given at home, three precautions must be taken:

(i) There must be an **adequate bactericidal titer** of the antibiotic in the serum before discharge.

(ii) **Compliance** with the oral regimen at home **must be ensured** after careful discussion with the patient and family.

(iii) The patient should be **followed up weekly** to check on his or her clinical condition and to monitor the serum bactericidal level.

(d) The **duration of therapy** will depend on the organism and the patient's clinical response. For *H. influenzae*, streptococci, or gram-negative cocci, a minimum of 2 weeks of therapy is suggested. For *S. aureus* or gram-negative bacilli, a minimum of 3 weeks is suggested. If the clinical response is slow or the ESR remains elevated, more prolonged therapy and reevaluation are necessary. Cases must be individualized, especially when *S. aureus* is involved (see Chapter 27). In gram-negative infections, if susceptible to trimethoprim-sulfamethoxazole or ciprofloxacin, an oral agent may be used.

(3) **In adults, there is far less experience with parenteral short-course therapy followed by oral therapy.** One group [152] suggests the bactericidal level should be a trough measurement and should be at least a 1:8 against the isolated pathogen. (See Chapter 25 for additional discussion of bactericidal levels.)

D. Prosthetic joint infections (see Prosthetic Joint Infections, below)

E. Repeated aspirations to monitor therapy. Repeated joint aspirations, within the first 5 to 7 days of therapy [101], serve to monitor effectiveness of the antimicrobial therapy and to remove debris that may be destructive to the joint. Within a few days of adequate therapy, the joint fluid should become sterile; for example, serial cultures of joint fluid that become negative within 5 days of the initiation of therapy have been considered to be indicative of a good clinical response [101]. Within 1 week, the leukocyte count should be substantially lowered if a good outcome is to be expected with the therapeutic regimen in use. In addition, fluid reaccumulation should be markedly decreasing. **In the absence of such indications of response**, despite appropriate antibiotic therapy as determined by cultures and sensitivity testing, **open surgical drainage is to be considered**, as discussed in section B.

F. Therapy for nonbacterial joint infections. Infectious disease consultation is advised for treatment of mycobacterial and fungal infections. See Chapters 11 and 17 for therapeutic options for fungal and mycobacterial infections, respectively.

VI. Prognosis. The prognosis in infectious (septic) arthritis varies greatly. In older children and adults without other comorbidities and for whom a large single joint is infected, the overall prognosis for survival and full return of joint function is excellent. In contrast, infants and neonates in whom the hip joint is involved may have permanent sequelae, including leg length discrepancy [153]. Similarly, in the elderly, permanent sequelae and accompanying osteomyelitis are more common, and death rates approaching 20% have been reported [154]. In a recent review, characteristics of patients with bacterial arthritis associated with a poor outcome included age of at least 60 years, preexisting (rheumatoid) arthritis, infection of the hip or shoulder, duration of symptoms of more than 1 week before treatment, involvement of more than four joints, and persistently positive cultures after a 7-day course of appropriate antibiotics [101].

PROSTHETIC JOINT INFECTIONS

Under optimal conditions, the overall rate of total joint replacement infections has decreased in recent years to 1% to 2% [155], although precise rates of infection may be difficult to obtain and depend on the joint replaced and the extent of time after the operation [156]. **Risk factors that appear to be associated with the development of infection in prosthetic joints include** advanced age, malnutrition, rheumatoid arthritis, diabetes mellitus, use of corticosteroids, and preexisting infection at another site. Additional risks include prior surgery in the affected joint, location and design of the implanted prosthesis (with knee arthroplasties having a higher incidence of infection than hips), and occurrence of a local hematoma or superficial wound infection in the postoperative period [155,157]. In a recent review, prior joint surgery, perioperative wound complications, and underlying rheumatoid arthritis were the most well-established risk factors [156]. Prosthetic joint infections have been recently reviewed elsewhere [156,158].

I. Initiation of infection. Bacterial contamination of the joint may be initiated either during or after implantation. Despite aseptic surgical techniques, intraoperative contamination can occur via air contamination, generally caused by dispersion of desquamated skin scales from individuals in the operating room; it may also occur from the patient's own skin or contact with the surgeon's hand through a punctured glove [159]. Significantly fewer infections have been found in operating rooms using ultraclean as opposed to conventional air circulation systems [160]. In contrast, deep infection initiated after surgery is caused by hematogenous spread of bacteria from distant sites. Most of these are believed to originate from cutaneous lesions, the respiratory tract, urinary tract, and oral cavity [102,105].

Most series have demonstrated that 80% to 90% of prosthetic joint infections, evident in the first 2 years after operation, originate in the operating room, with later hematogenously acquired infections accounting for the remainder [159].

II. Biopathogenesis. Within hours of implantation, the surface of the prosthesis is covered by a layer of glycoproteins, some of which act as receptors that facilitate the adherence of both tissue cells and bacteria. After adherence has taken place, many bacteria produce a slime, the glycocalyx, which renders adherence irreversible, permits optimal concentration of nutrients, and provides protection against both phagocytosis

Table 5.7. Microbiology of 1,033 Prosthetic Joint Infections^a Seen at Mayo Clinic from 1969 to 1991

Microorganism(s)	No. (%) of Prosthetic Joint Infections
Coagulase-negative staphylococci	254 (25)
<i>S. aureus</i>	240 (23)
Polymicrobial	147 (14)
Gram-negative bacilli	114 (11)
Streptococci ^b	79 (8)
Unknown ^c	83 (8)
Anaerobes	62 (6)
Enterococci	29 (3)
Other microorganisms	25 (2)
Total	1,033 (100)

^aAll cases met case definition of definite infection. See text for discussion section IV.D.

^bIncludes β -hemolytic streptococci and viridans group streptococci.

^cIncludes cases in which there was no growth on routine bacterial cultures, routine bacterial cultures were not obtained, or microbiological information was not available.

From Steckelberg JM, Osman DR. Prosthetic joint infections. In: Bisno AL, Waldvogel FA, eds. *Infections associated with indwelling medical devices*, 2nd ed. Washington, DC: American Society for Microbiology, 1994:266, with permission.

by leukocytes and antibiotics. After the initial invasion of bacteria into tissue, host defenses react within 2 to 5 hours to localize the infection and prevent spread to adjacent tissues. During this decisive period, antibiotics are successful in reducing the total number of bacteria and tilting the balance in favor of host defenses, but after this time their effect is very limited [159].

III. Microbiologic features. More than 50% of prosthesis-related infections are caused by gram-positive organisms. Most of these appear to be due to staphylococci, with coagulase-negative staphylococcal species outnumbering *S. aureus* in some series. Streptococci, including the anaerobic *Peptococcus* species, cause most of the rest of such infections. Enteric gram-negative bacteria account for 10% to 28% of infections in various series [159]. Many of these agents are skin commensals or transient skin contaminants (Table 5.7).

IV. Diagnosis

A. Clinical presentation. A high degree of clinical suspicion is required because the presentation is generally indolent and the degree of pain and systemic symptoms often are considerably less pronounced than in septic arthritis of a native joint. In addition, pain due to mechanical loosening (not due to infection) and that due to sepsis can present with a similar clinical picture. In joint sepsis, **pain is a prominent feature**, usually is constant, is exacerbated by weight-bearing, and increases over time. It occurs in 90% of patients, although such hallmarks of infection as fever, localized edema and erythema, and sinus tract drainage each occur in only 30% to 40% of patients. An acute or fulminant presentation is more common with virulent organisms such as *S. aureus* or pyogenic β -hemolytic streptococci, whereas a chronic indolent course is more typical of infection with less virulent organisms, for example, coagulase-negative staphylococci [156].

B. Radiographic studies

- 1. Serial radiograph findings.** Loosening or dislocation of the prosthesis in association with cortical bone resorption or periosteal reaction is suggestive of infection but may also be seen with mechanical loosening alone [161].
- 2. Bone scans.** Recent studies of traditional three-phase ^{99m}Tc bone imaging concluded that this test was "limited in its ability to discern between infection and aseptic loosening as the incidence of false negative results is unacceptably high" [162].
- 3. A summary of seven studies using ¹¹¹In-labeled autologous leukocytes** reported somewhat better results, with an average sensitivity of 79% and a

specificity of 81% [163]. ^{111}In -labeled nonspecific IgG scintigraphy may be slightly better still (i.e., overall sensitivity of 97% and specificity of 85%), but both false-positive and false-negative results occur.

4. **Conclusion. Although useful, none of these tests is entirely satisfactory in defining whether joint sepsis is present in all cases.** Therefore, technetium bone scanning alone cannot usefully distinguish septic and aseptic loose prostheses [158]. However, a positive scan may be highly suggestive of infection, which can then be confirmed by aspiration and/or biopsy. Gallium scanning has a high reported specificity, indicating that a positive result correlates well with confirmation of infection at aspiration or biopsy but has a low sensitivity [158].

C. Laboratory studies

1. **Aspiration of joint fluid and subsequent histologic and microbiologic examination of tissue samples obtained at surgery remain the tests of choice for a definitive diagnosis of prosthetic joint infection.** In one recent study, the sensitivity of fine-needle aspiration for detecting the infecting microorganism was 87% and its specificity was 95%, compared with biopsy cultures obtained at the time of surgery [164].

a. **Cultures should be obtained without recent antibiotic therapy.** Because of the critical importance of making a microbiologic diagnosis, in most nonacute cases, antimicrobial therapy should be withheld until all aspirate and/or intraoperative specimens have been obtained. If antimicrobial therapy has already been started, it should be stopped when possible for 10 to 14 days before any diagnostic procedure to avoid false-negative culture results [156].

b. **Good aerobic and anaerobic cultures** should be routinely processed. As much fluid for culture as possible should be obtained at the time of a diagnostic joint aspiration [156]. For chronic indolent infections, fungal and mycobacterial cultures are advised.

c. When prosthesis debridement or removal is performed, the surgeon should obtain multiple tissue samples for culture and histopathology. Intraoperative cultures should include **tissue** from the bone–cement interface, if possible, and samples of any purulence [156]. In chronic infections, mycobacterial and fungal cultures are also advised.

d. **Histopathologic examination** for inflammation, granulomas, and tissue stains for organisms can be very useful.

e. Careful susceptibility studies should be performed on any isolated bacterial pathogens.

f. The predictive value of a single positive surveillance culture at the time of a revision arthroplasty for a failed prosthesis is unknown; such a result requires careful correlation with the clinical context [156].

g. Cultures of drainage from sinus tracts do not reliably identify the etiologic microorganisms [156,158].

2. **Blood cultures** should routinely be obtained (e.g., two or three samples drawn 30–60 minutes apart).

3. Nonspecific tests such as the ESR and C-reactive protein may be of limited value in raising the clinician's level of suspicion and diagnosing the initial infection or in monitoring the response to therapy.

- D. In the recent Mayo Clinic summary, a **definite prosthetic joint infection** was defined by at least one of the following criteria: (a) two or more cultures from sterile joint aspirates or intraoperative cultures were positive for the same organism, (b) purulence was observed at the time of surgical inspection, (c) acute inflammation consistent with infection was present on histopathologic examination of intracapsular tissue, or (d) a sinus tract that communicates with the joint spaces was present [156].

- V. **Therapy. The optimal approach to treatment of the infected arthroplasty remains unclear.** There are few randomized prospective studies reported, and virtually none compares different treatment arms within a single well-controlled study.

A detailed discussion of the infectious disease considerations of the different surgical approaches appears elsewhere [156,158]. To consistently achieve microbiology cure, it is necessary to remove the prosthesis and all associated cement and completely debride

devitalized tissue and bone. Issues about reimplantation that remain controversial include the optimal time to reimplantation, the role of antibiotic impregnated cement, the need for antibiotic-impregnated polymethylmethacrylate spacers (e.g., in two-stage reimplantation for total knee prosthetic infections), and the optimal type and duration of administration of intravenous and oral antimicrobials [156]. **Therefore, we suggest close cooperation of the orthopedic surgeon and the infectious disease consultant in managing these patients.**

- A.** Nonetheless **two-stage replacement**, involving removal of the hip or knee prosthesis and a 6- to 8-week course of intravenous antibiotic therapy followed by reimplantation has been widely recommended [156,161,165]. Antibiotic-impregnated cement spacers commonly are used as adjunctive therapy in arthroplasty for replacement of the infected knee, in preparation for reimplantation. Success rates for microbiologic cure with this technique vary but average approximately 80% to 90%.
- B.** A growing number of reports have suggested that **implant salvage**, using either antibiotic therapy alone or antibiotics plus surgical debridement, may be feasible in selected patients. This approach has evolved out of multiple concerns, not the least of which are the potential surgical and medical complications attending joint removal and reimplantation in the generally elderly patients, many of whom have other underlying medical illnesses and the risk factors outlined earlier.
- 1.** In addition, new antimicrobial regimens may cure infections that previously were believed to be untreatable without removal of the device [166]. Data from both animal models [166,167] and human clinical trials now are available to support consideration of this approach. Treatment regimens combining rifampin with either quinolone or β -lactam antibiotics can be particularly effective with reported success rates of more than 80% in some studies [166,167], although such success also has been reported in some series not using such combinations [155,168,171]. Treatment durations have generally been prolonged (e.g., ≥ 6 –12 months).
 - 2. As encouraging as these recent studies may be, enthusiasm must be tempered by numerous other studies demonstrating poorer outcomes (success rates only in the 20%–40% range)** [155,169,170,172–174]. The treatment of these infections is clearly evolving.
 - 3. In our opinion, patients who might be considered for an attempt at implant salvage must meet at least the following criteria:**
 - a.** A loosened prosthesis is not present.
 - b.** The microorganism is susceptible to antibiotics, including oral antibiotics that the patient can tolerate.
 - c.** The patient is not septic, requiring immediate removal of the infected prosthesis. It should be recognized that cure rates using this approach appear to be higher with acute (generally defined as symptoms of less than 2–4 weeks' duration) as opposed to chronic infections.
 - d.** Finally, the patient must understand that failure may necessitate, but does not preclude, standard therapy, including prosthesis removal and subsequent reimplantation, arthrodesis, resection arthroplasty, or other treatment options. In contradistinction to others [160,169], we do not believe that infection with *S. aureus* represents a contraindication to this approach. Experience with gram-negative organisms is more limited.
- C. Debridement with retention of the prosthesis** procedures usually have been unsuccessful for chronic well-established infections [156]. For early acute infections (i.e., within less than 3 months of the primary surgery) in the presence of a draining infected hematoma without cellulitis, thorough open surgical debridement, irrigation, and antibiotics may salvage up to 70% of prosthetic hip or knee replacements [158]. Recently, delivery of high concentrations of antibiotic via implantable pumps has been used with promising success in acute prosthetic infections [158]. Further evaluation and experience with this technique is needed.
- D. Suppressive antimicrobial therapy** without concomitant surgical intervention **is not considered standard therapy** for prosthetic joint infection because satisfactory functional outcomes are so low [158]. In some situations, antibiotic suppression (long term) is combined with initial surgical debridement with the goal of suppression of symptoms and maintenance of a functioning joint. This may

be rational, and often the only option, in some carefully selected patients when (a) removal of the prosthesis is not feasible, (b) the organism is of low virulence and highly susceptible to oral antimicrobial agents, (c) the patient is not systemically ill, (d) the patient is compliant, and (e) the prosthesis is not loose [156].

- VI. Postoperative superficial wound infection, a major risk for subsequent prosthesis infection.** Aggressive early local care and intravenous antibiotic therapy of these infections have been highly successful in preventing the involvement and removal of the prosthesis [173]. In view of the rapid evolution of treatment options in infections of prosthetic joints, infectious disease consultation is advised.
- VII. Prophylaxis** Antibiotic prophylaxis reduces the frequency of deep wound infection after total joint replacement, and short courses of cefazolin commonly are recommended [175] (see Chapter 27). The use of operating rooms with ultraclean air has a similar effect [160]. Antibiotic-impregnated cement may be equally as effective, but these data are more preliminary. **See related discussion in Chapter 27.**

INFECTIOUS BURSTITIS

- I. Clinical presentation.** Septic bursitis most commonly involves the prepatellar or olecranon bursa.
- A. History.** The common background of patients is a history of either acute or chronic repetitive trauma to the knee or elbow. A history of concurrent superficial skin infection near to the involved area is frequently elicited. Infection is thought to occur due to local spread from the skin.
- 1. Pain and swelling,** usually acute over a few hours, occurs in the vast majority.
 - 2. Fever** occurs in one-half of cases.
 - 3. History of recent intrabursal steroid injection** is frequent in misdiagnosed cases [176].
- B. Physical examination**
- 1. There is usually bursal swelling** with maximal tenderness over the center of the bursa. There is a varying degree of local inflammatory reaction.
 - 2. Peribursal cellulitis** is frequent.
 - 3. Range of motion** of the joint is preserved, unlike septic arthritis.
- II. Diagnostic aids. Definitive diagnosis is via aspiration of bursal fluid that should be performed in all cases. Frequently, sympathetic joint effusions occur with septic bursitis. These effusions must also be sampled to ensure no concurrent joint infection exists.**
- A. Bursal fluid aspiration.** Grossly, fluid may vary from appearance from thin serous to frank pus.
- 1. Leukocyte counts** are frequently less than 20,000 cell/mm³ and may range from 1,500 to more than 400,000 cells/mm³ with predominance of polymorphonuclear leukocytes.
 - 2. Glucose levels** and protein levels are not helpful.
 - 3. Gram stains** are positive around 50% of the time. It is of particular importance to guide therapy in patients who have received prior antibiotics in whom fluid cultures may have been rendered negative.
 - 4. Urate crystal examination** should be performed because gout may mimic or occur with septic bursitis.
 - 5. Aerobic and anaerobic cultures** should be obtained on all specimens [176].
- B. Blood cell count.** The peripheral WBC count and ESR range from normal to markedly elevated and a leukocytosis greater than 10,000 cells/mm³ is seen in approximately 60% of cases.
- C. Radiography** is infrequently helpful.
- D. Blood cultures** are rarely positive when a single bursa is involved.
- III. Bacteriology of septic bursitis. *S. aureus* is involved in as many as 90% of cases.** Streptococcal species, particularly *Streptococcus pyogenes*, is the next most frequent. Coagulase-negative staphylococci account for 1% or 2%. Gram-negative bacteria, mycobacteria, and fungi are infrequently reported.
- IV. Differential diagnosis** includes septic arthritis, gout, trauma, or hemorrhagic olecranon bursitis in patients with uremia.

V. Therapy includes appropriate antibiotics and drainage, usually via repeated needle aspirations.

A. Antibiotics. Most empiric therapy should be directed against *S. aureus*. Further therapy is guided by results of culture and Gram stain. Oral therapy may be used in immunocompetent patients without significant systemic symptoms (e.g., fever) or overlying cellulitis.

1. For therapy of methicillin-susceptible *S. aureus*

a. Parenteral therapy. A semisynthetic penicillinase-resistant penicillin such as nafcillin or oxacillin, 1.0 to 1.5 g every 4 to 6 hours, can be given to adults. In children, 100 to 150 mg/kg/day in divided doses is given every 4 to 6 hours.

In the patient with a delayed penicillin reaction, a first-generation cephalosporin (e.g., cefazolin, 1 g every 8 hours in adults) is recommended. In patients with immediate type hypersensitivity to penicillin, clindamycin is recommended.

b. Oral therapy. Antistaphylococcal agents such as dicloxacillin or cloxacillin, 500 mg four times a day in adults, can be given. In the adult patients with delayed type penicillin hypersensitivity, an oral cephalosporin such as cephalexin or cephadrine, 500 mg to 1 g four times day, can be used. Oral clindamycin may be used in patients with immediate type hypersensitivity to penicillin.

2. If MRSA is suspected due to recent hospitalization or in patients receiving chronic hemodialysis, **vancomycin** is used.

3. Duration of therapy. In immunocompetent patients with uncomplicated disease, therapy may be continued for 1 week after sterilization of bursal fluid as determined by culture performed at the time of repeated aspiration. Immunocompromised patients require more prolonged therapy, generally in excess of 10 days of parenteral therapy before sterilization of the bursa.

B. Adequate drainage is essential and should be performed via needle aspiration every 1 to 3 days. Indications for surgical intervention include failure of needle aspiration to provide adequate drainage, bursa inaccessible to needle drainage, pointing abscess, foreign body or necrotic tissue removal, or recurrent or refractory disease.

VI. Response to therapy is determined by clinical improvement and demonstration of conversion of bursal cultures from positive to negative [176].

6. CENTRAL NERVOUS SYSTEM INFECTIONS

Allan R. Tunkel and W. Michael Scheld

MENINGITIS

Meningitis is inflammation of the meninges identified by an abnormal number of white blood cells in the cerebrospinal fluid (CSF). The meningitis syndrome may be caused by a wide variety of infectious and noninfectious diseases (Table 6.1). Here we review the common infectious causes of meningitis.

I. Epidemiology and etiology

A. Viruses are the major cause of the **acute aseptic meningitis syndrome**, a term used to define any meningitis, particularly one with a lymphocytic pleocytosis, for which a cause is not apparent after initial evaluation and routine stains and cultures of CSF [1]. The common viral agents that cause the acute aseptic meningitis syndrome are as follows.

1. Enteroviruses are currently the leading recognizable cause of the aseptic meningitis syndrome, accounting for 80% to 85% of all cases in which a pathogen is identified [1,2]. Enteroviruses are worldwide in distribution and spread by the fecal–oral, and perhaps respiratory, routes; periods of warm weather and sparse clothing may facilitate spread. Enteroviruses may also be recovered from houseflies, wastewater, and sewage [1]. The predominant enteroviruses isolated from patients with meningitis during the years 1970 to 1983 in the United States were (in decreasing order) echovirus 11; echovirus 9; coxsackievirus 115; echoviruses 30, 4, and 6; coxsackieviruses B2, B4, B3, and A9; echoviruses 3, 7, 5, and 21; and coxsackievirus B1 [2]. In addition, the newly numbered enteroviruses 70 and 71 have been reported to commonly cause central nervous system (CNS) disease [3–5].

Infants and young children are most susceptible because there is absence of previous exposure and immunity, although enteroviruses are also the most common causes of aseptic meningitis among adults [6]. In one large cohort study from Finland, children younger than 1 year of age had an annual incidence of viral meningitis of 219 cases per 100,000 population versus an incidence of 19 cases per 100,000 population in children between the ages of 1 and 4 years [7]. Immunodeficiency and possibly physical exercise also predispose to enteroviral meningitis [1].

2. Arboviruses. The most common vector-transmitted cause of aseptic meningitis is St. Louis encephalitis virus, a flavivirus [1]. Aseptic meningitis accounts for approximately 15% of all symptomatic cases of St. Louis encephalitis and may be as high as 35% to 60% in children. These infections are more common in warmer months when contact with the insect vector is more likely. Other arboviruses reported to cause aseptic meningitis include the California encephalitis group of viruses (e.g., La Crosse, Jamestown Canyon, and Snowshoe hare viruses, which are bunyaviruses) and the agent of Colorado tick fever, an orbivirus, which is seen in mountain and western regions of the United States and Canada.

3. Mumps virus infection commonly occurs in the winter and spring months. CNS disease caused by mumps virus can occur in patients without evidence of parotitis; 40% to 50% of patients with meningitis have no evidence of salivary gland enlargement at presentation. **In an unimmunized population, mumps is one of the most common causes of aseptic meningitis and encephalitis**, with symptomatic meningitis occurring in 10% to 30% of patients [8]. Males are affected two to five times more often than females, and the peak incidence is in children aged 5 to 9 years. Although the incidence of mumps has decreased markedly with widespread use of the attenuated live virus vaccine [1,8], vaccine-associated mumps meningitis also has been reported [9].

4. Lymphocytic choriomeningitis virus was one of the earliest viruses associated with human aseptic meningitis, although it now is reported rarely [1]. It is transmitted to humans by contact with rodents (e.g., hamsters, rats, mice) or their excreta through ingestion of contaminated food or exposure of open wounds

Table 6.1. Differential Diagnosis of the Meningitis Syndrome

Infectious etiologies**Bacteria**

Haemophilus influenzae
Neisseria meningitidis
Streptococcus pneumoniae
Listeria monocytogenes^a
Streptococcus agalactiae

Table 6.1. *Continued.*

Rheumatoid arthritis	Intrathecal injections ^m
Polymyositis	Chymopapain injection
Wegener granulomatosis	Miscellaneous
Lymphomatoid granulomatosis	Seizures
Polyarteritis nodosa	Migraine or migraine-like syndromes
Granulomatous angiitis	Mollaret's meningitis
Other cerebral vasculitides	Serum sickness
Familial Mediterranean fever	Heavy metal poisoning
Kawasaki syndrome	Malignancies
Vogt-Koyanagi-Harada syndrome	Lymphomatous meningitis
Medications	Carcinomatous meningitis
Antimicrobial agents ⁱ	Leukemia
Nonsteroidal antiinflammatory agents ^j	Intracranial tumors and cysts
Muromonab-CD3 (OKT3)	Craniopharyngioma
Azathioprine	Dermoid or epidermoid cyst
Cytosine arabinoside (high-dose)	Pituitary adenoma
Carbamazepine ^k	Astrocytoma
Immunoglobulin ^l	Glioblastoma multiforme
Phenazopyridine	Medulloblastoma
Ranitidine	Pinealoma
Procedure related	Ependymoma
Postneurosurgery	Teratoma
Spinal anesthesia	

^a May also present as encephalitis.

^b Primarily echoviruses and coxsackieviruses.

^c In the United States the major etiologic agents are the mosquito-borne California, St. Louis, Eastern equine, Western equine, and Venezuelan equine encephalitis viruses and the tick-borne Colorado tick fever.

^d Primarily herpes simplex virus type 2 but also herpes simplex virus type 1, varicella-zoster virus, cytomegalovirus, Epstein-Barr virus, and human herpesvirus-6.

^e More commonly presents as chronic meningitis or focal central nervous system lesions.

^f Brain abscess, sinusitis, otitis, mastoiditis, subdural abscess, epidural abscess, venous sinus thrombophlebitis, pituitary abscess, cranial osteomyelitis.

^g Scarlet fever, streptococcal pharyngitis, toxic shock syndrome, pertussis, diphtheria.

^h Mumps, measles, polio, pertussis, rabies, vaccinia.

ⁱ Trimethoprim, sulfamethoxazole, trimethoprim-sulfamethoxazole, ciprofloxacin, penicillin, isoniazid.

^j Ibuprofen, sulindac, naproxen, tolmetin.

^k In patients with connective tissue diseases.

^l Aseptic meningitis can occur after high-dose intravenous immunoglobulin.

^m Air, dyes, isotopes, antimicrobial agents, antineoplastic agents, steroids, dyes.

to dirt. The greatest risk is in pet owners, persons living in impoverished and nonhygienic situations, and laboratory workers [10]. Human-to-human transmission does not occur.

- 5. Herpesviruses** include herpes simplex viruses (HSVs) types 1 and 2, varicella-zoster virus, cytomegalovirus (CMV), Epstein-Barr virus, human herpesvirus 6, and human herpesvirus 7. Neurologic complications associated with the **HSVs are the most significant** [11]. HSVs account for 0.5% to 3.0% of all cases of aseptic meningitis. HSV aseptic meningitis is **most commonly associated with primary genital infection with HSV type 2 [12] and is less likely with recurrences of genital herpes [13]**. Primary genital infection with HSV type 1 and nonprimary genital infection with HSV of either type rarely result in meningitis [12]. Cases of Mollaret recurrent meningitis have been associated with HSV types 1 and 2 [14,15].

Acute aseptic meningitis has also been associated with herpes zoster in patients with or without typical skin lesions [16,17]. Single cases of Mollaret

recurrent meningitis have been associated with Epstein-Barr virus [18]. Meningitis from human herpesvirus 6 has been associated with roseola infantum [19], encephalitis [20], recurrent seizures in children [21], and after bone marrow transplantation [22]. CMV and Epstein-Barr virus may cause aseptic meningitis with a mononucleosis syndrome, particularly in immunocompromised hosts.

6. **Human immunodeficiency virus (HIV)** can infect the meninges early and persist in the CNS [23,24]. Meningitis associated with HIV may occur as part of the primary infection or in an already infected patient; HIV has been isolated from the CSF in some cases [25]. However, CNS infection often is clinically silent. Retrospective studies have noted that 5% to 10% of HIV-infected patients develop an acute meningoencephalitis during or after the mononucleosis-like syndrome that heralds initial infection [23,26].
- B. Bacteria.** Bacterial meningitis is an important problem worldwide [27]. The overall annual attack rate for bacterial meningitis in the United States from 1978 through 1981 was approximately 3.0 cases/100,000 population [28], although this varied based on age, race, and gender. This compares with an attack rate of 45.8 cases per 100,000 population in approximately 4,100 cases in Salvador, Brazil from 1973 through 1982 [29]. Bacterial meningitis is also a significant problem in hospitalized patients. Forty percent of 493 episodes in adults aged 16 years or older at the Massachusetts General Hospital from 1962 through 1988 were nosocomial, and these episodes had a high mortality [30].
1. ***Haemophilus influenzae***. In the early 1980's *H. influenzae* caused 45% to 48% of bacterial meningitis in the United States, with an overall mortality of 3% to 6% [28,31]. Most cases occurred in infants and children younger than 6 years, and more than 90% were caused by capsular type b strains. **The widespread use of conjugate vaccines has profoundly reduced the incidence of invasive *H. influenzae* type b childhood infections** (see section VII.B.1.b) [32], and it now causes 7% of bacterial meningitis in the United States. During 1995 in 22 counties of four states, the overall incidence of bacterial meningitis also was dramatically decreased to 0.2 cases per 100,000 population [33]. *H. influenzae* meningitis in older children and adults should suggest the presence of certain underlying conditions, including sinusitis, otitis media, epiglottitis, pneumonia, diabetes mellitus, alcoholism, splenectomy or asplenia, head trauma with CSF leak, and immunodeficiency (e.g., hypogammaglobulinemia) [34,35].
 2. ***Neisseria meningitidis*** causes 25% of cases of bacterial meningitis in the United States, most commonly in children and young adults, with an overall mortality of 3% to 13% [28,31,35]. Serotype B strains usually occur in sporadic outbreaks, serogroups A and C may occur in epidemics, and type Y strains may be associated with pneumonia. The incidence of serogroup C disease has been increasing, with several recent outbreaks reported in the United States, Canada, and Europe [36-38]; most cases have been caused by one strain of the electrophoretic type 37, termed ET-15. **Patients with deficiencies in the terminal complement components (C5-C8, and perhaps C9), the so-called membrane attack complex, have a markedly increased incidence of neisserial infections**, although their meningococcal case fatality rate of 3% is lower than the rate of 19% for the general population [39].
 3. ***Streptococcus pneumoniae***. Pneumococcal meningitis is most frequently observed in adults, accounting for 47% of total cases in the United States and carrying a mortality of 19% to 26% [28,31,35]. Patients often have contiguous or distant foci of infection such as pneumonia, otitis media, mastoiditis, sinusitis, and endocarditis. Risk factors for serious infection include splenectomy or functional asplenia, multiple myeloma, hypogammaglobulinemia, alcoholism, malnutrition, chronic liver or renal disease, malignancy, Wiskott-Aldrich syndrome, thalassemia major, and diabetes mellitus [40,41]. The pneumococcus is the most common etiologic agent of meningitis in patients who have a basilar skull fracture with CSF leak [42].
 4. ***Listeria monocytogenes*** causes 8% of cases of bacterial meningitis in the United States [35] but has a high mortality of 15% to 29% [28,31,35]. Serotypes 1/2b and

4b have been implicated in up to 80% of meningitis cases. Listerial infection is **most common in neonates** (up to 10% of cases); pregnant women may harbor the organism asymptotically in their genital tract and rectum and transmit the infection to their infants. **Other predisposing conditions include** older age (≥ 50 years), alcoholism, malignancy, immunosuppression (e.g., renal transplant recipients), corticosteroid therapy, diabetes mellitus, liver disease, chronic renal disease, collagen vascular diseases, and conditions associated with iron overload [43,44]. *Listeria meningitis* is found only infrequently in patients with HIV infection [45,46], despite its increased incidence in patients with deficient cell-mediated immunity. Meningitis can also occur in previously healthy adults.

5. ***Streptococcus agalactiae***. In the United States, this organism accounts for 12% of bacterial meningitis, with a mortality ranging from 7% to 23% [28,31,35]. The group B streptococcus is a **common** cause of meningitis **in neonates** [47], with 52% of cases reported during the first month of life [35]. The risk of transmission from mother to infant is increased when the inoculum of organisms and number of sites of maternal colonization is high; group B streptococcus has been isolated from vaginal or rectal cultures of 15% to 40% of asymptomatic pregnant women. Horizontal transmission has also been documented from the hands of nursery personnel to the infant. Most cases of neonatal meningitis are caused by subtype III organisms and occur after the first week of life. Group B streptococcal meningitis in adults appears to be increasing in frequency, often is associated with severe underlying diseases, and has a high mortality rate of 27% to 34% [48–50]. Risk factors for adults include age older than 60 years, diabetes mellitus, parturient women, cardiac disease, collagen vascular diseases, malignancy, alcoholism, hepatic failure, renal failure, and corticosteroid therapy; no underlying illnesses were found in 43% of patients in one study [49].
6. **Aerobic gram-negative bacilli** (e.g., *Klebsiella* species, *Escherichia coli*, *Serratia marcescens*, *Pseudomonas aeruginosa*, *Salmonella* species) have become increasingly important etiologic agents for bacterial meningitis [30,51]; mortality rates range from about 30% to 80%. Meningitis has occurred **after head trauma or neurosurgical procedures** and may also be found **in neonates, the elderly, immunosuppressed patients, and patients with gram-negative septicemia**. Some cases have been associated with disseminated strongyloidiasis in the hyperinfection syndrome, in which meningitis caused by enteric bacteria occurs secondary to seeding of the meninges during persistent or recurrent bacteremias associated with the migration of infective larvae [52]. Alternatively, larvae that invade the meninges may carry enteric organisms on their surfaces or within their own gastrointestinal tracts.
7. **Staphylococci**. *Staphylococcus aureus* accounts for 1% to 9% of cases of bacterial meningitis and is usually found in early postneurosurgical or posttrauma patients and in those with CSF shunts [53,54]. Rarely, *S. aureus* meningitis occurs as a complication of a temporary epidural catheter [55]. Other underlying conditions include diabetes mellitus, alcoholism, chronic renal failure requiring hemodialysis, injection drug use, and malignancies. Thirty-five percent of cases occur in the setting of head trauma or neurosurgery, and an additional 20% have infective endocarditis or paraspinal infection. Community-acquired sources also include sinusitis, osteomyelitis, and pneumonia. Mortality from *S. aureus* meningitis has ranged from 14% to 77%. *Staphylococcus epidermidis* is the most common cause of meningitis in patients with CSF shunts [54], accounting for 47% to 64% of cases.
8. **Other bacteria**. ***Nocardia meningitis*** usually occurs in the setting of predisposing conditions such as immunosuppressive drug therapy, malignancy, head trauma, CNS procedures, chronic granulomatous disease, and sarcoidosis [56]. **Enterococci** are unusual pathogens [57], generally seen in pediatric patients with CNS pathology and in adults with underlying illness (especially immunosuppressive therapy). **Anaerobic meningitis** is unusual, often polymicrobial, and generally associated with a contiguous focus (e.g., otitis, sinusitis, pharyngitis, brain abscess, head and neck malignancy, recent head and neck surgery

or wound infection, posttrauma, postneurosurgery) [58,59]. **Diphtheroids** may cause CNS shunt infections [54]. Streptococcal meningitis has complicated diagnostic myelography [60].

- C. Tuberculosis.** Virtually all mycobacterial infections of the CNS are caused by *Mycobacterium tuberculosis*. Tuberculous meningitis accounts for approximately 15% of extrapulmonary cases or approximately 0.7% of all clinical tuberculosis in the United States [61]. A disproportionately increased rate of CNS tuberculosis occurs in the U.S. homeless population and in nonwhite Americans. Most childhood cases occur during the first 5 years of life, although it is uncommon among those younger than 6 months. Other factors such as advanced age, immunosuppressive drug therapy, lymphoma, gastrectomy, pregnancy, diabetes mellitus, and alcoholism may lead to reactivation tuberculosis [62]. It is estimated that **HIV infection** accounts for almost 6,000 to 9,000 new cases of tuberculosis annually in the United States [63]. Extrapulmonary disease occurs in over 70% of patients with acquired immunodeficiency syndrome (AIDS) but in only 24% to 45% with less advanced HIV infection [64].

D. Spirochetes

- 1. *Treponema pallidum*** disseminates to the CNS during early infection and can be isolated from the CSF of patients with primary syphilis. CSF laboratory abnormalities are detected in 5% to 9% of patients with seronegative primary syphilis [65]. However, the actual rate of CNS invasion during the early stages is likely to be considerably higher. Clinical neurosyphilis can be divided into four distinct syndromes: syphilitic meningitis, meningovascular syphilis, parenchymatous neurosyphilis, and gummatous neurosyphilis. The incidence of syphilitic meningitis is greatest in the first 2 years after initial infection and is estimated to occur in only 0.3% to 2.4% of patients. In contrast, meningovascular syphilis occurs months to years after syphilis acquisition (peak incidence is at approximately 7 years) and is found in 10% to 12% with CNS involvement [65]. Parenchymatous neurosyphilis has two variants, general paresis and tabes dorsalis, which are relatively rare and do not become apparent until 10 to 20 years after acquisition of infection. Gummata are late manifestations of tertiary syphilis and may occur anywhere, although gummatous neurosyphilis is rare.

The overall incidence of neurosyphilis has increased in association with HIV infection [66,67]. In one report, 44% of patients with neurosyphilis had AIDS and 1.5% of AIDS patients were found to have neurosyphilis at some point during their disease [68]. In a review of neurosyphilis cases in San Francisco from 1985 to 1992, 75% were either infected with HIV or in a high-risk group for HIV [69] (see Chapters 16 and 18).

- 2. *Borrelia burgdorferi*** is the etiologic agent of Lyme disease. The nervous system is involved clinically in at least 10% to 15% of patients with Lyme disease [70,71], either while erythema migrans is still present or 1 to 6 months later. Using polymerase chain reaction (PCR), spirochetal DNA was detected in CSF samples from 8 of 12 patients with acute (<2 weeks) disseminated Lyme borreliosis [72], indicating that *B. burgdorferi* usually invades the CNS early in infection (see Chapter 21).

E. Fungi

- 1. *Cryptococcus neoformans*** is associated with bird droppings but can also be found in fruits, vegetables, milk, and soil. *C. neoformans* is the most common fungal cause of meningitis, usually occurring in persons who are immunosuppressed. Risk factors include reticuloendothelial malignancies (e.g., lymphoma), sarcoidosis, collagen vascular diseases (e.g., systemic lupus erythematosus), diabetes mellitus, chronic hepatic failure, chronic renal failure, organ transplantation, and corticosteroids [73]. *C. neoformans* meningitis also occurs in apparently healthy individuals. **Patients with AIDS currently constitute the highest risk group** [74]; 5% to 10% of AIDS patients eventually develop cryptococcal meningitis [75–77].
- 2. *Candida*** are normal commensals of humans. Tissue invasion usually occurs in persons with altered host defenses, including those with malignancies, neutropenia, chronic granulomatous disease, diabetes mellitus, thermal injuries, or

a central venous catheter and in those receiving corticosteroid therapy, broad-spectrum antimicrobial agents, or hyperalimentation [78,79]. *Candida* meningitis is uncommon, occurring in fewer than 15% of patients with CNS candidiasis [80–82]. *C. albicans* is the species most commonly isolated in CNS disease.

3. ***Coccidioides immitis*** is endemic in the semiarid regions and deserts of the southwestern United States (California, Arizona, New Mexico, Texas), where approximately one-third of the population is infected [83]. Less than 1% of patients will subsequently develop disseminated disease, usually within the first 6 months after infection. Of those with disseminated disease, one-third to one-half have meningeal involvement [84,85]. Disseminated disease has been associated with extremes of age, male gender, nonwhite race, pregnancy, and immunosuppression (e.g., corticosteroid therapy, organ transplantation, and HIV infection) [83].

F. Protozoa and helminths

1. **Amebae.** *Naegleria fowleri* is the main cause of primary amebic meningoencephalitis in humans [86,87]. Strains have been recovered from lakes, puddles, ponds, rivers, sewage, sludge, tap water, air-conditioner drains, and soil. Sporadic cases of primary amebic meningoencephalitis occur when persons, usually children and young adults, swim or play in water containing the amebae or when swimming pools or water supplies have become contaminated, often through failure of chlorination. Several cases (often caused by *Acanthamoeba* species or leptomyxid amebae) have been reported in patients [88–90] with advanced HIV.
2. ***Angiostrongylus cantonensis*.** Infection of humans by the larvae of the nematode *A. cantonensis* can lead to an eosinophilic meningitis [52,91]. *A. cantonensis* is widespread, and human infections are fairly common in many parts of the world (e.g., Thailand, India, Malaysia, Vietnam, Indonesia, Papua New Guinea, and the Pacific Islands, including Hawaii). The definitive hosts are rats, and they may spread the parasites from port to port on ships. Larvae invade the brain either directly from the bloodstream or after migrating through other organs. Once there, they mature into adult worms that migrate through the brain. *Baylisascaris procyonis* is a newly recognized cause of eosinophilic meningoencephalitis (see Chapter 21).

II. Clinical presentation

A. Viral meningitis

1. **Enteroviruses.** The clinical manifestations of enteroviral meningitis depend on host age and immune status [1].
 - a. **In neonates** fever is ubiquitous and usually accompanied by vomiting, anorexia, rash, or upper respiratory symptoms and signs. Neurologic involvement may be associated with nuchal rigidity and a bulging anterior fontanelle, although infants younger than 1 year are less likely to demonstrate meningeal signs. Mental status may be altered, but focal neurologic signs are uncommon. Meningoencephalitis in neonates may be severe, with morbidity and mortality as high as 74% and 10%, respectively [92].
 - b. **In contrast**, the clinical findings of enteroviral meningitis **beyond the neonatal period** are rarely those of severe disease and poor outcome [1,93]. The onset usually is sudden, with fever present in 76% to 100% of patients. More than half have nuchal rigidity. Headache (often severe and frontal) is nearly always present in adults; photophobia also is common. Nonspecific symptoms and signs include vomiting, anorexia, rash, diarrhea, cough, upper respiratory findings (especially pharyngitis), and myalgias. Other clues to enteroviral disease, in addition to time of year and known epidemic disease, include the presence of exanthems, myopericarditis, conjunctivitis, and specifically recognizable enteroviral syndromes such as pleurodynia, herpangina, and hand-foot-and-mouth disease [6]. The duration of enteroviral meningitis is usually less than 1 week, and many patients are improved after the lumbar puncture [94], probably as a result of reduced intracranial pressure. In contrast, a recent outbreak of enterovirus 71 infection in Taiwan involved patients 3 months to 8.2 years of age, the chief neurologic complaint was rhombencephalitis in 90%, and the case fatality rate was 14% [4].

- c. In children and adults with absent or deficient humoral immunity (e.g., agammaglobulinemia), which impairs clearance of enteroviruses, chronic enteroviral meningitis or meningoencephalitis may develop and last several years, often with a fatal outcome [95].
- 2. **Mumps virus.** The most frequent clinical presentation of mumps CNS infection is the nonspecific triad of fever, vomiting, and headache [8]. The fever usually is high and lasts 3 to 4 days. Salivary gland enlargement is present in only 50% or so of patients. Other findings include neck stiffness, lethargy or somnolence, and abdominal pain. Most patients have signs of meningitis without evidence of cortical dysfunction and, in uncomplicated cases, recover within 7 to 10 days. Mumps virus rarely causes encephalitis, seizures, polyradiculitis, polyneuritis, cranial nerve palsies, myelitis, Guillain-Barré syndrome, and fatality.
- 3. **Lymphocytic choriomeningitis virus** infection begins with nonspecific symptoms. After a brief improvement, approximately 15% of patients develop severe headache, photophobia, lightheadedness, lumbar myalgias, and pharyngitis. Late manifestations such as orchitis, arthritis, myopericarditis, and alopecia are also seen.
- 4. **Herpesviruses.** Meningitis caused by HSV type 2 usually is characterized by stiff neck, headache, and fever [12]. Neurologic complications were found in 37% of 27 patients with HSV type 2 meningitis and consisted of urinary retention, dysesthesias, paresthesias, neuralgia, motor weakness, paraparesis, concentration difficulties of nearly 3 months' duration, and impaired hearing [13]. All neurologic findings, however, subsided within 6 months. Recurrent meningitis was documented in five patients. Pharyngitis, lymphadenopathy, and splenomegaly should suggest Epstein-Barr virus infection. A diffuse vesiculopustular rash may be seen in patients with meningitis caused by varicella-zoster virus.
- 5. **Human immunodeficiency virus.** Acute HIV infection may cause a typical aseptic meningitis syndrome [23,25,26]. In addition, some patients may present with an atypical syndrome that is chronic, tends to recur, and often is associated with cranial neuropathies (usually V, VII, and VIII) or long tract findings. The most common features are headache, fever, and meningeal signs. Illness is self-limited or recurrent rather than progressive. HIV may occasionally cause a dramatic self-limited encephalitis or encephalopathy during the acute phase of infection.

B. Bacterial meningitis

- 1. **Clinical presentation.** Most patients have fever, headache, meningismus, and signs of cerebral dysfunction (i.e., confusion, delirium, or a declining level of consciousness ranging from lethargy to coma) [27,40,96]. In one review of community-acquired bacterial meningitis in adults, the classic triad of fever, nuchal rigidity, and change in mental status was found in only two-thirds of patients [30]. Another review found the absence of fever, neck stiffness, and altered mental status effectively eliminated the likelihood of acute meningitis in adults (sensitivity of 99% to 100% for the presence of one finding in the diagnosis of acute meningitis) [97].
- 2. **Meningismus** may be subtle, marked, or accompanied by Kernig or Brudzinski signs. These signs are elicited in only 50% or so of adult patients with bacterial meningitis, and their absence does not rule out the diagnosis.
 - a. **Kernig sign** is elicited with the patient in the supine position. The thigh is flexed on the abdomen with the knee also flexed, and the leg then is passively extended. The patient resists leg extension if there is meningeal inflammation.
 - b. **Brudzinski sign** is best known as the nape-of-the-neck sign in which passive neck flexion results in flexion of the hips and knees.
- 3. **Cranial nerve palsies** (especially III, IV, VI, and VII) and **focal cerebral signs** are seen in 10% to 20% of cases. **Seizures** occur in approximately 30% of patients. Signs of increased intracranial pressure may develop, including coma, hypertension, bradycardia, and palsy of cranial nerve III. Papilledema is seen in fewer than 5% of cases early in infection, and its presence should suggest an alternative diagnosis.

4. **A specific etiologic diagnosis may be suggested by certain symptoms or signs.**
- a. **Characteristic skin rash.** Nearly 50% of patients with meningococemia, with or without meningitis, present with a prominent rash located principally on the extremities [27,96]. The rash is typically **erythematous and macular early** in the course of illness but quickly **evolves into a petechial phase** and then further coalesces into a purpuric form (see Color Plate 4.8). The rash often matures rapidly, with new petechial lesions appearing during the physical examination. A similar rash may also be seen in patients who have undergone splenectomy with rapidly overwhelming sepsis caused by *S. pneumoniae* (Color Plate 4.7) or *H. influenzae* type b.
 - b. **Rhinorrhea or otorrhea due to a CSF leak** may result from a basilar skull fracture that produces a dural fistula between the subarachnoid space and nasal cavity, the paranasal sinuses, or middle ear. In these patients, meningitis may be recurrent and is most commonly caused by *S. pneumoniae*.
 - c. Patients with *L. monocytogenes* meningitis have an increased tendency to experience seizures and focal deficits early in the course of infection. Some have ataxia, cranial nerve palsies, or nystagmus due to rhombencephalitis [43,44], although there may be no evidence of parenchymal brain involvement.
5. **Some patients may not manifest the classic symptoms and signs of bacterial meningitis. For example, elderly patients,** especially those with underlying conditions (e.g., diabetes mellitus or cardiopulmonary disease), may present insidiously with lethargy or obtundation, no fever, and variable signs of meningeal inflammation [97]. **In patients with head trauma,** the symptoms and signs of meningitis may be present as a result of the underlying injury [42]. In all these patients, an altered or changed mental status should not be ascribed to other causes until bacterial meningitis has been excluded by CSF examination.

C. Tuberculous meningitis

1. **Children** with tuberculous meningitis commonly **present with** nausea, vomiting, and behavioral changes [61]. Headache is observed in fewer than 25% of cases. Seizures are infrequent (10% to 20% of cases) before hospitalization, although more than 50% may develop seizures during hospitalization. Some children develop an encephalitic course, characterized by stupor, coma, and convulsions without signs of meningitis.
2. **Adults.** In contrast, the clinical presentation in adults is usually **more indolent**, with an insidious prodrome characterized by malaise, lassitude, low grade fever, intermittent headache, and changing personality [98]. A meningitic phase develops within 2 to 3 weeks characterized by protracted headache, meningismus, vomiting, and confusion. **A history of prior tuberculosis is obtained in fewer than 20% of cases** [99]. Adult patients may also present with a rapidly progressive acute meningitis syndrome indistinguishable from bacterial meningitis [62].
3. **On physical examination,** fever is an inconstant finding, observed in 50% to 98% of cases [61,100]. Meningismus and signs of meningeal irritation are absent in 25% to 40% of children and adults with tuberculous meningitis, although 88% of patients admitted to an intensive care unit had meningeal findings in a review [101]. Up to 30% of patients have focal neurologic signs on presentation, usually unilateral or, less commonly, bilateral cranial nerve palsies; most often affected is cranial nerve VI, followed by cranial nerves III, IV, and VIII. Hemiparesis may result from ischemic infarction, usually in the middle cerebral artery territory. Chorea, hemiballismus, athetosis, myoclonus, and cerebellar ataxia are seen less frequently. Choroidal tubercles may be observed on funduscopic examination (~10% of cases).
4. **Coexisting HIV infection.** The clinical manifestations are not modified significantly by HIV infection [102,103]. Fever, headache, and altered mentation are the most frequent presenting symptoms; meningeal signs are absent in up to 50% of patients.

D. Spirochetal meningitis

1. ***Treponema pallidum***. Syphilitic meningitis usually presents with headache, nausea, and vomiting. In one series these were present in 91% of patients [65]. Meningismus was seen in 59% and fever in fewer than half of patients. Seizures occurred in 17% of patients, whereas cranial nerve palsies were found in 45% of cases (most commonly cranial nerves VII and VIII, followed by II, III, V, and VI). Focal abnormalities such as hemiplegia, aphasia, or mental status changes were less common.

Meningovascular syphilis is distinguished temporally and on the basis of focal neurologic findings as a result of focal syphilitic arteritis, which almost always occurs in association with meningeal inflammation [65]. Most patients experience weeks to months of an episodic prodrome that includes headache or vertigo, personality changes (e.g., apathy or inattention), behavioral changes (e.g., irritability or memory impairment), insomnia, or occasional seizures. Focal deficits may also occur and, if untreated, may progress to a stroke syndrome with irreversible neurologic deficits.

Coinfection with HIV may modify the clinical course of syphilis [66–68]. Patients with HIV infection are more likely to progress to neurosyphilis and to show accelerated disease courses. However, in one study of HIV-infected and noninfected patients with syphilis at sexually transmitted disease clinics in Baltimore [104], no significant differences were observed in clinical stage or in disease progression.

2. ***Borrelia burgdorferi***. Meningitis is the most important neurologic abnormality of acute disseminated Lyme disease. Headache is the single most common symptom (30% to 90% of patients), whereas neck stiffness is seen in only 10% to 20% [70]. Photophobia, nausea, and vomiting are intermediate in frequency. Approximately two-thirds of patients have systemic symptoms, including malaise, fatigue, myalgias, fever, arthralgias, and involuntary weight loss. If untreated, symptoms last from 1 to 9 months. Patients typically experience recurrent attacks of meningeal symptoms lasting several weeks, alternating with similar periods of milder symptoms.

Approximately half of all patients with Lyme meningitis have mild cerebral symptoms, usually consisting of somnolence, emotional lability, depression, impaired memory and concentration, and behavioral symptoms [70]. These symptoms may fluctuate in severity in untreated patients before they resolve. Transverse myelitis, spastic paraparesis or quadriparesis, disturbances of micturition, and Babinski sign are reported rarely during this stage. Approximately 50% of patients have cranial neuropathies. Facial nerve palsy is the most common (80% to 90%), is rapid in onset (often 1 to 2 days), and often is accompanied by slight ipsilateral facial numbness or tingling or ipsilateral ear or jaw pain. It is bilateral in 30% to 70% of cases, although the two sides are affected asynchronously in most cases. Other cranial nerves affected less commonly are cranial nerves II and III, the sensory portion of nerves V and VI, and the acoustic portion of nerve VIII. Recovery usually occurs within 2 months.

E. Fungal meningitis

1. ***Cryptococcus neoformans***. Cryptococcal meningitis presents differently in non-AIDS and in AIDS patients [73,75–77].
 - a. **In non-AIDS patients the presentation** is typically **subacute** over days to weeks. The most frequent complaint is headache; fever, meningismus, and personality changes also occur. Approximately 50% have confusion, irritability, and other personality changes reflecting meningoencephalitis. Ocular abnormalities (e.g., papilledema and cranial nerve palsies) occur in nearly 40% of cases; direct invasion of the optic nerve also may occur.
 - b. In contrast, the **presentation in AIDS patients** may be very subtle. The only clinical findings may be headache, fever, and lethargy. Meningeal signs occur in some patients. Photophobia and cranial nerve palsies often are absent. On the African continent, AIDS patients with cryptococcal meningitis have higher rates of neurologic compromise [105,106], possibly because of the advanced stage of illness at the time of presentation.

2. *Candida* meningitis may be abrupt or insidious in onset [80–82]. The most common symptoms are fever, headache, and meningismus. Depressed mental status, confusion, cranial nerve neuropathies, and focal neurologic signs may also be seen.
3. *Coccidioides immitis* meningitis may present acutely, although it most often follows a subacute or chronic course [84,85]. Complaints include headache, low grade fever, weight loss, and mental status changes. Approximately 50% of patients develop disorientation, lethargy, confusion, or memory loss. Signs of meningeal irritation usually are absent, although they have been reported in as many as one-third of cases. Nausea, vomiting, focal neurologic deficits, and seizures may also occur.

F. Protozoal and helminthic meningitis

1. **Amebae.** Primary amebic meningoencephalitis presents in two forms [86,87].
 - a. **Acute form.** After an incubation period of 3 to 8 days, there is the sudden onset of high fever, photophobia, headache, and progression to stupor or coma. This is usually indistinguishable from acute bacterial meningitis, although focal signs and seizures are more common in amebic meningoencephalitis. Early symptoms of abnormal smell or taste may be reported because of olfactory involvement. Confusion, irritability, and restlessness progress to delirium, stupor, and coma. Death in untreated patients generally occurs within 2 to 3 days from the onset.
 - b. **Subacute or chronic form.** Patients present more insidiously with low grade fever, headache, and focal signs (e.g., hemiparesis, aphasia, cranial nerve palsies, visual field disturbances, diplopia, ataxia, seizures); the olfactory bulbs usually are spared. Deterioration occurs over a period of 2 to 4 weeks until death. However, longer durations of illness have also been reported (range, 5 to 18 months).
2. *Angiostrongylus cantonensis*. Symptoms of meningitis begin 6 to 30 days after ingestion of raw mollusks or other sources of the parasite [52,91]. Findings include severe headache (90%), stiff neck (56%), paresthesias (54%), and vomiting (56%). Moderate fever is present in approximately half of the cases.

III. Diagnosis.

The diagnosis of meningitis ultimately is based on the findings in the CSF.

A. Viral meningitis

1. **Enteroviruses.** CSF pleocytosis is almost always present in enteroviral meningitis [1]. The cell count is usually 100 to 1,000/mm³, although counts in the several thousands have also been reported; higher CSF white blood cell counts have been associated with a greater likelihood of isolating the causative enterovirus. **Neutrophils may dominate the CSF profile early in infection, although this quickly gives way to a lymphocytic predominance over the first 6 to 48 hours.** However, in a recent retrospective chart review of 158 cases of meningitis (138 aseptic and 20 bacterial), 51% of 53 patients with aseptic meningitis and duration of illness of more than 24 hours had a neutrophil predominance in CSF [107], suggesting that a CSF neutrophil predominance is not useful as a sole criterion in distinguishing between aseptic and bacterial meningitis. An elevated CSF protein and decreased CSF glucose, if present, are usually mild, although extremes of both have been reported. A specific virologic diagnosis depends on virus isolation from the CSF in tissue culture, although the sensitivity for enteroviral serotypes is only 65% to 75%. Isolation of a non-polio enterovirus from the throat or rectum of a patient with aseptic meningitis is suggestive, but the mean shedding periods from those sites after infection are 1 week and several weeks, respectively, so shedding from a past infection cannot be ruled out. In addition, viral shedding can occur in 7.5% of healthy control subjects during enterovirus epidemics [1]. Rapid diagnosis by immunoassay techniques has been hampered by the lack of a common antigen among the various serotypes and the low concentrations of virus in body fluids. Recent advances in PCR technology promise to greatly facilitate diagnosis and are 94% to 100% specific for the diagnosis of enteroviral meningitis [6,108–110].

2. **Mumps virus.** In mumps meningitis, there is almost always a **CSF pleocytosis** (usually $< 500/\text{mm}^3$) **that is primarily mononuclear cells** ($> 80\%$ lymphocytes in 80% to 90% of patients) [8]. The CSF protein is normal in more than half of patients. The CSF glucose may be decreased in up to 25% of cases. A fourfold rise in mumps antibody titer by complement fixation or hemagglutination inhibition testing of paired acute and convalescent sera is diagnostic. Mumps virus can be grown from CSF in tissue culture for at least a week after the onset of disease, but sensitivity of this technique is highly variable (30% to 50% if collected from CSF early during the course of mumps CNS infection). Use of molecular diagnostic techniques, such as PCR, may have applicability in the diagnosis of mumps meningitis in the future.
3. **Lymphocytic choriomeningitis virus.** The CSF typically shows a lymphocytic pleocytosis (usually $< 750/\text{mm}^3$, although counts up to several thousand may be seen). Hypoglycorrhachia is seen in up to 25% of cases. No rapid detection method is available. The virus may be cultured from blood and CSF early in infection and later from urine. The diagnosis usually is made by a fourfold rise from acute to convalescent sera.
4. **Herpesviruses.** With HSV type 2 meningitis, there is a lymphocytic pleocytosis ($< 500/\text{mm}^3$) and a normal glucose. The virus has been cultured from the CSF and buffy coat of some patients. Using PCR, HSV type 2 was strongly associated with typical cases of Mollaret meningitis in patients without symptoms or signs of genital infection [15]. PCR also has confirmed the presence of varicella zoster DNA in the CSF of patients with herpes zoster meningitis [111].
5. **Human immunodeficiency virus.** The CSF in HIV-infected patients typically shows a mild lymphocytic pleocytosis (20 to $300/\text{mm}^3$), mildly elevated protein, and normal or slightly decreased glucose [26]. HIV has been isolated from the CSF in some patients with neurologic disease, although it can be isolated from HIV-infected patients without neurologic symptoms or signs as well [112,113]. A few mononuclear cells and elevated protein in CSF are common in HIV-positive patients throughout the course of infection. There is a correlation between CSF concentrations of HIV RNA (the "CSF viral load") and severity of AIDS dementia complex [114,115], although there is considerable overlap in CSF values of HIV RNA in relation to clinical neurologic severity. Thus, CSF viral load cannot be used alone for diagnosis or to predict severity of AIDS dementia complex [24].

B. Bacterial meningitis

1. **Cerebrospinal fluid. The diagnosis of bacterial meningitis rests on CSF examination by lumbar puncture** [27,96,116]. The opening pressure is elevated in virtually all cases, with values exceeding 600 mm H₂O suggesting the presence of cerebral edema, intracranial suppurative foci, or communicating hydrocephalus.
 - a. **The white blood cell count usually is elevated in untreated bacterial meningitis**—commonly 1,000 to $5,000/\text{mm}^3$ (range of < 100 to $> 10,000/\text{mm}^3$) **with a neutrophilic predominance**—although approximately 10% of patients with acute bacterial meningitis present with a lymphocytic predominance in CSF. This is more common in neonatal gram-negative bacillary meningitis and *L. monocytogenes* meningitis (approximately 30%). Patients with very low CSF white blood cell counts (0 to $20/\text{mm}^3$), despite high CSF bacterial concentrations, have a poor prognosis. **In up to 4% of cases, CSF pleocytosis will be absent [117]. This is most common in premature neonates** (up to 15% of cases) **and in infants younger than 4 weeks** (17% of cases). Normal CSF white blood cell counts also have been seen with meningococcal meningitis [118], accounting for almost 10% of cases in one study [119]. **Therefore, a Gram stain and culture should be performed on all CSF specimens even if the white blood cell count is normal.** A decreased CSF glucose concentration (< 40 mg/dL) is found in approximately 60% and a CSF-serum glucose ratio less than 0.31 in nearly 70% of patients [120]. The CSF protein is elevated in virtually all patients.

- b. Gram staining of CSF** permits a rapid accurate identification of the causative microorganism in 60% to 90% of patients; the specificity is nearly 100% [121]. The likelihood of detecting the organism by Gram stain correlates with the specific pathogen and the concentration of bacteria in CSF: Concentrations of no more than 10^3 colony-forming units/mL yield positive Gram stains approximately 25% of the time, whereas CSF concentrations of at least 10^5 colony-forming units/mL yield positive microscopy in up to 97% of cases. The yield of Gram stain also depends on the bacterial pathogen [122]. Bacteria are observed in 90% of cases of meningitis caused by *S. pneumoniae*, 86% of cases caused by *H. influenzae*, 75% of cases caused by *N. meningitidis*, and 50% of cases caused by gram-negative bacilli; the CSF Gram stain is positive in only one-third of patients with *L. monocytogenes* meningitis [44]. The probability of identifying organisms decreases with prior antimicrobial therapy (40% to 60% and <50% positivity on Gram stain and culture, respectively). In infants and children with bacterial meningitis, CSF cultures became sterile in 90% to 100% within 24 to 36 hours of “appropriate” antimicrobial therapy [117].
- c. Rapid diagnostic tests** [122]. **Counterimmunoelectrophoresis (CIE)** on CSF detects specific antigens of meningococci (serogroups A, C, Y, or W135), *H. influenzae* type b, pneumococci (83 serotypes), type III group B streptococci, and *Escherichia coli* K1. The sensitivity of CIE ranges from 50% to 95%, although the test is highly specific. CIE is rarely used today because it requires high-quality antisera, stringent quality control, special equipment, and an experienced technician for optimal sensitivity. Staphylococcal coagglutination and latex agglutination tests are more rapid (<15 minutes) and 10-fold more sensitive than CIE. **Latex agglutination techniques** detect the antigens of *H. influenzae* type b, *S. pneumoniae*, *N. meningitidis*, *E. coli* K1, and the group B streptococci in CSF. However, many of the kits do not include tests for group B meningococcus, and other kits probably are poor detectors of this antigen because of its limited immunogenicity. **One of these tests should be performed on all CSF specimens from patients with presumed bacterial meningitis, if the CSF formula is consistent with the diagnosis and the CSF Gram stain is negative.** However, a negative test does not rule out infection by a specific pathogen. The routine use of CSF bacterial antigen tests has been questioned [123], because positive results have not modified therapy and false-positive and false-negative results may occur.

PCR can amplify DNA from the common meningeal pathogens. In one small study of meningococcal meningitis [124], the sensitivity and specificity of CSF PCR were both 91%. A semi-nested PCR strategy for simultaneous detection of *N. meningitidis*, *H. influenzae*, and streptococci in 304 clinical CSF samples [125] had a diagnostic sensitivity and specificity of 94% and 96%, respectively, although some false-positive results occurred. Refinements in PCR may improve its usefulness in the diagnosis of bacterial meningitis, particularly when the CSF Gram stain, bacterial antigen tests, and cultures are negative.

Serum C-reactive protein has a high sensitivity (96%), high specificity (93%), and high negative predictive value (99%) in distinguishing Gram stain negative bacterial meningitis from viral meningitis on admission [126]. Elevated serum concentrations of procalcitonin also are useful in distinguishing between bacterial and viral meningitis; a serum procalcitonin concentration of more than 0.2 ng/mL has a sensitivity and specificity of 100% for bacterial meningitis [127].

- 2. Radiography.** Cranial computed tomography (CT) and magnetic resonance imaging (MRI) do not aid in the acute diagnosis but should be considered in patients who have persistent or prolonged fever, clinical evidence of increased intracranial pressure, focal neurologic findings or seizures, enlarging head circumference (in neonates), persistent neurologic dysfunction, or persistently abnormal CSF parameters or cultures [47,114]. Radiographic studies may be

particularly useful in patients with meningitis as a result of a basilar skull fracture with CSF leak [42,54], and CT may detect air-fluid levels, opacification of the air sinuses, or intracranial air; CT with reconstruction can also be used to document or localize fracture sites. Radioisotope cisternography, with cottonoid pledgets placed at the outlet of the nasal sinuses, can be used to document a CSF leak, although high-resolution CT with water-soluble contrast enhancement of the CSF (metrizamide cisternography) is the best currently available test for defining the site of leakage.

C. Tuberculous meningitis. Routine blood tests are not helpful in the diagnosis. A **syndrome of inappropriate antidiuretic hormone secretion**, resulting in hyponatremia, hypochloremia, and elevated urine osmolality and sodium, was documented in 17 of 24 children with tuberculous meningitis [128]. **Chest radiographic abnormalities** (usually reflecting primary tuberculosis) are common in children with CNS tuberculosis, whereas in adults the changes usually include apical scarring, calcified Ghon complexes, and nodular upper lobe disease [61]. Miliary radiographic disease has been documented in 25% to 50% of adults with tuberculous meningitis. Children with CNS tuberculosis usually have reactive tuberculin skin tests (positivity rates of 85% to 90%), although 35% to 60% of adults thought to have tuberculous meningitis do not react to first- or second-strength purified protein derivative (PPD) [99,100]. The rates of tuberculin reactivity are low in HIV-infected patients with active disease, ranging from 33% to 71% [64].

1. CSF examination. The CSF appearance in tuberculous meningitis is typically clear or opalescent. When the CSF is permitted to remain at room temperature or in a refrigerator for a short time, however, a cobweb-like clot, the classic **"pellicle" of tuberculosis**, may form secondary to the high fibrinogen content and presence of inflammatory cells [61]. A **moderate CSF pleocytosis** of more than 5 cells/mm³ is present in 90% to 100% of patients, although the counts seldom exceed 500/mm³ [100]. The initial differential count contains both lymphocytes and neutrophils, with conversion to a lymphocytic predominance over several weeks. Conversely, in patients receiving antituberculous chemotherapy, an initial lymphocytic predominance may become neutrophilic on subsequent CSF examinations [62], the so-called therapeutic paradox. The **CSF glucose concentration usually is modestly depressed** (median value, 40 mg/dL); hypoglycorrhachia has correlated with more advanced disease. Most patients have elevated CSF protein concentrations (median values of 150–200 mg/dL); values higher than 1,000 to 2,000 mg/dL have been reported usually in association with spinal block. In contrast, normal CSF protein concentrations were found in 43% of 37 HIV-infected patients with tuberculous meningitis [102].

Because of the low number of organisms in CSF, **identification by specific stains is difficult**. In many series, fewer than 25% of specimens are smear positive [61,99,101]. Staining any pellicle, layering the centrifuged sediment of large CSF volumes onto a single slide with repeated applications until the entire pellet can be stained at once, and obtaining repeated specimens may increase yield. One study demonstrated an 86% rate of acid-fast smear positivity when up to four separate CSF specimens were examined for each patient [100], although this rate has not been duplicated consistently. False-negative CSF cultures are common; even with four CSF specimens, almost 20% of patients have negative CSF cultures.

Based on the inadequate yield of CSF stains and cultures, several newer diagnostic modalities are being developed for the rapid diagnosis of tuberculous meningitis [61]. Some use biochemical assays to measure some feature of the organism or the host response (e.g., bromide partition test, adenosine deaminase assay), whereas others are immunologic tests that detect mycobacterial antigen or antibody in CSF (e.g., tuberculostearic acid antigen, enzyme-linked immunosorbent assay, latex agglutination). Despite the promise of these immunodiagnostic tests for rapid diagnosis of tuberculous meningitis, there are problems with cross-reacting antibodies against nonpathogenic mycobacteria and with the presence of bacterial or fungal antigenic moieties. **PCR** to detect fragments of mycobacterial DNA in CSF is an equally promising tool

[129]. The usefulness of these tests in the diagnosis of tuberculous meningitis requires large-scale confirmatory studies.

2. **Radiography. No radiologic changes are pathognomonic** for tuberculous meningitis [61]. On CT of the head, hydrocephalus frequently is present at diagnosis or develops during the course of infection. Contrast enhancement of the basal cisterns, with widening and blurring of the basilar arterial structures, also may be seen. Periventricular lucencies represent tuberculous exudate and tubercle formation adjacent to the choroid and ependyma. MRI may be superior to CT in identifying basilar meningeal inflammation and small tuberculoma formation. MR angiography has been used to detect the characteristic vascular narrowing and the rare complication of aneurysm formation [130].

D. Spirochetal meningitis

1. ***Treponema pallidum***. For diagnosis of CNS syphilis, no single routine laboratory test is definitive. Common nonspecific CSF abnormalities in syphilitic meningitis include a mononuclear pleocytosis (>10 cells/mm³ in most patients), elevated CSF protein concentrations (78% of patients), and mild decrease in CSF glucose concentrations (<50 mg/dL in 55% of patients) [65]. Oligoclonal bands and intrathecally produced antitreponemal antibodies frequently are present.

Serologic testing has been used to aid in the diagnosis of neurosyphilis, although testing of CSF specimens in patients with syphilis is problematic [67]. For example, CSF is subject to blood contamination in approximately 10% of lumbar punctures, which may lead to a false-positive CSF serologic test result; the likelihood of a false-positive test depends on the relative amount of contamination, the antibody titer in blood, and the sensitivity of the test. For patients with a serum venereal disease research laboratory test (VDRL) of less than 1:256, sufficient blood contamination to be visible to the naked eye is required to cause false-positive CSF VDRL results. **The specificity of the CSF VDRL for neurosyphilis is high, but the sensitivity is low (reactive tests in only 50% to 85% of patients)**. Therefore, a reactive CSF VDRL test in the absence of blood contamination is sufficient to diagnose neurosyphilis, and a nonreactive result does not exclude the diagnosis. A nonreactive CSF fluorescent treponemal antibody absorption test effectively rules out neurosyphilis, although the specificity of the test is much less than the CSF VDRL because of the possibility of leakage of small amounts of antibody from the serum into CSF. Furthermore, the significance of a reactive CSF fluorescent treponemal antibody absorption as a diagnostic tool for neurosyphilis is undefined. **PCR** can detect *T. pallidum* DNA in CSF from patients with acute symptomatic neurosyphilis [131], although further large-scale studies are needed to determine the sensitivity and specificity of this technique. Based on the difficulties in the diagnosis of neurosyphilis, elevation of CSF concentrations of white blood cells or protein in the appropriate clinical and serologic setting should lead to initiation of therapy (see Chapter 16).

2. ***Borrelia burgdorferi***. Typical CSF changes in Lyme meningitis are a pleocytosis (usually <500 cells/mm³), with more than 90% lymphocytes in 75% of cases [70]; plasma cells may also be present. There is usually an elevated CSF protein (up to 620 mg/dL) and a normal glucose, although the glucose can be low with illness of longer duration.

The best available laboratory test for diagnosis is demonstration of specific serum antibody to *B. burgdorferi*, which in a patient with a compatible neurologic abnormality is strong evidence for the diagnosis [70,71]. Specific IgM, IgG, or IgA antibody against *B. burgdorferi* also appears in CSF and indicates intrathecal antibody synthesis [71]. However, antibody tests are poorly standardized, and there is marked interlaboratory variability [132]. When the pretest probability of Lyme disease is 0.20 to 0.80, sequential testing with enzyme-linked immunosorbent assay and Western blot is recommended (see Chapter 21) [133,134]. PCR has occasionally identified *B. burgdorferi* DNA in CSF from patients with Lyme neuroborreliosis [71,72]. Culture of CSF is insensitive [71].

E. Fungal meningitis

1. ***Cryptococcus neoformans***. Most non-AIDS patients with cryptococcal meningitis have a CSF pleocytosis (range, 20–500 cells/mm³), with the proportion of

neutrophils usually lower than 50% [73]. **AIDS patients may have very low or even normal CSF leukocyte counts during active infection; as many as 65% have fewer than 5 white blood cells/mm³** [75–77]. CSF protein concentrations usually are elevated, with concentrations in excess of 1,000 mg/dL, suggesting subarachnoid block. CSF glucose concentrations may be normal in two-thirds of AIDS patients. CSF India ink examination is a rapid effective test (if the laboratory has significant experience) that is positive in 50% to 75% of patients with cryptococcal meningitis. This yield increases up to 88% in AIDS patients. Cryptococcal meningitis with completely normal CSF parameters has been described in AIDS patients [135]; normal indices were found in 17% of HIV-infected patients in one study from South Africa [105]. The yield of CSF culture is excellent in both non-AIDS and AIDS patients.

Diagnosis is aided by the latex agglutination test for detection of cryptococcal polysaccharide antigen [75–77]. The test is both sensitive and specific when samples are first heated to eliminate rheumatoid factor. The cryptococcal polysaccharide antigen may be positive in early infection even when the CSF culture is negative. In smaller laboratories, it may be a more reliable test than the India ink examination. A presumptive diagnosis is made with a CSF titer of 1:8 or higher. **Serum cryptococcal polysaccharide antigen may also be detected, particularly in severely immunosuppressed patients** (i.e., those with AIDS) [77], although the value of the serum polysaccharide antigen for screening patients suspected of having meningeal disease has not been established. Antigen titers generally are higher in serum than in CSF of patients with cryptococcal meningitis. Furthermore, extremely high CSF polysaccharide antigen titers have been reported in AIDS patients; early reports suggested that titers of 1:10,000 or higher predicted a poor outcome [76], although some patients have responded well to antifungal therapy despite high initial titers.

2. **Candida.** Patients with *Candida* meningitis usually have a CSF pleocytosis, with a mean of 600 cells/mm³; lymphocytes or neutrophils may predominate [80,81]. Direct microscopy of CSF detects yeast cells in approximately 50% of cases. Organisms are readily grown from CSF in most cases. A single positive culture from a patient with risk factors or symptoms is considered significant when CSF indices are compatible with meningitis and the fungus is isolated in pure culture [79].
3. **Coccidioides immitis.** CSF pleocytosis is seen in coccidioidal meningitis and may occasionally reveal a prominent eosinophilia [85,136]. Only 25% to 50% of patients have positive CSF cultures. Serum complement-fixing antibody titers in excess of 1:32 to 1:64 suggest dissemination [84,85]. CSF complement-fixing antibodies are present in at least 70% of cases of early meningitis and from virtually all patients as disease progresses. In fact, the antibody titers parallel the course of meningeal disease, although in patients who relapse CSF pleocytosis, elevated protein, or decreased glucose usually develop before detectable CSF antibody recurs. Complement-fixing antibodies may fail to develop in serum or CSF in patients with immunodeficiencies.

F. Protozoal and helminthic meningitis

1. Amebae

- a. **Acute form.** The CSF formula in patients with the acute form of primary amebic meningoencephalitis reveals a neutrophilic pleocytosis, low glucose, elevated protein, and red blood cells [86,87]. The Gram stain is always negative. However, examination of fresh warm CSF specimens can reveal the motile trophozoites.
- b. **Subacute or chronic form.** In patients with the subacute or chronic form of the illness, the CSF inflammatory response is less florid with a predominant mononuclear leukocytosis [86]. The CSF protein concentration is elevated, and the glucose is often normal or slightly reduced. Because amebae are not found in CSF, the diagnosis usually requires examination of a biopsy or necropsy specimen revealing the characteristic cysts. The value of serologic tests is variable. Serum immunofluorescence, amebic immobilization titers, and complement-fixing antibodies support the diagnosis, although

demonstration of rising titers is necessary as some normal persons have circulating antibodies.

2. ***Angiostrongylus cantonensis***. The combination of history of ingesting suspected food, moderate to high peripheral eosinophilia, and CSF eosinophilia suggests angiostrongyloidiasis [86]. The CSF leukocytosis is moderate, with 16% to 72% eosinophils and increased protein concentration; CSF larvae are found occasionally.

IV. Approach to the patient with meningitis. Initial management of presumed bacterial meningitis includes lumbar puncture to determine whether the CSF formula is consistent with that diagnosis [27,96,137]. If purulent meningitis is present, empiric antimicrobial therapy should be instituted based on results of Gram staining or rapid bacterial antigen tests. However, if no etiologic agent can be identified by these means or if there is a delay in performance of the lumbar puncture, empiric antimicrobial therapy should be instituted based on the patient's age and underlying disease status. Antimicrobial therapy should be ordered on initial clinical impression; in critically ill patients, the first dose may precede lumbar puncture. There are no prospective clinical data on the optimal timing of antimicrobial therapy in bacterial meningitis. In a recent retrospective study of 269 patients with community-acquired bacterial meningitis [138], delayed initiation of antimicrobial therapy was associated with adverse clinical outcome when the patient's condition advanced from a low- or intermediate-risk stage to a high-risk stage of prognostic severity, supporting the assumption that treatment of bacterial meningitis before it advances to a high level of clinical severity improves outcome. **In patients with a focal neurologic examination or papilledema and suspected bacterial meningitis, a CT of the head should be performed before lumbar puncture** to rule out the presence of an intracranial mass lesion because of the risk of herniation [120]. The true incidence of this problem is unclear but has been suggested to be much lower than 1.2% in patients with papilledema and approximately 12% in patients without papilledema but with elevated intracranial pressure. However, the time involved in waiting for a CT significantly delays initiation of antimicrobial therapy, with the potential for increased morbidity and mortality. Therefore, **emergent empiric antimicrobial therapy should be initiated before the CT. Blood cultures should be obtained before empiric antibiotic therapy.** Although CSF cultures may be sterile after initiation of antimicrobial therapy, pretreatment blood cultures and the CSF formula, Gram stain, or bacterial antigen tests will likely provide evidence for or against bacterial meningitis. Our choices of **empiric antimicrobial therapy** are shown in **Table 6.2**. Once the pathogen is isolated and susceptibility testing is known, antimicrobial therapy can be modified for optimal treatment (Table 6.3). Recommended dosages for CNS infections in adults are shown in Table 6.4; dosages for infants and children are shown in Table 6.5.

V. Antimicrobial therapy

A. Viral meningitis. Currently, **there is no specific antiviral chemotherapy for the enteroviruses; treatment is supportive** [2]. However, pleconaril has recently been shown to have beneficial effects on the clinical, virologic, laboratory, and radiologic parameters in patients with severe enterovirus infections [139]. Recovery of patients with HSV type 2 meningitis usually is complete without neurologic sequelae; it is not clear whether antiviral treatment alters the course of mild HSV type 2 meningitis. However, treatment with acyclovir generally is indicated for primary genital herpes infection [11]. Specific antiretroviral therapy should be considered for acute HIV infection.

B. Bacterial meningitis

1. *Haemophilus influenzae*

- a. Therapy for *H. influenzae* type b meningitis has been altered by the emergence of β -lactamase-producing strains. Resistance to chloramphenicol has also been described, more commonly from areas such as Spain (>50% of isolates) than from the United States (<1% of isolates) [27,96]. A prospective study found chloramphenicol to be bacteriologically and clinically inferior to ampicillin, ceftriaxone, or cefotaxime in the treatment of childhood bacterial meningitis caused predominantly by *H. influenzae* type b, even with chloramphenicol-sensitive isolates. The third-generation cephalosporins

Table 6.2. Empiric Therapy for Purulent Meningitis^a

Predisposing Factor	Common Bacterial Pathogens	Antimicrobial Therapy
Age		
0–4 wk	<i>Streptococcus agalactiae</i> , <i>Escherichia coli</i> , <i>Listeria monocytogenes</i> , <i>Klebsiella pneumoniae</i>	Ampicillin plus cefotaxime; or ampicillin plus an aminoglycoside (see Chap. 3)
1–23 mo	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>S. agalactiae</i> <i>Neisseria meningitidis</i> , <i>E. coli</i>	Third-generation cephalosporin ^b ; or ampicillin plus chloramphenicol ^c
2–50 yr	<i>S. pneumoniae</i> , <i>N. meningitidis</i>	Third-generation cephalosporin ^b ± ampicillin ^c
>50 yr	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>L. monocytogenes</i> , aerobic gram-negative bacilli	Ampicillin plus a third-generation cephalosporin ^b
Immunocompromised host	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>L. monocytogenes</i> , aerobic gram-negative bacilli (including <i>Pseudomonas aeruginosa</i>), <i>S. aureus</i>	Vancomycin + ampicillin + either ceftazidime or cefepime
Basilar skull fracture	<i>S. pneumoniae</i> , <i>H. influenzae</i> , group A β-hemolytic streptococci	Third-generation cephalosporin ^b
Head trauma; postneurosurgery	<i>Staphylococcus aureus</i> , <i>Staphylococcus epidermidis</i> , aerobic gram-negative bacilli (including <i>P. aeruginosa</i>)	Vancomycin + either ceftazidime or cefepime
Cerebrospinal fluid shunt	<i>S. epidermidis</i> , <i>S. aureus</i> , aerobic gram-negative bacilli (including <i>P. aeruginosa</i>), diphtheroids	Vancomycin + either ceftazidime or cefepime

^a Vancomycin should be added to empiric therapeutic regimens when highly penicillin-resistant or cephalosporin-resistant strains of *S. pneumoniae* are suspected; see text for details.

^b Cefotaxime or ceftriaxone.

^c See text for details.

(cefotaxime or ceftriaxone) are as effective as the combination of ampicillin plus chloramphenicol for bacterial meningitis. Thus, the **third-generation cephalosporins (cefotaxime or ceftriaxone) are recommended as empiric therapy for children with bacterial meningitis** [137].

- b. Several comparative trials have documented a slower rate of CSF sterilization and a higher incidence of hearing impairment in patients receiving cefuroxime for bacterial meningitis [140,141]. Furthermore, there have been cases of *H. influenzae* meningitis in patients receiving cefuroxime for nonmeningeal *H. influenzae* disease. Therefore, **cefuroxime is not recommended** as first-line treatment of bacterial meningitis. In addition, there have been case reports of delayed CSF sterilization in *H. influenzae* meningitis treated with ceftizoxime or ceftazidime. However, *in vitro* resistance of *H. influenzae* to the third-generation cephalosporins and fluoroquinolones has not yet been described.
- c. In a prospective randomized comparison of cefepime with cefotaxime for treatment of bacterial meningitis in infants and children, cefepime was found to be safe and therapeutically equivalent to cefotaxime [142] and is a suitable alternative.

Table 6.3. Specific Antimicrobial Therapy for Meningitis

Microorganism	Standard Therapy	Alternative Therapies
Bacteria		
<i>Haemophilus influenzae</i> β-Lactamase negative	Ampicillin	Third-generation cephalosporin ^a ; cefepime; chloramphenicol; aztreonam
β-Lactamase positive	Third-generation cephalosporin ^a	Chloramphenicol; cefepime; aztreonam; fluoroquinolone
<i>Neisseria meningitidis</i>	Penicillin G or ampicillin ^b	Third-generation cephalosporin ^a ; chloramphenicol; fluoroquinolone; meropenem
<i>Streptococcus pneumoniae</i> Penicillin MIC <0.1 μg/mL	Penicillin G or ampicillin	Third-generation cephalosporin ^a ; chloramphenicol
Penicillin MIC 0.1–1.0 μg/mL	Third-generation cephalosporin ^a	Meropenem; cefepime
Penicillin MIC ≥2.0 μg/mL	Vancomycin + a third-generation cephalosporin ^{a,c}	Meropenem; fluoroquinolone ^d
<i>Enterobacteriaceae</i>	Third-generation cephalosporin ^a	Aztreonam; meropenem; fluoroquinolone; trimethoprim-sulfamethoxazole
<i>Pseudomonas aeruginosa</i>	Ceftazidime ^e or cefepime ^e	Aztreonam ^e ; meropenem ^e ; fluoroquinolone ^e
<i>Listeria monocytogenes</i>	Ampicillin or penicillin G ^e	Trimethoprim-sulfamethoxazole; meropenem
<i>Streptococcus agalactiae</i>	Ampicillin or penicillin G ^e	Third-generation cephalosporin ^a ; vancomycin
<i>Staphylococcus aureus</i> Methicillin sensitive	Nafcillin or oxacillin	Vancomycin
Methicillin resistant <i>Staphylococcus epidermidis</i>	Vancomycin Vancomycin ^f	
Mycobacteria		
<i>Mycobacterium tuberculosis</i>	Isoniazid + rifampin + pyrazinamide	Ethambutol ^f ; ethionamide ^f ; streptomycin
Spirochetes		
<i>Treponema pallidum</i>	Penicillin G	Doxycycline ^g ; ceftriaxone ^g
<i>Borrelia burgdorferi</i>	Third-generation cephalosporin ^a	Penicillin; doxycycline
Fungi		
<i>Cryptococcus neoformans</i>	Amphotericin B ^h	Fluconazole; itraconazole ^g
<i>Candida</i> species	Amphotericin B ^h	Fluconazole ^g
<i>Coccidioides immitis</i>	Fluconazole	Amphotericin B ⁱ
Protozoa and helminths		
<i>Naegleria fowleri</i>	Amphotericin B ⁱ⁺ rifampin + doxycycline	

^a Cefotaxime or ceftriaxone.^b Some would use a third-generation cephalosporin for meningococcal strains that demonstrate intermediate sensitivity to penicillin; see text for details.^c Addition of rifampin should be considered.^d Currently under investigation in patients with pneumococcal meningitis; value has not been established.^e Addition of an aminoglycoside should be considered.^f Add to standard therapy in cases of suspected drug resistance; see text for details.^g Value of these antimicrobial agents has not been established.^h Addition of 5-flucytosine should be considered.ⁱ Intravenous and intraventricular administration.

MIC, minimum inhibitory concentration.

Table 6.4. Maximum Recommended Dosages of Antimicrobial Agents for Central Nervous System Infections in Adults with Normal Renal and Hepatic Function^a

Antimicrobial Agent	Total Daily Dose	Dosing Interval (hr)
Amikacin ^b	15 mg/kg	8
Amphotericin B ^c	0.6–1.0 mg/kg	24
Amphotericin B lipid complex	5 mg/kg	24
Ampicillin	12 g	4
Aztreonam	6–8 g	6–8
Cefepime	6 g	8
Cefotaxime	8–12 g	4–6
Ceftazidime	6 g	8
Ceftriaxone	4 g	12–24
Chloramphenicol ^d	4–6 g	6
Ciprofloxacin	800–1,200 mg	8–12
Doxycycline	200–400 mg	12
Ethambutol ^{e, f}	15–25 mg/kg	24
Ethionamide ^e	1 g	12
Fluconazole	400–800 mg	24
Flucytosine ^{e, g}	100 mg/kg	6
Gentamicin ^b	3–5 mg/kg	8
Imipenem	2 g ⁿ	6
Isoniazid ^{e, h}	300 mg	24
Itraconazole	800 mg	12
Liposomal amphotericin B	3–5 mg/kg	24
Meropenem	6 g	8
Metronidazole	30 mg/kg	6
Miconazole	1.5–3.0 g	8
Nafcillin	9–12 g	4
Oxacillin	9–12 g	4
Penicillin G	24 million units	4
Pyrazinamide ^{e, i}	15–30 mg/kg	24
Rifampin	600 mg	24
Streptomycin ^{j, k}	15 mg/kg	24
Sulfadiazine ^e	4–6 g	6
Tobramycin ^b	3–5 mg/kg	8
Trimethoprim-sulfamethoxazole ^l	10–20 mg/kg	6–12
Vancomycin ^{b, m}	2–3 g	8–12

^a Unless otherwise indicated, therapy is administered intravenously.

^b Need to monitor serum concentrations to ensure adequate peaks. See Chapter 27.

^c Can increase dosage to 1.5 mg/kg/day in severely ill patients.

^d Higher dose recommended for pneumococcal meningitis.

^e Oral administration.

^f Maximum daily dosage of 2.5 g.

^g Maintain serum concentrations of 50–100 µg/mL.

^h Initiate therapy at a dosage of 10 mg/kg/day (up to 600 mg/day).

ⁱ Maximum daily dosage of 2 g.

^j Intramuscular administration.

^k Maximum daily dosage of 1 g.

^l Dosage based on trimethoprim component.

^m May need to monitor cerebrospinal fluid concentrations in severely ill patients.

ⁿ In a patient with normal renal function, some clinicians may consider a higher dose. See Chapter 27.

Table 6.5. Recommended Dosages of Antimicrobial Agents for Central Nervous System Infections in Infants and Children with Normal Renal and Hepatic Function^{a,b}

Antimicrobial Agent	Total Daily Dose in Infants and Children (Dosing Interval in hr)
Amikacin ^c	20–30 mg/kg (8)
Amphotericin B	0.25–1.0 mg/kg (24)
Ampicillin	200–300 mg/kg (6)
Cefepime	50 mg/kg (8)
Cefotaxime	200 mg/kg (6–8)
Ceftazidime	125–150 mg/kg (8)
Ceftriaxone	80–100 mg/kg (12–24)
Chloramphenicol	75–100 mg/kg (6)
Ethambutol ^{d,e}	15–25 mg/kg (24)
Ethionamide ^{d,f}	10–20 mg/kg (12)
Flucytosine ^{d,g}	100 mg/kg (6)
Gentamicin ^c	7.5 mg/kg (8)
Isoniazid ^{d,h,i}	10–20 mg/kg (12–24)
Metronidazole	30 mg/kg (12)
Nafcillin	200 mg/kg (6)
Penicillin G	0.25 mU/kg (4–6)
Pyrazinamide ^{d,j}	15–30 mg/kg (12–24)
Rifampin ^{d,k}	10–20 mg/kg (12–24)
Streptomycin ^l	20–40 mg/kg (12)
Tobramycin ^c	7.5 mg/kg (8)
Trimethoprim-sulfamethoxazole ^m	10–20 mg/kg (6–12)
Vancomycin ^c	50–60 mg/kg (6)

^a Unless otherwise indicated, therapy is administered intravenously.

^b See Table 3.2 for neonate dosages.

^c Need to monitor peak and trough serum concentrations.

^d Oral administration.

^e Maximum daily dosage of 2.5 g.

^f Maximum daily dosage of 1 g.

^g Maintain serum concentrations of 50–100 µg/mL.

^h Some clinicians initiate therapy at 30 mg/kg for the first several weeks.

ⁱ Maximum daily dosage of 300 mg.

^j Maximum daily dosage of 2 g.

^k Maximum daily dosage of 600 mg.

^l Intramuscular administration.

^m Dosage based on trimethoprim component.

2. *Neisseria meningitidis*. The antimicrobial agents of choice for *N. meningitidis* meningitis are **penicillin G or ampicillin**, although these recommendations may change in future years [27]. Meningococcal strains have been reported from several areas (particularly Spain) that are relatively resistant to penicillin G, with a minimum inhibitory concentration (MIC) range of 0.1 to 1.0 µg/mL, due to altered penicillin-binding proteins 2 and 3 [143]. In one U.S. population-based surveillance study for invasive meningococcal disease, 3 of 100 isolates had penicillin MICs of 0.12 µg/mL [144]. In another active population-based surveillance study in seven geographically dispersed areas of the United States during 1997, 3 of 90 isolates were intermediately resistant to penicillin (MIC 0.12 µg/mL) [145]; 49 of the remaining 87 isolates had penicillin MICs of 0.06 µg/mL. The clinical significance of these isolates is unclear because patients with meningitis caused by these organisms recovered with standard penicillin therapy. However, isolated reports of penicillin treatment failure have been described [146,147]. Based on these data, some authorities would treat meningococcal meningitis with a third-generation cephalosporin (either cefotaxime or ceftriaxone)

pending results of *in vitro* susceptibility testing. Chloramphenicol is the standard treatment for meningococcal meningitis in developing countries because of its low cost and ease of administration. However, high-level chloramphenicol resistance (MIC ≥ 64 $\mu\text{g/mL}$) has recently been described [148], indicating the importance of continued surveillance for resistant strains. Trovafloxacin was found to be equivalent to ceftriaxone in children with meningococcal meningitis in one report [149], although concerns of liver toxicity preclude its use in the therapy of bacterial meningitis.

3. *Streptococcus pneumoniae*

a. The therapy for meningitis caused by pneumococci has been modified based on current pneumococcal susceptibility patterns. Numerous reports from throughout the world have documented strains relatively resistant to penicillin, with an MIC range of 0.1 to 1.0 $\mu\text{g/mL}$, as well as strains highly resistant to penicillin (MIC ≥ 2.0 $\mu\text{g/mL}$) [27,137,150–152]. The overwhelming majority of resistant strains are serotypes 6, 14, 19, and 23. The mechanism of this resistance is alterations in the structure and molecular size of penicillin-binding proteins. Most multiresistant strains in the United States have disseminated from a multiresistant serotype 23F clone of *S. pneumoniae* isolated in Spain as early as 1978.

Based on these antimicrobial susceptibility trends and because sufficient CSF concentrations of penicillin are difficult to achieve with standard high parenteral dosages (initial CSF penicillin concentrations of approximately 1 $\mu\text{g/mL}$), **penicillin is no longer recommended as empiric antimicrobial therapy when *S. pneumoniae* is considered a likely infecting pathogen. Indeed, early reports documented clinical failure in most patients with penicillin-nonsusceptible *S. pneumoniae* who were treated with penicillin [153]. For patients in whom relatively resistant strains are found, a third-generation cephalosporin (ceftriaxone or cefotaxime) should be used [27]; vancomycin plus a third-generation cephalosporin (either cefotaxime or ceftriaxone) should be used when highly resistant strains are suspected or isolated (see Chapter 27).**

b. Although a third-generation cephalosporin is the antimicrobial agent of choice for pneumococcal meningitis caused by isolates with intermediate penicillin resistance, pneumococcal strains resistant to the third-generation cephalosporins (MIC ≥ 2 $\mu\text{g/mL}$) have also been reported [27,154–156]. For the third-generation cephalosporins, pneumococcal meningitis strains with MICs no more than 0.5 $\mu\text{g/mL}$ are defined as susceptible, 1.0 $\mu\text{g/mL}$ as intermediate, and at least 2.0 $\mu\text{g/mL}$ as resistant. However, some patients have been treated successfully with only high-dose cefotaxime or ceftriaxone when the MIC to the third-generation cephalosporin is no more than 1.0 $\mu\text{g/mL}$. Clinical failures with chloramphenicol have been reported in patients with penicillin-resistant isolates [157], likely due to poor bactericidal activity against these strains. In one study, 20 of 25 children had an unsatisfactory outcome (i.e., death, serious neurologic deficit, poor clinical response). Chloramphenicol alone is not recommended for empiric therapy. **These data indicate the need to perform susceptibility testing of all pneumococcal isolates, at which time optimal antimicrobial therapy can be chosen.**

c. Vancomycin may not be optimal therapy for patients with pneumococcal meningitis [158]. Of 11 consecutive patients with pneumococcal meningitis caused by relatively resistant strains who were treated with intravenous vancomycin, all improved and 10 were eventually cured, but 4 failed vancomycin therapy [159]. Reasons for failure may have included variability in serum vancomycin concentrations or impaired CSF vancomycin penetration as a result of adjunctive dexamethasone administration. In addition, there are recent descriptions of *S. pneumoniae* strains that are tolerant to vancomycin [160,161]; tolerance may be a precursor phenotype to the development of resistance. **These data indicate the need for careful**

monitoring of, and perhaps even measurement of CSF vancomycin concentrations in, adult patients receiving vancomycin therapy for pneumococcal meningitis. Infectious disease consultation is advised. The addition of intrathecal or intraventricular vancomycin should be considered for treatment of unresponsive cases. Some investigators have recommended the addition of rifampin (if the organism is susceptible) to vancomycin for treatment of meningitis caused by highly resistant pneumococcal strains [153], although there are no firm data to support this. Meropenem, a new carbapenem with less proconvulsive activity than imipenem, yields microbiologic and clinical outcomes similar to either cefotaxime or ceftriaxone [162,163]. The newer fluoroquinolones (levofloxacin, moxifloxacin, gatifloxacin) are active *in vitro* against resistant pneumococci and in animal models of penicillin-resistant pneumococcal meningitis [27,164] but have not been studied in humans with this disease (see Chapter 27).

4. ***Listeria monocytogenes*.** The third-generation cephalosporins are inactive in meningitis caused by *L. monocytogenes*. Therapy for patients with *Listeria* meningitis should consist of ampicillin or penicillin G [43,44]; the addition of an aminoglycoside should be considered in proven infection because of *in vitro* synergy and enhanced killing in a variety of animal models. In the penicillin-allergic patient, trimethoprim-sulfamethoxazole, which is bactericidal against *Listeria in vitro*, should be used. Chloramphenicol has been associated with an unacceptably high failure rate in patients with *Listeria* meningitis. Vancomycin is also unsatisfactory for *Listeria* meningitis, despite favorable *in vitro* susceptibility results. However, intraventricular administration of vancomycin was successful in a case of recurrent *L. monocytogenes* meningitis [165]. Meropenem is active *in vitro* and in experimental animals and was successfully used in a pediatric renal transplant patient with *Listeria* meningitis [166]; meropenem may be a useful alternative in the future (see also Chapter 3).
5. ***Streptococcus agalactiae*.** Standard therapy for meningitis caused by the group B streptococcus is the combination of ampicillin plus an aminoglycoside [47]. This combination is recommended due to *in vitro* synergy and recent reports detailing the presence of penicillin-tolerant strains [49,50]. Alternative agents are the third-generation cephalosporins. Vancomycin is reserved for penicillin-allergic patients in whom cephalosporins are contraindicated (see also Chapter 3).
6. **Aerobic gram-negative bacilli**
 - a. The treatment of bacterial meningitis caused by enteric gram-negative bacilli has been revolutionized by the availability of the **third-generation cephalosporins** [27,137], with cure rates of 78% to 94%. Ceftazidime has enhanced activity against *P. aeruginosa*, and ceftazidime-containing regimens have successfully cured adult and pediatric patients with *P. aeruginosa* meningitis [167,168]. Concomitant intrathecal or intraventricular aminoglycoside therapy should be considered in patients who are not responding to conventional parenteral therapy. Although this rarely is needed at present, it was associated with a higher mortality than systemic therapy alone in infants with gram-negative meningitis and ventriculitis.
 - b. **Other antimicrobial agents.** Aztreonam attains excellent CSF concentrations and has been efficacious in the treatment of gram-negative meningitis [169]. Imipenem was effective in one case of *Acinetobacter* meningitis and eradicated bacteria from CSF in a study of 21 children (most cases caused by *H. influenzae* type b and *N. meningitidis*) [170]. However, a high rate of seizure activity (33%) limits its usefulness for bacterial meningitis. High-dose meropenem (2 g every 8 hours) given for 18 weeks was successful in a lymphoma patient with *P. aeruginosa* meningitis in whom therapy with ceftazidime plus gentamicin had failed [171] and in another patient with posttraumatic *P. aeruginosa* meningitis [172]. Intravenous meropenem was also successfully used in combination with intraventricular polymyxin B in a patient with ventriculoperitoneal shunt-associated ventriculitis caused by a ceftazidime-resistant *K. pneumoniae* [173]. The development of meropenem

resistance during treatment of *Acinetobacter* meningitis [174] indicates the need to consider emergence of resistance in patients who fail to respond despite initially appropriate antimicrobial therapy.

The fluoroquinolones (e.g., ciprofloxacin, pefloxacin) have been used successfully in some patients with gram-negative meningitis [27]. Their primary usefulness is for treatment of multidrug-resistant gram-negative organisms (e.g., *P. aeruginosa*) or when the response to conventional β -lactam therapy is slow (e.g., meningitis caused by *Salmonella* species). These agents should never be used as first-line empiric therapy in meningitis of unknown etiology because of their variable *in vitro* activity against pneumococci and *L. monocytogenes*.

7. **Staphylococci.** *S. aureus* meningitis should be treated with nafcillin or oxacillin [53], with vancomycin reserved for patients allergic to penicillin or when methicillin-resistant organisms are suspected or isolated. The addition of rifampin should be considered in patients not responding to therapy. Meningitis caused by coagulase-negative staphylococci, the most commonly encountered organism in CSF shunt infections, should be treated with vancomycin; rifampin should be added if the patient fails to improve [54]. Removal of the shunt often is necessary. Intraventricular teicoplanin, an investigational glycopeptide antimicrobial agent, was successful in seven patients with staphylococcal neurosurgical shunt infection [54,175].
8. **Duration of therapy.** Traditionally, the duration of antimicrobial therapy in patients with bacterial nonmeningococcal meningitis has been 10 to 14 days [176]. However, 7 days of therapy are safe and effective for *H. influenzae* type b meningitis, although treatment must be individualized and some patients may require longer courses. Meningococcal meningitis can be treated for 7 days with intravenous penicillin, though some authors have suggested that 4 days of therapy are adequate. In adults with meningitis caused by enteric gram-negative bacilli, treatment should be continued for 3 weeks to minimize relapses. Ten to 14 days are recommended for treatment of meningitis caused by *S. pneumoniae*, 14 to 21 days for *S. agalactiae*, and at least 21 days for *L. monocytogenes*, although these regimens are based more on tradition and anecdotes than on rigidly standardized clinical trials.

Completion of intravenous therapy for bacterial meningitis may be accomplished in the outpatient setting if several criteria are met: inpatient therapy for 6 days; afebrile 24 to 48 hours before discharge; no significant neurologic dysfunction, seizure activity, or focal findings; clinically stable or improving; taking all fluids by mouth; received first dose of the outpatient antimicrobial agent under medical supervision and without reaction; access to home health nursing; reliable intravenous line and infusion device, if needed; daily examination by a physician and reliable follow-up; patient and/or family compliance with the program; and a safe environment with access to a telephone, utilities, food, and a refrigerator [177,178].

- C. **Tuberculous meningitis.** Until the advent of effective chemotherapy, CNS tuberculosis was a uniformly fatal disease. Even now, the optimal drug regimen, dosage, route of administration, and duration of therapy remain undefined (for recommendations, see Tables 6.3 through 6.5). Therapy for tuberculous meningitis should be initiated on the basis of a strong clinical suspicion and should not be delayed until proof of infection is obtained. The principles of therapy for tuberculous meningitis are similar to those for treatment of tuberculosis elsewhere [61,62]. Isoniazid, rifampin, and pyrazinamide have very good CSF penetration; in the presence of meningeal inflammation, the peak CSF concentrations of isoniazid, rifampin, and pyrazinamide are approximately 90%, 20%, and 100%, respectively, of peak serum concentrations (see Chapter 11).

1. **Isoniazid-rifampin-susceptible strains.** In non-immunocompromised patients, a 6-month treatment regimen is recommended, consisting of isoniazid, rifampin, and pyrazinamide for the first 2 months and isoniazid and rifampin for an additional 4 months. Several studies have demonstrated the efficacy of this short-course regimen in patients with tuberculous meningitis [179,180].

However, some authors recommend 9 months of treatment, and we favor this approach [62]. Furthermore, HIV-infected patients usually require longer courses of therapy [64]. Several studies have reported similar outcomes in patients with or without HIV infection who have tuberculous meningitis. However, therapy for tuberculous meningitis may need to be individualized, with longer durations of therapy used in patients with a higher severity of illness.

2. **Multidrug-resistant strains and empiric therapy.** Drug-resistant tuberculosis has been increasing in frequency worldwide [61]. Risk groups include immigrants from countries in Asia, Africa, and the Americas; known contacts of drug-resistant cases; homeless and impoverished individuals; and residents of certain geographic areas in the United States, particularly adjacent to the Mexican border. In addition, secondary resistance may develop during chemotherapy if adherence is poor. In cases of suspected drug resistance or when the rate of isoniazid resistance is not known to be less than 4%, **ethambutol or streptomycin should be added to the three-drug regimen outlined in section 1 until susceptibility results have been obtained** (see Chapter 11).

Therapy of tuberculous meningitis caused by resistant organisms should also be guided by drug penetration into CSF [61]. Ethambutol penetrates poorly into CSF except when the meninges are inflamed. There is good evidence, however, that ethionamide crosses both healthy and inflamed meninges, with peak CSF concentrations comparable with those achieved in serum. The fluoroquinolones (e.g., ciprofloxacin and ofloxacin) also penetrate well into CSF and have good *in vitro* activity against *M. tuberculosis*. Amoxicillin-clavulanate or imipenem has been used in individual cases of meningitis caused by multidrug-resistant *M. tuberculosis*. Meningitis suspected to be caused by multidrug-resistant *M. tuberculosis* should be treated with at least five drugs until susceptibility studies are performed. Infectious disease consultation is advised. Preliminary data suggest that HIV-infected patients with meningitis caused by rifampin- or multidrug-resistant *M. tuberculosis* are more likely to die in the 60 days after collection of CSF than HIV-infected patients with fully susceptible or other resistant isolates [181].

D. Spirochetal meningitis

1. ***Treponema pallidum*.** With neurosyphilis, the goals are to arrest disease progression and to reverse clinical symptoms and signs [65]. Except for cranial nerve abnormalities, syphilitic meningitis usually resolves without therapy. The general prognosis for meningovascular syphilis after therapy is very good, except for patients with larger neurologic deficits before therapy; in this situation, therapy may halt progression and prevent further ischemic events caused by neurosyphilis.

The preferred treatment of CNS syphilis is intravenous penicillin G, 18 to 24 million units/day divided every 4 hours for 10 to 14 days [65,67,181a]. Alternatively, procaine penicillin, 2.4 million units intramuscularly daily, plus probenecid (500 mg orally four times a day) for 10 to 14 days can be used. Some experts recommend follow-up therapy with three weekly injections of benzathine penicillin G, although there are no data to support this practice. No large studies have been performed to evaluate alternative antimicrobial agents for neurosyphilis. On the basis of case reports, clinical experience, and extrapolations from animal studies, other agents with potential utility in the penicillin-allergic patient include the tetracyclines, chloramphenicol, and ceftriaxone. Erythromycin is not recommended based on treatment failures. HIV-infected patients with neurosyphilis need careful monitoring for response to therapy [67,182]. Follow-up lumbar puncture should be performed every 6 months in all patients until CSF changes have normalized. Standard therapy for neurosyphilis has failed in HIV-infected patients, probably because immunologic responses play an important role in controlling infection even with adequate antimicrobial therapy (**see Chapters 16 and 18**).

2. ***Borrelia burgdorferi*.** Intravenous ceftriaxone (2 g once daily) for 14 to 28 days is preferred for the neurologic manifestations of Lyme disease, including meningitis; cefotaxime (2 g every 8 hours) or penicillin G (20 to 24 million units/day)

are acceptable alternatives [70,71]. Acute meningeal and systemic symptoms resolve within days or weeks, whereas chronic disease takes months to improve [71]. CNS abnormalities are arrested by treatment, but some residual deficits may occur. There is no evidence to support treatment durations of longer than 4 weeks. However, no regimen has proven to be universally effective (see Chapter 21).

E. Fungal meningitis

1. *Cryptococcus neoformans*

a. Non-AIDS patients. Combination therapy with amphotericin B plus 5-flucytosine (5-FC) for 4 to 6 weeks is preferred. Untreated, cryptococcal meningitis was nearly always fatal. Amphotericin B improved the prognosis dramatically, although morbidity, mortality, and relapse rates remained high, especially in immunocompromised patients (cure rates $\leq 52\%$ after the first course of therapy). A large prospective trial in the pre-AIDS era compared combination therapy with amphotericin B (0.3 mg/kg/day) plus 5-FC (150 mg/kg/day) for 6 weeks to amphotericin B (0.4 mg/kg/day) alone for 10 weeks [183]. Combination therapy produced fewer failures, fewer relapses, more rapid CSF sterilization, and less nephrotoxicity than amphotericin B alone; cure or improvement occurred in 67% of patients given the combination versus 41% given only amphotericin B. Mortality between the two groups was not different. However, this study was criticized because of the low dose of amphotericin B used in the single-agent arm. A later trial compared a 4-week with a 6-week regimen of amphotericin B plus 5-FC therapy [184]. **The 4-week regimen could be used in** the subset of patients who, at presentation, had no neurologic complications, no underlying diseases or immunosuppressive therapy, a pretreatment CSF white blood cell count more than $20/\text{mm}^3$, and a serum cryptococcal antigen titer less than 1:32 and who, at 4 weeks, had a negative CSF India ink test and a CSF cryptococcal antigen titer less than 1:8. 5-FC toxicity was common (38%), indicating that 5-FC concentrations may need to be monitored (keep levels of 50 to 100 $\mu\text{g}/\text{mL}$) [185].

The optimal use of fluconazole is unclear. In a recently published report of 157 non-HIV-infected patients with CNS cryptococcosis [186], patients were more likely to receive an induction regimen with amphotericin B ($\sim 90\%$) and subsequent fluconazole (65%), suggesting a role for fluconazole in consolidation therapy for this population. **However, pending further data non-AIDS patients should receive 4 to 6 weeks of amphotericin B plus 5-FC** (see Chapter 17).

b. AIDS patients. A double-blind multicenter trial randomly assigned patients with a first episode of AIDS-associated cryptococcal meningitis to amphotericin B (0.7 mg/kg/day) without or with 5-FC (100 mg/kg/day) for 2 weeks, followed by 8 weeks of treatment with either itraconazole (400 mg/day) or fluconazole (400 mg/day) [187]. At 2 weeks, there were no significant differences in clinical outcome or CSF sterilization. At 10 weeks, 72% of the fluconazole recipients versus 60% of the itraconazole recipients had negative CSF cultures, although the clinical response rate was similar in both groups. In a multivariate analysis, the addition of 5-FC during the initial 2 weeks and treatment with fluconazole for the next 8 weeks were independently associated with CSF sterilization. **The preceding data support the initial use of amphotericin B, with or without 5-FC, for a period of approximately 2 weeks; this period may need to be prolonged in patients who are severely ill. This initial treatment period then is followed by fluconazole (400 mg/day) to complete a 10-week course.** Dosages of fluconazole up to 800 mg/day have benefited some AIDS patients with cryptococcal meningitis who failed primary therapy or who relapsed [188]. Lipid formulations of amphotericin B have been studied in AIDS patients with cryptococcal meningitis [189,190]. When liposomal amphotericin (4 mg/kg/day) was compared with amphotericin B (0.7 mg/kg/day), the median time to CSF sterilization was shorter with amphotericin B and, at 14 days, significantly more patients

had sterile CSF [190], although the time to clinical response and the failure rate did not differ between groups. **Further studies are needed before liposomal amphotericin B can be recommended.**

AIDS patients with cryptococcal meningitis have a high rate of relapse once antifungal therapy is discontinued [75,76]; the prostate gland may represent a sequestered reservoir for relapse. **Fluconazole (200 mg/day) is superior to amphotericin B (1 mg/kg/wk) and itraconazole (200 mg/day) in preventing relapses [191,192], and is the agent of choice for secondary prevention (see Chapter 18).**

2. **Candida.** The treatment of choice for *Candida* meningitis is amphotericin B with or without 5-FC [80,81]. Although there are no studies comparing the efficacy of single and combination therapy, some investigators recommend combination therapy based on more rapid CSF sterilization and possible reduction of long-term neurologic sequelae in newborns. Cure rates with amphotericin B alone have ranged from 67% to 89% in adults and 71% to 100% in neonates. However, up to 56% of surviving neonates had psychomotor retardation and 50% had hydrocephalus [80,81]. Increased mortality in adult patients is associated with a delay of more than 2 weeks from the onset of symptoms to diagnosis, a CSF glucose concentration less than 35 mg/dL, intracranial hypertension, and focal neurologic deficits. Fluconazole may be an acceptable alternative agent for the therapy of *Candida* meningitis [193,194].
3. **Coccidioides immitis.** Based on the results of a collaborative study [195], **fluconazole is recommended as first-line therapy for coccidioidal meningitis.** Fluconazole (400 mg once daily) was given to 50 consecutive patients with coccidioidal meningitis (including 9 with HIV) for up to 4 years (median of 37 months). Of the 47 assessable patients, 37 (79%) responded to treatment, with most improvement occurring within 4 to 8 months. However, 24% had a persistent CSF pleocytosis, indicating a need for careful follow-up. In nonresponders, increasing the dose of fluconazole (commonly done by physicians in endemic areas) or instituting intrathecal amphotericin B might be required. Fluconazole therapy may need to be continued indefinitely.

Amphotericin B was previously used, usually both intravenously and intrathecally [84,85]. Intrathecal administration may be via the lumbar, cisternal, or ventricular routes (i.e., through an Ommaya reservoir); the usual dosage is 0.5 mg three times weekly for 3 months, although 1.0 to 1.5 mg combined with hydrocortisone can be used. Mortality of 50% has been reported, although one study found a survival rate of 91% over after 75 months if larger doses of intrathecal amphotericin B (1.0 to 1.5 mg) were used [196]. Amphotericin is discontinued once the CSF has been normal for at least 1 year on an intrathecal regimen of once every 6 weeks. However, intrathecal amphotericin B is poorly tolerated, often leading to arachnoiditis.

F. Protozoal and helminthic meningitis

1. **Amebae.** Many antimicrobial agents have *in vitro* activity against free-living amebae [87]. These include amphotericin B, the tetracyclines, the imidazoles, qinghaosu, and rifampin. Only four patients reported in the literature have survived after therapy for primary amebic meningoencephalitis [86,87,197]. All received amphotericin B along with various other antimicrobial agents. The best-documented survivor received amphotericin B and miconazole intravenously and intrathecally, as well as rifampin, sulfisoxazole, and dexamethasone. However, no effective regimen has been established. Therapy with parenteral and intracisternal amphotericin B combined with rifampin and tetracycline for 2 to 3 weeks has been suggested.
2. **Angiostrongylus cantonensis.** Symptomatic treatment is indicated for eosinophilic meningitis caused by *A. cantonensis* [86]. Most patients recover within 1 to 2 weeks. Thiabendazole has been used in the early stages of larval migration, but the drug fails as soon as the worm reaches the CNS.

VI. Adjunctive therapy

- A. **Viral meningitis.** Adjunctive measures have been used in seriously ill patients with enteroviral meningitis [1]. Administration of gamma globulin by multiple

routes (including directly into the CNS) has led to stabilization or improvement of agammaglobulinemic patients with chronic enteroviral meningitis or meningoencephalitis. Neonates with overwhelming enteroviral sepsis and meningitis have received intravenous gamma globulin, maternal plasma, and exchange transfusions, with occasional successes [198].

B. Bacterial meningitis

1. Antiinflammatory agents. Despite effective bactericidal antimicrobial agents, morbidity and mortality from bacterial meningitis remain unacceptably high.

a. Animal models. Studies in animal models have demonstrated that development of a subarachnoid space inflammatory response is a major factor contributing to morbidity and mortality [27,96,136,199]. Therefore, investigators have examined whether attenuation of this response would improve outcome. In an experimental rabbit model of *H. influenzae* type b meningitis, treatment with ceftriaxone plus dexamethasone consistently reduced brain water content, CSF pressure, and CSF lactate to a greater degree than ceftriaxone alone, although the differences were not statistically significant. However, it was suggested that adjunctive dexamethasone might be more beneficial if administered early or even before the occurrence of antibiotic-induced bacterial lysis and release of microbial products. Using the same animal model, ceftriaxone administration led to a significant increase in CSF endotoxin concentrations followed by a rise in CSF tumor necrosis factor concentrations. Simultaneous administration of dexamethasone and ceftriaxone did not affect release of endotoxin into CSF but markedly attenuated CSF concentrations of tumor necrosis factor. Adjunctive dexamethasone therapy also resulted in a significant decrease in CSF leukocytosis and a trend toward earlier improvement in CSF concentrations of glucose, lactate, and protein. These parameters improved without any decrease in bacterial killing.

b. Clinical trials. Based on observations in animal models, several clinical trials were undertaken in the late 1980's and early 1990's to determine the effects of adjunctive corticosteroids on outcome in patients with bacterial meningitis [27].

(1) **A recently published meta-analysis of clinical trials from 1988 to 1996 [200] supported the routine use of adjunctive dexamethasone (0.15 mg/kg every 6 hours for 2 to 4 days) in infants and children with *H. influenzae* type b meningitis and, if commenced with or before antimicrobial therapy, suggested a benefit for pneumococcal meningitis of childhood.** Evidence was strongest for hearing outcomes. In contrast, a retrospective nonrandomized study of children with pneumococcal meningitis found that adjunctive dexamethasone was not beneficial [201], although the dexamethasone was administered before or within 1 hour of the first antibiotic dose and children in the dexamethasone group had a higher severity of illness. **When dexamethasone is used, the timing of administration is crucial. Administration of dexamethasone before or concomitant with antimicrobial therapy is recommended** for optimal attenuation of subarachnoid space inflammation; patients should be carefully monitored for the possibility of gastrointestinal hemorrhage.

However, vaccination against *H. influenzae* type b in infancy has decreased the incidence of serious infections due to *H. influenzae* type b by more than 90%. Therefore, most future cases of bacterial meningitis in the United States will be caused by bacteria for which there are only limited data regarding the benefit of adjunctive steroid therapy [202].

(2) **In adults or in patients with meningitis caused by other bacterial organisms, the routine use of adjunctive dexamethasone is not recommended pending results of ongoing studies.** However, some authors recommend its use in all cases of meningitis with a likely bacterial etiology (i.e., demonstrable bacteria on CSF Gram stain, which

may predict the patients at greatest risk of bacteriolysis-induced exacerbation of inflammation) [199], although there are no supportive clinical data. In adults with severely impaired mental status (stupor or coma), documented cerebral edema (e.g., by CT), or markedly elevated intracranial pressure (i.e., high opening pressure on lumbar puncture, palsy of cranial nerve VI), dexamethasone may be beneficial. Use of **dexamethasone is of particular concern in patients treated with vancomycin** for pneumococcal meningitis, because this may significantly reduce CSF vancomycin penetration (see section (4) following).

(3) **In neonates**, clinical trials on the role of corticosteroids in meningitis have not been performed. Therefore, their use is not suggested (see Chapter 3).

(4) **Penetration of antibiotics into the CSF** is becoming a greater concern in treating meningitis caused by penicillin-resistant *S. pneumoniae* (see section **V.B.3** and Chapter 27). In particular, vancomycin penetrates the CSF quite poorly. Furthermore, in a rabbit model, penetration of vancomycin into the CSF was reduced with concomitant dexamethasone therapy, with delayed CSF sterilization. Therefore, in areas where high-level penicillin-resistant *S. pneumoniae* are prevalent and empiric vancomycin is used, steroid therapy may prove harmful [202]. **For any patient receiving adjunctive dexamethasone who is not improving as expected or who has a pneumococcal isolate for which the cefotaxime or ceftriaxone MIC is at least 2.0 $\mu\text{g/mL}$, a repeat lumbar puncture 36 to 48 hours after initiation of therapy is recommended** to document the sterility of CSF [152].

2. Reduction of intracranial pressure. Several methods are available to reduce intracranial pressure [203], including elevation of the head of the bed to 30 degrees to maximize venous drainage with minimal compromise of cerebral perfusion, the use of hyperosmolar agents (e.g., mannitol) to move water from brain tissue into the intravascular compartment, and the use of corticosteroids. In addition, hyperventilation to maintain the PaCO_2 between 27 and 30 mmHg, which causes cerebral vasoconstriction and reduction in cerebral blood volume, has also been used, although some experts have questioned its routine use to reduce intracranial pressure in patients with bacterial meningitis [204]. Infants and children with bacterial meningitis who have initially normal CTs of the head can be treated with hyperventilation to reduce elevated intracranial pressure safely because it is unlikely that cerebral blood flow would be reduced to ischemic thresholds. However, in children with cerebral edema on head CT, cerebral blood flow is more likely to be normal or reduced. Therefore, hyperventilation might decrease intracranial pressure at the expense of cerebral blood flow, possibly reducing the latter to ischemic thresholds. These patients would likely benefit more from early use of diuretics, osmotically dehydrating agents (provided that intravascular volume is protected), and corticosteroids, although controlled trials have yet to be performed. Glycerol, an osmotic dehydrating agent that can be given orally, has been evaluated in 122 infants and children with bacterial meningitis [205]; 7% of the glycerol-treated patients and 19% of those not given glycerol had audiologic or neurologic sequelae ($p = 0.052$). However, further trials are needed before glycerol can be recommended.

Patients in whom elevated intracranial pressures continue despite these measures may be treated with high-dose barbiturates to decrease cerebral metabolic demands and cerebral blood flow [203]. Vasoconstriction in normal tissue also occurs during barbiturate therapy, thereby shunting blood to ischemic tissue and protecting the brain from ischemia. This is of unproven benefit, however, for meningitis and elevated intracranial pressure and must be considered experimental.

3. Basilar skull fracture. Patients who have suffered a basilar skull fracture with CSF leak may have persistent dural defects associated with recurrent episodes of bacterial meningitis. Although many will cease spontaneously, surgery is indicated for leaks that persist for several weeks or in patients who present with

delayed or recurrent infection [42]. Surgery is not indicated in the acute phase (<7 days) of leakage because there is no difference in outcome when patients with acutely repaired leaks are compared with those whose leaks stop spontaneously within 7 days.

4. **Cerebrospinal shunt infections.** All components of an infected CSF shunt should be removed at the beginning of antimicrobial therapy [54] and an external ventriculostomy placed to clear the ventriculitis and monitor CSF parameters. Many organisms can adhere to the prostheses and survive antimicrobial therapy with the shunt left *in situ*. Furthermore, the propensity for the entire shunt to be contaminated when one portion is infected argues against partial revisions. With externalization, treatment success is usually greater than 90% [54].
- C. **Tuberculous meningitis.** Despite chemotherapy inflammation often continues at the base of the brain, with subsequent organization of necrotic tissue and exudate, fibroblastic proliferation, and formation of dense fibrocollagenous tissue compressing adjacent structures and impeding circulation of CSF. **Corticosteroids** are the most commonly advocated adjunctive agents for tuberculous meningitis [61,62,98]; patients frequently defervesce, with clearing of sensorium and improvement in well-being even after only a few doses. Their primary value may be their ability to treat or avert the development of spinal block, possibly by lowering the CSF protein content; an improvement in overall mortality has been ascribed to their effect on this poor prognostic sign. However, an increase in significant neurologic sequelae has been observed in survivors who received corticosteroids. In contrast, a study from Egypt found reduced neurologic complications and case fatality rates in patients who received dexamethasone with antituberculous chemotherapy [206]. Another prospective, controlled, randomized study from the republic of South Africa found that corticosteroids improved survival and intellectual outcome in children with tuberculous meningitis [207]. Despite the controversy, **most authorities advocate the use of corticosteroids in selected cases** with extreme neurologic compromise, elevated intracranial pressure, impending herniation, or impending or established spinal block [61,62]. Some authors also recommend corticosteroids in patients with CT evidence of either hydrocephalus or basilar meningitis. Prednisone (approximately 1 mg/kg/day, tapered over 1 month) often is given, although other doses of dexamethasone or hydrocortisone have been used.
- D. **Fungal meningitis.** Patients with cryptococcal meningitis may have several complications despite antifungal therapy. Increased intracranial pressure and hydrocephalus has been noted in AIDS patients with cryptococcal meningitis, possibly due to increased CSF outflow resistance. Ventriculoperitoneal shunting, frequent high-volume lumbar punctures, acetazolamide, and corticosteroids have been used for these complications. However, the precise roles of these adjunctive measures (particularly corticosteroids) in the treatment of cryptococcal meningitis remain to be established. Shunting procedures can ameliorate the sequelae of elevated intracranial pressure in AIDS patients with cryptococcal meningitis [208–210].

VII. Prevention

- A. **Viral meningitis.** The cornerstone of **prevention of mumps is active immunization** with the live attenuated mumps vaccine [8]. Widespread use of the mumps vaccine has greatly reduced the incidence of mumps and mumps meningoencephalitis. Mumps meningitis has been reported in children 11 days to 2 months after vaccine administration, although it is not clear whether these cases represented vaccine failure or meningitis due to the vaccine strain of mumps virus.
- B. **Bacterial meningitis**
 1. ***Haemophilus influenzae***
 - a. **Chemoprophylaxis.** Several studies have documented the transmission to household contacts. Most secondary cases (75%) of *H. influenzae* type b meningitis occur within 6 days of onset of the index case, although untreated household contacts remain at increased risk for at least 1 month. The risk is markedly age dependent and highest for children younger than 2 years. Daycare outside the home may be another risk factor for transmission [27].

The **rationale for the use of chemoprophylaxis** to prevent secondary disease is eradication of nasopharyngeal colonization of *H. influenzae* type b, thereby preventing transmission to young susceptible contacts [27]. The chemoprophylactic agent of choice is rifampin (20 mg/kg/day, with a maximum dose of 600 mg, for 4 days) for all individuals, including adults, in households with at least one unimmunized or incompletely immunized child younger than 48 months or with an immunocompromised child of any age. Chemoprophylaxis is not recommended for daycare contacts 2 years or older unless two or more cases occur in the daycare center within a 60-day period. For children younger than 2 years, the determination of whether to administer prophylaxis needs to be individualized and should be considered more strongly in daycare centers that resemble households where children have prolonged contact. Rifampin is not recommended for pregnant women, because the risk of rifampin to the fetus has not been established. The index patient should also receive rifampin because some antibiotics (e.g., ampicillin) given for therapy do not eliminate nasopharyngeal colonization. Unimmunized or partially immunized children also should receive a dose of vaccine and be scheduled for completion of the required series.

- b. **Immunoprophylaxis.** The Immunization Practices Advisory Committee [27] recommends that all children should be vaccinated with one of the licensed *H. influenzae* type b conjugate vaccines (see Chapter 23).

2. *Neisseria meningitidis*

- a. **Chemoprophylaxis is recommended for close contacts of the index case, defined as** household contacts, daycare contacts, nursery school contacts, contacts who sleep or eat in the same dwelling, close contacts in a closed community such as a military barracks or boarding school, and anyone directly exposed to the patient's oral secretions (e.g., kissing, mouth-to-mouth resuscitation, endotracheal intubation, or endotracheal tube management) [27,211]. Chemoprophylaxis should be administered to the index case before hospital discharge unless ceftriaxone or cefotaxime were used for therapy.

b. Chemoprophylaxis regimens

- (1) **Rifampin.** The Centers for Disease Control and Prevention currently recommends **rifampin** at 12-hour intervals for 2 days in the following dosages [27,211]: adults, 600 mg; children beyond the neonatal period, 10 mg/kg; and infants younger than 1 month, 5 mg/kg. However, there are several problems with rifampin chemoprophylaxis, including efficacy of only 80% or so, adverse events, need for multiple doses over 2 days, and emergence of resistant organisms (up to 10%–27% of isolates).

- (2) **Alternatives. Ceftriaxone** (250 mg intramuscularly in adults and 125 mg in children) was shown to eliminate the meningococcal serogroup A carrier state in 97% of patients in one study for up to 2 weeks [212], although parenteral administration is required. A single dose of **oral ciprofloxacin** (500 or 750 mg in adults) is also very effective in eliminating the nasopharyngeal carriage of *N. meningitidis*; ciprofloxacin may well supplant rifampin for chemoprophylaxis in adults. Ciprofloxacin is not recommended for persons younger than 18 years because of concerns regarding cartilage damage. **In pregnant patients, ceftriaxone is the safest agent for chemoprophylaxis.**

- c. **Immunoprophylaxis.** The quadrivalent meningococcal vaccine (serogroups A, C, Y, and W135) is currently recommended for certain high-risk patients, including those who are close contacts of the primary case as an adjunct to chemoprophylaxis [27,211], although this is controversial and of unproven efficacy. The vaccine is not recommended for routine use in the United States because of the overall low risk of infection, inability to protect against serogroup B disease, and inability to provide lasting immunity to young children. However, because of an increase in invasive meningococcal disease in adolescents and young adults of high school and college age in the United States, the Advisory Committee on Immunization Practices recommends that college freshman dormitory residents and their parents are given

information about meningococcal vaccination and that other undergraduate students wishing to reduce their risk can also choose to be vaccinated [213] (see Chapter 23).

Conjugate vaccines against serogroups A and C meningococci have been developed. The United Kingdom became the first country to implement routine immunization with a monovalent serogroup C conjugate vaccine (three doses for children aged 2 to 4 months, two doses for children older than 4 months but younger than 1 year, and one dose for all others). In the first 9 months of use in a catch-up immunization program [214], vaccine efficacy was 92% in toddlers and 97% in teenagers.

3. *Streptococcus pneumoniae*

a. Chemoprophylaxis. The risk of secondary pneumococcal disease in contacts of infected patients has not been defined, although outbreaks have been described in closed populations such as gold miners, military recruits, and jail inmates [27]. Further studies are needed before chemoprophylaxis is recommended for contacts of patients with pneumococcal meningitis. Prophylaxis with oral penicillin in patients with sickle cell disease is not usually needed with the availability of the conjugate vaccine.

b. Immunoprophylaxis. The efficacy of the 23-valent pneumococcal vaccine in preventing pneumococcal meningitis has never been documented, although its use in high-risk patients would seem prudent. Vaccination for persons traveling to an area with a significant incidence of resistant pneumococci may also be warranted. The pneumococcal conjugate vaccine is 97.4% effective in preventing invasive pneumococcal disease in children caused by vaccine serotypes and is recommended for all infants less than 2 years of age [215,216]. See further discussion of the pneumococcal vaccine in Chapter 11.

4. Basilar skull fracture. Despite conflicting studies, a recent meta-analysis [217] suggested that **use of prophylactic antibiotics is not recommended** for patients with basilar skull fracture and CSF leak because they do not change the incidence of meningitis and may result in selection of resistant organisms (see Chapter 27).

ENCEPHALITIS

The syndrome of acute encephalitis shares many features with acute meningitis, although the likelihood of mental status changes early in disease before the onset of obtundation or coma is more common in encephalitis. Clinically, seizures are more likely to occur with encephalitis, and associated systemic illness is more prominent [218–221]. Numerous infectious and noninfectious agents have been reported to cause acute encephalitis (see Table 6.1 for agents of meningitis that may also cause encephalitis). Here **we concentrate on encephalitis caused by the herpesviruses, especially HSV, because these represent the most common and only currently treatable forms of viral encephalitis.** For a general review of viral encephalitis, see Whitley [221]; for a discussion of CMV infections of the CNS (which can include an encephalitis) in patients with AIDS, see McCutchan [221a].

I. Epidemiology and etiology

A. Herpes simplex virus. HSV infections of the CNS are among the most common (10%–20% of encephalitis viral infections in the United States) and most severe of all human viral infections of the brain and are associated with significant morbidity and mortality (>70% with ineffective or no therapy) [218]. HSV encephalitis occurs throughout the year (i.e., is nonseasonal) and in patients of all age groups, with whites accounting for 95% of patients with biopsy-proven disease. Most cases (94%–96%) are caused by HSV type 1.

B. Varicella-zoster virus. The actual incidence of CNS involvement during varicella is unknown, although it has ranged from 0.1% to 0.75% [219]. Herpes zoster is a consequence of reactivation of latent varicella-zoster virus; a direct correlation exists between cutaneous dissemination and visceral involvement, including meningoencephalitis. In general, the CNS complications of herpes zoster are associated with a higher morbidity and mortality than those of acute varicella, possibly due to the patient's advanced age and underlying disease status. A variety of varicella-zoster

virus-induced neurologic disorders have been described in AIDS patients, including multifocal leukoencephalitis, ventriculitis, myelitis, myeloradiculitis, and focal brainstem lesions [222].

II. Clinical presentation

- A. Herpes simplex virus.** Most patients with biopsy-proven HSV encephalitis present with an encephalopathic process characterized by **altered mentation and decreasing levels of consciousness with focal neurologic findings**, including dysphasia, weakness, and paresthesias [218]. **Fever and personality changes** are uniformly present. Approximately two-thirds of patients with biopsy-proven disease develop either focal or generalized **seizures**. HSV encephalitis may progress slowly or with alarming rapidity; commonly, there is progressive loss of consciousness leading to coma. Although clinical evidence of a temporal lobe lesion often is believed to be a result of HSV encephalitis, a variety of other diseases has been shown to mimic this condition, including various infections (abscess/subdural empyema), tuberculosis, cryptococcosis, toxoplasmosis, CMV, tumor, and subdural hematoma [177]. Immunocompromised patients with HSV encephalitis may develop more diffuse non-necrotizing encephalitis involving the cerebral hemispheres and brainstem [223].
- B. Varicella-zoster virus.** The most common neurologic abnormality associated with varicella-zoster virus is cerebellar ataxia; although meningoencephalitis and cerebritis are less common, they frequently are more severe [222]. Headache, fever, and vomiting often are accompanied by altered sensorium, with seizures occurring in 29% to 52% of patients. Focal neurologic abnormalities, including cranial nerve dysfunction, aphasia, and hemiplegia, have also been described. Encephalitis, the most common CNS abnormality associated with herpes zoster, is most common in patients of advanced age, after immunosuppression, and in those with disseminated cutaneous zoster. Some patients with ophthalmic zoster present with contralateral hemiplegia; this finding is seen in up to one-third of CNS abnormalities in herpes zoster. The zoster ophthalmicus usually precedes the hemiplegia by several weeks, although it has been reported to occur as late as 6 months after the rash.

III. Diagnosis

A. Herpes simplex virus

- 1. Routine studies of CSF** in patients with HSV encephalitis are **not diagnostic** [218,221]. The CSF white blood cell count is elevated (mean of 100 cells/mm³) in 97% of patients with biopsy-proven disease, with a lymphocytic predominance. The presence of **red blood cells in CSF suggests** the diagnosis but is not definitive. The CSF protein is elevated also (averaging approximately 100 mg/dL). Approximately 5% to 10% of patients with HSV encephalitis have normal CSF studies on first evaluation. Virus is isolated from CSF only 4% or so of the time.
- 2. PCR to detect HSV DNA is highly sensitive and specific** for the diagnosis of HSV encephalitis [224,225]. In one study, the sensitivity and specificity of PCR were 91% and 92%, respectively, in patients with biopsy-proven disease [225]; specificity would have been higher except that some tissue specimens were fixed in formalin, which killed the infectious virus. **The PCR test for HSV in CSF is now the optimal way to diagnose HSV encephalitis** [218].
- 3. Noninvasive studies may be useful** [218,221].
 - a. Electroencephalography** is a sensitive test (approximately 84%) that reveals characteristic spike-and-slow wave activity and periodic lateralizing epileptiform discharges located predominantly over the temporal and frontotemporal regions.
 - b. CTs** show low density areas with mass effect localized to the temporal lobe in 50% to 75% of patients at some time during the course of their illness.
 - c. MRI (with enhancement)** demonstrates lesions earlier and is superior to CT in localizing these lesions to the orbital-frontal and temporal lobes; MRI is considered by experts to be the most important and specific imaging technique for HSV encephalitis [226–228]. HSV encephalitis typically affects the temporal lobes, predominantly their inferior aspects. Involvement is usually asymmetric, and the deep white matter may demonstrate the earliest abnormalities. Some believe a normal MRI would be unusual even in early HSV encephalitis [226].

- d. **Radionuclide brain scans** may reveal increased uptake in both temporal lobes; brain scan is more sensitive than CT early in the disease course.
 - e. However, despite the availability of these diagnostic modalities, **none** is uniformly **satisfactory for the diagnosis of HSV encephalitis**.
4. In the past, the most specific means of diagnosing HSV encephalitis was a **brain biopsy** [218]. The presence of Cowdry type A intranuclear inclusions supports the diagnosis of viral infections, although these are found only in approximately 50% of cases. Brain tissue should also be subjected to immunofluorescence, which is a rapid, sensitive, and reliable method for detecting herpes antigen; virus can also be isolated from brain tissue. With the availability of PCR studies on CSF, brain biopsy now is seldom indicated (see section 2).
- B. Varicella-zoster virus.** The CSF often is abnormal in varicella-associated encephalitis with a lymphocytic pleocytosis and elevated protein [222]. The electroencephalogram usually reveals diffuse abnormalities (e.g., diffuse slowing), although focal abnormalities may occur even without seizure activity. With herpes zoster-associated encephalitis, the CSF also usually reveals a lymphocytic pleocytosis and elevated protein; however, up to 40% to 50% of patients with uncomplicated herpes zoster (i.e., without CNS involvement) may have a mild CSF pleocytosis or elevated protein. The virus has been cultured from brain tissue and CSF, detected by PCR, and viral inclusions are well-described in autopsy series. In patients with zoster ophthalmicus with contralateral hemiplegia, a unilateral arteritis or thrombosis of involved vessels may be seen on cerebral angiography and cerebral infarction may be seen on CT or MRI.
- IV. Approach to the patient with viral encephalitis.** Despite the number of viral organisms that may cause encephalitis, herpes simplex remains the only viral CNS infection for which therapy (i.e., acyclovir) is beneficial. Based on the ease of administration and good safety profile of acyclovir, an empiric course should be administered for patients with presumed viral encephalitis [221]. The availability of PCR will eliminate the need for biopsy in most instances, although in unusual cases it may be indicated. MRI is important when encephalitis is suspected [226,228]. Infectious disease consultation is advised.
- V. Antimicrobial therapy**
- A. Herpes simplex virus.** In biopsy-proven HSV encephalitis, **acyclovir** reduced mortality (19%) compared with vidarabine (55%), the previously accepted therapy [229]. Furthermore, 38% of patients in the acyclovir group returned to a normal level of functioning compared with only 15% to 20% of patients in the vidarabine group. In a recent study of 42 patients with HSV encephalitis, 30% died or had a severe neurologic deficit [230]; of the remaining 70%, most had persistent neurologic signs and/or symptoms. Acyclovir should be administered intravenously at a dosage of 10 mg/kg every 8 hours in patients with normal renal function. Although many patients have been treated for 14 days, many experts now prefer a 14- to 21-day course [231].
- B. Varicella-zoster virus.** Intravenous acyclovir is also the drug of choice for patients with varicella-zoster virus-associated CNS infection who are at high risk for progressive disease [232]. Although no clinical trial has established the value of antiviral therapy of herpes zoster-associated encephalitis, we believe acyclovir should be used in this setting.
- C. Other viruses.** Although ganciclovir or foscarnet commonly is given to HIV-infected patients with CNS symptoms, proof of efficacy against cytomegaloviral CNS disease is lacking. No therapy is of proven benefit for Epstein-Barr virus disease. The treatment of arboviral infections (e.g., eastern or western equine encephalitis, St. Louis encephalitis) is supportive.

BRAIN ABSCESS

I. Epidemiology and etiology

- A. Bacteria.** The likely bacterial species responsible for brain abscess formation depends on the pathogenic mechanism involved [233–235]. The most common are streptococci (aerobic, anaerobic, and microaerophilic), isolated in 60% to 70% of abscesses. These bacteria, particularly the *S. milleri* (also called *S. intermedius*) group, are normal inhabitants of the oral cavity, appendix, and female genital tract and have a

proclivity for abscess formation. *S. aureus* is isolated from brain abscess in 10% to 15% of patients, usually those with endocarditis or cranial trauma. The isolation of anaerobes has increased with use of proper techniques; *Bacteroides* species are isolated in 20% to 40% of cases, often in mixed culture. The enteric gram-negative bacilli (e.g., *E. coli*, *Klebsiella* species, *Pseudomonas* species) are isolated in 23% to 33% of cases; these usually are seen with otitic foci of infection or in the immunocompromised patient. Other bacterial species are isolated much less frequently (<1% of cases) and include *H. influenzae*, *S. pneumoniae*, and *L. monocytogenes*. In addition, *Nocardia* species are more often isolated in patients with defects in cell-mediated immunity, as in patients receiving corticosteroid therapy, in organ transplant recipients, and in patients with neoplastic disorders; some *Nocardia* cases have also been described in patients with AIDS.

B. Fungi. Many of the etiologic agents of fungal meningitis (see section I.E under Meningitis) may also cause brain abscesses [185]. For example, although *Candida* species may produce meningitis, focal CNS disease is more common. Indeed, *Candida* is the most common fungal species to cause brain abscess (often multiple, not macroscopic). However, several other fungal species need to be considered, especially in the immunocompromised host. For further discussion see Chapter 17.

1. Aspergillus species. Intracranial seeding of *Aspergillus* species occurs during dissemination of the organism from the lungs or by direct extension from a site anatomically adjacent to the brain [236]. The brain is involved in 40% to 70% of cases with disseminated disease. Most patients with *Aspergillus* brain abscesses are neutropenic and have an underlying hematologic malignancy. Other risk groups include patients with Cushing syndrome, diabetes mellitus, hepatic disease, and chronic granulomatous disease. Injection drug users, postcraniotomy patients, organ transplant recipients, HIV-infected patients, and patients receiving chronic corticosteroid therapy are also at risk.

2. Mucormycosis. Mucormycosis is one of the most fulminant fungal infections known [236]. Predisposing conditions include diabetes mellitus (70% of cases), usually in association with acidosis; acidemia from other profound systemic illness; hematologic neoplasia; renal transplantation; injection drug use; and use of deferoxamine. Fewer than 5% of cases involve otherwise normal healthy patients. CNS disease may result from direct extension (i.e., the rhinocerebral form) or by hematogenous dissemination from other sites of infection. Most infections are caused by the genus *Rhizopus*, and the genera *Absidia* and *Mucor* also have been isolated.

3. Pseudallescheria boydii. CNS disease may occur in both normal and immunocompromised hosts. This organism is being increasingly referred to as *Scedosporium apiospermum*, the asexual form of *P. boydii*. The organism may enter the CNS by direct trauma, by hematogenous dissemination from a primary site of infection, via an intravenous catheter, or by direct extension from infected sinuses [236,237]. Because of the presence of *P. boydii* in contaminated water and manure, there is an association between near-drowning and subsequent illness [238,239].

II. Clinical presentation

A. Bacterial brain abscess may have either an indolent or fulminant course [233–235].

1. The clinical manifestations occur secondary to the presence of a space-occupying mass lesion rather than systemic signs of infection. Findings include **headache (70%)**, which may be moderate to severe and hemicranial or generalized; **nausea and vomiting (50%)**, presumably due to increased intracranial pressure; **seizures (25%–35%)**, which usually are generalized; and **nuchal rigidity and papilledema (25%)**. Most patients also have **mental status changes**, ranging from lethargy to coma. **Focal neurologic deficits** are seen in approximately 50% of cases and will vary depending on the location of brain involved.

2. Fever is observed in only 45% to 50% of cases. Only approximately half of patients present with the triad of headache, fever, and focal neurologic deficit.

3. The clinical presentation of brain abscess also depends on the intracranial location [233]. For example, frontal lobe abscess often presents with headache, drowsiness, inattention, and deterioration of mental status; hemiparesis with

unilateral motor signs and a motor speech disorder also are common. Patients with cerebellar abscesses present with ataxia, nystagmus, vomiting, and dysmetria. Temporal lobe abscesses may cause headache, aphasia, or a visual field defect (e.g., upper homonymous quadrantanopia). Abscesses of the brainstem usually present with facial weakness, fever, headache, hemiparesis, dysphagia, and vomiting [190].

B. Fungal brain abscess. The clinical presentation of fungal brain abscess is similar to that caused by bacteria and depends on the intracranial location of the abscess and the fulminant nature of the organisms [236]. However, patients with certain fungal pathogens may present with specific symptoms and signs.

1. ***Aspergillus* species.** Patients most commonly present with signs of a stroke referable to the area of involved brain. Headache, encephalopathy, and seizures have also been described. Fever is not a constant finding, and meningeal irritation is rare.
2. **Mucormycosis.** Symptoms from rhinocerebral mucormycosis are referable to the eyes or sinuses and include headache (often unilateral), facial pain, diplopia, lacrimation, and nasal stuffiness or discharge; fever and lethargy have also been described [236]. Signs include development of a nasal ulcer, facial swelling, nasal discharge, proptosis, and external ophthalmoplegia. Orbital involvement is seen in two-thirds of patients. Cranial nerve abnormalities are also common. Because of the proclivity of the organism for blood vessel invasion, thrombosis is a striking feature of disease. Focal neurologic findings (e.g., hemiparesis, seizures, monocular blindness) suggest far-advanced disease. Invasion and occlusion of the cavernous sinus and carotid artery can occur as the disease progresses.
3. ***Pseudallescheria boydii*.** CNS infection with *P. boydii* usually becomes manifest 15 to 30 days after an episode of near-drowning but has varied [237–239]. Clinical presentation depends on localization in the CNS and includes seizures, altered consciousness, headache, meningeal irritation, focal neurologic deficits, abnormal behavior, and aphasia.

III. Diagnosis

A. Bacterial brain abscess. The diagnosis of brain abscess was revolutionized by the availability of CT, which is excellent for examining the brain parenchyma and the paranasal sinuses, mastoids, and middle ear [233,234]. Typically, CT reveals a hypodense lesion with a peripheral uniform ring of contrast enhancement. There may also be a surrounding hypodense area of brain edema. **MRI is now the first imaging procedure of choice** for patients suspected of having this disorder [240]. MRI offers significant advantages over CT, including the early detection of cerebritis, detection of cerebral edema with greater contrast between edema and brain, more conspicuous spread of inflammation into the ventricles and subarachnoid space, and earlier detection of satellite lesions. Administration of the paramagnetic agent gadolinium diethylenetriamine penta-acetic acid permits clear differentiation of the central abscess, surrounding enhancing rim, and cerebral edema.

B. Fungal brain abscess. Noninvasive studies (e.g., CSF examination, CT, MRI) for the diagnosis of fungal brain abscess usually are nonspecific, although some exceptions do exist [236]. For example, the finding of a cerebral infarct in a patient with risk factors for invasive aspergillosis suggests that diagnosis; such an infarction typically develops into either single or multiple abscesses. In rhinocerebral mucormycosis, CT and MRI typically show sinus opacification, erosion of bone, and obliteration of deep fascial planes; cavernous sinus involvement may also be seen on MRI. In injection drug abusers with cerebral mucormycosis, the most frequent site of CNS disease is the basal ganglia.

Definitive diagnosis of fungal brain abscess requires biopsy with appropriate fungal stains [236]. The mucicarmine stain will specifically identify *C. neoformans*. *Aspergillus* species appear as septate hyphae with acute-angle dichotomous branching, whereas typical nonseptate hyphae with right-angle branching are seen in mucormycosis. *P. boydii* appears as septate hyphae in clinical specimens, although the hyphae are narrower and do not show the dichotomous branching seen in aspergillosis. Fluorescent antibody staining is also a sensitive method for identifying *P. boydii*.

Table 6.6. Empiric Antimicrobial Therapy for Bacterial Brain Abscess

Predisposing Condition	Usual Bacterial Isolates	Antimicrobial Regimen
Otitis media or mastoiditis	Streptococci (anaerobic or aerobic), <i>Bacteroides</i> spp., Enterobacteriaceae	Metronidazole + a third-generation cephalosporin ^a
Sinusitis (frontoethmoidal or sphenoidal)	Streptococci, <i>Bacteroides</i> spp., Enterobacteriaceae, <i>Staphylococcus aureus</i> , <i>Haemophilus</i> spp.	Vancomycin + metronidazole + a third-generation cephalosporin ^a
Dental sepsis	Mixed <i>Fusobacterium</i> and <i>Bacteroides</i> spp., streptococci	Penicillin + metronidazole
Penetrating trauma or postneurosurgery	<i>S. aureus</i> , streptococci, Enterobacteriaceae, <i>Clostridium</i>	Vancomycin + a third-generation cephalosporin ^a
Congenital heart disease	Streptococci, <i>Haemophilus</i> spp.	Penicillin + a third-generation cephalosporin ^a
Lung abscess, empyema, bronchiectasis	<i>Fusobacterium</i> , <i>Actinomyces</i> , <i>Bacteroides</i> spp., streptococci, <i>Nocardia asteroides</i>	Penicillin + metronidazole + a sulfonamide ^b
Bacterial endocarditis	<i>S. aureus</i> , streptococci	Vancomycin + gentamicin or nafcillin + ampicillin + gentamicin

^a Cefotaxime or ceftriaxone; ceftazidime or cefepime is used if *Pseudomonas aeruginosa* is suspected.

^b Trimethoprim-sulfamethoxazole; include if *N. asteroides* is suspected.

IV. Approach to the patient with brain abscess

A. Microbiologic diagnosis. When a brain abscess is suggested by radiologic studies, a microbiologic diagnosis ideally should be made to guide antimicrobial therapy. CT has made it possible to perform stereotactically guided abscess aspiration. Specimens should be sent for Gram stain, aerobic and anaerobic cultures, Ziehl-Neelsen stain for *Mycobacteria*, modified acid-fast stain for *Nocardia*, and silver stains for fungi. Cultures for *Mycobacteria*, *Nocardia*, and fungi should also be performed.

B. Empiric antibiotic therapy. In patients with bacterial brain abscess, once a diagnosis is made either presumptively by radiologic studies or by CT-guided aspiration of the lesion, antimicrobial therapy should be initiated [233–235]. If an aspiration cannot be performed or if Gram staining is unrevealing, **empiric therapy should be initiated based on the presumed pathogenic mechanism of abscess formation** (Table 6.6).

- 1. Streptococci.** Because of the high rate of isolation of streptococci, especially the *S. milleri* group, from brain abscesses of different etiologies, high-dose intravenous **penicillin G** or another drug active against these organisms (e.g., a third-generation cephalosporin, either cefotaxime or ceftriaxone) should be included.
- 2. Anaerobes.** Although penicillin G is active also against most anaerobes, *Bacteroides fragilis* is an exception that may be isolated in a high percentage of cases. **Metronidazole** is the agent of choice against *B. fragilis* in this setting. Metronidazole attains high concentrations in brain abscess pus, and its entry into brain abscesses is not altered by concomitant administration of corticosteroids.
- 3. Enterobacteriaceae.** A **third-generation cephalosporin** or trimethoprim-sulfamethoxazole should be used when members of the Enterobacteriaceae family are suspected. Ceftazidime or cefepime is the agent of choice for *P. aeruginosa* brain abscess.
- 4. S. aureus.** Nafcillin should be used when *S. aureus* is considered likely (e.g., staphylococcal endocarditis, cranial trauma); vancomycin is reserved for patients allergic to penicillin or when methicillin-resistant organisms are suspected or isolated.

Table 6.7. Antimicrobial Therapy for Brain Abscess

Organism	Standard Therapy	Alternative Therapies
<i>Actinomyces</i> species	Penicillin G	Clindamycin
<i>Aspergillus</i> species	Amphotericin B ^a	Itraconazole ^b , voriconazole ^c
<i>Bacteroides fragilis</i>	Metronidazole	Chloramphenicol, clindamycin, ampicillin-sulbactam
<i>Candida</i> species	Amphotericin B ^a	Fluconazole ^b
<i>Cryptococcus neoformans</i>	Amphotericin B ^a	Fluconazole
Enterobacteriaceae	Third-generation cephalosporin ^d	Aztreonam, trimethoprim-sulfamethoxazole, fluoroquinolone, meropenem
<i>Fusobacterium</i> species	Penicillin G	Metronidazole
<i>Haemophilus</i> species	Third-generation cephalosporin ^d	Aztreonam, trimethoprim-sulfamethoxazole
<i>Listeria monocytogenes</i>	Ampicillin or penicillin G ^e	Trimethoprim-sulfamethoxazole
<i>Nocardia asteroides</i>	Trimethoprim-sulfamethoxazole or sulfadiazine	Minocycline, imipenem, a third-generation cephalosporin ^d , fluoroquinolone ^b
<i>Pseudallescheria boydii</i>	Voriconazole	Fluconazole ^b , itraconazole ^b , miconazole
<i>Pseudomonas aeruginosa</i>	Ceftazidime ^e or cefepime ^e	Aztreonam ^b , fluoroquinolone ^b , meropenem ^b
<i>Staphylococcus aureus</i>		
Methicillin-sensitive	Nafcillin or oxacillin	Vancomycin
Methicillin-resistant	Vancomycin	
<i>Streptococcus milleri</i> , other streptococci	Penicillin G	Third-generation cephalosporin ^d , vancomycin

^a Addition of flucytosine should be considered.

^b Efficacy not yet proven in brain abscess due to this organism.

^c May become the agent of choice.

^d Cefotaxime or ceftriaxone.

^e Addition of an aminoglycoside should be considered.

5. *Nocardia*. When a *Nocardia* species is suspected or proven, trimethoprim-sulfamethoxazole should be used [233]. Alternative agents include minocycline, amikacin, imipenem, the third-generation cephalosporins, and the fluoroquinolones. Combination therapies have been used in *Nocardia* brain abscess, and combination regimens containing a third-generation cephalosporin or imipenem along with a sulfonamide should be considered for immunocompromised patients or those in whom therapy fails [234] (see Chapter 17).

C. Modification of antibiotics after culture data. If positive cultures are obtained, antimicrobial therapy can be modified for optimal treatment (Table 6.7). Dosages of antimicrobial agents for CNS infections are shown in Tables 6.4 and 6.5.

D. Surgical therapy

1. Most bacterial brain abscesses require surgical excision for optimal therapy (see section 2 below for exceptions) [233,234]. Abscess aspiration by stereotactic CT guidance affords the surgeon rapid, accurate, and safe access to virtually any intracranial location and allows for swift relief of increased intracranial pressure. However, **aspiration has the major disadvantage of incomplete drainage of multiloculated lesions.** Complete abscess excision can be used when aspiration is unsuccessful and when abscesses exhibit gas on radiologic evaluation. Emergent surgery is indicated in patients developing worsening neurologic deficits. Excision is contraindicated in the early stages before a capsule is formed. All brain abscesses more than 2.5 cm in diameter should be aspirated or excised for optimal management [241].

- 2. Certain patients may require only medical therapy** [242,243]. Among these are patients with medical conditions that increase risk of surgery, multiple abscesses, abscesses in a deep or dominant location, concomitant meningitis or ependymitis, early abscess reduction with clinical improvement after antimicrobial therapy, and an abscess measuring less than 3 cm.
- E. Duration of antibiotic therapy.** High-dose intravenous antimicrobial therapy should be continued for 6 to 8 weeks; this often is followed by oral antimicrobial therapy if appropriate agents are available. A shorter course of therapy (i.e., 3 to 4 weeks) may be appropriate for patients who have undergone complete surgical excision of the abscess.
- Nocardial brain abscess should be treated for 3 to 12 months [233]. Surgical excision should also be performed for optimal therapy.
- F. Fungal brain abscess.** A combined medical and surgical approach usually is required for optimal treatment of fungal brain abscesses.
- 1. *Aspergillus* species.** Successful management for *Aspergillus* brain abscess includes excisional surgery or drainage in combination with antifungal therapy. Medical therapy is amphotericin B 0.8 to 1.25 mg/kg/day, with doses up to 1.5 mg/kg/day depending on the clinical response [244], although few instances of survival have been reported. Total doses of 3 g or more of amphotericin B are required. The addition of 5-FC may increase success rates, although no controlled trials have demonstrated the efficacy of this approach. Itraconazole has *in vitro* activity against *Aspergillus*, and high-dose therapy (800 mg daily for 5 months followed by 400 mg daily for 4.5 months) resulted in resolution of cerebral abscesses caused by *A. fumigatus* in an elderly asthmatic patient who was treated with corticosteroids [245]. Voriconazole has had mixed (though favorable when compared with historical data) results in open label trials [246].
 - 2. Mucormycosis.** Therapy of mucormycosis includes amphotericin B, correction of underlying metabolic derangements, and aggressive surgical debridement [235]. Surgery is essential because of the propensity of this organism to invade blood vessels and impede delivery of antifungal agents to the sites of infection. A possible adjunct to therapy is hyperbaric oxygen, although no prospective controlled studies have been performed to assess its efficacy. Anecdotal experience with use of granulocyte colony-stimulating factor has shown benefit; granulocyte colony-stimulating factor needs to be explored as potential adjunctive therapy in this disease.
 - 3. *Pseudallescheria boydii*.** *P. boydii* exhibits *in vitro* resistance to amphotericin B. Miconazole has been the antifungal agent of choice [236,237], although intravenous or intrathecal administration is required and relapses are common. One case of *P. boydii* brain abscess was successfully treated with voriconazole and aggressive surgical intervention [247]. We consider voriconazole to be the agent of choice (Table 6.7). Surgical drainage is the cornerstone of effective therapy.

7. EYE INFECTIONS

Marlene L. Durand

Eye infections include infections of the globe of the eye (e.g., keratitis, endophthalmitis) and infections of the surrounding tissues (e.g., lid infections, orbital cellulitis). The primary care physician is often the first physician to see a patient with an eye infection, but for conditions other than simple conjunctivitis, an ophthalmologist should be consulted. Many eye infections produce loss of vision if not correctly diagnosed and treated.

EYELID INFECTIONS

I. Anatomy. Each eyelid contains glands of Zeis (sebaceous) and Moll (sweat) adjacent to eyelash follicles (Fig. 7.1) and meibomian glands (sebaceous) within the tarsal plate (Fig. 7.2). The tarsal plate is the fibrous “skeleton” of each eyelid.

II. Hordeolum

A. Clinical characteristics. A hordeolum is an acute infection of either a meibomian gland (internal hordeolum) or a gland of Zeis (external hordeolum, also called a sty). An internal hordeolum is a painful erythematous papule that points to the inner surface of the lid, whereas a sty forms at the lid margin. The most common pathogen is *Staphylococcus aureus*.

B. Treatment

1. Apply warm compresses every 4 to 6 hours.
2. Apply topical antibiotic ointment (e.g., bacitracin) daily at bedtime.
3. If no response, incision and drainage should be considered.

III. Chalazion

A. Clinical characteristics. A chalazion is a firm painless papule on the inner surface of the eyelid. It arises within a meibomian gland as a result of a sterile inflammatory response to a previous hordeolum or to inspissated sebum. Most resolve within 1 month, but some require an intralesional injection of steroids. A sebaceous cell carcinoma of the eyelid may be mistaken for a recurrent chalazion.

B. Treatment. Intralesional steroids (triamcinolone acetonide) or surgical excision may be required.

IV. Marginal blepharitis.

A. Clinical characteristics. Marginal blepharitis is a diffuse inflammation of the eyelid margins. It is usually due to hypersecretion of sebum by the meibomian glands; superinfection with *S. aureus* may play a role. It may be mild, with only hyperemia and scaling at the lid margins (seborrheic blepharitis), or more severe, with destruction of the lash follicles and tiny lid margin ulcerations (ulcerative blepharitis). It is typically chronic and remitting and may be associated with seborrheic dermatitis or rosacea. Chronic blepharitis is one of the most common conditions seen by ophthalmologists [1].

B. Treatment. Gently scrub eyelids with warm water and baby shampoo twice daily. With acute inflammation, apply bacitracin ointment twice daily for 1 to 2 weeks. If there is associated rosacea, give oral tetracycline, 250 mg once daily for several months.

INFECTIONS OF THE LACRIMAL SYSTEM

I. Anatomy. Tears are produced primarily by the **lacrimal gland** (Fig. 7.3). They drain through **canaliculi** into the **lacrimal sac** and then drain into the nose beneath the inferior turbinate.

II. Dacryoadenitis

A. Clinical characteristics. Dacryoadenitis, or infection of the lacrimal gland, is rare. Acute dacryoadenitis presents as a tender, warm, red swelling of the lateral portion of the upper eyelid. Etiologies include *S. aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and Epstein-Barr virus, mumps, and adenovirus. Epstein-Barr virus can cause unilateral or bilateral dacryoadenitis [2]. Chronic dacryoadenitis is very rare and presents as a painless swelling of the gland. It is most often caused by viruses (e.g., mumps, Epstein-Barr virus, cytomegalovirus, coxsackievirus) but may be due to tuberculosis or syphilis. More common causes of

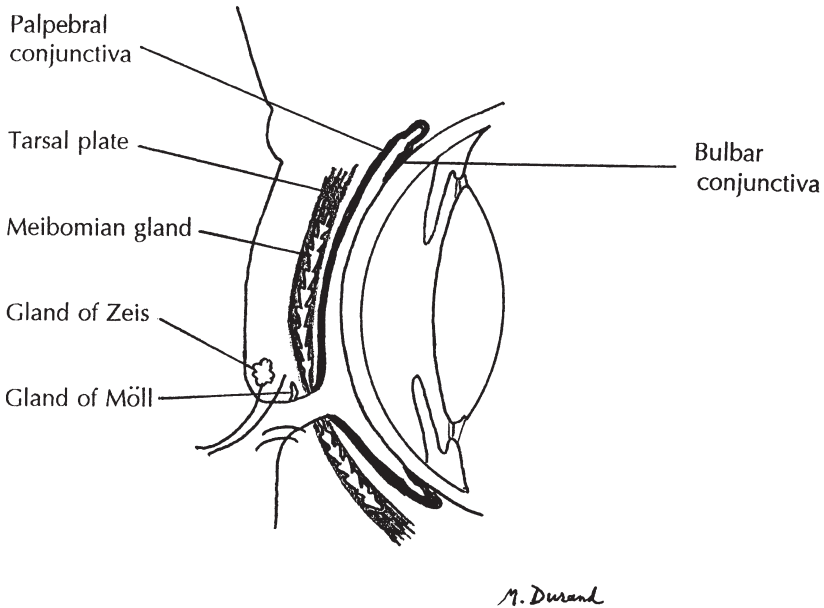

FIG. 7.1 Sagittal section of the eyelids and anterior eyeball.

chronic enlargement of the lacrimal gland are autoimmune disorders (e.g., Sjögren syndrome or sarcoidosis) and tumors.

- B. Treatment.** For probable bacterial infections, an intravenous (i.v.) antibiotic (e.g., cefuroxime) active against the bacteria listed above is used for the first few days, followed by an oral antibiotic (e.g., cefuroxime or amoxicillin-clavulanate) to complete 10 to 14 days of therapy.

FIG. 7.2 The meibomian, or tarsal, glands of the eyelids. (From Last R.J. *Eugene Wolff's anatomy of the eye and orbit*. Edinburgh: Churchill Livingstone, 1976, with permission.)

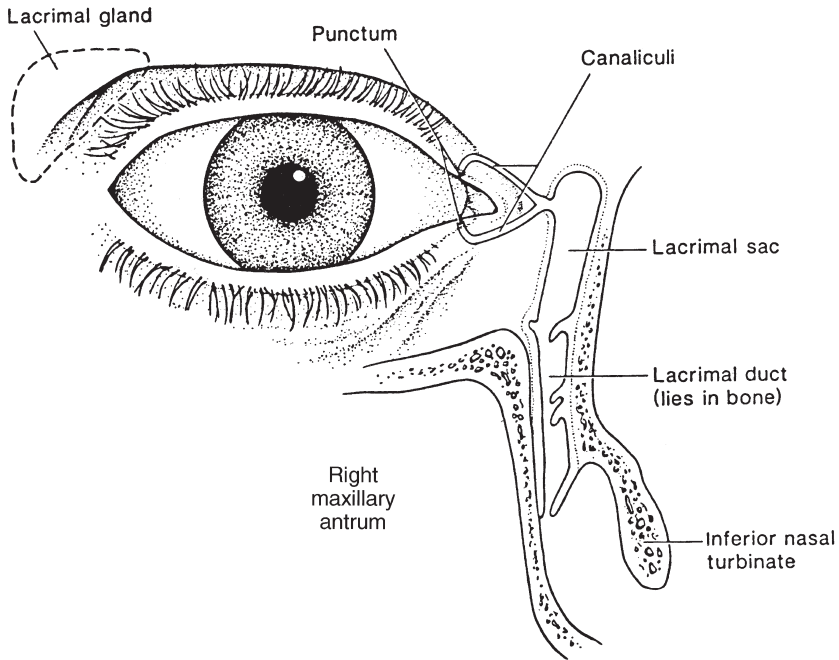

FIG. 7.3 The lacrimal system. (Modified from Barza M, Baum J. Ocular infections. *Med Clin North Am* 1983;67:131–152, with permission.)

III. Canaliculitis

A. Clinical characteristics. Canaliculitis is an inflammation of the canaliculi. The puncta are swollen, red, and pruritic (“pouting punctum”), and the involved eye has **epiphora** (excessive tearing). The most common pathogen is *Actinomyces israelii*. Yellow “sulfur granules” composed of aggregates of these organisms may be expressed from the puncta.

B. Treatment. Irrigation through the involved punctum (performed by an ophthalmologist).

IV. Dacryocystitis

A. Clinical characteristics. The most common infection of the lacrimal system is acute dacryocystitis (lacrimal sac infection). It usually results from obstruction of the lacrimal duct. The patient typically has epiphora for several months and then develops a painful, red, swollen, fluctuant area in the nasal corner of the eye. Common causes are *S. aureus*, *Streptococcus pyogenes*, *S. pneumoniae* (in infants), and *H. influenzae* (in children).

B. Treatment

1. Apply warm compresses every 2 to 4 hours.
2. Give systemic antibiotics for *S. aureus* and streptococci and, in children, for those plus *S. pneumoniae* and *H. influenzae* (e.g., Augmentin or i.v. Unasyn, depending on severity).
3. Consult an ophthalmologist for possible incision and drainage.

RED EYE

Red eye is a sign rather than a clinical entity. It is the most common ocular condition presenting to primary care physicians. Although it may be due to nonspecific conjunctivitis, a red eye may be the first sign of a serious eye condition. Conjunctivitis is **not** characterized by a decrease in vision or deep eye pain. If these symptoms are present, the patient should

Table 7.1. Differential Diagnosis of the Common Causes of an Acute Red Eye

	Conjunctivitis	Iritis ^a	Glaucoma ^b	Corneal Trauma/Infection
Incidence	Extremely common	Common	Uncommon	Common
Discharge	Moderate to copious	None	None	Watery or purulent
Vision	No effect	Slightly blurred	Markedly blurred	Usually blurred
Pain	None	Moderate	Severe	Moderate to severe
Conjunctival injection	Diffuse; more toward fornices	Mainly circumcorneal	Diffuse	Diffuse
Cornea	Clear	Usually clear	Steamy	Change in clarity related to cause
Pupil size	Normal	Small	Moderately dilated and fixed	Normal
Pupillary light response	Normal	Poor	None	Normal
Intraocular pressure	Normal	Normal	Elevated	Normal
Smear	Causative organisms	No organisms	No organisms	Organisms found only in corneal ulcers due to infection

^aAcute anterior uveitis.

^bAngle-closure glaucoma.

From Vaughan D, Asbury T, Riordan-Eva P, eds. *General ophthalmology*, 13th ed. Norwalk, CT: Appleton & Lange, 1992, with permission.

see an ophthalmologist immediately. Table 7.1 lists the differential diagnoses of an inflamed eye. Note the redness of conjunctivitis, due to dilation of the superficial conjunctival vessels, is most intense peripherally. Redness that is most intense centrally around the corneal edge (paralimbal injection or “ciliary flush”) is due to dilation of a deeper episcleral vascular plexus and indicates serious eye disease.

CONJUNCTIVITIS

Infectious conjunctivitis is the most common eye infection seen by the primary care physician. Distinguishing viral from bacterial conjunctivitis is difficult. Equally important is distinguishing these from other causes of red eye, as noted earlier. Most cases of acute conjunctivitis occur in young children, in whom *H. influenzae*, *S. pneumoniae*, and adenoviruses account for most cases [3]. Chlamydiae are intracellular bacteria, but for purposes of clarity chlamydial and bacterial infections are considered separately below.

I. Anatomy. The conjunctiva (Fig. 7.1) is a thin translucent mucous membrane that lines the eyelids (palpebral conjunctiva) and covers the anterior sclera, or “whites of the eyes” (bulbar conjunctiva). It does not cover the cornea but merges with the corneal epithelium at the **limbus** (corneal–scleral border). Goblet cells scattered in the conjunctiva add mucus to the tear film that lubricates the eye.

II. General clinical characteristics. Symptoms of conjunctivitis are similar regardless of etiology. Initially, there is mild to moderate unilateral discomfort—itching, burning, and discharge—that within a few days spreads to the other eye (except in hyperacute conjunctivitis, when symptoms progress rapidly).

A. Significant pain is not present. A painful red eye suggests a different diagnosis.

B. True visual impairment is not present. A thick conjunctival discharge may cloud vision, but this clears with blinking.

C. Distinction between viral and bacterial conjunctivitis. Viral conjunctivitis typically has a minimal conjunctival discharge that is clear, has follicles that are visible in the palpebral conjunctiva, and often has preauricular adenopathy. In bacterial conjunctivitis, discharge is thick and causes lids to stick together in the morning, the palpebral conjunctiva has papillae but not follicles, and preauricular adenopathy is absent.

1. **Follicles** are foci of lymphoid hyperplasia within the palpebral conjunctiva that give it a pebbly appearance. They are typical of viral or chlamydial infections. Children younger than 3 years lack conjunctival lymphoid tissue. Follicles do not form.
2. **Papillae** may be similar to follicles in appearance, but papillae have a central tuft of blood vessels seen with magnification and follicles are encircled by a blood vessel. Fine papillae, characteristic of bacterial or chlamydial infection, give the palpebral conjunctiva a smooth, red, velvety appearance. Giant papillae suggest a type of allergic conjunctivitis (vernal keratoconjunctivitis) or a reaction to contact lenses.

III. Viral conjunctivitis

A. Clinical characteristics. Viral is more common than bacterial conjunctivitis in developed countries. Preauricular lymphadenopathy, conjunctival follicles, and a thin watery discharge are characteristic of viral conjunctivitis.

1. **Adenovirus** is the most common cause of viral conjunctivitis. There are three manifestations. **Nonspecific follicular conjunctivitis** is the typical mild adenoviral conjunctivitis that resolves in 7 to 10 days. **Pharyngoconjunctival fever** is most often caused by serotypes 3, 4, and 7. It is transmitted through respiratory droplets, fomites, or through poorly chlorinated swimming pools. After an incubation period of 5 to 12 days, patients develop fever, pharyngitis, and conjunctivitis first in one eye followed in 1 to 3 days by disease in the other. **Epidemic keratoconjunctivitis (EKC)** is most often caused by serotypes 8 and 19. It is highly contagious. Outbreaks have originated in eye clinics [4]. Virus may be transmitted by unwashed hands [5] and can persist on doorknobs for up to 2 months. Incubation period is about 8 days. EKC usually affects young adults during fall and winter months, and in contrast with pharyngoconjunctival fever, conjunctivitis is unilateral in two-thirds of patients. There are no associated systemic symptoms. EKC is often painful due to corneal involvement (keratitis) in (80%) that occurs after 6 to 10 days [6]. Although conjunctivitis and pain resolve in 2 to 3 weeks, the keratitis may cause photophobia and decreased vision for months.
2. **Herpes simplex virus (HSV)** is a rare cause of follicular conjunctivitis alone, because it usually involves the cornea as well. It may be mistaken for EKC in the acute stage [7]. However, in HSV herpetic vesicles may often be found on the eyelids and lid margins (see section III under Infectious Keratitis and Chapter 4).
3. **Acute hemorrhagic conjunctivitis** is caused primarily by highly contagious enterovirus type 70 and a variant of coxsackievirus type A24. Recent outbreaks have occurred primarily in humid climates (e.g., India, Singapore). A large outbreak occurred in fall 1998 in the U.S. Virgin Islands [8]. The incubation period is short (8 to 48 hours), and disease lasts 5 to 7 days. It is characterized by subconjunctival hemorrhages, marked eyelid edema, tearing, and foreign body sensation.
4. **Molluscum contagiosum** is caused by an unidentified pox virus and is more common in patients infected with human immunodeficiency virus. The umbilicated lesions are common on the eyelids and may cause a chronic follicular conjunctivitis.
5. **Miscellaneous.** Conjunctivitis may be a component of other viral infections, such as influenza, varicella, rubella, rubeola, infectious mononucleosis, cytomegalovirus, and herpes zoster ophthalmicus. The conjunctival inflammation in these conditions, however, is usually a minor manifestation of a more generalized infection.

B. Diagnosis is based on clinical features (Table 7.2), although distinguishing viral from bacterial conjunctivitis may be difficult. Viral cultures are rarely indicated in

Table 7.2. Features That Distinguish the Common Causes of Conjunctivitis

Feature	Bacterial Conjunctivitis	Viral Conjunctivitis	Chlamydial Conjunctivitis
Conjunctival injection	Moderately severe	Minimal	Absent or minimal
Exudate	Moderate to profuse (polymorphonuclear)	Minimal (usually mononuclear)	Minimal in adults, copious in newborns
Sticking of lids on awakening	Yes	No	Absent in adults, present in newborns
Papillae (palpebral conjunctiva)	Present	Usually absent	May be present
Follicles (palpebral conjunctiva)	Usually absent	Present	Present in adults, absent in newborns
Preauricular lymphadenopathy	Absent	Present	Present in adults, absent in newborns
Response to antibiotic therapy	Yes	No	Yes
Duration of untreated disease	Up to several weeks	Several weeks	Persistent

From Baum J, Barza M. Infections of the eye. In: Gorbach SL, Bartlett JG, Blacklow NR, eds. *Infectious diseases*. Philadelphia: Saunders, 1992, with permission.

nonspecific viral conjunctivitis but may be helpful in suspected HSV conjunctivitis. In EKC, viral cultures are positive in 80% of patients during the first week of symptoms.

- C. Treatment.** Except for HSV conjunctivitis, viral conjunctivitis without corneal involvement warrants no specific therapy. These conditions usually are self-limited, lasting 7 to 10 days unless bacterial superinfection occurs. Patients should be advised to return immediately if symptoms worsen or if any eye pain develops. They should also be educated about the importance of good hand-washing in preventing spread of the disease to others. Patients with EKC should be advised that the infection is highly transmissible, and they should stay out of work for 2 weeks. They should also be reminded to wash their hands frequently and use a separate washcloth and towel.

HSV conjunctivitis may last 2 to 3 weeks. Patients with this diagnosis should be followed by an ophthalmologist. Antiviral therapy, both topical (e.g., trifluridine drops every 2 hours) and systemic (e.g., acyclovir 200 mg five times a day), is indicated.

IV. Bacterial conjunctivitis

A. Hyperacute (purulent)

- 1. Clinical characteristics.** Hyperacute bacterial conjunctivitis is the most severe form of conjunctivitis and usually caused by *Neisseria gonorrhoeae* and rarely by *N. meningitidis*. The patient presents with a purulent exudate that is so copious it reaccumulates as soon as it is wiped away. There is usually marked eyelid edema, chemosis (conjunctival edema), and tender preauricular nodes. A large series of **gonococcal conjunctivitis** found bilateral eye involvement in over one-third and keratitis (corneal infection) in two-thirds [9]. Keratitis may lead to corneal perforation. **Meningococcal conjunctivitis** may mimic gonococcal conjunctivitis but is followed by systemic meningococcal disease in nearly 20% of patients [10].
- 2. Diagnosis.** In a patient with hyperacute conjunctivitis, a Gram stain of conjunctival exudate that shows gram-negative diplococci, many intracellular, should prompt immediate therapy for *Neisseria* as soon as cultures are taken. Cultures of exudate should be plated directly onto chocolate and Thayer-Martin plates and these placed in a 5% carbon dioxide atmosphere as soon as possible. If delay in transport is anticipated, use a "Jembec" Thayer-Martin plate and a CO₂-generating tablet.

- 3. Treatment.** For treatment of neonates, see section VI. For gonococcal conjunctivitis in adults, the Centers for Disease Control and Prevention [11] recommends a single 1-g dose of ceftriaxone (intramuscular or i.v.). For highly penicillin-allergic patients, single-dose therapy with 500 mg oral ciprofloxacin will treat genital or pharyngeal infection and would presumably be adequate therapy for conjunctival disease in adults, although efficacy data are not available. Saline eye drops may be given to clear the exudate. We would also culture and treat for possible coexisting chlamydiae with either doxycycline (100 mg twice a day for 7 days) or azithromycin (1 g orally once) in adults. Patients with meningococcal conjunctivitis should be evaluated and treated for systemic meningococcal disease (see Chapter).

B. Acute

- 1. Clinical characteristics** include a thick mucopurulent exudate that causes the eyelashes to stick together when the patient awakens. Symptoms usually begin in one eye but become bilateral 1 to 2 days later. In children, the most common etiologies are *H. influenzae* and *S. pneumoniae*. The average age of one large series was 2 years, and conjunctivitis with acute otitis media was seen in 40% of patients [12]. *H. influenzae* was the most common pathogen (60%) in conjunctivitis-otitis cases. Outbreaks of bacterial conjunctivitis may occur, and *S. pneumoniae* that cannot be typed is a common cause. Sporadic cases may be related genetically to outbreak strains [13]. In adults, *S. aureus*, *S. pneumoniae*, and *H. influenzae* are etiologic. In one study of adults in a chronic care facility, bacteria were isolated in 38% of acute episodes, and *S. aureus* was the most common pathogen [14]. Gram-negative bacillary infections are rare except in patients with abnormal corneas or patients in intensive care units; *Pseudomonas* is particularly destructive. Unusual causes include *Borrelia burgdorferi* and *Bartonella hensleae*.
- 2. Diagnosis.** Conjunctival cultures and Gram stains may be helpful in suspected bacterial conjunctivitis and should always be obtained in patients with severe or hyperacute conjunctivitis and in patients who fail to respond to initial therapy. They should also be obtained in patients who have a filtering bleb from prior glaucoma surgery, because these patients are at increased risk for endophthalmitis (see section VI under Endophthalmitis).
- 3. Treatment.** Except for *Pseudomonas*, treatment is topical only (Table 7.3). Ointments can be given less frequently (every 4 to 6 hours) than eye drops (every 2 to 4 hours) and therefore are useful at bedtime but may transiently blur vision after each application during the day. Therapy may be stopped 48 to 72 hours after clearing of signs and symptoms (usually 7–10 days). Patients should be advised to avoid contamination of the ointment tube or dropper tip and to return if they are no better in 2 to 3 days.
- a. Empiric.** Begin broad-spectrum topical therapy while awaiting culture results. Erythromycin or bacitracin ointments are inexpensive and may be used for mild infection in adults (these cover only gram-positive organisms). Polytrim (trimethoprim and polymixin B) ophthalmic solution is a useful broad-spectrum agent; Polysporin ointment (bacitracin and polymixin B) and sulfonamides (e.g., 10% sulfacetamide or 4% sulfisoxazole) also provide broad-spectrum coverage. Topical gentamicin or tobramycin eye drops have a narrower spectrum and are more irritating to the corneal surface. Quinolone eye drops (e.g., ofloxacin) are well tolerated and provide broad-spectrum coverage but are very expensive. Their use for trivial conjunctival infections is discouraged because of concern for emerging bacterial resistance.
- b. Gram-positive infections.** Bacitracin (500 units/g) or erythromycin (0.5%) ointments, or any of the broad-spectrum agents listed, may be used for mild infections. Pneumococcal infections may be resistant to erythromycin and may require ofloxacin or levofloxacin eye drops. In severe pneumococcal conjunctivitis due to a highly resistant strain, vancomycin eye drops are indicated, but these must be compounded by the pharmacy because they are not commercially available.

Table 7.3. Some Commercially Available Antibiotic Eye Drops and Ophthalmic Ointments

Antibiotic	Trade Name ^a	Concentration
Bacitracin ^b	AK-TRACIN	500 units/g
Ciprofloxacin ^c	Ciloxan	0.3%
Ofloxacin	Ocuflax	0.3%
Levofloxacin	Quixin	0.5%
Erythromycin ^b	(generic)	0.5%
Gentamicin ^{b,c}	Genoptic, Gentacidin	0.3%
Sulfacetamide sodium ^b	AK-SULF, Cetamide	10%
Sulfacetamide sodium ^c	Ocu-Sul-10,-15; 30	10%, 15%, 30%
Sulfisoxazole diolamine ^c	Gantrisin	4%
Tetracycline ^{b,c}	Achromycin	1%
Tobramycin ^{b,c}	Tobrex	0.3%
Combinations		
Bacitracin and polymyxin B ^b	Polysporin	—
Neomycin, polymyxin B, and bacitracin ^b or gramicidin ^c	Neosporin	—
Trimethoprim and polymyxin B ^c	Polytrim	—

^a The trade name list is not all-inclusive. In addition, most of these antibiotics are available also as generic preparations.

^b Ointment available.

^c Solution (eyedrops) available.

c. Gram-negative infections. Use ciprofloxacin or an aminoglycoside. Because of high local concentrations achieved by topical application, aminoglycosides also provide some coverage of *S. aureus* (but not streptococci).

C. Chronic

- 1. Clinical characteristics.** Chronic conjunctivitis may be divided into follicular and nonfollicular. Nonfollicular is usually caused by *S. aureus* or occasionally *Moraxella lacunata*. It is often associated with chronic blepharitis. Anaerobes are a rare cause of chronic conjunctivitis. Chronic follicular conjunctivitis is usually caused by *Chlamydia trachomatis* (see below). Chronic conjunctivitis may also have a noninfectious etiology, such as allergic conjunctivitis.
- 2. Diagnosis.** Gram staining and cultures (including anaerobic) will identify the underlying pathogen.
- 3. Treatment** should be guided by culture results (see section B.3). Eyelid hygiene is important if there is blepharitis. Evaluation of the lacrimal system (for organism reservoir) may be indicated if symptoms recur.

V. Chlamydial conjunctivitis. *C. trachomatis* is responsible for two distinct ocular syndromes: trachoma, a blinding disease, and inclusion conjunctivitis, a relatively benign infection. Trachoma is caused by serotypes A–C, inclusion conjunctivitis by types D–K. Inclusion conjunctivitis occurs in sexually active adults and neonates; the neonatal disease is discussed in section VI.

A. Trachoma

- 1. Clinical characteristics.** Trachoma blinds 4.9 million people and is the second most common cause (after cataracts) of blindness in the world [15]. It is endemic in areas of Africa (e.g., Egypt, The Gambia, Tanzania), the Middle East (e.g., Saudi Arabia), and northern India. Initial infection may heal spontaneously, but blindness occurs only after many years of infection and reinfection that causes corneal vascularization and scarring. Person-to-person contact and flies are the major modes of transmission. Young children are the main reservoir for infection, and women are much more likely to have severe trachoma than men, probably because of their contact with children.

Trachoma has four stages: conjunctivitis, corneal vascularization, scarring, and scar retraction. Chronic recurrent follicular conjunctivitis, involving the upper

eyelid and extending to the cornea, is typical of trachoma and is rare in other ocular conditions.

2. **Diagnosis.** Giemsa stain, but not Gram stain, shows typical basophilic cytoplasmic inclusion bodies in conjunctival epithelial cells. However, the direct fluorescent monoclonal antibody stain [6] (e.g., MicroTrak), enzyme immunoassay (e.g., Chlamydiazyme), or DNA probe (e.g., ligase chain reaction) are more sensitive (87%–100%). Reference laboratories can isolate organisms but not routine media.
3. **Treatment.** The World Health Organization Global Alliance for the Elimination of Trachoma by the Year 2020 has adopted the “SAFE” strategy: surgery, antibiotic treatment, promotion of facial cleanliness, and environmental changes [16]. Village-wide treatment with azithromycin, one dose weekly for 3 weeks, resulted in a 64% to 93% decrease in village-wide prevalence rates at 1 year follow-up in three villages, a reduction superior to that achieved by 6-week daily therapy with 1% topical tetracycline [17].

B. Adult inclusion conjunctivitis

1. **Clinical characteristics.** Occurring in sexually active adolescents and adults, adult inclusion conjunctivitis is typically a low-grade, chronic, bilateral follicular conjunctivitis with a minimal mucopurulent discharge. It begins 2 to 19 days after exposure to infected genital or urinary tract secretions and occurs in approximately 1 in 300 patients with genital chlamydial infections. Indirect transmission in poorly chlorinated swimming pools may occur. Conjunctival follicles are present as in trachoma, but there is greater involvement of the **lower palpebral conjunctiva**, and preauricular adenopathy is more common. Moreover, the macropannus and scarring of trachoma are not present.
2. **Diagnosis.** See section V.A.2.
3. **Treatment.** Use oral erythromycin (500 mg four times a day) or a doxycycline (100 mg twice a day) for 2 weeks in adults. Azithromycin has been used as single-dose therapy for genital infections, but efficacy data for treating conjunctivitis are unavailable. Untreated inclusion conjunctivitis may lead to chronic follicular conjunctivitis lasting 3 to 12 months and to subepithelial corneal infiltrates.

VI. Ophthalmia neonatorum. Ophthalmia neonatorum (ON) refers to any conjunctival inflammation in the newborn. Most cases occur in the first 2 weeks of life. Chlamydiae are the most common infectious cause of ON, but gonococci are the most serious. Silver nitrate eye drops, tetracycline ointment, or erythromycin ointment all are equally effective in preventing gonococcal ON and equally poor at preventing chlamydial ON. In a study from Kenya, a 2.5% ophthalmic solution of povidone-iodine as prophylaxis against ON was more effective, less toxic, and less expensive than silver nitrate or erythromycin [18].

A. General guidelines. Because gonococcal infections are rapidly **destructive, consider conjunctivitis in the newborn as an ophthalmic emergency and obtain prompt ophthalmologic consultation.** Do not rely on the timing of the infection or the clinical appearance alone to make a specific diagnosis: There is too much overlap with other conditions. Obtain Gram stain, immunofluorescent stain for chlamydiae, routine cultures, and culture on chocolate and Thayer-Martin media for *N. gonorrhoeae*. If the stains are not diagnostic, begin topical erythromycin empirically while awaiting culture results.

B. Chlamydial conjunctivitis (neonatal inclusion conjunctivitis)

1. **Clinical characteristics.** Onset is classically 5 to 14 days after birth. There may be unilateral or bilateral involvement, with conjunctival hyperemia, eyelid edema, and profuse exudate. Newborns lack lymphoid tissue and fail to develop an acute follicular conjunctivitis, which is typical of the adult infection. *C. trachomatis* types D–K are responsible (as is true for adult inclusion conjunctivitis).
2. **Diagnosis.** See section V.A.2. Polymerase chain reaction may be as sensitive and specific as culture, though much faster, in detecting *C. trachomatis* in conjunctival and nasopharyngeal specimens from infants with conjunctivitis [19].
3. **Treatment.** Oral erythromycin (50 mg/kg/day in divided doses) for 10 to 14 days is the preferred agent. It eradicates nasopharyngeal carriage 80% of the time, and a second course may be necessary [11]. Topical erythromycin therapy may be

omitted if it is not tolerated. Parents should be treated for presumed chlamydial genital infection.

C. Gonococcal conjunctivitis

1. Clinical characteristics. Onset is on days 2 to 5. Initially, the exudate may be serosanguineous, frequently bilateral, with marked purulence and chemosis. Complications are rare with adequate therapy but include corneal ulceration and endophthalmitis.

2. Diagnosis. If the Gram stain shows gram-negative diplococci (many intracellular), the infant should be hospitalized, immediately evaluated for systemic disease (arthritis, meningitis, sepsis), and started on therapy as soon as cultures are obtained.

3. Treatment. Although a single-dose of ceftriaxone (25 to 50 mg/kg intramuscularly or intravenously; maximum 125 mg) is effective for gonococcal ON, we recommend daily therapy at this dose for at least 72 hours to ensure that cerebrospinal fluid and blood cultures are negative. Cefotaxime (50 to 100 mg/kg/day divided every 12 hours) may be used instead of ceftriaxone in neonates with hyperbilirubinemia. Prompt ophthalmologic consultation should be obtained in all cases. Parents should be evaluated and treated for genital disease.

D. Other infections. *S. aureus* infection has a variable onset (usually days 4 to 7) and results in an acute purulent conjunctivitis that is diagnosed by culture and Gram stain (in the absence of other detectable ocular pathogens). Topical erythromycin generally is effective for minor infections. For more serious infections, a systemic semisynthetic penicillin (e.g., oxacillin) for 7 days is suggested. (See Chapter 3, Table 3.2 for dosages of systemic antibiotics in neonates.) **HSV type 2** may cause a bilateral conjunctivitis in 15% to 20% of infected infants and may precede or follow dissemination. Onset occurs on days 2 to 14 postpartum. Treatment is with systemic acyclovir and topical antiviral therapy.

E. Chemical conjunctivitis is the most common noninfectious cause of ON, occurring in 90% of infants treated with prophylactic silver nitrate drops. The appearance of inflammation (eyelid edema, conjunctival hyperemia, watery discharge) within 24 hours of prophylaxis is diagnostic. Smears and cultures are negative. It resolves (without treatment) in 24 to 48 hours.

INFECTIOUS KERATITIS (INFECTION OF THE CORNEA)

Infectious keratitis, or infection of the cornea, can lead to loss of vision either because of the resulting corneal scarring or because of progression to perforation and endophthalmitis. These infections **should be managed by an ophthalmologist**. Recognition of corneal disease is the primary function of the generalist.

I. Anatomy. The cornea is the 1-mm-thick clear “window” of the eye that has a major role in focusing light: It accounts for almost three-fourths of the total refractive power of the eye. It has no blood vessels but has many sensory nerve fibers (cranial nerve V). It is composed of three layers: the epithelium, stroma or interstitium, and endothelium. The corneal epithelium is five cell layers thick and serves as a barrier to infection. Breaks in the epithelium may lead to bacterial invasion of the corneal stroma.

II. General principles. Keratitis may involve only the epithelium (epithelial keratitis), the stroma (interstitial keratitis), or both (ulcerative keratitis). The **major signs and symptoms** of acute keratitis are a **unilateral red eye with pain, photophobia, tearing, decreased vision, and a corneal defect**. A **hypopyon** (visible layer of pus in the anterior chamber) may be present and, in keratitis but not endophthalmitis, represents a sterile inflammatory response rather than intraocular infection. The cornea often appears cloudy due to corneal edema. In eyes with large corneal ulcers, the ulcer appears as a white defect in the corneal surface and may be seen with a flashlight. Some corneal ulcers, however, can only be seen with a slit lamp.

III. Viral keratitis

A. Herpes simplex. HSV is the most common cause of keratitis in the United States, with 500,000 cases diagnosed annually. Herpetic keratitis is third or fourth most common diagnosis in patients requiring corneal transplants [6]. Most (95%) cases of HSV keratitis are due to HSV type 1, with the exception of neonatal herpetic

keratitis. HSV 1 is usually acquired in childhood and remains latent in the trigeminal ganglion, which innervates the eye.

1. Clinical characteristics

- a. **Primary HSV** keratitis is rare, and the term refers to the first infection with HSV in a nonimmune patient. Patients present with multiple herpetic vesicles on the eyelids and periorbital area of one eye, and keratitis develops in approximately two-thirds of these patients.
- b. **Recurrent HSV** accounts for nearly all cases of HSV keratitis, including **initial episodes**. Patients complain of eye irritation (foreign-body sensation), photophobia, and decreased vision. Initial episodes usually involve only the corneal epithelium. On slit-lamp examination of the fluorescein-stained cornea, the typical branchlike dendritic forms can be seen in the epithelium. There is less discomfort than expected because diminished corneal sensation is part of this condition. **Recurrent episodes** occur in one-third of patients within 2 years of the initial attack. Recurrences may involve only the epithelium, but repeated attacks increase the risk of stromal involvement, which may result in permanent corneal scarring. In one large study, previous episodes of stromal keratitis increased the risk of subsequent stromal keratitis 10-fold [20]. Long-term acyclovir prophylaxis decreases this risk [21].

2. **Diagnosis.** The typical morphologic appearance of a dendritic ulcer (seen best with fluorescein dye) will usually allow a diagnosis, but its absence does not exclude HSV infection (especially in children). Viral cultures or direct fluorescent antibody tests on corneal scraping may confirm the diagnosis.

3. **Treatment.** The patient should be followed by an ophthalmologist. Patients with epithelial keratitis should be treated with oral antiviral agents active against HSV (e.g., acyclovir, valacyclovir, or famciclovir). Topical antiviral agents, such as 1% solution of trifluridine (Viroptic eye drops every 2 hours), idoxuridine (Herplex eye drops every 1 hour), and vidarabine (Vira-A 3% ointment five times daily) may also be used; trifluridine is the most effective. Topical 3% acyclovir ophthalmic ointment, not yet available in the United States, appears to be as effective as trifluridine. Topical steroids are contraindicated in epithelial keratitis but, when used with topical trifluridine, may be helpful in treating HSV stromal hepatitis [22]. Oral acyclovir does not seem to be effective in treating stromal keratitis [23]. Patients with frequent recurrences of HSV keratitis, or with stromal keratitis, should be given chronic prophylaxis with acyclovir 400 mg orally twice a day, because this decreases the risk of stromal recurrences [21].

B. Herpes zoster ophthalmicus is defined as herpes zoster involvement of the first (ophthalmic) division of the trigeminal nerve. It is due to reactivation of latent varicella and is most often seen in the elderly. Involvement of the eye occurs in approximately 75% of cases, corneal involvement in 55% [24].

1. **Clinical characteristics.** In 25% of cases, the disease begins with severe unilateral neuralgia. This is followed by typical skin lesions along the distribution of the first division of the trigeminal nerve. A rash on the tip of the nose (Hutchinson sign) signifies involvement of the nasociliary branch of this division. This is said to increase the risk of corneal involvement, although this has not been substantiated by some studies [24]. Involvement of the cornea is often stromal (deep), unlike HSV, which primarily involves the corneal epithelium. Pseudodendrites may occur and may be confused with HSV dendrites. The keratitis often is accompanied by an anterior uveitis (inflammatory cells in the anterior chamber; see under Uveitis, section III). Loss of corneal sensation is common and may persist for months. Herpes zoster and varicella-zoster virus infections are discussed further in Chapter 4.

2. **Treatment.** Oral acyclovir for 10 days decreases the incidence of keratitis and uveitis in patients with herpes zoster ophthalmicus while also decreasing the duration of skin lesions [25]. Acyclovir should be dosed at 800 mg orally five times daily, assuming normal renal function. Valacyclovir 1 g three times a day or famciclovir 500 mg orally three times a day may be used in place of acyclovir.

The role of topical antiviral agents in herpes zoster ophthalmicus is unclear. Topical steroids should not be used except by an ophthalmologist.

IV. Bacterial keratitis

A. Etiology. More than 30,000 cases of ulcerative keratitis occur in the United States annually [26]. Major risk factor for keratitis in a recent Swiss study were contact lens wear (36%), blepharitis (21%), trauma (20%), and xerophthalmia (15%) [27]. Overnight wear of soft contact lenses increases the risk of keratitis 10- to 15-fold [28,29].

Over 40% of keratitis cases are culture-negative but presumed bacterial. Most culture-positive cases are due to gram-positive organisms (75%–80%) and gram-negative bacilli in 20% to 25% [30]. However, a high proportion of gram-positive isolates in these series are coagulase-negative staphylococci, diphtheroids, and *Propionibacterium acnes*, organisms that may be an ocular surface colonizers rather than pathogens in keratitis. Assuming these are pathogens, the most common organisms are coagulase-negative staphylococci (39%), *S. aureus* (16%), *P. acnes* (9%), *Pseudomonas* (6%), *Serratia* (6%), viridans streptococci (6%), and *S. pneumoniae* (3%) [30]. *Pseudomonas aeruginosa* is the most common pathogen in contact lens-related cases.

B. Clinical characteristics. Bacterial keratitis usually presents as a corneal ulcer that is readily apparent as a gray–white well-circumscribed defect in the corneal surface. Patients present acutely with a painful red eye; usually the redness is most intense at the limbus rather than peripherally as in conjunctivitis.

C. Diagnosis. When bacterial keratitis is suspected, an ophthalmologist should see the patient immediately and scrape the cornea (under slit-lamp visualization) for Gram stain and culture (aerobic, fungal, and anaerobic, if possible). Because of the paucity of material, the scrapings should be placed directly on slides and culture media in the office and sent to the microbiology laboratory (rather than swabs). Many culture-negative cases will respond to broad-spectrum antibacterial therapy. However, failure of response to therapy in culture-negative cases warrants repeat corneal scrapings or biopsy for culture of organisms including aerobes, anaerobes, fungi, mycobacteria, and *Acanthamoeba* [31].

D. Treatment. The patient should be started on empiric broad-spectrum fortified antibiotic eye drops given for the first 24 to 48 hours every half-hour or hour around the clock. Severe cases should be admitted because they may require this regimen for several days. If two different antibiotic drops are used, the second should be given 5 minutes after the first to prevent washout. Frequency can be decreased (especially at night) as the eye improves.

Nearly all antibiotic eye drops used for treating keratitis must be made up by the hospital pharmacy, because they are more concentrated than commercially available preparations (Table 7.4). The exceptions are the quinolone eye drops. These are recent additions (ciprofloxacin eye drops approved 1990, ofloxacin 1996, levofloxacin 2000). It is controversial whether initial empiric therapy should include traditional combination therapy with cefazolin plus fortified tobramycin or a quinolone such as ofloxacin alone. Several studies have shown success rates of 85% to 90% with either regimen [30,32]. The topical quinolones have demonstrated safety and efficacy in adults [32]; safety in children younger than 12 years has not been established. However, we prefer initial empiric combination therapy (e.g., vancomycin plus tobramycin) for severe cases requiring hospitalization, particularly if the patient is using a quinolone eye drop at the time of admission. Ciprofloxacin-resistant bacterial keratitis cases have been reported, and resistance may be increasing [33]. Once cultures are positive, therapy can be tailored to the organism (Table 7.5).

Systemic antibiotics are rarely indicated, except for deep corneal ulcers with impending perforation or extension into the sclera. Choice of antibiotic should be made based on culture result.

V. Fungal keratitis

A. Etiology. Fungal keratitis (keratomycosis) is rare in the United States and Europe but common in tropical countries such as India. In the United States keratomycosis comprises less than 2% of infectious keratitis cases, and most cases of mold keratitis

Table 7.4. Concentration of Fortified Topical Antibiotic Solutions (Eye Drops) Used to Treat Bacterial Corneal Ulcers (Keratitis)

Antibiotic ^a	Concentration
Amikacin	20 mg/mL
Cefazolin	33, 50, or 133 mg/mL
Chloramphenicol ^b	5 mg/mL (0.5%) ^c
Ciprofloxacin ^b	3 mg/mL (0.3%)
Gentamicin	14 mg/mL
Levofloxacin	5 mg/mL (0.5%)
Ofloxacin	3 mg/mL (0.3%)
Ticarcillin	6 mg/mL
Tobramycin	14 mg/mL
Vancomycin	14 or 25 mg/mL

^a Start with a loading dose of 1 drop/min for 5 min, then 1 drop q30 min.

^b Available commercially at this concentration. All others must be made up by the hospital pharmacist.

^c Concentrations may be expressed either as milligrams per milliliter or as a percentage: 10 mg/mL = 1%.

occur in the South. Many different fungi cause keratitis; *Aspergillus*, *Fusarium*, and *Candida* have been most commonly reported, with *Candida* predominating in northern climates and *Fusarium* in the southern United States. Mold keratitis is more likely after corneal trauma with vegetable matter trauma (including from use of nylon-line lawn trimmers) [34], whereas *Candida* species are more likely pathogens in abnormal corneas (e.g., keratoconjunctivitis sicca), where they are often colonizers, especially in eyes receiving topical steroids.

B. Clinical characteristics. Fungal ulcers are indolent and usually have a different slit-lamp appearance than bacterial ulcers. Typically, there is a gray plaque-like infiltrate and ulcer with an irregular border, often with several smaller satellites and a sterile hypopyon.

C. Diagnosis. It may be difficult to isolate the causative organism. A fungal stain (e.g., calcofluor) should be performed, and corneal scraping should be plated on Sabouraud media for fungal cultures. If initial cultures are negative, repeat scrapings must be done and a corneal biopsy may be necessary.

D. Treatment. Mold keratitis is much more difficult to cure than yeast or bacterial keratitis. Topical antifungal therapy should be coordinated with the ophthalmologist (Table 7.6). For *Aspergillus*, give topical amphotericin, possibly with the

Table 7.5. Suggested Therapeutic Regimen for Bacterial Corneal Ulcers

Etiology	Topical Drops (q30 min)	Systemic (i.v.)
Empiric therapy	Cefazolin or vancomycin plus ciprofloxacin or tobramycin	If spread into sclera
<i>S. aureus</i>	Vancomycin or cefazolin (if oxacillin-sensitive strain)	
<i>S. pyogenes</i>	Cefazolin or vancomycin	
<i>S. viridans</i>	Cefazolin or vancomycin	
<i>S. pneumoniae</i>	Vancomycin (or cefazolin if penicillin-sensitive strain)	
<i>N. gonorrhoeae</i>	Ciprofloxacin	Ceftriaxone
<i>Pseudomonas</i>	Ciprofloxacin plus tobramycin	Ceftazidime or Ticarcillin plus
<i>Moraxella</i>	Ciprofloxacin plus gentamicin	
<i>Nocardia</i>	Sulfacetamide	

Table 7.6. Topical Treatment of Fungal Corneal Ulcers

Organism	Drug	Topical Concentration
<i>Candida</i>	Amphotericin	1.5 or 3 mg/mL (0.15% or 0.3%)
	Flucytosine	10 mg/mL
	Fluconazole	2 mg/mL
<i>Aspergillus</i>	Amphotericin	1.5 or 3 mg/mL
	Flucytosine	10 mg/mL
<i>Fusarium</i>	Natamycin	5%

addition of 5-flucytosine. For *Fusarium*, natamycin has been more successful than amphotericin. In England, topical econazole has proved useful, but this azole is not available in the United States. Systemic therapy with amphotericin is *not* indicated (benefit uncertain and significant toxicity). Oral itraconazole penetrates the cornea and eye poorly but may prevent scleral extension in peripherally located ulcers due to molds. For *Candida* keratitis, topical amphotericin is recommended, possibly with the addition of 5-flucytosine. Oral fluconazole achieves excellent corneal penetration, and both oral and topical therapy may be useful in treating *Candida albicans* keratitis. If lesions progress on topical and systemic therapy, corneal transplantation (keratoplasty) may be considered early by the corneal specialist.

VI. Parasitic keratitis

A. Etiology. *Acanthamoeba* is an amoeba that lives in tap water and is the most common cause of parasitic keratitis in industrialized countries. Over 90% of patients with *Acanthamoeba* keratitis wear contact lenses [35]. Patients who wear soft contact lenses or omit contact lens disinfection are especially at risk. The keratitis is usually chronic. Typically, the patient has been treated for several weeks with antibiotics before the diagnosis is considered. Hallmarks include a ring corneal infiltrate, a lack of corneal neovascularization despite chronicity, and severe pain, out of proportion to clinical findings. A ring infiltrate is a late sign, but nearly pathognomonic. Earlier signs include a dendritiform keratitis similar to HSV or a linear infiltrate starting near the center of the cornea and radiating to the limbus (radial keratoneuritis).

B. Diagnosis. Cultures require special techniques. Corneal scrapings should be placed in special transport media (Page saline) and on glass slides. In the microbiology laboratory, slides should be stained with calcofluor white to show the cysts and trophozoites. Page saline solution should be plated on nonnutrient agar that is overlain with an *Escherichia coli* "lawn." The amoebae will grow on this media after 48 to 72 hours and may be readily viewed under a light microscope. If these techniques fail, a corneal biopsy should be obtained for pathology and repeat culture.

C. Treatment. *Acanthamoeba* keratitis is difficult to cure, and advanced infections may fail medical therapy. Corneal transplant should be avoided in active infection, if possible, as recurrence in the corneal graft is common [36]. The therapy of choice is polyhexamethylene biguanide 0.02% (Baqacil), a cationic disinfectant used as a swimming pool cleaner. Initially, this should be given hourly around the clock. Ideally, a second topical solution, Brolene (propamidine isethionate 0.1%), should be added hourly for double therapy [37]. Brolene 0.15% ointment is useful at night after the patient has improved, when hourly treatment is no longer necessary. Unfortunately, Brolene is almost impossible to obtain in the United States, where it is investigational, but it is readily available in Great Britain. Neosporin drops (neomycin-polymyxin-gramicidin) may be used as a second agent in place of Brolene but are much less effective.

VII. Interstitial keratitis refers to infection of the corneal stroma (interstitium). There is no surface ulceration, and the cornea appears diffusely cloudy. Only limited agents cause this type of keratitis. The most common are recurrent herpes simplex and

syphilis. In the early 1900's, interstitial keratitis was a classic manifestation of congenital syphilis; patients often had no other stigmata of the disease. Interstitial keratitis may occur in either secondary or tertiary syphilis. Therefore, both a nonspecific (rapid plasma reagin [RPR]) and a specific (fluorescent treponemal antibody absorption [FTA-ABS] or treponema pallidum passive agglutination [TPPA]) test should be obtained, because late syphilis frequently has a negative RPR (all cases will have positive TPPA tests). All patients with ocular syphilis should be tested for human immunodeficiency virus. Interstitial keratitis also occurs in tuberculosis, leprosy, and Lyme disease.

ENDOPHTHALMITIS

Endophthalmitis means intraocular infection, but in general usage it refers to bacterial or fungal infection of the vitreous or aqueous. In nearly all cases, the vitreous is involved. Because the vitreous is in contact with the retina, retinal destruction may follow. Bacterial endophthalmitis usually presents over 12 to 24 hours, whereas fungal endophthalmitis is typically more indolent. Any type of endophthalmitis can cause loss of vision and should be treated as a medical emergency.

I. Anatomy. The vitreous body is a clear gel that fills the posterior segment of the eye (Fig. 7.4). It has a volume of approximately 4 mL. It is not regenerated but may be removed by vitrectomy and replaced with fluid. The aqueous occupies a smaller volume (0.25 mL) and is continuously regenerated, with a turnover time of 100 minutes. Probably because of this rapid turnover, the aqueous is more resistant to infection than the vitreous. The aqueous and vitreous are separated by the posterior capsule of the lens. Breaks in this can lead to "wicking" of the vitreous into the anterior segment of the eye, increasing the risk of endophthalmitis.

II. Etiology. Endophthalmitis is divided into six categories. The most common pathogens for each category are noted in Table 7.7 [38]. Organisms gain entry either through surgery, trauma, a filtering bleb, or the bloodstream, most commonly after cataract surgery.

FIG. 7.4 The globe of the eye.

Table 7.7. Endophthalmitis: The Most Common Pathogens and Recommended Initial Empiric Intravitreal Antibiotics

Category	Pathogens	Empiric Intravitreal Antibiotics
Postcataract	Coagulase-negative <i>Staphylococcus S. aureus</i> , streptococci	Vancomycin 1 mg plus ceftazidime 2 mg or amikacin 0.4 mg (400 μ g)
Chronic pseudophakic Bleb related	<i>P. acnes</i> <i>H. influenzae</i> , <i>S. pneumoniae</i> , viridans streptococci	Vancomycin 1 mg Vancomycin 1 mg plus ceftazidime 2 mg
Posttraumatic	<i>Bacillus cereus</i> , coagulase-negative staphylococci	Vancomycin 1 mg plus ceftazidime 2 mg
Endogenous	<i>S. aureus</i> , streptococci, gram-negative bacilli	Vancomycin 1 mg plus ceftazidime 2 mg or amikacin 0.4 mg (400 μ g)
Fungal	<i>Candida</i> , <i>Aspergillus</i> , <i>Fusarium</i>	Amphotericin 10 μ g

III. Diagnosis

A. Sampling techniques: vitrectomy versus needle aspirate. The aqueous can be aspirated by an ophthalmologist (usually a retina specialist) in the office or emergency room by inserting a needle into the aqueous and aspirating 0.1 mL of fluid for culture. The vitreous may also be sampled in the office by needle aspirate, using a 22- to 27-gauge needle, yielding 0.2 mL of vitreous gel for Gram stain and culture. Alternatively, the vitreous gel may be “debrided” through a vitrectomy procedure in the operating room. In this procedure, a 20-gauge vitrector, attached to a venturi-aspiration vitrectomy machine, cuts and aspirates the vitreous into a collecting cannister, whereas a separate cannula provides continuous infusion of balanced salt solution to maintain eye pressure. A vitrectomy can provide an initial undiluted vitreous sample if a syringe is attached by three-way stopcock to the vitrector tubing, but most of the vitreous is contained in dilute washings in the collecting cannister.

B. Culture techniques. Vitreous and aqueous samples are cultured on blood agar, chocolate agar, meat broth, and Sabouraud media. Samples sent in a syringe (usually 0.1–0.2 mL) should be plated directly, whereas the dilute washings (30–50 mL) obtained at vitrectomy surgery should be vacuum filtered through a 0.45- μ g filter and the filter paper divided and placed on culture plates. An unusual feature of Gram stains of the vitreous or aqueous is that they may contain **pigment granules** (a “dust” believed to come from the iris in inflammation or trauma). These may **resemble gram-positive cocci on Gram staining**, although they appear more refractile than bacteria and are more often football-shaped than spherical. Gram stains of the vitreous are positive in 50% of cases. Vitreous cultures are more often positive than aqueous cultures, and cultures of vitrectomy washings are more often positive than vitreous needle aspirate cultures (76% vs. 43%) [39].

IV. Acute postcataract endophthalmitis. There are over 2 million cataract operations performed in the United States annually, and endophthalmitis occurs in 0.1% to 0.2% of cases. Nearly all cases are due to bacteria that normally colonize the conjunctiva and are introduced into the aqueous during surgery.

A. Clinical characteristics. Symptoms develop over 12 to 48 hours, within 1 week of surgery in 75% and within 1 month in nearly all cases. Most patients present with blurred vision (94%), red eye (82%), and eye pain or discomfort (74%) [40]. Patients are otherwise well, afebrile, and have a normal or only slightly elevated white

blood count. The eye is injected and has decreased vision. In most eyes (85%), a hypopyon is visible. The view of the retina is poor, obscured by a cloud of intravitreal cells.

B. Bacteriology. With rare exception, all cases are bacterial. About 30% have negative cultures. Of the culture-positive cases, 94% are due to gram-positive bacteria: coagulase-negative staphylococci (70%), *S. aureus* (10%), streptococci (9%), and other gram-positives (5%). Gram-negative bacilli cause only 6% of cases [40].

C. Treatment. Endophthalmitis is a medical emergency that requires initial empiric therapy as soon as cultures are obtained. Note that the synthetic intraocular lens placed at the time of cataract surgery does not need to be removed. There are three components of therapy, and some remain controversial. Most ophthalmologists have changed their practice of treating endophthalmitis since 1995 as a result of the Endophthalmitis Vitrectomy Study (EVS) [40], a multicenter, randomized, prospective trial involving 420 patients. However, major flaws in this study's design have prompted some to question the results [41].

1. Intravitreal antibiotics. The need for intravitreal injection of antibiotics is unquestioned. Vancomycin 1 mg plus either ceftazidime 2 mg or amikacin 0.4 mg are given empirically, each antibiotic diluted by 0.1 mL and injected separately into the vitreous after a vitreous sample is obtained (or at the end of the vitrectomy case). Ceftazidime is less toxic to the retina than amikacin, so is favored by many.

A single intravitreal injection of antibiotic may not kill all bacteria, however. In the EVS, all patients received intravitreal vancomycin plus amikacin, but some patients who were recultured several days later had persistently positive cultures. Cultures were much less likely to be persistently positive (13% vs. 71%) if the patient's initial procedure was a vitrectomy rather than an aspirate biopsy [42].

2. Vitrectomy vs. needle aspirate. Vitrectomy (see section III) debrides the vitreous, analogous to draining an abscess. Until the EVS was published, ophthalmologists performed emergency vitrectomies on nearly all suspected cases for therapeutic reasons. Now, however, most ophthalmologists perform vitrectomies only for patients who present with the worst vision, "light perception," and perform needle aspirates on all others. The EVS randomized patients to receive either a VIT (vitrectomy) or a TAP (aspirate-biopsy) and concluded that in light perception patients, VIT was clearly beneficial. Only 20% of light perception patients in the VIT group were left with severe visual loss, versus 47% in the TAP group. In patients presenting with better vision, there was no apparent difference between VIT and TAP groups. However, this result of the EVS has been questioned because the TAP group was not homogeneous. Only one-third of the TAP group received a needle aspirate, whereas two-thirds had a vitreous "biopsy," performed using a vitrector in the operating room. Critics point out that this biopsy was really a mini-vitrectomy, so that the VIT group and most TAP patients were treated in a similar manner [41]. Of note, within the TAP group, patients who received the mechanized "biopsy" had a much better visual outcome than did patients who received needle aspirate alone [43]. We suspect that if the EVS had randomized vitrectomy versus needle aspirate, vitrectomy may have proven to be beneficial for many patients with endophthalmitis.

3. Systemic antibiotics. A blood-eye barrier exists that is similar to the blood-brain barrier. There are numerous studies in animal models of antibiotic penetration after intravenous therapy but few in humans. As in meningitis, inflammation greatly increases antibiotic penetration. Systemic antibiotics that penetrate the inflamed eye well include vancomycin [44], ceftazidime (better than other cephalosporins), and the quinolones (ciprofloxacin and ofloxacin have been studied). Aminoglycosides do not achieve therapeutic vitreous levels. Therefore, before the EVS, i.v. vancomycin plus i.v. ceftazidime had been standard empiric antibiotic coverage for endophthalmitis. The EVS randomized patients to receive either i.v. amikacin plus ceftazidime or no i.v. antibiotics and found there was no difference between the two groups. As a consequence, ophthalmologists rarely give systemic antibiotics for endophthalmitis, and most

publications report that they are not necessary. However, we believe systemic amikacin plus ceftazidime were poor choices for postcataract endophthalmitis (80% of culture-positive EVS cases were caused by staphylococci) and that the benefit of systemic antibiotics is therefore still unknown. One approach would be to treat all patients (after vitrectomy and intravitreal antibiotics) with i.v. vancomycin plus ceftazidime for 48 hours until vitreous culture results are known [45]. If cultures are negative or grow only coagulase-negative staphylococci and the eye is improving, systemic antibiotics could be stopped. If streptococci, *S. aureus*, or gram-negative bacilli grow, a 7-day course of systemic antibiotics might be appropriate.

4. **Other therapies.** Topical antibiotic drops are relatively harmless, although their value in endophthalmitis is unknown. Subconjunctival antibiotic injections are also of unknown benefit but carry risk so are not recommended.

V. Chronic pseudophakic endophthalmitis

- A. **Clinical characteristics.** The term “pseudophakic” refers to the synthetic intraocular lens placed during cataract surgery. This type of endophthalmitis is very rare. Unlike acute postcataract endophthalmitis, patients present with weeks to months of mild eye discomfort and mild decrease in vision. Examination reveals mild intraocular inflammation and a white plaque in the residual lens capsular sac.
- B. **Etiology.** *Propionibacterium acnes* cause nearly all cases but often fail to grow even with anaerobic cultures.
- C. **Treatment.** Vitrectomy and intravitreal injection of vancomycin 1 mg are standard therapy. Systemic antibiotics are not necessary. Removal of the intraocular lens and remnant lens capsule are often required for cure.

VI. Bleb-related endophthalmitis

- A. **Clinical characteristics.** A filtering bleb is created during glaucoma surgery to allow excess aqueous humor to leak out of the eye and to be resorbed by the overlying conjunctiva. This bleb is a defect in the sclera in which only the conjunctiva serves as a barrier between the aqueous and outside world. Occasionally blebs are created as a complication of other types of eye surgery. A bleb is visible on gross examination as a small swelling on the surface of the eyeball, usually beneath the upper lid. Endophthalmitis results when virulent bacteria gain entry into the eye via this thin-walled bleb. “Blebitis” may be the first sign of danger. Endophthalmitis usually develops acutely, often months to years after bleb surgery. Patients present with typical signs of acute endophthalmitis (eye pain, decreased vision). Because of the virulence of the usual pathogens, visual outcome is poor [46].
- B. **Etiology.** About 50% of cases are caused by *H. influenzae* or streptococci (viridans streptococci, *S. pneumoniae*); *Moraxella catarrhalis* is a less common pathogen.
- C. **Treatment.** Vitrectomy, intravitreal, and i.v. vancomycin plus ceftazidime is used. Simplify once culture results are known.
- D. **Prevention.** Because some cases are due to *S. pneumoniae*, we recommend that all patients with blebs are vaccinated with the pneumococcal vaccine.

VII. Posttraumatic endophthalmitis

- A. **Clinical characteristics.** Endophthalmitis develops acutely in 4% to 13% of patients who suffer penetrating eye trauma (“ruptured globe”) [47]. To prevent endophthalmitis, prophylactic systemic antibiotics (e.g., i.v. vancomycin and ceftazidime) are usually given for several days after the laceration has been repaired. Risk of endophthalmitis is much higher in lacerations caused by metal objects than by glass or after blunt trauma. Risk is also increased if primary closure is delayed more than 24 hours and if the lens has been disrupted [48]. With patients who develop endophthalmitis, symptoms and signs are the same as for postcataract endophthalmitis (see section IV.A). Onset is usually in the first 3 days for virulent organisms (*Bacillus*, gram-negative bacilli) but may be weeks to months for fungi. *Bacillus cereus* typically produces a ring-shaped corneal infiltrate and a fulminant endophthalmitis, with rapid loss of vision in the affected eye.
- B. **Bacteriology.** *Bacillus* species are uniquely important in posttraumatic endophthalmitis, accounting for 15% to 30% of cases. Coagulase-negative staphylococci

cause as many or more cases, but infection is much milder. Gram-negative bacilli (e.g., *Klebsiella*, *Pseudomonas*) or fungi usually cause fewer than 20% of cases. Streptococci were the major pathogens in children in one series [49].

- C. Treatment.** See section IV. **Because of the virulence of the usual pathogens**, we believe all patients should receive vitrectomy, intravitreal vancomycin plus amikacin, and i.v. vancomycin plus either ceftazidime or ciprofloxacin for the first 48 to 72 hours. Vancomycin is effective for *B. cereus*. Once cultures are finalized, antibiotics may be simplified and continued for 7 to 10 days if a virulent organism grows. A repeat intravitreal injection of vancomycin or ceftazidime (depending on culture result) at 48 hours may be necessary for persistent inflammation.

VIII. Endogenous endophthalmitis

A. Clinical characteristics. Patients with endogenous **bacterial** endophthalmitis complain of eye discomfort and decreased vision; 17% [50] have bilateral eye involvement. Although endophthalmitis may be the initial manifestation of bacteremia, there are often signs and symptoms related to the source of the bacteremia as well (e.g., endocarditis, urinary tract infection, gastrointestinal abscess, cellulitis, meningitis). However, systemic symptoms (fever, chills, weight loss, malaise) were present in only about half of the patients in one recent series [50]. Endocarditis was the most common source of infection (approximately 40% of cases) in this series. Endogenous **fungal** endophthalmitis, usually caused by *Candida*, is discussed below (see section IX).

B. Diagnosis. Multiple **blood cultures** should be drawn. Unlike postcataract or posttraumatic endophthalmitis, blood cultures are frequently positive (in 72% of cases [50]).

C. Bacteriology. The single most common bacterial pathogen in a recent series [50] was *S. aureus*, causing one-fourth of cases, whereas streptococci (including pneumococci) and gram-negative bacilli each caused about one-third of cases.

D. Treatment. Patients should receive vitrectomy and intravitreal antibiotics, in addition to the systemic antibiotics that are indicated for their underlying infection.

IX. Fungal endophthalmitis

A. Clinical characteristics. Endophthalmitis due to *Candida* usually occurs in the setting of candidemia and is usually due to *C. albicans*. The term "ocular candidiasis" includes both endophthalmitis, in which the vitreous is infected and cloudy, and the more common chorioretinitis, in which tiny white "fluff balls" can be seen in the retina but the vitreous is clear. The distinction is important, because treatment differs. Symptoms are similar, and in both the onset is usually subacute, and patients have decreased vision but rarely eye pain. The eye may be seeded during unrecognized candidemia in hospitalized patients, but the patient may be asymptomatic initially. In one prospective study, 9% of 118 patients with candidemia had chorioretinitis on a screening exam (patients were asymptomatic); no patients had endophthalmitis [51]. Symptoms may not become apparent until weeks later in untreated ocular candidiasis.

Endophthalmitis due to molds (e.g., *Aspergillus*, *Fusarium*) is very rare and occurs after penetrating trauma, eye surgery, or extension of fungal keratitis. Onset is often weeks after the event. Patients complain of eye pain and decreased vision. The vitreous is cloudy and appears to contain "cotton balls."

B. Diagnosis. Vitreous cultures should be sent for fungal stain (e.g., calcofluor) and culture.

C. Therapy. For patients with *Candida* chorioretinitis, treatment of the candidemia with systemic antifungals nearly always cures the intraocular infection as well. In *Candida* endophthalmitis, however, a vitrectomy plus intravitreal injection of amphotericin (10 μ g) is indicated in addition to systemic therapy. Systemic amphotericin is indicated for candidemia until the species of yeast is known and then can be changed to oral fluconazole if the isolate is a sensitive species (e.g., *C. albicans*). Treatment with fluconazole should be high dose (400 to 600 mg/day orally) for 6 weeks, with monitoring of liver function tests. In patients with mold endophthalmitis, a vitrectomy should be performed, any intraocular lens removed, and intravitreal amphotericin (10 μ g) injected. Weekly injections of amphotericin may be required. Successful therapy is rare, but systemic amphotericin therapy is

Table 7.8. Uveitis: Classification and the Most Common Infectious Etiologies

Category	Infection
Anterior uveitis	Herpes simplex
Iritis	Herpes zoster
Iridocyclitis	Syphilis
	Tuberculosis
Intermediate uveitis	Lyme disease
Cyclitis	
Vitritis	
Pars planitis	
Posterior uveitis	Toxoplasmosis
Choroiditis	Tuberculosis
Chorioretinitis	Candida
Retinitis	Herpes simplex, zoster (ARN)
	Cytomegalovirus
Panuveitis	Syphilis
	Tuberculosis
	Leptospirosis

Note that most causes of uveitis are not infectious but are autoimmune or idiopathic. The list of infectious agents refers to each category rather than subcategory.

not indicated because of lack of efficacy. Systemic azoles have not proved useful. Fluconazole has good penetration into the eye but very poor activity against filamentous fungi, whereas itraconazole has good *in vitro* activity against molds but does not cross the blood–eye barrier.

UVEITIS

- I. **Anatomy.** The eye has three concentric coats (Fig. 7.4): (a) a fibrous protective outermost coat composed of sclera (posterior five-sixths) and cornea (anterior one-sixth); (b) the highly vascular **uvea**, composed of iris, ciliary body, and choroid; and (c) the retina. The retina is in direct contact with the choroid, and inflammation of the choroid often involves the retina as well (chorioretinitis).
- II. **Classification.** Uveitis classification is confusing because there are different classification schemes [52] and because retinitis is usually included in posterior uveitis, even though the retina is not part of the uvea. Table 7.8 gives one classification. Anterior uveitis includes inflammation of the iris (iritis) or iris and ciliary body (iridocyclitis) and accounts for 50% to 90% of uveitis cases. Intermediate uveitis includes cyclitis (inflammation of the ciliary body), vitreitis (inflammation of the vitreous), and pars planitis (pars plana is the pigmented posterior zone of the ciliary body). It accounts for about 5% of uveitis cases. Posterior uveitis includes inflammation of the choroid (choroiditis) or retina (retinitis) or both (chorioretinitis) and accounts for 15% of uveitis cases. Panuveitis occurs in less than 10% of uveitis patients [52].
- III. **Anterior uveitis (iritis, iridocyclitis)**
 - A. **Clinical characteristics.** Patients usually present with a **painful red eye and decreased vision**. There may be pupillary constriction, photophobia, and tearing. On slit-lamp examination, there are cells and “flare” (protein) in the anterior chamber. The inner surface of the cornea may be speckled with keratic precipitates that are either fine (“granular”) or globular (“granulomatous” or “mutton fat” keratic precipitates). The term “granulomatous” is descriptive and does not refer to finding granulomas on pathology. Granulomatous keratic precipitates are less common than granular keratic precipitates and more often associated with sarcoidosis, syphilis, or tuberculosis. Note that topical steroids may change granulomatous keratic precipitates to granular keratic precipitates.

B. Etiology. Almost 90% of cases are idiopathic or have a rheumatologic etiology (e.g., sarcoidosis, ankylosing spondylitis, Reiter syndrome). The most common infectious cause is herpes (simplex and zoster), which accounts for 10% of anterior uveitis cases. Rarely, anterior uveitis is associated with syphilis, tuberculosis, or Lyme disease.

1. **HSV type I** causes recurrent anterior uveitis in up to 40% of patients with a history of herpetic keratitis. The virus may cause recurrent iritis or iridocyclitis without active corneal disease. Disease is thought due mainly to the immune reaction to the virus, and treatment with topical steroids and topical trifluridine is effective. The benefit of adding oral acyclovir for iridocyclitis was not clear in a prospective trial [53], although chronic suppressive therapy with acyclovir 400 mg orally twice a day reduced frequency of recurrence. **Herpes zoster virus** may cause an anterior chamber inflammation from iridocyclitis as part of **herpes zoster ophthalmicus**, and treatment is the same as for keratitis (see Infectious Keratitis, section III).
2. **Syphilis** in the acquired form may cause an anterior uveitis, is usually bilateral, and most often associated with secondary syphilis. In two-thirds of cases, the patient has granulomatous rather than granular keratic precipitates. Syphilis may also cause a posterior uveitis (see below) or panuveitis. **This diagnosis should be considered in any patient with uveitis and a positive RPR.** Syphilitic uveitis may also occur in latent and tertiary syphilis, so an FTA-ABS or TPPA should be requested, because many of these cases will have negative RPRs. A TPPA is preferred, as FTA-ABS may rarely be falsely positive in rheumatologic diseases [54]. In patients with ocular syphilis, a lumbar puncture is indicated to rule out coexistent neurosyphilis. Treatment for ocular syphilis is the same as for neurosyphilis (10 days of intravenous penicillin at 24 million units/day) (see also Chapter 16).
3. **Tuberculosis** may cause an anterior uveitis, but a more common manifestation is multifocal choroiditis (see below).

IV. Intermediate uveitis. Most cases are idiopathic (70%) or due to sarcoidosis (20%) or multiple sclerosis (8%). Lyme accounts for 0.6% of cases.

A. Lyme disease. Lyme disease is rarely associated with uveitis. Some reported cases may be suspect because diagnosis is often based on serology. Uveitis usually occurs in the later stages of the disease. Lyme can cause anterior uveitis, neuroretinitis, retinal vasculitis, choroiditis, and panuveitis, but intermediate uveitis—especially vitritis—may be the most common manifestation [55]. The vitritis is often severe and accompanied by a granulomatous anterior chamber reaction and inflammation of the optic disk (papillitis).

V. Posterior uveitis (including retinitis)

A. Clinical characteristics. Unlike patients with anterior uveitis, patients with posterior uveitis usually have no pain and present with subacute decrease in vision. Toxoplasmosis is the most common cause, accounting for 25% of posterior uveitis cases, whereas cytomegalovirus was common in patients with acquired immunodeficiency syndrome (AIDS) before highly active antiretroviral treatment (HAART).

B. Viral etiologies

1. **Cytomegalovirus** produces a retinitis in immunocompromised patients. Though now uncommon, it affected over 30% of patients with AIDS before the advent of HAART (see Chapter 18,19).
2. **Other herpesvirus infections.** **HSV and varicella-zoster virus** can cause a retinitis but more typically cause a keratouveitis (see section III.B). They are the most common causes of **acute retinal necrosis**. First described 30 years ago, acute retinal necrosis often starts as an iritis and then causes a fairly rapid (days to weeks) destruction of the retina [56]. The retinal destruction characteristically starts in the periphery. In one-third of patients, the other eye will become involved. Treatment with high-dose i.v. acyclovir (10 mg/kg every 8 hours for 2 to 3 weeks) is followed by oral therapy (e.g., valacyclovir for 4 to 6 weeks) to prevent disease in the other eye.

C. Bacterial etiologies

1. **Syphilis** was the leading cause of chorioretinitis in the early 1900's but is now uncommon. The most common ocular finding in congenital syphilis is a bilateral

chorioretinitis, whereas a patchy neuroretinitis with retinal hemorrhage is most common in acquired syphilis (seen mainly in latent or tertiary stages). Treatment is as described for syphilitic anterior uveitis (see section III.B.2).

2. **Tuberculosis** was once a common cause of posterior uveitis but is now rare. The most common ocular manifestation is a multifocal choroiditis, with multiple (five to several hundred) discrete lesions in the deep choroid. Vitreitis and an anterior granulomatous uveitis may also be seen. The diagnosis of ocular disease is not difficult in patients with evidence of tuberculosis elsewhere (e.g., in the lungs, lymph nodes, or renal system), because diagnosis may be confirmed by biopsy and/or culture from these other sites. However, ocular disease often occurs in patients with no other manifestations of tuberculosis. In these patients, diagnosis is a dilemma. There is no good diagnostic test for ocular tuberculosis. Cultures of the aqueous or vitreous are negative, and polymerase chain reaction of the vitreous has an unknown sensitivity and specificity. In four of the six cases in the literature with positive polymerase chain reaction for tuberculosis, there were no other manifestations of the disease and diagnosis was presumptive [57]. Biopsy of the choroid can be done but is not indicated because the procedure carries a high risk for loss of the eye. At present, diagnosis in patients with no other evidence of tuberculosis must be based on clinical judgment. Not all patients with a positive purified protein derivative (PPD) and uveitis have ocular tuberculosis, but some do. The diagnosis should be considered in patients with a positive PPD who have classic manifestations of ocular tuberculosis (e.g., multifocal choroiditis). Treatment for ocular tuberculosis should be for 12 months (see Chapter 11).

D. Fungal etiologies

1. **Candida** In a recent prospective study (see under Endophthalmitis), chorioretinitis developed in 9% of patients with candidemia. Treatment of the candidemia (see Chapter 17) will also treat the chorioretinitis.
2. **Cryptococcus** may cause a chorioretinitis. This is almost always seen in patients who also have cryptococcal meningitis (see Chapter 17).
3. **Presumed ocular histoplasmosis syndrome** is a syndrome of bilateral chorioretinal scars ("histo spots"), peripapillary atrophy, and maculopathy seen predominantly in patients who live in the Ohio and Mississippi River valleys of the United States. Although presumed to be due to *Histoplasma capsulatum*, there is no proof of this. No antifungal therapy is indicated.

E. Parasitic etiologies

1. **Toxoplasma gondii** is the leading cause of posterior uveitis. It produces a retinochoroiditis, usually as a result of reactivation of latent infection. The classic finding of ocular toxoplasmosis is of a yellow-white lesion adjacent to a brown-black retinal scar. The view of the retina is often hazy due to accompanying vitreal inflammation, so the funduscopic exam may have a "headlight in the fog" appearance. In contrast, vitreal inflammation is almost never seen in cytomegalovirus retinitis. In immunosuppressed patients, especially patients with AIDS, the retinal lesions are multifocal and often bilateral, and there may be associated central nervous system lesions. The diagnosis of ocular toxoplasmosis is clinical (i.e., by the appearance of the ocular lesions). There are no good laboratory tests. Serology is usually positive, but this is nonspecific because of the high prevalence of seropositivity in the general population. Serology may also be falsely negative.

Peripheral lesions that do not threaten vision may not require treatment. Treatment for vision-threatening lesions in adults includes sulfa drugs (e.g., sulfadiazine 1 g orally every 6 hours), pyrimethamine (25 mg/day orally) with folinic acid "rescue" (5 mg/day orally), and clindamycin (300 mg orally four times a day). Prednisone is often added in cases with severe vitreous inflammation and lesions threatening the macula. Sulfadiazine probably is superior to trimethoprim-sulfamethoxazole, although the latter (one Bactrim DS tablet orally twice a day) has been used successfully in immunocompetent patients. Note that patients should have frequent complete blood counts while on pyrimethamine. Recently, atovaquone has been successfully used to treat ocular toxoplasmosis [58].

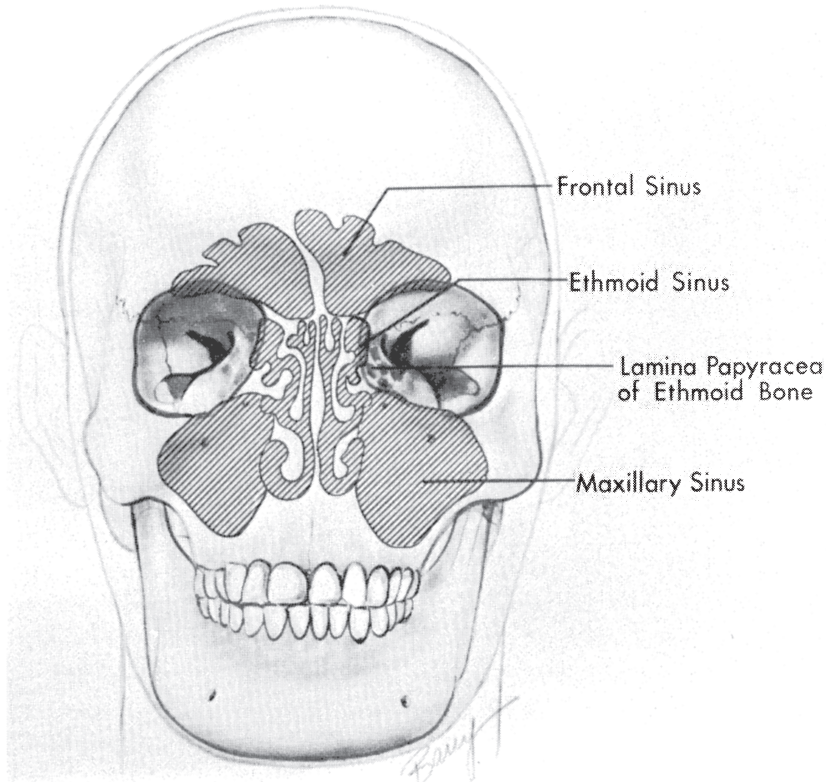

FIG. 7.5 The paranasal sinuses. (Modified from Lessner A, Stern GA. Preseptal and orbital cellulitis. *Infect Dis Clin North Am* 1992;6:933–952, with permission.)

Because all available therapies treat only the tachyzoites but not the tissue cysts, treatment suppresses but does not cure the infection, and recurrence of ocular toxoplasmosis occurs in two-thirds of patients.

VI. Other infectious causes of uveitis. Very rare causes of uveitis include leptospirosis, brucellosis, *Pneumocystis carinii*, Whipple disease, and *Toxocara canis*.

ORBITAL AND PERIORBITAL INFECTIONS

I. Anatomy. The orbit is surrounded by the paranasal sinuses (Fig. 7.5) and the bones of the orbit and the sinuses are shared (e.g., the medial wall of the orbit is the very thin lateral wall of the ethmoid sinus). The globe of the eye fills most of the anterior portion of the orbit, whereas loose fatty tissue and muscle fill most of the posterior part. The **orbital septum** is a fascial layer extending from the orbital rim periosteum to the tarsal plates in the eyelids, and it is a major barrier preventing superficial (**preseptal**) infection from extending posteriorly into the orbit. The orbital veins drain into the cavernous sinus. They have no valves so they freely communicate with the veins of the face and paranasal sinuses.

II. Etiology. Most orbital infections (50%–80%) are secondary to sinusitis, usually involving the ethmoid or frontal sinuses. Other orbital infections may follow trauma, surgery, dacryocystitis, or eyelid infections. Figure 7.6, adapted from the classic study by

FIG. 7.6 The five main categories of orbital infection: (a) Preseptal cellulitis, (b) orbital cellulitis, (c) subperiosteal abscess, (d) orbital abscess, (e) cavernous sinus thrombosis. (Modified from Chandler JR, Langenbrunner DJ, Stevens FR. The pathogenesis of orbital complications in acute sinusitis. *Laryngoscope* 1970;80:1414, with permission.)

Chandler, Langenbrunner, and Stevens [59], illustrates the five main categories of orbital infection. With the exception of cavernous sinus thrombosis, ocular findings are nearly always unilateral.

III. Preseptal (“periorbital”) cellulitis

A. Definition. Preseptal cellulitis is an infection that **involves the entire eyelid and surrounding tissues anterior to the orbital septum** but does not extend to the deeper contents of the orbit. Infection is secondary to sinusitis or upper respiratory infection in more than 50% of patients and to eye trauma in 25% [59]. Most patients are children younger than 10. *S. aureus*, streptococci, and *H. influenzae* are the most common pathogens. A mixed infection including oral anaerobes may occur after an animal or human bite to the lid area.

- B. Clinical characteristics. Pain, swelling, and erythema of the eyelid** and low grade fever are typical, although one-third of patients remain afebrile. The distensibility of the periorbital tissues results in severe eyelid edema. It is important to note that there are no signs of orbital involvement: no proptosis (anterior displacement of the eye), ophthalmoplegia (limitation of eye movement), pain with eye movement, or change in visual acuity. Proptosis may not be grossly apparent and should be measured with an instrument (Hertel exophthalmometer). If any orbital signs are present, orbital cellulitis must be considered.
- C. Diagnosis.** As in most cases of cellulitis, there is little to culture. Blood cultures should be obtained, and any draining wound should be cultured. If there is no obvious source, sinus disease should be excluded by sinus radiographs or computed tomography (CT) or by otolaryngology evaluation. An ophthalmology consultation should be obtained.
- D. Treatment.** In mild cases, oral antibiotics may be given with close (e.g., daily) follow-up. In more severe cases, i.v. antibiotics should be given initially and the patient observed in the hospital. Initial i.v. antibiotics include nafcillin (if a skin source is suspected) and ampicillin-sulbactam (if there is concomitant sinusitis or bite wound).

IV. Orbital cellulitis

- A. Definition.** Orbital cellulitis is diffuse infection of the orbital contents. Most infections follow sinusitis, but they may occur after trauma, preseptal cellulitis (and its etiologies), or, rarely, surgery.
- B. Clinical characteristics.** In addition to the eyelid swelling, redness, warmth, and tenderness seen in preseptal cellulitis, there is proptosis and pain with eye movement. There is often orbital pain, conjunctival hyperemia, and chemosis (conjunctival edema). Most patients are febrile and have elevated white blood cell counts. As the infection progresses, there is limitation of ocular motility. Orbital abscess or subperiosteal abscess should be considered if there is inferior and lateral displacement of the globe (i.e., the eye looks downward and outward).
- The major pathogens are *S. aureus*, group A streptococci, *S. pneumoniae*, viridans streptococci (e.g., *S. intermedius*), and *H. influenzae*. The incidence of *H. influenzae* as a cause of orbital cellulitis has decreased markedly since the advent of the HiB vaccine [60].
- 1. Noninfectious diseases** that can mimic orbital cellulitis are rapidly enlarging orbital neoplasms such as rhabdomyosarcoma or malignant melanoma.
- C. Diagnosis.** Cultures of blood, conjunctiva, and wounds (if present) should be obtained. Needle aspiration of the orbital soft tissues is not indicated. A lumbar puncture should be performed if there is any clinical suspicion of meningitis. A cranial CT to determine whether sinusitis or an abscess is present is important. **An ophthalmologist should be consulted regardless** and an otolaryngologist if sinusitis is present.
- D. Treatment.** Intravenous antibiotics should be started as soon as cultures are obtained. Antibiotics that penetrate the blood–brain barrier should be chosen even in the absence of signs of meningitis. Delay in treatment or inadequate antibiotics may result in loss of vision or even death.
- 1. Posttraumatic.** A semisynthetic penicillin (e.g., nafcillin).
 - 2. Postsurgical.** Broad-spectrum coverage (e.g., nafcillin and cefotaxime).
 - 3. After bite wounds or anaerobic infection.** Ampicillin-sulbactam is suggested. See related discussion in Chapter 4 under Animal Bites.
 - 4. Sinusitis-related** (or nontraumatic). Nafcillin plus a third-generation cephalosporin (e.g., cefotaxime or ceftriaxone).
- E. Mucormycosis** is a rapidly progressive necrotizing fungal infection of the paranasal sinuses that may present initially as a bacterial orbital cellulitis. There are subtle differences in presentation, however. In bacterial orbital cellulitis, the lids are red, hot, and tender; pain is usually limited to the orbit; and there are no paresthesias (except possibly decreased sensation in very swollen lids). In mucormycosis, the lids are often very edematous, may be faintly pink, but are often not red or hot. Patients with mucormycosis often have pain or paresthesias in the cheek, temple, or forehead where there is no sign of cellulitis, and these symptoms may

occur 1 to 2 days before any evidence of ocular or facial abnormality. Mucormycosis is very rare, and most cases occur in insulin-dependent diabetics (70% of cases) or immunocompromised hosts. Patients receiving desferrioxamine chelation therapy are also at risk. The fungus invades blood vessels, causing ischemic necrosis of tissues. It spreads rapidly (in days) from sinus focus to involve the orbit, followed by the cavernous sinus and brain. The **diagnosis** is suspected in the appropriate host by the appearance of an area of necrosis (e.g., black eschar) in the nasal mucosa on endoscopic examination. However, very rarely and in early disease, the mucosa may look normal, but deep surgical biopsy of the middle turbinate will show the invading hyphae [61]. Diagnosis must be confirmed by biopsy of tissue (usually intranasal or sinus), showing the characteristic nonseptate hyphae invading tissue. Therapy is with aggressive surgical debridement and intravenous amphotericin (or liposomal amphotericin).

V. Subperiosteal abscess

- A. Definition.** A subperiosteal abscess is a collection of pus between the periosteal lining and the bony wall of the orbit. If pus ruptures into the orbit itself, it is an orbital abscess (see section VI). A subperiosteal abscess usually results from the extension of an infection within a sinus.
- B. Clinical characteristics.** As in orbital cellulitis there is redness and swelling of the eyelids, proptosis, orbital pain, and usually a fever and an elevated white blood cell count. In addition, there is ophthalmoplegia and **displacement of the globe**. Because the ethmoid or frontal sinuses are most commonly involved, displacement tends to be downward and laterally (“down and out”). *S. aureus*, streptococci, and *H. influenzae* are the most common pathogens.
- C. Diagnosis.** Blood cultures should be obtained. Emergency consultations with an ophthalmologist and an ear, nose, and throat surgeon should be obtained as well as an emergency CT (the relative merits of CT vs. magnetic resonance imaging in this setting have not been defined). Sinus cultures obtained endoscopically may be helpful if surgery is delayed. At the time of surgery, aerobic and anaerobic cultures should be obtained and the material should be Gram stained.
- D. Treatment.** As in orbital cellulitis, delay in treatment may result in loss of vision. In most patients, immediate surgical drainage of the subperiosteal abscess and involved sinus should be performed. Intravenous antibiotics should include a semisynthetic penicillin and a third-generation cephalosporin (e.g., nafcillin and ceftriaxone) and should be started as soon as initial blood and sinus cultures have been taken.

VI. Orbital abscess

- A. Definition.** An orbital abscess is a collection of pus within the orbit. It results either from a consolidation of infection in orbital cellulitis or from rupture of a subperiosteal abscess. Progression of infection in the patient with orbital cellulitis despite adequate intravenous antibiotics or a decrease in either visual acuity or extraocular movement suggests development of an intraorbital abscess.
- B. Clinical characteristics.** The eyelids are red, warm, and swollen, and there is often marked chemosis. As in subperiosteal abscess, the **globe often is displaced downward and laterally. Eye mobility is severely limited**, and there is usually a marked decrease in vision. Fever and leukocytosis are common. *S. aureus* and streptococci are the most common pathogens. The distinction between orbital and subperiosteal abscess may be difficult to make clinically.
- C. Diagnosis.** Blood cultures should be drawn. **An emergency CT and emergency consultations with an ophthalmologist and an ear, nose, and throat surgeon** should be obtained. At surgery, the abscess material should be sent for Gram stain and aerobic and anaerobic cultures. In immunocompromised patients, smears and cultures for acid-fast bacilli and fungus should also be done.
- D. Treatment.** In this condition, as in subperiosteal abscess, emergency surgical drainage of the abscess is the most important component of therapy. Empiric i.v. antibiotics should be given as soon as possible, however, while awaiting this surgery. Delay in treatment may result in loss of vision. After blood cultures have been taken, empiric i.v. therapy with a semisynthetic penicillin and a third-generation cephalosporin (e.g., nafcillin and ceftriaxone) should be started. Antibiotics should be adjusted when culture results are available.

VII. Cavernous sinus thrombosis. Cavernous sinus thrombosis is a very rare but life-threatening complication of orbital infection that can occur when a septic phlebitis of the veins draining the orbit leads to thrombosis of the cavernous sinus. Because the cavernous sinus drains both orbits, thrombosis leads to bilateral eye findings (proptosis, periorbital edema, ophthalmoplegia). Because of the proximity of the cavernous sinus to the meninges, meningeal signs and frank meningitis can also occur. The patient appears very ill and may have papilledema in addition to “frozen” globes. The major pathogens are *S. aureus* and streptococci. Meningeal doses of broad-spectrum antibiotics (e.g., nafcillin, metronidazole, ceftriaxone) should be used. The use of anticoagulants is controversial.

8. UPPER RESPIRATORY TRACT INFECTIONS

Robert F. Betts

With the exception of β streptococcus group A, viruses cause most cases of upper respiratory tract infection (URI). The term URI is somewhat of a misnomer. The respiratory viruses infect all of the respiratory epithelial-lined respiratory system, producing rhinitis, pharyngitis, otitis, laryngitis, and bronchitis. Clinical manifestations vary by age and somewhat by specific virus subtype. However, any one of the many respiratory viruses can produce any one of the several syndromes listed. Most of these syndromes are self-limited. What makes them so important in the United States is that they consume so much medical attention and so much of our medical resources. Approximately 20 million office prescriptions per year in the United States are written for URIs [1,2]. The most common reason has been otitis media, but bronchitis and sinusitis are not far behind [1]. These infections accounted for more than 75% of prescriptions written annually in physicians' offices [1]. Therefore, a practical approach to these common problems is essential.

I. The "common cold": definition and pathophysiology

- A. Definition.** Although we strive to define this syndrome, there is certainly not common agreement as to its definition, certainly not by the lay public. Some include only a stuffy nose and a sore throat in the definition and call facial pain sinusitis and cough bronchitis, believing they are somehow different. Others include all the above. Virus in pure culture has been isolated from sinus puncture [3,4], from the middle ear [5], and in animals from the trachea.
- B. Pathophysiology.** Over the last several years a great deal of information has accumulated indicating that respiratory symptoms are caused by elaboration of inflammatory mediators in response to viral infection [6,7]. The viruses themselves, with the exception of influenza and perhaps adenovirus, are not cytotoxic. Observations indicate that rhinovirus can be detected in the nasal secretions without any symptoms whatsoever. When cytokines are produced, the syndrome takes shape [6,7].
- C. Anatomic changes.** Computed tomographic studies on subjects with rhinovirus caused by URI reveal **abnormalities of the sinuses in more than 85% of cases.** These abnormalities resolve without antibiotics [8,9]. **Mucopurulent rhinitis** (thick, opaque, or discolored nasal discharge) **frequently develops 1 to 3 days after the onset of the common cold.** Desquamated epithelial and polymorphonuclear cells in the nasal secretions provide this color change in the absence of virulent bacteria [9].

II. Specific syndromes

- A. Nasopharyngitis is characterized by rhinorrhea, sneezing, sore throat, cough, and, in children, low-grade fever.**
 - 1. Frequency.** Children may have three to eight and adults one to three colds per year [9].
 - 2. Etiology.** Rhinoviruses and coronaviruses account for most infections in children; rhinoviruses are especially important in adults.
 - 3. Course.** The **usual duration is 6 to 7 days** with peak symptoms on the second and third days. It often begins with a mild sore throat, and within 24 hours clear and copious nasal discharge develops, by which time the sore throat has decreased. Accompanying the discharge is frequent sneezing with obstruction of one or the other of the nasal passages. Mucopurulent discharge mentioned above then evolves. Cough occurs by the second or third day due to release of inflammatory mediators [7]. Systemic symptoms, but rarely fever, are present on days 2 to 4.
 - 4. Management: symptomatic therapy in rhinovirus colds (and probably other etiologies).**
 - a. Naproxen,** and other nonsteroidal antiinflammatory drugs (NSAIDs), begun at the very first symptoms in young adults significantly reduces symptoms of headache, malaise, myalgia, and cough [10]. Virus shedding is not altered. This suggests an important role for prostaglandin or cyclooxygenases in cough and in systemic symptoms [7,10].

- b. First-generation antihistamines.** Based on earlier studies, the role of antihistamines in the therapy of common colds was controversial [11]. However, if first-generation antihistamines are initiated at the onset of the very first symptoms, they are very beneficial in adults. First-generation antihistamines appear more beneficial than second generation [12]. **Clemastine fumarate** reduces sneezing and rhinorrhea [13]. Likewise, **brompheniramine maleate** (e.g., the antihistamine in Dimetapp) was similarly efficacious, and it also reduced cough [14]. Mild drowsiness, dry mouth, and dry throat are potential side effects in some patients. The combination of naproxen and a first-generation antihistamine are highly effective. It is hoped that a similar approach in children would reduce otitis manifestations, but that awaits further study.
- c. Intranasal ipratropium bromide (Atrovent) used for 4 days** provides specific relief of rhinorrhea and sneezing with common colds in adults [15,16].
- d. Pseudoephedrine plus acetaminophen** when given to subjects who had cold symptoms for less than 48 hours led to improvement of “sinus” pain, pressure, and congestion when compared with control subjects in a preliminary report. The combination was well tolerated, except that 4% of the pseudoephedrine-acetaminophen subjects complained of nervousness [17].
- e. Other.** Acetaminophen in children and acetaminophen or aspirin in adults have been used, but these have not proven as effective as other NSAIDs. Cold-water vaporization has been used.
- f. Antimicrobial agents should not be given for the common cold.** Controlled trials of antibiotics have shown that treatment fails to change the course and the outcome of the illness. Furthermore, they do not prevent bacterial complications [9]. One well-conceived study (none in the study had received the above outlined symptomatic therapy) indicated that a third of antibiotic recipients and a third of placebo recipients were better in a week. However, a higher percentage of the 10% from whom respiratory pathogens were isolated pretreatment and had received placebo had progression of symptoms at 1 week [18]. The results from this study support the approach of waiting 7 days before using antibiotics. By so doing, only the 5% to 10% with progression would receive therapy.
- g. Antiviral agents** At the moment, there is no clear evidence that treatment of common cold with an antiviral agent is useful. This may be because symptoms are more due to host response than to viral replication. Prophylaxis during either the season of heightened activity (September and May) or in the family setting may prove more useful [19].
- 5. Complications.** Otitis media or **bacterial sinusitis** may follow a cold that sometimes merits antibiotics. See below for specific discussions of these entities.
- 6. Transmission** is from person to person, requires close contact, and probably involves transfer of the virus from the hands of an infected person to an intermediate surface or directly to the hands of a susceptible person [20]. **Therefore, good handwashing can help prevent the spread of these viral infections.** Illness in one family member should prepare others to initiate symptomatic therapy outlined above at the earliest symptoms.
- B. Acute pharyngitis and tonsillitis**
- 1. Definition.** The onset of pain in the throat manifested especially on swallowing, sometimes associated with tonsil exudates.
 - 2. Etiology.** Most pharyngitis is due to virus (usually >70%) and is not exudative. Pharyngitis produced by Epstein-Barr virus (EBV) is often the only respiratory manifestation of this disease (see Chapter 9). The earliest manifestation of both *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* infection is pharyngitis without rhinitis. Group A *Streptococcus pyogenes* (GAS) are the major cause of bacterial pharyngitis. Arcanobacterium are an uncommon cause of bacterial pharyngitis, and *Corynebacterium diphtheriae* is rare in the highly vaccinated.
 - 3. Clinical presentation [21]. See Table 8.1.**
 - a. Pharyngitis caused by viruses** is suggested by a rapid progression to include rhinorrhea, obstruction of the nasal passage(s), cough, conjunctivitis, hoarseness (which have up to 80% negative predictive value), and absence

Table 8.1. Differentiating Features of Pharyngitis Caused by Group A Streptococci and Viruses

	“Classic” Streptococcal Pharyngitis	Viral Pharyngitis
Season	Late winter or early spring	All seasons
Age	Peak: 5–11 yr	All ages
Symptoms	Sudden onset Sore throat, may be severe Headache Abdominal pain, nausea, vomiting	Onset varies Sore throat, often mild Fever varies Myalgia, arthralgia Abdominal pain may occur with influenza A or Epstein-Barr virus
Signs	Pharyngeal erythema and exudate Tender enlarged anterior cervical nodes Palatal petechiae Tonsillar hypertrophy Scarlet fever rash Absence of cough, rhinitis, hoarseness, conjunctivitis, and diarrhea	Characteristic enanthems Characteristic exanthems Often with cough, rhinitis, hoarseness, conjunctivitis, or diarrhea

Modified from Tanz RR, Shulman ST. Pharyngitis. In: Long-SS, Pickering LK, Prober CG, eds. *Principles and practice of pediatric infectious diseases*. New York: Churchill/Livingstone, 1997:202, with permission.

of fever. Viral infection is especially common in children less than age 3 [22]. Adenovirus can cause a syndrome that largely presents as pharyngitis with associated conjunctivitis. Exudate is commonly detected. EBV has exudates and tonsil enlargement as a major component of its presentation (see Chapter 9).

- b. The **“classic” clinical features of GAS** are onset in winter or spring; school-aged child; abrupt onset of fever, sore throat, headache, and abdominal pain; pharyngeal tonsil inflammation, often (but only 50% of the time) with yellowish exudates; swollen uvula; and tender anterior cervical lymph nodes.
 - c. **Differential diagnosis.** Several experts have tried to differentiate the clinical presentation of GAS versus viral infections (Table 8.1).
4. **Laboratory testing should be performed when clinical and epidemiologic features suggest GAS infection but not if viral infection is considered likely** (see section II.B.3). The exception would be for acute EBV infection.

- a. **Throat culture for GAS infection.** The sensitivity of a single throat culture is approximately 95%. Plates that are negative at 24 hours should be reexamined at 48 hours [21]. Specimens should be obtained from the surface of both tonsils (or tonsil fossae) and the posterior pharyngeal wall. Other areas of the oropharynx and mouth are unacceptable [21].

About 50% of subjects with EBV mononucleosis harbor GAS in their pharynx. In the winter, 30% to 35% of asymptomatic grade-school children are colonized with group A streptococci. If these carriers acquire viral pharyngitis, a throat culture will show GAS. This type of patient is assumed to have GAS infection and is often treated. This is one reason those patients with a sore throat and characteristics of viral illness only should not be cultured.

- b. **Rapid streptococcal antigen test.** This test has excellent specificity (>95%), so a **positive test for clinical purposes establishes the diagnosis**. However, the sensitivity of the antigen test is only positive in 80% to 90% or even lower of those with a positive culture, so a **negative antigen test should be confirmed with conventional blood agar plate culture [21,22]**. An area of debate is whether those who are antigen negative and

culture positive may simply be colonized. Rapid identification and treatment of GAS pharyngitis can reduce the risk of spread of GAS infection, allowing these patients to return to school, day care, or work sooner and can reduce morbidity associated with this illness [21,22] (see section 4.d).

- c. **Antibody studies** (antistreptolysin O [ASO], streptozyme) are **not advised** except to confirm prior GAS infections in suspected acute rheumatic fever or acute glomerulonephritis. It is also helpful in prospective epidemiologic studies conducted to separate patients with acute infections from those who are carriers [21]. Monospot serology for EBV is very helpful to confirm that infection (see Chapter 9).
 - d. **When to treat.** To provide any symptomatic relief from the treatment, it must be initiated immediately. However, prior studies have shown that therapy can be safely postponed up to 9 days after onset of symptoms and still prevent acute rheumatic fever [21,22]. In those with signs and symptoms highly suggestive of GAS infection, empiric therapy can be started, and if the cultures are negative, therapy can be discontinued. If the ill individual has a history of rheumatic fever, treatment is indicated immediately. However, if not, GAS infection is usually a self-limited disease: Fever and constitutional symptoms disappear spontaneously within 3 to 4 days of onset even without therapy [21], which has resulted in difficulty reaching statistical significance for penicillin therapy in small placebo-controlled studies. Therefore the clinician has considerable flexibility in initiating therapy.
 - e. **Regimens.** Unless contraindicated, **penicillin remains the treatment of choice** for GAS pharyngitis [21,23], and twice daily regimens, if taken, are effective and may help improve compliance. Resistance to penicillin has not been described. Amoxicillin is an acceptable alternative to penicillin and is often used because it is more palatable and the cost is comparable. However, because of its broader antimicrobial spectrum, use of amoxicillin results in greater selective pressure for resistant bacteria [22]. Family members are not usually treated unless they exhibit symptoms and have positive cultures or strep screens or they have rheumatic heart disease [24]. Cultures after treatment do not need to be obtained if symptoms clear with treatment. **Common regimens are shown in Table 8.2. In the penicillin-allergic patient, erythromycin is the major alternative,** or clindamycin can be used. The more expensive second- and third-generation cephalosporins are 10 to 20 times more expensive than penicillin, excessively broad spectrum, and, although sometimes encouraged by the pharmaceutical industry, seldom indicated [25]. Tetracycline and sulfonamides are not used both because of resistance and because even with susceptible strains sulfonamides do not prevent rheumatic fever.
 - f. **Recurrent streptococcal pharyngitis** [21,23,26]. Some individuals will improve with penicillin but do not clear the organism and symptoms recur. One explanation has been that β -lactamase-positive organisms present in the oropharynx inactivate penicillin. If the organism is susceptible to clindamycin, use of that drug leads to successful eradication. Outbreaks of GAS and “ping-pong” spread within a family are discussed elsewhere [21].
- C. **Acute otitis media (AOM) can be classified as AOM or otitis media with effusion. The natural history of appropriately treated AOM includes persistent middle ear effusions for several weeks in most children.**
1. **Definition. AOM is fluid in the middle ear in association with signs or symptoms of** otalgia or otorrhea usually with fever [27]. **A middle ear effusion is virtually always present,** except in rare circumstances when the practitioner may observe signs of acute inflammation in the hours before fluid accumulates in the middle ear [27]. **Pneumatic otoscopy is used** to assess position, color, translucency, and mobility of the tympanic membrane [27].
 2. **Physical findings in AOM**
 - a. **Local signs** such as otorrhea with evidence of middle ear origin, bulging tympanic membrane with cloudy or yellow fluid behind it or if tympanic membrane is distinctly red, or local ear pain should be sought.

Table 8.2. Treatment Regimens for Acute Streptococcal Pharyngitis in Children

	Regimen	Cost of Course ^a
Oral agents		
Penicillin V	125 mg (if <27 kg) to 250 mg ^b (if >27 kg) b.i.d. for 10 days	\$3
Erythromycin Ethylsuccinate	40 mg/kg/day (to max. of 1,000 mg/day) in two to four divided doses for 10 days	\$20
Estolate	20–40 mg/kg/day (to max. of 1,000 mg/day) in two to four divided doses for 10 days	\$11–22 ^c
Cephalexin or Cephadrine (first-generation cephalosporin)	25–50 mg/kg/day in two or three divided doses for 10 days	\$10–80 ^d
Clarithromycin	15 mg/kg/day (to max. of 500 mg/day) divided b.i.d. for 10 days	\$30–55 ^c
Azithromycin	12 mg/kg once daily (with max. 500 mg on first day, 250 mg subsequent days) for 5 days	\$28
Clindamycin ^e	20 mg/kg day (max. 1.8 g/day) divided t.i.d. for 10 days	\$17.50
Parenteral agent		
Benzathine penicillin G ^f	600,000 units if <27 kg and 1.2 million units if >27 kg IM once only	\$6

- b. Fever** is presumably indicative of AOM **when there are associated local signs**; in the absence of these local signs, fever often may be unrelated to middle ear effusion.
 - c. Nonspecific signs and symptoms** that do not help make the diagnosis of AOM include rhinorrhea, cough, irritability, anorexia, headache, vomiting, or diarrhea.
3. Physical examination (PE) in otitis media with effusion. **Fluid** in the middle ear **in the absence of signs or symptoms of acute infection**.
4. **Diagnosis**
 - a. Myringotomy** is carried out by incision of the tympanic membrane. That or tympanocentesis leads to recovery of the organisms [28].
 - b. Physical findings.** Both redness and bulging should be present. Merely immobility is not sufficient to make the diagnosis because this can be present in secretory otitis media.
5. **Etiology [27,28].** Bacteria are isolated from 50% to 60% of cases and include *S. pneumoniae* (25%–50%), *Haemophilus influenzae* (**most cannot be typed**) (15%–30%), and *Moraxella catarrhalis* (**most are β -lactamase positive**) (3%–20%). Viruses have also been isolated in pure culture, including respiratory syncytial virus (RSV), rhinovirus, parainfluenza, and influenza [5]. *Mycoplasma pneumoniae* is a consideration and has been associated with bullous myringitis.
6. **Treatment** One of the most hotly debated topics is if, or when, to treat AOM. Controlled trials show nearly identical outcome in treated or untreated subjects.

There is spontaneous clearance of bacteria in at least 40% and perhaps as high as 80% of cases [27,28]. *Haemophilus* is more likely to clear spontaneously than is *S. pneumoniae* [29]. Additionally, virus in pure culture is isolated from the middle ear, and these cases would not benefit from antibiotics [5]. Another factor is the increasing incidence of pneumococcus with minimal inhibitory concentrations (MIC) to penicillin of at least 1 $\mu\text{g}/\text{mL}$ (see Chapter 11). Not only are these organisms resistant to penicillin, they are also resistant to macrolides (erythromycin/azithromycin), trimethoprim-sulfamethoxazole (TMP-SMZ), oral cephalosporins, and tetracycline. Whereas the resistance to amoxicillin (amoxicillin/clavulanate) is relative and can be overcome with higher doses [30], the resistance to the macrolides is absolute.

Careful evaluation in prospective studies has raised the question of whether antibiotics should be used at all [31,32]. Recognizing the high rate of spontaneous resolution, investigators from Holland believed that lack of pain control rather than persistent fever was the reason for apparent failure in most studies. The rationale for using antibiotics, to prevent mastoiditis or meningitis, is not supported by data [33]. Thus, newer thinking is to use acetaminophen for 72 hours and consider antibiotics if symptoms persist or consider continued observation [31–35]. Exceptions to that rule would be for those children with severe symptoms or perforation of the ear drum, which provides physicians some leeway [35]. Against this background, a consensus group gathered by the Centers for Disease Control and Prevention has made recommendations for treatment [36].

a. Amoxicillin is the antibiotic of choice. Most experts believe that the pneumococcus not only is the most common pathogen in AOM, but also is the most likely to cause severe or persistent symptoms or suppurative and systemic complications if treated inappropriately [29]. Consequently, treatment regimens must be active against *S. pneumoniae*. The dose recommended has been increased from 40 to 80 or even 90 mg/kg because of the number of relatively resistant pneumococcus with high MICs has been increasing (Table 8.3). This was done without benefit of good studies, but in a trial comparing azithromycin to amoxicillin, Dagan et al. [37,38] showed that amoxicillin at that dose eradicated carriage of pneumococcus more frequently than did azithromycin, regardless of the MIC. In addition, also without benefit of good studies, a dose for adults of 1.0 g every 8 hours has been suggested. Uncomplicated AOM may be treated with a short course (5–7 days) in selected patients [28,39].

b. Amoxicillin clavulanate Because β -lactamase + *Haemophilus* and *Moraxella* are etiologic possibilities, this drug is often chosen. It is more effective than azithromycin in eradicating *Haemophilus* species. [30,37]. If used

Table 8.3. Antibiotics for Acute Otitis Media in Children (e.g., Child Weighing 18.5 kg)

Drug	Daily Dosage ^a	Cost (10–Days Therapy) ^b
Amoxicillin	60–90 mg/kg in three doses	\$14 ^c
Amoxicillin-clavulanate	90/12.5 mg/kg** in two doses	\$128 ^c
Cefprozil	30 mg/kg in two doses	\$64
Erythromycin-sulfisoxazole	50/150 mg/kg in four doses	\$25
Trimethoprim-sulfamethoxazole	8/40 mg/kg in two doses	\$19
Clarithromycin ^d	15 mg/kg in two doses	\$30
Ceftriaxone	Single i.m. dose, 50 mg/kg (not to exceed 1 g)	\$40

^cActual costs will vary, depending on weight of child.

^dAzithromycin is used in acute otitis media.

at 90 mg/kg or 1.5 g every 12 hours, the incidence of diarrhea is less than with a dose of 1.0 g every 8 hours. Amoxicillin remains first line because the above two organisms are far more likely to clear spontaneously and are less virulent.

- c. **Cephalosporins** Parenteral ceftriaxone has a high cure rate. Many pediatricians administer a single dose intramuscularly in the office (50 mg/kg maximum dose) [40]. By contrast, many of the oral cephalosporins have insufficient activity against the pneumococcus to be effective [41]. For example, in the ferret model, amoxicillin is superior to cefuroxime [42]. Furthermore, oral cephalosporins are relatively expensive.
 - d. **Other. The macrolides** have been used for the last several years. However, the absolute resistance mentioned above [43] has led to two problems. First, although macrolides eradicate susceptible pneumococcus quite well, they have no effect on resistant organisms and failure results. Second and more importantly, in day-care settings, macrolide susceptible organisms (that are also susceptible to penicillin) are eradicated and replaced by macrolide absolute resistant organisms (that are also relatively resistant to penicillin) [38]. This does not happen with amoxicillin use. **TMP-SMZ** resistance has become so frequent that its failure rate is predicted to be unacceptable [44]. **Quinolone** antibiotics (moxifloxacin, gatifloxacin) have excellent activity against all the middle ear organisms but are not approved for children because of the theoretical interference with cartilage development.
7. **Persistent middle ear effusion** 2 to 8 weeks after therapy does not require retreatment [27]. Middle ear effusion persists for weeks to months (i.e., 70% of children have fluid in the middle ear at 2 weeks, 50% at 1 month, 20% at 2 months, and 10% at 3 months, despite appropriate therapy) [27]. If that child presents with another fever, their effusion will still be present. To justify antibiotics, focal signs should be present.
 8. **For chronic otitis media with effusion** (lasting >3 months) accompanied by significant bilateral hearing loss, bilateral myringotomy with insertion of tympanotomy tubes is effective [27,45].
 9. **Antibiotic prophylaxis.** Because of the potential consequences of the emergence of penicillin-resistant pneumococcus, experts advise prophylaxis only in special settings.
 - a. **Indications.** Children with three or more well-documented and separate episodes in the preceding 6 months or four or more episodes in the preceding 12 months is the only indication for which beneficial effects of prophylaxis is persistent and persuasive [27]. **Duration** of prophylaxis should be no longer than 6 months, because longer courses are less effective and may be more likely to promote colonization with resistant bacteria [27]. **Agents** that have been used include **sulfisoxazole** (75 mg/kg/day in one or two divided doses). This is the preferred agent and may be less likely than amoxicillin to produce colonization with β -lactamase-producing bacteria or resistant pneumococcus. Amoxicillin (e.g., 20 mg/kg once daily) has been used. Oral cephalosporins have not been shown to be effective.
 10. **Other interventions** that may reduce the incidence of AOM without the risks of antibiotic exposure should be undertaken [27]: eliminating smoking at home, eliminating pacifiers, and using influenza and conjugated pneumococcus vaccines [46].
- D. Acute bronchitis accompanies acute viral URI.** Even though most of these cases are viral in origin, antibiotics are commonly and unnecessarily prescribed for 66% of adults and 75% of children with uncomplicated acute bronchitis [2,47].
1. **Definitions/clinical diagnosis.** Bronchitis is inflammation of the bronchial mucosa, resulting in a productive cough. The **definition in normal children** is not well established. Most clinicians believe that a child with **cough, with or without fever or sputum production, excluding pneumonia, bronchiolitis, and asthma** [48], has bronchitis. Similarly, in adults without underlying chronic lung disease, acute productive cough, no or low-grade temperature, and no evidence of pneumonia on physical examination or chest x-ray makes the

diagnosis of bronchitis. However, the lack of consensus regarding nomenclature and clinical definition of cough illnesses leads to difficulty in comparing patient populations and results in reported studies.

2. **Etiology. Viruses cause most cases. In adults**, rhinoviruses, influenza, parainfluenza, and adenoviruses are common. **In children** parainfluenza, RSV, and influenza virus are especially important. The role for *Bordetella pertussis* (whooping cough) as a cause of protracted cough in adults is undergoing study. **In children** most prolonged-cough illnesses are allergic, postinfectious, or viral and do not require antibiotics. Because reactive airway disease is common, even in the absence of wheezing, many of these patients respond well to bronchodilator therapy [48]. Sputum or nasopharynx colonizers (e.g., *S. pneumoniae*, *H. influenzae*, *S. aureus*) can be isolated in the laboratory even when the underlying process is viral in origin.

Viruses can cause a protracted cough, but a protracted cough is less likely to be viral in origin. In the absence of purulent sputum, *M. pneumoniae* and *Chlamydia pneumoniae* should also be considered in older children, teenagers, and adults, especially adults exposed to school-aged children or teenagers with prolonged respiratory illnesses (i.e., >10 days).
3. **Clinical findings.** Fever is common in viral bronchitis, especially when caused by influenza and RSV, and in and of itself does not predict the need for antibiotics [48]. However, if fever persists in adults it may be a clue to bacterial superinfection. Examination of the chest may reveal sibilant rhonchi but no areas of consolidation. Chest roentgenograms reveal no densities.
4. **Diagnosis.** Historical clues pointing to a virus are the simultaneous presence of similar illness in close contacts. If the individual who seems to be the index case for the presenting patient was ill 2 weeks earlier, that points to *M. pneumoniae* and *C. pneumoniae*. Viral identification, especially by rapid diagnostic methods, supports an etiology and may delay un-needed antibiotic therapy. Gram stain of expectorated sputum may demonstrate organisms consistent with *S. pneumoniae*. If fever has persisted, isolation of a pathogenic bacteria supports the use of antibiotics and susceptibility studies directs therapy, but merely isolating an alleged respiratory pathogen does not mandate use of antibiotics. Children with chronic cough (>4 weeks) should be evaluated for reactive airway disease, tuberculosis, pertussis, cystic fibrosis, aspiration of a foreign body, or sinusitis.
5. **Therapy for normal subjects.** Principles are published for children [48], and these principles also apply to adults. Because bronchitis is part of the acute viral URI, the principles of early use of antihistamines and NSAIDs discussed under URI apply here and have the same clinical benefit.
 - a. **Nonspecific cough** in normal children or adults rarely warrants antibiotics [48]. Studies of acute bronchitis in adults and cough illness/bronchitis in children have shown no benefit of antibiotics. Furthermore, prophylactic use of antibiotics in these patients does not prevent or decrease the severity of bacterial complications after viral URI. Neither the character nor the culture results of sputum or nasopharyngeal secretions is helpful in determining the need for antibiotics. Virus- and bacteria-induced airway inflammatory changes can cause "purulent" sputum with leukocytes. **For protracted cough (>10 days) antibiotics may be indicated.** However, 20% of adults with culture-confirmed rhinovirus colds continue to have cough for more than 14 days after onset of symptoms if they do not receive antihistamines and NSAIDs at the time of first symptoms [48]. If the clinical history supports mycoplasma or chlamydia, an empiric course of a macrolide or doxycycline (in children >8 years of age) is suggested. In children, pertussis and *M. pneumoniae* (see section D.2) benefit from antibiotics.
6. **Patients with underlying lung disease** receive empiric antibiotics more commonly. **Children** with cystic fibrosis and other severe lung disease (e.g., bronchopulmonary dysplasia, lung hypoplasia, chronic aspiration) are more likely to benefit from antibiotics, and therapy must be individualized [48]. **Adults** with structural lung disease (e.g., bronchiectasis or obstructive lung disease/emphysema) also may benefit from antibiotics.

E. Acute exacerbations of chronic bronchitis. Chronic bronchitis typically is defined as the production of sputum on most days for at least 3 months per year for more than 2 years.

1. **Clinical presentation.** An acute exacerbation of chronic bronchitis is a clinical syndrome associated with an increase in cough and an increase of sputum (both amount and purulence or a change in color). There is increased breathlessness without evidence of clinical or chest roentgenographic pneumonia. Most do not have systemic symptoms.
2. **Causes of acute exacerbations** include environmental factors, such as exposure to cigarette smoke, pollutants, fumes, pollens, and the like; these are important cofactors. Respiratory viruses appear to play a more important role in these acute illnesses than does *M. pneumoniae*. Many of these patients are chronically colonized with *S. pneumoniae* and *H. influenzae*. Presumably, these colonizing bacteria become minimally invasive, and therefore patients are more symptomatic, in the setting of sluggish white blood cell function caused by the virus infection. **Viral and bacterial etiologies cannot be distinguished clinically.**
3. **Diagnosis.** Physical examination reveals wheezing and rhonchi but no evidence of consolidation. The role of sputum cultures in this setting is unclear. Often empiric antibiotics are used without a sputum culture. If in selected patients cultures are desirable (e.g., the patient with multiple antibiotic allergies), a sputum culture should be obtained **before** starting antibiotics, because cultures obtained after antibiotics are difficult to interpret.
4. **Therapy.** The precise role of antibiotics in acute flare-ups is unclear [49,50]. Because minimally invasive bacterial infections are not well tolerated in patients with chronic lung disease, antibiotics are often initiated. **Many of these patients seem to respond clinically**, and some studies have shown that in the most severely symptomatic patients, antibiotics help [49,50]. Therapy is directed primarily against *S. pneumoniae* and *H. influenzae*. Various regimens have been recommended for adults (Table 8.4). Duration of therapy varies, but typically **5 days of therapy** is sufficient to reestablish host bacteria “equilibrium.” **For recurrent bouts, antibiotic regimens can be rotated** with the hope of minimizing the selection of resistant pathogens.

F. Acute sinusitis. As previously discussed, in adults, and presumably in children, well-documented common colds are associated with changes of the sinuses, as revealed by computed tomography (CT) [8]. (See the earlier discussion under URI.) These changes reverse spontaneously in 80% of cases. Quite often, facial pain blamed on sinusitis is instead an atypical migraine syndrome and responds to Imitrex or other similar medications.

1. **Pathogenesis.** For viral respiratory infection (e.g., rhinovirus), the exact mechanisms that lead to disease in the sinus cavity are not known, but it is speculated

Table 8.4. Antibiotic Options in Adults with Acute Exacerbations of Chronic Bronchitis

Drug	Daily Dosage (for 5 days)	Comments
Amoxicillin	250 mg p.o. t.i.d.	Commonly used
Trimethoprim- sulfamethoxazole	1 DS tab b.i.d.	Good sputum levels, commonly used
Erythromycin ^a	250 mg q.i.d.	Not as active against <i>H. influenzae</i>
Cefuroxime axetil	250 mg b.i.d.	Expensive
Tetracycline hydrochloride	250 mg p.o. q.i.d.	On empty stomach
Doxycycline	100 mg b.i.d.	Compliance is better

^aFor patients who cannot tolerate the more cost-effective erythromycin preparations, azithromycin (500 mg on day 1 and then 250 mg once daily on days 2–5) or clarithromycin (250–500 mg b.i.d.) can be used.

that it is similar to that which causes rhinitis. Presumably, a virus stimulates inflammatory pathways and the parasympathetic nervous system, resulting in engorgement of the capacitance vessels in the venous erectile tissue of the nasal turbinate. Simultaneously, intercellular leakage of plasma into the nose and (presumably) sinuses, discharge of seromucous glands and goblet cells, and stimulation of pain nerve and sneeze and cough reflexes occurs [51]. Abnormalities are commonly seen on CT. Mucus and transudation of plasma into the sinus cavity presumably add to the viscosity of the material accumulating within the sinuses. Sinus disease may result from malfunction of the normal mucociliary clearance process, in part due to the very viscous secretions and partial/total obstruction (because of inflammation) of the usual drainage pathways of the sinuses. Furthermore, the opening of the osteomeatal complex is very narrow, and the walls of the passage are bone and thus not compliant. Natural drainage is very slow.

2. **Diagnosis.** Physical examination, if the disease is in the maxillary sinus, will illicit facial tenderness accompanied by pain on striking the upper molars. Postnasal drip may be conspicuous, and transillumination of the sinuses may be inhibited by fluid. However, the latter is unreliable. Coronal CT of sinuses may reveal fluid and/or thickened membranes, but this finding is present in both bacterial and viral sinusitis.
3. **Symptoms.** Excess nasal secretions, posterior nasal drip, facial pain, and pain in the vertex of the head are the classic complaints. If antihistamines and NSAIDs are initiated early, these complaints are reduced in frequency and severity.
4. **Complications.** Acute bacterial sinusitis has been reported to follow viral URI (sinusitis) in 0.5% to 5% of instances. Most cases of acute sinusitis resolve without antibiotic treatment [8,51,52]. The specific factors that determine whether bacterial invasion of the sinus will occur after a viral URI are unknown. Sneezing, coughing, and nose blowing may create pressure differentials that cause deposition of bacteria-containing nasal secretions into the sinus. Once bacteria are deposited into the cavity of an obstructed sinus, bacterial growth conditions are favorable; granulocyte phagocytosis may be impaired by the reduced oxygen tension in the obstructed sinus. This complication usually manifests about 7 days after onset. This process may take weeks to resolve [51].
 - a. **Other risk factors for acute bacterial sinusitis.** Swimming and nasal obstruction due to polyps, foreign bodies, and tumor precede this process in a few cases. **An allergic cause** can usually be established by a history of paroxysmal sneezing, itching eyes, allergen exposure, and similar prior episodes. Patients can often self-diagnose the problem [51]. Dental infection can be the source. Other less common risk factors include acquired immunodeficiency syndrome, abnormalities of white blood cell function, cleft palate, cystic fibrosis, and immune deficiencies such as agammaglobulinemia [51].
 - b. **Symptoms and signs.** Fever occurs in only 40% to 50%. Facial pain and tenderness (along with tenderness of an upper molar) are often found. Although some clinicians interpret **mucopurulent rhinitis** (thick, opaque, or discolored nasal discharge), especially in children, as indicating the presence of bacterial sinusitis, this sign is simply part of the natural course of a nonspecific uncomplicated URI. The nasal discharge in a cold changes from clear to purulent during the first few days of illness. In addition, the color and characteristics of the discharge do not predict whether bacteria will be isolated [52]. Cough is common in children and adults. Hyposmia (decreased smell sensation) is common. When the sinusitis follows a dental infection, a foul odor of the breath and molar pain are additional characteristics [51].
 - c. **Separating viral versus bacterial versus mixed** is not possible, by clinical parameters alone. **CTs are not recommended** because of their lack of specificity. Patients with a common cold have sinus abnormalities most of the time [8]. In his excellent review, Gwaltney [51] **emphasized that clinical parameters define classic bacterial sinusitis: "Classic" acute bacterial sinusitis will have fever, facial pain, marked tenderness** (over the involved sinus), **erythema, or swelling**. Also in this group are patients with molar pain or other evidence of an odontogenic cause of the infection. In

children, fever more than 39°C, periorbital swelling, and facial pain or dental pain is suggestive [52].

- d. **Rarely, sinusitis can be complicated by meningitis, brain abscess, or orbital infections.**
 - e. **Etiologic organisms.** Nasopharyngeal cultures do not reflect the bacteriology of the sinuses [52]. The **gold standard** is identification of organisms by puncture of the sinuses. However, this is generally used only in complex cases, and only about 60% of sinus aspirates in suspected cases of acute sinusitis yield bacteria. [52]. Puncture studies have shown that *S. pneumoniae* and *H. influenzae* account for 50% of cases in adults and children. *M. catarrhalis* is more common in children (about 20% of isolates) than in adults. A recent reviewer emphasizes that in children, acute sinusitis is usually caused by the same bacterial pathogens that cause AOM [52]. *S. aureus* and streptococcus group A cause less than 5% of cases. Anaerobic infections are infrequent in children. In adults, most anaerobic sinusitis arises from infection of the roots of premolar teeth, thus representing a pure bacterial infection [51]. Viruses alone may account for 10% to 15% [51,52]. The etiology of the cases that are negative on the bacterial culture has not been fully studied, but presumably viruses are important in most. The role of *C. pneumoniae* and *M. pneumoniae* has not been well established [51]. Fungi occasionally cause sinusitis and usually present with pressure changes, such as proptosis, and bony erosion [51].
 - f. **Roentgenographic studies** are indicated when (a) episodes of sinusitis are recurrent, (b) complications are suspected, (c) the diagnosis is unclear, (d) the patient is responding poorly, or (e) sinus surgery is contemplated [52]. Most clinicians have moved to coronal CTs or magnetic resonance imaging but only after acute URI has resolved. Abnormalities include air-fluid levels, opacification, or mucosal thickening of more than 4 mm [52]. **Loss of bony markings medially should not be interpreted as osteomyelitis.** These changes are simply pressure necrosis on a very thin wall. **A classic air-fluid level usually means an acute bacterial sinusitis** [51]. Opacification and mucosal thickening are often nonspecific and may be chronic or due to prolonged URIs. Until about ages 5 to 6, the frontal and sphenoid sinuses do not appear and may not be fully developed until adolescence. Misinterpretation of absent sinuses as opacified can lead to the overdiagnosis of sinusitis. In particular, films should be read with great caution in children less than 1 year of age [52].
5. **Therapy.** As with otitis media, acute sinusitis will often resolve even without antimicrobial therapy [52]. **Therefore only “classic” cases, or those with protracted symptoms (>8–10 days), or complex cases should be treated. Protracted sinonasal symptoms (>8–10 days) suggest that bacterial infection has complicated a viral URI.** The latter should have resolved or at least improved by 10 days. In children, prolonged nonspecific URI signs and symptoms without improvement for more than 10 to 14 days merit therapy, whereas children with symptoms improving by 7 to 10 days of onset probably have an uncomplicated viral URI.
- a. **Antibiotics.** (See Table 8.5) Randomized placebo-controlled trials of antibiotics for acute community-acquired bacterial sinusitis with the use of pretreatment and posttreatment sinus aspirate cultures have not been conducted. In several nonrandomized studies, appropriate doses of antibiotics are highly effective in eradicating or substantially reducing bacterial titers in the sinus cavity. When 10-day regimens are used, a bacteriologic cure rate of more than 90% has been achieved [51].
 - (1) **Amoxicillin for initial management of acute uncomplicated is successful in sinusitis as it is in otitis in most children** [34–36,52], and probably most adults, despite β -lactamase production by most isolates of *M. catarrhalis* and some *H. influenzae* [52]. For adolescents and adults, 500 mg orally three times a day and for children 60 to 80 mg/kg/day can be used.
 - (2) **For those unresponsive to amoxicillin in 48 to 72 hours or for whom amoxicillin is contraindicated or who are experiencing recurrent**

Table 8.5. Alternative Antibiotics for Sinusitis

Antibiotics	Oral Dose in Adults	Oral Dose in Children	Comment
Amoxicillin-clavulanate	875 mg b.i.d.	^a	Some view as an optimal agent of choice for penicillin-resistant <i>S. pneumoniae</i> in children (or adults)
TMP-SMZ	1 DS b.i.d.	^a	Misses some <i>S. pneumoniae</i>
Cefuroxime axetil	250 mg b.i.d.	^a	Expensive ^b
Cefprozil	250 mg b.i.d.	^a	Expensive ^b
Azithromycin	5-day course (Z pack)	^a	Macrolide with fewest gastrointestinal side effects ^b
Clarithromycin	250 mg b.i.d.	^a	
Advanced fluoroquinolone (e.g., levofloxacin)	500 mg q.d.	Avoid	Effective against penicillin-resistant <i>S. pneumoniae</i> , useful in adults allergic to penicillin/cephalosporins. Expensive

^aFor dosages in sinusitis, use same regimens as in acute otitis media. See Table 8.3.

^bMay miss some penicillin-resistant *S. pneumoniae*. See Chapter 11.

infections, a β -lactamase stable agent (e.g., amoxicillin-clavulanate) or a β -lactamase stable cephalosporin active against pneumococci (e.g., cefuroxime axetil) is suggested [30,37,51].

- (3) **See Table 8.5. Antibiotics are usually given for 10 days** [51] or for 7 days beyond the point of substantial improvement. Recently, in a report from the Netherlands, adults with acute maxillary sinusitis and abnormal conventional radiographs (mucosal swelling of more than 5 mm, complete shadowing, or a fluid level) were randomized to receive either amoxicillin 750 mg three times a day for 7 days or placebo. Amoxicillin (used because most of the organisms that they had identified in a preliminary study were susceptible) did not improve clinical outcomes [53]. This preliminary study is difficult to interpret because the critically important duration of sinus-like symptoms was not specified, the number of patients with diagnostic radiographic abnormalities (air-fluid level) was not specified, and it is well known that some improve without antibiotics. However, at least it implies that therapy in acute disease is not indicated.
 - (4) **In severely ill patients** with intracranial or orbital extension, intravenous therapy with ceftriaxone and vancomycin (to cover high-level penicillin-resistant *S. pneumoniae*) should be started. Infectious disease consultation is advised.
- b. Ancillary therapy** is directed at drainage of the nasal passages and sinuses and relief of sneezing, coughing, and systemic symptoms [51].
- (1) **Decongestants.** Although serial CTs show that decongestants have little or no effect in promptly draining the sinuses, they are commonly used. **Oral decongestants are preferred over topical** nasal decongestants, which are often associated with rebound vasodilatation and obstruction and pharyngeal irritation. Oral decongestants are safe for patients with stable hypertension who are receiving appropriate antihypertensive treatment [17,51].
 - (2) **Topical steroids are useful** if there is evidence of an **allergic component** to the patient's illness. The use of topical (or oral) steroids as decongestants has not been rigorously evaluated. In volunteers with rhinovirus-induced rhinosinusitis, topical steroids had little, if any, beneficial effect on nasal symptoms [51].
 - (3) **Mucoevacuant drugs** (e.g., guaifenesin) are used on theoretical grounds, but their usefulness has not been **established** [51].
 - (4) **NSAIDs** are useful in treating systemic symptoms such as fever and malaise and may be helpful in reducing cough [51]. Acetaminophen is also used as an analgesic.
 - (5) **Cough suppressants** with dextromethorphan or codeine may be needed to control cough.
 - (6) **Antihistamines.** Although there may be a reluctance to use first-generation antihistamines because of their anticholinergic activity and the possibility of their drying secretions and impairing drainage, testing under randomized, controlled, blinded conditions has shown a reduction of about 50% in sneezing and a reduction of about 30% in rhinorrhea and nasal mucus weights in volunteers with experimental rhinovirus colds. There was no evidence of other symptoms or prolongation of the overall illness, indicating that drying of secretions and impairment of drainage were not problems [51]. Therefore **the use of antihistamines (in adults) for symptomatic improvement in the early phase seems reasonable**. Whether antihistamines, by reducing sneezing and nasal secretions, are truly beneficial has not been proven. See related discussion under the common cold.
- c. Prevention [51]**
- (1) Prevention of **viral URI may be minimized** by avoiding contact with people with colds. Carrying out handwashing when contact occurs between infected and noninfected persons is useful. Covering the mouth with disposable nasal tissues when coughing or sneezing is desirable.

- (2) **Influenza vaccine** reduces attack rate in all age groups and reduces severity in the elderly, but it is effective only against influenza and not other viruses that cause respiratory illness.
- (3) **Prophylactic antibiotics** to prevent recurrent acute bacterial sinusitis are **not recommended** and will add to the selection of resistant pathogens.

G. Chronic sinusitis (defined as symptoms persisting for 6 months). Patients with chronic sinusitis need to be referred to an otolaryngologist for nasal endoscopy and/or CT study and consideration for drainage procedures.

1. **Etiology.** The organisms isolated from chronic sinusitis patients differ substantially from those isolated in acute sinusitis. In a small percent, *Haemophilus* species are isolated but coagulase-negative staphylococcus, *Pseudomonas aeruginosa*, anaerobic bacteria, and fungi are more common [54]. Thus, although antibiotics discussed in the section on acute sinusitis are used at times with protracted courses of 3 to 4 weeks, the rationale for that cannot be justified based on the organisms identified. However, many times when there is an acute infection, no attempt at isolation of the etiologic organism is carried out and antibiotics are administered with apparent response. No randomized studies have been conducted to ascertain the value of such treatment, which leaves the matter largely unresolved.
2. **Management.** Mechanical measures are the most important part of care of these patients. Irrigation with normal saline three times a day is one of the most important steps. If this simple step is unsuccessful, endoscopic enlargement of the openings will often prove useful. Unfortunately, loss of ciliary function is part of the disease process so that even this step may not prove entirely successful. However, overall, such procedures have proven to be quite cost-effective.

H. External otitis

1. External otitis is usually a superficial infection of the external auditory canal that is typically initiated by moisture and is often referred to as "swimmer's ear." It is most commonly caused by *Pseudomonas* species. Avoiding swimming and/or keeping the ears dry and using topical treatment usually suffice. Often the condition responds to careful cleaning of the canal by gentle suction or irrigation. In other instances, antibiotic drops (polymyxin, neomycin, and hydrocortisone [e.g., Cortisporin otic]) or dilute acetic acid or boric acid solutions (to lower the pH) suffice. This topic has been reviewed in detail elsewhere [55].
2. **Malignant external otitis** is an important infection caused by *P. aeruginosa* and is associated with a high mortality (20%), if untreated. This disease process begins as an external otitis that may progress to involve the cartilaginous tissue and may penetrate to the base of the brain. Cranial nerve (especially facial), sigmoid sinus thrombosis, and meningitis have resulted in death [56]. This disease occurs almost exclusively in elderly diabetics but has been described in nondiabetic patients who have underlying malignancy or are immunocompromised, including patients with acquired immunodeficiency syndrome. Ear, nose, and throat and infectious disease consultation are advised.
 - a. **Diagnosis is often difficult.** One must have a high index of suspicion. Patients complain of progressively increasing pain and tenderness of the tissues around the ear and mastoid region. They seldom have fever or systemic symptoms or a peripheral leukocytosis. Cranial nerve abnormalities may develop. Often there is persistent drainage from the external canal that yields *P. aeruginosa* on culture. The presence of granulation tissue at the junction of the osseous and cartilaginous portions of the external ear is a highly suggestive finding [56]. CTs can help detect early bone involvement and extent of the disease process. However, technetium phosphate radionuclide bone scans can identify early bony involvement when there is no destruction on CTs; gallium-67 citrate scans are also a sensitive indicator of infection [56].
 - b. **Treatment.** Topical therapy is ineffective. Most patients require hospitalization and, at least initially, for well-established infection combination parenteral antibiotics to achieve synergy against *P. aeruginosa*. Ticarcillin or piperacillin

is often combined with tobramycin (or another aminoglycoside to which the pathogen is susceptible). In the penicillin-allergic patient, ceftazidime can be combined with an aminoglycoside. Ciprofloxacin may be useful [56,57] in selected cases (i.e., early disease or for completion of therapy if the organism is susceptible). Serial gallium scans have been used to monitor response to therapy [56].

I. Epiglottitis/supraglottitis. Epiglottitis is an acute and severe inflammation of the epiglottis; some use the term supraglottitis for this condition, indicating inflammation not only of the epiglottis but also of the surrounding tissue [58]. Before the early 1990's, epiglottitis was primarily an illness of children and due usually to invasive *H. influenzae* b. Since the early 1990's and widespread use of *H. influenzae* b vaccinations in children in the United States, studies have shown a significant change in the epidemiology; epiglottitis now occurs almost exclusively in adults [58]. Although invasive *H. influenzae* b remains an important etiologic pathogen in adults, *S. pneumoniae* cause a significant number of cases; group A streptococci have also been isolated [59].

1. **Clinical presentation [57,60]. In children,** the onset of epiglottitis with *H. influenzae* b is classically abrupt, with sore throat, fever, and toxicity. The symptoms usually progress rapidly in such a manner that dysphagia, drooling, and respiratory distress with stridor become apparent. This diagnosis is still a concern in children who have not been adequately vaccinated against *H. influenzae*. **In adults,** recent series note that symptoms and signs may be more subtle: sore throat, painful or difficulty with swallowing, and muffled voice occur in most, and fever or chills, drooling, stridor, sitting erect, dyspnea, cough, and ear pain can also occur [58,60].
2. **Clinical diagnosis. This disease is a potential medical emergency and** requires a high index of suspicion **on the basis of the history and clinical findings. The diagnosis can be confirmed** by visualization of the epiglottis and supra-glottic area. This should only be performed by well-trained personnel; emergency equipment must be available **for maintaining the airway.**
3. **Laboratory and radiologic features.** Lateral neck roentgenograms may be useful early in less toxic patients who are not in respiratory difficulty. The epiglottis appears as an enlarged rounded shadow resembling a thumb. **Leukocyte count is usually elevated to more than 15,000/mm³, often with a pronounced left shift. Blood cultures should be obtained.**
4. **Management.** Swift and careful management is essential in this disease and directly correlates with the outcome. In the acutely ill patient, valuable time may be unnecessarily wasted obtaining roentgenograms. Ensuring an adequate airway must take priority. **In young children, nasotracheal intubation and thus emergency consultation (e.g., otolaryngology, anesthesia) is often necessary. In adults, need for intubation is less pressing.** Factors predictive of the need for airway intervention were stridor and sitting erect in one study [60].
5. **Antibiotics.** Parenteral cephalosporin (second- or third- generation agents; i.e., cefuroxime, ceftriaxone), which is effective against ampicillin-resistant *H. influenzae* or ampicillin-sulbactam or parenteral chloramphenicol in the patient in whom penicillins and cephalosporins are contraindicated, should be initiated immediately. If not contraindicated, we favor ceftriaxone or ampicillin-sulbactam, which are also very active against group A streptococcus, mostly *S. pneumoniae* and *S. aureus*. In a critically ill adult and/or in an area with a high incidence of high-level penicillin-resistant *S. pneumoniae*, we would add intravenous vancomycin (along with ceftriaxone) until at least blood culture data are available because more than 20% of adult cases may be due to *S. pneumoniae*. Corticosteroids may be used briefly to help reduce the postintubation edema that develops, but their efficacy has not been proven in this setting [60].

9. INFECTIOUS MONONUCLEOSIS AND PRIMARY EPSTEIN-BARR VIRUS INFECTION

John W. Sixbey

Infectious mononucleosis (IM) is an acute illness common in adolescents characterized by the classic triad of fever, pharyngitis, and lymphadenopathy; serologically by the transient appearance of heterophile antibodies (sheep or horse erythrocyte agglutinins); and hematologically by an absolute lymphocytosis reflecting the unusually strong T-cell response elicited by virally infected B-lymphocytes. The Epstein-Barr virus (EBV), or human herpesvirus 4, is the primary etiologic agent. Acute infection is accompanied by immunoglobulin M (IgM) antibodies specific to EBV. The exaggerated nature of the T-cell response suggests that the **syndrome is largely immunopathogenic** in nature. Atypical cases highlight the protean manifestations of EBV infection that can confound clinical diagnosis. Furthermore, other infectious agents, specifically cytomegalovirus (CMV), acute human immunodeficiency virus 1 (HIV-1), and *Toxoplasma gondii*, can cause an IM-like syndrome that must be distinguished. A clear understanding of **age-related patterns of the disease**, combined with knowledge of **serologic profiles characteristic of acute EBV infection**, facilitates a diagnosis of IM and institution of appropriate therapeutic measures [1,2].

I. Etiology. EBV is a DNA virus of the gammaherpesvirus subfamily. Its discovery in Burkitt lymphoma, together with a demonstrated biologic capability to confer unlimited growth potential on infected B cells in culture, led to its designation as the first **human tumor virus** [3]. EBV manipulates the different phases of B-cell development to establish lifelong infection of its host while promoting successful transmission to new individuals. Aside from IM, the virus has a causal role in Burkitt lymphoma, Hodgkin disease, nasopharyngeal carcinoma, posttransplantation lymphoproliferative disease, gastric carcinoma, and oral hairy leukoplakia of acquired immunodeficiency syndrome (AIDS). EBV's ability to infect both lymphocytes and epithelial cells provides a pathobiologic basis for these diverse disease associations.

A. The EBV link to IM was discovered serendipitously when a technician in the Henle laboratory, who devised immunofluorescent assays to EBV-specific antibodies, seroconverted after an episode of IM [4]. The finding was confirmed by large seroepidemiologic studies in college students [5–8]. Heterophile-positive IM occurred in patients without preexisting EBV antibody, and was followed by acquisition of EBV-specific antibodies.

B. IM, from an evolutionary standpoint, is a **disease of delayed primary infection** distinctive to upper socioeconomic groups. Most children in developing countries become infected with EBV during the first 3 years of life, and 100% are infected at the end of their first decade. Early primary infections, which are almost always asymptomatic, probably reflect parent-to-child oral transmission of EBV. By contrast, up to half of the children in Western countries are EBV seronegative at the end of their first decade of life, and some 5% of adults are seronegative.

II. Clinical features of IM

A. Age at primary infection. Patient age can have a major impact on clinical manifestations of primary EBV infection [9–16]. Most young children acquire the virus asymptotically, with fewer than 10% developing a syndrome resembling IM. When primary EBV infection is delayed until adolescence, clinical manifestations occur in up to 50% of cases. Primary infection of the elderly is uncommon, if only because 90% to 97% of all population groups studied have seroconverted by adulthood. However, cases in adults can be severe, with atypical clinical manifestations that may mislead the clinician and provide a diagnostic challenge.

B. Viral acquisition and incubation period. EBV is an ubiquitous agent that, paradoxically, is not highly contagious or efficiently spread. For instance, susceptible college roommates of students with IM undergo seroconversion at no greater frequency than the general student population [7,17]. Transmission requires intimate personal contact. Viral inoculation generally occurs via saliva passed between a susceptible individual and an asymptomatic oropharyngeal shedder of EBV (hence, the “kissing

disease”). In healthy EBV-seropositive adults followed prospectively over 15 months, 90% shed EBV in their saliva at least once, with 25% shedding virus on every occasion [18]. Immunocompromised patients have still higher rates of shedding. Symptomatic infection at adolescence may relate to a larger inoculum of transmitted virus and the ensuing T-cell reaction. In young children the route of transmission may be more indirect, with smaller virus inocula and inapparent symptomatology. Although EBV can be detected in the male and female genital tract, the implications of this distribution for person-to-person spread has not been demonstrated [19–22]. IM also has occurred subsequent to blood transfusion as well as bone marrow and organ transplantation.

No seasonal pattern has been documented. The incubation period for primary EBV infection is estimated to be 30 to 50 days. Little is known about early events of infection since timing of an exposure to an asymptomatic shedder is difficult to document. Onset of IM is usually preceded by several days of nonspecific prodromal symptoms that include chills, sweats, fever, and malaise.

C. Signs and symptoms. The classical clinical triad in IM is prolonged fever (10–14 days; 38°–40°C), sore throat, and lymphadenopathy. Additional common symptoms include malaise, headache, myalgias, sweats, and anorexia. Clinical findings that help support a bedside diagnosis include the following:

1. **Tonsillar enlargement, exudative tonsillitis, and pharyngeal inflammation.** Tonsillar enlargement is common, with tonsils occasionally meeting at midline. The pharynx is erythematous with an exudate present in a third of cases. The pharyngitis is indistinguishable from that caused by group A streptococcus or other viruses. Palatal petechiae occur in up to half.
2. **Lymphadenopathy.** Posterior and anterior cervical lymphadenopathy occurs in 80% to 90%, with submandibular, axillary, and inguinal nodes frequently enlarged.
3. **Hepatomegaly** is present in approximately 25%, with abnormal liver function tests in 80% of patients. Clinical jaundice may occur in up to 5% of cases.
4. **Splenomegaly** is present in more than half the cases over the course of illness. **Vigorous abdominal palpation during examination** should be avoided. Abdominal pain due to splenic enlargement is relatively uncommon and should alert one to the possibility of splenic rupture.
5. **Rash.** A rash, occurring in 5% to 10% of patients, is variable in presentation (maculopapular, petechial, scarlatiniform, urticarial, or erythema multiforme-like). **Ampicillin administration** produces a pruritic, maculopapular rash in 90% to 100% of patients, and may appear after cessation of the drug.

D. Hematologic abnormalities

1. **Lymphocytes.** The central hematologic manifestation of IM is an absolute and relative lymphocytosis, with monocytes and lymphocytes accounting for 60% to 70% of the total white cell count, some 10% to 20% of which are **atypical lymphocytes**. Atypical lymphocytes represent activated T cells (EBV typically infects B cells), are larger than the mature lymphocyte normally found in the circulation, and have a vacuolated cytoplasm, lobulated and eccentrically placed nuclei, with a cell membrane that is often indented by neighboring erythrocytes. Atypical lymphocytes are a hematologic hallmark of IM, but they are not pathognomonic; they are also found in CMV infection, viral hepatitis, toxoplasmosis, rubella, mumps, roseola, and drug reactions.
2. **Total white blood cell (WBC) count.** WBC counts generally range between 12,000 and 20,000/mm³, but WBCs up to 50,000/mm³ may occasionally be seen. A mild, self-limited neutropenia (2,000–3,000 granulocytes/mm³) is present in a majority of cases, although profound granulocytopenia also has been reported.
3. **Thrombocytopenia** (<140,000/mm³) may occur in half of the cases due to increased destruction by an enlarged spleen or antiplatelet antibodies.

E. Heterophile antibodies and elevated serum immunoglobulins. The early phase of acute IM is associated with mildly elevated levels of total serum IgG, IgM, and IgA, consistent with a **virus-driven polyclonal activation of the B-cell system**. Paralleling this general increase is the transient appearance of a

Table 9.1. Divergent Features of Epstein-Barr Virus–Induced Infectious Mononucleosis Related to Age at Onset

Feature	Age in Years

NR, not reported.

mix of heterophile and autoantibodies, usually of the IgM class. **Heterophile antibodies** occur as a **by-product of primary EBV infection** in about 90% of cases but **do not react with EBV antigens**. Originally described by Paul and Bunnell as sheep erythrocyte agglutinins, they form the basis for the commonly used rapid spot assays diagnostic for IM. Agglutinating antibodies to horse, goat, and camel erythrocytes as well as beef erythrocyte hemolysins are also demonstrable in serum of patients with IM. Other nonspecific antibody responses observed in patients include rheumatoid factors, antinuclear factors, antiplatelet and antineutrophil antibodies, cryoglobulins, and cold reactive antibodies to i antigen on RBCs.

F. Atypical presentations. Primary infection with EBV has been defined largely by the syndrome of IM. The spectrum of illness is quite broad, however, and individual cases may have all, some, or none of the classic triad mentioned above (Table 9.1) [23]. Attempts to exclude cases with unusual features or those that fail to meet all the classic criteria for IM may result in delayed diagnosis or misdiagnosis, particularly in **infants and the elderly** [9–16].

Although generally asymptomatic in younger children, primary EBV infection can produce symptomatology that when present is atypical for acute IM. Among 17 infants reported by Fleisher with serologic evidence of primary EBV infection, none developed signs or symptoms that were suggestive of acute IM [11]. Initial diagnoses varied from respiratory tract infection (43%) to otitis media (29%), pharyngitis (21%), and gastroenteritis (7%). Sumaya and Ench noted that in children under 4 years of age signs of upper respiratory tract infection were found in 51% versus 15% of older children [9]. Cutaneous rashes occur more frequently in younger children as does eyelid or periorbital swelling. A palpable spleen and liver were more frequent in children under 4 years of age.

Of the well-known triad of fever, pharyngitis, and lymphadenopathy, elderly patients are much less likely to have lymphadenopathy and pharyngitis than are younger patients [13–16]. Fever is present in almost all older patients, and abdominal pain, hepatomegaly, and liver function abnormalities occur in substantial numbers, frequently leading to an initial clinical impression of hepatitis. Older adults have fewer atypical lymphocytes and less significant lymphocytosis. Splenomegaly is less evident. The illness tends to be more prolonged in older adults.

III. Diagnosis. The clinical manifestations of fever, sore throat, lymphadenopathy together with atypical lymphocytosis and a positive heterophile test establish the diagnosis of EBV-induced IM.

A. Differential diagnosis. A variety of infectious agents can produce some of the clinical signs and symptoms of EBV-induced IM. Because they do not invoke a heterophile antibody response, these entities have been dubbed heterophile-negative mononucleosis and constitute some 10% to 15% of all cases. With careful attention to clinical and serologic features of the illness, IM-like entities can generally be differentiated from primary EBV infection.

1. **CMV infection.** CMV is responsible for about 8% of IM cases, or approximately half of the heterophile-negative cases. By comparison to those with EBV-induced disease, patients with the CMV mononucleosis-like syndrome tend to be older (25–35 years, although the syndrome also occurs in children [24]), pharyngitis and cervical lymphadenopathy is less frequent, and atypical lymphocytosis may be less intense. Acute CMV infection can be diagnosed by testing for the presence of IgM antibody to CMV.
2. **Acute retroviral syndrome.** Differentiating acute retroviral syndrome from IM is crucial and has obvious public health implications. Because acute HIV-1 infection may be particularly contagious, initiation of counseling may prevent further transmission. Early treatment also may reduce the incidence of HIV-1 complications. Acute retroviral syndrome presents with a broad array of signs and symptoms, with less than 20% of cases having classic features of IM [25]. A more acute onset and absence of exudative tonsillitis or tonsillar hypertrophy may help differentiate the syndrome from IM. A maculopapular rash (40%–80% of patients) and mucocutaneous ulceration are more characteristic of the acute retroviral syndrome. On the likelihood that health-care providers would perform testing for heterophile antibodies on patients that actually had acute retroviral syndrome, 563 heterophile antibody negative patient samples were retrospectively tested for HIV-1 RNA and p24 antigen. Approximately 1% were determined to have primary HIV-1 infection [26]. A rare false-positive heterophile test has been reported during the acute retroviral syndrome, probably as a consequence of EBV reactivation [27,28]. Clinicians considering a diagnosis of IM should also evaluate the patient's HIV risk behaviors and at least consider the diagnosis of primary HIV infection.
3. **Toxoplasmosis.** In the mononucleosis-like syndrome caused by acute toxoplasmosis, pharyngitis is not a prominent feature, the degree of lymphocytosis is mild, and liver functions are normal even in the presence of hepatomegaly. A history of ingestion of raw or undercooked meat or exposure to oocysts from cat feces may provide clues implicating this etiologic agent. The IgM immunofluorescent antibody test for *Toxoplasma gondii* is useful in diagnosing this disease.
4. **Streptococcal pharyngitis** may mimic IM in early stages. Throat cultures for β -hemolytic streptococci are positive in up to 30% of patients with IM. Therefore, isolation of this organism does not exclude a diagnosis of IM. Splenomegaly is absent in streptococcal sore throat, and normal hepatic enzymes serve as a differentiating factor.
5. **Hepatitis A.** Atypical lymphocytosis is of a lesser magnitude (<10% atypical). Transaminase enzymes are disproportionately higher than levels of alkaline phosphatase, whereas the reverse is true of EBV and CMV hepatitis. Generally in EBV-induced disease, liver function test results are elevated two to three times the upper limit of normal (>10 times normal suggests another diagnosis).
6. **Rubella virus.** Rubella may be manifested by fever, sore throat, lymphadenopathy, and a mild atypical lymphocytosis, but the characteristic exanthem and shorter clinical course are generally not confused with IM.
7. **Other miscellaneous causes** include human herpes virus 6, adenovirus, diphtheria, *Mycoplasma* species, *Bartonella henselae* (cat scratch disease), leptospirosis, and brucellosis. Various hematologic neoplasms can present with features mimicking IM.

B. Serologic diagnosis. Laboratory diagnosis of acute EBV infection depends primarily on serologic testing. EBV-induced IM results in the production of antibodies against both unrelated antigens as well as EBV-specific antigens.

1. Heterophile antibodies are detected as sheep and horse red cell agglutinins and beef cell hemolysins. The classic heterophile antibody titer is read as the greatest serum dilution at which sheep erythrocytes agglutinate, after preabsorption of test serum against guinea pig kidney to eliminate cross-reaction with Forssman and serum sickness antibodies. Commercially available spot tests (Monospot, Mono-Test, Mono-Latex, Monosticon) and solid-phase immunoassays (Immunocard Mono, Monolert) have largely replaced the classic Paul-Bunnell sheep cell agglutination assay because of ease of use.

- a. Heterophile antibody responses are generally present in 80% to 90% of cases by the third week of illness. **Repeat testing at weekly intervals** may be necessary in some patients, since up to 15% may not have detectable levels of heterophile antibody at presentation, then become positive on retesting in the second or third week of illness. Titers remain elevated for 3 to 6 months, but occasionally for as long as 1 year.
- b. False-negative rates with the rapid test kits are 10% to 15% [29]. **False-negative results are common in children under 4 years of age**, with fewer than 20% testing positive by the rapid slide test [9]. Hence, age of the patient is a critical consideration in the evaluation of heterophile-negative IM.
- c. False-positive results, although rare, have been reported in patients with lymphoma, hepatitis, and other viral infections.

2. EBV-specific antibody studies should be reserved for the approximately 10% of cases of IM that are heterophile-negative, for diagnosis in children under 4 years of age, or for diagnosis in patients with atypical presentations. The antibodies are measured either by immunofluorescence or enzyme-linked immunosorbent assay. Antibody profiles allow the differentiation of recent from remote infection.

- a. Presence of **IgM antibodies to viral capsid antigen (VCA)** is virtually diagnostic of acute EBV infection and is the most useful titer for general clinical purposes. VCA IgM usually disappears within 1 to 2 months. VCA IgG is also apparent at clinical presentation and is maintained for life. Detection of VCA IgG on a single sampling indicates only that infection with EBV has occurred sometime in the past.
- b. Antibodies to **Epstein-Barr nuclear antigen 1 (EBNA1)** appear later in the course of IM (2–4 weeks) and persist for life. **VCA IgM/VCA IgG in the absence of EBNA1 antibodies**, followed by the appearance of EBNA1 antibodies in convalescent serum (at 4–6 weeks), is diagnostic of acute EBV infection. Failure to develop EBNA1 antibodies, or loss of a preexisting titer, has been associated with chronic active EBV infection.
- c. Antibody to EBV early antigen (EA) may be detected in the majority of patients with IM, then falls to a low or undetectable level.
- d. **Healthy carriers** of virus are consistently VCA IgG and anti-EBNA1 positive. A significant number of virus carriers also maintain antibodies to EA. **Titers can differ markedly** among healthy individuals, and differences tend to be stable over time.

C. Virus isolation and molecular diagnostic techniques. Culture of Epstein-Barr virus from oropharyngeal secretions or peripheral blood is possible, but impractical in the clinical laboratory. The lymphocyte transformation assay requires 4 to 6 weeks, and viral isolation does not necessarily indicate acute infection, given the life-long carrier state established in all infected individuals. Quantitative PCR for estimating viral load in peripheral blood has been shown to be useful in the diagnosis and management of aberrant EBV infections, with high viral burdens demonstrated in peripheral blood of patients with chronic active EBV and posttransplantation lymphoproliferative disease [30,31]. The technique is unlikely to be helpful for the routine diagnosis of IM.

IV. Complications. Diagnostic confusion can result from the varied complications accompanying primary EBV infection, manifestations that in some cases are the sole presentation of illness. Most complications resolve fully, although rare fatalities do occur.

A. Hematologic.

1. **Autoimmune hemolytic anemia** occurs in up to 3% of cases, generally mediated by cold-agglutinin antibodies of anti-i specificity. The anemia resolves without treatment over a 1- to 2-month period in most individuals. Hemophagocytic syndrome also has been described.
2. Mild **thrombocytopenia** is common, but platelet counts of less than 1,000/mm³ with associated intracerebral bleeding can occur.
3. **Granulocytopenia** is usually mild and self-limiting, but deaths associated with bacterial sepsis have been reported.

B. Neurologic manifestations (<1% of cases) can be the first (and sometimes the only) manifestation of IM, with the heterophile antibody often being negative. **Nerve palsies and encephalitis** are the most common neurologic complications. Encephalitis seen with IM is acute in onset, rapidly progressive, and severe, but is usually associated with complete recovery. An "Alice-in-Wonderland" syndrome, characterized by metamorphopsia (distortion of size, shape, and spatial relations of objects), has been described. Aseptic meningitis, Guillain-Barré syndrome, Bell palsy, and transverse myelitis also have been reported.

C. Splenic rupture (0.2% of cases) must be considered whenever abdominal pain occurs. History of preceding trauma can be elicited in only half the cases, suggesting spontaneous rupture.

D. Upper airway obstruction is estimated to occur in up to 1% of cases.

E. Other complications rarely observed include myositis, myocarditis, pneumonitis, pancreatitis, acute renal failure, and death. Death is most commonly associated with neurologic complications, splenic rupture, or airway obstruction. A familial syndrome passed in an X-linked-recessive pattern (X-linked lymphoproliferative disease or Duncan syndrome) may result in overwhelming infection at primary infection with death (typically from a fulminant hepatic failure) in up to 40% of affected males.

V. Management. No therapy is indicated for the vast majority of cases of EBV-induced IM. Treatment is primarily supportive, but corticosteroid or antiviral therapy may be considered in special settings.

A. Specific antiviral therapy is not indicated for most cases of IM. Acyclovir (ACV), a nucleoside analogue that blocks EBV replication through inhibition of viral DNA polymerase, has little if any effect on the disease course, but is capable of preventing viral shedding from the oropharynx [32,33]. Symptoms are therefore unlikely to be the result of viral replication per se, and IM most likely represents an immunopathologic disease. (Contrast this to the effect of drug in oral hairy leukoplakia of AIDS, where ACV effectively resolves lingual lesions associated with exuberant EBV replication [34]). Use in immunocompromised patients at risk for EBV-induced lymphoproliferative disease with the idea of limiting additional B-cell recruitment by infectious virus may be ineffective. Elimination of EBV replication as an endogenous source of infectious virus does not translate into a reduced load of latently infected B cells in the circulation [35]. However, other considerations favoring therapy of primary EBV infections in specific immunocompromised hosts may exist [36]. Ganciclovir and cidofovir have demonstrated *in vitro* activity against EBV, but there are no clinical indications for their use in IM.

B. Salicylates or other analgesics are appropriate for control of fever, headache, and sore throat.

C. Corticosteroids have been useful in management of specific complications, although their value has not been confirmed in controlled studies. Prednisone at a dosage of 40 to 60 mg/day for 7 to 10 days, to be rapidly tapered once a clinical response is achieved, can be considered for the following complications:

1. **Impending airway obstruction** due to severe tonsillitis and pharyngeal edema
2. **Severe thrombocytopenia**
3. **Acute hemolytic anemia**
4. **Myocarditis**
5. **Neurologic complications**

D. Precautionary measures to protect against splenic rupture in the first few weeks after diagnosis might include care in splenic palpation and attention to constipation. Contact sports should be avoided until the spleen has resumed normal size.

E. Control measures

1. **Physical isolation of patients** is not indicated in hospital or home settings, given that intimate contact is required for virus transmission. Standard precautions are sufficient.
2. Individuals with acute EBV infection **should not be** selected as **tissue or blood donors** when possible, due to the enhanced cell-associated viral load accompanying primary infection.

VI. Prognosis Most cases of IM resolve spontaneously over a 3- to 6-week period, with periods of well-being interrupted by recrudescence of symptoms. Associated malaise is more gradual in its resolution, lasting up to 3 to 4 months in some individuals. As with all human herpesviruses, primary infection is followed by establishment of a life-long carrier state characterized by asymptomatic oropharyngeal shedding and the possibility for reactivation disease.

- A. Self-assessed failure to recover** completely from IM has been reported by 38% of patients at 2 months and 12% at 6 months, with persistent symptoms characterized mainly as fatigue and impaired functional status but without objective markers of disease [37].
- B. Chronic active EBV infection** [38–40] is a rare outcome of primary EBV infection that is characterized by **severe illness** lasting greater than 6 months and is associated with fever, **major organ involvement** (interstitial pneumonitis, bone marrow hypoplasia, hepatosplenomegaly, persistent hepatitis and hepatic failure, lymphadenitis, uveitis), a **highly unusual serologic profile to EBV** (IgG to VCA > 1:5120, EA > 1:640, and a low to undetectable EBNA1 titer), persistently high EBV loads in peripheral lymphocytes, and occasional development of natural killer cell or T-cell lymphoproliferative disease.
- C. The chronic fatigue syndrome** is not specifically related to EBV infection [41,42].
- D. Reinfection**, or serial acquisition of EBV strains, does occur [43,44]. Whether there are clinical manifestations or serologic responses characteristic of repeat infections remains to be resolved [45].
- E.** A history of IM has been linked epidemiologically to a threefold increased **risk for Hodgkin disease in younger adults** [46]. Although about half of all Hodgkin disease tumors contain EBV-positive Reed-Sternberg cells, a history of IM has not been predictive of which tumors will contain the virus [47].

10. INFLUENZA AND INFECTIONS OF THE TRACHEA, BRONCHI, AND BRONCHIOLES

John J. Treanor and Caroline Breese Hall

INFLUENZA

Influenza is a relatively specific syndrome resulting from infection with any influenza A or B virus. Infection with other respiratory viruses occasionally may result in influenza-like illness, but other viruses do not cause epidemics that affect all age groups. Infection with influenza A or B virus may result in any of the other viral syndromes discussed in this chapter. Influenza C virus infection results in only a small proportion of common cold illnesses and is not discussed in this chapter.

- I. **Etiology.** Influenza viruses are medium-sized enveloped viruses with a segmented RNA genome and are classified into types A, B, and C. The envelope of influenza A and B viruses contains two glycoproteins: the hemagglutinin (H) and the neuraminidase (N). Multiple subtypes of H and N exist for influenza A viruses, and standard nomenclature for these viruses includes the type, location, and year of isolation, strain designation, and H and N subtype for influenza A viruses.
- II. **Epidemiology.** Influenza occurs in yearly epidemics, with occasional worldwide epidemics referred to as pandemics. In a community, an epidemic due to a single subtype generally lasts 5 to 6 weeks, but more prolonged epidemics may occur. Attack rates may be as high as 10% to 20% and are usually highest in young children, whereas hospitalization rates are highest in the elderly. Yearly epidemic activity is manifested by increases in school absenteeism, visits to health-care facilities, admissions to hospitals for pneumonia, and deaths [1].

Influenza viruses have a high degree of antigenic variability, which allows for recurrent epidemics despite widespread prior exposure to influenza viruses in the population. Two forms of this antigenic variation are recognized: antigenic drift and antigenic shift.

- A. **Antigenic drift, which occurs in both A and B viruses,** is a relatively **minor antigenic change** within the H or N due to the accumulation of point mutations. The antigenically variant virus is able to infect individuals and spread within the population despite the presence of antibody to previous strains of virus, and epidemics of variable extent result.
 - B. **Antigenic shift** refers to **major antigenic change** within the H or N, resulting in a new subtype. These viruses enter a population that is immunologically naïve. Worldwide pandemics result (Table 10.1). Antigenic shift occurs only with influenza A viruses.
- III. **Clinical manifestations.** Characteristically, the onset of influenza is abrupt after an **incubation period** of 1 to 2 days. Many patients can recall the exact hour of onset.
 - A. **Symptoms. Systemic symptoms** predominate and include feverishness, chilliness or occasionally frank shaking chills, headaches, myalgias, malaise, and anorexia [2]. Malaise and fatigue may be quite prolonged. Myalgias may involve the extremities or the long muscles of the back, and may be accompanied by arthralgias. **Respiratory symptoms**, particularly dry cough or nasal discharge, also are usually present at the onset, but they are overshadowed by the systemic symptoms. Nasal obstruction, hoarseness, and dry or sore throat may be present as well, and these symptoms tend to become more prominent as the disease progresses. **Ocular symptoms**, although less commonly present, are helpful diagnostically and include photophobia, tearing, burning, and pain on moving the eyes. **In the young infant**, influenza mimics sepsis (fever and no localizing findings). Even in older children, influenza may be manifest occasionally as an undifferentiated febrile illness without respiratory or localizing symptoms. **In the elderly**, fever may be low grade or absent, and myalgias and feverishness minimal. The presentation is dominated by severe fatigue, malaise, and listlessness.
 - B. **Signs.** Early in the course of illness, the patient appears toxic, the face is flushed, and the skin is hot and moist. Eyes are watery and reddened.

Table 10.1. Major Antigenic Shifts and Pandemic Influenza

Year	Interval (years)	Designation	Changes in Indicated Surface Proteins	Results
1889	—	H3N2	—	Moderate pandemic
1918	29	H1N1	H, N	Most severe pandemic
1957	39	H2N2	H, N	Severe pandemic
1968	11	H3N2	H	Moderate pandemic
1977	9	H1N1	H, N	Mild

H, hemagglutinin; N, neuraminidase.

1. Fever is the most important finding. It usually rises rapidly to a peak of 100° to 106°F (38°–41°C) within 12 hours of onset of systemic symptoms. It usually is continuous but may be intermittent, especially if antipyretics are administered. On the second and third days of illness, the fever is usually 0.5° to 1.0°F (0.5°C) lower, and as the fever subsides, so do the systemic symptoms. Fever may last from 1 to 5 or more days.

2. Nasal and other respiratory findings. Clear **nasal discharge** is common. Nasal obstruction occurs less frequently. The mucous membranes are hyperemic, but exudate is not observed. Small, tender cervical lymph nodes may be present. Transient, scattered rhonchi or localized areas of rales are found in fewer than 20% of cases.

As systemic signs and symptoms diminish, respiratory complaints and findings become more apparent. **Cough** is the most frequent and troublesome symptom and may be accompanied by substernal discomfort or burning. Nasal obstruction and discharge and pharyngeal pain and injection also are common. Such symptoms and signs usually persist 3 to 4 days after fever subsides. Cough, lassitude, and malaise may last 1 to 2 weeks after disappearance of other manifestations.

IV. Laboratory findings are nonspecific. Leukocytosis of up to 15,000 cells/mm³ may be observed early in the illness, usually without a shift to the left. Mild leukopenia may be observed later. Pulmonary findings seen on radiography are described in section VII.A.

V. Diagnosis

A. Viral cultures. Specific diagnosis is best made by viral culture techniques.

Separate swab specimens of throat and nose are ideal and should be placed immediately into viral transport media for good results. In cases of tracheobronchitis or pneumonia, sputum constitutes the best specimen in adults, whereas in children a nasal wash is best. Specimens tested in cell cultures or embryonated chicken eggs may yield positive results as early as 3 days. For isolated or complicated cases, viral diagnosis is essential.

B. Direct antigen detection tests have become available in which the presence of influenza-specific antigens in respiratory secretions is detected immunologically. These tests include the Directigen Flu A + B (Becton-Dickinson), Quickvue Flu (Quidel Corporation), and Flu OIA (Biostar). In addition, the Zstat Flu test (Zymtek) identifies influenza through detection of viral neuraminidase activity. Each of these tests has a turnaround time of 30 minutes or less, with reported sensitivities of 60% to 90% compared with cell culture [3]. Generally, performance is better with nasopharyngeal swabs, washes, or sputum than with throat gargles or swabs [4,5].

C. Epidemiologic data are sufficient to make the diagnosis in most uncomplicated cases in adults. If influenza is prevalent in the community, most adults and older children with acute febrile respiratory illness, especially with nonproductive cough, have influenza [6]. However, in children, multiple respiratory viruses such as respiratory syncytial virus (RSV) and parainfluenza virus which may be present

concurrently, confound the clinical diagnosis. Elderly patients may not manifest the systemic symptoms seen in younger adults. A specific viral diagnosis should always be sought in hospitalized patients with complications of influenza.

VI. Treatment

A. Symptomatic. Symptomatic therapy such as that described for common colds, pharyngitis, and tracheobronchitis may be advised for fever, headache, myalgias, and cough. **Salicylates and salicylate-containing medications are not advised for children with influenza. The use of salicylates in children has been associated with Reye syndrome.** Acetaminophen and ibuprofen are commonly used as antipyretic agents.

B. Antiviral agents

1. Neuraminidase inhibitors: oseltamivir and zanamivir. These agents work through inhibition of the viral neuraminidase, an enzyme with critical roles in penetration of respiratory tract mucus and in the release of virus from infected cells. The neuraminidase inhibitors are active against both influenza A and influenza B viruses at millimolar concentrations or less [7]. Activity against influenza viruses include avian viruses with all nine known neuraminidase subtypes.

Both zanamivir and oseltamivir have been shown to be effective in the treatment of uncomplicated influenza of healthy adults, resulting in an approximately 30% more rapid resolution of illness and a more rapid return to normal activities [8,9]. Both drugs also have resulted in significantly reduced rates of influenza complications, such as pneumonia and bronchitis, and early treatment with oseltamivir also may result in less frequent subsequent hospitalizations. Treatment should be begun within 48 hours of symptom onset, and continued for 5 days, at dosages shown in Table 10.2.

Oseltamivir therapy in children results in more rapid resolution of fever and clinical symptoms, and reduced rates of otitis media [10]. Oseltamivir is approved for children as young as 1 year. Studies of neuraminidase inhibitors in elderly individuals and those with high-risk conditions have also generally shown a trend toward more rapid reduction of symptoms and possibly reduced complications.

Both oseltamivir and zanamivir are well tolerated when used for therapy. Approximately 10% of treated individuals experience mild nausea with the first dose of oseltamivir, particularly when administered on an empty stomach. Because food does not interfere with absorption, when possible, oseltamivir should be administered with food. In controlled trials of zanamivir, side effects have not been different from placebo. However, there have been multiple reports of significant bronchospasm when zanamivir has been administered to patients with acute influenza.

Resistance to neuraminidase inhibitors arises in approximately 3% of treatment courses with oseltamivir and less often with zanamivir. Resistance arises either through mutations within the neuraminidase site, which decreases binding, or through mutations in the hemagglutinin, which decrease the affinity of the virus for its receptor [11–13]. Both types of resistance appear to decrease the replication efficiency of the virus, and the resistant viruses have attenuated virulence in animals.

2. M2 inhibitors: amantadine and rimantadine. These chemically related agents act by inhibiting the influenza A virus M2 protein, an ion channel that is critical for viral uncoating. **Both drugs are active only against influenza A viruses** [14]. Treatment should be begun within 48 hours of symptom onset, and continued for 2 to 5 days, at dosages shown in Table 10.2.

Controlled trials of uncomplicated influenza in healthy adults showed that both drugs resulted in more rapid reductions in symptoms, more rapid return to normal activities, and reduced levels and duration of viral shedding when compared with placebo, aspirin, or acetaminophen [15,16]. The efficacy of the two drugs is similar. Treatment of children with either drug also has been shown to reduce the duration and severity of fever and other symptoms, but only amantadine is approved for this indication in the United States. Neither drug has

Table 10.2. Properties of Antiviral Agents for Influenza

Agents	M2 Inhibitors			Neuraminidase Inhibitors	
	Amantadine	Rimantadine	Zanamivir	Osetamivir	
Spectrum of activity	A only	A only	A and B	A and B	
Metabolism/excretion			None	Hepatic deesterification Renal tubular excretion	
Drug interactions	Antihistamines, anticholinergics increase CNS side effects	None	None	None (probenecid reduces renal clearance)	
Usual adult dose					
Therapy	100 mg orally b.i.d.	100 mg orally b.i.d.	10 mg (2 inhalations) b.i.d.	75 mg orally b.i.d.	
Prophylaxis	100 mg orally b.i.d.	100 mg orally b.i.d.	NA	75 mg/day orally	
Dosing in children					
Therapy	≤40 kg: 5 mg/kg/day	≤40 kg: 5 mg/kg/day	NA (≥7 years of age: adult dose)	<40 kg: 2 mg/kg orally b.i.d.	
Prophylaxis	≤40 kg: 5 mg/kg/day	≤40 kg: 5 mg/kg/day	NA	NA (≥13 years of age: adult dose)	
Dosage modifications					
Renal dysfunction	Reduce if CrCl ≤50 mL/min	100 mg/day if CrCl ≤10 mL/min	No change	Half dose for CrCl <10–30 mL/min	
Hepatic dysfunction	No change	100 mg/day orally if severe	Not studied	Not studied	
Elderly	100 mg/day orally	100 mg/day orally	No change	No change	
Main side effects	CNS (major) GI (minor)	CNS (minor) GI (minor)	Bronchospasm (not recommended in asthma)	GI (observed in 10–14% of prescribed courses)	

CNS, central nervous system; b.i.d., twice daily; NA, not applicable; GI, gastrointestinal; CrCl, creatine clearance. Adapted from Centers for Disease Control and Prevention. Prevention and control of influenza: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR* 2001;50(RR-4):1–32, with permission.

been evaluated in high-risk subjects or for treatment of complicated influenza (e.g., hospitalized patients or those with pneumonia).

Both amantadine and rimantadine are generally well tolerated when used for treatment, although minor central nervous system (CNS) disturbances such as difficulty concentrating and sleeping may be seen with amantadine. Amantadine may lower the seizure threshold and should be avoided in individuals with a history of seizures or seizure potential. Dosage reductions are recommended in the elderly (Table 10.2).

Viruses may become resistant to M2 inhibitors through single point mutations in the M2 protein [17], and such resistant viruses arise frequently (~30% of treatment courses or more) in treated individuals [18]. Resistant viruses are fully virulent in animal models and can be transmitted to and cause typical influenza in contacts.

C. Antibiotics should not be used in uncomplicated influenza because they are of no benefit and potentially harmful by causing resistant secondary bacterial infections to occur. Antibiotic therapy should be reserved for confirmed bacterial infections.

VII. Complications. The majority of influenza cases are not associated with any significant complications. However, a spectrum of complications has been well described.

A. Two kinds of **pulmonary complications** are well recognized: primary influenza viral pneumonia and secondary bacterial pneumonia. Comparative features of the secondary pulmonary complications of influenza are shown in Table 10.3.

1. Primary influenza viral pneumonia occurs predominantly in persons with cardiovascular disease (especially rheumatic heart disease with mitral stenosis) or in pregnant women. Cases rarely occur in young healthy adults, however.

a. Clinical manifestations. Following onset of symptoms, there is rapid progression of fever, cough, dyspnea, hypoxemia, and cyanosis [20]. Physical examination and chest radiography reveal bilateral findings, consistent with pulmonary edema, but no consolidation is seen. There are no pathognomonic findings.

b. Course and prognosis. These patients often show a **progressive downhill course unresponsive to antibiotics**. Serial arterial blood gases show progressive hypoxemia. Despite supportive care with artificial ventilation (including extracorporeal oxygenation), the mortality rate is high. At autopsy, findings include tracheitis, bronchitis, diffuse hemorrhagic pneumonia, hyaline membrane lining alveolar ducts and alveoli, and a paucity of inflammatory cells within the alveoli.

c. A relatively mild form of viral interstitial pneumonia may occur in young children that is clinically similar to the lower respiratory tract disease produced by other common respiratory viruses in infants, such as respiratory syncytial and parainfluenza viruses. These infants may present with a fever, mild cough, and upper respiratory tract symptoms, and may be admitted with the diagnosis of possible sepsis. Chest radiography typically shows interstitial infiltrates in one or more lobes. This type of lower respiratory tract involvement is part of the acute influenza syndrome rather than a secondary complication.

2. Secondary bacterial pneumonia is more common than primary viral pneumonia.

a. Clinical manifestations. This is encountered more frequently in the elderly or those with preexisting pulmonary disease. It starts with a typical influenza illness, often followed by a period of improvement lasting 1 to 4 days, and then a relapse. New fever is associated with symptoms and signs of bacterial pneumonia such as cough, sputum production, and often consolidation on physical examination and chest radiography. However, the period of improvement may not occur, and the course is variable. Gram stains and cultures of sputum may reveal predominance of a pathogen, most often *Streptococcus pneumoniae* or *Haemophilus influenzae*. Mixed bacterial pneumonias and *Staphylococcus aureus* secondary pneumonia also occur more frequently after influenza [21].

Table 10.3. Comparative Features of Pulmonary Complications of Influenza

Clinical Parameter	Primary Viral Pneumonia	Secondary Bacterial Pneumonia	Mixed Viral-Bacterial Pneumonia	Localized Viral Pneumonia
Setting	Cardiovascular disease; pregnancy; young adult (HswINI)	Elderly age; pulmonary disease	Same as for primary viral or secondary bacterial pneumonia	?Normal host
Clinical history	Relentless progression from classic 3-day influenza	Improvement, then worsening after 3-day classic influenza	Picture of A or B	Continuation of cough after classic 3-day syndrome
Physical examination	Bilateral findings, no consolidation	Consolidation	Consolidation	Area of rales
Sputum	Negative	Pneumococci	Pneumococci	Negative
Bacteriologic evaluation		Staphylococci, <i>H. influenzae</i>	Staphylococci, <i>H. influenzae</i>	
Chest roentgenogram	Bilateral findings	Consolidation	Consolidation	Segmental infiltrate
WBC count	Leukocytosis with shift to left	Leukocytosis with shift to left	Leukocytosis with shift to left	Usually normal
Isolation of influenza virus	Yes	No	Yes	Yes
Response to antibiotics	No	Yes	Yes	No
Mortality	High	Low	Low	Very low

- b. **Course and prognosis.** These patients **respond to specific antibiotic therapy** and supportive measures.
 - c. **Therapy.** Therapy should be guided by the results of sputum Gram stain and culture. Because the spectrum of bacterial etiologies is similar to that seen with community-acquired pneumonia (CAP), guidelines for CAP are reasonable [22]. This includes an oral macrolide such as azithromycin or clarithromycin or an oral fluoroquinolone with antipneumococcal activity in outpatients, and intravenous (i.v.) ceftriaxone (1 g every 24 hours), in hospitalized adults with normal renal function. In children, therapy should be directed against *S. pneumoniae* and group A streptococcus.
3. **Other pulmonary complications.** During an outbreak of influenza, **many cases are observed that do not fit clearly into either of the preceding categories.** Many of these patients have mixed viral and bacterial infection of the lung (Table 10.3), and most of these mixed infections respond to antibiotics. In addition, milder forms of influenza viral pneumonia involving only one lobe or segment have been described, which do not invariably lead to death and are often confused with pneumonia due to *Mycoplasma pneumoniae*.
 4. **Otitis media** occurs in up to 30% of children 3 to 4 days after onset of influenza.
- B. **Reye syndrome** is a rare hepatic and CNS complication occurring primarily in children who ingest salicylates **after influenza B** viral infection, but also after varicella and influenza A infection. It presents as encephalopathy and fatty degeneration of the liver. Since intensive educational campaigns began, the syndrome has almost disappeared.
 - C. **Myositis and myoglobinuria** with tender leg muscles and elevated serum creatine phosphokinase levels have been reported (mostly in children) after influenza A and influenza B infection, most commonly the latter. Symptoms may be sufficiently severe to prevent walking, but neurologic changes are not evident.
 - D. **Guillain-Barré syndrome (GBS)** has been reported to occur after influenza A infection, numerous other infections, and rarely after influenza immunization.
 - E. Both **myocarditis** and **pericarditis** have been associated rarely with influenza A and B viral infection. However, neither myocarditis nor pericarditis is observed commonly on autopsy of those dying of primary influenza viral pneumonia.
 - F. **Neurologic complications** besides Reye syndrome also may occur with influenza, such as encephalopathy and ataxia. Febrile convulsions are a relatively frequent complication of influenza in preschool children. A rapidly progressive encephalopathy with bilateral thalamic necrosis has been reported in children in Japan [23,24].

VIII. Prevention

- A. **Inactivated influenza vaccines** are 70% to 90% effective in the prevention of influenza illness when there is a good antigenic match between vaccine and epidemic viruses [25–27]. Vaccination of young adults is also associated with decreased absenteeism from work or school and is significantly cost saving in working adults [28]. Inactivated vaccine also is effective in prevention of influenza in children, with prevention of asthma exacerbations [29] and reductions in the rate of acute otitis media [30], and has substantial economic benefit in this age group [31,32]. Relatively few prospective trials of protective efficacy have been conducted in high-risk populations. In one recent randomized placebo-controlled trial in an elderly population, inactivated vaccine was approximately 58% effective in preventing laboratory-documented influenza [33]. In addition, numerous retrospective case-control studies have documented the effectiveness of inactivated influenza vaccines in these individuals. Vaccine is protective against influenza and pneumonia-related hospitalization in the elderly, and is accompanied by a decrease in all-cause mortality [34].
1. **Formulation.** Inactivated influenza vaccines consist of inactivated whole virus, disrupted virus (split-product), or purified H and N (subunit) vaccines. The immunogenicity of each is similar. Because of the frequent antigenic changes, the virus strains to be included in the vaccine must be updated regularly. The trivalent formulation of influenza vaccine contains one H3N2, one H1N1, and one B virus.

Table 10.4. Target Groups for Influenza Vaccination

Groups at increased risk for influenza-related complications

- Persons ≥ 65 years of age
- Residents of nursing homes and other chronic-care facilities that house persons of any age who have chronic medical conditions
- Adults and children who have chronic disorders of the pulmonary or cardiovascular systems, including asthma
- Adults and children who have required regular medical follow-up or hospitalization during the preceding year because of chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression (including immunosuppression caused by medications or by human immunodeficiency [HIV] virus)
- Children and teenagers (6 months to 18 years of age) who are receiving long-term aspirin therapy and therefore might be at risk for developing Reye syndrome after influenza infection
- Women who will be in the second or third trimester of pregnancy during the influenza season.

Persons 50–64 years of age and those who can transmit influenza to those at high risk

- Physicians, nurses, and other personnel in both hospital and outpatient-care settings, including emergency response workers
- Employees of nursing homes and chronic-care facilities who have contact with patients or residents
- Employees of assisted living and other residences for persons in groups at high risk
- Persons who provide home care to persons in groups at high risk
- Household members (including children) of persons in groups at high risk

Adapted from Centers for Disease Control and Prevention. Prevention and control of influenza: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR* 2001;50(RR-4):1–32; with permission.

2. **Indications.** Target groups for influenza vaccination [19] include (a) those who are at increased risk for influenza-related complications, (b) persons who can transmit influenza to those at high risk, and (c) individuals between the ages of 50 and 64. This last group contains a significant proportion of the individuals under the age of 65 who have high-risk conditions. An age-based strategy represents the most effective way to reach these patients, and vaccination beginning at age 50 is consistent with recommendations for annual physician visits (Table 10.4). In addition, vaccine may be used in any individual who wishes to avoid an unpleasant influenza illness.
3. **Administration. A single dose of vaccine is sufficient for most individuals, but two doses of vaccine are required in those who have not been primed by previous infection** or vaccination with similar antigen type, such as children under 9 years of age, or in the event of antigenic shift. Whole-virus vaccine should not be used in children under 12 years of age because of increased systemic reactions. Because the duration of protective immunity afforded by influenza vaccine appears to be limited and vaccine formulations change frequently, annual vaccination, usually in the late fall (e.g., late October or November) is recommended. Vaccine may be administered at the same visit as pneumococcal vaccine, which, although not given yearly, is also recommended for many of the same groups of individuals.
4. **Side effects** of influenza vaccine are **minimal**, consisting of mild soreness at the injection site in a minority of recipients. Systemic symptoms following vaccination are rare and occurred at approximately the same rate in vaccine and placebo recipients in controlled trials. In some years, GBS has been associated with influenza vaccine. The risk of GBS following vaccination is estimated at approximately one excess case of GBS for every million doses of vaccine [35].

- B. A live attenuated influenza vaccine** (FluMist) is also being considered for licensure in the United States for use in children and healthy adults. This vaccine has excellent efficacy in children under 6 years of age, in which a two-dose vaccine schedule provided 96% protection against influenza A and 90% protection against influenza B [36]. The vaccine also protected against a significant antigenic variant [37], suggesting that the live attenuated vaccine induces a broadly cross-reactive antibody response in children. Efficacy studies of FluMist have not been conducted in adults. However, a trial of a related monovalent vaccine in adults showed approximately equal efficacy to inactivated vaccine in the prevention of laboratory-confirmed influenza illness [38]. In addition, FluMist reduced the rates of severe febrile illness in adults during the influenza season [39]. Although the vaccine is well tolerated in high-risk and elderly subjects, there are insufficient data suggesting efficacy to recommend use in these populations.
- C. Chemoprophylaxis** with the drugs described in section VI.B above is also effective for prevention of influenza. All four agents appear to have similar levels of efficacy, with the proviso that amantadine and rimantadine are only effective against influenza A viruses, and that zanamivir, while shown to be effective for prevention of influenza in controlled studies, is not licensed for this indication in the United States. Studies of chemoprophylaxis have generally dealt with two situations: seasonal prophylaxis, in which an antiviral agent is administered throughout the influenza season, and postexposure prophylaxis, in which drug is given for a relatively shorter period of time following a known exposure to an influenza-infected person. Antiviral prophylaxis cannot substitute for vaccination, but can be considered for several situations listed below:
- 1. Seasonal prophylaxis.** Administration of amantadine, rimantadine, zanamivir, or oseltamivir for 4 to 6 weeks during influenza epidemics results in reductions of 70% to 90% in the rates of laboratory confirmed influenza [40–42]. In a comparative trial, the efficacies of amantadine and rimantadine were identical, but rimantadine was associated with a lower frequency of CNS side effects than was amantadine [40]. Zanamivir and oseltamivir have not been compared directly. Although seasonal prophylaxis has been the basis for many clinical trials, the circumstances in which this would be used clinically are rare. However, seasonal prophylaxis can be considered in high-risk patients in whom vaccination is not possible or is contraindicated, for immunodeficient individuals who do not respond to vaccination, or for unvaccinated individuals who care for high-risk patients.
 - 2. Postvaccination prophylaxis.** Development of a protective immune response following influenza vaccine can take as long as 2 weeks, so short-term prophylaxis should be used in high-risk patients who are not vaccinated until after influenza epidemic activity has begun. None of the four available agents are known to interfere with the immune response to inactivated vaccine.
 - 3. Family prophylaxis.** Many studies have demonstrated that short-term prophylaxis of family members with amantadine [43], rimantadine [44,45], zanamivir [46], or oseltamivir [47] following identification of an index case can reduce the rate of secondary family cases during the period in which prophylaxis is administered. An important observation of these studies has been that resistant influenza A viruses have emerged rapidly and have been transmitted to contacts when amantadine or rimantadine were used both for treatment of index cases and prophylaxis of contacts [48]. In contrast, resistant viruses have not been isolated in studies where the index case has received treatment and contacts have received prophylaxis with either zanamivir or oseltamivir.
 - 4. Outbreak prophylaxis in chronic care institutions.** Where a volatile mix of high-risk populations and crowding exists, explosive and devastating outbreaks of influenza can occur. Thus, once an outbreak of influenza is recognized, potentially exposed individuals should receive prophylaxis with an appropriate antiviral agent for a minimum of 2 weeks, or for 1 week after the last recognized case [49]. Amantadine-resistant viruses emerge rapidly in this setting, and where possible, amantadine- (or rimantadine-) treated patients should be isolated from those receiving prophylaxis. The neuraminidase inhibitors may

offer some advantages in this setting because of the less frequent resistance [50], but they are significantly more expensive.

- 5. Dosing and administration.** Dosing and administration of available chemotherapeutic agents are described in Table 10.2.

LARYNGITIS AND CROUP (ACUTE LARYNGOTRACHEOBRONCHITIS)

- I. Acute viral laryngitis** is an afebrile, self-limited illness characterized by **hoarseness** or sometimes loss of voice. Visualization of the larynx reveals erythema and some edema, with little involvement of the pharynx and nose. As an isolated syndrome, acute viral laryngitis occurs much less frequently than does acute viral rhinitis or pharyngitis. However, some degree of laryngitis occurs in 10% to 20% of patients with common colds, and a somewhat higher incidence exists in patients with acute viral pharyngitis. The viruses most frequently isolated are parainfluenza virus types 1, 2, and 3. Although presumably all the remaining respiratory viruses occasionally may be involved, none of these has been isolated regularly. **Bacteria are not a cause** of this syndrome. There is **no specific treatment**, but resting the voice and inhalation of steam or cold-water vapor often are helpful.
- II. Acute viral laryngotracheobronchitis (croup)** [51]. Acute laryngotracheobronchitis, or viral croup, is a clinically distinctive syndrome characterized by respiratory distress, inspiratory stridor, and subglottic swelling that occurs predominantly in children 6 months to 5 years of age.
- A. Etiology.** As discussed in Chapter 8, parainfluenza virus type 1 is the most frequent cause of croup [52]. Parainfluenza viruses types 2 and 3 and influenza A also are major agents. Influenza A is particularly important, for although it is a less frequent cause of croup than parainfluenza type 1, it tends to cause more severe disease. Less common causes of croup are RSV, influenza B virus, rhinoviruses, adenoviruses, enteroviruses, rubella virus, and *M. pneumoniae*. Overall, viruses may be recovered from croup cases more frequently (40%–75%) than from other types of respiratory illnesses.
- B. Epidemiology** of croup mirrors that of its major viral agents, occurring when parainfluenza type 1 is prevalent, which often is in the fall of every other year. Fewer upsurges of croup are seen with parainfluenza type 2 activity, which, although less predictable than type 1, also occurs in the fall [53]. The number of croup cases may increase with influenza A outbreaks (which usually occur between December and April). In contrast, parainfluenza type 3 viruses often cause outbreaks of infection in spring [54].
- C. Clinical manifestations** [51]. An upper respiratory tract infection usually precedes the onset of croup, which is heralded by a **distinctive cough** with a deep, brassy tone, called a seal's bark. Laryngitis and fever are common, particularly with influenza A and parainfluenza viral infections.
- 1. Stridor.** The development of **inspiratory** stridor is usually abrupt, often occurring at night, and is associated with respiratory distress. Obstruction of air flow occurs during both inspiration and expiration but is greater on inspiration because the negative inspiratory pressure tends to further narrow the subglottic area.
 - 2. Respiratory findings.** Retractions of the accessory muscles of the chest wall are common, and the **respiratory rate is increased** but usually to no more than 50 to 60 breaths per minute. Inspiration is prolonged and, on auscultation, rales, wheezes, and rhonchi may be heard. With increasing obstruction, the breath sounds may diminish and cyanosis may appear. The course of croup is variable and fluctuating.
 - 3. Hypoxemia** occurs in the hospitalized patients with croup. It arises from involvement of the lung parenchyma. Subglottic inflammation, which is most evident clinically, does not contribute to the hypoxemia until fatigue and hypercapnia ensue.
- D. Diagnosis.** The diagnosis is made on the basis of the characteristic clinical features and can be confirmed by a posteroanterior radiograph of the neck, which in viral croup shows the narrowing of the tracheal air shadow in the subglottic region. Viral cultures can be performed on respiratory secretions. It is important to distinguish this syndrome from other causes of airway obstruction, such as epiglottitis.
- E. Treatment.** Many and varied therapies have become legendary, their success being based on grandmothers' trials and the characteristic fluctuating course of croup.

1. **Oxygen is the mainstay** of treatment for the severely affected.
2. **The value of mist therapy has not been proved.** Water from the standard home-use vaporizer cannot reach the lower respiratory tract because of the large particle size.
3. **Nebulized racemic epinephrine** gives symptomatic relief by diminishing airway obstruction. However, the clinical improvement is transitory (<2 hours) and generally is not associated with an improvement in the arterial oxygen saturation. Side effects such as tachycardia may occur. Recommended doses are 0.25 mL of a 2.25% solution for children less than 6 months of age, and 0.5 mL for older children.
4. **Corticosteroids.** Steroids have been shown to confer significant benefits in the management of mild, moderate, and severe croup, including more rapid improvement in symptoms, reduced length of hospital stay, and reduced rates of intubation. Parenteral dexamethasone in doses over 0.3 mg/kg, nebulized corticosteroids, and oral dexamethasone (0.15–0.6 mg/kg) have all been shown to be equally effective [55]. Administration of single-dose steroid therapy in this setting has not been associated with significant side effects, and should probably be used on any patient with significant enough illness to require an emergency room or clinic visit [56].
5. Croup is largely a viral illness, so **antibiotics are not beneficial** and should only be used when concomitant bacterial infection is present.
6. **Ventilatory support** may be necessary for the rare hospitalized patients with significant obstruction not responsive to corticosteroids.

BACTERIAL TRACHEITIS

- I. **Bacterial tracheitis** is a relatively rare syndrome that mimics epiglottitis or severe viral croup [57]. Although this syndrome has been recognized only recently, and has been described mostly in children, it may occur at any age. It is important to differentiate bacterial tracheitis from viral croup because of its potential for rapid progression that necessitates intubation and because of the need for prompt antibiotic therapy.
- II. **Etiology.** Bacterial tracheitis usually is caused by *S. aureus* and *H. influenzae* type b, but group A streptococci and *S. pneumoniae* also have been associated with this syndrome.
- III. **Clinical manifestations.** Bacterial tracheitis affects those who have had previous tracheal injury or compromise, such as by intubation or sometimes by a preceding viral infection. The onset is acute, with stridor, dyspnea, and sometimes high fever. Abundant purulent sputum or secretions are usually evident and may cause rapid airway obstruction as in epiglottitis.
- IV. **Diagnosis is made by direct laryngoscopy**, which shows localized inflammation and membranous exudate in the subglottic area, and sometimes by a lateral soft tissue radiograph of the neck, demonstrating the subglottic narrowing with a shaggy, exudative membrane. The epiglottis is usually normal, however. Blood cultures are generally negative.
- V. **Treatment.** Therapy should be initiated as soon as possible with antibiotics for the most likely organisms, such as ceftriaxone. Cultures of the exudative membrane should subsequently allow the antibiotic regimen to be narrowed to cover the isolated pathogen.

BRONCHIOLITIS

Bronchiolitis is confined to children (mainly ages 1–24 months). It is **due primarily to infection with RSV** [58], but occurs with other viruses.

- I. **Symptoms.** After several days of typical upper respiratory tract illness, the infant develops a deepening cough and the onset of dyspnea and wheezing.
- II. **Signs.** The infant's respiratory rate increases, and retraction of the intercostal muscles is seen due to respiratory obstruction. On auscultation, rales, rhonchi, and expiratory wheezing are present and may fluctuate in intensity. Cyanosis may be present; even without overt cyanosis, however, hypoxemia is commonly present [59].
- III. **Chest radiography** shows hyperaeration with or without infiltrates. The infiltrates result either from the atelectasis, which is part of the pathology of bronchiolitis, or from a concomitant viral pneumonia, which is frequently also present.

IV. Diagnosis. Rapid diagnostic tests of respiratory secretions to detect RSV as well as other respiratory viruses such as parainfluenza and influenza viruses are widely available (see Chapter 25). Lacking those, a clinical diagnosis can be made, particularly during an outbreak of RSV infections, by the characteristic findings of acute respiratory signs with wheezing and hyperaeration in a child in the first 2 years of life. The major entities in the differential diagnosis are asthma, gastroesophageal reflux, and aspiration of a foreign body.

V. Therapy.

A. Antiviral therapy is available for some of the viruses responsible for bronchiolitis, but the use of such therapy for the most common etiology, RSV, remains controversial. Ribavirin therapy has resulted in diminished clinical severity and improved oxygenation in all of the randomized, placebo-controlled studies in which these outcomes were assessed. However, the numbers of subjects in such studies have been small, and studies have not confirmed significant long-term benefits in treated children. The high cost, difficult aerosol administration, and concern about potential toxicity among exposed health-care workers, combined with the conflicting results of clinical trials, have contributed to the controversy over its use. The American Academy of Pediatrics currently recommends that ribavirin be considered, primarily in selected high-risk infants, with the decision individualized according to the particular clinical circumstances [60].

B. Bronchodilators may produce modest short-term clinical improvements, but their use is controversial because benefit is not consistently observed in all infants and treatment may be associated with side effects such as tachycardia. Because a subgroup of infants with bronchiolitis appear to benefit from nebulized bronchodilators, a monitored trial may be warranted in infants with moderate to severe disease.

C. Corticosteroids are generally ineffective and are not indicated in previously healthy infants with bronchiolitis [61,62].

D. Antibiotics are not warranted, and bacterial suprainfections are rare. The mainstay of supportive therapy is the monitoring and maintenance of adequate oxygenation.

VI. Prevention. Prophylaxis against RSV lower respiratory tract disease, including bronchiolitis, may be provided by i.v. administration of RSV-IGIV (intravenous immune globulin), which contains high titers of RSV neutralizing antibody from selected donors, or intramuscular administration of palivizumab, a humanized mouse monoclonal antibody to RSV. Controlled studies of these agents have demonstrated significant reductions in hospital admissions in infants receiving monthly prophylaxis for 5 months during RSV season [63,64]. The American Academy of Pediatrics recommends that palivizumab or RSV-IGIV prophylaxis should be considered for infants under 2 years of age with chronic lung disease who required medical therapy within 6 months prior to the onset of the RSV season. Palivizumab is preferred because of its easy intramuscular administration and safety. Infants born at 32 weeks' gestation or earlier who do not have chronic lung disease also may be considered for such prophylaxis depending on other risk factors [65]. In general, decisions for use within both groups of infants must be individualized.

VIRAL PNEUMONIA

Pneumonia is covered in Chapter 11. However, because **viral pneumonia** is due to the same viruses responsible for other respiratory tract syndromes, see Chapter 8 for further discussion.

I. Infants and children. In infants and children under 5 years of age (especially under age 2), **viruses are the most common cause of pneumonia.** RSV, the parainfluenza viruses, and influenza A virus are the most important pathogens.

II. Otherwise healthy adults seldom have true viral pneumonia [66].

A. Young adults. The majority of cases are associated with influenza viruses (see section VIII). Adenoviruses also have been described as causes of significant outbreaks of atypical pneumonia in military recruits, and less often, in civilians. Adenovirus illness is typically mild, but more severe disseminated infections and deaths have been reported [67]. Chest radiographs taken in adults with varicella reveal infiltrates in 10% to 20%, most frequently with a nodular infiltrate with peribronchial distribution involving both lungs. RSV occasionally causes pneumonia in otherwise healthy

adults [68]. Clinical features of the hantavirus pulmonary syndrome include onset of severe pulmonary dysfunction after a 2- to 3-day prodrome of nonspecific influenza-like symptoms, fever, myalgias, cough, gastrointestinal symptoms, and headache [69]. Laboratory abnormalities include leukocytosis, increased hematocrit due to hemoconcentration, and thrombocytopenia with coagulopathy.

- B. Older adults** are much more likely to have bacterial pneumonia, although influenza virus can cause pneumonia, and RSV has recently been associated with pneumonia and exacerbations of chronic lung disease in the elderly [70]. It has been estimated that 2% to 4% of pneumonia deaths among the elderly in the United States may be due to RSV [71]. Parainfluenza viruses also have been reported as occasional causes of pneumonia in adults and in the elderly [72].
- C. Patients infected with the human immunodeficiency virus.** Cytomegalovirus (CMV) often is isolated from the respiratory secretions (or lung biopsies) of these patients. How often CMV is a primary pathogen (if ever) in this setting is unclear (see Chapter 18).
- D. Other immunosuppressed patients** may develop severe, life-threatening pulmonary infections with RNA and DNA viruses, including both viruses that are typical causes of lower respiratory tract disease in normal hosts, and other, more opportunistic viral pathogens. CMV is etiologic, particularly in lung and marrow transplant recipients. The highest risk is 1 to 3 months posttransplantation, with the peak incidence at 8 weeks. The presence of neutropenia, abnormalities of liver function test results, and mucosal ulcerations may be clinical clues to the diagnosis. Herpes simplex pneumonia has been reported largely in immunocompromised or debilitated individuals. The majority of cases present as a focal pneumonia as a result of contiguous spread from the upper respiratory tract; diffuse interstitial disease resulting from hematogenous spread occurs in up to 40% of cases [73]. Varicella-zoster virus is an important problem in individuals with hematologic malignancies and others with iatrogenic immunosuppression, with the greatest risk seen in organ transplantation. Adenoviruses are significant causes of morbidity and mortality in immunocompromised patients, particularly after transplantation. In contrast to infection in normal hosts, infection in immunocompromised subjects tends to be disseminated, with isolation of virus from multiple body sites including lung, liver, gastrointestinal tract, and urine [74].

RNA viruses have also received increasing recognition as potential causes of significant morbidity and mortality in this population [75]. RSV is well recognized as a cause of pneumonia in recipients of bone marrow [76] and solid organ transplantation [77]. Many cases are nosocomial. The illness typically begins with upper respiratory tract infection symptoms that progress over several days to severe, life-threatening lower respiratory tract involvement. Mortality rates of 50% or higher are typical if pneumonia supervenes, particularly if disease occurs in the preengraftment period [78]. Parainfluenza viruses also have been reported as a less frequent lower respiratory tract pathogen in both solid organ and bone marrow transplantation [75]. Influenza virus also may cause severe disease in transplant recipients [79] and leukemics. Rhinovirus infections in this population are also common, but tend to be associated less frequently with lower respiratory tract disease [80]. Measles giant cell pneumonia is a severe, usually fatal form of pneumonia in immunosuppressed individuals [81], who may present without rash or other typical manifestations of measles, and a high index of suspicion must be maintained.

11. LOWER RESPIRATORY TRACT INFECTIONS (INCLUDING TUBERCULOSIS)

Robert L. Penn and Robert F. Betts

Virtually any type of infectious agent can cause pneumonia. It develops when the host is confronted by a virulent organism for which he or she has no specific defense, or when the usual lung defense mechanisms are impaired regardless of the virulence of the organism.

Pneumonia can be induced by aspiration of minute quantities of virulent organisms, or by aspiration of larger quantities of virulent or nonvirulent organisms. In addition, aspiration of noninfectious gastric contents or inhalation of toxic fumes can produce an inflammatory pneumonitis that is sometimes followed by secondary bacterial infection. Another mechanism is inhalation of microorganisms in small-particle aerosols, as occurs in tuberculosis.

Occasionally microorganisms can embolize to the lung through the bloodstream, and frequently without evidence of airway disease. This most often occurs from right-sided endocarditis or from sites drained by the inferior or superior vena cava, for example the jugular vein.

GENERAL CONCEPTS OF ORGANISM–HOST INTERACTION

I. The organism

A. Availability. Colonization by an organism or acute exposure to an organism in the environment is an essential precondition for the development of pneumonia.

B. Virulence. The virulence of most bacterial respiratory pathogens is related to their ability to **adhere to receptor sites** on respiratory epithelial cells and pneumocytes, and to **resist natural host defenses in the lung**.

1. The virulence of the pneumococcus is related to its ability to adhere to receptor sites on respiratory epithelial cells and pneumocytes. **Receptor sites** on the pneumocyte for the pneumococcus increase twofold when there is associated inflammation (e.g., influenza).

2. **Importance of the capsule.** The ability of the pneumococcus to **resist phagocytosis via its capsule** enables it to survive and replicate in the alveolus. All species of *Streptococcus pneumoniae* that cause disease are encapsulated, and frequency and severity of disease are related to the quantity of capsule. Encapsulated *Haemophilus influenzae* type b can cause pneumonia that is associated with bacteremia, whereas nonencapsulated *H. influenzae* usually causes only exacerbations of bronchitis and occasionally bronchopneumonia. Its capsule and its ability to adhere to respiratory epithelium probably explain why *Klebsiella pneumoniae* causes pneumonia. *Klebsiella* species also elaborate cytotoxic enzymes.

C. Other factors. Unencapsulated organisms can cause pneumonia if the quantity aspirated is sufficiently high. For example, decaying teeth harbor high titers of anaerobic bacteria. Impairment of host defenses also favors the establishment of infection. Loss of ciliary activity is an important risk factor, as may occur from viral infection of the lower respiratory tract, drugs such as alcohol, airway obstruction from a tumor or a foreign body, or exposure to an irritant such as cigarette smoke.

II. Host defense mechanisms [1]

A. Upper airway defenses

1. **Mechanical defenses** such as air filtration, the epiglottic reflex, upper airflow turbulence, cough, and mucociliary clearance protect the lower airway. Neurologic or esophageal diseases enhance access to the bronchial tree. Inhaled toxins, abnormal bronchial secretions (e.g., cystic fibrosis), viral infections, endobronchial tumors, or foreign bodies (e.g., an endotracheal tube) impair these mechanical defenses.

2. **Secretory immunoglobulin A (IgA)** impairs microbial adherence and neutralizes viruses.

B. Lower respiratory defenses

1. **IgG and secretory IgA antibodies** both diffuse into mucosal secretions, while IgG predominates in the alveolar milieu. Vaccines or previous infections stimulate

antibody production. Mucosal applied vaccines more effectively stimulate IgA. Absence of antibodies is a risk factor, as occurs in multiple myeloma and agammaglobulinemia. Deficiencies of IgG₂ or IgG₄ predispose to recurrent sinus and bronchial infections, especially if combined with IgA deficiency.

2. **Complement** activation generates opsonins, chemotactic molecules, and lytic activity. The functional absence of complement in sickle cell disease and certain inherited deficiency states leads to increased incidence of sinopulmonary infections.
3. **Phagocytic defenses consist of alveolar macrophages and neutrophils.** Alveolar macrophages are the initial phagocytic defense and play a central role in recruiting neutrophils and other aspects of lung inflammation [1]. Either a quantitative or a qualitative defect in phagocytes may contribute to pyogenic infection. Impaired migration of phagocytes is a risk factor. For example, high alcohol concentrations impair neutrophil migration. Organisms such as *Legionella* and *Mycobacterium* species can survive within nonimmune alveolar macrophages. Optimal defense against facultative intracellular pathogens requires activation of macrophages via specific T-lymphocyte immunity.
4. **Other antibacterial substances** in the lower airways include lysozyme, fibronectin, free fatty acids, iron-binding proteins, defensins, cathelicidins, and collectins, including surfactant proteins [1].

CLINICAL APPROACH TO COMMUNITY-ACQUIRED PNEUMONIA (CAP)

I. Important history and epidemiologic data include the following points, as well as the season of the year [2–6]. Influenza, pneumococcal, and haemophilus etiologies are more prevalent in the winter.

- A. Family history.** Respiratory syncytial virus, influenza, *Mycoplasma pneumoniae*, and *Chlamydophila (Chlamydia) pneumoniae* are just a few examples of pneumonia that may spread within families, although *Mycoplasma* and *Chlamydophila* spread more slowly than the viruses.
- B. Travel history.** A history of travel to or residence in certain areas of the country is essential for acquisition of coccidioidomycosis, histoplasmosis, or blastomycosis (see Chapter 17). Travel to Southeast Asia or the South Pacific at any time should raise the possibility of infection with *Pseudomonas pseudomallei*, for illness can develop years after exposure.
- C. Unusual contacts.** Occupational exposures, outdoors activities, or contact with animals and birds or their excreta suggest such entities as hantavirus pulmonary syndrome, histoplasmosis, Legionnaires disease, plague, psittacosis, Q fever, and tularemia.
- D. Recent hospitalization, institutionalization, or antibiotic therapy.** Gram-negative pneumonias and infections caused by antibiotic-resistant organisms, including resistant pneumococci, are much more frequent in these patients.
- E. Infection with the human immunodeficiency virus (HIV) or the presence of HIV risk factors** suggests the possibility of both gram-negative and gram-positive bacterial pneumonias [7], as well as a variety of opportunistic pathogens such as *Pneumocystis carinii* and *Rhodococcus equi* (see Chapter 18).
- F. Age** is an important factor.
 1. In the **neonatal period**, *Streptococcus agalactiae* is an important cause of pneumonia acquired through contact in the birth canal (see Chapter 3).
 2. **The infant**
 - a. **Respiratory syncytial virus** (RSV), parainfluenza, and influenza are common in infancy and may occur in epidemics.
 - b. **Encapsulated bacteria.** Both *S. pneumoniae* and *H. influenzae* type b may cause pneumonia in children 5 to 18 months of age. This is related both to loss of maternal antibody and to the failure of children in this age group to form antibody to polysaccharide antigens. The incidence of invasive *H. influenzae* type b infections has declined among infants since the introduction of the *H. influenzae* type b conjugate vaccines in 1988. Hopefully, the pneumococcal conjugate vaccine will have the same effect on *S. pneumoniae* infections.

3. In **children** (3 months old to teenagers) with CAP, the most frequently identified causes are *S. pneumoniae*, *M. pneumoniae*, RSV, *Chlamydophila pneumoniae*, nontypable *H. influenzae*, and *Moraxella catarrhalis* [8]. RSV is more common in children under 5 years of age, and *M. pneumoniae* and *C. pneumoniae* are more common in older children. Recent studies have found the frequent occurrence of mixed infections [8].
 4. In **young adults** (18–45 years) *Mycoplasma* species and *Chlamydophila pneumoniae* are the most common causes year round, but influenza predominates during epidemics.
 5. **Older ambulatory adults** are just as likely as younger adults to have pneumococcal pneumonia and influenza [9]. However, one review noted an increased proportion of haemophilus, staphylococcal, and gram-negative pneumonias in the elderly [10].
 6. **Institutionalized older adults** are often colonized with gram-negative rods. Thus, when pneumonia develops, gram-negative pneumonia is more likely, although pneumococcal disease still is prevalent. Staphylococci (including methicillin-resistant strains), haemophilus, moraxella, anaerobes, viruses, and *Mycobacterium tuberculosis* also regularly cause pneumonia in this group [9].
- G. Predisposing conditions**
1. In **alcoholics**, *S. pneumoniae* is the most prevalent organism, but anaerobes, *H. influenzae*, *K. pneumoniae*, and *M. tuberculosis* also are regularly encountered.
 2. **Aspiration pneumonia** occurs in patients with alcoholism, drug abuse, recent general anesthesia, trauma, other causes for mental obtundation, stroke, swallowing problems, esophageal dysmotility (e.g., scleroderma, stricture, or achalasia), tracheoesophageal fistula, gastroparesis, feeding tubes, tracheotomy, seizure disorders, and other serious underlying diseases. Anaerobes are common pathogens in this setting, often as part of a mixed infection, unless the patient is edentulous. Nosocomial aspiration pneumonias also may involve aerobic gram-negative bacilli and *Staphylococcus aureus*. (See section II under Specific Therapy and Special Considerations.)
 3. **Chronic obstructive pulmonary disease** (COPD) is associated with *H. influenzae*, *S. pneumoniae*, *M. catarrhalis*, and *Legionella* pneumonias.
 4. **Cystic fibrosis** predisposes to staphylococcal, mucoid strains of *Pseudomonas aeruginosa*, *Stenotrophomonas maltophilia*, and *Burkholderia cepacia* infection. The latter gram-negative organisms usually appear after repeated courses of antibiotics.
 5. **Postinfluenza bacterial pneumonias** are commonly caused by staphylococci, *H. influenzae*, or *S. pneumoniae*.
 6. **Sickle cell disease** is an important risk factor for pneumococcal pneumonia.
 7. **Immunosuppression** predisposes to a wide variety of potential organisms.
- H. Hospital-acquired pneumonias** [11,12]. Oropharyngeal colonization by gram-negative organisms, especially *Klebsiella* species, increases in the infirm elderly, and with severe acute illness, prolonged hospitalization, diabetes, renal failure, intubation, or prior antibiotic exposure. **Gram-negative organisms must be considered when pneumonia develops in these settings.** Other important nosocomial pathogens include *S. aureus*, anaerobes from aspiration, *Legionella* species, fungi, and some viruses.
- II. Symptoms and signs.** For CAP, the individual often has had a recent, mild upper respiratory tract infection and then develops chills, fever, cough associated with pleuritic chest pain, dyspnea, and purulent sputum. However, the complete spectrum of these symptoms may be lacking, depending on the host and the organism.
- A. Host considerations**
1. **Neonates** with *Chlamydia* pneumonia usually are mildly ill and do not have fever (see Chapter 3).
 2. **Young infants** with viral pneumonia almost always present with respiratory distress and fever but, at times, infants may appear septic.
 3. **Elderly** patients often develop a change in eating habits or mental function with a minimum of respiratory symptoms [9]. Other important clues include

unexplained diminished activity, a fall, new incontinence, or the decompensation of an underlying medical problem. Fever may be minimal or absent. Tachypnea or tachycardia may be the first evidence of pulmonary involvement. Abnormalities on the chest radiograph may be difficult to interpret because of underlying heart and lung disease.

4. **Patients with chronic bronchitis** may exhibit a change in the quantity and type (color and general appearance) of sputum as the first sign of pneumonia.
5. **Neutropenic patients** may not produce sputum and may have few chest radiograph abnormalities.

B. Special considerations by organism

1. Anaerobic infections, tuberculosis, and pulmonary mycoses usually have a more gradual onset of symptoms than pyogenic bacterial pneumonias.
2. Some pneumonias characteristically have scant and nonpurulent sputum production, although this has proven to be nonspecific [2,6].
 - a. *M. pneumoniae* and *C. pneumoniae* usually have a gradual onset characterized by fever, protracted cough, and minimal sputum.
 - b. **Legionnaires disease** characteristically causes only a modest amount of sputum production and nonspecific systemic symptoms [13]. Other manifestations include relative bradycardia, renal abnormalities, delirium, diarrhea, and hyponatremia.
 - c. **Q fever, psittacosis, and viral pneumonias** are nonbacterial pneumonias discussed in section V under Specific Therapy and Special Considerations. A history of occupational or other exposure to animals and birds or a local epidemic of influenza may help increase one's index of suspicion for these diagnoses.

III. Physical examination. In addition to examination of the chest, special emphasis should be placed on a search for signs of nonpneumonic infection such as endocarditis, meningitis, and salpingitis. Evidence of an associated pleural effusion should be sought. Other relevant findings include deep venous thrombosis leading to pulmonary embolism, lymphadenopathy, or clubbing, suggesting neoplasia.

IV. Radiologic evaluation [14]. Chest radiography is always indicated [2]. Although the x-ray film yields useful clues, **it seldom identifies a specific etiologic diagnosis.**

The compromised host, the very young, and the very old pose special diagnostic problems. In some, the physical findings may be minimal, but the radiograph may clearly reveal the pneumonia. In others, particularly neutropenic patients, the initial radiograph may fail to show any infiltrates despite clinical findings of pneumonia.

A. Location of infiltrates

1. Infiltrates in the **apical segment of the lower lobe or in the posterior segment of the upper lobe suggest aspiration while recumbent**, whereas infiltrates in the **basal segment of the lower lobe suggest aspiration while more upright** [15]. However, aspiration in different postures may lead to pneumonia in other dependent locations.
2. **Upper lobe** involvement can occur in any pneumonia, but it is particularly common in **tuberculosis**, *Klebsiella* infection, and melioidosis. Lower lobe infiltrates in an immunocompetent host make tuberculosis less likely, but do not exclude this possibility. Involvement of the anterior segment of an upper lobe by itself usually is considered nontuberculous and possibly related to other infection or tumor.

B. Cavitation. Cavities must be distinguished from pneumatoceles or infiltration around a bulla. Comparison with the uninvolved lung can be helpful in the latter instance.

1. Cavities **without air-fluid levels** are **suggestive of tuberculosis**, but also may occur in fungal infections.
2. Cavities **with air-fluid levels** suggest abscess formation from staphylococci, anaerobes, gram-negative bacilli, coccidioidomycosis, nocardiosis, or melioidosis. **Occasionally, loculated pleural effusion in association with a bronchopleural fistula can mimic an abscess.**

- C. Volume loss.** If there is evidence of associated volume loss, correctable bronchial obstruction must be excluded.
- D. Pleural fluid.** Sampling pleural fluid may lead to a specific diagnosis and chest tube drainage. In addition, the presence of an effusion is suggestive of certain pathogens. (See the discussion on pleural effusions later in this chapter under Pleural Effusion versus Empyema.)
1. Pleural effusion without pneumonia suggests tuberculosis, tumor, or a subdiaphragmatic process.
 2. *M. pneumoniae* and *C. pneumoniae* infections may have small effusions that are not readily detected.
 3. Pneumococcal pneumonia frequently is associated with effusion. The fluid may be sterile or may represent a frank empyema. Thoracentesis is indicated to exclude an associated empyema if the effusion volume is sufficient.
 4. Anaerobic organisms, *Streptococcus pyogenes*, and *Escherichia coli*, as well as staphylococcal pneumonia in children, commonly produce pleural fluid.
 5. *M. tuberculosis* that has produced cavities, *K. pneumoniae*, and *P. pseudomallei* may be associated with pleural fluid.
 6. Influenza viral infections rarely are associated with effusion.
 7. Legionnaires disease may cause a pleural effusion, although large effusions are uncommon [13,16].
- E. Mediastinal adenopathy** is seen with lung cancer, and in acute pneumonias caused by tuberculosis, fungal infections, tularemia, and *M. pneumoniae* in children.
- F. Miscellaneous findings.** Pericardial effusion, widening of the mediastinum, evidence of a bronchopleural fistula, and free air under the diaphragm require further evaluation. Chemotherapy, radiation, drug reactions, pulmonary embolism, heart failure, vasculitis, and cancer can mimic the radiographic appearance of pneumonia [3,17].
- G. Follow-up chest radiography. Rapid changes in infiltrates** (e.g., over 5–36 hours) **seldom occur in pneumonia, and suggest pulmonary edema or atelectasis.** Although repeat radiologic evaluation may assist in management, this is often overused.
1. **If the patient is clinically improving,** follow-up radiography should be postponed. **Infiltrates due to pneumonia often take a month to clear completely,** and this varies with host factors and the microbial etiology [17]. Clearing may take **even longer in the elderly** (1–12 weeks). Therefore, it is wise to postpone a follow-up radiographic examination in the patient whose clinical response is appropriate. If at least partial clearing does not occur after 6 weeks, or pneumonias recur in the same location, then fiberoptic bronchoscopy should be considered [17].
Fibrosis or scarring may be present despite clearing of the infiltrate, particularly after aerobic gram-negative or anaerobic infections. More extensive scarring often is associated with tuberculosis and histoplasmosis.
 2. **If the patient is not improving** or develops a new fever, increasing pulmonary symptoms, or sputum production, **follow-up radiography is important** [17]. **Radiographs** may identify bronchial obstruction, a new pulmonary infection, an associated effusion that may be infected, an abscess, or noninfectious complications.
- V. Identification of the pathogen.** Recent guidelines for CAP support empiric management without diagnostic studies for those otherwise healthy adults with mild illness who are being treated as outpatients [2,4,6]. **However, identifying the pathogen provides a diagnosis and is of primary importance in further management** [2]. **Every effort should be made to obtain diagnostic specimens** (not be left to the untrained) **before initiating antibiotic therapy** [2]. Sputum for smear and culture, blood cultures, culture of any pleural fluid, and cerebrospinal fluid (CSF) if meningitis is a possible complication should be obtained.
- A. Normal mouth flora.** Common, normal colonizers of the oropharynx are listed in Table 11.1. These are often observed on Gram staining and routinely recovered on sputum cultures. **Isolation of these organisms from expectorated sputum**

Table 11.1. Common Colonizers of the Oropharynx

Organism	Incidence Range (%)
<i>Staphylococcus aureus</i>	35–40
<i>Streptococcus pyogenes</i> (group A)	0–9
<i>Streptococcus pneumoniae</i>	0–50
<i>Neisseria meningitidis</i>	0–15
<i>Haemophilus influenzae</i>	5–20
Gram-negative aerobic bacilli	2 ^a

^aApproximate percentage isolated by using routine culture techniques. With special broth cultures, more than 10% of normals may have gram-negative colonizers. Of elderly nursing home patients, 6%–40% may be found to be colonized with gram-negative organisms (as revealed by routine culture techniques).

Adapted from Sommers HM. The indigenous microbiota of the human host. In: Youmans GP et al., eds. *The biologic and clinical basis of infectious diseases* 2nd ed. Philadelphia: WB Saunders, 1980; with permission.

does not prove they are pathogens in the lower respiratory tract. (See the discussion of colonization vs. infection in section VIII.)

B. Methods of sputum collection [2,4,6]

- 1. Coughed specimens. Sputum from a deep cough,** not saliva, must be studied to minimize contamination by oropharyngeal colonizers. In at least 20% to 30% of cases, adequate sputum is not available; this is particularly true in the elderly and the acutely ill [18].
- 2. Nasotracheal aspirations** are always contaminated with some oral colonizers. However, the procedure may stimulate deep expectorations that produce an adequate specimen.
- 3. Bronchoscopy.** Passing the bronchoscope through the upper airway picks up colonizers unless special techniques are used (see further discussion in section VI).
- 4. Other.** Transtracheal aspiration (TTA), direct lung aspiration, and open lung biopsy bypass normal oropharyngeal colonizers. Thus, these specimens are suitable for anaerobic cultures. **Organisms seen in or cultured from these specimens usually represent lower respiratory tract pathogens.** (See further discussion in section VI.)

C. Gram staining of sputum[19]. The technique and interpretation of Gram stains is discussed in Chapter 25. This helpful procedure always should be attempted, although this view is not held by all clinicians [2,4,6]. The sputum Gram stain assists in several ways.

- Gram staining helps **assess the adequacy of the sputum specimen. If more than 10 squamous epithelial cells are seen per low-power field, the sample is contaminated with oral secretions.** A repeat sputum should be obtained, or an invasive method of specimen collection should be considered.
- A predominance of gram-positive cocci or gram-negative bacilli is helpful.
- Gram staining of pleural fluid, TTA, protected brush specimens, or percutaneous lung aspirates are even more valuable, because normal colonizers are absent.

D. Acid-fast smears and cultures should be obtained when upper lobe disease is present or when tuberculosis is otherwise suspected. The methods are described in Chapter 25.

E. Sputum: special studies.

- During epidemics, virus identification should be attempted.
- In a normal young adult, attempts at isolation of viruses and *M. pneumoniae* are reasonable. Viruses other than influenza are rare in normal adults.
- The compromised host usually should undergo mycobacterial, fungal, and viral studies.

4. *Legionella* studies should be performed on appropriate specimens when this is a possible diagnosis [3]. (See section VI under Specific Therapy and Special Considerations.)
 5. Fungal smears and cultures should be sent when patients from endemic regions present with compatible illness.
- F. If sputum is not available** and the patient is not ill enough for an invasive procedure, the clinician must use empiric antibiotics (see section B above and section IX) [2,4,6].
- VI. Invasive procedures** [20]. Fiberoptic bronchoscopy with a protected specimen brush (PSB) or bronchoalveolar lavage (BAL) is most widely used. **Their diagnostic value is significantly reduced by prior antibiotic therapy.** Percutaneous thin-needle lung aspiration is best reserved for accessible enigmatic lesions [21]. Open lung biopsy usually is considered only after other methods have proven nondiagnostic or in immunocompromised hosts.
- A. Indications. Most patients with CAP are successfully managed without an invasive procedure** [2,4,6]. The value of these tests for nosocomial and ventilator-associated pneumonias is unclear [12,22]. **Consider an invasive procedure if the severity of the illness or its rate of progression is significant enough to warrant the risks, and when:**
1. Adequate specimens are unobtainable using noninvasive techniques.
 2. The resulting specimens will be properly and quickly processed.
 3. There are no absolute contraindications present.
- B. Transtracheal aspiration** is used only infrequently at present and **should be performed only by experienced personnel.**
- C. Fiberoptic bronchoscopy methods.** Fiberoptic bronchoscopy has become widely available. **Oral contamination is unavoidable using fiberoptic bronchoscopy alone** without additional appropriate culture techniques.
1. **The PSB** consists of a double-sheathed tube sealed at the distal end [20]. After the bronchoscope is positioned, the whole PSB is pushed through the inner channel several centimeters beyond the bronchoscope. The inner sheath then is pushed beyond the plug, and a sterile brush is advanced through the open inner sheath, collecting 0.001 mL of secretions.
 - a. **Quantitative cultures are necessary** because contamination is inevitable. Organisms, including anaerobes, growing at $\geq 10^3$ /mL are considered significant.
 - b. **This procedure is useful in diagnosing acute nosocomial pneumonia in the mechanically ventilated patient** [23–25].
 - c. The **risks** are low and include pneumothorax, transient fever or infiltrates, and decreased oxygenation.
 2. **Bronchoalveolar lavage** [20]. BAL is performed by wedging the fiberoptic bronchoscope in a distal airway and injecting and aspirating 50 mL (mini-BAL) to 150 mL (standard BAL) of sterile normal saline through the bronchoscope. BAL samples a larger area of lung than the PSB and thus offers a theoretic advantage.
 - a. **Quantitative cultures of BAL fluid are necessary** to distinguish infecting from contaminating bacteria. Organisms, including anaerobes, growing at $\geq 10^4$ /mL are considered significant.
 - b. **Gram stain of BAL fluid sediment to detect intracellular organisms may provide a rapid indication of potential pathogens** [26]. Cytology and other stains also should be performed on samples from immunocompromised patients.
 - c. **BAL is useful in evaluating immunocompromised patients with pulmonary infiltrates, and in the diagnosis of ventilator-associated pneumonia** [24,26,27].
 - d. **Risks** include fever, infiltrates, and decreased oxygenation.
- D. Nonbronchoscopic methods** of bronchial aspiration, BAL, and PSB sampling in ventilated patients offer promise [28]. These blinded (nonvisualized) procedures are performed through an endotracheal tube without radiographic guidance, and

require quantitative cultures. Their diagnostic yield and risks are similar to those for bronchoscopic methods [28].

- VII. Other laboratory testing** depends in part on the site of care and the likely potential etiologies, and often is needed to determine the need for hospitalization (see section IX.A).
- A. Patients who are otherwise healthy and suitable for outpatient care** may be managed with no additional testing [2,4,6].
- B. Patients requiring emergency room evaluation or hospitalization** should routinely have additional tests [2,4,6].
1. **White blood cell (WBC) and differential count.** Leukocytosis or left shift is nonspecific. Leukopenia has been linked to a poor prognosis.
 2. **Abnormal renal or liver function tests** have been associated with bacterial and nonbacterial types of infection, and have implications for medication use.
 3. **Oxygen saturation. Pulse oximetry** should be performed on all patients requiring emergency room evaluation or hospitalization. **Arterial blood gas levels** should be determined on patients with severe illness or underlying obstructive lung disease [4,6].
 4. **HIV testing** may be indicated.
- C. Serologic studies** may be useful for epidemiologic purposes, to retrospectively determine an etiology, or to evaluate chronic pneumonia.
1. **Mycoplasmal pneumonia. Cold agglutinins are not specific for *Mycoplasma***, as discussed in section V.D.2 under Specific Therapy and Special Considerations. **Antibodies to *M. pneumoniae*** reach a diagnostic titer only after a delay.
 2. ***Chlamydomphila pneumoniae* and *Legionella*.** Diagnostic antibody titers develop only weeks after the patient is symptomatic. (See Specific Therapy and Special Considerations.)
 3. **Influenza.** Changes in antibody titers between acute and convalescent specimens can make a retrospective diagnosis. (See Chapters 10 and 25.)
 4. **Fungal serologic studies.** These may help to support a diagnosis of a pulmonary mycosis, especially in patients with a chronic pneumonia (see Chapter 17).
 5. **Q fever and psittacosis** are often diagnosed serologically.
- D. Antigen detection.** A positive antigen test establishes a specific etiology, but a negative test does not exclude a possible etiology. (See Chapter 25 for discussion of these techniques.)
1. **Latex agglutination test results to detect bacterial antigens in urine and serum are infrequently positive in patients with pneumonia.** Detection of antigen in pleural fluid may be helpful in patients pretreated with antibiotics. A commercial immunochromatographic test for pneumococcal antigen in urine may be helpful as an adjunct to smears and cultures for rapid diagnosis, but there is limited experience with this assay at present [2,29]. The Quellung reaction also is useful for the rapid diagnosis of *S. pneumoniae*, but the required expertise and reagents are not generally available [2].
 2. ***Legionella* urine antigen test** is useful for the rapid diagnosis of *Legionella pneumophila* serogroup I infection.
 3. **Influenza, RSV, and other respiratory viruses** may be rapidly diagnosed with commercially available antigen assays [2].
 4. **Serum cryptococcal antigen** is helpful in compromised hosts, including HIV infection (see Chapter 18).
- E. Nucleic acid detection.** Polymerase chain reaction (PCR) and probe techniques offer promise for rapidly identifying *Mycoplasma*, *Chlamydomphila* (*Chlamydia*), *Legionella*, tuberculosis, hantavirus, and some agents of biologic warfare. However, their utility for routine use in clinical laboratories for the rapid diagnosis of pneumonia is untested [30].
- F. Tuberculosis skin test.** The tuberculosis skin test is **not particularly helpful in a patient with CAP.** A positive test result does not mean that the pneumonia

is tuberculous, and a negative test result does not rule out tuberculosis. (See section III under Tuberculosis: Basic Concepts for additional discussion of skin testing.)

VIII. Colonization versus infection. *Colonization refers to the presence of organisms that are not causing disease.* The clinician must determine which organisms growing from a sputum or tracheal aspirate culture are colonizers so as to avoid unnecessary antibiotic therapy.

A. Clinical settings in which respiratory colonization must be distinguished from infection

1. Elderly patients have an increased incidence of colonization by *S. aureus* and gram-negative organisms, making it difficult to ascertain the true cause of a pneumonia [9].

2. Debilitated hospitalized patients.

a. Fever not due to pneumonia is frequent in patients who are hospitalized for another reason (e.g., surgery or myocardial infarction) or who require intensive care [12].

b. The chest radiograph often is abnormal but not because of a pneumonia. Atelectasis, congestive heart failure (CHF), and pulmonary infarction may mimic pneumonia.

3. After antibiotics have been given. Sputum cultures from febrile patients being treated with antibiotics frequently grow gram-negative organisms or staphylococci. In this circumstance **culture data alone should not dictate therapy in the absence of supportive clinical findings.**

B. Key points to help differentiate colonization from superinfection

1. Findings that support sputum colonization are a clinical course that is stable or improving, and an absence of marked sputum production [31]. If the recovering individual develops fever or leukocytosis and yet has stable respiratory signs with no increase in sputum, there will usually be another explanation such as phlebitis, line infection, candidemia, urinary tract infection, wound infection, *Clostridium difficile*, drug fever, or myocardial infarction.

2. Findings that support respiratory superinfection are fever, leukocytosis, and worsened respiratory status [31].

a. Respiratory changes are the key findings.

(1) Ventilatory status. Even minor additional pulmonary infection can precipitate respiratory deterioration [31], and when absent, superinfection is unlikely. However, respiratory deterioration also may result from other causes such as distant infection, CHF, or embolism.

(2) Production of nonpurulent sputum. If sputum is nonpurulent **without many polymorphonuclear leukocytes**, bacterial superinfection is unlikely unless the patient is leukopenic [31].

b. A chest radiograph that reveals a new infiltrate in the presence of worsened respiratory status and fever supports the diagnosis of pulmonary superinfection. However, **in practice the radiograph is not always helpful.** New infiltrates may not be noticeable because of diffuse lung injury, may lag behind the onset of superinfection, or may have a noninfectious cause.

3. Specific microbiologic diagnosis. When superinfection is suspected, blood cultures and sputum smears and cultures should be obtained. If not contraindicated, **an invasive procedure may help** differentiate between colonization and infection (see section VI).

IX. General concepts of therapy. Treatment of pneumonia usually is started prior to defining a specific etiology, and the clinician must consider several key factors when planning the initial management. The reader is referred to the latest versions of several published guidelines for adults with CAP for further information [2,4,6,32]. These guidelines exclude immunoincompetent patients, including those with HIV.

A. When to hospitalize. The Pneumonia Patient Outcomes Research Team (PORT) study defined a prediction rule for mortality in CAP [33]. This and other studies identified **certain factors associated with a poor outcome from CAP** (Table 11.2). **When present, particularly if multiple factors are present**

Table 11.2. Risk Factors for a Poor Outcome from Pneumonia

Age ≥ 65 years
Serious underlying conditions
Chronic lung, heart, liver, or renal disease
Malignancy
Diabetes mellitus
Malnutrition
Cerebrovascular disease, or recurrent aspiration
Alcoholism
Cystic fibrosis, or bronchiectasis
Immunodeficiency (including splenectomy)
Hospitalization for pneumonia within 1 year
Physical findings
Tachypnea ≥ 30 breaths/min
Hypotension
Fever $\geq 40^\circ\text{C}$ (104°F)
Hypothermia $< 35^\circ\text{C}$ (95°F)
Distant sites of infection
Altered level of consciousness
Laboratory findings
Leukocytosis $> 30,000$ cells/mm ³
Leukopenia $< 4,000$ cells/mm ³
Neutropenia $< 1,000$ cells/mm ³
Hypoxemia (room air PaO ₂ < 60 mm Hg)
Hypercapnia (room air PaCO ₂ > 50 mm Hg)
Anemia
Renal insufficiency
Complications
Mechanical ventilation required
Adult respiratory distress syndrome
Sepsis syndrome
Radiographic findings
Two or more lobes involved
Significant pleural effusion
Cavitation
Rapid spread

These factors have been associated with either death or a complicated course, particularly if multiple ones are present simultaneously [6].

together, hospitalization should be strongly considered [6]. However, **prediction rules should not override the judgment of the clinician about the need for hospitalization** [2,4,6]. Other considerations include emesis, risks for complications (increased by splenectomy, neuromuscular disorders, and immunosuppression), ability to follow instructions, home support, substance abuse, likelihood of follow-up, and patient preference. Furthermore, we strongly consider hospitalization for the clinical diagnosis of influenza-related pneumonia because of the risk for rapid deterioration.

B. Antibiotic principles. Antibiotics should be started as soon as possible [2,6]. Initial therapy is based on the clinical presentation, site of care, certain patient risk factors, and any organisms seen on Gram stains of sputum and pleural fluid.

1. Narrow-spectrum versus broad-spectrum initial coverage. Antibiotics with narrow coverage are indicated for patients who are only mildly ill and at least risk. Broader empiric coverage may be necessary for severely ill patients, those at greatest risk for complications (see Table 9.2), or those with

nondiagnostic smears and infection of uncertain etiology. **Antibiotics should be modified based on cultures, susceptibility data,** other diagnostic studies, and the initial response.

a. If the initial evaluation suggests pneumococcal pneumonia the possibility of drug-resistant *S. pneumoniae* (DRSP) must be kept in mind. Unless there is a high level of penicillin resistance, mild DRSP pneumonia usually responds to appropriate β -lactam therapy [32]. However, a macrolide or antipneumococcal fluoroquinolone should be added for moderate or severe infections. Gatifloxacin, moxifloxacin, and levofloxacin are the fluoroquinolones considered to have enhanced pneumococcal activity [32]. However, **treatment failures associated with levofloxacin resistance have been reported** [34].

(1) **Outpatients** may be given an oral β -lactam with reliable antipneumococcal activity such as amoxicillin, amoxicillin-clavulanate, cefuroxime, or cefpodoxime.

(2) **Inpatients not critically ill** may be given parenteral ceftriaxone or cefotaxime. Cefuroxime and ampicillin-sulbactam also may be used but are less active than the third-generation cephalosporins against DRSP [32].

(3) **Critically ill inpatients** should be given parenteral ceftriaxone or cefotaxime because of their superior activity against DRSP, plus a macrolide or an antipneumococcal fluoroquinolone. This is because **combination therapy may be superior to a β -lactam alone for severe pneumococcal pneumonia** [35]. Vancomycin should not be used routinely except in patients with suspected meningitis [32].

b. If gram-negative pneumonia is suggested, then broad-spectrum coverage for resistant organisms such as *Pseudomonas aeruginosa* should be given (e.g., piperacillin-tazobactam or ceftazidime).

c. If the clinical presentation is highly suggestive of mycoplasmal pneumonia, a macrolide (e.g., erythromycin) or tetracycline is sufficient.

2. Site-of-care and patient risk factors

a. Outpatients. A macrolide, doxycycline, or an antipneumococcal fluoroquinolone are appropriate because they cover the most commonly identified pathogens: pneumococci, *M. pneumoniae*, and *C. pneumoniae*. Clarithromycin or azithromycin are recommended over erythromycin if *H. influenzae* is suspected [2]. For patients under 50 years of age without comorbidities, a macrolide or doxycycline is preferred. For patients over 50 or those with comorbidities, an antipneumococcal fluoroquinolone is suggested. Because of concerns about the development of resistance, the fluoroquinolones are best reserved for this latter group. A combination of a reliable oral antipneumococcal β -lactam (amoxicillin, amoxicillin-clavulanate, cefuroxime, or cefpodoxime) plus a macrolide or doxycycline is an alternative [6].

b. Inpatients receiving care on a routine ward. A third-generation cephalosporin (cefotaxime or ceftriaxone) or a β -lactam/ β -lactamase inhibitor (ampicillin-sulbactam or piperacillin-tazobactam) plus either an antipneumococcal fluoroquinolone or a macrolide are recommended for this group [2,6]. An antipneumococcal fluoroquinolone alone is an alternative. Patients without risk factors for DRSP or enteric gram-negative bacilli may be given intravenous (i.v.) followed by oral azithromycin as monotherapy [36,37]. However, macrolide resistance is increasing among pneumococci, making this regimen less attractive [32].

c. Inpatients requiring intensive care. Intravenous therapy with an extended-spectrum cephalosporin (cefotaxime or ceftriaxone) or β -lactam/ β -lactamase inhibitor (ampicillin-sulbactam or piperacillin-tazobactam) plus a macrolide or an antipneumococcal fluoroquinolone is usually sufficient [2,6]. Patients with risk factors for pseudomonas infection (structural lung diseases including bronchiectasis and cystic fibrosis, >10 mg/day of prednisone, broad-spectrum antibiotics for at least 1 week during the prior month, and malnutrition) should be given a fluoroquinolone plus either piperacillin,

piperacillin-tazobactam, a carbapenem, or cefepime. When piperacillin-tazobactam is chosen, the dose must be increased to assure adequate antipseudomonal activity. (Aspiration is discussed in section II and *Legionella* in section VI under Specific Therapy and Special Considerations.)

3. Reevaluating initial regimens

- a. **Response to therapy** varies with the infecting organisms. In addition, host factors such as increasing age, underlying illnesses, extent of lung involvement, bacteremia and immunosuppression lengthen this process [2,6]. Many patients remain ill or even continue to worsen within the first 48 to 72 hours despite appropriate therapy, but once improvement begins, it should progress without complications [6]. **The expected responses** in an otherwise healthy adult with CAP are listed below.
 - (1) **Subjective feelings of improvement** usually occur within 1 to 3 days [2].
 - (2) **Fever** usually responds within 2 to 4 days in nonbacteremic pneumococcal pneumonia. Patients with *Mycoplasma* may become afebrile within 1 to 2 days, whereas patients with *Legionella* may take 5 days or longer to become afebrile [2].
 - (3) **Abnormal chest examination findings** may persist for longer than a week in up to 40% of patients [6].
 - (4) **Leukocytosis** usually has begun to resolve within the first 3 to 4 days.
 - (5) **Bacteremia** should no longer be present after 24 to 48 hours of appropriate antibiotics [2].
 - (6) **Radiographic improvement takes longer to occur than does clinical improvement**, and radiographs may initially progress even though clinical improvement has begun [2,6]. The role for follow-up radiographs is discussed in section IV.G under Clinical Approach to Community-Acquired Pneumonia.
- b. **Known etiology.** Isolates from blood, pleural fluid, or lower respiratory tract secretions are presumed etiologic agents. **Once a specific cause of pneumonia has been identified, therapy should be adjusted to the most effective narrow-spectrum regimen with the least toxicity and cost** [2,4,6]. This is true even for patients who initially responded to an empiric broad-spectrum regimen [38].
- c. **Unknown etiology.** Initial diagnostic studies are negative in up to 50% of cases [6].
 - (1) **If patients have responded to empiric therapy, it may be continued.** Pneumococci and several other treatable causes (*Mycoplasma*, *Chlamydophila*, and *Legionella*) are difficult to prove with standard sputum studies.
 - (2) **If gram-negative bacteria were not isolated from well-collected sputum, the diagnosis of endobronchial gram-negative pneumonia essentially has been excluded.** In these patients it is safe to stop specific gram-negative therapy after only a few days [38]. The exceptions are neutropenic patients and those with embolic pneumonia. In embolic pneumonia the blood cultures are often positive even when the sputum is negative.
- d. **Patients not responding to initial therapy** should be further evaluated for the following circumstances [2,4,6]:
 - (1) **The diagnosis of pneumonia was incorrect** and another illness is present, such as heart failure, atelectasis, adult respiratory distress syndrome (ARDS), or infarction.
 - (2) **The diagnosis of pneumonia was correct, but the chosen antibiotics failed.** This could be from **inadequate dosing** caused by patient nonadherence, poor absorption, vomiting, or drug interactions. In addition, there may be a **resistant pathogen**, such as DRSP, methicillin-resistant *S. aureus* (MRSA), many gram-negative bacilli, *Nocardia*, *Mycobacterium* species, and viral or fungal pathogens that do not respond to antibiotics.

- (3) **Thoracic complications** may delay the clinical response. These include lung necrosis or abscess formation, empyema, and airway obstruction from tumor, secretions, or a foreign body. Suppurative pericarditis is an uncommon complication.
 - (4) **Metastatic infections** from the lung include meningitis, septic arthritis, peritonitis, endocarditis, and solid organ abscess.
 - (5) **A new nosocomial infection** may cause deterioration. Examples are urinary infection, i.v. catheter-related sepsis, and *C. difficile* colitis.
4. **Switching from i.v. to oral therapy**, usually by day 3, is endorsed by the published guidelines [2,4,6]. Eligible patients must be improved, stable, taking oral agents, and have normal gastrointestinal function. The American Thoracic Society (ATS) recommends that four specific criteria be met: improved cough and dyspnea, decreasing WBC count, a functioning gastrointestinal tract, and no fever; however, patients do not have to be afebrile if they meet the other criteria [6].

Antibiotics chosen for oral therapy should achieve levels adequate for the suspected or proven pathogens, and when possible are based on susceptibility test results. **If the etiology is unidentified, providing similar oral coverage is easiest when a single agent or a narrow-spectrum i.v. regimen was chosen at the outset.** Otherwise, an antipneumococcal fluoroquinolone or a combination of oral agents usually is required. **Patients may be discharged the same day that oral therapy is instituted** [6]. Follow-up is used to reinforce adherence, identify side effects or intolerance, and to assure continued clinical improvement.

5. **Duration of therapy. There is a paucity of data to guide the optimal duration of therapy for patients without an identified etiology**, and the published guidelines do not specifically address this issue [2,4,6]. Suggestions range from 7 to 14 days for CAP based on the clinical response [4], 3 afebrile days [2] to 7 to 10 days [6] for pneumococcal pneumonia, and 10 to 14 days [6] to a minimum of 14 days [2] for other bacterial pneumonias, *M. pneumoniae*, *C. pneumoniae*, or Legionnaires disease in immunocompetent hosts [2].

SPECIFIC THERAPY AND SPECIAL CONSIDERATIONS

I. **Pneumococcal pneumonia** is the most common bacterial pneumonia in adults. Transient bacteremia occurs in 20% to 30% of patients.

A. **Risk groups** [39]. Cigarette smoking is a major risk factor for invasive disease in immunocompetent adults [40]. Immunosuppression from any cause is important, including acquired immunodeficiency syndrome (AIDS) [41], asplenia, and sickle cell disease. The elderly (particularly institutionalized), children under 2 years of age (particularly in day care), and patients with alcoholism, uncontrolled diabetes, and chronic lung, heart, or kidney diseases are at increased risk. Influenza may predispose to pneumococcal pneumonia (see Chapter 10).

B. **Clinical manifestations.** Pneumococcal pneumonia is the prototype of acute lobar pneumonia. Although there may be a preceding upper respiratory infection, **“classic” pneumococcal pneumonia** is usually so abrupt in onset that patients recall the exact time their pneumonia began. They initially experience chills, rigor, fever, dyspnea, dry cough, and pleuritic chest pain. There usually is a single rigor unless intermittent antipyretics are taken. Cough becomes productive of purulent sputum within the first 6 to 24 hours; a pinkish or rusty coloration indicates alveolar bleeding and is common. Examination reveals an acutely ill patient in obvious respiratory distress, with splinting of the involved chest and signs of consolidation with or without a friction rub. Radiographs show alveolar filling with air bronchograms in the affected lobes, unless there is significant underlying emphysema. Subsegmental infiltrates are less common.

This classic presentation is not the most common. A subacute presentation may occur more frequently [42], and in many cases it is difficult to clinically distinguish pneumococcal pneumonia from “atypical” pneumonia. Increased sputum production, pleural involvement, and leukocytosis favor a pneumococcal etiology [43].

1. **Complications** include shock, respiratory failure, empyema, meningitis, septic arthritis, purulent pericarditis, and endocarditis.
2. **The differential diagnosis** includes other bacteria, including *S. aureus*, *S. pyogenes*, *H. influenzae*, *K. pneumoniae*, and other gram-negative bacilli. Gram stains of sputum and pleural fluid help to rapidly identify the most likely organism.

C. Prognosis. Pneumococcal pneumonia continues to be associated with a significant rate of mortality [44]. In their study of bacteremic pneumonia, Austrian and Gold [45] found that overall mortality exceeded 15%. Those with preexisting cardiac disease, carcinoma, cirrhosis, and hematologic malignancies had a mortality rate of approximately 30%, compared with 7% among those without these comorbidities. Risk also was increased in patients over 50 years of age and those with multilobe involvement. Feikin et al. [44] found that β -lactam resistance did not increase mortality unless the organism had a penicillin minimum inhibitory concentration (MIC) of 4.0 $\mu\text{g}/\text{mL}$ or higher.

D. Antibiotic therapy. Antibiotic selection is critical because penicillin-resistant pneumococci, due to altered penicillin-binding proteins, are prevalent and there is evidence that combination therapy is superior to a β -lactam alone [35,46]. A survey of United States strains in 1999 to 2000 found intermediate penicillin resistance (a penicillin MIC of 0.12–1.0 $\mu\text{g}/\text{mL}$) in 12.7% and high-level resistance (MIC = 2.0 $\mu\text{g}/\text{mL}$) in 21.5% [47]. High-level resistance is associated with resistance to cephalosporins, chloramphenicol, trimethoprim-sulfamethoxazole (TMP-SMX), erythromycin, and clindamycin [46,47]. **Infections with penicillin-resistant pneumococci are associated with** the extremes of age, residence in or exposure to an institutional setting, including nursing homes and day care, close exposure to an infected person, recent antimicrobial therapy, comorbidities including immunosuppression, and alcoholism [6,48]. (See **Chapter 27.**)

1. **Empiric treatment** recommendations are summarized in section **IX.B.1.a.** under Clinical Approach to Community-Acquired Pneumonia, and should not routinely include vancomycin [32].
2. **Subsequent therapy should be based on susceptibility tests.**
 - a. **For penicillin-susceptible strains**, 2.4 million units per day of i.v. penicillin G is suggested; cefazolin (500 mg every 12 hours) or ceftriaxone once daily are alternatives for patients with a delayed penicillin reaction.
 - b. **For strains with a penicillin MIC of less than 4 $\mu\text{g}/\text{mL}$** , a penicillin or cephalosporin can be successful if the dose is raised to provide higher levels of drug [32].
 - c. **Infections caused by *S. pneumoniae* with an MIC of 4 $\mu\text{g}/\text{mL}$ or higher** can be treated with vancomycin, gatifloxacin, or moxifloxacin. There is limited outcome data using a fluoroquinolone for highly resistant infections.
3. **Patients with significant penicillin allergy** should be treated with vancomycin, gatifloxacin, or moxifloxacin. Alternatives with limited clinical experience include linezolid and quinupristin/dalfopristin [2].
4. **Meningeal infections** caused by pneumococci with any degree of penicillin resistance should be treated with vancomycin.
5. **Resistance to fluoroquinolones has been found** at a low rate in the United States, but the isolates also often are resistant to penicillin and other drugs [47,49,50]. Fluoroquinolone resistance seems to be increasing in Canada and may increase in the United States with increasing prescriptions for fluoroquinolones [49]. Resistance is based on mutations in DNA gyrase or topoisomerase subunits, or reduced drug penetration [49,50]. Ofloxacin, levofloxacin, and ciprofloxacin are least active *in vitro* against *S. pneumoniae*, whereas gatifloxacin and moxifloxacin are more active [47]. Because levofloxacin resistance has been associated with treatment failures and death [34], gatifloxacin or moxifloxacin is preferred.
6. For therapy of meningitis, see Chapter 6.

E. Vaccines

1. Rationale for pneumococcal vaccination

- a. **Prevention of disease** is important because of its frequent occurrence, associated mortality, and increasing antibiotic resistance [51,52].
- b. *S. pneumoniae* contains an **antiphagocytic capsule** of highly polymerized polysaccharides, and there are at least 90 distinct antigenic serotypes. Specific humoral immunity that leads to opsonophagocytosis is an important host defense against the pneumococcus. This is the basis for the current vaccines, which **stimulate the production of type-specific antibodies** against the capsule.

2. Vaccine composition. Two types of vaccine are currently available.

- a. The two **purified polysaccharide vaccines** contain the same 23 polysaccharide antigens (25 μ g each). These 23 serotypes have been shown to cause approximately 87% of bacteremic pneumococcal pneumonia in adults, virtually 100% of childhood bacteremia and meningitis, and 85% of acute otitis media [53]. The polysaccharide antigens are not immunogenic in children age 2 years and younger, and some serotypes are not reliably immunogenic until age 5 years [54]. In addition, the polysaccharide vaccine has not reduced nasopharyngeal carriage of the pneumococcus [52].
- b. The 7-valent **protein conjugate vaccine** was licensed in February 2000. It includes serotypes that, together with cross-reacting serotypes, accounted for 86% of bacteremia, 83% of meningitis, and 65% of acute otitis media in children age 5 years and younger [54]. The protein conjugate vaccine can be administered to infants as young as 6 weeks of age [54]. It reduces mucosal carriage of pneumococcal serotypes contained in the vaccine [51,52,54].
- c. **Both types of vaccine include important serotypes associated with antibiotic resistance**, although resistance is increasing among strains not contained in the protein conjugate vaccine [51,52].

3. Antibody response

- a. **Purified polysaccharide vaccines.** Because responsiveness to purified polysaccharide antigens is T-cell independent and under genetic control, it is not associated with long-term memory cells, children age 2 years and younger do not respond, and some healthy adults do not respond even after repeat immunization [39]. **Antibody responses comparable with most healthy young adults**, and with presumed partial protection for disease, have been demonstrated **in patients with asplenia caused by splenectomy or sickle cell disease** [39].

Lower antibody responses occur in the elderly, and patients with nephrotic syndrome or chronic renal failure, COPD, and insulin-dependent diabetes [39]. In general, **patients who are immunocompromised from any cause have a poor or absent response**; this includes patients with leukemia, lymphoma, multiple myeloma, and transplantation [39]. If patients with **Hodgkin disease** are **vaccinated at least 2 weeks before splenectomy, radiation therapy, or chemotherapy**, they manifest a better antibody response, although it declines during subsequent chemotherapy [39]. **Response in HIV-infected patients relates to the degree of immunosuppression**; those with AIDS or CD4⁺ counts of less than 500 cells/ μ L have reduced antibody responses [39] that are improved by at least 1 month of zidovudine. **Thus, persons with HIV should be vaccinated as soon as possible in the natural course of their infection.** Vaccination together with antiretroviral therapy may improve responsiveness to the purified polysaccharide vaccine [52].

- b. **Protein conjugate vaccine.** This vaccine is more immunogenic in inducing type-specific antibody responses in healthy young children, and results in an anamnestic response to subsequent purified polysaccharide vaccine [52,54]. Similar good responses occur in children with sickle cell disease and HIV infection, and in Alaska Native and American Indian children [54].

4. Effectiveness

- a. **Purified polysaccharide vaccines.** Their overall effectiveness in preventing invasive pneumococcal disease in immunocompetent persons ranges from 56% to 81% [39]. Protection varies markedly within certain populations, and a protective effect in immunocompromised patients was difficult to measure [55]. Efficacy is highest in immunocompetent adults under 55 years of age (93% protective), and declines with age at vaccination and time since vaccination [55]. **Vaccine efficacy averages 75% in immunocompetent patients 65 years and older, and is cost effective [39]. Efficacy has ranged from 65% to 84% among patients with moderate risk from underlying medical conditions such as diabetes, CHF, COPD, and asplenia [39,52].**
- b. **Protein conjugate vaccine.** This vaccine was 97.4% effective in preventing invasive disease from vaccine serotypes in a prelicensing trial [54]. A large Finnish trial in children found that vaccine reduced all pneumococcal otitis media episodes by 34%, serotype-specific pneumococcal episodes by 57%, and cross-reactive serotype pneumococcal episodes by 51% [56]. However, episodes from other serotypes of pneumococci increased by 33% [56].

5. Side effects

- a. **Purified polysaccharide vaccines.** Their safety has been well established [39]. **Mild local reactions** of pain, erythema, or discomfort occur in approximately 50% of recipients and last less than 48 hours. **Systemic reactions are rare** and include transient chills, fever to 40°C (104°F), and weakness. When current guidelines are followed, reactions to repeat vaccination are similar in type and frequency to initial vaccination [39,54]. There is no increase in reactions when purified polysaccharide vaccine is given after protein conjugate vaccine [54].
- b. **Protein conjugate vaccine [54].** In prelicensing evaluations, 10% to 13% of infants given a full four-injection vaccine series had erythema, 10% to 12% had induration, and 15% to 23% had local tenderness. Only erythema increased in size with subsequent doses. Fever of greater than 100.4°F occurred in 15% to 24%, and fever of greater than 102.2°F ranged from 0.9% after the first dose to 2.5% after the second dose. The rate of seizures within the first 72 hours was 1 per 7,000 doses, well below the rate previously seen with whole-cell pertussis vaccine. **Older children** generally had higher rates of local reactions, fussiness was their most common systemic effect, and fever of greater than 100.4°F after one dose occurred in 7% to 37%. Experience with the safety of giving protein conjugate vaccine after purified polysaccharide vaccine is limited.

6. Precautions and contraindications

- a. **Purified polysaccharide vaccines.** Their safety has not been adequately studied during the first trimester of pregnancy, but no adverse outcomes have been reported [39]. Therefore, vaccine should be given to high-risk women prior to pregnancy. They are contraindicated in patients with a prior hypersensitivity reaction to the vaccine or one of its components.
- b. **Protein conjugate vaccine.** It is best to delay vaccine until resolution of moderate or severe illness, although it may be given with minor illness [54]. Vaccine is contraindicated in patients with a prior hypersensitivity reaction to the vaccine or one of its components. Simultaneous administration of the protein conjugate vaccine with a purified polysaccharide vaccine is not recommended [54]. The current formulation (Prevnar, Wyeth Lederle Vaccines) should be used with caution in patients with latex sensitivity because its packaging contains natural rubber. There is no published information about the use of this vaccine in pregnancy.

7. Indications for use.

Recipients should be informed that the vaccine does not entirely eliminate the risk of pneumococcal pneumonia.

- a. **Purified polysaccharide vaccines** are approved for use in adults and children at least 2 years of age at risk for invasive pneumococcal disease and who

are capable of responding [39,52]. Note that the protein conjugate vaccine should be used initially in children up to age 5 years (see section **I.E.7.b**).

- (1) **Persons 65 years of age or older.** Everyone in this group should be vaccinated, including those with an unknown vaccination status and those who received vaccine before reaching 65 years of age but who have not been revaccinated in the prior 5 years.
 - (2) **Splenectomized patients,** including autosplenectomy from sickle cell anemia. Vaccine should be given at least 2 weeks prior to an elective splenectomy.
 - (3) **Patients with alcoholism, COPD, CHF, cyanotic congenital heart disease, cirrhosis, diabetes, nephrotic syndrome, or renal failure.**
 - (4) **HIV-infected adults and adolescents.**
 - (5) **Immunocompromised patients,** including those with leukemia, lymphoma, Hodgkin disease, multiple myeloma, generalized malignancy, solid organ or bone marrow transplants, immunosuppressive chemotherapy, and long-term steroid use. Both the physician and the patient must recognize that response to the vaccine may be limited. **Patients with Hodgkin disease and others about to undergo immunosuppression should be vaccinated at least 2 weeks before immunosuppressive therapy** (see section **I.E.3.a**).
 - (6) **In special settings or populations with a known increased risk, such as residents of nursing homes or long-term care facilities, Alaska Natives and American Indians, and those with CSF leak.**
 - (7) **Children 24 to 59 months of age previously given the protein conjugate vaccine and who are in one of the above high-risk groups** [54]. The purified polysaccharide vaccine should be given at least 2 months after the last dose of the protein conjugate vaccine.
- b. Protein conjugate vaccine is indicated for infants and children between 2 and 59 months of age** [54]. Note that the protein conjugate vaccine should not replace purified polysaccharide vaccine for adults and children age 5 years and older.
- (1) **All children up to 23 months of age.**
 - (2) **High-risk children 24 to 59 months of age.** This includes those with sickle cell hemoglobinopathies, anatomic or functional asplenia, HIV infection, congenital immunodeficiencies, renal failure, nephrotic syndrome, chronic cardiac diseases, chronic lung diseases, CSF leaks, diabetes, and immunocompromising conditions such as leukemia, lymphoma, Hodgkin disease, chemotherapy, radiation therapy, long-term steroid use, and solid organ transplants.
 - (3) **Other children 24 to 59 months of age who should be considered for vaccination** include all those 24 to 35 months of age, Alaska Native or American Indians, African Americans, and those who attend day-care centers.
 - (4) **High-risk children 24 to 59 months of age previously given a purified polysaccharide vaccine.** The protein conjugate vaccine should be started at least 2 months after the purified polysaccharide vaccine.
- 8. Dosage [39,54]**
- a. Purified polysaccharide vaccines.** The usual dose is a single 0.5-mL intramuscular (i.m.) or subcutaneous injection given at any time during the year. **The pneumococcal vaccine may be given simultaneously with influenza vaccination** at separate sites.
 - b. Protein conjugate vaccine.** Each dose is 0.5 mL administered i.m., given in schedule with other recommended vaccines. **Children who begin vaccination up to 6 months of age** are given a primary series of three doses at least 1 to 2 months apart, followed by an additional dose at 12 to 15 months of age and at least 2 months after the primary series. **Children who begin vaccination at 7 to 11 months of age** are given a primary series of two doses at least 1 to 2 months apart, followed by an additional dose at 12

to 15 months of age and at least 2 months after the primary series. **Children who begin vaccination at 12 to 23 months of age** are given only a primary series of two doses at least 2 months apart. **High-risk children who begin vaccination at 24 to 59 months of age** are given only a primary series of two doses at least 2 months apart. **Healthy children who begin vaccination at 24 to 59 months of age** are given only a single dose.

9. **Revaccination** currently is recommended only with the purified polysaccharide vaccines [39,54]. Candidates are highest risk patients and those with a poor antibody response (asplenia, HIV infection, leukemia, lymphoma, Hodgkin disease, multiple myeloma, malignancy, nephrotic syndrome, renal failure, organ or bone marrow transplants, and immunosuppression from chemotherapy or corticosteroids). All those 65 years of age and older who received the vaccine at least 5 years previously and were under 65 years old when initially vaccinated also should be revaccinated. The interval between doses should be at least 5 years, except in high-risk children age 10 years and under, who should be revaccinated 3 years after a prior dose of purified polysaccharide vaccine. Revaccination is contraindicated if there was a severe reaction to the initial dose.

II. Aspiration pneumonia [15] refers to pneumonia caused by macroaspiration. Patients with obtundation or a defective cough-epiglottic reflex are at highest risk.

A. Aspiration pneumonitis develops after sterile gastric acid aspiration, resulting in a chemical injury to the lung.

1. **No antibiotic therapy is usually required.** Institution of pulmonary drainage and careful observation are indicated. Early therapy does not prevent infection but instead selects for resistant organisms.
2. **For patients at risk for gastric colonization with pathogenic bacteria (those with small-bowel obstruction, antacid or antisecretory use, gastroparesis, and gastric tube feedings),** antibiotic therapy may be considered after specimens for Gram stain and culture are obtained. An invasive diagnostic procedure may help.

B. Community-acquired aspiration pneumonias account for 5% to 15% of CAP. The typical patient risk factors are discussed in section I.G.2 under Clinical Approach to Community-Acquired Pneumonia. Oral anaerobes, penicillin-sensitive pneumococci [57], and many other aerobic organisms are involved. **Clindamycin is a traditional agent for anaerobic aspiration pneumonia.** If used, at least 10 to 15 million units/day of i.v. aqueous penicillin G should be given because of increasing penicillin resistance among non-fragilis *Bacteroides* species, fusobacteria, other oral anaerobes, and the pneumococci [32,58–62]. However, the optimal dosage of penicillin for aspiration pneumonia is unknown. Although Marik [15] recommends levofloxacin or ceftriaxone, this is controversial [63]. Gatifloxacin and moxifloxacin, but not levofloxacin, have anaerobic activity and should be adequate for these infections, but there is little clinical experience with their use for this purpose. Seriously ill patients should be given a broad-spectrum regimen that includes coverage for anaerobes.

C. Hospital-acquired aspiration pneumonia. Hospitalized patients are at risk for gram-negative pneumonia. **Gastric and pharyngeal colonization by gram-negative bacilli and *S. aureus* may be important in the pathogenesis** [11,64]. Continuous gastric feedings or prophylaxis for stress ulcers with antacids or histamine (H_2) blockers are risk factors by overcoming the normal gastric acid barrier permitting bacterial growth in the stomach. Stress-ulcer prophylaxis with sucralfate, as compared with agents that raise gastric pH, has lowered the incidence of nosocomial pneumonia in some but not all studies [65,66]. Initial empiric therapy for patients hospitalized longer than 4 days or with severe illness should include an antipseudomonal β -lactam (e.g., piperacillin-tazobactam, cefepime, or imipenem) plus either an aminoglycoside or a fluoroquinolone to cover enteric gram-negative bacilli and pseudomonas [11,67]. Anaerobic coverage should be included for any patient with severe gum or dental disease, foul sputum, necrotizing pneumonia, or lung abscess [15]. If an antipseudomonal drug without useful anaerobic activity (ceftazidime, cefepime, and aztreonam) is chosen, then clindamycin or

- metronidazole should be added. See section **IX** for further discussion of nosocomial pneumonias.
- III. *H. influenzae*** causes bronchitis in patients with chronic lung disease (see Chapter 8). Primary pneumonia usually occurs in the elderly, patients with chronic lung diseases, and in HIV infection. Rapidly fatal pneumonia in younger adults with normal immune systems and ventilator-associated pneumonia also have been described [68,69]. In children under 5 years of age, the incidence of invasive disease has dramatically decreased since the introduction of the conjugated *H. influenzae* type b vaccines. However, in developing countries *H. influenzae* type b is still an important problem [70].
- A. Diagnosis.** A positive blood culture for *H. influenzae* confirms the diagnosis. In addition to type b, other encapsulated non-type b and nontypable strains occur and may be complicated by bacteremia [71]. Thus, latex agglutination for type b antigen in serum and urine is insensitive.
- B. Therapy.** Beta-lactamase production accounts for the frequent occurrence of ampicillin resistance.
- 1. Unknown ampicillin susceptibility or known ampicillin resistance.** If a well-obtained sputum shows pleomorphic gram-negative rods on Gram stain, ceftriaxone or cefotaxime should be used because they are active against β -lactamase-positive strains. Therapy can be modified when cultures become available.
 - 2. Known ampicillin-susceptible strains.** If the isolate is β -lactamase negative, penicillin or ampicillin is satisfactory. Most authorities recommend ampicillin, 1 to 2 g i.v. every 4 hours in adults, because of clinical experience. Therapy usually is continued for 10 to 14 days, and may be completed with oral amoxicillin. Cefuroxime, ceftriaxone, and cefotaxime also are very active. Fluoroquinolones, clarithromycin, azithromycin, and TMP-SMX are alternatives for the penicillin-allergic patient. (See further discussion in Chapter 27.)
- C. Prognosis.** In bacteremia, mortality may approach 36% in older adults [71]. The mother usually survives infection during pregnancy, but fetal loss is common [71].
- IV. Gram-negative pneumonias.** Most are hospital acquired, although community-acquired gram-negative pneumonias occur.
- A. Setting and etiology.** Important etiologies include the Enterobacteriaceae (*Klebsiella*, *Enterobacter*, and *Serratia*), *P. aeruginosa*, and other *Pseudomonas* species, and less common pathogens such as *Acinetobacter* species. Although uncommon overall, *K. pneumoniae* is the most commonly identified community-acquired gram-negative pneumonia [72].
- 1. Community-acquired** gram-negative pneumonias occur in the elderly from nursing homes, and patients with underlying lung disease, alcoholism, or chronic debilitating disease.
 - 2. Hospital-acquired** gram-negative pneumonia usually occurs with mechanical ventilation or aspiration, and in compromised hosts.
- B. Diagnosis.** Diagnosis can be difficult, and the clinician must distinguish colonization from true infection. (See section **VIII** under Clinical Approach to Community-Acquired Pneumonia.)
- C. Therapy.** Most authorities use two agents known to be synergistic *in vitro*, although definitive studies are lacking (see **Chapter 27**). We believe this is essential for patients with necrotizing infections or abscess formation. Partially because of poor antibiotic activity in sputum, **treatment is given for at least 2 weeks.** (See also section **IX.E.2.**) Empiric antibiotics should cover *Pseudomonas aeruginosa*, and may be narrowed when an organism is recovered.
- 1. Klebsiella.** Ceftriaxone, cefotaxime, and cefepime are active against *K. pneumoniae in vitro*, and monotherapy can be used [12]. Other potentially useful agents include imipenem, meropenem, piperacillin-tazobactam, the fluoroquinolones, and aztreonam. Nosocomial *Klebsiella* species can be multiply resistant; imipenem is often active against these isolates. (See discussion in **Chapter 27.**)
 - 2. Pseudomonas. Combination i.v. therapy commonly is used** to prevent the development of resistance, and to achieve synergy if possible. Recommendations

for suspected *Pseudomonas* pneumonia are given in section **IX.B.2.c** under Clinical Approach to Community-Acquired Pneumonia [2,4,6]. Hatchette et. al. [73] made similar recommendations based on their review of community-acquired *Pseudomonas* pneumonia. Monotherapy with an antipseudomonal β -lactam or quinolone is not optimal initial therapy (see related discussions in Chapter 27). When the infection is under good control, oral ciprofloxacin may be used for susceptible organisms to complete therapy. When aminoglycosides are used, serum levels should be monitored carefully as much to ensure adequate levels as to avoid toxicity.

3. Compromised hosts with pneumonia are discussed separately in section **VIII**.

V. “Atypical pneumonia” [74]

A. Historical view. Atypical pneumonia originally referred to those pneumonias that had clinical features distinct from classic lobar pneumonia.

- 1. A subacute illness**, with onset over several days.
- 2. Early nonspecific systemic manifestations** of fever, headache, and myalgias.
- 3. Cough is often the most prominent early respiratory symptom and initially nonproductive.** Dyspnea and pleuritic chest pain are rare.
- 4. Initially scant and mucoid sputum**, which may be purulent as illness progresses.
- 5. Chest physical findings** that often underestimate the extent of radiographic changes.
- 6. Leukocytosis** usually less than or equal to $15,000/\text{mm}^3$.

B. Distinguishing between atypical and typical etiologies on the basis of clinical and radiographic features alone is not reliable [2,6,74]. Thus, the clinician must be familiar with many possible etiologies to appropriately manage CAP [74].

C. There are numerous potential etiologies for atypical pneumonia. *M. pneumoniae* and *C. pneumoniae* are discussed in detail since they cause the syndrome most frequently, and a few of the others are briefly reviewed [74]. *Legionella* species are discussed in section VI.

D. *Mycoplasma pneumoniae* is the most common cause of “atypical pneumonia” [75]. The illness spreads in families with an incubation period of 2 to 3 weeks. **Those at greatest risk for infection are 5 to 20 years of age, although it occurs in all age groups** [76]. Outbreaks may occur in the community or in institutional settings [77,78]. **Only partial immunity follows infection**, and repeated infections in the same patient have been documented. In addition, patients with hypogammaglobulinemia have an increased susceptibility [79].

1. Clinical manifestations [80]

- a. Pharyngitis** is much more prominent than rhinitis and may be the earliest symptom. **Protracted cough with minimal sputum production is the most common symptom**, although occasional individuals will produce significant quantities of sputum. Bullous myringitis is a traditional clue in the diagnosis, but it is infrequent and may be present in other pneumonias. Pleurisy and easily demonstrable pleural effusions are unlikely to be due to mycoplasmal pneumonia. **Occasionally, *M. pneumoniae* produces severe illness**, especially in patients with sickle cell disease.
- b. Extrapulmonary manifestations** may occur either with or without the respiratory component [80,81]. These include vomiting or diarrhea, morbilliform skin rashes, erythema multiforme, arthritides, and several central nervous system (CNS) syndromes such as aseptic meningitis.
- c. A history of a similar illness 2 weeks earlier in a family member** may be elicited. In contrast, with viral illness contacts are usually ill at the same time.
- d. Radiographic findings** include segmental and subsegmental infiltrates that may be bilateral [14]. Features suggesting mycoplasmal pneumonia include the absence of consolidation, limited progression, relatively rapid resolution, and in some reports hilar adenopathy [82]. Computed tomography

(CT) scans may show ground-glass infiltration and nodules not readily seen on plain films [83].

2. **Diagnosis.** The organism grows slowly and is difficult to isolate, so most laboratories do not offer cultures for *Mycoplasma*. The diagnosis most often is made serologically.
 - a. **Cold agglutinins** develop in approximately half of patients, but **are not specific**. They have been seen in influenza, mononucleosis, other infections, and lymphoproliferative diseases. A titer of 1:128 or more is suggestive of *Mycoplasma* infection. Hemolytic anemia is an uncommon complication.
 - b. Commercially available **enzyme immunoassay** has replaced complement fixation (CF) as the preferred serologic test [77,84]. Major disadvantages to serodiagnosis are that information is unavailable during the acute illness, IgM antibodies may persist for prolonged periods, and reinfection may result in a poor IgM response. A fourfold or greater antibody increase occurring between acute and convalescent sera collected 4 weeks apart is diagnostic.
 - c. **Rapid diagnostic tests** undergoing evaluation include antigen capture assays, nucleic acid hybridization, and PCR. Particularly intriguing is the use of multiplex PCR for the simultaneous testing of multiple respiratory pathogens on the same specimen [85]. Studies to clarify their usefulness are needed because they can detect the carrier state that exists in the absence of active disease.
 3. **Differential diagnosis.** It may not be possible to differentiate between other infections, such as *C. pneumoniae*, Legionnaires disease, and even atypical presentations of bacterial pneumonia. Clinical features suggesting *Mycoplasma* infection include spread in family members or close contacts, the extrapulmonary findings cited previously, and absence of pleuritic symptoms [86].
 4. **Therapy.** Either **erythromycin or tetracycline for 14 to 21 days** will shorten the duration of illness and reduce the frequency of relapse. However, the organism may be shed for up to 4 months even with therapy. Erythromycin and tetracycline are equally effective; the adult doses are either 250 mg four times daily or 500 mg three times daily. Erythromycin 30 to 50 mg/kg/day in divided doses is given to children weighing under 25 kg, and no more than 1 g daily to those weighing over 25 kg. Clarithromycin and azithromycin have fewer side effects, but are much more expensive. Tetracycline should not be used during pregnancy, in nursing mothers, or in children under 8 years of age. Doxycycline can be used in place of tetracycline; the adult dose is 100 mg twice daily, and for children age 8 years and older 1 to 2 mg/kg twice daily. Levofloxacin and other newer fluoroquinolones are active *in vitro*, but they are more expensive and should not be used in children. Prophylactic antibiotics have been suggested during outbreaks in closed populations; five days of azithromycin helped control an outbreak in a long-term care facility [78]. (See Chapter 27.)
- E. *Chlamydia pneumoniae*.** *C. pneumoniae* is the **second most common cause of atypical pneumonia**. It occurs year round, is worldwide in its distribution, and may cause outbreaks [87,88]. Antibodies to *C. pneumoniae* are rare in preschool-aged children but increase rapidly in prevalence through adolescence and young adulthood. Seropositivity is high, up to 75%, among the elderly [88]. Aerosol transmission from human to human predominates, but environmental contamination and fomite spread also is possible [88]. The average person may have several infections over their lifetime [87], although these may represent reactivation of latent *C. pneumoniae* during another infection.
1. **Clinical manifestations. Most infections are asymptomatic or produce only mild illness.** *C. pneumoniae* accounts for **approximately 10% of CAP**, and nosocomial pneumonia is also possible. Combined infections have been frequent [87], but these may represent reactivation of *C. pneumoniae* during an unrelated pneumonia. Pneumonia, bronchitis, pharyngitis, otitis, and sinusitis are the most common syndromes. Many patients have a "biphasic" illness with early fever, and may be afebrile when they eventually seek medical care. Initial symptoms may include gradual onset of sore throat, pharyngitis, and hoarseness [87]. Pneumonia with nonproductive cough is delayed by 1 to 4 weeks in

primary infection, and approximately 1 week longer in reinfection [87]. Bronchitis with or without pneumonia may be subacute in onset, and may have a prolonged recovery phase. Pharyngitis and sinusitis, with or without otitis, also may occur by themselves or as part of pneumonia [87,88].

An elevated erythrocyte sedimentation rate (ESR) and a normal WBC count are the rule. The most common radiographic picture is unilateral subsegmental or segmental infiltrates indistinguishable from mycoplasmal infection or other etiologies for CAP that resolve rapidly [87]. Convalescence may be prolonged, but most patients recover. Severe pneumonia is more likely with increasing age and mixed infections; death is rare and occurs most frequently in the elderly and in those with underlying illness or mixed infection [88].

C. pneumoniae has been implicated in several other clinical syndromes. These include bronchospastic disease, endocarditis, myocarditis, and atherosclerosis [88].

2. **Diagnosis.** Cultures are not available in most centers. **Serologic diagnosis** uses the microimmunofluorescence test for *C. pneumoniae* IgM and IgG antibodies [88]. In primary infection IgM antibodies appear after a 2- to 4-week delay, so that acute and convalescent specimens should be separated by no less than 4 weeks. In reinfection cases IgM may not appear but IgG titers increase within 1 to 3 weeks. The older chlamydial CF test is nonspecific. Rapid diagnosis by specific antigen or DNA detection is not widely available [87,88].
 3. **Differential diagnosis.** Prospective studies have not identified any feature distinctive of *C. pneumoniae* infection. Hoarseness and sore throat may be a consistent finding with illness, but many other prevalent respiratory agents also cause these symptoms.
 4. **Therapy.** Clinical experience suggests that **macrolides, tetracyclines, and newer fluoroquinolones** are effective [2]. We favor doxycycline in adults, 100 mg twice daily, for 10 to 14 days. Clarithromycin, azithromycin, and the newer fluoroquinolones are active *in vitro*. Treatment failures and relapses occur. Relapses are treated with either the same or a different antibiotic. Excretion of the organism for up to 1 year after therapy has been described [88].
- F. *Chlamydia psittaci*** causes psittacosis. Psittacosis (or ornithosis) is a **systemic infection acquired from occupational or home contact with infected birds**, including parrots, parakeets, turkeys, and others. The onset may be abrupt, and the illness is potentially fatal. Diagnosis depends on acute and convalescent serologic studies. Tetracyclines are the agents of choice [89], and are given for 1 to 2 weeks after clinical improvement to minimize relapses.
- G. *Coxiella burnetii*.** This obligate intracellular parasite causes **Q fever** [90].
1. **Epidemiology.** Although *C. burnetii* is found on five continents and in at least 51 countries, the rates of Q fever vary widely from region to region [90]. Q fever is endemic to Nova Scotia, accounting for 5% of ambulatory patients with an identified cause of CAP [75]. Infections occur most commonly after exposure (often occupational) to infected aerosols from products of conception or from milk, wool, or fresh cheese from infected animals. Several outbreaks have occurred that were unrelated to traditional animal reservoirs for *C. burnetii*, involving exposure to stillborn kittens or parturient cats, sheep used in research, wild rabbits, manure, and living along a road used for a sheep drive [91,92].
 2. **Clinical findings. Acute Q fever** may include pneumonia, hepatitis, or both. Illness begins abruptly with rigors, fever, headache, and myalgias. Nonproductive cough is present in at least half of the patients with pneumonia. There may be relative bradycardia for the degree of fever. Chest examination often is unremarkable despite obvious radiographic infiltrates. Hepatomegaly indicates liver involvement; splenomegaly is much less frequent. Radiographic infiltrates usually are subsegmental or segmental, may have a pleural base, and are indistinguishable from other types of CAP. However, **rounded opacities** should suggest the possibility of Q fever pneumonia. Other laboratory findings are equally nonspecific. **Chronic Q fever** may rarely involve the lungs, presenting as pseudotumor or fibrosis [90]. **Serologic methods are the mainstay of diagnosis** [93].

3. **Treatment is suggested for all symptomatic acute *C. burnetii* infections** because of the potential for later chronic Q fever. **In adults**, 2 weeks of oral **doxycycline**, 100 mg twice daily, is the regimen of choice. Chloramphenicol is an alternative, but the newer fluoroquinolones are also effective [90]. Erythromycin treatment failures for pneumonia have occurred, but the addition of rifampin has been effective [94].
- H. **Viral pneumonia. In infants and children**, RSV, parainfluenza viruses, adenoviruses, influenza, and varicella-zoster virus are most common. **In adults, viral pneumonia is uncommon but influenza is the most important cause.** Adenovirus may cause outbreaks in military recruits and sporadic community cases. Respiratory infections in adults that cause hospitalization include RSV and influenza, particularly in the elderly and in contacts of children with RSV infection (e.g., adult family members and hospital personnel). In addition, nursing home outbreaks of RSV illness have been documented. For further discussion, see Chapter 10.
 - I. ***Pneumocystis carinii* pneumonia** should be considered in patients with HIV infection.
- VI. **Legionnaires' and related diseases.** A great deal has been learned about *Legionella* since the July 1976 outbreak of Legionnaires disease at the American Legion convention in Philadelphia [13].
 - A. **Microbiology.** There are at least 42 species and 64 serogroups of Legionellaceae, and at least 20 of them are proven human pathogens [95–97]. However, *L. pneumophila* serogroup 1 is responsible for 70% to 80% of *Legionella* pneumonias in the United States, and *L. micdadei* is the next most common cause [74,96]. Thus, the clinical aspects of these two species will be stressed.
 1. ***Legionella pneumophila*** is an aerobic, gram-negative, fastidious organism that grows best in 2.5% to 5.0% carbon dioxide on special media (e.g., charcoal yeast extract agar supplemented with α -ketoglutarate) containing cysteine [97]. Visible growth may take up to 10 days. Although this is a gram-negative bacillus, it does not stain well with ordinary Gram stain. **Special silver stains** (e.g., Dieterle) **are used to demonstrate the organism in tissue.**
 - a. The organism produces a β -lactamase and is resistant to penicillins and cephalosporins. It contains an endotoxin (not highly active biologically), and produces many enzymes and potential toxins whose role in virulence is uncertain [97].
 - b. **At least 15 serologic types** have been identified [96].
 2. ***Legionella micdadei*** is recognized as causing "Pittsburgh pneumonia" and infections previously believed to be due to *Rickettsia*-like organisms (i.e., the Tatlock and HEBA organisms) [95]. These organisms also grow on charcoal yeast extract agar. ***L. micdadei* is weakly acid-fast**, which may lead to a mistaken diagnosis of tuberculosis. It does not regularly produce β -lactamases.
 3. ***Legionella longbeachae*** infection has been associated with gardening and the use of potting soil [98].
 4. **Other *Legionella* species** causing disease in humans continue to be retrieved from new infections or recovered from samples of previously unidentified pneumonias [95].
 - B. **Incidence.** The exact incidence of infections due to *L. pneumophila* and related species is unknown; estimates show wide variation with locale and time. Overall, **2% to 9% of CAP** is due to these bacteria [13]. **The rates of hospital-acquired pneumonias** caused by *Legionella* also **vary**, depending on the medical center and the patient population.
 1. ***L. pneumophila*** causes 2% to 15% of pneumonias requiring hospitalization, and an even higher proportion of severe pneumonias requiring admission to the intensive care unit (ICU) [13].
 2. ***L. micdadei* causes nosocomial infections in the compromised host**, although community-acquired infections and outbreaks may occur [95,99,100]. Predisposing factors include transplantation, hematologic malignancy, high doses of corticosteroids, previous surgery, and underlying chronic lung disease or other serious illness.

- C. Epidemiology.** *Legionella* are aquatic organisms transmitted by water and air through airborne droplets or microaspiration [13,101]. Human-to-human transmission does not occur. Environmental reservoirs frequently contain algae that provide nutrients and amebae and protozoa that support intracellular multiplication; growth in water is further favored by elevated temperatures, iron, and limited bacterial competition.
- Soil excavation, air-conditioning systems, water evaporative condensers, and potable water have been point sources for outbreaks, especially in summer months. Sporadic cases occur year round. Following environmental exposure, the pneumonia attack rate is low and in the range of 0.1% to 5% [102], but the attack rate for Pontiac fever is higher [99].
- D. Host factors.** Legionellosis is seen in any age group. **Elderly or compromised patients may develop fatal infection.** Patients at greatest risk [13,95,97] are as follows:
1. **Immunocompromised patients**, including organ transplant recipients and persons receiving chemotherapeutic agents, radiation therapy, or corticosteroids **are at risk for nosocomial *Legionella* infection.** Legionellosis is uncommon in HIV- infected individuals.
 2. **Dialysis patients.**
 3. **Late-middle-aged to elderly men.**
 4. **Hosts with chronic underlying disease** (e.g., organic heart disease, lung disease, renal disease, and diabetes).
 5. **Alcoholics and smokers, particularly in the presence of COPD.**
 6. **Patients undergoing major surgery.**
 7. **Neonates with ventilator-associated pneumonia.**
- E. Clinical manifestations** [13,95,97]. There is a **broad spectrum** of disease due to *L. pneumophila* and *L. micdadei*.
1. **Asymptomatic infection** is well described, including in the outbreak setting [102].
 2. **Pontiac fever** is a non-pneumonic disease named after an outbreak in Pontiac, Michigan, in 1968. After a 1- to 2-day incubation period, there is an abrupt onset of fever, chills, headache, myalgias, and malaise. Acute symptoms usually last less than a week, the illness being self-limited even without specific therapy.
 3. **Pneumonia** is the most common symptomatic problem. **Clinical and laboratory manifestations of *Legionella* pneumonia are not distinctive**, although a scoring system has been used at one institution to identify patients with legionellosis [3]. Mixed infections have been reported.
 - a. **Pulmonary manifestations.** The spectrum of disease is **highly variable**. Mild to moderate illness (e.g., bronchitis or an atypical pneumonia syndrome) or moderate to severe pneumonia with adult respiratory distress syndrome may occur. Illness usually begins with nonspecific symptoms of malaise, myalgias, headache, and fever, after an incubation period of 2 to 10 days. An initially dry and nonproductive cough is present in approximately 90% of patients, and often progresses to produce purulent sputum. Temperatures of 39° to 40°C (102°–104°F) are common, as are shaking chills. Pulmonary symptoms steadily progress over several days. Chest pain and hemoptysis may falsely suggest pulmonary embolism. Early physical findings are often nonspecific and may include a pulse-temperature deficit [3] that may have been overemphasized [13]. Signs of consolidation develop, but pleural friction rubs are uncommon. **Radiologic findings are nonspecific.** Infiltrates that are initially unilateral and patchy frequently progress to bilateral consolidation. Nodular lesions, diffuse alveolar patterns, cavitation, and abscess formation may be seen. Small pleural effusions may develop, but large effusions are uncommon.
 - b. **Other manifestations** of pneumonic infections may include abdominal pain, nausea, vomiting, and diarrhea. Neurologic findings include headache, confusion, disorientation, delirium, and, although rare, focal neurologic findings. Results of lumbar puncture studies are normal. **Hyponatremia is**

found more commonly in *Legionella* pneumonia than with other etiologies of pneumonia.

- c. **Miscellaneous findings.** Hepatomegaly and liver function test abnormalities, disseminated intravascular coagulation, hypophosphatemia, and hematuria occur no more frequently than in other types of pneumonia.
4. **Extrapulmonary infections** have included bacteremia, lymphadenitis, **prosthetic valve endocarditis**, sinusitis, osteomyelitis, hemodialysis shunt infections, peritonitis, pancreatitis, pericarditis, myocarditis, cellulitis, wound infection, and abscesses in organs and soft tissues. These can result from hematogenous seeding or from direct inoculation with contaminated water.
- F. **Diagnosis [96,103]. Legionellosis should be sought in any at-risk hospitalized patient with limited sputum, sputum Gram stain showing leukocytes but few organisms, or a poor response to β -lactam antibiotics [13].**
 1. **Routine Gram stains of sputum** frequently show moderate to large numbers of polymorphonuclear leukocytes (and monocytes), often with no bacteria.
 2. **Cultures for *Legionella*** have a diagnostic specificity of 100%, and should be performed whenever possible. They require special media, so the laboratory should be alerted to their possibility, and **growth takes several days**. In centers with experience sputum culture has a sensitivity of 80% [13]; however, in routine clinical practice it may be 10% or less [96]. Bronchial washings, bronchoalveolar lavage, and lung tissue have sensitivities similar to sputum or higher [97]. The yield from pleural fluid culture is less. *Legionella* organisms also have been isolated from blood but the yield is low.
 3. **Direct fluorescent antibody (DFA)** testing of respiratory secretions, pleural fluid, or lung tissue is technically difficult. Results may not be reliable in inexperienced laboratories or when the screened serogroups do not reflect the locally prevalent *Legionella* [96]. Thus, the sensitivity of this test ranges from 33% to 68% [96]. Organisms may remain detectable by DFA for several days after starting antibiotics. Although specific, false-positive results have occurred in the presence of other bacteria, and from *Legionella* contamination of test reagents [96].
 4. **Antigen detection in urine of serogroup 1 only** is commercially available in kits. These tests have high specificity and a sensitivity of approximately 70% [13]. They may be positive well into the patient's illness and even after therapy has been started. Antigenuria may be prolonged so that a positive test may result from an unrelated prior infection. Also, false-negative results may be obtained from infection with other *Legionella* species. The tests can be used with other specimens, including pleural fluids [97].
 5. **PCR is promising** but not widely available [96]. PCR is capable of detecting any *Legionella* species, is very sensitive, and is rapid enough to affect empiric therapy.
 6. **Serologic studies** (immunofluorescence assay, enzyme-linked immunosorbent assay [ELISA], counterimmunoelectrophoresis, or agglutination tests) are 40% to 60% sensitive and have good specificity [13]. Sensitivity is highest for *L. pneumophila* (75%–80%), and is 50% or less for non-pneumophila species [96]. Because serum antibody may be delayed, samples should be obtained every 2 to 3 weeks for 4 to 12 weeks. False-positive results have been reported from cross-reaction with other organisms [96]. Thus, **serology is useful for epidemiologic purposes but does not influence initial patient management**.
With paired sera, a fourfold increase in either IgM or IgG titer to 1:128 or more is considered diagnostic of disease. **A single titer of 1:256 or more has a low positive predictive value and should not be used for diagnosis in an individual patient.**
- G. **Therapy.** *In vitro* antibiotic susceptibility tests for *Legionella* do not reliably predict clinical efficacy [16,95,97]. Thus, most therapeutic information has come from clinical experience, animal studies, or *in vitro* models of intracellular infection. In these models, erythromycin, tetracycline, rifampin, TMP-SMX, and the fluoroquinolones are effective; erythromycin is bacteriostatic. The penicillins,

cephalosporins, and aminoglycosides are ineffective. **In fact, a pneumonia that progresses during treatment with the latter should suggest the possibility of *Legionella* infection.** Treatment failures and relapses have been reported with erythromycin but also may occur with other agents.

1. **Isolation.** Special precautions are not required.
2. **Mildly ill** and previously healthy individuals may receive outpatient treatment with any of the alternatives listed below.
3. **In hospitalized adults, i.v. therapy should be given initially** but may be finished orally. **Most authorities no longer consider erythromycin the drug of choice** [2]. Recommended agents include the following:
 - a. **Azithromycin** 1,000 mg on the first day and 500 mg daily for the next 4 days can be given [13]. The duration is extended to 10 to 14 days with life-threatening infection or in immunocompromised hosts.
 - b. **A fluoroquinolone** (ciprofloxacin, levofloxacin, or gatifloxacin) may be given for 10 to 14 days, and extended to 21 days for life-threatening infection or in immunocompromised hosts. A quinolone is preferred in transplant patients to avoid potential drug interactions with cyclosporine or tacrolimus [95,104].
 - c. **Doxycycline** is given in a dose of 100 mg i.v. every 12 hours after a single 200-mg loading dose. The duration of therapy is the same as for the fluoroquinolones.
 - d. **Rifampin** is active *in vitro* and in animals, but **is never used alone.** It may be added (300–600 mg every 12 hours) when azithromycin or a fluoroquinolone are not used for immunocompromised hosts or severe infections; there is no benefit to adding rifampin to azithromycin or a fluoroquinolone [104]. The potential for drug interactions should be evaluated before using rifampin.
 - e. **Other agents** with reports of success include TMP-SMX (adult dose of 160 mg TMP and 800 mg SMX every 8–12 hours), imipenem, and clindamycin [13].

H. Prognosis is related to the underlying disease and the early institution of appropriate therapy. In nonimmunosuppressed patients, the mortality rate is low. In immunosuppressed patients, mortality may be as high as 50% if specific therapy is delayed [97].

I. Prevention. There is no vaccine for legionellosis. Routine cultures of the hospital water supply have been recommended, particularly in institutions caring for transplant and other immunosuppressed patients [97,100].

VII. Hantavirus pulmonary syndrome (HPS) [105]. Found worldwide, hantaviruses are enveloped negative-sense RNA viruses in the family Bunyaviridae. Hantavirus illnesses are most common in Asia and Europe and include syndromes of hemorrhagic fever with renal failure (e.g., Korean hemorrhagic fever) and nephropathia epidemica. In May 1993, an outbreak of unexplained ARDS in otherwise healthy adults was reported in the Four Corners area of Arizona, Colorado, New Mexico, and Utah. Intense investigation revealed a new hantavirus, the Sin Nombre virus. HPS has since been caused by at least four other new hantaviruses (New York, Monongahela, Bayou, and Black Creek Canal viruses) in different areas of the United States [106].

A. Epidemiology

1. **Rodents are the primary reservoir** for HPS viruses, including the deer mouse, white-footed mouse, rice rat, and cotton rat. The **predominant modes of transmission** to humans are ingestion or inhalation of aerosolized rodent excreta, and direct contact with rodents, rodent excreta, or rodent saliva. The majority of exposures have occurred in and around the home [106].
2. **Human-to-human spread has not occurred in the United States**, but has been implicated in an outbreak in Argentina [107].
3. **As of April 2001 there were a total of 283 cases from 31 states**, and since then the first case was reported from Vermont [106]. Most cases have occurred in the Southwest, and 60% have occurred in men. Ages ranged from 10 to 75 years with a mean of 37 years. **Case fatality since the 1993 outbreak has been 38%.** Updated information is available at www.cdc.gov/ncidod/diseases/hanta/hantvrus.htm.

B. Clinical manifestations. Classic HPS is described, although mild and asymptomatic infections occur.

1. A **brief prodrome usually lasts 3 to 6 days**. Common symptoms include fever, chills, myalgias, headache, dizziness, abdominal discomfort, nausea, and vomiting. Cough is not prominent initially. **Pharyngitis and coryza are not common features** of this syndrome.
2. **Pulmonary involvement is marked by the onset of cough, dyspnea, and tachypnea**. There may be rapid progression to respiratory failure. Fever, hypoxia, hypotension, and volume depletion become prominent. **Noncardiogenic pulmonary edema and depressed myocardial function** occur. Radiographs show bilateral interstitial edema, and pleural effusions are common.
3. **Laboratory abnormalities** have included leukocytosis with early myeloid forms and atypical lymphocytes, **hemoconcentration, thrombocytopenia**, proteinuria, microscopic hematuria, hypoalbuminemia, elevated blood urea nitrogen and creatinine, elevated lactate dehydrogenase (LDH) and transaminases, coagulopathy, and lactic acidosis [105,106].
4. **Improvement** is marked by diuresis, resolution of hemoconcentration, and increased oxygenation. Recovery may proceed rapidly, or may take weeks [105,106].

C. Diagnosis must rest on clinical suspicion early in the hantavirus pulmonary syndrome. HPS should be considered for patients with a febrile illness and unexplained respiratory failure. Information about diagnostic tests is available from local and state public health agencies, and the Centers for Disease Control and Prevention (CDC).

1. Culture is difficult and not readily available.
2. **Serology**. Specific IgM and IgG are detected in acute and convalescent samples using an ELISA. Either acute-phase IgM or a fourfold increase in IgG titer is diagnostic.
3. **Immunohistochemical staining** of tissue detects hantavirus antigens in tissue.
4. **PCR** can identify virus in tissue, serum, or blood and may be positive very early.

D. Therapy

1. Rapid institution of **supportive therapy in an ICU** has been critical to survival. Extracorporeal membrane oxygenation has been helpful in two of three reported cases.
2. There is **no evidence that ribavirin is effective** but a trial is underway.

E. Prevention involves minimizing exposure to rodents and their excreta. No vaccine is available.

VIII. Pneumonia in the compromised host [108–112]. Pneumonia is common in the compromised host, rapid deterioration may occur, and mortality of 40% to 50% is frequently reported. Patients at risk include those on immunosuppressive chemotherapy or moderate- to high-dose corticosteroids; those with transplants; patients with congenital or acquired immune deficits; HIV-infected patients; and those with malignancy, especially myeloproliferative or lymphoproliferative disorders (see Chapters 18 and 20).

A. The clinical dilemma

1. **Urgent problem**. Rapid evaluation before the patient deteriorates is necessary.
2. **Multiple infectious and noninfectious causes** may have the same clinical presentation. An invasive procedure often is necessary for diagnosis.
3. **Routine laboratory data often are nonspecific**. Many of the infectious agents causing the pneumonia cannot be diagnosed from routine sputum samples. Radiography cannot provide specific diagnoses.
4. **Multiteam approach**. Management requires the cooperative efforts of subspecialists in oncology, infectious disease, pulmonary disease, thoracic surgery, and pathology. If facilities are not available for such a multiteam approach, consideration should be given to transferring such patients to another institution.

B. Host factors

1. **Humoral deficiencies** include congenital or acquired hypogammaglobulinemias and hypocomplementemias. Humoral deficiencies commonly accompany

multiple myeloma, chronic lymphocytic leukemia, bone marrow transplantation, and cancer chemotherapies. These patients are at highest risk for infections caused by *S. pneumoniae* and *H. influenzae*, among other pyogenic bacteria.

2. **Neutropenia. The neutropenic host may not produce sputum, exhibit the expected findings on physical examination, or initially demonstrate radiographic abnormalities.** Frequent bacterial pathogens include streptococci, staphylococci, Enterobacteriaceae, and *P. aeruginosa*. Zygomycetes and *Aspergillus* species are common after prolonged antibiotic therapy.
 3. **Impaired cell-mediated immunity** may be part of a congenital immunodeficiency or may be acquired as a result of lymphomas, cytotoxic drugs, corticosteroids, radiation therapy, HIV infection, and malnutrition. Defective cellular immunity predisposes to *Nocardia* species, *Legionella* species, mycobacteria, *Cryptococcus neoformans*, *Histoplasma capsulatum*, cytomegalovirus (CMV), varicella-zoster virus, *Pneumocystis carinii*, and *Strongyloides stercoralis*. **Corticosteroids** are an important predisposing factor for many pathogens but particularly for *Nocardia*, *Legionella*, *M. tuberculosis*, most fungi, *P. carinii*, and *S. stercoralis*.
 4. **Combinations** of the conditions cited in sections VIII.B.1–3, in addition to impairments to nonimmune pulmonary defenses, are commonly present.
- C. Differential diagnosis** is extensive. The major considerations include the following:
1. **Infection.** With the exception of some viruses, most infections can be treated specifically if a particular organism or agent can be demonstrated.
 - a. **Bacteria.** Aerobic gram-negative bacteria (*Klebsiella* species, *E. coli*, *Pseudomonas* species) are common pathogens. *S. aureus* may be increasing in relative frequency as initial therapies have focused on gram-negative bacilli [108]. *L. pneumophila* and *L. micdadei* (see section VI) also must be considered.
 - b. **Tuberculosis** may reactivate during immunosuppression.
 - c. ***Pneumocystis carinii* pneumonia** occurs in AIDS, lymphocytic leukemia, Hodgkin disease, systemic lupus erythematosus, bone marrow or organ transplants, and newborns with agammaglobulinemia.
 - d. **Fungi**
 - (1) ***Aspergillus* species and Zygomycetes (including *Mucor* species)**
 - (a) **Most patients are granulocytopenic and often are febrile despite broad-spectrum antibiotic therapy.** Other clues to the diagnosis include pleuritic chest pain, bloody sputum, nasal and sinus abnormalities, and rapidly progressive nodular or cavitary infiltrates.
 - (b) Fungal elements invade vascular channels and cause thrombosis and pulmonary infarction. Dissemination to other organ systems, particularly the CNS, occurs. *Aspergillus* invasive tracheobronchitis is seen in lung transplant patients, and occasionally in heart, renal, or liver transplants [112].
 - (c) Repeated isolation of aspergilli from sputum is sufficient to initiate antifungal therapy, although false-negative results are common. Because there may be commensal organisms in the airways, particularly if there is underlying chronic lung disease, **demonstration of invasion of tissue by transbronchial biopsy or open lung biopsy is necessary to establish a definitive diagnosis.** However, this is often difficult in these very ill and frequently thrombocytopenic patients. In the bone marrow transplant patient, a positive sputum culture is 95% predictive for invasive disease [109].
 - (d) **Early therapy**, including amphotericin B and surgical debridement, is essential to increasing survival.
 - (2) Other fungi, such as *C. neoformans*, *H. capsulatum*, and *Coccidioides immitis* can cause pulmonary infection but are less common (see Chapter 17).

e. Viruses

(1) **CMV** is commonly reactivated in the compromised host, and almost always in transplant recipients [113]. However, reactivation is far more commonly asymptomatic than symptomatic. Thus, one needs to distinguish CMV infection from CMV disease. CMV is transmitted by fresh blood transfusion, WBC transfusion, or allografts. If an individual has no previous immunity, a primary infection develops. CMV pneumonia is most common in recipients of allogeneic bone marrow transplants, heart transplants, and liver transplants (see Chapter 20).

(2) **RSV, varicella-zoster virus, influenza, parainfluenza, and adenoviruses** are other important causes of viral pneumonias in compromised patients. Herpes simplex virus pneumonia is rare.

f. *Nocardia* causes pulmonary infection in patients with cardiac or renal transplantation and steroid use, among others (see Chapter 17).

g. Other infectious agents. *Toxoplasma gondii* and certain roundworms, especially *S. stercoralis*, may cause pneumonia in the compromised host.

2. **Tumor infiltration** can mimic pneumonia [114], particularly from lymphomas, leukemias, and alveolar cell carcinoma. **Leukostasis** with subsequent vascular occlusion in the lung can occur with high WBC counts.
3. **Drug-induced infiltrates** must be considered. Drugs that can induce lung disease include bleomycin, busulfan, methotrexate, mitomycin (with or without vinca alkaloids), the nitrosoureas (e.g., carmustine), cyclophosphamide, and the taxanes. Pulmonary edema may result from the use of i.v. cytosine arabinoside, or from cardiac toxicity secondary to anthracyclines.
4. **CHF** may, at times, be difficult to distinguish from diffuse interstitial pneumonia.
5. **Alveolar hemorrhage** may cause an infiltrate and predispose the patient to develop a superimposed bacterial pneumonia. Most patients are thrombocytopenic, with or without other coagulopathies.
6. **Idiopathic interstitial fibrosis** of any type may be present, including bronchiolitis obliterans with organizing pneumonia. Blood and bone marrow transplant patients also may have the **idiopathic pneumonia syndrome** with bilateral interstitial infiltrates and no cardiac or infectious cause [114].
7. **Radiation pneumonitis** may mimic an infectious process.
8. **Pulmonary infarction** is difficult to distinguish from acute infection.
9. **Collagen vascular diseases.** Pulmonary involvement mimicking pneumonia is most common in systemic lupus erythematosus, Goodpasture syndrome, and Wegener granulomatosis. It may be difficult to differentiate disease progression from infection, particularly if patients are receiving immunosuppressive therapy.
10. **Lung transplant patients** have noninfectious pulmonary infiltrates for several other reasons. Reperfusion injury in the donor lung may occur in the first few days after transplantation. Acute rejection usually presents within the first 3 months, and may recur during the first 1 to 2 years. Bronchiolitis obliterans usually presents later after transplantation and is marked by airway obstruction and not by lung infiltrates.

D. Initial clinical approach. The possibility of an infectious process should be assessed quickly because early effective therapy may be life saving [109,110].

1. **Diagnostic studies** have recently been reviewed [111].

a. Spontaneous or induced sputum stains for *Pneumocystis* and smears and cultures for bacteria, mycobacteria, fungi, and *Legionella* should be performed.

b. An invasive procedure to obtain lower respiratory tract secretions may be required (see section VI under Clinical Approach to Community-Acquired Pneumonia).

(1) **Bronchoscopy with BAL, PSB, or transbronchial biopsy** provides a specific diagnosis in many patients (25%–98%) [111], but is contraindicated in patients requiring mechanical ventilation or with severe

hypoxemia, and in those with bleeding diatheses. Major complications occur in fewer than 5% when biopsy is not performed, but increase significantly with biopsy; significant complications from biopsy include hemorrhage and pneumothorax [111].

- (2) **Open lung biopsy** has a diagnostic yield of 37% to 85% [111]. Open lung biopsy may be preferred for focal infiltrates not accessible by transthoracic biopsy or in whom the latter is contraindicated, in patients suspected of having certain noninfectious diagnoses (e.g., interstitial pneumonitis or drug reactions), in those with a rapidly advancing illness, and when other biopsies (e.g., transbronchial) are nondiagnostic. Open lung biopsy permits control of ventilation and bleeding, and provides a larger tissue sample that can be processed for rapid interpretation (e.g., frozen sections). In some patient populations, however, the results have infrequently influenced therapy or improved the eventual outcome, so **appropriate patient selection is critical** [111].
 - (3) An alternative to open lung biopsy is **video-assisted thoracoscopic surgery (VATS)**. VATS has a similar yield to open lung biopsy and may be particularly useful to assess pleural involvement. It can be performed after platelet transfusion if the patient is thrombocytopenic [111].
- c. **Blood cultures** should be obtained for every patient and, for some patients (e.g., those with AIDS), special media for mycobacteria and fungi may be included.
 - d. **Pleural fluid** should be examined when present if it can safely be obtained.
 - e. **Mucocutaneous lesions** should be scraped or examined via biopsy for microorganisms.
 - f. **Other specimens** (e.g., bone marrow, joint fluid, CSF, and urine) may be helpful.
 - g. **Serologic studies** may be obtained for *Legionella*, *Mycoplasma*, fungi, and viruses, but are rarely helpful in choosing initial therapy.
 - h. **Serial evaluations** of respiratory status should be monitored, including chest roentgenograms and arterial blood gases or oximetry. Progressive hypoxia may be the only early clue to the presence of *Pneumocystis* infection or other interstitial pneumonias.
2. **Host factors and the setting** in which the infection arose can help to narrow the possible etiologies. The specific underlying disease may predispose to specific pathogens, as discussed in section VIII.B.
 3. **The tempo of the illness and the type of radiographic abnormality** may be of some help in narrowing the diagnostic possibilities [110]. An acutely progressive illness favors gram-positive and gram-negative bacteria, pulmonary edema, embolism, hemorrhage, and leucoagglutinin reactions. A subacute to chronic illness should suggest CMV, *Pneumocystis*, *Mycoplasma*, *Nocardia*, and *Mycobacterium* species, and fungi, among other infections; radiation pneumonitis and drug toxicity would be among the noninfectious possibilities. Radiographic patterns (e.g., consolidative, nodular, or diffuse infiltrates) may help support certain infectious and noninfectious etiologies, but many pathogens are associated with more than one pattern. Thus, the roentgenographic appearance is best used in conjunction with an assessment of the tempo of the illness. A “wedge defect” or nodular defect in a febrile leukopenic patient, despite broad-spectrum antibiotics, raises the possibility of an invasive fungus, especially *Aspergillus* species.
- E. Initial therapy. It is imperative that a specific diagnosis is reached as quickly as possible. Empiric antiinfectives** should be started while awaiting the results of cultures. If the results of sputum stains and other rapid diagnostic studies are negative, therapy is based on host factors, setting, tempo of illness progression, and radiographic pattern.
1. **Neutropenic patients with pneumonia require combination therapy directed against gram-negative bacilli.** A β -lactam or newer fluoroquinolone plus an aminoglycoside is appropriate. Coverage for *Legionella* can be assured by adding a macrolide to regimens not including a fluoroquinolone. Vancomycin

may be added where MRSA is frequent. In patients already on antibiotics, adding amphotericin should be considered. When a cause is identified, specific therapy is substituted.

2. **In the very ill patient with diffuse infiltrates**, we empirically add TMP-SMX for *P. carinii* to an antibiotic combination directed against common bacteria and *Legionella*. If the infiltrate is focal and the patient is very ill, *Legionella* coverage is essential. Amphotericin B also may be given if *Aspergillus* or other fungal infections are likely. **An invasive diagnostic procedure should be planned within the first 24 to 48 hours.**

F. Reassessment of the management plan.

1. **If the initial studies are nondiagnostic and there is no response to empiric therapy** within 48 to 72 hours, then an invasive diagnostic procedure should be performed if not already done. An early multidisciplinary approach will help prevent unnecessary delays in this evaluation. Whether to perform an open lung biopsy or VATS initially, rather than begin with a transthoracic or transbronchial biopsy and then proceed to an open lung biopsy if negative, requires case-by-case assessment.
2. **If patients have clearly and quickly responded to the initial regimen and an alternative noninfectious diagnosis (e.g., pulmonary edema) is not established**, then continuing empiric therapy without an invasive procedure is acceptable. This also may be appropriate for patients with far-advanced underlying disease expected to be rapidly fatal even in the absence of infection, for patients in whom invasive procedures are contraindicated, or in patients who refuse the procedures.

G. Prevention. Prevention of pneumonia in the compromised host generally has involved strategies to prevent colonization, prophylactic antibiotics to prevent clinical infection, immunoprophylaxis, and modulation of the immune system. Avoidance of situations that lead to aspiration also is of value.

1. **Hand-washing** is the most important measure to prevent colonization in hospitalized immunocompromised hosts. Total protected environments with HEPA (high-efficiency particulate air) filtration of room air are useful for bone marrow transplant patients and others with prolonged neutropenia.
2. **TMP-SMX prophylaxis** has been shown to be of value in **preventing *P. carinii* pneumonia** in HIV-infected patients and in children with lymphatic leukemia. It has been more difficult to establish that antibacterial prophylaxis is reliably effective in preventing other pulmonary infections.
3. **Antifungal prophylaxis** with oral fluconazole has reduced invasive yeast infections, but resistant yeasts and *Aspergillus* infections may emerge.
4. **Antiviral agents** are effective as prophylaxis in certain specific populations such as kidney and bone marrow transplant recipients.
5. **Immunization** is important and should be given before immunosuppressive chemotherapy. Pneumococcal vaccine is indicated for elderly, asplenic, and other compromised hosts. Influenza vaccines, by reducing the frequency of influenza, should help prevent the secondary complication of pneumonia. Immunoglobulin may be given to patients with immunoglobulin deficiency or impairment, particularly from chronic lymphocytic leukemia, myeloma, or bone marrow transplantation in the postengraftment period.
6. **Growth factors**, such as granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF), speed recovery from cytopenias and can reduce the frequency of infections by shortening the period of neutropenia.

IX. Nosocomial pneumonia, pneumonia that develops after at least 72 hours of hospitalization, has the highest mortality rate of all hospital-acquired infections [11,12,64,65,115,115a].

A. Etiologies

1. **Bacteria** are the most frequent cause, and many infections are polymicrobial. Aerobic gram-negative bacilli are found in at least 55% to 85% of cases gram-positive cocci in 20% to 30% of cases, and 40% to 60% are mixed infections [11]. *H. influenzae* and *S. pneumoniae* have been recognized as causes of early

nosocomial pneumonia. Anaerobic bacteria are important in nursing home-associated pneumonia [116] and aspiration, but not in ventilator-associated pneumonias [117]. The incidence of *Legionella* infection varies, depending on the hospital and patient population. (See section VI.)

2. **Fungi** are important in immunocompromised hosts. *Aspergillus* species and other filamentous fungi are the most common isolates in this population.
 3. **Viral** etiologies for nosocomial pneumonia often are unrecognized because special studies for their detection are performed only infrequently. RSV, influenza A and B, parainfluenza, and adenovirus are most important.
- B. Pathogenesis.** Nosocomial bacteria gain access to the lungs most often through endotracheal tubes and aspiration. Inhalation of contaminated aerosols, hematogenous spread, and direct inoculation also occur but are less frequent.
1. **Colonization of the pharynx by gram-negative bacilli** is more common in aged, debilitated, or institutionalized patients, and this accounts for the high incidence of these organisms in nosocomial pneumonias (see also section II.C).

Clinical conditions that increase the pharyngeal carriage of gram-negative bacilli include endotracheal intubation, coma, acidosis, alcoholism, uremia, diabetes mellitus, prior antimicrobial therapy, and nasogastric tubes [65]. An increase in the adherence of gram-negative bacilli to oropharyngeal and tracheal cells may accompany many of these conditions; this can arise in part from antibiotic-induced reduction in normal flora, reduced salivary flow, increased salivary protease content, and changes in cellular surface carbohydrates.
 2. **Gastric colonization** also may be an important reservoir for gram-negative bacilli and *S. aureus* (see section II.C). This is **associated with conditions that raise intragastric pH over 4.0**, including aging, achlorhydria, enteral feedings, antacids, and H₂-blockers.
 3. **Bacteria in aerosols from** contaminated nebulizers, certain types of humidifiers, and anesthesia equipment may be directly inhaled into the lower airways.
- C. Risk factors** for bacterial nosocomial pneumonia have been identified [11,64,65, 115a]. **Endotracheal tubes** impair coughing and provide access to the lung. They also become coated with a biofilm of organisms that may be a reservoir for potential pathogens.
1. **Host-related factors** include age over 65 to 70 years, obesity, smoking, and underlying illnesses such as COPD, alcoholism, malnutrition, and prior immunosuppression.
 2. **Type of illness** also influences the risk for nosocomial pneumonia. **Thoracic and abdominal surgical procedures** are important predisposing events [118]. Other risk factors include a depressed level of consciousness, neurosurgical trauma, admission to an ICU, shock, and need for **mechanical ventilation**.
 3. **Other management practices and devices**, in addition to endotracheal intubation, increase risk. These include stress-ulcer prophylaxis that increases intragastric pH, insertion of a nasogastric tube, large-volume tube feedings, reflux of ventilator tube condensate into the trachea, changing ventilator tubing on a daily basis, improper care of respiratory devices, **breaks in common infection-control practices** that carry organisms from one patient to another, and **inappropriate use of antibiotics**.
- D. Diagnosis.** The steps differ depending on whether there is underlying lung disease and whether the patient is intubated. **A diligent search for noninfectious causes of fever and pulmonary infiltrates**, particularly in ventilated patients, must be made.
1. Clinical criteria often are used in **nonintubated patients**. These include the presence of fever, leukocytosis, cough, purulent sputum, and a new or progressive radiographic infiltrate. Caution must be used when applying these clinical criteria to patients with underlying lung diseases, because the criteria are non-specific [12].

2. The **diagnosis of ventilator-associated pneumonia (VAP) may be very difficult**, particularly in patients with accompanying ARDS [67]. VAP should be suspected and a chest radiograph obtained if at least two of the following are present: fever or hypothermia, leukocytosis or leukopenia, purulent sputum, and decreased oxygenation [22]. If the chest radiograph is abnormal, the patient should be treated for VAP [22]. We feel that if oxygenation is unchanged, another cause should be vigorously sought. Because clinical and radiographic criteria are nonspecific [119,120], expert practitioners apply additional diagnostic methods when available [115a,121].
 - a. **Quantitative cultures of tracheal aspirates.** Direct tracheal aspirate cultures cannot be used to make this distinction in the diagnosis of ventilator-associated nosocomial pneumonia. Using threshold concentrations of 10^5 or 10^6 organisms per milliliter or greater, quantitative tracheal aspirate cultures have varied and low sensitivity and specificity [122]. Because of the problems with false-positive and false-negative results and an incomplete understanding of the effects of antibiotic therapy on interpreting results, quantitative (and nonquantitative) cultures of tracheal aspirates are of limited value [122].
 - b. The detection of microscopic **elastin fibers in sputum** may be associated with any cause of lung necrosis. Thus, this study is not recommended [122].
 - c. **Quantitative cultures of PSB or BAL specimens offer the most promise** [23,25,26,28,121]. Gram stain to detect intracellular organisms on BAL specimens is specific but not as sensitive. Techniques are available to obtain these specimens with or without bronchoscopy. The effects of prior antibiotics are incompletely understood, but overall they have not been shown to alter the diagnostic yield. However, in an individual patient they may result in a false-negative culture by suppressing growth of true pathogens. For these reasons, quantitative cultures of PSB or BAL specimens should be obtained before making any changes in antibiotic therapy. It has not been demonstrated that the use of these procedures has an impact on patient outcome, although they may help promote the prudent use of antibiotics [115a].
 - d. **Open lung biopsy** is almost never necessary.
- E. **Therapy.** Effective therapy involves ensuring airway patency and adequate oxygenation, using pressors and other supportive measures, draining secretions, and administering antibiotics. **Administration of empiric antibiotics should not be delayed**, and must take into consideration local resistance patterns [115a,121]. **The best outcome occurs when initial antibiotics are active against the infecting organisms** [11,67]. Gram stains of reliable specimens are useful to help direct initial therapy. Whenever possible, **specific antibiotics should be substituted as specific pathogens become known. The ATS has published recommendations for empiric therapy [115], but these must be individualized to the specific institution, setting, patient characteristics, and local resistance patterns** [121,123]. Most regimens should have activity against *S. pneumoniae*, *H. influenzae*, and the gram-negative bacilli noted in section IX.A. (See also section IV.C.)
 1. **Early illness (<5 days) in patients without risk factors for resistant organisms** may be treated with ticarcillin-clavulanate, piperacillin-tazobactam, carbapenems, or an antipneumococcal fluoroquinolone. Ciprofloxacin monotherapy should not be used because it is less active against pneumococci and anaerobes. See Chapter 27 for a discussion of inducible β -lactamase resistance from cephalosporin overuse.
 2. **Patients with risk factors for resistant organisms and those with severe illness or necrotizing infection** should be treated with a combination regimen. Preliminary results suggest an improved outcome for an aminoglycoside plus piperacillin-tazobactam when compared with the aminoglycoside plus either ceftazidime or imipenem, particularly for *Pseudomonas aeruginosa* infections [11,67]. If *S. maltophilia* is a concern, then TMP-SMX is used.

3. Nafcillin or vancomycin should be included when *S. aureus* is suspected. Vancomycin is preferred if MRSA is possible.
 4. A macrolide or fluoroquinolone should be added whenever *Legionella* organisms are possible. See section VI.G for treatments of legionellosis.
- F. Prevention.** Strategies to prevent nosocomial pneumonias are based on an understanding of their pathogenesis and risk factors (see sections IX.B and XI.C). **Guidelines for the prevention of nosocomial pneumonia have been published** [64,65].
1. **The use of systemic antibiotics for pneumonia prophylaxis is not recommended.**
 2. **Hand washing and other routine infection-control practices are essential.**
 3. If possible, **elevate the head of the bed** to 30 to 45 degrees to prevent aspiration. Discontinue tube feedings, nasogastric tubes, and endotracheal tubes as soon as possible. **Continuous aspiration of subglottic secretions** in intubated patients should be considered. **Chlorhexidine oral care** is also effective [64].
 4. **Effective pain control and chest physiotherapy** (e.g., coughing, deep breathing, incentive spirometry) **should be priorities in postoperative patients.**
 5. **Stress-ulcer prophylaxis that does not elevate gastric pH** (e.g., sucralfate) is preferred.
 6. **Immunizations** should be **updated** and smoking curtailed, particularly prior to elective surgery.
 7. **Sterile equipment and water** should be used for procedures that contact mucous membranes. The internal parts of mechanical ventilators do not need to be sterilized.
 8. **Ventilator tubing condensate should not be allowed to drain into the patient's airway**, and tubing should be changed no more frequently than every 48 hours.
 9. Small-volume nebulizers should be filled with sterile fluids and not used for more than one patient unless sterile or high-level disinfected.
 10. **Selective decontamination** remains a promising strategy [124], but is not recommended for routine use because of lack of standardization and concern about promoting resistant organisms [125].
- X. Pneumonia in children** (1-month-olds to teenagers). Certain aspects of childhood pneumonia warrant emphasis [5,8,126,127]. For example, a very young child may have only fever and tachypnea, and rarely produces sputum. Neonates are discussed in Chapter 3.
- A. Age is of great importance in the likely etiologies** and their mode of presentation.
1. **Infants 1 to 3 months of age** are most likely to have pneumonia of viral origin (RSV, parainfluenza virus). Occasionally, the etiology will be bacterial, including group B streptococci, *H. influenzae*, *S. pneumoniae*, *S. aureus*, *S. pyogenes*, and *Bordetella pertussis*. Afebrile pneumonia in infants 1 to 3 months of age usually is caused by *Chlamydia trachomatis*. This illness is indolent and marked by poor feeding, failure to thrive, a chronic cough, conjunctivitis, tachypnea, and diffuse rales.
 2. **Between the ages of 3 months and 5 years**, *S. pneumoniae* and viruses predominate. RSV, parainfluenza virus, influenza types A and B, and adenovirus are most important. Mixed infections are common in younger children hospitalized with pneumonia. Encapsulated organisms (*S. pneumoniae*, *H. influenzae*, and *Neisseria meningitidis*) are more frequent in children over 3 months of age as maternal antibodies wane. Other bacteria and *Mycoplasma* are occasional pathogens in this age group. *H. influenzae* type b is important in unimmunized children.
 3. The causes of pneumonia **in children over 5 years of age** are more like those in young adults. Pneumococcal, mycoplasmal, and *Chlamydophila* predominate. As in adults, anaerobes occur in patients prone to aspiration. Group

A streptococci, *M. catarrhalis*, and *Legionella* species are less common in childhood pneumonias.

B. Radiographic clues

1. **Pneumonia with effusion** most likely has a **bacterial etiology** unless the tuberculin skin test is positive or there is a contact history for tuberculosis.
 2. **Lobar consolidation** implies a **bacterial process**. *S. pneumoniae* is the most likely pathogen, although *S. pyogenes* and *K. pneumoniae* may produce a similar picture.
 3. **Abscesses** are caused by staphylococci or, if putrid, anaerobic infection. **Pneumatoceles** may be seen with staphylococcal and other bacterial childhood pneumonias, and gram-negative infection in newborns.
 4. **Bronchopneumonias** (diffuse, patchy infiltrates) are usually **nonbacterial** in origin.
- C. **Management often is empiric** because clinical, laboratory, and radiographic features often cannot be used to distinguish between the possible causes.

1. Diagnosis

a. **Sputum culture is not useful in infants and young children.**

b. Nasopharyngeal secretions are used for **antigen detection** and **viral cultures**. Tests to detect bacterial antigens in the urine are not useful because they lack both sensitivity and specificity. **PCR** is promising but not widely available.

c. **Serologic studies** can provide a retrospective diagnosis.

d. **Cultures of blood and pleural fluid** are specific, but infrequently positive.

e. **Bronchoscopy** is reserved for those with serious illness, underlying diseases such as immunosuppression, and suspected obstruction or foreign body aspiration.

2. **Hospitalization.** The decision to hospitalize often is difficult. It should be considered for the very young, and those with immunosuppression, serious underlying disease, toxicity or hypoxemia, multilobar bacterial infection, significant pleural effusion, inadequate oral intake, failed outpatient care, or a family that is unable to cope.

3. **Antibiotic selection** is based on the chest radiograph, age of the child, host characteristics, and the Gram stain results of any pleural fluid or other available material. Amoxicillin, amoxicillin-clavulanate, a macrolide, or cefuroxime are appropriate for outpatients. Hospitalized patients should be given i.v. cefotaxime or cefuroxime; high-dose ampicillin and ampicillin-sulbactam are alternatives. Vancomycin is used if high-level penicillin-resistant pneumococci (see section I.C), MRSA, or meningitis are suspected [32]. A macrolide is added if atypical pathogens are suspected. Tetracyclines should not be used in children under 8 years of age, and the fluoroquinolones should not be given to patients under 18 years of age [128]. **If viral infection is suspected, antibiotics should be withheld.**

4. Children with recurrent severe bacterial infections or infection with an unusual organism may need to be evaluated for the presence of an immunologic defect.

XI. *S. aureus* causes only 1% to 10% of CAP, but up to 16% of hospital-acquired pneumonias [129]. It deserves emphasis because of its high mortality.

A. Settings

1. Most cases of staphylococcal **CAP** occur as a complication of influenza (see Chapter 10), in the elderly, or in those with significant underlying pulmonary or other illness; some patients may be nursing home residents.

2. **Nosocomial *S. aureus* pneumonia** occurs in hospitalized, debilitated patients. **Risk factors favoring MRSA** are prolonged hospitalization, serious underlying cardiopulmonary disease, and prior antibiotic use [129].

B. **Radiographic manifestations** of staphylococcal pneumonia are varied. **Children with a rapidly progressive pneumonia, pneumatoceles or abscesses, and early pleural involvement** are likely to have staphylococcal infections. In adults, infiltrates are often bilateral and multilobar. Pleural effusions are common, as are empyemas. **Embolic pneumonias** often have a circular appearance and may progress to central cavitation.

- C. Therapy** is given i.v. for 2 to 3 weeks. Vancomycin is used initially, but proven methicillin-sensitive *S. aureus* infection should be treated with oxacillin or nafcillin, 9 to 12 g/day in the adult and 200 mg/kg/day in children divided every 4 to 6 hours. Cefazolin may be used if it is not contraindicated for penicillin-allergic patients (see Chapter 27). Vancomycin is used for serious penicillin allergy or MRSA, which generally responds less well [129]. Linezolid and quinupristin/dalfopristin are alternatives to vancomycin.
- D. Isolation.** Droplet precautions are indicated during the first 24 to 48 hours of therapy.

PNEUMONIA AND BIOTERRORISM

The United States suffered its first use of anthrax for bioterrorism in the wake of the terrible events of September 11, 2001 [130]. Although this event used the mail to target journalists and politicians, future episodes may not be confined to the same risk groups. This section briefly reviews the features of those bacterial respiratory infections most likely to be used as part of a bioterrorist event [2]. Updated information is available on the CDC website (www.bt.cdc.gov), and local authorities.

- I. Anthrax** is caused by the spore-forming aerobic gram-positive rod *Bacillus anthracis*. Aerosol delivery provides the most danger, with the majority of cases presenting as **inhalational anthrax**. Cutaneous (see Chapter 4) and gastrointestinal anthrax also occur.
- A. Pathogenesis [131,132]. Inhalation of *B. anthracis* endospores** does not usually cause a true pneumonia [2]. The minimal infectious dose is unknown but must be relatively low, particularly when compared with the median lethal dose (LD₅₀) of 2,500 to 55,000 inhaled spores [132]. Spores are 1 to 5 μm in diameter, and if processed correctly may be dispersed for long distances by wind or other air currents. After gaining access to the alveoli they are transported to mediastinal and other regional nodes by alveolar macrophages. Germination and bacterial multiplication ensue, and hematogenous dissemination may lead to sepsis and meningeal involvement. The organism possesses an antiphagocytic capsule, protective antigen, lethal factor, and edema factor. Lethal toxin, formed by lethal factor binding to protective antigen, stimulates the release of inflammatory mediators and inhibits intracellular signaling by inactivating mitogen-activated protein kinase. Edema toxin, formed by edema factor binding to protective antigen, impairs cellular water homeostasis and can inhibit neutrophil function. Hemorrhage, edema, and necrosis ensue.
- B. The incubation period** is variable, but **may be prolonged**. Most cases that followed the accidental airborne release of anthrax spores in the 1979 outbreak in Sverdlovsk occurred 9 to 10 days after exposure [133]. However, fatal cases also occurred up to 6 weeks later. This and primate data led to recommendations of 60 days of prophylactic or therapeutic antibiotics [130].
- C. Clinical manifestations [131,134–136].** Inhalational anthrax is a biphasic illness.
- 1. Early signs and symptoms suggest an influenza-like illness (ILI).** Combinations of fever, chills, fatigue or malaise, nonproductive cough, nausea or vomiting, weakness, and chest discomfort predominate. Laboratory studies are equally nonspecific. Clinical features, in addition to the epidemiologic setting, help distinguish ILI from anthrax [137]. **Sore throat and rhinorrhea are common in ILI**, whereas chest discomfort, pleuritic chest pain, and nausea or vomiting are more frequent in anthrax. Chest radiographs are usually normal in ILI, but abnormal in anthrax (see section **I.D**).
 - 2. The next phase is heralded by progressive respiratory signs and symptoms**, which may occur after a short period of improvement. Patients have **dyspnea, worsened cough, and diaphoresis**. Sepsis syndrome and evidence of meningitis may be present. Laboratory studies may reveal **leukocytosis with left shift, elevated transaminases, and hypoxemia**. In this phase **death may occur within hours or days**.
- D. Radiographic studies provide important diagnostic clues** and may be abnormal early.

1. **Chest radiographs were abnormal on admission** in each of the initial 10 bioterrorism-related cases in the United States, although abnormalities may be overlooked [135]. Characteristic findings include **mediastinal widening, paratracheal or hilar enlargement, and pleural effusions**. Infiltrates may be present, particularly in the sickest patients [134,135]. Effusions or infiltrates may occur initially without mediastinal widening.
 2. **Chest CT is more sensitive than chest radiography in detecting the extent of mediastinal involvement**. Based on the initial experience, **early CT scanning is encouraged** when inhalational anthrax is considered possible [130,136].
- E. Diagnosis** [138]. Inhalational anthrax can be diagnosed quickly only with a high degree of suspicion.
1. **Blood cultures** should be obtained on all patients before the initiation of antibiotics.
 2. **Gram stain of buffy coat smears** may provide a rapid clue to the diagnosis, but the sensitivity of this procedure is unknown [134].
 3. **Pleural fluid** should be obtained when effusions are present, and Gram stained and cultured. Fluid is characteristically hemorrhagic with elevated protein and relatively few leukocytes. A positive Gram stain rapidly suggests the diagnosis. PCR is performed and a cell block for immunohistochemistry analysis is taken if results of other studies are negative.
 4. **CSF** should be obtained when there is a question of meningeal involvement. Fluid is frequently bloody with positive Gram stains [131].
 5. **Bronchoscopy** may provide a diagnosis if there are radiographic infiltrates [135].
 6. **Special studies for nonculture diagnosis**, including immunohistochemistry and PCR, are available through local public health authorities and the CDC. Serologic testing for IgG antibodies to the protective antigen is also available at the CDC and may be helpful in difficult cases.
 7. **Rapid diagnostic tests for influenza** should be considered.
 8. **Nasal swab cultures are of no value** for diagnosis or exclusion of this disease [139].
- F. Therapy for inhalational anthrax.** Early effective therapy is essential in improving outcome. The choice of antibiotics depends on the extent of illness and the susceptibility profile of the infecting strain. All the strains involved in the fall of 2001 had the same sensitivity pattern. This is in part the basis for the following recommendations [132,140].
1. A cephalosporinase and an inducible penicillinase are included in the *B. anthracis* genome, so that **cephalosporins and penicillins should not be used alone** [130].
 2. **Initial therapy. Combination i.v. antibiotics are recommended for initial treatment** of all patients with inhalational anthrax. The same treatment regimens listed below also are indicated for immunocompromised and pregnant hosts [132,140]. With mass casualties, oral therapy may be the only option [132].
 - a. **Adults** [140]
 - (1) **Either ciprofloxacin 400 mg every 12 hours or doxycycline 100 mg every 12 hours** should be used with one or two additional drugs (see below). Ciprofloxacin is preferred if meningitis is present because of better penetration.
 - (2) **Other active agents** that may be used in combination with ciprofloxacin or doxycycline include rifampin, vancomycin, penicillin, ampicillin, chloramphenicol, imipenem, clindamycin, and clarithromycin. It has been suggested but not proven that clindamycin has an antitoxigenic effect [136].
 - (3) **A successful initial regimen** is ciprofloxacin, rifampin, and clindamycin [136].
 - b. **Children** [132,141]. Because of the gravity of the infection and potential for penicillin failure, i.v. ciprofloxacin or doxycycline are also recommended for children.

- (1) **Either ciprofloxacin 10 to 15 mg/kg every 12 hours (maximum of 1 g/day) or doxycycline** should be used with one or two additional drugs [see section I.F.2.a.(2)]. Ciprofloxacin is preferred if meningitis is present, as noted above. The **dose of doxycycline** is 100 mg every 12 hours for children over 8 years of age and weighing over 45 kg, and 2.2 mg/kg every 12 hours for children weighing less than 45 kg or those under 8 years of age (maximum dose of 100 mg).
 - (2) Experience with other fluoroquinolones in children is limited.
3. **Continued therapy and duration.** All patients should receive antibiotics **for a total of 60 days** because of the potential for late germination of persistent spores.
 - a. **Adults may be switched to oral therapy** when there has been continued clinical improvement [140]. Ciprofloxacin 500 mg twice daily or doxycycline 100 mg twice daily to finish the 60 days is acceptable alone [135] or with rifampin [141].
 - b. **Children also may be switched to oral therapy** when there has been clinical improvement [141]. **Either ciprofloxacin 10 to 15 mg/kg every 12 hours (maximum of 1 g/day) or doxycycline** (oral doses equivalent to i.v. doses above) **should be continued for the first 14 to 21 days**, with or without another agent. **Amoxicillin may be used for sensitive isolates to finish the remainder of the 60 days** because of the potential for side effects with prolonged use of ciprofloxacin or doxycycline in children [141].
 4. **Adjunctive measures** include drainage of pleural effusions, and mechanical ventilation or other support in an intensive care unit. Steroids have been used for patients with extensive edema, respiratory compromise, and meningitis [140].
 5. Since **person-to-person transmission does not occur**, patients with inhalation anthrax may be cared for in routine hospital rooms using standard precautions.
- G. Prognosis.** The outcome from inhalational anthrax has been dismal, with a mortality rate in prior reports of 86% to 97% [130]. However, only 4 of the initial 10 United States patients in 2001 died [135]. Possible reasons for the improved survival rate include heightened awareness, use of newer diagnostic studies, early antibiotic combination therapy, and modern supportive care [135]. Patients who postpone seeking therapy, who are seriously ill at presentation, or who have effective treatment delayed have a worse prognosis [134].
- H. Antibiotic prophylaxis is indicated following airborne exposure** because of the serious nature of this illness. **The standard duration of prophylaxis is 60 days for individuals with a proven exposure risk** because of the potential for a prolonged incubation period. Because the inoculum is low, **penicillins are expected to be effective for prophylaxis** even though they are not recommended for treatment [141]. At least 32,000 individuals began prophylaxis after September 2001, and 5,000 were candidates for the full 60-day course [142]. **Appropriate law enforcement and public health authorities should be notified** [139].
1. **Adults** may be given either **ciprofloxacin 500 mg orally twice daily or doxycycline 100 mg orally twice daily** [143]. However, some prefer doxycycline because of concern about fluoroquinolone resistance with long-term and widespread ciprofloxacin use.
 2. **Pregnant women should be given ciprofloxacin** in the doses above, and doxycycline should be avoided [144]. **If the isolate is penicillin sensitive, then amoxicillin 500 mg orally three times daily** is an alternative.
 3. **Infants and children should be given oral amoxicillin 80 mg/kg/day** in three divided doses (maximum of 500 mg per dose) for penicillin-sensitive isolates [141].
 4. **Breast-feeding women should be given amoxicillin 500 mg orally three times daily** if the isolate is penicillin susceptible [141]. If amoxicillin is contraindicated, then ciprofloxacin or doxycycline may be used and the breast milk discarded [141].
 5. Initial surveillance efforts found **adherence and side effects with prophylaxis** to be similar to prior reported experience [142].

6. **Three options can be offered at the end of the 60-day course**, particularly for those individuals with high-level exposure and who were adherent with antibiotics [145]:
 - a. **Monitoring for illness after finishing 60 days of antibiotic prophylaxis.**
 - b. **Continued antibiotic until day 100**, with monitoring for illness and adverse drug reactions, because of the theoretic risk for illness up to 100 days after exposure.
 - c. **Anthrax vaccine** (three doses given over 4 weeks) **plus an additional 40 days of antibiotic prophylaxis.** Vaccine is available only as an “investigational new drug” through designated clinics. Informed consent and follow-up investigations are required.
7. **Future events may result in modification of these recommendations;** up-to-date information should be obtained from local, state, and federal public health officials.

II. Plague is caused by the gram-negative coccobacillus *Yersinia pestis*. Pneumonic plague is a potentially lethal disease that can be transmitted from person to person. This makes it useful for bioterrorism, which was recognized long before the biology of plague was understood [146]. Other forms of the disease are septicemic and bubonic plague.

- A. **Pathogenesis of pneumonic plague.** Plague persists as a worldwide enzootic infection of rats and other rodents [146]. *Y. pestis* is transmitted to its human host as **bubonic plague** through the bite of a flea. The majority of cases develop fever with acutely inflamed regional lymph nodes (buboes) 2 to 8 days after the original flea bite. A few patients develop primary septicemic plague with or without buboes. **Direct inhalation of the organism, from bioterrorism or via droplets from a patient with plague pneumonia, leads to primary pneumonic plague. Secondary pneumonic plague** occurs when the lung is involved by **hematogenous spread** from either bubonic or septicemic plague.
- B. **Clinical manifestations** [147]. Primary pneumonic plague usually has an incubation period of 2 to 4 days, ranging from 1 to 6 days [147]. **Illness begins abruptly**, and may have a fulminant course. Patients may have fever, chills, rigors, dyspnea, cough, malaise, and myalgias. Nausea, vomiting, diarrhea, or abdominal pain may be prominent in some patients. **Sputum is often bloody.** Physical examination would be expected to reveal a bubo only in secondary pneumonic plague. **Chest radiographs are nonspecific, showing patchy infiltrates or consolidation** that may be bilateral. Progression to death may be rapid, with sepsis, disseminated intravascular coagulation, and multisystem organ failure; this is not specific for plague but may be seen in any severe pneumonia.
- C. **Diagnosis of primary plague pneumonia** depends on a high index of suspicion.
 1. **Clinical clues** to the possibility of plague pneumonia as the result of bioterrorism include the clustered occurrence of severe pneumonias, the presence of hemoptysis and sepsis, and the rare finding of a cervical bubo [147].
 2. **Microbiological studies are very helpful. Gram stains** (or Wright, Giemsa, and Wayson stains) of sputum, blood, or bubo aspirate may reveal the characteristic bipolar staining of this small gram-negative bacillus or coccobacillus. The organism grows on standard media and in routine blood cultures.
 3. **Immunofluorescent stains** are diagnostic when available through public health laboratories. Immunoassay to detect the F1 antigen also may be helpful but is not readily available. PCR can be diagnostic as well but is not standardized.
- D. **Management** [147]. **Presumptive therapy should be started as quickly as possible for exposed patients who have a compatible illness.** Failure to respond may be an indication of antibiotic resistance, rare in natural infection.
 1. **With contained casualties, streptomycin** (30 mg/kg/day in 2 i.m. doses) **or gentamicin** (5 mg/kg/day i.v. or i.m., or 2 mg/kg load followed by 1.7 mg/kg every 8 hours i.v. or i.m.) **are preferred for adults and children with normal renal function.** Acceptable alternatives include i.v. doxycycline, ciprofloxacin, or chloramphenicol. Gentamicin is preferred in pregnancy. Immunocompromised patients are given one of these same treatment regimens. The duration of therapy

is 10 days, and may be finished orally (see section **II.D.2**) after the patient has clearly improved.

2. **With mass casualties, only oral therapy may be available.** Ten days of **doxycycline or ciprofloxacin** should be used to treat adults and children, with chloramphenicol an alternative except in children under 2 years of age. The doxycycline dosage is 100 mg twice daily for adults and children weighing at least 45 kg, and 2.2 mg/kg twice daily for children weighing less than 45 kg [147]. Ciprofloxacin dosage is 500 mg twice daily in adults, and 20 mg/kg twice daily in children. Doxycycline should be avoided if possible in children under 8 years of age. Doxycycline is preferred for the treatment of pregnant women in the setting of mass casualties.
3. **Prophylactic oral antibiotics should be given to all asymptomatic exposed individuals.** Doxycycline is preferred for this purpose, with the same restrictions and alternatives as listed for treatment of mass casualties. Patients should take prophylaxis for 7 days, and immediately report any fever or cough. The same prophylaxis is recommended for immunocompromised patients [147].
4. **All patients with plague should be placed in droplet isolation until after the first 48 hours of effective therapy and there is clinical improvement, or until pulmonary involvement is excluded.**
5. Supportive care in a critical care setting is often required.
6. **Public health authorities should be notified immediately** so that contacts may be traced and any needed vector control measures instituted.

III. Tularemia is caused by the pleomorphic gram-negative coccobacillus *Francisella tularensis*. The United States and former Soviet Union weaponized this agent, although the United States destroyed its biologic weapons arsenal by 1973 [148]. Clinical forms include ulceroglandular, glandular, oculoglandular, typhoidal, pneumonic, and oropharyngeal [149].

- A. **Pathogenesis.** Tularemia is a widespread zoonosis of small mammals, including rabbits. The organism may be transmitted to a human host by the bite of a tick or fly, and by direct contact with or ingestion of infected animals, excreta, water, soil, and vegetation. Tularemia pneumonia may result from direct inhalation of the organism (primary pneumonia), or from hematogenous spread to the lungs as a consequence of one of the other clinical forms. **Bioterrorist use would result in aerosol exposure, and most subsequent cases are expected to be primary pneumonic tularemia** [148]. However, such an exposure also could result in other forms of tularemia by the organism penetrating the skin (ulceroglandular, glandular, or typhoidal), conjunctivae (oculoglandular), or oral mucosa (oropharyngeal). Natural outbreaks of primary tularemia pneumonia are more likely to occur in a rural setting [148,150].
- B. **Clinical manifestations from a bioterrorism aerosol exposure** [148]. The incubation period for primary tularemia pneumonia is expected to be 3 to 5 days, and ranges from 1 to 14 days [148]. There would be a cluster of patients with the **abrupt onset** of a nonspecific febrile illness. **Progression to frank clinical pulmonary involvement may be rapid or subacute**, with the onset of dyspnea, cough without prominent sputum, and pleuritic chest pain. **Chest radiographs often show subsegmental or lobar infiltrates** that may involve more than one lobe, **pleural effusions, and hilar adenopathy**. Rounded densities, miliary changes, or cavitation are less common [149]. Pleural fluid studies are often similar to those found in tuberculous effusions [149]. Respiratory failure, sepsis, multisystem organ failure, and death may occur.
- C. **Diagnosis.** Results from routine laboratory studies are nonspecific, and rapid diagnostic tests for tularemia are not readily available [149].
 1. **Clinically**, the occurrence of a cluster of patients with unexplained atypical pneumonia, pleural involvement, and hilar adenopathy should raise suspicion.
 2. **Routine microbiologic specimens** including blood cultures should be submitted, and the laboratory alerted to the possibility of *F. tularensis* infection because it is fastidious and potentially dangerous to them. **Gram-stained smears of respiratory secretions** may help differentiate this illness from inhalational

- anthrax and plague pneumonia [148]. Definitive diagnosis is established by culture identification of the organism in clinical specimens.
3. Fluorescent antibody stains, antigen detection, and PCR techniques are available in only a few specialized laboratories but can provide a specific and rapid diagnosis [148].
 4. **Serologic assays are not useful acutely**, because increasing titers require 10 or more days. With a longer duration of illness, a diagnostic fourfold or greater increase in titer may occur between acute and convalescent specimens. A single tube agglutination titer of at least 1:160 or a microagglutination titer of at least 1:128 supports the diagnosis in the presence of a compatible clinical illness.
- D. Management of tularemia resulting from a bioterrorism event** [148]. Treatment regimens may need to be adjusted if susceptibility studies reveal antibiotic resistance.
1. **With contained casualties, therapy is similar to that listed for plague.** The total duration of treatment is 10 days with the aminoglycosides or ciprofloxacin, and is 14 days with doxycycline or chloramphenicol to reduce relapses. Treatment may be finished orally.
 2. **With mass casualties, oral therapy with doxycycline or ciprofloxacin is similar to that listed for plague**, except the duration is 14 days. Ciprofloxacin is preferred for the treatment of pregnant women in the setting of mass casualties [148]. Streptomycin or gentamicin is preferred for immunocompromised patients if possible.
 3. **Asymptomatic exposed individuals seen in the incubation period for tularemia should receive prophylaxis** with 14 days of either doxycycline or ciprofloxacin, with the same restrictions as listed for treatment of mass casualties. However, delayed discovery of a covert tularemia bioterrorism event may be more likely. In this circumstance prophylaxis is withheld and antibiotic treatment begun if a potentially exposed person develops an unexplained fever or flu-like illness within 2 weeks of the last presumed exposure [148].
 4. **Person-to-person transmission does not occur**, so standard precautions are used.
 5. **Hospital infection control and local public health authorities should be notified immediately** of any case of suspected or confirmed tularemia.

PARAPNEUMONIC EFFUSION AND EMPYEMA

Parapneumonic pleural effusion is pleural fluid found in association with pneumonia, lung abscess, or bronchiectasis [151]. An **empyema** is grossly infected or purulent fluid (pus) in the pleural space. **All complicated parapneumonic effusions and empyemas require drainage.**

I. Parapneumonic effusions

- A. Parapneumonic effusions progress through three pathologic stages** [151]. The initial stage is the exudative stage, when fluid is free-flowing and with relatively low numbers of neutrophils. Early exudative parapneumonic effusions are often sterile, and appropriate therapy in this stage will avoid the necessity for tube drainage. The fibropurulent stage occurs next with an increase in fluid, the influx of neutrophils, and an increasing chance for bacterial invasion. Glucose and pH decrease, and LDH increases. Fibrin is deposited on pleural surfaces with a tendency for fluid loculation, making effective bedside drainage very difficult. The final stage is organization. Pleural fluid is thick, and fibroblast growth into loculations results in a visceral pleural peel entrapping lung and requiring surgical decortication.
- B. Thoracentesis should be performed when there is at least 10 mm of pleural fluid on a lateral decubitus film**, and fluid sent for the following studies [151].
 1. **Differential cell counts.** High counts of **polymorphonuclear leukocytes suggest bacterial infection**, and an alternative etiology should be sought if this is not found [151]. A high percentage of small lymphocytes may be seen in tuberculosis and malignancies. Mesothelial cells are uncommon in tuberculous effusions. Uncommonly, 5% to 20% eosinophils are seen, but this is a nonspecific finding

associated with pneumothorax, hemothorax, Hodgkin disease, Churg-Strauss syndrome, benign asbestos effusion, drug reactions, and paragonimiasis.

2. **Chemistries. Glucose** may be reduced with pneumonia, malignancy, tuberculosis, hemothorax, paragonimiasis, and Churg-Strauss syndrome; it may be very low in effusions from rheumatoid arthritis. Tuberculous effusions may, on occasion, have normal glucose levels. **LDH** levels help classify parapneumonic effusions [151].
 3. **pH.** The pH of the pleural fluid may help distinguish complicated from benign effusions (see section **D**). Pleural fluid samples should be placed in wet ice, transported to the laboratory, and processed immediately. **A pleural fluid pH of less than 7.2 occurs in** effusions associated with bacterial infections, tuberculosis, esophageal rupture, malignancy, rheumatoid arthritis, hemothorax, urinorhorrax, paragonimiasis, Churg-Strauss syndrome, and systemic acidosis. The cause of pleural fluid acidosis in the absence of systemic acidosis is primarily leukocyte metabolism, but bacterial metabolism also may contribute. In empyemas caused by some *Proteus* species, the pH may be normal or high because of the urea-splitting activity of the bacteria.
 4. **Cultures. Gram stains with aerobic and anaerobic** cultures should be performed routinely. If tuberculosis and fungal infections are considered, one should obtain and centrifuge large volumes of fluid and then culture the sediment.
- C. Thoracic CT** scanning will help determine whether fluid is loculated or whether pleural fibrosis has occurred, localize fluid for drainage, and assess the underlying lung.
- D. Classification and management** [151,152]. Parapneumonic effusions are classified using radiographic and pleural fluid results. All effusions at least 10 mm thick on the lateral decubitus film require thoracentesis.
1. **Class 1 effusions are termed nonsignificant.** These are free-flowing effusions that are less than 10 mm thick on the lateral decubitus film. No thoracentesis is indicated.
 2. **Class 2 effusions are termed typical parapneumonic.** Fluid is free flowing and not purulent, with negative smears and cultures, a glucose level of greater than 40 mg/dL, pH greater than 7.2, and LDH less than 1,000 IU/L. **Therapeutic thoracentesis** should be done, and repeated if fluid rapidly recurs or the patient remains ill with a significant effusion.
 3. **Class 3 effusions are termed borderline complicated.** These have **either** a fluid pH between 7.0 and 7.2, an LDH of greater than 1,000 IU/L, or loculations even though the glucose level is greater than 40 mg/dL and smears and cultures are negative. **Serial therapeutic thoracentesis should be performed if the fluid is not loculated.** Tube drainage is indicated if the pH and glucose levels decrease and the LDH level increases, but not if these values normalize. **If a previously loculated fluid persists or the patient remains ill after an initial therapeutic thoracentesis, then chest tube drainage is required.** A thrombolytic can be instilled into the tube to try to improve tube drainage.
 4. **Class 4 effusions are termed simple-complicated.** These effusions are not loculated and do not appear purulent. However, the glucose level is less than 40 mg/dL, pH is less than 7.0, and results of Gram stain or culture are positive. **Either repeated thoracentesis or chest tube drainage is indicated.** If glucose, pH and LDH are improving on repeat thoracentesis, then serial thoracentesis can suffice. If glucose and pH remain low, tube drainage is needed.
 5. **Class 5 effusions are termed complex-complicated.** They are loculated, but otherwise meet the description of simple-complicated effusions. They should be **managed with chest tube insertion and intrapleural thrombolytics.** If drainage is not complete after one to two thrombolytic doses, surgical intervention is needed.
 6. **Class 6 effusions are termed simple empyemas.** These are either free flowing or confined to a single loculus. **Large-bore chest tube drainage** is indicated. Surgical decortication will be needed if an empyema cavity persists despite tube drainage.

7. **Class 7 effusions are termed complex empyemas.** Initial management of these multiloculated empyemas includes multiple large-bore chest tubes with intrapleural thrombolytics. Nonetheless, **thoracoscopy or thoracotomy is often required.**

II. Pleural empyema [153,154]. An empyema is **pus in the pleural space.** Some patients may be very toxic with an empyema, while others may have only low-grade fever. When frank pus is found, pleural fluid gram stain and cultures are important but glucose, pH, and LDH are not needed.

A. The underlying causes for empyemas include the following:

1. **Pulmonary infections** (pneumonia, aspiration pneumonia, and lung abscess)
2. **Postthoracotomy**
3. **Direct spread of infection** (e.g., from an abdominal or orofacial source)
4. **Esophageal rupture**, suggested by a fluid pH less than 6.0 or an increased amylase [155]
5. **Idiopathic**, believed to be the result of a pneumonia that has since resolved
6. **Hematogenous spread** (uncommon in adults but more frequent in children)

B. Bacteriology. Bacteria vary with age and predisposing conditions. Mixed infections are frequent, and organisms producing β -lactamases are often isolated.

1. **Anaerobes** play a significant role in empyemas complicating aspiration pneumonia, lung abscess, oropharyngeal infection, and intestinal infection. These include *Bacteroides* species, *Prevotella* species, *Fusobacterium nucleatum*, and *Peptostreptococcus* species, often in combination. Mixed aerobic and anaerobic infections are common.
2. **Aerobic bacteria.** Although once common, *S. pyogenes* is now seen less frequently. In contrast, pneumococci continue to be an important cause of empyema. *S. aureus* and aerobic gram-negative bacilli are common pathogens in postthoracotomy patients and in patients with nosocomial pneumonias. The importance of *H. influenzae* type b empyemas in children has been diminished by the protein-conjugate vaccine.

C. Management. The principles of empyema management are to control infection, minimize morbidity and hospitalization, and maximize resultant lung function.

1. **Adequate drainage.** Because pus in the pleural cavity represents infection in a closed space, **drainage is always necessary.** Only rarely is adequate drainage achieved by daily thoracentesis. Usually fluid is too thick or loculated, and image-guided chest tube drainage is necessary. If there is poor response in the first 24 hours and the patient is stable, then instillation over 2 to 3 days of intrapleural thrombolytics may be tried. Repeat imaging studies should be followed to assure complete drainage and a reduction in the cavity size. When this fails, early surgical intervention is indicated.

Video-assisted thoracoscopy may help break down loculations, provide for thorough irrigation, allow visual placement of drainage tubes, and may obviate the need for open thoracotomy. Even with careful patient selection, 10% to 20% of VATS procedures need to be converted to thoracotomy [154].

2. **Antibiotics** are initiated on the basis of the Gram stain findings and the clinical setting, and altered on the basis of culture results [153,155]. Empiric regimens for empyemas associated with pneumonia should provide aerobic and anaerobic coverage, while postthoracotomy empyemas require coverage for *S. aureus*, *P. aeruginosa*, and other aerobic gram-negative bacilli. In general, if adequate drainage can be achieved quickly, the authors will use i.v. antibiotics for approximately 14 days. However, the actual duration of therapy will depend on the underlying source, causative organisms, clinical response, and duration of significant pleural drainage or effusion. Because antibiotics achieve adequate levels, there is no need for intrapleural antibiotics [153]. However, bioavailability of aminoglycosides and some β -lactams in empyema fluid is poor [153,155]. Thus, it is best that aminoglycosides not be used alone to treat gram-negative empyemas.

3. **Bronchopleural fistula** may occur in association with empyemas or complicated parapneumonic effusions. **Rapid adequate percutaneous drainage is essential to prevent escape of purulent material into the bronchial tree and for cure. The initial clue is an air-fluid level in the pleural cavity.** Other

causes of an air-fluid level in infection include a ruptured esophagus and rupture of an underlying lung abscess. Gas formation from microbial growth is an uncommon cause, so that another explanation should be sought. CT scans are helpful in separating pleural from intraparenchymal air-fluid levels. Confirmation is achieved by placing the chest tube to water seal (i.e., bubbling is seen). Thoracic **surgical consultation is advised**.

LUNG ABSCESS

Lung abscess is a suppurative cavitary lesion in the lung parenchyma surrounded by inflammation and necrosis. Most lung abscesses are at least 2 cm in diameter when recognized, and may not contain an air-fluid level. Necrotizing pneumonia, an earlier manifestation of the same pathophysiologic process, consists of multiple small cavities within areas of acute consolidation. Pulmonary gangrene, the extreme manifestation of this process, is distinguished by extensive lung necrosis [156]. Mycobacteria and fungi (e.g., histoplasmosis and coccidioidomycosis) also can cause cavitating lung disease. Tuberculosis is discussed later in this chapter, and fungal infections are discussed in Chapter 17.

I. Types of lung abscesses. Primary lung abscess is due to a primary necrotizing lung infection. Secondary lung abscess is the result of an extrapulmonary infection that has spread to involve the lung, such as embolic abscesses from right-sided endocarditis. Lung abscesses can be further separated into the following categories:

A. Anaerobic. These are **due to aspiration of oropharyngeal organisms**. Most involve two to three anaerobes, and may include a nonanaerobic species. *Bacteroides* species, *Prevotella intermedia*, *P. melaninogenica*, other *Prevotella* species, *F. nucleatum*, *Veillonella*, and peptostreptococci are common. Frequent nonanaerobes are *Streptococcus intermedius*, and other microaerophilic and aerobic streptococci.

B. A specific abscess follows a necrotizing pneumonia due to a single organism, such as *K. pneumoniae*, *P. aeruginosa*, other gram-negative bacilli, *Legionella* species, *S. aureus*, *Nocardia* species, or *Actinomyces*. Melioidosis and paragonimiasis are more important causes of lung abscess in parts of the world other than the United States.

C. Septic emboli may result in abscess formation. Important sources include intravascular, pelvic, orofacial, gastrointestinal, and urinary infections. Organisms include *Fusobacterium necrophorum* from septic jugular vein phlebitis (Lemierre syndrome), *Bacteroides fragilis* from pelvic or intraabdominal infections, and *E. coli* from urinary, biliary, or gastrointestinal tract infections.

D. Infected lung bullae pose a special clinical problem [157]. Infection is a secondary phenomenon and does not cause lung necrosis. Illness is milder than with lung abscess; duration of symptoms is shorter; putrid sputum is rare, and normal leukocyte counts are common. The radiographic hallmark is an air-fluid level in a preexisting emphysematous bulla with minimal surrounding infiltrate. Response to penicillin suggests that oral anaerobic and aerobic bacteria are the causative organisms. Improvement with oral antibiotics and chest physiotherapy is prompt, and bronchoscopy and other invasive procedures are not indicated [157].

II. Clinical presentation and microbiology

A. Anaerobic lung abscesses often occur with poor dental hygiene and **risks for aspiration** (see section I.G.2 under Clinical Approach to Community-Acquired Pneumonia).

- Poor dental hygiene** allows for a high-titered inoculum **with aspiration** [158]. After aspiration, chest film evidence of an abscess takes 7 to 16 days to appear. **Anaerobic abscess is uncommon in the edentulous patient** unless there is a predisposing pulmonary disorder.
- Predisposing pulmonary disorders** include bronchogenic carcinoma or other bronchial obstructions, bronchiectasis, and pulmonary infarction [158]. COPD does not predispose to anaerobic lung infections.
- Symptoms** of cough, production of sputum (which often has a foul odor), weight loss, and malaise may be present for several days to weeks or months. Symptoms are **insidious and prolonged** compared with those of the typical bacterial pneumonia.

4. The patient with a lung abscess on roentgenography that does not fit the preceding description may have one of the secondary forms discussed next.
- B. Aerobic lung abscesses** most often result from necrotizing pneumonia. Patients with *S. aureus* or gram-negative pneumonias (which may be nosocomial) are usually acutely ill. Occasionally, the presentation is indolent and similar to an anaerobic abscess.
- C. Embolic pneumonias** are suggested by the clinical setting and blood culture results.
- D. Other causes.** Unusual bacteria, tuberculosis, other mycobacteria, fungi, and non-infectious causes are considered when patients do not fit the preceding categories.
- III. Diagnosis.** Useful diagnostic studies are those that verify the clinical impression and help identify infections due to resistant or unusual organisms.
- A. Radiographic appearance.** Aspiration-induced **anaerobic abscesses** involve the right lung more often than the left, and usually are found in dependent segments. These are the posterior segments of the upper lobes and the superior segments of the lower lobes when supine, and the basal segments of the lower lobes when upright. **Embolic abscesses** are suggested by multiple round cavities in the lower lobes (higher blood flow). **Airway obstruction** is suggested by atelectasis, a mass, or a foreign body. Hilar adenopathy, parapneumonic effusions, empyemas, and bronchopleural fistulas occur with any type. Prior films may demonstrate evolution of acute infiltrates to abscess formation.
- Concealed lung abscesses** are not evident on routine chest radiographs because of extensive infiltrates or effusions, inadequate drainage, or failure to obtain an upright view. They comprise up to 18% of lung abscesses, and are found by CT scan, surgery, or autopsy [159,160]. Delay in recognizing the true nature of the lung pathology may prove fatal [159].
- B. Elastin fibers in sputum** indicate a necrotizing infection [122], but this has not found wide clinical utility. One cannot predict which pneumonia will lead to a lung abscess.
- C. Sputum collection and evaluation**
1. **Expectorated sputum**
 - a. Sputum and breath often have a **foul odor in anaerobic** lung abscess.
 - b. **Gram-stained smears of expectorated sputum are useful.** Findings with anaerobic abscess include neutrophils, and a mixture of gram-positive and gram-negative organisms with no predominant type. In contrast, aerobic abscesses show a predominant morphology (e.g., *S. aureus* or aerobic gram-negative bacilli).
 - c. **Cultures of expectorated sputum are of little value** because they are inadequate for anaerobes and often contaminated with potentially pathogenic aerobes [158].
 - d. **Specimens for mycobacteria, fungi, and Legionella** studies may be necessary in selected patients with an unclear etiology or an atypical clinical course.
 2. **Invasive procedures.** Transtracheal aspirates, bronchoscopy with PSB or BAL for quantitative cultures, and percutaneous lung or abscess puncture provide specimens suitable for both anaerobic and aerobic cultures. Appropriate specimen handling is critical [158].
- Invasive procedures usually are unnecessary** with anaerobic abscess because the clinical diagnosis is reliable and the microbiology is predictable [161]. They may be helpful if an adequate expectorated specimen is unobtainable, if a delay in specific therapy is potentially life threatening, or if an unusual or resistant organism is suspected. Pulmonary consultation is advised.
- D. Blood cultures** should be obtained in febrile patients or when embolic pneumonia is possible (e.g., addicts, endocarditis, and intraabdominal or pharyngeal space infections).
- E. Acid-fast smears** help exclude *Mycobacterium*, although air-fluid levels are infrequent in tuberculosis. Some patients at risk for aspiration are also at risk for tuberculosis (e.g., alcoholics). The diagnosis of fungal pneumonia is discussed in Chapter 17.

F. Thoracentesis should be performed if sufficient quantities of pleural fluid are detected.

G. Fiberoptic bronchoscopy should not be routine [162], but is indicated for suspected cavitating carcinoma or bronchial obstruction, and significant hemoptysis. Absence of fever or systemic symptoms, no predisposing factors for lung abscess, no leukocytosis, and minimal or no surrounding infiltrate suggest underlying lung cancer [162].

IV. Management. Successful treatment is initially indicated by a rapid decrease in any foul odor to the sputum, an improved appetite, and the return of a subjective sense of well-being. Fever from anaerobic abscess should abate within the first week [58], but this may take up to 2 weeks. Large amounts of purulent sputum may continue for several weeks, but Gram stains should reveal a marked decrease in organisms. Chest radiographs first show a reduction in the surrounding infiltrate and a decrease in cavity fluid, but initially the cavity may enlarge as necrotic lung is expectorated.

A. Abscess drainage is essential.

1. Drainage usually occurs through the tracheobronchial tree. If the patient is raising sputum and is improving clinically and radiologically, drainage is adequate. Cautious chest physiotherapy and postural drainage should be reserved for patients having difficulty with secretions to minimize the risk for endobronchial spread of infection and respiratory failure.

2. Percutaneous catheter drainage [163]. This is particularly suitable when urgent drainage is needed because of life-threatening sepsis or a large fluid-filled abscess ($\geq 4\text{--}6$ cm) with a significant risk for aspiration of cavity contents, cough is ineffective, medical therapy fails, or the risk of surgical intervention is too great. Image guidance permits placement to avoid uninvolved pleura and lung, the detection of loculations, and an assessment of the drainage.

3. Surgery is required in only a few circumstances. Common indications include significant hemoptysis, suspected or proved lung cancer, abscess rupture with pyopneumothorax, and failure of medical therapy or catheter drainage.

4. Obstruction to drainage is suspected with unexplained deterioration, abrupt decrease in sputum production or tube output, or increasing amounts of cavity fluid.

B. Antibiotics are the mainstay of therapy (adult doses shown below).

1. Anaerobic abscess. Many oral anaerobes are **increasingly resistant to penicillin** due to penicillinase production.

a. Penicillin G alone has proven inferior in prospective, randomized trials [58].

b. Clindamycin resistance occurs in some *Peptostreptococcus*, *Sutterella*, *Fusobacteria*, non-perfringens *Clostridia*, and *Bacteroides* species [158].

c. Metronidazole should not be used alone because of a high clinical failure rate [58,158]. Metronidazole is relatively inactive for some *Sutterella*, anaerobic cocci, microaerophilic streptococci, *Actinomyces*, and *Propionibacterium* strains [158]. Long-term metronidazole may be complicated by its disulfuram-like interaction with alcohol, and peripheral neuropathy (see **Chapter 27**).

d. Alternative agents active against anaerobes but with less published clinical experience include ampicillin-sulbactam, amoxicillin-clavulanate, ticarcillin-clavulanate, piperacillin-tazobactam, cefoxitin, imipenem, meropenem, gatifloxacin, moxifloxacin, and chloramphenicol. Disadvantages include their very broad coverage, expense, and potential for uncommon but serious toxicities (e.g., seizures with imipenem, and aplasia with chloramphenicol).

e. Drugs that have limited anaerobic activity include the antistaphylococcal penicillins, ceftazidime, erythromycin and other macrolides, fluoroquinolones other than gatifloxacin and moxifloxacin, TMP-SMX, the tetracyclines, aztreonam, and the aminoglycosides [58,158].

f. Suggested regimens include higher doses of i.v. penicillin G (10–20 million units/day) to cover relatively resistant organisms [158] plus either oral or i.v. metronidazole (500 mg every 6 hours) or i.v. clindamycin (600 mg every 8 hours). In one study 21% of anaerobes were resistant to penicillin, 12%

resistant to metronidazole, and 5% resistant to clindamycin; however, almost all the anaerobes were susceptible to the combination of penicillin and metronidazole [161]. When the patient has been afebrile for at least 3 to 5 days, one can switch to oral therapy with penicillin V (750 mg four times daily), and either metronidazole or clindamycin (300–450 mg four times daily).

2. **Aerobic lung abscesses. Combination i.v. therapy is used initially for aerobic gram-negative necrotizing lung infections**, and based on local resistance patterns. Infectious disease consultation is advised. Coverage for MRSA and resistant gram-negative bacilli such as *P. aeruginosa* are often necessary. Antibiotic therapy should be narrowed when susceptibility studies are available. Therapy for embolic abscesses depends on the organism and the underlying focus (i.e., endocarditis).
3. **Duration of therapy. Oral therapy may be substituted** when there is clear and sustained improvement. In general, aerobic abscesses require longer i.v. therapy than anaerobic abscesses. **Antibiotics are continued** until there is a return to the usual state of health, sputum is minimal and not purulent, there is no infiltrate surrounding the cavity, the cavity has healed or is a stable thin-walled scar, and the ESR or C-reactive protein is normalized. **The optimal duration of total antibiotic therapy must be individualized**, and several months may be required to meet these goals.

C. Complications and outcome

1. **Empyema** can complicate lung abscess, with or without a **bronchopleural fistula**.
2. **Hemorrhage into the cavity** is suggested by hemoptysis and rapidly fluctuating air-fluid levels. An obstructing blood clot may be present, although hemorrhage alone may mimic obstruction.
3. **Aspiration of abscess contents** can cause rapid deterioration or sudden death.
4. Brain abscess, clubbing, and amyloidosis are rare in the antibiotic era.
5. **Prognosis** depends on the underlying conditions and etiologic agents. In an aerobic lung abscess, mortality has been as low as 4% in the antibiotic era; the average time to maximum cavity closure is estimated at 65 days [58]. Mortality in aerobic lung abscess is higher, particularly in immunocompromised hosts. Risk factors for a worse outcome include multiple abscesses, an abscess larger than 6 cm, prolonged symptoms, obstruction, old age, and debilitating chronic disease.

TUBERCULOSIS: BASIC CONCEPTS

Tuberculosis remains a worldwide health problem and presents with sufficient variability to cause diagnostic confusion [164,165]. The focus of this chapter is on *Mycobacterium tuberculosis* in the United States and four important presentations: primary pneumonia, post-primary disease, pleurisy, and disseminated disease. Other extrapulmonary manifestations, therapeutic agents and their toxicity, and chemoprophylaxis also are discussed.

I. Epidemiology

- A. **In the United States**, *M. tuberculosis* infects an estimated 15 million persons. Tuberculosis reemerged between 1985 and 1992, and approximately 67,000 more cases occurred than would have been anticipated had the earlier rate of decline continued [166]. **Each year since 1992 the number of tuberculosis cases have declined**, to 16,377 cases in the year 2000 for a rate of 5.8 cases per 100,000 population [164,166]. **At the same time the numbers of foreign-born persons with tuberculosis, and their proportion of the total cases, have continued to increase**. Disease risk is highest within the first years after immigration [167]. Thus, control of tuberculosis in foreign-born individuals will be of major importance in meeting the goals for eliminating tuberculosis in this country [167,168].
- B. **Outside the United States**, tuberculosis remains a tremendous problem. It is estimated that one-third of the world's population, almost 2 billion persons, is infected with *M. tuberculosis*. From this reservoir come 8 million new tuberculosis patients and approximately 3 million deaths each year [164]. Thus, 95% of tuberculosis disease occurs in developing countries, where there are few medical or public health resources and where concomitant HIV infection is common [164].

II. Pathogenesis of tuberculosis

A. Overview

1. **Reservoir.** Although some animals are susceptible to *M. tuberculosis* infection, **humans** are the only important natural reservoir for this organism.
 2. **Transmission.** Spread of *M. tuberculosis* is almost exclusively by **small-particle aerosols termed droplet nuclei**, and rarely by contaminated dust or fomites. Airborne particles bearing organisms are generated by coughing, sneezing, and even speaking or singing [164]. Inhaled droplet nuclei, each containing two to three bacilli, are of sufficiently small size (1–5 μm) to be deposited into the alveolar space [164]. Although a single organism is sufficient to infect animals, most human infections follow exposures to many more droplet nuclei and bacilli. Transmission depends on the numbers of bacilli expelled, their concentration in the air over time, the duration of an exposure to contaminated air, and host immunity [164].
 3. **Primary infection** results from exposure to airborne organisms produced by someone with active pulmonary tuberculosis. Organisms reach the alveoli (most often in the middle or lower lung zones), multiply intracellularly in alveolar macrophages, and **silently spread through lymphatics to hilar or other regional lymph nodes, and then through the bloodstream** to many sites [169]. *M. tuberculosis* bacilli continue to grow at some of these sites for 2 to 12 weeks until, in an immunocompetent host, **cell-mediated immunity develops** [164]. At this time granulomas are formed and growth of organisms is inhibited, but they are not killed. Consequently, organisms that have been dormant can become reactivated [170]. **In approximately 5% of normal hosts the original infection cannot be contained, and clinical disease develops rapidly or within the first 2 years** [164]. In the remaining 95% the original infection is controlled and remains subclinical.
 4. **Postprimary reactivation infection.** Clinical disease develops in 5% of immunocompetent persons at a time remote from the initial infection as a result of endogenous reactivation of a previously established quiescent focus [164]. **The preferential sites for reactivation are those of persistently high oxygen tension.** These include the **superior lung segments (except anterior), kidneys, bones, and CNS.**
 5. **Postprimary exogenous reinfection** occurs because protection following a previous infection is incomplete and may wane over time, even in immunocompetent patients [171]. The frequency of exogenous reinfection varies with the risk for infection [172]. With low risk, postprimary tuberculosis almost always is reactivation disease [172]. However, reinfections contribute to tuberculosis in HIV-infected persons, and may account for a significant proportion of adult disease in areas of the world with high rates of tuberculosis [173,174].
- B. The role of cellular immunity. Impairment of cellular immunity predisposes to development of clinical disease** due to progressive primary infection, exogenous reinfection, or from reactivation infection. The **major host defense against *M. tuberculosis* is the macrophage-lymphocyte system**, which is influenced by host genetic factors [169,175,176]. *M. tuberculosis* infection elicits a **Th1-type immune response** involving interferon- γ and tumor necrosis factor α (TNF- α) that activates macrophages to become more bactericidal through the generation of reactive nitrogen intermediates, and leads to granuloma formation [169,170]. The importance of TNF- α has been emphasized by the recognition that use of infliximab, an anti-TNF- α monoclonal antibody, is associated with the development of active tuberculosis, including extrapulmonary and disseminated disease [177]. **Analogous immunologic events also are responsible for many of the clinical findings in tuberculosis** [169]. Fever, anorexia, and weight loss may be mediated by cytokines induced by the infection. Tissue destruction and caseous necrosis are caused by altered cellular reactivity to the organism, or tissue delayed-type hypersensitivity. Understanding the critical differences in the pathways leading to protective immunity and tissue destruction will be essential for vaccine development.

C. **Organism factors** play a role in the development of disease, but these are poorly understood. Strains vary in their ability to be transmitted and cause infection, elicit cytokines, and grow in animals and macrophages [178–180]. However, genetic analysis of at least one hypertransmissible *M. tuberculosis* strain has not yielded clues to strain virulence [178].

III. Purified protein derivative (PPD) skin test [164,181]. Cellular immunity is inferred from a positive reaction to an intradermal antigen (delayed-type hypersensitivity). Antigen stimulates memory cells, which elaborate factors that attract uncommitted mononuclear cells to the area. These begin to accumulate at 24 hours and are fully manifest after 48 and 72 hours, accounting for the time the test is read.

A. The recommended method for skin testing is intradermal inoculation into the forearm of tuberculin PPD. This is available in only the 5-TU strength. In the United States and Canada, this strength is measured in tuberculin units (TU) and is based on achieving a biologic equivalence to the standard PPD preparation, PPD-S.

1. Intermediate-strength PPD contains 5 TU in the 0.1 mL injected. **All recommendations for interpreting skin testing are based on using this strength.**

2. Multiple puncture devices should not be used for diagnostic purposes [164].

B. The maximum diameter of induration at 48 to 72 hours is measured transversely to the long axis of the forearm using palpation and inspection in oblique and direct light. A ballpoint pen method may be used to reduce interobserver variation [164].

C. Interpreting the reaction. False-negative responses occur on initial testing in up to 25% of patients with active pulmonary tuberculosis [164]. False-positive reactions may result from infection with nontuberculous mycobacteria or from recent bacille Calmette-Guérin (BCG) vaccination. Thus, **three separate cut points for positivity have been defined** to optimize sensitivity and specificity for the test in different patient populations.

1. Five millimeters or more of induration is considered positive in persons with the highest likelihood of developing active disease. These include patients with close contact with active tuberculosis, radiographic findings consistent with old tuberculosis, HIV infection, organ transplants, and immunosuppression equivalent to taking more than 15 mg of prednisone daily for at least 4 weeks.

2. Ten millimeters or more of induration is considered positive in those who do not meet the preceding criteria but who are at high risk for tuberculosis. These include recent (<5 years) immigrants from countries where tuberculosis is prevalent; HIV-negative injection drug users; residents and employees of high-risk congregate settings such as prisons, nursing homes, health-care facilities, residential facilities for persons with HIV/AIDS, drug treatment centers, and homeless shelters; mycobacteriology laboratory personnel; persons with high-risk medical conditions, including silicosis, diabetes, chronic renal failure, leukemias and lymphomas, carcinoma of the head or neck and lung, more than 10% loss of ideal body weight, gastrectomy, and jejunoileal bypass; children under 4 years of age; infants, children, and adolescents exposed to high-risk adults; those with a recent (within 2 years) conversion of their skin test result; and any other locally identified high-prevalence population.

3. Fifteen millimeters or more of induration is considered positive in anyone.

D. Booster effect. A prior skin test in a previously sensitized individual may provide an immunologic boost that leads to an increase in induration from a negative to a positive interpretation (see section III.C), and thus mimic a skin-test conversion from recent infection. The booster effect may be seen within 1 week of an initial test, and the effect may persist for 1 year or longer. It may be found in individuals who have latent tuberculosis and waned PPD responsiveness, those who have previously received the BCG vaccine, or those previously exposed to nontuberculous mycobacteria [164]. It rarely occurs in children and becomes more important with

increasing age. **The clinician needs to be particularly aware of the booster effect in** annual screening programs involving serial skin tests, and serial skin tests performed for diagnostic or other purposes.

A two-step skin test to detect the booster effect is recommended for use in programs where repeated skin testing is anticipated [164]. If the initial PPD skin test result is negative, it is repeated in 1 to 3 weeks. The second skin test serves as the baseline response.

E. Causes of negative skin test reactions [164]. Subcutaneous or other inadequate injections, and use of impotent tuberculin preparations, should be excluded.

1. **The most common cause is the absence of infection with *M. tuberculosis*.**
2. **False-negative skin test results may occur with** recent or overwhelming tuberculosis; tuberculous pleurisy; acute nontuberculous infections (especially acute viral infection); live virus vaccinations; lymphoma or leukemia; sarcoidosis; other immunosuppressive diseases or drugs; renal disease; poor nutrition; newborn or advanced age; surgery; and burns.
3. **Anergy testing is no longer recommended** to identify tuberculosis infection or to help interpret a negative PPD test result [164,181].

F. Skin-test conversion

1. Conversion from a negative to positive reaction is an **increase of 10 mm or greater induration on a subsequent test** [164,181]. For persons who undergo repeated testing (e.g., health-care workers), **recent conversion** is defined as an increase of 10 mm or greater induration **within a 2-year period** and indicates recent tuberculous infection [164,181].
2. **False skin test conversion** may occur from the booster effect (see section III.D), concurrent infection with *Brucella* or other intracellular organisms resulting in nonspecific enhancement of tuberculin skin test reactivity, or correction of the cause for a prior false-negative skin test result giving the erroneous impression of skin test conversion even when there has simply been a return to baseline skin test reactivity.

G. Skin testing is targeted for populations at high risk for tuberculosis and thus candidates for preventive therapy [164,181]. These include groups at risk for recent *M. tuberculosis* infection, and those at increased risk for progression to active disease no matter the duration of infection (see sections III.C.1 and III.C.2). It also is appropriate for patients with findings compatible with tuberculosis but no definitive diagnosis. **Skin testing is discouraged for low-risk persons.**

IV. Diagnosis. The cornerstone of diagnosis is the presence of acid-fast bacilli (AFB) on smears from sputum and other clinical specimens, and the isolation of *M. tuberculosis* on culture.

A. Smears and cultures [164]. **Early morning sputum is best, and three specimens are sufficient.** All specimens usually test positive in untreated patients.

1. **Sputum induction using nebulized saline** is helpful for those unable to expectorate.
2. **Fiberoptic bronchoscopy** with bronchial washings, BAL, or biopsy may be needed when spontaneous or induced sputums fail to provide diagnostic specimens. **Expectorated sputums also should be collected in the immediate postbronchoscopy period, the next morning, and on subsequent days when available** because they may be the only positive samples.
3. **AFB smears** are discussed in Chapter 25. At least three AFB must be seen to consider a smear positive, using either a fluorochrome or a carbol-fuchsin method. **Screening with the fluorochrome stain is preferred** because it is easier and faster to read.

Sputum must contain 5,000 to 10,000 bacilli/mL before smears are reliably positive [164]. The estimated organism burden is 10^2 to 10^4 in fibronodular lesions, and 10^7 to 10^9 in cavitary lesions. Thus, **cavitary disease is usually smear positive and contagious.**

4. **Gastric aspirates and urines for smear and culture.** Aspiration of early morning gastric contents before the patient has eaten or arisen from bed may be used for children and adults from whom sputum cannot be obtained. The

first voided morning urine is the preferred specimen, and should be repeated on three separate days [164]. Because smears cannot distinguish saprophytic from pathogenic mycobacteria, smears of gastric aspirates and urines usually are not used. A review of a 10-year experience that excluded HIV-infected patients found only one possible false-positive urine smear and no false-positive smears of gastric aspirates, suggesting that positive acid-fast smears of gastric aspirates or urines are helpful [182]. However, smears from urine frequently test negative and may not be cost effective [164].

5. **Cultures may be positive when smears test negative** because cultures require only 10 to 100 viable organisms to become positive [164]. Thus, patients with negative smear results but positive cultures are four to five times less infectious than patients with positive smear results [183]. Nonetheless, smear-negative patients may still transmit tuberculosis [183].

6. **Time delay of cultures**

- a. **Solid media.** Approximately **3 to 8 weeks are required** for visible growth on traditional solid media, and another 3 to 4 weeks for susceptibility test results.

- b. **Automated liquid culture systems reduce the average detection time to 1 to 3 weeks** [164]. These systems also provide results for susceptibility testing to commonly used drugs in much shorter times than when using solid media [164].

7. **Rapid identification of any acid-fast growth** is generally accomplished using DNA probes to hybridize with mycobacterial ribosomal RNA. Probes are commercially available that identify the *M. tuberculosis* complex, the *M. avium* complex, *M. kansasii*, and *M. goodii*. High-performance liquid chromatography also may be used but is not as widely available. Investigational techniques include spoligotyping, polymerase chain restriction analysis, and DNA sequence analysis [164].

- B. **Newer rapid diagnostic methods** include nucleic acid amplification techniques, immunologic techniques, and tests to detect mycobacterial cellular components [164,184].

1. **Nucleic acid amplification (NAA) tests** are available to detect *M. tuberculosis* directly in clinical specimens [164,184,185]. The amplified mycobacterium tuberculosis direct test (MTD, Gen-Probe) and the Amplicor mycobacterium tuberculosis test (Roche Diagnostic Systems) use different techniques but have similar utility. Both detect nearly all sputum smear-positive and half of the smear-negative cases of culture-proven pulmonary tuberculosis [164,184]; only the MTD test has been approved by the U.S. Food and Drug Administration (FDA) for use with smear-negative sputum specimens [185]. Although a negative NAA test never excludes the possibility of tuberculosis, patients whose sputum is repeatedly AFB smear positive and NAA negative may be presumed to have nontuberculous mycobacterial infection if inhibitors are not found [185].

NAA tests should not replace routine AFB smears and cultures or clinical judgment [185]. The best way to use these expensive and technically demanding tests has not been defined, but the CDC and others have made preliminary proposals [184,185]. NAA tests may yield positive results even after successful chemotherapy because they can amplify nucleic acids from dead organisms [164]. Thus, they should be used only for diagnosis and not to follow therapy.

2. **Immunologic techniques for diagnosis** are being pursued in order to improve on the detection of both latent and active tuberculosis. These techniques include developing improved antigen mixtures for skin testing, identifying *in vitro* lymphocyte responses to *M. tuberculosis*, and developing improved methods of serodiagnosis [184,186]. It is hoped that current investigations will lead to improved immunodiagnosis for tuberculosis, and that this will help in future vaccine trials [186].

- V. **Clinical forms of tuberculosis.** Four important forms of tuberculosis are discussed below: primary tuberculous pneumonia, postprimary (reactivation) disease, pleurisy,

and disseminated (miliary) disease. Some of these can appear in combination. Therapy is discussed in section VII.

- A. Primary tuberculous pneumonia.** After initial inhalation (see section II.A.3), a symptomatic **primary pneumonia**, often with ipsilateral hilar adenopathy, occasionally develops, particularly at the extremes of age. Atelectasis may result from lymph node enlargement, particularly in young children. If the primary pneumonia progresses despite delayed hypersensitivity, it may be associated with cavitation or dissemination infection (progressive primary disease) [164,169].
- 1. Clinical manifestations.** Patients may have only a cough or may be very ill with high fever and inanition, depending on their age [169]. Sputum volume may be large and often contains abundant polymorphonuclear leukocytes.
 - 2. Diagnosis.** Skin test results frequently are negative. **Sputum AFB smear results often are highly positive.** Radiographic features may include lobar consolidation, cavitory disease with middle or lower zone infiltration, hilar adenopathy, and atelectasis.
 - 3. Communicability is potentially high** because of the large numbers of organisms in the sputum. Thus, **proper respiratory isolation is essential.**
- B. Postprimary (reactivation) tuberculosis is marked by upper lobe disease that often includes cavitation.** This usually occurs many months or years after the primary infection. Upper lobe disease also may quickly follow a primary infection if host immunity is insufficient, either with or without lower lobe involvement [169]. Infiltration is most common in the apical and posterior segments of the upper lobes and the apical segments of the lower lobes, and usually evolves to include air-filled cavities. Noncavitory nodules or infiltrates are more common in the elderly and the immunosuppressed. At this stage, the process almost always steadily progresses unless treated. Bronchogenic spread may involve lower and middle lobes, and may be bilateral.
- 1. Clinical manifestations.** Most individuals are moderately ill with anorexia, fatigue, productive cough, night sweats, fever, weight loss, and weakness. Sputum may be blood streaked. In some, the illness can be very severe, whereas in others with extensive parenchymal involvement, symptoms are minimal or nonexistent. Physical findings are nonspecific, and abnormalities in the chest may be minimal despite extensive disease. Large cavities may produce amphoric breath sounds.
 - 2. Diagnosis.** The chest roentgenogram may not readily show early infiltrates or distinguish active from inactive disease, and cannot yield a specific diagnosis; chest CT can provide further supportive information in difficult cases. A first-morning sputum sample should be sent for acid-fast smear and cultures (see Chapter 25); if the initial smear is negative, then a total of three (but no more than five) specimens should be examined. Sputum should be induced using nebulized hypertonic saline when spontaneous specimens are not produced. If this is unsuccessful, then fiberoptic bronchoscopy should be considered (see section IV.A). If bronchoscopy is not an option, then gastric aspirates should be sent. Three first-morning urine specimens also should be obtained when genitourinary involvement is suspected or when sputum smears are negative.
 - 3. Communicability is high** before therapy because of the large numbers of organisms in cavitory disease. **These patients should be placed in respiratory isolation.**
- C. Tuberculous pleurisy** may be a manifestation of either primary infection or post-primary disease. It also occurs as part of disseminated disease either alone or with simultaneous effusions in the pericardial and peritoneal spaces (tuberculous polyserositis). In the past, tuberculous pleurisy was more common in younger individuals as a consequence of recent infection. However, at present it is more common in older individuals [169]. Tuberculous pleural effusions are due to the breakdown of a subpleural focus releasing its contents into the pleural space, followed by acute inflammation from a cell-mediated hypersensitivity reaction [187]. In contrast, tuberculous empyema results when a bronchopleural fistula spills the contents of a cavity or other parenchymal focus into the pleural space [164].

1. **Clinical manifestations.** Onset of pleural involvement may be insidious or abrupt, and occasionally patients are very ill. **Symptoms may be minimal or include some combination of cough, fever, pleuritic chest pain, and dyspnea** [187]. Evidence for pleural effusion may be present on chest examination, although a pleural friction rub is usually not present. On chest radiography the effusion usually is unilateral and small, and infiltrates are not seen in approximately 30% of patients [164].

Tuberculous pleural effusions are self-limited, resolving spontaneously within several months. Without treatment the risk of subsequent clinical tuberculosis is high, developing in up to two-thirds of patients within the next 5 years [187]. Thus, **antituberculous chemotherapy is always indicated** to prevent active disease at other sites even though it may not shorten illness from pleurisy. A short course of corticosteroids has been proposed to speed recovery and fluid resorption, and prevent pleural fibrosis [169]. However, a recent systematic literature review failed to find sufficient evidence of a benefit from steroids [188], and complete thoracoscopic drainage leads to rapid improvement independent of corticosteroid use [189]. For these reasons **we do not recommend the routine use of corticosteroids for tuberculous pleurisy.**

2. **Diagnosis.** Unless pulmonary tuberculosis is also present, diagnosis of tuberculous pleurisy requires thoracentesis and usually a pleural biopsy. Diagnosis may be delayed if the patient has other potential causes for an effusion [190].

- a. **Pleural fluid** is an exudate with a predominance of lymphocytes; neutrophils may be prominent, however, particularly early in the illness [169,187]. Mesothelial cells should not constitute more than 5% of the total cell count. Glucose levels are most often normal but may be low. **Acid-fast smears of the pleural fluid are almost always negative.** The yield from pleural fluid cultures is usually less than 25%, but is highest when large-volume specimens are submitted and centrifuged [164,187].

- b. **Pleural biopsy.** A single biopsy procedure (collecting three or four tissue samples) **sent for histology, and acid-fast stains and cultures** will provide positive findings in approximately 67% of cases. This increases to approximately 90% after a second biopsy [190]. A combination of pleural fluid studies plus pleural biopsies for histology, acid-fast stains, and cultures should establish the diagnosis in 90% to 95% of patients. Biopsy directed by **pleuroscopy increases the yield** from a single procedure [164].

- c. **Skin tests.** The **intermediate PPD** is usually positive but **may be negative in up to 30% of patients** [187]. However, most patients with an initial negative test result eventually develop a positive reaction during therapy.

- d. **Other pleural fluid diagnostic tests** that have been proposed include PCR, measurement of adenosine deaminase levels, and interferon- γ levels [191]. These tests are not generally available and their value is uncertain, particularly in the United States where tuberculosis accounts for only a small proportion of exudative pleural effusions [164,187].

3. **Communicability** depends on the presence of concomitant pulmonary tuberculosis.

D. Disseminated (miliary) tuberculosis implies widespread disease due to failure to contain the organism. This can occur either as part of a primary infection or as a manifestation of postprimary tuberculosis. In the former, *M. tuberculosis* hematogenously spreads from the primary lung focus and continues to grow in multiple organs. In the latter, previously contained foci break down and allow hematogenous dissemination (see section II). On pathologic examination these sites are granulomatous nodules 1 to 2 mm in size that grossly resemble millet seeds, and thus the term *miliary tuberculosis* was applied to mean disseminated disease [164]. **Factors predisposing to dissemination include** extremes of age, minority race, malnutrition, measles, pertussis, AIDS, alcoholism, diabetes, pregnancy, malignancies, and immunosuppressive diseases or therapies [169].

1. **Clinical aspects.** There are no pathognomonic clinical features of disseminated disease, and the **onset of illness may be abrupt or very insidious.** Although cough and other respiratory symptoms may be present, **constitutional**

symptoms usually predominate. Patients may simply exhibit fever, night sweats, anorexia, weight loss, and weakness [164]. Prominent headache suggests meningitis, pleuritic chest pain suggests pleurisy, and abdominal pain suggests peritonitis. Physical findings are variable, but common abnormalities (in decreasing order) are fever, wasting, hepatomegaly, chest findings, lymphadenopathy, and splenomegaly [164]. The presence of skin lesions, and scrotal or genital masses should be sought. Choroidal tubercles may be seen on retinal examination and are very supportive of the diagnosis (see Chapter 7). Occasional patients will be profoundly ill and may have respiratory failure or other signs of sepsis.

2. Diagnosis

a. Chest radiography

- (1) **The miliary radiographic pattern is diffuse, 2- to 4-mm nodular lesions,** but this may not be visible initially. Thus, repeat chest films should be obtained if the initial film is unremarkable.
- (2) **Nondiagnostic chest films. Overall 15% of patients with disseminated tuberculosis do not have the classic miliary pattern,** but in some series this has been as high as 50% [164]. **Unfortunately, the diagnosis is often delayed because it is not considered unless the miliary radiographic pattern is present.** This frequently has been observed in older patients with reactivation of a nonpulmonary focus (late generalized tuberculosis) presenting with fevers and no clear etiology [169].

b. Acid-fast smears and cultures. Because the organism is often growing in inaccessible sites, invasive procedures are frequently required. See Chapter 25.

- (1) **Sputum AFB smear results are positive in approximately 33% and,** at best, sputum cultures are positive in only 50% to 76% of patients with disseminated disease. Bronchoscopy with transbronchial biopsy should be considered in patients with abnormal chest radiographs but negative sputums.
- (2) **Gastric cultures** are positive in 33% to 75% of patients.
- (3) **Urine cultures** are positive in 25% to 59%, even with a normal urinalysis.
- (4) **Results of bone marrow biopsy** for cultures may be positive in up to 33% of patients. Histopathologic examination may reveal granulomas in more than 80%.
- (5) **Liver biopsy cultures are helpful, as is histologic appearance.** Supportive diagnostic material usually is found, provided there is some abnormality suggesting hepatic involvement prior to biopsy.
- (6) **Lymph node biopsy** should be considered whenever accessible adenopathy is present. This procedure is associated with little morbidity and frequently reveals caseating granulomas or positive acid-fast smears.
- (7) **CSF examination** should be performed in patients with headaches or neurologic symptoms suggestive of tuberculous meningitis (see Chapter 6).

c. Histologic study of organs sampled for biopsy may be very helpful. Typical granulomas with central necrosis may be seen, and acid-fast organisms may be visible.

d. Skin test results are often negative.

e. Blood tests. The WBC count is usually normal [169], but can range from leukopenia to a leukemoid reaction so striking as to suggest leukemia. Monocytosis, lymphopenia, thrombocytopenia, and anemia also may be present. Alkaline phosphatase and transaminases may be elevated, but jaundice is uncommon. Hyponatremia occurs with meningeal involvement or adrenal insufficiency.

3. Relationship to fever of unknown origin (FUO). Disseminated tuberculosis should be considered in the evaluation of FUO (see Chapter 1).

4. **Communicability** depends on the presence of significant pulmonary involvement.

VI. Extrapulmonary tuberculosis. When extrapulmonary tuberculosis occurs **in the absence of disease in the lung, the extrapulmonary infection is responsible for the major clinical manifestations.** It also may occur with simultaneous pulmonary tuberculosis or as part of disseminated infection (see section **V.D**). Extrapulmonary tuberculosis did not decline in frequency when pulmonary disease was declining. It is found most often in children, ethnic and racial minorities, women, foreign-born individuals, and patients with HIV infection.

A. Clinical presentation

1. **Symptoms or signs usually are localized,** with minimal or absent constitutional symptoms. Often the diagnosis is reached during evaluation of a specific problem such as pyuria, ascites, pericardial effusion, or lymphadenopathy.
2. **Systemic illness.** A small percentage of patients have constitutional symptoms associated with extrapulmonary disease. These patients usually have more widespread disease, or also have pulmonary involvement.
3. **Chest radiographic evidence of pulmonary disease is not always seen** when active infection is present in an extrapulmonary focus. Fewer than 50% of patients with lymph node, renal, CNS, or bone tuberculosis have chest film changes.

B. Forms of extrapulmonary disease. Pleural and disseminated tuberculosis are discussed in section **V**.

1. **Meningitis.** See Chapter 6.
2. **Pericarditis.** See Chapter 12 under Pericarditis and Myocarditis.
3. **Renal disease.** See Chapter 15 under Genitourinary Tuberculosis.
4. **Bone disease.** See Chapter 5 under Special Forms of Osteomyelitis.
5. **Lymph node disease.** Lymphatic tuberculosis is found in all age groups, although it is most common in children under 15 years of age, women, and foreign-born individuals.
 - a. **Clinical manifestations** vary with the extent of nodal involvement and underlying host characteristics [192].
 - (1) **Isolated lymph nodes** are usually nontender and firm, although there may be overlying erythema. The most common sites of involvement are the cervical (scrofula) and supraclavicular areas, but mediastinal, mesenteric, or retroperitoneal nodal tuberculosis is also possible [164,169]. Cervical lymph node disease, including breakdown and drainage, can occur with either minimal or no constitutional symptoms. Hilar adenopathy can develop without obvious lung disease, and patients are usually symptomatic [193].
 - (2) **Generalized lymph node involvement** usually is part of disseminated disease. Constitutional symptoms, fever, and weight loss are common. The initial clinical impression may be of a lymphoreticular neoplastic process.
 - (3) **Lymph node involvement due to drainage of an infected organ** is a more common cause of lymph node infection than is primary lymph node disease. Children with hilar or other mediastinal adenopathy may develop atelectasis.
 - (4) **Lymph node involvement with atypical mycobacteria** is more common than with *M. tuberculosis*. Submandibular or cervical adenopathy is often due to *M. scrofulaceum* in young children, and to *M. avium* complex in older children. This is distinct from lymph node involvement with disseminated *M. avium* complex infection in AIDS (see Chapter 18).
 - b. **Diagnosis. Fine-needle aspiration biopsy** is now advocated over total excisional biopsy as the initial procedure because it frequently supports a presumptive diagnosis with limited risk for complications when combined with modern chemotherapy. However, the microbiologic yield is low [164,169].
 - (1) **Histologic features.** Biopsy and culture of the lymph nodes often reveal the diagnosis. Although fine-needle aspiration may reveal epithelioid cells and granuloma, AFB stains are usually negative. PCR may

improve the ability to demonstrate *M. tuberculosis* in fine-needle aspiration specimens [194].

- (2) **Tuberculin skin test.** Lymph node disease is more common in younger than in older patients, and the skin test result is often positive.

6. **Serous surface involvement** (pleural effusion, pericardial effusions, and peritonitis) usually results from breakdown of a contiguous focus with discharge of its contents into the serous cavity of a previously sensitized individual. A significant inflammatory reaction ensues despite the presence of relatively few intact organisms.

- a. **Clinical manifestations.** Serous involvement can mimic serositis of unexplained etiology. The peritoneum, the pericardial sac, and, as already mentioned, the pleura may be involved either singly or in any combination.

- (1) **Pleural effusions** are discussed in section V.B.

- (2) **Pericardial effusions** are discussed in Chapter 12.

- (3) **Peritonitis.** Patients with tuberculous peritonitis usually present with insidious onset of fever, abdominal pain or swelling, anorexia, weight loss, and an exudative ascites. The ascitic fluid protein content usually exceeds 2.5 g/100 mL, the serum ascites albumin gradient (SAAG) is less than 1.1 g/100 mL, and the ascites contains fewer than 3,000 white cells with a lymphocyte predominance. Many patients with tuberculous peritonitis have preexisting ascites from liver cirrhosis so that symptoms are attributed to that process and the diagnosis delayed [164,169]. In cirrhotic patients with tuberculous peritonitis the ascitic fluid may retain many of the characteristics of ascites due only to portal hypertension (e.g., total protein <2.5 g/100 mL and SAAG >1.1 g/100 mL); however, an elevated ascitic fluid LDH level may be a useful clue [195]. It also should be considered in chronic peritoneal dialysis patients with refractory peritonitis [196]. In women, tuberculous peritonitis may mimic ovarian carcinomatosis, including elevation of CA-125 [197].

- b. **Spontaneous resolution.** Serous effusions that develop in tuberculosis may resolve spontaneously and, at least temporarily, leave no evidence of overt disease. However, very frequently (usually within a few months but occasionally as long as a few years) additional focal disease develops.

- c. **Diagnosis**

- (1) **Pleural effusions.** See section V.C.

- (2) **Pericardial effusions.** See Chapter 12 under Pericarditis and Myocarditis.

- (3) **Peritonitis.** Organisms are seldom seen on smears of peritoneal fluid. Large volumes of fluid can be centrifuged and cultured, but even this method results in a suboptimal yield. The diagnosis depends on demonstration of caseous granulomas in peritoneal tissue. Laparoscopy to obtain peritoneal biopsy specimens is the procedure of choice [164]. Associated pulmonary parenchymal abnormalities are seen in fewer than 50% of patients, although coexisting pleural effusions are not uncommon. Results of liver function tests usually are normal, and liver biopsies generally are not helpful. The PPD skin test result may or may not be positive. Therefore, **tuberculous peritonitis should be considered in any unexplained exudative ascites** regardless of the skin test result. Adenosine deaminase activity in ascitic fluid and PCR may be useful adjuncts to the diagnosis of tuberculous peritonitis.

7. **Skin.** Most often the skin is involved by direct spread from an underlying tuberculous focus such as epididymitis or adenitis. Hematogenous involvement of the skin is rare and usually occurs in patients with AIDS [169].

- VII. **Tuberculosis and HIV Infection.** HIV-infected patients are at increased risk for reactivation infection, progressive primary infection, and reinfection [173]. **Thus, counseling and HIV antibody testing should be considered for almost all patients diagnosed with *M. tuberculosis* infection.** This is particularly true for patients with extrapulmonary disease or unusual manifestations of pulmonary tuberculosis. Furthermore, documentation of a positive PPD test result in an asymptomatic patient

should serve as a stimulus to assess the risks for HIV, and to offer HIV education, counseling, and antibody testing. **See Chapter 18 for a further discussion of mycobacterial infections in HIV-infected patients.**

VIII. Tuberculosis in the elderly [198,199]. The growing elderly segment of our population contains a significant reservoir of latent tuberculosis acquired when the disease was more prevalent. Reactivation of these infections accounts for approximately 90% of tuberculosis disease in the elderly, although reinfections and new infections are also possible [199].

A. Several risk factors for active tuberculosis may be present in the elderly. These include immunosenescence and concomitant predisposing diseases or conditions. Another risk is confinement in a nursing home, where reactivation tuberculosis occurs in 2% to 3% of skintest-positive individuals.

B. Atypical clinical manifestations and delayed diagnosis are common in the elderly. Awareness of the possibility of tuberculosis is essential to prompt diagnosis. Symptoms often are poorly articulated, and coexistent illness may provide alternative explanations for anorexia, cough, and weight loss. Radiographic findings are frequently atypical and misinterpreted, including midlung or basal infiltrates. Miliary disease and many of the forms of extrapulmonary tuberculosis are more frequent in the elderly than in younger patients, and the mortality rate is higher in the elderly.

IX. Tuberculosis in pregnancy poses special problems. It is current opinion that pregnancy does not increase the risk for active tuberculosis, alter the manifestations of infection, change the outcome from clinical infection, or change the response to chemotherapy [200]. Active tuberculosis may have an adverse impact on maternal morbidity and pregnancy outcome if there is delayed diagnosis, advanced pulmonary disease, extrapulmonary disease in sites other than lymph nodes, and no or inadequate therapy [200]. However, **with early diagnosis and effective treatment the outcome for both mother and child is equal to that for nonpregnant patients.** Thus, tuberculosis during pregnancy is not an indication for therapeutic abortion. Congenital tuberculosis is rare; most neonates with tuberculosis acquire their infection in the postpartum period from an adult.

Skin testing is the mainstay of screening during pregnancy because of the need to avoid radiographic studies. **Skin testing is recommended in pregnancy only for women with risk factors for latent infection or for progression to active disease** [181]. Pregnancy does not significantly alter the skin test response, and tuberculin is safe during gestation [181]. A chest radiograph with appropriate shielding is indicated if the skin test result is positive. See also section X.

X. Management of tuberculosis. Practice guidelines have been published by the Infectious Diseases Society of America [201] for implementing recommended antituberculous therapy [166,181,202]. Current treatment is based on the observations that certain combinations of agents given for shorter periods of time are as effective as older regimens, and intermittent dosing is an effective alternative to daily therapy. **Directly observed therapy is important to achieve adherence** and reduce the risk for developing drug resistance.

A. Principles of tuberculosis therapy

1. Comprehensive management must include public health efforts. These involve monitoring for adherence, toxicity, efficacy, and relapse; tracing contacts and evaluating the home; and community surveillance for outbreaks and drug resistance.

2. Importance of combination therapy. Mutations causing resistance to antituberculous agents are infrequent, unlinked phenomena. The rate of spontaneous resistance is approximately 1 in 10^6 organisms for INH (INH), 1 in 10^8 organisms for rifampin, only 1 in 10^{14} organisms to both INH and rifampin simultaneously, 1 in 10^4 organisms for ethambutol, and 1 in 10^6 organisms for streptomycin. Thus, resistance is avoided by using combination regimens.

3. Microbiologic diagnosis should be attempted on all patients, and *M. tuberculosis* isolates should routinely undergo susceptibility studies [164,201].

4. Drug resistance. Inadequate therapy is the most common explanation.

- a. **Factors favoring the development of resistance** include the use of a single agent for active infection, erratic adherence to proper therapy, suboptimal drug dosing, malabsorption of drugs, or the failure to include enough active agents for partially resistant organisms. **Patients previously treated with regimens not containing both INH and rifampin are presumed to harbor strains of *M. tuberculosis* resistant to the previously used drugs until proven otherwise** [202].
 - b. **Detecting resistance** may be done using agar media (results take many weeks) or using the liquid BACTEC method for faster results. With the agar proportion method, resistance is defined as the growth on drug-containing media of 1% or more of the number of organisms growing on control media [164]. Laboratories may report results at both a “critical concentration” of drug (the concentration that reliably inhibits wild-type bacilli but not resistant mutants in the same inoculum) and a higher concentration. Although resistance is determined at the critical concentration, results at the higher concentration may be useful to assess the degree of resistance [164]. Rapid methods to identify genetic resistance determinants have been developed, and an assay detecting the *rpoB* gene mutations for rifampin resistance is commercially available in Europe [184]. However, resistance genotyping is not ready for clinical application in the United States at present [164].
- 5. Multidrug-resistant (MDR) tuberculosis in the United States has declined** since 1993, both in patients previously untreated and in those with prior tuberculosis [203]. However, MDR tuberculosis is prevalent and increasing in other parts of the world [204].
- a. **Definitions. MDR refers to organisms resistant to both INH and rifampin.** In **primary resistance**, the patient from whom the isolate is obtained has never received the involved drugs. In **secondary resistance**, the patient has been treated with the drugs to which the isolate is resistant.
 - b. **Epidemiology.** Contributing to MDR strains are poor adherence to therapy, homelessness, crowding in jails and other institutions, the HIV epidemic, diminished public health resources, and immigration from areas with high rates of drug resistance. Past outbreaks of MDR tuberculosis have occurred in hospitals, prisons, congregate settings (e.g., homeless shelters), and other facilities. Nosocomial MDR tuberculosis in major urban areas has centered around HIV-infected patients (see Chapter 18). Failure to identify and isolate patients promptly, as well as premature discontinuation of isolation, has contributed to outbreaks.
 - c. **At least three active new agents should be used** when MDR tuberculosis is suspected or proven [202].
- 6. Directly observed therapy (DOT) is optimal** for all patients [166]. In DOT a health-care worker or other reliable person watches the patient take his or her medications.
- B. Treatment regimens.** The choice of agents depends on the local incidence of drug resistance. A four-drug regimen is used initially for the first 8 weeks of therapy when INH resistance is 4% or greater [202]. The continuation phase of therapy should include INH and rifampin for susceptible organisms. Recommended treatment regimens are effective for pulmonary and extrapulmonary forms of tuberculosis.
- 1. Regimens for initial empiric therapy**
 - a. **Four drugs are preferred** for almost all patients [169]. INH, rifampin, pyrazinamide, and either ethambutol or streptomycin are given for the first 8 weeks.
 - b. **Three drugs** may be used when local INH resistance rates are lower than 4% [202]. INH, rifampin, and pyrazinamide are given for the first 8 weeks.
 - c. **When resistance to multiple agents is prevalent**, five or six drugs should be used based on the known patterns of susceptibility in the community.
 - 2. Options to continue therapy for susceptible organisms** (i.e., organisms susceptible to INH, rifampin, and standard drugs)

- a. INH and rifampin may be used for the remaining 4 months of a minimum 6-month regimen. See section **IX.C.2** for the use of intermittent therapy.
 - b. Intermittent therapy with the initial four-drug regimen may be used to complete a minimum of 6 months of treatment (see section **IX.C.2**).
3. **Continuation therapy when susceptibilities are unavailable** is based on the clinical and radiographic response to treatment and the probability for resistance. Consultation with a tuberculosis expert is advised.
 4. **Treatment for resistant organisms must be individualized.** Patients with isolated INH resistance may be treated with rifampin, pyrazinamide, and ethambutol for a minimum of 6 months [166]. Patients with isolated rifampin resistance may be treated with INH, pyrazinamide, and streptomycin for a minimum of 9 months, or INH and ethambutol for a minimum of 18 months [166]. Isolated resistance to pyrazinamide is rare in *M. tuberculosis*, and should suggest infection with *M. bovis* because this organism is inherently resistant to this agent. However, *M. tuberculosis* strains resistant only to pyrazinamide have been reported recently in North America [205]. **Resistance to both INH and rifampin poses particular difficulties** because simultaneous resistance to other drugs is common. Most cases of MDR tuberculosis can be cured with intensive and prolonged chemotherapy combined with surgery when needed [166,206]. **Consultation with an expert in the therapy of MDR tuberculosis is advised.**
 5. **Addition of drugs to an existing regimen.** When there is concern about resistance or an inadequate response, at least two, and preferably three, new drugs should be added together. The addition of only one drug to a regimen to which resistance has occurred may result in resistance to the new drug as well.
- C. Frequency of drug administration**
1. **Daily therapy** was the standard for many years. Oral agents usually are given once daily in the fasting state in the morning.
 2. **Intermittent therapy may be given 2 or 3 times weekly.** Because fewer doses of medications are used, **all patients receiving intermittent regimens must be carefully supervised using DOT to ensure adherence.** The toxicities of intermittent and daily regimens appear similar. Because fewer doses and less monitoring for efficacy are needed, the cost of intermittent regimens usually is less than that of daily therapy. There are three options for intermittent therapy [166,202].
 - a. After daily therapy for the first 8 weeks with three or four drugs (see section **X.B.1**), INH and rifampin may be given two or three times weekly for a minimum of 16 weeks. This is used only when isolates are known to be susceptible to both of these drugs.
 - b. After daily therapy for the first 2 weeks, the four-drug regimen may be given twice weekly for the next 6 weeks. Twice-weekly INH and rifampin may be continued for a minimum of 16 more weeks, when isolates are known to be susceptible to both of these drugs.
 - c. The four-drug regimen may be given three times per week for a minimum of 6 months when isolates are known to be susceptible to INH and rifampin.
- D. Duration and type of therapy**
1. **Standard short-course regimens.** These have replaced longer courses as the **treatments of choice for tuberculosis for organisms susceptible to INH and rifampin.** The success of the 9-month regimen depends on the use of INH and rifampin together, and the 6-month regimen depends on the inclusion of pyrazinamide for the initial 2 months. The optimal use of short-course therapy requires familiarity with those situations for which it is not suitable (see section **X.D.2**).
 - a. **Six-month therapy.** The ATS and CDC have adopted minimum 6-month regimens as standard therapy for pulmonary tuberculosis [202]. This duration also is suggested for most cases of extrapulmonary tuberculosis. Treatment is given for a minimum of 6 months and for at least 3 months after sputum cultures become negative.

- b. Nine-month therapy.** Experience with the 9-month regimen has shown it to be effective for pulmonary and most extrapulmonary tuberculosis. It is used for susceptible organisms when INH and rifampin must be given alone or without the initial use of pyrazinamide.
- 2. Exceptions. Standard regimens should not be used in the following circumstances:**
- a. Suspected or proved INH resistance.** This may include patients from countries with a high incidence of primary INH resistance, those failing standard therapy, those who relapse after taking INH without rifampin, and close contacts of a patient with INH-resistant tuberculosis [202].
 - b. When rifampin is not used.** An older regimen should be chosen for these patients when isolates are susceptible (see section **X.D.4**).
 - c. When INH is not used.** Rifampin plus ethambutol for a minimum of 12 months is recommended for susceptible organisms [202].
 - d. When neither INH nor rifampin is used.** Three or four drugs to which the organism is susceptible are required for a minimum of 18 months.
 - e. In the presence of significant hepatic disease.** In such a case, ethambutol plus either INH or rifampin may be chosen. However, studies to date indicate minimal additive hepatic toxicity when patients with lesser degrees of liver disease are treated with INH plus rifampin [202].
 - f. With renal insufficiency.** Pyrazinamide is not recommended in patients with severe renal insufficiency, and blood levels of INH or ethambutol may be required [202]. Drugs to be avoided in patients with any impairment of renal function include streptomycin, kanamycin, capreomycin, and cycloserine.
 - g. When symptoms persist or sputum smears or cultures remain positive after 2 months of therapy,** this indicates treatment failure. Patients should be assessed for adherence and drug resistance. Expert consultation is advised [202].
 - h. When severe illness, miliary tuberculosis, or tuberculous osteomyelitis and arthritis are present** at any age, treatment is extended to a minimum of 12 months [202]. Infants and children with meningeal tuberculosis should be treated for at least 12 months [202]. Infectious disease consultation is advised.
 - i. In immunosuppressed patients.** These patients may receive any of the preceding options for initial and follow-up therapy, including intermittent regimens [169]. However, the **duration of therapy must be determined by the individual response to treatment.** See Chapter 18 for therapy of HIV-infected patients.
- 3. MDR tuberculosis** is treated for longer periods, depending on the extent of resistance and the clinical response [206].
- 4. Older (traditional) regimens.** Before the advent of the short-course regimens just outlined, combinations used for susceptible organisms had to be given for longer periods of time. Previously, therapy consisted of INH and ethambutol given for at least 18 months; streptomycin was added for the first 1 to 2 months. INH and streptomycin given for the full 18 months of treatment is an acceptable alternative but is potentially more toxic and requires many injections. Either of these regimens may be administered daily or twice weekly.
- 5. Pregnancy.** The 9-month regimen should be chosen in a pregnant patient, and ethambutol is added initially to INH and rifampin. Pyrazinamide is not advised for use in the United States during pregnancy because its teratogenic potential is undefined, although it is recommended elsewhere [200,202]. Pyridoxine should be given with any INH-containing regimen. Streptomycin has documented harmful effects on the fetus and should not be used (see **Chapter 27**). Kanamycin, capreomycin, cycloserine, and ethionamide also should be avoided because of their potential risk to the fetus [202]. Breast-feeding is permissible during treatment. Steps should be taken to prevent and detect transmission of maternal tuberculosis to the neonate. See also section **IX**.
- E. Infection control aspects.** Nosocomial tuberculosis is a recognized risk to patients and employees in health-care facilities. Transmission is most likely to occur

from patients who have unrecognized pulmonary or laryngeal tuberculosis, are not on effective antituberculous therapy, and have not been placed in proper (respiratory) isolation. Patients who have MDR tuberculosis can remain infectious for prolonged periods, increasing the risk for nosocomial or occupational transmission [207].

1. **Guidelines for preventing the transmission of *M. tuberculosis* in health-care facilities** have been presented in detail elsewhere [207].
2. **Isolation should be continued until the patient is noninfectious** [201].
 - a. The length of time required for a patient to become noninfectious after starting antituberculous therapy varies considerably. Isolation should be discontinued only when the patient is on effective therapy, is improving clinically, and has had three consecutive negative sputum smears collected on three separate days [207].
 - b. Patients who are improving may go home with positive smear results if public health authorities have completed their household evaluation, no continued contact is at increased risk for tuberculosis (e.g., immunosuppressed persons or infants), the patient agrees not to have any outside contacts with potentially susceptible persons, and arrangements for DOT and follow-up have been completed [201].
 - c. Isolation can be discontinued if the diagnosis of tuberculosis is ruled out.
- F. **Specific agents** [166,202,208,209]. Although there is significant experience with older agents, new drugs are needed to further improve efficacy, reduce toxicity, and shorten therapy [210].
 1. **INH** remains the single most important antituberculous agent. It is bactericidal and penetrates tissue well, including the CNS. It is metabolized primarily by the liver. Doses are reduced only in advanced renal failure, and ideally guided by serum levels.
 - a. **Dosage.** The **usual daily dosage in adults** is 5 mg/kg up to 300 mg orally given once each day. An intramuscular form is available. In life-threatening disease (e.g., meningitis or miliary disease), dosages of 10 mg/kg/day (up to 600 mg/day) often are recommended. The **usual daily dosage in children** is 10 mg/kg once each day (300 mg maximum), although higher doses in meningitis may be used [208]. **Dosages for intermittent regimens** are 15 mg/kg two or three times weekly for adults, and 20 to 30 mg/kg twice weekly for children, up to a maximum of 900 mg [202,208].
 - b. **Side effects**
 - (1) **Hepatitis is the major side effect** of INH. Ten percent or more of patients on INH have transaminase elevations, but only 1% overall have significant hepatitis (deaths have been reported). Risk factors for the development of hepatitis include alcoholic liver disease, increasing over age 30 years, being a woman of a minority race, malnutrition, pregnancy and the post-partum period, and acetaminophen use [209]. There is a fourfold increased risk of hepatitis when INH and rifampin are used together [169].

Any patient on INH should be warned about the symptoms of hepatitis. Mild hepatic dysfunction (e.g., alcoholism) does not preclude the use of INH (and rifampin). If possible, we avoid INH (and rifampin) when baseline transaminases are six to eight times the normal level until these levels improve. Most experts advocate monthly testing of high-risk patients and those with abnormal test results prior to the start of therapy. Liver function tests should be performed if suggestive symptoms occur, and the drug discontinued if hepatitis is present. Monitoring of serial aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels may help prevent serious sequelae of INH-induced hepatitis prior to symptoms. Elevations of the transaminases more than three to five times normal should lead to consideration of stopping INH [202].
 - (2) **Neurologic toxicity** can occur but is uncommon at the usual INH dose of 5 mg/kg [202]. Peripheral neuropathies usually can be prevented by

the concomitant administration of pyridoxine 10 to 25 mg/day. After an INH-induced neuropathy has occurred, pyridoxine 50 to 100 mg/day can be used as treatment. Routine prophylactic use of **pyridoxine with INH should be reserved** for patients predisposed to neurologic toxicity because of higher INH doses, pregnancy, diabetes, uremia, alcoholism, malnutrition, or prior seizures [181]. Children and adolescents on milk- and meat-deficient diets also should be given pyridoxine [208]. Seizures, optic neuritis, encephalopathies, and the hand-shoulder syndrome rarely occur.

- (3) **Hypersensitivity reactions** with fever, rash, and rheumatoid syndromes occur. Positive antinuclear antibodies and lupus erythematosus cell preparations may be seen.
- (4) **Concomitant phenytoin use.** Doses of phenytoin may have to be reduced when INH is used because INH delays renal clearance of phenytoin sodium. Levels of phenytoin should be measured and doses adjusted [202].

2. Rifampin is bactericidal for *M. tuberculosis*, and it penetrates tissues well, including the CNS. The spectrum of activity, pharmacokinetics, and adverse reactions are discussed in detail in **Chapter 27**.

a. Dosages

- (1) The **usual daily adult dosage** is 10 mg/kg up to 600 mg once daily (two 300-mg capsules), 1 hour before or 2 hours after meals. In children, the dosage is 10 to 20 mg/kg once daily, not to exceed 600 mg. Dosages are the same for the intermittent regimens [202,208]. In renal failure, the dose is not reduced.
- (2) **Fixed-dose combinations.** A combination of rifampin 120 mg, INH 50 mg, and pyrazinamide 300 mg (Rifater) has FDA approval for the initial 2 months of daily therapy. The dosage is four tablets each day for patients weighing 44 kg or less, five tablets for those weighing 45 to 54 kg, and six tablets for those weighing 55 kg or more. The combination of rifampin 300 mg and INH 150 mg (Rifamate) has been licensed in the United States since 1975.

b. Adverse reactions. Patients should be warned in advance that their **urine, tears, sweat, and saliva may have a red-orange, harmless discoloration**; soft contact lenses may become permanently discolored [202]. Other side effects include hepatotoxicity, which is the major concern; adverse drug interactions with a variety of agents; immunologic reactions, including hypersensitivity reactions and a flulike illness with sporadic use; and renal failure, thrombocytopenia, or hemolysis, which occur rarely. These are discussed in detail in **Chapter 27**. Rifampin may reduce the effectiveness of oral contraceptives.

The **potential for hepatotoxicity** deserves comment. Rifampin can cause mild liver function abnormalities and, at times, severe hepatitis. Severe hepatotoxicity may develop rapidly after the start of INH in combination with rifampin [169]. Risk for rifampin-induced hepatitis is increased in patients with preexisting alcoholic liver disease [209]. If hepatitis develops in a patient on INH and rifampin, both agents must be stopped. A primarily cholestatic pattern is most likely caused by rifampin, whereas either drug may cause transaminase elevations. See also section **XI.B.3**.

c. Other rifamycins. Two other agents related to rifampin are available in the United States. Rifapentine, approved in 1998, is a long-acting analogue of rifampin that can be given once or twice weekly. Rifabutin has less effect on the hepatic cytochrome P-450 system, and is used in place of rifampin for treatment of HIV-infected patients taking protease inhibitors (see Chapter 18).

3. Ethambutol is an oral agent that penetrates tissue well. Although CSF levels are 10% to 50% of plasma levels in the presence of meningeal inflammation, they are low relative to the critical concentration of ethambutol. Ethambutol is bacteriostatic.

- a. **Dosages.** Tablets are available in 100- and 400-mg strengths. In prolonged therapy, 15 mg/kg to a maximum of 2.5 g, given once daily, usually is recommended. Some authorities use 25 mg/kg/day for no longer than the first 2 months of therapy and then reduce the dosage to 15 mg/kg/day. The twice-weekly dose for children and adults is 50 mg/kg, and for three times per week in adults is 25 to 30 mg/kg, up to a maximum of 2.5 g [202,208]. Doses must be reduced in renal failure.
 - b. **Side effects.** Ethambutol can cause retrobulbar optic neuritis. The first manifestation may be loss of color vision. Thus, ethambutol should be avoided when possible in children too young to assess color discrimination [208]. This appears to be dose related and rarely occurs when the 15-mg/kg/day regimen is used. Hypersensitivity reactions, hyperuricemia, and gastrointestinal intolerance can occur.
4. **Pyrazinamide** has been used in both initial therapy and retreatment regimens. It is bactericidal and works well in an acid environment and intracellularly [202]. It is well absorbed orally and penetrates the CNS when the meninges are inflamed.
- a. **Dosages.** The usual dosage in children is 20 to 40 mg/kg given once daily, up to a maximum of 2 g [208]. One recommended daily dosing schedule for adults is 1.5 g for those weighing 50 kg or less, 2 g for those weighing 51 to 74 kg, and 2.5 g for those weighing 75 kg or more [166]. Suggested twice weekly doses for adults are 2.5 g for those weighing 50 kg or less, 3 g for those weighing 51 to 74 kg, and 3.5 g for those weighing 75 kg or more; suggested three times weekly doses for adults are 2 g for those weighing 50 kg or less, 2.5 g for those weighing 51 to 74 kg, and 3 g for those weighing 75 kg or more [166]. The twice-weekly dose in children is 50 mg/kg up to a maximum of 2 g/dose [208].
 - b. **Toxicity.** Nausea and vomiting are the most common adverse effects. Pyrazinamide does not significantly increase the risk for hepatotoxicity when used for the first 2 months in short-course regimens, and hepatotoxicity is less common with the currently recommended doses [202,209]. Hyperuricemia is common and may be used as an indication of compliance; acute gout is uncommon, although arthralgias may occur in adolescents and adults [202,208].
5. **Streptomycin.** This injectable agent is bactericidal at an alkaline pH and, like other aminoglycosides, poorly penetrates into the CNS.
- a. **Dosages.** The dosage for adults is 15 mg/kg i.m. once daily, up to 1 g; 10 mg/kg up to a maximum of 500 to 750 mg is used for patients over 60 years of age. The daily and twice-weekly dose for children is 20 to 40 mg/kg i.m. up to a maximum of 1 g [208]. The intermittent dose for adults is 25 to 30 mg/kg up to a maximum of 1.5 g for twice-weekly and thrice-weekly regimens [202]. The total amount administered should be less than 120 g [202]. Doses must be reduced in renal failure.
 - b. **Side effects.** Ototoxicity is the most serious side effect, and vestibular damage is more common than auditory loss. Renal toxicity is much less common than with other aminoglycosides. Hypersensitivity reactions can occur. (See **Chapter 27.**)
6. **Second-line drugs.** Paraaminosalicylic acid (PAS), cycloserine, ethionamide, capreomycin, kanamycin, amikacin, ciprofloxacin, ofloxacin, levofloxacin, rifabutin, and rifapentine are all useful drugs under appropriate circumstances [166,202,208]. Some are particularly useful for resistant forms of tuberculosis, and in treating atypical mycobacterial infections. Because side effects are common, the reader is advised to seek consultation before using these agents.
- G. Therapy for specific problems**
1. **Smear-negative, culture-negative pulmonary tuberculosis** presents with clinical and radiographic tuberculosis and a positive PPD skin test but negative smear results and cultures. Although their mycobacterial burden is low, these patients, if untreated, have a high rate of disease progression over the ensuing 5 years. Patients with negative smear results should begin standard therapy

while awaiting culture results. If cultures are negative and there is no concern about drug resistance, then it is appropriate to continue INH and rifampin for a total of 4 months of therapy [202].

2. **Extrapulmonary disease.** Extrapulmonary tuberculosis due to susceptible organisms can be treated in the same way as pulmonary tuberculosis if INH and rifampin can be used [166,202]. Extrapulmonary sites usually contain smaller numbers of bacilli than do pulmonary sites, and INH and rifampin penetrate these sites well. Exceptions that require longer therapy have been discussed in section **X.D.2.h**, and infectious disease consultation is advised. HIV infection should be considered in any patient presenting with extrapulmonary tuberculosis (see Chapter 18).
3. **Drug-resistant cases.** Drug resistance should be suspected in patients who relapse after receiving a regimen not containing both INH and rifampin [202]. At least two, and preferably three, new agents should be used pending the results of susceptibility tests. Relapses that follow INH with rifampin in short-course therapy for susceptible organisms often are caused by susceptible organisms and are retreated using the same regimen [202]. Complicating the decision regarding treatment options is evidence that reinfection may occur, particularly in immunosuppressed patients. Treatment of patients who are close contacts of persons with proven drug-resistant tuberculosis, of those who contracted the disease in countries with a high incidence of drug resistance, and of those who fail therapy is best guided by the results of susceptibility tests. See related discussions in sections **X.A** and **X.B**.
4. **HIV-infected patients.** Therapy for tuberculosis should be started whenever acid-fast bacilli are found in patients with HIV infections, because it is impossible to distinguish between *M. tuberculosis* and *M. avium* complex without cultures. The use of rifampin will increase the methadone dose needed to prevent withdrawal symptoms in patients on methadone maintenance. See Chapter 18.
5. **Tuberculosis in pregnancy.** The risks from tuberculosis during pregnancy to the mother and fetus far outweigh the risks from chemotherapy. See section **X.D.5** and section **IX**.
6. **Tuberculosis in children.** Following the principles in adult therapy, short course therapy has been recommended for use in children [202,208].
7. **Therapy in renal failure.** Antituberculous medications cleared by the kidney include streptomycin, kanamycin, capreomycin, ethambutol, and cycloserine. If one needs to use these drugs in renal failure, dosage should be adjusted and levels monitored.

H. Miscellaneous issues related to therapy

1. **Adjunctive corticosteroids** have been used in various forms of tuberculosis but are controversial. They are beneficial for outcome in tuberculous meningitis and pericarditis [211]. They are useful in patients with associated adrenal insufficiency, and also may provide a short-term benefit in severely toxic patients (e.g., with disseminated tuberculosis) [211]. Preliminary evidence from endemic areas suggests a benefit in patients with tuberculous peritonitis, but their routine use for this problem is not recommended until any benefit is proven to outweigh risks [212,213].
2. **Hospitalization is often necessary** for diagnostic evaluation and initiation of therapy, particularly for patients with severe disease or suspected drug resistance. Hospitalization also is necessary in severe drug reactions, life-threatening infections, coexisting illnesses requiring hospital care, and the rare circumstance in which there is a special threat to the community. Uncomplicated pulmonary disease occasionally can be managed entirely as an outpatient. See section **X.E** for duration of isolation.
3. **Follow-up cultures.** Guidelines for follow-up are available from state or county health departments. Usually sputum smears and cultures are performed monthly until three specimens test negative, and then cultures monitored at 2- to 3-month intervals during therapy. Patients successfully completing a standard regimen of INH and rifampin for susceptible organisms do not need routine follow-up [202].

4. **Follow-up radiography.** A repeat chest radiograph after 2 to 3 months of therapy helps assess response to treatment. More frequent films may be needed to adequately follow patients whose initial sputum smears were negative. In addition, a film taken at completion of therapy provides a useful baseline for future comparison. Routine annual radiography is not recommended for patients who remain well.

5. **Public health follow-up.** The local public health department should screen contacts of index cases, arrange for DOT, and follow up on discharged patients.

XI. Treatment of latent tuberculosis. Patients with a positive intermediate PPD test result but without active disease are considered to have latent tuberculosis, meaning that persistent dormant and viable bacilli are present with the potential for later reactivation. **Both skin testing and treatment for latent tuberculosis are indicated only in patients with a high risk for developing active tuberculosis [181]. This includes those with recent infection and those at increased risk for progression to active disease regardless of the duration of latent infection** (see section III.C). Recommendations recently have been updated [181,214,215].

A. Hepatotoxicity

1. **INH.** Before one initiates INH, the potential risks of INH-related hepatitis must be considered [see section X.F.1.b.(1)]. Hepatotoxicity increases with age and alcohol consumption. Patients with active liver disease, end-stage liver disease, or documented INH-related hepatotoxicity should not receive INH. We withhold INH if transaminases are three times normal or higher in patients with symptoms, and five times normal or higher in patients without symptoms [181].

2. **Rifampin plus pyrazinamide for 2 months.** Severe and fatal liver injury has been reported in HIV-negative patients receiving this regimen [181,214,215]. A few patients were given this regimen after recovering from INH-induced hepatitis. Fatal cases had onset of hepatitis in the second month of treatment.

B. Current treatment options may be given using DOT [181,215].

1. **INH for 9 months. This regimen is preferred for most adults and children,** including those with HIV. The daily dose is 5 mg/kg in adults and 10 to 20 mg/kg in children, up to a maximum of 300 mg. The twice-weekly dose is 15 mg/kg in adults and 20 to 40 mg/kg in children, up to a maximum of 900 mg. Pyridoxine (10 to 25 mg/day) may be given simultaneously to selected patients (see section X.F.1.b.(2)).

2. **INH for 6 months.** This regimen, dosed as above, provides a shorter option that may be used in selected patients at the discretion of public health authorities and providers. **It is not recommended for children, those with radiographic changes of prior tuberculosis, and HIV-infected patients.**

3. **Rifampin plus pyrazinamide daily for 2 months.** Trials in HIV-infected persons showed that 2 months of this combination is effective and safe. However, the potential for hepatotoxicity precludes its widespread use at present [215]. **Caution is urged,** particularly in those taking other potentially hepatotoxic drugs and those with alcoholism. It should not be used in children, patients with underlying liver disease, or for patients with previous INH-induced hepatitis. It may be considered for patients judged unlikely to complete a longer regimen, if monitoring can be assured. The pyrazinamide dose is 15 to 20 mg/kg and not more than 20 mg/kg, to a maximum of 2 g daily [215]. The rifampin dose is 10 mg/kg to a maximum of 600 mg daily. **Close monitoring is required, and no more than 2 weeks of medication should be dispensed at any one visit.** Treatment should be stopped permanently for transaminase elevation over five times normal without symptoms, any transaminase elevation with hepatitis symptoms, or any bilirubin elevation [215]. Women taking oral contraceptives with rifampin should use an additional form of contraception.

4. **Rifampin daily for 4 months.** This regimen may be used as an alternative for patients intolerant to INH, and for contacts of patients with INH-resistant and rifampin-susceptible isolates. The dose is 10 mg/kg to a maximum of 600 mg daily in adults, and is 10 to 20 mg/kg to a maximum of 600 mg daily in children. Rifabutin in adjusted doses may be substituted for rifampin in HIV-infected patients taking certain antiretroviral agents [181]. However, rifapentine use is

not recommended at this time [181]. Women taking oral contraceptives with rifampin should use an additional form of contraception.

C. Monitoring. Patients receiving INH or rifampin should be seen at least monthly [181], and every 2 weeks if receiving rifampin plus pyrazinamide [215].

1. **Patients should be cautioned about the symptoms of hepatitis** (anorexia, nausea, vomiting, malaise, abdominal pain, jaundice, etc.), **and advised to interrupt therapy and seek medical evaluation if these symptoms develop** [181,215]. This is especially important in patients who drink alcoholic beverages daily.
2. **Baseline liver function tests** should be performed in patients whose initial evaluation suggests an underlying liver disorder, those with a known liver disease, those with HIV infection, pregnant women and those within 3 months of delivery, regular users of alcohol, and anyone judged at risk for chronic liver disease [181].
3. **Serial monitoring** of liver tests should be performed in all patients whose baseline levels were elevated, and for patients at risk for hepatotoxicity (see section **XI.C.2**). Transaminases and bilirubin should be checked every other week in patients receiving rifampin plus pyrazinamide [215].
4. **Liver function tests should be checked in patients with hepatitis-like symptoms.**
5. Uric acid may be checked in patients with arthritis while receiving pyrazinamide.

D. Special considerations

1. **HIV infection.** The 9-month INH regimen is preferred. HIV-infected persons with negative skin tests do not benefit from treatment for latent tuberculosis unless they are contacts of an active case of tuberculosis [181]. See Chapter 18.
2. **Pregnancy.** Because the risk for active tuberculosis is not increased by pregnancy, many patients can safely wait until after delivery and the early postpartum period. This will prevent the increased risk for INH hepatitis during this time [181]. Women with recent infection and those with HIV, however, should receive treatment for latent tuberculosis during pregnancy [181]. An INH regimen is preferred; rifampin is considered an acceptable alternative despite limited experience [181]. Breast-feeding can continue during treatment. Pyridoxine is indicated for all pregnant and nursing women taking INH, and for nursing infants whose mothers are taking INH [208].
3. **Children who are contacts of contagious tuberculosis** should be evaluated for active disease. If the initial PPD is negative and active disease is excluded, then INH is given for 3 months. At this time the child should be reevaluated for active disease and the PPD repeated. If the repeat PPD remains negative, INH may be stopped [208]. If the repeat PPD is positive and active disease is excluded, then INH is continued to finish a total of 9 months of therapy [208].
4. **Immunosuppressed patients who are contacts of active tuberculosis cases** should receive full treatment for latent tuberculosis (after active disease is excluded) even if repeat skin test results remain negative [181].
5. **Contacts of patients with INH-resistant tuberculosis** that is susceptible to rifampin should receive the 4-month regimen of rifampin (or rifabutin) [181].
6. **Contacts of patients with MDR tuberculosis** will not benefit from treatment with INH or rifampin. Their treatment should be individualized on the basis of susceptibility results. High-risk patients may be given pyrazinamide and ethambutol, or pyrazinamide and a fluoroquinolone for 6 to 12 months; the longer duration should be used for immunosuppressed patients [181]. Pyrazinamide and ethambutol are preferred in children because of the need to avoid long-term treatment with fluoroquinolones in this age group [181]. Consultation with an expert in resistant tuberculosis is advised.

E. BCG vaccine. BCG vaccination **has very limited usefulness in the United States** [216].

1. **It is considered for** infants and children with negative skin tests who are repeatedly exposed to infectious cases of tuberculosis and cannot receive preventive therapy or cannot be separated from the index patient, or are repeatedly

exposed to a patient with infectious MDR tuberculosis and they cannot be separated from the index patient [208,216]. BCG vaccine should be considered for health-care workers in settings where exposure and transmission of MDR tuberculosis is likely and this cannot be controlled by other measures [216]. BCG is contraindicated in immunosuppressed hosts (including those with HIV infection) and pregnant women [216].

2. **A history of previous BCG vaccination** does not alter the interpretation of the PPD skin test result or the decision process to give treatment for latent tuberculosis [181].
3. New vaccines being developed include attenuated, subunit, and DNA vaccines. They are needed to help eliminate tuberculosis as a worldwide problem [217].

XII. Nontuberculous mycobacteria (NTM). Although NTM are less virulent than *M. tuberculosis*, their importance has been highlighted by the frequent occurrence of *M. avium* complex infections in patients with AIDS (see Chapter 18). It often is difficult for the clinician to determine whether the isolation of these mycobacteria is clinically significant. The ATS has published guidelines to help with their management [218]. A few general points warrant emphasis.

A. Incidence. Infections caused by NTM are not reportable in the United States. In association with the AIDS epidemic, NTM isolates became more common than isolates of *M. tuberculosis* [218]. In the pre-AIDS era, approximately 2% to 10% of all mycobacterial infections in the United States were due to NTM.

B. Classification. At least 50 species of NTM are considered potential pathogens.

1. **Bacteriologic methods** for classification traditionally have used growth rates and pigment production (e.g., Runyon group). The time needed for a mycobacterium to grow may provide the first clue to the presence of NTM infection.
2. NTM also can be **grouped clinically according to their likelihood of causing different types of infection** [219]. For example, *M. avium* complex and *M. kansasii* are common causes of chronic pulmonary infections, whereas *M. fortuitum*, *M. chelonae*, *M. abscessus*, and *M. marinum* are common causes for skin infections.
3. **Molecular methods** will become more important in the future.

C. Epidemiology and pathogenesis

1. **Sources.** Environmental sources are the likely reservoir for NTM infections. These include water for *M. avium* complex, *M. marinum*, *M. kansasii*, and many rapid growers [218]. Most NTM also have been isolated from soil.
2. **Transmission. Person-to-person spread does not occur.** Humans presumably acquire disease by inhalation or aspiration, which leads to pulmonary disease; local inoculation, which causes skin or subcutaneous infections; and ingestion, leading to mucosal entry with cervical adenitis or disseminated disease in AIDS.
3. **There is usually some underlying host defense impairment**, either local or systemic, in patients with NTM infection. Many, but not all, chronic pulmonary infections from *M. avium* complex and *M. kansasii* occur in patients with underlying structural lung disease, and those from rapid growers are associated with esophageal disorders predisposing to aspiration [220]. Cystic fibrosis patients with structural lung changes are also at risk for pulmonary NTM infection. With the exception of the strong association of AIDS with disseminated *M. avium* complex infections, however, specific immunodeficiencies have been postulated but not proven [220].

D. Diagnosis can be difficult because these organisms are both saprophytes and true pathogens. Furthermore, underlying disease can account for the presenting symptoms.

1. **Skin tests.** Antigens similar to the PPD previously prepared for some species showed considerable cross-reactivity and are not readily available. Most experts believe that they **were not useful in diagnosing the individual patient**. However, preliminary results using the *M. avium* sensitin antigen for skin testing are promising [220].
2. **Acid-fast smears.** One cannot reliably distinguish *M. tuberculosis* from an NTM or identify a specific NTM by smear characteristics.

3. ***Mycobacterium* studies.** Cultures should be performed as discussed in Chapter 25. Commercial probes are available for identifying *M. avium* complex, *M. kansasii*, and *M. goodii* growing in cultures.
4. **Clinical criteria for the diagnosis of infection** caused by NTM have been published [218]. These are most relevant for pulmonary infections caused by *M. avium* complex, *M. kansasii*, and *M. abscessus* and may not fit the diagnosis of infections caused by other species. The diagnosis of pulmonary NTM infection requires fulfillment of clinical, radiographic, and microbiologic criteria.
 - a. **A compatible clinical illness and the exclusion of other diseases.**
 - b. **Compatible persistent or progressive changes on chest radiograph or high-resolution chest CT.**
 - c. **Supportive microbiological results** consisting of at least three sputums or bronchial washes within 1 year with positive cultures and negative AFB smear results, or two sputums or bronchial washes within 1 year with positive cultures and 1 with a positive AFB smear result; or, a single bronchial wash with at least 2+ growth or at least 2+ AFB smear-positive results; or, a lung biopsy showing any degree of growth, or showing granulomas or AFB on smear with at least one culture-positive sputum or bronchial wash, or a normally sterile site outside the lung showing any growth on biopsy [218]. These criteria are the same for immunosuppressed patients except that 1+ or greater growth is accepted.
- E. **Clinical syndromes.** These are briefly summarized to emphasize the variety of possible clinical presentations [218,219].
 1. **Mycobacterial lymphadenitis in children** is usually caused by *M. avium* complex, and less often by *M. scrofulaceum*, which together account for 90% of cases; the remainder are caused by *M. tuberculosis*. However, in adults *M. tuberculosis* causes at least 90% of cases and NTM the remainder.
 2. **Pulmonary NTM infections** may not be distinguishable from tuberculosis. Patients usually complain of cough, sputum production, and fatigue but also may have fever, weight loss, and hemoptysis. *M. kansasii* and *M. avium* complex are most frequently involved. Many patients with chronic cavitary changes have underlying COPD, bronchiectasis, or other structural lung disorders. Older patients, often women, without underlying lung disease are more likely to have midzone nodular infiltrates.
 3. **Cutaneous infections**, for example from *M. marinum*, can present with slowly enlarging papules or verrucae, which may go on to ulcerate.
 4. **Bone and joint infections** may occur as a result of trauma, surgery, or other sources of direct inoculation.
 5. **Disseminated disease** similar to miliary tuberculosis may occur and is more likely to be seen in immunocompromised patients, particularly those with AIDS in whom *M. avium* complex can be isolated from blood or bone marrow cultures (see Chapter 18).
 6. **Nosocomial NTM infections** often involve rapid growers and are device-related, such as peritoneal and central i.v. catheters and indwelling CNS shunts.
- F. **Therapy** is individualized based on the species involved, susceptibility results, and host characteristics. Localized disease (e.g., a single lymph node or skin nodule) usually is treated by complete surgical excision alone. Documented pulmonary infections require multidrug regimens. **Review of recent guidelines and expert consultation is advised.** Treatment of *M. avium* complex in AIDS patients is discussed in Chapter 18.

12. CARDIAC INFECTIONS

Deborah E. Sentochnik and Adolf W. Karchmer

INFECTIVE ENDOCARDITIS

Infective endocarditis (IE) is a microbial infection of an endothelial surface of the heart. Valves are the most commonly involved structures, but infection may occur at the site of a septal defect, on chordae tendonae, or on mural endocardium. The term *infective endocarditis* includes infections of vascular endothelium such as may occur with patent ductus arteriosus, arteriovenous fistulas, and coarctation of the aorta. The syndrome can be caused by a broad array of bacterial species, fungi, mycobacteria, chlamydia, rickettsia, and mycoplasma. Bacterial endocarditis (BE) is the most commonly recognized form of the disease and is often characterized as acute (ABE) or subacute (SBE) on the basis of clinical presentation. Streptococci, staphylococci, enterococci, and fastidious gram-negative coccobacilli are responsible for the majority of cases of IE.

Endocarditis in intravenous drug users (IVDU) or in association with prosthetic heart valves presents special clinical and microbiologic features and is discussed in separate sections in this chapter. Antibiotic prophylaxis to prevent bacterial endocarditis is discussed in Chapter 27, section B.

I. Pathogenesis [1,2]. The characteristic lesion of IE is the **vegetation**, a variably sized amorphous mass of platelets and fibrin in which a dense population of bacteria and only a few inflammatory cells are enmeshed.

A. Endothelial damage. The hydrodynamics leading to endothelial damage include the impact of a high-velocity jet, flow from a high to low pressure chamber, and high-velocity flow across a narrow orifice. A platelet and thrombin complex forms at the site in response to the damage. It is at the same location as this sterile thrombus formation that principles of hydrodynamics also allow the maximum deposition of bacteria during bacteremia, that is, just beyond the low-pressure side of the orifice, or at the site of jet stream impact on the endothelium. IE is uncommon in association with low-pressure flow abnormalities such as an isolated atrial septal defect or pure mitral stenosis.

B. Bacteremia. Bacteremia allows the conversion of the sterile thrombus to a vegetation. Bacteremia rates are highest for events that traumatize the oral mucosa, especially the gingiva, and progressively decrease with procedures involving the genitourinary tract and the gastrointestinal tract [3]. A further increased risk of bacteremia occurs in the presence of a diseased mucosal surface, especially an infected one.

C. Bacterial factors. Bacterial adherence to the thrombus is crucial in order for infection to occur. Multiple factors that enhance adherence, including the ability to produce dextran, cause aggregation of platelets, and bind to fibronectin, appear to be important for most of the gram-positive organisms that commonly cause IE. Resistance to host defense mechanisms is also pivotal. The ability of many gram-negative bacilli to cause IE is limited by complement-mediated bactericidal activity of serum [2].

D. Intact endothelium. *Staphylococcus aureus* is the most common gram-positive organism of ABE able to infect intact vascular endothelium. The reasons for this are incompletely understood.

II. Clinical presentation

A. Patient population

1. Underlying heart disease. Fifty-five percent to 75% of patients with IE of native valves have predisposing conditions, including rheumatic heart disease, congenital heart disease, mitral valve prolapse, degenerative heart disease, asymmetric septal hypertrophy, or intravenous (i.v.) drug abuse [4–6]. As the population at risk has been decreasing in recent decades, rheumatic heart disease has become a less important predisposing condition, accounting for fewer than 20% of cases [7]. Mitral valve prolapse accounts for 7% to 30% of IE in native valves not related to drug abuse or nosocomial infection. The frequency of this underlying etiology for IE likely reflects the high frequency of the lesion in the

general population (2%–4% of healthy persons and 20% among young women). Increased risk of IE in patients with mitral valve prolapse occurs in those with both prolapse and a mitral regurgitation murmur [8]. Congenital heart disease is identified in approximately 10% of patients with IE. One-fourth to one-half of all cases of IE occur in patients with no identifiable underlying heart lesion. It is possible that clinically undetectable degenerative change is present.

2. **Nosocomial risk.** A substantial number of cases of nosocomial endocarditis associated with bacteremia from i.v. catheters, postoperative wound infections, genitourinary manipulation, hyperalimentation lines, and hemodialysis shunts have been described in patients hospitalized or treated for a variety of other illnesses [9].
 3. **Age.** The median age range of patients with IE has increased to 47 to 69 years in recent decades compared with 30 to 40 years in the preantibiotic and early antibiotic eras [2]. This likely reflects a larger number of older persons at risk and a smaller number of young people with rheumatic heart disease.
- B. Signs and symptoms** [10]. The presenting signs and symptoms of BE are **variable and often nonspecific**. The possibility of this diagnosis should be considered whenever a patient presents with **fever** of more than several days' duration with no other apparent cause and in association with a significant heart murmur. The **type of clinical presentation** can have practical implications with regard to probable bacterial etiology and the degree of urgency in instituting therapy; it is therefore useful to attempt to classify suspected BE as acute or subacute.
1. **SBE.** Patients with typical SBE have an insidious and poorly defined onset of a variety of symptoms that may include weakness, fatigue, anorexia, night sweats, weight loss, arthralgias, myalgias, fever, and neurologic symptoms. Symptoms may be present for weeks or months at the time of presentation. The onset may be related to antecedent events such as dental work, although in most cases no definite antecedent event is apparent.
 2. **ABE.** In contrast, patients with ABE usually have a more circumscribed and acute onset of chills, fever, back pain, arthralgia, and myalgia, and often look acutely ill. The patient may be seen within several days to a week from the onset of illness. Infections that antedate the onset of endocarditis may be identified, although, as in SBE, they often are not apparent. Some patients fall between these extremes and cannot be classified easily.
 3. **Peripheral signs** of BE, many of which are immunologically mediated, can include splenomegaly, petechiae, clubbing, and retinal and subungual (splinter) hemorrhage. Janeway lesions are small hemorrhagic or erythematous, non-tender macules on the palms and soles due to septic emboli. They occur more often in ABE. Osler nodes are small, subcutaneous, tender nodules found on the pulp of digits and are due to septic emboli or, possibly, vasculitis. Roth spots are pale-centered, oval, retinal hemorrhages, usually near the optic disk. More common in the preantibiotic era, these signs, which increase in incidence with increasing duration of untreated illness, are now seen in fewer than 20% of cases of BE.
 4. **Fever.** Because fever is almost always present in the patient who is not on antipyretics or antiinflammatory agents, a normal temperature pattern under reliable observation makes the diagnosis doubtful. Occasional exceptions to this rule occur in elderly patients or those with debilitating illness.
 5. **Cardiac signs**
 - a. **Murmurs.** A heart murmur is apparent in 85% or more of cases, and the absence of both fever and murmur makes the probability of BE slight, although it does not rule out the possibility entirely.
 - (1) **Valvular lesions.** The distribution of valvular lesions, as expected, varies with the type of underlying heart disease reported. If IVDUs are excluded, the vast majority of patients have either aortic or mitral valve involvement (in approximately equal proportions), or both. Tricuspid involvement is rare except in IVDUs, in whom it is common. Occasional cases of right-sided endocarditis have been described secondary to infected central venous catheters or pulmonary artery catheterization [11].

- (2) **Changing murmurs.** New murmurs or striking changes in the intensity of murmurs are the **exception** rather than the rule in patients with BE. Some change in intensity due to tachycardia, anemia, or fever is fairly common. If new murmurs or significant changes in murmur intensity occur, they are likely to represent either aortic or mitral insufficiency and are frequently associated with congestive heart failure (CHF).
- (3) **BE without a murmur** tends to be seen (a) early in the course of acute endocarditis that involves previously normal valves, (b) with infection that involves mural endocardium rather than valves, (c) with congenital bicuspid aortic valves, (d) in isolated tricuspid valve involvement, and (e) in some elderly patients.

b. Other cardiac signs

- (1) **CHF** results primarily from progressive valvular insufficiency, although associated myocarditis also may contribute.
 - (2) **Heart block and arrhythmias** might occur if there is involvement of the conducting system.
 - (3) **Pericarditis** rarely complicates BE but can result from extension of a mural or valvular ring abscess.
- 6. Embolic phenomena.** In either ABE or SBE, signs and symptoms of embolic phenomena may occur. These manifest as episodes of vascular occlusion that cause pain in the abdomen (mesenteric or splenic arterial involvement), chest (coronary or pulmonary emboli), or extremities. Hematuria may result from emboli to the kidneys, blindness from retinal artery involvement, and acute neurologic symptoms (including stroke) from cerebrovascular involvement. These signs and symptoms in combination with fever or a murmur should always suggest the strong possibility of underlying BE.
- 7. Central nervous system. Approximately one-third of patients with BE exhibit neurologic disturbances as a major presenting symptom or as a later complication of BE** [12,13]. Stroke is a common presenting neurologic problem, and toxic encephalopathy manifesting as a variety of severe mental disturbances without focal neurologic defects also is common. Meningitis, headache, visual impairment, mononeuritis, convulsions, brain abscess, mycotic aneurysm, and intracerebral bleeds also are seen. **The possibility of BE should be considered in patients of any age when fever or a murmur accompany these neurologic signs or symptoms.**
- 8. Rheumatologic manifestations.** Twenty-five percent to 40% of patients with BE have myalgias, especially low back pain, or arthralgias as a presenting or predominant symptom [14]. Arthritis is less common and is typically a nonspecific inflammatory response. Septic arthritis can be seen in ABE, especially with *S. aureus* infection.
- 9. The elderly.** Within this large group of patients, the diagnosis of BE is particularly prone to be missed or inordinately delayed. CNS or cardiac signs and symptoms frequently are ascribed to progression of underlying arteriosclerotic disease, and the possibility of BE thus is overlooked. The onset of symptoms often is insidious, fever may not be prominent, and a murmur may be absent [15,16]. The systolic murmurs that are common in elderly individuals may be erroneously regarded as insignificant.

III. Diagnosis. With the exception of microbiologic studies, laboratory findings are variable, nonspecific, and of little definitive value in the diagnosis of endocarditis.

A. Nonspecific findings

- 1. Erythrocyte sedimentation rate and C-reactive protein are elevated** in almost all patients with SBE [17].
- 2.** A mild to moderate normocytic-normochromic **anemia** is common. The severity tends to be related to the duration of the illness, and patients with ABE often are not anemic.
- 3. Peripheral leukocyte counts** usually are normal or moderately elevated, although prominent leukocytosis may be seen in acute infection.
- 4. Thrombocytopenia** may be seen in patients with ABE and in those with splenomegaly accompanying more chronic infections.

5. On **urinalysis**, microscopic hematuria and proteinuria are common, whereas red blood cell casts may appear if glomerulonephritis complicates the course.
- B. Blood cultures and bacteremia.** Blood cultures must be obtained whenever the diagnosis of BE is suspected; they will be positive in 85% to 95% of cases. (See Chapter 25 for the technique of obtaining blood cultures.) In endocarditis, as in other intravascular infections, bacteremia (when present) is persistent in the great majority of cases. The finding of intermittent bacteremia in a suspected case of endocarditis should suggest some other focus as a source.
1. **In suspected ABE.** When acute endocarditis is suspected and prompt therapy is believed to be indicated, three blood cultures, taken from separate venipuncture sites at 15- to 30-minute intervals over 1 to 2 hours, are adequate for identifying more than 90% of bacteremic patients with ABE; at the same time, they provide enough samples to minimize confusion over possible contamination.
 2. **In suspected SBE.** When the presentation of endocarditis is subacute and the need for therapy is not so urgent, three blood cultures over a 24-hour period are sufficient. If these cultures remain negative after 24 to 48 hours, another two or three sets should be obtained [18,19]. Culture of arterial blood or bone marrow offers no advantage over culture of venous blood.
 3. **In suspected fungal endocarditis.** Blood cultures for fungi should be obtained using a specific method such as lysis-centrifugation.
 4. **Laboratory involvement.** The laboratory should be advised that endocarditis is a possible diagnosis and told if any unusual bacteria are suspected that might require special processing. In addition, once a causative organism is identified, the laboratory should be requested to save the isolate until therapy has been completed. **Special culture** techniques that may help in diagnosis are discussed in Chapter 25.
 5. **Serologic tests** may be useful in diagnosis of IE due to *Bartonella* species, *C. burnetii*, *Chlamydia* species, *Legionella* species, or *Brucella* species.
- C. Resected emboli.** Resection of large emboli may be of diagnostic as well as therapeutic value in patients with suspected endocarditis and with negative blood cultures. Resected emboli should be cultured and examined histologically for bacteria and fungi. Polymerase chain reaction may be especially useful in this circumstance [20].
- D. Spinal fluid.** Purulent meningitis is rare in BE but can be seen in ABE due to a virulent organism such as *S. aureus* or *Streptococcus pneumoniae*. Spinal fluid in BE due to other organisms with signs of meningeal irritation typically has an aseptic profile, albeit with a slight predominance of polymorphonuclear cells, and cerebrospinal fluid (CSF) cultures are typically negative. With neurologic involvement, the CSF may show a mild pleocytosis (predominantly leukocytic), elevated protein level, and normal glucose level.
- E. Echocardiography.** Among patients with clinical and microbiologic evidence of endocarditis, two-dimensional echocardiography (2D echo) used across the chest wall (transthoracic echo, or TTE) identifies vegetations in approximately 65% of patients. In contrast, 2D echo with biplane imaging from the esophagus (transesophageal echo, or TEE) visualizes vegetations in 85% to 90% of these patients [21]. The ability to identify vegetations varies with vegetation size and location as well as body habitus and underlying diseases. TEE is particularly useful in patients with suboptimal TTE (e.g., those with pulmonary disease, obesity, chest wall deformities, and ventilator dependency). Furthermore, TEE is the approach of choice for evaluating the tricuspid and pulmonic valves and a prosthesis in the mitral position. In his editorial, Jameison concludes that TEE is better than TTE in finding evidence of vegetations, quantifying valvular dysfunction, and diagnosing the spread of infection; this advantage is especially noted in patients with prosthetic valve endocarditis [22]. Nevertheless, 2D echo, regardless of the approach, cannot distinguish between marantic and infective endocarditis (healed vs. actively infected vegetations) or thrombus and vegetation. Furthermore, in some patients 2D echo may not distinguish between vegetations and noninfective valve abnormalities (i.e., valve thickening or calcification). Given its less than 100% sensitivity for detecting vegetations as well as these other limitations, 2D echo **cannot be used**

to exclude BE, especially when the diagnosis is likely based on clinical information [21]. It also is generally an inadequate approach to screening for BE among patients in whom the clinical index of suspicion is not high. Whereas 2D echo-demonstrated vegetations are not required to establish the diagnosis of BE in a patient with positive blood cultures and a clinical syndrome indicative of endocarditis, the echocardiogram may provide clinically useful information among patients with a BE syndrome and negative blood cultures. The major utility of TEE over TTE in the diagnosis of native valve endocarditis arises when the TTE is a technically inadequate study or indicates an intermediate likelihood of endocarditis [22a,22b]. In patients with suspected endocarditis involving prosthetic valves, TEE is a superior diagnostic test. In patients with a moderate probability of endocarditis but with chest configuration or lung disease limiting the utility of TTE or those with relatively low probability of endocarditis (6%–10% likelihood), for example *S. aureus* catheter-related bacteremia, initial evaluation by TEE is cost effective [23]. Furthermore, 2D echo, particularly using the transesophageal approach, supplemented by pulsed, continuous, and color flow Doppler, may provide information regarding intracardiac complications of BE and cardiac hemodynamic status that is important in assessing prognosis and the role of surgical intervention in therapy [21,24] (see section **VIII.H**). See related discussions in section **IV.D** and section **V.B**, under Endocarditis Associated with Prosthetic Valves.

F. Diagnostic criteria. The von Reyn criteria established in 1981 to assist in diagnosis of infective endocarditis have largely been replaced by the now well-accepted Duke criteria [25], which have recently been modified by Li et al. [26]. These are summarized in Tables 12.1 and 12.2.

1. In 1981 von Reyn and colleagues published a set of criteria to help diagnose “definite,” “probable,” “possible,” and “rejected” cases of infective endocarditis. Limitations include the criteria’s retrospective nature and lack of prospective validation, the lack of inclusion of echocardiographic findings, the nonrecognition of i.v. drug use as an important predisposing condition for infective endocarditis, and the requirement for histopathologic confirmation of infective endocarditis [27].

Table 12.1. Definition of Infective Endocarditis According to the Modified Duke Criteria, with Modifications Shown in Italics

Definite infective endocarditis
Pathologic criteria
Microorganisms: demonstrated by culture or histologic examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen; <i>or</i>
Pathologic lesions: vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis
Clinical criteria
2 major criteria, <i>or</i>
1 major and 3 minor criteria, <i>or</i>
5 minor criteria
Possible infective endocarditis
1 major criterion and 1 minor criterion; <i>or</i>
3 minor criteria
Rejected
Firm alternate diagnosis for manifestations of endocarditis; <i>or</i>
Resolution of infective endocarditis syndrome with antibiotic therapy for ≤ 4 days; <i>or</i>
No pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for ≤ 4 days; <i>or</i>
Does not meet criteria for possible infective endocarditis, as above

Adapted from Li JS, et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. *Clin Infect Dis* 2000;30:633–638; with permission.

Table 12.2. Definition of Terms Used in the Modified Duke Criteria for the Diagnosis of Infective Endocarditis (IE), with Modifications Shown in Italics

Major criteria

Blood culture positive for IE

Typical microorganisms consistent with IE from 2 separate blood cultures:

Viridans streptococci, *Streptococcus bovis*, HACEK group^a *Staphylococcus aureus*; or

Community-acquired enterococci, in the absence of a primary focus; or

Microorganisms consistent with IE from persistently positive blood cultures, defined as follows:

At least 2 positive cultures of blood samples drawn >12 h apart; or

All of 3 or a majority of ≥ 4 separate cultures of blood (with first and last sample drawn at least 1 h apart)*Single positive blood culture for Coxiella burnetii or anti-phase I IgG antibody titer >1:800*

Evidence of endocardial involvement

Echocardiogram positive for IE (*TEE recommended in patients with prosthetic valves, rated at least "possible IE" by clinical criteria, or complicated IE [paravalvular abscess]; TEE as first test in other patients*), defined as follows:

Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation; or

Abscess; or

New partial dehiscence of prosthetic valves

New valvular regurgitation (worsening or changing or preexisting murmur not sufficient)

Minor criteria

Predisposition, predisposing heart condition or injection drug user

Fever, temperature $>38^{\circ}\text{C}$

Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions

Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor

Microbiologic evidence: positive blood culture but does not meet a major criterion as noted above^b or serologic evidence of active infection with organism consistent with IE
Echocardiographic minor criteria eliminated^aHACEK, *Haemophilus* species *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella* species, and *Kingella kingae*.^bExcluding single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis.Adapted from Li JS, et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. *Clin Infect Dis* 2000;30:633–638; with permission.

2. Modified Duke criteria for infective endocarditis are summarized in Tables 12.1 and 12.2. When used carefully over the entire clinical evaluation period (i.e., not limited to initial findings only), the criteria appear to be sensitive and specific.

- a. Erroneous rejection of the diagnosis of endocarditis is unlikely.
- b. When using these criteria to guide therapy in an individual patient, patients who are categorized as having possible infective endocarditis should be treated as having infective endocarditis. This may lead to treatment of some individuals who do not have the infection. The potential for overdiagnosis and excess treatment has been reduced by modifications that now require at least one major criterion or three minor criteria to designate possible endocarditis [26].
- c. The findings of echocardiography are important major criteria in the Duke diagnostic schema. TEE compared with TTE improved the sensitivity of the Duke criteria to establish definite endocarditis by 25%. The enhanced diagnostic effect of TEE was greatest when prosthetic valve endocarditis

was suspected and when the clinical likelihood of endocarditis was intermediate. In 4% the TEE finding resulted in alterations in therapy (rejected diagnoses became definite) [28]. See related discussion of echocardiography in section III.E and related discussions under Endocarditis Associated with Prosthetic Valves.

IV. Microbiologic features

A. Organisms

1. **Streptococci** account for approximately 55% of all cases of native valvular BE in the nonaddict population [2].
 - a. Approximately 35% of all cases are due to viridans streptococci, the single most common organism.
 - b. Approximately 10% are caused by enterococci.
 - c. Approximately 10% are caused by other nonhemolytic, microaerophilic, anaerobic, or nonenterococcal group D streptococci. Group A β -hemolytic streptococci are a rare cause.
2. **Staphylococci** (approximately 35% of cases) [2]. Most staphylococci causing BE are coagulase-positive. Coagulase-negative staphylococci are common in prosthetic valve endocarditis but infrequently cause disease on native valves.
3. **Miscellaneous organisms** (10% of cases). This includes HACEK organisms (*Haemophilus*, *Actinomyces*, *Cardiobacterium*, *Eikenella*, *Kingella*), pseudomonas [29], gram-negative enteric bacilli [30], pneumococci [31], and gonococci. Reports can be found of endocarditis caused by almost any bacterium [2,32]. *Bartonella* species [33] and *C. burnetii* [34,35] have emerged as causative organisms. *Tropheryma whippelli*, the cause of Whipple disease, can rarely cause IE [36,37].

B. Culture-negative endocarditis [38,39]. A small proportion of patients with BE have persistently negative blood cultures. In some series, this comprised 15% or more of all patients; however, the true proportion is probably less than 5%. The diagnosis usually is suspected in patients with fever of undetermined cause who have underlying heart disease or a newly discovered murmur.

The usual cause is prior antibiotic therapy, the effect of which can last for days and, if therapy was prolonged, even for weeks, rendering blood cultures negative. Fungi and organisms that are difficult to culture might also be responsible. A search for pathogens such as *C. burnetii*, *Chlamydia* species, *Bartonella* species and *Legionella* species may be worthwhile. Diagnosis may require serologic or other nonculture techniques.

C. Fungi [40]. Fungal IE can be seen in prosthetic valve endocarditis (PVE), where the most common cause is *Candida albicans*, and in the IVDU population, where nonalbicans *Candida* infections are most often seen.

D. Microbiologic and clinical correlations. Although overlap exists, there is a correlation between clinical presentation and the infecting organism. Bacteria with low inherent virulence such as viridans streptococci usually infect previously damaged heart valves. Damage due to infection tends to progress slowly, and patients are likely to have a subacute or chronic course.

More virulent organisms, such as *S. aureus*, may infect previously normal valves, and tend to produce acute systemic toxicity as well as rapid valve destruction. ***S. aureus* is the most commonly isolated organism in patients presenting with ABE.**

V. Treatment: basic principles

A. General considerations. Prolonged administration of relatively high doses of bactericidal antibiotics is indicated. Dense populations of metabolically dormant organisms exist on vegetations. The avascularity of the center of the lesion also contributes to the difficulty in achieving its permanent sterilization.

B. Laboratory aids

1. **Serum bactericidal titer (SBT).** The SBT is the highest dilution of the patient's serum during antibiotic therapy that kills 99.9% of the standard inoculum of the patient's infecting organism *in vitro*. Peak titers of 1:64 or 1:32 and trough titers of 1:32 obtained with a standardized SBT method correlate with bacteriologic cure. SBT is a poor predictor of bacteriologic failure. When using regimens

considered optimal on the basis of clinical experience, monitoring therapy using the SBT is not recommended [41]. It may be useful when treating patients with IE caused by organisms for which optimal therapy is not established or when using unconventional antimicrobial regimens.

2. **Antibiotic levels.** Vancomycin and aminoglycoside levels should be monitored.
 - C. **Initiating treatment.** When a patient has suspected BE, a decision must be made as to the urgency of initiating therapy on a presumptive basis before blood culture results are available. In the severely ill patient in whom ABE is suspected, it is reasonable to take three blood cultures over a 1-hour period and to institute therapy promptly because of the rapid progression of this disease. **In the patient who has a subacute or chronic illness and a nonspecific clinical picture, it often is best to await blood culture results before starting antibiotics.**
 - D. **Outpatient therapy** [42,43]. Patients who have responded to initial therapy and are afebrile, who are not experiencing threatening complications, who will be compliant with therapy, and who have a suitable home situation can be considered for outpatient therapy. Close laboratory and clinical monitoring should continue. Antibiotic choices should not be compromised.
- VI. **Antibiotic therapy for specific types of endocarditis. The following recommendations assume normal renal function;** drug doses may have to be adjusted for renal insufficiency, as is described in Chapter 27. The doses given here are for adult patients. Treatment in penicillin-allergic patients is discussed in section VII. Consensus recommendations for therapy from the American Heart Association writing group are published elsewhere [41].
- A. **Viridans streptococci**
 1. **Penicillin-susceptible viridans streptococci and *Streptococcus bovis* (minimum inhibitory concentration [MIC] \leq 0.1 μ g/mL).**
 - a. **Penicillin alone.** A four-week course of aqueous penicillin G 12 to 18 million units per day i.v. by continuous infusion or divided into doses given every 4 hours achieves bacteriologic cure in up to 99% of patients.
 - b. **Short course (2-week) combination therapy with penicillin (see a) and gentamicin 1mg/kg every 8 hours** has been associated with bacteriologic cure rates as high as 98% [43]. This regimen is appropriate for uncomplicated cases of endocarditis due to highly penicillin susceptible viridans streptococci occurring in patients at low risk for aminoglycoside toxicity. **This course is not recommended for patients with complications** such as shock, intracardiac abscess, or extracardiac foci of infection.
 - c. **Ceftriaxone once daily.** Ceftriaxone 2 g once daily plus either gentamicin (3 mg/kg) [44] or netilmicin (4 mg/kg) [45] given as a single daily dose for 14 days has been shown to be effective. However, experience with single daily dosing of aminoglycosides in the treatment of IE is limited, and these regimens are not currently recommended.
 2. **Viridans streptococci relatively resistant to penicillin (MIC $>$ 0.1 to $<$ 0.5) is treated with penicillin plus an aminoglycoside.** This combination synergistically kills viridans streptococci *in vitro*. Although streptomycin has been used in classic studies, gentamicin is the standard in clinical practice. An appropriate course consists of aqueous penicillin G 18 million units daily by continuous infusion or divided into six equal doses and gentamicin 1 mg/kg intramuscularly (i.m.) or i.v. every 8 hours for 2 weeks, followed by penicillin alone for an additional 2 weeks.
 3. **Abiotrophia species (previously called nutritionally variant streptococci), *Streptococcus adjacens*, and *Streptococcus defectivus*.** These organisms are generally more resistant to penicillin than are other viridans streptococci [46]. They should be treated with enterococcal IE regimens. Bacteriologic cure may be difficult, and relapse rates high.
 4. **Viridans streptococci with penicillin MIC of \geq 0.5** [47]. Enterococcal IE regimens should be followed.
 - B. ***Streptococcus bovis*** is treated the same as viridans streptococci.
 - C. ***Streptococcus pyogenes*, *Streptococcus pneumoniae*, and groups B, C, and G streptococci.** IE caused by these organisms has been either refractory to

antibiotic therapy or associated with extensive valvular damage. Penicillin G 3 million units i.v. every 4 hours for 4 weeks is recommended for treatment of endocarditis due to group A streptococci and pneumococci. Until a pneumococcus has been demonstrated to be sensitive to penicillin ($MIC < 0.1 \mu\text{g/mL}$) treatment with ceftriaxone plus vancomycin may be preferable [48]. Endocarditis due to group G, C, or B streptococci is more difficult to treat than that due to penicillin-susceptible viridans streptococci. Therefore, the addition of gentamicin to the first 2 weeks of a 4-week high-dose penicillin regimen is often recommended [49]. Surgery is commonly required.

- D. Enterococci.** Ninety percent of enterococcal endocarditis [50] is due to *Enterococcus faecalis*, with the remainder due almost entirely to *Enterococcus faecium*. Enterococci are less susceptible to killing by penicillin alone than are other streptococci and are resistant to clinically applicable levels of gentamicin. **Effective bactericidal therapy requires the use of a cell wall-active agent such as penicillin, ampicillin, or vancomycin with an aminoglycoside to achieve synergy.** Gentamicin 1 mg/kg i.v. or i.m. every 8 hours should be combined with one of these agents. Synergistic combination therapy results in cure rates of approximately 85% [41].
1. MICs to penicillin vary from 1 to 2 $\mu\text{g/mL}$, with most in the range of 1.0 to 4.0 $\mu\text{g/mL}$. Eighteen to 30 million units of i.v. penicillin G daily is appropriate when renal function is normal (see Chapter 27). Ampicillin 12 g per 24 hours i.v. given by continuous infusion or every 4 hours in six equally divided doses may be substituted. **Peak gentamicin levels need only be in the range of 3 $\mu\text{g/mL}$ for synergy to occur.** Although there is ample *in vitro* evidence for the role of gentamicin, most clinical evidence comes from using streptomycin in combination with penicillin. However, the ototoxicity of streptomycin, the need for intramuscular administration, and the substantial percentage of *in vitro* resistance has led to the standard use of gentamicin instead. The recommended duration of therapy is at least 4 weeks with both agents and 6 weeks if the symptoms were present for more than 3 months before appropriate antibiotic therapy was begun or in complicated disease [41].
 2. The incidence of **high-level gentamicin-resistant strains of enterococci** ($MIC \geq 500 \mu\text{g/mL}$) [51] **warrants routine laboratory screening of clinically significant isolates.** This characteristic is seen in 25% of *E. faecalis* and 50% of *E. faecium* infections. Of isolates with this gentamicin resistance, 30% to 40% are sensitive to streptomycin, whose resistance is mediated by a distinct genetic element. There are few well-documented cases of endocarditis due to aminoglycoside-resistant enterococci. Infectious disease consultation is advised. Optimal duration of antibiotic therapy is unknown. Successful therapy may include valve replacement. If high-level resistance to both gentamicin and streptomycin are found, therapy can be attempted with an 8- to 12-week course of a cell wall-active agent alone if susceptibility is demonstrated. See section D.4 below for other therapeutic considerations.
 3. **High-level penicillinase production**, especially among *E. faecium*, has been documented [52]. Screening for the production of this β -lactamase should be undertaken if therapy is to include ampicillin or penicillin. Vancomycin activity is not influenced by the enzyme. Unfortunately, many penicillinase-producing strains are also highly resistant to aminoglycosides, thus precluding the use of a known synergistic combination.
 4. **Enterococci resistant to vancomycin** and variably resistant to other glycopeptides are reported [53], as are isolates resistant to all available antibiotics. (See related discussion in Chapter 27.) There is some experience in the use of newer agents such as quinupristin/dalfopristin (susceptible *E. faecium* only) [54] and linezolid [55,56].
- E. Staphylococci** [41]
1. **Penicillinase-resistant semisynthetic penicillins.** Oxacillin or nafcillin 2 g i.v. every 4 hours is indicated. If the organism is ultimately found to be susceptible to penicillin ($MIC \leq 0.1 \mu\text{g/mL}$), aqueous penicillin G 18 to 24 million units per 24 hours should be used instead.

2. **Combination therapy.** There is *in vitro* and experimental *in vivo* evidence that low-dose gentamicin in combination with a semisynthetic penicillin effects more rapid killing of staphylococci and sterilization of valves than does penicillin alone. This suggests that addition of gentamicin 1 mg/kg every 8 hours for the first few days of treatment may be of value. Because clinical trials have failed to show an improved outcome with combined therapy [57], gentamicin generally should be omitted in patients with relative contraindications to its use, as is described for gentamicin use in cases of viridans streptococci (see section A.1.b).

From a practical standpoint, it may be reasonable to use combination therapy (if not contraindicated) for the first 3 to 5 days, in an attempt to clear the bacteremia rapidly and minimize damage to the heart valve [41]. The more long-term addition of gentamicin (1 mg/kg i.v. or i.m every 8 hours) or rifampin (300 mg orally every 8 hours), or both, in patients who are not responding to a β -lactam alone has been suggested [57]. Determination of serum bactericidal levels may be useful in this circumstance.

3. **Methicillin-resistant *S. aureus* (MRSA) BE** is treated with vancomycin. The usual initial dose is 1.0 g every 12 hours (see Chapter 27). Infectious diseases consultation is suggested.
 4. **Coagulase-negative staphylococci** account for 1% to 3% of native valve endocarditis [58]. Therapeutic options are similar to those for *S. aureus*, and there may be a role for combination therapy. Sensitivity testing should guide treatment decisions.
 5. **Duration of therapy.** Treatment should be continued for 4 to 6 weeks. The 6-week course often is suggested for patients with an initial delayed clinical response or complicated course.
 6. **Indications for surgery** are discussed in section VIII.G.1.
- F. Other forms of BE.** Infectious disease consultation is recommended.
1. **HACEK organisms** usually are treated with ampicillin or ceftriaxone plus gentamicin for 4 weeks. Ceftriaxone alone can be used [41].
 2. **Enteric gram-negative BE** is difficult to treat. The most potent agent, as determined by *in vitro* sensitivity testing, should be used and serum bactericidal levels followed. It is wise to combine most agents, especially the β -lactams, with gentamicin. Duration of therapy is 4 to 6 weeks [30].
 3. ***Pseudomonas aeruginosa*** endocarditis is seen almost exclusively in IVDUs. Tobramycin 5 to 8 mg/kg/day combined with an antipseudomonal penicillin (e.g., mezlocillin or piperacillin), ceftazidime, or ciprofloxacin for 6 weeks is usual therapy [29]. (See section VIII.G.2.)
 4. **Miscellaneous.** The reader is referred to recent articles dealing with endocarditis due to *C. burnetii* [34,35] and therapy for *Bartonella* species infections [33]. Published experience in the form of case reports or small series dealing with a specific causative agent should be reviewed when dealing with endocarditis due to unusual organisms.
- G. Initial treatment of suspected ABE prior to culture results.** Therapy should be directed to *S. aureus* because it is the most common organism in patients who have ABE. Vancomycin plus gentamicin is appropriate and also provides coverage for possible enterococcal infection. Oxacillin or nafcillin 2 g every 4 hours may be substituted for vancomycin in the patient at increased risk for nephrotoxicity. Antibiotic therapy aimed at both staphylococci and enterococci will cover, with few exceptions, any other bacteria that are likely to be present.
- H. Blood culture-negative endocarditis** [39]. Recommended therapy includes ampicillin plus an aminoglycoside as outlined in section D.1 on treatment of enterococcal endocarditis. Given that in the absence of confounding antibiotic therapy enterococci and staphylococci are unlikely to be causes of culture-negative IE, ceftriaxone may be used instead of ampicillin. (See section VIII.G.3.)
- I. Fungi.** Fungal endocarditis almost always requires a combined chemotherapeutic and surgical approach [59]. Amphotericin B is administered at 0.5 mg/kg/day. Most *Candida* and *Torulopsis* species are sensitive to flucytosine, and 150 mg/kg/day orally may be added to the amphotericin; flucytosine, however,

should not be used alone. The best results have been reported with early surgical intervention and prolonged postoperative antifungal therapy (see Chapter 17). Prolonged or indefinite fluconazole has been suggested for patients treated either medically or surgically [40,60]. There are reports of a subset of patients with candida IE cured by prolonged fluconazole administration. Infectious disease consultation is advised.

VII. Treatment of patients with a history of penicillin allergy. If the results of properly performed skin tests for penicillin allergy are negative, the chance of a serious immediate or accelerated reaction to penicillin administration is negligible. Most patients with a history of penicillin allergy have negative skin test results and can receive penicillin. Cephalosporins are often a useful alternative in penicillin-allergic patients, but a possibility of cross-reactivity does exist. This subject is covered in detail in Chapter 24. The doses outlined here are for adults who have normal renal function.

A. Sensitive viridans streptococci. For some patients it may be preferable to perform skin tests for penicillin allergy and to give penicillin G if the results are negative. If the patient has a history of a delayed penicillin allergy, cephalosporins can usually be administered (see Chapter 24). In these patients, ceftriaxone 2 g i.v. once daily can be used [41]. If the patient has a history of an immediate, severe reaction to penicillins, or if skin tests to a cephalosporin also are positive, or if one is waiting for skin tests to be performed, vancomycin 0.5 g every 6 hours or 1 g every 12 hours can be given. (See Chapter 27 for dosing regimens for vancomycin.) Therapy should continue for 4 weeks.

B. Penicillin G-susceptible *S. aureus*. Proceed in the same manner as for viridans streptococci. However, if a cephalosporin can be administered, a first-generation cephalosporin (e.g., cefazolin) should be used.

C. Penicillin G-resistant *S. aureus*. Most patients can be treated with semisynthetic penicillin after appropriate skin tests. If alternative drugs are necessary, either a first-generation cephalosporin, for example, cefazolin 2 g every 8 hours (in the patient with delayed allergy) [41] or vancomycin 0.5 g every 6 hours or 1 g every 12 hours (see Chapter 27), can be used. Therapy should continue for 6 weeks if possible. Some clinical failures are observed when vancomycin has been used as an alternate therapy in *S. aureus* endocarditis [61]. Therefore, in the penicillin-allergic patient, infectious disease consultation is advised to help determine the optimal antibiotic regimen.

D. Enterococci and other highly penicillin-resistant streptococci. Every effort should be made, including appropriate skin testing and consideration of desensitization procedures if necessary (see Chapter 24), to give penicillin or ampicillin to patients with endocarditis due to these pathogens. If neither of these drugs can be given, vancomycin 0.5 g every 6 hours or 1 g every 12 hours (see Chapter 27 for dosing regimens) for 6 weeks, is the best alternative. Although the MIC of vancomycin for enterococci averages approximately 3 $\mu\text{g}/\text{mL}$ or less, it usually is not bactericidal *in vitro* against enterococci, and the addition of gentamicin or streptomycin is advisable. The toxic effects of vancomycin plus an aminoglycoside may be additive, and it is important to observe the patient closely for any evidence of renal or eighth nerve toxicity. Should these occur, the aminoglycoside should be stopped. Serum levels should be monitored (see Chapter 27).

E. Streptococci with penicillin MIC between 0.2 and 0.5 $\mu\text{g}/\text{mL}$. Patients with immediate hypersensitivity reactions to penicillin should be treated with vancomycin alone for 4 weeks. For those with nonimmediate hypersensitivity, either vancomycin or ceftriaxone for 4 weeks combined with gentamicin for the first 2 weeks are appropriate regimens.

F. Other infections. The general principles outlined in sections A through D are applicable. The choice of alternative drugs should be guided by results of *in vitro* testing. Bactericidal antibiotics or antibiotic combinations should be used, and serum bactericidal levels should be monitored, if possible, when *in vitro* MBCs imply that it may be difficult to achieve adequate blood levels. For unusual or resistant bacteria, infectious disease consultation is advised.

VIII. Role of surgery in endocarditis [22]. Clinical judgment is an integral part of decisions regarding surgery.

- A. Progressive or significant heart failure that does not resolve with medical therapy.** Severe CHF in this setting carries a very high mortality rate with medical therapy alone. Heart failure that resolves with medical therapy is not considered an absolute criterion for prompt surgical intervention, although in conjunction with other problems it may contribute to a decision for surgical intervention.
- B. Fungal endocarditis** is a strong indication for surgery.
- C. Persistent bacteremia** (7–10 days) despite appropriate antibiotic therapy is considered a strong indication for surgery. Metastatic extracardiac foci of infection such as osteomyelitis, septic pulmonary emboli, and intraabdominal abscesses should be excluded. A TEE is indicated to look for a perivalvular or myocardial abscess [62].
- D. Emboli.** A single major embolic episode raises the question of surgery, and some have suggested that two major embolic episodes are a strong indication. However, the risk of further embolization in these patients is unknown, and precise recommendations are difficult. The size of the residual vegetation by echocardiography and the presence or absence of other clinical and echocardiographic findings that would benefit from surgery should weigh heavily in this decision.
- E. Relapse of infection.** Surgery may be indicated if relapse occurs after a single course of antibiotic therapy, particularly if infection involves a prosthetic valve and maximal therapy has been given. It is almost certainly indicated if relapse occurs after a second extended therapeutic course.
- F. Evidence of extension of infection. The development of persistent heart block or bundle branch block strongly suggests extension of infection** (see section IX.C.2); the onset of pericarditis suggests rupture of an annular abscess into the pericardial space. These, as well as detection of valvular ring or myocardial abscesses, left-to-right shunts with septal infection, and ruptured chordae tendineae or papillary muscle, all suggest the need for surgery, although they may not individually be absolute indications. See related discussion of myocardial abscess in section V.B.1 under Endocarditis Associated with Prosthetic Valves.
- G. Microbiologic considerations**
- 1. *Staphylococcus aureus*** endocarditis often is complicated by heart failure and periannular abscess [62,63]. It is also an independent predictor of in-hospital mortality [64]. **Early surgery should be considered in the presence of CHF or a perivalvular abscess or if bacteremia fails to clear within 7 to 10 days.**
 - 2. *Pseudomonas aeruginosa*** has been difficult to cure with medical therapy alone and has been regarded as an indication for early valve replacement [65]. However, with the advent of more potent antipseudomonal antibiotics, particularly the fluoroquinolones, this tenet is no longer absolute. (See section VI.F.3.)
 - 3. Culture-negative endocarditis.** Persistent unexplained fever while on empirical antibiotics likely represents ineffective antimicrobial therapy or unappreciated perivalvular infection.
- H. Echocardiographic findings as indications for cardiac surgery.** The echocardiogram can provide information regarding hemodynamic status and intracardiac complications of endocarditis, which is very useful in assessing the potential role of surgery in the therapy of BE [21,24]. See related discussion under section III.E.
- 1.** Echocardiographic quantitation of regurgitant flow across valves damaged by BE, combined with echocardiographic assessment of left ventricular function and clinical findings, allows accurate identification of patients who will benefit from surgical correction of valve dysfunction.
 - 2.** Similarly, judgment regarding the timing of surgical intervention is facilitated by echocardiographic findings. Simultaneous reading of the electrocardiogram (EKG) and an M-mode image of the mitral valve can identify premature closure (before the onset of systole) of the valve, which is a sign of left ventricular overload with cardiac decompensation and indicates a need for prompt surgical intervention.
 - 3.** The Doppler studies can reveal aberrant flow through fistulous connections, thereby identifying patients with invasive extravalvular disease. Similarly, the

TEE has been shown to be highly sensitive and specific, in comparison with TTE, for identifying paravalvular and septal myocardial abscesses (see section III.E) [62]. Also, by identifying pericarditis and pericardial effusion in patients with aortic valve BE, a finding often associated with aortic ring abscess, the echocardiogram may call attention to this intracardiac complication. These findings suggest the need for surgical intervention.

4. The demonstration of vegetations, especially large ones in patients with BE, often raises anxiety about serious emboli and the advisability of valve replacement. In many studies, patients with vegetations detectable by echocardiography have had higher rates of CHF and systemic embolization than patients without detectable vegetations, and in some series these rates are particularly increased when vegetations are greater than 10 mm in diameter.

Vegetation mobility and valve location also may be important factors in the rate of embolization [66,67]. However, studies relating imaged vegetations to embolic complications have not routinely distinguished whether complications preceded or followed echocardiography. In some studies echocardiography does not demonstrate vegetation characteristics that are associated with subsequent embolization [68]. Furthermore, the rate of embolic events in endocarditis decreases rapidly (over 2–3 weeks) with effective antimicrobial therapy. Additionally, decision analyses that weigh the risks of surgical intervention against the hazards of continued medical therapy are not available for these situations.

As a result, there is no general agreement as to the predictive value of demonstrable vegetations, whatever the size or location, in terms of the need for prompt surgical intervention. Decisions for surgery are based primarily on assessment of valve dysfunction, hemodynamics, antibiotic efficacy, and intracardiac complications, although the presence, size, mobility, and location of vegetations may be important additional considerations when, despite the primary assessment, the role of surgery remains uncertain [69].

I. Timing of surgery

1. **Hemodynamic considerations.** If there is valvular regurgitation and significant impairment of cardiac function, surgical intervention before the development of severe intractable hemodynamic dysfunction is recommended regardless of the duration of preceding antimicrobial therapy [65,70]. In those patients with valvular dysfunction but in whom infection is controlled and cardiac function maintained, surgery can be put off until a course of antibiotics is completed. If a patient will require a valve replacement in the near future and has a large vegetation that will put him or her at risk for systemic embolization, early surgery is indicated. (See section H.4.)
2. **Neurologic considerations.** The presence of recent neurologic injury may require modification of a planned surgery schedule. When control of infection and maintenance of cardiac function permit, it has been suggested that cardiac surgery should be delayed for 2 to 3 weeks after a significant embolic infarct and for at least a month after intracerebral hemorrhage [71]. Not all authorities agree [72], however, and the reader is referred elsewhere for a more complete discussion [2].

J. Postoperative antibiotics. Duration of antibiotic therapy following valve replacement is not clearcut. It has been suggested that the full course of antibiotics be given postoperatively if cultures of the blood or the valve are positive at the time of operation or if results of Gram staining of resected tissue are positive. Otherwise, the usual course should be completed, but a minimum of 2 weeks of postoperative antibiotic therapy should be given.

K. Survival after surgery for culture-positive active endocarditis has recently been reviewed [73–75]. Mortality rates of 20% to 30% or more have commonly been reported in the acute perioperative phase. However, the long-term outcome of hospital survivors is excellent. Subsequent reoperations for periprosthetic leak are common, but recurrent infection is uncommon.

L. See related discussions about the indications for surgery in section V.B under Endocarditis Associated with Prosthetic Valves.

IX. Course and complications of BE [76]

A. General. When appropriate antibiotic therapy is begun, symptomatic improvement, decline in fever, and reversion of blood cultures to negative are usually prompt. With sensitive organisms, this is likely to occur in 24 to 48 hours, but with more resistant ones, such as *S. aureus*, it may take several days to a week before definite improvement is noted, and it may be 2 weeks or more before the patient is afebrile. Many patients who have become afebrile will continue to be so through a course of therapy, without further difficulty.

Anemia usually persists during the course of therapy, and it may take weeks or months for the hematocrit to return to normal. **Splenomegaly** also tends to resolve very slowly. Some patients will continue to have petechiae or Osler nodes during or after a course of successful therapy. The occurrence of these does not necessarily reflect antibiotic failure. Significant **arterial emboli also may occur up to months after completion of therapy**, in the absence of any bacteriologically active disease.

B. Fever. One of the most common problems seen during the course of therapy is persistence or recurrence of fever after an afebrile period [77,78]. If the infecting organism is known to be sensitive and appropriate doses of antibiotics are being administered, simple bacteriologic failure is rarely the cause.

1. Causes of recurrent or persistent fever

a. Failure to control infection. If the infecting organism has a relatively high degree of antibiotic resistance, fever and positive blood cultures may persist despite optimal antimicrobial therapy. Failure to control infection in this circumstance indicates that valve replacement is necessary.

In one study, extensive cardiac infection with discrete abscesses extending from the valvular ring or with widespread tissue destruction without localized abscesses was the most common cause of persistent or recurrent fever; valve replacement was required [78]. More than half the cases were caused by viridans streptococci, and most were not accompanied by pericarditis or conduction defects.

b. Intravenous-related phlebitis (sterile or septic) can occur, particularly with indwelling catheters.

c. Metastatic abscess formation is more likely to occur in staphylococcal infection than in infection by other organisms. Splenic abscess occurs in 3% to 5% of patients with IE [76]. Drainage, which can often be accomplished percutaneously, is generally necessary for successful therapy [79]. It is desirable to treat abscesses as completely as possible before valve replacement [27].

d. Recurrent emboli from the endocardium or from deep venous thrombosis can occur.

e. Superimposed infections involving the urinary tract, respiratory tract, or other sites are not uncommon.

f. Drug fever is a common cause of recurrent fever in this setting (see Chapters 1 and 24).

2. Approach to the patient with recurrent or persistent fever

a. A careful **reevaluation of symptoms and physical findings**, aided by appropriate laboratory and other diagnostic procedures directed toward the possibilities listed in section 1, is indicated.

b. Drug fever is reviewed in Chapter 1.

C. Cardiac effects

1. CHF occurring during or after treatment of endocarditis is the most common serious cardiac complication of the disease and the major cause of mortality. CHF usually results from destruction of valves during the course of active disease or from subsequent shrinkage or scarring of valves or their supporting structures, although myocarditis also may contribute. Patients who develop aortic insufficiency are especially prone to rapid and severe cardiac decompensation. The role of surgery in these circumstances has been discussed previously.

2. Conduction abnormalities may occur. The appearance of new or changing conduction block suggests extension of infection to the myocardium and is associated with aortic valve involvement in most cases. It has been recommended

that valve replacement be considered in patients who develop conduction abnormalities that persist for more than a week during medical therapy and that are not secondary to drugs or ischemic heart disease [80].

3. **Coronary embolization** with myocardial infarction can occur and may contribute to CHF.
 4. **Valvular obstruction** due to large vegetations occasionally is seen and generally involves the mitral valve.
- D. Mycotic aneurysms** can be seen in 5% to 10% of cases of BE in autopsy series [81]. These can occur at any site in the arterial vasculature, usually at points of bifurcation. There is a 1% to 3% incidence of intracranial mycotic aneurysms [82]. There may be prodromal symptoms, such as headache before rupture, that warrant investigation such as arteriography. Mycotic aneurysms may resolve during antibiotic therapy. They should be monitored angiographically. Urgent repair should be considered for those that enlarge during or after antibiotic therapy. Repair of a ruptured aneurysm is indicated if anatomically feasible [2].
- E. Renal complications** [83,84]—specifically, focal or diffuse glomerulonephritis—may be seen in the course of endocarditis. Both types of glomerulonephritis are probably immunologically mediated by renal deposition of circulating immune complexes, often with decreased levels of serum complement.
1. **Focal glomerulonephritis** is the more common form and results in proteinuria and hematuria but rarely in renal insufficiency.
 2. **Diffuse glomerulonephritis** can cause significant renal failure. The picture sometimes is complicated by concomitant administration of nephrotoxic antibiotics or by the possibility of interstitial nephritis from penicillins. The occurrence of diffuse glomerulonephritis is related to duration of disease and is less common today than in the preantibiotic era. Renal insufficiency secondary to diffuse glomerulonephritis is likely to improve with appropriate therapy, although it may not respond well after extensive damage has occurred.
- F. Complications of antibiotic therapy**
1. **Drug fever** is discussed in Chapter 1.
 2. **Allergic drug reactions.** In addition to fever, prolonged administration of high-dose penicillins or cephalosporins results in a significant rate of allergic drug reactions (see Chapter 24).
 3. **Aminoglycoside toxicity** is discussed in Chapter 27.
 4. **Acute interstitial nephritis**, often accompanied by renal insufficiency, may be seen with the use of almost any penicillin or cephalosporin, although the incidence is much higher with methicillin (see Chapter 27).
 5. **Neutropenia** is relatively common secondary to β -lactams, especially after 15 days of therapy [85].
- X. Evaluating sustained bacteremia.** Diagnostic criteria should be applied to assess the likelihood of IE (see section III.F). Among patients with *S. aureus* bacteremia, the risk of IE is highest in community-acquired infection, in the absence of a peripheral focus, in IVDUs, in diabetics with chronic skin infections, and in patients with preexisting valve abnormalities [2,86,87]. The risk of nosocomial IE due to *S. aureus* bacteremia secondary to an i.v. catheter is significant [88]. Patients with *S. aureus* bacteremia who have known cardiac valve disease, develop a new significant murmur, or have persistent fever or bacteremia for 3 or more days after removal of a presumed primary focus of infection (e.g., intravascular catheter or abscess) and initiation of therapy merit echocardiographic evaluation because they are at high risk for IE [2].
- A review found IE in 12 of 34 cases of enterococcal bacteremia that were community acquired, but in only 1 of 118 that were of nosocomial origin [89].
- See section IV. B under Endocarditis Associated with Prosthetic Valves for discussion involving prosthetic valves.

ENDOCARDITIS ASSOCIATED WITH PROSTHETIC VALVES

The incidence of PVE is highest during the initial 6 to 12 months after valve replacement but continues at a low rate thereafter. By 4 to 5 years postoperatively, as many as 3% to 6% of patients may have had PVE. In most series, the rate of infection in mechanical and

bioprosthetic valves is similar. Rates of infection are similar for prostheses at the mitral or aortic position [90].

I. Time of onset of PVE

A. PVE occurring within 12 months (especially that within 2 months) of valve replacement presumably is likely to have been acquired at the time of operation or in the early postoperative period. Potential sources of contamination accounting for these cases are the heart-lung machine itself, coronary suction lines, other sources of intraoperative contamination, postoperative i.v. and urinary catheters, postoperative pneumonias, and sternal wound infections. In individual cases, however, a definite source of infection often is not identified.

B. PVE presenting more than 12 months postoperatively. Late infections presumably are caused by bacteremia unrelated to the initial surgical procedure and often occurring in a community setting.

II. Pathologic features. With mechanical valves, infection involves the valve annulus at the site of attachment, resulting in ring abscesses, with frequent extension to adjacent structures [90]. With **aortic valve** involvement, prosthetic detachment often leads to severe regurgitation, and extension of infection to conducting tissue may cause serious conduction defects. With **mitral prosthesis** involvement, severe regurgitation or conduction defects are less common, but obstruction by vegetative material may be encountered. With **bioprosthetic valves**, ring abscesses occur when infection arises in the year after valve replacement. Infection beginning later is more typically (but not always) confined to the valve leaflets. Infection may destroy the leaflets of bioprosthetic valves or may cause delayed-onset leaflet stiffness with later development of stenosis [90].

III. Microbiologic features. *S. epidermidis* and *S. aureus* together account for almost half the total cases of PVE. The microbiologic profile of PVE within 12 months of surgery differs from that of later onset.

A. In early PVE, *S. epidermidis* is the most common organism, with occasional infections by *S. aureus*, diphtheroids, gram-negative rods, and fungi.

B. In later-onset PVE, viridans streptococci, enterococci, *S. aureus*, and fastidious gram-negative coccobacilli often are encountered. Coagulase-negative staphylococci may cause 20% of these later infections. **Importantly, coagulase-negative staphylococci that cause PVE within 12 months of surgery often are methicillin resistant (>75%),** whereas those causing later-onset PVE are less commonly methicillin resistant (<30%) [90,91].

C. Culture-negative PVE occurs occasionally. Most often, it is the result of recent antimicrobial therapy. However, PVE due to *Legionella* species, mycelial fungi, *C. burnetii*, *Mycoplasma* species, mycobacteria, and occasional fastidious bacteria may cause PVE with negative routine blood cultures [90].

IV. Diagnosis

A. Clinical features. The clinical picture may be nonspecific or atypical, and precise diagnosis may be difficult, particularly during the initial weeks after surgery.

1. Fever. An unexplained and persistent fever in patients with prosthetic valves always raises the possibility of endocarditis. Therefore, serial blood cultures should routinely be drawn in febrile patients with prosthetic valves.

2. Cardiac findings of either a new regurgitant murmur (indicating a paravalvular leak) or unexplained refractory heart failure are important clues to the diagnosis of PVE.

3. The presence of embolic phenomena or immunologically mediated vasculitic lesions helps support the diagnosis, but their absence does not exclude the diagnosis.

B. As the time after surgery increases (>6 months), the clinical features usually are similar to those of BE in patients without prosthetic valves. However, the diagnosis of endocarditis in the early postoperative period often presents considerable difficulties, with multiple other nosocomial events confounding the evaluation of postoperative bacteremia. Patients with no cardiac or peripheral evidence of endocarditis are particularly problematic in this respect.

1. If sustained bacteremia is caused by relatively avirulent organisms that are not otherwise expected to be invasive (e.g., *S. epidermidis*, micrococci, or diphtheroids)

or if there is no apparent extracardiac source for bacteremia, the patient should be treated for endocarditis.

2. Transient bacteremia, with gram-negative rods especially, may or may not indicate endocarditis in this setting. It has been suggested that the postoperative patient with gram-negative rod bacteremia associated with an obvious extracardiac focus of infection and no clinical evidence of endocarditis need not be placed on prolonged therapy for presumed valvular infection. If bacteremia recurs after a course of therapy sufficient to eradicate the extracardiac focus, endocarditis must be seriously considered.

Some prefer to treat all valve recipients with bacteremia for presumed endocarditis. In one study, only 16% of valve recipients with nosocomial bacteremia (not due to PVE itself) went on to develop subsequent PVE [92]. Staphylococcal bacteremia and the presence of a prosthetic mitral valve was associated with an increased risk for PVE [92]. Infectious disease consultation is advisable.

3. Sustained *S. aureus* bacteremia should be treated as endocarditis.
4. Nosocomial candidemia in patients with prosthetic valves is not always associated with nor results in PVE. In one study of 44 patients, approximately 15% had obvious PVE when candidemia was identified and another 10%, often with early postoperative candidemia, subsequently developed PVE. The interval from candidemia to overt PVE may be long (26–690 days) [93].

C. Blood cultures

1. In the absence of antibiotic therapy, most patients with prosthetic valve BE (85%–95%) have positive blood cultures [90].
2. With some causes of PVE, however, blood cultures may be negative (see section III.C). Infections with *Candida* species can occasionally result in intermittent fungemia or negative cultures. With *Aspergillus* or other mycelial fungi causing PVE, blood cultures are usually negative. Fungal PVE may result in emboli to large vessels, and the diagnosis often depends on the demonstration of fungi in resected large emboli (see Chapter 17).
3. It is important that the etiology of PVE not be obscured by premature antibiotic treatment [90].
 - a. Indolent endocarditis, in the absence of hemodynamic instability that mandates surgical intervention, does not require immediate antimicrobial therapy. Antibiotics should be withheld briefly pending the isolation of an organism from blood culture [90].
 - b. If oral antibiotics that might render initial blood cultures sterile have been given, this delay (3–5 days) is particularly important because it allows blood cultures to be repeated without the interference of additional therapy [90].
 - c. Presentations of PVE that are acute or complicated by hemodynamic instability due to prosthetic valve dysfunction require that blood cultures be obtained and antibiotics administered promptly.

- D. **Other aids to diagnosis.** EKG demonstration of conduction defects, such as increasing P-R interval, complete heart block, or left bundle branch block, suggest infection invading the conduction system. **Echocardiography** may be useful in detecting large vegetations, prosthesis detachment, perivalvular abscess, or pericarditis. TEE, which is exceptionally useful in evaluating prostheses in the mitral position, is indicated when investigating patients with possible PVE. TEE provides excellent views of the posterior portion of the aortic prosthesis; the anterior aortic root area is better visualized from a transthoracic approach. In patients at high risk of PVE, repeat studies may detect abnormalities not noted on the initial echocardiogram. TEE is strikingly more sensitive in the detection of myocardial abscess in patients with PVE than is TTE [90]. Nondiagnostic TTE evaluations are insufficient to exclude the diagnosis of PVE [21,24,67].

V. Therapy for PVE

- A. **Antibiotic therapy** follows the same general principles previously outlined for native valve endocarditis [90]. Bactericidal antibiotics are used and administered parenterally. Because antibiotics are often given for 6 weeks, recovery of the causative organism and careful determination of susceptibility data are essential [90] (see section IV.C).

1. ***S. epidermidis***. Most *S. epidermidis* isolates from patients with PVE are resistant to semisynthetic penicillins such as methicillin (see section III), although this may not be apparent by routine disk diffusion tests or automated MIC tests using a low bacterial inoculum. Careful evaluation of these isolates using proper methods is necessary [90]. Strains that are resistant to methicillin are also resistant to cephalosporins and other β -lactam antibiotics when studied carefully.

The best results have been obtained with a combination antimicrobial regimen that includes rifampin and gentamicin if the organism is sensitive to these agents. The usual recommended dosages, assuming normal renal function, are vancomycin (see Chapter 27 for dosage regimens); rifampin 300 mg orally every 8 hours; and gentamicin 1.0 to 1.3 mg/kg every 8 hours. To prevent emergence of rifampin resistance, it has been suggested that vancomycin be adjusted to give peak levels of 25 to 35 $\mu\text{g/mL}$ and trough levels of 10 to 15 $\mu\text{g/mL}$ and that gentamicin dosage be adjusted to give a 5- $\mu\text{g/mL}$ peak and 1- $\mu\text{g/mL}$ trough [41,90]. Additive nephrotoxicity may result from simultaneous vancomycin and gentamicin administration; therefore, renal function should be monitored carefully (see Chapter 27). Ideally, the vancomycin and rifampin are given for 6 weeks and the gentamicin (if the strain is susceptible) for the first 2 weeks. If a strain is resistant to gentamicin and other aminoglycosides, a fluoroquinolone with enhanced gram-positive activity (if the strain is susceptible to it) may be used in lieu of the aminoglycoside [90]. **Most patients require valve replacement in addition to antibiotic therapy.**

For treatment of PVE caused by methicillin-susceptible *S. epidermidis*, a β -lactam antibiotic should be substituted for vancomycin in the combination regimen [41,58,90].

The treatment of PVE caused by *S. aureus* uses the same regimens recommended for treatment of *S. epidermidis* PVE. The decision to use vancomycin or a semisynthetic penicillinase-resistant penicillin is based on whether the isolate is methicillin resistant or whether the patient has a therapy-limiting penicillin allergy.

2. **Other organisms** are treated with high doses of i.v. antibiotics guided by sensitivities, as discussed earlier in section VI under Infective Endocarditis. Antibiotics usually are administered for at least 6 weeks; a longer course may be required for patients who do not respond promptly. **In the setting of PVE, every effort should be made to attain maximum bactericidal blood levels.** For example, it probably is best to add an aminoglycoside to penicillin for sensitive viridans streptococci infection, even though this may not be necessary for native valve infection.
3. **Initial therapy while awaiting culture results.** The decision to start antibiotic therapy before a microbiologic diagnosis has been established should be based on the clinical findings. Of particular importance is the possible need for urgent surgical intervention. In selecting antibiotics for empiric therapy, the clinical and epidemiologic circumstances must be weighed. The time that has elapsed since valve replacement may provide insight into potential causes of PVE (see section III) and should be carefully considered. In general, therapy should include vancomycin, gentamicin, and to provide coverage for HACEK organisms, a third-generation cephalosporin.

Antibiotics are adjusted when culture results become available. If blood cultures remain negative, the causes of culture-negative PVE should be sought. For patients with culture-negative PVE who remain febrile during empiric therapy, surgery should be considered. Infectious disease consultation is advised.

B. Surgery

1. **Indications for surgery** in PVE are similar to those previously discussed for native valve endocarditis [22,65] (see section VIII under Infective Endocarditis), and they **have been summarized in Table 12.3**. Some of these indications are not absolute but rather serve to prompt careful consideration of surgical therapy.

Because invasive infection unlikely to respond to antibiotics alone is often a feature of PVE beginning within 12 months after valve implantation, these patients often benefit from surgical intervention. Evidence of invasive disease

Table 12.3. Indications for Cardiac Surgery in Patients with Prosthetic Valve Endocarditis (PVE)

Moderate to severe heart failure due to prosthesis dysfunction (incompetence or obstruction)
Invasive and destructive paravulvular infection
Partial valve dehiscence
New or progressive conduction system disturbances
Fever persisting 10 or more days during appropriate antibiotic therapy
Purulent pericarditis
Sinus of Valsalva aneurysm or intracardiac fistula
Uncontrolled bacteremic infection during therapy
Infection caused by selected organisms
Fungi
<i>Staphylococcus aureus</i> ^a
Coagulase-negative staphylococci ^a
<i>Pseudomonas aeruginosa</i>
Relapse after appropriate antimicrobial therapy
Persistent fever during therapy for culture-negative PVE in absence of other causes of fever
Recurrent arterial emboli ^b
Renal failure with severe aortic regurgitation ^c

^aAlthough not a uniformly accepted indication for surgical treatment of PVE, several investigators favor surgical therapy for PVE caused by *S. aureus* or coagulase-negative staphylococci [90,95]. This may especially apply to patients who do not respond rapidly to antibiotic therapy.

^bRather than an indication for surgery, the potential for additional systemic emboli is often viewed as a factor that, in combination with other considerations, might help to justify surgery. Reviews suggest that recurrent emboli are rare in patients who are receiving appropriate antibiotics [90].

^cThe presence of deteriorating renal function in patients with endocarditis associated with severe aortic regurgitation is indicative of low cardiac output and should, in itself, stimulate urgent operation [22]. Modified from Karchmer AW. Infections of prosthetic heart valves. In: Bisno AL, Waldvogel FA, eds. *Infections associated with indwelling medical devices*. 3rd ed. Washington, DC: American Society for Microbiology, 2000: 145–72; Jamieson SW. Surgical therapy for infective endocarditis. *Mayo Clin Proc* 1995;70:598; with permission.

even in the absence of CHF warrants surgery [90,94]. PVE caused by *S. aureus* is unusually lethal, with low cure rates attributed to antibiotic therapy alone; affected patients should be considered for early surgical intervention [90]. Failure to achieve an afebrile status with appropriate antibiotic therapy, assuming drug fever and metastatic infection have been ruled out, is evidence of invasive disease and should prompt consideration of surgery.

Similarly, relapse after appropriate medical therapy usually is due to invasive disease; patients who experience such a relapse should be treated surgically. Failure of a patient with culture-negative PVE to become afebrile in 10 days indicates either inappropriate empiric therapy or invasive disease. Such patients should undergo surgery to clarify the etiology of PVE and debride invasive infection. Surgical intervention is appropriate and probably beneficial in as many as 40% to 50% of patients with PVE [90].

- 2. Results of PVE surgery** have been reviewed elsewhere, and operative mortality rates range from 20% to 30% [73]. However in a recent series, those who survived the surgical period had a good 5- to 10-year survival rate with about 70% at 5 years and 60% at 10 years [73]. There appears to be no striking difference in survival whether a valve replacement is with tissue or mechanical prostheses [22,73].

In a recent report, operative mortality was related to the presence of an abscess at the time of operation. Formation of an abscess cavity was commonly associated with staphylococcal infections, PVE, and the aortic site [22,73].

VI. Prevention of PVE. See Chapter 27.

ENDOCARDITIS IN INTRAVENOUS DRUG USERS

- I. Clinical characteristics and diagnosis.** Symptoms of endocarditis in IVDUs are usually of 1 to 2 weeks' duration at the time of presentation, and fever is almost always observed. Endocarditis often is difficult to predict on clinical grounds in the febrile IVDU, and it differs from that in nonaddicts in several respects [96,97].
- A.** Preexisting valvular abnormalities are usually absent.
 - B.** Tricuspid valve involvement approximates 50% to 75% of episodes. Repeated injections of particulate foreign material may damage the tricuspid endothelium, predisposing it to infection during a bacteremic episode. With isolated tricuspid involvement, a murmur is often undetectable. Neurologic and peripheral manifestations of endocarditis are relatively infrequent. Symptoms of cough, hemoptysis, dyspnea, and pleuritic chest pain associated with pneumonia or septic pulmonary emboli are common.
 - C.** Aortic or mitral valves are involved in roughly 25% to 33% of patients. Pulmonic valve involvement is rare. Left-sided endocarditis produces a clinical pattern similar to that seen in nonaddicts.
 - D.** There is a high rate of recurrence, presumably due to continued parenteral drug use [98].
- II. Microbiologic features.** *S. aureus*, the single most common organism responsible for endocarditis in IVDUs, accounts for approximately 60% of the total isolates and 80% of those in right-sided disease. Streptococci and enterococci comprise approximately 20% and cause left-sided endocarditis in the great majority of cases. *P. aeruginosa* and other aerobic gram-negative bacilli account for 10% to 15% and can display marked regional variation. Fungi, mainly *Candida* species, cause predominantly left-sided endocarditis and account for approximately 5%. Polymicrobial blood cultures are reported in nearly 5% and negative blood cultures in fewer than 10%.
- III. Treatment.** Antimicrobial therapy for endocarditis in drug addicts follows the same principles outlined earlier for the nonaddict population, except that presumptive therapy should include gram-negative coverage; indications for a surgical approach to left-sided disease also are similar. A short course (2 weeks) of a penicillinase-resistant penicillin and an aminoglycoside has been effective in uncomplicated right-sided IE caused by methicillin-sensitive *S. aureus* in drug users [99]. Dosing is as for standard staphylococcal IE therapy. Vancomycin should not be substituted in this setting [99]. Cloxacillin alone for 2 weeks also has been effective [100]. Patients with *S. aureus* tricuspid valve involvement usually do well, but occasional cases that are refractory to antimicrobial therapy require valvectomy with or without valve replacement.
- IV. Prognosis.** The mortality rate among addicts with staphylococcal endocarditis is considerably lower than that of the general population. This probably reflects the younger population involved, a lower incidence of underlying heart or other serious diseases, and the frequency of isolated tricuspid valve involvement. However, the mortality for repeated bouts of endocarditis and of gram-negative or fungal endocarditis remains high.

The course of BE in IVDUs who are HIV positive is similar to that in HIV-negative patients [101]. However, mortality is increased for those with a CD4 count below 200/mm [102].

PERICARDITIS AND MYOCARDITIS

I. Pericarditis [103]

- A. Clinical characteristics.** Pericarditis, sometimes accompanied by clinically significant myocarditis, may present as the sole or major manifestation of an infectious illness, or it may occur as a minor or incidental finding. The patient is usually febrile, and the diagnosis is suggested by symptoms of substernal pain or discomfort, which sometimes is relieved by sitting up and leaning forward; the presence of a pericardial rub is confirmatory. Occasionally, pericarditis may present with signs and symptoms of cardiac tamponade. Roentgenographic findings of an enlarged cardiac silhouette may be seen. Typical EKG changes are generalized ST segment elevations without reciprocal ST depression except in leads V₁ and aVR. Low-voltage QSR complexes may be seen with sizable pericardial effusions. Echocardiography is a sensitive and

reliable noninvasive procedure for demonstrating the presence of significant amounts of pericardial fluid.

- B.** The **cause** often is difficult to establish. Numerous noninfectious as well as infectious causes must be considered.
- 1. Noninfectious causes.** Among these are uremia, neoplasm, trauma, myocardial infarction, postmyocardial infarction (Dressler syndrome), connective tissue diseases (e.g., lupus erythematosus, rheumatoid arthritis), and rheumatic fever. History, physical examination, and appropriate laboratory studies should be directed toward ruling these out.
 - 2. Infectious causes** [104,105]. Although their true incidence is not known, **viral agents probably are the most common** cause of infectious pericarditis in the United States. Among proved or highly suspect viral agents, the most important are enteroviruses, especially coxsackievirus B, coxsackievirus A, and echovirus. Numerous other viral agents have been implicated. The most common diagnosis, especially in young patients without other apparent cause, is idiopathic or nonspecific pericarditis. This is often equated with viral pericarditis, although in most cases a definite viral cause cannot be proved. Much less common are cases of pyogenic or tuberculous pericarditis; nonetheless, it is important to rule these out in suggestive clinical settings. Other infectious agents known or suspected to cause pericarditis are fungi, rickettsiae, chlamydiae, mycoplasmas, protozoa, and *Legionella pneumophila*.
- C. Differential diagnosis.** Although the patient's history, physical findings, and ancillary diagnostic tests may help, specific diagnosis of presumed infectious pericarditis usually will depend on examination of pericardial fluid or on pericardial biopsy. However, these procedures often are not diagnostic and, in most patients, are not indicated. In a case of pericarditis in which the cause is still unknown after the usual diagnostic studies, one often needs to decide whether pericardiocentesis or pericardial biopsy should be performed. This decision must be individualized. Should any evidence of impending tamponade appear, a procedure is necessary for therapeutic purposes, and diagnostic information can be obtained at the same time.

In the case of the typical idiopathic pericarditis that appears to follow a relatively benign course, it usually is best to observe the patient and treat symptomatically. Should fever persist for more than a few weeks, or should the clinical course appear to be one of continued toxemia or deterioration, open drainage of the pericardium, with pericardial biopsy, may be indicated.

D. Specific infections

1. Viral, idiopathic, or nonspecific pericarditis

- a. Presentation.** In the case of viral, idiopathic, or nonspecific pericarditis, the illness tends to present acutely. In some cases, a history is obtained suggesting a viral respiratory or gastrointestinal infection that began 2 to 3 weeks previously. Signs and symptoms may be those of pericarditis alone, or there may be accompanying pleural effusions or pulmonary infiltrates.
- b. Course and complications.** The illness usually follows a benign course, resolving in 2 to 6 weeks, but symptoms may recur in 15% to 30% or more of patients [106]. The latent period between the preceding viral infection and the first symptoms of pericarditis, as well as the continued relapsing course observed in some patients, suggests a postinfectious, immunologically mediated process. Associated myocarditis, reflected by EKG changes, is frequent and occasionally is severe enough to cause cardiomegaly and CHF. Chronic cardiomyopathies have been observed in some patients. Hemorrhagic pericardial effusions, cardiac tamponade, and chronic constrictive pericarditis also have been described.
- c. Diagnosis.** The diagnosis often is presumptive and depends on observation of the clinical course after specific etiologies have been ruled out as carefully as possible.
 - (1) Cultures and serologic studies.** Viral cultures of the pharynx, fecal specimens, and pericardial fluid may be performed, but in most cases the results are negative. Examination of acute and convalescent sera for a fourfold or greater increase in antiviral antibody may be helpful if a specific virus has been isolated. Screening for antibody to all possible viruses is not practical.

- (2) **Pericardial drainage and biopsy** may be indicated in some patients for diagnostic purposes. Cardiac tamponade, or impending tamponade, occurs occasionally and requires drainage through an open surgical procedure or pericardiocentesis. Open drainage, which is preferred by many, offers an opportunity for examination of pericardial tissue. This is useful primarily in ruling out nonviral causes such as tuberculosis or tumor. The fluid and tissue can be cultured for virus and the tissue examined by histologic and immunofluorescent techniques. Histology is nonspecific, however, and viruses are isolated infrequently.
- (3) **Treatment.** Other than pericardial drainage when indicated, management for idiopathic and viral pericarditis consists of bed rest, pain control, and monitoring for evidence of hemodynamic compromise. Animal model data suggests nonsteroidal antiinflammatory agents, and prednisone may exacerbate the myocarditis that can accompany viral pericarditis [104]. These agents should thus be avoided if there is any clinical suspicion or chemical evidence of myocarditis. Idiopathic and viral pericarditis typically run a benign and self-limited course. Relapses may occur. Colchicine may be useful in these settings [107]. Steroids and other immunosuppressive regimens are sometimes used [108].
2. **HIV-related pericarditis** [109,110] is common enough that risk factors should be assessed in the presentation of pericarditis. When large symptomatic pericardial effusions in patients with HIV were aggressively investigated, two-thirds were found to have an identifiable cause [111]. Approximately one-third of HIV-positive patients with tamponade will have mycobacterial disease (*M. tuberculosis* or *M. avium-intracellulare*) [111].
3. **Purulent pericarditis** [112,113].
- a. **Presentation.** Purulent pericarditis almost always occurs in the setting of other serious disease or a surgical procedure and results from postoperative infections after thoracic surgery (commonly open heart surgery); contiguous spread of infection from pleural, mediastinal, or pulmonary foci; contiguous spread from intracardiac infections (endocarditis, myocardial abscess); or hematogenous spread of infection from distant foci. Although the patient is obviously ill, specific signs of pericarditis such as chest pain, pericardial rub, or EKG changes often are absent. The disease is likely to follow a rapidly progressive course and carries a high mortality rate.
- b. **Microbiologic features.** In the preantibiotic era, *Streptococcus pneumoniae*, usually associated with pneumonia, caused more than 50% of cases of purulent pericarditis; staphylococci and streptococci were the next most common causative agents. More recently, staphylococci and gram-negative bacilli account for the majority of cases, usually occurring after major surgery or in patients with uremic pericarditis, cancer, myocardial infarction, diabetes, and immunosuppressed states. Meningococci, streptococci, gonococci, *H. influenzae*, and a variety of other bacteria as well as fungi [114] also are reported.
- c. **Diagnosis and treatment. Prompt drainage of pericardial fluid is essential for diagnostic and therapeutic purposes.** This may be attempted with pericardiocentesis, but surgical intervention with drainage through a pericardial window usually is preferable due to the thick nature of the infected fluid and should not be delayed. Antibiotic therapy is guided by results of Gram stains and cultures of pericardial fluid or tissue. High doses of parenteral antibiotics, equivalent to endocarditis regimens, are used. The role of early pericardiectomy is controversial.
4. **Tuberculous pericarditis** [115]
- a. **Presentation.** Tuberculous pericarditis may occur as the only clinically evident manifestation of tuberculosis, or it may be accompanied by pulmonary or other (extrapulmonary) disease. Tuberculous pericarditis has its origins in extension from adjacent pulmonary, bone, or lymph node disease; retrograde lymphatic spread from tracheobronchial nodes; or hematogenous dissemination. The presentation may be acute, subacute, or chronic. The acute disease may be productive and granulomatous, with little effusion, or it may present

with abrupt accumulation of fluid and may cause tamponade. The presentation usually is insidious, however, with slow accumulation of pericardial fluid. Chronic constrictive pericarditis may result.

- b. **Diagnosis.** If pericarditis occurs in association with proven active pulmonary or extrapulmonary tuberculosis, the presumptive diagnosis usually is made and the patient is treated accordingly. Otherwise, specific diagnosis depends on examination of pericardial fluid or on pericardial biopsy. Acid-fast organisms usually are not seen in pericardial fluid, and diagnosis is made mainly on the basis of cultures of fluid and pericardial tissue and histologic examination of biopsy material. Granulomatous pericarditis should be regarded as tuberculous if no other cause can be found, even if acid-fast bacilli are not demonstrable histologically.
- c. **Treatment is with specific antituberculous agents.** Optimal regimens have not been clearly established. Data reviewed in Chapter 11 suggest that extrapulmonary tuberculosis due to susceptible organisms can be treated in the same way as pulmonary tuberculosis if isoniazid and rifampin are not contraindicated. (If alternate drugs must be used, infectious disease consultation is advised.) For additional discussion and specific dosage regimens, see Chapter 11 under Tuberculosis.

The indications for corticosteroid therapy and pericardiectomy are controversial. Steroids may hasten symptom resolution and decrease fluid reaccumulation [116].

II. Myocarditis [117]

- A. **Viral.** Most infectious myocarditis in the United States is of viral origin. Coxsackie B virus is the most common specific organism. It is suspected that many cases of myocarditis that are classified as idiopathic are also due to an undiagnosed viral etiology. Numerous other viruses have been reported to cause myocarditis.

1. **Pathophysiology.** In recent years, it has been concluded that the myocardial injury stems not from the virus itself, but from immunologic responses initiated by the virus. The responses leading to the immune-mediated injury are incompletely defined. Some individuals may be especially prone because of inherent immunoregulatory defects.
2. **Clinical presentation.** Sixty percent of individuals complain of an antecedent flulike illness. The spectrum of presenting symptoms ranges from malaise and mild chest pain to cardiogenic shock. Typical complaints include palpitations and chest pain that may be pericardial, ischemic, or atypical sounding by description. Heart block and syncope may be seen.
3. **Diagnosis.** No blood tests are diagnostic, and viral testing has the same limitations as in pericarditis. Nonspecific ST and T-wave changes on **EKG** are common. Supraventricular and ventricular arrhythmias are frequently seen. **Echocardiography** can show a broad array of abnormalities, including wall thickening and segmental wall motion abnormalities. **Indium 111-labeled antimyosin antibody** imaging can detect myocardial necrosis. **Contrast-enhanced magnetic resonance imaging** may be helpful.

The gold standard for diagnosis has long been the endomyocardial biopsy, but many experts now feel it is not routinely warranted [118].

4. **Treatment.** Neither immunosuppression nor immunomodulation have been of consistent benefit. At present, therapy consists of control of symptoms and potential cardiac complications.
 5. **Prognosis.** One-third of patients may have persistent abnormalities ranging from mild EKG changes to CHF. Although the association between acute myocarditis and dilated cardiomyopathy has almost been taken for granted for many years, the causal relationship has not been proven. It is unknown if any of those individuals with dilated cardiomyopathy represent end-stage viral myocardial infection.
- B. **Lyme disease.** The carditis associated with Lyme disease typically presents as conduction abnormalities. Related dilated cardiomyopathy has not been demonstrated outside of Europe [119]. See Chapter 21.
 - C. **Chagas disease.** American trypanosomiasis is the world's leading cause of CHF. In the United States, it needs to be considered in immigrant populations from South America. [120].

- D. HIV-related myocarditis** [121]. Dilated cardiomyopathy is a well-recognized feature of HIV. It may be due to HIV infection of myocardial cells, coinfection with other viruses such as CMV, or an immune-related response. Cardiotoxicity from illegal substances or HIV-related therapy also may play a role [122,123].

INFECTIONS OF PERMANENT CARDIAC PACEMAKERS AND IMPLANTABLE CARDIOVERTER DEFIBRILLATORS

- I. Permanent cardiac pacemaker infections** [124,125]. Pacemaker systems consist of a generator, which sits in a surgically created pocket below the subcutaneous or subfascial tissue in the chest or abdominal wall, and electrode leads, which may be epicardial or, more commonly, transvenous (in which case the electrodes are attached to the endocardium). The generator pocket and the intravascular and intracardiac portions of the leads eventually become encased in dense layers of endothelialized fibrous tissue.

A. Location

- 1. Generator units or the lead wires in their subcutaneous position.** These infections are commonly seen soon after pacemaker placement or generator exchange. Later infections may be seen as a result of necrosis of the skin overlying the generator or trauma to the generator. There may be signs of swelling, erythema, and pain over the generator. Drainage is more commonly seen in infections soon after implantation. Systemic signs and bacteremia may be present.
- 2. Epicardial electrodes** may become infected from spread from the generator pocket or direct contamination at placement. In addition to clinical findings noted above, pericarditis and mediastinitis may occur.
- 3. Intravascular portion of the transvenous electrode (pacemaker endocarditis)** [126,127]. This usually arises because of intravascular tracking of infection of the subcutaneous portion of the pacing device. An incidence of 0.5% has been noted. Bacteremic seeding from a remote site of infection can lead to this process. Unless infection occurs after recent pacemaker implantation or manipulation with obvious acute pocket infection and systemic toxicity, the diagnosis can be elusive. TEE is especially useful in demonstrating vegetations on the electrodes, tricuspid valve, or ventricular endocardium. Symptoms can range from fever and chills to overt septic shock.

B. Predisposing factors

 [128].

- 1. Skin necrosis** overlying the generator can predispose to infection. This is less common with subfascial than subcutaneous placement of the generator. Skin erosion can occur for multiple reasons, including body build, shift in generator placement, or poor nutrition.
- 2. Self-induced trauma**, such as from heavy lifting, repetitive movements involving the chest wall, or a direct blow to the generator pocket area, can occur.
- 3. Bacteremia** from a source other than an infected pacemaker can cause infection of the system in rare circumstances. **The pacemaker is at greatest risk for infection associated with bacteremia during the first few weeks after insertion.** The offending organisms would typically be staphylococci or streptococci from a remote site of infection. Therefore, it is important to treat promptly any infections, especially those of the skin or teeth, in patients with a pacemaker. Antibiotic prophylaxis to prevent pacemaker infection is not recommended.
- 4. Dermatologic conditions** may predispose the patient to pacemaker infection if the skin overlying the generator is not intact as a consequence [129].
- 5. Replacement or repositioning of the generator or electrodes** appeared to be a predisposing factor for infection in older studies. However, more recent studies have not borne this out, perhaps because current generators are smaller and lighter.

C. Microbiologic features

- 1. *S. aureus* and *S. epidermidis*** are responsible for about 75% of generator pocket infections. Other common skin flora as well as Enterobacteriaceae and *Candida* species can be seen. Infections in the initial 2-week postoperative period are most commonly due to *S. aureus* and are frequently associated with bacteremia [129].

2. Pacemaker endocarditis is also most frequently caused by staphylococcal species, but a wide variety of organisms can be seen. Of note, in the early postoperative period, an *S. aureus* bacteremia from a remote site is likely to cause pacemaker endocarditis. However, bacteremia with any organism months and years after placement can be treated as the uncomplicated bacteremia itself would be because pacemaker endocarditis would be unlikely [130].

D. Diagnosis [131] is based on the clinical picture as well as culture results from blood or a generator pocket abscess. Criteria include the following:

1. Local inflammation or abscess of the pocket, *or*
2. Secondary infection of the skin after erosion of the generator, *or*
3. Fever and positive blood culture results in a patient with a pacemaker and no other identifiable source of infection. TEE is a useful diagnostic tool [132].

E. Therapy [124,125]

1. Explantation and reimplantation.

- a. When infection is limited to the generator pocket or subcutaneous electrode without bacteremia, a one-step direct exchange of the pacing system can be performed while the patient is on antibiotics. In some cases, a two-step procedure is performed wherein the infected device is removed and the new pacer inserted at a different time while the patient is maintained with a temporary transvenous device.
- b. Pacemaker endocarditis or bacteremia accompanying pacemaker infection is best treated by removing the generator and the electrodes. This may be accomplished by traction or, in more difficult cases, by the Cooks electrode extraction system. However, surgical removal requiring cardiomy may be necessary. A temporary pacing system should be used. Antibiotics aimed at the causative organism and dosed for endocarditis should be given for a minimum of 2 weeks before a new permanent electrode is placed. There should be evidence of clinical response. If a patient's health status does not permit manipulations necessary to remove the entire system, prolonged courses of initial i.v. therapy followed by chronic suppressive oral antibiotics can be tried.

2. **Antibiotics.** Empiric choice of therapy should include an antistaphylococcal drug. If the patient is extremely ill, it is prudent to include gram-negative coverage while awaiting culture results.

II. Implantable cardioverter defibrillator (ICD) infections [124,125]. The technology of ICD systems continues to evolve. The technique of surgical placement of the pulse generator, extrapericardial or epicardial defibrillation patches, and a transvenous rate-sensing electrode has been largely supplanted by the use of a transvenously planted rate-sensing lead and a superior vena caval coil electrode as well as subcutaneous or epicardial electrodes all connected to a pulse generator that is placed subcutaneously or submuscularly. Infection rates have decreased from 2% to 11% [132] with the older technology to 0.8% to 1.5% with the newer systems [133,134].

A. Timing. The majority of ICD infections typically present within 6 months, and specifically within the initial 3 months, after placement.

B. Symptoms. Pain and erythema around the generator occur. Fluid collection or drainage may be present. These same findings may occur at the infraclavicular wound or subcutaneous patch wound. Epicardial patch infection may be accompanied by systemic toxicity and evidence of pericarditis.

C. Bacteriology. Patients are frequently bacteremic, especially if infection is due to *S. aureus* [135]. Cultures of the generator pocket may be positive even if the site looks normal. *S. aureus* and coagulase-negative staphylococci are the most frequently infecting organisms [133,135,136]. Multiple other bacteria, and on rare occasion atypical mycobacteria or yeast, can be the causative organisms. Polymicrobial infection occurs [135,136].

D. Therapy. Guidelines regarding therapy do not exist and management is complex. Removal of the entire ICD system appears necessary to eliminate infection, especially in the presence of systemic toxicity, bacteremia, or infection due to *S. aureus*. Infections involving only the generator site have been managed much as in the parallel situation in pacemaker infections. In cases where a patient's health status precludes removing the entire system and no virulent organisms are responsible for the

infection, i.v. antibiotics followed by continuous oral suppressive antibiotic regimens has been advocated [137–139]. Duration of parenteral therapy beyond that typically needed for soft tissue infection, regardless of whether the entire system is removed or not, should be determined by the potential for endocardial involvement and the implications of bacteremia (e.g., sustained *S. aureus* bacteremia). Decisions about replacing the ICD system after complete removal need to consider the risks and benefits of reimplantation versus antiarrhythmic drug therapy. Timing of replacement is in reality generally determined by the perceived threat of persistence of inducible arrhythmias.

13. GASTROINTESTINAL AND INTRAABDOMINAL INFECTIONS

Paul S. Graman and Robert F. Betts

GASTROENTERITIS AND FOOD POISONING

Acute onset of diarrhea is a common complaint. Whether a patient needs special evaluation, antibiotic therapy, or hospitalization must be routinely evaluated. Several reviews of this topic are available [1–10].

Adapted from a chapter by Richard E. Reese and Jerome F. Hruska.

I. Background

A. Prevalence and impact

1. In **developing countries**, diarrheal illness is the most common infectious disease, primarily affecting children under 5 years of age. Up to 1 billion cases occur annually in this age group, with an associated 4 to 6 million deaths worldwide [5]. Children experience approximately six bouts of diarrhea per year, and an estimated 10% of these episodes result in dehydration that requires therapy [4,10].
2. In the **United States**, it is estimated that there are up to 99 million cases of diarrhea or vomiting per year with an associated 10,000 deaths. Each child has two to three episodes of acute diarrhea annually [2,4]; the incidence among adults in developed countries averages one episode per year [6]. Among the total U.S. population, approximately 50% of persons with diarrhea or gastroenteritis restrict their activities for more than a full day, 8.2 million seek medical attention, and 250,000 require hospitalization. Despite the far greater number of episodes of diarrheal illness among children compared with adults, most deaths from diarrheal illness in the United States occur in the elderly. The death rate due to gastroenteritis is 2 to 3 per 100,000 population among children and young adults and approximately 15 per 100,000 for persons over age 74 [4].

B. Definitions

1. **Acute diarrhea** is defined as illness of less than 2 weeks' duration. Diarrhea lasting 2 to 4 weeks is considered **persistent**. Infectious agents commonly cause acute and persistent episodes. The term **chronic diarrhea** is often restricted to illness lasting at least 1 month [6].
 2. **Mild diarrhea** is three or fewer stools per day without abdominal or systemic symptoms, resulting in little or no alteration in daily activities [10].
 3. **Moderate or severe diarrhea** is four or more loose stools per day, usually associated with abdominal symptoms (cramps, nausea, vomiting, tenesmus, or systemic symptoms of fever, malaise, dehydration), and causing significant restriction of normal activity [6].
 4. **Dysentery** is a **generic term** that refers to a variety of disorders marked by cramping abdominal pain, tenesmus, and frequent stools, often of small volume. Stools contain blood and mucus, indicative of invasion or injury of the mucosa by a pathogen or its toxin (e.g., amebic, bacillary, *Shigella* dysentery) [10].
 5. **Gastroenteritis** refers to enteric infection characterized by vomiting as a predominant symptom with or without diarrhea.
 6. **Tenesmus** refers to straining, especially painful or ineffectual straining with a bowel movement or straining on defecation owing to spasms of an inflamed rectal sphincter as occurs in shigellosis [11].
- C. Pathogenesis in infectious diarrhea.** See reports published elsewhere [1–6,10] for a detailed discussion of this topic. However, **a few basic points deserve emphasis** for understanding clinical presentations and evaluations of patients with acute bacterial diarrhea. **Many pathogens use more than one mechanism** to overcome host defenses and cause illness.
1. **Adherence.** Bacteria colonize the bowel by resisting the clearing action of peristalsis. Some pathogens circumvent this by attaching or adhering to the mucosal surface. Attachment may increase the toxicity of enterotoxins by decreasing the distance they have to travel to reach target intestinal cells [2].

- a. **Bacterial surface protein structures** (pili or fimbria) bind to specific ligands or receptors on intestinal epithelial cells. This is an **important mechanism for enterotoxigenic *Escherichia coli* (ETEC)** [2].
 - b. **Adherence factor.** A distinctly different mechanism of enteroadherence is seen with **enteropathogenic *E. coli* (EPEC)**. Bacteria intimately adhere to intestinal epithelial cells based on a plasmid-conferred EPEC adherence factor, with effacement and destruction of microvilli and disruption of the cytoskeleton of underlying cells. No extensive intracellular invasion occurs, and the exact mechanism of diarrhea with EPEC remains unknown [2,3].
- 2. Invasion.** Certain enteroinvasive organisms can adhere to and invade mucosal epithelial cells. Invasion and multiplication elicits an **intense inflammatory response followed by cell death**. The mucosal inflammatory reaction is not clearly understood but probably involves the release of inflammatory mediators, including kinins, interleukins, leukotrienes, and other vasoactive agents. Clinically, one sees fever, abdominal cramps, malaise, and dysentery.
- Shigella* (which also forms a toxin called Shiga toxin) is the classic example. Enteroinvasive *E. coli* and *Salmonella* may use similar mechanisms [2].
3. **Enterotoxin production.** *Vibrio cholerae* binds to the intestinal mucosa and produces **cholera toxin**, which stimulates an increased amount of intracellular adenosine 3' 5'-monophosphate (cyclic adenosine monophosphate) through the adenylate cyclase system. In response, an active secretion of electrolytes and fluid into the intestinal lumen occurs. It is the classic prototype enterotoxin and stimulates production of voluminous quantities of watery stools, leading to potentially life-threatening dehydration. The **intestinal mucosa appears morphologically intact** and is believed to be capable of absorbing electrolytes in a normal behavior because of the empiric observation that oral solutions supplemented with glucose can be used to treat these patients. The overall effect leads to marked increase in the luminal small-bowel fluid that is delivered to the colon, and this fluid overwhelms colonic absorption capacity, thereby causing watery diarrhea [2]. **ETEC** has a similar mechanism.
 4. **Cytotoxins.** Some organisms secrete a toxin that causes cytotoxicity in tissue culture.
 - a. ***Shigella dysenteriae*. Shiga toxin is the classic prototype cytotoxin.**
 - b. **Enterohemorrhagic *E. coli* (EHEC) of serotype O157:H7** produce Shiga-like toxins that cause hemorrhagic colitis with bloody diarrhea. The toxin cleaves adenosine from host cell ribosomal RNA and inhibits protein synthesis [1]. Absorption of toxin into the systemic circulation also may mediate the associated hemolytic-uremic syndrome (HUS) [12].
 - c. **Enteropathogenic *E. coli* and *Vibrio parahemolyticus*** also secrete Shiga toxin.
- D. Intestinal factors** that may help prevent acquisition of diarrheal disease include gastric acidity and the normal bacterial flora.
1. **Gastric acid** destroys enteric bacteria and is an important factor in decreasing susceptibility to infection. Patients with gastric resections and achlorhydria have increased susceptibility to infection. In addition, bicarbonate taken orally has been documented to increase the attack rate of experimental *Shigella*, *E. coli*, and cholera.
 2. **Normal bacterial flora** of the bowel is believed to compete for space and nutrients with pathogenic organisms. In addition, short-chain fatty acids produced by many intestinal flora may be inhibitory of pathogens. It has been demonstrated that pretreatment with streptomycin lowers the required infective dose of experimental *Salmonella typhi* infections [1], presumably by changing bowel flora. See also the discussion of antibiotic-related diarrhea in Chapter 27, section A.
- II. Clinical approach to the patient with diarrhea**
- A. **History.** A careful history may provide clues to the type of infection involved [9].
 1. **High-risk groups or settings.** There are several settings in which patients are at greater risk than the general population for developing diarrhea [2,4].

- a. **Recent travel**, especially **international** travel and **camping** (e.g., using water from mountain streams), or travel to **coastal** areas, is a risk factor. For a discussion of travelers' diarrhea, see Chapter 22.
 - b. **Day-care children or family members** are at risk because there is close contact between children who are not toilet trained. The mode of transmission appears to be either from child to child or through fomites such as toys. Currently in the United States, it is estimated that more than 10 million children attend day-care centers [2]. Viruses commonly are identified in outbreaks, as are organisms that colonize at a low inoculum (e.g., *Shigella*, *Giardia*, and *Cryptosporidium* [4]).
 - c. **Chronic care facilities**. Patients appear to be at increased risk, often due in part to their debilitated state, fecal incontinence, or suppressed immune response [2].
 - d. **Homosexuals and patients with acquired immunodeficiency syndrome (AIDS)** are at especially high risk for infectious diarrheas. See Chapter 18 for a detailed discussion of diarrhea in AIDS patients.
 - e. **Other family members or very close contacts of an index case** of acute infectious gastroenteritis are at risk for similar illness.
2. **Medication exposure**
 - a. Antibiotic use currently or in the preceding 4 to 6 weeks can be associated with *Clostridium difficile* diarrhea.
 - b. Excessive use of **laxatives, antacids, or alcohol**. Chemotherapy causes diarrhea.
 3. **Common-source outbreak**. The clinician should inquire about picnics, banquets, fast-food restaurants, and associates with similar illnesses.
 4. **Pets**. Turtles, iguanas, and dogs have been implicated in cases of infectious diarrhea.
 5. **Seafood or shellfish** may have been improperly handled or prepared.
 6. **Certain symptoms may be helpful**. Even the number of episodes and type of diarrhea may provide clues to the pathogens involved (Table 13.1) [9].
 - a. **When vomiting is the predominant symptom**, viral gastroenteritis or a food-borne illness is suggested. Food poisoning due to preformed toxin (e.g., *Staphylococcus aureus*, *Bacillus cereus*) causes vomiting within 4 hours of ingesting the food [4]; see section IV.
 - b. **Mucus in the stool**, if in small amounts, raises the question of irritable bowel syndrome, but large amounts can be seen with invasive bacterial diarrheas.

Table 13.1. Clinical Features of Acute Diarrhea

Clinical Observation	Anatomic Consideration	Pathogens to Consider
Passage of few, voluminous stools	Diarrhea of small bowel origin	<i>Vibrio cholerae</i> , enterotoxigenic <i>Escherichia coli</i> , <i>Shigella</i> strains early in the infection, <i>Giardia</i>
Passage of many small-volume stools	Diarrhea of large bowel origin	<i>Shigella</i> , <i>Salmonella</i> , <i>Campylobacter</i> , <i>Entamoeba histolytica</i>
Tenesmus, fecal urgency, dysentery	Colitis	<i>Shigella</i> , <i>Salmonella</i> , <i>Campylobacter</i> , <i>E. histolytica</i>
Vomiting as the predominant symptom	Gastroenteritis	Viral agents (rotavirus, calicivirus, e.g., Norwalk virus) or intoxication (<i>Staphylococcus aureus</i> , <i>Bacillus cereus</i>)
Fever as a predominant finding	Mucosal invasion	<i>Shigella</i> , <i>Salmonella</i> , <i>Campylobacter</i> , viral agents (rotavirus, calicivirus)

Adapted from Bandres JC, Dupont HL. Approach to the patient with diarrhea. In: Gorbach SL, Bartlett JG, Blacklow NR, eds. *Infectious diseases*. Philadelphia: WB Saunders, 1992:572–575; with permission.

c. Blood in the stool indicates the possibility of inflammatory mucosal disease of the colon. EHEC (*E. coli* O157:H7) is the most common cause of bloody diarrhea in the United States [5]. Blood often is evident on gross examination of the stool. Usually there is no fever with O157:H7. Occult blood testing is more sensitive but less specific. Noninfectious causes, such as ischemic bowel disease, diverticulitis, ulcerative colitis, and radiation injury, are in the differential diagnoses.

Organisms that produce enterotoxins and are invasive such as *Campylobacter* species, *Aeromonas* species, *Shigella* species, and *V. parahemolyticus*, may initially cause watery diarrhea followed by bloody diarrhea.

d. Watery diarrhea is more likely seen in those infections in which organisms adhere, infect, or colonize but do not destroy the epithelium (parasites, EPEC, enteric viruses) [4], and when the small bowel is affected.

e. Fever suggests a mucosal invasive pathogen.

f. Systemic illness with HUS, characterized by acute hemolytic anemia, renal failure with uremia, and disseminated intravascular coagulation, occurs with shigellosis and EHEC [5].

7. A prior history of inflammatory bowel disease should be assessed in case the acute symptoms represent an exacerbation of this prior, more chronic problem.

B. Physical examination does not usually help determine the cause of the diarrhea.

1. Fever suggests an invasive bacterial organism.

2. Signs of dehydration in severe cases, especially in children, include dry mucous membranes, lethargy, postural hypotension, tachycardia, sunken fontanelles, skin with decreased turgor, and dry eyes [5]. Severe dehydration requires hospitalization.

3. Stool occult blood. In the patient with multiple episodes of diarrhea and mucosal irritation, occult blood might be present without representing a true invasive process.

C. Laboratory aids in diagnosis [8,13]

1. Gram staining of the stool usually is not helpful because most pathogens cannot be differentiated from the normal gram-negative bowel flora. *Campylobacter* may be suggested by Gram stain findings in stool specimens (see section **V.D.2**). Rarely is *S. aureus* a cause of colitis, but if it is, Gram stain is helpful. Stool culture also should be performed if the latter is suspected.

2. Fecal leukocytes give a clue as to the cause. Mucus can be examined. The presence of only a few leukocytes usually is an indeterminate result.

a. Fecal leukocytes occur in (a) bacterial infections that invade the intestinal wall, such as invasive *E. coli* and *Shigella* and *Salmonella* species; (b) **ulcerative colitis and Crohn disease**; and (c) ***C. difficile* diarrhea**, in which fecal leukocytes appear in nearly 50% of cases.

b. Fecal leukocytes are not seen in (a) viral gastroenteritis, (b) parasitic diarrhea, (c) enterotoxigenic bacterial diarrheas (*V. cholerae*, *Bacillus cereus*, ETEC, etc.), or (d) ***Salmonella* carrier states**.

c. Fecal lactoferrin is a sensitive marker for fecal leukocytes. A simple, rapid latex agglutination test for lactoferrin is available [5].

3. Stool cultures. Special media are needed to culture many of the bacterial agents that cause diarrhea. **If one suspects a particular pathogen, discussion with the microbiology laboratory supervisor leads to appropriate studies.** Special enriching techniques or media are required to isolate other agents such as *V. cholerae* and *V. parahemolyticus* (e.g., after exposure to coastal areas or seafood), *Yersinia enterocolitica*, *Campylobacter jejuni*, and EHEC. In addition, one should carefully mark the suspected agents on the laboratory specimen sheet [8].

4. Rotavirus detection is particularly useful for children under 3 years of age.

5. Ova and parasite (O&P) examination are discussed in section **D** and in section **II.A** under Gastrointestinal Parasites. In patients with chronic diarrhea, international travelers, homosexual men, and contacts of day-care centers with protracted symptoms, these specimens are especially useful to examine.

- 6. *Clostridium difficile* toxin** assay is useful for patients who are on or who have been on antibiotics in the preceding 4 to 6 weeks.
- 7. Proctosigmoidoscopy** examinations seldom are indicated except as follows:
- In homosexual men and in some cases of AIDS-related illness (see Chapter 18).
 - In chronic or recurrent diarrhea for possible inflammatory bowel disease.
 - In possible *C. difficile* diarrhea to provide an immediate answer.
 - In a potential case of *Entamoeba histolytica*, because ulcerations of the intestinal wall may be characteristic in this setting. Rectal mucosal biopsy also may help [5].
- 8. Radiographic studies** usually are not indicated.
- If toxic megacolon is a potential concern as a complication—for example, with *C. difficile* diarrhea—radiographic plain films are useful.
 - In chronic diarrhea, pancreatic calcifications suggest chronic pancreatitis.
 - Results of barium contrast studies of stool samples are nondiagnostic for the presence of O&P [5].
- 9. Miscellaneous studies**
- Peripheral white blood cell (WBC) counts** are nonspecific. Although it may be elevated in acute infectious diarrhea (e.g., *Salmonella* or *Shigella*) or *C. difficile* colitis, the WBC count also may be elevated in patients with dehydration due to nonbacterial processes.
 - Blood cultures.** In the febrile patient with gastroenteritis, blood cultures may be positive when other sources, including stool cultures, are negative.
 - Bone marrow cultures.** Biopsy specimens often are positive in typhoid fever. This may be useful in the workup of an unclear chronic fever.
 - Rose spots** (the transient skin rash of typhoid fever) can be sampled for biopsy and cultured.
 - Serologic studies.** In acute gastroenteritis, serologic studies **offer little help** except in the following special circumstances:
 - Amebiasis. Indirect hemagglutination** and other antiamebic antibody tests are a useful adjunct in the diagnosis of extraintestinal amebiasis (99%+ by day 7) or active intestinal infection (80%–90% positive) but **not for the asymptomatic** patient who is passing cysts (see section **IV.E** under Gastrointestinal Parasites).
 - Salmonella* O antigen** applies only to *S. typhi*. [14]. Of infected patients, 50% convert to seropositivity after 1 week and only by the fourth week do 90% to 95% of patients show an elevated titer. Often acute *Salmonella* gastroenteritis remits before there is any seroconversion making the test not useful in most cases. They may be helpful when persistent infection has allowed time for a host antibody response. The carrier state produces very little response.
Caution should be exercised in the interpretation of a single value. Previous seroconversion, typhoid immunization, and cross-reaction with Enterobacteriaceae O antigens can cause an isolated antibody elevation.
- D. Diagnostic workup.** Because pathogens are recovered from fewer than 10% of unselected stool samples, the cost per positive stool culture exceeds \$1,000, an extremely cost-ineffective workup. See reports published elsewhere [1,2,4,5] for a rational approach. After laboratory workup, 20% to 40% of all acute infectious diarrheas remain undiagnosed [4].
- If the history suggests a food-borne toxin–related illness, with nausea and vomiting a few hours after eating, see Table 13.2 for a summary of important pathogens and presentation. Food-borne toxins are discussed in section **IV**.
 - Afebrile stable patients with nonbloody diarrhea of short duration can be observed and treated conservatively with oral hydration and no extensive laboratory workup.
 - Determine risk factors (e.g., travel, camping, day care, antibiotic use, seafood exposure, sexual contact, etc.) that may suggest a specific etiology.

Table 13.2. Clinical Features of Agent-Specific Food-Borne Disease with Symptom Onset of Less Than 12 Hours

Organism or Agent	Incubation Period	Duration of Illness (range)	Diarrhea	Fever	Vomiting	Enterotoxin	Invasion	Foods Most Commonly Implicated	Comments
<i>Staphylococcus aureus</i>	1–8 h	24 h (8–18 h)	+	–	+++	++	–	Salads, cream-filled pastries, meats (pork, beef, poultry)	High attack rates (80%–100%) Outbreaks most frequent during summer
<i>Bacillus cereus</i> Emetic illness	1–6 h	9 h (2–10 h)	+	–	+++	++	–	Fried rice	Abdominal cramps often experienced Vomiting occurs more often than diarrhea
Diarrheal illness	6–14 h	20 h (16–48 h)	+++	–	+	+	–	Meats, vanilla sauce, cream-baked goods, salads, chicken soup	Diarrhea occurs more often than vomiting Organism may be found in stool of healthy person
<i>Clostridium perfringens</i>	8–24 h	24 h (8–72 h)	+++	–	±	++	–	Improperly stored beef, fish, or poultry dishes (after preparation); pasta salads, dairy products; Mexican foods	“Pig-bet” or necrotizing enterocolitis is a rare variant Stool has no white blood cells or blood Commercial kit available for detection of toxin in stool
Non O:1 <i>Vibrio cholerae</i>	6–72 h	2 days (2–12 days)	++	±	±	+	±	Seafood, grated eggs, potatoes	25% can have bloody diarrhea Illness similar to cholera but with much less dehydration
Puffer fish	<2 h	Variable	+	–	+	+	–	Fugu (especially prepared Japanese puffer fish), other puffer fish, vividly colored frogs of South America, blue-ringed octopus	Symptoms include paresthesias, ataxia, hypotension, seizures, cardiac arrhythmias, respiratory and skeletal muscle paralysis Mortality 30%–60% Treatment: gastric lavage and cardiorespiratory support Prognosis greatly improves if patient survives first 6 h

Paralytic shellfish	1–3 h	3 days (0.5–7 days)	–	–	+	–	+ Saxitoxin (i.e., a neurotoxin)	–	Most bivalved mollusks (shellfish), especially from endemic waters experiencing red tide blooms	Symptoms and treatment similar to puffer fish poisoning Mortality rate 5%–18% Etiology is concentration of toxic dinoflagellates in mollusks during red tide season (spring and fall) Most common form of fish intoxication in United States Commonly seen in Florida, Hawaii, and the Caribbean Symptoms similar to puffer fish poisoning ELISA available for detection of toxin
Ciguatera	1–6 h	Variable (can persist for months)	+	–	+	–	+ Ciguatoxin (i.e., a neurotoxin)	–	Barracuda, grouper, snapper, jacks, reef sharks	Treatment suggested with amitriptyline Symptoms: flushing, generalized or localized erythema, vertigo, generalized burning sensation Histamine levels can be assayed in implicated fish Treatment with antihistamines very effective Fish with unpleasant odor or clouded eyes should be avoided
Scombroid fish	<2 h	Variable (2–10 h)	±	–	+	–	– (preformed histamine causes symptoms; not an allergic reaction)	–	“Blood fish” (tuna, albacore, mackerel, skip jacks) under spoiling conditions	

ELISA, enzyme-linked immunosorbent assay.

Modified from Miranda AG, DuPont HL. Small intestine: infections with common bacterial and viral pathogens. In: Yamada T, ed. *Textbook of gastroenterology*. New York: JB Lippincott, 1991:1452–1453.

4. Further medical evaluation is indicated in patients with more severe diarrheal illness, as evidenced by one or more of the following [6]:

- a. Fever ($\geq 38.5^{\circ}\text{C}$)
- b. Profuse watery diarrhea with dehydration
- c. Bloody diarrhea or dysentery
- d. Passage of at least six unformed stools over 24 hours
- e. Prolonged diarrhea (lasting >48 hours)
- f. Severe abdominal pain
- g. Age at least 70 years
- h. Immunocompromised state (AIDS, transplantation, cancer chemotherapy)

5. Laboratory evaluation may proceed in a stepwise fashion:

- a. **Step 1: If the patient has mucus or blood in the stool or if fecal leukocytes (or lactoferrin) is present,** a stool culture that looks for *Shigella*, *Salmonella*, and *Campylobacter* is indicated. This screening approach can dramatically increase the yield of positive stool cultures and decrease the cost of workup [1,4]. Bloody diarrheal stools also should be cultured for *E. coli* O157:H7.

The clinician should alert the microbiology laboratory (see section II.C). With a history of antibiotic use, either currently or in the preceding 4 to 6 weeks, obtain a stool for *C. difficile* toxin before obtaining the stool culture. This is particularly important in the patient with onset of diarrhea more than 72 hours after admission to the hospital.

- b. **Step 2: If stools do not contain blood, mucus, or fecal leukocytes (or lactoferrin), examination for O&P is suggested if history is supportive.**

(1) It is usual to obtain three stools for O&P examination.

(2) If *Giardia* species are likely, the *Giardia* antigen test should be performed (see section IV.A.2).

(3) In children under 3 years of age in whom the fecal leukocyte test result is negative, an early examination for **rotavirus** is suggested (see section VI.A).

- c. **Step 3: If no parasites are found, then the differential diagnosis is narrowed to include viruses and certain difficult-to-culture bacteria** (e.g., *Yersinia*, *V. cholerae*, ETEC, EPEC, *Aeromonas hydrophila*, *Plesiomonas shigelloides*).

(1) Special media for *V. cholerae* should be used only for travelers to endemic areas.

(2) Discuss the microbiology workup with your laboratory supervisor.

III. Therapy. In most cases of infectious diarrhea, therapy consists of supportive care.

A. Fluid replacement

1. **Oral fluids** will suffice in most patients [15]. The World Health Organization has developed an oral solution that is inexpensive, easy to administer, and effective in all types of diarrhea and all age groups. The formula is based on the principle that glucose absorption in the small bowel facilitates sodium and fluid resorption from the intestinal lumen into the intravascular compartment [1,16].

- a. See Table 13.3. Premeasured packets of dry salts with a long shelf life, available in developing countries, are mixed with water to reconstitute the solution.

- b. Commercially available premixed oral electrolyte solutions (Pedialyte, others) are available in the United States for use in infants and children with mild to moderate diarrhea. A comparable solution can be made with 3 tablespoons corn syrup, 3/4 teaspoon salt, and 1/2 teaspoon sodium bicarbonate in 1 cup orange juice diluted with water to make 1 liter (1.05 quart) [5]. When there is associated nausea and vomiting, the patient can often be given small volumes of oral fluids on an hourly basis [16–17].

- c. Otherwise healthy persons with acute diarrhea and minimal or no dehydration will do well with sport drinks, dilute fruit juices, and other flavored soft drinks supplemented with saltine crackers, soups, and broth [6].

Table 13.3. Composition of World Health Organization Oral Rehydration Solution for Diarrheal Illness

Ingredient	Amount
Sodium chloride	3.5 g/L
Potassium chloride	1.5 g/L
Glucose	20.0 g/L
Trisodium citrate ^a	2.9 g/L

^aAn earlier formulation used sodium bicarbonate 2.5 g/L, had a shorter shelf life, but was physiologically equivalent and may still be produced in some countries.

Data from Centers for Disease Control. *Health information for international travel 2001–2002*. (the “Yellow Book”). Atlanta, GA: U.S. Department of Health and Human Services. Also available online at www.cdc.gov/travel/yb/index.htm.

- d. Oral replacement therapy is contraindicated only in patients with uncontrolled vomiting, with ileus, or where hospitalization and intravenous (i.v.) fluid are indicated.
 2. **Intravenous fluids** (normal saline with potassium chloride supplementation or Ringer solution) are used in patients who are severely dehydrated.
- B. Antimotility agents** [18–20]
1. Natural opiates such as paregoric or tincture of opium, diphenoxylate, or loperamide **provide symptomatic relief of acute diarrhea and cramps**. The latter are safer, come in convenient dosage forms, and are generally preferred. **They should be used only in adults with noninflammatory diarrhea and not with high fever or bloody stools** because these agents may potentiate the effects of bacterial disease by delaying clearance of the pathogen or its toxin. However, when used in conjunction with ciprofloxacin for bacillary dysentery in adults, loperamide has proved to be safe and effective. Treatment with diphenolate prolongs fever in shigellosis. HUS occurs more often in *E. coli* O157:H7 following antimotility drugs, and the neurologic manifestations may be more severe.
 2. **Loperamide** (Imodium) as **short-course therapy for adult travelers’ diarrhea** (see Chapter 22) has a good safety record, expected efficacy in reducing stool number by approximately 80%, and availability over the counter. **Diphenolate with atropine** (Lomotil) has central opiate effects that may endanger children who accidentally ingest the drug, and atropine side effects that may be unpleasant [6,17].
 3. These agents are not recommended for infants and young children.
- C. Antibiotics generally are not indicated.** The need depends on (a) the clinical course superimposed on underlying medical problems and age and (b) the pathogen involved.
1. In the patient who is **toxic and profoundly dehydrated** without evidence of a self-limited process, empiric antibiotics are indicated while awaiting cultures. Antibiotics are essential for patients whose history suggests a bacteremia. Fever, bloody stool, and fecal leukocytes suggest a bacterial cause that warrants treatment. Very young and very old patients should receive empiric therapy if they are toxic or significantly dehydrated. Ceftriaxone or fluoroquinolones are options.
 2. For further discussion of therapy of individual pathogens, see section V.
- D. Miscellaneous agents**
1. **Antisecretory agents.** The gastrointestinal (GI) peptide **somatostatin** and its synthetic analogues (**octreotide** and **vapreotide**) are powerful inhibitors of intestinal secretion. These agents have been used in controlling chronic

AIDS-related diarrhea of unknown etiology or diarrhea caused by microsporidia or cryptosporidiosis [6] (see Chapter 18).

2. Absorbent agents. Cholestyramine is a nonabsorbable exchange resin that has been used to absorb toxin, in *C. difficile* and chronic diarrhea.

E. Bismuth subsalicylate (Pepto-Bismol) has been used primarily in the prevention and therapy of travelers' diarrhea (see Chapter 22) or in conjunction with oral rehydration for diarrhea in young children [21], or for vomiting in patients with viral gastroenteritis [6].

F. Antiemetics used orally, parenterally, or rectally. Some examples are as follows:

1. Prochlorperazine (Compazine). For adults, 25 mg rectal suppository twice daily, or 5- or 10-mg tablets three or four times daily; or 5 to 10 mg intramuscularly (i.m.) every 4 hours not to exceed 40 mg/day when given i.m.

2. Trimethobenzamide (Tigan). For adults, 200 mg rectal suppository three or four times daily; oral capsules, 250 mg three or four times daily; or 200 mg i.m. three or four times daily.

IV. Agents causing rapid onset of illness (<12 hours after ingestion) (see Table 13.2)

A. Staphylococcal food poisoning is due to a **preformed enterotoxin** that is heat stable and **not destroyed by ordinary rewarming. Foods implicated are cream-filled pastries, custards, milk products, and meats that have been improperly refrigerated.**

1. Symptoms. Severe nausea, vomiting, abdominal pain, diarrhea, and prostration occur 1 to 6 hours after ingestion, last less than 1 day, and remit spontaneously.

2. Diagnosis is confirmed by isolation of *S. aureus* in the contaminated food.

3. Therapy is supportive. No antibiotic is indicated for this self-limited disease.

B. Bacillus cereus contamination resembles staphylococcal food poisoning and is caused by preformed enterotoxin in foods such as cereal (especially rice), dried foods, and dairy products. Illness is self-limited (abates in <24 hours) and not severe.

1. B cereus contamination can lead to two syndromes[22]. The emetic syndrome is caused by a high temperature-stable toxin. Fried rice subsequently held at room temperature is the leading cause. **The diarrhea syndrome** is mediated by a heat-and acid-labile enterotoxin.

2. Diagnosis of *B. cereus* contamination can be confirmed by the isolation of at least 10^5 *B. cereus* organisms per gram from implicated food [22,23]. Special cultures are necessary.

C. Clostridium perfringens food poisoning results from ingestion of foods harboring the organisms. The ingested *C. perfringens* multiply in the small intestine and produce the diarrhea-forming enterotoxin. **Treatment is supportive. Anaerobic cultures and Gram staining of the incriminated food will establish the diagnosis.**

D. Fish and shellfish poisoning is caused by toxins present in the tissues of fish. The topic has been reviewed elsewhere [24]. **See Table 13.2 for a summary.**

In ciguatoxic fish (barracuda, red snapper, and grouper), the toxin is acquired in the food chain of the fish; large fish weighing more than 2.8 kg are more likely to be toxic [25]. Scombroid fish poisoning (tuna, mackerel, bonito, skipjack) is due to production of a histamine-like toxin by marine bacteria that grow when these fish are improperly refrigerated or preserved [26]. Shellfish poisoning (mussels, clams, oysters, and scallops) occurs because toxic dinoflagellates usually associated with red tide are ingested by the mollusks and concentrated in their tissues. **All these toxic substances have no effect on the fish or shellfish and are heat stable to cooking temperatures.**

1. Symptoms including abdominal cramps, nausea, vomiting, and diarrhea occur within minutes to several hours after ingestion. Neurologic symptoms in ciguatera and shellfish poisoning include numbness, paresthesia, and nerve palsies. Case fatalities, which in some series are as high as 10%, have been due to respiratory paralysis.

2. Diagnosis is suggested by the epidemiologic features.

3. Therapy is primarily symptomatic. Inducing emesis, performing gastric lavage, and administering a cathartic agent should remove unabsorbed toxin.

V. Diseases causing delayed onset of GI symptoms (Table 13.4) [7]

A. *Salmonella* infections [14,27]. *Salmonella* organisms are motile, flagellated, aerobic or facultative anaerobic, gram-negative bacilli that do not ferment lactose or sucrose.

1. Nomenclature and serotyping. Serotyping is relevant both clinically and epidemiologically. Certain serotypes are associated with specific clinical syndromes, and serotyping of isolates serves as an important tool in defining and controlling epidemics [8,14]. *Salmonella* serotype typhimurium is conveniently written as *Salmonella typhimurium*. Alternatively, all nontyphoidal *Salmonella* organisms are classified as *Salmonella enterica* and further identified by serotype (e.g., *Salmonella enterica* serotype typhimurium). *Salmonella* organisms possess both somatic O antigens and flagella H antigens serotypes. More than 2,300 *Salmonella* serotypes are found in nature. Many are named for the city in which they were defined.

2. Epidemiology. Cases of salmonellosis must be reported to the state health department. In the United States, 800,000 to 4 million cases of salmonellosis occur each year, and approximately 500 are fatal [28]. An increasing number of cases are attributable to an increase in outbreaks associated with the mass production of food products and to an increase in reporting.

a. More than 98% of isolates are nontyphoidal, with important animal sources of human food (e.g., meat, poultry, eggs, dairy products) frequently contaminated with these organisms. Infection results from consumption of foods that are undercooked or cross-contaminated with these products [29].

S. enteritidis and *S. typhimurium* are the most common serotypes in the United States. Chickens may transmit *S. enteritidis* through infected oviducts that contaminate the egg before the shell is formed [30]. About 0.01% to more than 0.1% of eggs contain *S. enteritidis*, although the percentage may be higher in the northeastern United States [31]. When these eggs are used raw (such as in dressing for Caesar salad) or are undercooked (such as in “soft” scrambled eggs) the *Salmonella* organisms proliferate in the food. Eggs have been associated with 82% of *S. enteritidis* outbreaks in the United States [32].

b. Other common serotypes include *S. heidelberg*, *S. newport*, and *S. agona*.

c. The incidence of cases peaks during the summer and fall picnic season. Contamination of food-processing equipment and manufactured food products can result in large outbreaks of disease. About 224,000 persons developed *S. enteritidis* gastroenteritis in 1994 after eating a nationally distributed ice cream [33]. Less commonly, person-to-person spread via the fecal-oral route can occur.

d. Exotic pets, especially reptiles (snakes, turtles, iguanas), are a growing source of human salmonellosis, accounting for an estimated 3% to 5% of all cases [34]. Up to 90% of reptiles may be carriers of *Salmonella* organisms.

e. Antibiotic-resistant *Salmonella* organisms. Subtherapeutic concentrations of antibiotics put in the animal feed as nonspecific growth factors promote the emergence of antibiotic-resistant bacteria, including *Salmonella* species. During slaughtering this antibiotic-resistant gut flora contaminates the animal meat. A recent survey of ground meats in supermarkets found *Salmonella* organisms in 20% of samples, with 84% of the isolates resistant to at least one antibiotic and 53% resistant to three or more agents [35,36]. Multidrug-resistant strains of *S. typhimurium* (DT104) in the United States increased from 0.6% of isolates in 1980 to 34% in 1996 [28].

f. *S. typhi* is the most frequent isolate in developing countries but is uncommon in the United States. Animals do not serve as a reservoir of *S. typhi*. Food is infectious only if contaminated by humans during processing. In developing countries, transmission occurs primarily by direct fecal-oral spread between individuals or by fecal contamination of drinking water or food. In the United States, transmission is primarily by contamination of foodstuffs with human feces. In the United States, more than half of the cases occur in travelers.

3. Clinical syndromes of *Salmonella* disease include gastroenteritis, enteric fever, metastatic infection, and the carrier state.

Table 13.4. Clinical Features of Agent-Specific Food-Borne Disease with Symptom Onset of Greater Than 12 Hours

Organism or Agent	Incubation Period	Duration of Illness (range)	Diarrhea	Fever	Vomiting	Enterotoxin	Invasion	Foods Most Commonly Implicated	Comments
<i>Salmonella</i>	8–48 h	3 days (1–14 days)	+++	++	+	+	+(little mucosal damage)	Eggs, poultry, beef, dairy products	Infection with some serotypes can lead to severe complications in certain patients (those with malignancy, atherosclerosis, and AIDS) Treatment not recommended except in severe or disseminated disease because it prolongs carriage of organism Stool contains white blood cells and may contain blood
<i>Shigella</i>	24–72 h (up to 7 days)	3 days (1–14 days)	+++	+++	±	+	++	Salads (egg, tuna, poultry), milk	Low infective dose (10–10 ² organisms). Person-to-person transmission common Stools often contain blood, mucus, and pus Systemic symptoms (headache, malaise, lethargy) common
<i>Yersinia</i>	24–72 h (up to 6 days)	7 days (2–30 days)	+++	++	±	+	+	Milk (raw or chocolate), tofu	Abdominal pain is a prominent feature of illness and may be confused with appendicitis Presence of pharyngitis common in children Rheumatologic postinfectious complications have been reported
<i>Campylobacter</i>	2–11 days	3 days (2–30 days)	+++	++	±	+	+	Raw, milk, poultry, beef, clams, pet animals	Stool contains red and white blood cells Mostly resistant to trimethoprim-sulfamethoxazole

<i>Escherichia coli</i> (enterotoxigenic)	24–72 h	3 days (1–14 days)	+++	+	-	+	Salads, peeled fruits, meat dishes, pastries	-	Complications include meningitis and Guillain-Barré syndrome At least two toxins elaborated: heat-labile (similar to cholera toxin) and heat-stable Most common bacterial agent of travelers' diarrhea Antimicrobials do not shorten illness Fecal white blood cells and blood uncommon
<i>Vibrio parahaemolyticus</i>	4–96 h	3 days (2–10 days)	++	±	+	+	Oysters, crabs shellfish, sea water, contaminated food	-(not documented in humans)	Neurologic symptoms are results of parasympathetic and neuromuscular blockade Fatality rate 15% Treatment is early administration of antitoxin Infants under 1 yr of age should not be fed raw honey
<i>Clostridium botulinum</i>	12–36 h (may be as long as 8 days)	Weeks to months	±	-	±	++	Raw honey (infants), improperly canned products	-(neurotoxin)	Primarily an illness of infants and children Endemic in nature Respiratory symptoms common Can cause severe dehydration in children Affects primarily older children and adults Endemic in nature
Rotavirus	48–72 h	5 days (3–14 days)	+++	+	++	-	Fresh water, seafood	-(superficial damage to mucosa)	
Calicivirus (Norwalk and Norwalk-like viruses)	24–48 h	1 day (1–3 days)	++	+	++	-	Shellfish, drinking water	-(superficial damage to mucosa)	

AIDS, acquired immunodeficiency syndrome.

Modified from Miranda AG, DuPont HL. Small intestine: infections with common bacterial and viral pathogens. In: Yamada T, ed. *Textbook of gastroenterology*. New York: JB Lippincott, 1991: 1453–1455.

- a. Gastroenteritis.** *S. enteritidis*, *S. newport*, and *S. anatum* usually cause gastroenteritis. *Salmonella* organisms cause 10% to 15% of food poisoning cases in the United States [14]. There is an intestinal invasion with the production of fecal leukocytes and low-grade fever. In addition, an enterotoxin causes intestinal fluid secretion.
- (1) **Symptoms** develop 8 to 48 hours after ingestion of contaminated food; they include colicky abdominal pain, nausea and vomiting, and then loose, watery diarrhea. There may be fever to 38° to 39°C. Symptoms usually subside spontaneously in 2 to 5 days without sequelae. Certain underlying conditions (AIDS, achlorhydria, prior gastric surgery, and inflammatory bowel disease) predispose the patient to more severe disease [14].
 - (2) **Diagnosis** is made by isolating the organism from the stool or the ingested food. Stool leukocytes often are seen.
 - (3) **Treatment of uncomplicated gastroenteritis** due to nontyphoidal *Salmonella* species is primarily supportive. The disease is usually self-limited. Antibiotics have no proven value and use **may result in a higher rate of chronic carriage and relapse** [37,38]. **Bacteremia occurs in fewer than 5% of patients with *Salmonella* gastroenteritis. Use of antibiotics should be limited to preemptive therapy among patients at high risk for invasive disease:** (a) newborn infants, probably up to 3 months of age; (b) the elderly, because of the high risk for atherosclerosis or aneurysms; (c) those with AIDS, organ transplants, lymphoproliferative disease, or other immunosuppression; (d) patients with prosthetic joints, prosthetic vascular grafts, aneurysms, or prosthetic heart valves; and (e) those with underlying sickle cell disease [14,27]. A brief course of treatment (72 hours or until resolution of fever), usually with an oral fluoroquinolone, is appropriate.
- b. Enteric (typhoid) fever** usually is caused by *S. typhi* but, infrequently, other *Salmonella* organisms, such as *S. paratyphi* or *S. choleraesuis*, are etiologic.
- (1) **Symptoms.** Enteric fever is characterized by **sustained fever**, often of 2 to 4 weeks duration, hepatosplenomegaly, headaches, abdominal tenderness, and rose spots, which are slightly raised, discrete, irregular, blanching pink macules 2 to 4 mm wide and often seen on the anterior thorax. Leukopenia may be seen, as may sustained bacteremia without endothelial or endocardial seeding, but sometimes with metastatic seeding and immune complex deposition that leads to multiorgan dysfunction. Intestinal hemorrhage or perforation may result from the hyperplasia of the Peyer patches in the terminal ileum [14,27]. Surprisingly, **diarrhea occurs in as few as 50% of cases**, and then only as an early symptom. **Constipation may be a frequent complaint later in the illness.**
 - (2) **Diagnosis.** Culture of stool specimens, blood, bone marrow, or rose spots for *S. typhi* or other *Salmonella* species is useful. A serologic increase of febrile agglutinins against the somatic or O antigen for group D *Salmonella* is supportive. Serologic studies may be useful in epidemiologic evaluation.
 - (3) **Therapy.** The current agent of choice for *S. typhi* and *Salmonella* species is a fluoroquinolone or third-generation cephalosporin (e.g., ceftriaxone or cefotaxime) [39]. Alternative agents include trimethoprim-sulfamethoxazole (TMP-SMX), amoxicillin, and ampicillin after susceptibility studies return. Drug resistance is a recognized problem in countries such as Mexico. Azithromycin is effective in treating children with typhoid fever [40,41].
Treatment for uncomplicated enteric fever is 10 to 14 days, with extension to 4 weeks for metastatic foci. Oral ciprofloxacin 500 mg twice daily may obviate the need for prolonged i.v. therapy (see Chapter 27G).
 - (4) **Prevention.** Oral or parenteral typhoid vaccine are available (see Chapter 22).
- c. Metastatic infection.** *Salmonella* organisms metastasize to distant sites, particularly to intravascular lesions, the skeletal system, and the meninges [14,27].

- (1) **High-grade bacteremia** (>50% of three or more blood cultures) strongly suggests focal **intravascular infection**. *Salmonella* organisms have a predilection for arterial atherosclerotic plaques and aneurysms. Infectious disease consultation is advised.
- (2) **Osteomyelitis or suppurative arthritis** can occur at any skeletal site. Patients with sickle cell anemia or skeletal prostheses are predisposed.
- (3) **Meningitis** occurs principally in young children, especially newborn infants. **Hence, in young children with salmonella gastroenteritis, early therapy is indicated** [14].
- (4) **Antibiotic** therapy is the same as for enteric fever except that therapy is prolonged for endocarditis, osteomyelitis, or abscesses. Failures have occurred with oral fluoroquinolone therapy for these conditions, particularly when drainage is not optimal

d. Chronic carriers. The chronic carrier state (*i.e.*, **positive stool or urine cultures for more than 12 months**) develops in approximately 1% to 4% of adults with typhoid fever. In other *Salmonella* infections, the development of the carrier state occurs much less frequently (0.2%–0.6%). The carrier state may follow symptomatic disease or may be the only manifestation of infection; it may be the consequence of the ingestion of a small inoculum [27].

- (1) The persistence of the organism, in many cases, is due to **biliary tract carriage**. If biliary calculi are present, cholecystectomy and a 10- to 14-day course of antibiotics most often is required to cure the carrier state. This invasive approach eradicates infection in 90% of cases and may be appropriate for food handlers, medical personnel, and individuals with poor personal hygiene, and for other public health reasons. Antibiotics alone are unlikely to eradicate infection in patients with biliary calculi [14].

If gallbladder function is normal, cure of the carrier state may be attempted with a 4- to 6-week course of amoxicillin (6 g/day for 28 days) [42] or ciprofloxacin (500–750 mg orally twice daily for 28 days) [43]. Other fluoroquinolones such as norfloxacin (400 mg orally twice daily for 28 days), ofloxacin (200 mg twice daily), or TMP-SMX (160 mg TMP and 800 mg SMX twice daily in adults) have been used successfully [14]. However, even with use of the fluoroquinolones, eradication of the carrier state may be impossible (see Chapter 27G).

- (2) **Chronic urinary tract carriage** can occur. Predisposing factors include obstructive uropathy from renal stones, strictures, hydronephrosis, tumors, and schistosomiasis.

e. Special considerations

- (1) *Salmonella* causes severe infection with repeated recurrences in patients with AIDS (see Chapter 18).
- (2) Other patients with an increased susceptibility to *Salmonella* infections include patients with leukemia, lymphoma, renal transplants, underlying inflammatory bowel disease, and underlying schistosomiasis.

B. Shigellosis (bacillary dysentery). *Shigella* are nonmotile, gram-negative bacilli that do not ferment lactose. There are four serogroups: group A (*S. dysenteriae*), group B (*S. flexneri*), group C (*S. boydii*), and group D (*S. sonnei*). Most disease in the United States is produced by *S. sonnei* or *S. flexneri*.

1. **Pathogenesis and epidemiology.** Shigellosis is highly communicable; ingestion of as few as 200 viable bacteria will produce illness. This organism is spread in a family setting or in confined settings, such as a day-care center. Food-borne or waterborne transmission, although less common, is associated with large outbreaks [44] *Shigella* strains invade mucosal epithelial cells (see section **I.C.2**). The HUS that occasionally follows *S. dysenteriae* is due to *Shigella* toxin.
2. **Symptoms.** Many patients will have the classic biphasic illness in which initially a small-bowel type of diarrhea occurs, characterized by passage of a small number of voluminous watery stools. Approximately 24 to 48 hours after ingestion of the microbe, abdominal pain, high fever, and diarrhea occur, marking large bowel involvement. In a large percentage of cases, gross blood in the stool develops. Stools containing blood and mucus are passed accompanied by tenesmus [44].

3. **Diagnosis** usually is **made by stool cultures. Bacteremia is rare.** A sigmoidoscopic examination may be suggestive of this diagnosis when diffuse inflammation and shallow ulcers are seen. Leukocytes often are seen in stool smears.
 4. **Therapy.** Although mild disease often has responded to supportive care, **antibiotics are indicated** because they shorten the duration of illness and decrease the relapse rate. *In vitro* susceptibility tests should be performed because of the increasing problem of resistance to ampicillin and TMP-SMX. Currently, the agents of choice are the fluoroquinolones [39] (see Chapter 27G). Recommended duration of therapy ranges from one dose to 5 days of therapy [45]. Ciprofloxacin (500 mg twice daily for 3–5 days) can be used in adults. A single dose is effective in mild illness. Alternative regimens include TMP-SMX (160 mg TMP and 800 mg SMX twice daily in adults), ampicillin, azithromycin [46], and ceftriaxone [41,44].
- C. *Yersinia enterocolitica*** is a gram-negative coccobacillus formerly classified as a *Pasteurella* species. Although first recognized in 1933 in New York State, disease caused by this organism is more frequently reported in Scandinavia, northern Europe, Japan, and Canada than in the United States. Because the culture requires special techniques, the incidence of disease in the United States probably is underestimated [47–49].
1. **Symptoms.** Fever, abdominal pain, and diarrhea commonly appear together, but the latter **is present only 50% of the time.** Erythema nodosum, reactive arthritis, exudative pharyngitis, septicemia, and terminal ileitis or mesenteric lymphadenitis also occur. **The latter two mimic appendicitis.** However, at operation the appendix appears normal. A clustering of cases of mesenteric lymphadenitis should lead to the suspicion of *Y. enterocolitica* infection. The diarrheal illness is indistinguishable from that of other enteric pathogens. Symptoms commonly last 2 weeks on average.
 2. **Diagnosis. Special cold enrichment of cultures** is necessary to increase the isolation of *Yersinia*. Even then, isolation may take several days or may be missed. **The laboratory must be alerted.** Appendiceal tissue also can be cultured.
 3. **Treatment.** In most cases, resolution occurs spontaneously. The value of antimicrobial agents in *Y. enterocolitica* diarrhea or mesenteric adenitis has not been established. Therapy for mesenteric adenitis is symptomatic [47].
 - a. **Intestinal infection usually is self-limited**, and there have been few clinical studies of efficacy. Treatment of diarrhea should focus on appropriate management of fluid replacement.
 - b. **Treatment of extraintestinal disease or complications** should be based on *in vitro* susceptibility data. Most isolates have been shown to be sensitive to TMP-SMX, third-generation cephalosporins, aminoglycosides, fluoroquinolones, and tetracyclines [47]. In a retrospective review of 43 cases of bacteremic patients, fluoroquinolones alone or third-generation cephalosporins plus aminoglycosides or fluoroquinolones constituted the most effective treatment [50].
 4. **Epidemiology.** Infection occurs by ingestion of contaminated food or water. Natural reservoirs include pigs, sheep, cattle, horses, dogs, and cats. The ability of *Yersinia* to grow at low temperatures potentiates its ability to contaminate refrigerated meats and other food products. Isolates have been cultured from meat, mussels, poultry, oysters, cheese, and ice cream. Food-borne outbreaks of *Yersinia* in the United States have been associated with contaminated chocolate milk and pasteurized milk. Person-to-person transmission also may occur [47–49].
- D. *Campylobacter*.** *Campylobacter* is the most common bacterial cause of acute gastroenteritis in the United States, identified two to seven times more frequently than *Salmonella*, *Shigella*, or *E. coli* O157:H7. An estimated 2.4 million cases occur annually in the United States, affecting nearly 1% of the population [51]. *C. jejuni* is the most frequently isolated species (>99%). Most cases of *Campylobacter* diarrhea are sporadic, but outbreaks can occur. **Special techniques are required for isolation.** This may account for the failure in the past to discover the organism by routine culture [8].
1. **Symptoms. Diarrhea**, cramping abdominal pain, fever, and constitutional symptoms predominate. **Grossly bloody stools or occult blood** may be seen

in the majority of patients. Most patients are symptomatic only for a few days, although enteric symptoms may last up to several weeks. The incubation period is usually 48 to 72 hours after ingestion of the organism. Less than 1% of patients have bacteremia. The clinical presentation mimics other forms of acute bacterial diarrhea, and the diagnosis can be established only by culture. Guillain-Barré syndrome is a rare postinfectious complication of *C. jejuni* infection, estimated to occur fewer than 0.1% of cases [51,52].

2. **Diagnosis.** A special selective medium is required to identify *Campylobacter jejuni* from stool cultures (which may take 72 to 96 hours), but routine blood cultures support growth of the organism. Methylene blue **fecal smears** commonly **show leukocytes**.

Fresh stools can be screened for *Campylobacter* by direct microscopy. Leukocytes and red blood cells (RBCs) in the presence of bacteria with characteristic darting motility lead to a presumptive diagnosis. On Gram staining of stool, the presence of many small curved rods and reduced amounts of normal flora suggests *Campylobacter*.

3. **Treatment.** Gastroenteritis is usually self-limited, and antibiotic treatment is not required for the majority of cases.

- a. Treatment should be considered in patients with high fevers, bloody stools, prolonged illness (>1 week), pregnancy, human immunodeficiency virus (HIV) infection, and other immunocompromised states. In patients with protracted symptoms, treatment with antibiotic appears to shorten the illness and prevent relapses [51].

- b. **Treatments of choice are oral erythromycin** (500 mg twice daily for 5 days in adults), azithromycin (500 mg on day 1; 250 mg on days 2–5), or clarithromycin. Alternatives include fluoroquinolones, clindamycin, aminoglycosides, or imipenem [39,41,51].

- c. Rapidly increasing resistance to fluoroquinolones has been observed worldwide; 10% of isolates in the United States were resistant in 1998. Fluoroquinolones should not be used unless susceptibility is confirmed [53].

- d. Bacteremic patients deserve full therapeutic courses.

4. **Epidemiology.** *C. jejuni* is a known enteric pathogen in cattle, dogs, and fowl. Animals, symptomatic and nonsymptomatic, are the source of most human infections. In developed countries, 50% to 70% of infections are attributed to undercooked chicken. Cross-contamination during food preparation easily occurs. Sporadic infections from red meats, contaminated water, and contact with pets also occur. Large outbreaks, although unusual, have been associated with consumption of unpasteurized milk. Person-to-person transmission is unusual [51,52].

- E. ***E. coli* O157:H7.** *E. coli* has emerged as an **important cause of both bloody diarrhea and HUS**, the most common cause of acute renal failure in children [54–59]. In the United States alone, *E. coli* O157:H7 is estimated to cause more than 20,000 infections and as many as 250 deaths each year [57]. The organism has been referred to as an enterohemorrhagic strain (EHEC) because of its frequent production of bloody diarrhea in infected patients [55]. The *E. coli* serotype O157:H7 is designated by its somatic (O) and flagella (H) antigens.

1. **Pathogenesis.** These *E. coli* produce large amounts of toxins (Shiga-like) that are specified by bacteriophages that have infected the bacterial cells. A multi-state epidemic in the western United States in 1993 was traced to **contaminated hamburger patties** that were undercooked by a fast-food restaurant chain. Subsequent U.S. Food and Drug Administration (FDA) recommendations call for increasing internal temperature for cooked hamburgers to 155°F such that the interior is no longer pink [54]. In addition to undercooked ground beef, foods such as roast beef, unpasteurized milk, lettuce, and apple cider have been implicated, as well as poorly chlorinated municipal water [56], person-to-person transmission in child day-care centers [60], and swimming in a fecally contaminated lake [57,61].

E. coli O157:H7 live in the intestines of about 1% of healthy cattle and can contaminate meat during slaughter. Grinding of beef is likely to transfer contamination from the surface to the interior of the meat [54,57].

2. **Clinical syndrome.** The incubation period usually is 3 to 5 days. **Although asymptomatic carriage occurs, watery diarrhea, often bloody, is the prominent symptom in 90% of cases.** Vomiting can occur. **Fever is infrequent.** The absence of fever may lead clinicians to suspect a noninfectious cause for the diarrhea [57]. Abdominal cramps or pain can be severe in some patients, and most illness resolves in 5 to 7 days. ***E. coli* O157:H7 also causes a spectrum of other illnesses, including HUS in 6% to 14% of patients under 10 years of age.** It causes some cases of thrombotic thrombocytopenia purpura in adults, which has features similar to those of HUS in children. These clinical syndromes have been reviewed elsewhere [12,55,57,59]. HUS develops on average 1 week after the onset of diarrhea. Because patients clear the organism from the GI tract rapidly, up to two thirds of patients with HUS will not have *E. coli* O157:H7 in stools [55]. Children and the elderly are at highest risk for **complications**, with 5% to 10% of patients developing HUS. This is characterized by hemolytic anemia, thrombocytopenia, and renal failure, with a fatality rate of 3% to 5% [58].
3. **Diagnosis** is made by culture on special sorbitol-MacConkey agar, which is commercially available. Colonies of *E. coli* O157:H7, which does not ferment the sorbitol, can readily be identified and confirmed by serotyping with specific antisera [55]. **Most laboratories do not culture for this organism unless requested to do so.** Because of the increasing importance of this pathogen, microbiology laboratories now are encouraged to routinely culture for this organism in bloody and nonbloody diarrheal specimens [55,57]. Tests for rapid detection of *E. coli* O157:H7 antigens and Shiga-like toxin in stool are being developed. Antibodies to O157 lipopolysaccharide are positive in the first several months after the onset of HUS, although serologic testing is currently performed only in research laboratories [55].
4. **Therapy is supportive. Antibiotic-treated patients may be more likely to develop HUS** [57]. Even though most strains of *E. coli* O157:H7 are sensitive to antibiotics used to treat infective gastroenteritis, no clinical benefit has been demonstrated.
 - a. **Most experts suggest antibiotics not be used** [12,55,57,62]. In a recent prospective study of *E. coli* O157:H7 in 71 children under 10 years of age, HUS developed in 56% of children treated with antibiotics and in 8% of untreated children [12,59].
 - b. **Antimotility agents or narcotics are contraindicated** because they may delay clearance of the pathogen and toxin. Use of antimotility agents has been associated with increased risk for the development of HUS and increased severity of neurologic manifestations of the syndrome [57].
 - c. **Intravenous hydration** with isotonic saline is advised to correct hypovolemia that in turn may reduce toxemic injury to the kidneys. Oral fluid increases crampy abdominal pain, whereas i.v. fluid administration reduces symptoms [55].
5. **Prevention**
 - a. Thorough cooking kills *E. coli* O157:H7. Optimally, **ground beef should be cooked thoroughly** until the interior is no longer pink and the juices are clear [45,58].
 - b. **Patients infected** with *E. coli* O157:H7 should be considered **highly contagious** and should not return to day care or school unless illness has resolved. Some authorities have recommended that infected children be excluded until two consecutive stool cultures are negative for *E. coli* O157:H7. However, shedding of the organism may be intermittent. Supervised handwashing is the most important preventive measure [55,57,60]. The dose of *E. coli* O157:H7 that leads to symptomatic infection, like *Shigella*, is low.
 - c. **All cases of confirmed *E. coli* O157:H7 infection should be reported immediately to appropriate public health authorities.** Early detection can lead to measures that will help prevent additional cases from occurring.
- F. ***Vibrio parahaemolyticus*** is a gram-negative, halophilic, marine organism that was first isolated in 1950 as a cause of self-limited gastroenteritis [3,63]. It is common in

Japan, where it may account for up to 70% of recognized causes of gastroenteritis. It occurs rarely in the United States, in such coastal areas as eastern Maryland, the gulf coast of Louisiana and Florida, and on cruise ships sailing between Florida and the Caribbean [64].

1. **Symptoms.** Diarrhea, cramps, weakness, nausea, chills, headache, fever, and vomiting occur 3 to 76 hours **after ingestion of contaminated raw or improperly cooked shellfish.** The mean duration of illness is approximately 3 days [63].
2. **Diagnosis.** Isolation is achieved on special media. Stool specimens may be tinged with blood and contain fecal leukocytes indicative of invasive disease. Sigmoidoscopy demonstrates superficial ulceration in some cases.
3. **Treatment.** Resolution occurs spontaneously in most cases and therapy is not indicated. No studies on the efficacy of antibiotics in gastroenteritis have been reported, but most are sensitive to tetracycline and TMP-SMX.

G. *Clostridium difficile* (antibiotic-related) diarrhea. **This diagnosis should be considered in any patient with a new onset of diarrhea while taking antibiotics or within 4 to 6 weeks after completing a course of antibiotics.** Fever, abdominal tenderness, leukocytosis, and fecal leukocytes are common findings.

H. Travelers' diarrhea is discussed in Chapter 22.

I. Miscellaneous

1. Other *Vibrio* species can cause diarrhea and may be linked epidemiologically to the consumption of raw or undercooked shellfish [64].
2. **Cholera**, infection due to *V. cholerae*, is rare in the United States. Domestically acquired cholera has been reported from an endemic Gulf Coast focus involving shellfish or imported foods; international travelers also can acquire cholera [64–66].
3. *Aeromonas hydrophila* may be pathogenic at times and is found in fresh water in the United States, coastal waters, shellfish, and even farm animals [3,63,67, 68].
4. *Plesiomonas shigelloides* also may cause diarrhea from contaminated shellfish (e.g., raw oysters). Rare waterborne outbreaks occur in the United States [3,63, 69–71].

J. Parasitic disease may mimic bacterial gastroenteritis, *Giardia* species, and *Entamoeba histolytica*. See related discussions under Gastrointestinal Parasites.

VI. Viral gastroenteritis occurs commonly, producing an estimated **30% to 40% of the cases of infectious diarrhea in the United States.** A study of diseases affecting families in Cleveland over a 10-year period found that infectious nonbacterial gastroenteritis was second in frequency to the common cold and accounted for 16% of illnesses [71,72].

A. Etiology. Four major categories of human gastroenteritis viruses have been defined since the discovery of the Norwalk virus in 1972. Well-established medically important pathogens include **rotavirus, enteric adenovirus, calicivirus (including Norwalk or Norwalk-like viruses), and astrovirus** (Table 13.5). The specific cause of many bouts of gastroenteritis cannot be determined [3,8,72–74].

1. **Rotavirus** is the agent **responsible for 30% to 60% of all cases of severe watery diarrhea in children.** It is a double-stranded RNA virus that can undergo gene reassortment, leading to new serotypes. There are at least seven distinct antigenic groups (A to G), four of which cause most disease. Group A rotavirus is most common and is the **single most important cause of dehydrating diarrhea necessitating hospitalization in children under 2 years of age** in both developed and less developed countries. Virtually all children are infected in the first 3 to 5 years of life. In the United States approximately 1 million cases of rotavirus infection occur annually, resulting in over 50,000 hospitalizations of children and 20 to 40 deaths per year [3,75]. Mild disease is seen in older children, and at times adults may acquire disease, especially after close contact with infected infants. Infants under 3 months of age seem less likely to be infected, presumably because of immunity by passive transplacental transfer of maternal antibody. Breast-feeding has not been proven to prevent infection but may be associated with milder disease and should be encouraged [76].

Table 13.5. Medical Importance, Clinical and Epidemiologic Characteristics, and Diagnosis of Human Gastroenteritis Viruses

Virus	Medical Importance Demonstrated	Epidemiologic Characteristics	Clinical Characteristics	Laboratory Diagnostic Tests ^a
Rotavirus Group A	Yes	Major cause of endemic severe diarrhea in infants and young children worldwide (in winter in temperate zone)	Dehydrating diarrhea for 5–7 days; vomiting and fever common	Immunoassay, electron microcopy, PAGE
Group B	Partially	Large outbreaks in adults and children in China	Severe watery diarrhea for 3–5 days	Electron microscopy, PAGE
Group C	Partially	Sporadic cases in young children worldwide	Similar to characteristics of group A rotavirus	Electron microscopy, PAGE
Enteric adenovirus	Yes	Endemic diarrhea of infants and young children	Prolonged diarrhea lasting 5–12 days; vomiting and fever	Immunoassay, electron microscopy with PAGE
Calicivirus (Norwalk virus; Norwalk-like viruses)	Yes	Epidemics of vomiting and diarrhea in children and adults; occurs in families, communities, and nursing homes; often associated with shellfish, other food, or water	Acute vomiting, diarrhea, fever, myalgia, and headache lasting 1–2 days	Immunoassay, immune electron microscopy
Astrovirus	Partially	Pediatric diarrhea; reported in nursing homes	Watery diarrhea, often lasting 2–3 days, occasionally longer	Immunoassay, electron microscopy

PAGE, polyacrylamide-gel electrophoresis and silver staining of viral nucleic acid in stool.

^aLaboratory diagnostic tests, other than those for rotavirus group A, usually are available only in specialized research or diagnostic referral laboratories. Immunoassays are usually enzyme-linked immunosorbent assay or radioimmunoassays.

Adapted from Blacklow NR, Greenberg HB. Viral gastroenteritis. *N Engl J Med* 1991;325:252; with permission.

- a. **Transmission** is probably by the **fecal-oral route**. Rotavirus is shed in large numbers in the feces, and fecal infiltrates are infectious to volunteers [72]. Rotavirus can be found on toys and hard surfaces in day-care centers, suggesting fomites as a mechanism of spread. Respiratory transmission also may play a role. Waterborne transmission may occur in less developed countries [76].
 - b. **Infection is more common** in cooler, **winter** months in the United States, with spread typically from the Southwest to the Northeast each year.
 - c. **Clinical syndrome**. Rotavirus infection frequently is asymptomatic. In symptomatic infection, the incubation period is 1 to 3 days, with illness lasting 5 to 7 days in normal hosts, but the course may be more protracted in the immunocompromised host. **It is not possible to differentiate rotavirus-associated gastroenteritis from illness caused by other enteric pathogens on the basis of clinical criteria. Vomiting is common, as is dehydration.**
 - d. **Diagnosis**. Because large amounts of the rotavirus are in the stool, a wide variety of assays able to detect **rotavirus antigen in the stool** are sensitive and specific. Enzyme immunoassays (EIAs) and latex agglutinations assays are commercially available.
 - e. **Treatment** is symptomatic, preferably with oral rehydration fluids.
 - f. **Vaccine** to prevent rotavirus infection and disease is not currently available. A rhesus rotavirus tetravalent vaccine was incorporated into the routine childhood immunization schedule in 1999, but was withdrawn from the market the same year because of an association of this vaccine and intussusception [75,76].
2. **Enteric adenovirus** is second to the rotavirus in causing pediatric gastroenteritis, especially in children under 1 year of age. Estimates suggest that this virus accounts for 4% to 10% of pediatric diarrhea in children under 2 years of age [72].
- a. **Transmission** is from person to person.
 - b. No seasonal peak occurs.
 - c. Serotypes 40 and 41 cause diarrheal disease, usually without respiratory symptoms.
 - d. **Clinical syndrome**. The incubation period is 8 to 10 days. Asymptomatic infection may be observed, but watery diarrhea may last 5 to 12 days, with 1 to 2 days of vomiting. Low-grade fever and dehydration occur. Nosocomial and day-care center outbreaks are common, during which high rates of asymptomatic infections occur; spread to adults is uncommon.
 - e. A presumptive **diagnosis** can be made if large numbers of adenoviral particles are seen on electron microscopic examination of diarrheal stool; the virus cannot be cultured with conventional cell culture. Immunoassays and dot blot hybridization assays for adenoviruses 40 and 41 are available [74].
 - f. **Treatment** is symptomatic.
3. **Calicivirus** (including **Norwalk virus** and serologically related **Norwalk-like viruses**) **cause approximately 40% of the outbreaks of gastroenteritis** that occur in every situation where people gather in social, health-related, or recreational circumstances. Outbreaks also result from the ingestion of contaminated drinking or swimming water, poorly cooked clams and oysters from contaminated waters, and contaminated foods such as salads and cake frosting. These viruses cause explosive epidemics of diarrhea that can sweep through a community with a high attack rate, affecting all age groups [3,72,74,77,78].
- a. **Transmission** is by the fecal-oral route.
 - b. **Clinical syndrome**. The incubation period is 12 to 48 hours. Nausea and vomiting are common but watery diarrhea is the main symptom. Mild degrees of small intestinal malabsorption can persist for 2 weeks after the acute episode [72]. Disease caused by calicivirus in infants and young children is clinically indistinguishable from mild rotavirus illness, typically with vomiting and diarrhea lasting 1 to 2 days. Approximately 3% of the cases of diarrhea among infants and young children at U.S. day-care centers are caused by calicivirus.

- c. Diagnosis.** Because the calicivirus cannot be cultivated in the laboratory, the diagnosis can be established only by identifying viral antigen in the stool, and these tests are available only in research laboratories. Virus can be seen in fecal effluent by immune electron microscopy using serum from a convalescent subject. A monoclonal antibody–based enzyme-linked immunoabsorbent assay (ELISA) and a polymerase chain reaction (PCR) assay have been developed that can detect Norwalk virus in stool specimens, but these are not yet commercially available [74,78].
- d. Nomenclature.** Caliciviruses are often named after the locations of outbreaks of diarrheal illness attributed to these viruses (e.g., Norwalk, Hawaii, Snow Mountain).
- 4. Astrovirus** is a single-stranded RNA virus that is **a major cause of diarrheal illness in children** from infancy to 7 years of age. Antibody develops to many of the seven viral serotypes by about 4 years of age, indicating that this virus probably causes frequent infections in childhood. Although similar to rotavirus illness, it is less severe. The incubation period is 1 to 4 days. Nausea, vomiting, and occasionally fever may occur, but watery diarrhea lasting 2 to 3 days is the prominent symptom. Outbreaks have been described in residential homes for the elderly. Serum antibodies whose levels may decline with age may protect young adults. The virus can be recognized in stool specimens by means of electron microscopy, specific immunoassays, RNA probe hybridization, and PCR [3,72,74].
- B. Diagnosis**
- 1. In adults,** the diagnosis of viral gastroenteritis is, for all practical purposes, **a diagnosis of exclusion** because techniques are not routinely available to isolate the virus from stool [8].
- a. History.** There is no obvious history suggesting a bacterial or parasitic process (e.g., no recent international travel, no high fever or rigors, no recent seafood ingestion). The patient may well have been exposed to a friend or family member with similar GI symptoms.
- b. Stool examination.** The diagnosis of a viral process is supported, although not proven, by the absence of fecal leukocytes. The results of stool culture or O&P examination will be negative, and the decision of whether to order these tests must be individualized.
- 2. In children,** similar principles hold, but stools can be examined for rotavirus and, at times, enteric adenovirus.
- C. Therapy is supportive** with fluid replacement.

HELICOBACTER PYLORI AND PEPTIC ULCER DISEASE

Helicobacter pylori (formerly called *Campylobacter pylori*) has emerged as a major causative factor in the pathogenesis of peptic ulcer disease. Most peptic ulcers not caused by nonsteroidal antiinflammatory drugs (NSAIDs) are now thought to be associated with *H. pylori* infection. The organism's clinical role has been reviewed extensively [79–83].

- I. The organism** *H. pylori* is a curved, motile, microaerophilic gram-negative bacillus with flagella at one end that is found in the mucous layer overlying the epithelium of the gastric mucosa, and within the epithelial cells.
- A. *H. pylori* infection is found worldwide.** Prevalence of infection increases with age and is highest in disadvantaged socioeconomic groups. In developing countries, the prevalence of *H. pylori* colonization of gastric mucosa is nearly universal by the age of 20. Developed countries typically have a lower prevalence of *H. pylori*, particularly among younger persons. In North America more than 50% of asymptomatic persons over 60 years of age show evidence of active or past *H. pylori* infection [79]. Patients with active or inactive peptic ulcer disease, especially duodenal but also gastric, have *H. pylori* infection more often than age-matched controls, with an odds ratio of approximately 3:1 to 4:1 [84]. The only known important reservoir of *H. pylori* is humans. Although *H. pylori* has been cultured from domestic cats, there is no evidence that it is transmitted to humans from cats or other pets. Transmission is thought to occur person to person by fecal-oral or oral-oral exposures, although the route of transmission has not been confirmed. A higher prevalence of *H. pylori*

antibodies has been found among institutionalized adults relative to age-matched controls, suggesting person-to-person transmission in the institutional setting [85].

- B. Virtually all persons with *H. pylori* infection in the antral mucosa have focal epithelial cell damage and inflammation in the lamina propria.
 1. *H. pylori* produces urease, which seems important in colonization and is cytotoxic to human epithelial cells.
 2. Other cytotoxins produced by certain strains of *H. pylori* may function as virulence factors that damage epithelial cells and exacerbate the inflammatory process in susceptible hosts [81,86].
- C. The importance of ***H. pylori* in the pathogenesis of peptic ulcer disease** is evident in the high incidence of infection among patients with peptic ulcer disease and the lower relapse rates of ulcers after eradication of *H. pylori*.
 1. *H. pylori* infection is present in greater than 90% of patients with duodenal ulcers and 70% to 90% of those with gastric ulcers, excluding patients taking NSAIDs [81].
 2. **The strongest evidence for the pathogenic role of *H. pylori* in peptic ulcer disease is the marked decrease in recurrence rates of ulcers following the eradication of *H. pylori*** [82,83]. Among patients with duodenal ulcer and *H. pylori* infection, ulcer recurred in only 12% of those treated with triple antibiotics plus ranitidine, compared with recurrence in 95% of those treated with ranitidine alone [87].
 3. Overall, *H. pylori* appears to be a strong risk factor for development of ulcer disease, but its presence is not sufficient to cause ulcers. **Only 15% to 20% of people infected with *H. pylori* develop an ulcer during their lifetime.** Why *H. pylori* infection leads to peptic ulcer disease in a minority of infected persons is not known [81].
 4. The mechanism whereby infection with *H. pylori* results in peptic ulcer disease is not well understood. Physiologic factors in the host, such as increased acid secretion in response to infection, may enhance mucosal injury. Other host factors, such as concomitant smoking, the use of NSAIDs, and stress, may play synergistic roles [81,86].

II. Diagnosis of *H. pylori* infection [81]

A. Invasive techniques require endoscopy.

1. **Culture is not indicated** for diagnosis. Culturing for *H. pylori* involves obtaining the sample by endoscopy, and culture techniques are difficult. Culture is less sensitive than routine histologic analysis of tissue. Cultures are used in research studies to determine the susceptibility of *H. pylori* to antimicrobial agents.
2. **Endoscopy with biopsy**
 - a. **The organism may have a patchy distribution in the stomach**, especially in the body and fundus. Taking multiple biopsy samples improves the diagnostic yield.
 - b. ***Campylobacter*-like organism (Clo) test on endoscopic biopsy samples.** Mucosal tissue is directly inoculated into medium containing urea and phenol red, which turns pink if the pH rises above 6.0. This change occurs when urea in the gel is metabolized to ammonia by the urease produced by *H. pylori*. The test is commercially available and inexpensive, and can provide a diagnosis within 1 hour of inoculation of the biopsy specimen. Sensitivity and specificity are as high as 90% and 100%, respectively. **The low cost and excellent reliability of this test make it the endoscopic method of choice for diagnosis** [81,83].
 - c. **Histologic examination.** Experienced pathologists can diagnose *H. pylori* on hematoxylin and eosin staining, but false-negative results occur. Giemsa and Warthin-Starry stains permit easier visualization [83]. Histology is much more expensive than urease (Clo) testing; it is reasonable to obtain biopsy samples and perform the histologic examination only if results of the Clo test are negative [81,83].

B. Noninvasive tests

1. **The urea breath test is a sensitive, specific, noninvasive test to detect *H. pylori* infection.** A carbon 13- or 14-labeled urea solution is ingested. If

H. pylori is present in the stomach, urease produced by the organism will hydrolyze the urea to form ammonia and radiolabeled carbon dioxide. The latter is absorbed rapidly into the bloodstream and can be detected in the expired breath [81,88].

- a. The urea breath test is sensitive and specific in the initial diagnosis of *H. pylori* infection and the assessment of response to antimicrobial therapy.
 - b. Because antimicrobial drugs and proton pump inhibitors temporarily cause false-negative results, an interval of at least 4 weeks after completion of anti-*H. pylori* therapy should be allowed before breath tests are used for confirmation of cure.
2. **Serologic tests** are available, based on ELISA and other methods, which have very high sensitivity and specificity for detecting immunoglobulin G (IgG) antibody to *H. pylori*.
 - a. **An elevated antibody titer to *H. pylori* indicates current infection in the untreated patient**, because spontaneous clearance of infection is rare.
 - b. **Serology is not useful for early follow-up testing after therapy**. Although the antibody titer decreases after eradication of *H. pylori*, the rate of decline is uncertain. Titers must be followed for at least 6 months to determine a decline [81].
 3. Because of their excellent accuracy and low cost, **serology and urea breath test are the methods of choice to document infection with *H. pylori* in patients who do not otherwise require endoscopy**.
- C. **The optimal strategy for evaluation and management of patients with dyspepsia, only 15% to 30% of whom have peptic ulcer disease, remains controversial** [80,83,89].
1. **Noninvasive tests for *H. pylori* are commonly used in conjunction with endoscopy**. Some experts advocate that patients with dyspepsia undergo noninvasive testing for *H. pylori* followed by anti-*H. pylori* antibiotic therapy in *H. pylori*-positive subjects. Endoscopy is reserved for nonresponders. The safety and cost effectiveness of this approach are under investigation [80,83,90].
 2. Endoscopy is still required to establish a diagnosis of ulcer disease. Endoscopy is indicated in patients with dyspepsia associated with "alarm" markers for gastric or esophageal neoplasia (e.g., anemia, GI bleeding, anorexia, early satiety, vomiting, dysphagia, weight loss, or onset after age 50) [83,89].

III. Treatment of *H. pylori* associated with peptic ulcer disease

A. Consensus has evolved that *H. pylori* is:

1. **A cause of acute and chronic active gastritis.**
2. **A cofactor in the pathogenesis and recurrence of peptic ulcer diseases** (see section I.A).
3. **A Possible cofactor in gastric carcinoma**. However, there is no evidence that treatment of *H. pylori* infection prevents development of gastric carcinoma [91].
4. **Not conclusively established as a factor in nonulcer dyspepsia**. Eradication of *H. pylori* does not consistently result in resolution of symptoms [92,93].

B. Treatment to eradicate *H. pylori* is advocated for selected patients [79–83].

1. **All patients with gastric or duodenal ulcers who are infected with *H. pylori*** should receive antimicrobials, whether on initial presentation or on recurrence.
2. *H. pylori*-infected patients with peptic ulcer disease who are receiving maintenance therapy with antisecretory agents or who have a history of complicated or refractory disease should be treated.

C. Do not treat asymptomatic carriers and nonulcer dyspepsia.

1. Prophylactic antibiotics are **not** recommended to prevent future ulcers or gastric neoplasia in asymptomatic infected patients without ulcers.
2. Treatment is not routinely advised for patients with nonulcer dyspepsia. Patients may be tested for *H. pylori* on a case-by-case basis, and treatment offered to those with a positive result [80,92,93].
3. Mucosa-associated lymphoid tumors (MALTomas) of the stomach appear to regress in patients treated for *H. pylori* with antibiotics (see section IV.B.)

D. Treatment regimens. The optimal regimen has not been defined.

1. Attempts to eradicate *H. pylori* with single agents have not been effective and may lead to antimicrobial resistance [80,82].
2. **Multidrug regimens** are suggested. Antimicrobials used to treat *H. pylori* include bismuth subsalicylate (Pepto-Bismol), amoxicillin, metronidazole, clarithromycin, and tetracycline in various combinations of two or three agents, usually in addition to a histamine (H₂)-blocker (e.g., ranitidine) or a proton pump inhibitor (e.g., omeprazole). Regimens given for 7 to 14 days have been successful in eradicating *H. pylori* in 60% to 95% of cases. The longer duration of treatment is usually more efficacious. Obstacles to effective treatment include the presence of antibiotic-resistant *H. pylori*, poor patient compliance with complex regimens, and occurrence of side effects [79–83,94,95].
 - a. **Antimicrobial resistance** of *H. pylori* to metronidazole and clarithromycin is reported frequently; resistance to tetracycline and to amoxicillin is rare.
 - b. The **topical action** of effective antibiotics is important.
 - c. The **efficacy of many antibiotics is enhanced at increased gastric pH levels**, which may help to explain the higher rates of eradication of *H. pylori* when antimicrobial agents are combined with H₂-blockers or proton pump inhibitors.
 - d. **Reinfection** after eradication is uncommon and appears to occur at rates as low as 1% annually in developed countries [81].
 - e. **Side effects** are common with a triple-drug regimen and occur in up to 30% of recipients [82]. **Nausea and vomiting** may be seen in 20%. Alcohol should be avoided. Oropharyngeal or vaginal fungal infections can occur and may require topical therapy. **Diarrhea** may be reduced if tetracycline is used instead of amoxicillin. **Rash** is seen in 5% or fewer patients. *C. difficile* diarrhea has been reported in less than 1% of treated patients. Clarithromycin can cause a disturbance in taste that some patients find intolerable.
3. **Examples of common treatment regimens** are provided below. Options for treatment continue to evolve. See earlier reports [79–81,83,94,95] for a more detailed discussion.
 - a. Clarithromycin 500 mg twice daily plus metronidazole 500 mg twice daily (or amoxicillin 1 g twice daily) plus omeprazole 20 mg twice daily (or lansoprazole 30 mg twice daily) for 7 to 14 days.
 - b. Clarithromycin 500 mg twice daily plus metronidazole 500 mg twice daily (or amoxicillin 1 g twice daily or tetracycline 500 mg twice daily) plus ranitidine bismuth citrate (Tritec) 400 mg twice daily for 7 to 14 days.
 - c. Bismuth subsalicylate (Pepto-Bismol) two tablets (525 mg) four times daily plus metronidazole 250 mg four times daily plus tetracycline 500 mg four times daily for 14 days.
 - d. Regimen c plus omeprazole 20 mg twice daily for 7 days.

IV. Relationship of *H. pylori* to other GI diseases

- A. **Gastric carcinoma.** Several prospective and retrospective studies of gastric cancer have identified *H. pylori* colonization as a risk factor for this disease. This finding is not surprising, because chronic gastritis and atrophic gastritis, which are known to be associated with *H. pylori*, are also recognized risk factors for gastric carcinoma. However, the presence of *H. pylori* colonization is neither necessary nor sufficient for oncogenesis, and other factors also must be involved in the pathogenesis of gastric carcinoma [79,91].
- B. **Mucosa-associated lymphoid tumors** are non-Hodgkin lymphomas of the stomach that arise from B-lymphocytes. *H. pylori* colonization is strongly associated with gastric MALTomas. Recent studies suggest that eradication of *H. pylori* results in tumor regression in most patients [79].

GASTROINTESTINAL PARASITES

A detailed discussion of the epidemiology, clinical features, and treatment of intestinal parasitic diseases is beyond the scope of this book. However, basic concepts of diagnosis and therapy of the most common pathogens are presented here. Table 13.6 lists the vectors, most common clinical symptoms, sites of involvement in the host, and laboratory tests

Table 13.6. Helminth and Protozoan Infections of Human Gastrointestinal Tract

	Common Name of Parasite or Disease	Site in Host	Source of Infection, Intermediate Host, or Vector	Most Common Clinical Symptoms	Laboratory Diagnosis	Remarks
Nemathelminths (roundworms)						
<i>Ancylostomaa duodenale^a</i>	Old world hookworm; ancylostomiasis	Small intestine (attached)	Infective filariform larvae in soil	Anemia growth retardation, GI symptoms	Eggs in stool	Prophylaxis by excreta disposal. Iron therapy important in blood regeneration.
<i>Necator americanus^a</i>	New world or tropical hookworm; uncinariasis	Small intestine	Eggs from soil or vegetables	Vague abdominal distress	Eggs in stool	Worms migrate into bile, pancreatic duct, and peritoneum. Intestinal obstruction.
<i>Ascaris lumbricoides^b</i>	Large roundworm	Small intestine	Eggs in environment; autoinfection	Anal pruritus	Eggs in perianal region, cellophane tape swab	Entire family frequently infected. Personal hygiene important.
<i>Enterobius vermicularis^b</i>	Pinworm, seatworm; <i>Oxyuris</i>	Large intestine, appendix	Larvae in soil	Abdominal discomfort, diarrhea	Larvae in stool	Autoinfection occurs.
<i>Strongyloides stercoralis^a</i>	Cochin, Viet Nam diarrhea	Wall of small intestine	Infected pork, cyst (rarely bear)	Orbital edema, muscle pain, eosinophilia	Skin test, serology, muscle biopsy	Thorough cooking of pork and pork products to kill cysts.
<i>Trichinella spiralis^b</i>	Trichinosis	Intestinal wall; cyst in striated muscle	Eggs from soil or vegetables	Abdominal discomfort, anemia, bloody stools	Eggs in stool	Frequently with hookworm and <i>Ascaris</i> ; adults seldom symptomatic.
<i>Trichuris trichiur^b</i>	Whipworm, threadworm	Cecum of large intestine, ileum	Eggs from soil	Pneumonitis, eosinophilia	Serology	Eosinophilia, anemia, hyperglobulinemia.
<i>Toxocara canis, T. cati^b</i>	Visceral larva migrans	Liver, lung, brain, eye	Plerocercoid in freshwater fish	Anemia very rare	Eggs in stool	Prophylaxis by excreta disposal. Cook fish well.
Platyhelminths (Tapeworms)						
<i>Diphyllobothrium latum^b</i>	Fish or broad tapeworm	Small intestine	Eggs from feces in soil; autoinfection	Abdominal discomfort	Eggs in stool	Numerous worms, infection of children.
<i>Hymenolepis nana^b</i>	Dwarf tapeworm	Adults and cysts in small intestine	Cysts in beef	Usually no symptoms	Eggs and segments in stool	Usually only one worm.
<i>Taenia saginata^b</i>	Beef tapeworm	Small intestine				

<i>Taenia solium</i> ^b	Pork tapeworm	Small intestine	Cysts in pork	Usually no symptoms	Eggs and segments in stool	Uncommon in USA. Frequent in Mexico South America, Central America. Autoinfection possible. Uncommon in USA.
<i>T. solium</i> (cysts) ^b	Cysticercosis; verminous epilepsy	Muscle, brain, eye	Eggs from feces	Intracranial pressure, epilepsy	Biopsy, radiograph of calcified cysts; CT scan; serology	Uncommon in USA.
<i>Echinococcus granulosus</i> ^b	Hydatid cyst	Liver, lungs, brain, bones	Eggs from dog feces	Symptoms due to pressure in affected organs	Serology, CT scan; skin test	Uncommon in USA.
Platyhelminths (flukes)						
<i>Schistosoma haematobium</i> ^a	Schistosomiasis (bilharzia)	Veins of urinary bladder	Cercaria in fresh water, from snail	Urinary disturbances, hematuria	Eggs in urine, cystoscopy	Africa, Middle East.
<i>Schistosoma japonicum</i> ^a	Schistosomiasis	Veins of small intestine	Cercaria in fresh water, from snail	Dysentery, hepatic cirrhosis	Eggs in stool, liver biopsy	China, Japan, Philippines.
<i>Schistosoma mansoni</i> ^a	Schistosomiasis	Veins of large intestine	Cercaria in fresh water, from snail	Chronic dysentery, hepatic cirrhosis	Eggs in stool, rectal or liver biopsy	Africa, South America, common in Puerto Rico.
Protozoa						
<i>Entamoeba histolytica</i> ^b	Intestinal amebiasis	Lumen and wall of large intestine	Cysts in food and water, from feces	Mild to severe GI distress, dysentery	Cysts or trophozoites in stool; serology	Consider possibility of hepatic infection
<i>E. histolytica</i> ^b	Amebic hepatitis, amebic liver abscess	Liver	Cysts in food and water, from feces	Enlarged, tender liver; fever; leukocytosis	CT scan or ultrasonography; serology; cysts or trophozoites in stool	Treat intestinal amebic infection
<i>Giardia lamblia</i> ^b	Flagellate diarrhea	Upper small intestine	Cysts in food and water, from feces	Mild GI distress and diarrhea, weight loss	Enzyme immunoassay of stool; cysts and trophozoites in stool	More common in children than adults

GI, gastrointestinal; CT, computed tomography.

^aPortal of entry is the skin.

^bPortal of entry is the mouth.

Adapted from Brown HW, Neva FA. *Basic clinical parasitology*, 5th ed. New York: Appleton-Century-Crofts, 1983:8–17; with permission.

commonly used to make the diagnosis of intestinal parasitic infestation. For details, the reader is referred to texts and recent reviews devoted to this topic [96–98].

- I. Pathogenesis of symptoms usually is related to one of the following:
 - A. **Physical presence** of organisms in the GI tract with loss of nutrients or blood (as in hookworm, *Ascaris*, *Strongyloides*, fluke, and protozoa infestations)
 - B. **Inflammatory reaction** by the host to some parasite-related protein (as in schistosomiasis and trichinosis)
 - C. **Migration of parasite** (as in creeping eruption and visceral larva migrans)
- II. **Diagnosis**
 - A. **Stool examination is the most common means of identifying the pathogen.**
 1. **The clinician should contact the diagnostic parasitology or microbiology laboratory** for assistance.
 2. **Fresh stool specimens** are required to preserve the trophozoites of some parasites such as *E. histolytica*. The diagnostic laboratory often will reject a specimen unless it is fresh or placed in appropriate fixatives.
 3. **Many drugs and materials interfere** with the stool examination for parasites. **Iron**, Bismuth, castor oil or mineral oil, and particulate substances such as **Metamucil**, can interfere for up to 1 week after ingestion. **Barium**, gallbladder dye, **antibiotics**, iodine preparations, bismuth, antiamebic drugs, and some antimalarial drugs may make the stool difficult to examine correctly for as long as 3 weeks after ingestion.
 4. **Stool specimens should be collected before any medications or purgatives for radiologic procedures are given.**
 5. **Macroscopic examination** of the stool may reveal nematodes or proglottids. Adult worms may be washed in warm sodium chloride and examined fresh or fixed. Proglottids may be visualized clearly by mounting in 5% acetic acid [96].
 6. Saline and iodine **wet mounts** for microscopic examination are useful for trophozoites, cysts, ova, and certain helminth larvae.
 7. **Three stool samples for O&P** microscopic examination are suggested in selected patients, because a single examination may yield false-negative results. The specimen should be collected in a clean dry surface such as a bedpan or collection cup and should not be taken from the toilet or be contaminated with urine. O&P microscopic examination is time consuming and requires a skilled clinical parasitologist. O&P examination is recommended only in selected patients:
 - a. **ELAs for detection of *Giardia lamblia* and *Cryptosporidium* antigen in stool have largely replaced O&P examination. O&P examination should be reserved for patients in whom there is a high clinical suspicion of parasitic infection caused by organisms other than *Giardia* or *Cryptosporidium*.** These would include immigrants or returning travelers from tropical regions that have a high prevalence of endemic parasitic disease, or immunocompromised patients or others with persistent diarrhea in whom exclusion of other causes has been accomplished by laboratory testing [8,99].
 - b. **O&P examination is usually not appropriate in patients who develop diarrhea after 3 days of hospitalization.** In this setting, *C. difficile* colitis or antibiotic-associated diarrhea are far more common than parasites [8,99].
 8. **Artifacts or other objects can be mistaken for parasites.** This is especially true in old specimens. It is best to confirm one's observation by consulting with an expert.
 9. **Diagrams of common helminth eggs** are shown in Figure 13.1 and in Neva's text [96].
 - B. **Geographic exposure** is useful when considering a parasitic diagnosis. For example, hookworms survive poorly in cold, northern environments, and *Echinococcus* cysts are found primarily in shepherders of Basque origin in the western United States. The Centers for Disease Control and Prevention conducted a survey of stool specimens examined by public health laboratories in 1987. A total of 216,275 specimens were examined; parasites were found in 20.0%. Percentages were highest for protozoans: *Giardia lamblia* (7.2%), *Entamoeba coli* and *E. nana* (4.2% each),

FIG. 13.1 Relative size of helminth eggs. (Reprinted from Brooke MM, Melvin DM. *Morphology of diagnostic stages of intestinal parasites of man*. Publication No. (HSM) 72-8116. Atlanta: U.S. Department of Health, Education, and Welfare, 1972.)

Blastocystis hominis (2.6%), and *E. histolytica* (0.9%). The most commonly identified helminths were nematodes: hookworm (1.5%), *Trichuris trichiura* (1.2%), and *Ascaris lumbricoides* (0.8%) [100].

C. Scotch tape technique for pinworms is the test of choice for *E. vermicularis* infestations. The sticky side of clear tape is pressed against several areas of the perineum of a child with pruritus. Next the tape is placed sticky side down onto a clean glass slide, smoothed out with cotton gauze, and examined under the microscope.

D. Eosinophilia occurs in many, but not all, parasitic infestations. Its presence should raise one's suspicion of parasitic tissue infestation. **The following organisms usually elicit eosinophilia:** (a) *Trichinella* species, (2) visceral larva migrans, (3) filaria, (4) hookworms, (5) *Schistosoma* species, and (6) whipworms.

E. Serologic tests

1. Amebiasis serologic tests are discussed in section **IV.E.4**.

2. *Trichinella spiralis* infection can be confirmed by sending a blood specimen to the state or reference laboratory.

F. Duodenal aspirates have been useful in making the diagnosis in a small number of cases of giardiasis and strongyloidiasis when stool specimens were not positive for cysts, trophozoites, or larvae, and the diagnosis was strongly suspected.

G. Giardia antigen is discussed in section **IV.A.2**.

III. Therapy. A summary of the recommended drugs for treatment is given in Table 13.7.

IV. Discussion of selected parasitic diseases

A. Giardiasis. *Giardia lamblia* is the most frequently isolated intestinal parasite in the United States. The most common mode of transmission has been through contaminated surface water. However, person-to-person transmission in day-care centers and custodial institutions, transmission between male homosexuals via sexual contact, and food-borne transmission via fecal contamination can occur. Young children attending day care may spread infection to a parent or caregiver. Large-scale waterborne outbreaks have occurred in Leningrad, Colorado, New Hampshire, New York, Oregon, Utah, and Washington [97,101–103].

1. **Symptoms and life cycle.** Chlorination does not destroy the cystic stage. A week or two after the ingestion of contaminated water, explosive diarrhea, abdominal cramps, flatulence, nausea, vomiting, and low-grade fever may occur. Patients do not pass gross pus, blood, or mucus. Chronic infections result in milder, intermittent symptoms and malaise. The **spectrum of disease varies widely** from asymptomatic cyst passing to patients with acute symptoms to patients with persistent steatorrhea and weight loss. Weight loss occurs in approximately 50% of patients with chronic symptoms and averages 10 pounds [101].

Lactase deficiency after infection is **common**, especially in children. Patients who recover from giardiasis should be counseled to avoid lactose-containing products for approximately 1 month. Because hypogammaglobulinemic patients often have *Giardia* infection, and because achlorhydria patients are more susceptible to infection, it is believed that IgG and stomach acid both play a role in host defense.

2. **Diagnosis**

a. History of prolonged diarrhea without blood or mucus, weight loss, surface water exposure, exposure to day-care children, or a homosexual lifestyle, and mild malabsorption or lactose intolerance should raise suspicion for this diagnosis.

b. Stool examination. There are only two stages in the life cycle of this parasite: the trophozoites, which exist freely in the small bowel, and the cyst, which is passed into the environment [101,103]. **Fecal leukocytes are not present.**

(1) **Giardia antigen stool assays** have become the preferred test in many laboratories. A polyclonal or monoclonal antibody against cyst or trophozoite antigens is used to detect *Giardia* by EIAs or immunofluorescence; intact organisms are not required. The sensitivity is 85% to 98%, and the specificity is 90% to 100%. These tests are more sensitive than microscopic examination of the stool; a single stool tested by EIA may be sufficient to exclude giardiasis [8,101].

Table 13.7. Treatment of Common Parasitic Infections

Organism	Drug Choice	Adult Dose	Pediatric Dose		
<i>Giardia lamblia</i>	Metronidazole ^{a,b}	250 mg t.i.d. for 5 days	15 mg/kg/day in 3 doses for 5 days		
	Furazolidone	100 mg q.i.d for 7–10 days	6 mg/kg/day in 4 doses for 7–10 days		
	Paromomycin ^{b,c}	25–35 mg/kg/day in 3 doses for 7 days			
<i>Trichuris trichiura</i>	Mebendazole or Albendazole ^b	100 mg b.i.d for 3 days or 500 mg once 400 mg once ^d	Same		
	<i>Ascaris lumbricoides</i>	Mebendazole or Pyrantel pamoate ^b or Albendazole ^b	100 mg b.i.d for 3 days or 500 mg once 11 mg/kg once (max 1 g) 400 mg once	Same	
<i>Enterobius vermicularis</i>		Pyrantel Pamoate or Mebendazole or Albendazole ^b	11 mg/kg once (max 1 g); repeat after 2 wk 100 mg once; repeat after 2 wk 400 mg once; repeat after 2 wk	Same	
		<i>Entamoeba histolytica</i>	Asymptomatic	Iodoquinol ^e or	650 mg t.i.d. for 20 days
	Paromomycin			25–35 mg/kg/day in 3 doses for 7 days	Same
Intestinal disease ^f	Metronidazole ^a		500–750 mg t.i.d. for 10 days	35–50 mg/kg/day in 3 doses for 10 days	
Hepatic abscess ^f	Metronidazole ^a	750 mg t.i.d. for 10 days	35–50 mg/kg/day in 3 doses for 10 days		
<i>Dientamoeba fragilis</i>	Iodoquinol ^g or	650 mg t.i.d. for 20 days	40 mg/kg/day in 3 doses for 20 days (max 2 g/day)		
		Tetracycline ^{b,h} or	500 mg q.i.d for 10 days	40 mg/kg/day in 4 doses for 10 days (max 2 g/day)	
	Paromomycin ^b	25–30 mg/kg/day in 3 doses for 7 days	25–30 mg/kg/day in 3 doses for 7 days		
<i>Blastocystis hominis</i> ^h	Iodoquinol ^e or	650 mg t.i.d. for 20 days	—		
	Metronidazole ^a	750 mg t.i.d. for 10 days	—		

t.i.d., three times daily; q.i.d., four times daily; b.i.d., twice daily.

^aAvoid in pregnant women, especially first trimester.

^bApproved drug but considered investigational in this condition by the U.S. Food and Drug Administration.

^cNot absorbed. May be useful for treatment in pregnancy.

^dIn heavy infection, it may be necessary to extend therapy to 3 days.

^eDosage and duration of administration should not be exceeded because of the possibility of causing optic neuritis. Maximum dose 2 g/day.

^fTreatment should be followed by a course of iodoquinol or paromomycin (intraluminal drugs) in the dosage used to treat asymptomatic amebiasis.

^gContraindicated in patients under 8 years of age and in pregnant women.

^hWhether this organism is a true pathogen is controversial.

Adapted from The Medical Letter. Drugs for parasitic infections. *Med Lett Drugs Ther* 1998;40:1–12; with permission. (See this source for details of drug use, regimens for less common parasites, and summary of adverse effects of antiparasitic drugs.)

- (2) **O&P examinations** are appropriate for evaluating an international traveler. Three serial liquid stools, if examined properly, will demonstrate the organism in 90% of cases. Three stools over several days are preferred because cysts may be shed intermittently. Fresh and preserved specimens are examined. Because the organisms reside in the small bowel, in a minority of patients symptoms may precede stool positivity by 1 to 2 weeks [101].
- c. Duodenal sampling.** Occasionally patients with persisting symptoms suggestive of *Giardia* infestation have negative antigen tests and negative O&P examination results. In these patients, a string test or Entero-Test (HDC Corporation, San Jose, CA), duodenal aspirate, or duodenal biopsy may be considered [101].
- d. Serum anti-*Giardia* antibody tests** usually are not available and are used more in epidemiologic studies.
- 3. Therapy. All symptomatic patients deserve treatment.** Although some cases resolve spontaneously over 3 to 4 days, most persist until intervention with treatment.
- a. Metronidazole, although not FDA approved** for this indication, is the drug of choice for treatment of giardiasis. Efficacy is 80% to 95% (see Table 13.7).
- b. Furazolidone**, available in liquid suspension, is an alternative for children. It is well tolerated. Because it is only 80% effective, follow-up is important. It causes mild hemolysis if there is glucose-6-phosphate dehydrogenase deficiency [101].
- c. Tinidazole** (Fasigyn) is effective in a single dose of 2 g (not available in the United States).
- d. Albendazole** has been shown to have efficacy similar to metronidazole and fewer side effects, but clinical experience with this agent is limited [103].
- e. Therapy in pregnancy** remains an unclear issue. The suggested approach is as follows [101]:
- (1) Avoid treatment altogether in the first trimester if possible.
 - (2) Women with mild disease may delay therapy until after delivery. Nutrition and hydration must be maintained.
 - (3) For women with persisting symptoms of weight loss, nausea, or dehydration necessitating therapy, use of paromomycin, an oral aminoglycoside that is excreted in the feces nearly 100% unchanged, is advised, although its efficacy may be in the 60% to 70% range [101] (see Chapter 27I). The use of metronidazole in pregnancy remains debated (see Chapter 27Q), but it is a potential option in the third trimester (see Table 13.7).
- f. Persisting symptoms** may be due to lactose intolerance, and this warrants therapy as well as careful repeat stool examination.
- 4. Therapy of asymptomatic infection** (asymptomatic cyst passer) is **controversial**. Therapy may be indicated in the setting of an outbreak (e.g., in a child-care center or custodial institution) if reinfection is unlikely. Asymptomatic food handlers and day-care workers should be treated [97].
- 5. Empiric therapy** sometimes is used in situations where the clinical suspicion is high but stool examinations are negative.
- 6. Prevention** requires proper handling and treatment of community water supplies, appropriate disposal of human and animal waste, and good personal hygiene [102].
- a. Wilderness hikers or international travelers** must pay attention to preparing drinking water. Water needs to be boiled for at least 1 minute. An alternative is to use a filter system, but the pore size should be 1 μm or less. Halogenation of water with chlorine or iodine tablets is a less reliable treatment because it is highly dependent on the temperature, pH, and cloudiness of the water [102,103].
- b. Handwashing** is important before handling food and after every diaper change.
- B. *Trichuris trichiura* (whipworm) infestation**
- 1. Life cycle.** Infection occurs in humans by ingestion of embryonated eggs on contaminated hands, food, soil, or fomites. After a 10- to 30-day period in

the small intestine, the larvae migrate primarily to the cecum and appendix, where they embed their anterior end into the mucosa, with the posterior end free to “whip” in the lumen. These mature adults lay eggs, which pass to the soil and repeat the cycle. The distribution of whipworm is similar to that of *A. lumbricoides*.

2. **Symptoms** are correlated with the worm burden in the large bowel. Light infections may be asymptomatic. Infections produce their damage by mechanical and lytic damage to the mucosa, with petechial hemorrhages and disruption of integrity of the GI tract by bacteria. Heavy worm burdens produce diarrhea, abdominal pain, anemia, weight loss, weakness, and even rectal prolapse.
3. **Diagnosis** is made by **examination of fecal specimens** by direct smear, formalin-ether centrifugal sedimentation, or flotation techniques. Sigmoidoscopy can demonstrate adult worms attached to the colonic mucosa in severe infection.
4. **Treatment** (see Table 13.7). Stool examination should be performed 3 weeks after treatment to confirm eradication. A second treatment course should be undertaken if necessary.

C. *Ascaris lumbricoides* infestation

1. **Life cycle.** Infection results from ingestion of second-stage larvae that usually are contaminants of hands or soil. The larvae hatch in the small intestine, penetrate the intestinal wall, and are carried to the lungs through the portal vein or indirectly through the lymphatics. In the lung, they live and molt in the alveoli for 10 to 14 days. Subsequently, they migrate up the bronchi to the pharynx, are swallowed, and mature sexually in the small intestine 6 to 10 weeks later. The adult phase persists for approximately 9 months. Eggs are laid daily during this period. To become infectious to humans these eggs must be deposited in an external environment with adequate shade and moisture and a temperature conducive to hatching. **In the United States, the endemic areas include** southeastern parts of the Appalachian mountain range and areas of the southern and Gulf Coast states.
2. **Symptoms are related** primarily to the **mechanical presence of the parasites**. During the transient pulmonary stage, **Löffler syndrome** (pulmonary infiltrates with eosinophilia, dyspnea, cough, and fever) may occur. The adult worm's presence in the intestine usually is asymptomatic, except in cases where the worm **migrates into** various organs, causing obstruction of the common bile duct, pancreatic duct, appendix, or even the bowel itself if the mass of worms is large. At times, a patient, especially a child, may report having coughed up a worm or passed one through the rectum.
3. **Diagnosis.** Identification of *Ascaris* **eggs in the stool** is the primary means of diagnosis. Direct smears usually are sufficient, although concentration techniques may have to be used occasionally. In the patient with partial bowel obstruction due to a mass of *Ascaris* organisms, an upper GI barium study may demonstrate small bowel worms.
4. **Treatment** is summarized in Table 13.7.

D. *Enterobius vermicularis* (pinworm) infestation

1. **Symptoms.** Intense **pruritus ani** and, occasionally, **pruritus vulvae** are caused by the presence of adult worms and embryonic eggs. The 15-day life cycle is initiated by the ingestion of eggs on contaminated hands or in food or drink. Because the eggs are infectious when laid, autoinoculation can occur from anal scratching then oral transmission. The larvae emerge in the upper intestine, temporarily attach themselves, copulate in the lower small intestine, and then migrate to the anus to deposit their sticky eggs on the perianal skin. Irritability, restlessness, anorexia, and insomnia (in children) with enterobiasis have been attributed to a heavy worm infestation.
2. **Diagnosis.** Eggs are not found in stool. The **Scotch tape test is used** (section II.C) for diagnosis. Occasional worms may be seen on the perineum and identified.
3. **Treatment** is summarized in Table 13.7. Often, pinworm is epidemic among the entire family, and it is judicious to **consider treating all members simultaneously**.

E. *Entamoeba histolytica* infestation [97,104].

- 1. Life cycle.** Amebiasis is **acquired by the ingestion of cysts in contaminated water or in food that has been soiled** by a cyst carrier or contaminated by houseflies or cockroaches that have fed on human feces. The cysts undergo excystation in the small bowel. The trophozoites reach the large bowel and divide by binary fission. Some trophozoites may invade the colon and produce the characteristic flask-shaped ulcers. Others may invade the portal vein, lodge in the liver, and form a hepatic abscess. The trophozoites metamorphose into cysts as they are passed in the stools. If the diarrhea is loose and intestinal transit short, trophozoites may be seen in the stool.
- 2. Pathophysiology.** Virulent strains of *E. histolytica* have significant cytopathic properties *in vitro*, consistent with their ability to cause invasive colitis *in vivo*. The majority of individuals infected with *E. histolytica* are asymptomatic. The difference between commensal and invasive *E. histolytica* infection is attributable to the existence of distinct pathogenic and nonpathogenic strains. Nonpathogenic strains (*E. histolytica* variant *dyspar*) have never been found to cause amebic colitis or liver abscess. Nearly 10% of persons infected with *E. histolytica* harbor pathogenic strains. Although almost all these patients will mount a serum antibody response to pathogenic *E. histolytica* infection, only 1 of 10 patients with pathogenic strains have symptomatic disease [104].
- 3. Clinical symptoms** vary widely [104].
 - a.** *E. histolytica* has a number of diverse clinical presentations (Table 13.8).
 - b. The most common finding is asymptomatic intestinal infection without evidence of tissue invasion**, as defined by the absence of serum antibodies, blood in the stool, and mucosal ulcerations on colonoscopy.
 - c. Amebic colitis** has a subacute onset of bloody, mucoid diarrhea (onset over 7 days, duration 3–4 weeks), with abdominal pain, tenesmus, **fecal leukocytes**, fever, and positive serology for antiamebic antibodies (in 90% by day 7 of illness). **Fecal occult blood** test results are positive.
 - d. Liver abscess** classically presents with fever, right upper quadrant abdominal pain, and liver tenderness. Returning international travelers usually present within 5 months of their exposure. Diarrhea is seen in only 30% to 40% of those with liver abscess, and finding amebae in the stool is even less common [104].

Table 13.8. Clinical Syndromes Due to Infection by *Entamoeba Histolytica*

Intestinal
Asymptomatic cyst passers (colonization)
Symptomatic cyst passers
Acute rectocolitis
Fulminant colitis
Toxic megacolon
Perforation with peritonitis
Chronic nondysenteric colitis
Ameboma
Extraintestinal
Liver abscess
Lung abscess, empyema
Pericarditis
Brain abscess
Venereal disease
Cutaneous disease

Reprinted from Aucott JN, Ravdin JI. Amebiasis and “nonpathogenic” intestinal protozoa. *Infect Dis Clin North Am* 1993;7:467–485; with permission.

4. **Diagnosis of amebic colitis**
 - a. **A freshly passed liquid stool is examined** to identify the motile **trophozoites** of *E. histolytica*. Refrigeration at 4°C or storage in a fixative may allow some preservation (check with the parasitology laboratory). Three separate specimens should be examined (see section **II.A.3**). **Formed stools** in saline and iodine preparations are examined for amebic cysts. The formalin-ether concentration technique may help increase the yield.
 - b. **Serum antiamebic antibodies** develop only with pathogenic strains, and the absence of antibodies after 7 days of infection is strong evidence against invasive amebiasis.
 - c. **Colonoscopy** with scraping or biopsy of mucosal ulcers provides definitive diagnosis. Special stains (e.g., periodic acid-Schiff [PAS]) demonstrate the organism. A tissue diagnosis is especially indicated if corticosteroid therapy is being considered for the patient who has inflammatory bowel disease.
 5. **Diagnosis of amebic abscess** [104]
 - a. **Ultrasonography** of the liver and biliary tract is suggested. Computed tomography (CT) can be used in patients with nondiagnostic findings.
 - b. **Serum antiamebic antibodies are present** in 99% of patients with amebic abscess within 7 to 10 days of onset of illness.
 - c. If the clinical setting and evaluation are nondiagnostic, **fine-needle aspiration** under ultrasonographic or CT guidance can be performed. **Aspiration** of a liver abscess yields an “anchovy paste” fluid containing neither polymorphonuclear leukocytes nor amebae. The amebae occasionally are seen in the wall of the abscess.
 6. **Therapy.** Treatment is summarized in Table 13.7 [104].
 - a. **Asymptomatic *E. histolytica* infection.** It is unclear whether this condition routinely requires therapy. Treatment is recommended in asymptomatic persons from nonendemic areas, especially if the patient has underlying HIV infection or a positive test result for serum antiamebic antibodies that suggests infection with a pathogenic strain [104].
 - b. If metronidazole is the preferred agent (see Table 13.7) but is contraindicated or not tolerated, alternative regimens are available [104].
 - c. **Amebic abscess** usually responds to metronidazole therapy without the need to drain the abscess. It should be noted that metronidazole has excellent antibacterial activity against anaerobes, and several reports have warned that a metronidazole therapeutic trial cannot be used to differentiate an amebic abscess from an anaerobic liver abscess. (See the discussion in section **V.C** under Intraabdominal Infection.)
 7. **Prevention.** Avoiding fecal-oral contamination is the only effective means of preventing *E. histolytica* infection. Boiling is the only certain means of eradicating *E. histolytica* cysts in water [104].
- F. *Cryptosporidium parvum*** is a protozoan that has emerged as a major cause of chronic diarrhea in patients with AIDS and a common cause of waterborne outbreaks of diarrhea in immunocompetent persons. Transmission occurs by ingestion of oocysts that are excreted in the feces of infected humans or animals. Ingestion of as few as 30 oocysts is known to cause infection. Because infection is ubiquitous in mammals, and the oocysts are chlorine resistant, small, and difficult to filter, contamination of water sources for drinking or recreation may readily occur, resulting in large outbreaks of illness [97,105,106].
1. **In patients with AIDS, *Cryptosporidium*, *Microsporidia*, *Isospora belli*, cytomegalovirus (CMV), and *Mycobacterium avium* complex infections** are causes of chronic, often intractable, diarrhea. These are discussed in Chapter 18.
 2. **Outbreaks of cryptosporidiosis are most often waterborne.** In recent outbreaks of gastroenteritis associated with drinking water in the United States, *Cryptosporidium* caused 20% of the epidemics in which an infectious agent was identified. *Cryptosporidium* was also implicated in 50% of gastroenteritis outbreaks associated with recreational swimming pools, wade pools, lakes, or fountains [107,108]. A huge waterborne outbreak of cryptosporidiosis in Milwaukee

in 1993 resulted from contamination of municipal water supplies, affecting an estimated 403,000 persons (attack rate of 52%). Watery diarrhea was the predominant symptom (93%), but abdominal pain, low-grade fever, and vomiting were not uncommon, and 75% of infected immunocompetent patients experienced weight loss averaging 10 pounds. The mean duration of illness was 12 days [105,109]. Food-borne outbreaks have been attributed to contaminated apple cider, chicken salad, and uncooked vegetables. Person-to-person transmission is evidenced in numerous outbreaks of cryptosporidiosis in day-care centers and institutions, and secondary cases within households [105] (see related discussion in Chapter 18).

a. Diagnosis. Many laboratories use an immunofluorescent assay or EIA to detect *Cryptosporidium* in stool. Microscopic examination is also performed.

b. Treatment. Illness in immunocompetent patients is self-limited, and treatment is symptomatic.

G. *Dientamoeba fragilis* is an intestinal protozoan parasite that infects the cecum and ascending colon. Only the trophozoite forms are found in stool samples, and the organism does not invade tissue. Symptoms have been reported more frequently in children than in adults, although the pathogenic role of *D. fragilis* has been controversial. Surveys indicate prevalence of infection ranging from 0.5% in the United States (highest on the West Coast) to 4% in Canada. Asymptomatic carriers exist. *D. fragilis* is transmitted by the fecal-oral route. It has been hypothesized that *D. fragilis* is transmitted by the pinworm, *Enterobius vermicularis*, because *D. fragilis* has been observed in *E. vermicularis* eggs [97].

1. Clinical manifestations

a. Acute dysentery with mild to moderate diarrhea, abdominal pain, anorexia, nausea, vomiting, occasional fever, and malaise can occur.

b. Chronic, vague, nonspecific, abdominal pain that is dull, crampy, colicky, and usually in the lower abdomen can occur. It may occur after meals and last for hours. Symptoms may persist for months to years.

2. Diagnosis

a. Stool specimens. The diagnosis relies on observation of the binucleate trophozoites in a stained sample of fresh or preserved stool. At least three stool samples should be examined before any barium studies are performed. An immunofluorescence assay is being developed.

b. Routine laboratory and radiographic studies are nonspecific. No serologic test is available for diagnosis. Peripheral eosinophilia has been observed in 50% of cases. Concomitant *E. vermicularis* infection should be ruled out [97].

3. Therapy is summarized in Table 13.7. Stool specimens should be examined 3 to 4 weeks after therapy to determine whether the parasite has been eliminated.

H. *Blastocystis hominis* may be found in up to 25% of stool specimens examined. Only occasional patients have mild diarrhea. It is unknown whether *B. hominis* is a true pathogen or a commensal organism, or both. Controlled studies of an association between *B. hominis* and diarrhea are lacking [97,110–112].

Rarely, *B. hominis* has been implicated as a pathogen in AIDS patients, or patients on corticosteroids. Symptoms are nonspecific, including diarrhea, flatulence, abdominal pain, and anorexia. A trial of therapy in this setting may be reasonable if no other pathogen has been demonstrated (see Table 13.7).

INTRAABDOMINAL INFECTION

I. Clinical findings. In patients who present with abdominal pain, fever, abdominal tenderness, and leukocytosis, the question of an intraabdominal infection is raised.

A. The history and physical examination provide important clues. The reader is referred to basic surgical texts for detailed information on this topic [113]. A few points:

1. Percussion tenderness on examination is a useful indicator of focal infection. Right upper quadrant percussion tenderness suggests biliary source. Right lower quadrant tenderness suggests appendicitis or, in women, a focal pelvic infection. Left lower quadrant tenderness suggests diverticulitis; and so on.

Diffuse abdominal percussion tenderness, often with rebound tenderness, reflects a diffuse peritoneal irritation. Corticosteroids and analgesia may mask these findings.

2. **A rectal and, in women, a pelvic examination** should routinely be performed, especially in patients with mid- to lower abdominal pain.
 3. **Fever** may be modified by analgesics, NSAIDs, corticosteroids, and old age.
 4. **Leukocytosis** and a left shift are commonly, but not always, present.
- B. Serial clinical evaluations and surgical evaluation are indicated.**
- C. Empiric antibiotic therapy** is started before a specific diagnosis has been established, to help contain the infection and prevent the clinical septic syndrome described in Chapter 2.

Knowledge of the normal flora of the colon helps determine empiric regimens for peritonitis (see section II). Knowledge of the flora in the obstructed biliary tract helps to determine antibiotic regimens for cholangitis (see section I.D.3.a. under Biliary Tract Infections).

D. Cultures

1. **Blood cultures.** Three sets drawn at 10- to 30-minute intervals often help.
2. **Peritoneal fluid cultures.** Adequate quantities of infected fluid or tissue should have aerobic and anaerobic cultures. Immediately after the abdominal cavity has been opened, a syringe is used to take up as much pus and fluid free of air as can be obtained. If air bubbles are present, they should be removed from the syringe by injection into a sponge saturated with alcohol. **Pus is the best transport medium to maintain viability of bacteria. Dry or wet swabs should be used only if pus or fluid is not available** from the peritoneal cavity. The syringe containing pus can be taken immediately to the laboratory for processing, or 3 to 4 mL can be injected into the proper anaerobic culture tube (e.g., Port-a-Cult) and sent to the laboratory.

E. Diagnostic studies are reviewed later. See section III.D.4 and section IV.C.2 under Peritonitis for the role of abdominal CT scanning.

II. Antibiotic therapy for intraabdominal infections has recently been reviewed [114–116].

A. Microbiology. The source of infecting microorganisms in most patients with intraabdominal infection is the microflora of the GI tract.

1. **Normal GI flora.** More than 400 different species of bacteria are found in a single fecal specimen. Under healthy conditions, the stomach and small bowel harbor a sparse microflora generally not exceeding 10^5 bacteria per milliliter of contents. The number of bacteria increases in the middle and lower ileum, and there is an even greater augmentation across the ileocecal valve. **The colon harbors approximately 10^{11} organisms per milliliter, a number that approaches the theoretic limit that can fit into a given mass** [114].
2. Damage to the intestinal wall, either spontaneous perforation, sharp injury, or surgery with a later anastomotic leak, leads to contamination of the abdominal cavity.
 - a. **Cultures typically reveal a mixture of organisms**—on average, two aerobes and three anaerobes. Common bacterial isolates are shown in Table 13.9. Animal model studies show that *E. coli* is responsible for the initial peritonitis and septicemia phase that causes high mortality initially if not treated appropriately. **Abscess is** caused primarily by the anaerobes, particularly *Bacteroides* species. They have both a virulence factor (a polysaccharide capsule) and resistance to peroxide that could explain the emergence of these organisms as important pathogens in abscess formation [117].
 - b. The site of perforation of the GI tract is significant because an injury to the large bowel carries a high risk of abscess but so does injury to other parts of the intestinal tract [114].

B. Antibiotic therapy [114–122]. This should be directed at both aerobic and anaerobic bacteria. Otherwise, clinical failure is common. Monotherapy [114,117,119,120] is effective.

1. **Piperacillin-tazobactam.** This treatment is effective because it is active against the majority of infecting organisms [120]. **Ticarcillin-clavulanate**

Table 13.9. Bacteriology of Intraabdominal Infections

	Frequency of Isolation (%)
Aerobes	
<i>Escherichia coli</i>	65
<i>Proteus</i> species	25
<i>Klebsiella</i> species	20
<i>Pseudomonas</i> species	15
Enterococci	15
<i>Streptococcus</i> species (other than group A or D)	10
Anaerobes	
<i>Bacteroides fragilis</i>	80
<i>Bacteroides</i> species (other)	30
<i>Clostridium</i> species	65
<i>Peptostreptococcus</i> species ^a	25
<i>Peptococcus</i> species ^a	15
<i>Fusobacterium</i> species	20

^aSometimes grouped as anaerobic gram-positive cocci.

Reprinted from Gorbach SL. Treatment of intra-abdominal infections. *J Antimicrob Chemother* 1993; 31 (suppl A): 67; with permission.

(Timentin) has been used in this setting also. See the discussion of this agent in Chapter 27E.

2. **Cefoxitin** alone has been most widely studied. It was compared with either an aminoglycoside-containing regimen or a single broad-spectrum antibiotic regimen in 13 studies, which showed that cefoxitin alone is as effective as the comparative regimen [114,117]. Fewer studies have been conducted with **cefotetan**, which presumably is a reasonable alternative to cefoxitin. See Chapter 27 for a discussion of these two agents.
3. **Cefotaxime** has been shown to be superior to cefoxitin in one large series [119].
4. **Imipenem** in eight studies has been shown to be as good or even better than regimens containing an aminoglycoside [177,122]. However, it is not superior to piperacillin/tazobactam [120] nor to ciprofloxacin plus metronidazole [121]. The newer agent, ertapenem, is more appropriate for community acquired infection because its spectrum includes all of the enterobacteriaceae but not *Pseudomonas aeruginus* and other nosocomial organisms [123]. This saves imipenem for the hospital-acquired infections.
5. **Ampicillin-sulbactam** should not be used in this setting. A significant percentage of community-acquired *E. coli* are resistant to this agent; in the very ill patient, it may be more appropriate to use combination therapy (e.g., metronidazole and cefazolin). Ampicillin-sulbactam is reviewed in Chapter 27.
6. **Aminoglycosides**. Although historically ampicillin, clindamycin, or metronidazole, and an aminoglycoside were commonly used [124], **the current trend is away from this** [119–122]. See Chapter 27I for details about aminoglycosides.
 - a. **Limitations**. Ampicillin's only use is for enterococci that may be unimportant. Gentamicin is relatively inactive under conditions of reduced pH. Associated nephrotoxicity is an unacceptable risk, and the potential for inadequate serum levels because of the underdosing that is used to "protect" the kidney [114,117,124] yields inferior antibiotic activity. In addition, for community-acquired organisms, cephalosporins and broad-spectrum penicillin agents with β -lactamase inhibitors offer better options.
 - b. Gorbach in a review [117] concluded, "**There is now sufficient evidence to support the position that aminoglycosides are not needed and**

should not be used for the initial treatment of uncomplicated intra-abdominal infection.” Other reviewers have reached similar conclusions [124], and we concur with these recommendations.

- c. **Aminoglycosides are indicated in the therapy for intraabdominal infection when resistant gram-negative bacilli are suspected** [117]. In that situation, adequate serum levels must be achieved. These exceptions represent the minority of cases. They include (a) previous use of antibiotics, especially broad-spectrum antibiotics, in the past 30 days; (b) isolation of gram-negative bacilli resistant to β -lactam antibiotics and susceptible to aminoglycosides; (c) reoperation or recurrence of infection; and (d) prolonged hospitalization or nursing home stay preoperatively. The latter is especially important if these institutions have a background incidence of resistant gram-negative bacilli.
7. **Clindamycin and metronidazole** both have excellent anaerobic activity and have been used extensively in combination regimens for intraabdominal infection. In several comparative studies, both clindamycin and metronidazole performed equally well [117]. These agents are reviewed in detail in Chapter 27. Metronidazole may be a more cost-effective agent and possibly is associated with less *C. difficile* toxin diarrhea. Metronidazole is also more consistently active *in vitro* against *B. fragilis* than clindamycin (see Chapter 27Q). Metronidazole should be avoided in the first trimester of pregnancy and probably throughout pregnancy. In the past, these agents commonly have been combined with aminoglycosides. More recently, they have been combined with a first-generation cephalosporin (cefazolin) or a third-generation cephalosporin (e.g., ceftriaxone, ceftazidime, or cefotaxime) or aztreonam, but the aztreonam and metronidazole combination lacks activity against gram-positive organisms [115,125]. See Table 13.10.
8. **Coverage for enterococci.** There is debate about whether empiric regimens should cover enterococci. If enterococci are isolated from an intraabdominal source in a mixed culture, is specific therapy needed?
- a. Gorbach and others [114,116,118] have recently reviewed this question. Although enterococci are relatively common isolates (see Table 13.9), a review of multiple studies using combination therapy **without** specific activity against enterococci did not reveal clinical failure due to persistent enterococcal infection. Feliciano observed a low rate of complications caused by enterococcus when he used cephalosporins with no activity against enterococcus [119]. However, Barie argued to the contrary [126].
- Based on his review of accumulated studies, Gorbach [114,117] concluded, **“There appears to be no justification for the inclusion of specific**

Table 13.10. Empiric Antibiotics in Intraabdominal Infection, Including Peritonitis

Severity and Setting	Antibiotic Regimen (Assumes Normal Renal Function)
Community-acquired	
Mild-moderate	Cefazolin (1 g q8h) + metronidazole (500 mg q6h) ^a Cefoxitin (2 g q6h–q8h)
Severe	Piperacillin-tazobactam (3.75 g q6h) Ceftriaxone (2 g q24h) + metronidazole (500 mg q6h) Clindamycin (600 mg q8h) + gentamicin Imipenem (500 mg q6h or 1 g q8h)
Hospital-acquired	Piperacillin (3 g q4h or 4 g q6h) + metronidazole + an aminoglycoside Imipenem ± an aminoglycoside

q8h, every 8 hours; q6h, every 6 hours; q4h, every 4 hours.

^aCost-effective regimen.

anti-enterococcal therapy in the initial treatment of mixed infections. Furthermore, even the isolation of enterococcus in mixed cultures initially does not necessitate specific enterococcal antibiotic therapy.”

The triple antibiotic regimen of ampicillin, clindamycin, and gentamicin discussed above was used because of activity against enterococci as well as other bowel flora, but enterococcal therapy is not necessary. Inclusion of enterococci, in fact, leads to reduced activity against the more important gram-negative organisms for reasons discussed in section 6.a–c above. Gorbach stated that clinicians have “almost mythical adherence to the belief that this organism has some special pathogenic powers in intra-abdominal infections,” [117] and, therefore, it is hard not to want to “cover” for this pathogen.

- b. When should one cover enterococci [114,116,117]?** The following clinical situations serve as a guide:
 - (1) Patients with **persistent positive cultures** of these organisms in the absence of clinical improvement on nonenterococcal treatment regimens.
 - (2) Patients with multiple enterococcal positive blood cultures.
 - (3) Other reviewers suggest life-threatening intraabdominal sepsis with *Enterococcus* species isolated in pure culture or a predominance of gram-positive cocci in chains on the Gram stain of peritoneal fluid [115].
 - c.** The role that vancomycin-resistant enterococci (VRE) may play in nosocomially acquired intraabdominal sepsis is not well defined but is of potential concern in the patient at risk for VRE (see related discussions in Chapter 27P).
- 9. When should one cover for *Candida* species?** *Candida* is considered normal flora of the GI tract and consequently is commonly isolated. Its precise role in infection has been debated and recently reviewed [115,118].
- a.** When *Candida* is the sole isolate, or *Candida* is isolated from cultures of both peritoneal (or abscess) fluid and blood, or *Candida* invasion is identified on histologic examination of tissue, antifungal therapy is essential [115]. Other clinicians suggest that if *Candida* is isolated in high concentrations or increasing concentrations with sequential cultures, treatment is indicated, especially when host defenses are impaired [115,118]. Isolation of *Candida* from the peritoneum in acute pancreatitis also probably warrants specific therapy because these patients are more likely to have invasive disease than simple contamination [115].
 - b.** When *Candida* is one of the multiple organisms contaminating the peritoneum after surgical repair of a perforated viscus, antifungal therapy is not required.
 - c.** Therapeutic options include amphotericin B or fluconazole (see Chapter 17). Infectious disease consultation is advised.
- 10. Significance of *Pseudomonas aeruginosa* isolated from appendiceal specimens or specimens collected after penetrating trauma.** Rates of isolation vary from 5% to 20%. Clinical significance of the data is unclear, as is the need for antipseudomonal antibiotic therapy. Further data are needed [117].
- 11. Summary.** For empiric antibiotics for intraabdominal infection, many options are possible based on the principles and data presented here. **See the summary in Table 13.10.**
- a.** Monotherapy with cefoxitin or combination therapy with cefazolin plus metronidazole is rationale for mild to moderate community-acquired infection.
 - b.** For severe community-acquired infection, a broader combination such as piperacillin-tazobactam and metronidazole seems rational.
 - c.** For hospital-acquired infection or complex recurrent infections, aminoglycosides often are used in combination (see section II.B.6.C).

III. Peritonitis is a localized or general inflammation of the peritoneum. Microorganisms (e.g., bacteria, fungi) and irritating chemicals (bile salts, gastric contents, or talc) are the causes.

A. Classification. A classification system commonly used is shown in Table 13.11.

B. The **pathogenesis** of peritonitis is complex [127]. Some of the common ways it can occur are listed here.

- 1. Primary peritonitis** refers to inflammation of the peritoneum from a suspected extraperitoneal source, often via hematogenous spread.
 - a. Spontaneous peritonitis** usually occurs in patients with underlying ascites and is seen most frequently in patients with cirrhosis, nephrotic syndrome, and systemic lupus erythematosus (see section **F.1**).
 - b.** Peritonitis in patients with continuous ambulatory peritoneal dialysis (CAPD) is discussed in section **F.2**.
 - c.** Tuberculous peritonitis. See Chapter 11, section VI, under Tuberculosis: Basic Concepts.
- 2. Rupture of a viscus** can occur by innumerable means, including the following:
 - a. Traumatic injury** to the abdomen, including both sharp and blunt trauma
 - b. Ulcerated lesions** of the colon or upper tract, typhoid fever, necrotizing enterocolitis, or perforation of colonic diverticula
 - c. Ischemia**, vascular insufficiency, incarcerated hernias, volvulus, or neoplasia
 - d.** Ingestion of foreign bodies (e.g., toothpicks, bones, pins)
- 3. Pelvic inflammatory disease**, including salpingitis and endometritis, can produce localized lower abdominal peritonitis indistinguishable from appendicitis.

Table 13.11. Classification of Intraabdominal Infections

I. Primary peritonitis
A. Spontaneous peritonitis in children
B. Spontaneous peritonitis in adults
C. Peritonitis in patients with CAPD
D. Tuberculous, fungus and other granulomatous peritonitis
E. Other forms
II. Secondary peritonitis ^a
A. Acute perforation peritonitis (acute suppurative peritonitis)
1. Gastrointestinal tract perforation
2. Bowel wall necrosis (intestinal ischemia)
3. Pelvic peritonitis
4. Other forms
B. Postoperative peritonitis—surgical anastomotic breakdown
C. Posttraumatic peritonitis—blunt versus penetrating
III. Tertiary peritonitis—no clear pathogenic organism
IV. Other forms of peritonitis
A. Aseptic or sterile peritonitis
B. Granulomatous peritonitis
C. Metabolic such as drug or hyperlipemic-related peritonitis
D. Periodic peritonitis or porphyric peritonitis
V. Intraabdominal abscess
A. Associated with primary peritonitis
B. Associated with secondary peritonitis

CAPD, continuous ambulatory peritoneal dialysis.

^aSecondary peritonitis is often defined as the presence of purulent exudate in the abdominal cavity from an enteric source.

Adapted from Wittman DH, Walker AP, Condon RE. Peritonitis and intra-abdominal infection. In: Schwartz SI et al., eds.) *Principles of surgery*, 6th ed. New York: McGraw-Hill, 1994:1449; with permission.

4. **Surgical postoperative** leaks and anastomotic breakdowns can occur.
 5. **Tertiary peritonitis** [113] occurs after successful elimination of bacteria by antibiotics. Normally activated host defense systems continue to act through failure of autoregulation, resulting in an autoaggressive devastation of organ system functions. The clinical picture mimics occult sepsis. There is no effective therapy.
 6. **Noninfectious forms** of peritonitis are reviewed elsewhere [113].
 7. **Rupture of an abscess** can occur, such as of the pancreas or rarely a distended gallbladder.
- C. **Flora.** Bacterial peritonitis typically is caused by multiple organisms of the large bowel (see section II and Table 13.9).
- D. **Diagnosis**
1. **The patient's history**, remote and recent, is useful in delineating the present problem.
 - a. **A remote medical history** of diverticulitis, past surgery, and so forth should be noted.
 - b. **Travel** and family history with exposure to typhoid fever or tuberculosis should be noted.
 - c. **Accidents with blunt trauma**, such as a steering wheel-related injury should be noted.
 - d. **Recent surgical procedures** should be noted.
 - e. **History of appendectomy** will help eliminate the appendix as the cause.
 2. **Symptoms** can be grouped into two classes: **reflex** and **toxic. Corticosteroid use by a patient may mask typical signs and symptoms.**
 - a. **Reflex symptoms** include localized or generalized pain, nausea and vomiting (especially with an obstruction), and muscular rigidity. Rigidity commonly is seen in the early stages of an acute peritonitis.
 - b. **Toxic symptoms** from bacterial toxins, exudates, and intraperitoneal fluid include the following: distention, intestinal paresis, fever, and general toxemia.
 3. **For physical examination**, see section I.
 4. **Laboratory tests** that should be evaluated are as follows:
 - a. **Leukocyte count** usually is elevated but is nonspecific.
 - b. **Liver function tests should be performed and the serum amylase level determined.**
 - c. **Radiographic examination of the abdomen** may reveal air under the diaphragm (in the case of a ruptured viscus), paralytic ileus, intestinal obstruction, volvulus, or intussusception (barium enema). Findings suggestive of paralytic ileus are common [113]. A chest radiograph should be obtained to rule out any chest process that may be causing peritoneal signs and to demonstrate air.
 - d. **Scans.** Although it may only delay needed operative management [113], CT is indicated when there is suspicion of an intraabdominal abscess.
 - e. **Aspiration of peritoneal fluid** is a routine part of the workup of peritonitis in the setting of ascites or if trauma with hemorrhage into the peritoneal cavity is a concern. Fluid should be examined for leukocytes (with a differential count), bacterial and fungal organisms, amylase, gastric acid, and RBCs, as indicated by the particular case. Aerobic and anaerobic cultures of the fluid **should be obtained.**
 - f. **Laparoscopy** is used by some surgeons to avoid unnecessary open surgery. In some patients with superficial stab wounds, blunt trauma, or suspected pelvic inflammatory disease or appendicitis, it also may help localize an ectopic pregnancy or a ruptured spleen.
 5. The **differential diagnosis** of peritonitis is complex and reflects the many diagnoses raised in Table 13.11.
- E. **Treatment principles**
1. **Supportive care** is necessary in the patient with peritonitis. Use of nasogastric suction and i.v. fluid are routine.
 2. **Cause of the peritonitis.** Surgical consultation is imperative.

- a. Surgical repair of a ruptured viscus is essential.
 - b. Contaminating secretions, pus, or fecal material should be drained, and then the peritoneal cavity should be lavaged copiously.
3. **Systemic antibiotics (see section II)** to cover coliforms and anaerobes should be started preoperatively. Nonbacteremic patients receive 7 to 10 days of antibiotics, first intravenously and then orally. Shorter regimens may be effective in uncomplicated cases. In penetrating trauma-related peritonitis, 2 days of treatment may sometimes be adequate [117]. Another approach is to continue antibiotic therapy until fever is absent for 48 to 72 hours, all systemic signs of sepsis have resolved, and appetite and sense of well-being have returned [113]. Bacteremic patients receive a total of 14 days of i.v. and oral therapy to prevent complications at metastatic sites.

F. Special considerations

1. **Spontaneous bacterial peritonitis (SBP).** Spontaneous peritonitis is now more common in adults than in children and shows no predilection for one gender or the other. **Formerly, children (girls < 10 years of age) with nephrosis were the most commonly affected due to pneumococci or hemolytic streptococci. Now adults with cirrhosis or systemic lupus erythematosus are afflicted more commonly** [128].
- a. **Adults.** Spontaneous peritonitis usually is seen in patients with ascites, primarily with underlying cirrhosis [129]. Single organisms are the rule, with *E. coli* and *Klebsiella* species the major pathogens, accounting for 70% of infections. Gram-positive cocci may be seen in 10% to 20% and anaerobes in less than 5% [128,129]. (See section II.)
 - b. **Pathogenesis** [130]. The balance between host defenses and transmigration of enteric organisms, primarily gram-negative bacilli, determines whether SBP develops. There is a decreased ability to kill bacteria in low-protein, low complement ascites in these patients.
 - c. **Clinical features of SBP: a high index of suspicion is necessary.**
 - (1) Fever and abdominal pain are seen in 60% to 80% of patients.
 - (2) Onset or worsening of hepatic encephalopathy (60% of patients).
 - (3) Abdominal tenderness or rebound tenderness occurs in **only 50%**.
 - d. **Diagnosis.** A peritoneal tap is the most useful diagnostic test [128].
 - (1) **Peritoneal fluid cell count.** An absolute neutrophil count of greater than 250 cells/mm³ is a likely indication of peritoneal infection. However, patients with other inflammatory disease of the abdomen, such as tuberculous peritonitis, pancreatitis, secondary bacterial peritonitis due to perforation, and even cancer also will show elevated granulocyte counts.
 - (a) **SBP classically has been defined** by an ascitic neutrophil count of at least 250 cells/mm³, a positive ascitic fluid culture, and no obvious intraabdominal source of infection.
 - (b) **Culture-negative neutrocytic ascites (CNNA) is a variant of SBP.** An ascitic fluid neutrophil count of at least 500 cells/mm³, negative ascitic cultures with no prior antibiotics in the preceding month, absence of an intraabdominal source of infection, and no alternative explanation of the elevated neutrophils in the ascitic fluid defines CNNA. About one-third of patients with suspected SBP have CNNA. Response to antibiotics and mortality rates showed no statistically significant differences between SBP and CNNA. **Therefore, CNNA patients should be treated aggressively with i.v. antibiotics as would be done for SBP patients** [128].
 - (2) **Ascitic fluid pH** is low in spontaneous peritonitis, whereas in sterile ascitic fluid the pH is the same as for serum [113].
 - (3) **Gram stains of ascitic fluid** reveal organisms in only one-third of fluids that are subsequently culture positive [113,128]. If either gram-positive cocci or gram-negative rods are seen as single pathogen types, the diagnosis of spontaneous peritonitis is supported. If mixed gram-positive and gram-negative bacteria are seen, an intestinal perforation is more likely.

- (4) **Cultures of peritoneal fluid;** both aerobic and anaerobic cultures are essential. To maximize results, 10 mL of ascitic fluid should be routinely inoculated at the bedside in blood culture media.
 - (5) **Blood cultures** are positive in about one-third of patients with spontaneous peritonitis. **Urine cultures** are routinely suggested (see section b).
 - (6) **Protein content is not very useful** in diagnosing SBP because it is usually less than 2.5 g/dL. However, protein content may be a useful parameter in the differential diagnosis of pancreatic ascites and tuberculous peritonitis because these conditions generally are associated with ascitic protein levels of 3.0 g/dL or greater.
- e. Therapy** [128]. Once the diagnosis of SBP is made or highly suspected, i.v. antibiotics are indicated. See Chapter 27 for details.
- (1) **Cefotaxime** in adult patients with normal creatinine clearance (2 g every 8 hours) is suggested [128]. **Ceftriaxone** is also a useful agent (e.g., 1–2 g every 24 hours).
 - (2) **Cefoxitin or piperacillin/tazobactam** are other options. Ciprofloxacin has been effective [131].
 - (3) Monotherapy with aztreonam is **not recommended** because it does not cover gram-positive organisms, nor is ampicillin/sulbactam because 30% of *E. coli* are resistant. **Aminoglycosides** produce excess nephrotoxicity in liver disease.
 - (4) **A repeat paracentesis at 48 hours** to document decreased cell counts and negative cultures is often suggested [128,132].
 - (5) **Duration of antibiotic therapy.** Standard therapy has been 10 to 14 days, but a 5- to 7-day course of i.v. antibiotics appears to be effective. Some clinicians advocate determination of ascitic fluid polymorphonuclear count at 48 hours of treatment to determine duration of therapy [132].
- f. Prognosis.** A mortality rate of 30% to 40% has been observed in SBP. The probability of recurrence at 1 year is 70%, and recurrent episodes are associated with high mortality rates [128]. Many patients with SBP may be candidates for liver transplantation [129].
- g. Prevention of recurrent episodes of SBP** [128,129,133–135]. Norfloxacin (400 mg orally daily) and ciprofloxacin 750 mg weekly have reduced the 1-year recurrence rate. TMP-SMX also has been used in this setting [133]. There is no proven value for prophylaxis to prevent the initial case of SBP, although short-term prophylaxis has been useful in cirrhotic patients with an acute GI bleed [134].
- 2. For peritonitis in CAPD,** see reviews published elsewhere [113,136–138]. Several points deserve emphasis.
- a. Incidence.** An overall average is 1.3 episodes per patient per year.
 - b. Clinical presentation.** Abdominal pain, abdominal tenderness (often with rebound), and a cloudy appearance of the drainage dialysate fluid are common. Dialysate turbidity is often the earliest sign and sometimes the only sign. Fever is present in a few patients.
 - c. Bacteriology.** *Staphylococcus* organisms (coagulase-negative) and *S. aureus* (often methicillin resistant) predominate. *Streptococcus* species are isolated 10% to 15% of the time. Gram-negative bacteria or yeast occur in patients with recurrent episodes. A single organism usually is isolated. Gram stains of the effluent generally are negative, with 9% to 40% reported positive in several series. If multiple species or anaerobes are isolated, bowel perforation should be suspected.
 - d. Diagnosis.** Peritonitis can be assumed when the dialysate contains more than 100 leukocytes/mm³. This dialysate should be cultured and almost always is positive. Blood cultures usually are negative.
 - e. Therapy.** Intraperitoneal instillation of antibiotics helps facilitate outpatient therapy (Fig. 13.2) [138]. Some clinicians prefer the i.v. route. While awaiting cultures, a single i.v. dose of cefepime and vancomycin could be

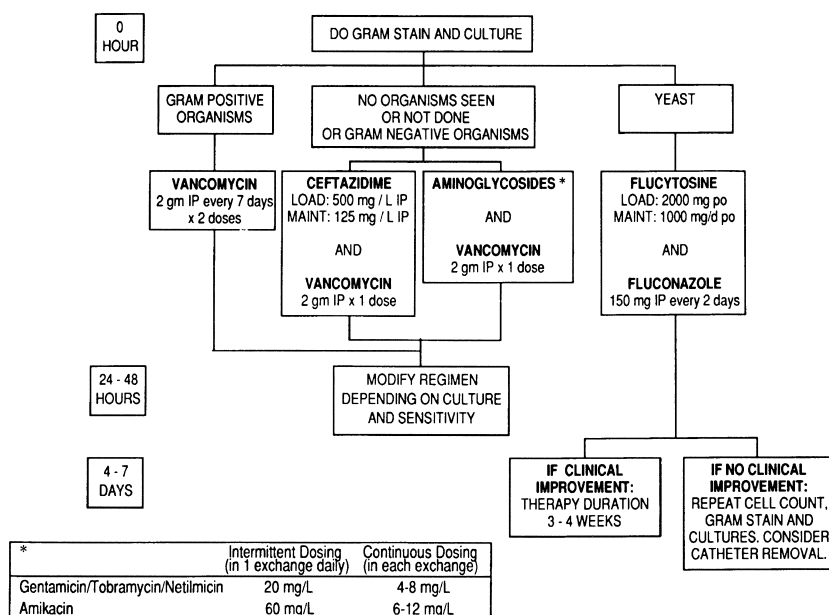

FIG. 13.2 Treatment of peritonitis, 1993 update. *IP*, intraperitoneal administration; *MAINT*, maintenance dose. (Reprinted from the Ad Hoc Advisory Committee on Peritonitis Management. Peritoneal dialysis-related peritonitis treatment recommendations. *Perit Dial Int* 1993;13:14; with permission.)

used. See Chapter 27A for antibiotics in renal failure. The catheter should be removed for severe skin catheter site infection, if peritonitis persists despite adequate therapy, or for fungal or *Pseudomonas aeruginosa* peritonitis [113,136–138].

- f. Sclerosing encapsulating peritonitis** occurs in 1% to 5% of patients with recurrent prior bouts of bacterial peritonitis, although the exact cause is unknown. Treatment is directed at such complications as bowel obstruction [113].

IV. General concepts of intraabdominal abscesses [139]. Onset may be insidious. The mortality rate associated with undrained hepatic, pancreatic, and retroperitoneal abscesses is 45% to 100%. The clinician should always search for intraabdominal abscess in febrile patients without any obvious cause of fever, especially in those who have a potential predisposing cause such as inflammatory bowel disease, diverticulitis, or a history of abdominal surgery or abdominal trauma.

A. Etiology and pathophysiology. The GI lesions or events that typically predispose to secondary peritonitis and intraabdominal abscess include Crohn disease, **perforation of a viscus, extension of preexisting infection** (e.g., secondary to pancreatitis), **surgical procedure or trauma** (e.g., anastomotic leak stab wound), or **intraabdominal ischemia**. Many abscesses are postoperative complications of biliary tract or GI surgery [139]. The use of laparoscopic procedures has led to a higher incidence of abscess after appendectomy [140] or due to spilled stones after laparoscopic cholecystectomy [141].

- 1.** Abscess formation creates an environment that readily supports the proliferation of anaerobic bacteria and produces conditions that impair the microbial activity of infiltrating neutrophils and of humoral factors, such as complement. Antibiotic transport to the suppurative focus is inhibited, and drugs within the abscess often are inactivated by a reduced local pH (e.g., aminoglycosides) [139].

2. **Abscesses can be found anywhere** within the abdomen, including the retroperitoneal space. Location may correlate with the original contamination, but may develop at distant sites such as subphrenic from a perforated appendicitis (Fig. 13.3).

B. Microbiology. Intraabdominal abscess reflects both quantitative and qualitative aspects of the microflora of the intestinal tract. This was discussed earlier in section II.A.

C. Diagnosis

1. Fever, chills, anorexia, weight loss, and, in some patients, abdominal pain are observed. An unexplained fever may be the only sign of an occult intra-abdominal abscess.
2. **An abdominal CT examination** is the most efficient means of diagnosing an abscess [113]. Because of the technical aspects and time delays, indium scans are used less frequently than CT scans. In an unusual setting (e.g., in the patient with an abnormal CT scan of the spleen in which multiple abscesses vs. multiple infarcts is the major differential diagnosis), a gallium or indium scan may be helpful [115,142].

D. Management.

1. **Drainage**, either percutaneously or operatively, is the primary mode of therapy. Patients with an undrained abscess do not do as well and may even die. The risk of complications due to delayed rupture of the abscess increases markedly. Abscesses cannot be eradicated by antibiotics alone (see section A.1) [113,115,118,143].
 - a. **Percutaneous aspiration, using CT and ultrasonographic guidance, is usually successful if the following criteria are met:** (a) There is a well-established, unilocular fluid collection; (b) a safe percutaneous route of access is available (e.g., abscess adjacent to the body wall); and (c) joint evaluation by a surgeon and a radiologist is performed so that there is immediate operative backup available in case of failure or complications [113]. The catheter is placed for drainage via gravity on low suction until the drainage volume is minimal (<10 mL/24 hours). Percutaneous **is preferred** to operative drainage of most intraabdominal abscesses [144]. Repeat scanning should show complete collapse of the abscess cavity [115].
 - b. **Pelvic abscesses** are drained through the rectum or vagina [113] (see Chapter 16).
 - c. **Open surgical drainage** is indicated when (a) percutaneous drainage cannot be accomplished safely; (b) percutaneous drainage fails; (c) infected pancreatic necrosis or carcinomatous abscess is present; (d) the abscess is associated with a bowel fistula; (e) multiple isolated, interloop abscesses are present [113]; or (f) there is a coagulopathy.
 - d. **Cultures** should be taken carefully at the time of drainage, with special attention to culturing anaerobically as well as aerobically.
2. **Empiric antibiotics** [113–122,124,125]. When an intraabdominal abscess is drained, empiric therapy should cover most of the common abdominal flora, until the culture results return. **Several regimens have been summarized previously** (see section II.B and Table 13.10). Most experts use antibiotics active against anaerobes as well as gram-negative aerobes. **The optimal duration of therapy for a drained abscess is not well defined.** Antibiotic administration should continue until all systemic signs of sepsis have resolved and the patient's appetite and sense of well-being have returned. It is not necessary to continue antibiotic therapy simply because drains remain in place. Oral therapy can be used to complete a course of therapy. Although some surgical reviews suggest that in uncomplicated cases, antibiotics can be stopped 48 to 72 hours after drainage has been established [113], a combination of i.v. and oral antibiotics for 7 to 10 days after drainage to ensure that contiguous soft-tissue cellulitis has been adequately treated is usually chosen. In bacteremic patients, a 14-day course is used to prevent complications at sites of metastatic spread.
3. **Nutritional support.** Often these patients are nutritionally depleted and may need parenteral or enteral nutrition. The enteral route is preferred, if possible.

FIG. 13.3 Areas of abscess formation within and adjacent to the peritoneal cavity are noted. They include the subphrenic space (1) and the subhepatic space (2); the lesser sac (3); interstices between loops of the small and large intestine (4); and the pelvic space (5). In the retroperitoneal space, abscesses may be perinephric (6); they also may be adjacent to or involve the pancreas, duodenum, or rectum. Because of intraabdominal circulation of infected material, abscesses may develop far from the original site of contamination. (Reprinted from Murray HW. Secondary peritonitis and intra-abdominal abscess. *Hosp Pract* 1990;25:109; with permission. Illustration by Laura Duprey.)

E. Special issues. Uncommon intraabdominal abscesses are discussed in section V.

F. Pancreatic abscess is discussed under section X.

V. Special types of intraabdominal abscess

A. Diverticulitis-related abscess.

B. Pancreatic abscess.

C. Hepatic abscesses [145–147] are usually due to pyogenic bacteria (discussed below) or to *E. histolytica* **and only rarely** to other organisms such as chlamydia.

1. Incidence. Pyogenic abscess is uncommon. Its incidence in hospital admissions ranges from 0.013% to 0.035% in reported series.

2. Pathogenesis. Liver abscess develops as a metastatic infection from an intraabdominal source to the liver, as a blood-borne infection, or from biliary tract ascending infection. Historically, the appendix and colon were the major sources of pyogenic abscesses, seeding the liver via the portal vein [145]. Recent reviews implicate the biliary tract in 20% to 35% of cases; appendicitis, diverticulitis, and so forth in approximately 25%; and idiopathic causes in 30% to 35%. Multiple liver abscesses are more likely to generate from the biliary duct system [148]. Other sources of hematogenous spread include urinary tract, pneumonia, or endocarditis in 3% to 25% of cases.

3. Clinical presentation. Symptoms are nonspecific or secondary to the original pyogenic source and include fever, chills, anorexia, nausea and vomiting, and weight loss. Signs may include an enlarged liver, right upper quadrant tenderness, jaundice, and right-sided pleural effusion.

4. Diagnosis

a. Leukocytosis, elevated alkaline phosphatase, and other liver function tests are nonspecific. **Results of liver function studies may be absolutely normal.**

b. Radiographic chest examination may show elevation or paralysis of the right hemidiaphragm or right pleural effusion.

c. CT usually is considered the procedure of choice, with a sensitivity of 100% in some series [145]. However, a CT scan may be falsely interpreted as malignancy. **Ultrasonography** has a sensitivity of 82% to 96% [145]. It may be the preferred initial test because it often identifies associated biliary tract abnormality.

d. Blood cultures are positive in up to 60% of patients but may not reflect all the bacterial pathogens involved when compared with liver abscess aspirates.

e. Aspiration of the abscess with good aerobic and anaerobic cultures provides both diagnostic and therapeutic roles.

f. Amebic abscesses are seen more frequently in men born abroad and in international travelers. These patients tend to have more focal right upper quadrant abdominal pain and less leukocytosis and left shift [146,149]. A serologic workup is diagnostically helpful (e.g., amebic hemagglutination test). (See section IV.E under Gastrointestinal Parasites.)

5. Microbiology. Either CT-guided or ultrasonographically guided aspiration will provide material for aerobic and anaerobic culture. Bacteria include aerobes and anaerobes in mixed or pure cultures [145,147]. *E. coli*, *Klebsiella*, and *Enterobacter* are the most common aerobic gram-negative rods. *Proteus* species, and *P. aeruginosa* are less common. *Klebsiella* is particularly common in Taiwan and Singapore [150]. Streptococci include enterococci, viridans streptococci, and microaerophilic species. *Streptococcus milleri* is an important pathogen [151]. *S. aureus* also can be isolated, usually in bacteremic patients. Anaerobic organisms, especially *Fusobacterium* and *Bacteroides* species are found in as many as 45% [145,152].

6. Treatment. Drainage of the abscess is critical. Antibiotics are adjunctive [153,154].

a. Drainage of abscess. The **optimal approach by which to drain the abscess is debated.** In recent years, ultrasonographically guided or CT-guided percutaneous catheter drainage has been favored. Surgical drainage

may be needed in selected patients and in patients who fail attempts at percutaneous drainage [145,148,153,154].

The mortality rate associated with multiple small abscesses is higher than with a solitary large abscess. Attempts should be made to drain all abscesses, including the small satellite abscesses through the larger ones, if feasible.

- b. Antibiotics** [113–125]. Empiric therapy uses regimens aimed at mixed aerobic- anaerobic GI-biliary flora. See options in Table 13.10 and section II.B.1–11.

For protracted therapy, antibiotic regimens should be individually fashioned according to the results of the cultures and sensitivities. Many clinicians recommend prolonged therapy (1–2 months) for a drained solitary abscess and no less than 4 months' therapy for multiple liver abscesses, to prevent relapses [145]. Many of these patients may be candidates for home i.v. antibiotic regimens if a good oral agent is not available.

- 7. Prognosis.** Mortality rates for hepatic abscesses have been reported to be in the 10% to 20% range, depending on underlying conditions.
- D. Splenic abscesses are rare** [155–159]. The incidence in autopsy series ranged from 0.2% to 0.7%, being higher in immunocompromised patients and those with AIDS [156].
 - 1. Pathogenesis.** The causes can be divided into (a) metastatic infections associated with bacteremia, (b) contiguous infection, (c) embolic noninfectious events causing ischemia and subsequent super infection (e.g. sickle cell anemia), (d) trauma with subsequent infection of a hematoma, and (e) immunodeficiency.
 - 2. Clinical presentation** often is **subtle**, regardless of the cause. **Fever** (93% of cases), **vague abdominal pain** (58%), and pain, often pleuritic in nature in the left hypochondria (40%), occur. Splenomegaly is seen in slightly more than half of patients. **Unexplained thrombocytosis in a septic intensive care unit patient with persistent left pleural effusion is suggestive** of splenic abscess.
 - 3. Diagnosis**
 - a. Leukocytosis** usually is seen but is nonspecific.
 - b. The chest radiograph** is surprisingly sensitive, showing abnormalities in 82%. Findings include left pleural effusion, elevation of the left hemidiaphragm, left lower lobe infiltrate, and mass effect in the left upper quadrant.
 - c. Blood cultures.** Approximately 50% of blood cultures are positive.
 - d. CT scanning** has a sensitivity of 96%, which proved significantly superior to ultrasonography (76% sensitivity) and gallium scanning (71%).
 - e.** The entity of hepatosplenic candidiasis is reviewed in Chapters 17 and 20.
 - 4. Microbiology** [156,158]. Approximately 30% of cases are due to gram-positive aerobes (staphylococci, streptococci); up to 25% to fungi (usually *Candida*), varying according to the number of immunocompromised patients in the series; 20% to 30% to gram-negative bacteria, including *Salmonella*; 20% to anaerobes; and up to 10% of specimens may be sterile.
 - 5. Treatment**
 - a. Splenectomy is the treatment of choice** [156–158]. Radiologically guided percutaneous drainage has been used, but treatment failure occurred in 30% in one series [156], though it was more successful in other small series [160].
 - b. Antibiotic therapy** is directed against the isolated organisms. Duration of therapy should be sufficient to treat the original source of the bacteremia. The treatment of fungal abscesses (e.g., **hepatosplenic candidiasis**) involves long-term systemic antifungal therapy (see Chapters 17 and 20). *Mycobacterium avium-intracellulare* treatment in AIDS patients is discussed in Chapter 18.
 - 6. Potential complications.** The most frequent complication of splenic abscess is rupture into the peritoneal cavity that causes an acute peritonitis [156,158].
- E. Retroperitoneal abscesses** are uncommon [161,162]. Because of their insidious presentation and delays in diagnosis, the mortality rate in modern series ranges from 25% to 45%.

1. **Etiology and pathogenesis.** The kidneys, ureters, pancreas, abdominal aorta, and inferior vena cava are in the retroperitoneum. The ascending colon courses through the retroperitoneum, and the duodenum and descending colon are contiguous with it. The bladder, uterus, and rectum are located in the pelvic extraperitoneal space. The most common causes of isolated retroperitoneal space abscess are renal infections and postoperative infections. Other causes include osteomyelitis of the spine with rupture into the retroperitoneal space, seeding of posttraumatic pelvic hematoma, acute cholecystitis, perforated appendicitis, diverticulitis, perforated colon carcinoma, ischiorectal abscess with penetration to the pelvic retroperitoneum, and a cryptogenic origin [162]. Tuberculosis is now uncommon.
 2. **Nonspecific presentation** with nonlocalized abdominal pain and variable GI symptoms occurs in the majority of cases. Chills occur in approximately 20%; fever is documented in nearly 80%. Abdominal tenderness is noted in the majority of cases.
 3. **Diagnosis** [162]
 - a. **Routine laboratory tests are not specific.** Even with a renal origin, results of urinalysis are often normal.
 - b. **Blood cultures** are positive in approximately 25% of cases, *E. coli* and *Bacteroides* species being the most common isolates.
 - c. **CT scanning is the most useful test.** The role of magnetic resonance imaging (MRI) awaits further clinical experience.
 4. **Microbiology** reflects the primary process.
 5. **Treatment** involves drainage and i.v. antibiotics [162,163].
 - a. The retroperitoneal approach (flank incision) and the pelvic approach (pre-sacral) are more effective surgical approaches than the transperitoneal approach.
 - b. **Percutaneous drainage may be the preferred** approach for drainage.
 - c. **Antibiotic coverage** is based on blood and drainage cultures, as well as on clinical setting. Aerobic and anaerobic cultures should be performed on any percutaneous or surgical specimens. Infectious disease consultation is advised.
- F. Psoas abscesses** are uncommon [164–166]. These were formerly synonymous with tuberculous disease of the spine or sacroiliac joint. Now most cases are a complication of intestinal disorders. **The psoas muscle is subject to any infectious process** of the ureters, renal pelvis, spine, appendix, and ascending colon.
1. **Etiology** [164,165]. In the United States, **adults** with psoas abscess have an underlying intestinal disease, **especially Crohn disease**, but also diverticulitis, osteomyelitis, or intraabdominal abscess. In fewer than 10%, there is a primary staphylococcal psoas abscess. **In children**, staphylococcal psoas abscess is more likely (up to 75% of cases). Children are more likely to have a history of preceding trauma or cutaneous staphylococcal abscess, which may seed the psoas.
 2. **Pathogenesis.** Organisms may enter the retrofascial space **directly by extension** from adjacent infection (e.g., in Crohn disease). In primary psoas abscess, hematogenous spread of staphylococci is most likely, with trauma playing a role in some cases [165].
 3. **Clinical presentation** [164–166]
 - a. **In adults**, symptoms often are nonspecific, but pain in the iliac fossa, groin, or hip, and tenderness of the iliac fossa are clues. Fever and leukocytosis may not be present. A positive psoas sign (pain on extension and elevation of the leg) is common, especially if there is underlying Crohn disease. The patient may complain of a limp. Frequently, the patient will lie with the hip flexed at all times. Weight loss is common. Psoas abscess rarely occurs in the elderly, and secondary abscesses usually are seen in 10- to 40-year-old patients.
 - b. **In children**, often there is hip or abdominal pain, more on the right than the left side. Many have fever and a limp or decreased use of the affected leg, and some have malaise, anorexia, or history of trauma. Usually there is

no discomfort on flexion or rotation of the hip. Children present similarly to adults.

4. Diagnosis. CT and ultrasonography are the most accurate tests for diagnosis, although neither reliably differentiates abscess in the muscle from hematoma or neoplasm. Clinical correlation and ultrasonographically guided or CT-guided **aspiration** of the mass with culture (aerobic and anaerobic) is useful diagnostically and therapeutically [88–90]. The role of MRI awaits definition by further clinical experience.

5. Treatment [164–166]

a. Open or percutaneous drainage is necessary. An open surgical procedure is required if the underlying pathogenesis is gastrointestinal (e.g., Crohn disease). A primary psoas abscess responds well to percutaneous drainage.

b. Antibiotics. For known or highly suspected primary abscesses, antibiotics aimed at *S. aureus* are used (see Chapter 27D and P). If it is unknown whether the abscess is primary or secondary or if a secondary abscess is present, broad-spectrum antibiotics for the underlying condition can be used until specific culture results are available. For example, if an underlying GI source is suspected or known, Table 13.10 suggests antibiotic options.

6. Prognosis. With appropriate therapy, the prognosis is generally good, especially with a primary psoas abscess. Secondary psoas abscesses have been associated with mortality rates as high as 18%, primarily because of delayed or inadequate therapy.

VI. Appendicitis and perforation. Appendicitis is best treated by surgical removal of the appendix before perforation occurs. Diagnosis is made primarily on clinical grounds. It is of interest that the incidence of acute appendicitis in the United States has decreased significantly in the past two to four decades. The reasons for this are unclear [167].

A. Pathogenesis. Obstruction predisposes the appendiceal wall to bacterial invasion by intraluminal bacteria. The common obstructions include fecaliths, enlarged lymphatic follicles, tumors, inspissated barium, and other foreign bodies such as worms. With distention, the mucosal lining is susceptible to impairment of its blood supply, and bacterial invasion of deeper tissues occurs. As this sequence worsens, tissue infarction can occur, with the potential for perforation at the antimesenteric border [167].

B. Microbiologic features. Cultures reveal polymicrobial involvement, with 5 to 10 different species typically isolated. *Bacteroides fragilis* and *E. coli* are almost universally isolated. *Pseudomonas* species may be seen in up to 40% of cultures [167] (see section II.B.10).

C. Clinical presentation is reviewed elsewhere [167]. **Acute appendicitis in the elderly is a much more serious disease than in younger adults:** 60% to 90% of elderly patients are found to have a ruptured appendix at operation. Fewer than 10% of patients undergoing surgery for acute appendicitis are over 60 years of age, but more than 50% of all deaths from appendicitis are in this age group. This is due to the delay in definitive treatment, greater frequency of progressive uncontrolled infection, and the high incidence of concomitant disease. The clinical presentation may be subtle, and fever or leukocytosis may be blunted in the elderly. Diagnostic accuracy for acute appendicitis is considerably lower in children than in adults. **Appendicitis in pregnancy** does not occur frequently, but diagnosis may be difficult because of displacement of the appendix [167]. **Appendicitis in AIDS patients** may not be associated with leukocytosis.

D. Ultrasonography has reduced the unnecessary appendectomy rate to 7% and the delay in operation beyond 6 hours to 2%. An inflamed appendix is visualized in 86% of cases. Enlarged mesenteric nodes and mural thickening of the ileum suggest bacterial enteritis due to *Y. enterocolitica* and *C. jejuni*. Laparoscopy is used to distinguish gynecologic disease and ileitis from appendicitis [167]. Laproscopic appendectomy is associated with a higher rate of abscess formation than open appendectomy [140].

E. Complications. The major complication is appendiceal rupture. This occurs in 20% to 30% of city hospital patients versus approximately 15% in private

hospitals. The incidence of rupture is higher in two population groups: geriatric and pediatric. Patients with appendiceal rupture tend to be quite ill, toxic, and dehydrated, with persisting local peritonitis. Usually there is obvious percussion and rebound tenderness of the right lower quadrant [167].

F. Therapy

1. Surgical intervention is routinely indicated for acute appendicitis and its complications. Schwartz cautions that to attempt to treat appendicitis with antibiotics alone is misguided because it ignores the obstructive cause of appendicitis. The timing of surgical intervention is discussed by Schwartz [167].

2. Antibiotics

a. For acute appendicitis without rupture, short courses of antibiotics to prevent wound infection (e.g., either a single dose of cefoxitin [2 g in adults] or up to three doses) are adequate in uncomplicated cases [113–125,167,168].

b. For appendiceal rupture with local peritonitis, see section **II** for antibiotic options. The optimal duration of therapy is unclear [117], but it seems prudent that the patient be treated until he or she is afebrile for 47 to 72 hours and is clinically improving. Oral antibiotics can be used to complete the course.

VII. Intraabdominal infections in the immunocompromised host (e.g., acute abdomen) have been reviewed elsewhere [115,169]. Certain issues deserve special emphasis.

A. Processes that can occur in any host (e.g., appendicitis) may occur. Peptic ulcer disease after renal transplantation is common if excess corticosteroids are used or H₂-blockers are not used. Acalculous cholecystitis (see section **IX.E** under Biliary Tract Infections) and acute cholecystitis with perforation appear with increased frequency in immunocompromised hosts [169]. Diverticulitis or CMV infection with colon perforation may be seen more frequently after renal transplantation. Appendicitis infrequently occurs in the immunocompromised host, except perhaps in children [169].

B. Special conditions in immunocompromised hosts

1. Neutropenic enterocolitis is a rare but well-recognized GI complication during therapy for acute and chronic leukemia, lymphoma, and solid tumors. It is the most **common cause of acute abdomen in patients with acute leukemia** [169]. The diagnosis is based on a high index of suspicion in patients with profound neutropenia, abdominal pain, and fever. Plain abdominal radiographs may show thickened air-filled loops of bowel, an obstructive pattern, or pneumatosis intestinalis (see section **8**). In most patients the condition does not progress to necrosis, perforation of the bowel, or peritonitis. Medical management consists of bowel rest, i.v. fluids, and broad-spectrum antibiotics. Indications for operation include persistent or worsening abdominal tenderness or a worsening clinical course.

2. Acute graft-versus-host disease [169] **may present as an acute abdomen** in bone marrow recipients. The syndrome of acute graft-versus-host disease usually starts 3 to 4 weeks (range 2–10 weeks) after marrow transplantation and consists of dermatitis (a red maculopapular rash on the trunk, palms, soles, and ears), crampy abdominal pain that may be aggravated by food, and profuse watery diarrhea. Abdominal features usually follow skin manifestations, but they can precede them. Patients may have abdominal distention and peritoneal signs on examination, probably due to transmural edema of the small intestine. Free perforation is rare. The treatment is increased doses of immunosuppressive agents.

3. Venooclusive disease. See Chapter 20.

4. Hepatitis with right upper quadrant abdominal pain can occur. Hepatitis C virus, CMV, and Epstein-Barr virus may be seen in these patients.

5. Cytomegalovirus GI disease can occur [170].

6. Hepatosplenic candidiasis is discussed in Chapters 17 and 20 and is associated with persisting fever, despite broad-spectrum antibiotics and resolution of leukopenia.

7. **Liver transplantation** recipients may experience surgical technical complications (see Chapter 20).
8. **Pneumatosis intestinalis** is an uncommon problem consisting of multiple gas-filled cysts in the wall of the small or large intestine. Radiologically, translucencies are found parallel to and just outside the gas-filled bowel lumen. Pneumoperitoneum can result if the cysts burst into the intestinal cavity. The patient is asymptomatic because no peritonitis results from the sterile gas. This condition is associated with a variety of conditions, including GI infections, lymphoma, leukemia, ischemic bowel disease, and intestinal obstruction. Surgical consultation is advised.
9. **Polymicrobial sepsis** in the immunocompromised host suggests possible intraabdominal pathology (e.g., abscess), and CT is recommended.
10. **Cholangitis** is caused by *Cryptosporidium*, by microsporidia such as *Enterocytozoon bienersi* or *Encephalitozoon intestinalis*, or by CMV [170–173].

VIII. Diverticulitis and related complications [173,174]

Diverticulosis is common. It afflicts approximately 30% of the population over 45 years of age and 60% of those over 70. It is estimated that approximately 10% to 20% of these people with diverticulosis will develop either hemorrhage or diverticulitis.

A. Pathogenesis [173,174]

1. **Diverticula form as outpouchings** of mucosa through weak portions of the colonic wall where branches of the marginal artery penetrate the colonic tunica muscularis.
2. **The pathogenesis** of diverticular disease **is unknown**. Aging, elevation of colonic intraluminal pressure, decreased dietary fiber, and increased dietary beef fat appear to be related. Decreased luminal fiber requires more colonic segmentation to propel the material aborally. Diverticula are seen in the right colon of Asians and the sigmoid and left colon of Occidentals.
3. **Forms of the disease**
 - a. **Simple diverticulosis** is generally asymptomatic. Although there may be shortening and narrowing of the bowel, there is no muscle thickening, and the diverticula frequently are reducible.
 - b. **Spastic colon diverticulosis** and **painful diverticular disease** are names given to symptomatic diverticulosis. Pathologic findings show a thickened sigmoid wall but no inflammation.
 - c. **Diverticulitis** results from a large or small perforation in the fundus that produces pericolic inflammation. Some perforated diverticula proceed to spontaneous healing, with fibrosis and granuloma formation next to a diverticulum.

B. Clinical presentation and evaluation [173,174]. See Table 13.12.

1. **Clinical presentation.** Diverticulitis presents like left-sided appendicitis. Inflamed diverticula of the transverse colon may simulate ulcer pain, whereas diverticulitis of the cecum and redundant sigmoid may mimic appendicitis.
 - a. The severity and persistence of pain, fever, leukocytosis, and elevated erythrocyte sedimentation rate (ESR), help to distinguish diverticulitis from benign conditions. It may be difficult to distinguish mild diverticulitis from irritable bowel syndrome with coincidental diverticula. However, the WBC count and ESR may be within normal limits.
 - b. True diverticulitis in patients under 40 years of age occurs and may be severe.
 - c. Abdominal findings may be minimal in the elderly and in those on corticosteroids.
 - d. Diverticulosis can present with GI hemorrhage, but **bleeding usually is not seen in diverticulitis** [173].
 - e. **Signs** of diverticulitis include left lower quadrant tenderness, tenderness on rectal examination in the left cul-de-sac, and occasionally a tender mass if an abscess or phlegmon has formed.
2. **Diagnosis.** In the face of known diverticulosis, fever, left lower quadrant abdominal pain and tenderness, leukocytosis, and an elevated sedimentation rate, a clinical diagnosis can often be made (see section **IA**).

Table 13.12. A Practical Approach to the Evaluation and Diagnosis of Acute Diverticulitis

Clinical

Usually >60 years of age

Left lower quadrant localized tenderness and unremitting abdominal pain

Fever, leukocytosis

Differential diagnosis

Elderly

Ischemia, Penetrating ulcer

Carcinoma

Volvulus

Obstruction

Nephrolithiasis or urosepsis

Middle-aged and younger

Appendicitis

Salpingitis

Inflammatory bowel

Penetrating ulcer

Urosepsis

Qualifiers

Extremes of age (more virulent), oriental ancestry (right-sided symptoms),

Corticosteroids, immunosuppressives, and chronic renal failure (abdominal examination insensitive)

Evaluations

Plain radiographs: Good first step; may show ileus, obstruction, mass effect, perforation.

Contrast enema: In mild to moderate disease when the diagnosis uncertain. Use water-soluble contrast. Otherwise delay examination for 6–8 wk.

Endoscopy: Relative contraindication. Perform only if necessary to exclude ischemic bowel, carcinoma, or perforation.

CT scan: Very helpful in staging, evaluating for other diseases. Should be considered in all cases of diverticulitis with a palpable mass or clinical toxicity, failure of medical therapy, and corticosteroid use. The test of choice to evaluate acute diverticulitis in most centers.

Ultrasonography: Can be a safe and helpful noninvasive test to evaluate acute diverticulitis. Examinations suboptimal due to intestinal gas in 15%, very examiner dependent.

Reprinted from Freeman SR McNally PR. Diverticulitis. *Med Clin North Am* 1993;77:1149–1167; with permission.

- a. **Plain films of the abdomen** are useful to exclude extracolonic air in an abscess or evidence of colonic obstruction.
- b. **CT scanning** has become the **test of choice, especially if the clinical diagnosis is not clear or a complication is suspected** [173] or if there is poor response to medical care [98]. **Any patient with a palpable abdominal mass should have a CT scan.** CT diagnostic criteria include localized colonic wall thickening (>5 mm) and inflammation of pericolic fat (poorly marginated, stranding, increased attenuation) or localized wall thickening and presence of periodic abscess [173]. CT scanning has the additional advantage of delineating extraluminal complications of diverticulitis and suggesting other diseases: tuboovarian abscess, colonic ischemia, mesenteric thrombosis, and pancreatitis, which at times may present like diverticulitis.
- c. **Contrast enema.** The **safety and utility** of a contrast enema to evaluate acute diverticulitis is **controversial**. Water-soluble contrast, but not barium, may be safe and useful in patients with mild to moderate diverticulitis [173]. No preparation of the bowel should precede a water-soluble contrast enema. Communication with the radiologist to limit the study to the segment

of colon in question with careful attention to the amount of pressure being applied is essential [174].

- d. **Endoscopy.** Most authorities consider uncomplicated diverticulitis a contraindication because of the risk of diverticular perforation with insufflations of the bowel during the procedure [173].
 - e. **Ultrasonography.** False-negative results were noted in 15% of the 54 patients examined. The effectiveness of this examination is very examiner dependent [173].
 - f. **Blood cultures** should be obtained in hospitalized patients to detect bacteremia.
3. **Complications** [173]
- a. **Fistulas.** With repeated attacks of diverticulitis, a fistulous tract can form among the bowel, bladder, integument, pelvic floor, and vagina.
 - b. **Obstruction** occurs usually after repeated episodes of subclinical diverticulitis. The colon becomes fixed, fibrotic, and stenosed. It is important to rule out other causes of colonic stricture such as carcinoma, Crohn disease, and ischemia.
 - c. **Perforation** of a diverticulum may cause peritonitis, although free peritoneal air on plain films is uncommon because the perforations are walled off.
 - d. **Abscess.** Failure of response to medical therapy within 24 to 48 hours or the palpation of an abdominal mass should prompt CT scanning.
 - e. **Frank rectal bleeding is not seen with diverticulitis.** If it is observed, other causes should be investigated.
- C. **Microbiologic evaluation** of diverticulitis and related abscesses is reflective of colon flora (see section II.A under Intraabdominal Infection).
- D. **Therapy** depends on severity and duration of illness, as well as on comorbid disease [96,98].
1. **Asymptomatic diverticulosis.** A high-fiber diet and bulk laxatives such as Metamucil are recommended. This type of diet reduces intraluminal pressure and usually produces a satisfactory subjective response. Foods with high-fiber content include fruits, vegetables, lettuce, and unrefined wheat. Unprocessed, or miller's, bran can be added to water, cereal, or milk. Harsh laxatives and high enemas should be avoided.
 2. **Mild acute diverticulitis can often be handled on an outpatient basis.** Typically, these involve patients with recurrent mild symptoms [173].
 - a. **Clear liquid diets** are suggested until symptoms improve.
 - b. **Oral antibiotics** are based on GI flora. TMP-SMX and metronidazole or ciprofloxacin and metronidazole (or clindamycin) are an alternative combination. A 1-week course often is effective (see Table 13.9).
 3. **Moderately to severely ill patients should be hospitalized.**
 - a. **GI rest.** Nothing should be taken by mouth for 48 to 72 hours or until symptoms improve, then liquid and semisolid foods may be taken as tolerated. Nasogastric suctioning is used if the patient is vomiting or has abdominal distention or obstruction.
 - b. **Intravenous fluids.**
 - c. **Antibiotics** aimed at mixed aerobic-anaerobic abdominal flora should be given (see options in Table 13.10). In moderately severe diverticulitis, ceftioxin appears to be as effective as gentamicin plus clindamycin [175]. The optimal duration is unclear, but some clinicians suggest 1 week [174].
 - d. **Pain control.** Meperidine may be used for severe pain. Morphine should be avoided because it increases intracolonic pressure.
 - e. **Clinical course.** Most patients improve in 48 to 72 hours, with a decrease in abdominal pain, leukocytosis, and fever. Failure to improve or worsening is an indication for possible surgical intervention. If not done initially, CT is indicated to determine if an abscess that could be drained is present.
 - f. **Surgery** for the initial attack is required in 20% to 30% of cases. **Indications** are reviewed elsewhere [173,174] but **include** failure to improve or deterioration with medical therapy; complications such as sepsis, fistula, or

obstruction; and recurrent disease. Early surgery is recommended for those under 40 years of age, for the immunocompromised, and for those with presumed right-sided diverticulitis [173].

IX. Biliary tract infections

A. Introduction. The anatomy of the gallbladder and the extrahepatic biliary system and the microbiology of the obstructed biliary system are important to the understanding of biliary tract infections.

B. Anatomic considerations are reviewed in detail elsewhere [176], but a few important features are highlighted here (Fig. 13.4).

1. **The gallbladder** is richly innervated and lies on the undersurface of the liver adjacent to the duodenum, pylorus, hepatic flexure of the right colon, and kidney. Diseases of these adjacent organs may clinically mimic diseases of the gallbladder-biliary system.
2. **The cystic duct** connects the gallbladder to the common bile duct. Its configuration and length are variable, and anomalies in this structure are common.
3. **Bile ducts.** The extrahepatic biliary tree begins with the Y-shaped **right and left hepatic ducts**, which join at the hilum of the liver, forming the **common hepatic duct**.

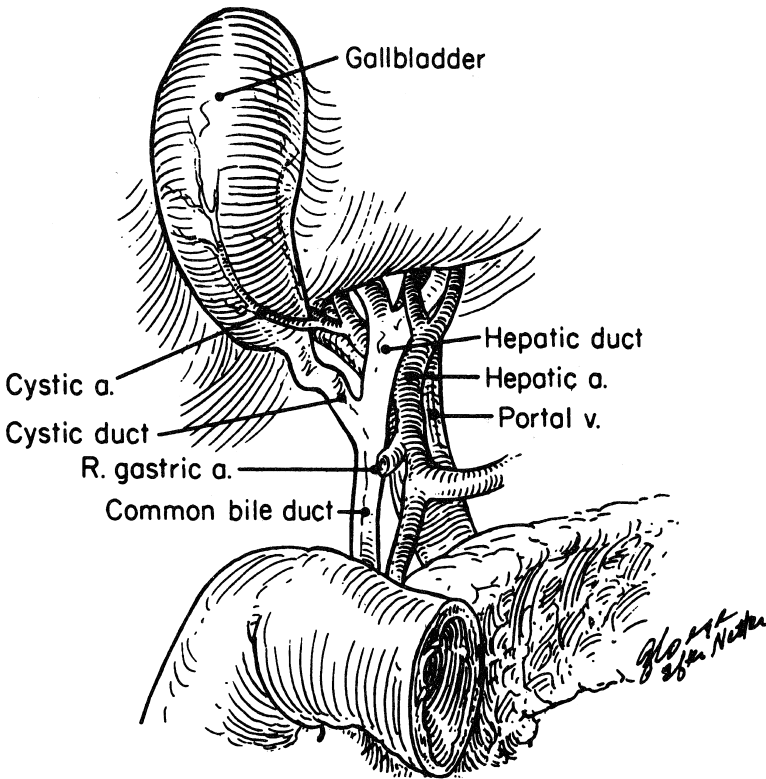

FIG. 13.4 Normal anatomy. The diagram depicts the relationships in the porta hepatis. The triangle of Calot is bordered by the edge of the liver, the cystic duct, and the hepatic duct. (Reprinted from Roslyn JJ, Zinner MJ. Gallbladder and extrahepatic biliary system. In: Schwartz SI, et al., eds. *Principles of surgery*, 6th ed. New York: McGraw-Hill, 1994:1368; with permission.)

The **common bile duct** is approximately 8 cm long and begins at the juncture of the cystic duct and the common hepatic duct and courses through the pancreas. It can be the site of involvement for benign and malignant disease. **It empties into the duodenum** at the papilla of Vater. Typically there is a common channel, created by the joining of the pancreatic and the distal common bile duct, which empties through a single orifice into the duodenum. This is important in the pathogenesis of gallstone pancreatitis.

4. Related terminology

- a. **Cholelithiasis:** the presence of gallstones in the gallbladder.
- b. **Choledocholithiasis:** the presence of stones in the common bile duct.

C. Diagnostic tests [176–179]

1. **Plain roentgenograms** of the abdomen are of limited value. Only 15% to 20% of gallstones comprise enough calcium to show up on routine films.
2. **Ultrasonography** has a diagnostic accuracy of 95%. The patient should be fasted for at least 6 hours prior to examination. Obesity interferes with adequate visualization. **Ultrasonography** is useful in identifying intrahepatic and extrahepatic ductal dilatation as well as masses that may cause biliary obstruction. **Sonographic signs** include gallstones (impacted in the neck or cystic duct), a thickened gallbladder wall, and intraluminal sludge. A positive Murphy sign, maximum tenderness over the ultrasonographically localized gallbladder, plus gallstones have a positive predictive value of more than 90%. The sensitivity of ultrasonography for acute cholecystitis is not as great as for stones. The presence of stones does not diagnose acute cholecystitis. Dimethyl iminodiacetic acid (HIDA) scans can be more helpful (see section 5).
3. **CT scanning** is only sensitive in identifying gallstones if thin cuts are used. However, it demonstrates biliary dilatation and masses in and around the biliary tract and pancreas. It is more useful than ultrasonography for evaluating the jaundiced patient.
4. **MRI's** role in the evaluation of hepatobiliary disease is still being analyzed.
5. **Biliary scintigraphy.** The HIDA scan uses technetium 99 labeling to **assess cystic duct patency. It is sensitive in diagnosing acute cholecystitis.**
 - a. **The patient must fast for at least 4 hours because two-thirds of nonfasted normal individuals have a contracted gallbladder and decreased gallbladder flow of tracer.**
 - b. **Patterns.** In a **normal** pattern, the gallbladder, common bile duct, and duodenum are all visualized within 60 minutes. In a **nonvisualization** pattern, the gallbladder is not seen, even on delayed views or after morphine sulfate administration. This **strongly implies acute cholecystitis** because it indicates cystic duct obstruction. The gallbladder may not be visualized in 60% to 90% of alcoholics, or among those on parenteral nutrition or the severely ill. Active hepatitis or pancreatitis also may yield a false-positive scan [178]. In **delayed visualization**, the gallbladder is seen after 1 to 4 hours despite intestinal visualization at 1 hour. This **suggests chronic cholecystitis**, although such a test is fairly insensitive in this setting and is abnormal only 45% of the time. This pattern also can be seen in acute cholecystitis. In the **persistent hepatocyte phase**, nonvisualization of the gallbladder and common bile duct and absent or delayed bowel activity is seen most commonly with common duct obstruction [178].
 - c. **An HIDA scan** is a functional test, whereas ultrasonography is an anatomic test [176].
6. **Cholangiography** [178]. Endoscopic retrograde cholangiopancreatography (ERCP) and percutaneous transhepatic cholangiography have replaced i.v. cholangiograms.
 - a. **ERCP** uses a side-viewing endoscope, permitting the biliary tract and pancreatic duct to be cannulated and visualized. ERCP has been especially useful in obstructive jaundice, in both benign and malignant disease.
 - b. **Percutaneous transhepatic cholangiography** is useful in patients with more complex problems, including duct strictures or tumors.

D. Acute cholecystitis**1. Pathogenesis**

- a. Calculi** lead to inflammation in 85% to 95% of cases. Pathogenesis includes stone obstruction of the cystic duct. Pressure on the mucosa by a calculus presumably causes impairment of venous return, ischemic necrosis, ulceration, gangrene, or perforation.
- b. Bacteria** have been cultured from 50% to 70% of acute cholecystitis cases. The origin of inflammation in the 30% or so without bacteria is felt to be chemical or physical.

2. Clinical presentation. Acute onset of right upper quadrant pain, nausea, vomiting, and fever are the most frequently presenting symptoms. Right upper quadrant tenderness, fever, and leukocytosis are common. Elevated liver function tests are less common.

3. Microbiology [179–181]. Healthy biliary tracts usually are sterile. In acute cholecystitis, infection appears to be a secondary phenomenon. Most bile cultures usually reveal a mixture of organisms [179]. Frequency is higher in the elderly, with jaundice in acute cholecystitis (vs. chronic), and when the common duct is obstructed.

- a. Microbiology.** GI bacteria predominate (see Table 13.9). Polymicrobial infections are the rule [180,181]. Isolation of *Klebsiella* or *Enterobacter* species plus enterococci point to the gallbladder. Anaerobes are more frequent after common duct or complex prior biliary procedures (especially biliary-intestinal anastomosis) and in the elderly.

- b. The source of bacteria** is assumed to be ascending spread from the duodenum.

4. Antibiotic therapy.

- a. Empiric antibiotic regimens** are aimed primarily at gram-negative bacteria. Cefazolin, ceftriaxone, and piperacillin/tazobactam are all equally effective. The need for antienterococci therapy is unclear. Anaerobes, when isolated, are in a low inoculum compared with the high inoculum associated with colon perforation. Therefore, in mild to moderately ill patients, antibiotics with optimal bowel anaerobic activity are not required. In the elderly or critically ill patient and the patient with prior common bile duct or complex biliary procedures, a therapeutic regimen that includes anaerobic activity is reasonable (Table 13.13).

- b.** Antibiotic regimens can be tailored on the basis of susceptibility data.

5. Management [179–181]

- a. Initial therapy** consists of fluids, nothing by mouth, parenteral analgesics, and antibiotics. If the patient is vomiting or there is gastric distention or

Table 13.13. Empiric Antibiotic Therapy in Biliary Tract Infections (When Renal Function Is Normal)

Setting	Antibiotic Regimen
Mild-moderate	Cefazolin (1–2 g q8h) Cefoxitin (2 g q6h–q8h) Piperacillin-tazobactam (3.75 g q6h) Ceftriaxone 2g q24h
Severe ^a	Ceftriaxone + metronidazole ^b Piperacillin-tazobactam + gentamicin Imipenem (500 mg q6h or 1 g q8h)
Complex nosocomial	Piperacillin, an aminoglycoside, + metronidazole or clindamycin; imipenem + an aminoglycoside

q8h, every 8 hours; q6h, every 6 hours; q24h, every 24 hours.

^aFever >102.5 bilirubin >3.

^bNeeded for anaerobic organisms.

ileus, placement of a nasogastric tube is indicated. Most patients respond to this treatment in 24 to 48 hours.

b. Cholecystectomy remains the treatment of choice for acute cholecystitis. Timing and the potential role of laproscopic cholecystectomy are reviewed elsewhere [176,181].

E. Acalculous cholecystitis. Acute inflammation of the gallbladder can occur without stones (5%–15% of cholecystitis cases) [181–183]. It has been recognized with increased frequency in recent years. **Risks include debilitated hospitalized patients** who have had major surgical procedures, major trauma, burns, sepsis, multiple transfusions, hyperalimentation, inadequate nutrition or multiorgan failure, or associated disease such as diabetes or malignancy.

1. Etiology and pathogenesis. The cause *may* involve bile stasis, cholecystoparesis, or gallbladder ischemia [182]. Histologically, there is intense injury to the blood vessels of the gallbladder tunica muscularis and serosa, possibly due to activation of Hageman factor, which occurs after transfusions, in endotoxemia, and after trauma [182,183].

2. Symptoms and findings are similar to those of calculous cholecystitis.

3. Diagnosis. HIDA scanning, ultrasonography, and CT scanning are used. Because each test has certain limitations, multiple complementary techniques may be necessary [183].

Preoperative diagnosis is difficult, and therapeutic intervention often is delayed with subsequently high morbidity and mortality [181].

4. Therapy. Urgent temporizing percutaneous transhepatic cholecystostomy or, preferably, cholecystectomy is advised [176]. Broad-spectrum antibiotics are used.

5. Prognosis. High mortality results from underlying disease, multiorgan failure, and sepsis.

F. Ascending cholangitis is due to infection of the biliary duct system. It is a **potentially lethal disorder requiring prompt treatment** [181,184].

1. Etiology. Obstruction is an important feature [181,185].

a. Choledocholithiasis. Stones that have migrated from the gallbladder and infection associated with stones are the most common causes of acute cholangitis.

b. Obstruction also can be due to pancreatic cancer, cholangiocarcinoma, cancer of the papilla of Vater, portahepatic metastases, biliary stricture, pancreatitis, and *A. lumbricoides*.

2. Pathogenesis. Bacteria enter the bile duct from the intestine or the bloodstream and infect the bile under pressure. Bile in a normal-pressure bile duct is difficult to infect.

3. Clinical presentation. Abdominal pain, fever, and jaundice are common symptoms. Charcot's triad of fever, right upper quadrant pain, and jaundice occurs in only 50% to 60% of patients. Septic shock is common, especially if therapy is delayed [186].

4. Diagnosis

a. Leukocytosis and elevated liver function tests (obstructive pattern) are common.

b. Blood cultures should be drawn.

c. Radiologic diagnosis. See IC 1–6 above.

5. Therapy

a. Supportive care includes i.v. fluids.

b. Broad-spectrum antibiotics may be administered, with optimal regimens for very ill patients (see Chapter 2).

c. Surgical consultation for biliary decompression. Approximately 85% to 90% of patients respond to antibiotics and supportive care alone. Those who fail or who deteriorate on medical therapy or even those who respond may require urgent bile duct decompression. Options for decompression include the following [177,181]:

1. Percutaneous transhepatic biliary drainage (PTBD) is not definitive and is associated with significant complications, including bleeding, bile leak,

fistulous communications between the biliary tree and vascular tree, and sepsis.

2. **Endoscopic sphincterotomy** in conjunction with decompression or biliary drainage with a nasobiliary catheter or endoprosthesis may be used when endoscopic extraction of a stone has failed.
3. **Surgical decompression** with bile duct exploration, with or without cholecystectomy, T-tube drainage, or biliary-enteric anastomosis, also may be used.
4. **Summary.** PTBD or endoscopic sphincterotomy is believed to be the treatment of choice in the seriously ill and high-risk patient. Elective surgery can be performed once the patient has stabilized; endoscopy treatment may be definitive for patients with previous cholecystectomy and retained common bile duct stones [181].

G. Miscellaneous infections

1. **Gallstone pancreatitis.** See the discussion under section X.
 2. **Empysematous cholecystitis** affects primarily diabetic men [176,187]. Gas within the wall or lumen of the gallbladder is characteristic. Pathogenesis is felt to be due to obstruction of the cystic duct with subsequent development of acute ischemia and proliferation of gas-forming bacteria. Patients are acutely ill and septic appearing. Plain abdominal radiographs show gas bubbles in the right upper quadrant or outlining the biliary tract. CT scans may be the most accurate study. Early surgery is indicated to control sepsis and avoid gallbladder perforation.
 3. **Perforation of the gallbladder** [176] occurs in 3% to 10% of cases of acute cholecystitis. Local ischemia, advanced age, and immunosuppression may be contributing factors.
 - a. **Free perforation** (rare), an acute abdomen, and septic presentation can occur.
 - b. **With pericholecystic abscess** formation, subacute presentation is common.
 - c. **Secondary fistula.** Communication between the gallbladder fundus and duodenum can occur, especially in chronic cholecystitis. This may be asymptomatic unless a gallstone enters the GI tract via the fistula and causes obstruction (**gallstone ileus**), usually in the terminal ileum. The combination of small bowel obstruction and air in the biliary tract is characteristic. Treatment consists of enterotomy proximal to the obstruction, removal of the impacted stone, and cholecystectomy [176].
 4. **Acute cholecystitis as a postoperative complication.** Many different antecedent operations are associated and need not be bowel procedures. Bile stasis and inspissation of the bile in the gallbladder leads to gallstones followed by obstruction. Disease occurs with the resumption of oral feedings, suggesting that contractions of the gallbladder in response to food may be a contributing factor. See section IX.E.
 5. **Post-ERCP cholangitis** sometimes occurs [188]. Presumably the procedure may introduce bacteria along with contrast media. The risk for sepsis is higher for patients with malignant causes of biliary obstruction. Antibiotics should include therapy for *P. aeruginosa* and other nosocomial pathogens while awaiting culture data.
 6. **Ceftriaxone** can cause gallbladder crystals and symptoms mimicking cholecystitis. Symptoms resolve after ceftriaxone therapy is discontinued. See Chapter 27F.
- X. Acute necrotizing pancreatitis, pancreatic abscess, and infected pancreatic pseudocyst.** **Acute pancreatitis** is usually a sterile inflammatory process caused by autodigestion of the pancreas. This section emphasizes infectious complications of acute pancreatitis [189–192].
- A. **Etiology** [189–192]. In up to 10% of cases, the cause may not be recognized.
 1. **Alcohol.** Seven to ten years of drinking usually occurs before pancreatitis develops.
 2. **Gallstones** or biliary sludge are etiologic more frequently in private hospitals, whereas alcohol is more common in Veterans' Administration hospitals.

3. Miscellaneous causes

- a. **Hypertriglyceridemia.** Pancreatitis is associated with triglyceride levels usually in excess of 1,000 mg/dL. Appropriate therapy can prevent recurrences.
 - b. **Abdominal trauma** (e.g., automobile accident) can result in pancreatitis.
 - c. **Postoperative pancreatitis** occurs after upper abdominal, renal, or cardiovascular surgery. Perioperative medications, not pancreatic trauma, are strongly implicated.
 - d. **Hypercalcemia** has been associated with pancreatitis.
 - e. **Pregnancy.** In the third trimester and in the first 6 weeks postpartum, pancreatitis can occur and probably is related to alcohol abuse or gallstone disease.
 - f. **Anatomic causes.** Tumors of the ampulla or pancreas, pancreatic or ampullary strictures, and periampullary diverticula can precipitate pancreatitis. Pancreatitis is the initial clinical presentation of 3% of patients with pancreatic cancer and 1.3% of patients with acute pancreatitis are found to have pancreatic carcinoma. Therefore, for patients over 45 years of age with idiopathic pancreatitis, duct visualization is mandatory.
 - g. **Infections.** Viruses (including mumps, rubella, coxsackie B virus, Epstein-Barr virus, CMV, and acute hepatitis A, B, and C), parasites (e.g., *Ascaris*), and *Mycoplasma pneumoniae* have been associated with pancreatitis. Acute pancreatitis for patients with AIDS is most often secondary to drug use [189] (see section 9).
 - h. **Complications of ERCP.**
 - i. **Drugs.** NSAIDs, erythromycin, thiazides, didanosine (ddI), pentamidine, estrogens, sulfonamides, and L-asparaginase are among the agents implicated [189].
 - j. **Systemic vasculitis** can be the cause of pancreatitis.
- B. Prognosis of acute pancreatitis.** Criteria have been developed (e.g., Ranson criteria, APACHE [Acute Physiology and Chronic Health Evaluation II] criteria) to help predict the survival of a given patient based on the severity of acute pancreatitis. They are reviewed elsewhere [189,190,192]. Patients with three or more Ranson signs either have severe pancreatitis or are at risk for severe disease. Related points deserve special emphasis.
1. **Approximately 80% of patients have mild disease;** most of these patients recover uneventfully. Pancreatic and peripancreatic necrosis are minimal [189].
 2. **Approximately 20% have severe pancreatitis with pancreatic or peripancreatic necrosis or pancreatic fluid collections** [192]. **Necrosis of either the duct system or the pancreatic parenchyma is the initiating event in most of the complications of acute pancreatitis and occurs in the absence of bacteria.** Necrosis occurs early in the clinical course, typically on the first day of symptoms.
 - a. About 10% of patients have fluid collections due to extravasation from the ductal system.
 - b. Another 10% of the total group has extensive necrosis (>10%–15% of the gland). Of these, nearly 50% (5% of the total group) will become infected. In the absence of necrosis, infection is rare, but the more extensive the necrosis, the higher is the risk for infection. Between 40% and 70% of patients with more than 30% necrosis will become infected. Infection increases until the third week and peaks in the fourth week. A high mortality rate (**80% of all deaths result from these difficult-to-treat infections**) occurs with early infection, with extensive necrosis, and in the very ill.
- C. Assessing infection**
1. Sterile pancreatitis or peripancreatic necrosis causes leukocytosis and fever. Clinically it is uncertain when or if there is superimposed infection. Also, 50% of patients with infection may not show clinical signs of an active infection [193].
 2. **CT scan with contrast** predicts who is at risk for infection. Poorly enhanced pancreatic tissue correlates well with the presence of pancreatic necrosis [193]. If gas bubbles are seen in the pancreatic region on the scan, infection is

Table 13.14. Frequency of Bacteria in Pancreatic Infection

<i>Escherichia coli</i>	25%
<i>Pseudomonas</i> species	15%
<i>Staphylococcus aureus</i>	17%
<i>Klebsiella</i> species	9%
<i>Proteus</i> species	9%
<i>Streptococcus faecalis</i>	3%
<i>Enterobacter</i> species	3%
Anaerobes	16%
<i>Candida</i> species	3%
Monomicrobial	76%
Polymicrobial	24%

presumed to be present. CT scan–guided aspirations of necrotic tissue for Gram stains and aerobic and anaerobic cultures will clarify whether infection actually exists. Commonly isolated organisms are shown in Table 13.14 [194]. Organisms resemble intestinal flora.

3. The mechanism by which colonic bacteria reach the injured pancreatic tissues is unclear. Infection of the injured pancreatic tissues appears to be a secondary phenomenon, thus raising the possibility that prophylactic antibiotics can prevent or limit infection [195].

D. Prophylactic antibiotics to prevent infectious complications. Recent studies suggest a benefit but the topic is complex [195–200].

1. **Mild pancreatitis.** Because most cases of pancreatitis are mild and there is no necrosis, antibiotics are not necessary in the majority of cases of pancreatitis.

2. **Moderate to severe pancreatitis includes those cases associated with necrosis.**

- a. **Timing of antibiotic initiation.** The approach that has been argued is to initiate antibiotics early, before infection develops [195]. Although this approach is logical, there are two factors that need to be weighed. First, the frequency of infection increases over the first 3 weeks and peaks at week 4 (see section X.B above). Second, almost a third of infecting organisms are not the typical bowel flora and those (including *Pseudomonas* species, *S. aureus*, and *Candida* species) are more difficult to treat. Perhaps they became a factor because typical gut flora was suppressed by early prophylaxis, allowing them to overgrow and invade. This issue is not resolved and needs further evaluation.

- b. **Antibiotic penetration into pancreatic tissue** [194].

- (1) **Piperacillin, cefotaxime, and ceftizoxime** penetrate pancreatic tissue and are active against the gram-negative bacteria that occur but less so against anaerobes.

- (2) **Imipenem** penetrates pancreatic tissue well and is active against common bacterial isolates.

- (3) The **fluoroquinolones** (e.g., ciprofloxacin) penetrate well and are active against the colonic gram-negative bacteria but not the anaerobic isolates.

- (4) **Aminoglycosides** do not penetrate pancreatic tissue well in usual dosage regimens and therefore are **not preferred agents**.

- (5) **Metronidazole** shows good penetration into pancreatic tissue. Because it is active against anaerobes, it is often combined with an antibiotic effective against the gram-negative bacteria.

- c. **Efficacy trials. Imipenem** recently was studied in a randomized multicenter clinical trial of antibiotic prophylaxis in 74 patients with a Ranson mean score of 3.7 [196] due to severe necrotizing pancreatitis. Disease originated in the biliary tract in 37, from alcoholism in 24, and from miscellaneous causes

in 13. Forty-one patients received medical therapy plus 500 mg of imipenem every 8 hours for 14 days, beginning at the time of CT demonstration of pancreatic necrosis. The other 33 patients received medical therapy alone. Pancreatic infection was proven by percutaneous aspiration or intraoperative cultures. The incidence of pancreatitis-related sepsis was much lower in treated patients (12.2 vs. 30.3%, $p < 0.01$) [196]. Neither the incidence of multiorgan failure that developed in 25 patients nor mortality nor the need for surgical intervention was affected by antibiotic therapy. That there is no effect on change of management has led some to conclude that prophylaxis is not beneficial [197]. Several other analyses found benefit [198–200].

- d. Commentary.** Because patients with severe necrotizing pancreatitis with infectious complications are prone to have protracted courses and often require repeated surgical intervention, they may acquire infections due to resistant bacteria [197]. Hence, one might want to save a broad-spectrum antibiotic such as imipenem for later use rather than early use in these high-risk patients. Studies comparing imipenem to other agents would be worthwhile. **A compromise approach** may be to use prophylactic antibiotics (e.g., a third-generation cephalosporin and metronidazole) in severe cases of necrotizing pancreatitis for 7 to 10 days and save imipenem for future infectious complications when resistant bacteria may be a problem.

E. Related issues

- 1. Surgical intervention.** The optimal approaches are still being evaluated [189,192,193], but when infection occurs, surgery is usually indicated. Typically, a surgical team directs the management of these patients. Aggressive surgical debridement (often requiring serial procedures) with open drainage in selected patients with extensive pancreatic and peripancreatic necrosis is advised. Enhanced CT scanning is very useful [192]. Percutaneous drainage of an area of infected necrosis, as a primary therapy, is believed by some to be an exercise in futility [192]. Further discussion of surgical indications is published elsewhere [193].
 - 2. Large fluid collections** can occur early in acute pancreatitis, within days or weeks of the onset of symptoms [192]. These fluid collections, unlike a pseudocyst, lack a wall of granulation or fibrous tissue. More than 50% of these collections disappear spontaneously. Therefore, aspirating before 4 to 6 weeks is unnecessary. Percutaneous CT-guided aspiration is a useful technique if infection is a concern.
 - 3. Fluid resuscitation** is important. Monitoring with a Swan-Ganz catheter often is essential in the care of the severely ill patient [192]. Acute renal failure is a common consequence of poor fluid resuscitation in pancreatitis. The hyperdynamic cardiovascular state is similar to that seen in patients with the septic syndrome (see Chapter 2). Patients with severe pancreatitis have diminished peripheral vascular resistance and decreased intravascular volume. Blood flow to the pancreas is reduced. It is believed that trypsin released into the surrounding tissues and the circulation triggers the complement cascade and kinin release. Furosemide should not be used because this leads to organ hypoperfusion followed by multiple organ failure [192].
 - 4. Biliary pancreatitis.** Patients with severe biliary pancreatitis and persistent signs and symptoms of obstruction or with cholangitis should undergo endoscopic or surgical relief of the biliary obstruction within the first 48 hours. Many clinicians prefer the endoscopic approach if skilled personnel are available [193]. Some clinicians feel that ERCP is indicated in all cases of biliary pancreatitis.
 - 5. Associated complications.** Fistulas from the bowel or pancreas, or bleeding from the retroperitoneal structures, are common. Multiorgan system failure, often as a consequence of underlying sepsis, is a common complication and is frequently associated with a fatal outcome. The overall mortality rate varies from 0% to 25%.
- F. Pancreatic abscess.** It may be difficult to distinguish between infected necrosis and early abscess formation. A true pancreatic abscess is a collection of pus

Table 13.15. Bacteriology of Pancreatic Abscesses

Organism	No. of Patients/Total	Percentage	Range (%)
<i>Escherichia coli</i>	164/494	33	11–49
<i>Enterobacter</i>	60/284	21	7–43
<i>Klebsiella</i>	26/189	14	7–42

and necrotic pancreatic tissue surrounded by an ill-defined wall (capsule), which occurs either within the pancreatic parenchyma or expands into the lesser sac and retroperitoneum. Although not common, pancreatic abscess is associated with a high mortality rate, between 2% and 5% [191,201–206].

- 1. Etiology.** The cause of pancreatitis that led to the abscess was alcohol in 32%, biliary tract in 25%, postoperative causes in 19%, and miscellaneous causes in 25% [203].
- 2. Pathogenesis.** As with infected pancreatitis, risk increases with the degree of necrosis.
- 3. Clinical presentation is nonspecific.** Following the episode of pancreatitis, there may be improvement and then deterioration. The presentation may be indolent, and some patients may not be febrile or have leukocytosis [204]. However, pancreatic abscess should be suspected in any patient with an acute or resolving pancreatitis whose course is complicated by persistent fever, abdominal pain, and leukocytosis, especially about 3 to 4 weeks after the onset of the initial attack [202].
- 4. Diagnosis**
 - a. CT scanning** is the best method to demonstrate the abscess [203,205]. CT may reveal a fluid collection that is indistinguishable from a pseudocyst. The presence of air within fluid collections or within the pancreas itself is strongly suggestive of a pancreatic abscess harboring gas-forming organisms. However, retroperitoneal air within peripancreatic fluid also may be seen in uninfected patients who develop a fistulous tract between the pancreas and an adjacent viscus. It is also seen in the postoperative patient, or in patients with a perforated duodenal ulcer [203].
 - b. CT-guided thin-needle aspiration** and culture of the fluid will clarify the diagnosis. Aerobic and anaerobic cultures should be performed routinely.
 - c. The role of MRI** is undergoing clinical evaluation. Only limited data are available with this technique [203].
 - d. Blood cultures** may occasionally be positive.
- 5. Microbiology** in pancreatic abscesses are only partially studied (Table 13.15). Many infections are polymicrobial, and the infrequency of anaerobic isolations may reflect poor culture technique [203].
- 6. Therapy**
 - a. Surgical drainage is essential** for a true pancreatic abscess [203–206].

In Altemeier's series in 1963 [206], 86% of those whose abscesses were drained surgically and treated with antibiotics survived. By contrast, if the diagnosis was missed and no surgical drainage was performed, 100% died. More recent data confirm a near 100% death rate without surgical drainage.

- (1) **Percutaneous catheter drainage** at times is regarded as a temporary maneuver until patients can tolerate definitive surgery. However, if the abscess fluid is thin in consistency and there is little particulate matter in it, percutaneous drainage may be adequate treatment.
- (2) **Open surgical drainage** is indicated if the fluid is thick, if rapid improvement does not occur after percutaneous drainage, or if there is CT evidence of considerable surrounding tissue necrosis in addition to the abscess [202].

b. Nutritional support with enteral or total parenteral nutrition is favored.

c. Antibiotics are useful to prevent bacteremia and aid in healing, and when used in conjunction with surgical drainage. The antibiotics should be selected on the basis of sensitivity testing against any organism isolated from blood or the abscess cavity at the time of surgery or on the basis of prior aspiration culture data. In the absence of culture data, therapy should be instituted as outlined in section **II.B**.

7. **Prognosis.** Despite aggressive surgical therapy coupled with antibiotics and nutritional support, the mortality rate in patients with pancreatic abscess is still 20% or more [201–203].

G. Pancreatic pseudocysts [203]. Despite considerable information generated by CT scanning and ultrasonography over the past 20 years, the natural history of pancreatic pseudocysts remains poorly understood, their classification system remains vague, and their nomenclature is controversial. Classically, the term *pancreatic pseudocyst* has been used to refer to all intrapancreatic and peripancreatic fluid collections, usually within a nonepithelialized capsule, arising in the setting of acute or chronic pancreatitis.

Fluid collection should be followed for change in size or the development of signs of infection. Such changes will determine appropriate therapy.

1. **Epidemiologic features.** Pseudocysts almost always arise in the setting of acute or chronic pancreatitis. In a summary of 11 series, the underlying condition was alcohol in 65%, biliary disease alone in 10%, both alcohol and biliary disease in 9%, postoperative trauma in 9%, and miscellaneous conditions in 14%.
2. **Pathogenesis.** The origin is not well understood. Presumably, pseudocysts develop as a result of the disruption of the ductal system, with subsequent leakage of activated pancreatic enzymes leading to necrosis of the gland and surrounding tissue. This is accompanied by the production of large volumes of exudate that dissect along retroperitoneal planes. Multiple pseudocysts occur in 10% of cases.
3. **Clinical presentation** [203]
 - a. Abdominal pain (60%–100%), nausea or vomiting (20%–70%), weight loss (30%–60%), palpable abdominal mass (20%–50%), jaundice (10%–20%), and abdominal tenderness (10%–60%) are seen. Probably 50% of cysts are nonpalpable, and up to 50% of palpable masses in patients with pancreatitis simply represent inflammation and edema rather than a pseudocyst.
 - b. **Routine laboratory tests** (WBC count, amylase levels, etc.) are nondiagnostic.
4. **Diagnosis.** **CT scanning** is the most accurate imaging technique, although the CT scan does not differentiate between a sterile and an infected fluid collection.
5. **Natural history of pancreatic cysts.** When serial ultrasonography or CT scanning is performed, **8% to 43% of the pseudocysts undergo spontaneous resolution**, usually within 6 weeks after onset. Therefore, it is suggested that drainage procedures be postponed until either the pseudocyst persists for more than 6 weeks or a complication arises. Some clinicians suggest prolonged observation unless the patient is symptomatic.

6. Complications of pancreatic pseudocysts [203]

- a. **Obstructive jaundice.** Pseudocysts at the head of the pancreas may obstruct the duodenum or compress the common bile duct.
- b. **Chemical pancreatitis** can occur if the pseudocyst ruptures acutely. This is associated with a high mortality rate.
- c. **Pancreatic ascites** can occur with a slow leak into the peritoneal cavity.
- d. **Hemorrhage** can occur, either within the cyst itself or as a result of the cyst eroding into a major artery or perforating into the GI tract.
- e. **Chronic pancreatic cysts** may be drained internally (e.g., cystogastrotomy, Roux-en-Y cystojejunostomy, anastomosis, or cystoduodenostomy).
- f. **Secondary cyst infection** can occur (see section C).

H. Infected pancreatic pseudocyst [203]

1. **Incidence.** The exact incidence is unclear; 0 to 25% of pseudocysts become infected. Further data gleaned from good aspiration culture studies are needed. Overall, this is believed to be an uncommon complication [203].
2. **Pathogenesis.** Secondary infection presumably results from (a) hematogenous seeding, (b) direct transmural passage of bacteria from adjacent bowel, and (c) possibly bacterial seeding after ERCP.
3. **Diagnosis.** Although persisting fevers, abdominal pain, and an abdominal mass in a patient with a known pseudocyst is suggestive, not all patients with infected pancreatic pseudocysts have these features. Laboratory tests are nondiagnostic.
 - a. **CT scanning** will demonstrate whether a pseudocyst exists.
 - b. **CT-guided or ultrasonographically guided percutaneous needle aspiration with aerobic and anaerobic cultures** will clarify whether the fluid is infected.
4. **Bacteriologic** data are limited [203]. Polymicrobial infection due to GI gram-negative and gram-positive organisms are typical.
5. **Therapy** [203]. When planning appropriate therapy for an infected pancreatic fluid collection, it is critically important to differentiate an infected pseudocyst from a pancreatic abscess. Whereas an infected pseudocyst can be treated successfully by drainage alone, this intervention would be completely inadequate for an abscess, for which open drainage and extensive debridement often are necessary.
 - a. **External drainage** is preferred if the cyst is infected. A large-bore catheter is placed into the infected cyst cavity, and the catheter then is brought out the abdominal wall. Percutaneous drainage has been used as an alternative.
 - b. **Internal drainage** may be a consideration in selected patients [207].

I. Pancreatic disease in AIDS (see Chapter 18).

1. **Drug-induced pancreatitis** can occur (see section **IA.3.i**).
2. **Neoplasms** of the pancreas, including Kaposi sarcoma and lymphoma, have been seen in up to 8% of patients in autopsy series.
3. **Infectious agents** have been demonstrated in autopsy series, and microorganisms involved include CMV, *Cryptosporidium*, cryptococci, *T. gondii*, *Candida* species, and *M. tuberculosis*. These are typically seen in the setting of disseminated infections.

14. HEPATITIS VIRUSES

James R. Burton, Jr. and Thomas A. Shaw-Stiffel

I. Introduction. Hepatitis denotes an inflammation of the liver. The causes of hepatitis are varied and include viruses, bacteria, protozoa, drugs, toxins, and autoimmune disease. The clinical symptoms and course can be similar regardless of the etiology.

A. Hepatitis viruses. Viral hepatitis is the most common cause of chronic liver disease (Table 14.1).

1. **Hepatitis A virus (HAV)**, also referred to as “infectious hepatitis.”
2. **Hepatitis B virus (HBV)**, also known as “serum hepatitis.”
3. **Hepatitis C virus (HCV)**, formerly known as “non-A, non-B hepatitis.”
4. **Hepatitis D virus (HDV)**, also known as the “delta agent,” requires coinfection with HBV.
5. **Hepatitis E virus (HEV)**, similar to HAV in many respects but with a different geographic distribution.

B. Systemic viral illnesses with a hepatitis-like component

1. **Epstein-Barr virus** (see Chapter 9)
2. **Cytomegalovirus** (see Chapter 9)
3. **Yellow fever virus** (see Chapter 22)
4. **Varicella-zoster virus** (see Chapter 20)
5. **Herpes simplex virus** (see Chapter 20)
6. **Miscellaneous** (e.g., rubella, rubeola, Coxsackie B virus, adenovirus, etc.)

C. Nonviral etiologies

1. **Infectious hepatitis** (e.g., toxoplasmosis and leptospirosis)
2. **Alcoholic hepatitis**
3. **Nonalcoholic steatohepatitis**
4. **Drug-induced hepatitis** (e.g., acetaminophen, halothane, isoniazid)
5. **Toxin-induced hepatitis** (e.g., mushrooms, phosphorus, carbon tetrachloride)
6. **Autoimmune hepatitis**

II. Approach to viral hepatitis. Determining the specific etiologic agent of viral hepatitis depends primarily on the patient’s epidemiologic setting and clinical history, as well as the use of laboratory tests to detect specific viruses and rule out other causes.

III. HAV

A. Classification and structure. HAV is a picornavirus with a nonenveloped single-stranded RNA strand and a diameter of 27 nm. Humans are the natural hosts.

B. Epidemiology

1. Transmission occurs almost always via the fecal–oral route, either sporadically or in epidemics after ingestion of contaminated food, water, or milk. Uncooked shellfish (e.g., clams, mussels, and oysters) from contaminated water are a common source. Fecal shedding of HAV can last for months after resolution of symptoms, and such patients could be a source of further viral spread in the community [1].
2. HAV is found worldwide with the highest prevalence in regions with low standards of sanitation, where asymptomatic infections occur early in life. As sanitation standards improve exposure is reduced, thus increasing the risk of acquiring HAV if exposed later in life when the clinical course can be more complicated.
3. Parenteral transmission is rare. Although roughly paralleling viral levels in the stool, systemic viremia is 100- to 1,000-fold lower in magnitude [2]. Viremia is likely the source of HAV spread among illicit intravenous drug users and hemophiliacs receiving solvent-detergent inactivated factor VIII preparations.
4. Sexual transmission is not a significant problem. However, men who have sex with men, especially those with oral–anal sexual contact, are at increased risk.

C. Pathogenesis

1. After HAV is ingested, it first replicates within the crypt cells of the small intestine before entering the bloodstream to spread to the liver.
2. HAV then enters the hepatocyte, sheds its coat, and initiates viral replication. The resulting new viral particles are released into the bile.

Table 14.1. Review of Viral Hepatitis

	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Genome	RNA	DNA	RNA	RNA	RNA
Route of infection	Predominately fecal–oral	Parenteral, sexual, and perinatal	Parenteral	Parenteral (requires co-infection with HBV)	Fecal–oral
Endemic areas	Low standards of sanitation	SE Asia, China, sub-Saharan Africa	Worldwide	Northern S. America Mediterranean region	Middle East, India northern Africa
Incubation	15–60 days (mean 30)	1–4 mo	2–12 weeks (mean 7)	1–4 mo	15–60 days (mean 40)
Vaccination available	Yes	Yes	No	Yes, if vaccinated against HBV	No
Diagnosis	Anti-HAV IgM	HepBsAg	Anti-HCV and HCV RNA by PCR	Anti-HDV in HepBsAg positive patient	Anti-HEV
Chronic hepatitis	No	Yes	Yes	Yes, requires HBV infection	No
Treatment	None needed	Interferon and Lamivudine	Interferon with/without ribavirin	High dose interferon	None needed

3. Hepatocyte necrosis is thought to occur via cell-mediated immunity in response to viral antigens expressed by hepatocytes rather than by direct cytopathic damage [3].
4. HAV may be found in the stool for 2 weeks before the onset of jaundice and then 1 week afterward [4]. Fecal shedding of HAV reaches its height just before the onset of hepatocellular disease, at which point the patient is also maximally infectious.

D. Clinical disease

1. HAV results in a wide range of clinical manifestations, from subclinical infection, to overt infections with or without jaundice, to acute liver failure and death. However, most cases are self-limited.
2. The mean incubation period of 15 to 50 days (mean, 30 days) [5] is followed by the acute onset of malaise, anorexia, nausea, vomiting, abdominal pain, and fever, all of which characterize “symptomatic” disease. Symptoms can last up to a week in jaundiced patients. Cigarette smokers tend to lose interest in smoking.
3. The liver can be enlarged and tender. Serum aminotransferases (alanine aminotransferase [ALT] and aspartate aminotransferase [AST]) are elevated during the symptomatic phase followed by an elevated total bilirubin.
4. Age at acquisition of HAV is a major determinant of the severity of illness [6]. Symptomatic icteric hepatitis occurs in most infected adults but is less common in children and rare under the age of 2. Jaundice is associated with symptomatic improvement. Jaundice typically resolves after 2 weeks.
5. Fulminant HAV is relatively rare, yielding about 100 deaths each year in the United States [6]. The risk increases with advancing age, especially over the age of 40.
6. Patients with chronic hepatitis B and C who acquire acute HAV may be more likely to have an adverse outcome, including fulminant hepatitis [7,8].
7. A small proportion of patients may develop a protracted, but usually self-limited, cholestatic phase after the acute illness. Short-course corticosteroids may help [9].
8. A tiny percentage of patients experience recurrent signs and symptoms of acute HAV [9]. This is self-limited, and full recovery is invariably the case.

E. Diagnosis

1. The diagnosis of acute HAV is made by detecting IgM-specific antibody to the virus (anti-HAV-IgM). This antibody is present before symptom onset. It peaks during the acute phase and becomes undetectable in most cases by 6 months, except in those with relapsing hepatitis in whom it usually remains present throughout the course.
2. The presence of IgG-specific antibody to the virus (anti-HAV-IgG) indicates either prior HAV infection or vaccination against HAV. This also implies protection if exposed once again to HAV. The level of this antibody peaks during the convalescent period and remains detectable for many years.

F. Management. Currently, there is no specific treatment for HAV other than supportive care. Corticosteroids are often helpful for the prolonged cholestatic form of HAV. Any patient with severe symptoms and/or signs of acute HAV should be monitored closely for a prolongation of the prothrombin time and/or the onset of hepatic encephalopathy, both of which suggest acute liver failure [10]. These should prompt early transplant referral.

G. Passive immunization

1. Passive immunization remains the intervention of choice for postexposure prophylaxis. Antibody response after active immunization (see below) takes 2 weeks to develop fully and does not provide effective early protection.
2. Because a substantial proportion of the population has been infected with HAV, pooled lots of gamma globulin (human immunoglobulin [HIG]) contain sufficient antibody for this purpose.
3. A single dose of HIG, 0.02 mL/kg in the gluteus muscle, confers immunity that lasts up to 6 months [9]. This is recommended for those exposed (or potentially exposed) to HAV who have no prior history of HAV infection.

4. Candidates for prophylaxis include household contacts of those with acute HAV, those known to have eaten uncooked food prepared by an infected individual, and those who will be traveling to at-risk areas of the world within 2 weeks, time insufficient for active HAV immunization.
5. Once clinical symptoms of HAV infection have developed, the patient is already producing antibody, and the administration of IG is not indicated.
6. It is important to note that the simultaneous administration of active and passive immunization reduces the ultimate antibody level by 50%.

H. Active immunization

1. Two recombinant inactivated HAV vaccines (Havrix, GlaxoSmithKline, Research Triangle Park, NC, and VAQTA, Merck, Whitehouse Station, NJ) have been available in the United States since 1995 and 1996, respectively. Both vaccines have been shown to be safe and effective. After vaccination, the levels of protective antibody approach the levels seen after natural HAV infection. A combination hepatitis A and B vaccine (Twinrix, GlaxoSmithKline) was approved in the United States in 2001.
2. The current HAV vaccine schedule involves an initial dose followed by a booster 6 to 12 months later. The vaccines are safe in children over the age of 2 years. Their safety in pregnancy is not known.
3. The following should receive HAV vaccination: children living in areas of the United States where the rates of HAV infection are at least two times the national average (e.g., ≥ 20 cases per 100,000 population), persons traveling to countries with intermediate endemicity, men who have sex with men, persons with clotting disorders, persons who use illegal drugs, and personnel in HAV research laboratories [11].
4. Side effects of vaccine include injection site soreness, erythema, and induration. Systemic reactions, including fever, occur in less than 5% of subjects.
5. Patients with chronic liver disease due to HBV and HCV should also be vaccinated, because they are at risk of more severe disease if they contract HAV [7]. Seroconversion rates after two doses of the HAV vaccine are the same in these individuals as in healthy subjects [12]. However, efficacy of vaccination in patients with advanced cirrhosis and in liver transplant recipients is currently unknown.

IV. HBV

A. Classification and structure

1. HBV is a DNA virus that belongs to the family of hepadnaviruses. The intact virion (or Dane particle) is a 42-nm sphere that contains the nucleocapsid, with its DNA of approximately 3,200 base pairs. HBV replicates via an RNA intermediate using viral-encoded reverse transcriptase.
2. The HBV genome consists of four open reading frames encoding for the surface envelope (pre-S/S), core (pre-core/core), polymerase, and X proteins. The S open reading frame encodes for the viral envelope protein, hepatitis B surface antigen (HBsAg), the hallmark of HBV infection. The X protein is crucial for viral life cycle *in vivo* and probably functions by interacting with multiple cellular pathways.
3. Seven genotypes of HBV (A through G) have been identified. Currently, there are insufficient data to correlate differences in clinical outcomes or responses to treatment with genotype.

B. Epidemiology

1. Worldwide, close to 400 million people are infected with HBV [13]. In the United States, HBV infection causes 5% to 10% of chronic liver disease and cirrhosis [14].
2. The distribution of HBV infection varies greatly throughout the world. Areas with the highest prevalence include southeast Asia, China, and sub-Saharan Africa, where approximately 10% of the population are chronic carriers [14]. Intermediate prevalence areas (3%–5%) include Mediterranean countries, Japan, Central Asia, the Middle East, Latin and South America, and indigenous population groups in the Arctic [15]. Low prevalence areas (0.1%–2%) include the United States, Canada, western Europe, Australia, and New Zealand [16].
3. The wide range of carrier rates in different parts of the world relates primarily to the individual's age at time of infection. The rate of progression to chronic

hepatitis approximates 90% for perinatally acquired infection, 20% to 50% for infection between the ages of 1 and 5 years, and less than 5% for infection acquired in adulthood [15].

4. Most infections in developed countries occur as a result of sexual activity, intravenous drug use, or occupational exposure. Less common causes include household contact, hemodialysis, and recipients of solid organs or blood products. No clear risk factors are identified in 20% to 30% of infected individuals [13].

C. Serologic markers of HBV infection

1. **HBsAg** is the hallmark of HBV infection. It is usually detectable 1 to 10 weeks after acute infection and 2 to 6 weeks before clinical symptoms. Patients who recover from acute infection clear HBsAg within 4 to 6 months. Persistence of HBsAg for more than 6 months implies chronic infection.
2. **Hepatitis B surface antibody (anti-HBs)** is a neutralizing antibody that confers protective immunity against HBV. Anti-HBs is found in patients who have recovered from HBV infection or responded to HBV vaccination.
3. **Hepatitis B core antigen** is the nucleocapsid that encloses the viral DNA. It is an intracellular antigen, not detected in the serum.
4. **Hepatitis B core antibody (anti-HBc)**. Anti-HBc-IgM develops initially and appears within 1 month after HBsAg. Anti-HBc-IgG develops later and is found in association with anti-HBs in those who have recovered from hepatitis B or with HBsAg in chronic HBV, between the disappearance of HBsAg and the development of anti-HBs, and for many years after recovery of acute HBV. Transmission of HBV occurs via organ donors with isolated anti-HBc.
5. **Hepatitis B e antigen (HBeAg)** signifies HBV replication and infectivity. HBeAg is a peptide derived from the core gene, modified and exported from the cell. It is associated with serum HBV DNA. In the recovery phase of infection, HBeAg is cleared, ahead of HBsAg. In chronic HBV, HBeAg remains detectable for years. With seroconversion from HBeAg to anti-HBe, HBV DNA disappears and liver disease remits. Spontaneous seroconversion occurs at a rate of 5% per year in the West but much less so in the Far East [17]. During seroconversion, some develop HBeAg-negative variants due to mutations of the HBV genome. These patients have anti-HBe but have low or undetectable levels of HBeAg. Transcription of pregenomic RNA is not affected, so viral replication and liver disease persist [18]. The highest prevalence of HBeAg-negative variants is in the Mediterranean region followed by Asia, whereas they are uncommon in North America and western Europe.
6. **HBV DNA** assays used to assess HBV replication include hybridization, branched DNA, and polymerase chain reaction (PCR) assays. Each differs in its detection limits. Detection of HBV DNA may precede HBsAg. Serum HBV DNA levels determine candidacy for treatment and response to therapy in chronic HBV. HBV DNA is often associated with HBeAg. Seroconversion to anti-HBe leads to the loss of HBV DNA, although it may remain detectable by more sensitive PCR assays.

D. Pathogenesis

1. HBV is not cytopathic for hepatocytes. Liver injury occurs via T cells cytotoxic for hepatocytes expressing surface hepatitis B core antigen. A successful immune response occurs if all infected cells are destroyed, viral replication ceases, and anti-HBs is generated (which prevents reinfection of hepatocytes). Alternatively, immune responses may inhibit viral replication without killing infected cells and minute amounts of virus remain in hepatocytes indefinitely, even if HBsAg and HBV DNA are not detectable [19].

E. Acute hepatitis B

1. The incubation period is 1 to 4 months, which may be followed by anorexia, malaise, nausea and vomiting, and right upper quadrant tenderness. As these symptoms subside, jaundice ensues and lasts up to 1 to 3 months.
2. Nearly 70% of patients with acute HBV infection have anicteric hepatitis (Fig. 14.1), whereas 30% develop jaundice. Acute liver failure develops in less than 1%. [15].

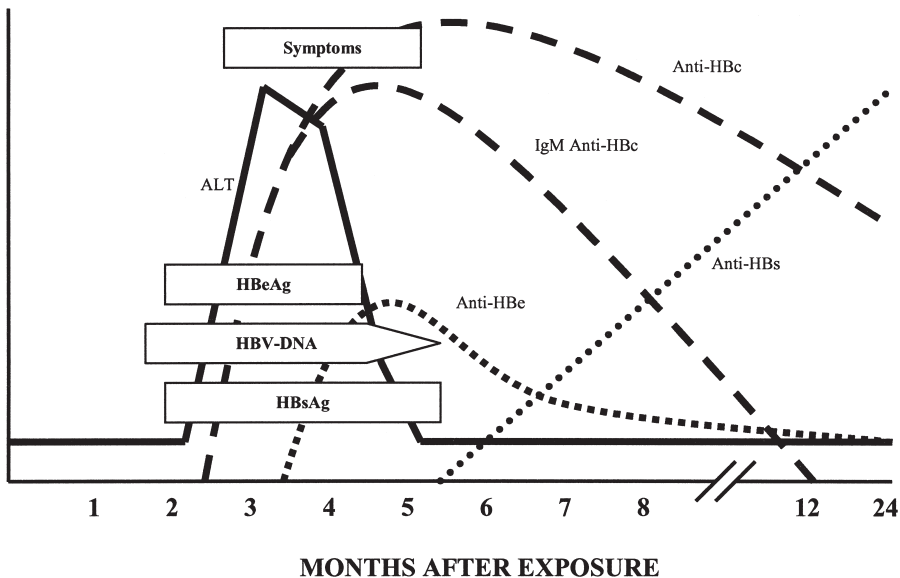

FIG. 14.1 A typical case of acute hepatitis B. HbsAg, hepatitis B surface antigen; HBV-DNA, hepatitis B virus DNA; HBeAg, hepatitis B e antigen; ALT, alanine aminotransferase; Anti-HBe, antibody to hepatitis e antigen; Anti-HBc, antibody to hepatitis core antibody; Anti-HBs, antibody to hepatitis B surface antibody.

- Elevations in aminotransferases to 1,000 to 2,000 IU/mL are common. Normalization occurs in 1 to 4 months, then bilirubin. Enzyme elevation for more than 6 months usually indicates chronic infection. Prothrombin time is the best prognosticator [20].

F. Chronic hepatitis B

- Patients who develop chronic HBV infection usually have a mild or subclinical presentation. Others manifest fatigue and right upper quadrant discomfort. Some have exacerbations mimicking acute hepatitis. Others develop end-stage liver disease characterized by ascites, encephalopathy, and variceal bleeding.
- A National Institutes of Health Workshop [21] defined chronic HBV as persistent HBV infection causing necroinflammatory liver disease with (a) positive HBsAg for more than 6 months, (b) serum HBV DNA levels higher than 10^5 copies/mL or positive hepatitis B core antigen by immunostaining, (c) persistent or intermittent elevation in AST/ALT levels, and (d) a liver biopsy showing chronic hepatitis.
- Predictors of progression to cirrhosis and hepatocellular carcinoma (HCC) include the state of the immune system, age, sex, geography, and genetics [22,23]. The overall reported incidence of HCC in surveillance studies is 0.8% to 4.1% [23].
- Patients with inactive hepatitis B (previously a “healthy carrier”) have detectable HBsAg for more than 6 months without any ongoing necroinflammatory disease. Most have lost HBeAg and developed anti-HBe, with HBV DNA levels less than 10^5 copies/mL and a persistently normal ALT/AST. In some, disease relapses after a period of inactivity.

G. Therapy.

The goal of treatment is to suppress HBV replication (disappearance of HBeAg and HBV DNA), thereby preventing the progression to cirrhosis and HCC.

- Interferon- α (IFN- α)** therapy was approved in 1992 for immunocompetent patients at doses of 5 to 10 million units (MIU) daily or three times a week for

16 weeks. A meta-analysis of 15 studies [24] demonstrated a sustained loss of HBV replication in those treated for at least 3 months (33% lost HBeAg vs. 12% of control subjects and 37% lost HBV DNA vs. 17% of control subjects). Eight percent lost all markers, including HBsAg, compared with 2% of control subjects. Favorable response factors included a negative human immunodeficiency virus (HIV) test, chronic active hepatitis on liver biopsy, moderately high ALT levels (>100 U/L), HBV DNA levels less than 200 pg/mL, and a history of acute hepatitis [25]. Wild-type virus (HBeAg positive) is associated with improved response rates compared with the situation with HBV variants (see section IV.C.5 above). In a 5-year follow-up of 103 patients treated with IFN- α , survival without clinical complications was significantly prolonged in patients who cleared HBeAg [26]. IFN- α is also associated with a decreased incidence of HCC [27]. IFN- α treatment of patients with decompensated cirrhosis (ascites, variceal bleeding, encephalopathy) is contraindicated because benefit is limited, severe adverse effects are common, and, most of all, during treatment significant flares in liver enzymes are seen and this may precipitate acute decompensation and the need for urgent liver transplantation.

2. **Lamivudine** (Epivir-HBV, GlaxoSmithKline) is a nucleoside analogue that inhibits HBV reverse transcriptase, thus inhibiting HBV replication. It has negligible side effects. Treatment-naïve patients or nonresponders to IFN- α with elevated AST/ALT and HBeAg and HBV DNA treated for 12 months were more likely to have HBeAg seroconversion (see section IV.C.5 above), sustained ALT normalization, and improvement on biopsy than placebo recipients [28–30]. Prolonging treatment to 2 years yields a further improvement in necroinflammation [31] and an increase in the sustained seroconversion rate [32]. Unlike IFN- α , lamivudine is effective against HBV variants (see section IV.C.5 above) [33] and is safe and effective in decompensated HBV cirrhosis [34].
 3. After 1 year, 15% to 30% of patients may develop **mutations in the YMDD motif** of the HBV polymerase gene [14]. Patients with this mutation have lower (but not undetectable) serum levels of HBV DNA than before treatment but improved ALT and histology, similar to patients without the YMDD mutation. Because the lamivudine-resistant mutants do not replicate as proficiently as the wild-type virus, stopping the drug results in a rapid reversion to wild-type that may be associated with a marked rise in HBV DNA and ALT levels [35].
 4. **Combination of lamivudine and interferon** appears to enhance the HBeAg seroconversion rate, particularly for treatment-naïve patients with moderately elevated baseline ALT levels [36]. However, this approach was not recommended at the recent National Institutes of Health Workshop on HBV [21].
 5. The observations with lamivudine monotherapy suggest that combining various antivirals in a cocktail as for HIV may lead to improved response and/or less resistance. Other nucleoside analogues (e.g., adefovir, entecavir, emtricitabine) are being investigated.
- H. HBV after transplantation.** HBV recurrence after transplantation has been reduced significantly with the use of long-term high-dose intravenous hepatitis B immune globulin (HBIG). Now lamivudine added to HBIG has led to further improvements in allograft and patient survival [37]. A cost-effective alternative is low-dose intramuscular HBIG in combination with lamivudine [38].
- I. Prevention/HBV vaccine**
1. HBV vaccine prevents disease and sequelae such as HCC. It is safe and effective. The most common side effect is pain at the injection site.
 2. Universal vaccination of newborns is routine in many countries, especially for infants born to HBsAg-positive mothers. Adults who should be vaccinated include health-care workers, sexual partners and family members of HBsAg-positive cases, patients with chronic liver disease, patients on hemodialysis, persons in institutions for the developmentally disabled and long-term correctional facilities, travelers staying for more than 6 months in countries with high endemic rates of HBV, and drug users.
 3. Current HBV vaccines consist of HBsAg produced in yeast using recombinant DNA technology. The vaccine is given intramuscularly, usually at 0, 1, and

6 months, at a dose for adults of 10 to 20 μg and for children 2.5 to 10 μg . In 1999 the U.S. Food and Drug Administration approved an optional two-dose schedule of Recombivax HB (Merck & Co., Inc., West Point, PA) for 11 to 15 year olds. For adults, the dose of Recombivax HB is 10 μg with the second dose given 4 to 6 months later.

4. An anti-HBs titers higher than 10 IU/L is deemed protective. Maximum antibody response occurs 6 weeks after the last dose, so testing is done 1 to 2 months after completing the series, except in infants born to HBsAg-positive mothers, in whom testing should be performed at ages 9 to 15 months. In normal subjects, a favorable response occurs in 90% to 95%, but in the elderly or the immunosuppressed, response can be as low as 40% to 60% [39]. Additional doses (one to three) are recommended for nonresponders. This yields a 25% to 50% response after one additional dose and 50% to 75% after three [39].
5. Although anti-HBs titers decrease over time, the duration of protection is probably lifelong, because most responders mount an amnesic anti-HBs response upon rechallenge. Booster doses of HBV vaccine are indicated only in hemodialysis patients. Serologic testing to monitor antibody levels is not recommended.

J. Postexposure prophylaxis should be provided for individuals known to be anti-HBs negative, those never vaccinated, and nonresponders to prior HBV vaccination. Individuals who have been vaccinated but whose anti-HBs status is unknown should have anti-HBs testing, and if titers are less than 10 mIU/mL they should undergo prophylaxis. The Centers for Disease Control and Prevention suggests administering both a single dose of HBIG and initiating a course of HBV vaccination.

V. HCV

A. Classification and structure. HCV is the only member of the genus *Hepacivirus* in the *Flaviviridae* family of viruses. It is an enveloped virus about 50 nm in diameter that contains a positive-sense single-stranded RNA genome.

B. Epidemiology

1. HCV was the most common blood-borne infection in the United States in the 1980's, but the incidence of HCV had declined by more than 80% to 36,000 in 1996 [40–42].
2. Some 3.9 million people (1.8%) have positive HCV antibody and 74% have detectable HCV RNA by PCR, indicating chronic infection [43,44]. In African Americans, the prevalence rate is 3.2%, compared with 1.5% for non-Hispanic whites. The highest prevalence is in men aged 30 to 49 years with large or repeated direct percutaneous exposures to blood [43].
3. After introduction of the sensitive ELISA II screening antibody in 1992, the risk for HCV infection has fallen to 0.001% per unit of blood transfused [45,46]. Another common source for HCV was the use of clotting factor concentrates before 1985. Transplantation of organs from infected donors also carried a high risk before HCV screening was initiated in the early 1990's.
4. **Intravenous drug use** now accounts for most cases of HCV transmission in the United States. For current users, the rate of HCV may be as high as 79% [40]. After 5 years of injecting, as many as 90% are infected with HCV [40].
5. **Intranasal cocaine use** (“snorting”) may also serve as a route for transmission, probably due to nasal ulceration and/or bleeding and the sharing of contaminated straws [47]. However, intranasal cocaine use in the absence of intravenous drug use is relatively uncommon.
6. In contrast to HBV, **sexual transmission** is relatively infrequent. Sexual partners of patients with HCV reveal a low rate of HCV, ranging from 0 to 4.4% (mean, 1.5%) [40]. The risk of HCV transmission from men to women and from men to men is greater than that transmission from women to men, but it is still less common than that for HBV or HIV.
7. The rate of HCV infection among health-care workers is no higher than that found in the general population [40]. The risk of acquiring HCV from a needle-stick injury is approximately 0.1%, but it rises to approximately 5% to 10% if the index case is confirmed to have viremia by PCR [48]. HCV transmission is particularly high in patients on hemodialysis in whom the prevalence is approximately 10% but occasionally is as high as 60% [49].

8. The rate of **vertical transmission** of HCV from mother to child is approximately 5%, but it may be 14% or more if the mother is HIV positive [40]. Elective cesarean section before membrane rupture is associated with lower HCV transmission rates compared with vaginal delivery or emergency cesarean section (0 vs. 7.4%; $p = 0.04$) [50]. The sensitivity of HCV RNA by PCR in infants is only 22% before 1 month of age, rising to 97% thereafter, which suggests that HCV infection occurs at the time of delivery [50].
9. **Nonsexual household contacts** (e.g., via razor blades, toothbrushes, or other household items) represent very low risk for HCV transmission.
10. HCV infection related to procedures (e.g., tattooing) is reported in other countries, but case studies have failed to reveal such an association in the United States [40].

C. Pathogenesis

1. Hepatocellular injury occurs from nonspecific immune mechanisms and a virus-specific immune response (both humoral and cellular), not from viral cytotoxicity.
2. HCV has great genetic heterogeneity. Isolates from around the world have been classified into six major genotypes. Individual isolates consist of closely related yet heterogeneous populations of viral genomes (i.e., quasi-species). This genetic diversity probably accounts for the ease with which HCV escapes the host's immune system and leads to chronic infection.

D. Acute hepatitis C

1. Acute hepatitis C is almost always asymptomatic and therefore rarely recognized.
2. HCV RNA typically becomes detectable in the serum by PCR about 7 to 21 days after exposure. Specific HCV antibodies appear within 20 to 150 days (mean, 50 days) [51].
3. Clinical symptoms (e.g., jaundice, fatigue, lethargy, myalgias, and right upper quadrant discomfort) occur in less than 20% of patients [41]. They occur within 2 to 12 weeks (mean, 7 weeks) after exposure [41]. Elevation in ALT is usually mild. Fulminant hepatitis is very rare. Those with clinical hepatitis are much more likely to completely clear HCV, probably due to a more vigorous immune response.

E. Chronic hepatitis C

1. After acute infection, approximately 15% appear to resolve infection with no detectable HCV RNA, a normal ALT, and no sequelae [52]. In the remaining 85%, chronic hepatitis develops [44]. HCV currently accounts for 40% of chronic liver disease in the United States, resulting in approximately 8,000 to 10,000 deaths each year [40]. The Centers for Disease Control and Prevention predicts that the mortality rate from HCV will triple by 2020. HCV-related end-stage liver disease is now the most common reason for liver transplantation in the United States [53].
2. The **natural history** of HCV remains a controversial issue because strategies to examine disease progression are complicated by both recall and selection bias. However, despite this it is estimated that 15% to 20% of persons who acquire HCV infection progress to end-stage liver disease (and its sequelae) during a 20- to 30-year period [54] and approximately 1% to 5% will develop HCC [40].
3. **Risk factors for more rapid disease progression** include the consumption of at least 50 g of alcohol on a daily basis, HCV acquisition after age 40, male gender, immunosuppression, and/or coinfection with HIV [55,56].
4. A key feature of chronic HCV infection is its seemingly indolent course with minimal, if any, symptoms and its discovery on routine blood studies. About 60% to 70% of patients with chronic HCV have a persistently elevated ALT. The remainder have either intermittently elevated or persistently normal ALT levels. On liver biopsy, patients with a persistently normal ALT tend to have less severe histologic findings and a lower rate of progression to cirrhosis.
5. Chronic HCV infection has been associated with numerous **extrahepatic manifestations**, the most common of which are thyroid dysfunction, porphyria cutanea tarda, Sjögren syndrome, vasculitis, and/or renal disease secondary to cryoglobulinemia and membranoproliferative glomerulonephritis.

F. Diagnosis

1. The first step is to detect test for **antibodies to HCV** using an enzyme immunoassay. After HCV exposure, the average time to develop antibodies is approximately 8 to 9 weeks [57]. Because the symptoms of acute HCV infection usually begin at 7 weeks, a negative anti-HCV antibody does not rule out hepatitis C. HCV RNA by PCR is more helpful in high risk situations (see below).
2. The recombinant immunoblot assay is rarely used today except to confirm positive ELISA II tests during blood donation screening.
3. **HCV RNA by PCR is used to confirm viremia.** It may be qualitative (viremia present or absent) or quantitative (which is slightly less sensitive but detects viremia in the vast majority of infected individuals). PCR is useful after a needle-stick injury, because this becomes positive within 6 to 8 weeks of exposure.
4. Determining **HCV genotype** does not aid in the diagnosis, but it does help decide on the duration of treatment, whenever deemed necessary (see below).

G. Therapy

1. In the past, a biochemical response (normalization of serum aminotransferases) to treatment was the primary end point, but currently the goal of treatment is the eradication of HCV RNA from the serum (i.e., a virologic response).
2. **End-of-treatment virologic response** indicates viral clearance from the blood at the end of treatment, whereas a **sustained virologic response (SVR)** indicates the absence of virus at 6 months after the end of treatment. Of patients who achieve an SVR, 96% will have undetectable HCV RNA in the serum and no histologic progression on serial liver biopsy when followed for a mean of 4 years [58].
3. **Relapsers** achieve an end-of-treatment virologic response but subsequently redevelop viremia. **Nonresponders** fail to clear HCV RNA after completing a course of treatment. A subcategory of nonresponders initially respond with a fall in HCV RNA titer (even to undetectable levels) only to “break through” despite ongoing treatment. Their outcome is similar to other nonresponders.
4. **Predictors of response** to antiviral therapy include HCV genotypes other than type 1 or 4, pretreatment levels of HCV RNA by PCR less than 2 million copies/mL or less than 850,000 IU/mL using the new World Health Organization system, absence of bridging fibrosis or cirrhosis, age less than 40 years, and female gender [59]. HCV genotype is the most important.
5. **Monotherapy with IFN- α ,** once the mainstay of HCV treatment, is now used only when combination treatment with ribavirin is not tolerated or contraindicated. For details see previous reports [60–64].
6. **Consensus interferon alfacon-1** (Infergen, Amgen, Thousand Oaks, CA) combines the most common amino acid sequences from 11 naturally occurring IFNs. In treatment-naïve patients, consensus interferon 9 μg subcutaneously three times a day leads to an SVR similar to that with standard-dose IFN- α monotherapy [65]. However, high-dose consensus interferon (15 μg subcutaneously three times a day for 48 weeks) enhances SVR to 13% in prior nonresponders and to 58% in relapsers after prior IFN- α [66].
7. Since its introduction in 1998, **ribavirin in combination with IFN- α 2b** (Rebetron, Schering-Plough, Kenilworth, NJ), so-called combination therapy, has become the gold standard. Patients must be able to tolerate the hemolysis and other side effects associated with ribavirin and have no specific contraindications to its use (see below). Ribavirin (1,000–1,200 mg orally in two divided doses a day) is an oral guanosine analogue and does not ameliorate viremia on its own, but when used in combination with IFN- α 2b it leads to a significant increase in SVR in treatment-naïve patients. After 48 weeks of combination therapy SVR is 38% compared with only 13% after 48 weeks of IFN- α 2b monotherapy [59]. Recent evidence suggests that the SVR can be improved further when the dose of ribavirin is based on body weight (and at least 10.6 mg/kg/day is given) [63]. This also appears to be the case if patients take 80% of their IFN- α 2b and 80% of their ribavirin for 80% of the time (the so-called 80-80-80 rule) [64]. Combination therapy also improves SVR in relapsers (48%) and nonresponders (35%).
8. **Pegylated IFN- α** was recently developed to overcome the rapid absorption and clearance of IFN- α . Pegylation involves the addition of a 40-kDa branched

polyethylene glycol (PEG) polymer to IFN- α 2a (PEG-IFN- α 2a, PEGASYS, Hoffman LaRoche Laboratories, Nutley, NJ) or a 12-kDa linear PEG polymer to IFN- α 2b (PEG-IFN- α 2b, PEG-Intron, Schering-Plough). Both are dosed once weekly. In a recent pivotal trial in treatment-naïve patients, PEG-IFN- α 2a 180 μ g subcutaneously for 48 weeks led to an SVR of 39% compared with 19% in patients treated with IFN- α 2a [67]. In compensated cirrhotics, PEG-IFN- α 2a achieved an SVR of 30% compared with 8% with standard IFN- α 2a, both given for 48 weeks [68]. In contrast, PEG-IFN- α 2b 1.5 μ g/kg subcutaneously once weekly for 48 weeks led to an SVR of only 23% versus 12% with standard IFN- α 2b [69]. There is additional benefit when ribavirin is added. In a recent phase III open-label trial, patients treated with PEG-IFN- α 2b 1.5 μ g/kg subcutaneously once weekly plus ribavirin 800 to 1,200 mg/day had an SVR of 54% compared with 46% with standard IFN- α 2b plus ribavirin [63].

- 9. Contraindications** to the use of IFN- α include decompensated liver disease, severe depression or bipolar illness, autoimmune disease, active drug or alcohol use, pregnancy, and significant comorbid disease (e.g., unstable coronary artery disease, epilepsy, diabetes, or hypertension). Contraindications to the use of ribavirin include anemia (hemoglobin less than 11 g/dL), hemolysis, renal insufficiency, coronary artery disease, and cerebral vascular disease. Because of ribavirin's teratogenic risk, it is contraindicated during pregnancy. It should also not be administered to any women at risk of becoming pregnant or their male partners without advising two forms of contraception while on ribavirin and for at least 6 months after it is stopped. Serial pregnancy tests are required.

H. HCV after liver transplantation. HCV recurrence is almost universal, but overall graft and patient survival for the first decade at least after liver transplantation appears to be unaffected [70]. By the second decade, the prevalence of HCV-related graft failure may begin to increase. The natural history of HCV infection appears accelerated in transplant recipients as compared with immunocompetent individuals [71]. Optimal antiviral strategies for hepatitis C after transplantation have yet to be developed.

I. Postexposure prophylaxis. Immunoglobulin is not effective to prevent HCV [40]. Although IFN- α begun early in the course of HCV infection is associated with a high rate of success [72], no data exist that treatment during the acute phase after exposure is more effective than treatment begun early in the course of chronic infection.

J. Prevention. Currently there is no vaccine for HCV. Efforts to develop one are not without formidable challenges because of high rates of mutation in the hypervariable region of the envelope protein, slow antibody response to envelope proteins with only modest titers during primary infection, and the lack of an appropriate animal model.

VI. HDV

A. Classification and structure. HDV is an unusual infectious agent (the so-called "delta" agent) that requires HBsAg for its survival. Although HDV can replicate independently, HBV must be present for complete HDV virion assembly and secretion. As a result, individuals with HDV are always dually infected with HDV and HBV. The 36-nm virion consists of a 1.7-kb single-stranded RNA genome (the smallest known to infect humans), the hepatitis delta antigen (delta-Ag), and an envelope composed of lipid and HBsAg. The envelope, which is required for virion formation and infection, is the only helper function provided by HBV.

B. Epidemiology

1. HDV is transmitted in the same fashion as HBV.
2. About 5% of HBV carriers worldwide are infected with HDV [16]. However, the geographic distribution of HDV does not parallel that of HBV because there are three distinct genotypes with differing geographic distributions and disease severity [73]. The most widespread is genotype I, associated with a broad spectrum of chronic disease.
3. Slowly progressive liver disease appears to predominate in some HDV-endemic areas such as the Mediterranean region, where transmission occurs by inapparent permucosal, percutaneous, or intrafamilial spread.

4. Despite the high prevalence of HBV in Asia, the prevalence of HDV infection (genotype II) is generally low and is associated with milder disease. Transmission usually occurs sexually or via intravenous drug use.
5. The most severe forms of HDV infection are seen in low prevalence areas (North America and northern Europe) among intravenous drug users.
6. Outbreaks of acute HDV infection (genotype III) have been seen in northern parts of South America where the disease often has a rapidly progressive course [74].

C. Clinical features

1. **Acute coinfection** with HBV and HDV occurs with simultaneous exposure to both viruses. Usually, coinfection is self-limited. As the immune response clears HBsAg, HDV infection also resolves. A small number become chronically infected with both.
2. **Superinfection** develops in those infected with HBV. Because HBsAg expression is established before HDV exposure, there is a more rapid course, with high levels of HDV RNA and delta-Ag. In at least 70%, HDV becomes chronic [75]. Chronic HDV is associated with rising titers of antibodies to hepatitis D, which are not protective because the delta-Ag is an internal virus component.

D. Diagnosis

1. **Total HDV antibody (anti-HDV) assays** are the only commercially available tests for HDV infection in many countries. Anti-HDV-IgM levels are transient and delayed if the course of HDV is self-limited. In chronic cases, anti-HDV-IgM is long lasting, present in high titers, and correlates with the severity of disease [16]. Anti-HDV-IgG titers are high in chronic HDV infection.
2. **Serum HDV RNA** is an early sensitive marker of HDV infection in patients with acute hepatitis D, and most cases with chronic HDV infection have a positive PCR.
3. **Tissue markers of HDV infection (delta-Ag)** detected by immunohistochemical staining of liver tissue are considered the gold standard to confirm ongoing HDV.

E. Therapy. Current options are limited. Controlled trials [76–78] have shown that in certain groups IFN- α normalizes ALT, eradicates serum HDV RNA, and improves liver histology. However, high doses of IFN- α (5 MIU daily or 9–10 MIU three times day) for 1 to 2 years are usually needed. Most patients relapse once therapy is stopped. With lamivudine, neither HDV viremia nor liver disease activity are improved [79].

F. Prevention of HDV infection involves the use of vaccination against its helper virus HBV. Vaccines specifically against HDV superinfection have not been successful.

VII. HEV

A. Classification and structure. HEV is a nonenveloped single-stranded RNA virus 32 nm in diameter. Viral particles were first isolated from the stool in 1983 and named HEV in 1988. Originally classified in the family *Caliciviridae* (e.g., Norwalk agent), HEV was recently found to be more similar to the rubella virus and beet necrotic yellow vein virus [80]. HEV remains unclassified at present. A number of different HEV strains have been identified, and the divergence appears to be based on geography.

B. Epidemiology

1. HEV is transmitted via the **fecal–oral route**. Risk factors include poor hygiene and contaminated water supplies. Person-to-person transmission accounts for few cases.
2. Unlike HAV, which has a worldwide distribution, HEV is restricted to tropical and subtropical developing countries. The highest endemic areas are the Middle East and northeast Africa, followed by India, Asia, and Mexico [81].
3. HEV causes epidemics of acute hepatitis [82,83]. In India, 90% of epidemic hepatitis is due to HEV, which follows a 10-year cycle for unknown reasons.
4. HEV mainly affects older children and adults. Serious disease seems to primarily occur in young adults from developing rather than developed countries, again for unknown reasons. In India, fewer than 5% of children under the age of 10 are seropositive [84] compared with the seropositivity rate for HAV (>90%) in the same population.

5. In the United States and northern Europe, up to 2% of the population has antibodies to HEV [85]. The prevalence of HEV antibody increases with age, and it is rarely found in those less than 30 years of age. The incidence of symptomatic disease is even lower. Cases in the United States usually have history of travel to HEV-endemic areas elsewhere in the world. Higher rates of HEV seropositivity in the United States have been reported in men who have sex with men and in intravenous drug users.
 6. HEV may be zoonotic [86]. In the United States, swine and rodents infected with an attenuated strain may be the source of infection of humans. This might explain the high prevalence of antibody in certain groups who have never had symptomatic disease.
 7. The greatest impact of HEV is on pregnant women, who have a high mortality rate (up to 20%–25%), especially during the second and third trimesters [87].
- C. Pathogenesis.** Like HAV, HEV enters through the gastrointestinal tract, reaching the liver via the portal vein, before being excreted in bile. Pathogenesis is poorly understood but probably involves both cytotoxic and immunologic mechanisms. The reason for the high mortality rates seen in pregnant women remains uncertain.
- D. Diagnosis.** As with HAV, acute HEV is diagnosed by the presence of the IgM class of HEV antibodies, typically present for 3 to 4 months. The IgG class is also usually detectable, and titers may rise to very high levels during the convalescence period. These IgG antibodies diminish over time and their ability to sustain immunity is unproven.
- E. Clinical features**
1. HEV infection is self-limited and does not progress to chronic liver disease.
 2. The incubation period is 15 to 60 days (mean, 40 days). One to 3 weeks after exposure, HEV is detected in the blood and feces. Fecal excretion may last approximately 3 to 5 weeks.
 3. Acute HEV resembles HAV, with low mortality rates except in pregnant women.
- F. Prevention and control measures**
1. In HEV-endemic regions, travelers should avoid water of unknown purity, uncooked shellfish, and fruits and vegetables not peeled by the travelers themselves.
 2. Passive immunoprophylaxis with IG has been shown to be effective in controlled clinical trials [88], but commercially available lots of IG from donors collected in regions where HEV is endemic probably lack sufficient antibody to be efficacious.
 3. HEV vaccines are currently under clinical evaluation.

15. GENITOURINARY TRACT INFECTIONS

Thomas T. Ward and Stephen R. Jones

Urinary tract infections (UTIs) are the most prevalent infection of adults for which antimicrobials are used. UTIs are most often an infection of otherwise healthy people and usually are treated on an outpatient basis. In the United States, symptoms of dysuria, urgency, or frequency result in three to four clinic visits per 100 women, and 80% or more of such episodes lead to the use of laboratory tests or to the prescription of drug therapy, or both. In addition to the inconvenience and cost posed by UTIs, infections occasionally result in protracted illness and serious disease, including gram-negative sepsis and death.

GENERAL APPROACH TO URINARY TRACT INFECTIONS

I. Terminology. The term **urinary tract infection** is a general one, referring only to the presence of bacteria in the urine. More appropriate terminology should indicate the anatomic area actually involved in infection.

A. Lower UTIs. In women, dysuria and increased urinary frequency may be seen with cystitis, urethritis, or vaginitis. As discussed later, attention to the patient's history, with detailed characterization of dysuric symptoms, may help differentiate the site of infection.

1. Cystitis refers to infection of the bladder and is itself frequently called **lower UTI**. This most common site of UTI is a **superficial mucosal infection** and is much easier to eradicate than renal parenchymal infection.

2. Urethritis, or inflammation of the urethra, frequently is caused by sexually transmitted pathogens.

a. Urethritis in men is associated with urethral discharge or dysuria, or both, but without increased frequency. This entity is discussed in detail in Chapter 16 under Urethritis.

b. Urethritis in women is associated with the same symptoms as cystitis. These patients often complain of dysuria and increased frequency, but their urine cultures are sterile or show small numbers of bacteria.

3. Prostatitis and epididymitis. Infections of the prostate may be associated with syndromes of acute and chronic disease. Chronic bacterial prostatitis is the principal cause of recurrent cystitis in men. Complications of prostatitis such as epididymitis may uncommonly occur.

B. Upper UTIs

1. Acute pyelonephritis refers to an **inflammatory process of the renal parenchyma**. This is most often due to bacteria but occasionally may be caused by fungi. These deep tissue infections are more difficult to eradicate than cystitis.

2. Chronic pyelonephritis refers to a histopathologic pattern of diffuse, interstitial, inflammatory disease of the kidneys that is not specific for infection. When related to infection, it is not possible to differentiate changes of active disease from residuum of past infection. Although this term continues to be used, it has **little clinical meaning**. Relapsing infection from presumptive, silent, persistent renal parenchymal infection is better termed **subclinical pyelonephritis**.

C. Uncomplicated versus complicated UTI

1. Uncomplicated UTI generally refers to cystitis in nonpregnant young adult to middle-aged women without underlying anatomic (structural) abnormality or neurologic dysfunction. These patients represent **the largest single group with UTI**. They are characterized by the ease with which their infections respond to antimicrobial therapy. Recently, sexually active young men with acute dysuria and uncomplicated cystitis have been described (see discussion under Urinary Tract Infection in Men, below).

2. Complicated UTI includes those UTIs that occur at sites other than the bladder (e.g., pyelonephritis) and those in children, most men, and pregnant women, as well as UTIs associated with obstruction, foreign body (e.g., catheter), elevated postvoiding residual volume (see section II.C.3.a), renal transplant recipients,

Table 15.1. Overview of the Epidemiology of Urinary Tract Infection by Age Group

Age Group (yr)	Females		Males	
	Period Prevalence (%)	Risk Factors	Period Prevalence (%)	Risk Factors
<1	1	Anatomic or functional urologic abnormalities	1.0	Anatomic or functional urologic abnormalities
1–5	4–5	Congenital abnormalities, vesicoureteral reflux	0.5	Congenital abnormalities, uncircumcised penis
6–15	4–5	Vesicoureteral reflux	0.5	None
16–35	20	Sexual intercourse, diaphragm use	0.5	Homosexuality
36–65	35	Gynecologic surgery, bladder prolapse	20.0	Prostatic hypertrophy, obstruction, catheterization, surgery
Over 65	40	As above, plus incontinence, chronic catheterization	35.0	As above, plus incontinence, long-term catheterization

From Stamm WE. Approach to the patient with urinary tract infection. In: Gorbach SL, Bartlett JG, Blacklow NR, eds. *Infectious disease*. Philadelphia: Saunders, 1992; with permission.

and surgically created ileal loop [1,2]. Some have further suggested a “**high-risk**” group, which includes a patient with immunosuppression, pregnancy, diabetes mellitus, sickle cell anemia, or UTI caused by an organism resistant to most antibiotics [2]. **Complicated UTIs** are characteristically more difficult to treat and may deserve radiographic or urologic investigation.

II. Epidemiology and pathophysiology. In early infancy (<3 months of age), UTIs occur more frequently in boys than in girls, but the ratio reverses thereafter; elderly men and women have about the same prevalence of infection (Table 15.1).

The normal urinary tract in men and women is bacteriologically sterile, with the exception of the distal urethra, which may be colonized with a variety of gram-positive and gram-negative bacteria.

A. Ascending infection. Work by Stamey [3] showed that the **ascending route of infection** (i.e., urethral organisms spreading to or invading the bladder) **is the most important** means by which the urinary tract becomes infected.

1. Microorganisms causing initial and recurrent infections in women are coliform bacteria that colonize the vaginal introitus, the urethra, and, subsequently, the bladder.

2. In men, the prostate plays a major role in recurrent UTIs. These infections may or may not be associated with obstruction of the urinary tract.

B. Hematogenous infection is much less common. UTIs secondary to bacteremia may occur but are rare.

1. Renal abscess. The kidney may be the site of the UTI in patients with bacteremia or endocarditis due to *Staphylococcus aureus*, as discussed under Intrarenal and Perinephric Abscess, later in this chapter.

2. Acute pyelonephritis can occur by the hematogenous route as a result of gram-negative bacteremia, but this is rare.

C. Determinants of infection. The inoculum of bacteria present, virulence of the organism, and defense mechanisms inherent in the urinary tract will determine whether infection is established [4,5].

1. **Inoculum size.** Size of the inoculum is particularly important and has been best studied in hematogenous infections. Experimental evidence has shown that delivery of large numbers of organisms to the kidney is required to initiate infection.
2. **Virulence of the organism.** The ability of bacteria to establish infection within the urinary tract varies with the individual strain. Nearly any species of bacterium or fungus can produce lower UTI. Only certain species, however, are likely to cause pyelonephritis. These include Enterobacteriaceae, *Pseudomonas* species, enterococci, and certain fungi.

Fimbria-mediated adherence (i.e., the ability to attach to a mucosal surface) by uropathogenic *Escherichia coli* to vaginal and uroepithelial cells determines infectivity and, in some cases, the propensity to develop upper UTI. Studies have characterized several specific bacterial protein ligands and host cell carbohydrate receptor sites. Cranberry juice has been purported to prevent adherence of uropathogens to uroepithelial cells, and regular use may decrease the frequency of bacteriuria [6,7].

3. **Host defense mechanisms.** As many as one-third of patients with bacteriuria undergo spontaneous cure. Defense mechanisms are present throughout the urinary tract and contribute to resistance of the tract to infection. Some examples follow.

- a. **Complete bladder emptying** is one of the most important defense mechanisms. When residual urine volumes are high, large numbers of bacteria may remain in the urine. The ability to expel bacteria is complete when voiding is complete. This concept is important in understanding the association between urinary infection and neurologic or urologic diseases (e.g., diabetes with neurogenic bladder or obstruction) that allow bacteria to grow in the residual urine [3]. A postvoiding residual urine volume of more than 100 mL is considered severe enough urinary retention to be associated with UTI [2].

- b. **High fluid intake and frequent voiding** may also be important. These may allow for washout of bacteria and form the basis for recommendations that patients with UTI increase their fluid intake and void frequently. Theoretically, such advice seems sound, but there is no evidence that hydration improves the results of appropriate antibiotic therapy.

- c. **The vesicoureteral valve** also may provide a barrier to the spread of infection by preventing reflux of bacteria once bladder bacteriuria is established.

- d. **Length of the urethra.** The relatively long urethra is believed to protect against infection in men. The shorter female urethra probably allows entry of bacteria from urethra to bladder, and this, in part, may account for the higher frequency of UTI in women.

- e. **Vaginal flora.** Vaginal colonization with lactobacilli appears to prevent vaginal colonization and bacteriuria with *E. coli* and other uropathogens. **By altering the normal vaginal flora, contraceptive diaphragm and spermicide use, as well as postmenopausal vaginal atrophy,** increase introital colonization with Enterobacteriaceae and result in an increased likelihood of recurrent UTIs [8].

4. **Urinary tract abnormalities.** A number of urinary tract abnormalities interfere with the defense mechanisms just noted [4,5].

- a. **Obstruction** anywhere in the urinary tract increases susceptibility of the kidney to infection. The exact role of urinary stasis in obstruction-related infection, however, has not been defined. Specific types of obstruction include ureteral obstruction (ureteral calculi and congenital abnormalities such as stenosis and ureteral valves) and urethral obstruction (prostatic hypertrophy).

- b. **Vesicoureteral reflux** increases the susceptibility of the kidney to infection by providing a route for ascending infection and interfering with the normal flow of urine. Reflux can be either the cause of infection or its result. Endotoxin from gram-negative bacteria inhibits ureteral peristalsis. During acute lower

UTI in adults, reflux from bladder to ureter often is present and resolves as the acute infection resolves.

- c. **Incomplete bladder emptying.** Because urine acts as a culture medium for bacterial growth, residual urine can serve as a source of infection.
 - d. **Foreign bodies** also serve as a nidus for infection. Renal **calculi** and **indwelling bladder catheters** are the foreign bodies implicated most frequently in UTI.
5. **Diabetes mellitus in women** appears to increase the frequency of UTI, including upper tract infections and nosocomial infections [9]. The cause of the high prevalence of UTI with upper tract involvement is speculative, and a combination of factors is probably involved, including bladder dysfunction as a result of diabetic neuropathy, structural abnormalities (e.g., cystocele, rectocele), recurrent vaginitis, and underlying vascular disease [9].

III. Clinical manifestations. Localization studies make it clear that clinically it is very difficult, if not impossible, to distinguish upper from lower UTIs. Urinary frequency, dysuria, lower abdominal–suprapubic discomfort, and even costovertebral angle (CVA) or flank discomfort are nonspecific and may be seen both in upper and lower UTI [5].

A. Lower UTIs. Clinically, it is not possible to distinguish cystitis from urethritis in women; vaginitis may also cause dysuria. UTI symptoms in men should direct attention to excluding concurrent prostate disease.

1. Acute cystitis

- a. **Dysuria**, or burning during or just after urination, and urgency and increased frequency of urination often are associated with cystitis. Suprapubic pain, fullness, or a sensation of pressure may also be present. Gross or microscopic hematuria occurs in approximately 50% of women with acute cystitis [2] but is uncommon with other causes of dysuria. Obstructive symptoms may predominate in men. The patient may complain of CVA or flank discomfort, making these latter findings unreliable in distinguishing upper from lower UTI.

Physical examination often is unremarkable; the patient may complain only of pain on suprapubic palpation. Patients should be examined for CVA tenderness. Inspection and palpation of the external genitalia along with rectal examination should be performed in men. In women, vaginal examination may be indicated.

Ordinarily, no systemic symptoms are present in uncomplicated lower UTI. Fever generally is absent, although low-grade temperature elevations are not uncommon. In women, prior episodes of confirmed cystitis and diaphragm use suggest a diagnosis of cystitis [8].

- b. **Vaginitis** also must be considered because it may present with dysuria caused by irritation of the mucosal surface by the urine stream. **Vaginitis should be suspected when patients complain of perineal, labial, or external dysuria, which may be accompanied by odor, itching, or vaginal discharge.** Patients may describe the pain on urination as being more delayed than the discomfort that often begins before or at initiation of voiding with cystitis or urethritis. If these symptoms are present, a pelvic examination should be performed and appropriate vaginal, cervical, and urethral cultures obtained. See Chapter 16 for a discussion of vulvovaginitis.

2. Urethritis

- a. **Urethritis in women** is a very common problem. Studies have shown that as many as **one third of women presenting with symptoms of lower UTI have urethritis without cystitis.** These patients exhibit symptoms of increased frequency and dysuria, and therefore the clinical presentation is identical to that in cystitis. Patients usually are afebrile. Urinalysis demonstrates pyuria but not bacteriuria. Clues in the history that suggest a sexually transmitted cause of urethritis include suspected or proved sexually transmitted disease in a sex partner or the presence of a new or multiple sex partners.
- b. **Urethritis in men** frequently is suggested by concurrent dysuria and urethral discharge. Urinalysis may demonstrate pyuria. Historic clues to sexually transmitted disease should be sought, as discussed above. Urethritis in men is discussed in Chapter 16.

3. **Prostatitis** symptoms may be those of cystitis, with dysuria, frequency, and urgency, or symptoms of bladder outlet obstruction may predominate, with hesitancy, diminished stream, nocturia, or postmicturition dribbling. Perineal or low back pain may, on occasion, be the only manifestation. Physical examination findings that help differentiate acute from chronic prostatitis are discussed in section III under Urinary Tract Infection in Men, below. Examination should include inspection and palpation for evidence of urethral discharge, penile lesions, local epididymal or testicular disease, and inguinal adenopathy [10].

B. Upper UTIs. Clues from the history that suggest an increased likelihood of upper UTI include a prior history of pyelonephritis or structural abnormalities of the urinary tract, UTIs in childhood, diabetes, prolonged symptoms with the current episode (7 or more days), and failure to respond to short-course therapy administered for presumed cystitis.

1. **Pyelonephritis** [11]. Some patients with **acute pyelonephritis** have characteristic findings of high fever (39.5°–40.5° [103°–105°F]), shaking chills, and lumbar pain. Many authorities argue that **fever may be the most reliable clinical finding** in differentiating between upper and lower UTI. Presence of shaking chills implies that the UTI may be complicated by bacteremia. These findings may develop rapidly over a period of a few hours or 1 to 2 days and occur with or without antecedent or concurrent symptoms of lower UTI. Nausea, vomiting, and diarrhea or constipation also may be seen. Examination often reveals CVA and flank tenderness, but this may be a nonspecific finding. Urinalysis in most patients reveals significant pyuria (at least 10 leukocytes/mm³ or per high power field of the unspun sediment), but 4% to 5% of cases of pyelonephritis do not involve pyuria [12].

Some authors have subdivided syndromes of pyelonephritis [11].

a. Uncomplicated pyelonephritis, which usually refers to pyelonephritis in women, includes many episodes of acute pyelonephritis, pyelonephritis in pregnancy, and silent (subclinical) pyelonephritis.

b. Complicated pyelonephritis is generally the result of structural and functional abnormalities (e.g., obstruction, including prostatic hypertrophy, calculi, reflux, neurogenic bladder) and/or urologic manipulations (catheters, renal transplantation) and is seen in those with underlying disease (e.g., diabetes, immunosuppression, cystic renal disease) and the elderly.

2. **Renal abscesses** present with signs and symptoms identical to pyelonephritis and should be **considered** in the patient with upper UTI whose **fever persists beyond 48 to 72 hours despite appropriate antimicrobial therapy** [13].

IV. Laboratory diagnosis of UTI focuses on the determination of the presence or absence of pyuria and bacteriuria. Rapid tests for the detection of leukocytes and bacteria in urine are available. Comprehensive laboratory testing in every patient is not needed for clinical management; indiscriminate use of urine cultures results in unnecessary costs. The management of UTI, the most common infection for which adults receive antimicrobial agents, should emphasize cost-effective strategies.

A. Microscopic examination of urine. Laboratory diagnosis in the patient with suspected UTI should usually begin with microscopic examination for leukocytes in the urine sediment. **Pyuria still is considered a useful indicator of UTI, and its absence should suggest an alternative diagnosis.** Pyuria in the elderly may be a nonspecific finding, but its absence means that bacteriuria is unlikely (see section V.C under Urinary Tract Infection in the Elderly, below).

When a health-care provider has a long-standing relationship with a reliable patient who has recurrent uncomplicated UTIs, it is reasonable and cost-effective not to do a urinalysis (or culture) but rather to treat empirically.

1. **Pyuria.** Unspun or spun urine (2,000 rpm, for 5 minutes) can be used. The most accurate method for diagnosis is counting leukocytes in unspun urine using a chamber method [2,14], although many clinical laboratories find this a cumbersome technique. Although different levels for pyuria have been proposed, a white blood cell (WBC) count of 10 cells/mm³ by the counting chamber method seems to be the best diagnostic cutoff [2]. When examining spun urine sediment, more than 10 WBC per high power field indicates pyuria.

- a. The **leukocyte esterase dipstick** is used widely as a rapid alternative office test for the detection of pyuria; it is 75% to 95% sensitive in detecting pyuria associated with infection. Although not as reliable as the chamber method to define pyuria, the leukocyte esterase dipstick is an acceptable alternative [14]. (See related discussion in section C.)
 - b. The WBC count may vary depending on urine flow, state of hydration, previous antibiotic treatment, and method of specimen collection.
 - c. “Sterile pyuria” may be associated with acute urethritis, renal tuberculosis, foreign body or tumor of the urinary tract, nonbacterial infections in the genital tract [12], and a poorly understood entity called interstitial cystitis, which is typically seen in women with chronic dysuria and urgency. (The etiology and treatment of this problem remains unclear [15].)
 - d. **The absence of pyuria in the symptomatic patient suggests that cystitis is not the cause of dysuria**, and urethritis or vaginitis should be considered as alternative diagnoses.
2. **Bacteria** seen on microscopic examination, especially of the unspun urine, can be a useful test for the presumptive diagnosis of UTI. Generally, bacterial counts of fewer than 10^5 colony-forming units (CFU)/mL cannot be seen microscopically in unspun urine. Falsely elevated numbers of bacteria may be noted if the specimen was improperly collected or if the specimen was allowed to stand at room temperature for long periods of time. Numbers of bacteria may be decreased by the same factors that cause low numbers of WBCs in urine.
- a. **A Gram stain** of one drop of freshly voided unspun urine can be done quickly and easily. The finding of one bacterium or more in each oil-immersion field suggests the presence of at least 10^5 CFU/mL urine. When several fields must be searched for the presence of bacteria, the quantitative counts are generally lower, ranging from approximately 10^4 to 10^5 CFU/mL. With experience in its use, this Gram stain technique has been shown to correlate well with the quantitative urine culture.

Gram stains of urine are especially useful in patients with presumed urosepsis, severe pyelonephritis, and in those at risk for enterococcal UTI (e.g., elderly men). If the Gram stain of the unspun urine shows gram-positive cocci, enterococci may be the pathogen and empiric therapy should be active against enterococci. By contrast, if the Gram stain of unspun urine reveals gram-negative bacilli, empiric therapy aimed at enterococci is not necessary.
 - b. **Microscopic examination of spun urine** for WBCs and bacteria can be done under high dry power. With this method, the presence of more than one bacteria on a Gram stain correlates well with more than 10^4 bacteria/mL [16].
3. **Hematuria**, as detected by rapid dipstick methods within the office setting, occurs in approximately 50% of women with acute cystitis but is uncommon in urethritis or vaginitis. Thus, microscopic hematuria in acutely dysuric young women is a marker of cystitis.
4. The **nitrate test** is sensitive for detecting more than 10^5 CFU/mL of Enterobacteriaceae, but it may miss cases of cystitis with lower colony counts and it will not detect enterococci and staphylococci.
- B. Urine culture.** Urine is normally a sterile body fluid. Care in urine collection for culture is important to prevent contamination from the urethra, vagina, or perineum. It is to be emphasized that obtaining a clean-catch, midstream, voided urine is cumbersome and difficult for many patients.
- It has become common practice and is more cost effective in women who have uncomplicated UTIs (i.e., symptoms of cystitis and urinalysis findings of pyuria) to prescribe treatment without an initial or follow-up urine culture [17,18]. **Urine cultures still are advised in pyelonephritis, complicated UTI** (see section I.C), and **in recurrent UTI** (except in recurrent episodes of UTI that are clearly associated with sexual activity) [2]. Cultures are also suggested to help assess for asymptomatic bacteriuria in certain settings, including pregnancy, before and after urologic manipulation, and after definitive removal of a chronic indwelling Foley catheter [2].

1. **Clean-catch urine specimen.** Collection of the urine specimen should be done with care. The specimen can be split, with a portion being used for urinalysis and the rest for culture.
 - a. **Female patients** can be instructed to wash their hands, straddle or squat over the toilet, and spread the labia with the nondominant hand. Then, using the dominant hand, they should swab the vulva three times, front to back, with sterile gauze pads soaked in sterile water or with a sponge soaked in a mild nonhexachlorophene soap. The first 10 mL of voided urine is the urethral specimen and is discarded, unless it is saved to help diagnose urethritis. The urine specimen collected in a sterile cup during the middle of voiding (midstream sample) is used for culture. It should be quickly processed or refrigerated [2].
 - b. **Male patients** can be instructed to retract the foreskin and clean the glans penis three times using gauze pads or sponges. However, some studies have questioned the necessity of these steps in a male, when only a midstream collection is necessary [2]. (See related discussion under section III.A.1 under Urinary Tract Infection in Men, below.)
 - c. **Other collections. In the very obese, acutely ill, or infirm, a single straight (in-and-out) catheterization may be performed to obtain a clean sample for urinalysis and culture.** Suprapubic aspirations also can be performed and may be particularly useful in children.
2. **Urine culture interpretation.** It is important for physicians and microbiology laboratory personnel to work together in interpreting how the bacteriologic workup of urine should be approached in the laboratory.
 - a. **Clean-catch urine.** The older criterion proposed that urine counts exceeding 100,000 CFU/mL (i.e., $\geq 10^5$ bacteria/mL) were significant, and counts of 10,000 CFU/mL or less from clean-catch specimens were generally considered contaminants. Studies from Stamm [14], Stamm et al. [19,20], and Kunin [21] emphasized that approximately one-third of women with acute lower UTI have colony counts in midstream urine of between 10^2 and 10^4 CFU/mL. **In acutely dysuric women with confirmed pyuria, therefore, the threshold for significant bacteriuria should be 10^2 CFU/mL or more of a single or predominant uropathogen** (e.g., *E. coli*, *Pseudomonas aeruginosa*, *Staphylococcus saprophyticus*). Low colony counts of diphtheroids, lactobacilli, *Gardnerella vaginalis*, and *Staphylococcus epidermidis* are consistent with contaminants [14].
 In men, only limited data on the significance of lower colony counts in voided urine are available; in one study comparing voided urine with bladder specimens, approximately one-third of men with bladder bacteriuria had colony counts in midstream urine of greater than 10^3 CFU/mL but less than 10^5 CFU/mL [22]. **In dysuric men, growth of 10^3 CFU/mL or more of a single or predominant uropathogen should be regarded as significant for presumptive UTI.**
 - b. **Multiple isolates.** Voided urine cultures revealing two or more species of bacteria with no predominant organism are seen frequently. In people with normal urinary tracts, these usually represent contaminated urine samples; therefore, the culture should be repeated, with meticulous care in the collection of the specimen.
 - c. **Straight catheter and suprapubic aspiration specimens.** Colony counts are considered to be significant if greater than 10^2 CFU/mL of a single or predominant uropathogen are cultured.
 - d. **Indwelling catheter.** Culture of urine specimens obtained by indwelling catheter frequently yields multiple isolates that change rapidly over time. Identification and susceptibility testing is most commonly performed on the one or two organisms that are clearly predominant at 10^4 CFU/mL or more.
 - e. **Limitations of urine culture** [12]
 - (1) **Transport time.** Delays in transport from collection of the urine specimen to processing in the laboratory can affect colony counts considerably. In general, a urine culture should be processed as soon as possible after

collection. Urine specimens may be stored at room temperature for 1 hour or in a refrigerator for up to 48 hours without appreciable changes in bacterial counts. **Storage at room temperature for 2 hours or more will result in significant increases in bacterial counts, and the results of such specimens cannot be reliably interpreted.**

- (2) **Fastidious microorganisms.** Standard urine culture procedures are directed toward routine uropathogens. Unusual microorganisms should be considered in patients with unexplained pyuria or when there is suspicion of sexually transmitted disease. Mycobacteria, fungi, gonococci, chlamydiae, and viruses require special transport media or special culture techniques.

- C. Rapid diagnostic tests.** Multiple tests have become available to detect pyuria and bacteriuria more rapidly. The most reliable chemical measurement of pyuria is the leukocyte esterase dipstick test; although somewhat less sensitive than microscopic examination for leukocytes, it is a useful alternative for the detection of pyuria when urine microscopy is unavailable [23] (see section A.1.a.).

Newer bacteriuria screening tests use nephelometry, bioluminescence, or a colorimetric filtration system. They yield comparable results, and all have a sensitivity similar to the urine Gram stain; none of the tests detect fewer than 10^4 CFU/mL. Because a urine culture is often not done in young to middle-aged women with uncomplicated UTI, the need for these rapid culture screens has diminished. For recurrent UTI or complicated UTI, a urine culture with susceptibilities is advised (see section B).

- D. Blood cultures.** As many as 30% to 40% of patients with pyelonephritis will have positive blood cultures. In general, blood cultures should be obtained in those patients with a fever and a history of rigors, as well as in patients sufficiently ill to be hospitalized, especially if prior antibiotic therapy may have selected out resistant pathogens. The need for blood cultures has been debated by some in this cost-conscious era. If complex UTIs (e.g., pyelonephritis) with or without bacteremia are to be treated for 2 weeks, the need for blood cultures may be superfluous [15]. However, the availability of potent oral agents has led to the use of shorter courses of therapy in some patients with mild disease. This is an unresolved issue, and the approach needs to be individualized.

- V. Microbiologic features of UTIs.** Organisms causing UTI are derived primarily from the aerobic members of the fecal flora. In women these microorganisms colonize the perineum as a way station to the urinary tract, and in men the prostate may be colonized or subclinically infected.

- A. Bacteria.** Bacteria involved include members of the family Enterobacteriaceae: *E. coli* and *Klebsiella*, *Enterobacter*, *Serratia*, *Proteus*, and *Providencia* species are most frequently seen in uncomplicated UTI. Of these, *E. coli* accounts for up to 80% of all infections. *Pseudomonas* species and group D streptococci account for approximately 5% to 10% of uncomplicated infections and are associated most often with instrumentation of the urinary tract.

Coagulase-negative staphylococci (e.g., *S. saprophyticus*) may be pathogenic more often than was previously realized. Formerly believed to be urinary contaminants, *S. saprophyticus* have been documented in urine by suprapubic catheterization, ureteral aspiration, and renal biopsy culture. Generally, patients with UTI due to *S. saprophyticus* are young female patients aged 16 to 25 years old, have pyuria, and have symptoms of lower UTI. *S. saprophyticus* is rarely the cause of UTI in hospitalized patients unless there has been instrumentation of the genitourinary tract. The organism will be recovered on serial cultures if it is a significant pathogen. Cefixime and certain other oral cephalosporins have relatively poor *in vitro* activity against *S. saprophyticus*, yet in limited clinical studies they have appeared active.

See Table 15.2 for a list of microbial species commonly associated with UTIs.

- B. Fungi.** The presence of fungi in the urine often presents a diagnostic dilemma. For the purpose of this and later discussions, the term **fungi** will refer to yeasts such as *Candida albicans*, other *Candida* species, and *Torulopsis glabrata* (*Candida glabrata*). Fungi are isolated most frequently in diabetics, in patients with indwelling

Table 15.2. Microbial Species Most Often Associated with Specific Types of Urinary Tract Infections (UTIs)

	Acute Uncomplicated Cystitis (%)	Acute Uncomplicated Pyelonephritis (%)	Complicated UTI (%)	Catheter-Associated UTI (%)
<i>E. coli</i>	79	89	32	24
<i>S. saprophyticus</i>	11	0	1	0
<i>Proteus</i>	2	4	4	6
<i>Klebsiella</i>	3	4	5	8
Enterococci	2	0	22	7
<i>Pseudomonas</i>	0	0	20	9
Mixed	3	5	10	11
Other	0	2	5	10
Yeast	0	0	1	28
<i>S. epidermidis</i>	0	0	15	8

From Falagas ME, Gorbach SL. Practical guidelines: urinary tract infections. *Infect Dis Clin Pract* 1995;4:242; with permission.

bladder catheters, in those receiving antibiotics, and, occasionally, in patients who have had previous instrumentation of the urinary tract.

C. Viruses. Viruria occurs in a variety of systemic illnesses such as measles, mumps, and infections with herpes simplex virus, cytomegalovirus, and adenovirus. There is indirect evidence to suggest that viruses may also be responsible for certain renal lesions, including glomerulonephritis. The role of varicella-zoster virus in hemorrhagic cystitis is well documented, and adenovirus has been strongly implicated as a cause of a similar syndrome. Adenovirus type 8 has been associated with hemorrhagic cystitis in children.

D. *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and herpes simplex virus. These are the major causes of urethritis in women, an infection in which dysuria may falsely suggest a diagnosis of cystitis [19].

E. *Trichomonas vaginalis* and *Candida* species. These are the principal pathogens associated with vaginitis, an alternative cause of dysuria in young women that may be confused with UTI (see Chapter 16).

VI. Indications for urologic workup. In treating patients with UTIs, the question of when to perform a urologic evaluation often arises. The goals of radiologic imaging studies and urologic evaluation are to identify correctable anatomic abnormalities (e.g., obstruction) that may predispose to recurrent UTIs and/or prevent adequate response without urologic intervention. It is indicated when urinary lithiasis is suspected or proven and to evaluate persistent hematuria.

Although the intravenous pyelogram was commonly used in the past [24], in recent years **renal ultrasound and abdominal computed tomography (CT) have commonly replaced the intravenous pyelogram** [2,14,15]. Renal ultrasound is very useful to assess noninvasively for obstructive uropathy. CT will help identify renal abscesses.

A. UTI in male patients. UTIs in men are infrequent compared with their incidence in women, and bacteriuria in men may be the first sign of an anatomic or functional abnormality.

1. In boys, the first UTI warrants ultrasonographic evaluation of the kidneys (to detect malformation or scarring) and voiding cystography (to detect vesicoureteral reflux and urethral obstruction) [25]. See related discussion under Urinary Tract Infection in Children, below.

2. In young men, there has been recent recognition that uncomplicated cystitis can occur and that urologic evaluation usually is unrewarding in those who respond to a 7-day course of therapy (see Urinary Tract Infection in Men, below). In older men, persistent or recurrent bacteriuria is frequently an indication of prostatic enlargement and obstruction or of chronic prostatitis. In addition to a

physical examination of the prostate, intravenous pyelogram and cystoscopy may also be useful. For further discussion, see sections II and III under Urinary Tract Infection in Men, below.

- B. UTI in female patients.** When to initiate investigation in female patients is controversial, particularly in the highly prevalent group of middle-aged to older women with recurrent UTIs, a group who rarely exhibit anatomic or functional abnormalities.
1. Imaging studies should be performed after the first UTI in girls younger than 5 years of age, older girls with recurrent UTIs, and in any child with pyelonephritis. As in boys, renal ultrasonography and voiding cystography are indicated; however, radionuclide voiding cystography can be substituted as a screening test to detect the presence of vesicoureteral reflux. If the facilities are available, radionuclide cystography greatly reduces ovarian radiation exposure in comparison with conventional fluoroscopic voiding cystourethrography. See related discussion under Urinary Tract Infection in Children later in this chapter.
 2. Most recurrent UTIs in women are exogenous reinfections rather than relapsing infections due to the same organism. Documented relapsing infections should prompt urologic evaluation to exclude a treatable anatomic defect. Postmenopausal women should be evaluated for increased postvoiding residual associated with bladder or uterine prolapse.
- C. Pyelonephritis.** Upper UTI should manifest a clinical response within 72 hours of initiation of appropriate antimicrobial therapy. If flank pain or fever persists for longer than 72 hours, ultrasonography or CT should be performed to exclude unrecognized obstruction or intrarenal or perinephric abscess. Routine radiologic imaging studies for all cases of pyelonephritis are generally unrewarding and unnecessarily expensive. Patients with a prolonged clinical course, recurrent upper UTI, or a childhood history of infection should be evaluated for anatomic or functional abnormalities.

GENERAL MANAGEMENT PRINCIPLES OF URINARY TRACT INFECTIONS

I. Nonspecific treatment [26]

A. Hydration. Forcing fluids has long been advocated in the initial treatment of UTI. There are theoretic reasons for and against it. The benefit of hydration has never been critically documented in clinical studies; it probably is not necessary once appropriate antimicrobial treatment has been instituted.

B. Urinary analgesics. Such pain relievers as phenazopyridine hydrochloride (e.g., Pyridium, 200 mg orally three times a day after meals) may be useful to relieve symptoms of severe dysuria or urethral irritation but generally are necessary only for the first 24 to 48 hours of treatment if they are used at all. It is best to prescribe only a small number of tablets, for a 1- or 2-day period, because many patients mistakenly will use the drug as primary treatment and will avoid consulting a physician in the event of relapse or reinfection. It should be stressed to the patient that this drug is only adjunctive treatment and is not an antibiotic. Phenazopyridine should be avoided in pregnancy and probably in nursing mothers also.

II. General principles of antimicrobial therapy [26]. The choice of therapy in UTI will depend on the patient's age and gender, on whether the infection is symptomatic or asymptomatic, on the presumed site of infection (upper vs. lower), and on whether the UTI is recurrent. **Specific treatment guidelines based on these considerations are discussed in this section and are summarized in Table 15.3.** Factors such as whether the infection is community or hospital acquired and host considerations such as the presence of impaired renal function or abnormal collecting systems often influence the likely causative pathogen, the severity of illness, and the response to therapy and therefore will influence the choice of antimicrobial agent.

A. Choice of antimicrobial agent. Many antimicrobial agents with a broad gram-negative spectrum of activity are effective in the treatment of UTI [27]. Most UTIs are localized to the collecting system, and active urine levels are achieved after oral administration of essentially all commonly used antimicrobial agents. Bacteriostatic

and bactericidal drugs are of equal efficacy. Given the availability of several drugs microbiologically active against known or suspected uropathogens, considerations in choosing empiric antimicrobial therapy are the patient's history of drug allergy, relative drug toxicities, and cost of available agents.

1. Resistance to sulfonamides, ampicillin, and amoxicillin is now present in 25% to 35% of *E. coli* strains causing outpatient cystitis, making these agents **no longer the standards for empiric therapy** of gram-negative UTIs [28].

Although resistance to trimethoprim and trimethoprim-sulfamethoxazole (TMP-SMX) has been increasing nationwide, in some geographic areas it still is sufficiently uncommon that these two antimicrobial agents remain the empiric therapies of choice on the basis of cost. Resistance to nitrofurantoin and to the fluoroquinolones among *E. coli* remains below 5% in most areas. If a geographic area has a high incidence of TMP resistance to common urinary pathogens (e.g., >15%–20%), then a fluoroquinolone is a reasonable alternative (see Chapter 27).

2. UTIs are the most common indication for which antimicrobial agents are prescribed. Small increments in cost of individual therapies have the potential for large aggregate expense. Because of cost and concern with emergence of resistance, the fluoroquinolones should be reserved for UTIs in which resistance to older less expensive agents has been demonstrated or is likely. For this reason, fluoroquinolones are usually not the agents of choice for first episodes of uncomplicated cystitis (see Chapter 27).

3. With renal functional impairment, dosage modification is necessary for agents that are primarily renally excreted (see Chapter 27).

UTIs in patients with **end-stage renal disease** pose a therapeutic challenge because of the lack of the usual high concentration of antimicrobial agents in the urine. In general, the penicillins and cephalosporins have little nephrotoxicity, attain adequate urine levels despite severe renal functional impairment, and may be the agents of choice in renal failure.

4. Oral and parenteral therapies are equally effective in the treatment of UTI provided that the patient is able to take and absorb oral medication adequately. Most patients with pyelonephritis who are ill enough to require hospitalization should be treated initially with parenteral agents until there is symptomatic improvement and fever subsides. (See section III.A under Urinary Tract Infection in Women.) Then, therapy can be completed with an oral regimen.

B. Duration of therapy. This primarily depends on the presumed site of infection. **For cystitis** in women, short-course therapy, usually for 3 days, is preferable to the historic 7- to 14-day therapeutic regimen because it is equally efficacious, costs less, is associated with fewer side effects, has a lower incidence of emergence of resistant gastrointestinal flora, and allows for better compliance. **The authors support the Infectious Diseases Society of America guidelines advocating 3-day regimens as more effective than single-dose therapy.** (For single-dose therapy, the best results have been observed with TMP-SMX, 320/1,600 mg, as a single dose. Single-dose therapy with drugs such as amoxicillin and the oral cephalosporins, which are excreted rapidly, has been less efficacious.) Short-course regimens of documented efficacy are shown in Table 15.3 and are discussed in section II.D.2 under Urinary Tract Infection in Women. **For pyelonephritis**, a 2-week course of antibiotics is advised [11].

Extended-duration antimicrobial therapy may be indicated for recurrent infection (as discussed later) and in pyelonephritis failing a 14-day regimen. See section III.A under Urinary Tract Infection in Women.

III. Determinants of specific antimicrobial therapy. Asymptomatic and symptomatic, acute and recurrent, upper and lower UTIs in children, in men and women, in the elderly, and in catheterized patients are discussed separately and in detail later in this chapter. General comments regarding several of these major determinants of therapy follow.

A. Age and gender. Children with UTIs and severe vesicoureteral reflux are at high risk for progressive renal scarring and eventual functional impairment. Most UTIs in women represent cystitis, which is easily treated. UTI in men is usually related

Table 15.3. Antibiotic Therapy for Adults with Symptomatic Urinary Tract Infection (UTI)

Syndrome	Duration	Route	Medication	Dose ^a (mg)	Interval
Cystitis, females, uncomplicated ^b	3 d	p.o.	TMP ^c	100	q12h
			TMP-SMX ^c	160/800	q12h
			Tetracycline	500	q6h

			Ciprofloxacin ^d	250	q12h
			Levofloxacin	250	q24
			Cefixime	400	q24h
	Cefpodoxime proxetil	100	q12h		
	7 d (see text)		Nitrofurantoin	100	q6h
			Amoxicillin + clavulanate	500	q12h
Cystitis complicated ^f	1 d		Fosfomycin ^e	3000	Single dose
	10–14 d ^g	p.o.	Same as 3-d regimens for uncomplicated cystitis (shown above)		
			Also: Lomefloxacin ^d	400	q24h
			Enoxacin ^d	400	q12h
Urethritis, female	See Chapter 16				
Urethritis, male	See Chapter 16				
Prostatitis, acute ^h	4 wk ^{g,i}	p.o.	TMP ^c	100	q12h
			TMP-SMX ^c	160/800	q12h
			Ciprofloxacin ^j	500	q12h
			Levofloxacin ^j	250	q24h
Prostatitis, chronic ^h	6–12 wk ^g	p.o.	TMP ^c	100	q12h
			TMP-SMX ^c	160/800	q12h
			Ciprofloxacin ^j	500	q12h
			Levofloxacin ^j	250	q24h
Pyelonephritis, outpatient ^k	14 d ^g	p.o.	TMP ^c	Same as 3-d regimens for uncomplicated cystitis	
			TMP-SMX ^c		
			Amoxicillin + clavulanate		
			Ciprofloxacin	500	q12h
			Enoxacin	400	q12h
			Gatifloxacin	400	q24h
Pyelonephritis, hospitalized patient ^k	14 days ^g	i.v. and p.o. ^l	See footnote ^m	250	q24h

^aSee individual chapter discussions for dose modification in renal failure and details of intramuscular and intravenous regimens.

^bShort-course therapy (3 days) is preferable to single-dose regimens [1,27]; therefore, the 3-day regimens are emphasized. **Uncomplicated** UTI is cystitis in nonpregnant adult women (young to middle-age), without genitourinary tract structural abnormality or bladder neurologic dysfunction.

^cPreferred antibiotic selections on the basis of cost; empiric use limited to those geographical areas where frequency of resistance is less than 20%.

(Table Footnote Continued.)

^dThe fluoroquinolones are reserved for regions having a higher frequency of more resistant pathogens (see Chapter 27). These agents should be avoided in pregnancy, nursing mothers, and adolescents younger than 17 years of age.

^eFosfomycin single dose therapy has comparable efficacy to 7-day nitrofurantoin therapy.

^fSee definition of uncomplicated UTI in footnote b. Other UTIs, including those in men, are, by definition, complicated.

^gSusceptibility of pathogen to selected antibiotic must be confirmed with *in vitro* susceptibility testing.

^hIn acute prostatitis, symptoms included fever, acute perineal pain and discomfort, and, usually, signs of an acute lower UTI such as dysuria, frequency, and urgency. The rectal examination reveals a swollen prostate that often is exquisitely tender on palpation, and prostatic massage may precipitate bacteremia. In chronic prostatitis, the prostate can remain a persistent source of UTI, with recurrent episodes of UTI. Symptoms are variable, including asymptomatic bacteriuria, perineal or low back discomfort, and relapsing UTI. For further discussion, see text.

ⁱSome experts prefer to treat both acute and chronic prostatitis for protracted periods of time (e.g., 4–6+ weeks) to eradicate the infection clearly.

^jOther fluoroquinolones are potentially useful agents in this setting, but there is less experience with their use in prostatitis (see Chapter 27).

^kThe decision regarding outpatient or in-hospital treatment of acute pyelonephritis is primarily one of clinical judgment. It is influenced by the patient's clinical condition, age, underlying disease, and potential compliance. In general, older or frail patients, bacteremic patients, toxic patients, and noncompliant patients will require inpatient therapy initially [5].

^lChange from intravenous to oral therapy when the patient has clinically improved and is afebrile at least 24–48 hours.

^mThe optimal regimen for a patient admitted with acute pyelonephritis depends on many factors. Enterococci can be in part ruled out if a Gram stain of the urine shows no gram-positive cocci.

- In patients without prior UTI and only moderate illness, cefazolin, 1 g q6–8h, is reasonable.
- In patients who are very ill or who have a history of prior UTI (therefore the potential of a resistant gram-negative infection), ampicillin-sulbactam (3 g q6–8h) with or without an aminoglycoside or ampicillin (1.5 g q4h) and an aminoglycoside (see Chapter 27) can be used, especially if enterococci are a concern. Vancomycin (see Chapter 27) can be used instead of ampicillin in the penicillin allergic patient.
- If *Pseudomonas aeruginosa* is a concern, an aminoglycoside should be used initially until culture data are available. In addition to the above regimens, it may be given with an anti-pseudomonal penicillin (e.g. piperacillin or ticarcillin) or carbapenem (e.g. imipenem or meropenem). Ceftazidime or cefepime with an aminoglycoside may be used initially when enterococci are not also a concern.
- In patients in whom enterococci is not a concern, a third-generation cephalosporin (e.g., ceftriaxone 2 g q24h) can be used.
- Intravenous TMP-SMX, fluoroquinolones, and aztreonam are options for the patient unable to receive the aforementioned regimens. Neither TMP-SMX nor aztreonam is active against enterococci.
- For activity against enterococci, ampicillin, ampicillin-sulbactam, or vancomycin is preferred. The fluoroquinolones also are active against many enterococci.

TMP, trimethoprim; SMX; sulfamethoxazole.

Adapted from Hooton TM, Stamm WB. Diagnosis and treatment of uncomplicated urinary tract infection. *Infect Dis Clin North Am* 1997;11:551; and Warren JW, Abrutyn E, Hebel JR, et al. Guidelines for antimicrobial treatment of uncomplicated acute bacterial cystitis and acute pyelonephritis in women. *Clin Infect Dis* 1999;29:745, with permission.

to prostatic enlargement or infection. Women have many more UTIs than men until approximately age 65, after which time the prevalence of bacteriuria rises with age and functional status in both men and women.

B. Asymptomatic versus symptomatic bacteriuria. Detection of asymptomatic bacteriuria is often the result of laboratory screening procedures because, as the term implies, such patients are indeed symptomless. Asymptomatic bacteriuria is likely to occur in patients with indwelling catheters, patients with urologic abnormalities, pregnant women, the elderly, and approximately 5% of school-aged girls.

Because of the problems of contamination of clean-catch specimens, this diagnosis should not be based on the results of a single urine culture.

1. Criterion to establish the diagnosis of asymptomatic bacteriuria

- a. Two consecutive clean-catch specimens having greater than 100,000 organisms/mL, with the same organism in both specimens.
- b. Alternatively, a single urethral catheter specimen with greater than 100 organisms/mL.

2. Approach to the treatment of asymptomatic bacteriuria depends on an appreciation of the prognosis of the untreated infection and the long-term results that are anticipated from therapy. The side effects and cost of therapy are of paramount importance.

a. Screening for asymptomatic bacteriuria in children is controversial.

Although bacteriuria can be associated with hypertension and renal insufficiency, these complications are rare as is asymptomatic bacteriuria, occurring in only 1% to 2% of children. Although there is up to a 3% prevalence of asymptomatic bacteriuria in premature infants, the difficulties in obtaining a clean urine specimen make screening neonates impractical. (See related discussion in section IV.D under Urinary Tract Infection in Children, below.)

b. Screening for asymptomatic bacteriuria in adults is of particular value in two situations: before urologic surgery and during pregnancy.

Postoperative infectious complications are reduced by treating bacteriuria preoperatively. The importance of routine screening during the first trimester is discussed in section 1.C under Urinary Tract Infection in Women, below.

C. Localization of the site of infection. It is well recognized that upper UTI (pyelonephritis) requires longer duration therapy than lower UTI (cystitis). As previously discussed, the clinical presentation may not be reliable enough to make an accurate distinction between upper and lower infection. Although several methods have been developed to help distinguish upper from lower UTI, such methods are either invasive with resultant considerable patient discomfort or are not widely available for clinical application. They are sometimes used in clinical research studies.

1. Invasive techniques include ureteral catheterization with direct culturing and the bladder washout technique with sequential sampling of bladder and ureteral urine. Both techniques are complex urologic and microbiologic procedures, requiring close cooperation between physicians and the clinical laboratory.

2. The noninvasive technique that has received most attention is the antibody-coated bacteria test [29]. The test detects antibodies against infecting bacteria that are believed to form when tissue infection (upper tract or prostatitis) is present (in contrast to cystitis). Because it is not widely available, the test has been used primarily as an epidemiologic and research tool and, to date, has not had a major role in influencing management of UTI in a given patient.

3. In most clinical settings, therapy is based on clinical manifestations, recognizing that most UTIs are lower tract infections. Patients with fever and flank pain are likely to have upper tract disease.

The outcome of therapy has implications about whether upper versus lower tract infection may be present. **Relapse of infection after short-course therapy in women is associated with upper UTI.**

D. Recurrent UTI. Repeated episodes of UTI can be either **reinfection** (i.e., new infections with new organisms) or **relapse** (i.e., a recrudescence of a prior partially treated infection). The distinction is an important one to make because it has implications both for the type and extent of workup indicated for therapy. **Reinfections** tend to occur more than 2 weeks after completion of therapy for the initial episode and are more frequent after uncomplicated cystitis. **Relapses** tend to occur within 2 weeks after completion of therapy of complicated UTI [2].

1. Reinfection is more common than relapse in women; conversely, in men most recurrent infection is due to relapse. After successful therapy of a prior infection, recurrence of symptoms and evidence of **clinical infection with a new organism** (either a new bacterial species or a new serologic type of *E. coli*) indicates reinfection. In general, most reinfections occur within weeks to months of the preceding UTI.

a. Reinfection in women (of childbearing age to middle age) is common. As discussed under Urinary Tract Infection in Women (see below), it is recommended that women with three or more symptomatic lower UTIs within a 6-month period should receive extended-duration (6- to 12-month) prophylactic therapy.

b. Reinfection in men is a much less common cause of recurrent infection than is relapse and, as discussed under Urinary Tract Infection in Men (see below),

is most commonly related to prostatic enlargement causing partial urethral obstruction.

2. **Relapse** refers to the recurrence of symptoms and clinical infection after the cessation of treatment. Implied in this definition is that relapse involves the **same organism** or same serotype of *E.coli* that caused the initial infection. Most relapses occur shortly after the patient has completed a course of therapy (i.e., perhaps within a few days and certainly within 1 month).
 - a. **Setting.** Relapse is likely to occur if there is persistent infection in the renal parenchyma or prostate gland, if the patient does not receive the proper antibiotic therapy, or if there is an underlying renal pathologic process, such as renal calculi.
 - b. **Implications. Relapse often implies underlying urologic abnormality.** Therefore, **urologic evaluation is mandatory**, particularly if previous antibiotic therapy was adequate on the basis of susceptibility data.
 - c. The **approach** should be directed initially at defining the underlying urologic defect, if possible. **If no correctable urologic defect is found and the patient has failed conventional 10- to 14-day therapy, one may presume there is a deeply seated tissue infection. In this group of patients, prolonged therapy (e.g., 4–8 weeks) may eradicate the infection.**
 - d. **Suppressive therapy.** If a prolonged course of therapy also fails, chronic suppressive therapy may be necessary. *In vitro* susceptibility results should be used to determine the choice of chronic suppressive antibiotic therapy. The agent should be administered in full therapeutic dose. In recurrent UTI, there are limited indications for this approach. The major use is in patients with urologic abnormalities that cannot be corrected surgically. **This approach should not be taken in patients with indwelling urethral catheters.**

URINARY TRACT INFECTION IN WOMEN

Women constitute the largest group of patients with UTI [5]. Most such UTIs represent cystitis, but the overlapping clinical symptoms of urethritis or vaginitis may cause confusion. **In most patients, short-course antibiotic therapy (3 days) may be administered empirically on the basis of symptoms along with urinalysis confirmation of pyuria, without the use of pretherapy or posttherapy urine cultures.** Recurrent UTI poses a frequent and troublesome problem.

I. Asymptomatic bacteriuria

- A. **Significance.** There are insufficient data regarding the long-term effects of asymptomatic bacteriuria in young or middle-aged nonpregnant women. Many patients in this group will clear their bacteriuria spontaneously and will not require treatment.
- B. **Approach. The current consensus is that this entity in the nonpregnant adult patient does not require treatment**, provided there is no urinary tract obstruction.
- C. **Pregnancy.** It is important to screen for and treat asymptomatic bacteriuria in women only during pregnancy because morbidity associated with UTI in pregnant women has been clearly demonstrated [5,30]. Asymptomatic bacteriuria occurs in about 5% of pregnant women with the most common onset between weeks 9 and 17 of pregnancy. Approximately 40% of pregnant women with asymptomatic bacteriuria will develop acute pyelonephritis in their pregnancy if not treated [2]. Pyelonephritis in the mother and low birth weight in the infant are sufficiently common complications to warrant mandatory screening for bacteriuria during gestation. Treating pregnant bacteriuric patients lowers the subsequent incidence of symptomatic UTIs by 80% to 90% [30]. Increased rates of premature labor have been seen in pregnant women with symptomatic UTI. The mechanisms for premature labor developing in patients with symptomatic infection are not completely clear but may be related, in part, to microorganism production of phospholipase A₂. Human term labor is believed to be initiated by amniotic and chorionic phospholipase A₂ [30].
 1. **All pregnant women should be screened for the presence of bacteriuria** on the first prenatal visit and again at the 28th week in women with a history

of frequent UTIs. If only a single cost-effective screening culture is done, the 16th gestational week may be an optimal time [30]. Cultures with colony counts exceeding 10^5 bacteria warrant therapy. The significance of lower colony counts of clean-catch samples is less well defined [10].

2. **Treatment.** Because of the risk of pyelonephritis and subsequent stillbirth or prematurity, **asymptomatic bacteriuria in pregnant women should be treated. Oral antimicrobials that are safe to give during pregnancy** include amoxicillin, cephalosporins, nitrofurantoin, and sulfonamides. **(The use of sulfonamides should be avoided in the third trimester.) Recommended duration of therapy is 7 to 10 days** [30].
3. **Follow-up. Eradication of bacteriuria is the goal.** This should be confirmed with follow-up cultures at 1 and 4 weeks after therapy ends.

If infection returns with the same bacterium, a relapsing infection from an occult source should be suspected. In this setting, a second course of antibiotics for a longer duration and an agent based on susceptibility data may be tried. If infection is present on further follow-up cultures, then a short course of antibiotics to which the bacterium is susceptible can be used to suppress the infection, followed by nitrofurantoin, 50 to 100 mg daily at bedtime, until delivery, with the hopes of suppressing recurrent infection. (For susceptible pathogens, chronic suppression with amoxicillin or a cephalosporin is also a potential regimen.) Serial urine cultures should be performed to detect the possibility of a resistant pathogen. Follow-up urine cultures should be performed after delivery, and urologic evaluation should be undertaken 3 to 6 months after delivery [30].

4. See related discussion in section V.

D. Diabetes mellitus in women. Although studies are limited, many experts believe that asymptomatic bacteriuria in diabetics without obvious anatomic abnormalities should be treated when detected because of the frequency of upper UTI in diabetics when bacteriuria is present [9].

II. Lower UTI [5,31]. Women with dysuria but without fever constitute the largest group of UTI patients and the largest group of adults for whom antimicrobials are prescribed. With such women, the **first step is to exclude vaginitis from the differential diagnosis**. Women with vaginitis usually experience dysuria as an external discomfort, and those with cystitis have a deeper and more visceral dysuria. If vaginitis is suspected, a pelvic examination should be done. Clinical and laboratory evaluation of vaginitis or cervicitis should be performed as described in Chapter 16.

A. Cystitis. Women with lower UTIs form a homogenous group of patients who are appropriately managed as outpatients. As a common outpatient illness, this type of UTI presents a challenge to the primary care provider. Because a UTI generally is seen more as a nuisance and an inconvenience than a harmful state, the practitioner may be lulled into unwarranted indifference and may thus not acknowledge uncommon but significant events (e.g., the presence of occult or subacute pyelonephritis with or without mechanical or neurologic dysfunction). However, with confirmation of pyuria on urinalysis, there is an opportunity for use of cost-effective antimicrobial therapy. The absence of comorbidity and the limited extent of the infection makes this bacterial infection particularly appropriate for short-course therapy, now the standard of management for lower UTI (see section D.2). The **microbial agents responsible** include *E. coli* (60%), other Enterobacteriaceae organisms (20%), and *S. saprophyticus* (10%).

B. Urethritis. Acute onset of dysuria along with pyuria also occurs with urethritis. Previously discussed clues about the nature of the dysuria may help distinguish cystitis from urethritis (see section III under General Approach to Urinary Tract Infections, above). Recent onset of dysuria in patients who have a new coital partner in the month before onset of symptoms and who have not had symptoms of a UTI in the preceding 2 years may signal urethritis due to a sexually transmitted infection. *C. trachomatis*, trichomoniasis, gonorrhea, and herpes simplex virus may be the etiologic agent (see Chapter 16).

Strong consideration should be given to performing a pelvic examination in sexually active women with dysuria.

1. Obtain a culture or Gram stain for the gonococcus.
 2. If ulcerations are present, herpes simplex virus cultures should ideally be performed.
 3. Testing of a first-void urine sample by nucleic acid amplification methods is at least as sensitive as culture for *C. trachomatis*; choice of the most appropriate diagnostic test will depend on local test availability and cost.
- C. Vaginitis** as a cause of dysuria should be suspected in the patient who lacks pyuria; has vaginal discharge, odor, pruritus, or dyspareunia; relates external dysuria; or has dysuria without frequency or urgency.
- D. Clinical approach to acute dysuria.** If vaginitis is excluded, the next step is to examine the urine sediment for leukocytes.
- 1. Diagnostic clues**
 - a. A positive leukocyte esterase test or the presence of more than 10 WBCs within a high power field of spun urine is consistent with but not diagnostic of UTI or urethritis.
 - b. In the patient with acute dysuria, if pyuria is not present the probability of infection is less than 5%. The diagnosis of vaginitis should be considered in the absence of pyuria.
 - c. If pyuria is present, the unspun urine should be examined carefully using a Gram stain for bacteria, and if bacteria are seen in most fields under oil immersion, it is likely that the urine contains 100,000 bacteria or more per milliliter. If bacteria are not seen, then the infection may still be bacterial with low colony counts or it may be nonbacterial.
 - 2. Therapy**
 - a. **Most authorities advocate administering empiric short-course antibiotic therapy for uncomplicated UTI without obtaining an initial urine culture.** Indeed, treatment decisions are made and completed before culture results would be available, and this approach is supported by cost-effectiveness studies [18].
 - b. **Not all antimicrobials have been shown to be effective in short-course therapy,** and only the doses and agents with proven efficacy should be used (Table 15.3). **Overall, most experts favor the 3-day regimen over the single-dose regimen** [2,15].
 - (1) **Short-course (3-day) therapy is indicated for only those women with uncomplicated infections.**
 - (2) **Contraindications for short-course therapy** include pregnancy, suspected upper UTI or known prior pyelonephritis, relapsing infection, recent antibiotic use or bladder instrumentation, suspected or known urinary tract structural abnormality, childhood UTIs, symptoms for longer than 7 days, recent diaphragm use [2], and inability to provide follow-up. Because of the high rate of upper UTI in **diabetic women**, many experts do not recommend 3-day regimens for acute uncomplicated UTI in diabetic women; a 7-day regimen is preferred [1,9]. Furthermore, **use of the β -lactams in 3-day regimens is less effective** than other 3-day regimens (e.g., TMP-SMX, quinolones), and therefore experts prefer 7- to 10-day courses of cephalosporins rather than use of a 3-day course, even for uncomplicated cystitis [15,26,32]. Macrodantin, likewise, is not quite as effective in 3-day regimens when compared with TMP-SMX or the quinolones [15]; a 7-day course of therapy is recommended.
 - 3. Indications for urine culture**
 - a. **Urine culture should be obtained** in acutely dysuric women who lack pyuria, in situations when urethritis and cystitis are not clearly distinguished clinically, in patients with relapsing or frequent recurrent infections, in complicated UTIs, and in pregnant women.
 - b. **In women with sterile cultures,** acute dysuria, and pyuria, chlamydial urethritis should be suspected. The sexually active woman should have a pelvic examination with appropriate urethral or cervical cultures. Empiric therapy with tetracycline, 500 mg orally every 6 hours for 7 days (or doxycycline, 100 mg orally twice daily), or azithromycin, 1 g orally as a single dose (see

Chapter 16), should be administered if not contraindicated (see Chapter 27), and test-of-cure cultures should be obtained as appropriate.

4. Follow-up

a. **If symptoms resolve with short-course therapy, no follow-up culture is necessary.**

b. If short-course therapy fails or symptoms recur, then a urine culture should be obtained.

(1) Such patients should be suspected of having occult or subclinical pyelonephritis [2]. See section VI under General Approach to Urinary Tract Infections (above) for decisions on urologic evaluation.

(2) Significant bacteriuria ($>10^2$ CFU/mL) should be treated with at least 14 days of antibiotics directed by susceptibility testing.

5. It is unclear how to treat dysuric patients with negative cultures and with no pyuria. Vaginitis should be excluded in all such patients. Observation and a short course of phenazopyridine hydrochloride (e.g., Pyridium) may be reasonable.

E. **Recurrent cystitis** requires that urine cultures be obtained and susceptibility tests be performed.

1. **Antibiotic therapy** directed by susceptibility test results should be administered for 7 to 14 days.

2. **Follow-up urine cultures** should be obtained at 1 and 4 weeks after the end of therapy.

III. Upper UTI

A. **Pyelonephritis.** The syndrome of acute pyelonephritis includes dysuria and increased frequency accompanied by **fever** (temperature usually exceeds 102°F) or definite CVA tenderness; the patient may also appear septic. However, upper UTI may be difficult to distinguish from lower UTI or so-called silent (subclinical) pyelonephritis. Up to 30% of women in a primary care setting and up to 80% of indigent patients suffering from clinically apparent cystitis in emergency rooms also have silent invasive bacterial infections of renal parenchyma; this infection is indistinguishable from lower UTI because most patients have dysuria and pyuria but not back pain. (See section III.B under General Approach to Urinary Tract Infections, above.)

Women who fail short-course antibiotic therapy for presumed lower UTI should be assumed to have subclinical or occult pyelonephritis [2]. Subclinical pyelonephritis is more common in pregnant women with UTI, in patients who have had a UTI before age 12, and those who have had previous pyelonephritis or more than three UTIs in the past year. Patients with UTI and positive blood cultures have pyelonephritis with invasive tissue infection.

Painless complicated pyelonephritis, which in fact is a different entity than subclinical pyelonephritis, can be observed in diabetics, renal transplant patients, and alcoholics. These patients have minimal symptoms due to autonomic nervous system damage associated with underlying disease but often have severe pyelonephritis [11].

1. **Microbiologic features.** *E. coli* causes approximately 85% of all cases of community-acquired pyelonephritis. Other members of the family Enterobacteriaceae cause approximately 10%, and gram-positive bacteria such as *Streptococcus faecalis* or *S. saprophyticus* the remainder. More antibiotic-resistant gram-negative aerobes, including *P. aeruginosa*, should be anticipated in patients with hospital-acquired infection and in women who have had recurrent UTIs or who have recently failed antimicrobial therapy (Table 15.2).

2. **Principles of antibiotic therapy.** The best way to treat pyelonephritis is poorly defined in the literature, and despite initial therapy with 2 weeks of an antibiotic effective *in vitro*, approximately 20% of patients may fail this therapy (i.e., patients may have relapsing infection) [11].

a. The relatively high failure rates reported may in part be due to the absence of sufficient levels of antibiotic in renal tissue to sterilize the infected medulla. Whether or not the antibiotic must reach inhibitory concentrations in the bloodstream and urine and renal tissue to be effective in pyelonephritis is debated, but some reviewers believe it is important for inhibitory levels to be attained in both the kidney tissue and urine of patients with pyelonephritis [11].

- b. Laboratory studies have suggested that pyelonephritic and endotoxemic kidneys accumulate more aminoglycosides (e.g., gentamicin, tobramycin) and quinolones than β -lactams (e.g., cephalosporins). TMP-SMX penetrates renal tissue adequately [11]. Furthermore, renal tissue levels of aminoglycosides are prolonged, and their effectiveness in treating pyelonephritis is confirmed in the animal model [11].

Therefore, especially while awaiting susceptibility data, when parenteral therapy is needed for acute gram-negative bacilli pyelonephritis, **aminoglycosides are clinically effective and cost effective if not contraindicated** (see Chapter 27). Because of their prolonged tissue levels, even 48 to 72 hours of initial aminoglycoside therapy may be effective; therapy can then be narrowed based on susceptibility data [14].

3. **Outpatient versus inpatient therapy.** The decision regarding outpatient or in-hospital treatment of acute pyelonephritis is primarily one of clinical judgment. It is influenced by the patient's clinical condition, age, underlying disease, and potential for compliance. In general, patients who are older or more frail, bacteremic, toxic, or immunocompromised will require inpatient therapy initially. In mild cases in which the actual diagnosis of upper or lower UTI may be unclear, outpatient therapy is reasonable [33].
- a. **Outpatient therapy.** Empiric therapy with oral antibiotics should be started as outlined in Table 15.3 pending receipt of urine culture results and susceptibility data. **Antibiotics usually are given for 2 weeks** because renal parenchymal infections are more difficult to treat than superficial bladder infections.
- b. **Inpatient therapy** with empiric, parenteral, antimicrobial treatment is indicated for many patients with pyelonephritis.
- (1) Initial antibiotic therapy should include agents that are known to be active against anticipated pathogens. Doses should be appropriate to provide sufficient drug levels within the renal parenchyma and at distant nonrenal sites, as indicated in Table 15.3. Intravenous ampicillin alone probably is inadequate. Up to 30% of organisms may be resistant, even in community-acquired infections [4].
 - (2) However, ampicillin (or vancomycin in the penicillin-allergic patient) should be used when urine Gram staining suggests the possibility of enterococcal infection (i.e., gram-positive cocci).
 - (3) Patients in whom multiple antibiotic-resistant isolates are anticipated (e.g., hospital-acquired infection) should be given agents that have broad gram-negative coverage, to include *P. aeruginosa*. Often, the most cost-effective agent is an aminoglycoside, unless contraindicated. Aztreonam, ceftazidime, cefepime, and imipenem may be used as alternatives to an aminoglycoside. See Chapter 27 for a discussion of these agents.
 - (4) Therapy should be modified to the narrowest spectrum agent possible and to a less expensive antibiotic when the results of susceptibility tests are available.
 - (5) Once the infection is well controlled with intravenous therapy, outpatient therapy with either oral or intravenous antibiotics is reasonable.
4. **Duration of therapy.** In pyelonephritis, antibiotics usually are given for a **total of 14 days** [34]. Because of the occasional difficulties in eradicating renal tissue infection in patients failing 14-day therapy, longer courses of therapy (e.g., 4–6 weeks) should be used. For the hospitalized patient, parenteral therapy usually is continued until the patient has clinically improved and is afebrile for 24 to 48 hours. Then the patient can be placed on oral antibiotics. This decision must be individualized, particularly in a patient with complications such as obstruction or bacteremia.
5. **Response to therapy.** It is important to recognize and treat the complications of acute pyelonephritis. Nearly all patients with uncomplicated acute pyelonephritis are afebrile after 3 days of effective antimicrobial therapy, and the remainder are afebrile by 4 days [13,35]. **The persistently febrile patient may have a collection of undrained pus in or around the kidney, a metastatic site**

of infection, or obstruction with pyonephrosis, or she may have received ineffective therapy. If fever or toxicity persists beyond 48 hours of appropriate therapy, an obstructive uropathy or renal abscess should be excluded (e.g., with renal ultrasonography). **Intrarenal and perinephric abscesses** are discussed later in this chapter. Diabetics have an increased incidence of these complications [9].

- 6. Follow-up.** Approximately 48 hours after initiation of therapy, results of susceptibility testing will be available. If the organism isolated is **not** susceptible to the treatment given, treatment should be changed to the most appropriate drug.
 - a.** The urine should become sterile 2 or 3 days after initiation of appropriate therapy, with no bacteria noted in the urine sediment. Some authorities recommend routine culturing of the urine at 2 to 3 days to assess response to therapy. This rarely is done in outpatient settings but may be indicated in hospitalized patients, especially if there is a question of resistant organisms, if the infection is complicated by mechanical or neurologic obstruction, or if the patient is not responding clinically.
 - b.** Whereas antibiotic treatment may relieve or reduce the patient's symptoms, such treatment does not always result in bacteriologic cure. For this reason, follow-up after treatment is important. Recommendations of experts in the field vary with regard to the extent of follow-up, but the **minimum follow-up should be a repeat urine culture 1 to 2 weeks after completion of antimicrobial therapy** in all patients. In patients with frequent UTIs, repeat cultures at 4 to 6 weeks after treatment may be useful.

7. Urologic evaluation generally is indicated for any patient with relapsing pyelonephritis.

B. Infection in patients with known urinary tract abnormalities. In patients with known renal calculi, obstructive uropathies, or other abnormalities, antibiotic therapy may suppress infection temporarily but may not eradicate it. Treatment of these patients therefore should be directed toward correction of the underlying abnormality if this is possible.

C. Miscellaneous. UTIs in patients with polycystic kidney disease are difficult to treat, in part because of the poor penetration of antibiotics (e.g., aminoglycosides) into cystic fluid [36]. Infectious disease consultation is advised in these difficult cases. UTI in the setting of renal transplantation is discussed in Chapter 20.

IV. Recurrent infections. The healthy young woman who has had two UTIs within the last 6 months and is now presenting with her third is a candidate for long-term prophylactic therapy to prevent recurrent symptomatic bacteriuria [37].

A. The **source** of the recurrent bacteriuria is usually reinfection from the periurethral flora, or less commonly it may be the result of persistent or relapsing infection in the upper urinary tract—that is, smoldering pyelonephritis. Some women will clearly indicate sexual intercourse as a causal factor for recurrent infections [38].

B. Prophylactic therapy. In patients with reinfection, 6 to 12 months of continuous preventive or antibiotic therapy has been shown to decrease recurrences by 95% during the period of active treatment [39,40]. **Prophylactic therapy should be initiated only after the acute episode is bacteriologically cured.** For individuals with reinfection immediately after discontinuation of prophylactic therapy, more extended duration of prophylaxis (2 or more years) has been shown to be effective.

C. Recommended prophylactic antibiotics of equal efficacy include TMP-SMX, one-half regular tablet at bedtime every other night; TMP, 100 mg/day at bedtime; or nitrofurantoin, 50 or 100 mg/day at bedtime (see related discussions in Chapter 27).

D. Alternative approaches

- 1.** Some prefer **patient-administered short-course therapy** at the onset of symptoms, which may be more efficacious, economical, and desirable than conventional prophylactic therapy [41]. This approach probably is justified only for the highly motivated, compliant, and well-educated patient with uncomplicated infection.

2. **Postintercourse, single-dose prophylactic therapy** can be effective inpatients who identify intercourse as a precipitating factor [38].
3. **In postmenopausal women**, topically applied intravaginal estradiol cream is a possible alternative to antimicrobial prophylaxis [42].
4. Drinking **cranberry juice** daily may reduce the frequency of UTI [6,7].

E. Behavioral changes may be important [15]

1. Voiding after intercourse has been suggested as a way of reducing UTI episodes related to sexual intercourse.
2. If a diaphragm and spermicide are used for contraception, an alternative method [8] may reduce the frequency of recurrent UTI.
3. Voiding when the urge to void occurs rather than delaying may help some individuals (e.g., school teachers who postpone voiding during school hours).

F. Urologic evaluation

1. When accurate classification is possible, women with recurrent infections characterized as **relapse** should be examined at least once for the presence of mechanical (e.g., obstruction or stones) or neurologic dysfunction of the urinary tract. The role of suppressive long-term antibiotic therapy in these patients is discussed in section III.D under General Management Principles of Urinary Tract Infections, above.
2. Women with sporadic **reinfections** that respond to short-course therapy or low-dose prophylaxis usually do not have urologic abnormalities. Therefore, invasive evaluation is not warranted.

V. UTI in pregnancy [30]

- A.** The overall **prevalence of bacteriuria** in pregnancy ranges from 4% to 7% in most studies but is as high as 11% in socially indigent multiparas and as low as 2% in private patients [30]. Pyelonephritis in pregnancy occurs in 3% to 7% of pregnant women who have asymptomatic bacteriuria [11]. Sickle cell trait has been associated with bacteriuria also. Catheterization should be avoided in the pregnant patient because pregnancy sets the stage for the development of symptomatic infection [30].

B. Physiologic changes with pregnancy

1. The most impressive changes involve dilatation of the collecting system, called **hydronephrosis of pregnancy**. This is a normal condition in pregnancy and extends to the level of the pelvic brim. The changes are more pronounced on the right side. Dilatation begins as early as the seventh week of gestation and gradually progresses until term. Although the precise explanation for the development of hydronephrosis is unclear, both mechanical and hormonal factors are involved.
2. In the third trimester, the **bladder** undergoes a relative **change in position**, becoming an abdominal rather than a pelvic organ, and undergoes a progressive **decrease in tone** due to hormonal changes.
3. The net effect of these changes is to increase the risk of UTI, especially in the third trimester.
4. After delivery, in the absence of infection, the hydronephrosis returns to normal in 66% of patients by 1 month and in most patients by 2 months [30].

C. Therapy

1. **Asymptomatic UTI.** See discussion in section I.C.
2. **Symptomatic UTI** deserves 7 to 10 days of antibiotic therapy based on susceptibility data. (Antibiotic use in pregnancy is discussed in Chapter 27.) Short 3-day courses are not recommended.
3. **Pyelonephritis.** Hospitalization is usually advised. Empiric therapy with a broad-spectrum cephalosporin (e.g., ceftriaxone) is appealing until culture data are available that may allow one to use a narrower spectrum cephalosporin. Aztreonam is another possible parenteral β -lactam antibiotic [2,11]. There is some concern about using aminoglycosides in pregnancy because of the potential of ototoxicity for the fetus [11] (see Chapter 27). The duration of therapy for pyelonephritis has not been well studied. After a 2-week course of an appropriate antibiotic based on susceptibility data, suppression with nitrofurantoin until delivery is rational [30] (see section I.C).

- D. Follow-up.** See related discussion in section I.C.

URINARY TRACT INFECTION IN MEN

UTI in men [43] occurs most commonly in those with prostatic hypertrophy and partial urethral obstruction or in association with persistent infection of the prostate gland. UTIs in children and the elderly are discussed separately (see below).

I. Asymptomatic infections. Bacteriuria is uncommon without symptoms in the healthy man, although it is relatively common in the elderly man (see section I under Urinary Tract Infection in the Elderly, below).

A. Screening for bacteriuria in asymptomatic healthy men is not suggested.

B. Therapy. If bacteriuria is found by chance, it should lead to an investigation to exclude predisposing structural or functional abnormalities of the urinary tract, especially chronic prostatitis. Routine antibiotic treatment in asymptomatic men is not supported by available data. Patients should be treated before genitourinary instrumentation.

II. Lower UTI

A. It is important to recognize the concept of the relationship between lower UTI in men and prostatitis. Prostatitis may cause symptomatic infection with or without bladder infection. Bladder infection in the man with a mechanically normal urinary system often is associated with bacterial prostatitis [44,45]. However, uncomplicated cystitis alone can also occur (see section B.1.c). Instrumentation is the most common identifiable cause of infection, but in most cases the events leading to infection are not clear. Obstruction is often coexistent with and inseparable from instrumentation.

B. General approach to lower UTI in men

1. Clinical presentation. The history is important.

a. Dysuria alone (with or without urethral discharge). Initially, one should identify patients having dysuria alone, with or without a urethral discharge, because these patients usually have urethritis rather than a true UTI. Most men between the ages of 15 and 30 years will have either nonspecific urethritis or gonococcal urethritis. The clinical approach to this problem is discussed in Chapter 16 under Urethritis.

b. Patients may have dysuria, frequency, and urgency, symptoms similar to those seen in uncomplicated UTI in women. Acute perineal pain and discomfort may occur in patients with prostatitis, as discussed in section III. **Prostatitis is particularly common in men between 40 and 45 years of age who present with a UTI.**

c. Uncomplicated cystitis can occur in sexually active young men with acute dysuria. Risk factors include homosexuality with anorectal intercourse, lack of circumcision, human immunodeficiency virus infection with a CD4 lymphocyte count of less than 200 cells/mm³, or a sexual partner with vaginal colonization with uropathogens [2,31]. Urethritis should be excluded and/or treated (see Chapter 16).

2. Diagnosis

a. Examination of any urethral discharge should be performed if possible, as discussed in Chapter 16 under Urethritis. This will usually allow one to make the distinction between nonspecific urethritis and gonococcal urethritis.

b. Routine urinalysis and quantitative urine culture are essential for proper evaluation of patients with no urethral discharge but with symptoms of a UTI.

c. Rectal examination. If the prostate gland is swollen, firm, and exquisitely tender, an associated acute prostatitis is likely; this entity is discussed in section III.

d. Prostatic localization technique. A technique for localizing the site of UTI in men is discussed in section III.B. This technique is seldom performed at present, and the methodologic validity of testing is questionable. However, **it may be useful in the diagnosis of chronic prostatitis** and in the evaluation of men with relapsing UTI [45]. It appears to be used with diminishing frequency, even by urologists. **It is not appropriate in acute prostatitis.**

3. Treatment
